between nitrosobenzene and a Grignard reagent was carried out as follows: prior to the sealing of part A of the reaction vessel, the ether used as a solvent was evaporated as completely as possible under a high vacuum (about 10^{-6} mmHg), and this part was connected with part B of the vessel (see Fig. 1). Thereafter, part B of the vessel which contained nitrosobenzene was evacuated under a high vacuum, a known amount of tetrahydrofuran was distilled into this vessel, and the vessel was sealed off from the vacuum line. Nitrosobenzene and a Grignard reagent which had been separated from each other by a break seal were mixed at the dry ice - acetone temperature in the absence of air and moisture. The reacting mixture was then inserted into the cavity, which had previously been cooled to the desired temperature with a stream of boiling liquid nitrogen. The reaction temperature in the cavity was controlled by regulating the boiling rate of liquid nitrogen. The reaction vessel is shown in Fig. 1.

Materials.—*Nitrosobenzene.*—Commercial Fulka special-grade reagent was twice recrystallized from ethanol. This sample did not show any ESR signal in tetrahydrofuran. M. p. 68°C.

p-Nitrosotoluene.—This was prepared by the oxidation of *p*-tolylhydroxylamine with an aqueous ferric chloride solution.[2] This sample did not show any ESR signal in tetrahydrofuran. M. p. 48.5°C.

Phenylmagnesium Bromide.—Phenylmagnesium bromide was prepared from bromobenzene and magnesium turnings of reagent grade suitable for the Grignard reagent in ether. This reagent was stored in a sealed bottle, and the upper transparent solution was used for the reaction. The concentration of this reagent was determined by the acid titration method.[3] This Grignard reagent did not show any ESR signal in tetrahydrofuran.

p-Tolylmagnesium Bromide.—*p*-Tolylmagnesium bromide was prepared from *p*-bromotoluene and reagent-grade magnesium turnings for the Grignard reagent in ether. The succeeding treatment was the same as in the case of phenylmagnesium bromide. This reagent did not show any ESR signal in tetrahydrofuran.

Methylmagnesium Iodide and Ethylmagnesium Bromide.—Methylmagnesium iodide and ethylmagnesium bromide were prepared according to the method used for the above two reagents.

Results and Discussion

The Identification of Free Radicals.—The reaction between phenylmagnesium bromide and nitrosobenzene was carried out as follows: after the two reacting components (the mole ratio of the Grignard reagent to nitrosobenzene is 1/1～5/1) had been mixed in a dry ice - acetone bath, the color of the mixture suddenly became brown, and at the same time strong ESR signals, which indicate the existence of free radical species, could be observed. This free radical was identified as diphenylnitric oxide by a comparison of the hyperfine structure of its ESR spectrum with that of pure diphenylnitric oxide, which was prepared by the oxidation of diphenylhydroxylamine with silver oxide[1] (see Fig. 2 and Eq. 1).

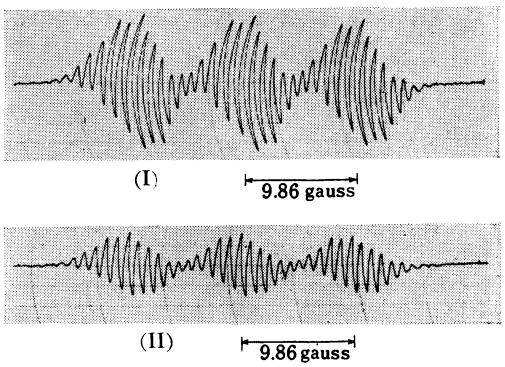

Fig. 2. A comparison of ESR spectra of the free radical produced with that of pure diphenylnitric oxide.
(I) ESR spectrum of the reaction mixture resulting from the reaction between nitrosobenzene and phenylmagnesium bromide.
(II) ESR spectrum of pure diphenylnitric oxide.

$$C_6H_5NO + C_6H_5MgBr \longrightarrow C_6H_5-\underset{\displaystyle O}{\underset{|}{N}}-C_6H_5 \quad (1)$$

The reaction between phenylmagnesium bromide and *p*-nitrosotoluene was carried out in just the same way as that between phenylmagnesium bromide and nitrosobenzene. A large amount of a free radical was also observed

in this reaction. This free radical was identified as *p*-methyldiphenylnitric oxide by a comparison of its hyperfine structure with a known sample.[1]

The reaction between *p*-tolylmagnesium bromide and nitrosobenzene was also examined, and the features of the reaction were quite the same as that of the above two. The ESR signals of the free radical produced were just the same as those of the free radical obtained in the reaction between phenylmagnesium bromide and *p*-nitrosotoluene (see Fig. 3 and Eq. 2).

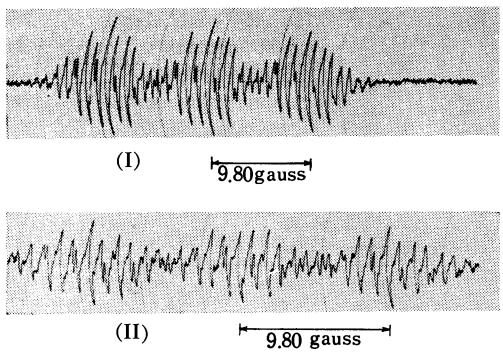

Fig. 3. A comparison of the ESR spectra.
(I) ESR spectrum of the reaction mixture resulting from the reaction between nitrosobenzene and *p*-tolylmagnesium bromide.
(II) ESR spectrum of the reaction mixture resulting from the reaction between *p*-nitrosotoluene and phenylmagnesium bromide.

$$\begin{matrix} C_6H_5NO+ \\ p\text{-}CH_3C_6H_4MgBr \end{matrix} \longrightarrow p\text{-}CH_3C_6H_4\text{—}N(\cdot)\text{—}C_6H_5 \quad (O) \longleftarrow \begin{matrix} p\text{-}CH_3C_6H_4NO+ \\ C_6H_5MgBr \end{matrix} \qquad (2)$$

The above three reactions indicate that the production of free radical species is due solely to the reaction between nitrosobenzene and the Grignard reagent and not to any other cause, such as the decomposition of nitrosobenzene.

The reaction between nitrosobenzene and methylmagnesium iodide and the reaction between nitrosobenzene and ethylmagnesium bromide were also examined. A large amount of free radicals could be observed in these reactions by the ESR technique. The free radical species, however, could not be identified because of the complication of their hyperfine structures (see Fig. 4).

The Equilibrium between the Free Radicals Produced and the Grignard Reagent.—In several

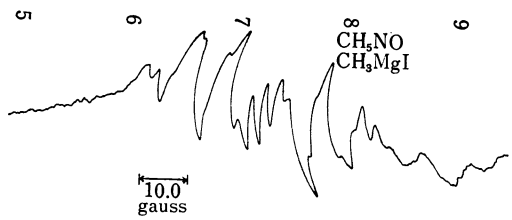

Fig. 4. The ESR spectra of free radicals produced by reaction between nitrosobenzene and methylmagnesium bromide.

preliminary reactions, it was found that the total amount of free radicals in the reaction mixture is considerably influenced by the mole ratio of the two reacting components. The quantitative determination of the free radicals in the reaction mixture was performed by the overmodulated modulation technique of ESR[4] (sweep range, about 200 gauss; modulation amplitude, 11.2 gauss; crystal current, 60 mamp.). A solution of diphenylpicrylhydrazyl in tetrahydrofuran whose concentration was known was used as the standard sample. The results obtained are shown in Table I.

The change in the concentration of free radicals on the successive addition of nitrosobenzene to the solution with a constant amount of the Grignard reagent (phenylmagnesium bromide) was examined by the successive breaking of break seals; thereby the reaction mixture and a known amount of nitrosobenzene in a vacuum tube (in this case, the Grignard reagent dissolved in 10 ml. of tetrahydrofuran is in part B of the reaction vessel and nitrosobenzene is in part A of the vessel) were separated. The results are shown in Table II.

Although the above two series of reactions suggest the existence of an equilibrium in the reaction mixture, the analysis of the reaction product was carried out when nitrosobenzene was mixed with a large excess of phenylmagnesium bromide in order to ascertain whether or not the disappearance of the free radicals is caused by a further reaction, such as a formation of diphenylamine. Thus, two vessels, containing phenylmagnesium bromide dissolved in tetrahydrofuran and nitrosobenzene dissolved in tetrahydrofuran respectively, were degassed and connected with each other by using a break seal; then they were cooled to $-80°C$ and mixed by breaking the seal. The whole reaction vessel was kept at this temperature for thirty minutes after mixing. A rather large amount of a white crystalline precipitate was formed. Then the reaction

DPHA : Diphenylhydroxylamine

mixture was allowed to stand until its temperature reached 0°C. The reaction mixture was hydrolyzed by a usual method under a stream of nitrogen. After the evaporation of tetrahydrofuran, an almost colorless crystalline mass was obtained. This was nearly pure diphenylhydroxylamine. Recrystallization of this sample from ligroin gave pure diphenylhydroxylamine (m. p. 59~60°C) (see Table III). The results of this reaction indicate unambiguously that the disappearance of free radicals which occurs when a large excess of phenylmagnesium bromide to nitrosobenzene is used is not brought about by a further reaction.

Furthermore, the dependency of the concentration of free radicals in the reaction mixture on the temperature was examined by the ESR technique. The results are shown in Fig. 5. The plots in Fig. 5 were completely reproducible at each temperature.

Reaction Mechanism.—It was described above that free radical species could not be observed

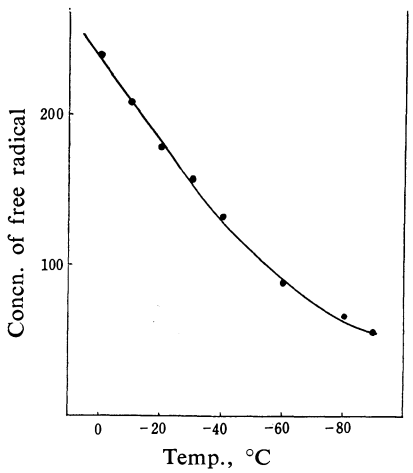

Fig. 5. Change in free radical concentration with temperature.
Sample : reaction mixture between 2.5×10^{-4} mol. of nitrosobenzene and 7.5×10^{-4} mol. of phenylmagnesium bromide.

in the reaction mixture at the equilibrium state in which the mole ratio of the reacting components (C_6H_5NO/C_6H_5MgBr) was 1/10. However, even in this reaction mixture, free radicals could be detected shortly after the mixing of the reacting components (2~3 min. at −50°C) by ESR and until its equilibrium was attained. This fact excludes the possibility (of Eq. 3) that a Grignard-type complex is formed at first through an ionic mechanism, and that then this complex dissociates into free radicals:

$$C_6H_5NO+C_6H_5MgBr \longrightarrow C_6H_5-\underset{\underset{O-MgBr}{|}}{N}-C_6H_5 \rightleftarrows C_6H_5-\underset{\underset{O\cdot}{|}}{N}-C_6H_5+\cdot MgBr \quad (3)$$

From the discussion so far, it seems reasonable to conclude that the reaction between nitrosobenzene and a Grignard reagent proceeds through the free radical mechanism and that the following equilibrium exist between the free radicals formed and the mixture of Grignard reagents:

$$C_6H_5NO+(C_6H_5MgBr)_n \longrightarrow \begin{matrix} C_6H_5 \\ C_6H_5 \end{matrix}\!\!>\!N-O\cdot+\cdot MgBr(C_6H_5MgBr)_{n-1} \underset{\uparrow}{\downarrow} \left(\begin{matrix} C_6H_5 \\ C_6H_5 \end{matrix}\!\!>\!N-OMgBr\right)(C_6H_5MgBr)_{n-1} \quad (4)$$

Although the Grignard reagent is one of the most familiar reagents to organic chemists, its structure is still the subject of great controversy.[5] It has been accepted, in general, that the reagent is an equilibrium mixture, that is:

$$2\ RMgX \rightleftarrows RMgR+MgX_2 \quad (5)$$

However, a simple mixture of one mole of RMgR and one mole of MgX_2 is less reactive than the reagent prepare from Mg and RX.[6] On the other hand, it was confirmed that a large excess of the Grignard reagent ($C_6H_5\cdot MgBr$) can combine with pure diphenylnitric oxide to result in the disappearance of this free radical (see Fig. 6).

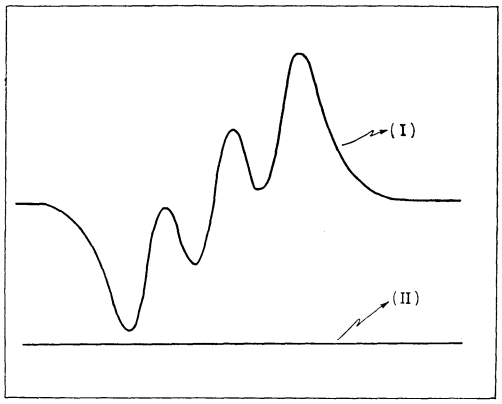

Fig. 6. Reaction of diphenylnitric oxide with phenylmagnesium bromide, ESR spectra of solutions.
(I) 1.25×10^{-4} mol. solution of diphenylnitric oxide in 10 ml. THF.
(II) After addition of 7.5×10^{-4} mol. of phenylmagnesium bromide to solution I.

These facts seem to suggest that the Grignard reagent contains some sort of $(MgBr)_2\cdot(RMgBr)_n$-type complex.[7] Therefore, the existence of an equilibrium between diphenylnitric oxide and an excess of the Grignard reagent seems not surprising.

The author wishes to express his sincere gratitude to Professor S. I. Weissman for his fruitful suggestions, discussions, and encouragement. This work was done with the financial support of the National Science Foundation of the U. S. A.

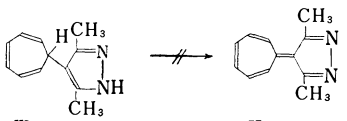
7) The Grignard reagent can produce ketyl-like free radicals from the ketones, which can be easily reduced to the corresponding metal ketyls. This investigation will be reported on later.

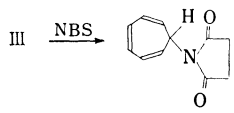
The Fragmentation Reaction of 4-(7-Tropyl)pyrazoles by Bromination[1]



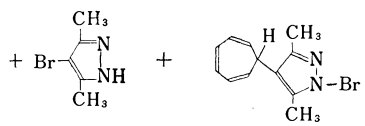
By Toshio MUKAI and Haruki TSURUTA

(Received on February 24, 1964)

Because of its peculiar ring system, a synthesis of sesquifulvalene (I) has been attempted by many chemists. Recently Prinzbach and Rosswog[2] and Kitahara and Funamizu[3] reported the synthesis of I, but they failed in the isolation of I in a pure state, it being very unstable. In an attempt to synthesize a nitrogen analog (II) of sesquifulvalene by the dehydrogenation of 3, 5-dimethyl-4-(7-tropyl)-pyrazole (III), the present authors found that, instead of the expected product resulting, fragmentation had occurred during the bromination-dehydrobromination of III, yielding tropyrium ino and pyrazole derivatives. This report will describe details of the results obtained.



I



III II

3, 5-Dimethyl-4-(7-tropyl)pyrazole (III) was obtained quantitatively from the reaction of tropylacetylacetone[4,5] with hydrazine. The acetylation of III gave a monoacetate. The dehydrogenation of III by heating it with chloranil in xylene afforded a dark green resinous material. The treatment of III with alkaline hydorgen peroxide[6] resulted in the recovery of III. Refluxing III with selenium dioxide in dioxane afforded a viscous oil which could not be purified.

The reaction of III with *N*-bromosuccinimide in *t*-butanol containing water and pyridine[7] yielded three kinds of products besides succinimide: colorless crystals (IV) $C_{11}H_{11}O_2N$ (m. p. 144~146°C); colorless crystals (V) $C_5H_7N_2Br$ (m. p. 122°C), and an oil (VI) $C_{12}H_{13}N_2Br$ (b. p. 150~160°C/3 mmHg). On the basis of their elementary analyses and their ultraviolet and infrared spectra (see Experimental section), IV and V were confirmed to be *N*-(7-tropyl)succinimde[8] and 4-bromo-3, 5-dimethylpyrazole[9] respectively. From its elementary analysis and the fact that it has no absorption due to the NH stretching vibration, but still has the tropyl group, (see Experimental section) VI was assumed to be 1-bromo-3, 5-dimethyl-4-tropylpyrazole. Further evidence for the structure of VI was provided by its NMR spectrum,[10] which has the multiplicities, chemical shifts (τ value), relative areas and interpretations of the signals produced in carbon tetrachloride shown below: two singlets, at 8.12 and 8.03 τ, relative area 3 and 3, two methyl groups in the pyrazole ring; a triplet, at 6.58, 1, C_7-proton of the tropyl group; three multiplets, centered at 5.02, 4.59 and 4.08, 2, 2 and 2, the protons of the $C_{1,6}$, $C_{2,5}$ and $C_{3,4}$ of the tropyl group. VI did not yield the expected sesquifulvalene derivative (II) on attempted dehydrogenation with collidine at 100°C or when refluxed with sodium acetate in ethanol; it was recovered unchanged.

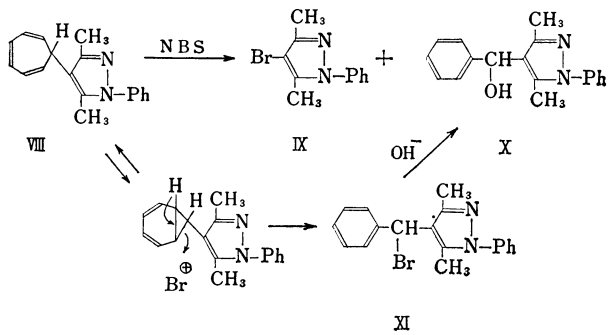
When III was heated with *N*-bromosuccinimide in carbon tetrachloride in the presence of benzoyl peroxide, the same products, IV, V, VI and succinimide, were obtained as when a polar solvent was used, as above. The bromination of III, when carried out by the addition of bromine in a chloroform solution, yielded V, benzaldehyde and yellow plates (VII) $C_7H_7Br_3$ (m. p. 115°C(decomp.)), which has no maximum in the ultraviolet spectrum. When VII was heated in ethanol or water, it yielded benzaldehyde. These facts indicate that VII was probably identical with the compound obtained by Dewar and Petit[11] by the bromination of tropylium ions; the identity of the two compounds was confirmed by a comparison of their infrared spectra and by a mixed melting point determination. The fragmentation of III can be explained by the



V

11) M. J. S. Dewar and R. Petit, *J. Chem. Soc.*, **1956**, 2026. They proposed the following structure for VII:

following mechanism (p. 1019), which is initiated by the attack of a bromonium ion; the driving force would be the formation of the stable tropylium ion.

It has already been reported by Conrow[3] that the fragmentation of the tropyl derivatives, in general, results from the action of an acid or of electrophilic reagents. For example, tropylmalononitrile, tropylmalonic acid and IV are readily cleaved into tropylium ions and the corresponding components. This situation can be clearly seen from a comparison of the NMR spectra of the above three compounds measured in chloroform or pyridine and that measured in trifluoroacetic acid (Figs. 1, 2 and 3). 3, 5-Dimethyl-4-(7-tropyl)pyrazole (III), however, was recovered unchanged after treatment with acetic acid containing perchloric acid, and the NMR spectrum of III in trifluoroacetic acid showed that the fragmentation of III dose not occur, but that a salt is formed, being clear from the shift to a lower field of signals due to the protons of the methyl groups at the pyrazole and due to the C_7-proton of the tropyl group (Fig. 4).

The hydrobromide salt of III was obtained as colorless crystals (m. p. 195°C (decomp.)) when hydrogen bromide gas was passed through a benzene solution of III.

In order to compare it with the bromination of III, 3, 5-dimethyl-1-phenyl-4-(7-tropyl)pyrazole (VIII) was brominated with *N*-bromosuccinimide or bromine under the same condition as were used above. VIII or the bisphenylhydrazone of tropylacetylacetone was obtained by the reaction of tropylacetylacetone with phenylhydrazine, depending on the reaction conditions. The bromination of VIII in chloroform with bromine also afforded the fragmentation products, tropylium ions and 4-bromo-3, 5-dimethyl-1-phenylpyrazole[12] .(IX) as an oil (b. p. 175~180°C/2 mmHg), as well as a considerable amount of an unidentified viscous oil. The reaction of VIII with *N*-bromosuccinimide in *t*-butanol containing pyridine and water resulted in the formation of IX and colorless crystals (X), $C_{18}H_{18}ON_2$ (m. p. 102~106°C). The infrared spectrum of X shows the presence of the hydroxyl group at 3230 and 1020 cm^{-1}. The NMR spectrum of X in carbon tetrachloride reveals no signal characteristic of the tropyl group, but the following multiplicities, chemical shifts (τ value), relative areas and assignments of the signals: a singlet, at 8.13, 6, the methyl groups of the pyrazole ring; a singlet, at 5.14, 1, the hydroxyl-proton; singlet, at 4.56, 1, the benzylic proton; diffused singlet, at 2.96, about 10, protons of the benzene rings. From these data, X was assumed to be 3, 5-dimethyl-4-(α-hydroxybenzyl)-1-pheylpyrazole. Compound XI may be an intermediate in the formation of X from VIII, but it must be examined further.

From this series of experiments, it became clear that the 1-phenyl derivative (VIII) also suffered from fragmentation when brominated with *N*-bromosuccinimide or bromine.

However, the yield of tropylium ions and IX from VIII was rather lower than in the case of III. This may be attributed to the effect of the 1-phenyl group. The treatment of VIII with perchloric acid in acetic acid or with hydrogen bromide in benzene resulted in the recovery of VIII without the formation of the corresponding salt.

Experimental[13,14]

3, 5-Dimethyl-4-(7-tropyl)pyrazole (III). — To a solution of 3.12 g. (16.4 mmol.) of 7-tropylacetylacetone dissolved in 48 ml. of ethanol, 2.1 ml. (32.8 mmol.) of 80% hydrazine hydrate was added; the reaction mixture was then refluxed on a water bath for 2 hr. After the ethanol had been removed, the solution was diluted with water and extracted with ether. The ether-extract was washed with water, dried over magnesium sulfate, and evaporated to

13) All melting points are uncorrected.

14) The microanalyses were carried out by Miss Ayako Iwanaga and Miss Mutsuko Suzuki in this Laboratory.

yield 3 g. of III, which on recrystallization from ethanol afforded colorless prisms (m. p. 144～146°C). IR in Nujol: 3195, 3135, 3086, 1575, 1442, 1389, 1311, 1279, 1149, 1042, 1006, 847, 765, 749, and 705 cm^{-1}. λ_{max}^{MeOH} mμ (log ε): 260 (3.55).

Found: C, 77.20; H, 7.21; N, 14.80. Calcd. for $C_{12}H_{14}N_2$: C, 77.38; H, 7.58; N, 15.04%.

A solution of 200 mg. of III dissolved in 0.5 ml. of acetic anhydride was heated on a boiling water bath for 30 min. and evaporated under reduced pressure to give 240 mg. of an acetylated compound of III (m. p. 36～41°C.) Recrystallization from ethanol afforded colorless needles (m. p. 36～41°C) IR in KBr disk: 1720, 1598, 1424, 1382, 1370, 1336, 856, 750, and 710 cm^{-1}.

Found: C, 73.50; H, 6.88; N, 12.00. Calcd. for $C_{14}H_{16}ON_2$: C, 73.65; H, 7.06; N, 12.27%.

The Reaction of 3, 5-Dimethyl-4-(7-tropyl)pyrazole (III) with *N*-Bromosuccinimide. — *a) In a Polar Solvent.*—To a solution of 800 mg. (4.3 mmol.) of III dissolved in 20 ml. of *t*-butanol, 8 ml. of pyridine and 3 ml. of water, 900 mg. (5.0 mmol.) of *N*-bromosuccinimide was added. The mixture was then allowed to stand for 48 hr. at room temperature and extracted with chloroform after being diluted with water. The chloroform-extract was washed with water, dried over magnsium sulfate, and evaporated up to an oil containing some crystals. After being diluted with a small amount of ethanol or benzene, 180 mg. of crystals (m. p. 142～145°C) were filtered out, on recrystallization from ethanol or ethyl acetate these afforded colorless plates (IV) (m. p. 144～146°C.) IR in Nujol: 1779, 1695, 1408, 763, 748, 708, and 678 cm^{-1}. λ_{max}^{MeOH} mμ (log ε): 258 (4.13).

Found: C, 70.55; H, 5.58; N, 7.41. Calcd. for $C_{11}H_{11}O_2N$: C, 69.82; H, 5.86; N, 7.40%.

IV was found to be identical with authentic *N*-(7-tropyl)-succinmide[8] (m. p. 146°C) by mixed melting point determination and by a comparison of their infrared spectra.

After the solvent had been evaporated, the filtrate of the crude IV was dissolved in petroleum ether-benzene and chromatographed through a column containing 30 g. of alumina. The evaporation of the elute with the same solvent gave 270 mg. of a yellow oil (VI) (b. p. 150～160°C/3 mmHg) IR in oily state: 3030, 2925, 1548, 1471, 1422, 1345, 1266, 1065, 743, and 706 cm^{-1}. λ_{max}^{MeOH} mμ (log ε): 230 (3.86) 265 (3.52).

Found: C, 54.38: H, 4.62; N, 9.70. Calcd. for $C_{12}H_{13}N_2Br$: C, 54.34; H, 4.90; N, 10.26%,

The subsequent elute with benzene-ether (49 : 1) gave 40 mg. of IV (m. p. 139～142°C) while the elute with ether-ethanol (60 : 1) afforded 390 mg. of crystals, (m. p. 116～119°C) which on recrystallization from ethanol-water gave colorless crystals (V) (m. p. 122°C), IR in Nujol: 3225, 3123, 1586, 1431, 1310, 1098, 1042, 1000, 830, and 768 cm^{-1}. λ_{max}^{MeOH} mμ (log ε): 226 (4.04).

Found: C, 34.28; H, 4.00; N, 16.02. Calcd. for $C_5H_7N_2Br$: C, 34.68; H, 4.07; N, 15.51%.

V was confirmed to be identical with authentic 4-bromo-3, 5-dimethylpyrazole,[9] (m. p. 122°C) by mixed melting point determination.

b) In a Nonpolar Solvent.—A solution of 800 mg. (4.3 mmol.) of III, 740 mg. (4.2 mmol.) of *N*-bromosuccinimide and 50 mg. of benzoyl peroxide dissolved in 16 ml. of carbon tetrachloride was refluxed in a nitrogen atmosphere for 3 hr. After the succinimide which separated had been filtered off, the filtrate was concentrated by distillation at reduced pressure to give a mixture of an oil and crystals. Filtration afforded 180 mg. of IV (m. p. 140～144°C) and an oily part. The latter was chromatographed using 30 g. of alumina by the same way as in a). Thus, 380 mg. of VI, (as an oil) and 200 mg. of V (m. p. 110～118°C) were obtained.

The Reaction of 3, 5-Dimethyl-4-(7-tropyl)pyrazole (III) with Bromine.—Into a solution of 500 mg. 2.7 mmol.) of III in 2 ml. of chloroform, a solution of 860 mg. (5.4 mmol.) of bromine in 0.6 ml. of chloroform was stirred while the solution was being cooled by ice. The mixture was stirred for 20 min. The crystals which formed during the reaction were filtered off to give 210 mg. of yellow crystals, (m. p. 104～106°C) which on recrystallization from ethanol afforded crystals (VII) (m. p. 115°C (decomp.)). IR in Nujol: 3050, 3005, 1586, 1274, 1218, 976, and 866 cm^{-1}.

Found: C, 25.77; H, 2.10. Calcd. for $C_7H_7Br_3$: C, 25.37; H, 2.11%.

VIII was identified with the compound (m. p. 115°C (decomp.)) which was obtained by the bromination of tropylium ions[11] by a comparison of their infrared spectra. The ethanolic filtrate of VII, upon being treated with 1.2 ml. of an ethanol solution containing 240 mg. of 2, 4-dinitrophenylhydrazine, afforded 80 mg. of 2, 4-dinitrophenylhydrazone of benzaldehyde (m. p. 220°C). The chloroform-mother liquor was poured into water and shaken. The separated chloroform layer was washed with water and dried over magnesium sulfate. The evaporation of the chloroform afforded 460 mg. of an oil, which was then dissolved in benzene and chromatographed through a column containing 22 g. of alumina. The evaporation of thebenzene-elute gave 20 mg. of an oil, which then afforded 2, 4-dinitrophenylhydrazone of benzaldehyde. The elute with ether gave 90 mg. of 4-bromo-3, 5-dimethylpyrazole (V) (m. p. 121°C). The elute with ether-ethanol (15 : 1) gave 270 mg. of colorless crystals (m. p. about 175°C) (Found: C, 56.51; H, 5.19; N, 15.17%), which were difficult to recrystallize from the usual solvents. IR in Nujol: three peaks about 3145, 1585, 1542, 1492, 731, and 695 cm^{-1}.

The Stability of 3, 5-Dimethyl-4-(7-tropyl)pyrazole (III) towards Acids.—a) Hydrogen bromide gas was passed into a solution of 200 mg. (1.1 mmol.) of III dissolved in 6 ml. of benzene, giving colorless crystals. Filtration gave 145 mg. of colorless crystals (m. p. 193°C (decomp.)) which, on recrystallization from a mixture of ethanol and ethyl acetate, gave crystals (m. p. 195°C (decomp.)).

Found: C, 54.23; H, 5.63; N, 10.40. Calcd. for $C_{12}H_{15}N_2Br$: C, 53.93; H, 5.66; N, 10.48%.

After standing the filtrate afforded 80 mg. of crystals (m. p. 132～155°C). The hydrobromide salt was added to an aqueous solution of sodium bicarbonate and extracted with ether. The ether-extract was washed with water, dried over sodium

sulfate, and evaporated to give III (m. p. 139~142°C) quantitatively.

b) To a solution of 200 mg. of III in 7 ml. of acetic acid, 0.3 ml. of 60% perchloric acid was added. Since no tropylium perchlorate precipitated when the mixture had been stood for 30 min., one further ml. of 60% pechloric acid was added to the solution. After being diluted with water and neutralized with a 2N sodium hydroxide solution the solution was extracted with ether. The ether-extract was washed with water, dried over sodium sulfate, and evaporated, giving 180 mg. of III (m. p. 145°C).

The Preparation of 3, 5-Dimethyl-1-phenyl-4-(7-tropyl)pyrazol (VIII) and Bisphenylhydrazone of 7-Tropylacetylacetone.—a) To a solution of 2 g. (10.7 mmol.) of 7-tropylacetylacetone in 25 ml. of ethanol, 1.5 ml. (13.8 mmol.) of phenylhdrazine was added. The reaction mixture was refluxed on a water bath for 1 hr. and then diluted with a large amount of water and extracted with ether. The ether-extract was washed with water and dried over magnesium sulfate, and the ether was evaporated to give 2.5 g. of an oil containing crystals. The filtration afforded 680 mg. of colorless crystals (m. p. 122~125°C) as the first crop and 240 mg. of crystals (m. p. 123~125°C) as the second crop. The residual part was dissolved in benzene-petroleum ether and chromatographed through a column containing 60 g. of alumina. The evaporation of the elute with the same solvent gave 390 mg. of a brownish yellow oil. 1.1 g. of crystals (m. p. 116~125°C) was obtained from the elute with benzene. The crystals obtained here were combined and recrystallized from ethanol, giving colorless prisms (VIII) (m. p. 126~127.5°C). IR in Nujol: 1577, 1565, 1505, 1450, 1427, 1386, 1364, 1137, 1070, 1015, 914, 856, 804, 800, 767, 752, 713, 702, and 683 cm^{-1}. λ_{max}^{MeOH} $m\mu$ (log ε) : 245 (4.01).

Found: C, 81.97; H, 6.73; N, 10.68. Calcd. for $C_{18}H_{18}N_2$: C, 82.40; H, 6.92; N, 10.68%.

b) A solution of 0.5 g. (2.7 mmol.) of 7-tropylacetylacetone and 0.9 g. (8.1 mmol.) of phenylhydrazine in 10ml. of ethanol was refluxed on a water bath for 20 min. and then allowed to stand in a refrigerator overnight. The crystals which precipitated were collected and recrystallized from ethanol to yield 200 mg. of bisphenylhydrazone of 7-tropylacetylacetone as colorless needles (m. p. 165~167°C). IR in Nujol: 3448, 1603, 1504, 755, 745, 725, and 695 cm^{-1}.

Found: C, 77.94; H, 6.77; N. 14.84. Calcd. for $C_{24}H_{26}N_4$: C, 77.80; H, 7.07; N, 15.12%.

The Bromination of 3, 5-Dimethyl-1-phenyl-4-(7-tropyl)pyrazole (VIII).—To a well-stirred solution of 600 mg. (2.3 mmol.) of VIII in 2 ml. of chloroform, a solution of 400 mg. (2.5 mmol.) of bromine in 1.5 ml. of chloroform was added drop by drop while the solution was being cooled by ice. The reaction mixture was then stirred for 30 min., diluted with a large amount of chloroform, and washed with water. The addition of acetylacetone to the water-washing afforded 30 mg. of 7-tropylacetylacetone (m. p. 123°C), indicating the presence of tropylium ions.[4] The chloroform-layer was dried over sodium sulfate and evaporated, yielding 670 mg. of a brownish yellow oil. This oil was dissolved in petroleum ether - benzene (1 : 1) and chromatographed through a column containing 20 g. of alumina. The evaporation of the elute with the same solvent afforded 230 mg. of an oil, which on distillation under reduced pressure gave two fractions, b. p. 175~180°C/2 mmHg (IX) and b. p. 215~220°C/2 mmHg (Found: C, 74.83; H, 6.92; N, 8.82%), in a ratio of 2 : 1. IX has the following data: IR in an oily state: 1595, 1546, 1504, 1465, 1412, 1377, 1362, 1080, 1041, 1022, 739, 793, 696, and 682 cm^{-1}.

Found: C, 54.11; H, 4.47; N, 10.19. Calcd. for $C_{11}H_{11}N_2Br$: C, 53.59; H, 4.38; N, 11.11%.

The infrared spectrum of IX was superposed on that of an authentic sample of 4-bromo-3, 5-dimethyl-1-phenylpyrazole.[12] The elutes with ether and ethanol afforded 220 mg. of a viscous oil which was not further studied.

The Reaction of 3, 5-Dimethyl-1-phenyl-4-(7-tropyl)pyrazole (VIII) with *N*-Bromosuccinimide.—To a solution of 800 mg. (3.0 mmol). of VIII in 20 ml. of *t*-butanol containing 7 ml. of pyridine and 2 ml. of water, 650 mg. (3.7 mmol.) of *N*-bromosuccinimide was added, and the resulting mixture was allowed to stand at room temperature for 48 hr. The solution was then diluted with water and extracted with chloroform. After being washed with water and dried over magnesium sulfate, the chloroform-extract was evaporated at reduced pressure to give 465 mg. of a viscous oil. The oil was dissolved in petroleum ether - benzene and chromatographed through a column containing 14 g. of alumina. The evaporation of the elute with the same solvent afforded 90 mg. of a yellow oil (b. p. 165~175°C/2 mmHg) which was found to be identical with IX by a comparison of their infrared spectra. The elute with benzene-ether (1 : 1) and ether gave 125 mg. of a viscous oil, which crystallized after standing for a long period of time. These crystals were difficult to recrystallize from usual organic solvents, but on digestion with ethyl acetate they gave colorless crystals (X) (m. p. 102~106°C). IR in Nujol: 3230, 1595, 1562, 1507, 1487, 1427, 1331, 1283, 1256, 1165, 1144, 1022, 810, 790, 769, 729, and 702 cm^{-1}. λ_{max}^{MeOH} $m\mu$ (log ε) : 251 (4.07).

Found: C, 77.37; H, 6.22; N, 10.17. Calcd. for $C_{18}H_{15}ON_2$: C, 77.67; H, 6.52; N, 10.07%.

The Stability of 3, 5-Dimethyl-1-phenyl-4-(7-tropyl)pyrazole (VIII) towards Acids.—a) A solution of 100 mg. of VIII in 2 ml. of benzene was saturated with hydrogen bromide gas and allowed to stand at room temperature for 2 hr., during which no crystal formed. After the solution had been washed with water and dried over magnesium sulfate, the removal of the benzene regenerated 65 mg. of VIII, (m. p. 126~128°C).

b) To a solution of 50 mg. of VIII in 1.5 ml. of acetic acid, 0.1 ml. of 60% perchloric acid was added; no crystal formed during a 5-min. period. Then 0.1 ml. of 60% perchloric acid was added to the solution and the solution was allowed to stand at room temperature for 20 min. After being diluted with a large amount of water, the solution was extracted with ether. The ether-extract was

washed with water, dired over magnesium sulfate, and evaporated to give 35 mg. of VIII (m. p. 122~125°C).

The authors wish to take this opportunity to express their deep gratitude to Professor Tetsuo Nozoe for his kind guidance throughout the course of this work. They also wish to thank Professor Genjiro Hazato and his colleages of the Chemical Institute of Non-aqueous Solutions, Tohoku University, for their measurement of the NMR spectrum and the Sankyo Co. for the donation of research funds which covered a part of the expenses of this work.

Studies on the Chemical Decomposition of Simple Sugars. XV. The Synthesis of 1-O-Benzoyl-3,4; 5,6-di-O-isopropylidene-L-xylo-2-hexulose

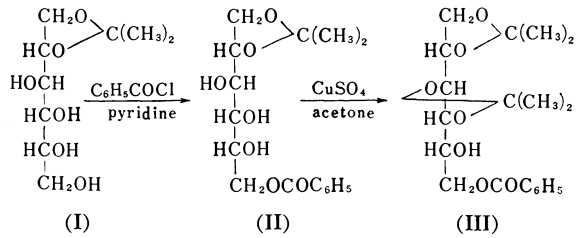
By Hiroyuki MIZOIRI, Akira SERA and Ryozo GOTO

(Received February 24, 1964)

Syntheses of keto-hexuloses have been made by many investigators since 1941. For instance, some synthetic procedures working through the condensation of acetylated aldonyl chlorides with diazomethane[1] and the oxidation of substituted hexitols with chromium trioxide[2,3] have been reported. However, the synthesis of diisopropylidene-keto-L-sorbose has not been reported. In accordance with the research program in our laboratory studying the decomposition mechanism of simple sugars, 1-*O*-benzoyl-3,4; 5,6-di-*O*-isopropylidene-L-*xylo*-2-hexulose, i. e., 1-*O*-benzoyl-3,4; 5,6-di-*O*-isopropylidene-keto-L-sorbose, has been synthesized. As the starting compound 1,2-*O*-isopropylidene-D-sorbitol was used.

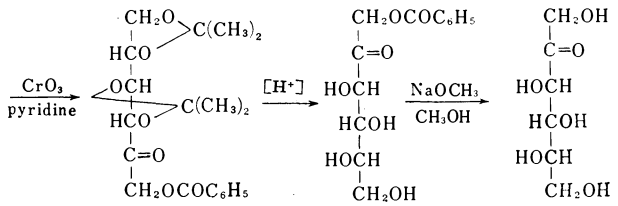
The benzoylation of 1,2-*O*-isopropylidene-D-sorbitol[4] (I) with an equimolar amount of benzoyl chloride in anhydrous pyridine gave 1,2-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol (II). When II was treated with acetone in the presence of anhydrous copper sulfate, diacetone-monobenzoyl-D-sorbitol (III) was obtained. After the debenzoylation of III, one mole of di-*O*-isopropylidene-D-sorbitol obtained consumed one mole of sodium periodate. Therefore, III was confirmed to be 1,2; 3,4-di-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol, and the presence of 1,2; 4,5-di-*O*-isopropylidene isomer was excluded.

Compound II has three adjacent hydroxyl groups, attached to the carbons 3, 4 and 5. The adjacent hydroxyl groups attached to C_4 and C_5 have an erythro-, and those attached to C_3 and C_4 have a threo-configuration. In order to condense with acetone to form a five-membered ring, the two hydroxyl groups must have an eclipsed conformation. In such circumstances, the twist around the C_4–C_5 bond axis causes a large steric repulsion between the bulky groups (R_2 and $R_1 + C_3$ in Fig. 1), while that around the C_3–C_4 bond axis makes the steric repulsion (Fig. 2) so small that the condensation with acetone may take place and 1,2; 3,4-di-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol is produced exclusively.



The oxidation of 1,2; 3,4-di-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol (III) with chromium trioxide gave 1-*O*-benzoyl-3,4; 5,6-di-*O*-isopropylidene-keto-L-sorbose (IV) in a 49% yield. The deacetonation of ketose (IV) was effected by using the ion-exchange resin, Amberlite IR-120 (H-form). The crystalline 1-*O*-benzoyl-L-sorbose (V) obtained was debenzoylated by transesterification with methanol in the presence of sodium methoxide to give crystalline L-sorbose (VI).

Further investigations related to those described in this communication are in progress.



Experimental

1,2-*O*-Isopropylidene-6-*O*-benzoyl-D- sorbitol (II).—To an ice-cooled solution of 1,2-*O*-isopropylidene-D-sorbitol (18 g.) in 130 ml. of anhydrous pyridine, benzoyl chloride (12 ml.) was added with vigorous stirring drop by drop. After standing overnight at

(Fig. 2.) eclipsed threo-form

room temperature, the solution was concentrated under reduced pressure. The resulting sirup was poured into 300 ml. of ice and water, and the crystalline precipitate was filtered and recrystallized from isopropyl ether containing a small amount of ethanol. 1,2-*O*-Isopropylidene-6-*O*-benzoyl-D-sorbitol(II) (m. p. 120.0~124.6°C) was obtained. After several recrystallizations, the compound had a m. p. of 124.7~125.1°C (13.5 g.), $[\alpha]_D^{25}$ +3° (*c* 1, pyridine).

Found: C, 58.91; H, 6.88; C_6H_5CO, 34.14, 33.17. Calcd. for $C_{16}H_{22}O_7$: C, 58.86; H, 6.74; C_6H_5CO, 32.21%.

Infrared spectrum: ν_{OH}, 3540, 3450; $\nu_{C=O}$, 1709; $\nu_{C=C}$, 1604, 1589 cm^{-1}.

Moles of periodate consumed/one mole of II: 2.08 (15 min.), 2.09 (20 min.), 2.09 (30 min.) and 2.13 (45 min.). Moles of formic acid produced/one mole of II: 1.05 (17 min.), 1.12 (1 hr.), 1.16 (2 hr.) and 1.24 (4 hr.).

1,2; 3,4-Di-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol (III).—To a solution of 1,2-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol (II) (2 g.) in 70 ml. of anhydrous acetone, 5 g. of anhydrous copper sulfate was added, and the mixture was gently refluxed for 30 hr. After the inorganic salt had been filtered off, the filtrate was concentrated under reduced pressure to a sirup, which crystallized slowly when 10 ml. of isopropyl ether was added. The crude material (1.3 g.) had a m. p. of 66.7~67.1°C. After several recrystallizations from isopropyl ether, 1,2; 3,4-di-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol (III) showed a m. p. of 68.2~68.5°C, $[\alpha]_D^{25}$ +19.3° (*c* 1.03, pyridine).

Found: C, 62.19; H, 7.14. Calcd. for $C_{19}H_{26}O_7$: C, 62.28; H, 7.15%.

Infrared spectrum: ν_{OH}, 3550; $\nu_{C=O}$, 1713 cm^{-1}.

After the benzoyl residue of III had been removed, the product was oxidized with sodium periodate in aqueous dioxane. Moles of periodate consumed/one mole of 1,2; 3,4-di-*O*-isopropylidene-D-sorbitol; 1.18 (10 min.), 1.21 (20 min.), 1.25 (40 min.) and 1.28 (50 min.).

When copper sulfate was replaced with zinc chloride in the above procedure, 1,2-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol was recovered unchanged (90%).

1-*O*-Benzoyl-3,4; 5,6-di-*O*-isopropylidene-L-*xylo*-2-hexulose (IV). — Chromium trioxide (9 g.) was added to anhydrous pyridine while being agitated mechanically. To this mixture, 1,2; 3,4-di-*O*-isopropylidene-6-*O*-benzoyl-D-sorbitol (III) (7 g.) was added quickly, and the mixture was kept at 60°C for 7 hr. while being continuously stirred. The mixture was then poured into 300 ml. of ice and water and extracted with ether (200 ml.×7). The ethereal solution was washed successively with dilute hydrochloric acid, aqueous sodium hydrogen carbonate, and water, and then dried over anhydrous

magnesium sulfate. The removal of the solvent gave white crystalline needles (3.4 g.; m. p. 69~70°C). After several recrystallizations from aqueous ethanol, 1-*O*-benzoyl-3,4; 5,6-di-*O*-isopropylidene-L-*xylo*-2-hexulose (IV), (m. p. 75.0°~75.4°C) was obtained. $[\alpha]_D^{25}$ −38.4° (*c* 1, pyridine).

Found: C, 62.70; H, 6.86. Calcd. for $C_{19}H_{24}O_7$: C, 62.62; H, 6.64%. Infrared spectrum: $\nu_{C=O}$, 1742, 1724; $\nu_{C=C}$, 1604, 1588 cm^{-1}. No absorption peak was observed near 3550 cm^{-1}, where the parent compound had an absorption peak.

1-*O*-Benzoyl-L-sorbose (V).—Amberlite IR-120 (H-form) (7 g.) was added to a solution of 1-*O*-benzoyl-3,4; 5,6-di-*O*-isopropylidene-L-*xylo*-2-hexulose (IV) (3 g.) in 100 ml. of acetone and water (3 : 1 by volume). The mixture was kept at 40°C for 30 hr. After the resin had been removed by filtration, the filtrate was concentrated under reduced pressure. A crude material (2.2 g.) was obtained (m. p. 122~125°C). After several recrystallizations from isopropyl ether containing a small amount of ethanol, 1-*O*-benzoyl-L-sorbose (V) showed a m. p. of 132.5~133.0°C. $[\alpha]_D^9$ −2.1° (*c* 5, methanol). (Reported[2] m. p. 133.5°C, $[\alpha]_D^{26}$ −3.4° in methanol (*c* 5)).

Found: C, 54.66; H, 5.74. Calcd. for $C_{13}H_{16}O_7$: C, 54.93; H, 5.67%.

Infrared spectrum: ν_{OH}, 3540, 3350 (broad); $\nu_{C=O}$, 1709, 1697; $\nu_{C=C}$, 1610, 1595 cm^{-1}.

L-Sorbose (VI).—1-*O*-Benzoyl-L-sorbose (V) (1.7 g.) was dissolved in 25 ml. of anhydrous methanol, and the solution was cooled with an ice-bath. Into the cold solution, 6 ml. of 0.1 N sodium methoxide in anhydrous methanol was added. After 2 hr., the cooling bath was removed and the solution allowed to stand overnight at room temperature. The solvent was then distilled off under reduced pressure to a sirup, which crystallized spontaneously (900 mg.; m. p. 158~161°C). After several recrystallizations from aqueous ethanol, L-sorbose showed a m. p. of 164~165°C; it was undepressed when the substance was admixed with an authentic specimen of L-sorbose. $[\alpha]_D^9$ −42.9° (*c* 2.4, water).

Found: C, 40.14; H, 6.83. Calcd. for $C_6H_{12}O_6$: C, 40.00; H, 6.71%.

Studies on the Disproportionation Reaction of Methylnaphthalene

By Etsuro ECHIGOYA, Tōru WATANABE and Kiyoshi MORIKAWA

(Received February 25, 1964)

The disproportionation reaction of toluene and xylene over a silica-alumina catalyst has been studied by several investigators,[1-3] but that of methylnaphthalene (M. N.)[1] has been scarcely studied at all.

This work has been done in order to clarify the promoter action of chromium oxide on the silica-alumina catalyst[4] and also to obtain a kinetic equation for the disproportionation reaction of methylnaphthalene over the catalyst.

Experimental

The reaction was studied by means of the flow method under various pressures. As the reactor for this reaction, a quartz tube (I. D. 2.5 cm.) and a stainless steel tube (I. D. 2.9 cm.), both containing 30 cc. of the catalyst, were used under

atmospheric pressure and 3~6 atms. respectively. The flow sheet of this reaction under pressure is shown in Fig. 1. Methylnaphthalene was diluted with hydrogen which was free from oxygen and was introduced into the reactor.

The reaction products from the reactor were caught by methanol - dry ice cold traps and were analyzed by means of the gas chromatographic method.

Raw Material.—The methylnaphthalene employed in these experiments was provided by Mitsui Chemical Industries and was an equiliburium mixture of α and β isomers. (The sulfur content was about 1 wt.%).

Catalysts. — *Nalcat.* — The fine powders (over 100 mesh) of the commercial nalcat silica-alumina cracking catalyst (aluminum oxid content, 12~13 wt.%) were pelletized to a 4 mm. in diameter.

Chromium Oxide - added Nalcat. — Nalcat powders were immersed in a chromic sulfate solution (1 wt.%), and a small amount of dextrin (5 wt.%) was used as a binder in pelletizing.

Chromia - Alumina Gel Mixed Catalyst. — Aqueous gels of alumina and chromia, both prepared by precipitation from nitrate solutions (3 N) with aqueous ammonia, were kneaded well and dried in granules. The Chromium oxide content of this catalyst was 15 wt.%.

Results and Discussion

Reactions under Atmospheric Pressue. — The Effect of Reaction Temperature on the Disproportionation of Methylnaphthalene. — The reaction over the nalcat catalyst was carried out under the following conditions: SV, 600 hr^{-1}; mole ratio of hydrogen to methylnaphthalene, 4.5. The amounts of liquid

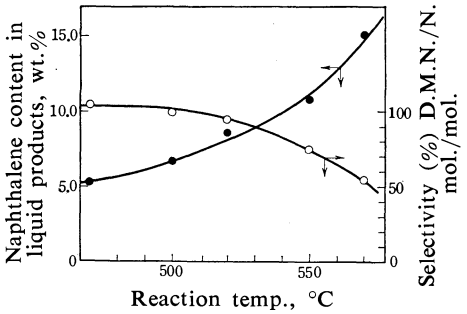

Fig. 2. Activity of SiO_2-Al_2O_3 catalyst for the disproportionation reaction of M. N.
S.V.=600 (hr^{-1}), H_2/M.N.=4.5 (mol. ratio)

products (%) recovered varied a little from experiment to experiment. Figure 2 shows that at lower temperatures, 450~520°C, the yield of naphthalene was quite small (about 7%), but that the selectivity of this reaction was excellent (about 100%); on the other hand, at higher temperatures, 550~570°C, the yield increased up to 15%, but the corresponding selectivity decreased to about 55% because of the increased demethylation reaction.

The Effect of the Chromium Oxide added to the Silicon Oxide - Aluminum Oxide Catalysts on the Disproportionation Reaction. — When several kinds of silica-alumia catalysts were tested, the nalcat was found to give the best result and, therefore, the promoter effect of chromium oxide for this catalyst was examined with nalcat. Figure 3 shows that, as the amount of chromium oxide increased, the yield of naphthalene varied through a maximum, while the selectivity varied through a minimum, in the temperature range of 520~560°C.

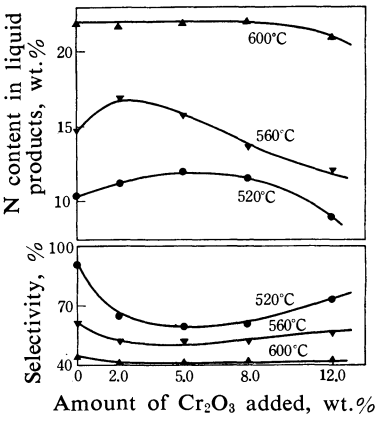

Fig. 3. Effect of addition of Cr_2O_3 on the activity of SiO_2-Al_2O_3 catalysts for the disproportionation reaction of M. N.

The activity of the chromia-alumina catalyst was quite low at 520°C under the same reaction conditions, and the yield of methylnaphthalene was only 4 wt.% even at 560°C. Naphthalene obtained over this catalyst was produced by demethylation, not by disproportionation reaction.

The Structure of Chromium Oxide - added Catalyst.—The nalcat catalyst showed diffuse X-ray patterns, indicating its amorphous structure, while the chromium oxide - added catalyst (5 wt.%) gave markedly sharp diffraction patterns of chromium oxide crystals.

The chromium oxide crystal content was estimated from this pattern to be 3.5 wt.%, amounting to 70% of the chromium oxide added.

The residual 30% of chromium oxide might be in an amorphous state, but its chemical state is not clear.

The mean magnitude of the crystallite of the chromium oxide - added catalyst was calculated by the Scherrer method to be D_{110}=400 Å. This crystal might be free from carriers, since this value was almost the same as those found

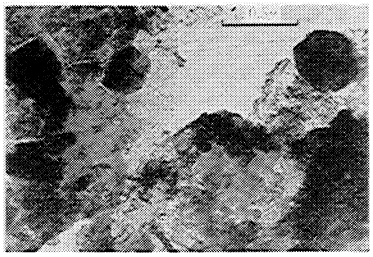

Fig. 4. Electron Micrograph (taken by Mr. A. Kitahara of T. I. T.)
Sample: Cr_2O_3 (5 wt%) on nalcat.

in literature for pure chromium oxide crystals.

Figure 4 shows the electro-micrograph of chromium oxide (5 wt.%)-added nalcat, which was examined by a one-step powder replica method, depositing carbon vapor. This picture shows that many fine crystals (30~80Å), besides a few large hexagonal single crystals (2000~5000Å), exist in very fine nalcat particles.

On the basis of the above results, it may be concluded that most of the added chromium oxide (about 70%) did not chemically combine with silica-alumina and did not widely disperse on the surface, but rather developed into large crystals. The residual chromium oxide (about 30% which was not observed as crystals in the electro-micrographic picture would be in a very finely-dispersed state and exert a promoter action on this reaction, thus explaining the results of Fig. 3 satisfactorily.

Experiments under Pressure. — The experiments under pressure were carried out to study the kinetics of the disproportionation reaction of methylnaphthalene over the chromium oxide (5 wt.%) - added silica-alumina catalyst.

The change in catalytic activity with reaction time was tested under the following conditions: reaction temperature, 470°C; reaction pressure, 17 atm.; mole ratio of H_2 to methylnaphthalene, 10, and contact time, 11 sec. The selectivity for this reaction was almost 100%, but the conversion decreased as the reaction proceeded.

It was further found that there was little difference between the activity of the nalcat with and without chromium oxide. The former, however, was used for this kinetic study under pressure, with carbon deposit being avoided as much as possible.

A Kinetic Analysis of this Catalytic Reaction Accompanied by Activity Degradation. — The rate of the reaction in the flow system may commonly be obtained from the relationship between the conversion and the time factor (W/F). The catalytic activity, however, decreased gradually as the reaction proceeded. Therefore, the degradation curves as shown in Fig. 5 were prepared; they indicate the change in catalytic activities with the reaction time at the constant value of W/F and at each reaction temperature. The initial activities of the catalyst at each W/F can be obtained by extrapolating each curve to the zero reaction time point.

The following reaction conditions were used: the catalyst, 30 cc. (19.2 g.); reaction temperature, 470~430°C; mole ratio H_2 to M. N., 10.0; feed rate of M.N., 12 g./hr.~40 g./hr. (W/F 60~250 hr. g. cat./mol. M. N.), and reaction pressure range, 3.0~15.0 atm. The reaction products were collected four times every two hours and were analyzed. The conversion of the disproportionation reaction was assumed to be twice that of the dimethylnaphthalene (D. M. N.) (mol.%) found. The side reaction of destruction, which may be connected with the carbon deposition, occured

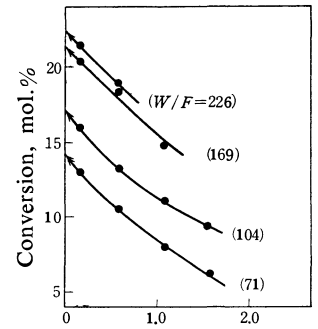

Fig. 5. Chart to read the initial activities of catalysts from the degradation curves.

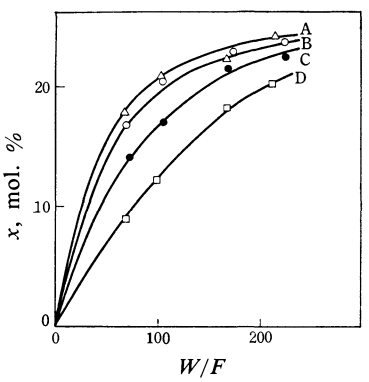

Fig. 6. Relationship between x and W/F under the definite pressures.
H_2/M.N. (mol. ratio), 10.0 Temp., 470°C
π; Total pressure (atm.)

B π=11.0 D π=3.0

to some extent. Figure 6 shows the experimental results, that is, the relationship between the conversion, x, and the time factor, W/F, under several different pressures.

Analysis of the Experimental Results Obtained. — According to the concept of the Langumuir-Hinshelwood mechanism, three rate-controlling steps: (1) adsorption, (2) surface reaction and (3) desorption, may be considered for this surface reaction.

The initial reaction rates r_0 obtained from Fig. 6 were plotted against the corresponding total pressures, π, as Fig. 7-I shows. The shape of the curve in this figure indicates that step 2, the surface reaction, may be the real rate-controlling step for this reaction.

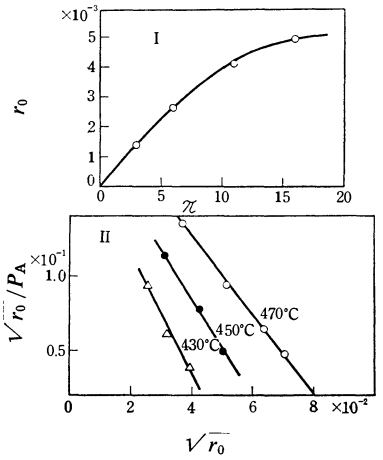

Fig. 7. I: Initial rate vs. total pressure.
II: $\sqrt{r_0}/P_A$ vs. $\sqrt{r_0}$.

Thus, the rate equation (r) and the initial rate equation (r_0) for this reaction may be expressed as follows:

$$r=\frac{k(K_A^2P_A^2-(1/K)K_RK_SP_RP_S)}{(1+K_AP_A+K_AP_A+K_SP_S+K_IP_I)} \quad (1)$$

$$r_0=\frac{kK_A^2P_A^2}{(1+K_AP_A+K_IP_I)^2} \quad (2)$$

Assuming that K_IP_I would be negligibly small in comparison with K_AP_A,

$$\sqrt{r_0}/P_A=a-\sqrt{r_0}+\sqrt{c} \quad (3)$$

where a is K_a and c is $k\,K_a^2$.

The plots of $\sqrt{r_0}/P_a$ vs. $\sqrt{r_0}$ gave straight lines, as Fig. 7-II shows; from this figure a and c can be estimated, while the rate equation at 470°C is given by the following equation.

$$r=\frac{0.0523(1-x)^2-0.414x^2}{(11.0/\pi+2.55(1-x)+7.71x)^2} \quad (4)$$

The full lines in Fig. 8, which were calculated using Eq. 4, agree with the experimental data satisfactorily. Figure 9 shows the temperature dependency of k and K_A, from which the activation energy of this reaction and the heat of adsorption of methylnaphthalene can be estimated to be 32.4 kcal./mol. and 12.6 kcal./mol. respectively.

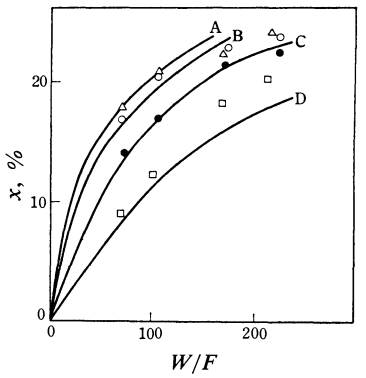

Fig. 8. Test of Eq. 4 with experiments. Full lines indicate the calculated ones after Eq. 4, and all the points indicate the estimated initial activities from the observed conversion-time curves (cf. Fig. 4).
A $\pi=16.0$ atm. C $\pi=6.0$
B $\pi=11.0$ D $\pi=3.0$
React. temp. 470°C

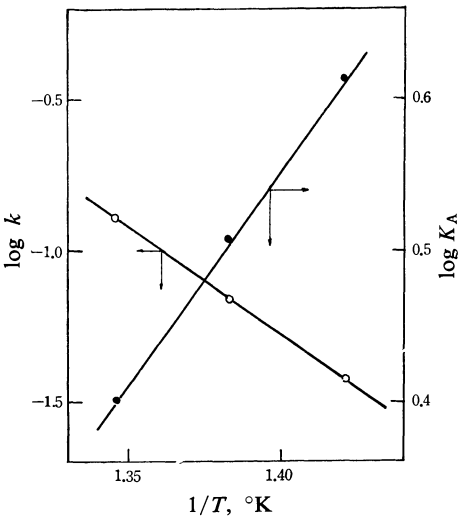

Fig. 6. Temperature dependency of k and K_A.

Summary

The effect of the addition of chromium oxide on the activity of silicon oxide - aluminum oxide for the disproportionation reaction of methylnaphthalene has been studied.

1) As the amount of chromium oxide added increased the yield of naphthalene increased, but the selectivity for this reaction decreased

in the low temperature range of 450～520°C. The 5 wt.%, chromium oxide added catalyst gave the best results.

2) It has been concluded, from the observation of X-ray and electromicrograph of the chromium oxide-added nalcat catalyst, that most of the chromium oxide added developed into large hexagonal crystals which had little activity and that the residue (about 30%), which is supposedly dispersed very finely, is probably responsible for the promotion of the catalytic activity.

3) It has been concluded from the analyses of the experimental data obtained that this disproportionation reaction can be expressed by the kinetic equation based on the surface reaction which is rate-controlling.

Nomenclature

r: reaction rate (mol. M. N./hr. g. cat.)
k: rate constant of surface reaction
K: equilibrium constant
K_A: adsorption equilibrium constant of methylnaphthalene
K_R: adsorption equilibrium constant of naphthalene
K_S: adsorption equilibrium constant of demethylnaphthalene
K_I: adsorption equilibrium constant of hydrogen
P_a: partial pressure of methylnaphthalene (atm.)
P_R: partial pressure of naphthalene (atm.)
P_S: partial pressure of demethylnaphthalene (atm.)
P_I: partial pressure of hydrogen (atm.)
x: conversion of disproportionation reaction (mol.%)
μ: total pressure (atm.)

The authors wish to thank the Mitsui Chemical Co. and the Maruzen Petroleum Co. for providing samples and the Nippon Petroleum Co. for its analyses of the sulfur content of the samples.

They would also like to express their appreciation to Dr. T. Shirasaki for his help in the X-ray and electro-micrograph observation.

Terpenoids. VIII. Sesquiterpenoids from the Wood Oil of "Sugi" (Cryptomeria japonica D. Don.)[*1,*2]

By Shizuo NAGAHAMA[*3]

(Received February 26, 1964)

The main components of the oil of Sugi wood have been shown to be sesquiterpenoids.[1-5] Among these, however, a cadinene has been the only component unsatisfactory characterized, except for the recent work by Sumimoto and his co-workers[6] on the isolation and characterization of cryptomeridiol (selinan-4α, 11-diol).

The results of experiments on two samples of Sugi-wood oil, kindly supplied by Professor Tamio Kondo, are described in this paper.

Oil I, obtained by steam-distillation, was analyzed by distillation, followed by chromatography; the complete results are given in Table I. Sesquiterpene alcohols are distributed over all fractions, and two alcohols are obtained

in the crystalline form. The one, $C_{15}H_{26}O$, (m. p. 140~141°C), was identified as pilgerol (=δ-cadinol) by a direct comparison with the sample provided by Professor Erdtman.*4 It seems quite probable that the "isocryptomeriol" (m. p. 135~136°C) described by Kimura[2b] is identical with this alcohol. Another alcohol (m. p. 63~74°C) was still impure, but its infrared spectrum was almost identical with that of β-eudesmol.[7],*5 Furthermore, a new monocyclic ketone, named cryptomerion, $C_{15}H_{22}O$, was isolated from fraction 7.

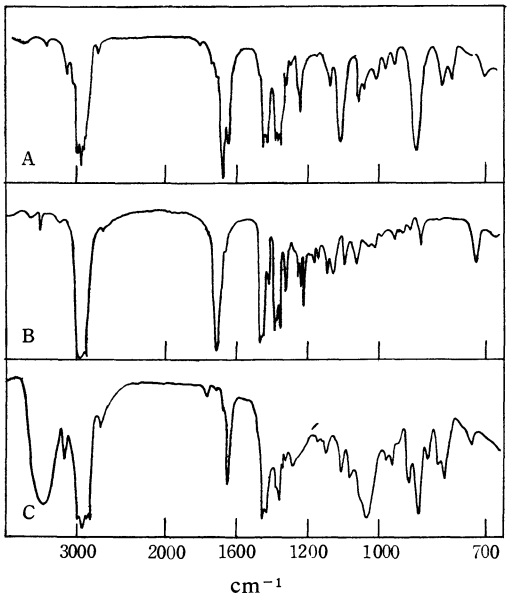

Fig. 1. Infrared spectra of cryptomerion (A); hexahydrocryptomerion (B); and unsaturated alcohol (C).

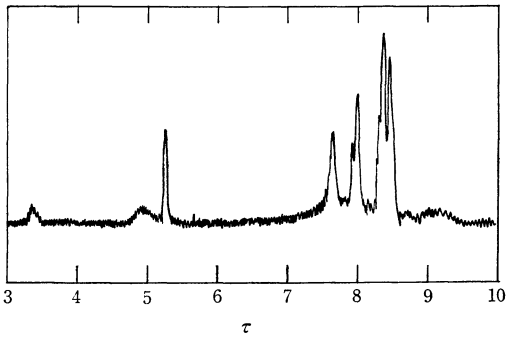

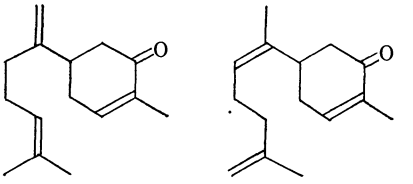

Fig. 2. NMR spectrum of cryptomerion (CCl_4 solution 10%).

Cryptomerion possesses an α,β-unsaturated ketone group (λ_{max} 236, 304 mμ and ν_{max} 1685 cm^{-1}; Fig. 1A). The infrared spectrum of the corresponding unsaturated alcohol (Fig. 1C) obtained by reduction of cryptomerion with lithium aluminum hydride clearly shows the presence of a terminal methylene group (ν_{max} 3130, 1650 and 888 cm^{-1}). The NMR spectrum*6 of cryptomerion (Fig. 2) indicates the presence of the following groups; one hydrogen and one methyl group on the conjugated ketone system (τ value 3.38 and 8.00), one hydrogen on a trisubstituted double bond (4.98), one terminal methylene group (5.25), one methylene group adjacent to the carbonyl group (7.66), and two methyl groups on one (or two) double bond(s) (8.37 and 8.46). The catalytic reduction of cryptomerion gave a hexahydroderivative (Fig. 1B), which was reduced to the corresponding hydrocarbon by the Huang-Minlon method. The infrared spectrum of this hydrocarbon is identical with that of hexahydrobisabolene.[8],*7 When the groups detected by the NMR spectrum are arranged on the bisabolane skeleton, the possible structures are limited to two, namely, I and II. Structure I is preferred for cryptomerion from the biogenetic point of view.[9]

(I) (II)

Oil II, obtained by methanol extraction, was used for the analysis of sesquiterpene hydrocarbons. The fraction corresponding to fractions 1 to 4 of oil I was distilled by a spinning-band column (the results are shown in Table II) with each fraction subjected to the chromatographic separation. Fractions 10 to 13 show two main peaks in the gas chromatography. They were separated pure by chromatography and identified as δ-cadinene[10] and

calamenene.[10] From fraction 13 and from the pot residue a small amount of pure calacorene[10] was separated. Fractions 1 to 3 are complex mixtures of hydrocarbons; at least seven peaks were observed in gas chromatography, besides δ-cadiene and calamenene, and a small amount of copaene*6 was separated from fractions 1 and 2.

Experimental

The Analysis of Oil I.—The oil obtained by steam distillation was brown and viscous n_D^{22} 1.5130, d_{22} 0.982. The neutral fraction (24 g.) was distilled with a concentric column 26 cm. high, and each fraction was chromatographed on an alumina or silica gel column. The results are tabulated in Table I.

Sesquiterpene Alcohols.—Fraction 6 (2.0 g.) was chromatographed on an alumina column (25 g.). A mixture of alcohols (oil) was eluted by a mixture of petroleum ether and ether. The next fraction was solidified (m. p. about 60°C) (300 mg.); the melting point was raised to 63~74°C after repeated crystallization from petroleum ether. 3, 5-Dinitrobenzoate, m. p. 125~136°C. This alcohol was considered to be impure β-eudesmol. The fractions eluted by ether gave another crystalline alcohol (257 mg.), which was recrystallized from petroleum ether and sublimed under reduced pressure. M. p. and mixed m. p. with authentic pilgerol, 140~141°C; $[\alpha]_D$ −100° (*c* 0.48, chloroform). The infrared spectra of the two alcohols are superimposable. Crued pilgerol was also obtained from fractions 4 (21 mg.), 5 (420 mg.) and 7 (42 mg.).

The Presence of Ethers.—Fraction 2 (3.33 g.) was chromatographed on a silica gel column (65 g.). After the elution of hydrocarbon (2.51 g.) with petroleum ether, a fraction (705 mg.) was eluted with ether. This fraction, on further chromatography on an alumina column (15 g.), afforded fractions of n_D^{24} 1.4745~1.4725 (total, 200 mg.). The infrared spectra of these fractions showed strong bands at 1135~1070 cm^{-1}.

Cryptomerion.—Fraction 7 (1.5 g.) was chromatographed on an alumina column (20 g.), Petroleum ether eluted an oily diterpene hydrocarbon (102 mg.) and a ketone (243 mg.) successively. The same ketone was obtained from a commercial (root ?) oil. The ketone (cryptomerion) showed n_D^{26} 1.5050, d_{26} 0.954, MR 68.19. Calcd. for $C_{15}H_{22}OF_3$, 67.90, $[\alpha]_D$ −38° (*c* 1.45, chloroform), λ_{max} 236 and 304 mμ (ε 9600 and 110, ethanol). Infrared spectrum, Fig. 1A. 2, 4-Dinitrophenylhydrazone m. p. 168~171°C.

Hexahydroketone. — n_D^{26} 1.4597, d_{26} 0.884, $[\alpha]_D$ +17° (*c* 0.92, chloroform) (infrared spectrum, Fig. 1B) was obtained by catalytic hydrogenation with Willstätter's platina black in ethanol. 2, 4-Dinitrophenylhydrazone, m. p. 74~77.5°C.

Found: C, 62.29; H, 8.08; N, 13.69. Calcd. for $C_{21}H_{32}O_4N_4$: C, 62.35; H, 7.97; N, 13.85%.

The Huang Minlon reduction of the hexahydroketone (208 mg.) gave a saturated hydrocarbon (123 mg., purified through an alumina column). Its infrared spectrum was identical with that of hexahydrobisabolene.[8] The lithium aluminum hydride reduction of cryptomerion gave an oily unsaturated alcohol (infrared spectrum, Fig. 1C). 3, 5-Dinitrobenzoate, m. p. 65.5~67°C (from petroleum ether).

Found: C, 63.33; H, 6.25; N, 6.68. Calcd. for $C_{22}H_{26}O_6N_2$: C, 63.75; H, 6.32; N, 6.76%.

The Separation of Sesquiterpene Hydrocarbons from Oil II.—The fractions (b. p. 105~115°C/10 mmHg (31.5 g.) and 115~140°C/10 mmHg (24 g.)) of oil II (which was obtained by methanol extraction) were distilled by a spinning-band column (Tokyo Kagaku Seiki Model SB 815); the fractions boiling below 131°C/11 mmHg were combined and distilled twice on sodium metal and finally by the same spinning-band column. The results of the final distillation is shown in Table II.

The Isolation and Identification of Individual Hydrocarbons.—The purity of the fractions was determined by gas chromatography.

Apparatus.—Shimadzu gas chromatograph, Type GC-2A. Column PEG 6000 on Shimalite; 2 m. Temp., 180°C. Carrier gas, H_2. The infrared spectra were compared with those published by F. Šorm,

TABLE II.

V. Herout and their colleagues in Collection Checkoslovak Chem. Communs.*[7]

Copaene.—Fraction 1 was chromatographed on an alumina column (100 g.), and the first fraction (412 mg.) was rechromatographed twice to yield copaene (70 mg. n_D^{26} 1.4813).

δ-Cadinene.—Fractions 8—13 were chromatographed on a hundred-fold of alumina. The first fraction yielded δ-cadinene, n_D^{28} 1.5072, d_4^{28} 0.9133, $[\alpha]_D$ +27.8° (*c* 4.1 1, chloroform). Dihydrochloride, m. p. 118°C, $[\alpha]_D$ −36.1° (*c* 3.39, chloroform).

Calamenene.—The tail fractions of the chromatography of fractions 5—13 yielded calamenene, which was then purified by further chromatography. n_D^{28} 1.5155, d_4^{28} 0.9276, $[\alpha]_D$ −67.0° (*c* 2.40, chloroform).

Calacorene.—On chromatography the pot residue yielded a middle fraction calacorene of high purity (88 mg.) n_D^{23} 1.5405.

The author wishes to express his gratitude to Professor Tamio Kondo, of the Faculty of Agriculture of this University, for supplying the materials and to Professor Emeritus Saburo Akiyoshi, who took a special interest in this work, for his encouragement. He wishes also to thank Miss Reiko Tomita and Miss Katsumi Mera for their infrared and ultraviolet measurements.

The Radiation Annealing of Phosphorus-32 with Cobalt-60 Gamma-rays for Several Neutron-irradiated Inorganic Phosphorus Compounds

By Kichizo TANAKA

(Received February 7, 1964)

The distribution of chemical species formed by neutron capture in several oxy-acids has been shown to depend on thermal and radiation effects during neutron irradiation in a nuclear reactor.

Boyd, Cobble and Wexler[1] pointed out that the chemical yield of bromine-82 as bromide was considerably influenced by the time of neutron irradiation in a reactor when the bromine-82 of a high specific activity was produced by the Szilard-Chalmers effect in potassium bromate. They showed that the shorter the irradiation time in a reactor, the higher the chemical yield of bromine-82 of a high specific activity. Cobble and Boyd[2] also indicated that the retention as bromate was increased by re-irradiation with cobalt-60 gamma-rays for neutron-irradiated potassium bromate. Maddock and Müller[3] observed that the retention increased in neutron-irradiated calcium bromate when it was re-irradiated with 1.8 MeV. electrons. Green, Harbottle and Maddock[4] noticed that the distribution of chemical species containing chromium-51 formed by the neutron irradiation of potassium chromate in a reactor was changed by re-irradiation with gamma-rays. Claridge and Maddock[5] reported that the retention increased for potassium dihydrogen phosphate and ammonium

hydrogen phosphate when they were irradiated with 1.8 MeV. electrons or an ultraviolet light. However, their results are somewhat ambiguous, as has been pointed out by Wazer,[6] because they used the precipitation method in separating the chemical species.

In their recent paper, Baba, Tanaka and Yoshihara[7] reported that the retention increased in several neutron-irradiated phosphates when they were thermally treated; in their experiment, the chemical species were separated by one-dimensional paper-partition chromatography. They observed that all phosphorus-32 species other than parent species decreased when heated for over 10^4 min. in the temperature range of 85~200°C. The rate of the decrease in the polyphosphate was larger than that of the reduced species. The fractional amount of the reduced species was extremely small[8] at long irradiations or at irradiations at a high power operation in nuclear reactors. This fact can not be explained by the process expected from the thermal annealing experiments. In the preparation of phosphorus-32 of a high specific activity by the Szilard-Chalmers effect,[9] the decrease in the recovery might be attributed to the radiation annealing effect. In the present paper, radiation annealing with cobalt-60 gamma-rays was studied for several neutron-irradiated inorganic phosphorus compounds, mainly in dehydrated forms.

Experimental

Target Materials.—Series of sodium orthophosphates and potassium orthophosphates, sodium orthophosphates, sodium orthophosphite, sodium hypophosphite and sodium pyrophosphate were used in anhydrous forms. Hydrated salts were dehydrated by heating and then drying them in vacuo over phosphorus pentoxide overnight. The anhydrous salts thus prepared were assayed for purity by the radioactivation method and by flame photometry, as has been previously reported[7].

Neutron Irradiation.—The salts were sealed in a polyethylene tube and subjected to neutron irradiation in hole No. 12 (a vertical hole; the nominal neutron flux was 0.48×10^{12} n/cm^2-sec.) for 15 hr. and in hole No. 16 (a pneumatic tube, the nominal neutron flux was 0.64×10^{12} n/cm^2-sec.) for 2 hr. in JRR-1 (a waterboiler type, operated at 40 kW.). Immediately after irradiation, the samples were cooled with dry ice to avoid any change in the distribution of the chemical species containing phosphorus-32 during storage.

Gamma-ray Irradiation.—Neutron-irradiated samples were again sealed in a polyethylene tube or in a glass ampoule and exposed to high intensity gamma-rays from a cobalt-60 source of 0.7×10^4 curies in a thermally-controlled vessel at temperatures from −196°C to 100°C. The irradiated samples were then stored in a vessel cooled with dry ice.

Chemical Separation.—The chemical species containing phosphorus-32 were separated by one-dimensional paper-partition chromatography by the same procedure as before.[7] The decomposition of the sample by gamma irradiation was measured by colorimetric analysis of the products separated from the parent species by the anion exchange method.[10,11]

Counting Procedure.—After it had been developed and dried, the paper was cut into pieces 1 cm. wide and the radioactivity was measured by a thin end-window-type GM counter at a constant geometry. Counting was made at least ten days after the termination of neutron irradiation in order to avoid errors from the radioactivity of sodium-24 or potassium-42.

Thermal Annealing.—Neutron-irradiated sodium orthophosphates were subjected to thermal annealing at an elevated temperature, as has been previously reported,[7] and the effect of neutron irradiation conditions on thermal annealing behaviors was tested for the phosphorus-32 species. The distribution of chemical species containing phosphorus-32 obtained from irradiation for 2 hr. in a pneumatic tube was considerably different from that of 15 hr. irradiation in the vertical hole of the JRR-1. In both cases, however, all the chemical species other than parent species decreased, only the parent species increased with the salts were heated, and the polyphosphate was more predominantly annealed than the reduced species. It was concluded that the thermal-annealing behavior does not depend on the neutron irradiation conditions. All samples were stored in two vessels: one portion was stored at 30°C, and the other at a lower temperature obtained by cooling with dry ice. During the storage for 16 days, no change was observed in the distribution of chemical species containing phosphorus-32.

Results and Discussion

The Decomposition of the samples by Gamma-ray Irradiation.—When the phosphate salts are irradiated by gamma-rays, the decomposition of the sample may be expected as a result of radiation effects. Pyrophosphate was detected in the gamma-irradiated orthophosphates. Except for the case of dipotassium hydrogen phosphate, the amounts of pyrophosphate formed by gamma irradiation were so small that the amounts detected were near the detection limit (approximately 5 μg. per gram of the sample),

even at the total dose of 1×10^7 r. The estimated G values of pyrophosphate formation are tabulated in Table I. Pyrophosphate was also formed when orthophosphates containing hydrogen in the molecule were heated above 150°C. Because pyrophosphate formation in the orthophosphate salts was prominent as a result of thermal reaction at an elevated temperature, the effects of gamma-rays on the formation of pyrophosphate could not be detected in this case. The formation curves obtained by irradiation at temperatures of 150~200°C for sodium dihydrogen phosphate and disodium hydrogen phosphate were exactly the same as those obtained by the thermal reaction, within the range of experimental error. The formation of no polyphosphates other than pyrophosphate was observed by the anion exchange separation for all samples. The evolution of gaseous products was not studied; this evolution may be disregarded considering the results obtained by Sellers and his co-workers.[12]

The Change by Gamma Irradiation of the Chemical Species Containing Phosphorus-32.— The distribution of chemical species containing phosphorus-32 in neutron-irradiated phosphates varies with the irradiation conditions in the reactor. All the salts were irradiated in the same capsule to compare the annealing effects of irradiation for the different salts.

The radiation annealing of species containing phosphorus-32 in several orthophosphate salts (irradiated for 2 hr., in a pneumatic tube of the JRR-1 and re-irradiated with cobalt-60 gamma-rays at −50°C) results in an increase in retention and in a decrease in the reduced species. The behavior of the polyphosphates in irradiation varies considerably among the different orthophosphates studied. The results are shown in Figs. 1—3, where the fraction of each species is plotted against the radiation dose. The retention as orthophosphate increases rapidly in the low dose region and gradually in the higher dose region. This is more prominent in the case of sodium dihydrogen phosphate. The polyphosphate in di-

sodium hydrogen phosphate and in trisodium phosphate shows a fast rise in the initial low-dose region and gradually approaches a plateau, whereas the polyphosphate in sodium dihydrogen phosphate initially increases and then decreases. However, the reduced species clearly decreases in all of the orthophosphate salts studied. These changes in fractions are summarized in Fig. 4 for disodium hydrogen phosphate. In the figure, experimental results are given by the solid line, while the dotted lines show the estimated values obtained by the analysis of the curves, assuming the plateau values for each corresponding curve.

—○— the polyphosphate fraction
—□— the orthophosphate fraction
—△— the reduced species fraction
--■-- estimated increase of the orthophosphate fraction
--●-- estimated increase of the polyphosphate fraction

The estimated values for the increase in the polyphosphates and those for the orthophosphate are linear on a semilog plot. This suggests that the reactions in the increase in the polyphosphates and orthophosphate follow the first order kinetics, in which the sum of these increases in two fractions corresponds to the decrease in the reduced species. The number of species in the sample is proportional to their percentages in the sample. The ordinates show the logarithmic number of species on an arbitrary scale. By an analysis of these curves, two main processes of the radiation annealing of species containing phosphorus-32 are indicated: (I) the reduced species to the polyphosphate, and (II) the reduced species to the orthophosphate. The reduced species is converted to the phosphorus(V) state by oxidation with a potassium permanganate solution, whereas the polyphosphate is not changed. The polyphosphate is converted to the orthophosphate by hydrolysis with a mineral acid such as hydrochloric or sulfuric acid. The polyphosphate thus contains phosphorus(V). The radiation-induced oxidation process is a predominant reaction in the radiation annealing of orthophosphate salts. This finding is in good agreement with the recent results of Claridge and Maddock[13] which have indicated that phosphorus(III) is oxidized to phosphorus(V) by irradiation with an ultraviolet light or by 1.8 MeV. electrons in several neutron-irradiated phosphates.

The radiation-annealing curves obtained by 15 hr. irradiation in a reactor (with a vertical hole of the JRR-1) seemed to be similar to those by shorter irradiations, except that the polyphosphate fraction is slightly lower in the former. Besides the two main processes stated, other processes were observed; the third process III, the polyphosphate to the orthophosphate, is indicated by the results listed in Table II. The decrease in the polyphosphate at longer irradiations in a reactor suggests that the polyphosphate curve. in Fig. 4 shows a pseudoplateau attained by the rate equilibrium between the two processes, " the reduced species to the polyphosphate " and " the polyphosphate to the orthophosphate." The polyphosphate fractions in the other orthophosphate salts studied show the same behavior as that in disodium hydrogen phosphate.

Annealing behaviors were also studied for neutron-irradiated sodium orthophosphite and sodium hypophosphite. Little change was observed in the distribution of chemical species containing phosphorus-32 in gamma irradiation in the dose range from 1.0×10^6 to 1.5×10^7 r. for these two salts. The hypophosphite fraction in sodium orthophosphite and the orthophosphite fraction in sodium hypophosphite salts were found to be unchanged.

The Effect of the Dose Rate.—The dose-rate dependence of the annealing behavior was studied in the dose range of 3.7×10^4 to 2.1×10^6 r./hr. at the total dose and at the temperature used above. The results obtained are shown in Table II. Only slight differences are observed among the different dose rates.

The Rate Constants in Gamma-ray Annealing.—Assuming that the radiation annealing of chemical species containing phosphorus-32

* k_1, a rate constant corresponding to the increase of the polyphosphate fraction
** k_2, a rate constant corresponding to the increase of the orthophosphate fraction
*** k_3, a rate constant corresponding to the decrease of the polyphosphate fraction

follows the kinetics which contains several processes of the first order,[14] the rate constants for these processes can be defined. Since the rate is proportional to the number of species containing phosphorus-32, the formula, $dN_i/dt=k_iN_i$, expresses the process, where k_i is the rate constant for the change in the number of species and N_i is the number of species which contribute to the i-th process. The rate constant can be obtained at a fixed dose rate. The annealing curves were obtained for the several orthophosphate salts, and an analysis was made in order to estimate the rate constant from the numbers of the increases of the polyphosphates and orthophosphate, as Fig. 4 shows. In the case of polyphosphate, a correction was made for the contribution of the third process, which resulted in the slow decrease in the polyphosphate. The results obtained for the rate constants at given temperatures are shown in Table III. In the table, k_1 is the rate constant for the reduced species to the polyphosphate (process I) and k_2 is the rate constant for the reduced species to the orthophosphate (process II). In these estimates, samples were irradiated for 2 hr. in a pneumatic tube of the JRR-1. In order to estimate k_3, the rate constant for the polyphosphate to the orthophosphate (process III), samples were irradiated for 15 hr. in the vertical hole. In gamma irradiation at −50°C, only a slight change induced by this process is observed, even at the highest dose of 5×10^{7} r. The rate constants obtained for sodium or potassium orthophosphates are of the order of 10^{-4} hr^{-1} (−50°C, 1.7×10^{5} r./hr.). The rate constants obtained at 20°C are listed in Table III.

Similar experiments were made to estimate the rate constants for sodium pyrophosphate. The decrease in the reduced species uniquely

follows the first-order kinetics, and the rate constant is $1.7\times10^{-3}\,hr^{-1}$ ($-50°C$, 1.7×10^{5} r./hr.). This value is one order smaller than those for the orthophosphate salts.

The Effect of Temperature During Gamma Irradiation.—The temperature dependence of gamma-ray annealing is studied for all the salts mentioned. The decrease in the reduced species in sodium or potassium orthophosphates and in sodium pyrophosphate is clearly affected by the temperature during gamma irradiation. In Fig. 5, the decrease in the reduced species in sodium and potassium orthophosphate salts is plotted as a function of the total dose at 20°C. In the salts containing hydrogen atoms, the decrease in the reduced species is divided into two parts: the initial rapid decrease corresponding to processes I and II, and the slow decrease which is predominant in trisodium and tripotassium phosphates, as Fig. 5 shows. The former process is the same as that observed at $-50°C$. The decrease in the reduced species corresponds to the sum of the increases of the polyphosphate and orthophosphate. However, the latter slow process, which is not clearly observed at $-50°C$, is probably a different

—●— Na_2HPO_4 —■— K_2HPO_4
—◑— Na_3PO_4 —◫— K_3PO_4

process from those mentioned above; it probably corresponds to the slow increase in the orthophosphate.

The changes in the reduced species in disodium hydrogen phosphate at several different temperatures are shown in Fig. 6. In a series of the sodium orthophosphate salts and in a

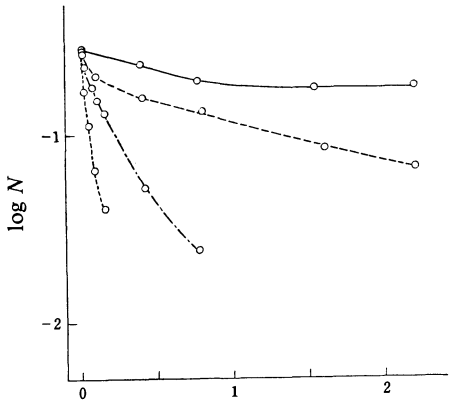

Fig. 6. Gamma ray annealing as functions of temperature during gamma ray irradiation—the decrease of ^{32}P for the reduced species fraction in disodium hydrogen phosphate.

—○— at $-196°C$ —--○--- at 20°C
--○-- at $-50°C$ ----○---- at 100°C

series of the potassium orthophosphate salts studied, the reduced species considerably decreased, even irradiation at $-196°C$. If the log k is plotted against $1/T$, the curve is quite different from the linear shape, where T is the absolute temperature. The log k decreases as the temperature is lowered to approximately $-20°C$, then it nearly approaches a constant at $-196°C$. The reaction induced by gamma irradiation at a low temperature seemed to involve another process. The process is apparently different from the higher temperature process above $-20°C$.

Comparisons of Gamma-ray Annealing with the Chemical Form of the Samples.—From the comparison of the decreases in the reduced species by the gamma irradiation for the series of the orthophosphate salts, it is clear that the higher the hydrogen content in the sample, the greater the decrease in the reduced species.

Disodium hydrogen phosphate dodecahydrate was also studied. The change in the distribution of chemical species containing phosphorus-32 are similar to those in the anhydrous salt. The rate of decrease in the reduced species in sodium pyrophosphate is also affected by the temperature during gamma irradiation, whereas in sodium orthophophite and sodium hypophosphite, no change in chemical species by gamma irradiation is observed, even in irradiation at 20°C.

The rate-constant values obtained can not be compared in detail with the other observations in oxy-acid salts because the experimental conditions are different. However, the rate of the change of retention in orthophosphate salts is at least approximately 10^2 times greater than

those in the other salts; namely, for bromine-82 in potassium bromate,[2] and chromium-51 in potassium chromate.[15]

From the results of the present experiment, it is to be expected that the neutron irradiation for relatively long periods of time or at high operating power will give the reduced species of low fractions in sodium or potassium orthophosphate salts.[8]

Summary

Radiation annealings with cobalt-60 gamma-rays have been investigated for several neutron-irradiated inorganic phosphorus compounds. The group separation technique by one-dimensional paper-partition chromatography was adopted to separate chemical species containing phosphorus-32. The reduced species in the sodium and potassium orthophosphate salts and in the sodium pyrophosphate salt decreased upon gamma irradiation, and an increase in the retention was observed. However, the polyphosphate increased initially in the several orthophosphate salts.

Three processes has been observed, the rate constants for these processes have been estimated, and two other processes have been suggested. The main process is the oxidation of the reduced species to phosphorus(V) species.

Radiation annealing have been studied for phosphates as a functions of the dose rate, the total dose of irradiation, and the temperature during gamma irradiation, it has been found that annealings are dependent upon the total dose and the temperature during irradiation and are independent of the dose rate. In orthophosphates and pyrophosphate, chemical species other than the parent species are easily annealed by gamma irradiation, whereas no detectable annealing has been observed in sodium orthophosphite or sodium hypophosphite.

In series of sodium and potassium orthophosphates, annealing was affected by the hydrogen content of the salts.

The author wishes to express his appreciation to Dr. Kenjiro Kimura, Director of this Institute, to Dr. Nagao Shibata, and to Professor Shizuo Fujiwara of the University of Tokyo for their interest and encouragement. The author also wishes to express his thanks to Professor Nobufusa Saito of the University of Tokyo, to Dr. Kenji Yoshihara, and to Mr. Hiroshi Baba for their discussions.

Spectrophotometric Studies of the Metallic Chelates of 2-Picolylamine. I. The Electronic Absorption Spectra of Some Nickel, Copper(II) and Cobalt(III) Chelates

By Shunji UTSUNO and Kôzô SONE

(Received March 2, 1964)

2-Picolylamine (2-aminomethylpyridine; abbreviation: "pic") is a chelating agent which is structurally intermediate between ethylenediamine ("en") and 2,2'-bipyridine ("bip"). Recently Sutton[1] found that 2-picolylamine forms a large number of chelates with various metals, and that their properties in many respects resemble those of ethylene diamine chelates.[2] His data on the absorption spectra of these chelates were of special interest to us, since they reflect a number of important features of their electronic structures; this interest inspired us to carry out a series of more detailed spectrophotometric studies of these and related chelates, the first results of which shall be reported in this paper.

Experimental

Reagents.—The 2-picolylamine used in this work was the product of the Aldrich Chemical Co. (Milwaukee, Wisc., U. S. A.). In the preparation of the chelates, it was used without further purification; in the spectral study of the systems contain-

1) G. J. Sutton, *Australian J. Chem.*, **13**, 74, 222, 473 (1960); **14**, 37, 545, 550 (1961); **15**, 232, 563 (1962).

2) The stabilities of some of these chelates were studied also by D. E. Goldberg and W. C. Fernelius (*J. Phys. Chem.*, **63**, 1246 (1959)) and T. J. Lane, C. S. C. and J. W. Thompson (*J. Am. Chem. Soc.*, **82**, 4179 (1960)).

ing the free ligand, it was purified by vacuum distillation (b. p. 89°C/15 mmHg). All the other reagents used were "Extra Pure" chemicals, most of which were the products of the Wako Pure Chemicals Co. (Osaka, Japan).

Apparatus. — The visible, ultraviolet and near infrared spectra of the aqueous solutions of the chelates were measured with a Shimadzu QR-50 quartz spectrophotometer, using silica cells of 10 mm. and 1 mm. light paths.

The Preparation of the Chelates.—These chelates —[Co pic$_3$](ClO$_4$)$_3$, [Co pic$_2$(NO$_2$)$_2$]NO$_3$·1/2H$_2$O, Ni·pic$_2$Cl$_2$, [Ni pic$_3$]Cl$_2$·2H$_2$O and Cu pic$_2$Cl$_2$– were prepared according to the methods of Sutton.[1] When all these chelates were analyzed with respect to their metals, satisfactory agreement between experimental and theoretical values was obtained in every case. In addition, the following chelates (a)—(d) were prepared for the present study:

(a) Ni pic Cl$_2$·H$_2$O. — NiCl$_2$·6H$_2$O (2.4 g.; 10^{-2} mol.) was dissolved in 3 ml. of water by heating, and 2-picolylamine (1.1 g.; 10^{-2} mol.) was added. When the blue mixture was concentrated by heating, green crystals were formed; after cooling, they were washed with 95% ethanol and then with absolute ethanol and ether. (Yield, 2.12 g.; 83%) (Found: Ni, 22.68; C, 28.33; H, 4.04; N, 11.21. Calcd. for $C_6H_{10}N_2Cl_2ONi$: Ni, 22.95; C, 28.17; H, 3.94; N, 10.95%).

(b) Ni pic SO$_4$·2H$_2$O.—NiSO$_4$·6H$_2$O (2.6 g.; 10^{-2} mol.) was dissolved in 5 ml. of water by heating, and 2-picolylamine (1.1 g.; 10^{-2} mol.) was added. The mixture was left standing for a week or more in a dessicator or in the open air, and the greenish blue crystals which formed were filtered, washed repeatedly with ethanol and then with ether, and dried at room temperature in the open air. The obtained crystals contained about 3 molec. of water of crystallization; when they were heated at 150°C for several hours, a part of the water was lost, leaving the pale blue dihydrate. (Yield, 2.58 g.; 86%). (Found: Ni, 19.28; C, 22.84; H, 4.12; N, 9.42. Calcd. for $C_6H_{12}N_2SO_6Ni$: Ni, 19.64; C, 23.10; H, 4.04; N, 9.37%).

(c) Cu pic Cl$_2$.—CuCl$_2$·2H$_2$O (1.7 g.; 10^{-2} mol.) and 2-picolylamine (1.1 g.; 10^{-2} mol.) were dissolved separately in 90% ethanol (10 ml. each). When the two solutions were mixed, a green precipitate was formed at once; this became blue when the mixture was heated for some time. After the completion of this color change, the precipitate was filtered and washed with ethanol and ether. The pale blue crystalline powder which was obtained was recrystallized by dissolving it in 10 ml. of water by heating and then adding the same volume of ethanol. (Yield, 2.16 g.; 90%). (Found: Cu, 25.92; C, 29.32; H, 3.23; N, 11.72. Calcd. for $C_6H_8N_2Cl_2Cu$: Cu, 26.19; C, 29.71; H, 3.32; N, 11.55%).

(d) Cu pic SO$_4$·2H$_2$O.—CuSO$_4$·5H$_2$O (2.5 g.; 10^{-2} mol.) was dissolved in 5 ml. of water, and 2-picolylamine (1.1 g.; 10^{-2} mol.) was added. The mixture was left standing overnight in a refrigerator, and the blue crystals which separated out were washed with ethanol and ether, dried at room temperature in the open air, and recrystallized from water. (Yield, 2.37 g.; 79%). (Found: Cu, 21.13; C, 26.71; H, 3.14; N, 10.44. Calcd.:[3] Cu, 20.91; C, 26.92; H, 3.01; N, 10.46%).

Results and Discussion

The Formation of Some Nickel and Copper Chelates. — Sutton[1] prepared a number of nickel chelates of 2-picolylamine with metal: ligand ratios of 1:2 and 1:3, and copper chelates with the ratio of 1:2. On the other hand, it is well known that both ethylenediamine and 2,2'-bipyridine can form 1:1, 1:2 and 1:3 chelates with these metals, either in an aqueous solution or in the state of crystalline complexes; therefore, it is to be expected that 2-picolylamine can also form 1:1 chelate with nickel and copper, and a 1:3 chelate with copper, at least in aqueous solutions, and probably in the state of crystalline complexes, too. In fact, Fernelius et al.[2] found that such 1:1 complexes of considerable stability are formed in solution, and now we have found the crystals of the Ni pic Cl$_2$·H$_2$O, Ni pic SO$_4$·2H$_2$O, Cu pic Cl$_2$ and Cu pic SO$_4$·2H$_2$O chelates can be easily obtained from the solutions of their components. The nickel chelates are greenish blue (sulfate) or green (chloride), and they give blue solutions in water, while the copper chelates are blue, both in the solid state and in aqueous solutions.

The common coordination numbers of Ni^{2+} and Cu^{2+} are 6 and 4 respectively, and the tendencies of organic amines, water, Cl^- and SO_4^{2-} to form coordinate bonds with these ions generally decrease in the order: amines $>H_2O>$ anions. Therefore, the most probable coordination formulas of the copper chelates are [Cu pic Cl$_2$] and [Cu pic (OH$_2$)$_2$]SO$_4$ respectively, while the coordination of both water and anions must be assumed to explain the compositions of the nickel chelates. In aqueous solutions, however, the coordinated anions seem to be displaced by water, forming the chelate ions $[Cu\ pic\ (OH_2)_2]^{2+}$ and $[Ni\ pic(OH_2)_4]^{2+}$; this is proved by the fact that the solutions of all these chelates show the immediate reactions of their anions, by the fact that the absorption spectra of these solutions are practically independent of their anions (i. e., the curves of Ni pic Cl$_2$·H$_2$O and Cu pic Cl$_2$ are nearly identical with those of Ni pic SO$_4$·2H$_2$O and Cu pic SO$_4$·2H$_2$O respectively), and, further, by the fact that these spectra are quite insensitive to the addition of their anions in a considerable excess.

3) While the value for Cu refers to the dihydrate ($C_6H_{12}N_2SO_6Cu$), those for C, H and N refer to the anhydrous state, since this chelate loses all of its water in the course of vacuum dessication prior to the organic analysis (5 mmHg, 80°C, 2 hr.).

*: Data of the present study.
a) According to Ito (Ref. 6a), these chelates should be formulated as $[Cu\ bip\ (OH_2)_4]^{2+}$ and $[Cu\ bip_2\ (OH_2)_2]^{2+}$, respectively.

TABLE II. STRONG ULTRAVIOLET BANDS OF 2-PICOLYLAMINE CHELATES

Chelate	λ_{max} (log ε_{max})	Chelate	λ_{max} (log ε_{max})	
(2-Picolylamine)	260 (3.48)	$[Co\ pic_3]^{3+}$	~260 (3.95, sh.)	
$[Ni\ pic\ (OH_2)_4]^{2+}$	260 (3.46)	$[Co\ pic_2\ (NO_2)_2]^{+}$	338 (3.70)	252 (4.34)
$[Ni\ pic_2\ (OH_2)_2]^{2+}$	260 (3.74)	*cis*-$[Co\ en_2\ (NO_2)_2]^{+}$	323 (3.68) a)	
$[Ni\ pic_3]^{2+}$	260 (3.98)	*trans*-$[Co\ en_2\ (NO_2)_2]^{+}$	339 (3.44) a)	249 (4.37) a)
$[Cu\ pic\ (OH_2)_2]^{2+}$	247 (3.59)			
$[Cu\ pic_2]^{2+}$	247 (3.92)			

a) Data of Kuroya and Tsuchida (Ref. 12a.). Later data of Basolo (Ref. 12b) in MeOH-H_2O agree reasonably well with these authors', but add one more band at 240 mμ (log ε_{max} 4.22) for *cis*-$[Co\ en_2\ (NO_2)_2]^{+}$.

We also tried to prove our second expectation, i.e., the formation of the chelate ion. $[Cu\ pic_3]^{2+}$, and we found rather convincing evidence for its existence in solution. Figure 1 shows three representative curve taken from our data on the absoprtion spectra of aqueous solutions containing $[Cu\ pic_2]^{2+}$ and free 2-picolylamine; it can be seen that, with the increase in free ligand concentration, the absorption band of $[Cu\ pic_2]^{2+}$ at 580 mμ is gradually intensified and shifted toward a longer wavelength, until, in a 8.46 M solution of 2-picolylamine (the highest concentration tried), the λ_{max} and ε_{max} values become 612 mμ and 109 respectively. A comparison of these data with the spectra of the $[Cu\ en_2]^{2+}$-ethylenediamine system studied by Bjerrum and Nielsen[4] reveals the general resemblance of these two systems, and an approximate analysis of the data by their method indicates that the chelate ions $[Cu\ pic_3]^{2+}$ are progressively formed in these solutions. The third stability constant (k_3) of this chelate was estimated to be 2~3, which is somewhat larger than the k_3 value (~0.1) of $[Cu\ en]^{2+}$ reported by Bjerrum and Nielsen, but much

smaller than the value of $[Cu\ bip_3]^{2+}$ (~2000) reported by Irving and Mellor.[5] This fact, and the fact that the λ_{max} and ε_{max} values of $[Cu\ pic_3]$ given above are quite near to the values of $[Cu\ en_3]^{2+}$ reported by Bjerrum and Nielsen, are new examples of the close resemblance between 2-picolylamine and ethylenediamine chelates, a resemblance which has already been pointed out by Sutton[1] and which will be discussed further in the next section.

The Electronic Absorption Spectra of the Chelates.—The visible, ultraviolet and near infrared spectra of the chelates prepared are summarized in Figs. 2—4 and in Tables I and II. Table I shows the λ_{max} and $\log \varepsilon_{max}$ values of the relatively weak absorption bands appearing between 350 and 1000 mμ, bands which are undoubtedly due to the ligand-field splittings of the metal 3d orbitals; this table also presents the data of the corresponding ethylenediamine and 2,2'-bipyridine chelates taken from the literature.[6] The results already mentioned in the preceding section, and the remark of Sutton[1] that Ni pic_2 Cl_2 and Cu pic_2 Cl_2 are converted into $[Ni\ pic_2\ (OH_2)_2]^{2+}$ and $[Cu\ pic_2]^{2+}$

in their aqueous solutions, were taken into account in the preparation of this table.

It can be seen from this table and from the corresponding curves in Figs. 2—4 that, in general, the spectrum of a 2-picolylamine chelate is intermediate between those of the ethylenediamine and 2,2'-bipyridine chelates of the corresponding structure. This is what one can expect from the structure of 2-picolylamine; however, it can be seen further that, in most cases, the spectral similarity to the ethylenediamine chelates is more apparent than that to the 2,2'-bipyridine chelates. This fact is in conformity with the remark of Sutton mentioned above; two groups of chelates can be distinguished in this respect: (i) those in which the λ_{max} values decrease in the order: ethylenediamine ≳ 2-picolylamine > 2,2'-bipyridine and (ii) those in which they increase in

the order: ethylenediamine ≲2-picolylamine< 2, 2'-bipyridine.

The chelates $[Ni\ R\ (OH_2)_4]^{2+}$, $[Ni\ R_3]^{2+}$, and $[Co\ R_3]^{3+}$ belong to the first group. According to the concept of the spectrochemical series,[7] this type of spectral change means that the strength of the effective ligand field increases in the order; ethylenediamine ≲ 2-picolylamine < 2, 2'-bipyridine. In fact, this is a very conceivable order, because it is generally accepted that, in the 2, 2'-bipyridine chlates, there is a special stabilization of the resonance system of the bipyridine molecule because of the chelate formation, presumably through the formation of metal-ligand π-bonds and the introduction of some "aromaticity" into the chelate ring. On the other hand, such effects are absent in ethylenediamine chelates, and, in the case of 2-picolylamine chelates, it is apparent that they are, at most, much smaller than in 2, 2'-bipyridine chelates, since there is only one pyridine ring and no conjugation between the ring and the $-CH_2NH_2$ chain in their ligand. Therefore, we can expect that the most effective binding of the metal ions, or, in other words, the operation of the strongest ligand field, is realized in 2, 2'-bipyridine chelates, and that the corresponding effects decrease in ethylenediamine and 2-picolylamine chelates in just the observed order.

$[Cu\ R_2]^{2+}$ and $[Cu\ R\ (OH_2)_2]^{2+}$ belong to the second group. Here the chief factor governing the spectra seems to be a different one, i. e., the steric effect. It has formerly been pointed out by Ito[8] that the spectro-chemical series in its simple form is not obeyed by many of the copper(II) complexes; according to him, their λ_{max} values are strongly influenced by their actual coordination number. A similar opinion was expressed by Jørgensen, who further argued that it is possible to study the shape of a copper(II) complex from the magnitude of the σ_{Cu}/σ_{Ni} ratio for it, i. e., the ratio between the wave number of its absorption band and that of the first band of the corresponding nickel complex. According to him, the complex is highly tetragonal if this ratio is 1.6~1.8, and if it is smaller than this, the tetragonality is accordingly lower; for example, $[Cu\ en_2]^{2+}$ (the 1.73 ratio) belongs to the former group, while $[Cu\ bip_2]^{2+}$ (the 1.1 ratio) belongs to the latter, most probably because of the steric repulsion caused by the 6, 6'-H atoms of bipyridine molecules, a repulsion which deforms the chelate strongly from the planar structure favored by copper(II).[5]

Now the λ_{max} value of $[Cu\ pic_2]^{2+}$ is much closer to that of $[Cu\ en_2]^{2+}$ than to that of $[Cu\ bip_2]^{2+}$, and the value of σ_{Cu}/σ_{Ni} is 1.56. These data indicate that this chelate is nearly tetragonal in shape, and that the repulsion between the ligands is quite small. This indication is again a very reasonable one, since it can be expected that this chelate exists chiefly in the trans-planar form in solution, and the model of this form is practically free from the repulsion of this kind.

In the chelates $[Cu\ R\ (OH_2)_2]^{2+}$, the steric repulsion of this kind should be completely absent. The differences among the λ_{max} values of the three chelates of ethylenediamine, 2-picolylamine and 2, 2'-bipyridine are, accordingly, quite small, but they are still in the same order as those of $[Cu\ R_2]^{2+}$. This may be due to the existence of some kind of steric effect even in this case, although we cannot be very certain about its nature.[9,10]

In the chelates, $[Ni\ R_2\ (OH_2)_2]^{2+}$ the spectral order is rather irregular (ethylenediamine>

7) Cf. C. K. Jørgensen, "Absorption Spectra and Chemical Binding in Complexes," Pergamon Press, London (1962), Chapter 7.

8) H. Ito, Ref. 6a.

9) It is interesting to compare the spectral data in Table I with the values of the stability constants of these chelates reported by Irving and Mellor (Ref. 5) and by Goldberg and Fernelius (Ref. 2). Although the data of these two sets of authors are not strictly comparable with each other, it can be seen that there exists a certain degree of parallelism between the spectral and stability data; for example, the order of stabilities for the chelates $[Ni\ R_3]^{2+}$ is; ethylenediamine<2-picolylamine≪2, 2'-bipyridine, while that for $[Cu\ R_2]^{2+}$ is: ethylenediamine> 2-picolylamine≫2, 2'-bipyridine.

10) The existence of some steric effect in $[Cu\ bip(OH_2)_2]^{2+}$ and $[Cu\ phen(OH_2)_2]^{2+}$ was also pointed out by Irving and Mellor (Ref. 5).

2, 2'-bipyridine > 2-picolylamine). If R is a symmetrical ligand (ethylenediamine or bipyridine), this type of chelate can exist in either a cis or in a trans form; if R is unsymmetrical (2-picolylamine), two cis and two trans forms are possible. However, as in the case of the copper chelates, the formation of the trans chelate will be hindered in the case of $[Ni \cdot bip_2(OH_2)_2]^{2+}$, and the cis form will be formed predominantly in solution; on the other hand, in the case of ethylenediamine and 2-picolylamine chelates, the trans forms will be more stable because of their higher symmetries, and, therefore, they will be formed predominantly in solution. This difference may be, at least in part, the reason for the irregular order observed here.[11]

Apart from the bands shown in Table I, the chelates studied also have a band or bands in the ultraviolet region which are much stronger than those in Table I (cf. Table II). 2-Picolylamine itself shows a strong band at 260 mμ while the nickel chelates also show a band at this wavelength. In the case of the copper chelates, this band is considerably broadened, and the apparent maximum is shifted to 247 mμ. $[Co\ pic_3]^{3+}$ also shows a shoulder at abuot 260 mμ. $[Co\ pic_2(NO)_2]^{+}$ shows two strong bands at 338 and 252 mμ, the latter of which is still much stronger than the band of 2-picolylamine. A comparison of the absorption curve of this chelate with those of the two isomers of $[Co\ en_2(NO_2)_2]^{+}$ indicates that these bands are not due to the absorption of coordinated picolylamine, and that they should, rather, be ascribed to the absorption of coordinated NO_2^- ions, which probably occupy trans positions with regard to each other.[12] Thus, these spectral data support the original view of Sutton[1] that this chelate has the trans structure, although the corresponding cis isomer could not be obtained by him, and our several trials in this direction all ended in failure.

11) However, the spectrum of $[Ni\ bip_2(OH_2)_2]^{2+}$ cited in Table I is that in its alcoholic solution, and, therefore, it is also possible that this irregularity is due to some effect of this solvent on the structure or electronic state of chelate. All the other data in this table refer to the spectra of aqueous solutions.

Summary

1) In addition to the nickel chelates (1 : 2 and 1 : 3) and copper chelates (1 : 2) already described by Sutton, it has been found that 2-picolylamine also forms 1 : 1 chelates (chlorides and sulfates) with these metals, which can be obtained in the state of crystals, and the chelate ions $[Cu\ pic_3]^{2+}$ of low stability, in solution.

2) A comparison of the electronic absorption spectra of all these chelates and two cobalt(III) chelates of 2-picolylamine with those of the chelates of ethylenediamine and 2, 2'-bipyridine has indicated that, in general, the spectrum of a 2-picolylamine chelate is intermediate between the spectra of the corresponding chelates of the latter two ligands; however, the similarity to the ethylenediamine chelate is more apparent in most cases.

3) Certain structural features of the 2-picolylamine chelates have been discussed on the basis of these spectral data.

Bis(succinimidato)copper(II) Complexes with Pyridine, Picolines and Lutidines

By Seiko MIKI and Shoichiro YAMADA

(Received March 3, 1964)

Succinimidate, which is derived when succinimide (Fig. 1) loses a proton, forms a number of copper (II) complexes with different amines bound together. In a previous communication,[1] a series of red bis(succinimidato)-bis(alkylamine)copper(II) complexes were examined, and the factors favoring the formation of these red copper(II) complexes discussed. In order to confirm and extend the conclusions previously derived, it was thought to be interesting to examine complexes of a similar type with other amines. The present paper deals with bis(succinimidato)copper(II) complexes combining pyridine, picolines and lutidines.

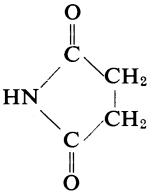

Fig. 1. Succinimide.

Experimental

Materials. — *Pyridine Complexes.* — [Cu(*sucim*)$_2$-(*py*)(OH$_2$)] was prepared in violet, cubic crystals according to the method of Tschugaeff,[2] where *sucim* and *py* denote a succinimidate ion and a pyridine molecule respectively. The crystals were stable in the atmosphere and were recrystallized from ethanol containing a few drops of pyridine.

Found: C, 43.9; H, 4.60; N, 11.6. Calcd. for $C_{13}H_{15}N_3O_5Cu$: C, 43.8; H, 4.24; N, 11.8%.

[Cu(*sucim*)$_2$(*py*)$_2$] was prepared, by a method similar to that used for [Cu(*sucim*)$_2$(*py*)(OH$_2$)], from 10 g. (0.1 mol.) of succinimide, 3 g. (0.05 g. atom) of copper powder, and 12 g. (0.15 mol.) of pyridine, with ethanol as a solvent. Since this compound was rather unstable in the atmosphere, the product was filtered in the dry air and stored in a tightly-closed bottle or in a desiccator containing sodium hydroxide. The crystals were recrystallized from an ethanol-pyridine mixture. The brown-red crystals, which were not quite free from the mother liquor, turned violet on exposure to the air, a co-ordinated pyridine molecule being replaced by a water molecule in the atmosphere. The compound was comparatively stable in the atmosphere when completely free from the mother liquor.

Found: C, 51.7; H, 4.50; N, 13.4. Calcd. for $C_{18}H_{18}N_4O_4Cu$: C, 51.7; H, 4.34; N, 13.4%.

Picoline Complexes. — [Cu(*sucim*)$_2$(*α-pic*)(OH$_2$)·CH$_3$OH] was prepared from 3 g. (0.05 g. atom) of copper powder, 10 g. (0.1 mol.) of succinimide and 10 g. (0.1 mol.) of α-picoline by a procedure similar to that used for [Cu(*sucim*)$_2$(*py*)$_2$], except that 50 ml. of methanol was used as a solvent. The notation '*pic*' denotes picoline. The product was filtered in the dry air and dried over phosphorus pentoxide in a vacuum desiccator. Recrystallization was carried out from methanol containing a suitable amount of the amine. Since these crystals turned from blue to green in the atmosphere, the compound was stored in a desiccator over sodium hydroxide.

Found: C, 45.0; H, 5.45; N, 10.0. Calcd. for $C_{15}H_{21}N_3O_6Cu$: C, 44.7; H, 5.25; N, 10.4%.

[Cu(*sucim*)$_2$(*α-pic*)$_2$] was obtained from [Cu-(*sucim*)$_2$(*α-pic*)(OH$_2$)·CH$_3$OH]. An excess of [Cu·(*sucim*)$_2$(*α-pic*)(OH$_2$)·CH$_3$OH] was added to methylene dichloride containing a small amount of α-picoline, and the solution was stirred for two hours; the blue crystals of the starting complex changed to red microcrystals. The product was filtered in the dry air and dried over phosphorus pentoxide in a vacuum desiccator. Recrystallization of the compound was carried out from ethanol containing an excess of α-picoline. The brown-red color of these crystals soon turned green in the atmosphere. The compound, however, was comparatively stable in the air when completely free from the mother liquor.

Found: C, 53.9; H, 4.99; N, 12.8. Calcd. for $C_{20}H_{22}N_4O_4Cu$: C, 53.9; H, 4.97; N, 12.6%.

[Cu(*sucim*)$_2$(*β-pic*)$_2$·2H$_2$O] was prepared by a method similar to the oxidation method of Tschugaeff, except that the filtration of the product was carried out in the dry air. The product consisted of deep-blue, needle-like crystals, which were hygroscopic. The crystal changed its color from deep-blue to red when stored for half a day over phosphorus pentoxide in a vacuum desiccator. The red compound is most probably [Cu(*sucim*)$_2$-(*β-pic*)$_2$], which is considered to be formed by the removal of two co-ordinated water molecules from [Cu(*sucim*)$_2$(*β-pic*)$_2$·2H$_2$O].

Found: C, 49.9; H, 5.29; N, 11.3. Calcd. for $C_{20}H_{26}N_4O_6Cu$: C, 49.8; H, 5.44; N, 11.6%.

Red crystals of [Cu(*sucim*)$_2$(*β-pic*)$_2$] were obtained from a methylene dichloride solution of [Cu-(*sucim*)$_2$(*β-pic*)$_2$·2H$_2$O]. When the solution was evaporated over phosphorus pentoxide in a vacuum desiccator, red crystals separated out. Since these

1) S. Yamada and S. Miki, This Bulletin, **36**, 680 (1963).
2) L. Tschugaeff, *Ber.*, **38**, 2900 (1905).

red crystals turned blue immediately on exposure to the air, it was quite difficult to analyze the complex and to examine its properties. However, a comparison with other complexes of a [Cu(*sucim*)$_2$-(*pic*)$_2$]-type shows that the red product is most probably [Cu(*sucim*)$_2$(β-*pic*)$_2$].

[Cu(*sucim*)$_2$(γ-*pic*)$_2$·H_2O] was easily prepared by a method similar to the oxidation method of Tschugaeff. The complex was obtained as violet-blue, cubic crystals which were stable in the atmosphere.

Found: C, 51.8; H, 5.22; N, 12.2. Calcd. for $C_{20}H_{24}N_4O_5Cu$: C, 51.8; H, 5.21; N, 12.1%.

[Cu(*sucim*)$_2$(γ-*pic*)(OH$_2$)] was prepared by a procedure similar to that used for [Cu(*sucim*)$_2$(α-*pic*)$_2$], except that [Cu(*sucim*)$_2$(γ-*pic*)$_2$·H_2O] was used in place of [Cu(*sucim*)$_2$(α-*pic*)(OH$_2$)·CH_3OH]. The compound was obtained as violet microcrystals. The compound was comparatively stable in the atmosphere when completely free from the solvent or mother liquor.

Found: C, 44.4; H, 4.61; N, 11.8. Calcd. for $C_{14}H_{17}N_3O_5Cu$: C, 45.3; H, 4.62; N, 11.3%.

[Cu(*sucim*)$_2$(γ-*pic*)$_2$] was obtained in brown-red, plate-like crystals by a method similar to that used for [Cu(*sucium*)$_2$(*py*)$_2$], except that 14 g. (0.15 mol.) of γ-picoline was used in place of 12 g. of pyridine. On exposure to the atmosphere, the crystals changed into blue crystals of [Cu(*sucim*)$_2$(γ-*pic*)$_2$·H_2O].

Found: C, 53.5; H, 4.88; N, 12.8. Calcd. for $C_{20}H_{22}N_4O_4Cu$: C, 53.9; H, 4.97; N, 12.6%.

Cu(*sucim*)$_2$(γ-*pic*)(OH$_2$)$_n$·CH_3OH was obtained as deep-blue crystals by the same method as that used for [Cu(*sucim*)$_2$(α-*pic*)(OH$_2$)·CH_3OH]. When exposed to the air, or when stored over phosphorus pentoxide in a vacuum desiccator, the product underwent decomposition. Accurate elemental analyses, therefore, were difficult, but the analyses agreed with the above formula, with n having a value between one and two.

Lutidine Complexes. — [Cu(*sucim*)$_2$(2,4-*lut*)$_2$]·0.5-H_2O, in which the notation '*lut*' denotes lutidine, was obtained as red crystals by a method similar to that used for [Cu(*sucim*)$_2$(*py*)$_2$], except that 15 g. (0.15 mol.) of 2,4-lutidine was used in place of 12 g. of pyridine. On exposure to the air, the crystals gradually decomposed, finally forming a sky-blue powder.

Found: C, 53.8; H, 5.48; N, 12.3. Calcd. for $C_{22}H_{27}N_4O_{4.5}Cu$: C, 54.7; H, 5.64; N, 11.6%.

[Cu(*sucim*)$_2$(3,5-*lut*)$_2$·H_2O] was obtained, by a method similar to the oxidation method of Tschugaeff, from 5 g. (0.05 mol.) of succinimide, 1.5 g. (0.025 g. atom) of copper powder, and 5.5 g. (0.05 mol.) of 3,5-lutidine. This complex formed blue plate-like microcrystals which were stable in the air.

Found: C, 53.2; H, 5.88; N, 11.5. Calcd. for $C_{22}H_{28}N_4O_5Cu$: C, 53.7; H, 5.74; N, 11.4%.

Red crystals of [Cu(*sucim*)$_2$(3,5-*lut*)$_2$] were obtained by the same method as that used for [Cu-(*sucim*)$_2$(β-*pic*)$_2$], except that [Cu(*sucim*)$_2$(3,5-lut)$_2$·H_2O] was used in place of [Cu(*sucim*)$_2$(β-*pic*)$_2$2H_2O]. On exposure to the atmosphere, the compound readily absorbed water to form [Cu(*sucim*)$_2$(3,5-*lut*)$_2$$H_2O$].

Cu(*sucim*)$_2$(OH$_2$)$_2$ was obtained as a sky-blue powder by a procedure similar to that used for Cu(*sucim*)$_2$(*py*)(OH$_2$), using 10 g. (0.1 mol.) of succinimide, 3 g. (0.05 g. atom) of copper powder and 11 g. (0.1 mol.) of 2,6-lutidine.

Found: C, 33.1; H, 4.19; N, 9.73. Calcd. for $C_8H_{12}N_2O_6Cu$: C, 32.5; H, 4.09; N, 9.47%.

All the compounds prepared in the present work, with the exception of Cu(*sucim*)$_2$(OH$_2$)$_2$, were soluble in chloroform, methylene dichloride, ethanol, methanol and pyridine, forming a greenish-blue or a dark-blue solution.

Pyridine, α-picoline and 2,6-lutidine, used as solvents for spectral measurements, were purified by distillation after having been dried over potassium hydroxide for several weeks.[3] The chloroform, which was purchased from Wako Co., was of extra-pure reagent grade, containing less than 0.05% water.

Measurements.—Quantitative dichroism measurements of the crystals were carried out at room temperature by Tsuchida and Kobayashi's microscopic method,[4] using polarized light in the visible and ultraviolet regions. The symbol α represents the absorption coefficient per mm. of a crystal. No correction was made for reflection on the surface of the crystal.

The absorption spectra of the compounds in organic solvents were determined at room temperature with a Beckman DU spectrophotometer.

Reflection spectra were determined with a Hitachi EPU 2A spectrophotometer. The symbols in the text are those conventionally used.

Results and Discussion

The Configuration of Bis(succinimidato)copper(II) Complexes with Pyridine.—As has been discussed in a previous paper,[1] a succinimidate ion is combined with a copper(II)-ion through its nitrogen atom when this behaves as a unidentate (Fig. 1).

The electronic absorption spectra of bis(succinimidato)copper(II) complexes with pyridine are shown in Fig. 2. The absorption bands between 50 and 70×10^{13} sec^{-1} observed with [Cu(*sucim*)$_2$(*py*)$_2$] in the crystalline state are regarded as "ligand field bands" which are due to the *d-d* transitions.[1] The main band maximum (about 62×10^{13} sec^{-1}) lies in a frequency region much higher than that of the cupric complexes of an ordinary kind. In the same way as in the previous paper,[1] the high frequency of the ligand field band maximum shows that [Cu(*sncim*)$_2$(*py*)$_2$] has a square-planar configuration of the [Cu(N)$_4$]-type, with the fifth and the sixth co-ordination sites left vacant.

The crystal structure analysis of the complex

is not yet available, and usually the planes of the complexes in the crystal are not exactly parallel to each other. However, it may readily be found that the A- and B-absorption in Fig. 2 represent the main features of the xy- and the z-absorption respectively of the square-planar complex, since previous studies have shown that, for ligand field absorption band, the xy-absorption has a larger oscillator strength than the z-absorption.[5]

The violet complex, [Cu(*sucim*)$_2$(*py*)(OH$_2$)], in the crystalline state shows a peak at about 58.2×10^{13} sec^{-1} which is remarkably dichroic and which is regarded as a ligand field band due to the cupric ion. The frequency at the band maximum is regarded as quite high for a cupric complex of the [Cu(N)$_3$O]-type. Thus, [Cu(NH$_3$)$_4$]$^{2+}$ and [Cu *en*$_2$]$^{2+}$ in water show absorption maxima at 49.2 and 54.6×10^{13} sec^{-1} respectively. It is concluded that [Cu(*sucim*)$_2$(*py*)(OH$_2$)] has a square-planar configuration of the [Cu(N)$_3$O]-type, with the fifth and the sixth sites left vacant.

The Configuration of Bis(succinimidato)copper(II) Complexes with Picolines and Lutidines. —The electronic absorption spectra of bis(succinimidato)copper(II) complexes with picolines and lutidines in the solid state were determined. An inspection of the data given in Table I indicates that there are three main types of succinimidato-copper(II) complexes with the amines, which are red, violet and deep-blue respectively. The difference in color between these types is so apparent that

Cu(*sucim*)$_2$(*α-pic*)$_2$ (1, solid; 4, soln.), Cu(*sucim*)$_2$(*γ-pic*)(OH$_2$) (2, solid; 5, soln.) and Cu(*sucim*)$_2$(*γ-pic*)$_2$·H$_2$O (3, solid; 6, soln.). The solid spectra were determined by the reflection method.

in most cases it is possible to assign a compound to one of these types with little ambiguity (Table I). Besides these, there is a green type for *α*-picoline.

A typical spectrum of the red crystals is shown in Fig. 3. From the data in Table I, it is found that the red crystals show the main peak of the ligand field band at about 61.5×10^{13} sec^{-1} or at higher frequencies. The red crystals, which are denoted as type I, consist of square-planar complexes of the [Cu(*sucim*)$_2$(amine)$_2$]-type, since the frequency of the main peak of the ligand field band is exceedingly high.

The deep-blue or indigo crystals of type III show the peak of ligand field bands at about 50×10^{13} sec^{-1}, a frequency which corresponds to a much lower frequency than the peak for the red, square-planar complexes of the [Cu(N)$_4$]-type. Thus, deep-blue crystals of [Cu(*sucim*)$_2$(*β-pic*)$_2$·2H$_2$O] and [Cu(*sucim*)$_2$(*γ-pic*)$_2$·H$_2$O] show their ligand field bands at

about 50.8 and 52.0×10^{13} sec^{-1}, respectively (Table I). These frequencies are much lower than those of the square-planar complexes of the $[Cu(N)_4]$-type, and are very close to the values for the complexes, which have already been established to consist of a $[Cu(N)_4(O)_n]$-type, n being either one or two.[1,6] It may be concluded that, in the crystals of $[Cu(sucim)_2(\beta\text{-}pic)_2\cdot2H_2O]$ and $[Cu(sucim)_2(\gamma\text{-}pic)_2\cdot H_2O]$, one or two molecules of water occupy additional co-ordination sites above and below the $[Cu(N)_4]$-plane to form a quinque-co-ordinate, tetragonal-pyramidal or a sexa-co-ordinate, pseudo-octahedral complex of the $[Cu(N)_4(OH_2)_n]$-type.

The complexes classified as type IV may be interpreted in a similar way. It is most likely that in these complexes the methanol molecule is combined with the copper(II) ion, $[Cu(N)_3(O)_n]$ being thereby formed, where n is either two or three.

Of the compounds of type II, the pyridine compound, $[Cu(sucim)_2[(py)(OH_2)]$, has been discussed above. The violet compounds of type II reported in the present paper show the peak of the ligand field bands at about 55 to 59×10^{13} sec^{-1}, a frequency which is slightly lower than the frequency for the red crystals but remarkably higher than the frequency for the complexes of the $[Cu(N)_4(OH_2)_n]$-type. It is, therefore, presumed that the violet crystals of type II consist of square-planar complexes of the $[Cu(sucim)_2(amine)(OH_2)]$-type, in which the fifth and the sixth co-ordination sites around the copper(II) ion are left vacant.

In the case of α-picoline, a green type is also obtained when the red crystals of $[Cu(sucim)_2(\alpha\text{-}pic)_2]$ are left to stand in the atmosphere. The green type of the α-picoline complex shows a peak corresponding to the ligand field band at about 51.5×10 sec^{-1}; the band is, however, quite broad. It is most likely that the compound is polynuclear, with hydroxyl groups serving as bridges, judging from its properties. The detailed structure of the compound is not established in the present study. A similar procedure for the preparation of the red compound using 2,6-lutidine instead of the other lutidines or picolines gives none of the three types; instead, a pale-blue compound with an empirical formula of $Cu(sucim)_2(OH_2)_2$ was obtained. The pale-blue complex of $Cu(sucim)_2(OH_2)_2$ shows a ligand field band at about 45×10^{13} sec^{-1} which is comparatively symmetrical. Although the precise structure of the compound has not yet been completely clarified, the low frequency of the band maximum indicates that the compound consists of a sexa-co-ordinate complex of the $[Cu(N)_2(O)_4]$-type, with oxygen atoms of water molecules possibly serving as bridges.

It should be noted that the quadri-co-ordinate copper(II) complexes of type I show ligand field bands which are less symmetrical, with a shoulder on the lower frequency side of the main band. This fact may be understood mainly in terms of the symmetry of the complexes, since the tetragonal nature of the ligand field is regarded as more pronounced in the complexes of type I than in those of type II as well as of type III.

General Consideration.—It is to be noted that the red crystals of the $Cu(sucim)_2(pic)_2$ formula were isolated with all of the α-, β- and γ-picolines. The red crystals of all the compounds obtained are quite unstable, taking up molecules of water in the atmosphere to turn green in the case of the α-picoline and deep-blue in the case of the β- or γ-picoline complexes.

The red complexes of β- and γ-picoline readily take the fifth and the sixth ligands, while the corresponding complex of α-picoline does not. Moreover, the isolation of the blue crystals of the $[Cu(sucim)_2(amine)_2(OH_2)_n]$-type is possible only with β- and γ-picolines, not with α-picoline. These facts may be understood mainly in terms of the steric factor.

The behavior of the lutidine-complexes of the $[Cu(sucim)_2(lut)_2]$-type may be interpreted in the same way as that of the corresponding complexes of picolines. Thus, the red 2,4-lutidine-complex in the atmosphere does not combine with a water molecule at the fifth or the sixth co-ordination sites; instead, the bond between the copper(II) ion and lutidine is readily broken, the original square-planar complex being changed into sky-blue $Cu(sucim)_2(OH_2)_2$. On the other hand, the red complex, $[Cu(sucim)_2(3,5\text{-}lut)_2]$, takes up one water molecule at the fifth site. The isolation of the blue crystals of the $[Cu(sucim)_2(lut)_2(OH_2)_n]$-type is found to be possible with those lutidines with no substituent on the α-carbon atom. This behavior is quite similar to that of the corresponding picoline-complexes of copper(II).

It should also be noted that the red pyridine-complex, $[Cu(sucim)_2(py)_2]$, has a much weaker tendency to combine additional ligands at the fifth and sixth co-ordination sites than do the complexes of the picolines and lutidines. Moreover, the square-planar, violet complex of $[Cu(sucim)_2(py)(OH_2)]$ is formed when the red $[Cu(sucim)_2(py)_2]$ is left in the air, but the corresponding violet complex is not formed with the picoline- or lutidine-complexes under the same conditions. Instead, the deep-blue complex of $[Cu(sucim)_2(pic)_2(OH_2)_n]$ or $[Cu(sucim)_2(lut)_2(OH_2)_n]$ is formed when the red

6) S. Miki and S. Yamada, to be submitted shortly.

complex of the $[Cu(sucim)_2L_2]$-type is left in the atmosphere. The corresponding deep-blue complex was not isolated with pyridine. It seems certain that bis(succinimidato)copper(II) complexes of pyridine have a stronger tendency to keep the fifth and sixth co-ordination sites vacant. This difference between the pyridine complexes and the complexes of picolines may be ascribed to the nature of the copper(II)-ligand bond, since the steric factor alone can not explain these differences. A definite explanation of this is not given in the present paper, but it may be ascribed to the difference in the π-bonding contribution, if it is assumed, on the basis of the concepts presented previously, that the π-bonding is important in stabilizing the square-planar configuration with the fifth and the sixth sites left vacant.[1)]

The Configuration of Bis(succinimidato)copper(II) Complexes in Non-donor Solvents.—The electronic absorption spectra of red diaminebis(succinimidato)copper(II) complexes were examined in chloroform (Table II and Fig. 3). An enormous bathochromic shift of the ligand field band (about $18\times10^{13}\,sec^{-1}$) is observed on going from the solid to the solution. It is considered that the molecular configuration in the solid state is not present in the solution. Since Beer's law is obeyed, and since the solution is unchanged in several days, there is a very slight possibility of the decomposition of the complex. Moreover, the shift is much larger than that which would be expected if the solvent molecules were co-ordinated to the copper(II) ion, since the bonding of the solvent molecule with the copper(II) ion would be very weak. In the same way as has been discussed previously,[1)] it is considered that the molecule of $[Cu(sucim_2)(amine)_2]$ in the solution is distorted from the square-planar configuration.

The violet and deep-blue complexes of types II and III also show ligand field bands at about 44 and $45\times10^{13}\,sec^{-1}$. The observed bathochromic shift on going from the solid to the solution is quite remarkable for the shift expected if the co-odination of chloroform molecules to the cupric ion takes place. It is considered that the field produced by ligands surrounding the copper(II) ion is distorted from the tetragonal symmetry to a considerable extent.

The bathochromic shift on going from the solid to the solution in the case of type III is considerably smaller than that in the case of types I and II, although the shift in the former case is still so great that some configurational change is to be assumed. A detailed discussion of them will be deferred until more materials become available.

The absorption spectra of these complexes in methylene dichloride are quite similar to those in chloroform. The molecular configuration of these complexes, therefore, is considered to be similar in all these solvents.

The absorption spectra of the compounds of type I in ethanol are similar to the spectra of the compounds in chloroform. Therefore, the same conclusion as that above is obtained. On the contrary, the absorption spectra of the complexes of types II and III in ethanol are more complicated, and the discussion of them will be deferred until more materials become available.

The Configuration of Bis(succinimidato)copper(II) Complexes in Pyridine, Picolines and Lutidines.—In donor solvents such as pyridine, the situation may be different from that in non-donor solvents. The red bis(pyridine)bis(succinimidato)copper(II) in pyridine shows a ligand field band at about $47\sim48\times10^{13}\,sec^{-1}$, a frequency which is much higher than that (about $44\times10^{13}\,sec^{-1}$) of the same compound in non-donor solvents. It may thus be inferred that the pyridine molecules are probably bound with the copper(II) ion to complete its sexa-co-ordination, the tetragonal symmetry of the ligand field being kept.

On the contrary, the red complexes of type I in 2,6-lutidine show a ligand field band at about $58\times10^{13}\,sec^{-1}$, a frequency which is much higher than those of the same compounds in pyridine as well as in other non-donor solvents (Fig. 4). It is most certain, from the steric ground, that the molecules of 2,6-lutidine are not bound with the copper(II) ion in the same sense as the molecules of pyridine are bound. The high frequency of the band maximum of the complex in 2,6-lutidine (Fig. 4) is taken as indication that the symmetry of the ligand field around the copper(II) ion is tetragonal,

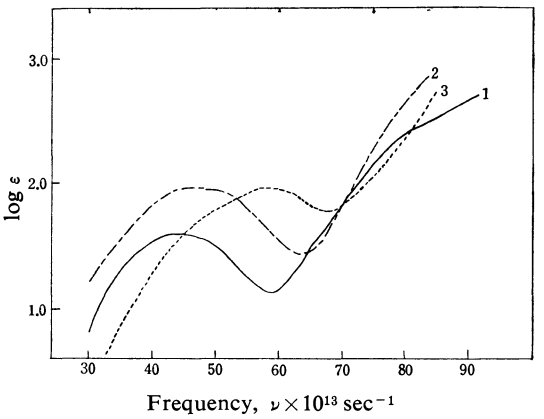

Fig. 4. UV-spectra of $Cu(sucim)_2(\alpha\text{-}pic)_2$ in organic solvents.

1, Chloroform; 2, Pyridine; 3, 2,6-Lutidine

and that the slight bathochromic shift of the band maximum relative to the band maximum of the crystal may be due to a feeble effect of the 2,6-lutidine molecules on the copper(II) ion. It is likely that the 2,6-lutidine molecules point toward the copper(II) ion at a farther distance in such a way that the ligand field around the copper(II) ion keeps the tetragonal symmetry.

Summary

Bis(succinimidato)copper(II) complexes with pyridine and its derivatives have been prepared, the derivatives involving α-, β- and γ-picoline, 2,4-lutidine and 3,5-lutidine. Depending upon the reaction conditions the following types of complexes have been obtained: (1) red complexes of [Cu(*sucim*)$_2$(amine)$_2$], (2) violet complexes of [Cu(*sucim*)$_2$(amine)(OH$_2$)], and (3) indigo or dark-blue complexes of [Cu(*sucim*)$_2$-(amine)$_2$(OH$_2$)$_n$]. When 2,6-lutidine is employed, however, none of the three types is obtained; rather, a blue compound with the formula of Cu(*sucim*)$_2$(OH$_2$)$_2$ is isolated.

The configuration of the three types of complexes has been examined, mainly on the basis of the electronic absorption spectra. The complexes of types 1 and 2 consist of quadri-coordinate complexes with a square-planar configuration. The compounds of type 3 consist of quinque- or sexa-co-ordinate complexes.

The configuration of these complexes of the three types in non-donor solvents has also been discussed.

The Beckmann Rearrangement of Alkyl Methyl Ketoximes

By Masato KAWAKAMI and Yasuhide YUKAWA

(Received March 19, 1964)

The mechanism of the Beckmann rearrangement has been discussed by several authors with attention to the intermediate, the stereospecificity, and the kinetics. Kuhara and his co-workers established the kinetics of the rearrangement of benzophenone oxime acetate[1]. Pearson et al. studied the effect of substituents on the rate of substituted acetophenone oximes[2] and symmetrical dialkyl ketoximes in sulfuric acid.[3] Ogata and Okano measured the rate of cyclohexanone oxime in oleum.[4] For the reaction in sulfuric acid, it has been known that the rate-determining step involves the breaking of the nitrogen-oxygen bond. The actual migration may rapidly proceed after the fission (the iminonium ion mechanism) or simultaneously with the fission (the concerted mechanism). At first sight, the stereospecificity of the reaction would support the concerted mechanism, since the group trans to the nitrogen-oxygen bond migrates preferentially. However, one can assume the formation of an ion pair between the iminonium ion and the hydroxyl ion, followed by rapid migration; therefore, the iminonium ion mechanism does not conflict with the stereospecificity of the reaction. Pearson reported that the polar effect of the aryl group in aryl methyl ketoximes influenced the rate of the reaction. A good linearity was found between the rates and Hammett's sigma values corrected for the additional electrophilic resonance effect using Yukawa-Tsuno's equation.[5] The effect can be explained satisfactorily either by the concerted mechanism or the iminonium ion mechanism. The direct participation of the aryl group in the former or the polar assistance through the C=N bond to the breaking of the N–O bond in the latter fits the equation as well.

The rates of the rearrangement of the several

alkyl methyl ketoximes were measured and the influence of the steric bulkiness of the migrating group were studied in this paper.

Experimental

Ketoximes.—The ketoximes used were prepared by the usual procedure from the corresponding ketones and were purified by recrystallization from petroleum ether or by distillation under reduced pressure.

n-Amyl methyl ketoxime	b. p. 107~107.5°C/21 mmHg
Cyclopentyl methyl ketoxime	b. p. 114~116°C/20 mmHg
2-Methylcyclopentyl methyl ketoxime	b. p. 120.5~121°C/20 mmHg
Cyclohexyl methyl ketoxime	m. p. 60°C
Cycloheptyl methyl ketoxime	m. p. 53~54°C b. p. 145°C/23 mmHg

Rearrangement Products.—After one milliliter of sulfuric acid had been added to 0.5 g. of ketoxime contained in a 30 ml. Erlenmeyer flask, the flask was held in the thermostat at 80°C for 10~15 hr. Ten milliliters of water was then added to the flask and the reaction mixture refluxed for 5~7 hr. to hydrolyze the acetamides produced. The solution was made strongly basic by adding a concentrated aqueous solution of potassium hydroxide, and the amine was extracted with 10 ml. of ether three times. After the removal of the solvent, it was derived to *N*-alkyl-*N'*-phenylurea by the reaction with phenyl isocyanate or to *N*-alkylbenzamide by Schotten-Baumann reaction. The melting points of these derivatives were not depressed by admixture with respective authentic samples prepared by the usual procedure.

N-Cyclohexyl-*N'*-phenylurea (from cyclohexylmethyl ketoxime), m. p. 182~182.5°C

N-Cycloheptyl-*N'*-phenylurea (from cycloheptyl methyl ketoxime), m. p. 182.5~183°C

Spectra of the 2,4-Dinitrophenylhydrazones in the Visible and Ultraviolet Region.—The absorption spectra of the 2,4-dinitrophenylhydrazones of alkyl methyl ketones in carbon tetrachloride were measured with a Hitachi photo-spectrometer. The spectra were essentially identical. The absorption curve in the case of *n*-amyl methyl ketone is shown in Fig. 1. The absorbance at 410 mμ was chosen for quantitative analysis. The correlation of the optical density with the concentration of the 2,3-dinitrophenylhydrazone of *n*-amyl methyl ketone is shown in Fig. 2.

Analysis of Ketoximes.—Pearson's method for the analysis of acetophenone oxime was modified as follows. A stock solution of ketoxime in 10% sulfuric acid was prepared. An aliquot of the solution was added from a burrett to each 100 ml. glass-stoppered flask with the flasks being weighed

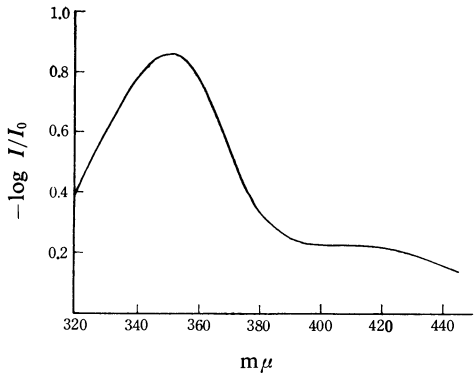

Fig. 1. The absorption curve of 2,4-dinitrophenylhydrazone of *n*-amyl methyl ketone.

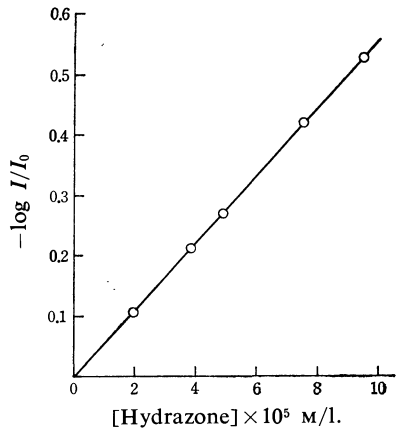

Fig. 2. Correlation of the optical density at 410 mμ to the concentration of 2,4-dinitrophenylhydrazone of *n*-amyl methyl ketone.

accurately before and after the addition. Twenty-five milliliters of 4% sulfuric acid and 0.300 g. of 2,4-dinitrophenylhydrazine were added to each flask. The flask was then sealed with a glass stopper and placed in a bath at 50°C for about 18 hr. After the flask had cooled, 25 ml. of carbon tetrachloride was added. The flask was then thoroughly shaken and allowed to stand for 18 hr. at room temperature. The carbon tetrachloride layer was transferred to a 100 ml. measuring flask using a separatory funnel fitted with a cotton filter. Another 5 ml. of carbon tetrachloride were added to wash the funnel and cotton filter and were combined with the filtrate. The combined solution was then diluted to 100 ml. with carbon tetrachloride. The optical density of this solution was determined at 410 mμ using a photo-spectrometer. A typical run is shown in Fig. 3.

Rate Determination.—About 500 mg. of ketoxime was weighed accurately and then dissolved in 20 ml. of sulfuric acid which had been weighed exactly in a glass-stoppered flask. The flask was sealed and immersed in a thermostatted bath (49.70~49.95°C±0.01°C). At approximately equal time intervals, from zero time to a half-life, each 2 ml. portion of the solution was pipetted out and the

Taft's σ : R. W. Taft, Jr., *J. Am. Chem. Soc.*, **75**, 4231 (1953).
* Calculated from D. E. Pearson's data (Refs. 2 and 3).

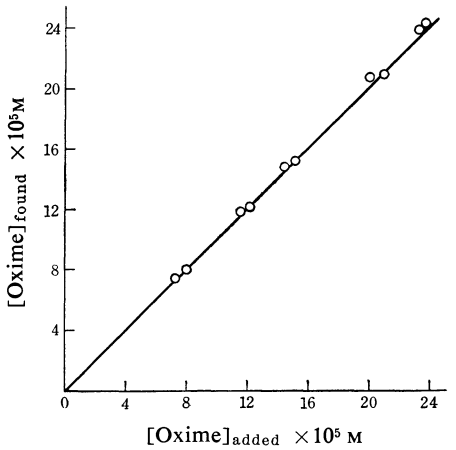

Fig. 3. Analysis of *n*-amyl methyl ketoxime.

quantity of unchanged keoxime was determined.

The rate is first order to ketoxime, the rate constant was calculated by the following equation.

$k=\ln(a/(a-x))\ (1/t)$

k: rate constant
t: time in minutes
a: concentration of initial ketoxime
x: concentration of reacted ketoxime at time t

The results are shown in Table I.

Results and Discussion

The first order rate-constants are given in Table I. The sequence of the rates was found to be: cycloheptyl≈cyclohexyl>2-methylcyclopentyl>cyclopentyl>*n*-amyl. As the steric bulkiness of the alkyl group in oximes is far greater than that of methyl, oximes have a methyl-syn configuration. It has been known that the group trans to the hydroxyl group in oxime migrates preferentially in sulfuric acid.*

Actually, the migration of the bulkier group was ascertained from the derivatives of the main products in the reaction, and the measured rates are those for the migration of alkyl groups.

The effect of the alkyl group upon the rates of reaction cannot be explained on the basis of the polar effect only, and there is no corre lation between the relative rates and Taft's sigma star values. The results can be elucidated only by the steric effect of the migrating group. The bulkiness of the *n*-amyl group would be smaller than that of cyclopentyl. Those of cycloheptyl and cyclohexyl would be the greatest, as these two groups have a non-planar ring.

If we consider the steric compression between the migrating alkyl group and the non-migrating methyl group, the sequence can be understood. When steric compression decreases in the transition state, the greater the steric compression in the initial state, the faster the reaction rate. The compression decreases during the reaction by means of: 1) the expansion of the angle between the migrating group and the non-migrating group, and 2) the increase of the length of the bond between the migrating group and the carbonyl carbon.

Our results can be explained by considering that the decrease of the steric compression might happen at the rate-determining step. On the basis of Pearson's data,[3] the ratios of k(diethyl ketone)/k(acetone) and k(diisopropyl ketone)/k(acetone) are 53 and 3400 respectively. The striking value in diisopropyl ketone may be also explained because the steric compression between two isopropyl groups is very much greater than that between two methyl groups or two ethyl groups. Pearson reported that the rate of *o*-methylacetophenone was much faster than that of acetophenone and explained the phenomenon as follows: The resonance interaction between phenyl group and the *d*-oximinoethyl group is diminished by the steric effect of the ortho substituent;

* This does not always hold in other media. (cf. S. Kim and Y. Yukawa, Unpublished.)

therefore, the ring system is geometrically more susceptible to participating with the nitrogen atom. Yukawa and Tsukamoto suggested the presence of the resonance inhibition due to the steric compression between the *o*-tolyl group and the methyl group of the oxime in its ultra-violet absorption spectra and also noticed the effect of the resonance inhibition in the aryl-carbonyl bond on the relative stability of *o*-substituted benzophenone oxime isomers.[6]

These suggestions agree with the above explanation of our results. The decrease in the steric compression seems to contribute to the rate. This implies that the migrating group participates in the cleavage of the N–O bond in the rate-determining step in sulfuric acid. The iminonium ion mechanism can not offer any explanation, but the concerted mechanism is supported. The carbon-14 kinetic isotope effect in a Beckmann rearrangement undertaken to confirm the mechanism will be reported in a succeeding paper.

*Sesquiterpenes from Dictyopteris divaricata. I**

By Toshi IRIE, Koji YAMAMOTO and Tadashi MASAMUNE

(Received March 23, 1964)

In 1951, Takaoka and Ando[1] isolated a sesquiterpene alcohol from *Dictyopteris divaricata*, Okamura, and they suggested that it was a new type of cadinol. Recently acquired knowledge about the constitution and stereochemistry of sesquiterpenes[2] has prompted us to re-examine the sesquiterpenes of the brown alga.

The methanol extracts of the air-dried seaweed, *Dictyopteris divaricata*[3] (92 kg.), were concentrated to a small volume in vacuo, and the residual light brown oil was then distilled with steam. The ether extracts of the distillate were washed with 5% aqueous potassium hydroxide and then by 1 N hydrochloric acid.

The neutral essential oil (790 g.)[4] thus obtained was subjected to fractional distillation in vacuo; each fraction was chromatographed on alumina or silica gel, the homogeneity was tested by gas chromatography and thin-layer chromatography, and six components were isolated in a pure state.

Four sesquiterpenes among them were identified as (−)-copaene,[5] (−)-γ_1-cadinene,[6] cadalene and (−)-δ-cadinol[7] by a comparison of their infrared absorption spectra and other physical constants with those the corresponding sesquiterpenes given by Šorm.[8] The alcohol was also shown to be identical with that isolated by Takaoka and Ando.[1]

A new hydrocarbon (b. p. 97°C/5 mmHg, $[\alpha]_D^{23}$ +12.8°) showed an infrared spectrum which was superimposable on that of (−)-β-elemene.[8] The NMR spectrum showed the presence of one quaternary methyl (τ=9.07, s), two methyls attached to the double bond (τ=8.38, ss), one vinyl group (τ=4.45, q; 5.35, d; 5.43, d) and four olefinic protons (τ=5.45~5.65). These data have shown that the hydrocarbon is the optical antipode of (−)-β-elemene. This was further confirmed by a comparison of the retention time on gas chromatography with that of authentic (−)-β-elemene.[9]

The further investigation of another sesquiterpene, a newly isolated secondary alcohol, $C_{15}H_{24}O$, $[\alpha]_D^{23.5}$ −13.6°, is now in progress; details will be presented elsewhere.

* Checked by gas chromatography on PEG-4000

Experimental

The melting points are uncorrected. Fractional distillation was carried out with a high-efficiency concentric-tube Kyowa fractionator. The gas chromatographic analyses were carried out with a Hitachi gas chromatograph KGL-2 at 200°C, using PEG-4000 and helium gas. The ultraviolet and infrared spectra were measured using a Hitachi ESP-2 spectrophotometer and a Nippon Bunko 401-G spectrophotometer respectively. The NMR measurements were performed with a Nippon Denshi 60 Mc. spectrophotometer, and carbon tetrachloride and tetramethylsilane were used as the solvent and the internal standard respectively.

The Extraction and Fractionation of the Essential Oil.—The air-dried seaweed, *Dictyopteris divaricata*, Okamura (92 kg.), was extracted with methanol at room temperature for two weeks, after which the methanol extracts were concentrated in vacuo. The light brown residual oil then distilled with steam, and the distillate was extracted with ether. After the solvent had been removed from the ethereal extracts, 890 g. of a light yellow essential oil was obtained (yield, 0.97%).

The crude essential oil was dissolved in ether, and the ethereal solution was washed with 5% aqueous potassium hydroxide and then by 1 N hydrochloric acid. The neutral fraction thus obtained amounted to 790 g. (0.86%). Gas chromatography showed that this fraction consisted of at least thirteen components. The neutral fraction was then fractionated in a nitrogen stream under diminished pressure using a high-efficiency (theoretical plates about 80) fractional column. The results are shown in Table I.

(−)-Copaene.—Fraction D-3 was subjected to redistillation in vacuo, and a fraction boiling at 87~87.5°C/3 mmHg was then chromatographed on silica gel. (−)-Copaene, $C_{15}H_{24}$ ($n_D^{21.5}$ 1.4922, $[\alpha]_D^{23}$ −26.1°, IR (liquid film): 3040, 1642, 1320, 1177, 1166, 1156, 1045, 1032, 1010, 930, 879, 824, 777, 740 cm^{-1}) was obtained from the fraction eluted with petroleum ether.

The NMR spectrum showed peaks at 5.20 (1H, singlet), 8.28 (3H, doublet, J=2.4 c.p.s.), 9.02 (3H, singlet), and 9.08 τ (6H, doublet, J=6.6 c.p.s.).

(+)-β-Elemene.—Fraction D-5 was redistilled in vacuo, and a fraction boiling at 97°C/5 mmHg (yield 66.2%) was collected. This was chromatographed on silica gel. A pure hydrocarbon n_D^{22} 1.4920, $[\alpha]_D^{23}$ +12.8°, was obtained.

Found: C, 87.87; H, 11.69. Calcd. for $C_{15}H_{24}$: C, 88.16; H, 11.84%.

The infrared spectrum (liquid film) (3080, 1640, 1003, 907, 885 cm^{-1}) was superimposable on that of (−)-β-elemene.[8] The NMR spectrum showed peaks at 4.45 (1H, quartet, J=9.5, 17.5 c.p.s.), 5.35 (1H, doublet, J=9.5 c.p.s.), 5.43 (1H, doublet, J=17.5 c.p.s.), 5.45~5.65 (4H), 8.38 (6H, singlet), and 9.07 τ (3H, singlet). When the comparison of this hydrocarbon and authentic (−)-β-elemene was carried out by Šorm[9] using gas chromatography, the same retention time was observed.

(−)-γ_1-Cadinene.—Fractions D-9, 10, and 11 were combined and redistilled in vacuo, and a fraction boiling at 108.5~109°C/5 mmHg was identified as (−)-γ_1-cadinene ($[\alpha]_D^{25}$ −19.6°, IR (liquid film): 3070, 1642, 886, 833, 812 cm^{-1}).

Cadalene.—Fraction D-15 was chromatographed on neutral alumina, and the first petroleum ether eluate yielded cadalene, $C_{15}H_{18}$, (picrate, m. p. 111~113°C. UV: λ_{max}^{EtOH} 231 (4.67), 290 (3.72), 325 mμ (log ε 2.75); IR (liquid film): 3070, 1625, 1603, 1517, 828, 806, 777 cm^{-1}; NMR: 2.23 (2H, multiplet), 2.75 (1H, doublet, J=2 c.p.s.), 2.92 (2H, singlet), 6.38 (1H, multiplet), 7.42 (3H, singlet), 7.50 (3H, singlet), 8.64 (3H, doublet, J=5.7 c.p.s.) and 8.66 τ (3H, doublet, J=5.7 c.p.s.).

(−)-δ-Cadinol.—The D-16 residue was distilled in vacuo; the results are shown in Table II.

9) F. Šorm, private communication.

TABLE II. VACUUM DISTILLATION OF THE RESIDUE D-16 (10 ml.)

Fraction	B. p., °C/mmHg	Yield, ml.
D-16-1	123.5~128/3	1.60
2	128~131/3	1.00
3	131.5~132.5/3	0.54
4	130.5/2.5	0.51
5	130.5~133/2.5	0.53
6	139~146.5/1.5	0.52
7	149.5~170/1.5	0.58

Fraction D-16-3, boiling at 131.5~132.5°C/3 mmHg, (417 mg.) was chromatographed on neutral alumina, and from the benzene-ether (3 : 2) eluate, colorless crystals (m. p. 110~130°C) were isolated (71 mg.) ; these were repeatedly recrystallized from methanol to have an m. p. of 137.5~138.5°C and $[\alpha]_D^{27}$ −108°.

Found : C, 81.22 ; H, 11.75. Calcd. for $C_{15}H_{26}O$: C, 81.02 ; H, 11.79%.

The infrared spectra in chloroform, 3590, 1133, 1117, 1101, 947, 873 cm^{-1}, and in Nujol, 3305, 1108, 871 cm^{-1}, were identical with those of (−)-δ-cadinol. NMR : 4.64 (1H, doublet), 8.37 (3H, singlet), 8.77 (3H, singlet), 9.11 (3H, doublet, J=5.5 c.p.s.) and 9.21 τ (3H, doublet, J=5.5 c.p.s.). The cadinol isolated by Takaoka and Ando[1] was found to be identical with this (−)-δ-cadinol on the basis of a mixed melting point determination and the infrared spectra.[10]

A Sesquiterpene Alcohol.—The D-16 residue (25 g.) was chromatographed on neutral alumina, and from the benzene-ether (4 : 1) eluate, a sesquiterpene alcohol (1.73 g.) was obtained, $[\alpha]_D^{23.5}$ −13.6°C.

Found : C, 81.87 ; H, 10.91. Calcd. for $C_{15}H_{24}O$: C, 81.76 ; H, 10.98%.

IR (liquid film) : 3360, 1033, 1015 (OH), 3080, 1643 885 cm^{-1} (>C=CH_2) ; NMR : 4.77 (1H, multiplet), 5.36 (2H, broad singlet), 6.65 (1H, multiplet), 8.27 (3H, singlet), 8.42 (3H, singlet) and 9.29 τ (3H, doublet). The structure elucidation of this alcohol is in progress.

The authors wish to express their thanks to Dr. Yoshiaki Ando, the Institute of Health, Hokkaido, for his helpful suggestions and for providing them with a sample of cadinol, and to Professor F. Šorm, the Czeckoslovak Academy of Science, for his kind advice. They are also indebted to Mr. Shigezo Shimokawa for his NMR measurements and to Miss Akiko Maeda for her microanalyses.

The Ultraviolet Absorption Spectra of Nitramide and Ethyl Nitrate

By Koji KAYA, Keiji KUWATA and Saburo NAGAKURA

(Received March 24, 1964)

The electronic absorption spectra of various molecules which contain both electron donating and accepting groups have been studied by several workers from both experimental and theoretical points of view.[1-9] Consequently, it has been found that these molecules exhibit absorption bands characteristic of the interaction between electron donor and acceptor. The absorption bands of this kind have been called intramolecular charge-transfer bands from an analogy with Mulliken's nomenclature[10] for the intermolecular case.

In the present paper, the study of the intramolecular charge-transfer band was extended to nitramide and ethyl nitrate, in which the nitro group as an electron acceptor and the amino or ethoxyl group as an electron donor are connected directly with each other. Our principal purposes are to discover intramolecular charge-transfer bands for these two systems, and to obtain quantitative knowledge about the interaction between the nitro group and the amino or ethoxyl group by combining the experimental data of the absorption spectra

with the theoretical results based on the molecular orbital calculations.

Experimental

Materials.—Ethyl nitrate was synthesized from ethanol and nitric acid.[11] It was purified by distillation and stored in a desiccator at low temperature.

Nitramide was synthesized by the decomposition of nitrourethane and was purified by recrystallization from petroleum ether.[12] It was stored in a desiccator with potassium hydroxide under reduced pressure and at low temperature.

Measurement.—The ultraviolet absorption measurements down to 1900 Å were made with a Cary recording spectrophotometer, model 14 M, quartz cells 0.1 and 1 cm. long being used.

A vacuum ultraviolet spectrophotometer constructed in our laboratory[13] was used for the measurements in the vacuum ultraviolet region. In this case, a quartz cell 0.01 cm. thick was used for the measurements of solutions, and gas cells 0.7 cm. and 3 cm. long and equipped with lithium fluoride windows were used for the measurements in the gaseous state.

The absorption spectra of nitramide and ethyl nitrate was measured in various solvents. We succeeded in measuring the absorption spectrum in the gaseous state for ethyl nitrate, but we could not do so for nitramide because of its explosive character at high temperatures. The observed absorption spectra are shown in Figs. 1 and 2. The peak wavelengths, molar extinction coefficients and oscillator strengths are tabulated in Table I.

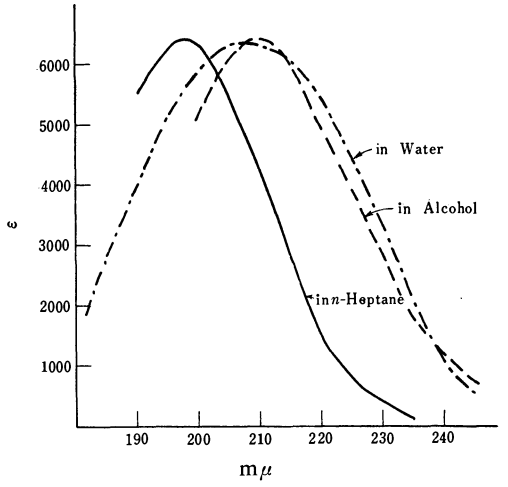

Fig. 1. The ultraviolet absorption spectra of nitramide.

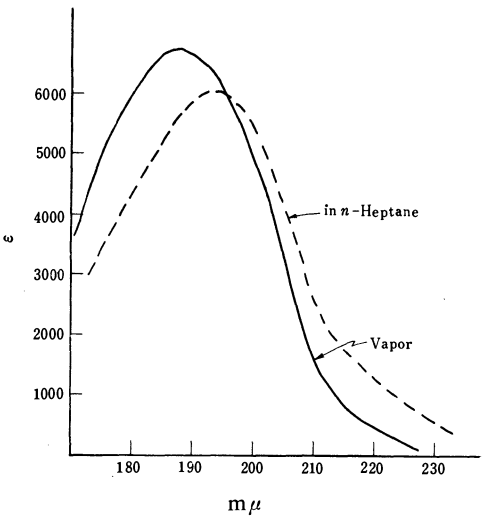

Fig. 2. The ultraviolet absorption spectra of ethyl nitrate.

TABLE I. THE OBSERVED PEAK WAVELENGTHS AND MOLAR EXTINCTION COEFFICIENTS FOR NITRAMIDE AND ETHYL NITRATE

Sample	Solvent	λ_{max}(mμ)	ε_{max}
Nitramide	Water	207~208	6300
	Alcohol	209	6400
	n-Heptane	198	—
Ethyl nitrate	*n*-Heptane	193	5800
	Gas	190	6800

Theoretical

The π-electron energy levels and the wave functions of nitramide and ethyl nitrate were calculated by taking into account the configurational interaction among several electron configurations. That is to say, each of the two molecules was separated into the two components, the electron donor (NH_2 or C_2H_5O) and the electron acceptor (NO_2). The interaction between them was considered by means of the configurational interaction among π-electron configurations which have been constructed by putting the six π-electrons into the appropriate orbitals of the components. The electron configurations actually taken up in the present calculation are shown in Fig. 3. In addition to the ground configuration, G, a charge-transfer configuration, CT, which is caused by an electron transfer from the electron donor toward the electron acceptor, three locally excited configurations, LE_1, LE_2, LE_3, and one doubly excited configuration, D, were considered. A characteristic point in the present calculation is that we took the locally excited configuration LE_3, corresponding to the transition within the electron donating group,

and the D configuration corresponding to a two electron excitation.

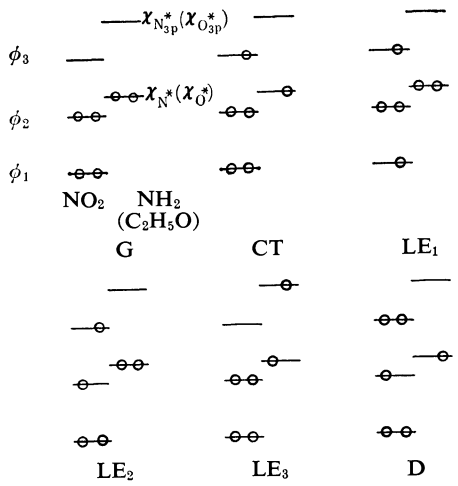

Fig. 3. The electron configurations of nitramide and ethyl nitrate.

The geometrical structure of nitramide was studied by Beevers and Trotman-Dickenson[14] with the X-ray crystal analysis technique and by Tyler[15] with the microwave spectrum analysis technique. The bond lengths and bond angles determined by the latter, which are shown in Fig. 4, were used in the present calculations. There has been no investigation of the structure of ethyl nitrate, so we assumed the structure of ethyl nitrate from the electron diffraction data of methyl nitrate by Pauling and Brockway[16] and from the X-ray crystal analysis data of pentaerythritol tetranitrate by Booth and Llewellyn.[17] The bond lengths and bond angles of ethyl nitrate used in the present calculation are also shown in Fig. 4.

The above-mentioned structure of ethyl

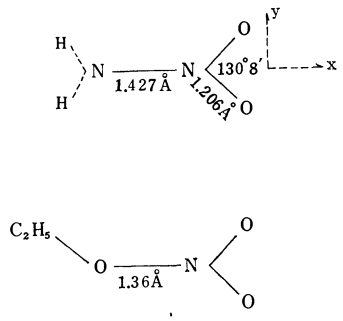

Fig. 4. The geometrical structures of nitramide and ethyl nitrate.

nitrate shows that the lone-pair electron orbital on the oxygen atom of the ethoxyl group is pure 2p. The situation is the same for planar nitramide. According to the study by Tyler, however, the two hydrogen atoms of the amino group of gaseous nitramide are out of the $N-NO_2$ plane by 51°47′. In this case, the lone-pair electron orbital of the nitrogen atom on the amino group can be represented by the hybridization of 2p and 2s orbitals.

In the present study, we first calculated the π-electron structures for the planar ethyl nitrate and nitramide molecules, and then we considered the effect of the distortion from the planarity for nitramide.

The energy of the ground configuration was taken as the standard. The energy of the charge-transfer configuration (H_{CT}) was calculated by the following equation:

$$H_{CT}=I_D-A_{NO2}+E(D^+-A^-) \qquad (1)$$

Here, I_D is the ionization potential of the electron donating group (NH_2 or C_2H_5O); it was determined to be 10.25 and 10.44 eV. for the amino and ethoxyl groups respectively, from the ionization potentials of ammonia and ethanol obtained by Watanabe.[18] A_{NO2} is the electron affinity of the electron accepting group (NO_2); it was assumed to be +0.40 eV, the value taken for a series of nitro compounds.[19,20] $E(D^+-A^-)$ is the electrostatic interaction energy between the electron donor and the acceptor after electron migration and can be represented by the following equations:

$$\left.\begin{aligned} &E(NH_2^+-NO_2^-)=0.4912(N^*N^* \mid NN) \\ &\quad -1.4912\ (N^*N^* \mid OO) \text{ for nitramide} \\ &E(C_2H_5O^+-NO_2^-)=0.4912(O^*O^* \mid NN) \\ &\quad -1.4912\ (O^*O^* \mid OO) \text{ for ethyl nitrate} \end{aligned}\right\} \qquad (2)$$

where $(\mu\mu \mid \nu\nu)$ indicates the two center Colomb repulsion integral between the $2p\pi$ atomic orbitals on the μ and ν atoms, and where N* is the nitrogen atom of the NH_2 group, O* is the oxygen atom of the C_2H_5O group, and N and O indicate the nitrogen and oxygen atoms of the NO_2 group respectively.

Two center Coulomb repulsion integrals were evaluated by Pariser and Parr's method.[21] The evaluation of these integrals needed valence state ionization potentials and electron affinities, so they were taken from the tables of Pritchard and Skinner[22] and of Moore[23].

TABLE II. THE ENERGIES AND WAVE FUNCTIONS OF THE CONFIGURATIONS

Energy	Wave function[a]
$H_G=0$ eV.	$\varphi_G=(1\bar{1}2\bar{2}N^*\bar{N}^*)$
$H_{CT}=4.96$ eV. (NH_2NO_2) 5.13 eV. ($EtONO_2$)	$\varphi_{CT}=1/\sqrt{2}\{(1\bar{1}2\bar{2}N^*\bar{3})+(1\bar{1}2\bar{2}3\bar{N}^*)\}$
$H_{LE_1}=6.26$ eV.	$\varphi_{LE_1}=1/\sqrt{2}\{(1\bar{1}2\bar{3}\bar{N}^*N^*)+(1\bar{1}32N^*\bar{N}^*)\}$
$H_{LE_2}=11.15$ eV.	$\varphi_{LE_2}=1/\sqrt{2}\{(1\bar{3}2\bar{2}N^*\bar{N}^*)+(3\bar{1}2\bar{2}N^*\bar{N}^*)\}$
$H_{LE_3}=8.18$ eV. (NH_2NO_2) 10.99 eV. ($EtONO_2$)	$\varphi_{LE_3}=1/\sqrt{2}\{(1\bar{1}2\bar{2}N^*\bar{N}^*_{3p})+(1\bar{1}22N^*_{3p}N^*)\}$
$H_D=9.43$ eV.	$\varphi_D=1/\sqrt{2}\{(1\bar{1}233\bar{N}^*)+(1\bar{1}3\bar{2}N^*\bar{3})\}$

a) The exact formula for $(1\bar{1}2\bar{2}N^*\bar{N}^*)$ as an example is as follows;
$(\bar{1}12\bar{2}N^*N^*)=1/\sqrt{6!}\sum(-1)^p p\begin{Bmatrix}\phi_1(1)\phi_1(2)\phi_2(3)\phi_2(4)\chi_N^*(5)\phi_N^*(6)\\ \alpha(1)\beta(2)\alpha(3)\beta(4)\alpha(5)\beta(6)\end{Bmatrix}$ [b,c]

b) ϕ_1, ϕ_2 and ϕ_3 are the SCF molecular orbitals of the nitro group calculated by Tanaka *(J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **78**, 1643(1957)) and are represented as below;
$\phi_1=0.7133\,\chi_N+0.7009/\sqrt{2}\,(\chi_O+\chi_{O'})$
$\phi_2=1/\sqrt{2}\,(\chi_O-\chi_{O'})$
$\phi_3=0.7009\,\chi_N-0.7133/\sqrt{2}\,(\chi_O+\chi_{O'})$
Here, χ_N and χ_O ($\chi_{O'}$,) indicate the $2p\pi$ atomic orbitals of the nitrogen and the two oxygen atoms of the nitro group.

c) χ_N^* and $\chi_N^*{}_{3p}$ are the $2p\pi$ and the $3p\pi$ atomic orbitals of the nitrogen atom of the amino group in the case of nitramide. In the case of ethyl nitrate, N^* and $N^*{}_{3p}$ must be changed into χ_O^* and $\chi_O^*{}_{3p}$ which represent the $2p\pi$ and the $3p\pi$ atomic orbitals of the oxygen atom of the ethoxyl group.

TABLE III. THE OFF-DIAGONAL ELEMENTS USED IN THE PRESENT CALCULATION

$H_{G\cdot CT}=0.9912\ \beta_{NN}^*(\beta_{NO}^*)$ $\quad H_{CT\cdot LE_1}=-0.7133\ \beta_{NN}^*(\beta_{NO}^*)$
$H_{CT\cdot LE_3}=0.7009\ \beta_{NN}^*{}_{3p}\ (\beta_{NO}^*{}_{3p})$ $\quad H_{LE_2\cdot D}=0.7133\ \beta_{NN}^*(\beta_{NO}^*)$
$H_{G\cdot LE_1}=H_{G\cdot LE_3}=H_{CT\cdot LE_2}=H_{LE_1\cdot LE_3}=0$

$\beta_{NN}^*=\int\chi_N H_{core}\chi_N^*d\tau=-2.14$ eV. $\quad \beta_{NO}^*=\int\chi_N H_{core}\chi_O^*d\tau=-2.18$ eV.

$\beta_{NN}^*{}_{3p}=\int\chi_N H_{core}\chi_N^*{}_{3p}d\tau=-2.52$ eV. $\quad \beta_{NO}^*{}_{3p}=\int\chi_N H_{core}\chi_O^*{}_{3p}d\tau=-2.49$ eV.

As has been mentioned above, we considered three locally excited configurations, LE_1, LE_2, LE_3. Among these, LE_1 and LE_2 are caused by local excitation within the nitro group. The energy of the LE_2 configuration, H_{LE2}, is lower than that of the LE_1 configuration. H_{LE2} was taken to be 6.26 eV. from the position of the observed $\pi\rightarrow\pi^*$ transition band of nitromethane.[19] Concerning the energy of the locally excited configuration LE_1, the corresponding value has never been observed; therefore, it was calculated by the following equation:

$$H_{LE1}=-2\sqrt{2}\,\beta_{NO}+K_{13} \qquad (3)$$

where β_{NO} is the core resonance integral between the $2p\pi$ atomic orbitals of the nitrogen and oxygen atoms of the nitro group and K_{13} represents the exchange repulsion integral between the lowest (ϕ_1) and the highest (ϕ_3) π molecular orbitals of the nitro group, the actual forms of which are shown in Table II. The value of β_{NO} was calculated by the following approximate equation:[24]

$$\beta_{\mu\nu}=\frac{(I_\mu+I_\nu)S_{\mu\nu}\beta_{CC}}{2(I_C S_{CC})} \qquad (4)$$

Here, I_μ I_ν and I_C are the ionization potentials of the μ atom, the ν atom and the carbon atom of benzene respectively. $S_{\mu\nu}$ and S_{C-C} are the overlap integrals between $2p\pi$ atomic orbitals of the μ and ν atoms[25] and between the $2p\pi$ atomic orbitals of the neighboring carbon atoms of benzene respectively. By the use of the above equation, β_{NO} was evaluated to be -3.25 eV. The K_{13} value was resolved into two center Coulomb integrals and found to be 1.96 eV. Therefore, the value of H_{LE} was determined to be 11.15 eV.

The energy of the LE_3 configuration corresponding to the $2p\rightarrow3p$ transition within the

	W_0-W_2			6.49		0.59

electron-donating group was determined to be 8.18 eV. and 10.99 eV. for the NH_2 and C_2H_5O groups, respectively. The former value was obtained by adding the energy difference between the 3s and 3p orbitals[23] to the observed Rydberg transition energy of ammonia.[26] The latter value was assumed to be equal to the difference between the 2p and 3p orbitals of the oxygen atom taken form Moore's table.[23] The energy of the doubly excited configuration D was evaluated by the following equation:

$$H_D=H_{LE_1}+I_D-A_{NO_2}{}^*+E^*(D^+-A^-)$$
$$=9.430\,\text{eV. for } NH_2NO_2$$
$$=9.426\,\text{eV. for } EtONO_2 \qquad (5)$$

Here $A_{NO_2}{}^*$ is the electron affinity for bringing an additional electron into the ϕ_3 orbital of the nitro group in the locally excited state LE_2; it was assumed to be 1.03 eV.[27] $E^*(D^+-A^-)$ is the electrostatic interaction energy between the electon donating and accepting groups in the D configuration and was evaluated by the use of the above-mentioned two center Coulomb integrals of the $(\mu\mu\,|\,\nu\nu)$ type. The energies and the wave functions of the configurations used in the present calculations are tabulated in Table II.

The off-diagonal matrix elements of the total electronic Hamiltonian which represent the magnitudes of the interaction between different configurations were evaluated according to the formulations by Pople[28] and by Longuet-Higgins and Murrell.[6] They are given in Table III in terms of the core resonance integrals $\beta_{NO}{}^*$, $\beta_{NN}{}^*$, $\beta_{NO_3p}{}^*$ and $\beta_{NN3p}{}^*$. The definitions and values of these

26) A. B. F. Duncan, *Phys. Rev.*, **50**, 700 (1936).

27) According to the exact calculations, the energy difference between A^*_{NO2} and A_{NO2} can be written as follows:

$$A^*_{NO2}-A_{NO2}=J_{23}+K_{23}-J_{33}=+0.63\,\text{eV}. \qquad (6)$$

Here, J_{ij} and K_{ij} represent, respectively, the Coulomb and exchange repulsion integrals between the ϕi and ϕj molecular orbitals of the nitro group.

28) J. A. Pople, *Trans. Faraday Soc.*, **49**, 1375 (1953).

core resonance integrals evaluated by Eq. 4 are also shown in Table III.

Using these diagonal and off-diagonal matrix elements, we set up the secular equations of the fourth and second orders for the symmetric and antisymmetric configurations respectively. Solving these equations by an electronic computer, a Facom 202 in our Institute, we obtained the π-electron energy levels and the wave functions for planar nitramide and ethyl nitrate. The energy levels and wave functions are shown in Figs. 5 and 6 and in Table IV. From these results, the transition

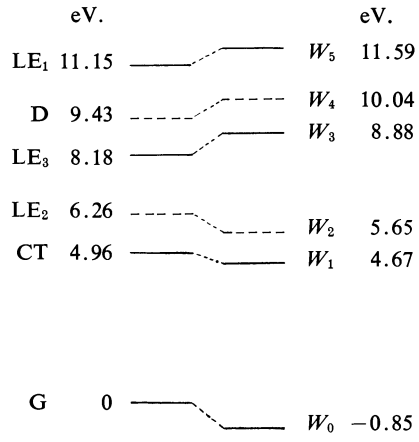

Fig. 5. The π-electron energy levels of nitramide.

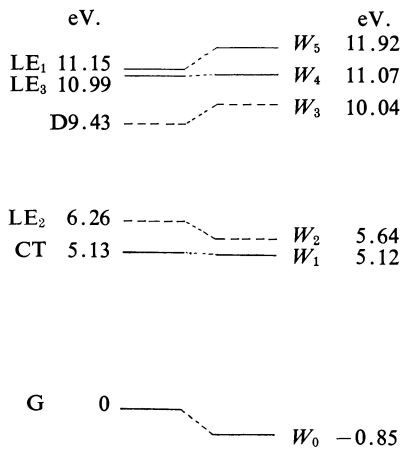

Fig. 6. The π-electron energy levels of ethyl nitrate.

energies and oscillator strengths were calculated for the longest two $\pi \rightarrow \pi^*$ transition bands of nitramide and of ethyl nitrate. The results are shown in Table V, together with the observed results.

As may be seen in the paper by Tyler,[15] there is some doubt concerning the planar structure of nitramide. Therefore, it seems to be necessary to consider the effect of the distortion from planarity on the absorption spectrum of nitramide.

From one 2s and three 2p atomic orbitals of the nitrogen atom of the amino group, four hybridized orbitals, which are independent and orthonormal from each other, are constructed; two of them are directed towards the two hydrogen atoms of the amino group, and the third one, towards the nitrogen atom of the nitro group. The last one constitutes the lone pair electron orbital of the amino group. If we take the coordinate of the molecule as shown in Fig. 4, the geometrical structure of nitramide determined by Tyler leads to the conclusion that the principal axis of the lone pair orbital is on the xz plane and makes an angle of 14°35′ from the z axis.

Since this angle is rather small and therefore, the lone pair electron orbital has an overwhelmingly large contribution from the π-electron orbital,[29] the effect of distortion from the planarity of the molecule on the calculated energy levels and wave functions may be thought to be small. This is shown to be true by the actual calculations. The theoretical result calculated by considering the changes of the core resonance integral β_{NN}^* and of the two center Coulomb integrals due to the distortion from the planarity is very similar to that for the planar molecule, as is seen in Table IV. Therefore, we will hereafter consider only the case of planar nitramide.

Results and Discussion

As is easily seen in Figs. 1 and 2, both nitramide and ethyl nitrate show rather broad bands near 200 mμ. The peak wave lengths and the molar extinction coefficients obtained by us are summarized in Table I. The ultraviolet spectrum of nitramide was first measured by Jones.[30] According to his results, nitramide has its absorption maximum at 225 mμ in an aqueous solution. This result is obviously different from our result, which shows the absorption maximum near 200 mμ. Our sample was identified by the aid of the infrared absorption measurements and of the elementary analysis of nitrogen. Therefore, Jones' finding on the ultraviolet absorption spectrum of nitramide may conceivably be erroneous.

According to the theoretical results shown

29) The lone pair orbital of the amino group ϕ_N^* can be written as follows:

$$\phi_N^* = 0.4448\ \chi_{2s} + 0.8668\ \chi_{2pz} + 0.2255\ \chi_{2px}$$

where χ_{2s}, χ_{2qz} and χ_{2px} represent the 2s, $2p_z$ and $2p_x$ atomic orbital wave functions on the nitrogen atom of the amino group.

30) R. Jones, *Canad. J. Reaserch*, **B27**, 828 (1949).

in Table V, the first $\pi \rightarrow \pi^*$ band corresponding to the $W_0 \rightarrow W_1$ transition should appear at 225 and 208 mμ for nitramide and ethyl nitrate respectively, with the oscillator strength value of 0.14 and 0.15. As will be mentioned below, however, another strong band corresponding to the $W_0 \rightarrow W_2$ transition may be expected to appear near 200 mμ for either of these two molecules. Therefore, it seems reasonable to consider that the $W_0 \rightarrow W_1$ transition band may be covered by the $W_0 \rightarrow W_2$ transition band. This expectation seems to be supported by the broadness of the observed bands. As may easily be seen by comparing the wave function of the first excited state with that of the ground state, the first $\pi \rightarrow \pi^*$ band may be regarded as an intramolecular charge-transfer band caused by interaction between the electron donating group (NH_2 or OC_2H_5) and the electron accepting group (NO_2).

The present calculation shows that near 200 mμ there should exist the $W_0 \rightarrow W_2$ transition bands, which have the character of local excitation within the nitro group. Their calculated oscillator strengths are 0.61 and 0.59 for nitramide and ethyl nitrate respectively. Therefore, the observed broad bands of nitramide and ethyl nitrate can be interpreted as the superposition of the two bands corresponding to the $W_0 \rightarrow W_1$ and $W_0 \rightarrow W_2$ transitions. Of course, the $W_0 \rightarrow W_2$ transition band makes the main contribution to the observed band, since the calculated oscillator strength value of this band is about five times larger than that of the $W_0 \rightarrow W_1$ transition band.

By looking at the findings on the energy value, W_0, of the ground state given in Table IV, it may be seen that the ground state is lower by 0.85 eV. = 19.5 kcal./mol. for both nitramide and ethyl nitrate than the unperturbed ground configuration. These stabilization energies, which are mainly brought about by interaction between the ground and charge-transfer configurations, may be regarded as corresponding to the vertical resonance energy due to the resonance hybrid between the following two structures for each molecule:

$$H_2N\text{–}NO_2 \leftrightarrow H_2N^+\text{=}NO_2^-$$

$$H_5C_2O\text{–}NO_2 \leftrightarrow H_5C_2O^+\text{=}NO_2^-$$

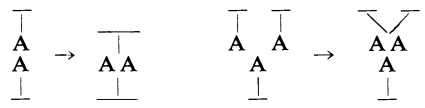
A Theory of Gel Formation with a Multifunctional Interunit Junction

By Tokio YAMABE and Kenichi FUKUI



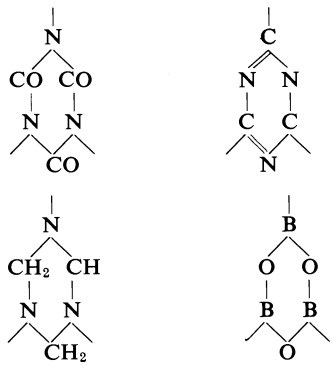
(Received March 10, 1964)

The ways in which high polymer substances are formed from monomeric units or by the crosslinking of polymer chains may be classified according to the number of functional groups involved in the formation of an interunit junction. Each case may be referred to as polymerization by a bi-, a ter-, a quadri-, a ···, or a multifunctional interunit junction. A schematic representation follows:

Polymerization:

Crosslinking:

bifunctional interunit junction



terfunctional interunit junction

In the polymerization by a bifunctional interunit junction, the theory of molecular size distribution and gel formation has been studied by Flory,[1] Stockmayer[2] and many other

1) P. J. Flory, "Principles of Polymer Chemisty," Cornell University Press, Ithaca, New York (1953), Chaps. 8 and 9.

2) W. H. Stockmayer, *J. Chem. Phys.*, **11**, 45 (1943); **12**, 125 (1944).

researchers.[3] The theory of gel formation with a terfunctional interunit junction has been developed by the present authors[4] for the case in which any monomer possesses equivalent f functional groups. Recently such a type of polycondensation by a terfunctional interunit junction has come to our attention as we attempted to prepare thermosetting resins. For example:

where the interunit junctions are the isocyanuric ring, the *s*-trizine ring, the hexahydro-*s*-triazine ring, and the boroxin ring respectively. These interunit junctions are applicable to the crosslinking of polymer chains, as was realized in the crosslinking of polyacrylonitrile[5] or of polyacrylhydroxanic acid.[6] In the present paper, the theory is extended to a more general case than those previously considered, namely, the case of the formation of a multifunctional interunit junction (say, j functional: $j=2, 3, 4, \cdots$) not only in the polycondensations of a monomer with f equivalent functional groups ($f \geqq 2$), but also in the cross linking of a system of chains with an arbitrary initial size distribution. Of course, the $j=2$ case is equivalent to that of the bifunctional interunit junction, while $j=3$ is equivalent to that of a terfunctional interunit junction. Here the methods developed by Stockmayer are employed to derive the distribution of molecular sizes up to the gel point, and as was done in his papers, we also neglect the formation of macrorings, namely, rings which contain two or more endocyclic interunit junctions, for the first approximation.

f-Functional Monomer

In this part, each monomer possesses f equivalent functional groups, and those monomers are combined as polymer by a j-functional interunit junction, where j is the number of functional groups composing an interunit junction. If ν is the number of interunit junctions in an n-mer, and if the symbol ${}_jM_\nu^{(f)}$, is used for the number of n-mers ($n=(j-1)\nu+1$), the total number of units, N, and the total number of molecules, M, can be expressed as follows:

$$\sum_{\nu \geqq 0}((j-1)\nu+1)\,{}_jM_\nu^{(f)}=N \tag{1}$$

$$\sum_{\nu \geqq 0}{}_jM_\nu^{(f)}=M \tag{2}$$

Therefore, the most probable molecular size distribution may be written as:

$${}_jM_\nu^{(f)}=A\frac{{}_jW_\nu^{(f)}}{N!}B^n \tag{3}$$

where ${}_jW_\nu^{(f)}$ is the number of different ways in which a polymeric molecules can be formed from n monomeric units (therefore, with ν interunit junctions) and is equal to:

$${}_jW_\nu^{(f)}=\frac{f^{(j-1)\nu+1}((f-1)(j-1)\nu+f-1)!\,((j-1)\nu)!}{\nu!\,((fi-f-j)\nu+f)!\,\{(j-1)!\}^\nu} \tag{4}$$

A and B are Lagrangian multipliers to be determined from Eqs. 1 and 2. Those summations can easily be evaluated by introducing Eq. 3 into Eqs. 1 and 2; the results are:

$$N=\frac{AB}{(1-\alpha)^f} \tag{5}$$

$$M=B\left(1-\frac{j-1}{j}f\alpha\right) \tag{6}$$

where

$$\frac{(fB)^{j-1}}{(j-1)!}=\alpha(1-\alpha)^{(f-1)(j-1)-1} \tag{7}$$

The molecular size distribution may then be rewritten:

$${}_jM_\nu^{(f)}=f\cdot N\times\frac{((f-1)(j-1)\nu+f-1)!\,((j-1)\nu)!}{\nu!\,((j-1)\nu+1)!\,((f-1)\nu-\nu+f)!}\times\alpha^\nu(1-\alpha)^{(f-1)(j-1)\nu-\nu+f} \tag{8}$$

The fraction of reacted functional groups is obtained from Eqs. 5 and 6:

$$p=\frac{\sum_{\nu \geqq 0}j\nu\,{}_jM_\nu^{(f)}}{fN}=\frac{j(N-M)}{(j-1)N}=\alpha \tag{9}$$

which means that α is equal to the fraction of reacted functional groups. The number and weight-average molecular size can easily be calculated from Eq. 6 and by direct summation:

3) M. Gordon *J. Chem. Phys.*, **22**, 610 (1954); F. E. Harris, ibid., **23**, 1518 (1955); L. C. Case, *J. Polymer Soc.*, **26**, 333 (1957).
4) K. Fukui and T. Yamabe, *J. Polymer Sci.*, **45**, 305 (1960).
5) K. Takemoto, *Chemistry (Kagaku)*, **17**, 124 (1962).
6) W. Kern and R. C. Schulz, *Angew. Chem.*, **69**, 153 (1957).

$$\langle W\rangle_{\mathrm{av.}}=\frac{\sum_{\nu\geqq 0}(j-1)\nu+1)^2{}_jM_\nu^{(f)}}{\sum_{\nu\geqq 0}((j-1)\nu+1){}_jM_\nu^{(f)}}$$

$$=\frac{1+(j-1)\alpha}{1-(f-1)(j-1)\alpha} \tag{10}$$

$$\langle N\rangle_{\mathrm{av.}}=\frac{\sum_{\nu\geqq 0}((j-1)\nu+1){}_jM_\nu^{(f)}}{\sum_{\nu\geqq 0}{}_jM_\nu^{(f)}}$$

$$=\frac{N}{M}=\frac{1}{1-(j-1)f\alpha/j} \tag{11}$$

Therefore, the gel point is characterized by the following equation:

$$\alpha_{\mathrm{gel}}=\frac{1}{(f-1)(j-1)} \tag{12}$$

For the special case of $j=2$, Eqs. 10 and 11 become:

$$\langle n\rangle_{\mathrm{av.}}=\frac{1}{1-f\alpha/2},\qquad \langle w\rangle_{\mathrm{av.}}=\frac{1+\alpha}{1-(f-1)\alpha}$$

which agree with Stockmayer's results,[2] For yet another case, $j=3$, these equations are:

$$\langle n\rangle_{\mathrm{av.}}=\frac{1}{1-2f\alpha/3},\quad \langle w\rangle_{\mathrm{av.}}=\frac{1+2\alpha}{1-2(f-1)\alpha}$$

which are in accord with our previous results.[4]

The Crosslinking of Polymer Chains

In this section, the theory of the crosslinking of polymer chains by a j function interunit junction will be treated. For the sake of simplicity, the treatment is restricted to cases in which all units in the chains carry a functional group, all of which are assumed to be equivalent and of the same reactivity. Let the system contain N_1 monomeric chains, N_2 dimeric chains,$\cdots$, N_s s-meric chains,$\cdots$, etc. The number-average size of the chain that initially exist is thus:

$$\lambda_n=\frac{\sum_s sN_s}{\sum_s N_s}=\frac{1}{\sum_s W_s/s} \tag{13}$$

and the weight-average size is:

$$\lambda_w=\frac{\sum_s s^2N_s}{\sum_s sN_s}=\sum_s sW_s \tag{14}$$

where W_s, the weight fraction of s-meric chains, is given by:

$$W_s=\frac{sN_s}{\sum_s sN_s} \tag{15}$$

and where, therefore,

$$\sum_s W_s=1 \tag{16}$$

The description of any crosslinked molecules requires the specification of the number of chains of each size which it coniains. We denote by n_1, n_2, n_3,$\cdots$, n_s, etc., these numbers of chains and represent any particular set of these numbers by the symbol $\{n_s\}$. The symbole $m\{n_s\}$ will be used for the number of molecules described by a particular set $\{n_s\}$ (which is joined with ν j-functional interunit juctions). The most probable molecular size distribution is, therefore, written as:

$$m\{n_s\}=A\cdot{}_jW_\nu\{n_s\}\prod_s \xi_s n_s/n_s! \tag{17}$$

where A and ξ_s are Lagrangian multipliers which must be so chosen that

$$N_t=\sum_{\mathrm{all}\{n_s\}} n_t m\{n_s\} \tag{18}$$

$$M=\sum_{\mathrm{all}\{n_s\}} m\{n_s\} \tag{19}$$

and ${}_jW_\nu\{n_s\}$ is the number of different ways in which a molecule described by $\{n_s\}$ can be constructed from its constituent chains by ν interunit junctions. The use of the Stockmayer method for calculating this number gives the result:

$${}_fW_\nu\{n_s\}=\frac{(\sum_s(s-1)n_s)!((j-1)\nu)!}{(\sum_s(s-1)n_s-(\nu-1))!\,\nu!\,((j-1)!)^\nu}\prod_s s^{n_s} \tag{20}$$

where

$$\sum_s n_s=(j-1)\nu+1 \tag{21}$$

Using Eq. 20, Eq. 17 may be rewritten as folloms:

$$m\{n_s\}=(\sum_s sN_s)\frac{(\sum_s(s-1)n_s)!((j-1)\nu)!}{\nu!(\sum_s(s-1)n_s-(\nu-1))!}\times\alpha^\nu(1-\alpha)^{\sum_s(s-1)n_s-(\nu-1)}\times\prod_s\frac{W_s^{n_s}}{n_s!} \tag{22}$$

where

$$s\xi_s=\{(j-1)!\,\alpha(1-\alpha)^{-j}\}^{1/(j-1)}W_s(1-\alpha)^s$$

$$A=(\sum_s sN_s)\{(j-1)!\,\alpha(1-\alpha)^{-j}\}^{-1/(j-1)}$$

which satisfies the conditions of Eqs. 18 and 19, as is shown in the Appendix. After the evaluation of the necessary sums, the number- and weight-average molecular sizes are obtained as follows:

$$\bar{P}_n=\frac{\sum_s(\sum sn_s)m\{n_s\}}{\sum m\{n_s\}}=\frac{1}{1-(j-1)\alpha\lambda_n/j} \tag{23}$$

$$\bar{P}_w=\frac{\sum_s(\sum sn_s)^2m\{n_s\}}{\sum_s(\sum sn_s)m\{n_s\}}=\frac{1+(j-1)\alpha\lambda_w}{1-(j-1)(\lambda_w-1)\alpha} \tag{24}$$

Therefore, the gel-point is given by

$$\alpha_{gel}=\frac{1}{(j-1)(\lambda_w-1)} \tag{25}$$

Of course, for the special case of $j=2$, these results are consistent with those of Stockmayers.

In the above formulations, the size distribution of the chains which initially exist is arbitrary, but the distribution of almost all the synthesized polymer chains is the most probable distribution. In this case, the molecular size distribution and the average sizes in the course of cross linking are found to be as follows. It is well known that the most probable molecular size distribution of chain polymers is given by $W_s=s\rho^{s-1}(1-\rho)^2$, where s is the number of units in a chain, and ρ is the probability that the reactive group in the unit has reacted. Let $m_{p,\nu}$ be the number of crosslinked polymeric molecules composed of p units and jointed with functional interunit junctions. This $m_{p,\nu}$ can be expressed:

$$m_{p,\nu}=\sum m\{n_s\} \tag{26}$$

where the summation should cover all possible sets, $\{n_r\}$, with the conditions:

$$\sum_s n_s=(j-1)\nu+1,\quad \sum_s sn_s=p \tag{27}$$

Equation 26 easily be evaluated, with the result that

$$m_{p,\nu}=\frac{((j-1)\nu)!\,(p+(j-1)\nu)!}{\nu!((j-1)\nu+1)!\,(p-j\nu)!\,(2(j-1)\nu+1)!}\times\alpha^\nu(1-\alpha)^{p-j\nu}\rho^{-(j-1)\nu-1}(1-\rho)^{2(j-1)\nu+2} \tag{28}$$

Form Eqs. 23 and 24, the number- and weight-average size are found to be;

$$\bar{P}_n=\frac{1}{1-\rho-(j-1)\alpha/j} \tag{29}$$

$$\bar{P}_w=\frac{(1+\rho)(1+(j-1)\alpha)}{1-\rho-2(j-1)\alpha\rho} \tag{30}$$

$$\alpha_{gel}=\frac{1-\rho}{2(j-1)\rho} \tag{31}$$

since $\lambda_n=1/(1-\rho)$, and $\lambda_w=(1+\rho)/(1-\rho)$ for the case of chains with the most probable distribution. When $j=2$, the result is consistent with that of Ohiwa derived by the kinetical method.[7]

Appendix

We wish to show that the distribution law:

$$m\{n_s\}=\{\sum_s sN_s\}\frac{(\sum_s(s-1)n_s!\,((j-1)\nu)!}{(\sum_s(s-1)n_s-(\nu-1))!\,\nu!}\times\alpha^\nu(1-\alpha)^{\sum_s(s-1)n_s-(\nu-1)}\prod_s\frac{W_s^{n_s}}{n_s!}$$

satisfies the conditions:

$$N_t=\sum n_t m\{n_s\} \tag{A-1}$$

$$M=\sum m\{n_s\} \tag{A-1}$$

Putting $\nu_t=n_t-1$ and $\nu_s=n_s(s\neq t)$, and expanding the power of $(1-\alpha)$ in Eq. A-1, we have;

$$\sum n_t m\{n_s\}=(\sum_s sN_s)W_t\sum_{q=0}\frac{(-\alpha)^q}{q!}\sum_{\nu=0}^{q}\binom{q}{\nu}(-1)^\nu\times\sum\frac{(\sum_s(s-1)\nu_s+(t-1))!\,(\sum_s\nu_s)!}{(\sum_s(s-1)\nu_s+(t-1)-(q-1))}\times\prod_s\frac{W_s^{\nu_s}}{\nu_s!} \tag{A-3}$$

where $\sum_s\nu_s=(j-1)\nu$

Consider now the function:

$$\mathscr{H}(x)=(1-(\sum_s W_s x^{s-1})^{j-1})^q x^{t-1}$$

$$=\sum_{\nu=0}^{q}\binom{p}{\nu}(-1)^\nu\sum(\sum_s\nu_s)!\prod_s\frac{W_s^{\nu_s}}{\nu_s!}\times x^{\sum_s(s-1)\nu_s+t-1}$$

where q is an integer greater than one.

Repeated differentiations give:

$$\left[\left(\frac{d}{dx}\right)^{q-1}\mathscr{H}(x)\right]_{x=1}=\sum_{\nu=0}^{q}\binom{p}{\nu}(-1)^\nu\times\sum\frac{(\sum_s(s-1)\nu_s+t-1)!\,(\sum_s\nu_s)!}{(\sum_s(s-1)\nu_s+t-1-(q-1))!}\prod_s\frac{W_s^{\nu_s}}{\nu_s!}$$

which is recognized as the sum required in Eq. A-3. However, since this derivative necessarily contains the $(1-(\sum_s W_s)^{j-1})$ factor, its value is zero, and the sum of Eq. A-3 is reduced to the term of $q=0$. Evaluating these, we obtain

$$\sum n_s m\{n_s\}=\frac{W_t}{t}(\sum_s sN_s)=N_t$$

Since the procedure for the summation of Eq. 18 resembles that used above, it may be omitted.

The Intramolecular Force Field and Normal Vibrations of Isotactic Polypropylene and Deuterated Derivatives[*1]

By Tatsuo MIYAZAWA and Yoshiko IDEGUCHI

(Received February 24, 1964)

The infrared active normal vibrations of isotactic polypropylene (IPP), poly(propylene-2-d_1) (IPP-CD), poly(propylene-1, 1-d_2) (IPP-CD_2) and poly(propylene-3, 3, 3-d_3) (IPP-CD_3) in the 1500~650 cm^{-1} region have been treated in previous studies.[1,2] The high-frequency CH stretching modes of the CH, CH_2, and CH_3 groups have been separated and the internal rotation modes have not been taken into account since the internal rotation potential terms do not contribute much to the frequencies above 650 cm^{-1}. Thus, the "effective" potential constants have been calculated, by the method of least squares,[3] from the observed frequencies. In the present study, a complete normal coordinate treatment of isotactic polypropylene and deuterated derivatives was made, one in which the CH stretching modes and the internal-rotation modes about the CH–CH_2 and CH–CH_3 bonds were all taken into account.

Normal Coordinate Treatment

Internal Coordinates.—A general method for the treatment of the molecular vibrations of helical polymers has been described.[1] The internal coordinate (or the local symmetry coordinate) vectors, $R_{1,n}$~$R_{18,n}$, of the nth repeating unit of isotactic polypropylene have been given in Eqs. 1—6 of Ref. 2. In addition, the C–H stretching coordinates and the internal rotation coordinaten shown below were used in the present study:

$$R_{19,n}(\text{CH stretch.}) = \Delta r(1,n;\ 5,n) \tag{1}$$

$$\begin{bmatrix} R_{20,n}(\text{CH}_3 \text{ sym. stretch.}) \\ R_{21,n}(\text{CH}_3 \text{ asym. stretch.}) \\ R_{22,n}(\text{CH}_3 \text{ asym. stretch.}) \end{bmatrix} = \begin{bmatrix} 1/3^{1/2} & 1/3^{1/2} & 1/3^{1/2} \\ 1/6^{1/2} & 1/6^{1/2} & -2/6^{1/2} \\ 1/2^{1/2} & -1/2^{1/2}, & 0 \end{bmatrix} r(\text{CH}_3)_n \tag{2}$$

$$\begin{bmatrix} R_{23,n}(\text{CH}_2 \text{ sym. stretch.}) \\ R_{24,n}(\text{CH}_2 \text{ asym. stretch.}) \end{bmatrix} = \begin{bmatrix} 1/2^{1/2} & 1/2^{1/2} \\ 1/2^{1/2} & -1/2^{1/2} \end{bmatrix} r(\text{CH}_2)_n \tag{3}$$

where the elements of the vector $r(CH_3)$ in Eq. 2 are $\Delta r(3,n;\ 7,n)$, $\Delta r(3,n;\ 8,n)$, and $\Delta r(3,n;\ 9,n)$; the elements of the vector r-$(CH_2)_n$ in Eq. 3 are $\Delta r(2,n;\ 4,n)$ and $\Delta r(2,n;\ 6,n)$; and Δr's are the stretching coordinates for which the numbering of carbon and hydrogen atoms has been shown in Fig. 1 of Ref. 2.

The internal-rotation coordinates[4] for the nth unit are;

$$\begin{aligned} R_{25,n}(\text{CH–CH}_3 \text{ bond}) &= \Delta t(1,n;\ 3,n) \\ &= [\Delta\tau(2,n-1;\ 1,n;\ 3,n;\ 7,n) \\ &\quad + \Delta\tau(2,n-1;\ 1,n;\ 3,n;\ 8,n) \\ &\quad + \Delta\tau(2,n-1;\ 1,n;\ 3,n;\ 9,n) \\ &\quad + \Delta\tau(2,n;\ 1,n;\ 3,n;\ 7,n) \\ &\quad + \Delta\tau(2,n;\ 1,n;\ 3,n;\ 8,n) \\ &\quad + \Delta\tau(2,n;\ 1,n;\ 3,n;\ 9,n) \\ &\quad + \Delta\tau(5,n;\ 1,n;\ 3,n;\ 7,n) \\ &\quad + \Delta\tau(5,n;\ 1,n;\ 3,n;\ 8,n) \\ &\quad + \Delta\tau(5,n;\ 1,n;\ 3,n;\ 9,n)]/9 \end{aligned} \tag{4}$$

$$\begin{aligned} R_{26,n}(\text{axial CH–CH}_2 \text{ bond}) &= \Delta t(1,n;\ 2,n) \\ &= [\Delta\tau(2,n-1;\ 1,n;\ 2,n;\ 4,n) \\ &\quad + \Delta\tau(2,n-1;\ 1,n;\ 2,n;\ 6,n) \\ &\quad + \Delta\tau(2,n-1;\ 1,n;\ 2,n;\ 1,n+1) \\ &\quad + \Delta\tau(3,n;\ 1,n;\ 2,n;\ 4,n) \\ &\quad + \Delta\tau(3,n;\ 1,n;\ 2,n;\ 6,n) \\ &\quad + \Delta\tau(3,n;\ 1,n;\ 2,n;\ 1,n+1) \\ &\quad + \Delta\tau(5,n;\ 1,n;\ 2,n;\ 4,n) \\ &\quad + \Delta\tau(5,n;\ 1,n;\ 2,n;\ 6,n) \\ &\quad + \Delta\tau(5,n;\ 1,n;\ 2,n;\ 1,n+1)]/9 \end{aligned} \tag{5}$$

$$\begin{aligned} R_{27,n}(\text{equatorial CH–CH}_2 \text{ bond}) &= \Delta t(2,n;\ 1,\ n+1) \\ &= [\Delta\tau(1,n;\ 2,n;\ 1,n+1;\ 2,n+1) \\ &\quad + \Delta\tau(1,n;\ 2,n;\ 1,n+1;\ 3,n+1) \\ &\quad + \Delta\tau(1,n;\ 2,n;\ 1,n+1;\ 5,n+1) \\ &\quad + \Delta\tau(4,n;\ 2,n;\ 1,n+1;\ 2,n+1) \end{aligned}$$

*1 This is Part VI of *Molecular Vibrations and Structures of High Polymers*. The present study was, in part, published at the Confernce on Vibrational Spectra of High Polymers, Milan, July, 1963.

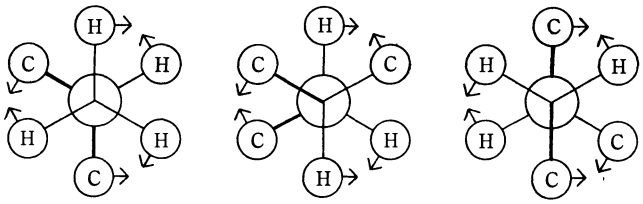

Fig. 1 The internal-rotation modes about the C-methyl bond (t_{C-CH_3}), about the axial C-C bond (t_{CC}^{ax}), and about the equatorial C-C bond (t_{CC}^{eq}) of isotactic polypropylene chain (the right-handed helix). Main chain C-C bonds are drawn with heavy lines.

$$+\Delta\tau(4,n;\ 2,n;\ 1,n+1;\ 3,n+1)$$
$$+\Delta\tau(4,n;\ 2,n;\ 1,n+1;\ 5,n+1)$$
$$+\Delta\tau(6,n;\ 2,n;\ 1,n+1;\ 2,n+1)$$
$$+\Delta\tau(6,n;\ 2,n;\ 1,n+1;\ 3,n+1)$$
$$+\Delta\tau(6,n;\ 2,n;\ 1,n+1;\ 5,n+1)]/9 \qquad (6)$$

where $\Delta\tau$'s are the torsional coordinates. These internal-rotation coordinates are schematically shown in Fig. 1. The elements of the inverse kinetic energy matrix associated with the internal-rotation modes were calculated by the use of the general formulas.[4]

Potential Function.—In deriving the potential energy matrix, the modified Urey-Bradley field was supplemented with these internal-rotation potential term.[4,5]

$$V(\text{internal-rotation}) = \frac{1}{2}\sum_n \{Y(\text{CH–CH}_2)\,[\Delta t(1,n;\ 2,n)]^2 + Y(\text{CH–CH}_2)\,[\Delta t(2,n;\ 1,n+1)]^2 + Y(\text{CH–CH}_3)\,[\Delta t(1,n;\ 3,n)]^2\} \qquad (7)$$

The potential constants of isotactic polypropylene used in the present study are listed in Table I. Common potential constants, K(C–C) and Y(C–C), were used for the axial and equatorial CH–CH$_2$ bonds, since the arrangements of the carbon and hydrogen atoms adjacent to these C–C bonds are the same. The repulsion constants, F(H–C–H) and F(C–C–H), were transferred from the ethane molecule as treated by Takahashi and Shimanouchi.[6] The initial set of the remaining potential constants (except for the CH stretching constant) were transferred from the previous study[2] and were then adjusted by the method of least squares[3] with reference to the fundamental frequencies of IPP, IPP-CD, IPP-CD$_2$, and IPP-CD$_3$ as observed by Peraldo and Farina[7] in the region above 650 cm^{-1} and to the far infrared frequencies of IPP in the region below 650 cm^{-1}.[1,8] The adjustments of the potential constants were repeated until

finally, for each constant, the calculated correction was reduced to a point where it was negligible compared with the standard error. In the adjustment of the potential constant, the element of the Jacobian matrices were calculated by the equation reported previously.[9] The standard errors were calculated according to the method derived by Ogawa and Miyazawa.[10]

Potential Constants. — The final set of the potential constants and their standard errors are listed in Table I. The C–H stretching constants, K(C–H), of the CH_2 and CH groups are calculated to be slightly smaller than for the CH_3 group, where the repulsion constants, F(H–C–H) and F(C–C–H), have been transferred from ethane. The stretching-interaction constants, p(C–H), for the CH_3 and CH_2 groups were taken independently, but they have finally been calculated to be the same. Therefore, a common stretching-interaction parameter may be used for the CH_3 and CH_2 groups.

The stretching constants, K(C–C), for the CH–CH_2 and CH–CH_3 bonds were also taken independently, but these two constants finally coincided within the standard errors. Therefore, these two constants may well be reduced to a common parameter $[(2.240+2.270)/2 = 2.255]$.

The bending constants of the H–C–H angle of the CH_3 and CH_2 groups are nearly the same, but the difference is greater than their standard errors. The bending constants for the C–C–H angles of the CH_3, CH_2, and CH groups all lie in the range between 0.235 and 0.215 mdyn./Å.

The values of the intramolecular tension [κ] and angle-interaction term [l(C–C–H)]*2 for the CH_2 group are almost negligible compared with the corresponding standard errors; accordingly, these parameters may well be neglected, at least in the treatment of polypropylene. It may be recalled that the corresponding contants for malonitrile, $CH_2(CN)_2$, are also negligible.[5]

The trans and gauche coupling constants of IPP agree closely with those of ethane ($T=0.107$ and $G=-0.024$) and of polyethylene ($T=0.100$ and $G=-0.033$).[5]

The internal-rotation constants, Y(C–C), may be used for estimating the barrier height of the internal-rotation potential, which is assumed to be threefold and sinusoidal. Thus, the potential barrier for the CH–CH_2 bond of the main chain and for the CH–CH_3 bond are estimated to be 5.7±1.4 and 2.9±0.1 kcal./mol. (approximately corrected for anharmonicity[4]) respectively.

The diagonal elements of the potential energy matrix associated with genuine vibrational modes may be obtained satisfactorily from the observed frequencies, although the off diagonal elements are not necessarily so.[5] Accordingly, the final values of the diagonal elements associated with "local" symmetry coordinates of isotactic polypropylene are listed in Table II.

The A and E($2\pi/3$) frequencies of IPP, IPP-CD, IPP-CD_2, and IPP-CD_3 were calculated with the final set of potential constants and are listed in Tables III—IX, together with the observed frequencies. The calculated and observed frequencies are also compared in Figs. 2 and 3. For the region above 650 cm^{-1}, the r.m.s. frequency deviations are: IPP: 0.9%; IPP-CD: 0.9%; IPP-CD_2: 0.8%; and IPP-CD_3: 1.0%; while the overall r.m.s. deviation was 0.9%. Since the calculated frequencies agreed so closely with the observed frequencies, the potential energy distributions were also calculated as aids in assigning the infrared bands. The distributions, $(PED)_{ii}$,

are shown in Tables IV–IX, which list only the terms greater than 15%.

The calculated frequencies of IPP below 650 cm^{-1} did not agree with the observed frequencies as closely as did the calculated higher frequencies. The potential constants, H(C–C–C), F(C–C–C), κ(CH), and Y(C–C) [CH–CH_2 bond], are primarily associated with these low frequency vibrations, accordingly, their standard errors are calulated to be relatively large. The correction terms for the Urey-Bradley force field are undoubtedly necessary for more refined treatments of the low frequency vibrations, but they have not been established as yet. The r. m. s. frequency deviation for the vibrations of IPP below 650 cm^{-1} is 3.7% except for the ν_{26}^E vibration at 106 cm^{-1}. This lowest frequency vibration is possibly considerably affected by the intermolecular force field.

C–H and C–D Stretching Vibrations

The infrared spectra of IPP and deuterated derivatives in the 3000~2000 cm^{-1} region have been measured by Peraldo and Farina,[7] by Liang et al.[11] and by McDonald and Ward.[12] Their assignments, as well as the

*1,*2 See *1,*2 of Table IV.

observed spectra, were critically reviewed in the present study with reference to the calculated frequencies and their possible shifts due to the anharmonicity. It was expected that the observed C–H stretching frequency would be slightly lower than the calculated C–H stretching frequency, while the observed C–D stretching frequency would be slightly higher than the calculated frequency in the final stage of the calculation based on the method of least squares.

The observed frequencies, intensities, and dichroism of IPP and deuterated derivatives,[7] the calculated frequencies, and the vibrational assignments are shown in Table III. When the potential energy distribution was calculated for each vibration, the potential energy was found to be localized in the single mode as listed in Table III.

The band at about 2870 cm^{-1} has been assigned by Liang et al.[11] to the CH_3 symmetric stretching vibration.*3 The parallel component (A) is weaker than the perpendicular component (E), in accordance with the expected intensity ratio of $I_A/I_E=0.4$.[13] The bands due to the CH_3 asymmetric stretching mode[7,11-13] are split into two components of nearly the same intensity; the parallel component at about 2960 cm^{-1} is assigned to the mode which is antisymmetric with respect to the H–C–CH_3 plane [denoted as $\nu_a(CH_3)_0$[13]]. The dichroism of this component has been estimated to be $I_E/I_A=0.1$. The perpendicular component at about 2950 cm^{-1} is assigned to the mode which is symmetric with respect to the H–C–CH_3 plane [denoted as $\nu_a(CH)_i$[13]]. The dichroism of this component has been estimated to be $I_A/I_E=0.8$. The stretching vibrations of the CD_3 groups are observed at 2215 cm^{-1} (∥) and 2204 cm^{-1} (⊥) [asymmetric] and at 2066~2067 cm^{-1} [symmetric].

The nondichroic band at 2838 cm^{-1} has been assigned to the CH_2 symmetric stretching mode.[7,11-13] The perpendicular band at about 2880 cm^{-1} is assigned, in the present study, to the CH_2 antisymmetric stretching vibration.*4

*3 Krimm assigned this band to an overtone,[13] whereas McDonald and Ward[12] assigned the two bands at 2925 and at 2868 cm^{-1} to the CH_3 symmetric stretching modes.

13) S. Krimm, *Fortschr. Hochpolymer.-Forsch.*, **2**, 51 (1960).

*4 This band has been assigned to the CH_3 symmetric stretching mode (E) [13] or to an overtone.[11,12]

*1,*2 See *1,*2 of Table IV.

The corresponding bands of the CD_2 group are observed at about 2170 cm^{-1} (antisymmetric stretching), while the bands due to the CD_2 symmetric stretching mode[7] appear to be split into the parallel component at 2085 cm^{-1} and the perpendicular component at 2092 cm^{-1}. The stretching vibrations of the CHD group of poly(propylene-1-d_1) are observed at 2870 cm^{-1} (CH stretching) and at about 2135 cm^{-1} (CD stretching).[7,14]

The strong perpendicular bands at about 2920 cm^{-1} are assigned to the stretching vibration of tertiary CH group in the present study.*5 The perpendicular component has been expected to be stronger than the parallel component ($I_A/I_E=0.8$).[13] The band due to the CD stretching vibration[7] appears to be split into the weak parallel component at 2154 cm^{-1} and the strong perpendicular component at 2162 cm^{-1}.

*5 This band has been assigned to the CH_2 antisymmetric stretching mode.[11-13] Instead, the bands near 2800 cm^{-1} have been assigned to the CH stretching modes.[12,13]

14) T. Miyazawa and Y. Ideguchi, to be published.

Infrared Bands in the 1500~650 cm^{-1} Region

In our previos study, the potential energy distributions for the vibrations lying in the 1500~650 cm^{-1} region have been approximately calculated and the vibrational assignments of the infrared bands discussed in detail.[2] In the present study, the potential energy distributions (PED) were refined by a complete normal coordinate treatment (Table IV–VII). However, the potential energy distributions did not change essentially, except as noted below: (1) The potential energy of the vibrations of IPP at 1377~1379 cm^{-1} are associated almost exclusively with the CH_3 symmetric deformation mode, although in the previous treatment a slight coupling with the C–H bending modes was deduced. (2) As for the C–H and C–D bending modes, and the degenerate deformation and rocking modes of the CH_3 and CD_3 groups, the fractions of the potential energy associated with the axial and equatorial components have changed more or less for several vibrations. Except for these changes, the detailed analyses of the infrared bands reported previously are still valid. Therefore,

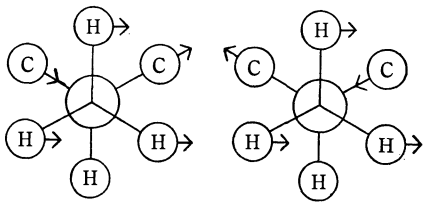
the nature of the infrared bands of IPP, IPP-CD, IPP-CD_2 and IPP-CD_3 will be briefly described.

$[-CH_2CH(CH_3)-]_p$.—The perpendicular band at 1460 cm^{-1} and the parallel band at 1454 cm^{-1} are assigned to the CH_3 asymmetric deformation vibrations, while the bands at 1377~1378 cm^{-1} are assigned to the CH_3 symmetric deformation vibrations. The bands of IPP, IPP-CD, and IPP-CD_3 at 1435~1440 cm^{-1} are assigned to the CH_2 bending vibrations. The abnormal dichroic behavior of the bands of IPP and IPP-CD may possibly be due to the slight coupling of the CH_2 and CH_3 deformation modes.[2)]



In the 1370~1200 cm^{-1} region, the observed bands are due to the hybridized vibrations of the CH_2 wagging and twisting modes and the axial and equatorial CH bending modes.*6 The interactions among these modes are primarily due to the trans- and gauche-coupling terms in the vibrational potential function. These vibrational couplings depend upon the internal-rotation about the main-chain CH–CH_2 bonds. The remarkable spectral change upon the fusion of the isotactic sample may be understood in relation to the coupling of the CH_2 and CH modes across the CH–CH_2 bonds.

The infrared bands of IPP in the 1200~800 cm^{-1} region arise from the hybridized vibrations of the axial and equatorial C–C stretching modes, the C–methyl stretching modes, the axial and equatorial CH_3 rocking modes, and the CH_2 rocking modes. The strong parallel bands at 1168, 998, and 973 cm^{-1} are primarily due to the C–C stretching and CH_3 rocking modes. The parallel bands at 973 cm^{-1} and 1168 cm^{-1} arise from the coupled vibrations of the antisymmetric stretching mode of the axial and equatorial C–C bonds and of the methyl rocking modes, which is nearly antisymmetric with respect to the H–C–CH_3 plane. For the

group, the atomic displacements of the vibrations at 973 cm^{-1} and 1168 cm^{-1} are schematically

*6 The intrinsic frequencies of the CH_2 wagging and twisting modes are located at 1330~1340 cm^{-1} and 1270~1290 cm^{-1} respectively, while the intrinsic C-H bending frequency is located at 1305~1325 cm^{-1}.

(a) (b)

Fig. 4 Atomic displacements of the vibrations of $H-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{C}{C}}-H$ group at 950 cm^{-1} (a) and at 1150 cm^{-1} (b).

shown in Figs. 4a and 4b respectively. The band at 998 cm^{-1} arises from the C–methyl stretching mode and the methyl rocking mode in the H–C–CH_3 plane. The parallel band at 842 cm^{-1} is due either to the ν_{19}^A vibration or to the ν_{20}^A vibration. The ν_{19}^A vibration is associated with the methyl rocking mode (in the H–C–CH_3 plane) as coupled with the nearly symmetric stretching mode of the axial and equatorial C–C bonds and the C–methyl bonds.

[–CH_2–$CD(CH)_3$–]$_p$—Since the intrinsic C–D bending frequency is much lower than 1250 cm^{-1}, the CH_2 wagging and twisting modes of this molecule are not coupled with the C–D bending modes. The bands at 1342 cm^{-1} (∥) and 1334 cm^{-1} (⊥) are due to the CH_2 wagging modes, while the bands at 1291 cm^{-1} (∥) and 1273 cm^{-1} (⊥) are due to the CH_2 twisting modes. The infared bands of IPP–CD in the 1250～750 cm^{-1} region arise from the coupled vibrations of the C–D bending modes, the CH_3 and CH_2 rocking modes, and the C–C stretching modes. The intrinsic frequencies of all these modes may be located in the 1100～800 cm^{-1} region. It is remarkable to note that the contributions of the C–D bending modes are greater than 15% for many vibrations in the 1250～750 cm^{-1} region.

[–CD_2–$CH(CH_3)$–]$_p$.—For this molecule, the intrinsic CD_2 wagging and twisting frequencies are shifted lower than 1200^{-1}, and, consequently, the CH bending modes are not coupled with the CD_2 bending modes. The bands at 1327 cm^{-1}, 1325 cm^{-1}, 1313 cm^{-1}, and 1303 cm^{-1} arise almost exclusively from the C–H bending modes.

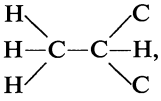
The bands primarily due to the CD_2 bending modes are observed at 1058 cm^{-1} (∥) and 1051 cm^{-1} (⊥), while the band due to the CD_2 rocking modes are observed at 764 cm^{-1} (∥) and 811 cm^{-1} (⊥).

The CD_2 wagging and twisting modes are strongly coupled with the methyl rocking modes and the C–C stretching modes and give rise to the infrared bands in the 1200～800 cm^{-1} region.

[–CH_2–$CH(CD_3)$–]$_p$.—The strong bands of IPP–CD_3 at 1051 cm^{-1} (∥) and at 1054 cm^{-1} (⊥) are due to the CD_3 asymmetric deformation modes. The CD_3 symmetric deformation modes are strongly coupled with the axial and equatorial C–C stretching modes and give rise to bands in the 1100～1000 cm^{-1} region. The parallel bands at 791 and 703 cm^{-1} and the perpendicular bands at 759 and 743 cm^{-1} arise from the CD_3 rocking modes.

Far Infrared Vibrations of Isotactic Polypropylene

The far infrared spectra of the uniaxially oriented films of isotactic polypropylene have been measured in the 600～300 cm^{-1} region[1] and in the 400～80 cm^{-1} region[8] (the dichroism has been measured in the region above 100 cm^{-1}). (A preliminary normal coordinate treatment had previously been made as an aid in the vibrational assignments.[8]) The potential energy distributions of the far infrared vibrations of isotactic polypropylene were recalculated in the present study and are listed in Table VIII.



These low frequency vibrations are associated with the C–C–C bending modes of the $C-CH_2-C$ and $C-CH\langle^{C}_{C}$ groups and with the internal-rotation modes about the C–methyl bond and the equatorial and axial C–C bonds. The weak bands at 200 cm^{-1} (∥) and 210 cm^{-1} (⊥) arise from the internal-rotation modes of the CH_3 group about the C–methyl bond. The low frequency modes of isotactic polypropylene are not localized in a repeating unit. Therefore, these modes give rise to well-defined bands only for highly-ordered helical conformations in the crystalline region.[8]

The far infrared spectra of the deuterated derivatives of isotactic polypropylene have not been published. However, the frequencies and potential energy distributions calculated for deuterated derivatives are shown in Table IX.

Liquid Spectra of Isotactic Polypropylene

Well-defined infrared bands observed in the liquid spectra of isotactic polypropylene and deuterated derivatives have been discussed before with reference to the potential energy distributions calculated for the helical structure. Moreover, the liquid bands arising from the CH_3 symmetric and asymmetric deformation modes, the CH_2 bending wagging, and twisting modes and the CH bending modes,

and the CD_3 rocking modes have already been analyzed.[2]

For isotactic polypropylene, two strong bands are observed at 971 and 1151 cm^{-1} in the liquid state; these are naturally considered to arise from the C–C stretching modes and the methyl rocking modes. An empirical analysis has been made before in view of the "intrinsic" methyl rocking frequency.[2] In the present study, the normal vibrations of the model system,  , were treated. The elements of the potential energy matrix were transferred from the corresponding elements of isotactic polypropylene. In the 1200~800 cm^{-1} region, three A' vibrations (symmetric with respect to the H–C–CH_3 plane) were calculated at 864, 1015 and 1062 cm^{-1}, whereas two A'' vibrations (antisymmetric with respect to the H–C–CH_3 plane) were calculated at 948 cm^{-1} (ν_a) and 1134 cm^{-1} (ν_b). The atomic displacements of the ν_a and ν_b vibrations are schematically shown in Fig. 4. The calculated vibration at 948 cm^{-1} appears to correspond to the liquid frequency of 971 cm^{-1}, and its potential energy is associated 60% with the rocking mode and 40% with the C–C stretching modes. On the other hand, the calculated vibration at 1134 cm^{-1} corresponds to the liquid frequency of 1151 cm^{-1}, and its potential energy is associated 50% with the C–C stretching mode and 20% with the methyl rocking mode. If either one of these vibrations is excited in phase throughout the main chain, as is shown in Fig. 5, the vibrations of adjacent units will

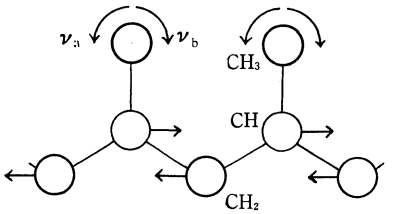


Fig. 5. In-phase vibrations of the ν_a or ν_b mode.

tend to displace the common CH_2 group in nearly the same direction (at least not in the opposite direction), and only minor vibrational interactions may be expected among CH–CH_3 groups. Such a vibrational mode may not be very sensitive to changes in the internal-rotation arrangements, and accordingly, well-defined strong absorption peaks may be expected, even in the liquid state. In support of these considerations, the in-phase ν_a and ν_b vibrations give rise to the strong bands at 973 cm^{-1} and 1168 cm^{-1} for isotactic polypropylene (in the crystalline region) and to the strong bands at 1153 cm^{-1} and 974 cm^{-1} for syndiotactic polypropylene (in the crystalline region).[15]

The strong parallel band of isotactic polypropylene at 998 cm^{-1} disappears on melting. As Table IV shows, this band is due to the hybridized vibration of the methyl rocking mode, the C–methyl stretching mode, and the CH_2 twisting mode. The coupling with the CH_2 twisting mode depends upon the internal-rotation about the main-chain CH–CH_2 bonds. This vibration, therefore, is very much affected by the rearrangements of the main-chain conformations and does not give rise to a well-defined band in the liquid state.

Summary

The infrared active normal vibrations of isotactic polypropylene and its deuterated derivatives in the crystalline state have been treated. The modified Urey-Bradley-Shimanouchi force field has been used for the calculations. A total of 23 potential constants have been adjusted by the method of least squares with reference to a total of 166 frequencies observed by Peraldo and Farina. The standard errors of the potential constants have also been calculated. The r. m. s. deviation of the calculated frequencies from the observed ones is as small as 0.9%. The potential energy distributions have also been calculated for the discussion of the nature of the observed infrared bands. Vibrational assignments of the liquid bands of isotactic polypropylene have also been made.

The authors wish to thank Professor Takehiko Shimanouchi and his group at the University of Tokyo for their stimulating discussions and Mr. Hiroatsu Matsuura of Osaka University for his assistance in the preparation of all the figures.

NOTES

The Separation of Lanthanons by Paper Precipitation Chromatography with 8-Quinolinol. II. The Separation and Detection of Lanthanum, Cerium, Praseodymium and Uranium

By Hideo NAGAI

(Received May 17, 1963)

It was shown in the preceding paper[1] that the use of an aqueous *n*-butyric acid solution saturated with isobutanol (as a developer) made it possible to obtain rare earth ions on oxine-impregnated filter paper in the form of separated circular bands of precipitates.

In the present study, a modified developer composed of a *n*-butyric acid solution and a water-miscible organic solvent has been applied to the separation of ions from mixtures containing lanthanum, cerium(III), praseodymium and uranyl ions. It has been found that the separation is much improved by the use of the new developer when a small amount of uranyl ions is added to the sample solution.

Experimental

The apparatus, the method of development and the preparation of the sample were essentially the same as have been reported previously,[1] but some changes were made:

1) The distance between the liquid surface of the developer and the oxine-impregnated filter paper was 3.5~4.0 mm. when a container 6 cm. in diameter was used. The width of the strip at the center of the filter paper disk was 3.5~4.0 mm., larger than that of the strip used in the previous study.[1]

2) Oxine (1.000±0.003 g.) in 80 ml. of ethanol was used to impregnate 100 sheets of filter paper (Toyo Filter Paper No. 5B, 9 cm. in diameter). In order to obtain reproducible results, it is essential to keep the oxine content in the filter paper disk as constant as possible.

3) A *n*-butyric acid solution (1~3%) could be used as the developer when a small quantity of uranyl nitrate (ca. 1 mg./ml. as uranium) was added to the sample solution, although the results were not satisfactory because of the low dissolution. *n*-Butyric acid solutions containing various organic solvents were examined and found to be much more useful for the separation of ions.

4) A 2.5% solution of *n*-butyric acid was used as one of the components of the developer. This concentration of the acid is higher than that used in the previous study.[1]

5) After development, the chromatograms were exposed ammonia vapor in order to insure the precipitation of the oxinates. The color of the cerium band thereupon changed from yellow to violet, but most of the cerium which had been coprecipitated together with the other rare earth elements (contaminants of the other rare earth bands) remained unchanged. The distribution of cerium was determined in detail by spraying about a 3 N aqueous solution of potassium chromate.

Development.—Table I shows the results obtained with mixtures in water of organic solvents and 2.5% *n*-butyric acid in various proportions (20± 1°C).

There is almost no change in the chromatogram when only a small quantity of the organic solvent (shown by ±) is added. Then the development is gradually improved as the quantity of organic

* This table is explained below.

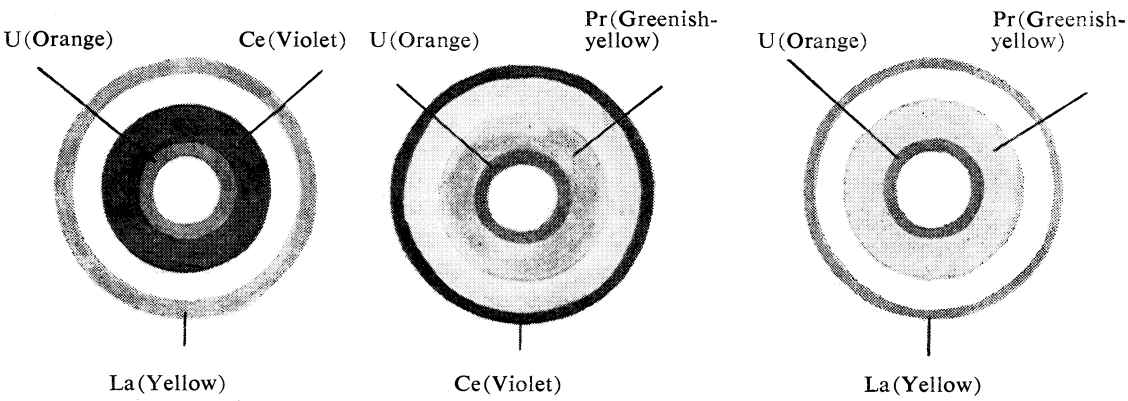

Fig. 2. Chromatograms of ternary mixtures.

solvent is increased (the degree of improvement is indicated by +, ++, and +++). When the mixing ratio of organic solvent is increased beyond this region, some of the bands begin to dissolve before the completion of the development; the chromatogram obtained is an intermediate one between the precipitation- and soluble-type chromatograms. This region is indicated as M. When the mixing ratio of the organic solvent is increased further, the chromatogram finally comes to be a true soluble type (indicated as S). In the present study, the author does not deal with these regions, M and S.

When a sample solution containing uranyl, praseodymium, cerium and lanthanum ions was developed in precipitation chromatography with a suitable developer, the bands of the components were formed in the order described above counting from the center to the periphery (Fig. 1). Table I shows that a 30 : 1 mixture of 2.5% *n*-butyric acid and isopropanol is the best developer. In this case, however, a considerable amount of the lanthanum ions was retained in the praseodymium and cerium bands. This defect was reduced by adding dioxane to the developer. The best result, in this experiment, was obtained with a developer composed of 2.5% butyric acid, isopropanol and dioxane in a volume ratio of 50 : 4 : 1. It is important to stop the development immediately after the formation of the bands of all the components; thus, in order to obtain satisfactory results, the development is stopped when the uranyl band formed begins to dissolve slightly. The results of the development were as follows.

When all of the four cations were present, the only band which could be obtained in an almost pure state was the uranyl band (the innermost). The lanthanum band (the outermost) was slightly contaminated by cerium. The praseodymium and the cerium bands, between the two bands mentioned above, however, almost entirely overlapped one another, and a considerable quantity of lanthanum was contained in these bands, although the characteristic color of each band could still be observed (praseodymium, a greenish yellow, and cerium, violet).

Better results were obtained with samples containing three kinds of ions, two kinds of rare earth ions and the uranyl ion. The uranyl ion was separated in an almost pure state in all cases, and the separation of praseodymium and cerium, which had been almost impossible before, was possible, though the separation was not satisfactory. Concerning the separation of lanthanum and cerium the lanthanum band was found to be almost pure; the cerium band, however, was contaminated by a considerable quantity of lanthanum. The separation of lanthanum and praseodymium was most satisfactory in these experiments; the amount of lanthanum in the other band was much less than that in the case of the separation of cerium and lanthanum. Figure 2 shows these chromatograms.

Discussion

Optimum Mixing Ratio. — When chromatograms were obtained with a series of organic solvents, with various mixing ratios the area of a band was the largest at the optimum

mixing ratio. It might be that the rate of precipitation was the slowest in this solution, as in the case of the other precipitation reactions.

The Estimation of the Separation of Ions.— In order to estimate the degree of the separations, the following methods were employed; observation under day- and ultraviolet-light, a radioautogram, and spraying with a potassium chromate solution. A radioautogram is a very convenient way to find out the distribution of the components (Fig. 1), but several months are necessary to determine the distribution of cerium. The potassium chromate spray can, however, give almost the same results as the long exposure-radioautography does.

The author wishes to express his appreciation to the Ministry of Education for having made available part of the Scientific Research Fund of the Ministry of Education for this study.

The Synthesis of L-*Theanine*

By Toshiyuki FURUYAMA, Takeshi YAMASHITA and Saburo SENOH

(Received February 15, 1964)

In the course of investigations of flavor substances in Japanese green tea, Sakato discovered L-glutamic acid γ-ethyl amide in the water extract and named theanine.[1] The synthesis of this substance has since been reported by several authors.[2-8] Sakato et al.,[3] for instance, synthesized it from *N*-carbobenzoxy-L-glutamic acid γ-ethyl ester, and Hashizume[4] and Tsuchiya et al.,[8] from pyrrolidonecarboxylic acid.

The synthesis described here is based on the reaction between amino groups of amino acids and carbon disulfide in the presence of alkali, giving dithiocarbamates and protecting the amino group.[9] The procedure is as follows: In the solution of 10 ml. of ethanol and 2 ml. of carbon disulfide, 4 g. of γ-methyl L-glutamate was dispersed. To the mixture, 50 ml. of anhydrous ethylamine*1 was added under cooling with ice-water. The solution was left to stand for ten days at room temperature in a sealed flask. The excess ethylamine, carbon disulfide and ethanol were then distilled off in vacuo. The residual oily material was suspended in 25 ml. of 5 N acetic acid and heated for 30 min. at 60°C under reduced pressure. The carbon disulfide which had protected the amino group of the product was split off by this procedure. The residual solution was concentrated to some extent, and ethanol added. L-Theanine crystallized out in a yield of 1 g. Recrystallization from water-ethanol afforded L-theanine (m.p. 215°C with decomp.) and $[\alpha]_D^{18}$ +8.7° (*c* 1.743, water).*2

Found: C, 48.11; H, 8.06; N, 16.01. Calcd. for $C_7H_{14}O_3N_2$: C, 48.26; H, 8.10; N, 16.08%.

The favorable protection of the amino group with carbon disulfide gave L-theanine without any racemization. Boissonnas previously synthesized optically-pure L-glutamine by protecting the amino group by carbon disulfide.[10] When his scheme was used, scarcely any formation of pyrrolidonecarboxylic acid occured. The present reaction appears to proceed in a manner analogous to Boissonnas' scheme.

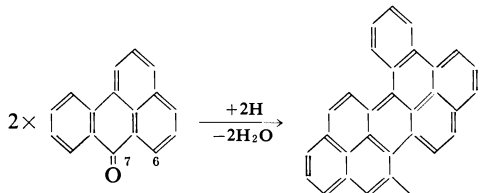
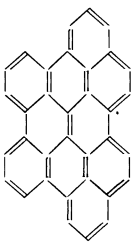
A New Method of Synthesizing Tetrabenzo[a, cd, j, lm]perylene and Dibenzo[cd, lm]perylene



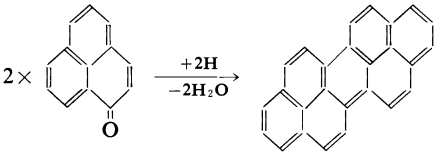
By Junji AOKI

(Received February 2, 1964)



When the 6- and 7-positions of one benzanthrone (I) molecule couple with the 7- and 6-positions of another one, tetrabenzo[a, cd, j, lm]perylene (II) is formed. Similarly, by a coupling related to the carbonyl groups of two moles of benzonaphthenone (IV), dibenzo[cd, lm]perylene (V) is formed. Although the syntheses of these two hydrocarbons have already been carried out by Clar,[1,2] the procedures were quite different. Tetrabenzoperylene (II) was prepared by the condensation of two moles of benzanthrone in a benzene solution through the action of zinc dust and anhydrous aluminum chloride, while dibenzoperylene (V) was synthesized by the zinc dust fusion of benzonaphenone.

However, the present author has succeeded in the synthesis of both of them by the one following method.



A mixture of ketone (1 part), copper powder (1 part), zinc chloride (5 parts) and sodium chloride (1 part) is kept at 220~230°C for 30~60 min. Then the mixture is treated with diluted hydrochloric acid, and the insoluble part collected. After the extraction of this material with chlorobenzene or *o*-dichlorobenzene, the crude product is purified by recrystallization or chromatography.

I II

III

IV V

This method is not only easy to perform, but it gives rather a good yield. The author, therefore, recommends it as a general method for the condensation of such a substance.

Experimental

Tetrabenzo[a, cd, j, lm]perylene (II) and Dibenzo[hi, uv]bisanthene (III).—A mixture of benzanthrone (5.0 g.), copper powder (5.0 g.), zinc chloride (25 g.) and sodium chloride (5 g.) was kept at 220°C for 30 min. As the reaction proceeded, the reaction mixture became thicker and its color changed from red to black. Then the mixture was treated with warm water containing a small amount of hydrochloric acid, and the insoluble part was collected, washed and dried. Yield, 11.1 g. This product was refluxed with 100 g. of chlorobenzene for 2 hr., and the insoluble material and copper powder were removed by hot filtration. When the filtrate was concentrated, 3.95 g. of a brown crystalline powder was obtained (insoluble part, 6.65 g.). A solution of 1 g. of this product in 30 cc. of chlorobenzene was passed through a column of alumina and eluted with chlorobenzene. The first passing yellow band was separated and concentrated, giving long, fine, yellow needles (0.2 g.) which melted at 331°C (uncor.). This product was soluble in an organic solvent with a lemon yellow color and a strong grey blue fluorescence, while in a concentrated sulfuric acid solution it is blue. The absorption spectrum in benzene was identical with that of II reported by Clar.[2]

Found: C, 95.94; H, 4.34. Calcd. for $C_{34}H_{18}$· (II): C, 95.75; H, 4.25%.

On the other hand, 2.0 g. of above product (3.95 g.) was refluxed with 50 g. of benzene, and, after hot filtration, the insoluble part was sublimated in a high vaccum (10^{-3}~10^{-4} mmHg). The orange sublimed material was collected and recrystallized from *o*-dichlorobenzene and then chlorobenzene, giving orange crystals (m. p. 305~307°C). This substance is soluble in xylene with a greenish

1) E. Clar, D. R. P. 621861.
2) E. Clar, *Chem. Ber.*, **76**, 458 (1943).

yellow color and a green yellow fluorescence, while in a concentrated sulfuric acid it is blue. Found: C, 95.95; H, 3.92. Calcd. for $C_{34}H_{16}$(III): C, 96.20; H, 3.80%. This by-product is considered to be the III reported by Clar.[2]

Dibenzo[cd, lm]perylene (V). — A mixture of 2.0 g. of benzonaphthenone (IV), 2.0 g. of copper powder, 10 g. of zinc chloride and 2 g. of sodium chloride was kept at 220~230°C for 40 min. Then the mixture was treated with diluted hydrochloric acid, and the insoluble part was collected, washed and dried. Yield, 5.0 g. This material was refluxed with alcohol (30 ml.) for 2 hr. After the solution had cooled the insoluble part was filtered off and refluxed with xylene (50 g.) for 2 hr. The insoluble substance was then removed by hot filtration, and the filtrate was concentrated, giving 1.1 g. of a brown solid. This crude product was twice recrystallized from *o*-dichlorobenzene, giving 0.6 g. of gold yellow leaflets (m. p. 373~374°C). The sample, purified by means of chromatography on alumina with chlorobenzene, melted at 375~376°C (uncor.), and the absorption spectrum in alcohol was identical with that of V reported by Clar.[2] Found: C, 95.42; H, 4.53. Calcd. for $C_{26}H_{14}$(V): C, 95.68; H, 4.32%.

Infrared-Active Lattice Vibrations in a Few Fluorite-type Crystals

By Minoru TERADA and Masamichi TSUBOI

(Received February 24, 1964)

In an attempt to obtain information about the crystalline force field, we have observed the infrared absorptions of three metal oxides with fluorite-type lattices, namely, uranium dioxide (UO_2), thorium dioxide (ThO_2), and cerium dioxide (CeO_2).

The sample of UO_2 was prepared by the Mitsubishi Metal Mining Company, that of ThO_2 was prepared by the Linsay Chemical Company (U.S.A.), and that of CeO_2 was prepared by Dr. Hiroshi Takahashi (the University of Tokyo), who kindly placed it at our disposal. The fact that all three of these samples fluorite-type crystal structures[1] was ascertained by an X-ray diffraction method.* The infrared absorption measurement was carried out by the use of a far-infrared spectrophotometer constructed by Professor H. Yoshinaga and his collaborators.[2] Each of the samples were mounted on the spectrophotometer in the form of a dispersion in a polyethylene film[3] (mostly with 200 mg. of oxide per 1.5 g. of polyethylene and 0.2 mm. thick).

The results of our infrared absorption measurement are shown graphically in Fig. 1. As may be seen in the figure, each of these oxides shows only one strong absorption band in the spectral region 4000~200 cm^{-1}. This is just what was expected from the crystal structure of these oxides. In a previous paper,[4] it has been shown that the fluorite (CaF_2)-type lattice (space group O_h^5) has only one infrared-active (F_{1u}) lattice vibration, and that its frequency ν (cm^{-1}) is given approximately by

$$4\pi^2c^2\nu^2=(4/3)K(\mu_F+2\mu_{Ca}) \qquad (1)$$

In this equation, c is the velocity of light, K, the stretching force constant of the Ca-F bond, and μ_F and μ_{Ca}, the reciprocal masses of the F and Ca atoms respectively. Table I gives the observed frequencies ν of the oxides in question and the metal-oxygen bond stretching force constants K as calculated by Eq. 1. In the third column of Table I, the metal-oxygen bond distances,[1] r, are also given.

As may be seen in Table I, the metal-oxygen bond is strongest in UO_2, next strongest in

1) V. M. Goldschmidt and L. Thomassen, *Videnskaps-selsk. Skr.*, 5, 12 (1923).

* In an X-ray diffraction examination kindly made by Dr. Y. Iitaka (the University of Tokyo), the sample of CeO_2 used gave sharp reflections: at d=0.81569, 0.82518, 0.85549, and 0.91454 Å (the calibration has been made by the use of silicon powder). These reflections are indexed as (622), (533), (620), and (531) respectively, with a fluorite-type cell and with a=5.411 Å. The exact cell dimension has been obtained, by an extrapolation at $2\theta=180°$ (2θ being the angle of diffraction), as a=5.4108 Å. On the basis of the results of the examination and by referring, for example, to "Standard X-ray Diffraction Powder Patterns" (United States Departmet of Commerce, National Bureau of Standards), the sample used may be considered to be practically pure CeO_2 for the present purposes.

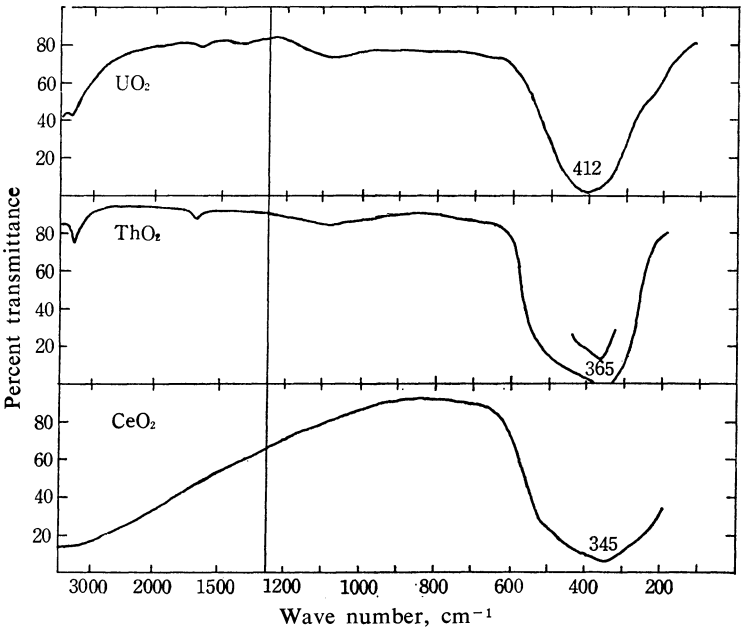

Fig. 1. Infrared absorptions of uranium dioxide, thorium dioxide, and cerium dioxide crystals, all of which have the fluorite type structures.

TABLE I

	Frequency ν cm^{-1}	Force constant, K mdyn./Å	Bond length, r Å
UO_2	412	1.057	2.36
ThO_2	365	0.827	2.42
CeO_2	345	0.685	2.34

ThO_2, and weakest in CeO_2. (However, the metal-oxygen bond length is shortest in CeO_2.) It is noticeable that the metal-oxygen bond stretching force constants in the oxides in question are much greater than the Ca-F bond stretching force constant (0.31 mdyn./Å) in fluorite crystal[4] or the Na-Cl bond stretching force constant (0.11 mdyn./Å) in sodium chloride crystal,[4] where the Ca-F or the Na-Cl bond is considered to be ionic. On the other hand, the metal-oxygen bond stretching force constants in question are much smaller than the C-C, C-Si, or U-O bond stretching force constants (2.8, 2.0, or 1.7 mdyn/Å respectively) in diamond,[4] silicon carbide,[5]** or α-uranium trioxide[6] crystals respectively; where the C-C, C-Si, or U-O bond is considered to be rather covalent.

We wish to express our sincere thanks to Professor H. Yoshinaga and Dr. A. Mitsuishi for their kindness in allowing us to use the far-infrared spectrometer of Osaka University.

** For hexagonal silicon carbide, the stretching force constant of the C-Si bond (1.890 Å in length) along the c axis is slightly lower than that of the C-Si bond (1.886 Å in length), which makes a nearly tetrahedral angle with the c axis. The difference, however, was found to be less than 0.1 mdyn./Å. It was also found that the force constant of the latter C-Si bond is practically equal to the force constant of the C-Si bond (1.886 Å in length) in cubic silicon carbide.

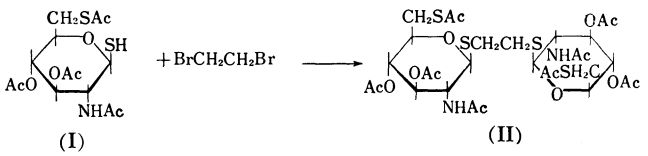
The Preparation of Bis(2-acetamido-6-acetylthio-O-acetyl-glucopyranosyl)sulfides

By Tadao Ishii and Teiichiro Ito

(Received March 6, 1964)

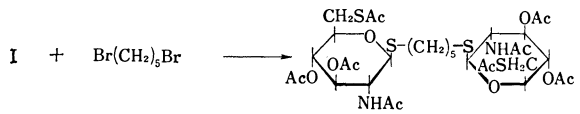
In 1959 M. Černý and J. Pacák[1] reported that 2, 3, 4, 6-tetra-*O*-acetyl-1-thio-β-D-glucopyranose condensed with alkyl halides, giving alkylthioglucopyranosides. The present work describes the application of this procedure to 2-acetamido-3, 4-di-*O*-acetyl-6-*S*-acetyl-2, 6-dideoxy-1, 6-dithio-β-D-glucopyranose (I)[2,3] for the preparation of bis (2-acetamido-6-acetylthio-*O*-acetyl-glucopyranosyl) sulfides.

The treatment of compound I with ethylene dibromide in acetone containing potassium carbonate afforded bis-(2, 2'-diacetamido-3, 4, 3', 4'-tetra-*O*-acetyl-2, 6, 2', 6'-tetra-deoxy-6, 6'-di-*S*-acetyl-6, 6'-dithio-β, β'-D-glucopyranosyl) ethylene disulfide (II) in an 80% yield. It showed $[\alpha]_D^{22}$ −23° in chloroform. Bis(2, 3, 4, 6, 2', 3', 4', 6'-octa-*O*-acetyl-β, β'-D-glucopyranosyl) ethylene disulfide was reported[1] to have $[\alpha]_D$ −38.5° in chloroform.



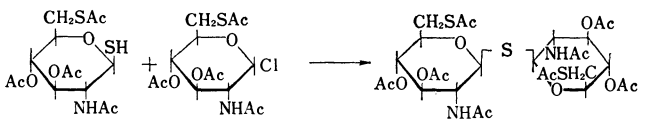
By a similar procedure, bis(2, 2'-di-acetamido-3, 4, 3', 4'-tetra-*O*-acetyl-2, 6, 2' 6'-tetra-deoxy-6, 6'-di-*S*-acetyl-6,6'-dithio-β, β'-D-glucopyranosyl) pentamethylene disulfide (III) was prepared from compound I and pentamethylene dibromide.

When compound I was treated with 2-acetamido-3, 4-di-*O*-acetyl-2, 6-dideoxy-6-*S*-acetyl-6-thio-D-glucopyranosyl chloride[3] (V) in acetone containing potassium hydroxide, bis (2, 2'-diacetamido-3, 4, 3', 4'-tetra-*O*-acetyl-2, 6, 2', 6'-tetra-deoxy-6, 6'-di-*S*-acetyl-6, 6'-dithio-β, β'-D-glucopyranosyl) sulfide (IV) was formed. The β, β' configuration has been suggested for compound IV on the basis of a comparison of rotation ($[\alpha]_D^{21}$ −16° in chloroform) with that of bis (2, 2', 3, 3', 4, 4', 6, 6'-octa-*O*-acetyl-β, β'-D-glucopyranosyl) sulfide ($[\alpha]_D^{18}$ −38° in chloroform).[4]



Experimental

Melting points are uncorrected.



Bis(2, 2'-di-acetamido-3, 4, 3', 4'-tetra-*O*-acetyl-2, 6, 2', 6'-tetradeoxy-6, 6'-di-*S*-acetyl-6, 6'-dithio-β,β'-D-glucopyranosyl) Ethylene Disulfide (II).—Into a solution of 2-acetamido-3, 4-di-*O*-acetyl-6-*S*-acetyl-2, 6-di-deoxy-1, 6-dithio-β-D-glucopyranose (I) (1 g.) and ethylene dibromide (0.25 g.) in dry acetone (7.5 ml.), a solution of potassium carbonate (0.35 g.) in a small amount of water was added. After the solution had been stirred for 30 min. at room temperature, the solution was poured on ice water. The precipitates were filtered, washed with water

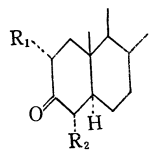
The Structure of "α-Cholestanol"



By Nobukatsu KATSUI, Yumiko YASUNARI, Isamu SUZUKI, Tadashi MASAMUNE and Toshi IRIE

(Received March 17, 1964)

"α-Cholestanol" obtained[1,2] by the treatment of cholesterol with sodium and isoamyl alcohol, has been presumed to be isoamylated dihydrocholesterol,[3,4] but it has received no generally accepted structural assignment. We will now describe findings which show Diels and Abderhalden's "α-cholestanol" ($C_{32}H_{58}O$, m. p. 124~127°C, sintering at 120°C, $[\alpha]_D$ −15° ($CHCl_3$)) to be 2α-isoamylcholestan-3β-ol (I).

VI

III: R=H
V: R=Ac

The secondary alcoholic function of I has been well characterized[2,3,5] by the formation of a benzoate and by oxidation to a ketone (II) named "α-cholestanone" ($C_{32}H_{56}O$, m. p. 118~120°C, $[\alpha]_D$+23° ($CHCl_3$), $[\alpha]_D$+22°C (MeOH), ν_{max} 1702 cm^{-1} ($CHCl_3$)). The absence of a double bond has now been confirmed by the following results; (i) Neither I

nor II had any peak due to an olefinic proton in the NMR spectra (ii) the ketone II was stable to acid or base and showed no absorption due to α,β-unsaturated ketone in the infrared and ultraviolet spectra.

The reduction of II with lithium aluminum hydride in ether gave rise to I (80%), along with an isomeric alcohol III (16%) ($C_{32}H_{58}O$; m.p. 95~96°C), which had a larger R_f value than the former I on thin layer chromatography. The acetylation of I with acetic anhydride and pyridine at room temperature yielded an acetate (IV) ($C_{34}H_{60}O_2$, m.p. 67~68°C, $[\alpha]_D$ −32° ($CHCl_3$), ν_{max} 1245 cm^{-1} (CS_2) (type A),[6] τ_{CDCl_3} 5.60 (half-width 23 c.p.s.)). The same treatment of III afforded an isomeric acetate (V) ($C_{34}H_{60}O_2$, m.p. 97~98°C, ν_{max} 1241 and 1234 cm^{-1} (CS_2) (type B)[6], τ_{CDCl_3} 5.14 (half-width 6 c.p.s)). All these results indicate[6,7] that the alcohol I has an equatorial hydroxyl group and that its isomer III has an axial one.

The lower carbonyl-stretching frequency of II, compared with those of the usual 3-keto steroids, suggests[8,9] that II is a C-2 or C-4 alkylated steroid, and the rotatory dispersion curve showed a positive Cotton effect, implying that the ketone was a derivative of 5α-cholestane. By following Atwater's procedure,[10] Δ^4-cholesten-3-one was isoamylated, using isoamyl iodide and potassium in boiling *t*-butyl alcohol; we thus isolated 4-isoamyl-Δ^4-cholesten-3-one (VI) (m.p. 66~67°C, $[\alpha]_D$+92° ($CHCl_3$), λ_{max} 251 mμ (ε 15400, ethanol), ν_{max} 1670 and 1605 cm^{-1} (Nujol)). The NMR spectrum of VI showed no signal due to the olefinic proton. Thus, all the spectral behavior indicated that an extra alkyl group was introduced at the C-4 position, as had been expected. The Birch reduction of VI under the conditions employed for the reduction[6] of 4-methyl-Δ^4-cholesten-3-one afforded the corresponding dihydro compound, $C_{32}H_{56}O$ (m.p. 68~69°C, $[\alpha]_D$+26° ($CHCl_3$), ν_{max} 1702 cm^{-1}), which had a positive Cotton effect. In view of the analogous reduction products of 4-methyl-[8] or 4-ethyl-Δ^4-cholesten-3-one,[11] the dihydro compound may be assigned the 4α-isoamylcholestanone structure (VII). The physical constants and the infrared spectrum of VII were different from those of II.

The isoamylation at the 2-position of cholesten-3-one was then attempted by a procedure[8] similar to that used for monomethylation, treating it with isoamyl iodide and potassium in boiling *t*-butyl alcohol for 10 min. The resulting crude product was successfully separated in a few components by chromatography on alumina. The material (16%), which was eluted with petroleum ether - benzene (24 : 1 and 4 : 1), had an m.p. of 118~120°C and was found to be identical with "α-cholestanone" (II). Since the direct alkylation of cholestanone should afford 2α-alkyl derivative,[8] the ketone II can be identified as 2α-isoamylcholestan-3-one. In agreement with this structure, there is no appreciable solvent effect[8] in the specific rotation of II, as has been mentioned above. Therefore, "α-cholestanol" is 2α-isoamylcholestan-3β-ol.

The Determination of Submicrogram Quantities of Selenium by Means of a New Catalytic Reaction

By Motoharu TANAKA, Takuji KAWASHIMA and Harunaga MIWA*

(Received March 28, 1964)

The following reaction has been proposed for the determination of glyoxal:[1,2]

It was found that the reaction is catalyzed by selenium(IV). The effect of selenium(IV) on the rate of formation of the " blue compound " is demonstrated in Fig. 1. The absorption maximum of the resulting " blue compound " is found at 600 mμ.[1,2]

The procedure given by Ullmann and Mauthner[3] was followed, with a slight modification in the preparation of 2, 3-diaminophenazine. The product does not melt below 360°C, in accordance with the findings of Dechary et al.[1]

2, 3-Diaminophenazine hydrochloride (12.5 mg.) is dissolved in 250 ml. of 0.1 M hydrochloric acid. If some crystals separate out, it is necessary to warm the solution before use.

To 5 ml. of sample solution containing 0.1～0.2 μg. of selenium, 1 ml. of the 2, 3-diaminophenazine solution, one drop of 40% glyoxal and 1 ml. of 50% hypophosphorous acid are added. The acidity is adjusted to a pH value of about 0.65 with 1 M hydrochloric acid, and the whole diluted to 10 ml. The solution is then kept at 60°±1°C in a thermostat for 12 min. Then it is cooled quickly with tap-water and the extinction read at 600 mμ, using a similarly-treated reagent blank as a reference. The extinction should be read within 30 min., preferably within 10 min.

A typical calibration curve is shown in Fig. 2.

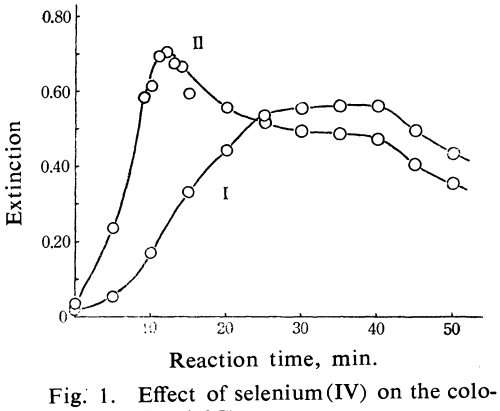

Fig. 1. Effect of selenium(IV) on the coloration (at 60°C).
Curve I: Reaction in the absence of selenium;
Curve II: Reaction in the presence of 0.5 μg. of selenium in 10 ml.

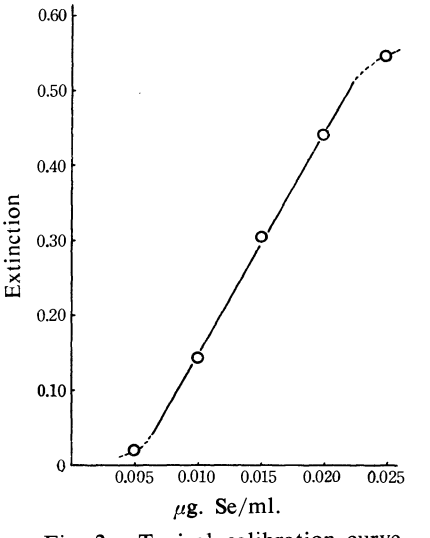

Fig. 2. Typical calibration curve.
Condition: Heating for 12 minutes at 60°±1°C; pH 0.65; effective light path of 16 mm.

The molar extinction coefficient is calculated from the difference in extinctions for 0.01 μg. and 0.02 μg. Se/ml. on the molar basis of

* Present address: Iwakuni Plant, Mitsui Petrochemical Industries, Ltd., Iwakuni, Yamaguchi.

selenium : $\varepsilon_{600m\mu}=1.46\times10^6$. By an appropriate modification of such conditions as the reaction time, the reaction temperature and the pH, it is possible to extend the range of concentration for the determination and/or to double the sensitivity.

The following elements do not interfere with the determination of 0.1 μg. selenium, at least up to the specified quantities: Mg(1 mg.), Ca(10 mg.), Ba(4 mg.), Ni(10 mg.), Co(10 mg.), Mn(II) (1 mg.), Zn(150 μg.), Al(40 μg.), Mo(VI) (60 μg.), Fe(III) (10 μg.), and V(V) (5 μg.). Cu(II), V(V) (>10 μg.), Te(IV), As(III) and As(V) interfere, giving rise to a similar coloration. The addition of EDTA is effective in suppressing the interference of copper (II).

Details will be published elsewhere.

On the Anomalous Gas Evolution in the Electrooxidation of Absolute Methanol

By Kazuo SASAKI, Chisato HAMAGUCHI and Shigeo NAGAURA

(Received April 9, 1964)

The mechanism of the electrooxidation of methanol has recently become the subject of great interest in connection with the present development of liquid fuel cells. Although this problem has thus been quite familiar to us, however, the mechanisms so far proposed can not be accepted with full agreement.

Here, we would like to report an interesting finding concerning the electrooxidation of a non-aqueous methanolic solution of inorganic salts. In this experiment, the methanol used had been dehydrated by single distillation in the presence of metallic magnesium. About 0.1 mol./1. each of sodium methylate, sodium hydroxide and sodium perchlorate were used as supporting electrolytes. The current densities were 2 to 5 mamp./cm^2 for the most part, but 10 to 20 mamp./cm^2 in some cases; these values of current density will be referred to as lower and higher current densities below. The solution was deaerated by nitrogen before the electrolysis.

The anodic product of the electrooxidation of absolute methanol is formaldehyde, in the case of an aqueous solution, on the other hand, methanol is oxidized to carbon dioxide via formic acid. Usually the gas evolution from the anode could hardly be observed except when a higher current density was applied; however, a minor amount of gas was found to be accumulated at the bottom of the sintered glass disk used to separate the cathode chamber and so prevent the mixing of the cathode gas. Through careful examination we have found an anomalous phenomenon, that is, the formation of the anode gas at the lower surface of the glass filter and not at the anode itself. This was quite reproducible.

We first suspected this to be a misconception caused by some errors. However, even when the anode was shielded from the cathode chamber by triplicated glass filters, the gas is still formed at the nearest glass filter surface. The shape of the electrolytic cell or the relative spacing of two electrodes and the separater in the electrolytic cell did not appreciably affect the anomaly. The effects of the kind of electrolyte, sodium methylate, sodium hydroxide and sodium perchlorate were also examined, but there was no appreciable effect.

Furthermore, the following facts were ascertained. When the abnormal gas formation once occurred, it continued during the electrolysis. The gas formation ceased upon the discontinuance of the current, but it resumed at the resumption of the current, provided that the time of the discontinuance of the current did not exceed two or three minutes. When the period of current discontinuance lasted more than five to ten minutes, the gas formation is not restored by the electrolysis. Thus, the gas formation disappeared when the electrodes had been kept in the solution for a prolonged time without passing a current through. However, even in such a case, we could see the anomaly when the anode was dried in air. This clearly indicates that the gas formation is a phenomenon induced by the anodic reaction and not by other reasons. Perhaps the existence of a catalytic amount

of oxygen is required for this gas formation. The above experiments were made with platinized platinum anode. Although the anomaly was also found for the smooth platinum anode, it was occasional and the reproducibility was poor.

The relative composition of the gases evolved from the anode surface (at the higher current density) and of the separater was determined by a mass spectrometer; it is given in Table I.

TABLE I

	Methanol	Formaldehyde	CO
Gas evolved from the anode surface	0.84	0.06	0.19
Gas accumulated at the separater	0.79	0.21	0.00

Beside solvent methanol, formaldehyde was the only component of the gas, while carbon monoxide was the main component of the gas evolved from the anode surface.

At the end of the electrolysis for the gas collection, the concentration of formaldehyde could never exceed 10^{-3} in its mole ratio to methanol: this proportion could not cause such a high concentration of formaldehyde as was observed in the evolved gas.

On the basis of the facts described, we propose the following sequence of reactions:

At the anode

$$MeOH \rightarrow MeO + H^+ + e \quad (1)$$

Detachment and diffusion

$$MeO(ads) \rightarrow MeO\ (bulk) \quad (2)$$

Disproportionation

$$2MeO \rightarrow MeOH + HCHO \quad (3)$$

We have some evidence that the radicals formed by electrooxidation are methoxyl (CH_3O) and not hydroxymethylene radicals (CH_2OH),[1] although it seems that the real process of methoxyl radical formation is not so simple as to be expressed by Eq. 1. The methoxyl radical is comparatively stable,[2] and the following decomposition is heavily endothermic ($q = -20$ to 35 kcal.[3]).

$$MeO \rightarrow HCHO + H$$

Therefore, it is not surprising that an appreciable number of the radicals formed by Eq. 1 do not undergo further oxidation upon the electrode surface but detach from the electrode and diffuse into the bulk solution. If the association of two radicals occurs, large exothermic disproportionation ($q = +85$ kcal. for Eq. 3) would occur readily, presumably at the glass filter surface.

A Kinetic Structure of Ammonia Synthesis

By Kenzi TAMARU

(Received April 28, 1964)

The adsorption measurements during surface catalysis[1] have been extended to the study of the reactivity of chemisorbed species on the catalyst surface as a function of the pressures and coverages of such species as reactants, products and intermediates.[2] Accordingly, the mechanism of the overall reaction can be elucidated by studying each step in the overall reaction.

The ammonia synthesis on a doubly promoted iron catalyst has been treated by the new approach, and the chemisorption of nitrogen and its desorption, the reaction between the chemisorbed nitrogen and hydrogen to form ammonia have been separately studied under the reaction conditions.[2-4] The rates of the three steps ($\vec{V}_1$, $\overleftarrow{V}_1$ and $\vec{V}_2$, respectively) are expressed in the following manner according to the experimental results:

$$\vec{V}_1 = AP_{N_2} \exp(-\gamma x) \quad (1)$$

$$\overleftarrow{V}_1 = B \exp(\beta x) \quad (2)$$

1) K. Tamaru, This Bulletin, **31**, 666 (1958).
2) K. Tamaru, *Catalyst* (*Shokubai*), **4**, 30 (1962).
3) K. Tamaru, *Trans. Faraday Soc.*, **59**, 979 (1963).
4) K. Tamaru, This Bulletin, **37**, 771 (1964).

$$\vec{V}_2 = CP_{H_2} \exp(\alpha x) \quad (3)$$

where x is the amount of nitrogen chemisorbed A, B, C, α, β, γ, are constants, and P_N and P_H are the pressures of nitrogen and hydrogen respectively.

If we postulate that the backward reaction of the latter step ($\overleftarrow{V}_2$) is first order as to ammonia, as has been reported in the case of a tungsten catalyst, $\overleftarrow{V}_2$ should conform to the following equation from the equilibrium conditions:

$$\overleftarrow{V}_2 = D(P_{NH3}/\sqrt{P_{H_2}})\exp(-\delta x) \quad (4)$$

where $B/A = C^2/(D^2K_p)$, $\alpha+\beta = 2(\gamma+\delta)$, and K_p is the equilibrium constant of the reaction, $N_2+3H_2=2NH_3$.

The $\overleftarrow{V}_1/\vec{V}_2$ ratio can be taken as a criterion to identify the rate-determining step of the overall reaction; if it is much larger than unity, the latter step is rate-determining, while if it is much smaller than unity, the former step is.

$$\overleftarrow{V}_1/\vec{V}_2 = (B/C)\exp[(\beta-\gamma)x]/P_{H_2} \quad (5)$$

The experimental results revealed that β is approximately equal to γ and that the activation energy for $\overleftarrow{V}_1$, which is the sum of that for $\vec{V}_1$ and the heat of adsorption of nitrogen, is markedly larger than that for $\vec{V}_2$. Accordingly, at a higher temperature and a lower pressure of hydrogen, the latter step is likely to be rate-determining.

If the steady-state approximation is applied, the kinetic expression of the overall reaction can be derived in the following way:

$$\vec{V}_1+\overleftarrow{V}_2 = \overleftarrow{V}_1+\vec{V}_2$$

$$AP_{N_2}\exp(-\alpha x)+D(P_{NH_3}/\sqrt{P_{H_2}})\exp(-\delta x) = B\exp(\beta x)+CP_{H_2}\exp(\gamma x)$$

$$\exp[(\alpha+\beta)x/2] = \frac{1}{2(B+CP_{H_2})}\left[D\frac{P_{NH_3}}{\sqrt{p_{H_2}}}+\sqrt{D^2\frac{P^2_{NH_3}}{p_{H_2}}+4AP_{N_2}(B+CP_{H_2})}\right] \quad (6)$$

$$\text{Overall rate } (V_0) = \vec{V}_1-\overleftarrow{V}_1 = AP_{N_2}\exp(-\alpha x)-B\exp(\beta x) \quad (7)$$

Equation 6 gives the nitrogen coverage under given reaction conditions, while Eq. 7 gives the overall reaction rate at the nitrogen coverage.

If the former step is rate-determining, the Temkin-Pyzhev treatment[5] is exactly applicable as follows:

$$V_0 = A^{\frac{\beta}{\alpha+\beta}}(K_pB)^{\frac{\alpha}{\alpha+\beta}}P_{N_2}(P^3_{H_2}/P^2_{NH})^{\frac{\alpha}{\alpha+\beta}} - (A/K_p)^{\frac{\beta}{\alpha+\beta}}B^{\frac{\alpha}{\alpha+\beta}}(P^2_{NH3}/P^3_{H_2})^{\frac{\beta}{\alpha+\beta}} \quad (8)$$

From the experimental results, $\alpha/(\alpha+\beta)=0.6$ was obtained, which conforms to the value hitherto obtained kinetically.

If the synthesis reaction proceeds in the presence of a negligible amount of ammonia, V_0 can be expressed as follows, putting P_{NH_3} as zero in Eqs. 6 and 7:

$$V_0 = AP_{N_2}[(AP_{N_2}/(B+CP_{H_2})]^{\frac{-\alpha}{\alpha+\beta}} - B[AP_{N_2}/(B+CP_{H_2})]^{\frac{\beta}{\alpha+\beta}} \quad (9)$$

The orders of the forward reaction as to nitrogen and hydrogen are, accordingly, $\beta/(\alpha+\beta)$ and $\alpha/(\alpha+\beta)$ respectively, provided $CP_{H_2} \gg B$. It is of great interest to note that Temkin et al.[6] recently reported that the ammonia synthesis in the presence of a negligible amount of ammonia is half-order as to both nitrogen and hydrogen. On the basis of this fact, they suggested that the hydrogenation step of the chemisorbed nitrogen participates in the rate-determining step of the overall reaction. Equation 9 reasonably agrees with the observed kinetics, which seemingly supports the validity of the general kinetic treatment of the overall reaction on the basis of the kinetics of each component step of the overall reaction.

Electron Paramagnetic Resonance Spectra of Phosphate Glasses Irradiated with Gamma-rays

By Yasuo NAKAI

(Received April 30, 1964)

The electron spin resonance (ESR) of irradiated glasses has been reported on several times in the past five years,[1] since the paramagnetic centers have been expected to contain localized electrons and holes.

ESR study of the defect centers in irradiated glasses containing phosphorus was first reported on by Karapetyan and Yudin.[2] They observed an ESR spectrum consisting of two lines at $g=2.0038$. This two-line structure was attributed to hyperfine interaction with a P nucleus. In the present investigation, it was found that there are three distinct types of defect centers in irradiated phosphate glasses.

Phosphate glass samples with the composition of (RPO_3) [R=Li, Na, Ca, Ba,], where R/P=1, were irradiated at room temperature with Co^{60} gamma-rays ($5\sim6\times10^6$r.). The derivative curve was obtained with a Varian 4501 ESR spectrometer at room temperature, employing a modulation frequency of 100 kc./sec.

The irradiated lithium phosphate glasses ($LiPO_3$) exhibit the ESR spectra of two strong lines (P_1 and P_2) and of the other two weak absorption lines (Fig. 1). One of the weak

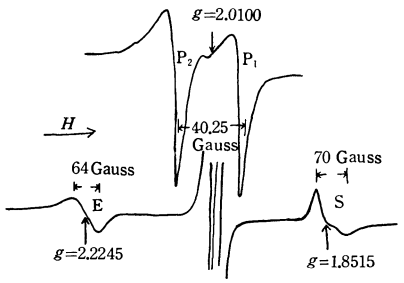

Fig. 1. The ESR spectrum obtained for a γ-ray irradiated (5×10^6 r.) lithium phosphate glass ($LiPO_3$).

absorption lines appear to display a broad derivative peak on the low magnetic field side ($g=2.2245$), and the other, a broad asymmetric derivative peak on the high magnetic field side ($g=1.8575$). The former is denoted by E, and the latter, by S.

The intensity of the two-line structure can easily be reduced by heating at 100°C. The fading speed by the thermal treatment is dependent on the kinds of alkali or alkaline earth modifiers. The derivative peaks denoted by P_1 and P_2 are spaced with a spacing of 40.25 gauss, and the g value at the center of these two peaks is observed to be $g=2.0100$. This two-line structure has the same response to both the thermal annealing and the optical bleach, and it is independent of the type of alkali or alkaline earth modifiers.

The observed g value of the two-line structure is larger than that of the free electron. This suggests that the paramagnetic center is a hole trapped on a singly bonded oxygen. The hyperfine structure arises from the overlap of the hole orbital on a phosphorus atom with a spin of 1/2. The principal values of g in the axial field are given by $g_{\parallel}=2.0243$ and $g_{\perp}=2.0100$.

The process of this creation can perhaps be interpreted as follows. An electron in the π-orbital of oxygen associated with the P=O link is thrown out because of the action of γ-rays. Thus, migrating through the valence zone, the formed hole goes to the nucleus of a four coordinate phosphorus ion.

Karapetyan and Yudin have interpreted the magnetic centers of phosphate glasses as arising from electron capture in the (PO_4) groups, not as oxygen vacancies in the vicinity of the alkali or alkaline earth ions. In this present work, however, we found that the shapes of the other weak resonance lines (E and S) were dependent on the kinds of alkali or alkaline earth ions. The resonance spectra in irradiated phosphate glasses containing a calcium or barium modifier appear as is shown in Fig. 2. In the case of a sodium or potassium modifier, the spectra disappear on both the low and the high magnetic field sides. The sample of (KPO_3), however, is not in the state of glass but is a highly polymerized crystal.

In phosphate glasses modified with such ions

as calcium, barium or lithium, that can coordinate with the tetrahedral oxygen atom in the glass network, the two weak resonance lines seem to appear just as well as with a low dosage of γ-rays irradiation.

The g value of the E band is far larger than that of the free electron, and yet it depends upon the kinds of alkaline earth ions. Consequently, it is possible that it has something to do with new valence zone of alkali ions coordinated with the oxygen atom in the glass network.

The intensity of the S band is hardly reduced at all by heat treatment at 200°C for 5 hr. This suggests that the S band may arise from electrons trapped at oxygen vacancies in the vicinity of the alkali ions, as has been assumed previously.[3)]

The Electrometric Titration of Thorium with Tellurite

By V. K. SHARMA and J. N. GAUR

(Received August 27, 1963)

Berzelius prepared tellurites of thorium, zirconium, berylium, aluminium, yttrium, etc. by mixing a solution of each of their salts with a sodium tellurite solution.[1] We ourselves have previously used tellurite for the estimation of zirconium by electrometric methods.[2] Results of similar investigations with thorium have been reported in the present communication.

Experimental

Solutions from thorium nitrate (99.0% pure) and potassium tellurite (97.0% pure) were prepared and standardized by gravimetric methods.

Conductometric Measurements.—Solutions prepared from conductivity water were used for the purpose of conductometric titrations.

When thorium nitrate solutions are taken into the cell, two breaks, at ratios of approximately 1 : 1 and 1 : 2, are obtained, whereas reverse titrations show only one break, at the 1 : 2 ratio. Results of direct as well as reverse titrations have been incorporated in Table I, while typical curves are shown in Fig. 1.

TABLE I

that there is a sharp change in pH from the acidic side to the alkaline side at the end point. Thus, the possibility of using phenolphthalein for the visual detection of the end point can not be ruled out. In was actually found that phenolphthalein gave reliable results, even in dilute solutions of thorium nitrate, and that hence potassium tellurite could be used for the direct volumetric estimation of the thorium nitrate solution. Results are summarized in Table III.

TABLE III

2) V. K. Sharma and J. N. Gaur, *J. Electroanal. Chem.*, **5**, 375 (1963).

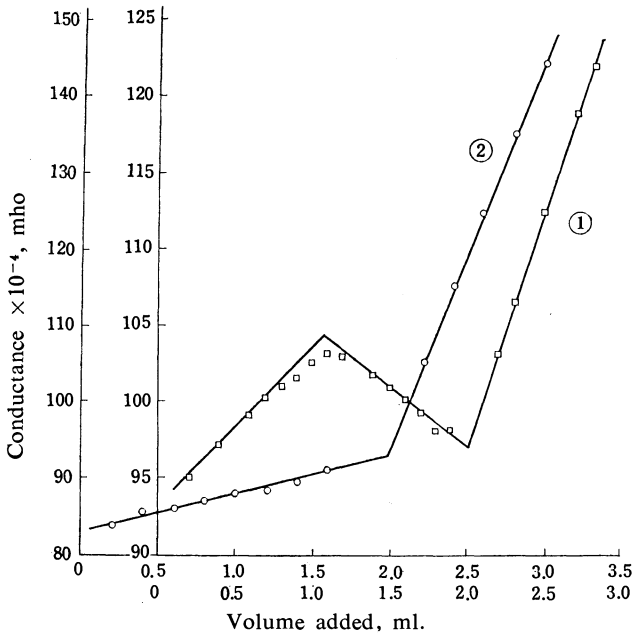

Fig. 1. Titration of (1) 20 ml. 0.0025 M $Th(NO_3)_4$ with 0.05 M K_2TeO_3 and (2) 20 ml. 0.01 M K_2TeO_3 with 0.05 M $Th(NO_3)_4$.

Discussion

Conductometric and potentiometric titrations show a sharp break at 1:2 (Th:Te) ratio; hence, thorium can be estimated using potassium tellurite by conductometric and potentiometric methods. A direct estimation of thorium can also be effected using phenolphthalein as an indicator, as is evident from the results of Table III. All these titrations show the formation of normal thorium tellurite.

Summary

Potentiometric and conductometric titrations of thorium nitrate solutions with tellurite show a sharp break at the 1:2 (Th:Te) ratio. Direct volumetric titrations using phenolphthalein as an indictator also show the 1:2 ratio, indicating the formation of normal tellurite. The estimation of thorium by potentiometric, conductometric and direct volumetric titrations using potassium tellurite has been suggested.

ESR Studies of the Negative Ions of Biphenyl Derivatives. II. Electron Spin Resonance Hyperfine Spectra of 3-Methyl Biphenyl, m, m'-Bitolyl, 2-Methyl Biphenyl, and o, o'-Bitolyl Mononegative Ions

By Kazuhiko Ishizu*

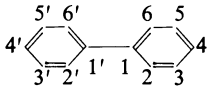
(Received September 13, 1963)

In a previous paper,[1] the author reported the results of an ESR study of 4-methyl biphenyl and *p, p'*-bitolyl mononegative ions; this study has also provided us with some information on methyl proton splitting which will be referred to later in this paper.

In this article, work on the ESR spectra of 3-methyl biphenyl, *m, m'*-bitolyl, 2-methyl biphenyl, and *o, o'*-bitolyl mononegative ions will be presented in order to clarify further the effect of methyl substitution at various positions on the biphenyl ring in terms of hyperconjugation and the steric effect.

Experimental

The radical anions were produced with potassium metal in dimethoxyethane (DME) and also in tetrahydrofuran (THF). The experimental procedures were described in the preceding paper.



Results

The resolution of the observed hyperfine lines in the ESR spectra for each specimen was found to be better in DME than in THF, except for 3-methyl biphenyl; thus, the spectra observed in DME will be discussed.

With reference to the theoretically-calculated spin density given in Table II, the hyperfine structures of the observed spectra were interpreted adequately by assuming that the magnitude of the methyl splittings and of the ring-proton splittings were almost equal to those at the same positions on biphenyl, in which the splitting ratios at the para-, ortho-, and meta-positions were approximately 8 : 4 : 1.

The proton hyperfine splittings at the meta- and the ortho-positions were derived from an analysis of the terminal and the next-inner groups of the spectrum, while those at the para-positions were derived through the trial and error method by observing the intense splittings around the center of the spectrum.

The general structure of a biphenyl ring is:

In the following sections, ΔH_n and ΔH_n (CH_3) represent the hyperfine coupling constants* of, respectively, the ring protons and of the methyl protons attached to the ring carbon C_n, where n denotes a position on the biphenyl ring.

3-Methyl Biphenyl.—The observed spectrum measured in DME at room temperature is shown in Fig. 1(a). Although he made careful observations in range from room temperature to −60°C, the author could not observe any good resolved patterns of ESR hyperfine lines; thus, it was difficult to determine the coupling constants precisely. The integral intensity of each hyperfine line, however, seems to be in good agreement with the theoretical intensity, as is shown in Fig. 1 (b).

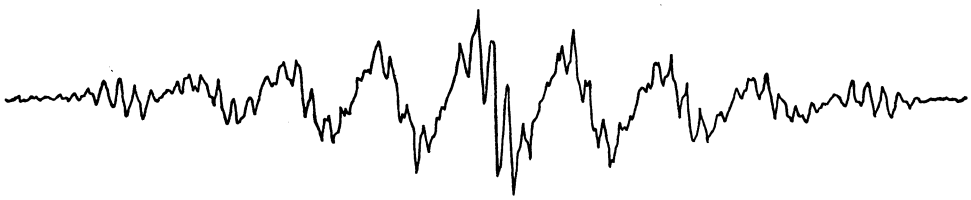
The overall width, the number of the groups in which hyperfine lines flocked, and the location of strong intensity lines in the spectrum were all similar to the conditions in biphenyl. Thus, one may assume that the para (ΔH_4 and $\Delta H_{4'}$)-, or the ortho (ΔH_2, $\Delta H_{2'}$, ΔH_6 and $\Delta H_{6'}$)- ring proton splittings are about 5.4 gauss and 2.7 gauss respectively, not far from those of biphenyl. The ring-proton splitting ($\Delta H_{3'}$, $\Delta H_{5'}$ and ΔH_5) and the methyl proton splittings ($\Delta H_3(CH_3)$) at the meta-positions were all about 0.43 gauss.

The methyl splitting was identified from the integration of the septet lines in the terminal groups.

The proton hyperfine splittings thus determined are:

$$\Delta H_4 \simeq \Delta H_{4'} = 5.4 \text{ gauss}$$

$$\Delta H_2 \simeq \Delta H_{2'} \simeq \Delta H_6 \simeq \Delta H_{6'} = 2.7 \text{ gauss}$$



$$\Delta H_3(CH_3) = \Delta H_{3'} = \Delta H_5 = \Delta H_{5'} = 0.43 \text{ gauss}$$

***m, m'*-Bitolyl.**—The observed spectrum measured at −15°C is shown in Fig. 2(a). The overall width and the grouping of every hyperfine line in the spectrum can be easily

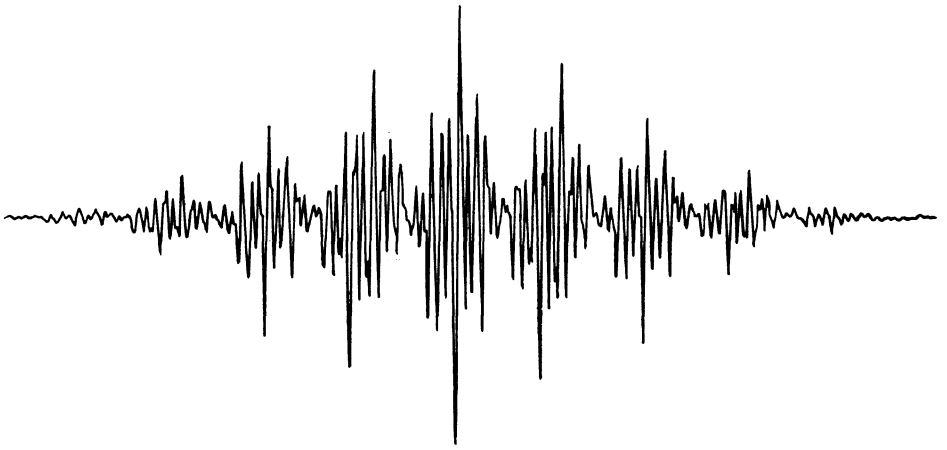
compared with those of biphenyl. The observed spectrum consists of three triplets originating from a pair of para (5.15 gauss)-, and two pairs of ortho (2.82, 2.33 gauss)-, ring protons. Each line then splits further into a triplet septet caused by a pair of the metaring protons and the six methyl protons.



With reference to Hückel's MO calculation, in which $\rho_6 > \rho_2$*, the ΔH's of each proton thus determined are as follows:

$\Delta H_4 = 5.15$, $\Delta H_6 = 2.82$, $\Delta H_2 = 2.33$, $\Delta H_3(CH_3) = 0.49$, $\Delta H_5 = 0.27$ gauss.

The relative intensities of the hyperfine lines estimated on the basis of these ΔH's are shown in Fig. 2(b).

2-Methyl Biphenyl.—The spectrum measured at room temperature is shown in Fig. 3(a). As is illustrated in Fig. 3(b), the terminal group of the spectrum consists of six lines, whose relative intensity ratios are 1 : 1 : 2 : 2 : 1 : 1, and the line spacing is alternatively 0.42 and 0.23 gauss. One would expect the hyperfine structures of these six lines to appear as a triplet due to a pair of equivalent ring-proton splittings (0.65 gauss), followed by a doublet due to a pair of equivalent ring-proton splittings (0.42 gauss) at the meta-positions. Thus, it may reasonably be expected that any coupling constant of the remaining meta-proton will be too small to split the hyperfine lines. One may assume that an equivalent pair exists for the meta-ring protons in the non-substituted phenyl group, taking the theoretical prediction of spin density into account. Thus, the ring proton splittings at each meta-position are determined to be:

* ρ_n: a theoretically-calculated spin density on the ring carbon atom, C_n, of the biphenyl ring.

10 gauss

Fig. 2 (a)

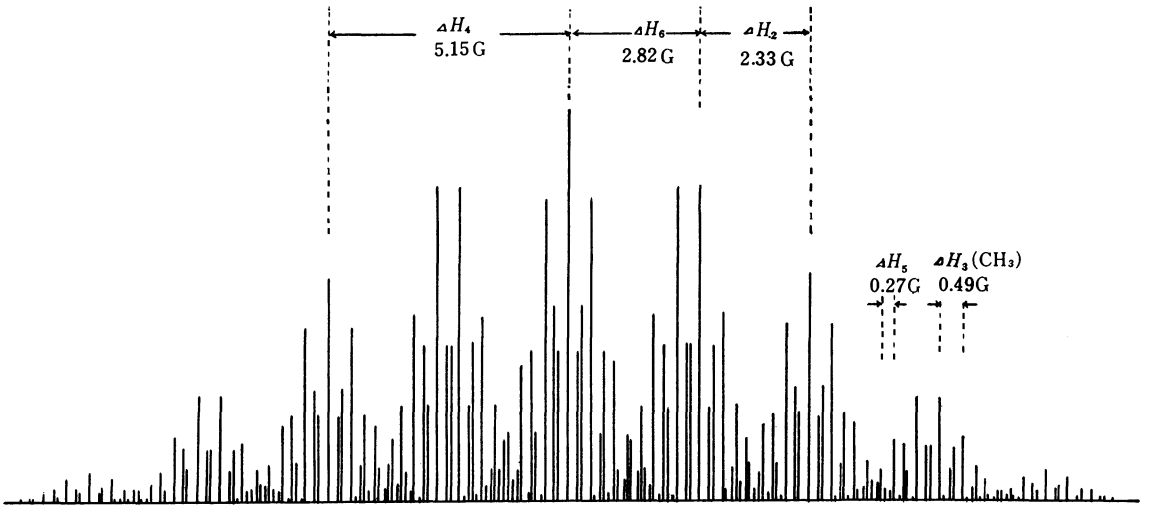


Fig. 2 (b)

Fig. 2. *m*, *m'*-Bitolyl.

(b) : Calculated spectrum based on experimentally determined proton coupling constants

$\Delta H_{3'}=\Delta H_{5'}=0.65$, $\Delta H_5=0.42$, and

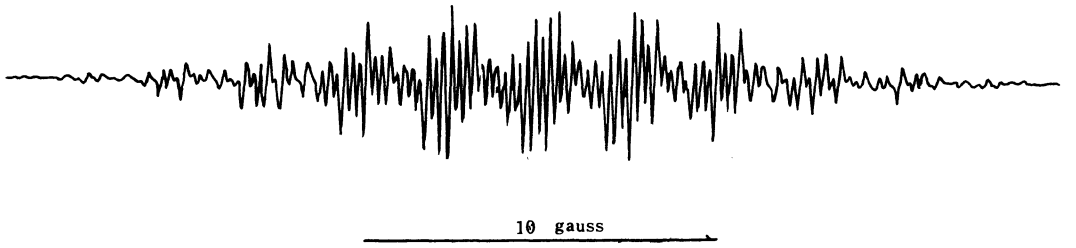
$\Delta H_3<0.03$* gauss.

The analysis of the wing groups in the spectum shows that the ring and the methyl protons at the ortho-positions will give two kinds of splittings, a triplet (2.88 gauss) and a quintet (2.41 gauss), respectively.

Taking the theoretical spin density at the ortho-positions into account, a triplet is assigned to the ortho-ring proton splittings in the non-substituted phenyl group, and a quintet, to an ortho-ring proton and the three methyl proton splittings in the substituted phenyl group; that is, $\Delta H_{2'}=\Delta H_{6'}=2.88$ and $\Delta H_2(CH_3)=\Delta H_6=2.41$ gauss. Finally, the para-(ΔH_4, $\Delta H_{4'}$) proton splitting was found to be 5.25 gauss by the trial and error method. The relative intensities of the hyperfine lines are shown in Fig. 3 (c).

The $\Delta H_{5'}$ thus determined are:

$\Delta H_4=\Delta H_{4'}=5.25$, $\Delta H_{2'}=\Delta H_{6'}=2.88$,



$\Delta H_2(CH_3)=\Delta H_6=2.41$,

$\Delta H_{3'}=\Delta H_{5'}=0.65$, $\Delta H_5=0.42$, and

$\Delta H_3<0.03$ gauss.

all three groups at the wing of the spectrum illustrated in Fig. 4(b), are equal to 1 : 2 : 3 : 4 : 3 : 2 : 1. The ring proton and the methyl proton splittings at the ortho-positions are all equal; that is, $AH_2(CH_3) = AH_6$. Furthermore, the proton splitting ratio at the meta-position is equal to 2 : 1. The AH's thus determined are as follows:

$AH_4 = 5.12$, $AH_2(CH_3) = AH_6 = 2.20$,

$AH_5 = 0.56$, and $AH_3 = 0.28$ gauss.

The spectrum which has been constructed on the basis of the observed coupling constants is shown in Fig. 4(c). Table I gives the overall width, the g-values, and the observed coupling constants of both ring protons and methyl protons in mononegative ions of biphenyl and its derivatives.

Discussion

The Ring Proton Splitting.—The theoretical spin density on both ring carbons and methyl protons were derived by means of Hückel's MO calculation, assuming that each aromatic ring would be on a plane and estimating the resonance integral between neighboring ring carbon atoms (β_{C-C}) and the Coulomb integral

of a ring carbon atoms (α_C) to be the same as those of benzene (β, α).

Coulson-Crawford's[2] parameters were employed here for the calculation of the methyl fraction ($-C_1-C_2\equiv H_3$); that is, $\beta_{C_1-C}=0.7\ \beta$, $\alpha_{C_2}=\alpha-0.1\ \beta$, $\beta_{C=H_3}=2.5\ \beta$, and $\alpha_{H_3}=\alpha-0.5\ \beta$. The overlap integrals were disregarded for the above cases. For the ring proton splitting, Jarret's[3] calculation agreed well with the observed values, deviating by only about 15%, indicating that the ring-proton splitting parameter is 28 gauss.

However, with regard to the observed proton splitting given in Table I, some distinct spin distribution can be recognized in the case of both ortho-derivatives compared with those of the other meta- or para-derivatives. In the case of 2-methyl biphenyl, there is a certain difference in spin distribution at the ortho- and the meta-positions between a substituted and a non-substituted phenyl group; this difference may be due to a steric effect caused by the methyl group. In the case of o, o'-bitolyl, the magnitude of the proton splitting at the ortho-positions was much reduced, whereas that at the para-position was not.

Comparing the ring-proton splitting ratios $\Delta H_4/\Delta H_6$ of o, o'-bitolyl negative ions with those at the para- and the ortho-positions of other derivatives (e.g., $\Delta H_4/\Delta H_6$ or $\Delta H_4/\Delta H_2$), the largest value was obtained in the case of o, o'-bitolyl (2.35), although those of the others are all within the 1.80~2.17 range; moreover, the theoretical values are all equal to 1.76, including that of o, o'-bitolyl.

Recently McLachlan[4] has suggested that a reduction of the ring-proton splitting will take place selectively at the ortho- and at the meta-positions, so that $\Delta H_4/\Delta H_6$ will increase when both phenyl rings are assumed to be twisted in the biphenyl negative ion. Thus, a large $\Delta H_4/\Delta H_6$ value in the o, o'-bitolyl negative ion will probably indicate the presence of steric hindrance, as will be described in the following section.

The Methyl Proton Spitting.—In an ESR investigation of methylated, aromatic free radicals, hyperconjugation has been studied from two distinct theoretical points of view. One is the molecular orbital theory, in which the π-π coupling between the methyl group and the odd-ring orbital is considered to play an important role. Several workers' investigations have applied the method to the study of methyl substituted semiquinones[5] and methyl anthracene[6], using Coulson and Crawford's parameters. The other is the valence bond theory; McLachlan[7] calculated the hyperfine

splitting produced by protons of a methyl group in a π-electron radical such as Würster's blue, invoking the spin exchange polarization between the odd electron and the methyl group.

Taking these theoretical studies of hyperconjugation into consideration, the methyl proton splitting in each methylated biphenyl may be calculated in the following way.

The spin density (a_M) on the methyl protons is calculated on the basis of Hückel's MO method, utilizing Coulson-Crawford's parameters; then the theoretical methyl proton splittings (a_M) are calculated by making use of the following relation 1. The results are shown in Table III (A).

$$a_M = \rho_H \times 502 \text{ gauss} \quad (1)$$

where the splitting of a bare proton was estimated to be 502 gauss.

Furthermore, by referring to McLachlan's suggestion, the theoretical methyl splittings (a_M) were calculated on the basis of Hückel's spin density (ρ_C) on the corresponding ring carbon atoms of the biphenyl negative ion, using the following relation 2;

$$a_M = Q_M \rho_C \quad (2)$$

where Q_M is the methyl proton splitting parameter (which had been found to be 25~28 gauss after McLachlan)

Here, Q_M is estimated to be 28 gauss, since the magnitudes of the observed methyl splittings are all close to those of the ring proton at the relevant positions on the biphenyl ring. The results are shown in Table III (B).

TABLE III. THE ODD π ELECTRON ENERGY LEVELS AND THE EXPERIMENTAL AND THEORETICAL METHYL SPLITTINGS OF METHYLATED BIPHENYL MONO-NEGATIVE IONS

	Energy ($\times\beta$)	Methyl splitting (gauss)		
		(A)	(B)	(C)
Biphenyl	−0.704	—	—	—
4-Methyl-	−0.702	6.27	4.42	5.42
p, p-Bitolyl	−0.699	6.27	4.42	5.63
3-Methyl-	−0.704	0.80	0.56	0.43
m, m'-Bitolyl	−0.704	0.80	0.56	0.49
2-Methyl-	−0.703	3.71	2.52	2.41
o, o'-Bitolyl	−0.702	3.71	2.52	2.20

(A) Theoretical methyl splitting predicted by the Hückel's MO method by using the Coulson-Crawford parameters.
(B) Theoretical methyl splitting calculated from the relation $a_M = Q_M \rho_C$.
(C) Experimentally determined methyl splitting.

The molecular orbital calculations (A) agree well with the observed (C) and the calculated values in the case of the para-derivatives, while McLachlan's predictions (B) give satisfactory results in the case of the meta-derivatives.

As for the energy level of the odd π orbital shown in Table III, which was calculated in the course of the molecular orbital treatment (A), it is recongnized that the most effective perturbation of the energy level occurs in the case of the para-substitution, whereas there is no change in energy level in the case of the meta-derivatives compared with that of a biphenyl negative ion.

In the process of the interaction between the unpaired electron and the methyl group in these negative ions, when the π-π interaction is dominant, it may be assumed that the delocalization of the unpaired electron will perturb the energy level of the odd π orbital; thus, the magnitude of the methyl splitting will vary according to the perturbed energy level of the odd π orbital. Therefore, the theoretical methyl splitting calculated by the molecular orbital method A would be close to the observed values in this case.

However, when spin polarization is an important process, the perturbation of the energy level is assumed to be small. Thus, it may reasonably be expected that the hyperfine interaction of the methyl proton will be solely proportional to the spin density on the relevant ring carbon atoms of the unsubstituted negative ion; hence, McLachlan's prediction B would be more reliable than A.

From these arguments for the theoretical calculation, one may assume that the π-π interaction between the methyl group and a ring π orbital is likely to be the main process of hyperconjugation in the case of the para-derivatives. On the other hand, spin polarization would be dominant in the case of the meta-derivatives.

In the case of the ortho-derivative, one may suppose that the steric effect may change the methyl splitting as well as the ortho-ring proton splitting. In the case of 2-methyl biphenyl, the theoretical value obtained by the relation 2 is in good agreement with those observed. However, in the case of *o, o'*-bitolyl, the magnitude of the observed methyl splitting is appreciably less than that of the 2-methyl biphenyl negative ion or the theoretical value. It will be established in the following section that the reduction of the methyl splitting originates in steric hindrance in the case of the *o, o'*-bitolyl negative ion.

The Effect of Steric Hindrance.—In order to confirm the steric effect on both the ring

proton and the methyl proton splitting, the spin density was calculated with the modification that the resonance integral of C_1–C_1 bond was estimated to be $\beta \cos\theta$, where θ is a twisting angle between both phenyl rings. The dependence of the spin density of the ring carbon atoms and that of the methyl splitting on the twisting angle θ are shown in Figs. 5 and 6 respectively.

In Fig. 6(a), the methyl splitting is presented by the relation 1 on the basis of the spin densities on the methyl protons which were calculated for twisted models of the o,o'-bitolyl negative ion. In Fig. 6(b), the methyl splitting is calculated by utilizing the relation 2 described in the last section on the basis of the theoretical spin density of a twisted biphenyl negative ion.

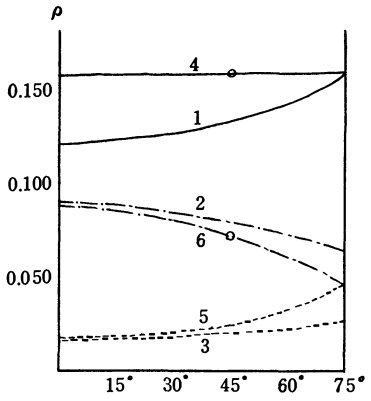

Fig. 5. Dependence of theoretical spin density of ring carbon atoms on twisting angle θ between the phenyl rings in o,o'-bitolyl negative ion, where the numbers represent the positions on the biphenyl ring.

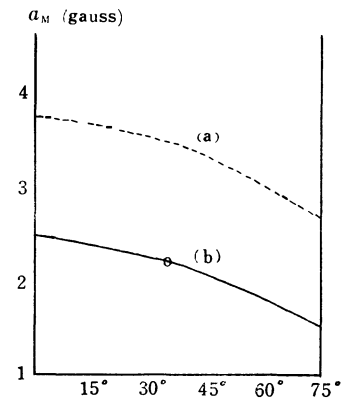

Fig. 6. Dependence of theoretical methyl splitting on twisting angles θ between the phenyl rings in o,o'-bitolyl negative ion.
(a) is plotted with the theoretical methyl splitting predicted by the Hückel's MO method using the Coulson-Crawford's parameter, applied for the twisted model of o,o'-bitolyl negative ion.
(b) is plotted with the theoretical methyl splitting obtained from the relation $a_M = Q_M \rho_C$, where the spin density on the ring carbon atom (ρ_C) are calculated for twisted biphenyl negative ion, and the methyl splitting parameter Q_M is estimated to be 28 gauss.

As is illustrated in Fig. 5, the spin density on the ring carbon atoms at the para (ρ_4)-position was enhanced gradually with an increment of θ, while conversely, those of the ortho (ρ_2, ρ_6)-positions were reduced.

This is a possible reason why the observed ring-proton splitting ratio, $\Delta H_4/\Delta H_6$, becomes larger in the o,o'-bitolyl negative ion than in other derivatives.

One will see that the theoretical spin density ratio, ρ_4/ρ_6, approaches the observed proton splitting ratio around $\theta = 45°$. Furthermore, it will be found that the magnitude of theoretical methyl splitting decreases with the increment of θ, as is shown in Fig. 6; hence, the theoretical value becomes equal to the observed values around $\theta = 30°$ in Fig. 6(b). In Fig. 6(a), the theoretical value is considerably larger than the observed values because of overstimated parameters in the methyl fraction.

When the results of both the ring proton splitting and the methyl proton splitting discussed in twisted models of the o,o'-bitolyl negative ion were put together, Hückel's calculation led to the conclusion that the two phenyl rings are twisted about 30°~45° from each other.

It has been well known on the basis of the investigation of the electronic spectra,[8] that the phenyl rings are twisted out about 70° in the neutral molecule of o,o'-bitolyl. When these twisting angles in the negative ion are compared with those in the neutral molecule, one may conclude that there is a greater tendency toward coplanarity between the two phenyl rings in the negative ion than in the neutral molecule of o,o'-bitolyl.

Recent ESR studies of such other ortho-derivatives as o-terphenyl,[9] o,o'-dinitro-biphenyl[10] have also suggested that this conclusion is justified.

Summary

The electron spin resonance of 3-methyl-biphenyl, 2-methyl-biphenyl, m,m-bitolyl, and o,o'-bitolyl has been observed. The overall

width and ring-proton coupling constants of the mononegative ions of each methylated biphenyl have been interpreted by utilizing the calculated spin density derived by Hückel's MO treatment. It has been found that the splitting parameters of the ring proton and the methyl proton were both about 28 gauss.

Hyperconjugation has been effected through the π-π interaction in the case of the para-derivatives, while spin polarization is important in the case of the meta-derivatives. In the case of the ortho-derivatives, the magnitude of the methyl splitting decreased with steric hindrance, which either brought about a fair amount of unbalanced spin density on biphenyl carbon atoms, or markedly reduced the magnitude of the ortho-proton splitting.

From Hückel's calculation, one may conclude that both of the phenyl rings are twisted about $30°\sim45°$ in the *o,o'*bitolyl negative ion, in which the twisting angle is much smaller than that in the neutral molecule.

The author wishes to thank Professors Hideo Takaki and Ryozo Goto for making the ESR spectrometer available for this study. He is also much obliged to Dr. Yasuo Deguchi for his helpful discussions and encouragement through the course of this work. The author wishes to express his gratitude to Professor Kenichi Fukui and to Dr. Keiji Morokuma for their computations of molecular orbitals. He is also indebted to Mr. Isao Yokomichi for the synthesis of the samples.

The Colorimetric Determination of Minute Amounts of Iodide and Iodate in Sea Water by Means of Their Catalytic Effects

By Norinobu YONEHARA

(Received November 6, 1963)

It is known that iodine in sea water exists in the form of both iodide and iodate. Sugawara and Terada[1] determined the iodide and total iodine contents in sea water, but the method they proposed requires a considerable amount of sample and a time-consuming procedure. Barkley and Thompson[2] determined the iodate and total iodine contents in a relatively small amount of sample by using an amperometric or spectrophotometric method. The amperometric method was, however, accompanied by a somewhat complicated procedure, while the spectrophotometric method was applicable only to the determination of total iodine. The present author and others have reported in a preceding paper[3] a colorimetric method for the determination of ultramicro amounts of iodine in the form of both iodide and iodate by utilizing their catalytic effect on the color-fading of ferric thoicyanate. By this method, the iodate and total iodine contents in river and rain waters can be determined. However, as for sea water, this method is suitable for determining only the total iodine, but not the iodate iodine, because the separation of iodide from iodate is not performed quantitatively in the presence of the large amount of chloride contained in sea water. In the present work, therefore, the quantitative separation of iodide from iodate in sea water is attempted by means of the oxidation of iodide with an appropriate oxidizing agent. Because it improves the concentration of the reagents concerned and the conditions of the reaction, this catalytic method appears to be more sensitive and accurate than the method previously proposed, at least sensitive and accurate enough to determine the iodate and total iodine contents in sea water.

Experimental

Apparatus.—A Hirama photoelectric-colorimeter with a 460 filter (with maximum transmission at 460 mμ) and 10 mm. cells was used to measure the absorbance.

The reaction was carried out at 60.00±0.05°C using a water bath with a Taiyo Thermo Unit.

Reagents. — All the chemicals used were of guaranteed reagent quality.

Ferric Ammonium Sulfate - Nitric Acid Solution.— Six grams of ferric ammonium sulfate dissolved in 100 ml. of a 7.0 N nitric acid solution was stored in a brown glass bottle.

Potassium Thiocyanate Solution (0.01 M).—A potassium thiocyanate solution (0.1 M), standardized by Volhard's method, was diluted to a 0.01 M solution and stored in a brown glass bottle.

Sodium Nitrite Solution (0.014 M). — Sodium nitrite, 0.483 g. dissolved in redistilled water, was diluted to 500 ml. in a volumetric flask, and stored in a brown glass bottle.

Sodium Chloride Solution (20 g. of Chloride per l.). —Sodium chloride (32.970 g.) was dissolved in redistilled water and diluted to exactly 1 l.

Standard Iodide Solution. — A potassium iodide solution (0.1 M) was standardized by Volhard's method;[4] the working solution was then prepared by diluting this solution adequately.

Standard Iodate Solution. — Potassium iodate 0.843 g. was dissolved in redistilled water and diluted to exactly 500 ml. The working solution was prepared by successive dilutions.

Procedures and Calibration Curves. — The chlorinity of sea water was determined, and then it was diluted with redistilled water, to give a chlorinity of 2%.

Procedure (1) (for the Determination of Total Iodine).—Ten milliliters of the diluted sample is taken into a glass tube. One milliliter of a 0.014 M sodium nitrite solution and 1.0 ml. of a 0.01 M potassium thiocyanate solution are added and thoroughly mixed. The glass tube is then placed in the water bath at 60.0±0.1°C for about 10 min. The reaction is initiated by adding 2.0 ml. of a nitric acid solution of ferric ammonium sulfate (at the same temperature), mixing them thoroughly, and replacing the glass tube in the water bath.

After 20 min. ±5 sec. after the addition of the ferric ammonium sulfate solution, the absorbance of the solution is measured at the wavelength of 460 mμ, using redistilled water as a reference. It is recommended that the solution in the glass tube be removed from the water bath and poured into the cell 20 sec. before the scheduled time.

The calibration curve I shown in Fig. 1 was obtained by procedure 1 by using standard iodide and iodate solutions of known concentrations and containing chloride of the concentration of 2000 p. p. m. As can be seen in Fig. 1, in the cases of iodide and iodate, the absorbance is identical for the corresponding concentrations.

Procedure (2) (for the Determination of Iodate in the Presence of Iodide).—To 10.0 ml. of the diluted sample taken in a separatory funnel, 1.0 ml. of a 0.014 M sodium nitrite solution is added and thoroughly mixed, followed by the addition of 2.0 ml. of a nitric acid solution of ferric ammonium sulfate, mixing, and the further addition of 5 ml. of carbon tetrachloride. The separatory funnel is shaken for about 10 sec. and the layers allowed to separate. The aqueous layer is then transferred to the glass tube; a small amount of carbon tetrachoride does not disturb the subsequent procedure. The glass tube containing the aqueous layer thus obtained is placed in the water bath at 60.0±0.1°C for about 10 min. Then the reaction is initiated by adding 1.0 ml. of a 0.01 M potassium thiocyanate solution (at the same temperature); the solution is mixed thoroughly, and the glass tube with the solution is replaced in the water bath. At 20.0 min. after mixing, the absorbance of the solution is measured in the same way as in procedure 1.

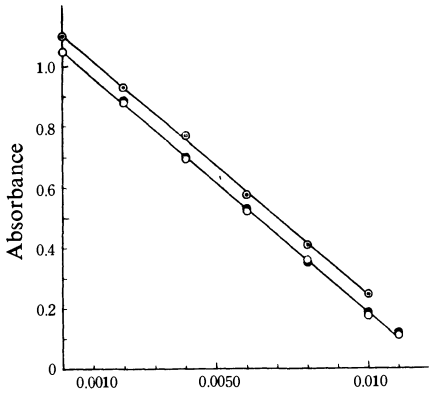

Fig. 1. Calibration curves.
In the presence of 2000 p. p. m. chloride
-○- I^- and -●- IO_3^- (I)
-⊙- IO_3^- (II)

The calibration curve II shown in Fig. 1 was obtained by procedure 2 by using standard iodate solutions of known concentrations and containing chloride of the concentration of 2000 p. p. m.

A difference between calibration curves I and II in Fig. 1 is probably caused by a loss (about 0.2 ml.) of solution during the extraction of procedure 2.

The catalytic reaction should be carried out in a dark place, thus avoiding an acceleration of the fading by sun light.[5]

Results and Discussion

The Effect of the Reaction Time.—Ten milliliters of a 0.010 p. p. m. iodide solution in the presence of 2000 p. p. m. chloride, 1.0 ml. of a 0.014 M sodium nitrite solution, 1.0 ml. of a 0.01 M potassium thiocyanate solution, and 2.0 ml. of a nitric acid solution of ferric ammonium sulfate were mixed and kept at 60°C. Reaction rate curve I shown in Fig. 2 was obtained by measuring the absorbances of this solution at various reaction times. Curves II and III in Fig. 2 were obtained by using a 0.005 p. p. m. iodide solution and redistilled water. It may be seen in Fig. 2 that the reaction rate increases with the amount of iodide and that differences in absorbances

-⊙- Redistilled water (III)

among the three curves increase with the reaction time. These results indicate that the sensitivity of the method increases with the reaction time. The solution with 0.010 p. p. m. iodide becomes almost colorless after 25 min. A reaction time of 20 min. is adequate because of the high sensitivity.

The Effect of Chloride.—In the absence of chloride, iodate showed a different catalytic effect on the reaction rate than did iodide.[5] However, it has been reported by Dubravčić[6] that iodate showed the same catalytic effect as iodide in the presence of a large amount of chloride in the ceric-arsenous acid method. The same effect was also found in this color-fading method. In the present work, the effects of chloride have also been examined, therefore.

Three curves, I, II and III, shown in Fig. 3 were obtained by procedure 1 by using both iodide and iodate solutions containing various amounts of chloride. In the presence of more than 1000 p. p. m. chloride, iodide solutions show the same absorbance as that of iodate solutions in the same concentrations. The presence of 2000 p. p. m. chloride is adequate to determine the amount of total iodine. Sea water diluted ten times, containing chloride of about 2000 p. p. m., is, consequently, suitable for determination by this method. Satisfactory results obtained by using mixtures of iodides and iodates of different concentration

ratios are listed in Table I.

The Concentration of Reagents. — A suitable concentration of a sodium nitrite solution was first sought. As iodide and iodate react with each other in an acidic solution, iodide must be oxidized to free iodine and then removed before the iodide-iodate reaction takes place. In the previous paper[3] a nitric acid solution of ferric ammonium sulfate was used for oxidation, but in the presence of a large amount of chloride, the separation of iodide from iodate was not quantitative. Both a sodium nitrite solution and a nitric acid solution of ferric ammonium sulfate are used for the oxidation of iodide. These reagents are not only the oxidizing agents, but also the reagents in the catalytic fading reaction. As an

oxidizing agent, 1 ml. of a 0.014 M nitrite solution was necessary for the quantitative separation of iodide from iodate.

After a satisfactory concentration of a nitrite solution was determined, the concentration of the thiocyanate solution was adjusted to provide a suitable calibration curve covering the range from 0.001 to 0.01 p. p. m. of iodine.

The Removal of Iodide. — An attempt was made to remove the iodide of various concentrations in solutions by procedure 2. The results listed in Table II show that satisfactory removals of iodide were carried out by this procedure. Absorbances by using iodide solutions are identical with that of the redistilled water within the range of experimental error.

The results listed in Table III were obtained by precedure 2 in the presence of various amounts of both iodide and iodate. As can be seen in Table III, the iodate remains quantitatively in the aqueous layer, while the iodide is completely removed. In the experiments described above, the extraction in procedure 2 was carried out within 15 min.

after the addition of the oxidizing agent. However, when this period was prolonged over 40 min., the results did not have a tolerable reproducibility.

The Effect of Diverse Ions.—To make clear the effect of diverse ions on this method, some experiments were made in the presence of 0.005 p. p. m. of both iodide and iodate ions, and in their absence. The experimental results are given in Table IV. Nitrate does not interfere at 1000 p. p. m., but it gives a slightly low absorbance at 6200 p. p. m. (about 0.1 M). Sulfate does not significantly interfere at 300 p. p. m. Oxidizing or reducing agents interfere at relatively low concentrations. Mercury and silver interfere remarkably. Most sea waters do not contain these substances in concentrations which cause serious interference. Most ions commonly occuring in sea water do not interfere.

The Results of Determination.—The determinations of the total iodine and iodate-iodine were made by using mixed solutions containing known amounts of iodide and iodate and 2000 p. p. m. of chloride. The results listed in Table V indicate the maximum error of ± 0.0003 μg. per l. Iodide-iodine is calculated by the difference between the total-iodine and the iodate-iodine.

The total iodine and iodate-iodine contents in several sea waters were determined by using sea water diluted about ten and twenty times with the addition of known amounts of chloride to give the concentration of 2000 p. p. m. of chloride. The results listed in Table VI are calculated to original concentrations, and the comparison of the two results mentioned above shows good agreement. The method was also checked by adding known amounts of both iodide and iodate to sea water to show the good recovery of both iodide and iodate (Table VII).

According to these results, it may be concluded that the present method is quite satisfactory for the determination of iodide and iodate contents in sea water.

Summary

In the presence of 2000 p. p. m. chloride, iodide and iodate show the same catalytic effect on the color-fading reaction of a solution of ferric thiocyanate. The total iodine content in sea water may be determined by estimating the absorbance of a sample diluted about ten times.

The iodide in the sample is first oxidized to free iodine by a sodium nitrite solution and a nitric acid solution of ferric ammonium sulfate. The resulting free iodine is removed by extraction with carbon tetrachloride. The iodate which remains quantitatively in the aqueous layer is determined by a similar procedure. The difference between the total iodine and the iodate-iodine gives the iodide-iodine.

By this method, the iodate and total iodine contents in sea water can be determined rapidly and accurately. It takes only about 2 ml. of sea water to determine both the total iodine and the iodate-iodine.

The author wishes to express his thanks to Professor Iwaji Iwasaki of the Tokyo Institute of Technology for advice and encouragement given in the course of the work. Thanks

are also due to Dr. Satori Utsumi of the Nihon University for his valuable advice. He is also much obliged to the members of the Laboratory of Analytical Chemistry and Geochemistry, Tokyo Institute of Technology, for their fruitful discussions.

*The Tautomerism and Methylation of 3, 6-Disubstituted Pyridazines**

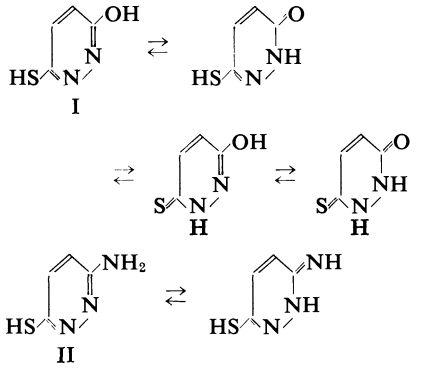
By Makoto FUJISAKA, Yoshio UENO, Hiroyuki SHINOHARA and Eiji IMOTO

(Received December 10, 1963)

The tautomerism of heteroaromatic compounds containing two different potentially tautomeric groups has not been widely studied. A recent investigation of 4-amino-6-hydroxypyrimidine and its related compounds reported by Brown and Harper[1] represents the only published case in which a 6-hydroxyl group exists predominantly in the keto form. This paper will deal with the tautomerism of 3, 6-disubstituted pyridazines which contain two different potentially tautomeric groups, such as OH, SH and NH_2. Furthermore, the attempted methylation of 3,6-disubstituted pyridazines will be discussed in connection with their tautomeric forms.

TABLE I. IONIZATION CONSTANTS OF SUBSTITUTED PYRIDAZINES, IN WATER AT 20°C

Compound R	Compound R′	Acidic pK_a	Basic pK_a
SH	OH	3.32	−1.39
SCH_3	OH	10.11*	(−)
SH	OCH_3	6.95*	−2.36
SCH_3	OCH_3	—	1.84
Cl	NH_2	—	3.85
SH	NH_2	9.05*	−0.14
SCH_3	NH_2	—	5.61
Cl	$NHCH_3$	—	4.01
SH	$NHCH_3$	9.46*	−0.04
SCH_3	$NHCH_3$	—	5.94
Cl		—	3.51
SH		9.31	−0.06
SCH_3		—	5.13
			
R			
OH		5.46*	−1.32
SCH_3		—	(−)



* These values were obtained by potentiometric titration and the values without asterisk were measured by means of spectrophotometric method. (−) means that spectrophotometric method did not allow to give pK_a value.

* Part of the data given in this article were presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

Results and Discussion

The compounds studied in this work are listed in Table I, together with their ionization constants in aqueous solutions. These compounds were prepared by the method shown in Fig. 1, and their pK_a values were determined by potentiometric titration or the spectrophotometric method.[2]

Preferred Tautomeric Forms. — The conceivable tautomeric forms for 3-hydroxy-6-mercaptopyridazine (I)[3] and 3-amino-6-mercaptopyridazine (II)[4] in aqueous solutions may be written as follows:

I

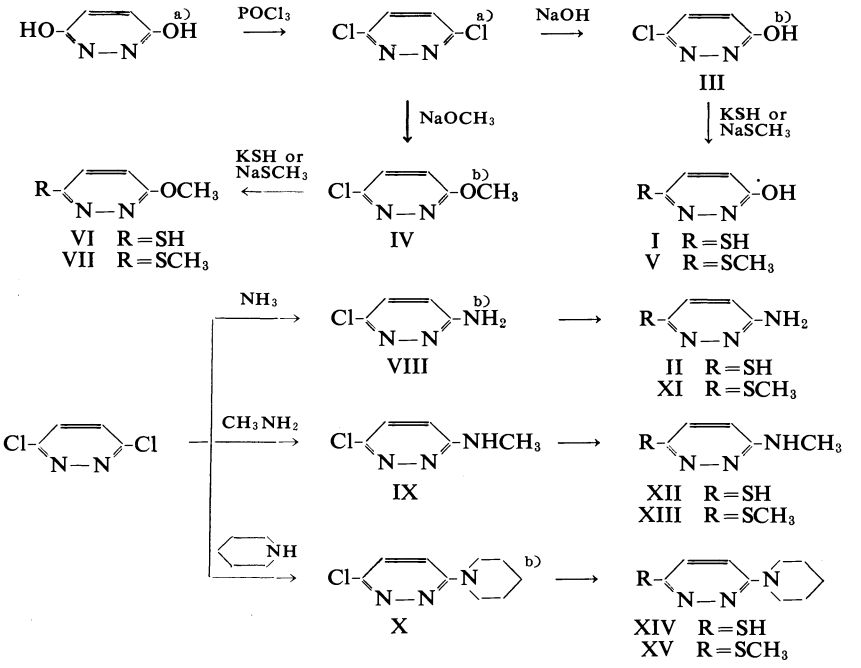
II

1) D. J. Brown and J. S. Harper, *J. Chem. Soc.*, **1961**, 1298.

2) L. A. Flexser, L. P. Hammett and A. Dingwall, *J. Am. Chem. Soc.*, **57**, 2103 (1935).

3) J. Druey, Kd. Meier and K. Eichenberger, *Helv. Chim. Acta*, **37**, 121 (1954).

4) H. G. Morren, Belg. Pat. 579291 (1959).



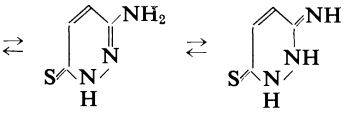


Fig. 1. The synthesis of the compounds.

a) R. H. Mizzoni and P. E. Spoerri, *J. Am. Chem. Soc.*, **73**, 1873 (1951).

b) J. Druey, Kd. Meier and K. Eichenberger, *Helv. Chim. Acta*, **37**, 121 (1954).

These compounds are also capable of existing in three forms, i. e., the neutral, anionic and cationic forms, depending on the pH values of the solutions. In the pH regions above the acidic values and below the basic values of their pK_a's, these compounds would be largely in the anionic and cationic forms respectively. In the pH range between the acidic and basic values of their pK_a's, these compounds would predominantly be in neutral forms and exhibit the tautomeric equilibria shown above.

In order to assign the preferred tautomer of 3-hydroxy-6-mercaptopyridazine (I) in an aqueous solution, the ultraviolet spectrum of the neutral species of I measured at pH 3.02 was compared with that of 3-mercapto-6-methoxypyridazine (VI) in which the tautomerism of the hydroxyl group of I had been inhibited. The spectra of the two compounds closely resemble each other in shape, as is shown in Fig. 2. Thus, it is highly probable that the lactim form predominates over the lactam form in the tautomerism of I. Furthermore, since the spectrum of I is markedly different from that of 3-methoxy-6-methylthiopyridazine (VII), the proportion of the thiolactam form of I should be very large. However,

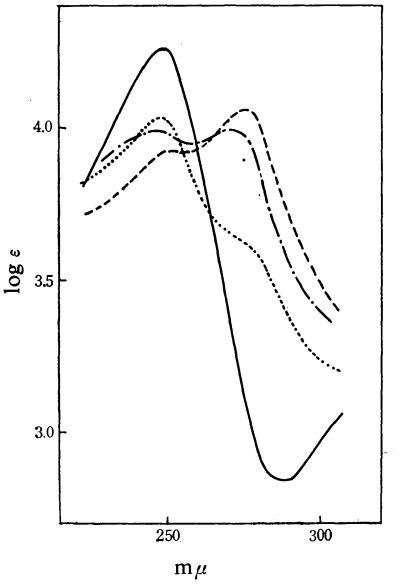

Fig. 2. Ultraviolet absorption spectra of neutral species in the aqueous solution;

---- 3-hydroxy-6-mercaptopyridazine (I) (pH 3.02),

- - - - 6-mercapto-3-methoxypyridazine (VI) (pH 2.87),

—— 3-hydroxy-6-methylthiopyridazine (V) (pH 6.28) and

------ 3-methoxy-6-methylthiopyridazine (VIII) (pH 5.38).

the spectrum of the neutral species of 3-hydroxy-6-methylthiopyridazine (V) differs from that of the compound VII. This seems to mean that V exists predominantly in the lactam form.

For assigning the preferred tautomers of 3-amino-6-mercaptopyridazine (II), 3-mercapto-6-methylaminopyridazine (XII) and 3-mercapto-6-piperidinopyridazine (XIV) in aqueous solutions, the tautomerism between amino and imino forms for II and XII was first examined. The ultraviolet absorption spectra of 3-amino-6-chloropyridazine (VIII) and 3-chloro-6-methylaminopyridazine (IX) were measured and compared with that of 3-chloro-6-piperidinopyridazine (X), in which the tautomeric hydrogen atom is lacking. The spectra of VIII, IX and X closely resemble one another in shape, as may be seen in Fig. 3.

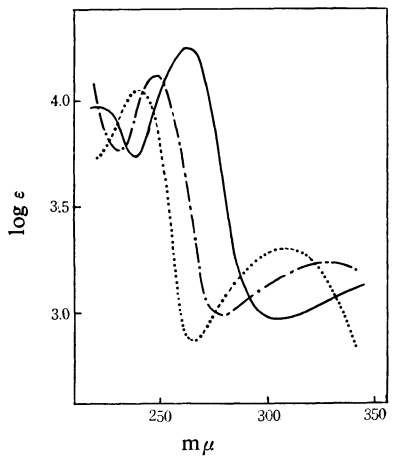

Fig. 3. Ultraviolet absorption spectra of neutral species in the aqueous solution;
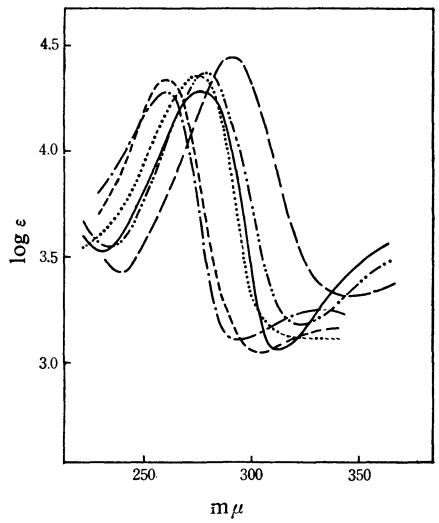
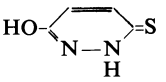
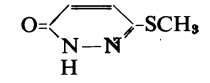
------ 3-amino-6-chloropyridazine (VIII) (0.1N NaOH),
—·— 6-chloro-3-methylaminopyridazine (IX) (0.1N NaOH) and
—— 6-chloro-3-piperidinopyridazine (X) (0.1N NaOH).

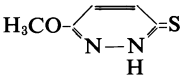
Therefore, the amino group of II and the methylamino group of XII may exist predominantly in the amino and methylamino forms respectively. The marked differences which appeared in the spectra of the neutral species of the three pairs, II and XI, XII and XIII, and XIV and XV, (cf. Fig. 4), provide strong evidence that II, XII and XIV exist predominantly in the thiolactam forms rather than in thiol forms in aqueous solutions.

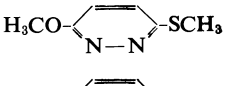
The Infrared Spectra of Substituted Pyridazines. — The infrared spectra of substituted pyridazines were measured in the solid states to verify the above conclusions. The results

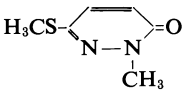


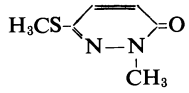


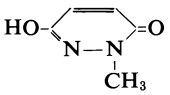


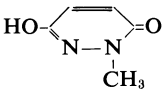


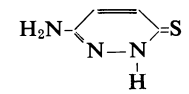


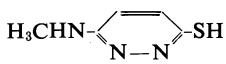


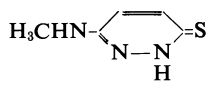


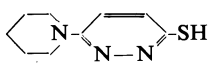


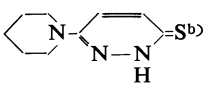


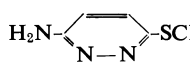


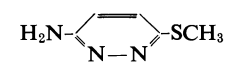


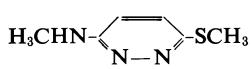


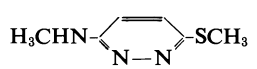


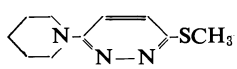












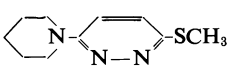


Fig. 4. Ultraviolet absorption spectra of neutral species in the aqueous solution;
—— 3-amino-6-mercaptopyridazine (II) (pH 5.38),
---- 3-amino-6-methylthiopyridazine (XI) (pH 6.28),
-·-·- 3-methylamino-6-mercaptopyridazine (XII) (pH 5.38),
- - - - 3-methylamino-6-methylthiopyridazine (XIII) (pH 6.28),
—— 6-mercapto-3-piperidinopyridazine (XIV) (pH 6.33) and
------ 6-methylthio-3-piperidinopyridazine (XV) (0.1N NaOH).

are summarized in Table II. As Table II illustrates, the structures of pyridazine derivatives in the solid states may be presumed to be identical with those of the neutral species suggested above in aqueous solutions.

The Ultraviolet Absorption Spectra of I and II in Various Solvents. — Since tautomerism is known to be affected by the nature of the solvents, the ultraviolet absorption spectra of I and II were measured in various solvents with different dielectric constants. Figure 5 shows that the absorption maxima shift toward the longer wavelength region with the decrease in dielectric constants for the solvents used.

Methylation of Compounds I and II. — The methylation of I and II with methyl iodide or dimethyl sulfate was studied. The results are listed in Table III. The thiol groups of I and II were found to be methylated more readily than the amino or the hydroxy groups under any conditions examined. However, when the methylation of I was carried out with dimethyl sulfate under the conditions described in Table III, a compound with an m.p. of 27~29°C, (XVI), was obtained as the major product. The results of the elementary analysis of XVI were in agreement with the calculated values

Estimated band intensities are given as strong (s), medium (m) and weak (w), and a shoulder band is shown as (sh). a) E. Spinner, *J. Chem. Soc.*, **1960**, 1237. b) The structure of this compound was not certain because $\nu_{C=S}$ could not be found for this compound.

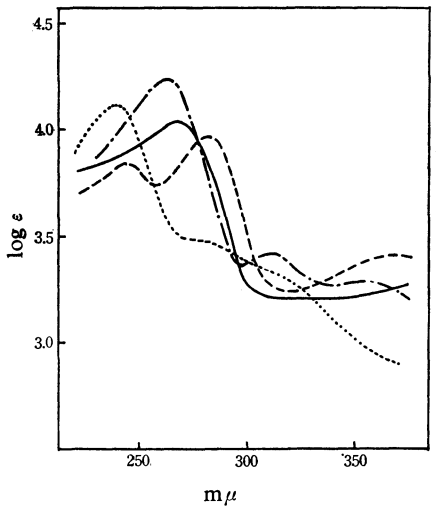

Fig. 5-a. Ultraviolet absorption spectra of 3-hydroxy-6-mercaptopyridazine; ---- in ethanol, —— in ethanol-water 1 : 1, —·— in water and ------ in 40% sulfuric acid.

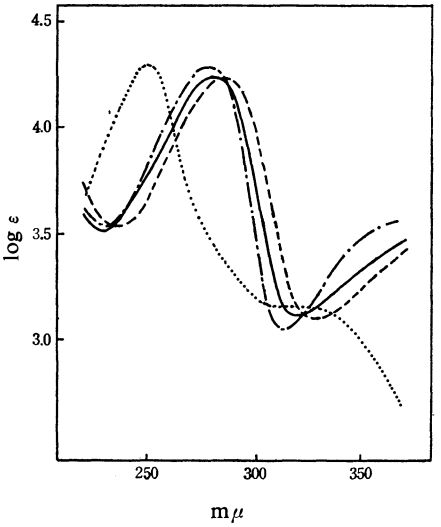

Fig. 5-b. Ultraviolet absorption spectra of 3-amino-6-mercaptopyridazine; ---- in ethanol, —— in ethanol-water 1 : 1, —·— in water and ------ in 20% sulfuric acid.

for the dimethylated compound of I. The spectrum of the neutral species of XVI closely resembles that of the neutral species of 3-hydroxy-6-methylthiopyridazine (V), the preferred tautomeric form of which was proposed in a previous section of this paper to be the lactam form (see Fig. 6).

The infrared spectrum of XVI shows a very strong absorption band at 1682 cm^{-1} due to carbonyl stretching vibration. On the basis of these results, the most reasonable structure assigned for XVI seems to be 2-methyl-6-methylthio-2, 3-dihydropyridaz-3-one.

Table III. Methylation of I and II

Compound	Methylating agent	Solvent	Added base	Reaction Temp. °C	Reaction Time hr.	Product	Yield %
I	CH_3I[a]	CH_3OH	$NaOCH_3$	70	1	V	78

---- 3-hydroxy-6-methylthiopyridazine (V) (0.1M H_2SO_4).

Experimental

The Measurement of pK_a's Values.—pK_a values for the compounds which were soluble in water were measured by potentiometric titration, and those for the compounds which were sparingly soluble in water, by the spectrophotometric method.

The Measurement of the Ultraviolet Spectra.—The ultraviolet spectra were measured with a Hitachi EPS-2 spectrophotometer. The measurements were made in buffered, acidic or alkaline solutions and the pH value of each solution was adjusted so that more than 99% of the compound might exist in the form of neutral, cationic or anionic species in the solution, as expected from the pK_a values for the compound.

The Measurement of Infrared Spectra. — The infrared spectra were recorded with a Hitachi EPI-2 spectrophotometer by means of the potassium bromide disk technique.

Materials.—The compounds, I,[3] II,[4] 3-amino-6-chloropyridazine,[3] 3-chloro-6-hydroxypyridazine[3] and 3-chloro-6-methoxypridazine,[3] were synthesized by the known methods and purified until their physical constants gave values identical with those given in the literature.

3-Chloro-6-methylaminopyridazine (IX).—A mixture of 3.5 g. of 3,6-dichloropyridazine[5] and an aqueous solution containing 1 g. of methylamine was heated in a sealed tube at 120~130°C for 9 hr. After it had cooled, the resultant solid was collected by filtration. Recrystallization from water gave 2.3 g. of colorless needles of IX, m. p. 198~199°C. Found: N, 29.28. Calcd. for $C_5H_6ClN_3$: N, 29.27%.

A General Method for the Preparation of 3-Substituted 6-Mercaptopyridazine from 3-Substituted 6-Chloropyridazine. — A mixture of 3-substituted 6-chloropyridazine and 2 N ethanolic potassium hydrogen sulfide was heated in a sealed tube. After it had cooled, the reaction mixture was filtered to remove potassium chloride, and then the filtrate was evaporated to dryness under reduced pressure. The residue was recrystallized from a suitable solvent to obtain the product, as is shown in Table IV.

A General Method for the Preparation of 3-Substituted 6-Methylthiopyridazine from 3-Substituted 6-Chloropyridazine.—A mixture of 3-substituted 6-chloropyridazine and a 40% aqueous solution of sodium thiomethylate was heated in a sealed tube. The reaction mixture was then evaporated to dryness under reduced pressure, and the residue was recrystallized from a suitable solvent to obtain the product, as is shown in Table V.

The Methylation of I with Methyl Iodide.—a) To a solution of sodium methoxide which had been prepared from 0.3 g. of sodium and 20 ml. of methanol, 1.3 g. of 3-hydroxy-6-mercaptopyridazine (I) and 1.5 g. of methyl iodide were added. The mixture was heated in a sealed tube at 70°C for 1 hr. and then cooled and filtered to remove sodium iodide. The filtrate was evaporated to dryness, and the residue was dissolved in water and then acidified to precipitate the product. Recrystallization from water gave 1.1 g. of colorless crystals (m. p. 131.5 ~133°C, undepressed on admixture with an authentic sample of 2-hydroxy-6-methylthiopyridazine (V)). The reaction products were always the same although the molar ratios of I to methyl iodide changed from one to two.

b) When sodium hydrogen carbonate was used instead of sodium methoxide, only V was obtained, in a 63% yield.

The Methylation of I with Dimethyl Sulfate.—A mixture of 1 g. of I and 1 g. of dimethyl

5) R. H. Mizzoni and P. E. Spoerri, *J. Am. Chem. Soc.*, 73, 1873 (1951).

sulfate was heated on a steam bath for 1 hr. After the reaction mixture had been made alkaline by the addition of an aqueous solution of sodium carbonate, the solid which precipitated was collected by filtration. Recrystallization from water gave 0.8 g. of colorless crystals of V, m. p. 130~132°C. When the alkaline solution was extracted with ether, the ether extract gave 0.1 g. of colorless crystals, (m.p. 27~29°C) after evaporation.

The Methylation of II with Methyl Iodide.—a) The methylation was carried out in a sealed tube at 70°C for 1 hr. by a procedure similar to that used in the methylation of I. The product, 3-amino-6-methylthiopyridazine (XI), recrystallized from benzene, melted at 116~117°C and was not depressed on admixture with an authentic sample.

b) When sodium hydrogen carbonate was used instead of sodium methoxide, the reaction product was also only XI, in an 81% yield.

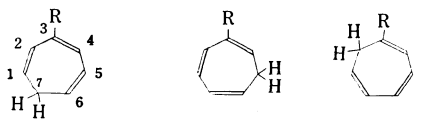
The Thermal Isomerization and Nuclear Magnetic Resonance Spectra of Tropyltropolones

By Takahiro TEZUKA

(Received December 13, 1963)

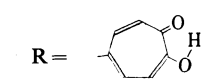
Nozoe et al.[1] have obtained five different tropyltropolones by the reaction of tropylium ions with tropolone. Of those tropyltropolones, structures for isomeric 5-tropyltropolone (II) and 3-tropyltropolone (III) have been suggested on the basis of ultraviolet spectral data.[1]

In order to obtain a more definite basis for the assigned structures, the present author has compared the nuclear magnetic resonance (NMR) spectra of several tropilidene derivatives and found the assigned structure to be correct. This paper will deal with these results, as well as with the thermal isomerization of tropyltropolones.



In the 40 Mc. NMR spectra of 5-tropyltropolone (I), a triplet (J=4.0 c.p.s.), a quartet, a multiplet and a triplet (J=1 c.p.s.) appear at 7.34, 4.82, 3.87 and 3.44 τ respectively. The proton ratio of these absorptions is 1 : 2 : 2 : 2 (Fig. 1). In the NMR spectra of the other 7-substituted tropilidenes (III, IV, V, VI, VII, VIII and XI), the same coupling patterns concerning the absorption of the tropyl group appear at approximately the same position and with the same proton ratio as those of 5-tropyltropolone, as is indicated in Table I. Therefore, the author has classified the proton absorptions of the tropyl group of those derivatives into four groups: A, B, C and D.*

A is a triplet (J=4~6 c.p.s.) at 6.5~7.8 τ (the position of which is especially affected by the substituent group at C_7), B is a quartet at 4.5~4.8 τ, C is a multiplet at 3.6~3.9 τ, and D is a triplet (J=2~3 c.p.s.) at 3.3~3.5 τ.



Proton assignments of tro ilidene have been made by Burton et al.[2] and by Isobe[3]. A comparison of these results shows that the absorptions A, B, C and D should be assigned to the protons at C_7, C_1+C_6, C_2+C_5 and C_3+C_4 respectively.

Taking this assignment into account, we will compare the NMR spectra of isomeric 5-tropyltropolone (II) with I to derive a reasonable structure for II.

Three possible formulae can be written for the isomeric 5-tropyltropolone structure (IIa, IIb and IIc):

IIa IIb IIc

The triplet at 7.71 τ in the NMR spectrum of II rules out the formula IIc. The formula

1) T. Nozoe, T. Mukai and T. Tezuka, This Bulletin, **36**, 1470 (1963).

* The 60 Mc. NMR spectra of phenyltropilidene (VII), taken with a Varian Associate HR-60 spectrometer, reveals that the basic coupling pattern is just the same as that of 40 Mc. The only difference is that the former has the fine structure of the each peak, A, B, C and D, due to the long-range coupling. The author wishes to thank Dr. Roy King for his measurement of the NMR spectra and his discussions.

2) R. Burton, L. Pratt and G. Willikinson, *J. Chem. Soc.*, **1961**, 594.

3) T. Isobe, presented at the 12th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1959.

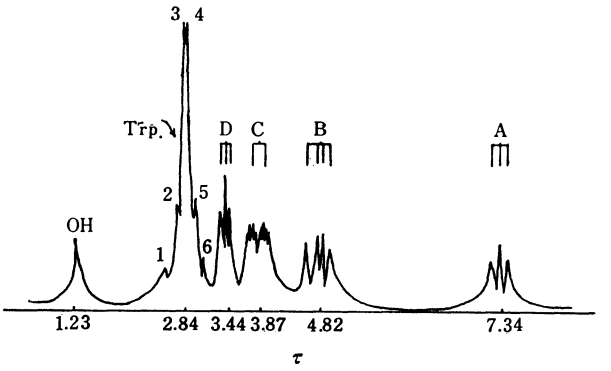


Fig. 1. NMR spectrum of compound I at 40 Mc.

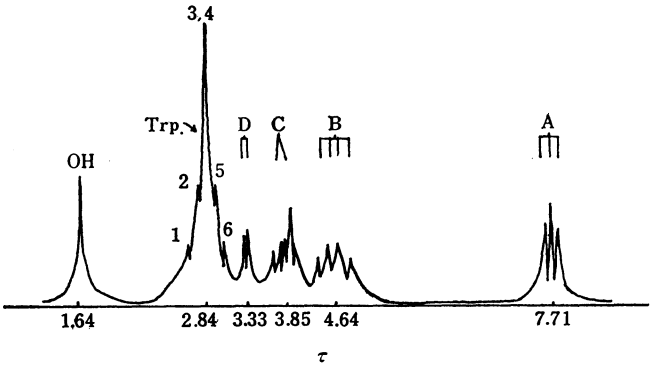

Fig. 2. NMR spectrum of compound II at 40 Mc.

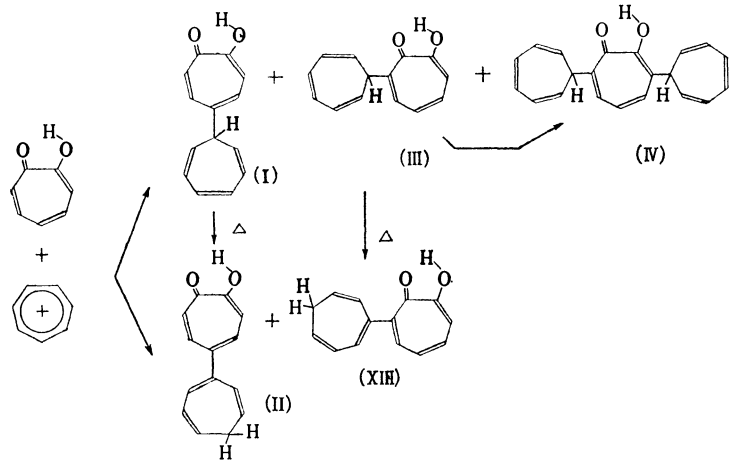
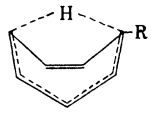


IIb may also be ruled out for the following reasons.

In the NMR spectra of I and II, the most significant difference is observed in the absorptions C and D. In the NMR spectrum of II (Fig. 2) a doublet (J=4.4 c.p.s.) and a multiplet appear at 3.33 τ (corresponding to the D absorption) and at 3.85 τ (C) respectively, while in the NMR spectrum of I a triplet and a multiplet apprear at 3.44 τ (D) and at 3.87 τ (C) respectively. The proton ratio of the absorption D to the absorption C of II is 1 : 2, while that of I is 2 : 2. These results are most reasonably explained by assuming the formula IIa thus ruling out IIb. A proton of C_4 in IIa appears at 3.33 τ, giving rise to a doublet, and the protons of C_2+C_5 at 3.84 τ, giving the multiplet. Therefore, the formula IIa is concluded to be correct for the structure of II; this is quite consistent with Nozoe's result.[1]

Nozoe et al.[1] have also mentioned that the isomeric 5- and 3-tropyltropolones, II and XIII, were obtained when the raection mixture of tropylium ions and tropolone was distilled at 180°C while the other tropyltropolones, I, III and IV, were obtained when the separation was carried out with the reaction mixture by recrystallization. This evidence seems to suggest that the isomeric tropyltropolones II and XIII come from either I, III, or IV by thermal isomerization when distilled. This assumption is justified as follows. The distillation of 5-tropyltropolone (I) at 180°C gives an oil (b. p. 173°C/3 mmHg) which soon crystallizes to afford the isomeric 5-tropyltropolone (II) (m. p. 98°C) in a good yield. Because only a small amount of 3-tropyltropolone (III) is available, the thermal isomerization reaction has not been carried out with III. The same treatment of 3, 7-ditropyltropolone (IV), however, gives neither the isomeric 3, 7-ditropyltropolone nor 3- and 5-tropyltropolones, XIII and II. Therefore, it may be concluded on the basis of the evidence given by Nozoe et al.[1] and by the present author that the isomeric 3-tropyltropolone (XIII) comes from III by thermal isomerization. 3, 7-Ditropyltropolone (IV) is derived from 3-troplytropolone (III) by the reaction of one mole equivalent of tropylium ions.



The above relationship between tropyltropolones can be given as:

The isomer IIa was the only product obtained by the isomerization of I. The reason for this is that the most stable isomer with regard to the length of the conjugated system

and the steric conditions is IIa. While IIc has the longest conjugation system between three double bonds of the tropyl group and the tropolone molecule, the methylene group of C_7 prevents the coplanality of the tropyl group with the tropolone molecule, thus inhibiting the resonance stabilization, and making IIc less stable than IIa. In IIb, there is no such steric hindrance, but the conjugated system is shorter; thus IIb is less stable than IIa.

For the mechanism of the migration of hydrogen in the thermal isomerization of 7-d-tropilidene, Ter Borg et al.[4] have proposed the 1, 5-transannular migration of hydrogen, as is pictured in XIV. It is also probable that the 1, 5-transannular migration of hydrogen is involved in our case, as is indicated in XV.[5] The conjugation of the tropolone molecule in the transition state decreases the activation energy for this migration, facilitating the isomerization.

XIV: R=D XV: R=Tropolone

The auther wishes now to discuss the NMR spectra of the tropilidene derivatives listed in Table I.

The most striking fact to be pointed out is the difference in the chemical shift of the methine and methylene protons (absorption A) of those derivatives. Looking at the chemical shift of methine protons of the compounds I, VII and VIII, we find that these protons appears at a lower field by 0.4~0.5 p.p.m. than the methylene protons of tropilidene (XII). On the other hand, the methylene protons of the tropyl derivatives, II, IX and 3-phenyltropilidene,[11] which are the isomer of I, VIII and VII respectively, appear at approximately the same position as tropilidene (XII). Obviously, the cause of this low field shift of the methine protons should be attributed to the effect of the phenyl or tropolone molecule substituted at the C_7 of tropilidene. However, it is rather surprising that the low field shift is not so large as would be expected from the usual substituent effect of the phenyl group.[6]

α-Protons are usually affected by the phenyl group to show a low field shift of approximately 1.5 p.p.m. when the phenyl group is substituted for hydrogen on an alkane.[6] Thus the methylene protons of *n*-propane appear at 8.75 τ, while the methine proton of isopropylbenzene appears at 7.10 τ.[6]

The reason for this small shift seems to be that the double bonds of the tropyl group have some shielding effect upon the methine proton.[7,8] Although the theory and the magnitude of the shielding effect of the tropyl group are not clear, we can understand such a tendency of the tropyl group when we look at the NMR spectrum of ditropyl (XI). The shift of the methine protons of XI are slightly higher than that of the methylene protons of tropilidene, suggesting that the double bonds of the tropyl group have the effect of increasing the effective shielding of the methine proton at C_7.[7,8]

The fact that the methine proton of 5-tropyltropolone (I) shifts to a low field by the

TABLE I. THE PROTON CHEMICAL SHIFT OE THE TROPYL GROUP IN THE SUBSTITUTED TROPILIDENES

No.	Compound	Group A (τ)	B	C	D	Ref.
I		7.34 (J=4.0)	4.82	3.87	3.44	1 (J=c.p.s.)
II		7.71 (J=6.0)	4.64	(3.85)	(3.33)	1
III		6.50 (J=5.7)	4.76	3.88	3.52	1
IV		6.48 (J=5.1)	4.64	3.76	3.40	1
V		6.37 (J=4.8)	4.82	3.87	3.63	10
VI		6.58	4.72	3.80	3.46	10
VII		7.30 (J=5.0)	4.78	3.80	3.34	11,12
VIII		7.41	4.57	3.85	3.33	5
IX		7.67	4.50	3.62	3.28	5
X		7.75 (J=6.7)	4.64	—	—	14
XI		8.10 (J=3.0)	4.82	3.88	3.42	13
XII		7.84 (J=6.2)	4.81	3.94	3.54	2,3

same degree as in phenyl tropilidene (VII) indicates that the tropolone molecule also has the effect of deshielding the methin protons by the same degree as benzene. Probably, the six-π-electron circulation in the tropolone molecule occurs when it is placed in a magnetic field as in the benzene molecule.

One more point of interest is that the different coupling patterns of the tropolone ring protons are observed with different tropyltropolones. The ring protons of 5-tropyltropolones (I and II) are expected to show A_2B_2-type coupling, while 3,7-ditropyltropolone (IV) show AB_2-type coupling. Actually, the symmetrical A_2B_2-type coupling[9] are observed at 2.84 τ in the NMR spectra of I and II, as is indicated in Figs. 1 and 2. In the case of I, six lines can be recognized.

An unsymmetrical coupling pattern of the

tropolone ring proton of compound IV[1],* is oberved which is very similar to the theoretical pattern of the AB_2 system.[9] Almost the same coupling is observed for the ring protons of compound VI.[10],*

The methine proton lines of the tropyl group of compounds III, IV, V and VI, in which the tropyl groups are present at the ortho-position of tropolone, appear at an even lower field than those of compounds I, VII and VIII. The chemical shifts of those protons are lower by 1.3 p.p.m. than the methylene protons of tropilidene. The methine protons of III, IV, V and VI will be greatly deshielded by both the ring current and the oxygen functions of of tropolone. However, the details of these effects are too complicated to discuss here; further studies are necessary.

Experimental

Isomeric 5-Tropyltropolone (II) from I. — I (500 mg.) was heated at 180~200°C for 20 min. and then distilled to give an oil, b. p. 170°C/4 mmHg, which soon crystallized to afford 500 mg. of crystals, m. p. 80~85°C. Recrystallization from the mixed solvent of ethanol and benzene gave yellow needles, m. p. 98°C (II), identified by a mixed melting point determination and by a comparison of the infrared spectra with those of an authentic sample.[1]

3, 7-Ditropyltropolone (IV) from III.—A mixture of 250 mg. of III and 117 mg. of ditropylether[14] in 2.5 ml. of absolute ethanol was heated under reflux for 3 hr. The evaporation of the solvent gave 360 mg. of crystals, m. p. 90~100°C, which afforded yellow needles, m. p. 135°C (IV), on recrystallization from ethanol. The crystals obtained were confirmed to be identical with 3,7-ditropyltropolone[1] by mixed melting point determination and by a comparison of infrared spectra.

NMR Spectra Measurement.—The NMR spectra of the tropyl derivatives (I—X) were measured with a Varian Associates V 4200 B spectrometer (40 Mc.) in carbon tetrachloride solutions, using cyclohexane as an inner reference.* The NMR spectrum of IX was measured with a 60 Mc. Hitachi NMR spectrometer in a carbon tetrachloride solution, using tetramethyl silane as an inner reference.

The author wishes to express his gratitude to Professor Tetsuo Nozoe for his guidance throughout this study. The author also wishes to express many thanks to Professors Toshio Mukai, Kahei Takase, Taro Isobe, Dr. Takashi Toda and Mr. Kenichi Abe for their helpful discussions and assistance.

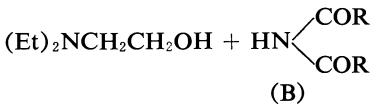
*The Reaction of 2-(Diethylamino)ethanol with Imides**

By Tsuyoshi OGATA



(Received December 27, 1963)

In the previous paper of this series,[1] it was reported that the imides of dibasic acids (A) were condensed with 2-(diethylamino)ethanol (C) with the elimination of water, while the imides of monobasic acids (B) were converted into the corresponding amides and the esters of the aminoalcohol (C) in good yields.

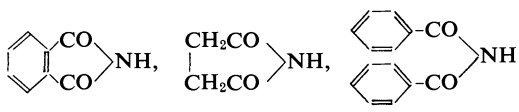
$$(Et)_2NCH_2CH_2OH + HN\begin{matrix}CO\\CO\end{matrix}R \rightarrow (Et)_2NCH_2CH_2N\begin{matrix}CO\\CO\end{matrix}R + H_2O \quad (1)$$

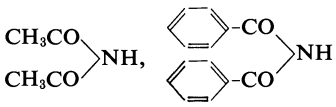
(C) (A)

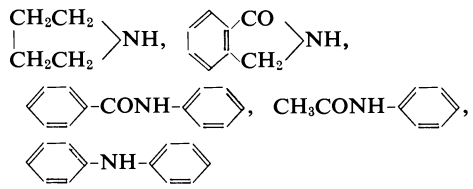
$$(Et)_2NCH_2CH_2OH + HN\begin{matrix}COR\\COR\end{matrix} \rightarrow (Et)_2NCH_2CH_2O\cdot COR + RCONH_2 \quad (2)$$

(B)

The present investigation has been undertaken to clarify the cause of the different in reactivity on the aminoalcohol (C) between the imides of dibasic acids (A) and those of monobasic acids (B).







Experimental Results and Discussion

The Reaction of 2-(Diethylamino)ethanol (C) with Imides or Their Analogues.[1]—The rerults summarized in Table I show that: 1) The presence of two carbonyl groups attached to

TABLE I. RELATIVE REACTIVITIES OF IMIDES AND THEIR ANALOGUES ON THE AMINOALCOHOL (C)

No.	Imides or their analogues	Type of reaction	Note
(I)		Eq. 1	The aminoalcohol (C) does not react below 180°C. Usual alcohols and amino-*t*-alcohol do not react with imides (A).
(II)		Eq. 2	Usual alcohols react with imides (B).
(III)		No reaction	
(IV)		No reaction	

an imino group is essential to both reactions, 1 and 2.

2) The imides of dibasic acids (cyclic imides)** (A) are condensed with the aminoalcohol (C) with the elimination of water.

3) The imides of monobasic acids (straight-chain imides)** (B) are converted into the corresponding amides and the esters of the aminoalcohol (C).

4) Usual alcohols do not react with the imides of dibasic acids (A). Therefore, a diethylamino group in the aminoalcohol (C) is necessary for reaction 1.

5) The imides of monobasic acids (B) react with alcohols in the same manner as with the aminoalcohol (C). Thus, an attack of the alcohol or the aminoalcohol (C) on acyl groups seems to be easier than that on an imino group of imide (B).

Reaction of 2-(Diethylamino)ethanol (C) with Unsymmetrical Imides of Monobasic Acids (B).[2] —In these experiments the reactivities of the two acyl groups in imide were compared. The experimental data are shown in Table II.

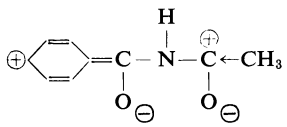
The data in Table II lead to the following conclusions:

1) In the cases of I, II, IV, and V, unsymmetrical imides predominantly yield the esters of the stronger acids. In the cases of VI and VII, however, unsymmetrical imides yield the esters of the weaker acids exclusively. Therefore, it seems that the steric influence predominates over the acidity of the acyl group.

2) I and II, where the parent acids are of approximately the same strength, gave the esters in a different molar ratios. These results may be explained by the greater steric hindrance of the isobutyryl group over that of the propionyl group.

3) In the case of III, the ester of the weaker acid forms predominantly.

As Fig. 1 shows, the resonance in the benzoyl group would disperse the postive charge of the carbonyl carbon atom into a benzene ring, making the benzoyl group less susceptible to a nucleophilic attack than the acetyl group, which would be polarized by the inductive effect of the methyl group.[3]



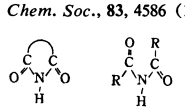


Fig. 1.

Reaction Mechanism

1) In discussing the reaction mechanism, it is first necessary to consider the role of a diethylamino group in 2-(diethylamino)ethanol (C).

Recently, Komori and his co-workers[4]

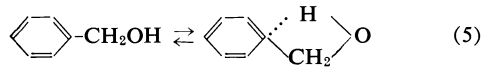
reported that, in the preparation of polyhydroxyethylene alkyl ether from alcohol and ethylene oxide in the presence of tertiary amine serving as a catalyst, the reaction rate increased in proportion to the basicity of the amine and considerably decreased as *N*-substituents of the amine became bulky. In this reaction, therefore, it seems that a hydroxyl group in alcohol is activated by tertiary amine, as is shown in Eq. 3.

$$ROH + R'_3N \rightarrow R-\overset{\delta-}{O}-H\cdots\overset{\delta+}{N}R'_3 \qquad (3)$$

Douheret and Pariaud[5] suggested the presence of an intramolecular hydrogen bond in dialkylaminoethanol on the basis of their measurement of its infrared sepctrum in carbon tetrachloride. Therefore, a hydroxyl group in 2-(diethylamino)ethanol seems to be activated by a diethylamino group, as is shown in Eq. 4.

$$(Et)_2NCH_2CH_2OH \rightleftharpoons$$



(4)

Furthermore, in the reaction of benzyl alcohol on dibenzamide, benzamide and benzyl benzoate were produced in good yields.[1] In the case of lauryl alcohol, however, in spite of a longer reaction time, benzamide

5) G. Douheret and J. C. Pariaud, *J. Chim. Phys.*, **59**, 1021 (1962).

and lauryl benzoate were produced in lower yields than in benzyl alcohol.

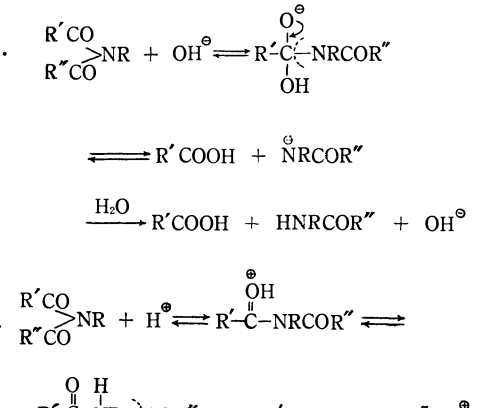
Ōki and Iwamura[6] concluded that in benzyl alcohol there is an interaction between an aromatic nucleus and a hydroxyl group, as is shown in Eq. 5. Therefore, it seems that a hydroxyl group is activated by an aromatic nucleus and that, toward dibenzamide, benzyl alcohol is more reactive than lauryl alcohol.

(5)

2) Lamberton and Standage[7] investigated the alkaline and acid hydrolysis of some *N*-acylbenzamides ($x\,C_6H_4CONRCOR'$) and found that in the alkaline medium the ortho-substituent x almost completely prevented the attack of hydroxyl ions on the nearer carbonyl group, while meta- and para-substituent did not have such a steric effect. Thus, *N*-acyl ortho-substituted benzamides gave ortho-substituted benzamide ($x\,C_6H_4CONHR$) and acid (R'COOH) upon alkaline hydrolysis, while meta- and para-substituted benzamides gave the stronger acid preferentially.

In the acid hydrolysis, on the other hand, the ortho-substituent showed no sign of the steric effect. In meta- and para-substituted benzamides, the weaker acid was liberated preferentially.

From these facts, it may be generally concluded that in the alkaline hydrolysis, the S_N2-type mechanism is operative, as is shown in Fig. 2-A, while in the acid hydrolysis, the results are explicable by the formation of acylium ions, as is shown in Fig. 2-B.



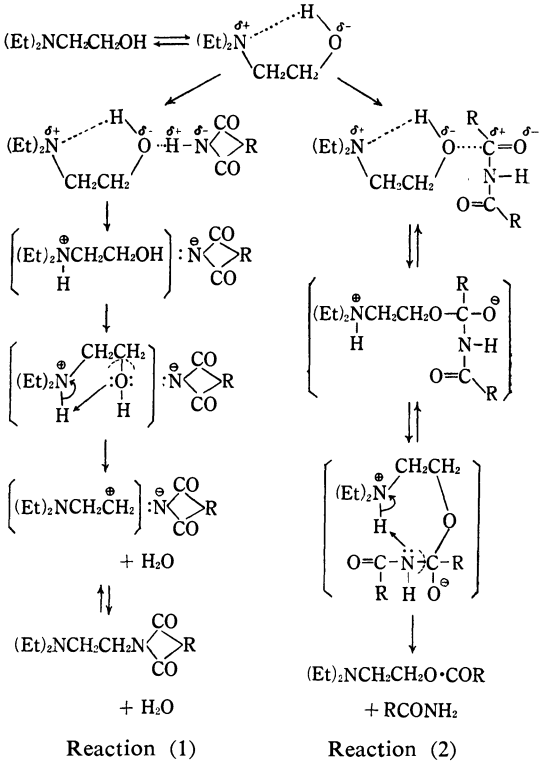


Fig. 2.

Tedder[8] summarized the reactions of unsymmetrical carboxylic anhydrides on amines or ethanol and showed that these reactions proceeded in the same fashion as the alkaline hydrolysis of diacylamines mentioned above. Furthermore, he showed that Friedel-Crafts acylation by unsymmetrical carboxylic anhydrides in the presence of aluminum chloride proceeded in the same fashion as the acid hydrolysis of diacylamine, and that the ketones derived from the weaker acids were produced preferentially.

On the basis of these data, reasonable conclusions may be deduced as follows:

i) In the case of the imides of monbasic acids (B), a nucleophilic attack of the aminoalcohol (C) will occur preferentially at the more positive carbonyl group and, when the position is sterically hindered, at another, less hindered carbonyl group.

Reaction (1) Reaction (2)

Fig. 3. Reaction mechanism of 2-(diethylamino)ethanol with imides

ii) In the case of the imides of dibasic acids (A), it seems that, on account of the steric hindrance of the carbonyl group of the imide, a nucleophilic attack of the aminoalcohol (C) is almost completely prevented and that an attack of the aminoalcohol (C) will

*The Absorption Spectra of Thiourea and Potassium Iodide on Nickel Metal**

By Wataru SUËTAKA

(Received January 6, 1964)

Organic or inorganic compounds are extensively used for corrosion inhibitors. Many interesting studies on the mechanism of corrosion inhibition have been reported; the chemical adsorption of organic compounds or inorganic ions on metal surfaces is considered to be the most important process.[1] The great majority of works, however, have been gravimetric or electrochemical. Because these data do not directly furnish information about the interaction between inhibitor molecules or ions and metal surfaces, there has been much speculation on this point. Absorption sorption spectroscopy has proven to be one of the most powerful tools for studying intermolecular interaction. Absorption spectra of organic compounds adsorbed on silica or alumina have been studied by several investigators, and many interesting results have been published.[2] Inorganic surface complex formation on different adsorbents has also been revealed by diffuse reflection spectra.[3]

Thiourea and the iodine ion are effective corrosion inhibitors. They have a very strong absorption band near 230 mμ, a band which facilitates the measurement of the spectrum of adsorbed species. Thiourea has the most simple structure in the homologue, and the potassium ion has no absorption band near 230 mμ. For these reasons thiourea and potassium iodide were chosen to investigate the mechanism of corrosion inhibition. In the present paper the absorption spectra of thiourea adsorbed on nickel surfaces and the diffuse reflection spectra of its solid complexes with some divalent metal salts will be reported on. The absorption spectra of the iodine ion on nickel surfaces in aqueous solutions will also be described.

Experimental

Absorption spectra were observed by means of a Hitachi EPU-2A photoelectric spectrophotometer. A diffuse reflectance attachment of the R-3 type was employed for the measurement of the diffuse reflection spectra of solid thiourea complexes. The spectral slit widths of the absorption and diffuse reflection spectra were 2 and 5 mμ respectively.

The reflection cells shown in Fig. 1 were used for measuring the absorption spectra of thiourea

or the iodine ion adsorved on nickel. A light beam was reflexed twice at the nickel surfaces in the cell. Nickel of a 99.9% purity was used for the adsorbent and reflection mirror, since its ion in an aqueous solution has no remarkable absorption band in the observed region of the spectra and does not interfere with the measurement of the spectra of the inhibitors. The surfaces of nickel were polished with the 0/4 emery paper and with buff. The polished plates were then cleaned successively in dilute hydrochloric acid and pure water. The

energies of light which had passed through a reflection cell filled with a solution and of light which had passed through the same cell filld with pure water were measured over the 215~320 mμ region. The ratio of the energies gave an absorption curve. The lengths of the light path in the reflection cells were estimated from the intensity of a weak absorption band at 260 mμ of acetone of known concentrations. The concentrations of acetone were sufficiently high to avoid any significant change in the intensity of the band by adsorption.

Complexes of thiourea with cadmium, zinc and nickel chlorides were prepared by the method reported by Nardelli et al.[4] Fine particles of the complexes, the diameters of which were less than 40 μ, were collected for the diffuse reflectance measurement. No diluent was used so as to avoid any eventual change in the spectrum by adsorption on a diluent. Magnesium oxide was used as the reference standard.

Corrosion inhibitors are used in an acid solution. The surfaces of nickel are generally covered with an oxide layer which dissolves in acid. The absorption spectra were, therefore, observed in acid solutions for the most part.

Thiourea, acetone, potassium iodide, nickel chloride and sulfate, cadmium chloride, zinc chloride, hydrochloric acid and sulfuric acid of guaranteed grades were used in the experiments. Water was purified by distillation and ion exchange. Immediately after the purification, the specific electric conductivity of water was less than 2×10^{-7} mho/cm.

Results and Discussion

Thiourea. — The Absorption spectra of a thiourea solution as measured with a reflection cell and an absorption cell are shown in Fig. 2. In this figure a considerable intensity decrease in a band at 236 mμ in the reflection spectrum can be clearly seen. It is considered that nickel or nickel oxide on the surfaces of metal plates is dissolved in the dilute acid solution used in the experiment, though the dissolved quantity might be very small, and that the nickel ion in the solution can form complexes with thiourea. The absorption band of thiourea may change in its position and intensity upon complex formation. The hypothesis that the observed intensity decrease arose from the complex formation in the solution might be postulated. The absorption spectra of thiorurea in acid or in water with or without nickel salt were also observed (Table I). The change in the intensity of the absorption band upon the addition of salt is very small and can be considered to be within the limit of experimental error. A slight blue shift of band was observed only for a solution containing salt in a high concentration. The hypothesis can, therefore, be ruled out from the results of the experiments mentioned above.

An intensity decrease in the absorption band upon adsorption has been reported by some investigators.[5] At first sight, the intensity decrease observed in the present work may be considered to be one example of this phenomenon. The observed reduction in intensity, however, seems to be too large to be regarded as the result of an intensity change upon adsorption, since the number of thiourea molecules in the solution is probably larger than that on nickel surfaces and since the

5) M. Robin and K. N. Trueblood, *J. Am. Chem. Soc.*, **79**, 5138 (1957); H. Kobayashi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **80**, 1399 (1959); K. Fueki, K. Hirota and H. Otouma, Paper presented at the 15th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1962.

contribution to the intensity of the absorption band from the molecules in solution should be larger than that from the molecules on nickel surfaces. Furthermore, the intensity decrease upon adsorption is generally accompanied by a change in band shape, and the bands of adsorbed molecules are diffuse.[5] The absorption band observed with the reflection cell has the same shape as that observed with the absorption cell, as Fig. 2 shows. It is difficult, therefore, to deduce that the observed intensity decrease was caused by the reduced intensity of the absorption band of adsorbed molecules.

The structure of thiourea and of a number of its complexes with divalent metal salts was studied with infrared absorption spectra and X-ray diffraction techniques. These studies have shown that sulfur-to-metal bonds are formed in these complexes.[6] The interatomic distance between sulfur and its nearest neighbors in the crystals was determined by the X-ray diffraction method. A value of 2.45 Å was calculated for the distance between sulfur and the cadmium atom in a thiourea-cadmium chloride complex,[7] and the distance of 3.45 Å was reported for the intermolecular contact between sulfur and the amino group in a thiourea crystal.[8] The observed interatomic distance between sulfur and cadmium is almost equal to the sum of the covalent radii, 2.52 Å.[9] The interatomic distance between sulfur and hydrogen in a thiourea crystal can be estimated to be larger than 2.45 Å, because the length of the N–H bond is about 1.0 Å. The sum of the covalent radii of sulfur and hydrogen is 1.34 Å,[9] which is considerably shorter than the estimated distance. The intermolecular perturbation to the thiocarbonyl group can, therefore, be deduced to be larger in the complex than in thiourea.

The diffuse reflection spectra of thiourea and its complexes with cadmium, zinc and nickel chlorides in the form of fine powder were observed. The obtained results are shown in Fig. 3, except for the spectrum of the thiourea-nickel chloride complex, in which an absorption band at a longer wavelength due to thiourea was difficult to isolate because of overlapping with a strong absorption band of nickel. A diffuse reflection spectrum of cadmium chloride is also shown in this figure for the sake of comparison. The bands near 250 mμ of complex crystals are considered to correspond to a band at 273 mμ of thiourea. This blue shift of the band is probably caused by the perturbation of electronic states through the sulfur atom. In this connection, a blue shift of the band at 236 mμ of thiourea in solution upon adsorption on nickel surfaces can be expected, because in acid solutions protons attach to amino groups and the sulfur atom may play an important role upon adsorption.[10]

The concentration of adsorbed thiourea was estimated on the assumption that the absorption band of adsorbed molecules shifted to the unobserved region of shorter wavelengths (Table II). A roughness factor of 2 was assumed in the calculation, since the surfaces were polished mechanically. On the other hand, nickel plates were dipped in solutions of thiourea for several minutes. After the plates had been withdrawn, the solutions were subjected to the measurement of the absorption spectrum. The results obtained are shown in Table III. The reproducibility of the experiment is rather poor, but a remarkable intensity decrease is clearly seen. The reduction in intensity can be considered to be caused by the removal of thiourea adsorbed on nickel from the solution. The values of the concentration of adsorbed molecules on dipped nickel surfaces calculated with the assumption of the same roughness factor, values which are shown in Table III, are in fairly good agreement with the values shown in Table II. The agreement of the

calculated concentrations can be considered to support the hypothesis that the intensity decrease observed in the reflection spectra arose from the large blue shift of the absorption band upon adsorption.

The decomposition of thiourea on nickel surfaces should be taken into account. It is believed, however, to be of small importance, because, as can be seen from Table II, the concentration of thiourea on nickel surfaces did not vary with the change of concentration in the solution. A more conclusive result would be obtained from research into the absorption spectrum of adsorbed thiourea in the shorter wavelengths, which could not be measured in the present work.

Potassium Iodide.—The results of the absorption spectrum measurement of potassium iodide obtained with the reflection cells are collected in Table IV. In this table, the results of normal absorption measurement are also shown. While a remarkable intensity reduction of the

charge transfer band of the iodine ion at 226 mμ in reflection measurements was observed for acid solutions, no important change was seen for solutions in pure water. Nickel plates could be attacked by the acid solution used to a slight extent, and the resulting nickel ions in the solution might cause an intensity decrease of the absorption band. The absorption spectrum of potassium iodide in a dilute (1×10^{-3} N) sulfuric acid aqueous solution containing nickel sulfate in the concentration of 7×10^{-4} mol./l. was observed in the 200~320 mμ region. The addition of the nickel salt caused only a negligible reduction in the intensity of the band at 226 mμ. These facts suggest that, while a strong interaction can be expected between the iodine ion and the nickel surface in acid solutions, the interaction should be very small in pure water. A new absorption band was observed at 310 mμ in the reflection measurement of acid solutions (Fig. 4). The nickel ion in an acid aqueous solution, the concentration of which is as high as 1.0 mol./l., does not show an absorption band at the same wavelength. This band may arise from nickel atoms on the metal surfaces or from a surface complex formed on the nickel plates, but it is premature to advance a discussion of this point.

Summary

The absorption spectra of thiourea molecules adsorbed on nickel surfaces in acid aqueous solutions have been observed by means of reflection cells. A new band did not appear in the observed region, but the intensity of the absorption band at 236 mμ decreased remarkably. The absorption spectra of potassium iodide have also been observed with reflection cells. For acidic solutions an absorption band at 226 mμ decreased in intensity and a new band appeared at 310 mμ, while for the solutions in pure water no change in the spectrum has been observed. The observed results have been discussed and a hypothesis of surface complex formation presented.

The author wishes to express his deep thanks to Professor Saburo Shimodaira for his valuable discussion. Thanks are due to Mr. Takuya Sato for his assistance in the experiment.

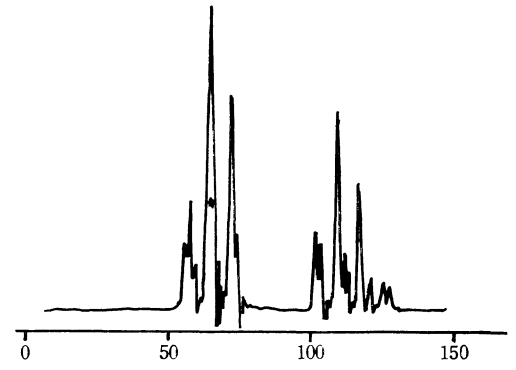
The Low Temperature NMR Spectrum of Triethylaluminum

By Osamu YAMAMOTO

(Received January 23, 1964)

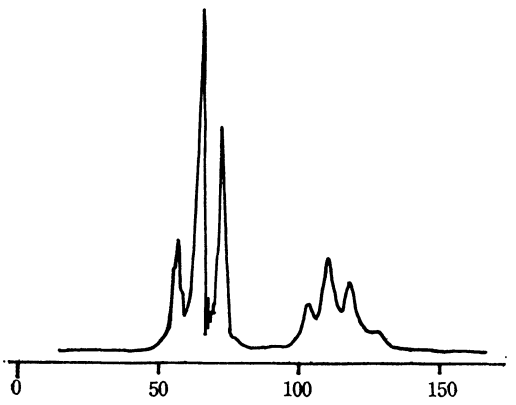
In a previous paper,[1)] the author reported on the NMR spectra of triethylaluminum and diethylaluminum monohalides at room temperature and pointed out an anomaly in the δ value of triethylaluminum: in general, the δ value (the internal chemical shift betweeen methyl and methylene protons in the ethyl group) for metal ethyl compounds increases when one of the ethyl groups is replaced by a halogen atom. In contrast with this, the δ value for triethylaluminum (-0.72 p. p. m. for a pure liquid sample) is larger than that for diethylaluminum chloride (-0.81 p. p. m. for pure liquid). In the previous paper it was suggested that this anomaly may be attributed to the rapid exchange of the

1) O. Yamamoto, This Bulletin, **36**, 1463 (1963).



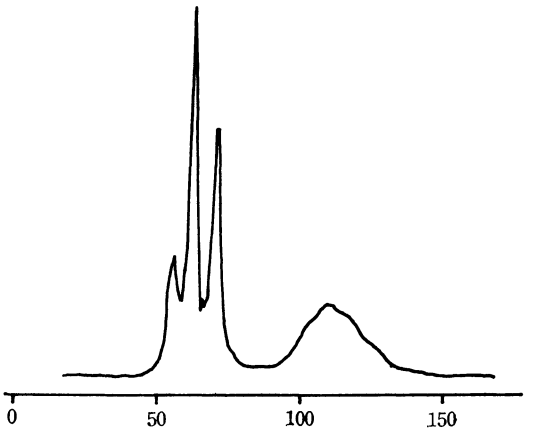
ethyl groups between bridge and terminal positions in the triethylaluminum dimer, so that a weighted mean of two kinds of ethyl spectra is observed as the spectrum of triethylaluminum at room temperature. If this suggestion is valid and if the rapid exchange becomes slower as the temperature is lowered, the NMR spectrum of triethylaluminum at a sufficiently low temperature will show two separate ethyl signals, due to the terminal and bridge groups respectively. To confirm this, the low temperature spectra of triethylaluminum have been studied in this work.

Experimental

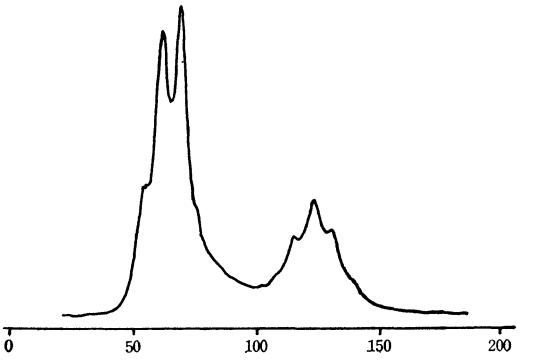


The measurement of the NMR spectea and the preparation of the samples were made in the manner previously reported,[1] except that a Varian-temperature variable cell at 60 Mc. was employed for the low temperature measurements and toluene was used as the solvent. The temperature in the cell was calibrated by the usual technique.

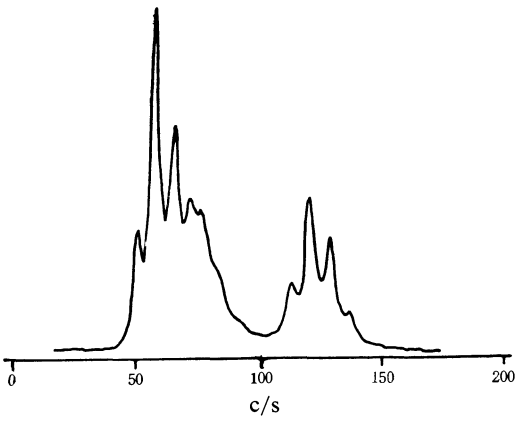
Results and Disussion



The NMR spectra of triethylaluminum in toluene (a 31.3 mol.% solution) obtained at various temperatures are shown in Fig. 1.



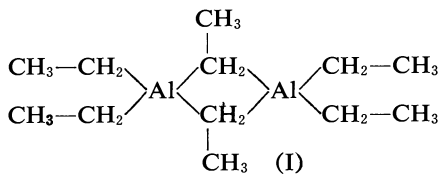
(a) 29.5°C



(b) −29°C

(c) −40°C

(d) −61°C



(e) −80°C

Fig. 1(a—e). The NMR traces of triethylaluminum in toluene (31.3 mol.% solution) at various temperatures (chemical shifts are referred to the methyl signal of solvent toluene). The intensity scale was changed arbitrarily from one to the others.

When other samples with different concentrations were also measured, they were found to give similar spectra, with only slight differences in the chemical shift due to the dilution effect. As is shown in the figures, the signals of an A_3B_2 pattern, which are quite sharp at room temperature, broaden as the temperature decreases, especially for methylene signals (the higher-field side ones). At $-40°C$, the methylene signals are almost collapsed. As the temperature decreases further, the signals become slightly sharper; at the same time, a group of new signals appears on the higher-field side of the methyl signals. At $-80°C$, the temperature which seems to be the lowest limit for the apparatus used, the spectrum of triethylaluminum consits of three groups: a triplet with the strongest intensity at the lowest field, a quartet at the highest field, and a group of new signals in the middle portion. The quartet signal is found to be at a higher field than the methylene quartet at room temperature, while the triplet is at only a slightly lower field than the methyl signals at room temprature.

Muller and Pritchard[2] and Growenewege and others[3] observed two singlet signals for trimethylaluminum at $-75°C$, but only one singlet signal at room temperature. The two singlet signals were separated by about 1 p. p. m. from one another and were positioned at either side of the original signal found at room temperature. They concluded from their NMR studies that, in a dimeric structure for trimethylaluminum with a bridged form[4] similar to the I shown below, the rapid exchange of the methyl group occurs between bridge and terminal positions at room temperatune. Judging from a consideration of the intensity of the $-75°C$ spectrum, the higher-field side singlet was due to terminal methyl groups, and the lower-side one, to bridge methyl groups, in the dimer.

In a similar way, if the following methylene-bridged structure I is assumed for triethylaluminum, an assignmet of the signals will be obtained rather straightforwardly:

(I)

In model I, the bridge-forming group is the methylene group. By analogy with the methyl compound, the signals of the protons in the bridge-forming group at a sufficiently low temperature will appear at a lower field when the group is in the bridge position, and at a higher field when it is in the terminal position, than the averaged signals at room temperature. On the other hand, the signals of the protons which do not directly take part in the bridge formation are expected to show only a small change in their resonance position through the exchange process. In the spectrum obtained at $-80°C$, the methylene signals show a considerable shift (about 12 c. p. s. to a higher field) from the position at room temperature, while the methyl signals show only a small shift (about 6 c. p. s. to a lower field). Thus, the methylene-bridge model I seems to be reasonable for the structure of triethylaluminum.

Since the bridge methylene signals are at a lower field than for the terminal methylene, the higher field quartet of triethylaluminum at $-80°C$ must be responsible for the terminal methylene, and, correspondingly, the triplet at a lower field, for the terminal methyl, and the middle portion, for the bridge ethyl group. It is considered that a group of signals with a complex appearance in the middle portion results from the fact that the δ value in the bridge ethyl group becomes comparable to the coupling constant (presumably about 8 c. p. s.) between the methyl and methylene protons.

To confirm this assignment, the intensity ratio between the highest side quartet and the remainder of the signals was measured and found to be 0.39, while the expected value for the formula I is 0.37. This agreement between the observed and the expected values is very good.

Thus, as in the case of trimethylaluminum, triethylaluminum gives a single ethyl spectrum at room temperature because of a rapid exchange between the terminal and the bridge ethyl groups, and a compound spectrum of two kinds of ethyl groups at a sufficiently low temperature because of the decreased exchange rate.[5] In contrast with the methyl compound, however, the bridge-forming group in triethylaluminum is the methylene group.

This seems to be the first positive experimental evidence that triethylaluminum forms a dimer bridged *through the methylene group*, although formula I has been used for the triethylaluminum dimer in the literature.[6]

2) N. Muller and D. E. Pritchard, *J. Am. Chem. Soc.*, **82**, 248 (1960).

3) M. P. Growenewege, J. Smidt and H. de Vries, ibid., **82**, 4425 (1960).

4) P. H. Lewis and R. E. Rundle, *J. Chem. Phys.*, **21**, 986 (1953).

5) Unfortunately the rate and the activation energy for the exchange process can not be found because of the complex nature of the spectrum.

6) For example, see H. Zeiss, "Organometallic Chemistry," Reinhold Publishing Corportaion, New York (1960), p. 207.

The σ values for the terminal and bridge ethyl groups are calculated from the $-80°C$ spectrum to be -1.11 p. p. m. and about -0.2 p. p. m. respectively. Since the monohalogen derivatives of triethylaluminum are halogen-bridged dimer,[7] the ethyl groups are always at the terminal position. Thus, in comparing the δ values of triethylaluminum and diethylaluminum monohalides, the value for the terminal group should be used. Since the δ value of diethylaluminum monochloride in benzene (at almost the same concentration of aluminum compound as that in the present work) is about -0.85 p.p. m.,[1] triethylaluminum has a smaller δ value in its terminal ethyl group than do diethylaluminum monohalides. Therefore, the general trend for the δ values of metal ethyl compounds stated at the beginning of this paper still holds for the case of aluminum compounds, and the origin of the anomaly mentioned in the previous paper is elucidated satisfactorily.

Electron Spin Resonance of Peroxy Radicals in Gamma-irradiated Polytetrafluoroethylene

By Hazime TANAKA, Akira MATSUMOTO and Nobuhisa GOTO

(Received January 25, 1964)

Quite a few ESR investigations have been carried out on polytetrafluoroethylene (PTFE) irradiated by gamma- or X-rays.[1-8] When irradiation and measurements have been made in the absence of oxygen, the ESR spectra of PTFE specimens have been found to consist mainly of double quintets, arising from the fluoroalkyl radical, $-CF_2\dot{C}FCF_2-$, produced by the removal of a fluorine atom from the polymer chain. Some measurements of the oriented samples have also been made; they have given information concerning the relation between the polymer structure and the ESR spectra.[7]

The double-quintets signal disappeared, giving an asymmetrical spectrum, when PTFE specimens irradiated in vacuo were aged in air.[3] The kinetics of this reaction was analyzed under the assumptions: $\dot{R}+O_2 \rightleftarrows R\dot{O}_2$, and $[\dot{R}]+[R\dot{O}_2]=[\dot{R}]_0$, where $\dot{R}$ and $R\dot{O}_2$ represent fluoroalkyl radical and its peroxy radical respectively and $[\dot{R}]_0$ was the initial concentration.[9] On the other hand, it has been reported[8] that the ESR spectra of peroxy radicals can be separated into two components. One of them is associated with the peroxy radical derived from the aforesaid fluoroalkyl radical, while the other is ascribed to the peroxy radical originating in the chain scission-type radical.

This paper intends to pretent an examination of the transition process from the spectrum observed in vacuo to the spectrum which is obtained in a specimen aged in air, considering two sorts of peroxy radicals, and also an examination of the stability of these peroxy radicals under heat treatment. The nature of the peroxy radicals will be discussed in the light of data on the orientation dependence of their ESR spectra and the crystalline arrangement of PTFE.

Experimental

All the ESR spectra were measured at a frequency of 24000 Mc./sec. with a superheterodyne-type spectrometer,[10] which displays the first derivative

10) This spectrometer was designed and constructed by the Applied Electric Laboratory Co. It consists of an automatic frequency-control unit, two 24V10 klystrons, a klystron power supply, a sweep generator an electromagnet, a magnet power supply, and a field scanning unit.

of the resonance curve. Some spectra were recorded as absorption figures with an integrator. For the determination of the correct line width, proton resonance signals at 36.5 Mc./sec. with 100 kc./sec. side bands were recorded. Small quantities of 1,1-diphenyl-2-picrylhydrazyl (DPPH) were employed as a standard for the g-factor and intensity of spectra.

The specimens of PTFE films and powder were supplied by the Daikin Kogyo Co., Ltd. The film, 0.2 mm. thick, had a density of 2.17, and the degree of crystallinity was estimated to be about 55%.[11] In preparing oriented samples, the film was stretched further by using a screw-jacket elongation apparatus up to 200%. All samples were placed in quartz tubes 3 mm. in o. d. In the case of irradiation in vacuo, the samples were sealed off after evacuation with an oil diffusion pump for 24 hr. The irradiation was carried out with Co-60 gamma rays, the intensity of which was about 10^5 rad./hr. the total dose reached up to about 10^7 rad.

Results and Discussion

The ESR Spectrum of Peroxy Radicals in Powder.—The dominating feature of the ESR spectrum in the powder sample irradiated and measured in vacuo is the double quintets. This spectrum shows a slight asymmetry, as a result of the g-anisotropy. This appears more clearly in the present K-band measurement than in the reported X-band spectra.[1-4]

Upon exposure of the sample to oxygen, the double quintets disappear rapidly and new resonance lines build up. This new spectrum gives an appearance of the superposition of two components, one symmetric and the other asymmetric, as may be seen in Fig. 1. Matsugashita and Shinohara obtained the symmetrical signal and the asymmetrical signal, which disappear upon the re-evacuation of the oxygenated sample, at 250°C and 150°C respectively.[8] In the present case, no treatment is required to resolve them. The intensity of the symmetrical component, I_s, is obtained under the assumption that the line shape is Lorentzian. By subtracting I_s from the total intensity, the intensity of the asymmetrical component, I_a, is obtained. If the sample is irradiated in the presence of air, the intensity ratio of the symmetrical component, I_s/I_a, increases by a factor of two.

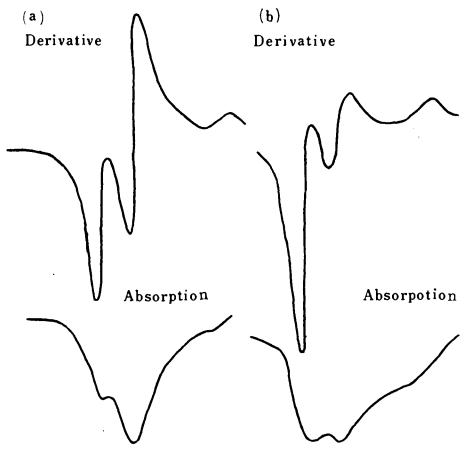

Fig. 1. ESR spectra of peroxy radicals in PTFE powders, (a) irradiated and observed in air, (b) irradiated in vacuo and observed in air.

The Transition Process.—In order to examine the transition process from the spectrum in vacuo to that of oxygenated sample, a small quantity of oxygen is introduced, with a velocity of 10^{-3} cc./min. (reduced to 1 atm.), into a sample tube containing about 30 mg. of PTFE powder irradiated in vacuo. The variation of the spectrum with time is shown in Fig. 2. A decrease in the double quintets

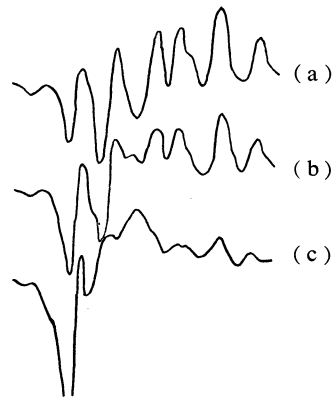

Fig. 2. Changes in shape of ESR spectrum in PTFE powder, upon exposure of oxygen.

accompanies the increase in the asymmetrical component. The intensity of each component in the double quintets, I_{dq}, is expressed by:

$$I_{dq} = I^{\circ}_{dq} \exp(-\lambda t) \qquad (1)$$

where I°_{dq} is the initial intensity of each component of the double quintets, t is the time in minutes, and λ is a constant (0.035/min. in the present case). The intensity of the asymmetrical component in the oxygenated spectrum, I_p, is given by:

$$I_p = I_p^{\infty}\{1-\exp(-\lambda t)\} \qquad (2)$$

where I_p^{∞} is the intensity of the asymmetrical component after equilibrium, and λ is the same constant in Eq. 1. The initial intensity

of the double quintets agrees with the final intensity of the asymmetrical component.

These results accord with those of Tsvetkov, Lebedev and Voevodskii,[9] though the present experiment was carried out with samples smaller in size and at lower oxygen pressures. The experiment shows only that the fluoroalkyl radical is converted into the peroxy radical, $-CF_2CF(O\dot{O})CF_2-$ which gives the asymmetrical component of the ESR spectrum in air, but it does not bring out information about the symmetrical component.

The Thermal Stability of Peroxy Radicals.—The intensity ratio of the symmetrical component to the asymmetrical component changes upon heat treatment. In the experiment, three groups of PTFE powder were used: (1) irradiated and heated in air, (2) irradiated and heated in vacuo before aging in air, and (3) irradiated in vacuo and heated in air. The change in I_s/I_a when it is heated for 30 min. at various temperatures is shown in Fig. 4. It is evident that the radical which gives the symmetrical component is unstable at temperatures above 150°C; the I_s/I_a ratio decreases rapidly at an annealing temperature of 150°C, though the I_a intensity does not change greatly until 250°C.

It has bee reported[12] that one of the peaks of the mechanical loss tangent of crystalline PTFE exists near 130°C in the dynamical measurement at 1 c./sec. This shows the presence of a configurational transition of the material in this temperature region.[13] The decomposition of the radical species which give a symmetrical spectrum must be related to this transition. From the symmetrical profile, this "heat sensitive radical" must be trapped in the region where the motional freedom of the polymer, for example, vibrational or rotational motion, is large and local order does not exist. The "heat sensitive radical" does not seem to come from the fluoroalkyl radical which gives the double quintets signal, but from radicals of a different type, for example, the type with "carbon-carbon bond" breakage. The scission of the main chain destroys the local order and gives much more motional freedom. The situation holds even after aging in air, so that the peroxy radical derived from the scission-type radical shows a symmetrical spectrum. As the temperature rises beyond 130°C, the chain motion increases and the radicals trapped at the ends of the chains disappear as a result of recombination and decomposition. This estimate accords substantially with that of Matsugashita and Shinohara.

The asymmetrical spectrum, on the contrary, holds even above about 250°C. It must originate from the fluoroalkyl radical trapped in PTFE crystallite.

The Anisotropy of the *g* Factor in an Oriented Sample.—Further investigation of the asymmetric component has been undertarken from the point of view of the angular dependence of its *g* factor. The ESR spectrum of peroxy radicals in oriented films can be resolved into two singlets when the axis of the molecular chain is along the orientation axis. One has a stronger intensity than the other.

The resonance field position of the strong signal changes as a function of the angle between the orientation axis and the external magnetic field; the *g* factor shows a maximum

● Weaker signal

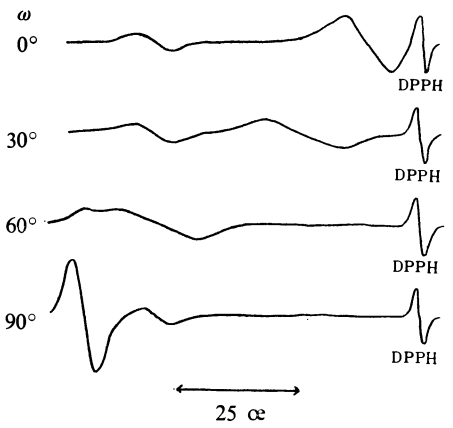

Fig. 5a. Change of the ESR spectrum with the angle, ω, between the orientation of PTFE films and the magnetic field.

value of 2.0230 when the magnetic field is perpendicular to the orientation axis, and it reaches a minimum value of 2.0065 when the magnetic field is parallel to the orientation axis, as may be seen in Fig. 5. The weak signal hardly changes its field position throughout the angle variation. Its g factor, 2.018, agrees with the value obtained from the symmetrical component in the powder spectrum. It becomes evident that the weak signal gives nearly the same profile in both oriented films and powder, while the strong signal appears asymmetric in powder because of its g anisotropy.

The Origin of the g Anisotropy—One can consider the origin of the g anisotropy in the oriented sample to be as follows. The fluoroalkyl radical to which the oxygen molecule is attached forms the peroxy radical, $-CF_2CF(OO)CF_2-$. To the first approximation it is assumed that the local order of original PTFE does not change markedly during the desertion of the fluorine atom and the insertion of the oxygen molecule. The crystal structure of PTFE is pseudo-hexagonal at room temperature,[14] and its C–C chain has a torsion whose period is 6.5 carbon atoms along the crystal c axis (see Fig. 6). Now, we suppose

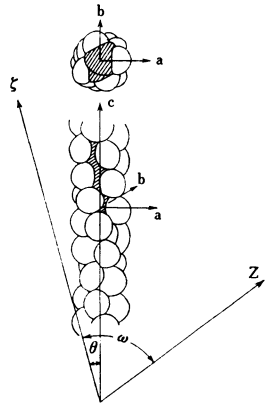

Fig. 6. The crystal structure of polytetrafluoroethylene.
▨ C atom ○ F atom

that the oxygen molecule in the defect of the fluorine atom forms a C–O–O bond perpendicular to the crystal c axis. The unpaired electron localized on the oxygen atom has an axially symmetrical distribution around the C–O–O axis. We choose three Cartesian coordinates, (x, y, z), (ξ, η, ζ), and (x', y', z'), connected with each other by the Eulerian angles shown in Fig. 7, where the system x', y', z' is connected with the system (ξ, η, ζ) by three angles, θ, φ and ψ, and where ω is an angle between the ζ axis and the z axis. In these systems we assume that the crystal c

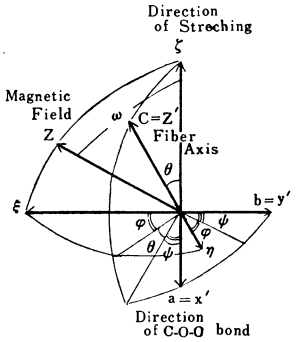

Fig. 7. The relation among three Cartesian coordinate systems, xyz, $\xi\eta\zeta$, and $x'y'z'$.

14) I. Nitta, "X-sen Kessyogaku," Maruzen, Tokyo (1961).

axis of PTFE is along the z′ axis, and that the x′ axis is approximately in the direction of the C–O–O bond, which is the symmetrical axis of the unpaired electron density. The ζ axis is taken as in the direction of the orientation axis, while the z axis is in the direction of the external magnetic field. Then, the rotation of the ζ axis in the z−x plane about the y axis is expressed only by the angle ω.

If the principal values of the g tensor are g_1, g_2, and g_3, the g factor can be written as follows:

$$g^2=g_1^2\alpha^2+g_2^2\beta^2+g_3^2\gamma^2 \tag{3}$$

where α, β, and γ are the direction cosines of the external magnetic field with respect to the principal axis system. We can assume that g_1 is the g factor along the x′ axis, and that g_2 $(=g_3)$ is perpendicular to it. The direction cosines in Eq. 3 may be calculated easily using the above assumption. The defects of the fluorine atom are distributed at random about the crystal c axis, so that the angles φ and ψ have no definite values. Therefore, we must caluculate the average values of α^2, β^2, γ^2 with respect to the equally-probable distribution of φ and ψ.

$$\langle\alpha^2\rangle,\langle\beta^2\rangle=\frac{1}{4}\{(1+\cos^2\theta)+(1-3\cos^2\theta)\cos^2\omega\}$$

$$\langle\gamma^2\rangle=\frac{1}{2}\{(1-\cos^2\theta)-(1-3\cos^2\theta)\cos^2\omega\} \tag{4}$$

Then,

$$g^2=\frac{1}{4}[\{(g_1^2+3g_2^2)+(g_1^2-g_2^2)\cos^2\theta\}+\{(g_1^2-g_2^2)+3(g_2^2-g_1^2)\cos^2\theta\}\cos^2\omega] \tag{5}$$

For the purpose of comparing the calculated results with the experimental data, it is convenient to introduce the new parameters $g_\parallel$ and $g_\perp$; $g_\parallel$ is the component of g along the crystal c axis, while $g_\perp$ is perpendicular to it: $g_{11}=g_2$, $g_\perp=\sqrt{(g_1^2+g_2^2)/2}$.

$$g^2=\frac{1}{2}[\{(g_\perp^2+g_\parallel^2)+(g_\perp^2-g_\parallel^2)\cos^2\theta\}+\{(g_\perp^3-g_\parallel^2)+3(g_\parallel^2-g_\perp^2)\cos^2\theta\}\cos^2\omega] \tag{6}$$

Equation 6 shows the axial symmetry of g around the orientation axis. If $\theta=0$, Eq. 6 becomes

$$g^2=g_\perp^2+(g_\parallel^2-g_\perp^2)\cos^2\omega \tag{7}$$

and as a simple approximation; $g\fallingdotseq g_\perp-\Delta g\cos^2\omega$, where $\Delta g=g_\perp-g_\parallel\langle\langle g_\perp, g_\parallel$.

The results shown in Fig. 5 show this axially symmetrical property of the g factor. The deviation of the experimental data from the curve, $g=2.0230-0.0165\cos^2\omega$, suggests the presence of distribution in θ. The values of g_1 and g_2 are estimated as 2.037 and 2.0065 respectively.

If the local order of PTFE does not exist, the average values of $\langle\alpha^2\rangle$, $\langle\beta^2\rangle$, and $\langle\gamma^2\rangle$ in Eq. 4 become 1/3, and the value of the g factor is 2.017, which is in good agreement with the value obtained from the symmetrical component of the ESR spectrum in air.

The spectrum of the powder sample, taken off the symmetrical component, must be composed of the sum of randomly-oriented radicals. It shows a fairly good agreement with the curve obtained from the calculations under the assumptions[15,16] of axial symmetry, a Lorentzian line shape and the random orientation of the crystallites, as Fig. 8 shows.

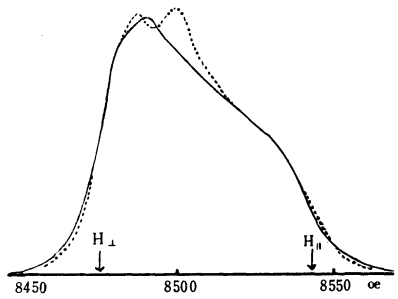

Fig. 8. ESR absorption curve of peroxy radicals in irradiated PTFE powder. Calculated curve obtained from the observed values in oriented sample; $g_\parallel=2.0065$, $g_\perp=2.0230$, and $b=10$ oe. (b: half width at half power.)
—— Calculated ------ Experimental

Summary

In the oriented sample of irradiated PTFE, the ESR spectrum of peroxy radicals consists of two singlets. One of them has an angular dependent g factor: $g=2.0230-0.0165\cos^2\omega$, where ω is an angle between the orientation of the PTFE crystal and the direction of the magnetic field applied. This spectrum shows an asymmetrical profile in a powder sample. It has been interpreted in the light of the crystalline arrangement of PTFE. Additional peroxy radical, which gives an angle-independent ESR signal, is unstable at temperatures above 150°C.

Sorboses. V. The Reactions of the Tosyloxy Groups of 2,3-O-Isopropylidene-α-L-sorbofuranoses in Liquid Ammonia[1]

By Kanji TOKUYAMA

(Received January 28, 1964)

The results presented in the preceding paper demonstrated that liquid ammonia is an excellent solvent for the nucleophilic displacement reaction of *O*-tosylsorbofuranoses.[1] In this paper we will report on some further examples of the nucleophilic displacement of *O*-tosyl derivatives of 2,3-*O*-isopropylidene-α-L-sorbofuranose (I) in liquid ammonia.

Reactions with Liquid Ammonia

The treatment of 1-*O*-tosyl-2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (II)[2] with liquid ammonia resulted in the formation of the secondary amine, di(1-deoxy-2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose-1-)-amine (III), but not of the primary amine, 1-deoxy-1-amino-2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (IV) ; this latter was, however, obtained in the presence of sodium amide. On the other hand, as has been reported in a previous paper,[3] the treatment of 1,6-di-*O*-tosyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (V)[4] and 6-*O*-tosyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (VI) with liquid ammonia, even in the absence of sodium amide, gave the primary amines, namely 1,6-dideoxy-1,6-diamino- (VII) and 6-deoxy-6-amino-2,3-*O*-isopropylidene-α-L-sorbofuranose (VIII) respectively. These facts suggest that the reactivities of the tosyloxy groups of sorbofuranoses are influenced by free hydroxyl groups.

Potassium Cyanide in Liquid Ammonia

The treatment of II with potassium cyanide in ethanol did not give any derivatives with a nitrile group, only 2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (IX).[5] Similarly, 6-*O*-tosyl-1,4-anhydro-2,3-*O*-isopropylidene-α-L-sorbofuranose (X)[3] was obtained by the treatment of V with potassium cyanide in ethanol. Ammonium cyanide also did not give the nitrile derivatives. As these unexpected results

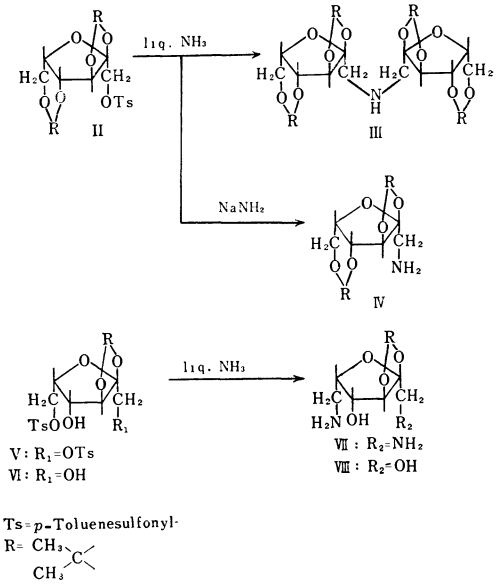

Chart 1.

seemed to be due to the fact that potassium cyanide is insoluble in organic solvents, containing dissolved tosylsorboses, we searched for suitable solvents with better solubilities for both sugars and potassium cyanide; we found liquid ammonia to be suitable for the above purpose.

The heating of II with potassium cyanide in liquid ammonia gave a sirup, the infrared

3) K. Tokuyama, M. Kiyokawa and N. Hōki, This Bulletin, **36**, 1392 (1963).
4) H. Ohle, *Ber.*, **71**, 562 (1938).
5) T. Reichstein, *Helv. Chim. Acta*, **17**, 311 (1934).

spectrum of which showed the bands of an amide at 1620 and 1690 cm^{-1}, but no bands of a nitrile group. Therefore, the structure of the sirup was determined to be 1-deoxy-1-carbamoyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XI). The cyanation of II to 1-deoxy-1-cyano-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XII), followed by hydrolysis or by ammonolysis, seemed to give XI or 1-deoxy-1-amidino-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XIII), which was then hydrolyzed to XI.

When the above-described reaction was carried out under strictly anhydrous conditions, another kind of alkaline sirup was obtained; this was easily converted into XI by the evolution of ammonia gas. The purification of the sirup was unsuccessful because of its instability for humidity, but the treatment of it with diethyl malonate in the presence of sodium gave a sirup, the ultraviolet spectrum of which showed an absorption maximum at 250 and 280 mμ in an alkaline medium, suggesting that it is a pyrimidine derivative. Therefore, the structure of the former sirup was determined as XIII and that of the latter sirup, as 2-(1'-deoxy-2', 3': 4', 6'-di-*O*-isopropylidene-α-L-sorbofuranose-1')-4, 6-dihydroxypyrimidine (XIV). The infrared spectrum of XIII exhibited bands, at 1713 and 1668 cm^{-1}, which should be ascribed to an amidino group. As these two bands were shifted to wave numbers higher and lower respectively than those of a guanidine,[6] XIII

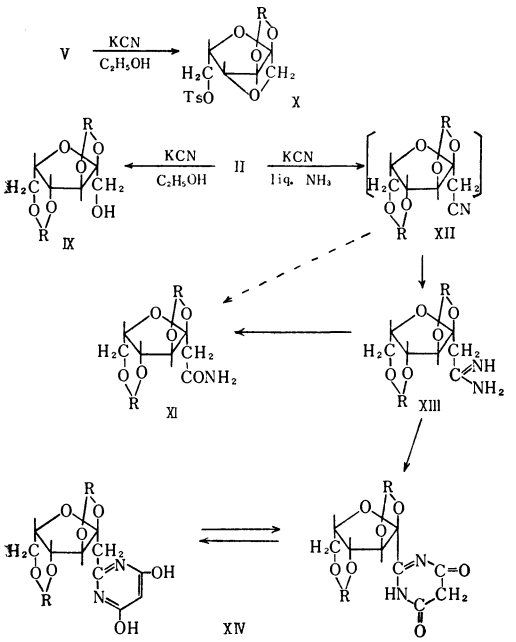

Chart 2.

6) J. Fabian, M. Legraud and P. Poirier, *Bull. soc. chim. France*, **85**, 1461, 1499 (1956).

was supposed to be a dimer. This fact was also supported by the weak absorption bands of the amino group at 3000 and 3200 cm^{-1}. On the basis of above-described facts, it is clear that II was converted into XI via XIII, which was derived from the probable intermediate, XII. On the other hand, when II was treated with potassium cyanide in liquid ammonia containing a small amount of water, only IV was obtained. This means that the equilibrium between potassium cyanide and liquid ammonia shown in Eq. 1[7] shifted to the right side because of the decomposition of ammonium cyanide by water:

$$KCN + NH_3 \rightleftharpoons NH_4CN + KNH_2 \qquad (1)$$

Potassium Thiocyanate in Liquid Ammonia

No displacement reaction of the tosyloxy group of sorbofuranose by thiocyanate was observed in either liquid ammonia or ethanol. Since the treatment of II with potassium thiocyanate in liquid ammonia gave IV, potassium thiocyanate was considered to react like sodium amide.

Sodium Hydroxide in Liquid Ammonia

Sodium hydroxide in liquid ammonia has received renewed attention in recent years because its reactivities are similar to those of sodium amide in liquid ammonia; e.g., it reacts with diethyl malonate to give the sodium salt or accelerates the amination reaction.[8] The treatment of II with a large excess of sodium hydroxide in liquid ammonia at room temperature or on heating on a boiling water-bath gave IX, but not IV. This appears to be the first reported example of hydroxylation with sodium hydroxide in liquid ammonia. Although only an equimolecular sodium hydroxide to a tosylsorbose would be required for this purpose, no displacement was observed under these conditions. This means that the reaction occurred on the surface of sodium hydroxide, which is insoluble in liquid ammonia. The treatment of V with sodium hydroxide gave 1, 4-anhydro-2, 3-*O*-isopropylidene-α-L-sorbofuranose (XV)[9] in liquid ammonia. Similarly, I and XV were obtained from VI and 1-*O*-tosyl-2, 3-*O*-isopropylidene-α-L-sorbofuranose (XVI)[1] respectively. These reactions were observed with potassium hydroxide, but not with lithium hydroxide.

9) The formation of X by the tosylation of XV clearly established the structure of XV.

Sodium Hydrosulfide in Liquid Ammonia

As has been described above, the tosyloxy group was displaced by a hydroxide group with sodium hydroxide in liquid ammonia to give a hydroxyl compound. Therefore, similar displacement reactions by sodium hydrosulfide in liquid ammonia were investigated. Although the solubility of hydrosulfide in liquid ammonia is much higher than that of sodium hydroxide,[10] no displacement of the tosyloxy group by a mercapto group was observed at room temperature. The treatment of II, VI, XVI and V with sodium hydrosulfide in liquid ammonia at room temperature recovered the starting materials without any aminated compounds. However, the heating of II on a boiling water-bath with a sodium hydrosulfide-liquid ammonia solution gave the product when the tosyloxy group is replaced by a mercapto group, 2, 3 : 4, 6-di-*O*-isopropylidene-1-thio-α-L-sorbofuranose (XVII).[1]

Similarly, the heating of V with sodium hydrosulfide gave 1, 4-anhydro-2, 3-*O*-isopropylidene-6-thio-α-L-sorbofuranose (XVIII),[11] which

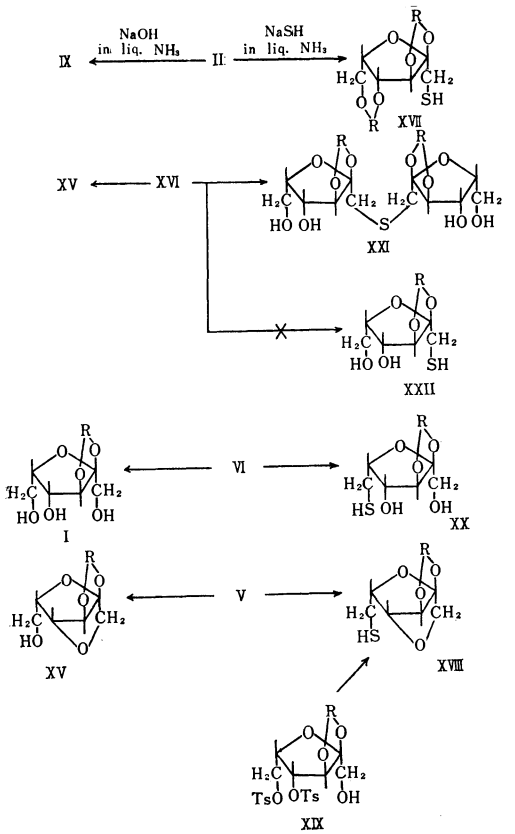

Chart 3

was also obtained from 4, 6-di-*O*-tosyl-2, 3-*O*-isopropylidene-α-L-sorbofuranose (XIX)[3] by the same reaction. Furthermore, 2, 3-*O*-isopropylidene-6-thio-α-L-sorborfuranose (XX)[1] was obtained from VI, and di-(1-deoxy-2, 3-*O*-isopropylidene-α-L-sorbofuranose-1-)-sulfide (XXI), from XVI. In the last case, 2, 3-*O*-isopropylidene-1-thio-α-L-sorbofuranose (XXII)[1] was not formed.

From the standpoint of the introduction of a mercapto group into a sugar, the above-described method, composed of only one step, considered to be much more convenient for use in the preparation of thiosugars than others reported hitherto.

Experimental

The Reactions of 1-*O*-Tosyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (II) with Liquid Ammonia.—i) A solution of II (5 g.) in liquid ammonia (8 ml.) was heated on a boiling water-bath for 60 hr. After the liquid ammonia had been removed, the residue was extracted with chloroform; the extract was then washed with water, dried, and evaporated to give a dark brown sirup (3 g.). A solution of the sirup (3 g.) and *p*-nitrobenzoyl chloride (2 g.) in dry pyridine (10 ml.) was stirred at room temperature for 3 hr. The reaction mixture was poured into a saturated aqueous solution of sodium carbonate under cooling and extracted with chloroform. The chloroform extract was washed with water and evaporated in vacuo. Recrystallization of the residue from ethanol gave *p*-nitrobenzoate of III (1.7 g.); m. p. 252°C (decomp.).

Found: C, 57.28; H, 6.67; N, 4.30. Calcd. for $C_{31}H_{42}N_2O_{13}$ (650): C, 57.31; H, 6.47; N, 4.31%.

ii) A solution of II (2 g.) in liquid ammnoia containing sodium amide (prepared from sodium (0.2 g.) in liquid ammonia (10 ml.)) was heated on a boiling water-bath for 20 hr. The reaction mixture was neutralized with ammonium chloride. After the ammonia had been removed, the residue was extracted with chloroform, and the extract was washed with water and evaporated. Recrystallization of the residue from *n*-hexane gave IV (0.6 g.); m. p. 71.5°C, $[\alpha]_D^{23}$ −3.7 (*c* 1.035, chloroform).

Found: C, 55.82; H, 8.14; N, 5.20. Calcd. for $C_{12}H_{21}NO_5$ (259): C, 56.03; H, 8.24; N, 5.44%.

The Reactions of 1-*O*-Tosyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (II) with Potassium Cyanide.—i) A solution of II (1 g.) and dry potassium cyanide (3 g.) in liquid ammonia (10 ml.) (dried with sodium) was heated on a boiling water-bath for 45 hr. After the ammonia had been removed, the residue was extracted with dry ether, and the ether extract was dried with sodium sulfate and evaporated in vacuo to obtain a sirup, XIII (0.3 g.), which could not be purified. a) After the sirup had been heated with a trace of water at 80°C for 1 hr., the residue was purified by silica-gel chromatography with benzene. A pale yellow sirup, XI, was obtained. The yield was 0.1 g., $[\alpha]_D^{22}$ −4.8 (*c* 1.011, chloroform).

10) S. Takizawa and Y. Abe, paper presented at the 16th Annual Meeting of the Chmical Society of Japan, Tokyo, April, 1963.

11) As the mild hydrolysis of XVIII gave XX, the structure of XVIII was confirmed.

Found: C, 54.20; H, 6.83; N, 4.75. Calcd. for $C_{13}H_{21}NO_6$ (287): C, 54.36; H, 7.13; N, 4.31%.
b) A solution of XIII (0.3 g.,), sodium (0.15 g.) and diethyl malonate (0.6 g.) in absolute ethanol (10 ml.) was warmed at 60°C for 8 hr. After the ethanol had been removed, water (15 ml.) was added to the residue and the insoluble sirup was removed by decantation. When the aqueous solution was made weakly acidic with acetic acid, a brown sirup was precipitated. This was dissolved in a 1 N sodium carbonate solution and reprecipitated with acetic acid. After this procedure had been repeated several times, XIV was obtained as a brown sirup (8 mg.), which was very hygroscopic.
Found: N, 7.80. Calcd. for $C_{16}H_{22}N_2O_7$ (354): N, 7.91%.

ii) A solution of II (1 g.), potassium cyanide (2 g.) and one drop of water in liquid ammonia (10 ml.) was heated on a boiling water-bath for 45 hr. After the ammonia had been removed, the residue was extracted with chloroform, and the extract was washed with water and then evaporated. Recrystallization from *n*-hexane gave IV (0.4 g.); m. p. 71.5°C.

iii) A mixture of II (1 g.) and potassium cyanide (2 g.) in ethanol (10 ml.) was simultaneously boiled and stirred for 20 hr. and then poured into water and extracted with chloroform, from which IX (0.5 g.) was obtained m. p. 78°C. X (0.5 g.) from V (1 g.) was obtained by the same procedure; m. p. 115°C.

The Reaction of 1-*O*-Tosyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (II) with Potassium Thiocyanate in Liquid Ammonia.—A solution of II (1 g.) and potassium thiocyanate (1 g.) in liquid ammonia (8 ml.) was heated on a boiling water-bath for 40 hr. or kept at room temperature for two weeks. After the ammonia had been removed, the residue was extracted with chloroform, from which IV (0.5 g.) was obtained.

The Reactions with Sodium Hydroxide in Liquid Ammonia. — *1-O-Tosyl-2, 3 : 4, 6-di-O-isopropylidene-α-L-sorbofuranose (II).*—A mixture of II (3 g.) and powdered sodium hydroxide (2 g.) in liquid ammonia (12 ml.) was kept at room temperature for 10 days or heated on a boiling water-bath for 40 hr. The ammonia was allowed to evaporate, the residue was extracted with acetone, and the solution was dried and evaporated. Recrystallization from *n*-hexane gave IX (1.4 g.); m. p. 78°C.

1, 6-Di-O-tosyl-2, 3-O-isopropylidene-α-L-sorbofuranose (V).—A mixture of V (1 g.) and sodium hydroxide (1 g.) in liquid ammonia (10 ml.) was kept at room temperature and occasionally shaken for two weeks. After the ammonia had been removed, the residue was diluted with water and extracted with chloroform, which was evaporated to give a sirup. Recrystallization of the sirup from *n*-hexane gave colorless needles (XV) (0.4 g.); m. p. 92°C, $[\alpha]_D^{24.5}$ −34.5 (*c* 1.051, chloroform).

Found: C, 53.47; H, 6.90. Calcd. for $C_9H_{14}O_5$ (202): C, 53.41; H, 7.01%.

A solution of the crystals (0.4 g.) and *p*-nitrobenzoyl chloride (0.8 g.) in dry pyridine (2 ml.) was stirred at room temperature for 5 hr. The raction mixture was then poured into a saturated solution of sodium hydroxide and extracted with chloroform, from which *p*-nitrobenzoate of XV was obtained (0.6 g.). M. p. 5°C (decomp.) (recrystallized from ethanol).

Found: C, 54.58; H, 4.71; N, 4.01. Calcd. for $C_{16}H_{17}NO_8$ (351): C, 54.70; H, 4.80; N, 3.99%.

6-O-Tosyl-2, 3-O-isopropylidene-α-L-sorbofuranose (VI).—A reaction mixture of VI (1 g.) and powdered sodium hydroxide (1 g.) in liquid ammonia (12 ml.) was worked up by the procedure used for the reaction of II. The yield of I was 0.5 g. (recrystallized from ethyl acetate).

1-O-Tosyl-2, 3-O-isopropylidene-α-L-sorbofuranose (XVI).—A reaction mixture of XVI (1 g.) and sodium hydroxide (1 g.) in liquid ammonia (12 ml.) was worked up by the procedure used for the reaction of V. The yield of *p*-nitrobenzoate of XV was 0.5 g.; m. p. 85°C (decomp.).

The Reactions with Sodium Hydrosulfide in Liquid Ammonia. — *1-O-Tosyl-2, 3 : 4, 6-di-O-isopropylidene-α-L-sorbofuranose (II).*—A solution of II (1 g.) and sodium hydrosulfide (1 g.) in liquid ammonia (10 ml.) was heated on a boiling water-bath for 50 hr. After the ammonia had been removed, the residue was diluted with water and then extracted with chloroform. This was washed with water, dried, and evaporated. Recrystallization from *n*-hexane and ethyl acetate gave XVII (0.2 g.); m. p. 136°C.

1, 6-Di-O-tosyl-2, 3-O-isopropylidene-α-L-sorbofuranose (V).—A mixture of V (2 g.) and sodium hydrosulfide (2 g.) in liquid ammonia (10 ml.) was heated on a boiling water-bath for 44 hr. After the ammonia had been removed, the residue was diluted with water and extracted with chloroform; the extract was then washed with water, dried, and evaporated to obtain a sirup. The sirup was chromatographed on silica gel: first fraction (benzene) 100 ml.; second fraction (benzene : ether, 9 : 1, v/v), 100 ml., and third fraction (benzene : ether, 7 : 3, v/v), 1 l. From the third fraction, XVIII (600 mg.) was obtained as a sirup; $[\alpha]_D^{27}$ +19.2 (*c* 1.184, chloroform).

Found: C, 49.14; H, 6.69; S, 14.56. Calcd. for $C_9H_{14}O_4S$ (218): C, 49.34; H, 6.42; S, 14.79%.

The Reaction of 4, 6-Di-O-tosyl-2, 3-O-isopropylidene-α-L-sorbofuranose (XIX) with Sodium Hydrosulfide in Liquid Ammonia was the same as that of XV with sodium hydrosulfide in liquid ammonia.

6-O-Tosyl-2, 3-O-isopropylidene-α-L-sorbofuranose (VI).—A solution of VI (2.5 g.) and sodium hydrosulfide (2.5 g.) in liquid ammonia (25 ml.) was heated on a boiling water-bath for 40 hr. After the ammonia had been removed, the residue was diluted with water and extracted with chloroform; the extract was then washed with water, dried, and evaporated. The recrystallization of the residue from ethyl acetate and *n*-hexane gave XX (0.6 g.); m. p. 160°C.

1-O-Tosyl-2, 3-O-isopropylidene-α-L-sorbofuranose (XVI).—A solution of XVI (2.5 g.) and sodium hydrosulfide (2.5 g.) in liquid ammonia (25 ml.) was heated on a boiling water-bath for 40 hr. XXI was obtained by the above-described procedure. Yield, 0.5 g.; m. p. 108°C. $[\alpha]_D^{25.5}$ +32.7 (*c* 0.954, chloro-

form).

Found: C, 49.21; H, 6.91; S, 7.29. Calcd. for $C_{18}H_{30}O_{10}S$ (438): C, 49.40; H, 6.85; S, 7.19%.

The Tosylation of 1, 4-Anhydro-2, 3-*O*-isopropylidene-α-L-sorbofuranose (XV).—A solution of XV (0.5 g.) and tosyl chloride (1.0 g.) in dry pyridine (3 ml.) was stirred at room temperature for 6 hr. The reaction mixture was then poured into a saturated solution of sodium carbonate and extracted with chloroform; from the extract X (0.9 g.) was obtained. M. p. 115°C.

The Hydrolysis of 1, 4-Anhydro-2, 3-*O*-isopropylidene-6-thio-α-L-sorbofuranose (XVIII).—A solution of XVIII (0.5 g.) in 80% methanol (20 ml.) containing sodium hydroxide (0.1 g.) was boiled for 2 hr. under a nitrogen stream. After cooling, the solution was diluted with water, extracted with chloroform, washed with water, and dried. The removal of the chloroform gave XX (0.2 g.); m. p. 160°C.

The author wishes to express his grattiude to Dr. Ken'ichi Takeda, Director of the labratory, and to Dr. Kaname Hamamoto, Assistant Director of this laboratory, for their encouragement. He is also indebted to Dr. Yoshiki Matsui of this laboratory for his valuable discussions of the infrared spectra.

The Stability of Fused Rings in Metal Chelates. II. Copper(II) Complexes of Schiff Bases Derived from Pyruvic Acid and Amino Acids or Diamines[1]

By Akitsugu NAKAHARA, Haruyo YAMAMOTO and Hironobu MATSUMOTO

(Received February 1, 1964)

It has long been observed that an increase in the number of rings within a particular chelate structure results in the greater stability of the chelate. For example, when Calvin and Bailes[2] studied polarographically the relationship between structure and stability for the salicylaldimine copper(II) chelates, they concluded that the effect of tying together the coordinating groups to form additional rings is most essential in stabilizing the chelate. The same trend was also pointed out by Schwarzenbach[3] for a number of zinc complexes from a comparison of their formation constants. No attempt has, however, yet been made to investigate systematically how the structural factors of individual rings in a metal polydentate influence the stability of the whole fused-ring system.

The present paper is a report on a more or less quantitative survey to determine the influence of an alteration of the size of individual rings upon the stability of the fused-ring system in copper(II)-Schiff base chelates. Spectroscopic and polarographic methods were applied to determine the relative stability of those chelates. Glycine, β-alanine, ethylenediamine and trimethylenediamine were selected as amino compounds to form Schiff bases with carbonyl compounds, such as pyruvic acid, acetylacetone and salicylaldehyde. Consequently, we have succeeded in isolating four new copper(II) complexes derived from pyruvic acid. The preparation and properties of these new chelates will also be described in this paper.

Experimental

The Preparation of Copper(II) Chelates.—*Copper(II) Chelate of the Schiff Base Derived from Pyruvic Acid and Glycine, A.*—To a solution of 12.5 g. of glycine in 50 ml. of aqueous ethanol (two to one by volume mixture) was added 14.3 g. of pyruvic acid. The resulting mixture was stirred and heated at about 40°C. To this was added 33.3 g. of copper(II) acetate monohydrate. The reaction mixture was kept at 40°C for about two more hours while being constantly stirred. A dark blue solution was gradually obtained, accompanied by a precipitation of pale blue microscopic crystals. The precipitate was filtered by suction and recrystallized from a small amount of water.

The final pure product appears as thin, pale blue plates which begin to decompose at 192°C. The compound is soluble in water and is slightly soluble in ethanol, but it is insoluble in acetone

or chloroform.

Found: C, 23.13; H, 4.23; N, 5.57; H_2O, 20.50. Calcd. for dihydrate of A, $[Cu(pyv=gly)(H_2O)]\cdot 2H_2O$: C, 23.00; H, 4.21; N, 5.36; H_2O, 20.65%.

Copper(II) Chelate of a Schiff Base Derived from Pyruvic Acid and β-Alanine, B.—To a solution of 6.5 g. of β-alanine in 50 ml. of water 6.4 g. of pyruvic acid was added. The mixture was stirred and heated at about 45°C. To this was added copper(II) hydroxide or oxide freshly precipitated from an aqueous solution containing 20 g. of copper(II) sulfate pentahydrate. The resulting mixture was kept at 45°C for about five hours while being constantly stirred. The color of the solution gradually changed from dark green to bluish geen. The solution was then filtered to remove unreacted copper(II) hydroxide and was allowed to stand at 0°C. Beautiful blue monoclinic crystals were obtained after 24 hr. The compound was found to decompose at 210°C. The compound is soluble in water and ethanol, but it is insoluble in acetone or chloroform.

Found: C, 26.15; H, 4.64; N, 5.11; H_2O, 19.43. Calcd. for dihydrate of B, $[Cu(pyv=\beta\text{-ala})(H_2O)]\cdot 2H_2O$: C, 26.20; H, 4.73; N, 5.09; H_2O, 19.65%.

Copper(II) Chelate of the Schiff Base Derived from Pyruvic Acid and Ethylenediamine, C.—To a solution of 7.5 g. of ethylenediamine in 100 ml. of methanol in an ice-bath, 22 g. of pyruvic acid was gradually added. After the completion of a vigorous reaction, the resulting mixture was stirred and heated at about 50°C. Hereupon an yellowish orange precipitate resulting from the formation of the Schiff base was obtained. The precipitate was filtered by suction and dissolved in 100 ml. of water without further purification. To this was added cupric oxide freshly precipitated from an aqueous solution containing 35 g. of copper(II) sulfate pentahydrate. The resulting mixture was kept at 50°C for two hours while being constantly stirred. The reaction mixture was filtered while it was warm. A large amount of acetone was then added to the filtrate. Hereupon, a dark green, crystalline solid was deposited. To purify the chelate, the above procedure of adding a large amount of acetone to the concentrated aqueous solution of the chelate was repeated several times. Since the compound which had not completely dried readily became sticky on being exposed to air, in order to accomplish complete dehydration it was necessary to dry the compound in vacuo for three days.

The compound appears green and was found to decompose at 184°C. The compound is soluble in water but insoluble in common organic solvents.

Found: C, 37.92; H, 4.26; N, 10.42. Calcd. for C, $[Cu(pyv=en=pyv)]$: C, 36.71; H, 3.82; N, 10.71%.

Copper(II) Chelate of the Schiff Base Derived from Pyruvic Acid and Trimethylenediamine, D.—To a solution of 8.8 g. of trimethylenediamine in 10 ml. of water 22 g. of pyruvic acid was added. The solution changed to yellowish orange on account of the formation of the Schiff base. To this was added copper(II) hydroxide or oxide freshly precipitated from an aqueous solution containing 32 g. of copper(II) sulfate pentahydrate. The resulting mixture was kept at 45°C for three hours while being constantly stirred and was then filtered. When the solution was allowed to stand at 0°C, blue crystals were deposited. These were recrystallized from water to give beautiful needles which decompose at 208°C. The compound is soluble in water and pyridine, but insoluble in ethanol, acetone and chloroform.

Found: C, 36.54; H, 4.75; N, 9.61. Calcd. for monohydrate of D, $[Cu(pyv=trim=pyv)]\cdot H_2O$: C, 36.85; H, 4.77; N, 9.54%.

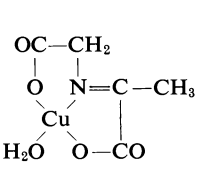
Copper(II) Chelates of Schiff Bases Derived from Acetylacetone and Diamines, E and F. — These two chelates were prepared according to the directions of McCarthy et al.[4] The compound E in the crystalline state appears purple right after the recrystallization from methanol, but when it comes in contact with water vapor, when allowed to stand in the atmosphere, it gradually changes green. This is probably because of an additional coordination of the water molecule around copper(II), as has been demonstrated for the copper(II) chelates of salicylaldehyde-Schiff bases.[5,6]

On the other hand, the compound F only appears green in spite of having no crystal water. The compound E was found decompose at 144°C, while F decomposed at 97°C. Both the two compounds are readily soluble in common organic solvents but only slightly soluble in water.

Copper(II) Chelates of Schiff Bases Derived from Salicylaldehyde and Diamines, G and H. — These two chelates were prepared by the method of Pfeiffer et al.[7] from a mixture of 1 : 2 : 1 copper(II) : salicylaldehyde : ethylene- or trimethylenediamine. No decomposition was observed, at least below 260°C, for these two compounds. The chelate G is green in the crystalline state, purple in a chloroform solution and bluish green in a pyridine solution. It is insoluble in water, ethanol and acetone. On the other hand, the chelate H is purple in the crystalline state and green in chloroform and pyridine solutions. The color of these chelates is apparently closely related to the additional coordination of solvent molecules around copper(II) as well as to their original chelate structure. This point, however, awaits further investigation.

Spectroscopic Measurements. — The visible and ultraviolet absorption spectra of the chelates were determined with a Shimadzu spectrophotometer Type QB-50 at room temperature. The solvent used here was water in all cases, and the concentrations of the solutions varied from 10^{-3} to 10^{-5} M.

Polarographic Measurements. — Measurements were made with a Yanagimoto recording polarograph model PA-102. An "H" cell was used, the reference electrode being a saturated calomel electrode and the whole cell being thermostated at 25±0.5°C.



Pure distilled mercury was used throughout. C. p. chemicals were used in all cases. Tank nitrogen was bubbled without any further purification

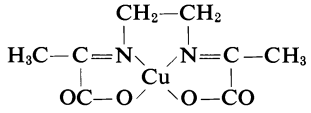
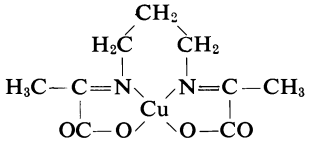
through the samples to remove dissolved oxygen. The concentration of the copper(II) chelates varied from 10^{-4} to 10^{-3} M. The supporting electrolyte used was 0.1 M potassium nitrate in all cases. As for the maximum suppressor, methyl red was employed in all cases. A point was plotted for each individual drop on the rising part of the curve, and at least six values were used along the mid-portion of the curve. The plot of log $i/(i_d-i)$ against the voltage invariably resulted in a straight line with an allowable scatter of points and a slope of either nearly 0.06 or 0.03. The half-wave potential was taken as that value of the voltage for which the log term was zero.

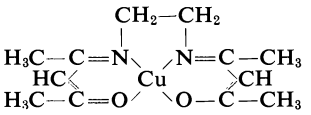
Results and Discussion



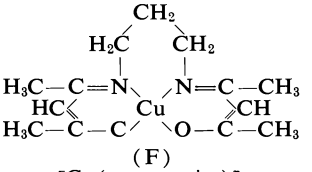
As was described in the preceding section, pyruvic acid condenses in the presence of copper(II) with glycine, β-alanine, ethylenediamine and trimethylenediamine, giving rise to the respective copper(II)-Schiff base chelate. It seems quite reasonable to assign the following structures, A → D, to the four copper(II) chelates on the basis of the analytical data and the quadri-coordinating character of copper(II) complexes.



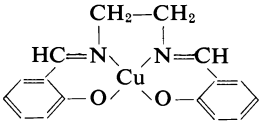
(A)
[Cu(pyv=gly)(OH$_2$)]



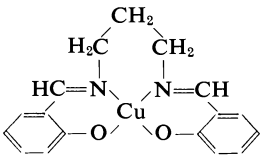
(B)
[Cu(pyv=β-ala)(OH$_2$)]



(C)
[Cu(pyv$_2$=en)]



(D)
[Cu(pyv$_2$=trim)]



(E)
[Cu(acac$_2$=en)]

(F)
[Cu(acac$_2$=trim)]

(G)
[Cu(salal$_2$=en)]

(H)
[Cu(salal$_2$=trim)]

The difference in structure between A and B, or between C and D, is only the number of methylene groups in the same part of the organic residues. The four atoms bound to copper(II) are exactly the same in each pair. In other words, the skeletal structure of A consists of two adjacent five-membered rings, 5-5,* while that of B is five- and six-membered rings, 5-6.* In the same way, the skeletal structures of C and D are expressed as 5-5-5 and 5-6-5 respectively.

From a comparison of the properties of the respective aqueous solution, A is considered to be less stable than B. For instance, A is more difficult to recrystallize from water than B because it is accompanied by a decomposition to some extent in an aqueous solution. A slight difference is observed also in a comparison of their decomposing temperatures, as is shown in Table I.

Since the decomposing temperature of A is distinctly lower than that of B, the same relationship in relative stability, A<B, is supported here again. This situation seems to be characteristic of this type of fused-ring system, since it has been known that glycine generally forms a more stable chelate ring than β-alanine.[8-10] The same characteristic is observed also in a comparison of the other pair, C and D. Trimethylenediamine seems to be more favorable than ethylenediamine to forming stable interlocked rings around copper(II) between two pyruvate residues, unlike when they are respectively coordinated to a metal to form a single ring.[11,12] The difference in stability is observed to be much greater in

* Hereafter the notation "5-5" will be adopted for this type of fused rings. In the same manner, the fused rings in B, C and D will be expressed as 6-5, 5-5-5 and 5-6-5 respectively.

this particular case, C<D. While D is readily recrystallized from hot water to give typical beautiful crystals, C is not satisfactorily recrystallized from any solvent, as has been described in the preceding section. The same order in stability is confirmed from a comparison of their decomposing temperature, as is shown in Table I.

The influence of the ethylene- and trimethylene-diamine chelate rings upon the stability of the respective fused-ring system, however, is reversed in the case of the acetylacetone- or salicylaldehyde-Schiff base complex, as is clear from Table I, E>F, G>H. The evidence for this is not obtainable from the same preliminary tests as employed above, but it is given by spectroscopic and polarographic data, as will be discussed in the later part of this paper. At any rate, ethylenediamine is considered to have an advantage over trimethylenediamine in forming fused rings around copper(II) with two acetylacetone or salicylaldehyde residues. This is probably a very important example to demonstrate the influence of the alteration of the size of individual rings upon the stability of the whole fused-ring system in metal polydentates. That is to say, a five-membered ring stabilizes the fused-ring system more than a six-membered ring does when either is respectively located between two six-membered rings, while the same five-membered ring stabilizes the fused-ring system less than the six-membered ring does when either is located between two five-membered rings, (5-5-5<5-6-5, 6-5-6>6-6-6).

Hence, it may be concluded that the stability of a fused-ring can not be predicted from the simple summation of the stabilty of the individual rings contained in the fused-ring system. It is considered that this is because no stress on any individual ring in metal polydentate chelates is deposited in the same ring; rather, it spreads to some extent over the whole fused-ring system, being sometimes strengthened and at other times weakened or even completely cancelled by another stress on another ring in the system.

After all, the stability of metal polydentate chelates increases with the decreasing stress over the whole fused-ring system.

For example, ethylenediamine, which is located between two pyruvate rings as a bridge in a polydentate ligand, does not weaken the stress on the adjacent copper-pyruvate rings, probably because of its too short chain, but trimethylenediamine is supposed to be long enough to weaken the stress in such a case. The above consideration can easily be supported by a simple test making use of the Stuart model. On the other hand, if the adjacent metal chelate rings are six-membered rings, such as metal-acetylacetone or -salicylaldehyde, it is not necessary to assume a significant stress on those metal-chelate rings. Hence, trimethylenediamine, which is located between two those six-membered rings, would preferably be unfavorable to forming a stable structure because of its too long chain. Ethylenediamine may fit in such a situation contrary to the above case. The greater stability of the β-alanine-pyruvate complex, B, compared with the glycine-pyruvate complex, A, is explainable from the same point of view.

Spectroscopic Studies.—It is also of interest to compare the relationship between the structure and the light absorption for those copper(II) chelates. The color of A is pale bule, while that of B is a little more intense blue. The chelate C appears green, while D appears blue. This is a great difference compared with their difference in structure.

The visible and ultraviolet absorption spectra

(H)	2:1 Salicylaldehyde: Trimethylenediamine	6-6-6	Violet (cryst.) Green (in chloroform) Green (in pyridine)	ν, 49.6 log ε, 2.37 (in $CHCl_3$)	$E_{1/2}$, −0.66 V., irrev.

of those four chelates in an aqueous solution are shown in Fig. 1 (A and B), and in Fig. 2 (C and D), while their numerical data are shown in Table I.

It is expected that the greater the stress through the fused-ring system, the greater the weakening of the ligand field around copper(II). Moreover, the weakening of the ligand field is supposed to be reflected in the degree of bathochromic shifting of the absorption band.

Therefore, the ligand-field absorption band in each spectrum may be considered to be a measure of the stability of those chelates. From this point of view, a more or less quantitative survey may be made on the basis of spectroscopic studies to decide the influence of the alteration of the size of individual rings upon the stability of the whole fused-ring system in copper(II) chelates. The stability order, (A) 5-5<(B) 5-6; (C) 5-5-5<(D) 5-6-5, is confirmed here again by the results of the spectroscopic investigation. As to the acetylacetene-Schiff base chelates, the same stability order as mentioned above, (E) 6-5-6>(F) 6-6-6, is reaffirmed in the same way.

Polarographic Studies. — A comparison of half-wave potentials for the same type of complexes under the same conditions may be an important approach to ascertaining the relative stability of the complexes against the reduction at the dropping mercury electrode. Of course, the more negative the value of the half-wave potential, the greater the stability of the complex. The numerical data are summarized in Table I.

It is necessary to consider at least two electrode reactions for the cases of the comparatively unstable chelates, such as A, B, C and D: (1) the direct reduction of the copper(II) chelate; and (2) the reduction of unchelated Cu^{2+}, which is produced by the dissociation of the copper(II) chelate. This is because each polarogram more or less contains a reduction wave which coincides with that of the simple cupric ion as well as with that of the copper(II) chelate concerned. Since, however, the redution wave of simple cupric ion* mostly appears considerably away from that of the chelated copper(II), there was no interference with the determination of the half-wave potentials.

* The half-wave potential of the simple cupric ion for the reduction of Cu^{2+} to Cu^0 was determined to be +0.05 V. vs. SCE at 30°C in a 0.1 M potassium nitrate solution containing 0.01% gelatine.

On the other hand, it is unnecessary to take the decomposition of complexes into account for the cases of fairly stable chelates such as E and F, since the dissociation is slow compared to the direct reduction of the chelate at the electrode. The absorption spectra of those very stable chelate solutions also showed no indications of dissociation occurring.

The half-wave potential presented by Calvin and Bailes.[2] for the copper(II) chelate of salicylaldehyde-ethylenediamine, G, is −0.75 V., showing a considerable discrepancy with the present value, −0.94 V. (cf. Table I). This is understandable when we remember the difference in the conditions applied in the respective measurements. In the present work, the measurements for G and H were made with a 0.1 M potassium nitrate solution of a 50% (by volume) mixture of pyridine and water, using methyl red as the maximum suppressor. Calvin and Bailes used hydrochloric acid instead of potassium nitrate, and used no maximum suppressor. At any rate, it is not significant to discuss the cases of G and H quantitatively since they are certainly not reversible waves. At the same time, it is not necessary to know the precise values of the half-wave potentials in all cases either, since our present purpose is a qualitative comparison of the effects of changes in structure upon the nature of the chelate. However, all the polarograms other than those of G and H are supposed to be at least good enough for a semi-quantitative discussion.

The order in stability established by the polarographic studies shows a precise coincidence with that obtained from preliminary tests or spectroscopic studies previously described: (A) 5-5 < (B) 6-5; (C) 5-5-5 < (D) 5-6-5; (E) 6-5-6 > (F) 6-6-6; (G) 6-5-6 > (H) 6-6-6.

Summary

The preparation and some properties of four new copper(II) chelates of Schiff bases produced from pyruvic acid and amino acids or diamines have been reported.

The relative stability of these compounds as well as of other rather popular copper(II) chelates has been discussed on the basis of spectroscopic and polarographic investigations.

It has been demonstrated that any stress on any individual ring in metal polydentate chelates does not generally tend to be deposited in the same ring, but rather spreads to some extent over the whole fused-ring system, sometimes strengthened and at other times weakened or even completely cancelled by another stress on another ring in the system. Therefore, the stability of fused rings should not be discussed on the basis of a simple summation of the stability of individual rings contained in the fused-ring system. It has been concluded that the stability of metal polydentate chelates increases with a decrease in stress over the whole fused-ring system.

A part of the expenses for this work was defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

The Thermal and Radiation Oxidation of Benzene to Phenol in Aqueous Solutions Containing Metal Ions at Elevated Temperatures. V. The Thermal Oxidation of Phenol and Maleic Acid

By Kazuo SHIMADA, Nobutake SUZUKI, Nobue ITATANI and Hiroshi HOTTA*

(Received February 3, 1964)

The thermal oxidation of phenol in aqueous solutions was studied under the same conditions as for that of benzene to phenol in order to understand the benzene oxidation reported on in previous papers,[1] for the phenol produced might be also oxidized successively to other compounds. The oxidation of maleic acid was also studied with reference to this subject.

Experimental

Oxidation Procedure. — 5.35×10^{-2} M of phenol was dissolved in neutral and 0.1 N sulfuric acid solutions, to which ferrous, ferric and cupric sulfates were then added by 0.01 M as metal ions. These solutions were oxidized for 30 min. at 100~200°C under an oxygen pressure of 30 atmospheres (at room temperature) by means of that procedure mentioned in Part II.[2] For reference, the same experiment was also carried out without any metal ions. This initial concentration of phenol is about 2~3 times as great as the largest amount of phenol produced in the previous oxidation of benzene.[2]

Analytical.—After a thermal oxidation, the aqueous solutions were quantitatively analyzed directly by gas chromatography using a polyethylene-glycol (PEG 6000) column at the several temperatures (cf. Table I), depending upon the products to be

TABLE I. TEMPERATURE OF PEG COLUMN, °C

Formaldehyde	100
Acetic acid	130
Formic acid	130
Phenol	180

analyzed. The order of the substance described in Table I is that of their retention time. Some of their peaks were assigned by other methods (to be mentioned later) as well as by the retention time. Some products were also identified by thin-layer chromatography.

The concentration of iron species in the solution after the reaction was determined by the same methods as in Part II.[2]

Results

The results in all the figures except Figs. 2, 3 and 9 are shown by circle (⊙ and ●), triangle (△ and ▲) and square (▣ and ■) marks for ferrous, ferric and cupric sulfates respectively. The open marks and solid lines are for the neutral solutions, while the solid marks and dotted lines are for the 0.1 N sulfuric acid solutions. The results without any metal ion are shown by crosses (×) for the aqueous solution and by circle crosses (⊗) for the 0.1 N sulfuric acid solution.

Phenol and Metal Ions after Reaction.—The amounts of phenol after reaction are shown in Fig. 1. The results can be interpreted in the terms used for the effect of metal ions on the benzene oxidation in previous papers.[1,2] The decomposition of phenol is suppressed in the acidic solutions, in which the concentration of ions is lowered. The effect of cupric sulfate can be understood by the fact that the concentration is high even at elevated temperatures,

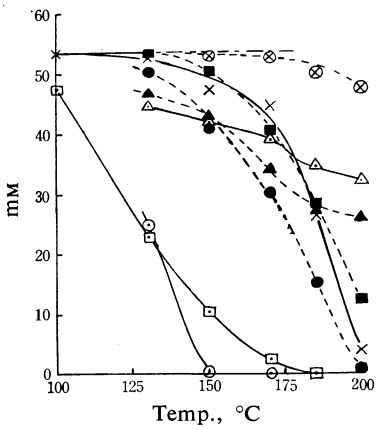

Fig. 1. Amounts of phenol after reaction in the solutions of ferrous (⊙ and ●,) ferric (△ and ▲) and cupric (▣ and ■) sulfates, and without any metal ion (× and ⊗). The results of the aqueous solutions are represented by open marks and crosses (×), and those of the 0.1 N sulfuric acid solutions by solid marks and circle crosses (⊗).

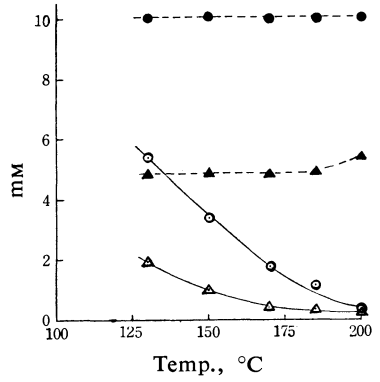

Fig. 2. Concentrations of iron species (⊙ and ●) and ferrous species (△ and ▲) after reaction in the ferrous sulfate solutions. Open marks are for the neutral solution, and solid marks for the 0.1 N sulfuric acid one.

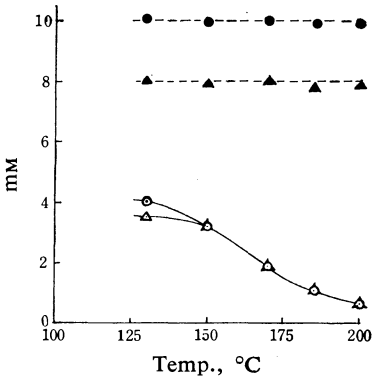

Fig. 3. Concentrations of iron and ferrous species after reaction in the ferric sulfate solutions. Marks are the same as in Fig. 2.

unlike iron salts.[1]

The total concentrations of iron species (⊙ and ●) and the contents of ferrous species (△ and ▲) dissolved in the solutions of ferrous and ferric sulfates after reaction are shown in Figs. 2 and 3 respectively. The open marks are for the neutral solutions, while the solid marks for the 0.1 N sulfuric acid solutions.

Acetic and Formic Acids.—The amounts of acetic acid produced are shown in Fig. 4. Acetic acid was identified by the mass-spectrum of the fraction obtained by gas chromatography, the chemical shift of its unclear magnetic resonance spectrum, and the behavior for extraction procedure, as well as by the retention time of the gas chromatography. It was also confirmed by the presence of acetaldehyde among the products, as will be mentioned below.

There was a peak other than that of acetic acid for the gas chromatography of the samples oxidized at 200°C. This is supposed to be of

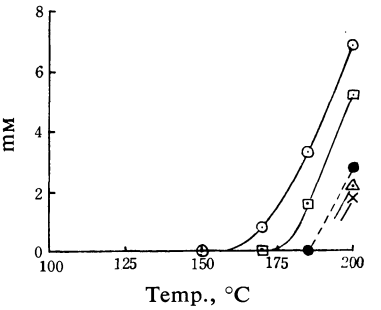

Fig. 4. Amounts of acetic acid produced in the various solutions. Marks are the same as in Fig. 1.

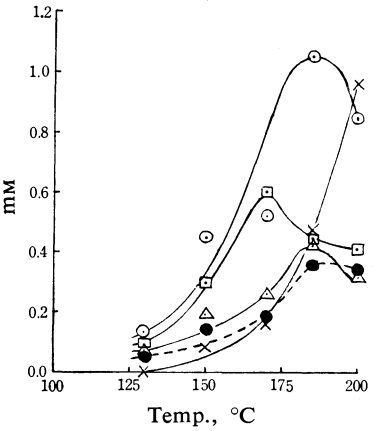

Fig. 5. Amounts of acetaldehyde produced in the various solutions. Marks are the same as in Fig. 1.

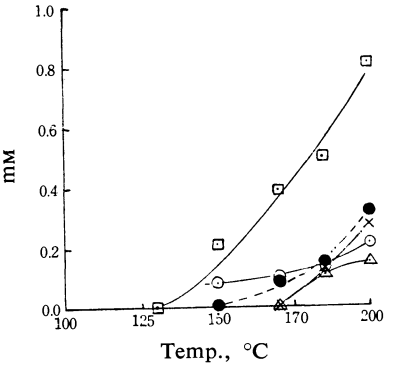

Fig. 6. Amounts of formaldehyde produced in the various solutions. Marks are the same as in Fig. 1.

formic acid judging from the retention time and the behavior of the extraction procedure, especially, the fact that the peak disappears when extracted by ether.

Aldehydes and Acetone. — The amounts of acetaldehyde and formaldehyde are shown in Figs. 5 and 6 respectively. The amounts of acetone produced are also shown in Fig. 7.

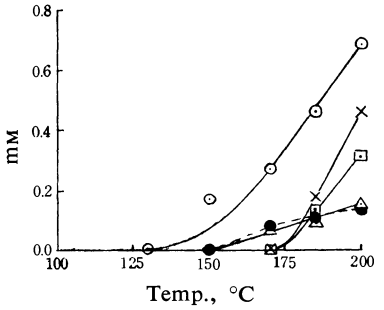

Fig. 7. Amounts of acetone produced in the various solutions. Marks are the same as in Fig. 1.

The carbonyl compounds were identified as their 2,4-dinitrophenyl hydrazone according to Johnson and Scholes.[3] They gave two absorption peaks at 360 and 560 mμ in the ethanolic alkaline solution dissolved after having been extracted into carbon tetrachloride. The former peak is usually given by monoaldehydes, and the latter by glyoxal and *p*-quinone. The uncorrected melting points of the hydrazones, given from the sample oxidized at 200°C in the aqueous solution of cupric sulfate, were 138~141°C and 160°C for the fraction dissolved in methanol, and 270~280°C for the insoluble fraction respectively. The melting points of the related hydrazones in the literature[4] are listed in Table II.

Table II. Melting point of 2,4-dinitrophenyl hydrazone derivatives, °C

Acetone	126
Acetaldehyde	147, 168
Formaldehyde	166
p-Quinone	267~268
Glyoxal	328

The reduction of ferric ions to ferrous ions, as seen in Figs. 2 and 3, is due not only to their reactions with aldehydes, but also to those with hydroperoxides in the chain oxidation process, as has been pointed out in our previous papers;[1] that is,

$$ROOH + M^{2+} = ROO + H^{+} + M^{+}$$

Carbon Dioxide.—The concentrations of carbon dioxide dissolved in the aqueous phase at the first day after reaction are shown in Fig. 8. They have been estimated approximately according to Seidell's textbook.[5]

Thin-layer Chromatography.—Some products

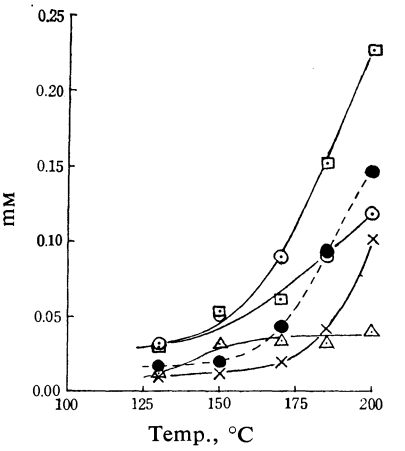

Fig. 8. Concentrations of carbon dioxide dissolved in the aqueous solutions at the first day after reaction. Marks are the same as in Fig. 1.

were detected by thin-layer chromatography using silica gel as an adsorbent on a glass plate[6] as follows (the detailed results will be described elsewhere).

When the sample, oxidized at 130°C in the aqueous solution of ferrous sulfate, was developed on the plate with a solvent composed of benzene 75+ethyl formate 24+formic acid 1, there were three spots of low R_f-values and two spots of high R_f-values. The former spots, colored by bromocresol green, were identified as oxalic, maleic and fumaric acids, and the latter spots, colored by a 5% iodine solution of ethanol, as *o*- and *p*-dihydroxybenzenes, from their R_f-values. The sample, oxidized at 200°C, gave only the spot of oxalic acid, suggesting that all the above products except oxalic acid decomposed at the higher temperature. *o*- and *p*-Dihydroxybenzenes have been reported to be found in the aqueous oxidation of phenol by Fenton's reagent or by X-rays at room temperature.[7]

Discussion

When the production of the decomposition products is compared with the consumption of phenol in Fig. 1, the amounts of the decomposition products are found to increase at higher temperatures, at which almost a part of phenol is consumed, suggesting that there are some fairly stable intermediates. This is shown clearly by the results concerning the aqueous solution of ferrous sulfate.

Since maleic and fumaric acids are detected by thin-layer chromatography, the oxidation

of these acids (4.33×10^{-2} M) in the aqueous solution of ferrous sulfate by means of the same procedure as was used for phenol was examined by gas chromatography and by the absorptiometry of 2,4-dinitrophenylhydrazone derivatives. The results, shown in Fig. 9, indicate that maleic acid gave acetic acid, acetaldehyde and formaldehyde. However, since fumaric acid is very stable, it did not give these products except for a trace amount of acetaldehyde. Therefore, it is likely that maleic acid is the stable precursor of these products in the oxidation of phenol. This is also supported by the fact that the amounts of acetic acid and aldehydes increase with the rise in temperature, while maleic and fumaric acids decrease at higher temperature, as is seen in thin-layer chromatography. Acetone was not given by these acids.

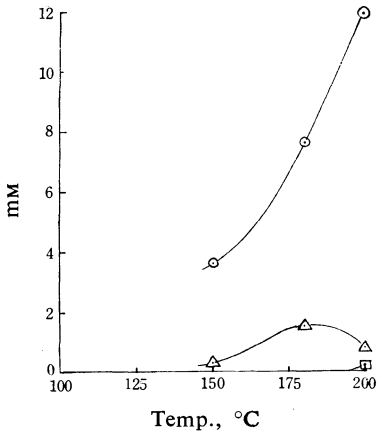

Fig. 9. Amounts of products from maleic acid (4.33×10^{-2} M) in the aqueous solution of ferrous sulfate; acetic acid (⊙), acetaldehyde (△) and formaldehyde (▣).

According to Bernatek et al.,[8-10] the ozonolysis of phenols, i.e., phenol, catechol, resorcinol and quinol, gives carbon dioxide, formic acid, oxalic acid and glyoxal, while that of *p*-benzoquinone gives formic acid, mesooxalic dialdehyde, glyoxylic acid, oxalic acid, maleic acid and carbon dioxide. However, they did not detect acetic acid and acetone.

Summary

The products of the oxidation of phenol in the aqueous solution (100~200°C) were analyzed by gas chromatography and by thin-layer chromatography. The amounts of the decomposition products, acetic acid, formic acid, acetaldehyde, formaldehyde, acetone and carbon dioxide, increase with a rise in temperature. On the other hand, maleic acid, fumaric acid and dihydroxybenzene decrease with a rise in temperature. Since the oxidation of maleic acid gives acetaldehyde, formaldehyde, and acetic acid, these products are considered to be produced through maleic acid from phenol. However, acetone is not given from maleic acid, but from phenol.

The Thermal and Radiation Oxidation of Benzene to Phenol in Aqueous Solutions Containing Metal Ions at Elevated Temperatures. VI. The By-products of Benzene Oxidation

By Hiroshi HOTTA, Nobutake SUZUKI, Nobue ITATANI and Kazuo SHIMADA

(Received February 3, 1964)

The oxidation of benzene catalyzed by metal ions has been discussed in previous papers,[1-3] in which the phenol yield has been shown to increase very little with the rise in temperature above 170°C. The present paper will analyze the by-products and compare them with those of phenol oxidation, which were reported on in Part V.[4]

Unpurified benzene was oxidized thermally in aqueous solutions of 0.01 M ferrous and cupric sulfates, while purified benzene was oxidized with gamma-ray irradiation in these solutions, both procedures being the same as in previous papers.[1,3] The products were then analyzed by means of gas chromatography as in Part V.[4] The amounts produced are shown in Fig. 1 for the ferrous solution and in Fig. 2 for the cupric solution, with open marks

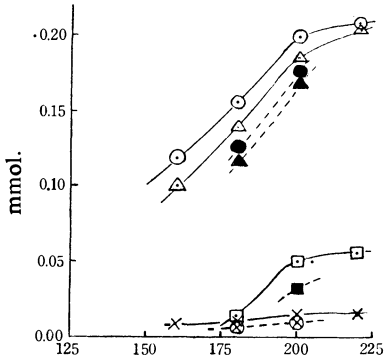

Fig. 1. Amounts of products produced in the aqueous solution of ferrous sulfate for the thermal oxidation of unpurified benzene (open marks and ×) and the radiation oxidation of purified benzene (solid marks and ⊗) : phenol by optical absorption, ⊙ and ● ; phenol by gas chromatography, △ and ▲ ; acetic acid by GC, ▣ and ■ ; and acetaldehyde by GC, × and ⊗.

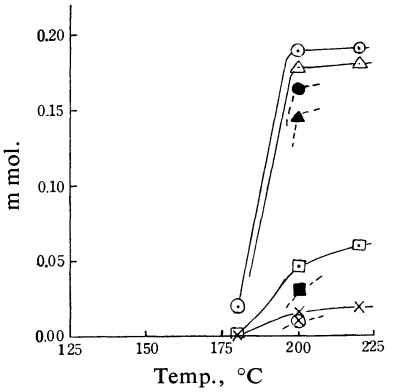

Fig. 2. Amounts of products produced in the aqueous solution of cupric sulfate ; marks are the same as in Fig. 1.

representing unpurified benzene and solid marks, purified benzene respectively. In the figures, the amounts of phenol dissolved in the aqueous phase, as analyzed by gas chromatography, are shown by triangles (△ and ▲). They are somewhat smaller than the amounts analyzed by optical absorption after ether extraction as in Parts II[1] and IV[3] and shown by circles (⊙ and ●). The amounts of acetic acid produced, shown by squares (▣ and ■), increased with the rise in temperature, even at 220°C, at which point the amount of phenol did not increase so much. The amounts of acetaldehyde produced, shown by crosses (×) for unpurified benzene and by circle-crosses (⊗) for purified benzene, did not increase at temperatures higher than 200°C, as in the case of phenol. The other products which had been found in the decomposition of phenol in Part V[4] were also detected in the present study. Formaldehyde and acetone were found to be in the greatest quantity by about 1.5×10^{-6} mole at 200°C.

When these results are compared with those in Part V, it may be concluded that the phenol produced is violently decomposed to acetic acid through acetaldehyde at high temperatures. That is, the saturation of the phenol yield at elevated temperatures is neither due to the self-inhibition effect of phenols on the oxidation

3) N. Suzuki and H. Hotta, ibid., 37, 224 (1964).
4) K. Shimada, N. Suzuki, N. Itatani and H. Hotta, ibid.. 37, 1143 (1964).

reactions,[5,6] nor to some termination and competing reactions with the chain-carrying radicals.[1] No biphenyl was detected for any of the ether extracts from the aqueous and benzene phases or in the inorganic precipitates after the reaction; gas chromatography with a PEG column at 180°C was the method employed.

Dihydroxybenzene, which was detected by thin-layer chromatography in Part V,[4] was found, by optical absorption for the thermal oxidation of benzene, in the ferrous sulfate solution by Terakawa et al.[7]

The presence of aldehydes among the oxidation products suggests that the reduction of ferric ions to ferrous ions, as seen in Part II,[1] is partly due to their reactions with aldehydes, not only to those with hydroperoxides, as has been discussed previously.[3]

The temperature dependences of the phenol yield in Figs. 1 and 2 are somewhat different from those in previous papers.[1,3] The present yields are somewhat smaller than those in the previous ones at the corresponding temperature, and they increase even at the temperature where there was saturation previously.[1,3] This is due to the difference of impurities in benzene, as has been discussed in Part IV.[3] In fact, the present unpurified benzene is rather pure, as may be seen by comparing Table I (the result of gas chromatography using a TCP-column at 70°C) with Table I of Part IV.[3]

Table I. Impurities in unpurified benzene, M

Carbon disulfide	2.7×10^{-4}
n-Hexane	1.7×10^{-4}
Cyclohexane	trace
Cyclohexene	trace
Thiophene	$<6\times10^{-4}$
Toluene	1.8×10^{-3}
Xylene	0

As may be seen in Figs. 1 and 2, phenol is produced from the purified benzene, which gave no appreciable peak of impurities in gas chromatography, unlike as in Part IV.[3] Therefore, the idea that the oxidation is initiated by benzene itself, as was assumed in Part II,[1] cannot be discarded, even if the impurities promote the oxidation process.

The Reaction Rate in Binary Mixed Solvents

By Yasuhiko KONDO* and Niichiro TOKURA*

(Received February 3, 1964)

The rate-determining factors in the reactions in a solution are considered to be (1) the type of reaction, (2) the nature of the chemical species of the reaction, and (3) the nature of the solvent used for the reaction, in addition to (4) such ordinarily-accepted factors as the reaction temperature, the concentration of the solutes and the viscosity of the solution. Studies of these factors up to the present time seem to have been concentrated on (2) and (4). The dependence of the reaction rate on the kind of the solvent, generally referred to as "the solvent effect," includes quite complicated problems, such as "the selectivity of the solvent,"[1] the details of which have not yet been solved.

Various attempts have been made to specify the type of effect exerted by solvents on the reaction rate. For example, several reports have been published on the participation of the solvent[2] and on the effects of the dielectric constants,[3] the *Y*-values[4] or the *Z*-values[5] of the solvents. However, all these researches relate only to a few special reactions. The

determination of the reaction rate can hardly be made for each quantity since each solvent has different selectivities during the course of the reaction.

When two solvents with different selectivities are chosen and mixed, the selectivity is expected to vary with the composition; therefore, the examination of the reaction rate in such mixtures must be profitable for the study of the dependence of the reaction rate on the nature of the solvent. To discuss the reaction rate in a mixed solvent system, the most important problem is whether there exists a general relation between the rate and the composition, a relation which would enable us to construct an empirical formula. Therefore, first an attempt was made to obtain a formula which would generalize the reaction.

The meanings of the parameters which appear in the experimentally-deduced formula will also be discussed.

The Method and the Results

When the relation between the rate constant and the composition of the solvent is discussed, the first problem to be solved is the choice of the measures with which the rate constant, k, and the composition, n, of the solvent are to be expressed. Log k was adopted for the purpose of discussing the reaction rate from the view point of the free energy of activation. Molar fraction was adopted for the expression of the composition of the solvent for the convenience of the discussion of the reaction rate, the rate equation of which is

$$k=\kappa(\boldsymbol{k}T/h)e^{-\Delta F^{\neq}/RT}$$

This equation is based on the absolute rate theory; in it, k is the rate constant, κ is the transmission coefficient, $\boldsymbol{k}$ is the Boltzmann constant, and $\Delta F^{\neq}$ is the free energy of activation.

If there is no selectivity, the plot of log k vs. the composition of the mixed solvent, x, should be linear. Howerer, the relation, as Fig. 1 shows, generally curves upward or downward. This indicates that the rate constant, $\boldsymbol{k}$, in the mixed solvent system would consist of two components, one of which depending on a linear correlation of log k vs. x (the linear plot in Fig. 1) and the other corresponding to the deviation from ideality.

Further treatment enables us to clarify the situation. When the deviation of log k from the linear correlation, $\Delta \log k$, taken on the abscissa, the curve shown in Fig. 2 is obtained. The general features of Fig. 2 indicate the following points. (In the figures, the pure solvent which gives the larger rate constant, A, is placed on the right end of the abscissa.

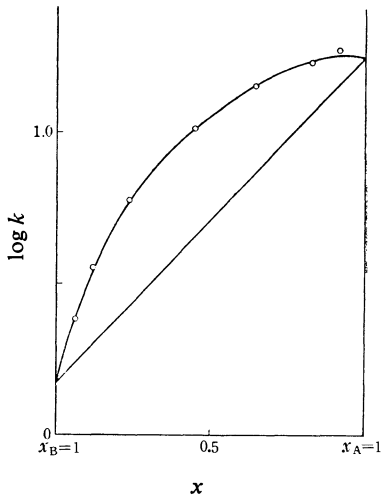

Fig. 1. Correlation between log k vs. the composition of the solvent mixture x.
The Menschutkin reaction in acetone (x_A)-benzene (x_B) mixture, between triethylamine and ethyl iodide.[11] Temp. 40°C

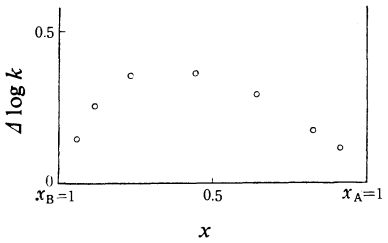

Fig. 2. A relationship between $\Delta \log k$ vs. x.
The Menschutkin reaction between triethylamine and ethyl iodide.[11]
x_A: Acetone, x_B: Benzene, Temp. 40°C

1) $\Delta \log k$ is always positive; i.e., $\Delta \log k>0$.

2) The maximum of $\Delta \log k$ lies at a molar composition smaller than $x_A=0.5$, where x_A is the molar composition of the solvent A.

Over twenty reactions in various solvent systems were examined to find if the above rules hold true (Table I). These reactions were the most elementary reactions involving (1) the chlorination of aromatic hydrocarbons, (2) the acylation of aromatic bases, and (3) the Menschutkin reactions, the details of which will be described in the following part of this paper.

An empirical equation is derived as follows:

(1) The part of the relation showing the linearity where the additivity rule is rate controlling is:

$$\log k_1=x_A \log k_A+x_B \log k_B \qquad (1)$$

where x_A and x_B are the molar compositions of the components A and B, and k_A and k_B are the rate constants of the same reaction in

the pure solvents A and B ($k_A > k_B$), respectively.

(2) The part representing the deviation from linearity may be expressed in correspondence with the theory of non-electrolyte solutions as follows:

$$\Delta \log k = x_A x_B \{a + b(x_A - x_B) + c(x_A - x_B)^2 + d(x_A - x_B)^3\} \quad (2)$$

Thus, the resultant rate formula must be:

$$\log k \text{ (mixture)} = (1) + (2) = \log k_1 + \Delta \log k = x_A \log k_A + x_B \log k_B + x_A x_B \{a + b(x_A - x_B) + c(x_A - x_B)^2 + d(x_A - x_B)^3\} \quad (4)$$

In view of the significance of the mixed solution, this equation may reasonably be accepted for the purpose of studying the reaction rate in a mixed solution.

The appicabilty of expression 4 depends on the third terms in the equation, where *a*, *b*, *c* and *d* are the parameters indicating the deviation from ideality or the long and short range interactions of the solvents. For the estimation of these parameters, the following method was adopted. The empirically-found $\Delta \log k$'s were plotted against the molar composition of the solvents. A curve passing through these plots was then drawn. From this curve the values of $\Delta \log k$'s at some selected points ($x_A = 0.15$, 0.35, 0.65 and 0.85 molar fractions) were obtained and substituted into Eq. 4. A number of the simultaneous equations thus obtained were solved to obtain the values of the respective parameters, *a*, *b*, *c* and *d*.

The curves calculated by the *a*, *b*, *c* and *d* parameters and the experimental plots of $\Delta \log k$ vs. x_A are compared in Figs. 3 and 4. As is indicated in Table I. The experimental results can be expressed with a good accuracy for various reactions by the appropriate choice of parameters.

Discussion

The Theoretical Derivation of Expression 4.— When the solvent effect of a reaction in a solution is discussed, it is necessary to take the effect of solvation into consideration. Taking the state in a vacuum as the standard, the relationship of the free energies with the reaction process is considered. In Fig. 5 the free energies of activation in a vacuum and in a solution are compared.

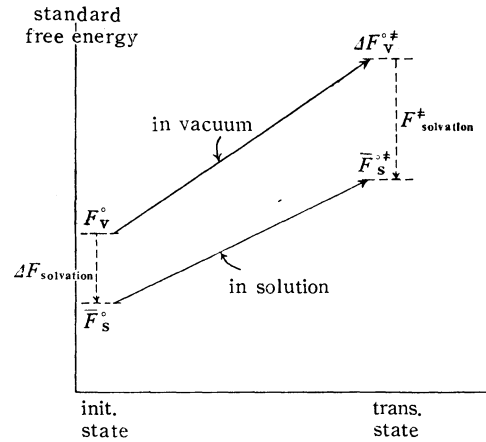

Fig. 5

The free energies of activation are indicated as:
Free energy of activation in a vacuum:

$$\Delta F_v^{\circ\ddagger} = \Delta F_v^{\circ\ddagger} - F_v^{\circ}$$

Free energy of activation in a solution:

$$\Delta \bar{F}_s^{\circ\ddagger} = \Delta \bar{F}_s^{\circ\ddagger} - \bar{F}_s^{\circ}$$

$$\bar{F}_s^{\circ} = F_v^{\circ} + \Delta F_{solvation}$$

and

$$\bar{F}_s^{\circ\ddagger} = F_v^{\circ\ddagger} + \Delta F^{\ddagger}_{solvation}$$

where F_v°, $F_v^{\circ\ddagger}$, $\bar{F}_s^{\circ}$ and $\bar{F}_s^{\circ\ddagger}$ are the free energies of the initial and the transition states in

a vacuum and in a solution respectively, and where $\Delta F_v^{\circ\ddagger}$ and $\Delta \overline{F}_s^{\circ\ddagger}$ are the free energies of activation in a vacuum and in a solution respectively.

Therefore,

$$\Delta \overline{F}_s^{\circ\ddagger} = \Delta F_v^{\circ\ddagger} + (\Delta F_{\text{solvation}}^{\ddagger} - \Delta F_{\text{solvation}}) \quad (5)$$

The reason why the solvent effect appears in the reaction in a solution must be due mostly to the difference in $(\Delta F_{\text{solvation}}^{\ddagger} - \Delta F_{\text{solvation}})$ for various solvents. What is most important in the discussion of the solvent effect is $\overline{F}_s^{\circ}$ and $\overline{F}_s^{\circ\ddagger}$, namely, the standard free energies of the initial and the transition states in the solution.

The free energies of the standard state of a solute in solvents 1 and 2 are expressed by $\overline{F}_1^{\circ}$ and $\overline{F}_2^{\circ}$, and the free energy of the solute in the standard state in a mixture of 1 and 2, by $\overline{F}_{12}^{\circ}$; x_1 and x_2 are the molar fractions of solvents 1 and 2 in the mixture. The next relation is assumed to hold when the free energy of the solute in the mixed solvent affected by component 1 is $F_{1x_1x_2}^{\circ}$:

$$\begin{aligned}\overline{F}_{1x_1x_2}^{\circ} = \overline{F}_1^{\circ} &+ \boldsymbol{RT}\cdot a_{12}x_2^2 + \boldsymbol{RT}b_1x_2^2(x_1-x_2) \\ &+ \boldsymbol{RT}\cdot c_{12}\cdot x_2^2(x_1-x_2)^2 \\ &+ \boldsymbol{RT}\cdot d_{12}\cdot x_2^2(x_1-x_2)^3 \end{aligned} \quad (6)$$

Similarly, the free energy of the solute affected by component 2, $\overline{F}_{2x_1x_2}^{\circ}$, is as follows:

$$\begin{aligned}\overline{F}_{2x_1x_2}^{\circ} = \overline{F}_2^{\circ} &+ \boldsymbol{RT}\cdot x_1^2\{a_{21} + b_{21}\cdot(x_2-x_1) \\ &+ c_{21}\cdot(x_2-x_1)^2 + d_{21}(x_2-x_1)^2\} \end{aligned} \quad (7)$$

and in a 1—2 system:

$a_{12}=a_{21}$, $b_{12}=-b_{21}$, $c_{12}=c_{21}$ and $d_{12}=-d_{21}$

When n_1 mole of the solute in solvent 1 is mixed with n_2 mole of the solute in solvent 2, the total free energy of the solute in the solvent is $(n_1+n_2)\overline{F}_{12}^{\circ}$; therefore,

$$\begin{aligned}(n_1+n_2)\overline{F}_{12}^{\circ} &= n_1\overline{F}_1^{\circ} + n_1\boldsymbol{RT}x_2^2\{a_{12} \\ &+ b_{12}(x_1-x_2) + c_{12}(x_1-x_2)^2 + d_{12}(x_1-x_2)^3\} \\ &+ n_2\boldsymbol{RT}x_2^2\{a_{21} + b_{21}(x_2-x_1) + c_{21}(x_1-x_1)^2 \\ &+ d_{21}(x_2-x_1)^3\} = n_1\overline{F}_1^{\circ} + n_2\overline{F}_2^{\circ} + (n_1\boldsymbol{RT}x_2^2 \\ &+ n_2\boldsymbol{RT}x_1^2)\{a_{12} + b_{12}(x_1-x_2)^2 + c_{12}(x_1-x_2)^2 \\ &+ d_{12}(x_1-x_2)^3\} \end{aligned} \quad (8)$$

Since $n_1/(n_1+n_2)=x_1$ and $n_2/(n_1+n_2)=x_2$

$$\begin{aligned}\overline{F}_{12}^{\circ} = x_1\overline{F}_1^{\circ} + x_2\overline{F}_2^{\circ} &+ \boldsymbol{RT}x_1x_2\{a_{12} + b_{12}(x_1-x_2) \\ &c_{12}(x_1-x_2)^2 + d_{12}(x_1-x_2)^3\} \end{aligned} \quad (9)$$

A similar relation holds for $\overline{F}_{12}^{\circ\ddagger}$. Therefore, the free energy of the activation in the mixture is:

$$\begin{aligned}\Delta \overline{F}_{12}^{\circ\ddagger} = \overline{F}_{12}^{\circ\ddagger} - \overline{F}_{12}^{\circ} &= x_1\Delta\overline{F}_1^{\circ\ddagger} + x_2\Delta\overline{F}_2^{\circ\ddagger} \\ &+ \boldsymbol{RT}x_1x_2\{a'_{12} + b'_{12}(x_1-x_2) \\ &+ c'_{12}(x_1-x_2)^2 + d'_{12}(x_1-x_2)^3\} \end{aligned} \quad (10)$$

where a'_{12}, b'_{12}, c'_{12} and d'_{12} are the arithmetic sums of the initial and the transition states respectively.

According to the absolute reaction rate theory cited above,

$$\boldsymbol{RT}\ln k = \text{const} - \Delta F^{\ddagger}$$

Consequently, it is clear that the following relation holds so long as Eqs. 6 and 7 are valid;

$$\begin{aligned}\log k_{12} = x_1\log k_1 + x_2\log k_2 + x_1x_2 \\ \times\{a + b(x_1-x_2) + c(x_1-x_2)^2 + d(x_1-x_2)^3\} \end{aligned} \quad (11)$$

In the above discussion, the free energies of standard state in pure solvents are $\overline{F}_1^{\circ}$ and $\overline{F}_2^{\circ}$. When two solvents are mixed together, the free energy of the mixture is sufficiently expressed by $(x_1\overline{F}_1^{\circ} + x_2\overline{F}_2^{\circ})$ if the change is ideal. Actually, however, various interactions occur; therefore, a series of terms must be added as corrections. The parameters of the solution, then enable us to determine the interaction in the real mixtures.

A Discussion of the Calculated Parameter: The Nature of *a*.—The important factors which determine the rate constant of the reaction are; (1) the type of reaction (or the charge type), (2) the nature and the structure of the reaction species, and (3) the nature of the solvent used, as has been mentioned above. The four parameters in Eq. 11, *a*, *b*, *c* and *d*, are the quantities that relate to the rate constant. Therefore, it is quite reasonable to suppose that *a*, *b*, *c* and *d* are affected by the three factors described above as is the rate constant.

It is sure from the nature of the proposed formula 11 that *a* is the most important parameter of the four. The value of *a* may easily be calculated, since it is $\log k/x_1x_2$ at an equimolar mixture of solvents 1 and 2. When the mixed solution consists of equal or nearly equal molar amounts of the components (1 and 2), Eq. 11 reduces to:

$$\log k_{12} = x_1\log k_1 + x_2\log k_2 + x_1x_2a \quad (12)$$

Moreover, in discussing the deviation from

ideality, the parameter a is convenient for the mixed solution, while the ideal mixture exhibits the following relation;

$$\log k_{12} = x_1 \log k_1 + x_2 \log k_2 \quad (13)$$

The three kinds of reaction shown in Table I will now be considered. Although the magnitude of a can not be determined from the type of reaction only, it keeps an almost constant value even when the reactants vary over a wide range as long as the solvent system is the same during reactions of the same type (for example, Nos. 1 and 2, Nos. 3, 4 and 5, Nos. 7, 8, 9 and 10, Nos. 15 and 16, Nos. 17, 18 and 19, and Nos. 20 and 21 in Table I). However, it changes greatly if the solvent system is different, even when both the reaction and the reactants are the same (for example, Nos. 4 and 6, and Nos. 9, 11, 12, 13 and 16 in Table I). From the characteristics of a's described above, it can be concluded that a is sensitive to the type of reaction and the solvent system, but that it is not affected by the nature of the reactant as long as the solvent system and the type of reaction are the same.

The Theoretical Derivation of The Additivity of the Parameter a.—The following formulae will hold when a two-component system changes ideally for three kinds of solvent, the components being 1, 2 and 3 respectively:

$$\Delta\overline{F}_{12}^{\circ\ddagger} = x_1\Delta\overline{F}_1^{\circ\ddagger} + x_2\Delta\overline{F}_2^{\circ\ddagger} \qquad x_1+x_2=1 \quad (14)$$

$$\Delta\overline{F}_{23}^{\circ\ddagger} = x_2\Delta\overline{F}_2^{\circ\ddagger} + x_3\Delta\overline{F}_3^{\circ\ddagger} \qquad x_2+x_3=1 \quad (15)$$

$$\Delta\overline{F}_{13}^{\circ\ddagger} = x_1\Delta\overline{F}_1^{\circ\ddagger} + x_3\Delta\overline{F}_3^{\circ\ddagger} \qquad x_1+x_3=1 \quad (16)$$

Let us now discuss the relation among $\Delta\overline{F}_{12}^{\circ\ddagger}$, $\Delta\overline{F}_{23}^{\circ\ddagger}$ and $\Delta\overline{F}_{13}^{\circ\ddagger}$. When a 1—2 solvent system and a 2—3 solvent system are mixed,

$$\Delta\overline{F}_{12}^{\circ\ddagger} + \Delta\overline{F}_{23}^{\circ\ddagger} = x_1\Delta\overline{F}_1^{\circ\ddagger} + x'_2\Delta\overline{F}_2^{\circ\ddagger} + x'_2\Delta\overline{F}_2^{\circ\ddagger} + x'_3\Delta\overline{F}_3^{\circ\ddagger} \quad (17)$$

where (x_1 and x_2) are the molar fractions in the 1—2 system and (x'_2 and x'_3) are those in the 2—3 solvent system, (x_1 and x_2) being independent of (x'_2 and x'_3). If the condition $x_1+x'_3=1$ is satisfied, the sum for each independent system comes to show the behavior of the 1—3 system. Thus, the activation free energy of the 1—3 system can be calculated from the sum of the 1—2 and 2—3 mixed component systems:

$$\Delta\overline{F}_{12}^{\circ\ddagger} + \Delta\overline{F}_{23}^{\circ\ddagger} = x_1\Delta\overline{F}_1^{\circ\ddagger} + (1-x_1)\Delta\overline{F}_1^{\circ\ddagger} + (1-x_3')\Delta\overline{F}_2^{\circ\ddagger} + x_3'\Delta\overline{F}_3^{\circ\ddagger} \quad (17')$$

Since $x_1+x_3'=1$,

$$\Delta\overline{F}_{12}^{\circ} + \Delta\overline{F}_{23}^{\circ\ddagger} = \Delta\overline{F}_2^{\circ\ddagger} + x_1\Delta\overline{F}_1^{\circ\ddagger} + x_2'\Delta\overline{F}_3^{\circ\ddagger} \quad (18)$$

If ($x_1+x_3'=1$) is rewritten as ($x_1+x_3=1$),

$$\Delta\overline{F}_{12}^{\circ\ddagger} + \Delta\overline{F}_{23}^{\circ\ddagger} = \Delta\overline{F}_2^{\circ\ddagger} + \Delta\overline{F}_{12}^{\circ\ddagger} \quad (19)$$

The above consideration may be continued further and applied to the system which has the term a the deviation from an ideal system:

$$\Delta\overline{F}_{12}^{\circ\ddagger} = x_1\Delta\overline{F}_1^{\circ\ddagger} + x_2\Delta\overline{F}_2^{\circ\ddagger} + \boldsymbol{RT}x_1x_2a_{12}, \qquad x_1+x_2=1 \quad (20)$$

$$\Delta\overline{F}_{23}^{\circ\ddagger} = x_2\Delta\overline{F}_2^{\circ\ddagger} + x_3\Delta\overline{F}_3^{\circ\ddagger} + \boldsymbol{RT}x_2x_3a_{23}, \qquad x_2+x_3=1 \quad (21)$$

$$\Delta\overline{F}_{13}^{\circ\ddagger} = x_1\Delta\overline{F}_1^{\circ\ddagger} + x_3\Delta\overline{F}_3^{\circ\ddagger} + \boldsymbol{RT}x_1x_3a_{13}, \qquad x_1+x_3=1 \quad (22)$$

As before, when $x_1+x_3=1$,

$$\begin{aligned}\Delta\overline{F}_{12}^{\circ} + \Delta\overline{F}_{23}^{\circ} &= x_1\Delta\overline{F}_1^{\circ\ddagger} + (1-x_1)\Delta\overline{F}_2^{\circ\ddagger} \\ &\quad + \boldsymbol{RT}x_1(1-x_1)a_{12} + x_3\Delta\overline{F}_\infty^{\circ\ddagger} \\ &\quad + (1-x_3)\Delta\overline{F}_2^{\circ\ddagger} \boldsymbol{RT}x_3(1-x_3)a_{23} \\ &= \Delta\overline{F}_2^{\circ\ddagger} + x_1\Delta\overline{F}_1^{\circ\ddagger} + x_3\Delta\overline{F}_3^{\circ\ddagger} \\ &\quad + \boldsymbol{RT}x_1x_3(a_{12}+a_{23}) \end{aligned} \quad (23)$$

If the relation of Eq. 19 holds as in the ideal change, the relation

$$a_{12} + a_{22} = a_{13} \quad (24)$$

must also hold.

The Additivity of the Parameter a in the Menschutkin Reaction.—Relation 24, obtained above, may be applied to the case of the Menschutkin reaction.

When benzene, acetone and nitrobenzene are taken as the solvent components 1, 2 and 3 respectively, the relation among them is described in Table II and in Fig. 6. While $a_{12}+a_{23}=2.03$ from the sum of the average values of a_{12} and a_{23} as listed in Table II, the average value of a_{13} experimentally obtained

TABLE II. THE PARAMETER a'S IN THE MENSCHUTKIN REACTION AT 100°C, IN BENZENE (1), ACETONE (2) AND NITROBENZENE (3) SYSTEMS

Benzene-acetone a_{12}		Acetone-nitrobenzene a_{23}		Benzene-nitrobenzene a_{13}	
Triethylamine+EtI	1.07[11]	Pyridine+MeI	0.80[9]	Triethylamine+MeI	1.94[8]
Pyridine+MeI	1.40[9]			Triethylamine+*i*-PropI	2.20[8]
				Pyridine+MeI	2.10[9]
				Pyridine+*i*-PropI	1.96[8]
Average	1.28			Average	2.05

is 2.05. Therefore, it was found that the additivity rule 24 holds among these three a's if the deviation from ideal is taken into account up to the first term, as in Eq. 12.

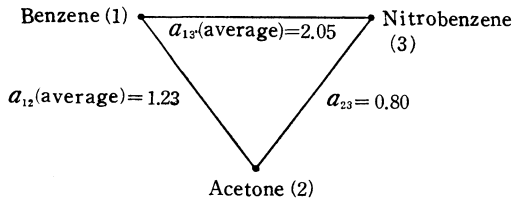

Fig. 6.

Summary

The reaction rate in binary mixed solvents have been discussed and following facts confirmed:

1) A linear relation does not hold between $\log k$ and the molar fraction of the components in most cases.

2) The deviation from linearity is usually positive, and the maximum deviation is found at $x_A \leq 0.5$, x_A is the molar fraction of a component in which the rate is faster than in another component.

3) The experimental results may be expressed with good accuracy by the formula:

$$\log k = x_A \log k_A + x_B \log k_B + x_A x_B a + b(x_A - x_B) + c(x_A - x_B)^2 + d(x_A - x_B)^3$$

4) The parameter a depends upon the type of reaction and the solvent system, but it does not depend on the nature of the reactants.

5) The additivity of has been proved theoretically and confirmed a for the Menschutkin reaction in various solvent mixtures.

The Preparation and the Co-ordination Chemistry of Cobalt Complexes with Schiff Bases Derived from Salicylaldehyde and Alkyl Amines

By Hiroaki NISHIKAWA and Shoichiro YAMADA

(Received February 5, 1964)

The cobalt complexes of Schiff bases involve many problems of fundamental importance in the co-ordination chemistry of cobalt. As a step to the elucidation of these problems, the present authors previously characterized and discussed the electronic absorption spectra of the Schiff-base complexes of cobalt(II), which necessarily have a square-planar configuration because of their steric condition.[1] It is now appropriate and possible to make a similar study of these cobalt complexes which are not necessarily required to take a square-planar configuration by the steric reason alone. The present paper deals with the preparation and the stereochemistry of cobalt(II) and cobalt-(III) complexes of *N*-alkyl-salicylideneimines (Fig. 1).

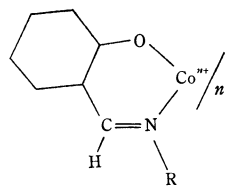

Fig. 1. Cobalt-complexes of *N*-alkyl-salicylideneiminate.

Experimental

Materials. — Bis(*N*-α-branched alkyl-salicylideneiminato) (cobalt(II) complexes were prepared in the atmosphere by the following two methods. 1)[2] A mixture of calculated amounts of cobalt(II) acetate tetrahydrate, salicylaldehyde, and an α-branched-alkyl amine was heated in ethanol. To this solution a 4 N solution of sodium carbonate (about 75% of the calculated amount) was added to neutralize the acetic acid which was expected to be liberated

in the reaction. When the solution was cooled or evaporated, the red crystals of the compound were obtained in a good yield. 2) Bis(salicylaldehyde)-cobalt(II) dihydrate, $Co(sal)_2 \cdot 2H_2O$,* and a slight excess of an α-branched alkyl amine were heated in methanol or ethanol for about ten minutes. When the solution was evaporated, red crystals were obtained in a good yield.

Bis(*N*-isopropyl- and bis(*N*-*s*-butyl-salicylideneiminato)cobalt(II) were reported previously.[2]

Bis(*N*-*t*-butyl-salicylideneiminato)cobalt(II) was obtained in the form of prismatic red crystals. Recrystallization was carried out from ethanol. The crystals are quite soluble in common organic solvents.

Found: C, 64.41; H, 7.03; N, 6.73. Calcd. for $C_{22}H_{28}N_2O_2Co$: C, 64.2; H, 6.86; N, 6.81%.

The compound has also been reported by Sacconi et al.[3]

Bis(*N*-1-ethylpropyl-salicylideneiminato)cobalt(II) was obtained in red, needle-like crystals. Recrystallization was carried out from *n*-hexane. It is very soluble in common organic solvents.

Found: C, 65.4; H, 7.41; N, 6.46. Calcd. for $C_{24}H_{32}N_2O_2Co$: C, 65.6; H, 7.34; N, 6.37%.

In general, the above-described compounds of cobalt(II) are stable, and they are not oxidized either in solution or in the crystalline state in the atmosphere.

Tris(*N*-*n*-alkyl-salicylideneiminato)cobalt(III) complexes were prepared by a method previously reported.[2] There was a mistake in the original direction; a 4 N sodium carbonate ought to be employed instead of a 0.3 N solution.

All these cobalt(III) complexes, which are obtained as dark-green crystals, are very stable to the air both in the crystalline state and in solution.

Tris(*N*-methyl-,[4] tris(*N*-ethyl-,[5] tris(*N*-*n*-propyl-[2] and tris(*N*-*n*-butyl-salicylideneiminato)cobalt(III)[2] were reported earlier.

Bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II) complexes are readily oxidized by the atmospheric oxygen. For the preparation of these complexes, it is necessary to carry out the procedures in an oxygen free atmosphere. Recently Sacconi et al.[6] reported the preparation of bis(*N*-*n*-butyl- and bis(*N*-*n*-amyl-salicylideneiminato)cobalt(II). The present authors have succeeded in preparing these complexes by the following novel method, which is also applicable to the synthesis of bis(*N*-*n*-alkyl-salicylideneiminato)-cobalt(II) in general: A methanolic solution of bis(salicylaldehyde)cobalt(II) dihydrate, $Co(sal)_2 \cdot 2H_2O$, and a trace of formaldehyde was boiled in a flask. When the space in the flask was filled with the methanol vapor, a slight excess of the amine was added quickly; then the flask was closed with a stopper in order to prevent the air from coming in. The closed flask was heated under stirring at the boiling temperature of the solvent for a reaction period of from 10 to 40 min.; then the solution was left to cool. The crystals which separated out were filtered quickly in the air and dried in vacuo.

For the preparation of bis(*N*-methyl-salicylideneiminato)cobalt(II), 3.0 g. of bis(salicylaldehyde)-cobalt(II) dihydrate and 2.5 ml. of a 30% aqueous solution of methyl amine were used, with 60 ml. of methanol, as a solvent, containing 2 ml. of a 37% formaldehyde solution. Following the general method described above, the reaction was continued for 10 min. at about 60°C. After the closed flask was left at room temperature for a day, brown crystals separated out.

Found: C, 58.7; H, 4.98; N, 8.58. Calcd. for $C_{16}H_{16}N_2O_2Co$: C, 58.7; H, 4.92; N, 8.56%.

Bis(*N*-ethyl-salicylideneiminato)cobalt(II) was prepared from 3.0 g. of bis(salicylaldehyde)cobalt(II) dihydrate and 1.4 g. of a 70% aqueous solution of ethyl amine. The solvent used was methanol (60 ml.) containing 26 ml. of water and 2 ml. of a 37% aqueous solution of formaldehyde. The general method was followed, the reaction being continued for 30 min. at 60°C. After the reaction was over, the cooled flask was left at room temperature for a day; well developed red plate-like crystals then separated out.

Found: C, 60.9; H, 5.67; N, 7.80. Calcd. for $C_{18}H_{20}N_2O_2Co$: C, 60.9; H, 5.67; N, 7.89%.

Bis(*N*-*n*-propyl-salicylideneiminato)cobalt(II) was prepared and red crystals by a method similar to that used in the case of bis(*N*-ethyl-salicylideneiminato)cobalt(II).

Found: C, 62.9; H, 6.41; N, 7.08. Calcd. for $C_{20}H_{24}N_2O_2Co$: C, 62.7; H, 6.31; N, 7.31%.

Bis(*N*-*n*-butyl-salicylideneiminato)cobalt(II) was prepared in red crystals from 3.0 g. of bis(salicyl-aldehyde)cobalt(II) dihydrate and 2.5 g. of *n*-butyl amine. The solvent employed was methanol (80 ml.) containing 2 ml. of a 37% aqueous solution of formaldehyde. The same general method was followed, the reaction being continued for about 10 min. at 60°C.

Found: C, 64.3; H, 6.78; N, 6.83. Calcd. for $C_{22}H_{28}N_2O_2Co$: C, 64.2; H, 6.85; N, 6.81%.

This complex has also been prepared by Sacconi et al.[6] by a more complicated method.

Bis(*N*-benzyl-salicylideneiminato)cobalt(II) was prepared from 3.5 g. of bis(salicylaldehyde)cobalt-(II) dihydrate and 3.5 g. of benzyl amine, with 60 ml. of methanol as a solvent. The same general method was followed, the reaction being continued for about 20 min. at 60°C. After the flask, in which crystals of the compound had already started to separate out, was left to cool, well-developed red crystals were collected. This compound had been prepared previously by Endo[4] using another method.

Found: C, 70.0; H, 5.02; N, 5.77. Calcd. for $C_{23}H_{24}N_2O_2Co$: C, 70.2; H, 5.05; N, 5.84%.

Comparison shows that this compound, which gradually undergoes oxidation in organic solvents in the atmosphere, is less stable to oxidation than the *N*-α-branched alkyl-derivatives, but more stable than the corresponding *N*-*n*-alkyl-derivatives.

* The notation "sal" represents an anion formed when a proton is liberated from a molecule of salicylaldehyde.

Measurements.—The electronic absorption spectra of the complexes in solution were determined with a Beckman DU spectrophotometer. The solvents used were chloroform, benzene, ethanol and pyridine. It was confirmed that Beer's law was obeyed in the concentration range of the present work, which varied between 10^{-2} and 10^{-5} molar.

Results and Discussion

Cobalt(II) Complexes of Schiff Bases Derived from Salicylaldehyde and α-Branched Alkyl Amines.—Examination with a Stewart model shows that the steric condition due to the *t*-butyl groups prevents bis(*N*-*t*-butylsalicylideneiminato)cobalt(II) from taking a planar configuration.[7] The absorption spectrum of this compound in benzene, which is shown in Fig. 2, is essentially similar to the spectrum of the compound in such other organic solvents as methanol, ethanol and pyridine; therefore, no remarkable solvent effect on the structure of the molecules is present in the case of this compound. The absorption bands due mainly to the ligand groups come into the region of quite low frequencies, being superposed on a part of the ligand-field bands. It is generally possible, however, to see the main features of the ligand-field bands of these cobalt complexes. The ligand-field bands are quite different from those of the related cobalt(II) complexes with a square-planar configuration.[1] The spectum of bis(*N*-*t*-butylsalicylideneiminato)cobalt(II) also bears an apparent resemblance to the spectrum of such tetrahedral cobalt(II) complexes as tetrahalogeno-cobalt(II) ions. As with the spectra of tetrahalogeno-cobalt(II) complexes with a tetrahedral configuration, the absorption band of bis(*N*-*t*-butylsalicylideneiminato)cobalt(II) with the main peak at about 24.6×10^{13} sec^{-1} is assigned to the spin-allowed transition, $^4A_2\rightarrow{}^4T_1(F)$. The next band, at 54 to 60×10^{13} sec^{-1}, is similarly assigned to the transition $^4A_2\rightarrow{}^4T_1(P)$. In the corresponding *s*-butyl, isopropyl or 1-ethylpropyl complexes, the steric hindrance to the square-planar configuration is more or less serious enough to prevent the square-planar configuration, but this is not so complete as in the case of the *t*-butyl derivative. The absorption spectra of these complexes in non-donor solvents, however, are quite similar to the spectrum of the *t*-butyl-complex with ligand-field bands in the visible and near-infrared regions characteristic of the tetrahedral cobalt(II) complexes (Fig. 2). It may be concluded that bis(*N*-isopropyl-, bis(*N*-*s*-butyl- and bis(*N*-1-ethylpropyl-salicylideneiminato)cobalt(II) are distorted significantly from the square-planar configuration. The assignment of the ligand-field bands of these tetrahedral complexes is made in a way similar to that used for the *t*-butyl complex.

5, R′=isopropyl (—·····—)

It is significant that bis(*N*-α-branched alkyl-salicylideneiminato)cobalt(II) complexes show quite similar spectra, with absorption bands at nearly identical frequencies, when the substituent represents *t*-butyl, isopropyl, *s*-butyl, 1-ethylpropyl and cyclohexyl groups. Since the extent of the steric hindrance to the square-planar configuration of the cobalt(II)-complex is expected to be different for these substituents, the above observation suggests that the distortion from the square-planar configuration occurs to a nearly equal extent among all the above cobalt(II) complexes with α-branched alkyls as substituents. Judging from the considerable distortion from the square-plane in the case of the *t*-butyl-derivative, it is concluded that the tetrahedral configuration is most likely for these cobalt(II) complexes.

Cobalt-Complexes of Schiff Bases Derived from Salicylaldehyde and *n*-Alkyl Amines.—In the preceding part of this paper, it has been concluded that the configuration around the cobalt(II) ion in bis(*N*-α-branched alkyl-salicylideneiminato)cobalt(II) complexes is tetrahedral. It seemed interesting, therefore, to examine whether the configuration around the cobalt(II) ion is tetrahedral or square-planar in bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II)

7) S. Yamada and H. Nishikawa, This Bulletin, **36**, 755 (1963).

complexes, in which there is no serious steric hindrance to either the tetrahedral or the square-planar configuration.

The *N*-*n*-alkyl-substituted complexes of cobalt(II) are so readily oxidized that these complexes can not be prepared by the conventional procedures in the atmosphere which have proved applicable to the preparation of the *N*-α-branched alkyl-complexes. Diehl and Chao[8] reported the preparation of bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II) with methyl, ethyl, *n*-propyl, *n*-butyl and *n*-amyl groups as the substituent. These compounds, however, were not obtained in the form of crystals, but only as a solid mass. Sacconi et al.[6] recently reported the *n*-butyl- and *n*-amyl-derivatives of this series, but their method is not quite suitable for the preparation of the methyl-, ethyl- and *n*-propyl-derivatives, which are particularly susceptible to oxidation.

The present authors succeeded in synthesizing cobalt(II) complexes of the Schiff bases, with methyl, ethyl, *n*-propyl and *n*-butyl as the substituent, by means of a new method which proved applicable to the synthesis of the corresponding compounds with higher alkyls. The electronic spectra may be used diagnostically in examining the configuration of the cobalt(II) complexes of this type, since the spectrum of the square-planar cobalt(II) complex is quite different from that of the tetrahedral cobalt(II) complex.[1,2,7] Bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II) complexes all show absorption spectra similar to each other and to the spectra of bis(*N*-α-branched alkyl-salicylideneiminato)cobalt(II) complexes (cf. Fig. 3). It may be concluded that these bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II) complexes have a tetrahedral configuration.[9] In the spectra of bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II), an absorption band with the main peak at about 25×10^{13} sec^{-1} is assigned to a transition $^4A_2\rightarrow{}^4T_1(F)$.

5, R'=Methyl, in chloroform (—···—)

The absorption maxima of the ligand-field bands of the *n*-alkyl-substituted cobalt(II) complexes are nearly identical with those of the *t*-butyl-derivative, which is regarded as remarkably distorted from the square-planar configuration on the steric ground alone. In the corresponding complexes of copper(II) and nickel(II), a gradual shift of the ligand-field band toward a lower frequency was observed in the following order, depending upon the extent of the distortion from the square-plane: *n*-alkyl, isopropyl, *t*-butyl.[7] It may, therefore, be concluded that the distortion from the square-planar configuration in bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II) complexes is as great as in the corresponding *t*-butyl derivative. It is thus clear that the configuration of the bis(*N*-alkyl-salicylideneiminato)cobalt(II) complexes, in general, is tetrahedral, whether or not there is steric hindrance to the square-planar configuration. The configuration around the cobalt(II) ion in bis(*N*-*n*-butyl-salicylidene iminato)cobalt(II) has been reported to be tetrahedral from magnetic measurements and X-ray powder photographs.[6,10]

Comparison readily reveals that the tetrahedral configuration is much more stabilized in the cobalt(II) complex than in the nickel(II) and the copper(II) complex[7] when complexes with identical ligands are compared. This is in agreement with what has been predicted on the basis of the crystal-field theory,[11] which demands much more crystal-field stabilization energy for the cobalt(II) ion with a d^7 configuration than for the nickel(II) and copper(II) ions. The color of bis(*N*-methyl-salicylideneiminato)cobalt(II) in the solid state is different from that of the other bis(*N*-alkyl-salicylideneiminato)cobalt(II) in the solid state,

8) H. Diehl and T. S. Chao, *Iowa State Coll. J. Sc.*, **22**, 126 (1947).

9) It was formerly stated that bis(*N*-methyl-salicylideneiminato)cobalt(II) was square-planar (H. Nishikawa, S. Yamada and R. Tsuchida, *Z. anorg. u. allg. Chem.*, **316**, 278 (1962)). In the light of the present work, this statement is not correct, although the configuration of the corresponding cobalt(II) complexes of ethyl, propyl and higher alkyls was correctly concluded in that paper to be distorted from the square-planar configuration.

10) E. Frasson and C. Panatoni, *Z. Krist.*, **116**, 154 (1961).

although both of them consist of tetrahedral molecules in non-donor solvents. The examination of the methyl-substituted complex in the solid state is now in progress; it will be reported later, together with other materials.

The electronic absorption spectra of bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II) complexes in pyridine have been examined; some of them are shown in Fig. 4. The spectra of

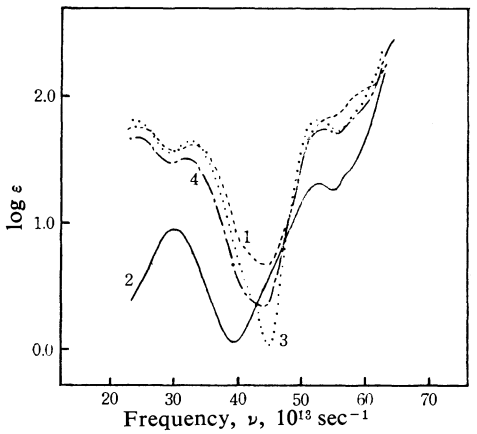

Fig. 4. Electronic absorption spectra of Co·(O·C$_6$H$_4$·CH : NR)$_2$.
1, R=*n*-Butyl, in ethanol (----)
2, R=*n*-Butyl, in pyridine (——)
3, R=*s*-Butyl, in ethanol (·····)
4, R=*s*-Butyl, in pyridine (—·—)

these *n*-alkyl-derivatives in pyridine, which are quite different from the spectra of the same compounds in non-donor solvents, may be interpreted as those of the sexa-co-ordinate cobalt(II) complexes. It may, therefore, be concluded that bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II) complexes in pyridine combine with two additional pyridine molecules to form sexa-co-ordinate complexes of cobalt(II). In agreement with this seems to be a fact that the recrystallization from pyridine of these cobalt(II) complexes yields crystals of the compounds with two molecules of pyridine per formula, molecules which are most probably bound with the cobalt(II) ion.

The absorption band at about 30×10^{13} sec^{-1} is assigned to the $^4T_{1g} \rightarrow {}^4T_{2g}$ transition, and the absorption band at about 53.6×10^{13} sec^{-1}, to the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transition, on the basis of the notation of the O_h field symmetry.

On the contrary, the *N*-α-branched alkyl complexes keep their tetrahedral configuration in pyridine, since their spectra in pyridine are closely similar to their spectra in non-donor solvents (Fig. 4) and since they give no pyridine adducts on recrystallization from pyridine. This behavior is considered to be due partly to the steric condition originating from the branched alkyl groups, which prevent a pyridine molecule from combining with the cobalt(II) ion to a greater or lesser extent. This behavior also shows that the tetrahedral configuration is more favored for cobalt(II) than for nickel(II), since bis(*N*-isopropyl-salicylideneiminato)nickel(II) in pyridine, for example, is sexa-co-ordinate with the solvent molecules combined.[12] It is worth noting that this is exactly the case with the cyclohexyl-derivative. Bis(*N*-cyclohexyl-salicylideneiminato)cobalt(II) in pyridine does not keep a tetrahedral configuration, but probably forms a quinque-co-ordinate complex of cobalt(II), with a molecule of pyridine as one of the ligands.[13]

Tris(*N*-*n*-alkyl-salicylideneiminato)cobalt(III). —The electronic spectra of tris(*N*-*n*-alkyl-salicylideneiminato)cobalt(III) complexes, which are very stable in the atmosphere, are quite similar to each other. Only some of them are, therefore, shown in Fig. 5. The spectra

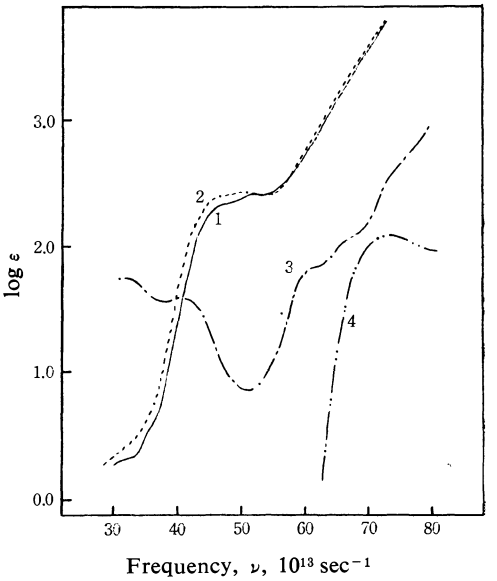

Fig. 5. Electronic absorption spectra of:
1, Co(O·C$_6$H$_4$·CH : N·CH$_3$)$_3$, in benzene (——);
2, Co(O·C$_6$H$_4$·CH : N·*n*-C$_3$H$_7$)$_3$, in benzene (----);
3, Co(O·C$_6$H$_4$·CH : N·*n*-C$_3$H$_7$)$_2$, in ethanol (—·—);
4, HO·C$_6$H$_4$·CH : N·CH$_3$, in chloroform (—··—).

12) S. Yamada and H. Nishikawa, unpublished.
13) The pyridine solution of the cyclohexyl-substituted complex obeys Beer's law; therefore, an equilibrium between the original complex and the pyridine adduct seems to be non-existent. Upon recrystallization from pyridine, this cobalt(II)-complex yields an adduct with one molecule of pyridine. The details will be presented later elsewhere.

of these complexes, which are quite different from the spectra of the cobalt(II)-complexes with the corresponding Schiff bases show, a ligand-field band at about $50\times10^{13}\,sec^{-1}$, a band which is assigned to the $^1A_{1g}\rightarrow{}^1T_{1g}$ transition in the notation of the O_h field symmetry. Judging from the maximum frequency of this band, the Schiff bases of this type stand a little higher than water and acetylacetonate, but much lower than ammonia in the spectrochemical series.

Bis(*N*-α-branched alkyl-salicylideneiminato)-cobalt(II) is stable in solution as well as in the solid state. An ordinary procedure of refluxing cobalt(II) acetate, salicylaldehyde and one of the α-branched alkyl amines in the atmosphere yields the cobalt(II)-complex, but no cobalt(III)-complex. So far, all attempts with α-branched alkyls as a substituent, even those using oxidizing agents, to prepare tris-(*N*-alkyl-salicylideneiminato)cobalt(II) have been unsuccessful. This is probably due to the steric condition. This also shows the relatively high stability of the tetrahedral configuration for bis(*N*-α-branched alkyl-salicylideneiminato)cobalt(II).

The Relative Stability of Tetrahedral Cobalt(II) Complexes.—The tetrahedral bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II) complexes are much more easily oxidized to give tris(*N*-*n*-alkyl-salicylideneiminato)cobalt(III) than the corresponding *N*-aryl-substituted cobalt(II)-complexes. Thus, by refluxing cobalt acetate, salicylaldehyde and one of the *n*-alkyl amines in the atmosphere, the cobalt(III) complexes of the Schiff bases are obtained in the form of dark green crystals, while a similar procedure using aromatic amines instead of the *n*-alkyl amines yields red crystals of the cobalt(II) complexes of the corresponding Schiff bases. Moreover, when heated on a water-bath, tris-(*N*-aryl-salicylideneiminato)cobalt(III)-complexes in solution convert themselves into the cobalt(II)-complexes, while tris(*N*-*n*-alkyl-salicylideneiminato)cobalt(III)-complexes do not.

This difference between *n*-alkyl and aromatic amines may be due partly to the steric factor, which destabilizes the octahedral tris(*N*-aryl-salicylideneiminato)cobalt(III)-complexes. This fact also seems to show that the *N*-*n*-alkyl-salicylideneiminate yields a stronger ligand field than the *N*-aryl-salicylideneiminate ion, since it is known that the higher stability of the sexa-co-ordinate cobalt(III)-complex is attained with ligands producing a stronger ligand field.

The stability of the quadri-co-ordinate cobalt(II)-complex to oxidation by atmospheric oxygen seems to be correlated with the strength of the field produced by the ligands. Inspection shows that, in the spectrochemical series, water as ligand lies on the border above which the cobalt(III)-complex is more stable than the cobalt(II)-complex in the atmosphere. Thus the hexaquo-cobalt(III)-complex is known although it readily changes into the hexaquo-cobalt(II)-complex. On the other hand, the acetylacetonate ion, which is just above water in the series, forms a stable cobalt(III)-complex, but its cobalt(II)-complex is readily oxidized to yield the cobalt(III)-complex in the atmosphere, unless sexa-co-ordinate diaquo-bis(acetylacetonato)cobalt(II) is formed. Since *N*-alkyl- or *N*-aryl-salicylideneiminate ions lie slightly above water and acetylacetonate in the spectrochemical series, the observed stability of *N*-substituted salicylideneiminato-cobalt-complexes is found to be understandable in terms of the strength of the ligand field. Inspection also reveals that those ligands, such as halide and isothiocyanate, which stand below acetylacetonate in the spectrochemical series form tetrahedral cobalt(II)-complexes which are stable in the atmosphere, unless sexa-co-ordinate complexes are formed.

Bis(*N*-benzyl-salicylideneiminato)cobalt(II).—Bis(*N*-benzyl-salicylideneiminato)cobalt(II) in non-donor solvents shows an absorption spectrum quite similar to the spectra of the other cobalt(II)-complexes which have been concluded to be tetrahedral (Fig. 3). It may similarly be concluded that the *N*-benzyl-substituted complex of cobalt(II) has a tetrahedral co-ordination.

The compound is comparatively stable to oxidation in the atmosphere. The stability of the complex to oxidation seems to lie between that of the *N*-*n*-alkyl and *N*-α-branched alkyl derivatives, as may be inferred from the following properties of these complexes: 1) The *N*-benzyl-substituted cobalt(II) is considerably stable in the atmosphere, while the *N*-*n*-alkyl-derivatives of cobalt(II) are very susceptible to the atmospheric oxygen and are likely to give the cobalt(III)-complexes. When left in the air for a long time, however, the *N*-benzyl-derivative of cobalt(II) undergoes oxidation to the cobalt(III) state. 2) In the typical procedure using cobalt(II) acetate, salicylaldehyde and benzyl amine in the atmosphere, bis(*N*-benzyl-salicylideneiminato)cobalt-(II) is formed as red crystals; on prolonged heating these crystals are changed into dark green crystals of tris(*N*-benzyl-salicylideneiminato)cobalt(III).

This behavior may be regarded as showing that the field of *N*-benzyl-salicylideneiminate to the metal ion is weaker than that of the *N*-alkyl-substituted one but stronger than that of the *N*-aryl-substituted one.

Summary

A novel method has been described for preparing bis(*N*-*n*-alkyl-salicylideneiminato)cobalt(II), where *n*-alkyl represents methyl, ethyl, *n*-propyl, *n*-butyl and higher alkyls. Bis(*N*-α-branched alkyl-salicylideneiminato)cobalt(II)-complexes have been prepared by a simpler method, where α-branched alkyl denotes isopropyl, 1-ethylpropyl, *s*-butyl, *t*-butyl and cyclohexyl. The benzyl derivative has also been prepared. Tris(*N*-*n*-alkyl-salicylideneiminato)cobalt(III) complexes have been prepared.

On the basis of electronic absorption spectra, it has been concluded that bis(*N*-alkyl-salicylideneiminato)cobalt(II)-complexes have a tetrahedral configuration, whether the alkyl used as a substituent represents an *n*-alkyl or an α-branched alkyl.

The relative stability and the configuration of cobalt(II)-complexes have been discussed.

The present authors are grateful to the late Professor Ryutaro Tsuchida for his interest in this work, and to Professor Yoshiharu Izumi and Dr. Kensaku Morihara of the Protein Research Institute for advice about the syntheses of some of the ligands. Special thanks are also due to Professors Tokuichi Tsumaki and Juitsu Endo for their painstaking and pioneering work in this field of co-ordination chemistry. This work was supported in part by the Ministry of Education.

*Thermogravimetric Analysis of Polyoxymethylene**

By Shoichi IGARASHI,** Itaru MITA and Hirotaro KAMBE

(Received February 11, 1964)

Several studies[1,2] of the thermal decomposition of polyoxymethylene in the bulk state have been made; in them the weight loss of the polymer has been measured during its degradation at a constant temperature in the 100~350°C range. Recently, Dudina and his co-workers[3-7] have also extensively studied the thermal and thermo-oxidative degradation of polyoxymethylene. However, there has been little attempt to make a thermogravimetric analysis (TGA) of polyoxymethylene. In this technique the temperature of the polymer is elevated at a constant rate until the sample decomposes completely; then the general character of the thermal degradation process and the thermal stability of the polymeric materials can be determined.

The data presented in this paper are based largely on the thermogravimetric analysis of polyoxymethylene, acetylated polyoxymethylene and commercial Delrin resin, both in air and in nitrogen. The derivative thermogravimetric analysis (DTGA) curves of the three samples show two peaks in each case. In order to clarify the above observations, the effect of the concentration of oxygen on the DTGA curve was also investigated. From the TGA in a vacuum, some knowledge of the volatility of pyrolysates and their thermal decomposition character in a very low concentration of oxygen has been obtained.

It has been found that the first stage is due to the chain depolymerization as well as to the oxidative decomposition and that the second stage is to be attributed to the random degradation of a stable fragment formed during first-stage decomposition. Moreover, an increase of carbonyls in the polyoxymethylene as a result of the degradation has been confirmed by the infrared absorption method.

Experimental

Materials.—The polyoxymethylene ($[\eta]=1.6$ g./

100 ml. in *p*-chlorophenol at 60°C) used in this work was supplied by the Toyo Rayon Co., Ltd. It was free from additives. The acetylation of polyoxymethylene was carried out using acetic anhydride and sodium acetate at 139°C.[1] Commercial Delrin 5000X was also used without further purification.

Apparatus. — The automatic recording thermobalance[8] used in this work consists of a tungsten spring balance and a linear variable differential transformer to detect the elongation of the spring. The temperature of the furnace regulated by a program controller.

Procedure. — A weighed quantity of polymer (eigher 100 mg. or 10 mg.) was placed in a glass crucible with a diameter of 12 mm. and a depth of 10 mm. The weight loss of the polymer was recorded against the time using the automatic recording thermobalance while the sample was heated at the rate of about 1°C/min. or, in some cases, at 0.5°C/min., from room temperature to about 350°C in various concentrations of oxygen. The DTGA curves were obtained by the graphical differentiation of the weight loss versus the temperature curves.

The isothermal decomposition of polyoxymethylene was conducted in nitrogen at temperatures ranging from 200 to 240°C and in air at 177~225°C.

The infrared spectra were recorded with a Shimadzu IR-2A spectrophotometer. The sample, decomposed partially during the thermogravimetric measurements, was used after having been rapidly cooled to room temperature. The infrared analysis was carried out by using potassium bromide pellets.

Results

Thermogravimetric Analysis in Nitrogen and in Air.—The TGA curves of polyoxymethylene, acetylated polyoxymethylene and Delrin using a sample of 100 mg. in nitrogen are shown in Fig. 1. All of these polymers show two peaks in each DTGA curve. Polyoxymethylene alone shows a large peak at 200°C, whereas the others exhibit no large weight loss in this temperature. The temperature at which the sample decomposes completely becomes higher in the order of polyoxymethylene, acetylated polyoxymethylene and Delrin.

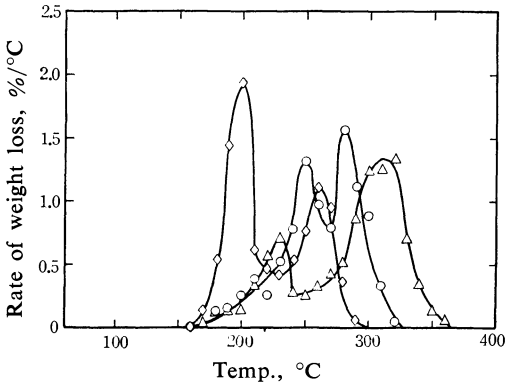

Fig. 1. Thermogravimetric analysis curves for polyoxymethylene (POM), acetylated polyoxymethylene (POMAc) and Delrin in nitrogen atmosphere.
◇ POM, ○ POMAc, △ Delrin 5000X

The DTGA curves of these polymers using a sample of 100 mg. in air are shown in Fig. 2. In each curve of these polymers, two peaks were observed, as in nitrogen. However, both polyoxymethylene and acetylated polyoxymethylene showed a large weight loss over the range from 150 to 200°C. In the case of oxidative decomposition, the completely decomposing temperature is the highest for Delrin and the lowest for polyoxymethylene.

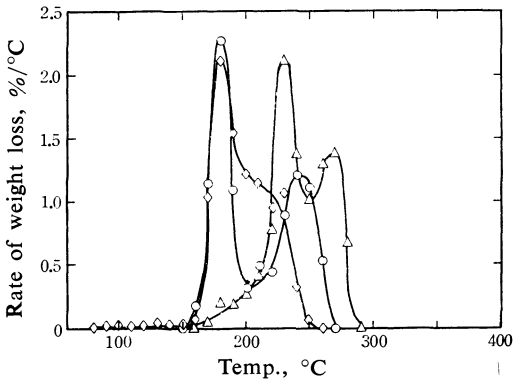

Fig. 2. Thermogravimetric analysis curves for polyoxymethylene (POM), acetylated polyoxymethylene (POMAc) and Delrin in air.
◇ POM, ○ POMAc, △ Delrin 5000X

Isothermal Decomposition of Polyoxymethylene in Nitrogen and in Air.—The thermal decomposition of polyoxymethylene was isothermally studied at temperatures in the 200~240°C range. The plot of the logarithm of the weight loss of the sample against the time in nitrogen is shown in Fig. 3. A deviation of the reaction rate from the first-order law was observed. The decomposition seems to occur in two stages.

The plot of the logarithm of the weight loss of the sample against the time at various temperatures in air is shown in Fig. 4. In this case, no simple straight line was observed; accordingly, the oxidative decomposition is more complex than the thermal decomposition in a nitrogen atmospher (cf. Fig. 3).

Effect of the Concentration of Atmospheric Oxygen on Thermal Decomposition. — As has been mentioned above, the thermal decomposition of polyoxymethylene is significantly affected by the concentration of oxygen.

8) H. Kambe and S. Igarashi, *Rept. Aeronaut. Res. Inst., Univ. Tokyo*, **28**, 145 (1963).

(△) 0.24 mol. %; (◇) 5.6 mol. %;
(○) 21.0 mol. %

Therefore, TGA measurements were performed in various concentrations of oxygen. The typical curves for the decomposition of polyoxymethylene shown in Fig. 5 indicate a significant difference between the DTGA curves. The weight loss at the first stage, from 150 to about 200°C, increases with the concentration of oxygen. The weight of the sample used in these measurements was about 10 mg. From Figs. 2 and 5, the weight loss at the first stage for experiments using a sample of 10 mg. may be seen to have been greater than for measurements using a sample of 100 mg. in air (i.e., 21.0 mol. % of oxygen). This will be discussed furthere below.

The DTGA curves for the decomposition of acetylated polyoxymethylene are shown in Fig. 6. The weight loss at the first stage, from 150 to about 200°C, increases with the concentration of oxygen. The weight losses at the first stage in the decomposition for polyoxymethylene and its acetylated sample calculated from Figs. 5 and 6 are plotted against the concentration of oxygen in mole per cent in Fig. 7. The weight loss of the first peak for both samples increases clearly with the concentration of oxygen, and the weight loss for polyoxymethylene is greater than that for acetylated polyoxymethylene.

The effects of the concentration of oxygen on the thermal decomposition of polyoxymethylene and acetylated polyoxymethylene are listed in Table I.

a) In air.
b) In nitrogen.

Thermogravimetric Analysis in a Vacuum.—We consider that the effect of oxygen on the decomposition of polyoxymethylene can be eliminated by carrying out the thermogravimetric measurements in a vacuum. The DTGA curves of polyoxymethylene and acetylated polyoxymethylene in a vacuum are shown in Fig. 8. Polyoxymethylene shows a sharp peak at about 180°C and a second peak over the range from 200 to 330°C. For polyoxymethylene, there is no significant difference between the curve obtained at 1°C/min. and that at 0.5°C/min.

Acetylated polyoxymethylene shows two peaks in the DTGA curves; the former is in the region from 150 to 200°C, and the latter, from 200 to 340°C. Moreover, the first peak is smaller than the second one.

The TGA results obtained in the several atmospheres are summarized in Table II.

Infrared Analysis of Partially-Degraded Polyoxymethylene.—Infrared analysis was carried out for polyoxymethylene heated from room temperature to a desired maximum temperature. A great change in the infrared spectra

a) Isothermal decomposition.

of the absorbance at the 1740 cm^{-1} band to that at the 2940 cm^{-1} band is plotted against the weight loss and also against the maximum heated temperature in air and in nitrogen in Fig. 9. The results obtained by infrared analysis are listed in Table III.

Discussion

Thermal Decomposition Character.—Dainton, Ivin and Walmsley,[9] Schweitzer and MacDonald,[1] and Kern and Cherdron,[2] found that the thermal degradation of polyoxymethylene is of the chain-depolymerization type, involving the successive release of formaldehyde from a hydroxyl end group, and that the oxidative degradation may occur at random along the chain. Recent investigation[3] has revealed that the isothermal decomposition of polyoxymethylene occurs in two stages.

As is shown in the DTGA curves in Figs. 1 and 2, polyoxymethylene, acetylated polyoxymethylene and Delrin undergo thermal and oxidative degradation in two stages. The results in Fig. 1 clearly show that the polyoxymethylene with an acetyl end group is thermally more stable than the original polymer with a hydroxyl end group; the weight loss of the former in the 200°C region is smaller than that of the latter. Although polyoxymethylene is stabilized by the acetylation of the hydroxyl end group, the stabilization of the chain ends has a minor effect on the oxidative decomposition, as may be seen in Fig. 2. This means that, in air, the chain scission due to oxidation occurs at random points along the chain. Since the decomposition of polyoxymethylene in the 200°C region occurs also in nitrogen, it may be deduced that its oxidative decomposition in this stage occurs as a combination of random degradation and chain depolymerization. Delrin shows a good thermal stability at temperatures in the above-mentioned region. This may be attributed to the effects of a stabilization of the end group and of an antioxidant added to the polymer upon decomposition.

The two steps of degradation observed by TGA are confirmed by the isothermal decomposition, as is shown in Fig. 3. Each peak in the DTGA curve may correspond to two straight lines in the isothermal decomposition, which is a reaction of the first order. The isothermal decomposition character of polyoxymethylene in air illustrated in Fig. 4 is similar to that reported by Kern.[2]

The effect of the concentration of oxygen on the DTGA curve is shown in Figs. 5 and 6 for polyoxymethylene and acetylated polyoxymethylene, respectively. The weight losses of the first stage in the 200°C region increases with the concentration of oxygen, as Fig. 7 shows. This indicates that the oxidative decomposition occurs more easily as the concentration of oxygen increases. Acetylated polyoxymethylene undergoes the oxidative decomposition entirely, but polyoxymethylene decomposes preferentially at the chain ends in addition to the decomposition which occurs as a result of the random attack of oxygen. This may be a reason why the weight loss of polyoxymethylene is larger than that of acetylated polyoxymethylene.

The thermogravimetric measurements were conducted in a vacuum at 10^{-2} mmHg. The results in Fig. 8 reveal clearly that the

9) F. S. Dainton, K. J. Ivin and D. A. G. Walmsley, *Trans. Faraday Soc.*, 55, 61 (1959).

degradation occurs in two stages in such a low concentration of oxygen. The fraction of the weight loss in the first stage of polyoxymethylene is larger than that obtained in nitrogen at atmospheric pressure (see Table II). The rate of the vaporization of the degradation products from polyoxymethylene will depend on the pressure of the atmosphere. There is no significant difference between the curves obtained at different heating rates, as Fig. 8 shows. Accordingly, it is interesting that the thermal decomposition polyoxymethylene did not all occur in one stage. It is deduced that the second stage of weight loss corresponds to the decomposition of the stable fragments formed during the first stage of degradation. The scission of the main chain of the acetylated polyoxymethylene molecule occurs mainly over the range from 200 to 340°C. The small peak below 200°C is probably to be attributed to the thermal decomposition of an unacetylated polyoxymethylene.

The Mechanism of Decomposition. — The results in Fig. 9 and in Table III show that the carbonyl groups are formed during the decomposition of polyoxymethylene in each atmosphere and that its amount increases with the degree of degradation. The carbonyls are formed even in a vacuum. Since the oxygen remaining in a vacuum had no influence on the DTGA curve, it may be supposed that this formation is due to the interchange of the ether linkage into the carbonyl group (see step II below).

The following mechanism for the thermal decomposition of polyoxymethylene in the absence of oxygen is proposed:

$$\mathrm{HO\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}}\sim$$

$$\rightarrow \mathrm{HO\cdot} + \mathrm{\cdot CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}}\sim \quad \text{(I)}$$

monomer, etc.

$$\sim\mathrm{CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}}\sim$$

$$\rightarrow \sim\mathrm{CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH\text{-}O\text{-}}\sim + \mathrm{\cdot H}$$

$$\rightarrow \sim\mathrm{CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2}$$

$$+\mathrm{O{=}CH\text{-}O\text{-}CH_2\text{-}O\text{-}}\sim \quad \text{(II)}$$

In the light of the above mechanism, it may be deduced that a stable fragment with carbonyl groups at the chain ends decomposes in the second stage in the DTGA curve of polyoxymethylene in a vacuum.

In the presence of oxygen, the following scheme is well known:

$$\sim\mathrm{CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}}\sim + \mathrm{O_2}$$

$$\rightarrow \sim\mathrm{CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH(OOH)\text{-}O\text{-}}\sim$$

$$\rightarrow \sim\mathrm{CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH(O\cdot)\text{-}O\text{-}}\sim$$

$$+\mathrm{\cdot OH}$$

$$\rightarrow \sim\mathrm{CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O\text{-}C(=O)H}$$

$$+\mathrm{\cdot O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}}\sim$$

The fact that the quantity of carbonyl groups formed in the decomposition in air is larger than that in nitrogen, as has been mentioned already, reflects the above mechanism for the oxidative degradation of polyoxymethylene.

Effect of Sample Size on the Thermogravimetric Analysis Curve.—It may be seen from Figs. 5 and 6 that the temperature of the second stage is altered to a lower temperature with an increase in the concentration of oxygen. Moreover, it should be noticed that the feature of the DTGA curve is dependent on the weight of the sample used for measuring. For instance, by comparing the curve for polyoxymethylene using a sample of 100 mg. in air (see Fig. 2) with that for polyoxymethylene using sample of 10 mg. in air (i. e., 21.0 mol. % of oxygen in Fig. 5), it is confirmed that the DTGA curve for the oxidative decomposition is greatly affected by the weight of the sample used. A similar effect for the oxidative decomposition of polyethylene has been reported in a previous paper.[10]

Summary

The character of the thermal decomposition of polyoxymethylene, acetylated polyoxymethylene and Delrin in air and in nitrogen has been studied by thermogravimetric analysis. Two peaks have been observed in each atmosphere in the derivative thermogravimetric analysis curves for these samples.

It has been confirmed that the feature of doublet peaks is related to the concentration of oxygen during the decomposition and, thus, that the first stage is due to the chain depolymerization as well as to the oxidative decomposition, and that the second stage is to be attributed to the random degradation of a stable fragment formed during the first stage decomposition.

An increase of carbonyl groups in the polymer molecule with the degradation was confirmed by infrared spectroscopy.

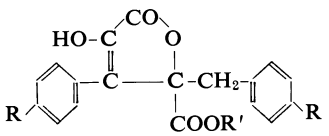
The Base-catalyzed Condensation of Nitrophenylpyruvates. I. α-Oxo-β-(o-nitrophenyl)-γ-(o-nitrobenzyl)-γ-ethoxycarbonyl-γ-butyrolactone

By Takeo SAKAN, Masahiko KATO, Toshio MIWA and Nobuo NAKAMURA

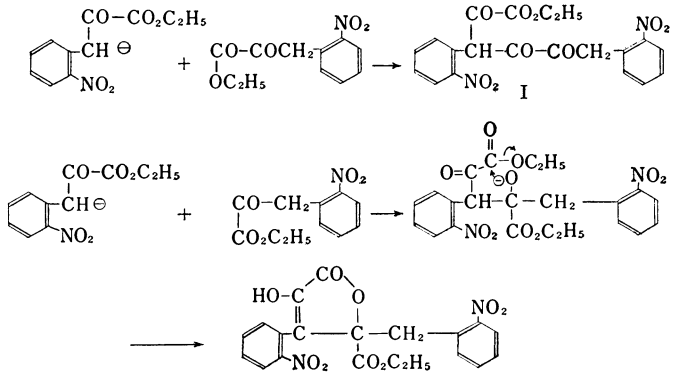


(Received February 11, 1964)

In connection with our synthetic study of the amino acid metabolism, we wished to prepare a quantity of ethyl *o*-nitrophenylpyruvate. The ester had been studied extensively by Wislicenus and Thoma,[1] who prepared it by the condensation of *o*-nitrotoluene with ethyl oxalate in the presence of potassium ethoxide in dry ether.

We attempted, however, to prepare the ester more economically by modifying the DiCarlo method[2] for the acid. *o*-Nitrotoluene was condensed with ethyl oxalate in the presence of sodium ethoxide in boiling ethanol. The reaction mixture was saturated with hydrogen chloride. From a benzene solution of the reaction product, the keto ester was isolated as a bisulfite adduct. When the adduct was decomposed with mineral acid, a crystalline substance, $C_{20}H_{26}O_9N_2$, insoluble in benzene was obtained. This compound usually appeared as needles decomposing at 180°C; however, it was occasionally obtained as rhombi decomposing at 183.5°C. Most of the reactions were carried out with the former.

A comparison of the composition of this compound with that of ethyl *o*-nitrophenylpyruvate indicated that the compound had been formed by the condensation of two moles of the pyruvate with a loss of one mole of ethanol. The enolate anion from the starting ester might attack another mole of the ester, either at the ester carbonyl or at the keto carbonyl, to form a triketo ester I or a ketolactone ester II respectively.



Hemmerlé[3] has found the self-condensation products of phenylpyruvic esters to be α-oxo-β-phenyl-γ-benzyl-γ-alkoxycarbonyl-γ-butyrolactone (III, R=H). Cagniant[4] obtained analogous compounds III (R=NO_2 and CH_3O, R'=H) from *p*-nitro- and *p*-methoxyphenylpyruvic acids.

III

Similarly, the compound obtained here also may probably be expressed by the structure II. This will be established by the following chemical evidence.

The compound II is weakly acidic and soluble in aqueous alkali. The acetylation of II with acetic anhydride gave a monoacetate IV, and treatment with diazomethane yielded

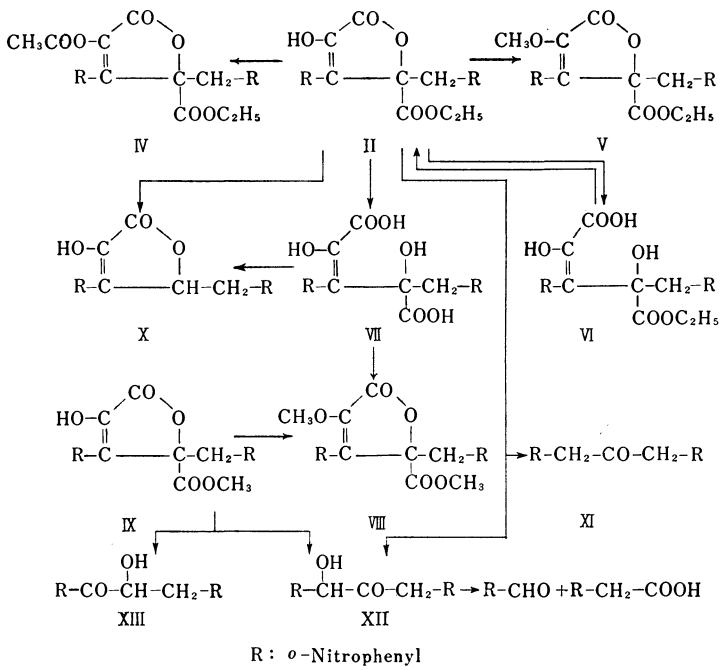

Chart 1.

a monomethyl ether V. They were no longer acidic.

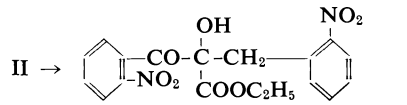
The hydrolysis of II with aqueous sodium hydroxide at room temperature for one and a half hours gave a pale green acid, VI, melting at ca. 95°C.[5] The methylation of the acid VI with diazomethane gave the methyl ether V, while esterification with ethanolic hydrogen chloride formed the original ester II.

In contrast to the above hydrolysis, the hydrolysis of II with aqueous sodium hydroxide at room temperature for 22 hr. gave an acid, VII, decomposing at 144.5~145°C. This acid, on treatment with diazomethane, was changed to a methyl ether VIII (m. p. 169.5~170.5°C), whose composition, $C_{20}H_{16}O_9N_2$, was less by CH_2 than that of the ethyl ester V. The methyl ether VIII was identified with the enol methyl ether of the methyl ester IX which was prepared by the condensation of *o*-nitrotoluene with methyl oxalate under the same conditions as used for the ethyl ester II.

The attempted esterification of the acid VII with ethanolic hydrogen chloride gave a lactone X (m. p. 191~191.5°C), the structure of which was determined on the basis of its composition, $C_{17}H_{14}O_7N_2$, and its infrared spectrum (see Experimental). This compound was still weakly acidic, as was to be expected from its structure, and gave a methyl ether with diazomethane. The hydrolysis of II with a mixture of hydrochloric and acetic acids gave the same compound X; however, the hydrolysis was very hard.

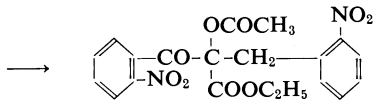
The oxidation of II or IX with alkaline hydrogen peroxide gave various results, as did the alkaline hydrolysis.[5] Three neutral products were isolated. One of them, a ketone XI, $C_{15}H_{12}O_5N_2$, was identified with the 1,3-bis(*o*-nitrophenyl)-2-propanone prepared by the nitration of dibenzyl ketone. The positions of the nitro groups in the synthetic sample were confirmed by permanganate oxidation to *o*-nitrobenzoic acid. The second product, XII ($C_{15}H_{12}O_6N_2$; m. p. 142~143°C), gave a positive Fehling reaction indicative of a ketol function. This compound was assumed to possess the structure XII from the fact that the Treibs oxidation of this compound yielded *o*-nitrobenzaldehyde and *o*-nitrophenylacetic acid. The third product, XIII (m. p. 95°C), was isomeric with the ketol XII and was tentatively assigned the structure of 1,3-bis(*o*-nitrophenyl)-2-propanol-1-one from its infrared spectrum (see Experimental); however, it gave a negative Fehling reaction.

Jarrousse[6] has noted that the α-ketol analogous to XIII obtained by the decarboxylation of an acid that had been obtained by the permanganate oxidation of di-(phenylpyruvic acid) is isomerized readily to the α-ketol corresponding to XII. The fact that no such



5) The product was erratic, varying in response to slight differences in the reaction conditions, and so was hard to purify.

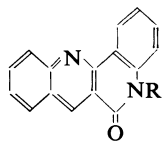
6) J. Jarrousse, *Ann. chim.*, **9**, 157 (1938).



isomerization was observed with the compound XIII made the postulated structure doubtful.

The above transformations of the compound II are summerized in Chart 1.

The permanganate oxidation of II in acetone gave a hydroxy ester XIV (m. p. 131.5~132°C), together with *o*-nitrobenzoic and oxalic acids. This compound gave a negative ferric chloride reaction; its structure was postulated from the composition, $C_{18}H_{18}O_8N_2$, and its infrared spectrum (see Experimental). The acetylation of XIV with acetic anhydride gave an acetate, XV. The acetate was so stable that it was sublimed without decomposition on attempted pyrolysis under reduced pressure.[7]



XIV

XV

The hydrolysis of XIV with hydrochloric acid gave *o*-nitrophenylacetic acid in a 69% yield. The mechanism of the unexpected formation of this acid has not been clarified.

The hydrogenation of XIV in the presence of palladium-on-carbon gave yellow crystals melting at 354°C. This compound exhibited an ultraviolet spectrum completely identical with that of 5-methylquino[4, 3-b]quinoline-6(5*H*)-one[8] (XVII) and was assigned the structure of the quinoquinolone XVI.

XVI: R=H
XVII: R=CH_3

Experimental[9]

α-Oxo-β-(*o*-nitrophenyl)-γ(*o*-nitrobenzyl)-γ-ethoxycarbonyl-γ-butyrolactone (II).—Into a sodium ethoxide solution prepared from 23 g. of sodium and 270 cc. of ethanol was added a mixture of 137 g. of *o*-nitrotoluene and 146 g. of diethyl oxalate in one portion with stirring at room temperature. The resulting deep-red mixture was heated while continuously being stirred at 125°C for half an hour. After cooling, the mixture was acidified by bubbling dry hydrogen chloride. The precipitated sodium chloride was filtered off, and the filtrate was concentrated. The residue as a benzene solution was treated with aqueous sodium bisulfite (360 g. in 600 cc. of water) to form a quantity of precipitates. The precipitates were filtered, washed with benzene, and decomposed by treatment with diluted sulfuric acid (90 cc. in 350 cc. of water) and 250 cc. of benzene at 50~60°C for one hour. The insoluble material was then filtered from the cooled mixture (43.8 g.). The benzene layer of the filtrate was diluted with ether and then extracted with 10% aqueous sodium carbonate. The acidification of the extract gave an additional 6.4 g. of the precipitates, which were combined with the above-mentioned insoluble material (total 50.2 g., 23%) and twice recrystallized from ethanol to yield pure ester II as a powder, decomposing at 182~182.5°C. ν_{max} 3330 (OH), 1773, 1698 (C=O or C=C), 1529, 1348, 1335 cm^{-1} (NO_2). (Found: C, 56.07; H, 3.74; N, 6.45. Calcd. for $C_{20}H_{16}O_9N_2$: C, 56.08; H, 3.77; N, 6.54%.) Allowing the mother liquor of recrystallization to evaporate gave a mixture of needles and rhombi; these two forms of crystals were separated by hand. Since the needles (Found: C, 56.21; H, 3.94%), decomposing at 183.5°C, showed the same infrared spectrum as the ester in powder, the ester in powder was assumed to be mainly composed of this form. The rhombi decomposed at 183.5°C (Found: C, 56.18; H, 4.01%). ν_{max} 3330 (OH), 1748 (C=O), 1695 (C=C), 1522, 1355 cm^{-1} (NO_2).

Monoacetate IV.—Heating 0.5 g. of II with acetic anhydride for five hours at 100°C gave 0.5 g. of IV, which, after recrystallization from acetic acid, melted at 170.5~171°C (Found: C, 56.49; H, 3.95; N, 5.97. Calcd. for $C_{22}H_{18}O_{10}N_2$: C, 56.17; H, 3.86; N, 5.96%).

Monomethyl Ether V.—A solution of 1 g. of II in aqueous potassium hydroxide (0.39 g. in 8 cc. of water) was treated with 0.9 g. of dimethyl sulfate to give a yellow oil which solidified in a short time. Extraction with benzene, followed by washing with aqueous sodium carbonate and the evaporation of the solvent, gave yellow plates, which, after three recrystallizations from benzene, melted at 140.5~141.5°C (Found: C, 57.12; H, 4.09; N, 6.53; mol. wt. (Rast): 406. Calcd. for $C_{21}H_{18}O_9N_2$: C, 57.01; H, 4.10; N, 6.33%; mol. wt. 442).

The methylation of 1 g. of II in methanol with diazomethane gave 0.9 g. of the methyl ether V melting at 137~138.5°C. Recrystallization from benzene gave 0.73 g. of a pure material which melted at 137.5~138.5°C. Mixed melting point determination with the above methyl ether did not show any depression.[10]

The Alkaline Hydrolysis of II.—*Carboxylic Acid VI.*—A solution of II (2 g.) in 23 cc. of N aqueous sodium hydroxide was allowed to stand

7) Steric circumstances might hinder the formation of a six-membered-ring transition state favorable for pyrolysis.

8) J. T. Braunholtz and F. G. Mann, *J. Chem. Soc.*, **1955**, 381.

9) All melting points are uncorrected. The infrared spectra were measured in Nujol mull and are expressed in ν_{max} cm^{-1}. The authors are much indebted to Mr. Jun'ichi Gōda and his associates for their elementary analyses and to Mrs. Michino Butsugan and Miss Hiromi Tokuda for their infrared spectral measurements.

10) The discrepancy between the melting points is due to the use of different thermometers.

for half an hour at room temperature. Acidification with N hydrochloric acid precipitated a pale-green acid, which, after recrystallization from acetic acid-ligroin, decomposed at 95°C, solidified at 100°C, and then decomposed at 159~165°C again. ν_{max} 3300 (OH), 1786, 1695 (C=O).

Carboxylic Acid VII.—Allowing a solution of II in 20 cc. of 2 N sodium hydroxide to stand for 22 hr. at room temperature gave an acid VII, which, after three recrystallizations from acetic acid-ligroin, decomposed at 152.5°C. (Found : C, 52.64; H, 3.04; N, 6.80. Calcd. for $C_{18}H_{14}O_{10}N_2$: C, 51.68; H, 3.37; N, 6.70%).

The Attempted Esterification of the Acid VI with Ethanolic Hydrogen Chloride.—Into a solution of 200 mg. of acid VI in 5 cc. of dry ethanol hydrogen chloride was bubbled for half an hour, and then the mixture was refluxed for 40 min. After the removal of the solvent, the residue was dissolved in ether, washed with aqueous sodium bicarbonate and water successively, and dried. The distillation of the ether left a colorless powder, decomposing at 182~183°C, in a quantitative yield. It was identified with II by admixture test and infrared comparison.

The Methylation of the Acid VI with Diazomethane.—The methylation of VI with methanolic diazomethane afforded a neutral compound melting at 146.5~147°C, which was identified with the methyl ether V by mixed melting determination and infrared comparison.

The Attempted Esterification of the Acid VII with Ethanolic Hydrogen Chloride. — *α-Oxo-β-(o-nitrophenyl)-γ-(o-nitrobenzyl)-γ-butyrolactone (X).* — A suspension of 0.14 g. of VII in 4 cc. of dry ethanol was refluxed for 30 min. while hydrogen chloride was being introduced. Rubbing the neutral fraction with benzene-ethanol gave 88 mg. of crystals, which, after recrystallization from ethanol, melted at 187~189°C. ν_{max} 3300 (OH), 1745 (C=O), 1695 cm^{-1} (C=C).

Found : C, 57.59; H, 3.36; N, 7.64. Calcd. for $C_{17}H_{12}O_7N_2$: C, 57.31; H, 3.40; N, 7.86%.

α-Oxo-β-(o-nitrophenyl)-γ-(o-nitrobenzyl)-γ-methoxycarbonyl-γ-butyrolactone (IX). — Into a sodium methoxide solution prepared from 11.5 g. of sodium and 94 cc. of methanol, 59 g. of dimethyl oxalate and then 68.5 g. of *o*-nitrotoluene were added. The mixture was refluxed vigorously for 20 min. and acidified by the introduction of dry hydrogen chloride. After the removal of salt by filtration and that of the solvent by evaporation, the residue was treated with ice and benzene to separate a yellow, insoluble material. The benzene layer, after filtration, was extracted with three portions of 10% aqueous sodium carbonate, and the extract was acidified with 2 N hydrochloric acid to give reddish brown precipitates, which were combined with the above-obtained, insoluble material and recrystallized from ethanol to yield colorless crystals decomposing at 185~186°C. (Found : C, 55.31; H, 3.62; N, 7.03. Calcd. for $C_{19}H_{14}O_9N_2$: C, 55.07; H, 3.38; N, 6.76%.)

α-Methoxy-β-(o-nitrophenyl)-γ-(o-nitrobenzyl)-γ-methoxycarbonyl-$\Delta^{\alpha,\beta}$-butenolide (VIII).—*The Methylation of the Acid VII with Diazomethane.*—The methylation of VII with diazomethane in methanol gave a methyl ether melting at 169.5~170.5°C. (Found : C, 56.29; H, 4.03; N, 6.83. Calcd. for $C_{20}H_{16}O_9N_2$: C, 56.08; H, 3.77; N, 6.54%.) This methyl ether was identified with the methyl ether VIII synthesized below by the admixture test and by an infrared spectral comparison.

The Methylation of Compound IX.—The methylation of IX with methanolic diazomethane gave a methyl ether which, after recrystallization from benzene, melted at 167°C.

The Oxidation of Compound II or IX with Alkaline Hydrogen Peroxide.—*The Formation of 1, 3-Bis(o-nitrophenyl)-2-propanone.*—A solution of 2 g. of II in 20 cc. of N sodium hydroxide was treated with 40 cc. of 30% hydrogen peroxide. An exothermic reaction occurred. The mixture was allowed to stand overnight, and was then acidified and extracted with ether. The ether extract, after being washed with aqueous sodium bicarbonate, gave yellow crystals, which, after recrystallization from ethanol, melted at 136~137°C. This material was identified with the specimen synthesized below by the admixture test and by a comparison of the infrared spectra.

The Formation of Compound XII.—A solution of 1 g. of II in 5 cc. of N sodium hydroxide was left to stand with 20 cc. of 30% hydrogen peroxide for two days. Within one hour the mixture became cloudy. After extraction with ether, an additional amount of N sodium hydroxide was added to the aqueous layer to cause an exothermic reaction. The mixture was then allowed to stand overnight and extracted with ether. The combined ether extracts were shaken with aqueous sodium bicarbonate. The aqueous layer was acidified with hydrochloric acid and extracted with ether again. The extract, after the removal of the solvent, left a yellow oil, which solidified and was repeatedly recrystallized from ethanol to give the ketol XII, melting at 142~143°C. This compound reduced the Fehling solution. ν_{max} 3480 (OH), 1727 cm^{-1} (C=O). (Found : C, 57.44; H, 3.93; N, 8.64. Calcd. for $C_{15}H_{12}O_6N_2$: C, 56.96; H, 3.82; N, 8.86%.)

The Formation of Compound XIII.—A solution of 3 g. of compound IX in 60 cc. of N sodium hydroxide was allowed to stand for 50 min. and then treated with 2 cc. of 30% hydrogen peroxide. The mixture was left overnight and then acidified to give 2.39 g. of precipitates decomposing at 151~159°C. The precipitates were dissolved in 12 cc. of N sodium hydroxide and treated with 48 cc. of hydrogen peroxide. After the mixture had been left to stand overnight, it was acidified to give precipitates, which afforded 0.81 g. of an acid fraction and 0.98 g. of neutral fraction. The acid fraction was treated with hot benzene. The benzene-soluble acid (0.21 g.) melted at 131~134°C and was identified with *o*-nitrophenylacetic acid. The benzene-insoluble fraction was methylated with diazomethane to give a compound melting at 166°C, which was identified with the methyl ether VIII. The neutral fraction was recrystallized from benzene to give 0.25 g. of a compound melting at 138~141°C, which was found to be identical with the compound XII obtained above. From the mother

liquor of the recrystallization compound XIII (m. p. 95°C) was obtained. This compound did not reduce the Fehling solution. ν_{max} 3380 (OH), 1705 cm^{-1} (C=O).

Found: C, 57.34; H, 3.93; N, 8.34. Calcd. for $C_{15}H_{12}O_6N_2$: C, 56.96; H, 3.82; N, 8.86%.

1, 3-Bis(*o*-nitrophenyl)-2-propanone.—Into 4 g. of fuming nitric acid (d=1.53) was added a mixture of 2 g. of dibenzyl ketone and 4 g. of acetic anhydride at −3∼−5°C with stirring. After 40 min. the mixture was poured onto ice, and the resulting oil was extracted with benzene. The benzene extract was washed successively with aqueous sodium bicarbonate and water, followed by drying and chromatography on active alumina. The first fraction eluted with benzene yielded colorless plates (450 mg.), which, after recrystallization from ethanol, melted at 141∼141.5°C. (Found: C, 60.23; H, 4.06; N, 9.31. Calcd. for $C_{15}H_{12}O_5N_2$: C, 60.00; H, 4.00; N, 9.33%.) This compound, on oxidation with potassium permanganate in aqueous alkali, produced *o*-nitrobenzoic acid (m. p. 147°C).

The Treibs Oxidation of Compound XII.—Into a warm solution of XII in 2 cc. each of methanol and ethanol was added one drop of a vanadium pentoxide solution, prepared from 100 mg. of vanadium pentoxide and 5 cc. of 30% hydrogen peroxide, and then 0.8 cc. of 30% hydrogen peroxide in three portions; white precipitates were thus produced. After the addition of a sufficient amount of acetone to make a clear solution, the solution was left to stand for three days. The solvent was distilled off and the residue, after the addition of water, was extracted with benzene-ether. The acid fraction gave an acid melting at 137.5∼138°C, which was identified with *o*-nitrophenylacetic acid by mixed melting point determination. The neutral fraction was converted to a 2, 4-dinitrophenylhydrazone decomposing at 235∼250°C, which was identified with that of *o*-nitrobenzaldehyde, decomposing at 250°C, by infrared comparison.

The Permanganate Oxidation of Compound II.—Into a solution of 2.57 g. of II in 400 cc. of acetone 2.53 g. of potassium permanganate was added in one portion, and then the mixture was stirred for 7 hr. at room temperature. The acetone solution, after the filtration of manganese dioxide and the distillation of the solvent, gave 1.66 g. of a residue, which, after recrystallization from benzene-ligroin, melted at 131.5∼132°C. ν_{max} 3485 (OH), 1730 (shoulder), 1712 cm^{-1} (C=O). (Found: C, 55.87; H, 4.30; N, 7.21. Calcd. for $C_{15}H_{16}O_8N_2$: C, 55.67; H, 4.15; N, 7.21%.)

Acetate XV.—A mixture of 0.5 g. of XIV and 5 cc. of acetic anhydride was heated for one hour in the presence of one drop of concentrated sulfuric acid to give a crude acetate in a quantitative yield. Two recrystallizations from ethanol provided the pure acetate melting at 129°C. ν_{max} 1745, 1705 cm^{-1} (C=O) (Found: C, 56.33; H, 4.38; N, 6.70; mol. wt. (Rast), 423. Calcd. for $C_{20}H_{18}O_9N_2$: C, 55.81; H, 4.22; N, 6.51%; mol. wt., 430).

The Hydrolysis of XIV.—A mixture of 400 mg. of XIV, 100 cc. of 2 N hydrochloric acid and 30 cc. of acetic acid was boiled under reflux for 18 hr. The acid fraction gave 100 mg. of *o*-nitrophenylacetic acid (m. p. 136.5°C). The neutral fraction gave 88 mg. of the recovered XIV.

The Hydrogenation of XIV.—A solution of 200 mg. of XIV in 40 cc. of acetic acid was hydrogenated in the presence of 40 mg. of palladium-on-carbon under ordinary pressure. Six molar equivalents of hydrogen were absorbed in 5 hr., 20 min. After the catalyst had been removed, the solvent was distilled under reduced pressure to give 170 mg. of a yellow powder, which, after recrystallization from acetic acid, decomposed at 354°C. The analytical sample was purified by sublimation at 270°C/10 mmHg. ν_{max} 3175 (NH), 1667cm^{-1} (C=O). λ_{max}^{EtOH} mμ (log ε): 227 (4.54), 233 (4.52), 274 (4.82), 290 (4.36), 362 (3.66). (Found: C, 77.68; H, 4.33; N, 12.34. Calcd. for $C_{16}H_{10}ON_2$: C, 78.03; H, 4.09; N, 11.38%.)

The Base-catalyzed Condensation of Nitrophenylpyruvates. II. The Absorption Spectra of α-Oxo-β-aryl(or alkyl)-γ-aryl-methyl(or alkyl)-γ-ethoxycarbonyl-γ-butyrolactones

By Takeo SAKAN, Masahiko KATO and Toshio MIWA

(Received February 11, 1964)

In the preceding paper,[1] the base-catalyzed condensation of ethyl *o*-nitrophenylpyruvate (in situ) was reported to give a dimeric condensate, the structure of which was confirmed by chemical means to be α-oxo-β-(*o*-nitrophenyl)-γ-(*o*-nitrobenzyl)-γ-ethoxycarbonyl-γ-butyrolactone (I). However, the infrared spectra of this compound and its derivatives do not agree, in some respects, with their structures. In order to make a correct interpretation of the spectra, those compounds in which the two *o*-nitrophenyl groups in compound I had been substituted with two methyl or two phenyl groups were prepared and their absorption spectra were comparatively examined. Table I lists the compounds used in this study and the references for their preparation.[2,3]

Infrared Absorption Spectra

The spectral data[4] are listed in Table II. The ester $\nu_{C=O}$ of compounds II, III, and IV appeared in the normal position for esters[5] (1740~1742 cm^{-1}), and there is no such effect of an α-alkoxyl group on carbonyl as that observed by Jones and his co-workers[6] in ketones and by Singh[7] in a lactone. This is probably due to the presence of a double bond in the α, β-position of the lactone. On the other hand, the absorption spectra of II and V, and of IV and VI[8] showed that the $\nu_{C=O}$ due to lactone had shifted by 8~15 cm^{-1} to a higher wave number region in II and IV, apparently due to the presence of an ethoxycarbonyl group. The $\nu_{C=O}$ and ν_{OH} of lactone carbonyl and enol in II and V are split in two, even in a dilute solution; this is considered to show that these compounds are present as a mixture of enols with and without hydrogen bonding,[9] because the intramolecular hydrogen bond of VII-type is a labile five-membered ring.[10] A dicarbonyl type is possible but, since compounds of this type exist completely in the enol type[11] in an aqueous solution (dielectric constant of the solvent: 81[12])[13] and since a

4) Infrared absorption spectra were measured with a Hitachi model EPI-2 infrared spectrophotometer. We are indebted to Miss Hiromi Tokuda for the measurements.

XIV	288	(4.30)

ν_{OH} of a very strong intensity appears in their infrared absorption spectra in carbon tetrachloride (dielectric constant of the solvent: 2.24[12]), it is apparent that they are mainly present in the enol type in these solution.[14] When the hydroxyl is methylated (III), ν_{OH} disappears and the lactone $\nu_{C=O}$ alone remains, at 1783 cm^{-1}. When this is derived to an acetate, IV, there is no change in the $\nu_{C=O}$ of ethoxycarbonyl, but the lactone $\nu_{C=O}$ shifts further to a higher wave number region as a result of the interaction of the lactone with the newly-introduced acetate group.

VII

In the compounds with a phenyl ring, XI and XII, the $\nu_{C=O}$ due to lactone is shifted by 5~7 cm^{-1} to a lower wave number side than that of the corresponding compounds with a

methyl group (II and III) as a result of conjugation with the phenyl ring,[15] while the ester $\nu_{C=O}$ is shifted by 9～10 cm^{-1} to a higher wave number region, now being present at 1747～1750 cm^{-1}. The reason for the latter shift is still not clear.[16] The splitting of the ν_{OH} of compounds XI and XIV in two, without the splitting of the carbonyl $\nu_{C=O}$, is probably due to hydrogen bonding with the π-electron of the phenyl ring.[17]

In the infrared absorption spectra of I and X with an enol structure, there are only one $\nu_{C=O}$ due to lactone carbonyl and one ν_{OH} in the higher wave number region, and practically no evidence of an intramolecular hydrogen bonding. In the methyl ether compound VIII and the acetate IX, absorptions in the $\nu_{C=O}$ region are similar to that of the corresponding III and IV with a methyl group in place of the phenyl. This indicates that the *o*-nitrophenyl ring is not conjugated with the lactone ring.

15) In CH_3=$CHCO_2CH_3$ (*trans*) and C_6H_5CH=$CHCO_2C_2H_5$ (*trans*), the difference is −11 cm^{-1}, not greatly different from the above shift. See J. L. H. Allan, G. D. Menkins and M. C. Whiting, *J. Chem. Soc.*, **1955**, 1874.

16) The change in absorption wave numbers may be due to interaction with π-electrons of the phenyl ring.

17) There is no splitting of the $\nu_{C=O}$ and a close proximity of the hydroxyl and phenyl ring is possible. Such an example has been observed in the β-phenylethyl alcohol derivatives. See G. Büchi, L. Crombie, P. J. Godin, J. S. Kaltenbornn, K. S. Siddalingiah and D. A. Whiting, *J. Chem. Soc.*, **1961**, 2843.

Ultraviolet Absorption Spectra

The results[18] are shown in Table III. As has already been stated, α-oxo-γ-butyrolactone is completely enolized in an aqueous solution and is expected to be present chiefly in the enolized form in the ethanol solution (dielectric constant of the solvent: 25.7[12]) in which its ultraviolet absorption spectrum was measured. Actually, the absorptions of the enols, II and XI, are shifted by 7 and 5 mμ respectively to a longer wavelength region than those of the methyl ethers, III and XII,[19] without any change in their intensity; this is evidence for the above assumption.[20]

Compared to the spectrum of II, that of the acetate IV shows a hypsochromic shift of 31 mμ; this is in good agreement with the generally accepted value of 34 mμ.[21] The absorption maximum of V seems to have shifted slightly to a shorter wavelength side; the reason for this is not clear.

In general, α, β-unsaturated carbonyl compounds with a phenyl group in the β-position show the so-called K-band in a region of wavelengths longer by 40～65 mμ than those with a methyl group in the same position, as is illustrated in Table IV. Consequently, in compounds with a phenyl group such as R_1, the absorptions of XI and XII show a bathochromic shift of 46～48 mμ compared to the corresponding methyl compounds, II and III,

18) The ultraviolet apsorption spectra were measured with a Hitachi model EPS-2 recording spectrophotometer.

19) P. Grossmann, *Z. physik. Chem.*, **109**, 327 (1924). The difference between the enol form of ethyl acetoacetate (245 mμ) and ethyl β-ethoxycrotonate (232 mμ) is 13 mμ.

20) H. Schinz and M. Hinder (*Helv. Chim. Acta*, **30**, 1349 (1947)) have reported that α-oxobutyrolactones have an absorption maximum at 232 mμ (log ε 4.1); but the direct bonding of a methyl group with the chromophore group should cause a shift of about 10 mμ to the longer wavelength region and 242 mμ in II seems to be a normal value.

21) K. Hirayama, "Zikken Kagaku Kōza," I/1, Maruzen, Tokyo (1957), p. 104.

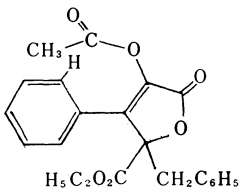
indicating that the phenyl group is in conjugation with the enol in the α-oxobutyrolactone ring. The presence of the absorption of the acetate XIII on a longer wavelength side than is to be expected is inexplicable.[22] The absorption maximum of XIV is in a normal position and is not different from that of XI.

In compounds with an *o*-nitrophenyl group, absorptions in the enol I and the enol methyl ether VIII are in a shorter wavelength region than those of the corresponding compounds with a phenyl group. In these cases, the introduction of an *o*-nitrophenyl group probably prevents the conjugation of the phenyl group with the α,β-unsaturated lactone ring and the *o*-nitrotoluene-type absorption (λ_{max} 260 mμ) of a weak intensity overlaps the absorption of II or III to show the absorption in a somewhat longer wavelength region. In the deethoxycarbonylated compound X this steric hindrance is diminished slightly and a weak conjugation appears,[25] which probably results in the presence of absorption in a longer wavelength region and with an increased intensity. Since there is no absorption absorption around 235 mμ in the acetate IX the of the *o*-nitrotoluene system alone must have appeared in a weak intensity.

Conclusion

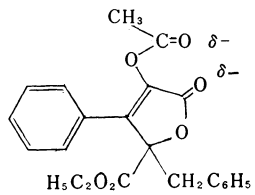
To summarize the above results, we may say that all compounds in which R_1 is methyl show absorptions in the position to be expected for an enol and its ether and ester. Compounds in which R_1 is phenyl have the lactone ring and phenyl ring in the same plane and a complete conjugation is established. The compounds in which R_1 is an *o*-nitrophenyl group, however, do not have the *o*-nitrophenyl ring and lactone ring in the same plane; they are present as separate and individual chromophores. However, a slight conjugation phenomenon is observed in X in which the ethoxycarbonyl group has been liberated.

Experimental



The α-oxo-β-methyl-γ-ethyl-γ-butyrolactones (II, IV, V, and VI) were synthesized according to the procedure reported by Monnin.[2] Compound III, a new compound, was prepared by the addition of an ether solution of diazomethane to a solution of II in methanol-ether (1 : 1 v/v); after the mixture had stood overnight, it was distilled. These were all oily substances and were confirmed through elemental analysis and a comparison of their physical constants (Table V).

The α-oxo-β-phenyl-γ-benzylbutyrolactone derivatives (XI, XII, XIV) were synthesized according to the method of Hemmerlé.[3] Compound XII was obtained by heating XI with acetic anhydride on a water bath for one hour. The melting points of these compounds are compared in Table VI.



The synthesis of α-oxo-β-(*o*-nitrophenyl)-γ-(*o*-nitrobenzyl)-butyrolactone derivatives (I, VIII, IX, X) has been reported in a previous paper.[1]

22) It appears that conformation i is impossible because of steric interference, and that conformation ii, with two oxygen atoms in close proximity, will result. Consequetly, the unshared electron pair of ether oxygen in the ester takes part in the conjugation system; this probably causes the shift of the absorption to a longer wavelength region. Such a consideration has been used by Jones and his co-workers,[23] and by others[24] in explaining infrared absorption spectra.

(i)

(ii)

In comparing the infrared absorption spectra of IV and XIII, the $\nu_{C=O}$ of XIII is found to be shifted to a little higher wave number side by the same cause.

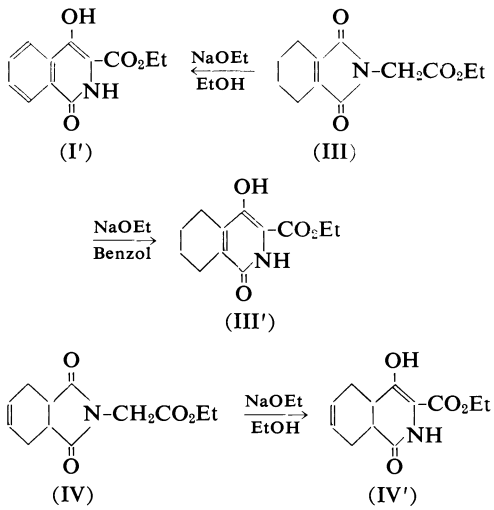
25) The conjugation phenomenon is manifested as the function of $\cos^2\theta$, where θ is the angle formed by the two rings. E. A. Braude and F. C. Nachod, "Determination of Organic Structures by Physical Methods," Academic Press, New York (1955), p. 174.

Beiträge zur Umlagerung der Cyclischen Imidoester

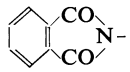


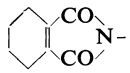
Von Tsuneyuki NAGASE

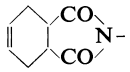
(Eingegangen am 12. Februar, 1964)

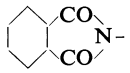
Im Laufe eines synthetischen Versuches im hiesigen Laboratorium brauchten wir 5, 6, 7, 8-Tetrahydroisochinolin-Derivate, die an der C_3-Stellung eine Nitril- order Carbalkoxyl-Gruppe tragen. Über 3-Cyano-5, 6, 7, 8-tetrahydroisochinolin (A), von dem Sempervirin abgeleitet wurde, hat schon Swan[1] geschrieben, es wurde aber über seine Darstellung nichts berichtet. Die Einwirkung von Kaliumcyanid auf 3-Chlor-5, 6, 7, 8-tetrahydroisochinolin (B) ergab kein (A) sondern 3-Carboxy-5, 6, 7, 8-tetrahydroisochinolin (C) mit nur ca. 20%iger Ausbeute.[2] Andererseits wurde nun gezeigt, dass 3-Carbäthoxyisochinolin (D) aus α-Phthalimidoessigsäureäthylester (I) durch Umlagerung nach Gabriel und Colmann[3] mittels Natriumäthylates über 3-Carbäthoxy-4-hydroxyisocarbostyril (I') ableitbar ist.[4]

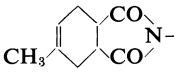
Diese Umlagerung, die nicht nur beim (I) sondern auch bei verschiedenen aromatischen *o*-Dicarboximidoderivaten, wie α-Phthalimidoketonen,[5] Chinolyl-[6] oder Cinchomeronylimidoessigsäureäthylester,[7] mit Erfolg festgestellt wurde, verlief beim α-Δ^1-Tetrahydrophthalimidoessigäthylester (III) leider nicht glatt. Beim Erhitzen von III mit Natriumäthylat in abs. Äthanol wurde kein 3-Carbäthoxy-4-hydroxy-5, 6, 7, 8-tetrahydroisocarbostyril (III'), sondern I', das Dehydrierungsprodukt von III', mit einer Ausbeute von nur 5～6% der Theorie erhalten und erst beim Erhitzen mit demselben Katalysator in Benzol wurde, III' mit ebenso geringer Ausbeute isolient. α-Δ^4-Tetrahydrophthalimidoessigsäureäthylester (IV) ergab dagegen beim Erhitzen mit demselben Katalysator in abs. Äthanol 3-Carbäthoxy-4-hydroxy-5, 8, 9, 10-tetrahydroisocarbostyril (IV') mit einer Ausbeute von 63% der Theorie.

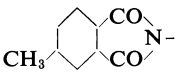


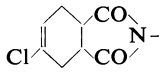


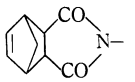


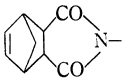


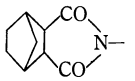


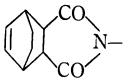


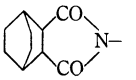












Um dieses merkwürdig verschiedene Verhalten beider Ester bei der Umlagerung, das vermutlich von sterischem und polarem Effekt beeinflusst wird, näher zu untersuchen, wurde nun die Reaktion auch bei einigen nicht aromatischen Cyclischen *o*-Dicarboximidoessigester, deren Eigenschaften in Tabelle I gezeigt werden, weiter probiert. Die Tabelle II stellt die Eigenschaften der normalen Umlagerungsprodukte samt ihren Ausbeuten dar. Die Verbindungen, bei denen keine Umlagerung stattfand, spalteten ihren Imidoring und ergaben die entsprechenden Carbonamidosäuren, deren Eigenschaften samt ihren Ausbeuten in der Tabelle III gezeigt wurden.

Diese Ergebnisse zeigen, dass die Umlagerung nicht nur bei den aromatischen und alicyclischen *o*-Dicarboximidoderivaten, sondern auch selbst beim Succinimidoessigsäureäthylester (II) erfolgt. Sehr merkwürdig ist die Tatsache,

dass die Umlagerung beim α-4-Methyl-Δ^4-tetrahydrophthalimidoessigsäureäthylester (V) nur mit einer Ausbeute von 8～10% der Theorie erfolgt, während sie beim entsprechenden Chlorderivat (VIII) oder beim gesättigten α-4-Methylhexahydrophthalimidoessigsäureäthylester (VII) mit mehr als 60%iger Ausbeute stattfand.[8] Ferner ergaben die bicyclischen *o*-Dicarboximidoessigester, deren gebrückte carbocyclische Ringe im Vergleich zum VII ziemlich gespannt sind, kein Umlagerungsprodukt, sondern die entsprechende Carbonamidosäure unter Abspaltung ihres Imidoringes.

Für den Verlauf dieser Base-katalysierten

8) Die Stellung der Substituenten in den Umlagerungsprodukten wurde noch nicht festgestellt.

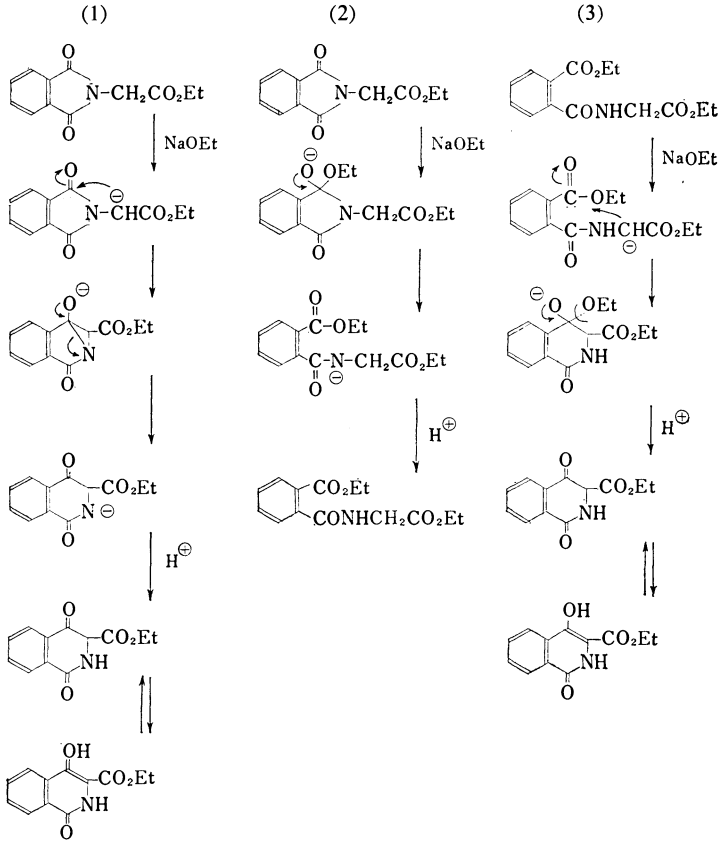
Umlagerung sind die nachfolgenden Mechanismen denkbar.



Der Mechanismus 2 wurde durch Misserfolg der Umlagerung beim *N*-Benzylphthalimid gestützt,[9] bei welchem die Reaktion, wegen der Schwierigkeit der Bildung des für den Reaktionsverlauf nach 3 nötigen Carbanions, mit der Stufe des Phthalamidoesters gehindert ist.

Die Konformation des *N*-Carbäthoxymethyl-bicyclo[2, 2, 1]hepten-(5)-2, 3-dicarboximides (IX) bzw. des entsprechenden *N*-Carbäthoxymethyl-bicyclo[2, 2, 2]octen-(5)-2, 3-dicarboximides (XII), das durch Diels-Alder-Reaktion von Cyclopentadien bzw. Cyclohexadien mit Maleinsäureanhydrid hergestellt wurde, ist sicher cis-endo-Form und der mit dem ebenen Imidoring kondensierte Cyclohexenring ist boot-förmig. Das π-Orbital der cyclischen Doppelbindung an der Stellung 5 und die Imidoring-Ebene sind fast parallel und liegen ziemlich nahe beieinander, sodass ein elektrostatischer Feldeffekt zwischen ihnen denkbar ist. Die elektrophile Aktivität der beiden Carbonyl-Kohlenstoffe im Imidoring wird vermutlich durch Feldeffekt der Doppelbindung in der Masse neutralisiert, sodass keine Umlagerung, sondern nur die Ringspaltung stattfindet. Dieses Ergebnis, sowie die Tatsache, dass XII, dessen Ringspannung im Vergleich zum

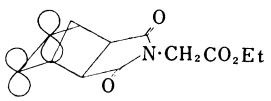
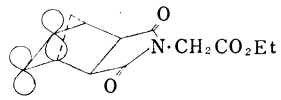
XIII′	 *cis-*	178～179	80	$C_{12}H_{17}O_5N$	56.40 56.55	6.71 6.61	5.49 5.26

IX geringer ist, ebenfalls nur das Ringspaltungsprodukt ergibt, scheint mit dem Mechanismus nach dem Sinn von 3 schwer vereinbar zu sein. Ein derartiger Feldeffekt wurde auch bei der elektrophilen Addition von 2, 4-Dinitrobenzolsulfenylchlorid auf *cis-endo-* und *cis-exo*-Bicyclo [2, 2, 1] hepten-(5)-2, 3-dicarbonsäureanhydrid[10] oder bei der Epoxydierung des 7-Diphenylmethylen-*N*-methyl-bicyclo [2, 2, 1] hepten-(5)-2, 3-dicarboximides[11] bemerkt, bei welchem die ungesättigte Eigenschaft der Kerndoppelbindung durch Feldeffekt des Anhydridringes oder Imidoringes vermindert ist.

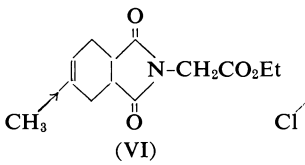


(IX)



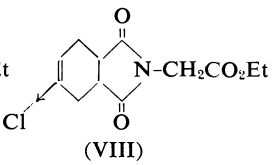
(XII)

Mit dieser Erklärung allein ist jedoch die Spaltung des Imidoringes beim *cis-exo*-Carbäthoxymethyl - bicyclo [2, 2, 1] hepten - (5)-2, 3-dicarboximid (X) schwer verständlich, bei welchem das π-Orbital und der Imidoring fast senkrecht zueinander liegen. Zu bemerken ist dabei, dass die Distanz zwischen der Ringebene und der Brückenmethylen-Gruppe im Vergleich zu IX weit kleiner geworden ist.[12] Hierbei scheint irgendein anderer Einfluss einzugereifen.



(X)

Bei der Verbindung, die ausgenommen diese Brückenmethylen-Gruppe eine ähnliche Konformation besitzt, sollte diesser Effekt noch deutlicher erscheinen. So findet beim α-Δ^4-Tetrahydrophthalimidoessigsäureäthylester (IV), welcher aus *cis*-Δ^4-Tetrahydrophthalsäureanhydrid abgeleitet wurde und dementsprechend eine cis-Form darstellt, die Umlagerung ziemlich glatt statt. Beim *cis*-Δ^4-Tetrahydrophthalsäureanhydrid ist nach Buckels[13] die von den zwei möglichen boot-förmigen Konformationen stabiler, in der der Anhydridring *quasiäquatorial* liegt. Diese Vermutung wurde durch das Ergebnis der Epoxydierung, sowie durch das Ergebnis von Imid unterstützt.[14] Die Konformation von IV entspricht daher derjenigen der Verbindung, die aus X nur durch Ausfallen der Methylenbrücke entstanden ist. Sein Imidoring ist von dem π-Orbital der Doppelbindung an der Stellung 4 weiter entfernt und liegt beinahe senkrecht dazu und ist daher von dem letzteren weniger beeinflusst, sodass die Umlagerung ziemlich glatt stattfindet.



(IV)

Beim 4-Methyl-Δ^4-derivat (VI) wird der induktive Effekt der Methylgruppe die Elektronendichte der Doppelbindung vergrössern, so dass die Umlagerung in der Masse gestört wird, während beim 4-Chlor-Δ^4-derivat (VIII), wegen des umgekehrten induktiven Effekts des Chloratoms, die Umlagerung ebenso glatt erfolgt, wie beim X sowie bei den gesättigten Derivaten (V und VII). Bei der entsprechenden Δ^1-Verbindung (III) wird die Imidocarbonylgruppe wegen der Konjugierung mit der Doppelbindung etwas deaktiviert und ferner wird die Spannung des halbsessel-förmigen Cyclohexenrings im Vergleich zur Δ^4-Verbindung grösser, so dass die Neigung zur Aromatisierung vor der Umlagerung beobachtet wird.

Imidoessigester. — Ein Mol Imid wurde durch Einwirkung von 1 Mol Kaliumäthylat in abs. Alkohol-Lösung in das Kaliumsalz übergeführt und nach dem Abdestillieren des Lösungmittels 1 Mol Monochloressigsäureäthylester zugegeben und im Ölbad auf 150～155°C 2 Stunden lang erhitzt. Nach dem Erkalten wurde das Reaktionsgemisch mit kaltem Wasser behandelt und dann mit Chloroform geschüttelt. Die Chloroform-Lösung wurde nach dem Trocknen über Natriumsulfat eingeengt und der Rückstand durch Umkristallisieren aus Äthanol oder durch Destillieren unter vermindertem Druck gereinigt.

Umlagerung der Imidoessigester. — *Umlagerung des cis-Δ^4-Tetrahydrophthalimidoessigsäureäthylester (IV).*—Zu einer Lösung von 2.1 g Natrium in 40 ccm abs. Äthanol wurden 7.11 g IV zugegeben und auf dem Wasserbad unter Rückfluss 1 Stunde lang erhitzt. Nach dem Erkalten wurde das Lösungsmittel unter vermindertem Druck abdestilliert, der Rückstand nach Zusatz einer geringen Menge Wasser mit 10%iger Salzsäure angesäuert. Die hierbei ausgeschiedenen Kristalle wurden abgesaugt und aus Äthanol umkristallisiert. 4.62 g (65%) farblose Nadeln von Schmp. 148～150°C (IV'). IR ν (KBr) : 1670 cm.$^{-1}$ UV λ_{max}^{EtOH} 294, 232 mμ. Färbte sich purpur mit Eisenchlorid-Lösung.

Einwirkung von Natriumäthylat auf N-Carbäthoxymethyl - bicyclo [2, 2, 2] octen - (5) - 2, 3 - dicarboximid (XII).—Zu einer Lösung von 0.07 g Natrium in 5 ccm abs. Äthanol wurden 0.26 g. XII zugegeben und auf dem Wasserbad 30 Min lang unter Rückfluss erhitzt. Bei analoger Aufarbeitung wie bei IV und beim Umkristallisieren des Produktes aus Äthanol-Wasser wurden 0.225 g Nadeln von Schmp. 136～137°C (XII') erhalten.

Die Umlagerungsreaktion der anderen Ester wurde wie bei IV durchgeführt.

Dehydrogenierung vom Umlagerungsprodukt (IV'). —0.1 g IV' wurde mit 0.05 g 10% iger Pd-Kohle innig gemischt und auf dem Ölbad 30 Min lang auf 170°C erhitzt. Nach dem Erkalten wurde das Reaktionsgemisch mit Äthanol extrahiert und die vom Katalysator abfiltrierte Lösung eingeengt. Die hierbei ausgeschiedenen Kristalle ergaben beim Umkristallisieren aus Äthanol 0.08 g Nadeln von Schmp. 193～194°C. Eine Mischprobe mit 3-Carbäthoxy-4-hydroxy-isocarbostyril (I') zeigte keine Schmelzpunkterniedrigung. Die IR-und UV-Spektren beider Präparate stimmten auch völlig überein.

Ich bin Herrn Professor Eiji Ochiai von diesem Institut für die Anregung zu dieser Arbeit und das ihr entgegengebrachte Interesse, und Herrn Dr. H. Tanida von der Shionogi A. G. für seine freundliche Diskussion dieser Abhandlung zu grossem Dank verpflichtet. Alle Analysen dieser Abhandlung wurden von der mikroanalytischen Abteilung dieses Institutes durchgeführt, wofür ich sehr dankbar bin.

The Thermal Decomposition of Zinc Oxide

By Tatsuya IMOTO, Yoshio HARANO and Yasuhide NISHI

(Received February 19, 1964)

In previous papers on the reduction of zinc oxide by hydrogen,[1-3] it has been suggested that the reduction is not a surface reaction, but a successive reaction consisting of the following two processes: the decomposition of zinc oxide into zinc vapor and oxygen, and the subsequent reaction of oxygen with hydrogen. Further, the former is a rate-determining step in the presence of a small amount of zinc oxide and the latter an excessive amount of it respectively.

The present work was carried out in order to obtain information of the decomposition process in the reduction and to discuss further the reduction mechanism.

As for the thermal decomposition of zinc oxide, it has been known that zinc oxide decomposes into zinc vapor and oxygen rather than subliming as zinc oxide vapor.[4,5] When Moore and Williams[6] investigated the decomposition rate in a stream of oxygen, nitrogen and zinc vapor by measuring the weight loss, they found that the rate is fastest in zinc vapor. No quantitative studies of the decomposition, however, have yet been carried out.

Experimental

The decomposition rate was determined by using a thermobalance and a McLeod gauge. The zinc oxide used in this work was the same commercial superior product supplied by the Sakai Chemicals Co., Ltd., as was used in the previous work.

Since zinc oxide is a structure-sensitive compound and since its surface state is affected by a slight variation in the pretreatment, it was necessary to fix the standard pretreating conditions as follows: after evacuating below 10^{-5} mmHg for one hour at 190°C, the reaction tube was heated to the standard temperature (740°C) within half an hour, and then the reaction system was kept at 740°C for half an hour. During the heating process, the evacuation was stopped. The pressure of the oxygen evolved in this interval was estimated to be one in the initial decomposition equilibrium. Then the system was reevacuated below 10^{-5} mmHg and the decomposition was started. In this work, 200 min. was taken as a standard decomposition time.

Results and Discussion

The relation between the initial amount (w_0) and the decomposed amount of zinc oxide after 200 min., at 740 and 780°C (Δw), is shown in Fig. 1. In Fig. 1 it can be seen that, when

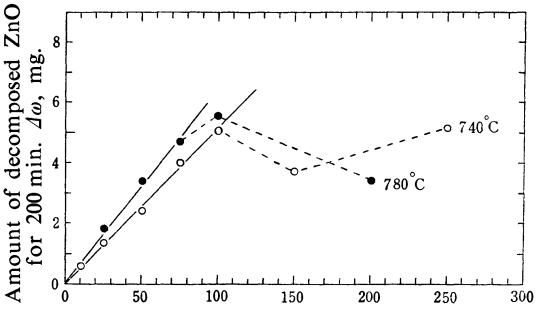

Fig. 1. The relationship between initial and decomposed amount of zinc oxide.

the amount of zinc oxide is less than 100 mg. at 740°C, the ratio ($\Delta w/w_0$) is nearly constant. On the other hand, when there is more than 100 mg. of zinc oxide, the relation deviates from linearity and the ratio is occasionally observed to be smaller than the former one. The deviation from linearity seems to take place because of the decrease in the effective surface of zinc oxide by its aggregation rather than because of the decrease in the surface of the zinc oxide lying in the lower part of the basket. Since the aggregation increases with a rise in the temperature, the deviation tends to appear in a smaller region of zinc oxide. Moreover, when pre-sintered and then crushed zinc oxide is used, the linearity appears over a wider range.

The decomposition ratios ($\Delta w/w_0$) at 740°C are plotted against the time for various initial amounts (w_0: 25, 50, 75 and 100 mg.) in Fig. 2. This figure shows that the relations between the ratio and the time are represented by an identical curve, regardless of the amount

of zinc oxide, and that in the early stages, the decomposition proceeds rapidly, but after it has proceeded for about half an hour, it proceeds at a nearly constant rate which is slower than that in the earlier part. Since the curve in Fig. 2 is nearly straight under these experimental conditions, the decomposition rate seems to be proportional to the surface area of zinc oxide.

Gray[7] investigated the sintering of zinc oxide and reported that the surface area of zinc oxide rapidly decreases in the initial half hour, but that it scarcely varies thereafter. In this work, zinc oxide was kept at a decomposition temperature for half an hour before the reaction. It is, however, still doubtful whether or not the faster decomposition stage is caused by the incompleteness of the sintering. Therefore, the following experiment was undertaken with zinc oxide which had been presintered for about two hours at the decomposition temperature in order to sinter it completely; the results obtained are shown in Fig. 3-b. From Fig. 3, it was found that the b decomposition curve has the same profile and the same slope as does the a standard curve which is identical with that in Fig. 2, and that zinc oxide also decomposes rapidly for the initial half hour. Consequently, the initial rapid decomposition seems not to be due to the variation in the surface area during the reaction.

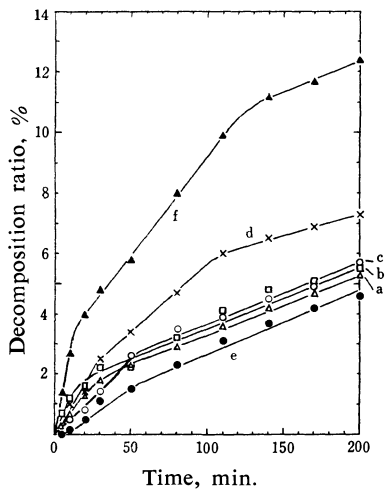

Fig. 3. Decomposition profiles of zinc oxide pretreated at various conditions (at 740°C).

▲ f H_2 treatment

The effect of the surface state on the decomposition rate is also shown in Fig. 3. Curves c and d show the results obtained with zinc oxide pretreated in vacuo. After sintering, the samples were exposed to air at a sintering temperature of 800°C, in case c, or cooled down to room temperature in vacuo and then exposed to admitted air, in case d. Sample c is fluffy and white, whereas sample d is coarse and gray. Such phenomena were also reported by Gray,[7] who found the surface pretreated as in sample d to be rich in zinc. Curve c is the same as the standard one (curve a), whereas curve d is different and has a longer stage of initial rapid reaction. Curves e and f show the results obtained with the sample pretreated in an atmosphere of oxygen (80 mmHg) or hydrogen (40 mmHg) respectively. In case e, the initial rapid decomposition does not appear, while in case f the reaction proceeds much faster than in the others.

The initial decomposition equilibrium pressures of oxygen in the standard experiments at 740°C are shown in Table I. In Table I,

TABLE I. INITIAL DECOMPOSITION PRESSURE OF OXYGEN (mmHg)

Sample mg.	Pretreatment period at 740°C	
	0.5 hr.	2.0 hr.
100	1.30×10^{-1}	1.15×10^{-1}
75	0.92×10^{-1}	1.45×10^{-1}
50	1.07×10^{-1}	1.42×10^{-1}
		1.30×10^{-1}
25	0.61×10^{-1}	0.99×10^{-1}
10	0.67×10^{-1}	

the pressure slightly fluctuates, there is, however, no difference between the samples kept at the decomposition temperature for half an hour and that kept for two hours. Assuming

7) T. J. Gray, *J. Am. Cer. Soc.*, 37, 534 (1954).

that an amount of zinc corresponding stoichiometrically to oxygen is also evolved during the pretreatment, the weight loss of zinc oxide may be calculated to be 0.07 to 0.16 mg., since the volume of the reaction vessel is 358 cc. and the volume ratio of the vessel outside and inside of the electric furnance is 1.47. If only oxygen is evolved, the weight loss would be 0.014 to 0.032 mg. From the facts that the weight loss during the above standard pretreatment was unmeasurable (less than 0.03 mg.) at 740°C and that no deposition of zinc metal on the cooler part of the reaction vessel was observed, one may say that oxygen is evolved without any accompanying evolution of zinc vapor. Therefore, the surface of the zinc oxide will be rich in zinc. Since the equilibrium decomposition pressures of oxygen in both the a and b cases were identical (cf. Table I), their surface states may also be considered to be the same. Therefore, the a and b decomposition curves (in Fig. 3) may be almost identical. On the other hand, when zinc oxide is pretreated in an atmosphere of oxygen at a higher pressure than the equilibrium pressure, no evolution of oxygen takes place, and hence, no initial rapid decomposition is observed.

As a result, it may be suggested that the fewer oxygen atoms relative to zinc atoms are involved on the surface of zinc oxide, the faster the initial reaction proceeds and the longer its rapid stage becomes. Consequently, the rate of the decomposition of zinc oxide treated by hydrogen will be very fast, since the surface has a marked deficiency of oxygen. Oxygen on the surface of the zinc oxide pretreated in vacuo will be quite scarce. On the other hand, when zinc oxide pretreated in vacuo is exposed to air at a high temperature, relatively many zinc atoms on its surface will be reoxydized and the surface will return to the original state.

Further, when the surface affected by the pretreatments has disappeared as decomposition proceeds, each sample will decompose at the same rate, regardless of the various pretreatments. Figure 3 also indicates the above suggestion.

As has been mentioned above, the pretreatment causes the surface state of zinc oxide to deviate from its stoichiometry and accelerates its initial decomposition rate. Now let us cmpare the extent of the deviation from stoichiometry with the amount of decomposition acceleration. Extraporating the linear parts of the a and b curves in Fig. 3, an intersection with the ordinate of 1.5%, is obtained. That is, the evolution of oxygen in a and b accelerates the decomposition by 1.5%. The amounts of zinc oxide which result in the non-stoichiometric state upon the evolution of oxygen, are calculated to be 0.08 to 0.02% of the initial zinc oxide, 25 to 100 mg. (assuming the non-stoichiometric substance to be zinc), and 0.16 to 0.04% (assuming, Zn_2O*1) ; hence these values are too small to explain the value of 1.5%.

Consequently, the accelerated decomposition will be caused not only by the non-stoichiometric substance, but also by the lattice defect

○ Standard ● H_2 treated

resulting from the lack of oxygen.

The results at various temperatures obtained with zinc oxide pretreated under standard conditions and by hydrogen are shown in Figs. 4 and 5. From Figs. 4 and 5, the initial reaction rates,*2 which are thought to be dependent upon the pretreatments, shown in Table II are obtained. Figure 6 shows the Arrhenius plots, from which the activation energies have been found to be 9.7 and 16.6 kcal./mol. The latter value, 16.6 kcal./mol., is in good agreement with the 17.0 kcal./mol. value obtained in the previous studies[2] of the rate of the reduction of zinc oxide by hydrogen controlled by the decomposition process of zinc oxide.

Considerations Upon the Rate of Oxygen Evolution.—After the decomposition had proceeded into the linear stage, as is shown in Fig. 2, the evacuation from the reaction system was stopped and the amount of oxygen which had accumulated in the system was measured. Figure 7 shows the typical curves of the accumulating rate of oxygen. Assuming that the rate of the oxygen evolution is proportional to the

*2 The slopes of the lines in the initial reaction stage in Figs. 4 and 5 represent the initial reaction rate.

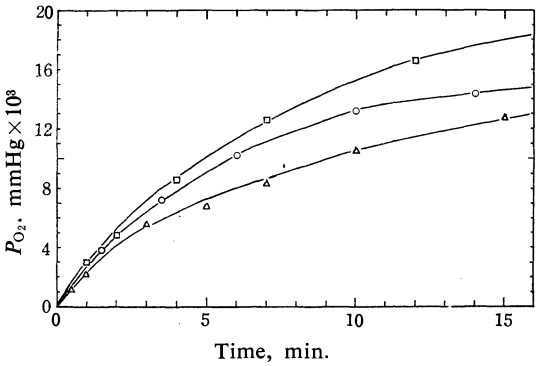

Fig. 7. Typical curves of accumulating rate of oxygen.
△ 100 mg. $P_e=13.8\times10^{-3}$ mmHg

○ 10 mg. $P_e=16.1\times10^{-3}$ mmHg

pressure difference of oxygen between that at the decomposition equilibrium, P_e, and that at time t, P_{O_2}, the rate equation may be given by Eq. 1:

$$\frac{dP_{O_2}}{dt}=k_0(P_e-P_{O_2}) \qquad (1)$$

Integrating Eq. 1,

$$-\log\frac{P_e-P_{O_2}}{P_e}=k_0't \qquad (2)$$

In Fig. 8, the $\log(P_e-P_{O_2})/P_e$ obtained from Fig. 7 is plotted against the time. Figure 8 shows that every datum gives good straight lines and that Eqs. 1 and 2, based on the above assumption, are satisfied.

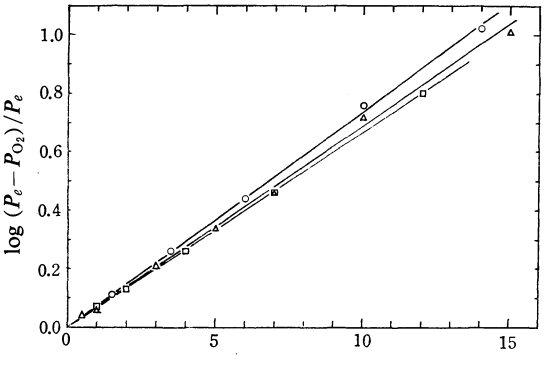

Fig. 8. $-\log(P_e-P_{O_2})/P_e$ vs. t.
△ 100 mg. □ 30 mg. ○ 10 mg.

The amount of zinc oxide is plotted against k_0' in Fig. 9, where the k_0' value is independent of the initial amounts of the zinc oxide, provided that zinc oxide is present in a larger amount. Consequently, in this region, the diffusion process of oxygen from the surface of

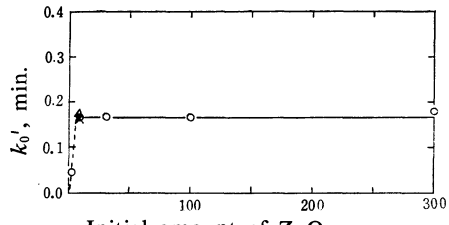

Fig. 9. The relationship between k_0' and the amount of zinc oxide.
○ 700°C × 740°C △ 780°C

zinc oxide into the ambient gas is considered to be the rate-controlling step in the overall decomposition. On the contrary, at smaller amounts of zinc oxide, the decomposition rate is found to be proportional to the amount of zinc oxide; hence, the rate of the overall reaction is controlled by the decomposition process.

From the initial decomposition rate (3.2×10^{-3} mmHg/min.) at $t=0$, $w_0=10$ mg. in Fig. 7, the rate of the weight loss is calculated to be 0.033 mg./hr. if only oxygen is evolved, and 0.17 mg./hr. if both oxygen and zinc are stoichiometrically evolved. When the above values are compared with the experimental value, 0.12 mg./hr., obtained from the slope in Fig. 2 (where w_0 is assumed to be 10 mg.), it may be concluded that the evolution of oxygen is predominant over the vaporization of zinc and that zinc oxide grows richer in zinc as the decomposition proceeds.

A Comparison of the Rate Constants of the Decomposition with the Reduction by Hydrogen. —As has been mentioned above the activation energy of the decomposition of zinc oxide is found to be in good agreement with that of the reduction by hydrogen controlled by the decomposition process. In this section, in order to discuss further the relations between these two reactions, their rate constants will be compared. The following two results, obtained at nearly the same temperature, are chosen for the comparison: at 738°C, $k_2'=0.158$ cmHg$^{1/3}\cdot$min^{-1}, sample 40 mg., from Ref. 2., and at 740°C, $k=0.00274$ min^{-1}, from Table II in this paper. The rate constant, k_2', of the reduction of zinc oxide was obtained according to Eq. 3, which had been deduced from the assumption that the reduction rate is proportional to the surface area of zinc oxide:

$$(P_0-P_\infty)^{1/3}-(P-P_\infty)^{1/3}=k_2'(t-t_0) \qquad (3)$$

where

$$k_2'=k_1\left(\frac{\pi n}{3a}\right)^{1/3}\left(\frac{2}{\rho}\right)^{2/3} \qquad (4)$$

$$a=\frac{(P-P_\infty)}{w} \qquad (5)$$

where k_1 is the reduction rate per unit surface area in a unit of time, g./cc. min., n is the number of zinc oxide particles, w and ρ are the mass and density of zinc oxide respectively, and P_0 and P_∞ are the hydrogen pressures when the reduction starts to obey Eq. 3 and the zinc oxide is completely used up respectively (shown in Fig. 10). In this work, the characteristic value, a, defined by Eq. 5 equals 0.00947 g./(cmHg of hydrogen) at 738°C.

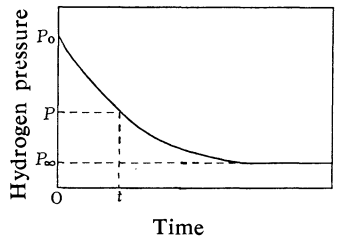

Fig. 10. The typical curve of the reduction of zinc oxide by hydrogen, which proceeds according to Eq. 3.

Since the amounts of zinc oxide is 40 mg. and since its specific surface area is 10 m^2/g.,*3 n is calculated to be 1.2×10^{13}. Therefore, from Eqs. 4 and 5, k_1 is given by Eq. 6:

$$k_1=k_2'\left(\frac{3a}{n\pi}\right)^{1/3}\left(\frac{\rho}{2}\right)^{2/3}$$
$$=2.85\times10^{-6}\ \text{g./cm}^2\cdot\text{min.} \qquad (6)$$

On the other hand, in this decomposition of the pellet-type zinc oxide, the decomposed amounts in 200 min. at 780°C, Δw, were 0.6 and 0.8 mg. for the samples with the surface areas of 4.41 and 4.39 cm^2 respectively, and, hence, 0.7 mg. for 4.40 cm^2 on the average. From Fig. 1, the decomposed amount, Δw, of 0.7 mg. will be found to correspond to the initial amount w_0 (10 mg.) of zinc oxide powder. Therefore, the effective specific surface area for the decomposition of zinc oxide powder is 4.40 cm^2/10 mg.$=$440 cm^2/g.*3 Consequently, the decomposition rate per unit of surface area in this work is 0.00274 min^{-1}/440 (cm^2/g.) $=6.23\times10^{-6}$ g./cm$^2\cdot$min. Considering the experimental errors and the requirement of some assumptions for the comparison, the above value, 2.85×10^{-6} g./cm$^2\cdot$min., may be regarded to be in good agreement with the experimental value, 6.23×10^{-6} g./cm$^2\cdot$min.

A Discussion of the Reverse Reaction. —During the course of the investigation of the

*3 There is the marked difference in the specific surface area of zinc oxide between the two samples, the one used in the decomposition, and the other in the reduction. This may be caused by the difference in particle diameter. The former contains about 30 wt.% which is larger than 250μ in particle diameter whereas in the latter only 0.03% are larger than 44 μ.[1] The electron-microscope study also shows the above fact.

TABLE III. THE WEIGHT LOSS OF ZINC OXIDE AND PRESSURE CHANGE OF HYDROGEN DURING HYDROGEN PRETREATMENT

88	780	29.1	59.66	32.2	25.8

reduction of zinc oxide by hydrogen,[1-3] a deposit consisting of zinc oxide and zinc metal was observed on the cooler part of the reaction vessel. The following three reasons for zinc oxide film may be suggested.

1) The sublimed zinc oxide condenses on the cooler part of the vessel before it is reduced by hydrogen.

2) Zinc oxide decomposes into zinc vapor and oxygen, and then the reverse reaction takes place to produce the zinc oxide.

3) Zinc oxide is produced by the reaction of zinc vapor and gaseous water.

In this study of the decomposition, the zinc oxide film was not produced on the cooler part of the reduction tube. Therefore, reasons 1 and 2 above have been found to be invalid. Reason 3 was also supported by the additional observation that hydrogen, which is produced by the reaction*4 of water and zinc, will contribute to the reduction of zinc oxide again. Table III shows the weight loss by the pretreatment of zinc oxide placed in the basket, the initial hydrogen pressure for the pretreatment, and the hydrogen pressure cooresponding to the weight loss (each value being converted at 0°C). In all the runs (except No. 79 and 80 in Table III), the hydrogen pressure corresponding to the weight loss caused by the reduction of hydrogen*6 is found to be higher than the initial hydrogen pressure. Consequently, the hydrogen reproduced by reason 3 is suggested to reduce further the zinc oxide placed in the basket.

*4 Since the equilibrium constant K of the reaction: $ZnO(s)+H_2 \rightleftarrows Zn(g)+H_2O(g)$ is very small*5, the vapor pressure of wate is very low. Consequently, the reduction rate can be followed by measuring the pressure in the system as reported in Ref. 1.

*5 $K=1.1\times10^{-3}$, $P_{H_2O}=0.85$ mmHg at 1 atm. H_2, 723°C
$K=2.4\times10^{-3}$, $P_{H_2O}=1.85$ mmHg at 1 atm. H_2, 823°C
from G. B. Taylor and H. W. Starkweather, *J. Am. Chem. Soc.*, 52, 2314 (1930).

*6 In this case, the decomposed amount of zinc oxide is much less than the amount of zinc oxide reduced by hydrogen.

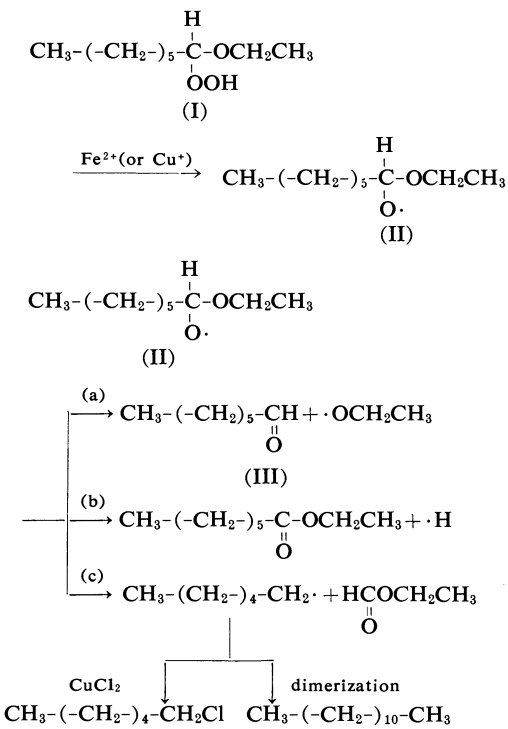
*The Redox Reaction of 1-Ethoxy-n-heptyl Hydroperoxide**

By Shinji MURAI, Noboru SONODA and Shigeru TSUTSUMI

(Received February 27, 1964)

In our previous study of the redox reaction of an ether-hydroperoxide,[1] we reported that hexane-1, 6-diol diformate and γ-butyrolactone are produced by the redox reaction of tetrahydrofuran hydroperoxide (a heterocyclic ether hydroperoxide) with ferrous sulfate, and that, in the case of the reaction with cuprous and cupric chlorides, 3-formoxypropyl chloride and γ-butyrolactone are produced. We then suggested that these products might be formed by carbon-carbon bond fission and carbon-hydrogen bond fission at the α-position of the 2-tetrahydrofuranoxy radical generated as an intermediate. The corresponding carbon-oxygen bond fission might lead to the formation of *a carbonyl product*, 4-hydroxybutanal, which was obtained in a trace amount. Now it has become desirable to investigate the redox reaction of the hydroperoxide of a linear ether; therefore, the redox decomposition of 1-ethoxy-*n*-heptyl hydroperoxide (I) has been carried out in order to clarify the nature of these reactions.

Results and Discussion



Analytically pure 1-ethoxy-*n*-heptyl hydroperoxide (I) was prepared by the ozonolysis of octene-1 in ethanol. The decomposition reaction of the hydroperoxide (I) was carried out using some metal ions such as ferrous or cuprous ions. When the hydroperoxide I was decomposed in the presence of ferrous sulfate at 7~9°C, ethyl formate, *n*-heptanal, ethyl heptanoate and *n*-dodecane were obtained; they might be formed through the fragmentation of the 1-ethoxy-*n*-heptoxy radical (II) produced by the reductive cleavage of the hydroperoxide I with ferrous ions. In the presence of cupric and cuprous chlorides, the decomposition of I gave ethyl formate, *n*-hexyl chloride, *n*-heptanal and ethyl heptanoate, whereas the formation of *n*-dodecane was not observed because of the chlorination of the *n*-hexyl radical with the cupric chloride used as an alkyl radical scavenger. The *n*-heptanal (III) obtained in both reactions is *the carbonyl product* corresponding to the product which might be given by the carbon-oxygen bond fission of the radical II. However, the mechanism of the carbonyl-product formation is more complicated, as will be discussed later. The results are summarized in Table I.

TABLE I. DECOMPOSITION PRODUCTS OF 1-ETHOXY-*n*-HEPTYL HYDROPEROXIDE

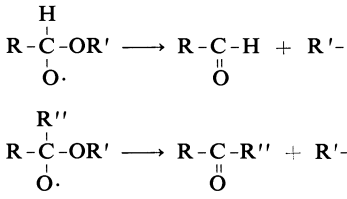
n-Hexyl chloride	—	20
n-Heptanal	38	26
Ethyl heptanoate	27	26
n-Dodecane	18	0

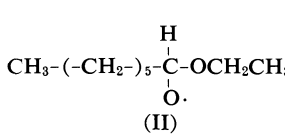
a) see Experimental section.

In these reactions, the initial step may be the reductive cleavage of the hydroperoxide I to yield the radical II, which would then react according to the following scheme:



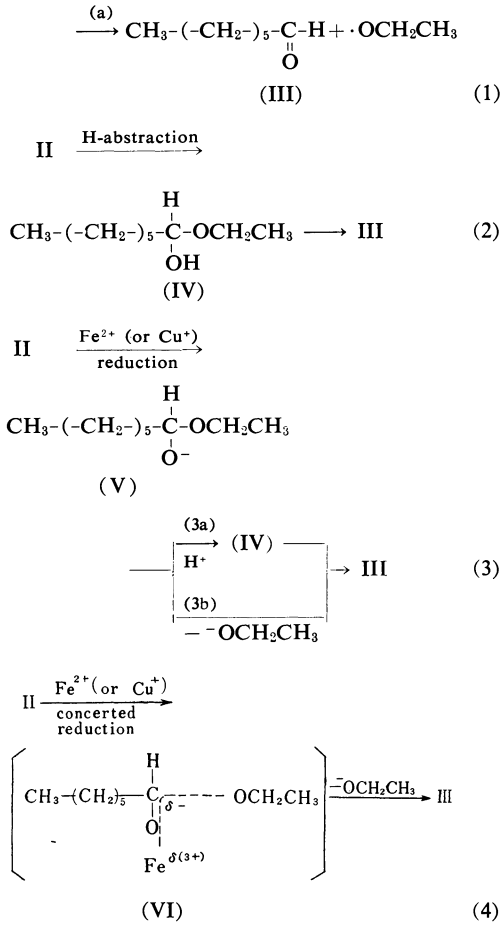
* Presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

1) S. Murai, N. Sonoda and S. Tsutsumi, This Bulletin, 36, 527 (1963).



In these reactions, path a comprises the homolytic cleavage of the carbon-oxygen bond, while paths b and c also comprise the fission of the carbon-hydrogen bond and of the carbon-carbon bond of the radical II respectively. The *n*-hexyl radical produced in path c would dimerize to produce *n*-dodecane and also would give *n*-hexyl chloride in the presence of cupric chloride used as an alkyl radical scavenger.

Little attention has been paid to the formation of carbonyl products, aldehydes or ketones in the redox decomposition of the ether-hydroperoxides.



In some cases the hydroperoxides were prepared from carbonyl compounds or ethers and were subjected to reaction without isolation; thus, it was more difficult to clarify the formation of carbonyl products in the redox reaction, and in other cases no effort was made to detect them.[2] Sharp and Patrick reported the formation of aldehydes in a small amount in the ferrous ion-catalyzed decomposition of ether-hydroperoxides.[3] However, the hydroperoxides were not reacted in isolation and were reacted at a rather high temperature, which would induce thermal decomposition. Milas et al. suggested[4] the possible formation of 2-hydroxytetrahydropyran[5] in the ferrous ion-catalyzed decomposition of 2-hydroperoxytetrahydropyran, but the formation of this compound was not reported in a recent investigation of this same system.[6]

In contrast with these results, a rather large amount of a carbonyl compound, *n*-heptanal, was obtained in the present experiment. Some possible reaction pathways for the formation of *n*-heptanal (III) are:

(II)

(III) (1)

(IV) (2)

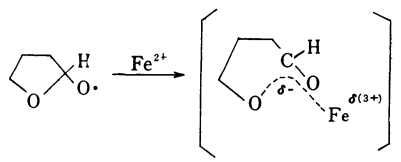
(V) (3)

(VI) (4)

It may be assumed that the pathway shown by Eq. 4 is the most plausible from the following consideration; since the transition state for the homolytic cleavage of an alkoxy radical involves the stretching of the breaking bond, the free energy of the activation for the cleavage would be expected to be raised as the stability of the leaving radical is decreased. Therefore, the homolytic cleavage of the carbon-oxygen bond, Eq. 1, would be unable to compete with the carbon-carbon bond cleavage (step c) or the carbon-hydrogen bond cleavage (step b) because of the relative instability of the leaving ethoxy radical. Furthermore, as to Eq. 2, there may exist a few hydrogen donors for H-abstraction except the hydroperoxide itself and its decomposition products, which may be insufficient in amount to serve efficiently. Equation 3 shows the reduction of the alkoxy radical II to the corresponding anion V, followed by the protonation 3a or by the leaving of the ethoxide ion 3b. Such a reduction of an alkoxy radical with reducing metal ions has been reported by Kochi.[7]

2) For example, a) J. K. Kochi and F. F. Rust, *J. Am. Chem. Soc.*, **84**, 3946 (1962); b) R. V. Digman and D. F. Anderson, *J. Org. Chem.*, **28**, 239 (1963).

3) D. B. Sharp and T. M. Patrick, Jr., *J. Org. Chem.*, **26**, 1389 (1961).



4) N. A. Milas, R. L. Peeler, Jr., and O. L. Mageli, *J. Am. Chem. Soc.*, **76**, 2322 (1954).

5) This compound is in equilibrium with 5-hydroxypentanal and corresponds to the carbonyl product.

6) E. A. Youngman, F. F. Rust, G. M. Coppinger and H. E. De La Mare, *J. Org. Chem.*, **28**, 144 (1963).

7) J. K. Kochi, *J. Am. Chem. Soc.*, **84**, 1193 (1962).

Equation 3, however, cannot explain the different results that, in the present reaction of the hydroperoxide of the linear ether, a carbonyl product was obtained in a better yield than in the case of the cyclic ether system reported on previously.[1] This result may be explained most reasonably in terms of the concerted reduction, Eq. 4, in which the partial breaking of the carbon-oxygen bond might be more sterically favorable in the transition state VI than in a cyclic ether system VIII.

(VIII)

⟶ 4-Hydroxybutanol

Because of the reasons described above, it seems reasonable to assume that *n*-heptanal is produced by the reduction of radical II with ferrous or cuprous ions, followed concertedly by the leaving of the ethoxide ion, which may be a suitable leaving anion.

There assumptions are also supported by the fact that cyclohexanone was generated as a carbonyl product in the redox reaction of 1-ethoxycyclohexyl hydroperoxide under the same conditions as is described above.[8]

Experimental

1-Ethoxy-*n*-heptyl Hydroperoxide (I). — Eighteen grams of 1-octene was dissolved in 350 ml. of ethanol, and a stream of ozone containing oxygen was passed at −70°C until the completion of the reaction was indicated by the liberation of iodine in an aqueous solution of potassium iodide at the gas outlet. The solvent and the cleavaged fragment were removed under reduced pressure at room temperature, and then further removed in vacuo (0.5 mmHg) at room temperature for three hours. The residual colorless oil (26 g.) showed infrared absorptions at 3400 cm^{-1} (-OH) and 1100 cm^{-1} (C-O-C) and reacted positively to a lead tetraacetate test. The amount of active oxygen was determined by iodometry to be 9.27% (Calcd. for $C_9H_{20}O_3$: 9.08%). Molecular weight (in benzene) 180 (Calcd. for $C_9H_{20}O_3$: 176.3%).

The Reaction of 1-Ethoxy-*n*-heptyl Hydroperoxide (I) with Ferrous Sulfate.—Into a solution of 15.0 g. of ferrous sulfate heptahydrate in 70 ml. of water 8.0 g. of the hydroperoxide I was vigorously stirred, drop by drop, over a period of 20 min. at 7~9°C. The stirring was then continued for a further three hours at a room temperature. From the reaction mixture a low boiling material was distilled out directly, at room temperature and at 10 mmHg, in to a trap cooled at −70°C.

After the removal of water from this trap by a separatory funnel, 1.1 g. of ethyl formate was obtained. By gas chromatographic analysis this fraction was shown to contain a small amount of *n*-hexane and hexene-1, but no effort was made to make a quantitative determination of these compounds.

The reaction mixture, after the removal of the low boiling material, was extracted with five 100 ml. portions of ether. The ether extract was dried over anhydrous magnesium sulfate. The evaporation of the ether gave 6.0 g. of products which were estimated by gas chromatography to contain 2.2 g. of *n*-heptanal, 2.3 g. of ethyl heptanoate and 1.5 g. of *n*-dodecane; column, Silicon DC-550 and PEG 6000; column temperature, 130°C; carrier gas, H_2. The 2, 4-dinitrophenylhydrazone of *n*-heptanal was prepared by treating the above-mentioned reaction mixture with a hydrochloric acid solution of 2, 4-dinitrophenylhydrazine; its melting point and mixed melting point with an authentic sample were each 108~109°C.

The Reaction of 1-Ethoxy-*n*-heptyl Hydroperoxide (I) with Cuprous Chloride and Cupric Chloride.—Into a suspension of 5.0 g. of cuprous chloride and 8.8 g. of cupric chloride dihydrate in 100 ml. of water 8.0 g. of the hydroperoxide I was vigorously stirred, drop by drop, over a period of 30 min. at 5~7°C. The stirring was then continued for a further three hours. The reaction mixture was treated in the manner mentioned above. From the low boiling product, 0.7 g. of ethyl formate, and from the ether extract, 1.0 g. of *n*-hexyl chloride, 1.5 g. of *n*-heptanal and 2.1 g. of ethyl heptanoate were obtained, although no formation of *n*-dodecane was observed by gas chromatographic analysis.

Summary

1) The reaction of 1-ethoxy-*n*-heptyl hydroperoxide with ferrous sulfate has given ethyl formate, *n*-heptanal, ethyl heptanoate and *n*-dodecane, while the reaction with a mixture of cuprous and cupric chlorides has given ethyl formate, *n*-hexyl chloride, *n*-heptanal and ethyl heptanoate.

2) The formation of *n*-heptanal in both reactions has been attributed to the reduction of the 1-ethoxy-*n*-heptanoxy radical with ferrous or cuprous ions to the corresponding anion, followed concertedly by the leaving of the ethoxide ion.

3) The probable reaction pathway, especially the difference between the natures of the heterocyclic ether syetem and the linear ether system, has been discussed.

Studies of the Organic Reaction of Metal Carbonyl. V. The Reaction of Cobalt Hydrocarbonyl with Olefin—The Effects of the Reaction Conditions and of the Structure of Olefin

By Yoshinobu TAKEGAMI, Chikao YOKOKAWA, Yoshihisa WATANABE, Hiromitsu MASADA and Yasukazu OKUDA

(Received February 27, 1964)

In connection with the oxo reaction, several studies[1-4] of the reaction of cobalt hydrocarbonyl with olefin have been published. It have been established[3,4] that 1-olefin gives two isomeric acylcobalt carbonyls and aldehydes in this reaction. Heck and Breslow[3] have suggested that the direction of the addition of cobalt hydrocarbonyl to some olefins, such as methyl acrylate and isobutylene, at 0°C is essentially the reverse of that of hydroformylation reaction at 120°C. It has thus seemed of considerable interest to study the reaction in greater detail. Previous work[5] in this laboratory has shown that some alkyl- and acylcobalt carbonyls isomerize readily. It is, accordingly, considered that the distribution of two isomeric acylcobalt carbonyls is affected by the isomerization as well as by the direction of the addition.

In the present paper, this type of reaction has been investigated by examing the effect of the reaction conditions and the structure of olefin, mainly on the nature of the reaction and on the distribution of the products.

Experimental

The Reaction Procedures.—The reactions under one atmosphere of carbon monoxide or nitrogen were carried out in the way described in previous papers,[5,6] using 50 ml. of a 0.09 M cobalt hydrocarbonyl solution in toluene. The reactions under two atmospheres of carbon monoxide were carried out using a 200 ml. glass autoclave.

The Analytical Procedures.—The solution of crude products was treated with iodine and alcohol as described previously,[5,6] and the excess of iodine was reduced with crystalline sodium thiosulfate. After concentration, the analyses of the reaction products were carried out by gas chromatography and by means of the infrared spectra, which were measured on a Shimadzu model IR-27 spectrophotometer.

The Materials.—Ethyl acrylate, styrene, *n*-butyl vinyl ether and pentene-1 were commercial products, all of which had been proved to be sufficiently pure by gas chromatography.

Results and Discussion

The Reaction of Ethyl Acrylate.—The results of the reaction of ethyl acrylate, which were carried out under one atmosphere of carbon monoxide or nitrogen at various temperatures, are summarized in Table I and Fig. 1.

The gas absorption curves in Fig. 1 indicate that the amount of gas absorbed increased with a decrease in the reaction temperature, though the rate of the gas absorption decreased; for instance, at −15°C, 0.6 mol.*1 of the gas was absorbed in 4 hr.; then the gas absorption ceased, but at 25°C about 0.4 mol. of the gas was absorbed in half an hour.

The reaction temperature had a significant effect on the distribution of the products; at

*2 B: a ester with the branched structure, diethyl methylmalonate.
S: a ester with the straight structure, diethyl succinate.
*3 At first under nitrogen atmosphere and then under carbon monoxide.

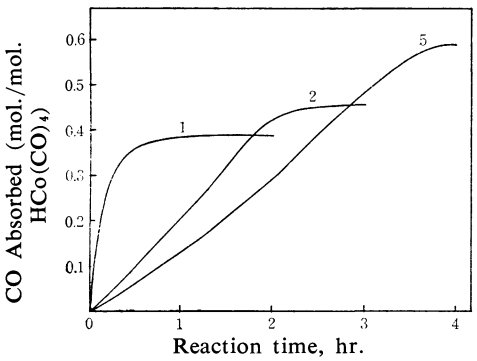

Fig. 1. CO Absorption vs. time plots for the reaction of ethyl acrylate at various temperatures.
Number corresponds with Exp. No. in Table I.
Curve 1; at 25°C, curve 2; at 0°C and curve 5; at −15°C.

25°C, diethyl succinate*2 was the major product, and only a trace of diethyl methylmalonate*3 was also identified (Exp. 1). On the other hand, at 0～−20°C, diethyl methylmalonate was the major product, and only a small amount of diethyl succinate was formed (Exp. 2—6). These facts, it would seem, can be interpreted by the following assumption; at a relatively low temperature, some effect of the ester group (-COOEt) on the adjacent carbon atom is more important, and then α-carbon atom is selectively carbonylated to form the acylcobalt carbonyl with the branched structure. However, at 25°C the steric effect is more important, and then a more stable acylcobalt carbonyl with a straight chain structure is formed.

At 0 and −10°C, the quantity of diethyl methylmalonate formed was more than that expected from the amount of the gas absorbed. It would seem that this fact can be explained by the following equilibrium:

$$\begin{array}{l} \text{C–C–COOEt} \\ \quad\vert \\ \text{COCo(CO)}_3 \end{array} + \text{CO} \rightleftarrows \begin{array}{l} \text{C–C–COOEt} \\ \quad\vert \\ \text{COCo(CO)}_4 \end{array}$$

At nitrogen atmosphere also had a significant effect on the distribution of the products, as was demonstrated by Exps. 7 and 8; even at 0 and −10°C, diethyl succinate was the major product, and a relatively large amount of diethyl methylmalonate was also formed, though the yield of the esters was not good. Under a nitrogen atmosphere, however, the color of the reaction solution changed much more readily than under carbon monoxide from yellow to brown; it took less than five minutes, even at −10°C. The reaction was carried out in two stages at 0°C, at first under a nitrogen atmosphere for 20 min. and then under a carbon monoxide. At the second stages, only 0.09 mol. of the gas was absorbed, and the yield of the esters was comparable to that under nitrogen (cf. Exps. 7 and 9). This fact seemed to indicate that under nitrogen, side reactions other than the formation of the acylcobalt carbonyl occurred rapidly to consume a large part of cobalt hydrocarbonyl used. Such a effect of a nitrogen atmosphere has been also observed in the reaction of olefin oxide with cobalt hydrocarbonyl.[6]

Heck and Breslow[3] have suggested that a nitrogen atmosphere promotes the carbonylation of olefin and that the inhibitory effect of a carbon monoxide atmosphere may be explained by the following equilibrium:

*2,*3 Believed to have been derived from the corresponding acylcobalt carbonyls by cleavage with iodine and ethyl alcohol. Identified by gas chromatography and infrared spectrum using authentic samples.

that is, cobalt hydrotricarbonyl is more reactive.

In regard to this assumption, the reactions were carried out under two atmospheres of carbon monoxide to examine the effect of the pressure of carbon monoxide on the reaction. The resuluts are summarized in Table II. Under these conditions, the reaction seemed to occur relatively more smoothly because a larger amount of the gas was absorbed than under one atmosphere of carbon monoxide (cf. Exp. 11 and 13*4), suggesting that higher pressures of carbon monoxide are more advantageous fos this reaction, the formation of the acylcobalt carbonyls. This observation is not interpreted by Heck and Breslow's assumption. The reaction temperature, under these conditions, had almost the same effect on the distribution of the products as under one atmosphere of carbon monoxide.

In order to examine the effect of the atmosphere in greater detail, pentene-1 and methyl iodide were submitted to reactions with cobalt hydrocarbonyl and potassium cobalt tetracarbonyl respectively. The results are summarized in Table III.

Pentene-1 is evidently less reactive than ethyl acrylate (cf. Fig. 4). In this case, the reaction temperature (25～10°C) had no effect on the distribution of the products; ethyl *n*-caproate was the major product, and ethyl α-methylvalerate was the minor (Exps. 14—17). Under a nitrogen atmosphere at 0°C, only 0.03 mol

of the ester, mainly ethyl α-methylvalerate, was identified independently of the reaction time from 5 min. to 13 hr. (Exps. 18—21); C_6-aldehyde seemed not to be formed its 2,4-dinitrophenylhydrazone was not obtained.

The reaction was carried out in two stages, as has been mentioned above: at the second stage under carbon monoxide, a small amount of the gas was absorbed (Exps. 22 and 23), and the amount of gas evolved by the treatment with an excess of iodine after the reaction was comparable to that calculated for the cobalt hydrocarbonyl used. However, the reaction of methyl iodide with potassium cobalt tetracarbonyl was not affected evidently by the pre-treatment with a nitrogen atmosphere (Exps. 25—27). Therefore, in the reaction of pentene-1 under nitrogen, a large part of the cobalt hydrocarbonyl used seemed to be consumed in less than 5 min. by side reaction other than the carbonylation. It may, accordingly, be concluded that a carbon monoxide atmosphere is advantageous for the carbonylation of olefin.

The Isomerization of Acylcobalt Carbonyl.— As has been described above, the reaction temperature and atmosphere have a significant effect on the distribution of the products from ethyl acrylate. In regard to this fact, several reactions were carried out in two or three stages by changing the reaction temperature (from 25°C to −10°C or from −10°C to 25°C, etc.) and by changing the reaction atmosphere in the course of an individual run.

By the change of the reaction temperature from 25°C to −10°C, the distribution of the products was not affected, as in Exps. 28 and 1. However, by the change from −10°C to 25°C or 15°C, the distribution was remarkably affected (cf. Exp. 4); at the first stage, at −10°C, about 0.6 mol. of the gas was absorbed in about 200 min. and the gas absorption ceased, but at the second stage, at 25°C, about 0.4 mol. more of the gas was absorbed in about 60 min. (curve 29 in Fig. 2) and then diethyl succinate was obtained as the major product (Exp. 29). This fact indicates that the acyl-cobalt carbonyl (or/and the alkyl-) with the branched structure isomerized to that with the

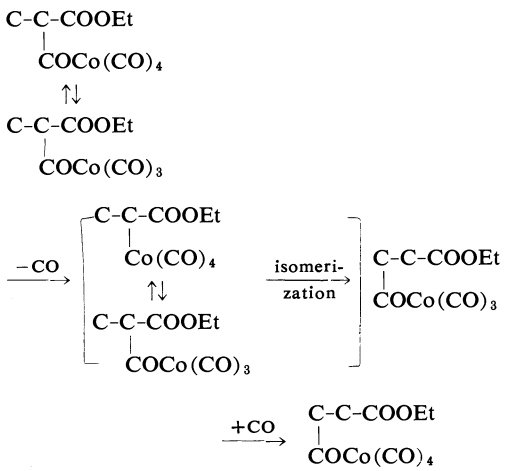
Curve 32; at first at −10°C and then at 15°C.

straight one in this treatment; this may be represented as follows:



that is, the gas absorption at the second stage seemed to be due to the acylcobalt tricarbonyl with the straight-chain structure formed by the isomerization. The reverse isomerization, from the acylcobalt carbonyl with the straight-chain structure to that with the branched one, occurs only with difficulty, it seems.

When the reaction temperature at the second stage was set at 15°C, the gas evolution occurred first, followed by the gas absorption (curve 32 in Fig. 2). In this case diethyl succinate predominated in the product, but a relatively large amount of diethyl methylmalonate was also formed (Exp. 32); at 15°C, the isomerization also occurred, but more slowly than at 25°C. The gas evolution seemed to be due to the following change, as has been reported previously:[5]

Thus, it seems that the overall reaction scheme may be represented as follows:

that is, the carbon monoxide-lacking state, such as in the alkylcobalt tetracarbonyl and the acylcobalt tricarbonyl, seemed to undergo isomerization.

Even at 25°C, when the reaction was carried out only for 10 min., the proportion of diethyl methylmalonate formed was larger than that formed in the reaction which was carried out for 2 hr. (Exps. 34 and 1), suggesting that, at 25°C, the acylcobalt carbonyl with the branched structure is formed at first and that it then isomerizes rapidly to that with the straight structure. Thus, at an elevated temperature this type of isomerization is considered to occur more easily. The distribution of the products obtained in the oxo condition seems to be considerably affected by the isomerization as well as by the direction of the addition of cobalt hydrocarbonyl to a C=C bond.

Under two atmospheres of carbon monoxide, the same isomerization occurred with the change in the reaction temperature from 0°C to 25°C, but more slowly than under one atmosphere of carbon monoxide (cf. Exps. 33 and 29). The fact that a relatively high pressure of carbon monoxide is unfavorable for the isomerization seemed to support the above mechanism.

Even at 0°C under one atmosphere of carbon monoxide, this isomerization occurred very slowly; after 15 hr. the amount of diethyl succinate was almost comparable to that of diethyl methylmalonate (Exp. 36). On the other hand, under nitrogen this isomerization occurred more rapidly than under carbon monoxide; at 0°C, when the reaction was carried out for only 10 min., mainly diethyl methylmalonate was formed (Exp. 37), but after 2 or 4 hr. diethyl succinate predominated (Exps. 38 and 7). Thus, a nitrogen atmosphere promotes the isomerization.

By the change of the reaction atmosphere in such stages, as from carbon monoxide to nitrogen, the distribution of the products was also affected (Table V). When the reaction was carried out in two stages at 0°C, at the second stage under nitrogen about 0.2 mol. of a gas was evolved in about 20 min., and then the gas absorption followed slowly, as is shown in Fig. 3 (curve 40). The amount of the isomerized product, diethyl succinate, increased with an increase in the reaction time under nitrogen (Exps. 39—41); a nitrogen atmosphere promoted the isomerization. This observation seemed to be interpreted well by the mechanism of the isomerization.

As has been described above (Exp. 9), pretreatment for 20 min. with a nitrogen atmosphere remarkably reduced the amound of the gas adsorbed at the second stage under carbon monoxide. However, when the reaction was carried out at first under carbon monoxide for

(——) under a carbon monoxide.

only 15 or 30 min.,*5 a nitrogen atmosphere for 30 min.*6 (or 120 min.) at the second stage did not prevent the gas absorption at the third stage under carbon monoxide (Exps. 43—46); in these runs the overall amount of gas absorbed was almost comparable to that absorbed when the reaction which was carried out under carbon monoxide (cf. Exp. 2). This fact seemed to support the consideration that, under nitrogen at the first stage, the cobalt hydrocarbonyl used is rapidly consumed by some side reaction other than the carbonylation. In these case the proportion of the isomerized product, diethyl succinate, also increased with an increase in the reaction time under nitrogen.

The Reaction of *n*-Butyl Vinyl Ether and Styrene.—With relation to ethyl acrylate, the effects of the reaction conditions on the reactions of *n*-butyl vinyl ether and styrene have been also investigated; the results are summarized in Tables VI and VII. These olefins are much more reactive than ethyl acrylate and pentene-1 (cf. Fig. 4);*7 with *n*-butyl vinyl ether, even at −30°C, 0.96 mol. of the gas was absorbed in one hour. In these cases, the reaction temperature and the atmosphere had a similar effect on the distribution of the products and on the isomerization, as in the reaction of ethyl acrylate; under carbon mono-

S: ethyl hydrocinnamate.

xide at a relatively low temperature (0∼−30°C), esters with a branched structure, ethyl α-*n*-butoxypropionate*8 and ethyl α-phenylpropionate,*9 predominated (Exps. 48—50 and 55—57), but at 25°C, esters with a straight-chain structure, ethyl β-*n*-butoxypropionate*10 and ethyl hydrocinnamate,*11 were mainly obtained (Exps. 47 and 53). Under nitrogen, even at 0°C, the esters with the straight-chain structure predominated (Exps. 51 and 58). Moreover, the isomerization of the acylcobalt carbonyls with the branched structure to those with the straight-chain structure occurred with the change in the reaction temperature from −20°C or 0°C to 25°C (Exps. 52 and 59). However, the isomerization of α-phenylpropionylcobat carbonyl seemed to occur more slowly than in the cases of ethyl acrylate and *n*-butyl vinyl ether (cf. Exps. 29, 52 and 59). Thus, the *n*-butoxy and phenyl groups have an effect essentially similar to that of the ester group of ethyl acrylate on this type of reaction.

At an elevated temperature (in the oxo condition), the formation as the main products of branched aldehydes, methylphenylacetaldehyde and α-butoxypropionaldehyde, from styrene and *n*-butyl vinyl ether[7] respectively, may be explained by the following reaction scheme:

*8 Identified by gas chromatography and by means of its infrared spectrum, which had a band at 1760 cm^{-1} corresponding to a carbonyl grop with α-electronegative substituents.
*9 Infrared spectrum, 1720 cm^{-1}.
*10 Infrared spectrum, 1735 cm^{-1}. Further evidence; the retention time of the products (esters) increased as the molecular weight of the alcohol used for the cleavage reaction increased.
*11 Identified by using authentic ethyl hydrocinnamate.

7) H. Adkins and G. Krsek, *J. Am. Chem. Soc.*, 70, 383 (1948); 71, 3051 (1949).

that is, the methylphenylacetyl and α-butoxypropionylcobalt carbonyls formed at the first step undergo reduction more rapidly than isomerization to give the corresponding aldehydes. On the other hand, in the case of ethyl acrylate, the isomerization of the branched acylcobalt carbonyl seems to occur more rapidly than the reduction; therefore, an aldehyde with a straight-chain structure, ethyl γ-oxobutyrate, is mainly formed.

Summary

It has been observed that the reaction of 1-olefin with cobalt hydrocarbonyl is remarkably affected by the reaction conditions and by the structure of olefin.

Some functional groups, such as the ester, *n*-butoxy and phenyl groups, adjacent to a C=C bond increase the reactivity of the C=C bond; the order of the reactivity is *n*-butyl vinyl ether, 10^3>styrene, 20>ethyl acrylate, 5>pentene-1. (The numbers indicate the relative reactivities, which have been roughly calculated from the gas absorption curve.)

At a relatively low temperature (below 0°C), the α-carbon atom of the C=C bond of all these olefins except pentene-1 is selectively carbonylated; the reaction scheme may be considered to be as follows; suggesting that cobalt hydrocarbonyl is acting as an acid:

$$C{=}C{-}X \xrightarrow{H^+} C{-}\overset{+}{C}{-}X \xrightarrow{[Co(CO)_4]^-} C{-}C{-}C \quad (Co(CO)_4 \text{ on the second C})$$

$$\xrightarrow{CO} C{-}C{-}X \quad (COCo(CO)_{3,4} \text{ on the second C})$$

X: -COOEt, -O-*n*-C_4H_9 and -C_6H_5

However, these acylcobalt carbonyls with the branched structure isomerize to those with the straight one:

$$C{-}C{-}X \quad (COCo(CO)_{3,4}) \xrightarrow{\text{isomerization}} C{-}C{-}X \quad (COCo(CO)_{3,4})$$

A relatively high temperature (25°C) and a nitrogen atmosphere promote this isomerization considerably. The reverse isomerization seems to occur only with difficulty. On the other hand, these olefins mainly give the β-carbon carbonylated product at 25°C, the formation of which seems to result from the two successive reactions, the carbonylation of the α-carbon atom and the isomerization of the corresponding acylcobalt carbonyl. However, the distribution of the products from pentene-1 is not affected by the reaction temperature.

A relatively high pressure of carbon monoxide is advantageous for this reaction. Under a nitrogen atmosphere, some reaction other than the carbonylation seems to occur very rapidly, consuming a large part of the cobalt hydrocarbonyl used; a nitrogen atmosphere has an inhibitory effect on the carbonylation.

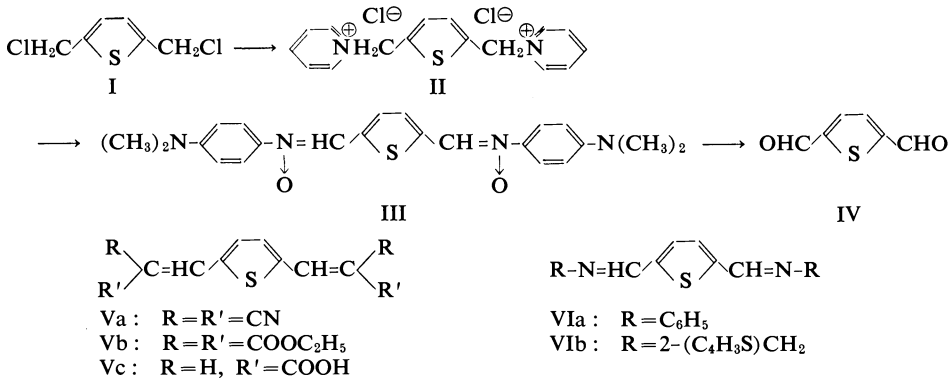
The Preparation of 2,5-Thiophenedicarboxaldehyde

By Tyo Sone

(Received March 7, 1964)



Although thiophenedicarboxaldehydes are of interest as synthetic intermediates, only two of them have appeared in the literature; Steinkopf and Köhler prepared 3,4-dichloro- and 3,4-dibromo-2,5-thiophenedicarboxaldehydes by hydrolyses of the corresponding 3,4-dihalogeno-2,5-bis-(dihalogenomethyl)thiophenes.[1]

The present paper will describe the preparation of 2,5-thiophenedicarboxaldehyde (IV) from 2,5-bis(chloromethyl)thiophene (I). In general, the procedures used for the preparation of benzene derivatives can not always be applied to the thiophene analogues, and such is also the case in the preparation of IV. In connection with an investigation of the reactions of methoxymethylthiophenes, the present author previously attempted to synthesize IV by treating 2,5-bis(methoxymethyl)thiophene with bromine in carbon tetrachloride, but instead of the expected dialdehyde a small amount of another material containing bromine was obtained.[2] The method was virtually identical with that described by Markees for preparing terephthaldehyde from *p*-bis(methoxymethyl)-benzene.[3] The cupric nitrate oxidation of I

or the application of the Sommelet procedure to I was also unsuccessful.

The dialdehyde was easily available by means of Kröhnke's method.[4] The reaction of I with pyridine afforded 1,1'-(2,5-thiophenediyldimethylene)bis[pyridinium chloride] (II) almost quantitatively. The reaction of II with *p*-nitroso-*N*,*N*-dimethylaniline gave α,α'-(2,5-thiophenediyl)bis[*N*-(*p*-dimethylaminophenyl)-nitrone] (III), which was converted into IV by hydrolysis with hydrochloric acid (overall yield, 60%.) The application of the Sommelet procedure to a mixture of 4- and 5-chloromethyl-2-thiophenecarboxaldehydes[5] afforded only a small amount of the dialdehyde.

The dialdehyde IV is highly reactive and reacts with various active methylene compounds and amines to give the corresponding condensation products (V) and the Schiff bases (VI) respectively.

2-Methyl-5-thiophenecarboxaldehyde (VII) was easily chloromethylated by the usual chloromethylation procedure to give 2-methyl-3-chloromethyl-5-thiophenecarboxaldehyde (VIII), which was then converted into 2-methyl-3,5-thiophenedicarboxaldehyde (IX) by the Sommelet procedure. Similarly, the chloromethylation of 2-methyl-5-acetylthiophene (X), followed by oxidation, gave 2-methyl-5-acetyl-3-thiophenecarboxaldehyde (XII). 2-Methyl-3,5-thiophenedicarboxylic acid (XIII), which is difficult to obtain by the usual manner, was prepared from IX by silver oxide oxidation.

Experimental[6]

1,1'-(2,5-Thiophenediyldimethylene)bis[pyridinium chloride] (II).—When a mixture of 2,5-bis(chloromethyl)thiophene[7] (I, 4.5 g.), pyridine (5.2 g.), and absolute ethanol (5 ml.) was warmed on a water bath, colorless precipitate separated within a few minutes. After the mixture had been warmed for a further 30 min., the precipitate was collected and washed with ether, by which process II was obtained in a nearly quantitative yield. Recrystallization from ethanol afforded colorless hygroscopic crystals (m. p. above 280°C).

Found: N, 7.60. Calcd. for $C_{16}H_{16}Cl_2N_2S$: N, 8.25%.

α,α'-(2,5-Thiophenediyl)bis[*N*-(*p*-dimethylaminophenyl)-nitrone] (III).—Into a mixture of II (9.2 g.), *p*-nitroso-*N*,*N*-dimethylaniline (7.5 g.), and ethanol (150 ml.), a solution of sodium hydroxide (2 g.) in water (50 ml.) was stirred while the mixture was being ice-cooled. After being stirred for 1 hr. under ice cooling and then at room temperature for a further 2 hr., the mixture was diluted with water (100 ml.) and allowed to stand overnight. The brownish red precipitate which deposited was collected and recrystallized from ethanol; m. p. 254~255°C (decomp.). Yield, 8.0 g. (72%).

Found: C, 64.63; H, 5.49; N, 13.36. Calcd. for $C_{22}H_{24}O_2N_4S$: C, 64.68; H, 5.92; N, 13.71%.

2,5-Thiophenedicarboxaldehyde (IV).—III (8.2 g.) was added to ice-cooled 2 N hydrochloric acid (160 ml.), and the resultant brownish red solution was stirred for 30 min. while being cooled with ice, during which time a pale yellow precipitate was formed. The mixture was allowed to stand overnight at room temperature. The precipitate was collected and washed well with cold water to give 2 g. of the crude aldehyde (m. p. 115~116°C). The filtrate was extracted with ether, and the ether was evaporated to give an additional 0.3 g. of the product (m. p. 109~114°C). The total yield was 82.5%. Recrystallization from petroleum ether gave pale yellow leaflets (m. p. 115~116°C).

Found: C, 51.53; H, 2.88. Calcd. for $C_6H_4O_2S$: C, 51.41; H, 2.87%.

UV λ_{max}^{MeOH} mμ (log ε): 290 (4.23), 269 (4.15; shoulder), IR (KBr disk): ν_{CO} 1664 cm^{-1}.

2,5-Bis(2,2-dicyanovinyl)thiophene (Va). — A mixture of IV (140 mg.), malononitrile (150 mg.), and absolute ethanol (2 ml.) was allowed to stand for a few minutes while occasionally being stirred; by this method yellow crystals precipitated (190 mg.; m. p. 265~266°C (decomp.)). Recrystallization from a mixture of acetone and methanol afforded fine yellow needles (m. p. 265~266°C (decomp.)).

Found: C, 60.29; H, 1.32; N, 23.47. Calcd. for $C_{12}H_4N_4S$: C, 61.00; H, 1.70; N, 23.71%.

2,5-Bis(2,2-diethoxycarbonylvinyl)thiophene (Vb). —A mixture of IV (140 mg.), ethyl malonate (400 mg.), piperidine (2 drops), and absolute ethanol (2 ml.) was allowed to stand overnight. The mixture was then treated with 2 N hydrochloric acid, and the precipitate thereby formed was collected by filtration and washed with dilute ethanol (200 mg.; m. p. 65~68°C). Recrystallization from petroleum ether afforded pale yellow leaflets (m. p. 68~69°C).

Found: C, 57.06; H, 5.65. Calcd. for $C_{20}H_{24}O_8 \cdot S$: C, 56.59; H, 5.69%.

2,5-Bis(2-carboxyvinyl)thiophene (Vc).—A mixture of IV (350 mg.), malonic acid (550 mg.), piperidine (3 drops), and pyridine (3 ml.) was heated on a water bath for 3 hr. and then, after 5 min. refluxing, acidified with hydrochloric acid. The precipitate thereby formed was collected (490 mg.; m. p. above 300°C). Recrystallization from ethanol yielded a brownish yellow powder.

Found: C, 53.19; H, 3.89. Calcd. for $C_{10}H_8O_4S$: C, 53.56; H, 3.59%.

2,5-Bis[(phenylimino)methyl]thiophene (VIa). —After a mixture of IV (140 mg.), aniline (200 mg.), and ethanol (2 ml.) had been allowed to stand at room temperature, a yellow precipitate began to separate (270 mg.; m. p. 201~202°C). Recrystallization from a mixture of ethanol and benzene afforded pale yellow leaflets (m. p. 202~203°C).

Found: C, 74.79; H, 4.67; N, 9.41. Calcd. for $C_{18}H_{14}N_2S$: C, 74.45; H, 4.85; N, 9.64%.

2,5-Bis[(2-thenylimino)methyl]thiophene (VIb). —A mixture of IV (140 mg.), 2-thenylamine (240 mg.), and ethanol (5 ml.) was allowed to stand at room temperature; a precipitate formed within 10 min. (230 mg.; m. p. 133~137°C). Recrystallization from ethanol afforded coloress leaflets (m. p. 146~147°C).

Found: C, 58.19; H, 3.93; N, 8.03. Calcd. for $C_{16}H_{14}N_2S_3$: C, 58.14; H, 4.26; N, 8.47%.

The Chloromethylation of 2-Methyl-5-thiophenecarboxaldehyde (VII).—Into a mixture of VII (12.6 g.), trioxane (5.0 g.), zinc chloride (5.0 g.), and carbon tetrachloride (50 ml.), a stream of dry hydrogen chloride was stirred over a 30 min. period. Then the mixture was gradually warmed to 50°C and stirred for 1 hr. at the same temperature, while a stream of hydrogen chloride continued to pass through. The resultant solution was diluted with water, and then the layers were separated. The organic layer was washed well with water, a dilute sodium carbonate solution, and again with water, and then dried. After the carbon tetrachloride had been removed, the residue was fractionated in vaccuo, yielding 13.8 g. (79%) of crude 2-methyl-3-chloromethyl-5-thiophenecarboxaldehyde (VIII) (b. p. 105~110°C/2.5~3 mmHg; m. p. 49~51°C), which was recrystallized from a mixture of ether and petroleum ether to give colorless needles (m. p. 50~51°C).

Found: C, 48.07; H, 4.09. Calcd. for C_7H_7ClOS: C, 48.13; H, 4.03%.

UV λ_{max}^{MeOH} mμ (log ε): 222 (3.95), 264 (4.03), 299 (4.00). IR (KBr disk): ν_{CO} 1659 cm^{-1}.

2-Methyl-3,5-thiophenedicarboxaldehyde (IX).— A mixture of VIII (7.0 g.), hexamethylenetetramine (5.6 g.), and chloroform (20 ml.) was heated on a water bath for 30 min. and then cooled, after which the resulted salt was filtered off. The salt was dissolved in a mixture of water (30 ml.) and acetic acid (30 ml.) and boiled for 30 min. The solution was cooled and extracted with chloroform. The extract was dried, and the chloroform was evaporated to give 3.5 g. the crude aldehyde (m. p. 102~104°C, 57%). Recrystallization from boiling water afforded colorless needles (m. p. 106~107°C).

Found: C, 54.56; H, 4.14. Calcd. for $C_7H_6O_2S$: C, 54.52; H, 3.92%.

UV λ_{max}^{MeOH} mμ (log ε): 246 (4.49), 290 (3.99). IR (KBr disk): ν_{CO} 1690, 1665 cm^{-1}.

The Chloromethylation of 2-Methyl-5-acetylthiophene (X).—Paraformaldehyde (4.5 g.), X (14.0 g.), zinc chloride (5 g.), and carbon tetrachloride (50 ml.) were used; the procedure was the same as described previously for VII. Crude 2-methyl-3-chloromethyl-5-acetylthiophene (XI, 14.0 g. (74%) b. p. 130~135°C/3~3.5 mmHg; m. p. 69.5~71.5°C) was recrystallized from petroleum ether to yield colorless leaflets (m. p. 72~73°C).

Found: C, 50.70; H, 5.07. Calcd. for C_8H_9ClOS: C, 50.92; H, 4.80%.

UV λ_{max}^{MeOH} mμ (log ε): 223 (4.00), 264 (4.03), 297 (4.02). IR (KBr disk): ν_{CO} 1654 cm^{-1}.

2-Methyl-5-acetyl-3-thiophenecarboxaldehyde (XII).—This aldehyde (m. p. 110~111°C, 330 mg.) was obtained from XI (2.0 g.), hexamethylenetetramine (1.8 g.), and chloroform (8 ml.) by the method used with IX. Recrystallization from ligroin gave colorless needles, but it did not alter the melting point.

Found: C, 57.26; H, 4.92. Calcd. for $C_8H_8O_2S$: C, 57.12; H, 4.80%.

VU λ_{max}^{MeOH} mμ (log ε): 246 (4.65), 283 (4.10). IR (KBr disk): ν_{CO} 1659, 1680 cm^{-1}.

2-Methyl-3,5-thiophenedicarboxylic Acid (XIII). —Into a mixture of silver oxide (0.4 g.) and an aqueous sodium hydroxide solution (10%, 8 ml.), 0.2 g. of IX was swirled. After the reaction mixture had been allowed to stand overnight, the black silver was filtered off. The filtrate was acidified with hydrochloric acid, and the precipitate which separated thereby was collected (180 mg., m. p. 258~260°C (decomp.)). Sublimation under reduced pressure raised the melting point to 275~276°C (decomp.) (lit.[8] m. p. above 250°C (decomp.)).

Found: C, 44.99; H, 3.55. Calcd. for $C_7H_6O_4S$: C, 45.16; H, 3.24%.

UV λ_{max}^{MeOH} mμ (log ε): 222 (4.36), 259 (3.92). IR (KBr disk): ν_{CO} 1680 cm^{-1}.

Summary

The application of Kröhnke's method to 2, 5-bis(chloromethyl)thiophene has afforded 2, 5-thiophenedicarboxaldehyde, from which some condensation products with amines and active methylene compounds have then been derived. 2-Methyl-5-acetyl-3-thiophenecarboxaldehyde and 2-methyl-3, 5-thiophenedicarboxaldehyde have also been prepared, from 2-methyl-3-chloromethyl-5-acetylthiophene and 2-methyl-3-chloromethyl-5-thiophenecarboxaldehyde respectively, by the Sommelet procedure.

The author wishes to express his deep gratitude to Professor Yasuo Matsuki for his unfailing guidance throughout the course of this work.

A Geochemical Study of Selenium in Volcanic Exhalation and Sulfur Deposits

By Tetsuro SUZUOKI

(Received February 21, 1964)

Several investigations have previously been made concerning the abundance and behavior of selenium in various terrestrial materials. Recently, Anderson[1] summarized the geochemical work on this chemical element. Many studies reveal that selenium is usually enriched in pneumatolytic and high temperatured hydrothermal sulfide rather than in sulfide ores of low temperatured hydrothermal or sedimentary origin.[2,3] It has also been reported that most of the selenium in sedimentary sulfide or rock is not accumulated in pyrite but in independent minerals such as ferroselite.[4] As to the native sulfur, it is known that selenium is usually concentrated in sulfur deposits of volcanic origin. The variation of selenium content in Kilauean sulfur deposits was regarded as being due to a partial sublimation of selenium during deposition.[1,5] It is also said that the low selenium content in the sulfur which is produced in Mexico, West Indies, and Iceland may represent a selenium-poor, residual fraction of sulfur.

It was found by the continuous observation of the chemical constituents of the condensed water from an exhalation collected at a fumarole of the Showashinzan volcano on Hokkaido Island, Japan (42°30'N, 140°53'E), that the behavior or sulfur in volcanic gases was different from that of the other constituents.[6] According to Matsuo and Mizutani, the sulfur content showed less variation with time than do those of such other constituents as halogen and boron.

This study was undertaken to investigate the content and distribution of selenium in volcanic matter from fumarolic gases and associated sulfur sublimates at the Nasudake (36°07'N, 139°57'E) and Kuju (33°07'N, 131°13'E) volcanoes, Japan.

Sampling Sites and Samples

Nasudake volcano is situated at 36°07'N 139°57'E on Honshu, Japan. The activity of the volcano is moderate at present, but a large amount of volcanic gases is emitted from fumaroles near the top of the dome. As is shown in Fig. 1, these fumaroles are divided into three groups, NA, NB, and NC and ND, according to their locations, which are roughly in the order of decreasing gas temperature, ranging from 420 to 120°C.*

Kuju volcano is situated at 33°07'N 131°13'E in the north-eastern part of Kyushu Island, Japan. The active, high-temperatured fumaroles are gathered in the area KA near the top of volcano. These fumaroles also are divided into three groups according to their locations

Sulfur is economically mined in both volcanoes. It is, however, usually difficult to collect gas sample directly from the natural outlet of a fumarole. Because, in order to collect a sulfur deposit efficiently, the gases emitted from the fumaroles are introduced into tunnels, as is shown schematically in Fig. 3. Therefore, most of samples were collected from leaks and from the outlets of tunnels.

Two kinds of sulfur deposits were collected, one obtained at leaks and the other, at the outlets of tunnels. The former (deposit I) is a sublimation deposit from gases, while the latter (deposit II) is the solidified sulfur from the out-flow of the liquid.

At Nasudake, three samples of condensed water and sulfur deposits from the NB area were collected from three different leaks of the same tunnel. At Kuju, two kinds of sulfur deposits, as has been mentioned above, were collected from the outlet of each tunnel.

The Method of Sampling and Analysis

Sampling Method.—Fumarolic gases are introduced into an ice-cooled water trap as is shown in Fig. 4. Water and other condensable substances are trapped in a cold trap containing sodium hydroxide. Selenium, sulfur and chlorine in condensed water are analyzed in laboratory.

Analytical Method. — 1) *Sulfur* is determined by the gravimetric method as barium sulfate after oxidation.

2) *Chlorine* is determined by the colorimetric method with mercuric thiocyanate and iron alum.[7]

3) *Selenium* is determined by the colorimetric

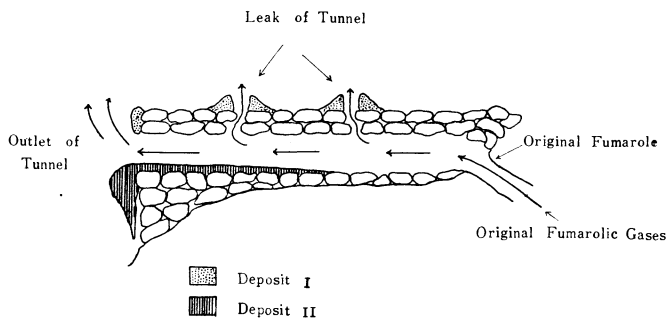

Fig. 3. Schematic diagram of artificial tunnel, which is made of piled stones.

* There are fumaroles at Nasudake and Kuju, the gas temperature of which may be 500°C or higher. It is, however, diffcult to get a gas sample directly from those fumaroles.

method using 3,3'-diaminobenzidine.[8,9] As 3,3'-diaminobenzidine reacts only with quadrivalent selenium, it is necessary to convert all the selenium to a quadrivalent state. Selenium of various ionic forms is first oxidized with hydrogen peroxide to a sexivalent state, and then reduced, by using hydrochloric acid, to a quadrivalent state. Generally the oxidation proceeds smoothly, while the reduction is strongly affected by the concentration of hydrogen chloride and by the time of heating. As is shown in Figs. 5 and 6, a time for heating of longer than 90 min. and a concentration higher than 4 M for hydrochloric acid are required for complete reduction. The concentration of hydrochloric acid must be adjusted during the heating, because selenium forms volatile compound such as Se_2Cl_2 and $SeO_2 \cdot HCl$ when the concentration of acid rises. Sulfate ion interferes with the coloration when its concentration exceeds 16 g.-SO_4/l. in the final solution (ca. 50 ml.) for solvent extraction.[10] In addition, the S/Se ratio (by weight) should be kept below 5.6×10^4 in the final solution. The excess amount of sulfate is removed as barium sulfate after reducing the selenate to selenite in order to avoid the coprecipitation of selenium.

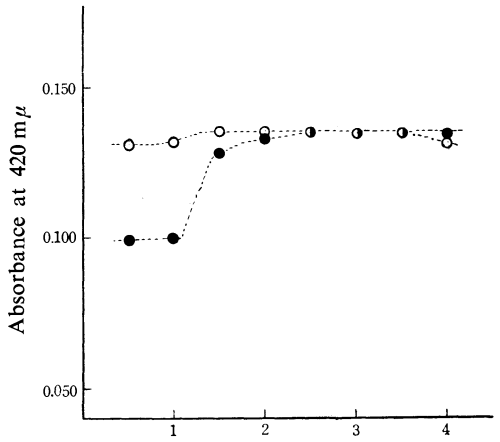

Fig. 5. Time of heating and reduction of selenium(VI) to selenium(IV).
●: 4 M HCl solution ○: 8 M HCl solution

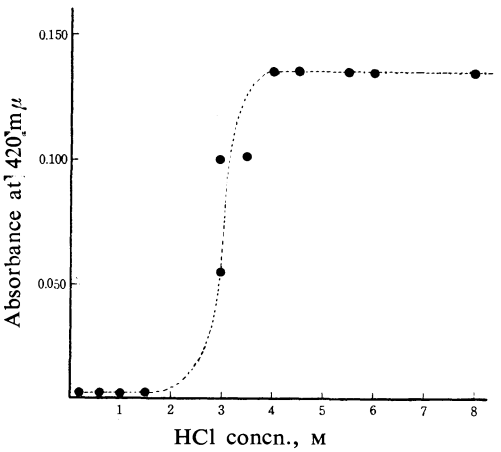

Fig. 6. HCl concentration and reduction of selenium(VI) to selenium(IV).

The Procedure of Sample Preparation for the Solvent Extraction of Selenium.—Native sulfur is pulverized and ground about finer than 100 mesh. One tenth to 0.3 g. of ground sulfur and 2 g. of sodium hydroxide are put into a test tube and heated on a water bath. Hydrogen peroxide is added to the tube until free sulfur disappears. An aliquot of this solution or condensed water is then transferred into a 100 or 200 ml. beaker with a few grams of sodium hydroxide. A small amount of hydrogen peroxide (30%) is added to the solution to assure complete oxidation. The solution is heated on a water bath to approximate dryness. After the residue is neutralized with a (1 : 1) hydrochloric acid solution, the volume of the solution is doubled with concentrated hydrochloric acid. The solution is then heated on a water bath for 180 min., after which the solution is neutralized again with dilute ammonium hydroxide (1 : 1). To remove the excess sulfur, a 20% barium chloride solution is added to the solution after it has been heated with hydrochloric acid. The barium sulfate precipitate is removed by centrifuge, and the filtrate is neutralized with ammonium hydroxide. After the solution is evaporated to a volume less than about 50 ml.

* Type I and II represent respectively deposit I and II which are described in page 1201.

Results

In Tables I and II, the selenium, sulfur, and chlorine contents in condensed water and two types of sulfur are given. The amount of selenium and sulfur in the tables represent the total amounts, regardless of their chemical forms.

A) The following results were obtained for condensed water and the sulfur deposits of the Nasudake volcano:

Condensed Water.—The sulfur content ranges from 4390 to 25400 p.p.m. In the NB area it was several times higher than in other areas. The NB area is thus characterized by a higher total concentration of sulfur. The chlorine content and selenium content range from 390 to 8340 p.p.m. and 0.01 to 0.35 p.p.m. respectively. The variation in the selenium content is greater than those of sulfur and chlorine.

Sulfur Deposits. — The selenium content in deposits I and II ranges from 49 to 368 p.p.m. and 20 to 404 p.p.m. respectively.

15) J. N. Friend and J. P. Allchin, *Mineralogist Mag.*, **26**, 9 (1941).

B) The following results were obtained regarding the sulfur deposits of the Kuju volcano:

Sulfur Deposits. — The selenium content in deposits I annd II ranges from 14.8 to 355 p.p.m. and 15.2 to 741 p.p.m. respectively.

Selenium is richer in deposit II than in deposit I. The selenium content in the sulfur deposits of Kuju is a little higher than that of Nasudake. It may be said that volcanic gases and sulfur from the two volcanoes contain various amounts of seleninum according to the location of the fumaroles. A comparison of the selenium contents in various volcanic sulfurs is given in Table III. It should be noted that the selenium content in sulfur from Mt. Kilauea, Hawaii, is about ten times higher than that of several volcanoes, the selenium contents of which have been determined by the present author.

C) The Continuous Observation of Fumarolic Gas at Nasudake.—A continuous observation over a short period was made in order to study the time variation of the sulfur and selenium contents in volcanic gases from a certain fumarole at the Nasudake volcano. The sulfur and selenium contents of seven samples which were collected from a fumarole (NA-3a) at intervals of 40 min. were determined (cf. Table IV). As Table IV shows, the time variation of the sulfur content in condensed water is small, whereas a considerable variation, ranging from 0.20 to 0.31 p.p.m., was found in the selenium content.

TABLE IV. THE TIME VARIATION OF SELENIUM AND SULFUR CONTENT IN THE CONDENSED WATER FROM NA-3a FUMAROLE OF NASUDAKE (30 AUGUST 1962)

Sample	Time hr. min.	S p.p.m.	Se p.p.m.	S/Se $\times 10^4$

7	13 40	4440	0.23	1.93

Discussion

As it is known that selenium forms certain volatile compounds with chlorine, the relationship between selenium and chlorine was studied. The results showed that there is no correlation between the two elements in condensed water. This suggests that selenium is not exclusively transferred by fumarolic gases in the form of a compound with chlorine. It was also found that selenium and sulfur in condensed water have no correlation with each other.

The relation between the temperature of gases at the outlet of the fumarole and the selenium content in condensed water and sulfur deposits was also considered. As is shown in Fig. 7, the higher the temperature, the higher the selenium concentration. A sharp correlation between the S/Se ratio (by weight) and the outlet temperature was also observed, as may be seen in Figs. 8, 9 and 10. The

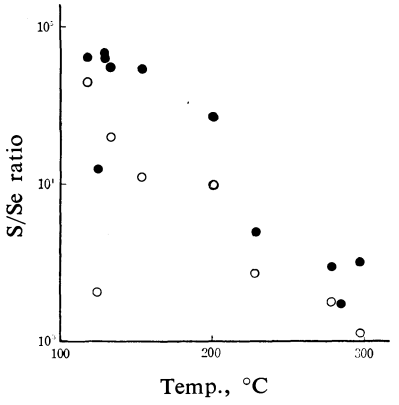

Fig. 10. Relationship between S/Se ratio and gas temperature in sulfur deposit from Kuju.

●: Deposit-I ○: Deposit-II

S/Se ratio in both condensed water and sulfur deposits has an inverse correlation with the gas temperature. This fact implies that the fractionation between selenium and surfur depends on the temperature of the fumarolic gases. The values of the $r=\{$(S/Se) condensed water/(S/Se) volcanic sulfur$\}$ ratio for condensed water and sulfur deposits from the same outlet of fumaroles are listed in Table V. These values which extend from 7.5 to an extremely high number, may be said to reflect the degree of the fractionation of selenium and sulfur between volcanic gases and sulfur deposits. In addition, this factor is controlled by other factors related to the mechanism of the transportation of chemical elements in volcanic gases. The relationship between the ratio r and the outlet temperature is given in Fig. 11, which shows the temperature dependency of the ratio r.

TABLE V. VALUE OF (S/Se) CONDENSED WATER/(S/Se) VOLCANIC SULFUR RATIO (r)

Locality, No.	Temp., °C	r
Na-2a	261	7.3
NB-2	195	23.6
NB-1	181	50.0
NB-3	118	93.0

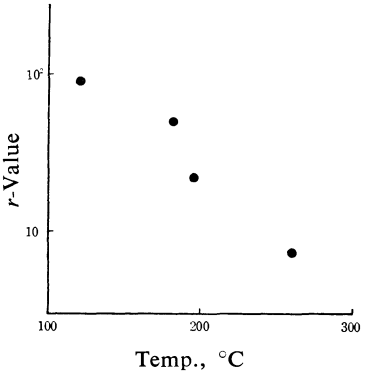

Fig. 11. Relationship between gas temperature and (S/Se) condensed water/(S/Se) volcanic sufur ($=r$).

The same correlation of the selenium content with the temperature was also observed in deposit I, as is shown in Figs. 9 and 10. On contrary, some of deposit II is high in selenium content and low in S/Se ratio, unlike deposit I. The variation of the S/Se ratio in deposit II independently of the outlet temperature may be explained as follows. From field observation, it is known that deposit II is formed through the movement of separated sulfur in a liquid form toward the outlet of tunnel and that then the sulfur is deposited at the outlet of the tunnel. Judging from the outlet temperature of the tunnel, most of the sulfur and selenium would be completely trapped inside the tunnel during the effusion processes. From the above considerations, the lack of relationship between the temperature and the selenium content (and the S/Se ratio) in deposit II might be due to the difference in the mode of deposition rather than to that in temperature between the two types of deposits. In addition, the S/Se ratio in deposit II might depend mainly on the temperature at the original outlet on the fumaroles. Accordingly, the S/Se ratio in deposit II will be taken to serve to estimate the physical and chemical conditions at original outlet such as the S/Se ratio, the temperature, and the structure of the tunnel. From the observed data, it was found that the same separation process due to temperature gradient as in the tunnel occurs also inside the natural conduit of volcanic gases, and that the source gas at some fumarole areas (NC and ND) has

an essentially lower selenium concentration than that in other areas.

The NA area is regarded as the most active area in Nasudake, as has been mentioned before. If fumarolic gages in this field have the same origin, it may be said that the S/Se ratio in the original volcanic gases of Nasudake is close to that found in NA fumarolic gases of the highest temperature (1.8×10^4).

Conclusion

On the basis of our observations, it may be concluded that the temperature at the fumarole outlet is one of the main factors controlling selenium concentration in volcanic gases and sulfur deposits. In the case of sulfur deposits collected at the outlet of tunnels, deposit II, the temperature of the source gases and the structure of the tunnel seem to play an important role in governing the selenium content. The variation in selenium content in the volcanic sulfur suggests the fractional distillation of selenium and sulfur through either natural or artificial conduits of volcanic exhalation. On the basis of findings that the S/Se ratio in sulfur deposits and gases increases with the decrease in the temperature at the sampling sites, it may also be concluded that the S/Se ratio gives an indication of the condition which governs the effussion process of volcanic gases.

There remain, however, a number of problems to be solved concerning selenium in volcanic matter, such as the mechanism of the fractionation of selenium and sulfur, and the reason for the variation in selenium content with respect to each fumarole and its general area.

Summary

Regarding selenium in volcanic materials collected at fumaroles of the Nasudake (36° 07'N, 139°57'E) and the Kuju (33°07'N, 131° 13'E) volcanoes, Japan, the following results have been obtained.

1) The selenium content in condensed water has no relation to that of sulfur and chlorine. The selenium content in certain sulfur deposits is strongly affected by the mode of occurrence, such as sublimation and solidification, as well as by the outlet temperature of the fumarole. The ratio of selenium to sulfur in both condensed water and sulfur deposit is related with gas temperature at the outlet of fumarole. The higher the gas temperature, the lower the degree of fractionation between selenium and sulfur.

2) The S/Se ratio in the original volcanic gases at Nasudake is close to 1.8×10^4, found in fumarolic gases with the highest temperature. The S/Se ratio in sulfur deposit is at least one-seventh that in condensed water.

3) Continuous observation over a short period (3 hr.) showed that the selenium content in condensed water varies considerably with time, while the sulfur content remains constant.

This study was made under the guidance of Professor Shinya Oana, Institute of Earth Sciences, Faculty of Science, Nagoya University, to whom the present author wishes to express his hearty thanks. Thanks are also due to Dr. Yoshihiko Mizutani and Mr. Tsutomu Sugiura for their help in the collection of samples.

The author wishes also to thank Professor Yasuo Miyake and Dr. Sadao Matsuo, Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, who gave him valuable advice on many points.

*The Catalytic Hydrogenolysis of 5,6β-Epoxy-5β-cholestan-3β-ol**

By Shigeo NISHIMURA, Michio SHIOTA and Aiko MIZUNO

(Received March 11, 1964)

In the catalytic hydrogenolysis of 5,6β-epoxy-5β-cholestan-3β-ol and related 5β,6β-epoxy-compounds, there often occurs a rather extensive over-hydrogenolysis beyond the mere reductive cleavage of the oxide ring. Chuman[1] obtained 5α-cholestane in the catalytic hydrogenolysis of 5,6β-epoxy-5β-cholestan-3β-ol (I) with platinum oxide in acetic acid. 3β-Acetoxy-5,6β-epoxy-5β-cholestane (II) has also been reported to give 5α-cholestane and 3β-acetoxy-5α-cholestane, along with 3β-acetoxy-5α-cholestan-6β-ol, under similar conditions.[1,2] Such an over-hydrogenolysis has also been found to take place in the catalytic hydrogenolysis of 5,6β-epoxy-5β-cholestan-3α-ol[3] and 3α-chloro-5,6β-epoxy-5β-cholestane.[4] From the observations that the reduction of the epoxide II with lithium aluminum hydride afforded about 20% of 5β-cholestane-3β,5-diol along with 60% of 5α-cholestane-3β,6β-diol, and that the yield of the 3β,5β-diol nearly amounted to the sum of 5α-cholestane and 3β-acetoxy-5α-cholestane obtained in the catalytic hydrogenolysis, it has been suggested that 3β-acetoxy-5β-ol was also produced in the catalytic hydrogenolysis, but further reduced to give 5α-cholestane and 3β-acetoxy-5α-cholestane.[5] There is no evidence for the assumption, however, and it seems not probable that the catalytic hydrogenolysis or the dehydration, followed by the hydrogenation, of the 5β-hydroxy compound would be involved in the reaction, because the 5β-hydroxyl group is not activated by any unsaturated groups and the condition of the reaction is not so drastic.

This paper will present the results of the reinvestigation of the catalytic hydrogenolysis of 5,6β-epoxy-5β-cholestan-3β-ol with platinum, (7:3) rhodium-platinum and palladium oxides as catalysts. 5β-Cholestane-3β,5-diol[6] was also subjected to hydrogenolysis with platinum oxide in order to observe the behavior of the tertiary hydroxyl group under the conditions.

Table I summarizes the products formed in the catalytic hydrogenolysis of the epoxide I in acetic acid at room temperature and under the atmospheric pressure of hydrogen. The elimination of oxygen groups increases with respect to the catalysts in the following order: (7:3) rhodium-platinum, platinum, palladium. In every case 5β-compounds, which had not been isolated previously, were also produced, though in smaller yields than the corresponding 5α-compounds. Palladous oxide, which caused the most extensive over-hydrogenolysis, gave no diols and only a trace of 5α-cholestan-3β-ol-6-one. The catalyst also gave a considerable amount of 5α-cholestan-3-one, along with 5α-cholestan-3β-ol. These carbonyl compounds were not found in the products obtained with platinum and (7:3) rhodium-platinum catalysts. Platinum oxide and (7:3) rhodium-platinum oxide gave 3,6-diols in 36% and 74% yields respectively, the 5α-diol being formed more predominantly than the 5β-diol. Thus, the compounds carrying no oxygen at C_6 were produced mostly on palladous oxide, while in only a 25% yield on (7:3) rhodium-platinum oxide.

If these compounds were formed via 5β-cholestane-3β,5-diol, the hydrogenolysis of the oxide ring of the epoxide I should have occurred almost exclusively at C_6 on the palladium catalyst, while mostly at C_5 on the (7:3) rhodium-platinum catalyst. It may be rather unreasonable to assume that there exists such a great difference in selectivity between the catalysts in the mere hydrogenolysis of the oxide ring in acetic acid at room temperature.*1 Further evidences against

1* The catalytic hydrogenolysis of 1,2-epoxy-1-methylcyclohexane in acetic acid at room temperature gave 7% of 1-methylcyclchexanol and 93% of 2-methylcyclohexanol with platinum oxide, 8% of 1-methylcyclohexanol and 92% of 2-methylcyclohexanol with (7:3) rhodium-platinum oxide, and 8.5% of 1-methylcyclohexanol, 53.5% of 2-methylcyclohexanol and 38% of 2-methylcyclohexanone with palladous oxide. Thus, the ratio of 1-methylcyclohexanol to 2-methylcyclohexanol or to 2-methylcyclohexanol plus 2-methylcyclohexanone differs only slightly between the three catalysts (unpublished results by the present authors).

a) All the reductions were carried out in acetic acid at room temperature and atmospheric pressure of hydrogen.

the assumption are the facts that 5β-cholestane-3β, 5-diol does not absorb any hydrogen in the presence of platinum oxide in acetic acid, and that the starting diol was recovered unchanged.[7] From these results, it is very probable that the over-hydrogenolyzed products would be formed via a different reaction path from that via the 3β, 5β-diol. These results will be best explained if we assume that the epoxide I is partly isomerized to cholest-4-ene-3β, 6β-diol (III) during the catalytic hydrogenolysis, and that this is further hydrogenated to give hydrocarbons, cholestanols (or cholestanone) and cholestanediols as illustrated in Fig. 1. The isomerization of an epoxide to an allylic alcohol has been described, for example, by Fieser and Goto,[8] who have shown that 7α, 8α-epoxy-5α-cholestan-3β-ol acetate is isomerized to the allylic alcohol V upon

IV V

standing briefly in chloroform shaken with 10% sulfuric acid. The hydrogenolysis of the epoxide I not accompanied with the isomerization may occur simultaneously, since the hydrogenolysis of the epoxide I gives a greater yield of 5α-cholestane-3β, 6β-diol than the hydrogenation of cholest-4-ene-3β, 6β-diol (see Table I). The attack of hydrogen from the β-face will be more hindered in the hydrogenolysis of the oxide ring at C_5 than in the hydrogenation of the 4, 5-double bond of the cholestenediol. The formation of carbonyl

7) The difficult hydrogenolysis of the tertiary hydroxyl group of a saturated compund in acetic acid at room temperature was also confirmed in the hydrogenation of *cis*- and *trans*-1-methyl-4-*t*-butylcyclohexanol, using platinum oxide as the catalyst.

8) L. F. Fieser and T. Goto, *J. Am. Chem. Soc.*, **82**, 1693 (1960).

compounds on a palladium catalyst may also be explained without difficulty by means of the schema shown in Fig. 1. Cholest-4-ene-3β, 6β-diol formed from the epoxide I is partly isomerized to 5α-cholestan-3β-ol-6-one*2 and mostly hydrogenolyzed to give cholest-4-en-3β-ol, which affords 5α-cholestan-3-one, along with hydrocarbons and cholestanols. Such an isomerization is supposed to occur to some extent also on (7 : 3) rhodium-platinum oxide, which would hydrogenate the resulting ketone to the corresponding alcohol. However, platinum oxide will give rise to this isomerization to a much less extent, as is expected from the fact that the isomerization of allyl alcohol to propionaldehyde during the hydrogenation in ethanol at room temperature occurs to the extent of about 30% on palladous oxide and about 20% on (7 : 3) rhodium-platinum oxide, while there is practically no isomerization on platinum oxide.[9]

Experimental

Catalysts.—The catalysts were prepared by the fusion of their chlorides with sodium nitrate according to the procedures described in the literature.[10-12]

Hydrogenation.—The hydrogenation was carried out at an ordinary temperature and pressure, using acetic acid as the solvent. The substrate was added after the metal oxide had been pre-reduced to black with hydrogen in the solvent.

5, 6β-Epoxy-5β-cholestan-3β-ol. — This compound (200 mg.) was hydrogenated with 50 mg. of the catalyst in 30 ml. of acetic acid. The hydrogenation was completed in 30 min. with platinum oxide (1.7 mol./mol. of hydrogen being absorbed), in 50 min. with (7 : 3) rhodium-platinum oxide (1.2 mol./mol. of hydrogen being absorbed), and in 1 hr. 20 min. with palladous oxide (1.8 mol./mol. of hydrogen being absorbed).

Cholest-4-ene-3β, 6β-diol. — When this compound (70 mg.) was hydrogenated with 30 mg. of platinum oxide in 15 ml. of acetic acid, 2.3 mol./mol. of hydrogen was absorbed in 20 min. The hydrogenation with (7 : 3) rhodium-platinum oxide in acetic acid has already been described in a previous paper by one of the present authors (S. N.) and Mori.[13]

5β-Cholestane-3β, 5-diol.—This compound (30 mg.) was subjected to hydrogenolysis with 15 mg. of platinum oxide in 15 ml. of acetic acid for about 1 hr., but no hydrogen was absorbed. Though the melting point of the recovered material was somewhat lower than that of the starting 3,5-diol, the following analytical values show that the recovered material did not lose any hydroxyl group :

Found : C, 80.19 ; H, 11.91. Calcd. for $C_{27}H_{48}O_2$: C, 80.14 ; H, 11.96%.

Analysis of the Products.—The reaction mixture was neutralized with aqueous sodium hydroxide and extracted with ether, and the residue after the evaporation of the ether was analyzed by gas-liquid partition chromatography with a GC-1B of Shimadzu Seisakusho, Ltd. (hydrogen-flame ionization-detector type) and a column of 1% SE-30 silicone on Chromosorb W (60~80 mesh).

The authors wish to thank Dr. Nobuo Ikekawa for his gas chromatographic analysis and for his discussion of the results, and Mrs. Misako Nohira for her collaboration in this work.

A part of the expense has been defrayed by a grant given by the Ministry of Education, to which the authors' thanks are due.

*2 It may also be possible that 5α-cholestan-3β-ol-6-one was formed directly from the epoxide I, but the fact that a much larger amount of 5α-cholestan-3-one was formed, along with the 6-one, seems to suggest that the more probable course of the occurrence of 3β-ol-6-one would be the one via III.

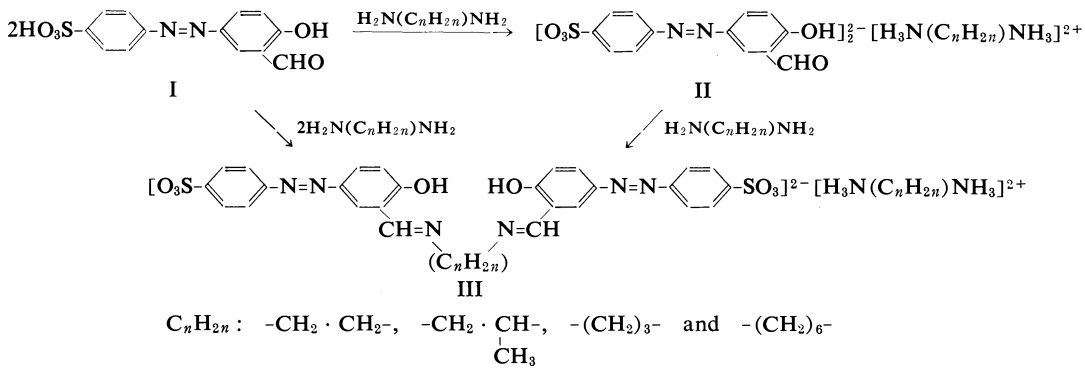
The Metal Chelates of p-(3-Formyl-4-hydroxyphenylazo)benzene Sulfonic Acid and Its Derivatives



By Mitsunori TANAKA

(Received March 14, 1964)

Several syntheses of *p*-aminosalicylaldehyde have been attempted in the hope that the physiological activity of *p*-aminosalicylic acid in the treatment of tuberculosis would be improved by changing the lipophobic carboxyl group into a lipophillic aldehyde group. These attempts, however, have resulted in the formation of a resinous product of a high molecular weight because of the spontaneous condensation of the amino group of one molecule with the aldehyde group of the other. Derivatives of *p*-aminosalicylaldehyde in which the amino group is protected by an acyl group, thus preventing condensation or polymerisation, have been synthesized.

The present work is a preliminary study to approach the synthesis of *p*-aminosalicylaldehyde derivatives retaining a free amino group formed by the reductive cleavage of azo linkage in an azo compound derived from salicylaldehyde. As the aromatic amino component to be used for the diazotization and for the subsequent coupling to salicylaldehyde sulfanilic acid was adopted, since it was expected both to enhance the solubility of the resultant azo compound and to ease in the isolation of the *p*-aminosalicylaldehyde derivative from the amino component formed on reduction. We tried to suppress the chemical activity of the aldehyde group by coordinating the oxygen atom of the aldehyde group with a metal atom and by allowing the aldehyde group to react with a diamine. In this way, the reaction products of *p*-(3-formyl-4-hydroxyphenylazo)-benzene sulfonic acid or 5-(*p*-sulfophenylazo)-salicylaldehyde (I) with several alkylenediamines and their metal chelates were synthesized.

A number of complex salts of hydroxyazo-compounds whose azo group participates in the complex formation are known[1], but there

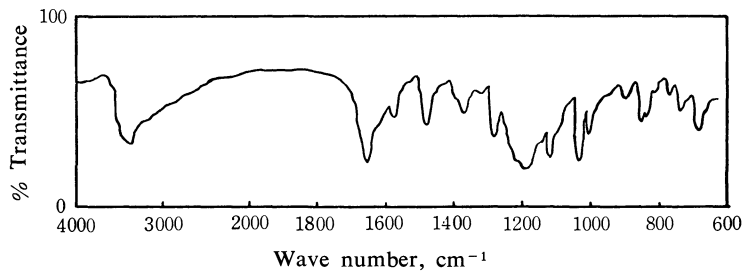


Fig. 1. Infrared spectrum of the *p*-(3-formyl-4-hydroxyphenylazo)benzene sulfonic acid.

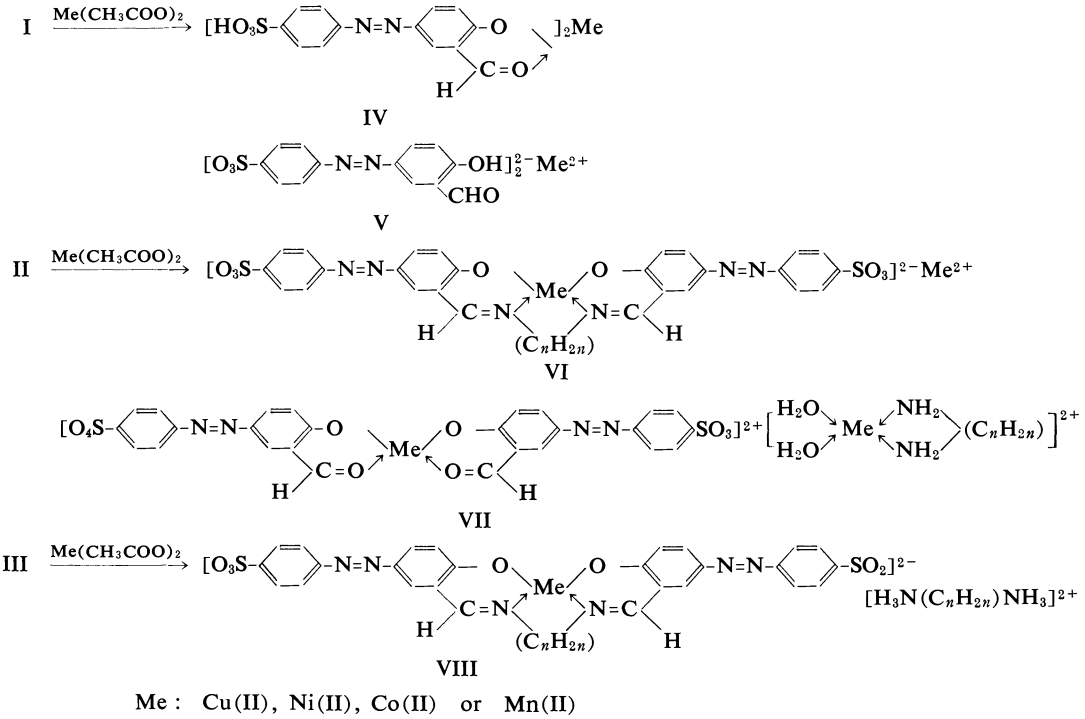
1) For instance, A. H. Knight, *J. Soc. Dyecs Colourists*, **66**, 34 (1950); N. M. Mackenzie, H. E. Millson and B. L. West, *Ind. Eng. Chem.*, **44**, 1017 (1952); H. Pfitzner, *Angew. Chem.*, **62**, 242 (1950).

are a few instances[2] in which the nitrogen atoms of the azo-groups do not coordinate with central metal ions. The metal chelates in the present paper belong to the latter group.

The starting material, *p*-(3-formyl-4-hydroxyphenylazo) benzene sulfonic acid (I), was prepared by a modified Tummely[3] method; the barium salt of the sulfonic acid was used in place of sodium salt for the isolation of the free acid with a satisfactory purity and in a better yielde.



When two moles of the sulfonic acid (I) was treated with one mole of alkylene diamine, alkylene diammonium salts (II) of sulfonic acid invariably formed; those were confirmed by their infrared spectra. No formation of Schiff's base between aldehyde and diamines could be observed. As the alkylene diamine components, ethylene diamine, propylene diamine, trimethylene diamine and hexamethylene diamine were used. Figures 1 and 2 show the infrared spectra of the sulfonic acid and its ethylene diammonium salt respectively. The band in the 3200~3000 cm^{-1} region in Fig. 2 indicates the presence of a $-NH_3^+$ vibration.

On the the other hand, when the sulfonic acid was mixed with each of the above alkylene diamines in a molar ratio of 1 : 1, the Schiff's base represented by formula III was formed. Of course, the base could also be obtained from alkylene diammonium salt (II) by the action of 0.5 mol. of alkylene diamine. The infrared spectrum of one of the bases is given in Fig. 3. The band at 1625 cm^{-1} can be assigned to the -CH=N- vibration, which has already been discussed by Murase.[4]

The metal compounds of the sulfonic acid could be obtained easily when the latter was treated with metal acetates in an aqueous ethanolic medium. These metal compounds cannot be considered to be ionic metal sulfonates (V) on the basis of their infrared spectra (Fig. 4); they must be genuine chelate compounds as represented by formula IV.

It is generally accepted that, in the case of such a sulfonic acid, the formation of simple metal salts does not cause any appreciable change in their infrared spectra.

However, when the curves in Fig. 4 are compared with the curve of the original sulfonic acid (Fig. 1), a considerable change is observed. For instance, the carbonyl band of the free acid at 1650 cm^{-1} shifts towards the 1600 cm^{-1} region in the copper compound (Fig. 4, curve Cu), indicating the presence of a strong chelation; the magnitude of the shift is comparable to that between salicylaldehyde and its copper chelate.[5] The nickel, cobalt or

Me : Cu(II), Ni(II), Co(II) or Mn(II)

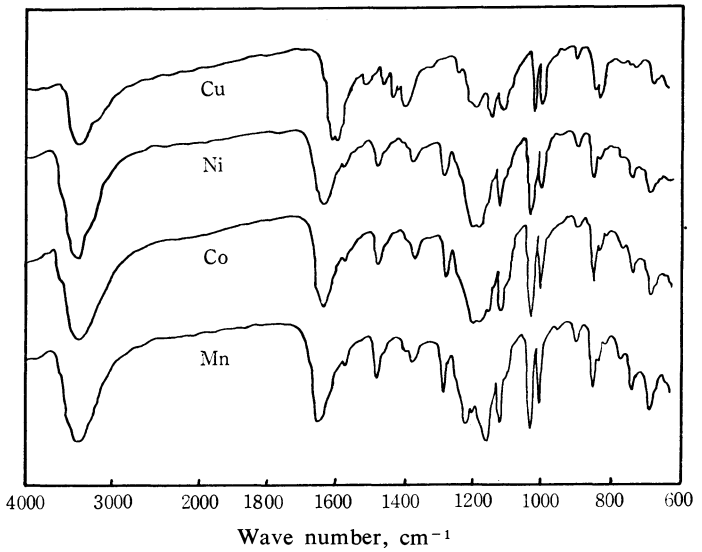

Fig. 4. Infrared spectra of the bis[5-(*p*-sulfophenylazo)salicylaldehyde]metal chelates.

manganese compound also shows a definite shift, though its magnitude is not as large.

The chelate compounds corresponding to formula VI were obtained when one mole of the alkylene diammonium salts (II) was mixed with 2 mol. of metal acetates. Figs. 5a and 5b give the infrared spectra of the copper and the nickel compounds (formula VI); the presence of the -CH=N- vibration band at 1600 cm^{-1} excludes formula VII for the nickel compound, for formula VII would require the chelated carbonyl absorption to be present at a greater wave number (ordinarily at 1640 cm^{-1}), as can be seen, for example, in the case of bis(salicylaldehyde)-nickel[5] or the nickel chelate of the sulfonic acid mentioned above (Fig. 4, curve Ni). Moreover, the band in the 3200~3000 cm^{-1} region of the $-NH_3^+$ vibration in Fig. 2 apparently has disappeared in the infrared spectra shown in Figs. 5a and 5b. Therefore, it can be concluded that, during the reaction, alkylene diamine is replaced by

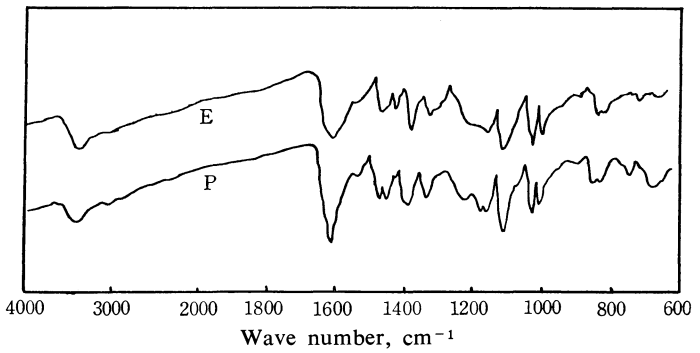

Fig. 5a. Infrared spectra of the copper(II) salt of *N*, *N*-bis[5-(*p*-sulfophenylazo)salicylidene]-alkylene diamine-copper(II).

Ni: Ethylene diamine, Cu: Trimethylene diamine

a bivalent metal ion and that the diamine molecule enters into condensation with the aldehyde group to form a Schiff's base. In the case of the copper or cobalt compound, the data indicate the same conclusion.

By the reaction of metal acetates with the alkylene diammonium salts of *N, N'*-bis[5-(*p*-sulfophenylazo)salicylaldehyde] alkylene diamine (III) or by the reaction of the metal acetates with the sulfonic acid (I) and alkylene diamines, the chelates represented by formula VIII were obtained; they are supported by the analytical data and infrared spectra (Fig. 6).

Experimental

The Infrared Spectra.—Those in Figs. 1, 2, 3, 4, 5a and 6 were measured with an Hitachi I. R. spectrophotometer, model EPI-2, and that in Fig. 5b, with an Hitachi I. R. spectrophotometer, model EPI-S2.

Chelating Agent. — *p-(3-Formyl-4-hydroxyphenylazo)benzene Sulfonic Acid (I).*—The sodium salt of the sulfonic acid was prepared by Tummely's method.[3] For the isolation of free sulfonic acid, the sodium salt was dissolved in water, and then, by the addition of an aqueous barium chloride solution, it was converted into barium salt, which was obtained as a yellowish brown precipitate. It was then decomposed with a theoretical amount of dilute sulfuric acid in an aqueous solution. The barium sulfate was removed, and the filtrate was concentrated in a vacuum desiccator. The sulfonic acid crystallized out as red or yellowish red prisms.

Alkylene Diammonium p-(3-Formyl-4-hydroxyphenylazo)benzene Sulfonate (II).—As the diamine components, ethylene diamine, propylene diamine, trimethylene diamine and hexamethylene diamine were used. One thousandth mol. of alkylene diamine was added slowly to a warm aqueous or ethanolic solution of 0.002 mol. of sulfonic acid (I). The sulfonate, which immediately separated out, was filtered and recrystallized from hot water, forming yellow needles or prisms. The analytical data are given in Table I.

Percentages were calculated according to the Formulae a) $C_{30}H_{30}O_8N_8S_2Cu \cdot 2H_2O$, b) $C_{30}H_{30}O_8N_8S_2Ni \cdot H_2O$, c) $C_{32}H_{34}O_8N_8S_2Cu \cdot 4H_2O$, d) $C_{32}H_{34}O_8N_8S_2Ni \cdot 5H_2O$, e) $C_{32}H_{34}O_8N_8S_2Cu \cdot 4H_2O$, f) $C_{32}H_{34}O_8N_8S_2Ni \cdot 6H_2O$ and g) $C_{38}H_{46}O_8N_8S_2Cu \cdot 5.5H_2O$.

In the case of the copper chelate of the propylene diamine analogue, it was prepared by mixing the sulfonic acid (I), propylene diamine and copper acetate in an aqueous solution.

Alkylene Diammonium Salt of N, N'-Bis[5-(p-sulfophenylazo)salicylidene]alkylene Diamine (III).—To a warm solution of 0.002 mol. of the sulfonic acid (I) in 100 ml. of water, a solution of 0.002 mol. of alkylene diamine in 10 ml. of water was added. The yellow precipitate thus obtained was recrystallized from a large quantity of water, a pyridine-water mixture, or an ethanol-water mixture. The salts are listed in Table II.

Metal Chelate. — *Bis-[5-(p-sulfophenylazo)salicylaldehyde]metal Chelate (IV).*—The copper, the nickel, the cobalt and the manganese chelates were synthesized by adding a solution of 0.0005 mol. of metal acetate in 10 ml. of water to a solution of 0.001 mol. of the sulfonic acid (I) in 50 ml. water. The mixture was heated on a water-bath for a short time and then left to cool. The precipitate was collected and recrystallized from water. The results are listed in Table III.

The Metal Salt of N, N'-Bis[5-(p-sulfophenylazo)-salicylidene]alkylene Diamine-metal Chelate (VI).—Four alkylene diammonium sulfonates of Table I were used as the ligand components, and copper and nickel acetate as the metal components. The chelates thus obtained are listed in Table IV. A solution of 0.001 mol. of copper acetate or nickel acetate in 10 ml. of water was added to a warm solution of 0.0005 mol. of the alkylene diammonium salt (III) in 200 ml. of water (50 ml. of a pyridine-water mixture was used for the preparation of copper chelates). The mixture was filtered when necessary, boiled for a short time, and concentrated on a water-bath until the precipitation of the chelate was completed. The chelates thus obtained were recrystallized from a pyridine-water mixture or from an ethanol-water mixture. All of the nickel chelates were obtained in the form of hydrates or pyridinates. They are listed in Table IV.

Alkylene Diammonium Salt of N, N'-Bis[5-(p-sulfophenylazo) - salicylidene]alkylene Diamine-metal Chelate (VIII).—These salts are listed in Table V. A solution of 0.0005 mol. of metal acetate in 20 ml. of water was added to a solution of 0.0005 mol. of the salt (III) in 100 ml. of a hot pyridine-water mixture (in the case of the ethylene diamine analogue, 800 ml. of hot water was used). The mixture was heated for a short time and concentrated on a water-bath to an adequate volume. The precipitate was then collected and recrystallized from an ethanol-water mixture or a pyridine-water mixture.

The author wishes to express his thanks to President Dr. Tokuichi Tsumaki of the Kyushu Institute of Technology and to Professor Dr. Tamotsu Yoshida and Dr. Masaru Yamaguchi of Kyushu University for their exceedingly kind direction of this work. The author also wishes to thank Professor Dr. Yoshiya Kanda of Kyushu University for his measurement of the infrared spectra and Mr. Michio Shido and his group for their elementary analysis.

Vibrational Spectra of Tetracyanoethylene

By Tohru TAKENAKA and Soichi HAYASHI

(Received March 17, 1964)

Since tetracyanoethylene (TCNE) was synthesized for the first time by Cairns et al.,[1] much attention has been directed to the π-complexes formed by TCNE with aromatic compounds. However, previous work on the vibrational spectra and assignments of this molecule has been very limited. The infrared spectrum of TCNE was first reported by Looney and Downing,[2] who also gave the C≡N and C=C stretching frequencies in the infrared and Raman spectra. When we were almost finished with the present work, Long and George[3] published a paper in which the infrared and Raman spectra of the powdered solid were treated, together with the infrared spectrum of solution, and tentative assignments were given on the basis of spectra correlations.

On the other hand, in the normal coordinate treatments of molecules with π-electron systems, it was found necessary to supplement the basic Urey-Bradley force field (UBFF)[4,5] with additional cross terms, for example, "resonance-interaction terms" between the C—C stretching coordinates in benzene,[6-8] and

" trans-interaction terms " between trans-hydrogen bending coordinates[9] or " bond-flexibility terms "[9,10] in ethylene and its derivatives. Thus, one might not expect the basic UBFF to be a satisfactory description of the potential function for TCNE, for in this case it is well recognized that resonance plays an important structural role.

In the present work, we have studied the polarized infrared spectrum of a highly-oriented crystal of TCNE and the Raman spectrum of a sample consisting of several lumps of the crystals. The infrared spectra of the powdered solid, solution, and vapor were also measured for comparison. In order to make vibrational assignments and to determine the force constants for this molecule, the normal coordinate treatments for the in-plane vibrations were carried out by using the basic UBFF and also a slight modification of it.

Experimental and Observed Spectra

A sample of TCNE kindly supplied by Dr. Kenichi Kudo was twice sublimed at 130~140°C/1~2 mmHg. The colorless, crystalline solid thus obtained melts at 199~200°C in a sealed capillary tube, the melting point being in good agreement with the literature values.[1,11]

Infrared Spectra. — The infrared absorption spectra in the region 4000~480 cm^{-1} were obtained by using a Perkin-Elmer model 21 spectrophotometer equipped with a lithium fluoride or sodium chloride prism, and by a Nippon Bunko model DS-301 (double monochromator) spectrophotometer equipped with two potassium bromide prisms. For measurements in the far-infrared region, 500~200 cm^{-1}, a Parkin-Elmer model 221 spectrophotometer equipped with a cesium bromide prism and a Nippon Bunko model DS-402G grating spectrophotometer were used.

Solid. — The highly-oriented, tabular crystals of TCNE were carefully prepared by the gradual heating of the purified solid up to about 140°C with a slight temperature gradient and at a pressure of 1~2 mmHg. The maximum size of these crystals was ca. 6×3 mm.; polarization microscopic examination was used to choose the best oriented crystal to be placed in the spectrophotometer beam. By X-ray diffraction studies, it was found that the solid TCNE prepared in the present work has the same crystal form as that (monoclinic crystals of the space group $P2_1/n$—C_{2h}^5) obtained by Bokoe and Trueblood[12] by recrystallization from a mixture of carbon tetrachloride and ethyl acetate, and that the crystals grew elongated along the b axis with the tabular ($\bar{1}01$) face.

Infrared polarization measurements for the crystal were made with silver chloride transmission polarizers, except in the far-infrared region, where transmission polarizers made of polyethylene sheets were used. The observed absorption spectra are shown in Fig. 1. The solid and broken lines represent the absorption curves obtained with polarized radiation, with the electric vector perpendicular to and parallel to the direction of crystal growth respectively. From Fig. 1, it may be seen that the absorption bands can be classified by their dichroic properties into three groups: (1) a group of bands which exhibit a high parallel dichroism ($\parallel$ band), (2) a group of bands which show nearly the same absorption intensities for both the parallel and perpendicular polarized radiations with a slight predominance of absorption intensity for the former · ($\parallel \perp$ band), and (3) a group of bands which exhibit perpendicular dichroism ($\perp$ band). The observed bands, their relative intensities, and their dichroic properties are listed in Table I. The infrared spectrum of the powdered solid was also recorded by the use of the potassium bromide disk and Nujol mull; this procedure showed the same frequencies and relative intensities as those in the spectrum of the crystal.

Solution. — The infrared spectra of TCNE were

also measured for the saturated solution in dichloromethane or dibromomethane by using various fixed-thickness cells (0.2~1.0 mm.). The solution spectrum over the region 4000~200 cm^{-1} could be obtained by using either of these solvents, thus avoiding the strong interference due to solvent absorptions. Because of the limited solubilities of TCNE in these solvents, however, only the absorption bands which correspond to the relatively intense bands in the solid spectrum were observed. The observed bands and their relative intensities are given in Table I.

Vapor.—The vapor spectrum in the region 4000~650 cm^{-1} was obtained by using a 10 cm. cell kept at ca. 200°C[13] by electric heaters. From Looney and Downing's data[2] the vapor pressure of TCNE was estimated to be more than 150 mmHg at this temperature. The spectrum obtained gave broad bands instead of fine structures due to the rotation of the molecule. The observed bands and their relative intensities are given in Table I, together with similar data for the corresponding bands of solid and solution. The correspondence of the bands among vapor, solution, and solid is fairly good as far as the comparison can be made indicating intermolecular forces in the solid phase are so weak that the intense bands of solid TCNE are correlated with the fundamental vibrational modes of the vapor molecules.

Raman Spectrum.—The Raman spectrum of solid TCNE was recorded photoelectrically by using a Cary model 81 spectrometer and photographically by using a Yuki Gosei model RL-II spectrometer. Several lumps of crystals prepared in the same way as those for the infrared polarization measurement were used as samples. The observed frequencies and their relative intensities are summarized in Table I. Attempts to determine the depolarization ratios by using the polarized incident-light technique were unsuccessful.

The Symmetry of Molecule and Selection Rule

According to X-ray analysis by Bekoe and Trueblood,[12] a TCNE molecule in crystal should have the site symmetry of C_i; in fact, slight difference is found between two C-C bond lengths of one wing of the molecule, and also between two bond angles formed by the two C-C bonds and the C=C bond (the C-C bond lengths: 1.454±0.007 Å and 1.443±0.006 Å; the C-C=C bond angles: 120.2° and 122.4°). However, it is reasonable to assume that the vibrational spectra of the crystal can virtually be treated under the molecular point group V_h for the following reasons: (1) The difference between the two C-C bond lengths, as well as that between the two C-C=C bond angles, is very small, as has been described above, and the planarity of the molecule is fairly

13) Since it was shown[11] that TCNE slowly evolves hydrogen cyanide when exposed to moist air even at room temperature, the gas cell was evacuated before heating, but weak bands due to hydrogen cyanide were still observed at ca. 3320 and 712 cm^{-1}.

TABLE II. SYMMETRY COORDINATES* FOR TETRACYANOETHYLENE

Species	Symmetry coordinate	Mode
A_g	$S_1=\Delta R$	C=C stretching
	$S_2=1/2(\Delta r_2+\Delta r_3+\Delta r_4+\Delta r_5)$	C-C stretching
	$S_3=1/2(\Delta l_6+\Delta l_7+\Delta l_8+\Delta l_9)$	C≡N stretching
	$S_4=1/\sqrt{3}\{(\Delta\alpha_0+\Delta\alpha_1)-1/2(\Delta\beta_2+\Delta\beta_3+\Delta\beta_4+\Delta\beta_5)\}$	C-C-C bending
	$S_5=1/2(\Delta\theta_6+\Delta\theta_7+\Delta\theta_8+\Delta\theta_9)$	C-C≡N bending
B_{1g}	$S_6=1/2(\Delta r_2-\Delta r_3+\Delta r_4-\Delta r_5)$	C-C stretching
	$S_7=1/2(\Delta l_6-\Delta l_7+\Delta l_8-\Delta l_9)$	C≡N stretching
	$S_8=1/2(\Delta\beta_2-\Delta\beta_3+\Delta\beta_4-\Delta\beta_5)$	C-C-C rocking
	$S_9=1/2(\Delta\theta_6-\Delta\theta_7+\Delta\theta_8-\Delta\theta_9)$	C-C≡N bending
B_{2u}	$S_{10}=1/2(\Delta r_2-\Delta r_3-\Delta r_4+\Delta r_5)$	C-C stretching
	$S_{11}=1/2(\Delta l_6-\Delta l_7-\Delta l_8+\Delta l_9)$	C≡N stretching
	$S_{12}=1/2(\Delta\beta_2-\Delta\beta_3-\Delta\beta_4+\Delta\beta_5)$	C-C-C rocking
	$S_{13}=1/2(\Delta\theta_6-\Delta\theta_7-\Delta\theta_8+\Delta\theta_9)$	C-C≡N bending
B_{3u}	$S_{14}=1/2(\Delta r_2+\Delta r_3-\Delta r_4-\Delta r_5)$	C-C stretching
	$S_{15}=1/2(\Delta l_6+\Delta l_7-\Delta l_8-\Delta l_9)$	C≡N stretching
	$S_{16}=1/\sqrt{3}\{(\Delta\alpha_0-\Delta\alpha_1)-1/2(\Delta\beta_2+\Delta\beta_3-\Delta\beta_4-\Delta\beta_5)\}$	C-C-C bending
	$S_{17}=1/2(\Delta\theta_6+\Delta\theta_7-\Delta\theta_8-\Delta\theta_9)$	C-C≡N bending

* Redundant coordinates are excluded.

good.[12] (2) The correspondence of the infrared bands among vapor, solution, and solid is fairly good. (3) The infrared bands of the crystal are classified into three groups according to their dichroic properties. Thus, the normal vibrations of TCNE divide into symmetry species as follows:

$$\Gamma = 5A_g(R) + 4B_{1g}(R) + 4B_{2u}(IR) + 4B_{3u}(IR) + 2A_u(\text{inactive}) + 2B_{1u}(IR) + 2B_{2g}(R) + B_{3g}(R)$$

where the first four are the in-plane vibrations, and the rest are the out-of-plane vibrations.

Normal Coordinate Treatment for In-plane Vibrations

The *GF* matrix method developed by Wilson[14] was used. A representative of each type of internal coordinate is shown in Fig. 2, while the symmetry coordinates are shown in Table II. The equilibrium bond lengths adopted are those determined from X-ray analysis by Bekoe and Trueblood:[12] $R_0=1.317$ Å, $r_0=1.449$ Å,[15] and $l_0=1.15$ Å. For the bond angles, $\alpha_0=\beta_0=120°$ and $\theta_0=180°$ were assumed for the sake of simplicity. In order to solve the secular equation, the symmetrization of the *GF* matrix was made according to the usual method.[16-18]

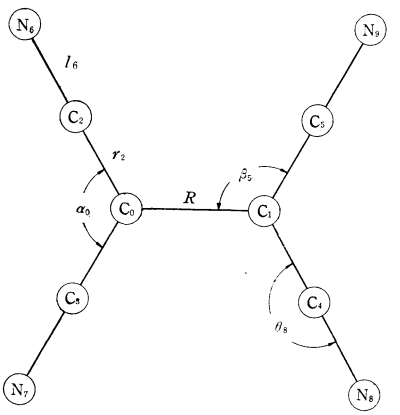

Fig. 2. Internal coordinates for tetracyanoethylene.

The numerical calculations were carried out by using the KDC-1 electronic digital computer constructed in the Faculty of Engineering of Kyoto University.

The basic UBFF[4,5] was used at first as the potential function for TCNE. Then, three bond-stretching (K(C=C), K(C-C), and K(C≡N)), three angle-bending (H(C-C-C), H(C-C=C), and H(C-C≡N)), and four non-bonded repulsion force constants (F(C-C-C), F(C-C=C), F(C-C≡N), and C) were necessary. The constants, C, represents the repulsion between two

carbon atoms in the cis-position.[9,19,20] Since Urey-Bradley force constants transferable to conjugated nitriles have not been reported, for the first calculation the force constants were assumed to have the values found for alkylnitriles,[21,22] tetrahalogenoethylenes,[20] and methyl-substituted ethylenes.[23] Repetitions of the calculation with several sets of force constants were then carried out by the trial-and-error method by the use of the Jacobian matrix.[24] The final set of force constants thus obtained is shown in Column I of Table III, and the frequencies calculated with these constants are compared in Column I of Table IV with the observed values. The agreement is satisfactory except in the case of the frequency 679 cm^{-1} (ν_3) of the A_g species.

In order to obtain a better agreement for this frequency, the basic UBFF was modified by introducing new cross terms between the C–C and C=C bonds to take the presumed resonance interaction into account. The modified potential function is written as:

$$2V_{\text{mod. UBFF}} = 2V_{\text{UBFF}} + 2\rho\sum_{i=2}^{5}(\Delta R)(\Delta r_i)$$

The new cross terms appear only on the A_g factor of the $\boldsymbol{F}$ matrix. Hence, by putting $\rho = 0.75$ mdyn./Å, $K(C{=}C) = 7.79$ mdyn./Å, and other constants equal to those of Set I, considerable improvements were made for the frequencies of the A_g species without any altration of the frequencies for other species. The

results are shown in Column II of Table III and Table IV. The additional introduction of cross terms between the C–C and C≡N bonds improved the situation little. Table V shows the potential energy distribution (for Set II) among the symmetry coordinates calculated from the expression:[25]

$$P_{tj}=L_{tj}^2F_{tt}/\sum_i L_{tj}^2F_{tt}$$

where L_{tj} denotes the element of the $\boldsymbol{L}$ matrix whose columns are the characteristic vectors of the $\boldsymbol{GF}$ matrix.

Vibrational Assignments

In-plane Fundamental Vibrations. — In view of the fact that, in the polarized infrared spectrum of the TCNE crystal, the two medium-strength bands observed at 2262 and 2230 cm^{-1} (due to the C≡N stretching modes) exhibit a ∥ ⊥ and a ∥ dichroism respectively, it is evident that one of the two species, B_{2u} and B_{3u}, should have one of these dichroic properties, and the remaining one, the other.

On the other hand, comparisons of the four C–X stretching frequencies on each tetrahalogenoethylene ($X_2C=CX_2$) belonging to the point group V_h always result in the sequence $\nu(B_{1g})>\nu(B_{2u})>\nu(B_{3u})>\nu(A_g)$,[20] as is shown in Table VI. Therefore, it is reasonable to

TABLE VI. C–X STRETCHING FREQUENCIES (cm^{-1}) OF $X_2C=CX_2$ MOLECULES (POINT GROUP V_h)

Species	X=F*	Cl*	Br*	CN Present work
A_g	778	447	265	679
B_{1g}	1340	1000	880	1284
B_{2u}	1337	908	766	1155
B_{3u}	1186	777	635	959

* Ref. 20.

assume that the four C–C stretching modes of TCNE should be arranged in the same sequence of frequencies. Thus, the two strong infrared bands at 1155(∥) and 959 cm^{-1}(∥ ⊥) are associated with the B_{2u} and B_{3u} C–C stretching modes respectively, while the two medium-strength Raman lines at 1284 and 679 cm^{-1} are associated with the corresponding B_{1g} and A_g modes respectively (Table VI). These assignments are confirmed by the present normal coordinate analysis. In each species, the potential energy of this vibration is predominantly associated with the C–C stretching mode, its magnitude depending upon the species. These assignments are different from those given by Long and George,[3] who attributed the two infrared bands at 1155 and 959 cm^{-1} to the B_{3u} and B_{2u} C–C stretching modes respectively, and the two Raman lines at 1250[26] and 1280 cm^{-1} to the corresponding B_{1g} and A_g modes respectively.

The assignments of the C–C stretching modes reveal that the infrared acitive species B_{2u} and B_{3u} should have a ∥ and a ∥ ⊥ dichroism respectively. Hence, the ∥ ⊥ band at 2262 cm^{-1} is assigned to the B_{3u} C≡N stretching mode, and the ∥ band at 2230 cm^{-1}, to the corresponding B_{2u} mode. Since the two strong Raman lines at 2250 and 2237 cm^{-1} (due to the C≡N stretching modes) have almost the same intensity, it is difficult to assign these lines to the respective species experimentally. Therefore, with the aid of the normal coordinate

25) Y. Morino and K. Kuchitsu, *J. Chem. Phys.*, **20**, 1809 (1952).

26) We could not find this Raman line in our spectrum even in careful measurements (see Table I).

	825	w	∥	$579(B_{3u})+251(B_{1g})=830(B_{2u})$
	804	m	⊥	$444(B_{3u})+360(B_{2g})=804(B_{1u})$
	696	w	∥	$444(B_{3u})+251(B_{1g})=695(B_{2u})$; $959(B_{3u})-251(B_{1g})=708(B_{2u})$
	675	w	∥ ⊥	$429(B_{2u})+251(B_{1g})=680(B_{3u})$
	444	w	∥ ⊥	$579(B_{3u})-122^*(A_g)=457(B_{3u})$

* Calculated value for ν_5 (see Table IV).

analysis, we attributed the former to the A_g mode and the latter to the B_{1g} mode.

The strongest Raman line, at 1573 cm^{-1}, is undoubtedly to be assigned C=C stretching mode (A_g). In fact, the potential energy of this vibration is primarily associated with the C=C stretching mode (78%), although the contributions of the C–C stretching (13%) and C–C–C bending modes (8%) are appreciable.

A strong infrared band at 579 cm^{-1} and a medium-strength one at 429 cm^{-1} exhibit ∥ ⊥ and ∥ dichroisms and are assigned to the B_{3u} and B_{2u} vibrations respectively. As Table V shows, the band at 579 cm^{-1} (calculated as 591 cm^{-1}) is due to the hybridized mode of the C–C–C bending (57%), C–C≡N bending (22%), and C–C stretching modes (17%). The band at 429 cm^{-1} (calculated as 433 cm^{-1}) is also due to the hybridized mode of the C–C–C rocking (51%)[27] and C–C≡N bending mode (49%). In the region 600∼500 cm^{-1} of the Raman spectrum, three very weak lines are observed at 592, 536 and 508 cm^{-1}. Of these Raman lines, the most intense one, at 536 cm^{-1} (calculated as 530 cm^{-1}), is attributed to the A_g mode involving the C–C–C bending (63%)[28] and C–C≡C bending modes (30%). The line at 508 cm^{-1} (calculated as 503 cm^{-1}) is attributed to the B_{1g} mode involving the C–C–C rocking (49%), C–C≡N bending (20%), and C–C stretching modes (26%). The assignment of the remaining line, at 592 cm^{-1}, will be discussed later.

A weak Raman line at 251 cm^{-1} is assigned to the lowest B_{1g} vibration. The potential energy of this vibration is associated with the C–C≡N bending (85%) and C–C–C rocking modes (13%). The Raman line assigned to the lowest A_g vibration (calculated as 122 cm^{-1}) and two infrared bands assigned to the lowest B_{2u} and B_{3u} vibrations (calculated as 111 and 157 cm^{-1} respectively) could not be observed, because their frequencies are lower than the 200 cm^{-1} limit of the present work. In each species, the potential energy of this vibration of associated predominantly with the C–C≡N bending mode but also partly with the C–C–C bending (or rocking) mode, the distribution of the energy between these two modes depending upon the species.

Out-of-plane Fundamental Vibrations.—Since the B_{2u} and B_{3u} species have been shown to have ∥ and ∥ ⊥ dichroisms, respectively it is apparent that the out-of-plane vibrations of the B_{1u} species give rise to ⊥ bands in the infrared spectrum. For this reason, and also because of its reasonable frequency, the strong infrared band at 555 cm^{-1} (⊥) is assigned to the B_{1u} C–C–C wagging mode. By using a frequency correlation with this mode, the very weak Raman line at 592 cm^{-1} is assigned to

27) Long and George gave a 715 cm^{-1} (medium-strength) infrared band in Table 6 of their paper,[3] and assigned it to the B_{2u} C–C–C rocking mode. This band, however, could be identified neither in their own spectrogram (Fig. 3 of Ref. 3) nor in that obtained by Looney and Downing (Fig. 1 of Ref. 2). No band was observed at this frequency in our spectrum either (see Fig. 1 and Table I).

28) Long and George[3] assigned the Raman line at 678 cm^{-1} to the A_g C–C–C bending mode. In the present work, however, this line (679 cm^{-1}) was attributed to the A_g C–C stretching mode as mentioned above.

the corresponding B_{2g} mode.

In the region 400~300 cm^{-1} of the Raman spectrum, a pair of very weak lines are observed at 370 and 360 cm^{-1}. Each of these lines may be associated with one of the B_{2g} and B_{3g} C–C≡N (out-of-plane) bending modes, because these correlate well with the corresponding modes of malononitrile, which have been observed at 371 and 337 cm^{-1}.[22] Here, the line at 370 cm^{-1} is tentatively assigned to the B_{3g} mode, and the line at 360 cm^{-1}, to the B_{2g} mode, in consideration of the assignments for combination vibrations mentioned below. No infrared ⊥ band to be assigned to the B_{1u} C–C≡N (out-of-plane) bending mode was observed in the region higher than 200 cm^{-1}. The results obtained for the out-of-plane fundamental vibrations are summarized in Table VII.

TABLE VII. ASSIGNMENTS OF OBSERVED BANDS (LINES) DUE TO OUT-OF-PLANE FUNDAMENTAL VIBRATIONS OF TETRACYANOETHYLENE

	Freq. cm^{-1}	Intensity	Assignment
Infrared band	555 (⊥)	s	C-C-C wagging (B_{1u})
	—		C-C≡N bending (B_{1u})
Raman line	592	vw	C-C-C wagging (B_{2g})
	360	vw	C-C≡N bending (B_{2g})
	370	vw	C-C≡N bending (B_{3g})

Overtone and Combination Vibrations.—Besides the bands (lines) assigned to the fundamental vibrations, there remain three weak Raman lines and a number of infrared bands, including five medium-strength ones, which are attributable to the overtone or combination vibrations. According to the selection rule, these Raman lines and infrared bands were assigned as is shown in Table VIII. It may be noticed that all the Raman lines are exclusively associated with the A_g mode. Since the A_u frequencies have not yet been established, the overtones and combinations involving the A_u vibrations were not considered. Nevertheless, for each of the observed frequencies, one or two possible assignments were found, and the agreement between the calculated and observed values is satisfactory, as Table VIII shows.

Summary

The polarized infrared spectrum of a highly-oriented crystal of TCNE have been measured, tegether with the Raman spectrum of a sample consisting of several lumps of the crystals. The infrared spectra of the powedered solid, solution, and vapor have also been observed for comparison. Under the assumption of the V_h symmetry, the normal vibrations of TCNE have been calculated for the in-plane modes by the use of the ***GF*** matrix method. The basic UBFF, as well as the modified one containing cross terms between the C=C and C–C bonds, has been used as the potential function for this molecule. The frequencies calculated with the modified UBFF agree well with the observed values. The potential energy distributions have also been calculated, and the nature of the in-plane fundamental vibrations has been elucidated. The tentative assignments have been made to the out-of-plane fundamental vibrations and to the overtone and combination vibrations.

The authors wish to express their gratitude to Professor Rempei Gotoh for his continuing interest and encouragement during the course of this work. Thanks are also due to Dr. Katsunosuke Machida of Kyoto University for his helpful discussions, to Dr. Kenichi Kudo of Sumitomo Atomic Energy Industries, Ltd., for supplying the TCNE, to Dr. Tatsuo Miyazawa of Osaka University for giving the chance to use the Perkin-Elmer model 221 spectrophotometer, and to Dr. Yoshiki Matsui of Shionogi and Co., Ltd., and Miss Michiko Matsushima of the Government Chemical Industrial Research Institute of Tokyo for measuring the Raman spectra of TCNE.

Calculation of the State Energies of Benzaldehyde. I. Semi-Empirical Molecular Orbital Method

By Kōzō INUZUKA and Toshio YOKOTA

(Received March 9, 1964)

Experimental and theoretical studies of the electronic structures of organic molecules have been made by many authors. In particular, the benzene molecule, a representative aromatic compound, has been investigated thoroughly. Studies now extend to the electronic structures of the derivatives of benzene. Benzaldehyde is an example of these derivatives. The ultraviolet absorption measurement of benzaldehyde at longer wavelengths (n-π transition) has been carried out by Imanishi et. al.[1] The theoretical assignment of the absorption bands at shorter wavelengths (π-π transition) has been made by Tanaka.[2] Recently, the phosphorescence and the S–T absorption spectra of benzaldehyde were measured by Kanda.[3]

For benzaldehyde there are experimental data concerning the singlet and triplet states, which can be compared with the results of the theoretical calculation. In spite of these experimental studies, however, there are few theoretical considerations of its electronic structure.

The semi-empirical molecular orbital method proposed by Pariser and Parr[4] succeeded in the calculation of the π, π state energies and was extended to that of the n, π state energies by Anno et al.[5,6] In this article, the calculation of the state energies of benzaldehyde will be carried out by the use of the semi-empirical molecular orbital method.

Calculation Procedure

Conventional Hückel Type LCAO MO's.—In the calculation of electronic state energies of benzaldehyde, we adopted the molecular structure model shown in Fig. 1. In actual benzaldehyde, which belongs to the C_s-symmetry group, all electronic transitions are allowed. Therefore, if we take account of the C_s symmetry we must solve an 8th-order seqular equation. Calculations then become more complex and tedious. In the present calculations we assume a simplified model with the C_{2v} symmetry for the structure of the benzaldehyde molecule and use Hückel type MO's.

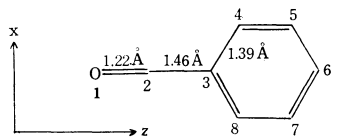

Fig. 1. The C_{2v} model* of benzaldehyde
* The bond distances were estimated from the calculated bond order and the experimental data for carbonyl compounds.

The Coulomb integral, α_1, of the oxygen atom and the resonance integral, β_{12}, between the carbon atom, 2, and the oxygen atom, 1, are expressed as:

$$\alpha_1 = \alpha + \delta_1 \cdot \beta$$

$$\beta_{12} = \rho_{12} \cdot \beta$$

where α is the Coulomb integral of the carbon atom and β is the resonance integral over the neighboring carbon atoms in benzene. The resonance integral, β_{23}, between the benzene ring and the carbonyl group is given by the usual approximation:

$$\beta_{23} = (S_{23}/S)\beta$$

where S_{23} is the overlap integral between the carbon atoms 2 and 3, and S the overlap integral of the neighboring carbon atoms in benzene. In the present calculations, the numerical values of the parameters δ_1 and ρ_{12} and the S_{23}/S ratio are chosen as follows:

$$\delta_1 = 1.5, \qquad \rho_{12} = \sqrt{2}, \qquad S_{23}/S = 0.894$$

The results of the calculations for Hückel MO's and their energies are listed in Table I, where χ_i is the $2p\pi$AO of the ith-atom.

In addition to the above MO's, the benzaldehyde molecule has a nonbonding orbital which can be represented approximately as follows:

$$\varphi_n = \chi_n$$

where χ_n is the $2p\pi$ AO of the oxygen atom. Its nodal plane is perpendicular to the molecular plane and contains the CO axis. Therefore, the symmetry of χ_n is b_1.

State Energies without Configuration Interaction.—In order to calculate the state energies of benzaldehyde by the methods proposed by Pariser and Parr[4] and by Anno et al[5,6] we need the values of the core integrals and the electronic repulsion integrals. The problem of obtaining these values

1) S. Imanishi, K. Semba, M. Ito and T. Anno, This Bulletin, 25, 150 (1952).

is reduced to the calculation of Coulomb repulsion integrals over atomic orbitals, Coulomb integrals, α_p, and resonance integrals, β_{pq}. The values of Coulomb repulsion integrals are evaluated by the use of the equation derived by Roothaan and by Anno et al.[5] in the case of $r>2.80$ Å and $r\leqq 2.80$ Å respectively. The value of the resonance integral β_{CC} over carbon and oxygen atoms is calculated by

the use of Kon's formula,[8] while the value of β_{CC} over carbon atoms is obtained by Pariser and Parr's formula.[4] The Coulomb penetration integrals, which are needed to evaluate the Coulomb integrals, α_p, are estimated approximately by taking account of the integrals over only the nearest neighboring atoms. The π electronic states belong to the irreducible representations, A_1 and B_1, of the symmetry group C_{2v}. Electronic transitions from the ground state, A_1, to the excited A_1 and B_1 states will have a transitions moment directed along the z axis and the x axis respectively. In the n-π excitation, there are two symmetry types, A_2 and B_2, since the symmetry of the n orbital is b_1. Type A_2 is forbidden, but type B_2 is allowed. The transition moment is perpendicular to the molecular plane; that is, it is parallel to the y axis. This conclusion comes from the assumption of C_{2v} symmetry. In actual benzaldehyde, which has a C_s symmetry, the n-π transition of the A_2 type will also be allowed. In Table II we show all the energies of the n-π and π-π transitions within the range of about 10 eV. These energies are in poor agreement with the experimental values.

State Energies with Configuration Interaction.— Configuration mixing with respect to the π-π transition leads to an 11th-order seqular equation for the $^1A_1$ singlet state, a 10th-order equation for the $^3A_1$ triplet state, and two 6th-order equations for the $^1B_1$ and $^3B_1$ states respectively. As configurations of remarkably higher energies have a negligible effect on lower-lying states, we need consider only the configurations listed in Table II. In the present calculations of the π-π transition, we solve a 7th-order seqular equation for the $^1A_1$ state and a 6th-order equation for the $^3A_1$ state. In the case of n-π transition, configuration mixing leads to two 3rd-order seqular equations, for $^1A_2$ and $^3A_2$ respectivly. The solution of these seqular equations leads to a set of state energies and wave functions. These results are listed in Tables III and IV. The ground state energy is lowered by 0.168 eV.

From a comparison with Tables II and IV, it may be seen that the effect of the configuration interaction for the states separated by a small energy is large and that it is important for complex molecules.

Discussion

Benzaldehyde has four absorption bands in the region from 400 to 190 mμ. An absorption band on the longer wavelength side of this region was measured by Imanishi et al.[1] They assigned this band to an n-π transition and observed that the 0-0 band of the n-π transition is at 26,929 cm^{-1}. The energy, 3.614 eV. in Table IV, which is the $^1A_1$-$^1A_2$ transition energy, may correspond to the above n-π transition. In the present calculations, this transition is forbidden because of the assumption of the C_{2v} symmetry, but it is allowed in the actual molecule, with a symmetry C_s. The observed oscillator strength of this transition is 0.55×10^{-3}.[3]

Three absorption bands are observed in the region from 300 to 190 mμ. These are assigned to π-π transitions. The band at 285 mμ (4.50 eV.) is the weakest of them; it may correspond to the energy 5.333 ev. in Table IV, although the calculated value is larger than the observed value. Therefore, this band at 285 mμ is assigned to the $^1A_1$-$^1B_1$ transition. The next stronger band is at 233 mμ (5.32 eV.)[2]; this may be correlated with the energy 5.567 eV. in Table IV and is assigned to the $^1A_1$-$^1A_1$ transition. The strongest band is at 195 mμ (6.36 eV.);[9,10] it may be assigned to the $^1A_1$-$^1A_1$ transition (6.658 eV.). In the above assignments, the theoretically-calculated values of the oscillator strengths of these π, π bands are in poor agreement with the results of the experiments.

According to the experiment of Kanda,[3] the

10) H. B. Klevens and J. R. Platt, Technical Report, Laboratory of Molecular Structure and Spectra," (1953-1954).

S–T absoption spectrum appears at 25,195 cm^{-1} (3.22 eV.), and its oscillator strength is 1.8×10^{-1}. In Table IV this may be related to the energy 3.124 eV. of the n, π triplet state. Therefore, the above band may be assigned to $^1A_1$–$^3A_2$ transition.

The exsistence of π, π triplet states has not yet been confirmed experimentally, but in the present calculations three lower-lying π, π triplet states are obtained. The energies of these triplet states are about 4 ev; they are also listed in Table IV. These values seem reasonable judging from an average S–T separation for the π-π transition.[11]

The charge densities for the ground and two excited states are shown in Fig. 2. In the ground state, the charge density of the meta position is higher than those of the ortho- and para-positions. This is consistent with the tendency toward a meta orientation of the carbonyl group for electrophylic reagents. Similarly, from Fig. 2 it may be seen that the $^1B_1$ state has a tendency toward a para orientation and that the 1st $^1A_1$ excited state has a tendency toward meta and ortho orientations. Tanaka[2] pointed out that the transition from the ground state to the 1st $^1A_1$ excited state is attended with the migration of electrons from the benzene ring to the carbonyl group, and he assigned it to the charge transfer band. A similar phenomenon is seen in Fig. 2. The charge density on the carbonyl group becomes larger in the 1st $^1A_1$ excited state than in the ground state. This is in agreement with Tanaka's assignment. The calculation of charge density is very sensitive to the wave function used. Therefore, it is better to calculate it by the use of SCF MO's under a C_s symmetry than by the use of Hückel MO's assuming a C_{2v} symmetry. The results of such improved calculations[12] will be reported in the near future.

(III) in the 1st excited $^1A_1$ state.

Summary

The electronic structure and the nature of the electronic transitions in the benzaldehyde molecule have been elucidated by the use of a semi-empirical MO method assuming a C_{2v} symmetry. The results of the calculations conform to the observed values for the singlet and triplet states in spite of the use of a crude approximation. In benzaldehyde, it has been found that the n, π triplet state is the lowest. The charge transfer band may be explained by means of our calculations.

The authors wish to express their thanks to Mr. Masuo Suzuki and Dr. Toshinori Munakata for their kind assistance in carrying out the digital computations. They also wish to express their gratitude to Professor Yoshiya Kanda of Kyushu University, who had the kindness to send them his experimental data. NOTES

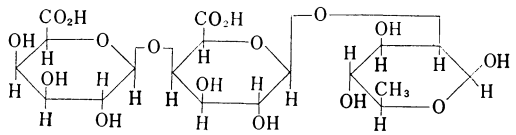
Studies of the Mucilage of the Root of "Tororo-aoi" (Abelmoschus manihot, MEDIC). IV.[1] *An Aldotriouronic Acid Isolated from the Mucilage*

By Saburo INOKAWA, Ryozo GOTO, Toshiro BAN, Takane UCHIDA and Kiyoaki WAKAIZUMI

(Received March 2, 1964)



There have been many studies[2] of the mucilage of "Tororo-aoi" (*Abelmoschus manihot*, MEDIC), and the purified mucilage has been found to be composed of rhamnose and galacturonic acid, but the chemical structure of the mucilage has not yet been clarified in detail.

Oshibuchi[3] has suggested the presence of an aldotriouronic acid (rhamno-di-galacturonic acid) in the hydrolysate of the mucilage. In the present paper, the chemical structure of this aldotriouronic acid will be determined.

Hydrolysis of the mucilage with 4 percent sulfuric acid, followed by the precipitation of the neutralized hydrolysate with ethanol, gave a mixture of barium salts, from which an aldotriouronic acid was isolated as white crystals $[\alpha]_D^{13}$ +74° (*c* 1, water) by de-ionizing the mixture with ion-exchange resins and using cellulose column chromatography. The aldotriouronic acid was found to be composed of rhamnose and galacturonic acid by hydrolysis and paper chromatography. The equivalent weight of the aldotriouronic acid, as determined by titration with alkali, was 260, which shows that the aldotriouronic acid consists of rhamnose and galacturonic acid in a mole ratio of 1 : 2.

The aldotriouronic acid was converted into a neutral trisaccharide by the reduction of the methyl ester of the methyl glycoside with sodium borohydride. The methylation of the trisaccharide gave a derivative which, on acid hydrolysis, gave 2, 3, 4, 6-tetra-*O*-methylgalactose, 2, 3, 6-tri-*O*-methylgalactose, and 3, 4-di-*O*-methylrhamnose.

The structure of the aldotriouronic acid is, therefore, determined to be *O*-α-D-galacturonosyl-(1→4)-*O*-α-D-galacturonosyl-(1→2)-*O*-L-rhamnose, the anomeric configuration of which is supposed from the optical rotation:

Experimental

Paper-partition chromatography was carried out with the upper layer of butanol - acetic acid - water (4 : 1 : 5). Paper ionophoresis was carried out in a 0.2 M borate buffer at pH 10. R_{gal} and R_G (or M_G) values are proportional to the rates of the migration of galactose and 2, 3, 4, 6-tetra-*O*-methylglucose respectively. The *R* values observed were compared with those of authentic samples.

The Preparation of Purified Mucilage.—After the roots of "Tororo-aoi" had been ground and soaked in distilled water for 2 days at 0°C, the mucilage was filtered through a cotton cloth. The crude mucilage was then homogenized with a mixer, filtered through a cellite-bed, and precipitated with ethanol-ether (8 : 2), and the precipitate was redissolved in water, re-precipitated with ethanol, washed with absolute ethanol and dry ether, and dried in vacuum.

The Partial Hydrolysis of Purified Mucilage with Dilute Sulfuric Acid.—Dry purified mucilage (10 g.) was heated in 4 percent sulfuric acid 100°C for 11 hr. The filtered solution was neutralized with barium carbonate and then filtered, and the filtrate was concentrated under reduced pressure to a light syrup (100 ml.), which was then stirred into ethanol (400 ml.). The precipitate was washed thoroughly with 80 percent ethanol, absolute ethanol, and dry ether, and dried in a vacuum. The precipitate was redissolved in water (100 ml.) and the solution was poured into ethanol (400 ml.), washed, and dried similarly to give a white powder

(4.1 g.). On a paper chromatogram after having been de-ionized with IR-120 resin, the product gave two spots, namely, galactose and R_{gal} 0.32.

The Isolation of Aldotriouronic Acid. — The white powder (2 g.) described above was de-ionized with IR-120 resin, and a portion corresponding to R_{gal} 0.32 was separated on a cellulose column (5× 40 cm.) with butanol - acetic acid - water (12 : 3 : 5) to give white crystals (0.40 g.), $[\alpha]_D^{13}$ +74° (*c* 1, water). On titration with a 0.005 N sodium hydroxide solution, the equivalent weight of the material was 260 (calc. for rhamno-di-galacturonic acid; 258). The crystals were then completely hydrolysed with 2 N sulfuric acid in a sealed tube at 100°C for 24 hr. The neutralized solution, de-ionized with IR-120 resin, gave rhamnose and galacturonic acid on a paper chromatogram.

The Identification of the Aldotriouronic Acid. —The aldotriouronic acid (300 mg.) was refluxed with 1.8 percent methanolic hydrogen chloride (50 ml.) for 7 hr., neutralized with silver carbonate, and filtered. The filtrate was evaporated to dryness, the residue dissolved in water (6 ml.), and the solution added slowly to a solution of sodium borohydride (200 mg.) in water (3 ml.). After 2 hr., the excess borohydride was destroyed by adding dilute acetic acid, and the solution was de-ionized with IR-120 and IR-45 resins and evaporated under reduced pressure to dryness to give white prisms (120 mg.), $[\alpha]_D^{13}$ +2° (*c* 1, water). The crystals were completely hydrolysed, and the neutralized solution gave only rhamnose and galactose on a paper chromatogram.

The crystals were methylated three times with methyl sulfate and sodium hydroxide, and, after the extraction of the acidified mixture with chloroform, the product was further methylated three times with methyl iodide and silver oxide to give a pale yellow oil (100 mg.).

The oil was hydrolysed with N sulfuric acid (10 ml.) at 100°C for 18 hr. in a sealed tube. The hydrolysate was neutralized with barium carbonate and extracted with chloroform. The chloroform solution was evaporated to give a syrup (30 mg.) which gave an intensive spot (R_G 0.89) and a faint spot (R_G 0.74) on a paper chromatogram. The aqueous residual solution was de-ionized with IR-120 resin and evaporated to give a syrup (10 mg.) which gave an intensive spot (R_G 0.74), a faint spot (R_G 0.89), and a very faint spot (R_G 0.58) on a paper chromatogram. The spots at R_G 0.74 and 0.58 corresponded to 2,3,6-tri-*O*-methylgalactose and 4-*O*-methylrhamnose respectively. The spot at R_G 0.89, by paper ionophoresis,[4] was separated into two spots, $M_G \fallingdotseq 0$ and M_G 0.39, which corresponded to 2,3,4,6-tetra-*O*-methylgalactose and 3,4-di-*O*-methylrhamnose, respectively.

This work was partially supported by a grant from the Hattori Hokokai, to which the authors' thanks are due.

Thermal Effects on the Lattices of η- and γ-Aluminum Oxide

By Hiroaki YANAGIDA and Goro YAMAGUCHI

(Received April 13, 1964)

In a previous paper,[1] the present authors found that the lattice dimensions and the tetragonal axial ratio of γ-aluminum oxide vary with hydrothermal and heat treatments and proposed that η-aluminum oxide may be an end-member of the γ-aluminum oxide series with little tetragonal deformation. In the present paper, the lattice dimensions of η- and γ-aluminum oxide will be measured with a high temperature X-ray diffraction apparatus at various temperatures and after various heat treatments in order to discuss further the relation between η- and γ-aluminum oxide.

The γ-aluminum oxide examined had a tetragonal axial ratio of 1.0357 and was obtained from a hydrothermal treatment, at 500°C under 50 atm. for 20 hr., of γ-aluminum oxide which had been formed from the dehydration

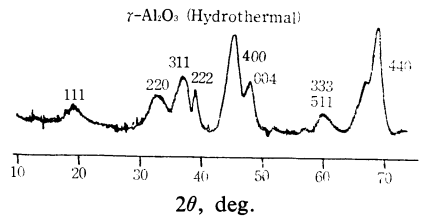

Fig. 1 The X-ray diffraction diagram of γ-Al_2O_3(hydrothermal), Cu$K\alpha$ ray.

1) G. Yamaguchi and H. Yanagida, This Bulletin, 35, 1896 (1962).

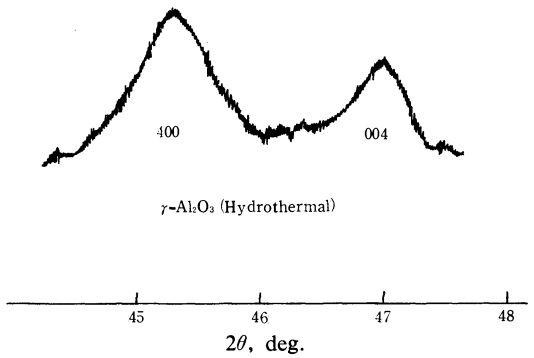

Fig. 2. The slow-scanning X-ray diffraction pattern of γ-Al_2O_3 about the (400) peak in the spinel indices; Cu$K\alpha$, 35kV., 12 amp. 1°1° 0.2 mm. slit system; rate meter 8; time constant 4 sec.; scanning speed 1°/4 min. Geigerflex.

of well-crystallized boehmite AlOOH in air at 700°C. The X-ray diffraction diagram is shown in Fig. 1, while the slow-scanning pattern about the (400) peak in the spinel indices is in Fig. 2. This specimen contained 7.5% water at 150°C. Another γ-aluminum oxide with the axial ratio of 1.0183 was also examined; it contained 3.5% water at 150°C.

The η-aluminum oxide with little tetragonal deformation was obtained from the dehydration, at 700°C in air, of bayerite $Al(OH)_3$ which had been formed by the neutralization of an aqueous solution of aluminum chloride by ammonia. The (400) peak of this specimen is hardly split at all. This had 3.8% water at 150°C.

The curves plotting the heating temperatures versus the lattice dimensions of η-aluminum oxide and γ-aluminum oxide are shown in Tables I and II and in Figs. 3 and 4. The curve for η-alumnum oxide is reversible whereas that for γ-aluminium oxide is not reversible. The lattice dimensions of γ-aluminum oxide decrease, and, at the same time, the degree of tetragonal deformation is lowered through the heat treatments numbered 5—9 in Table I and in Fig. 3. The axial ratios decreased 1.0357 to 1.0332 and 1.0183 to 1.0158. Curves plotting the heating temperatures versus the amount of water in or on the aluminas are shown in Fig. 5, in which the axial ratios of the starting γ-aluminum

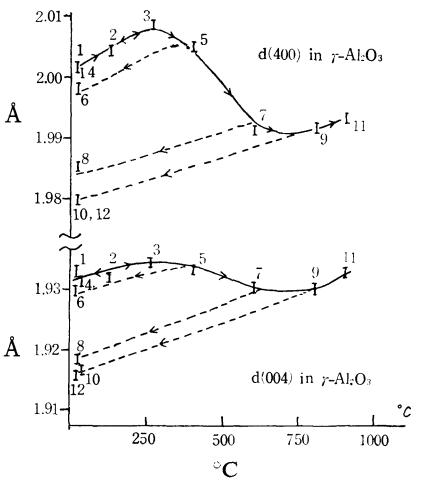

Fig. 3. The lattice dimension of γ-Al_2O_3 measured with a high temperature X-ray diffraction apparatus; Cu$K\alpha$, 35kV., 15 amp.; 1°1° 0.2 mm. slit system; rate meter 8; time constant 4 sec.; scanning speed 1°/4 min. Geigerflex.

oxide are also indicated. We can see the loss of water from the aluminas take place through the heat treatments. The changes in the lattice dimensions and the tetragonal axial ratio are accompanied by the loss of water from the γ-aluminum oxide, while the loss of water from the η-aluminum oxide does not cause those changes.

These results lead us to consider that a certain type of water should be present in the lattice of γ-aluminum oxide with considerable tetragonal deformation, especially in such a hydrothermal substance,[1] but the water of this type is not there in the lattice of η-aluminum oxide as an end-member of the γ-aluminum oxide series with little tetragonal deformation. Unfortunately, we cannot discuss the type of water and the relation between the amount of this water and the axial ratio in the present work. We will try to clarify the relation in a later paper.

A New Reagent for the p-Nitrophenylation of Carboxylic Acids

By Shumpei SAKAKIBARA and Noriyoshi INUKAI*

(Received May 2, 1964)

The *p*-nitrophenylester of acylamino acid is well known to be a convenient intermediate in peptide synthesis. Bodanszky[1] originally prepared this compound by heating a mixture of *p*-nitrophenol and carbobenzoxy amino acid chloride or mixed anhydride. Since then, Schwyzer et al.[2] have developed two new reagents, di-*p*-nitrophenyl sulfite and tri-*p*-nitrophenyl phosphite, for the *p*-nitrophenylation of carbobenzoxy amino acid. Later, Bodanszky and du Vigneaud[3] prepared the same *p*-nitrophenylesters by using dicyclohexylcarbodiimide as a coupling reagent.

In the present study, it was found that *p*-nitrophenyl trifluoroacetate (I) was a useful reagent for the same purpose. A solution of trifluoroacetic anhydride (62 g., 0.3 mol.) and *p*-nitrophenol (28 g., 0.2 mol.) in dry benzene

Soc.*, **81**, 5688 (1959). e) M. Bodanszky and V. du Vigneaud, ibid., **81**, 6072 (1959). f) The reaction was carried out for two hours at room temperature. g) Found: C, 55.88; H, 4.36; N, 10.61. Calcd. for $C_{18}H_{17}N_3O_7$: C, 55.81; H, 4.42; N, 10.85%. h) The reaction was carried out by refluxing the pyridine solution for about 10 min.

(Z: Carbobenzoxy; PNP: *p*-nitrophenyl; DMF: dimethyl formamide)

(60 ml.) was refluxed for about 5 hr., and then the solution was concentrated to dryness; the yield of crystalline product I was quantitative (m. p. 37～39°C). This product was used without further purification in the following reactions. A part of the product was subjected to sublimation in vacuo for analysis; m. p. 36～38°. Found: C, 41.11; H, 1.89. Calcd. for $C_8H_4O_4NF_3$: C, 40.86; H, 1.71%. A solution of a carboxylic acid such as carbobenzoxy amino acid (0.005 mol.) in dry pyridine (1.5～3 ml.) was treated with I (0.005 mol.) at room temperature. After about 10 min., water (20 ml.) was added to the reaction mixture to precipitate the resulting *p*-nitrophenylester of the carboxylic acid as crystals. The product was collected by filtration and then recrystallized from a suitable solvent system. The yields and physical constants of the reaction products are listed in Table I. In contrast with this, it was confirmed that the mono-, di- or trichloroacetic acid *p*-nitrophenylester was only reactive with carbobenzoxy amino acids in boiling pyridine, and gave poor yields of the desired products, together with colored by-products.

In carbobenzoxy peptides, however, the ester-exchange reaction of I was slower than that in carbobenzoxy amino acids. In these cases, the heating of the reaction mixture or the prolongation of the reaction time at room temperature was necessary in order to complete the reaction, and the racemization of the *C*-terminal amino acid residues might occur to some extent during the reaction. The advantages of the new method over the Schwyzer method[2] are as follows: 1) Since the reaction occurred within 10 min. at room temperature (with acylamino acids), such undesirable side-reactions as racemization were few. 2) The only co-product of the reaction was trifluoroacetic acid, which can easily be removed from the reaction mixture. Therefore, the product could easily be purified.

A Polarographic Study of the Tetracyanomono(ethylenediamine)-cobaltate(III) Complex

By Nobufumi MAKI and Kuwako OKAWA*

(Received May 7, 1964)

Previously, the $[Co^{III}(CN)_4(SO_3)_2]^{5-}$ ion (probably the trans-form) was found to be reduced in one step to the cobaltate(I) complex in a sulfite medium at the dropping mercury electrode (DME).[1]

In the present report, the tetracyanomono(ethylenediamine)cobaltate(III) complex, K-$[Co^{III}(CN)_4\ en]\cdot H_2O$ (cis-form)[2], will be found to be reduced irreversibly to the metal through the cobaltate(I) complex in a 0.5 M sodium sulfate solution containing 2 M ethylenediamine.

More specifically, the $[Co^{III}(CN)_4\ en]^-$ ion gave rise to well-defined two-step waves at the DME. The ratio of the height of the first wave to that of the second was roughly 2 : 1. The first wave, corresponding to an acceptance of two electrons, represents the reduction from the cobalt(III) to the cobalt(I) state, while the second, corresponding to a gain of one electron, represents the reduction to the metal.

The limiting current of both waves was proportional to the concentration of the complex in the range between 10^{-2} and 10^{-4} F and was diffusion-controlled.

In the absence of excess ethylenediamine, the wave of apparently one step, corresponding to a three-electron reduction, was obtained.

Figure 1 shows the d.c. polarograms for this complex in the presence or in the absence of excess ethylenediamine. For the sake of comparison, the wave of the two electron-reduction of the dicyanobis(dimethylglyoximato)cobaltate(III) complex, whose resulting cobaltate(I) complex was ascertained by isolation in vacuo[3] is also shown. It can be seen that the wave-height is roughly proportional to the electron-number of the reduction process.

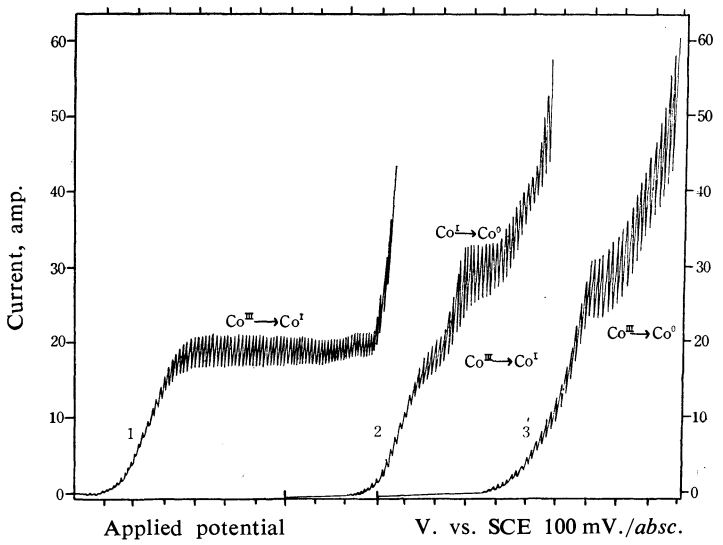

Fig. 1. D. C. polarograms of cyano-cobaltate(III) complexes obtained at the concentration of $5\cdot10^{-3}$F/1(25°C).

TABLE I. HALF-WAVE POTENTIALS OF THE CYANO-COBALT(III) COMPLEXES (25°C)

Compund	$E_{1/2}$ of 1st wave Co(III) → Co(I)	$E_{1/2}$ of 2nd wave Co(I) → Co(0)	Supporting electrolyte
$Na[Co(CN)_4\ en]\cdot 3.5\ H_2O$	-1.36_4	-1.51	0.5 F Na_2SO_4+2 M en 0.0078% Triton X 100*
$Na_5[Co(CN)_4(SO_3)_2]$	-1.36	No reduction	0.5 F Na_2SO_3
$K_4[Co(CN)_5SO_3]\cdot 2\ H_2O$	-1.53_5	No reduction	1 F KCl

* Triton X 100=Alkyl-aryl-polyether alcohol (Rohm & Haas Inc.)
Voltage unit : volt vs. SCE. Concentration of the complex : $5\cdot 10^{-3}$ F/l

These overall processes of the electrode reaction are considered to be most plausible:

$$[Co^{III}(CN)_4\ en]^- \xrightarrow{e} [Co^{II}(CN)_4\ en]^{2-} \xrightarrow[(A)]{e} [Co^{I}(CN)_4\ en]^{3-}$$

$$[Co^{II}(CN)_4(OH_2)_2]^{2-},\ \text{etc.} \xleftarrow{(B)} [Co^{II}(CN)_4\ en]^{2-}$$

$$[Co^{I}(CN)_4\ en]^{3-} \xrightarrow{e} [Co^{0}(CN)_4]^{4-} \xrightarrow{2e} \text{Co(metal)}$$

(aquated species)

The reaction takes place in two ways. When the aquation of the cobalt(II) ion is prevented, the reaction proceeds mainly along path A rather than along path B. Otherwise, the aquated cobalt(II) ions would all be reduced to the metal directly, not through the cobalt(I) state.

Therefore, the resulting cobalt(I) complex was presumed to have the hexacoordinate formula, $[Co^{I}(CN)_4\ en]^{3-}$, in solution, judging from the properties of the other tetracyano complexes.[1,4]

This is the first time that the type of polarographic reduction Co(III)→Co(I)→Co(0) has been observed for the cobalt(III) complexes.

Electrical Conductivity of α, α'-Diphenyl-β-picrylhydrazyl under High Pressure

By Hiroo INOKUCHI, Ichimin SHIROTANI and Shigeru MINOMURA

(Received May 26, 1964)

Recently, several examinations of the effect of pressure on such molecular crystals as polycyclic aromatic compounds, have been reported.[1,2,3] As a function of the intermolecular distance, in this article we will present the effect of pressure on the electrical conductivity of the organic free radical, α, α'-diphenyl-β-picrylhydrazyl (DPPH), and also on that of some polycyclic aromatic compounds.

The electrical resistance cell employed consisted of a cylinder and two opposed pistons of Carboloy, with truncated cone ends and press-fitted in hard-steel outer jackets. The specimen (1.2 mm. in diameter and 0.08 mm. thick), encased in a pellet of pyrophyllite, was compressed between the flat centre sections of the pistons.[4] The piston was electrically insulated from the press with mica. Because of the fairly low insulation of the high pressure cell itself, $10^7\ \Omega$, it was not possible to measure the resistivity of the specimen above $10^7\ \Omega$ cm. An appropriate apparatus for the measurement of a high resistance, up to $10^{11}\sim10^{12}\ \Omega$, with a boron nitride pellet is now being prepared.

The abrupt change in the electrical resistance of bismuth or lead at a phase-transition point was used to calibrate the pressure applied to the cell. The transition of bismuth occurs at 2.5×10^4 kg./cm^2 and 8.8×10^4 kg./cm^2, and that of lead, at 1.61×10^5 kg./cm^2.

2) R. S. Bradley, J. D. Grace and D. C. Munro, *Trans. Faraday Soc.*, **58**, 776 (1962).
3) G. A. Samara and H. G. Drickamer, *J. Chem. Phy.*, **37**, 474 (1962).
4) A. S. Balchan and H. G. Drickamer, *Rev. Sci. Inst.*, **32**, 308 (1961).

A sharp drop in the electrical resistance of the purified free radical[5] was found at a lower pressure range, 10^4 kg./cm^2, as is illustrated in Fig. 1. The atmospheric resistivity of DPPH was found to be $10^{13}\,\Omega$cm. at room temperature.[5]

The behaviour was reproducible, and no chemical change could be found under high compressiron. Under the high pressure, the molecules are brought closer together, and this leads to a larger molecular orbital overlap between neighbouring molecules. A quantitative treatment with a band theory for this increments of the overlapping of molecular orbitals will be reported elsewhere.[6]

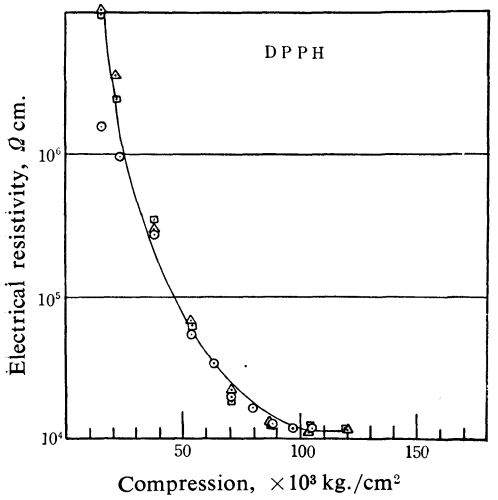

Fig. 1. The resistivity change of DPPH under high pressure.
Different marks, △ ▣ ⊙, are shown different specimens of the free radical.

No chemical reactions among the free radical molecules were found under the compression of 10^5 kg./cm^2. A further compression, however, may induce a solid phase reaction in the D. P. P. H. crystal. A similar result for several organic semiconductors, violanthrone, pentacene and quaterrylene, was obtained as illustrated in Table I.

Table I. The semiconductivity ($\rho=\rho_0\cdot\exp(\Delta\varepsilon/2kT)$) of polycyclic aromatic compounds under a high pressure

Compound	At atmospheric pressure		at 1.6×10^5 kg./cm^2	
	$\rho_{15°C}$**	$\Delta\varepsilon$**	$\rho_{15°C}$**	$\Delta\varepsilon$**
Quaterrylene	1.2×10^8	0.60	6×10^3	0.16
Violanthrone	2.3×10^{10}	0.78	7×10^2	0.18
Pentacene*	10^{14}	1.5	6×10^3	0.14

* A decomposition of the compound under a high pressure may occur.

The Formation of Three Isomeric Mononitro Derivatives in the Nitration of 2-Thenyl Chloride

By Tyo SONE and Yasuo MATSUKI

(Received June 3, 1964)

It is commonly assumed that the electrophilic substitution of thiophene derivatives with an *o*-, *p*-directing group in the 2-position occurs almost exclusively at the 5-position because of the overlapping of the directive effects of the nuclear sulfur atom and the substituent; it occurs at the 3-position to only a minor extent. Recently, it has been suggested by the NMR technique that, besides the 5-substituted isomers, considerable amounts of the 3-substituted ones are formed in the nitrations of 2-methylthiophene,[1] 2-thenyl chloride (I)[2] and 2-thenyl acetate.[3] However, no report on the formation of 4-substituted isomer has been made. A further study of the product obtained from the nitration of I has revealed the formation of, in addition to

2) T. Sone and Y. Matsuki, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **83**, 496 (1962).
3) T. Sone, K. Takahashi and Y. Matsuki, This Bulletin, 35, 1420 (1962).

the 3- and 5-substituted isomers, the 4-substituted isomer, which would not be expected from the assumption mentioned above.

Figure 1 shows the NMR spectrum of the product at 60 Mc. (b. p. 105~109°C/2 mmHg)[2] in the nitration of I by the nitric acid - acetic anhydride procedure. The assignment of the peaks to each of the isomers is based on the ring-coupling constants[1] and on the couplings[4,5] between the methylene protons and the ring protons. A set of four strong peaks, consisting of two triplets and a doublet (J= 4.1$_5$ c. p. s. and J_{CH_2}=0.8 c. p. s.), is typical for the ring protons of 5-substituted 2-thenyl derivatives[4,5] and can be assigned to 5-nitro-2-thenyl chloridet (II), the main product. The

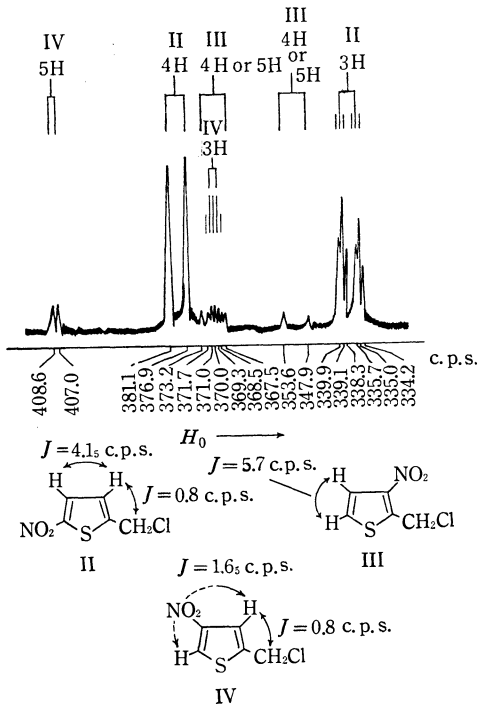

Fig. 1. NMR spectrum of the ring protons of a mixture of 5-nitro-2-thenyl chloride (II), 3-nitro-2-thenyl chloride (III) and 4-nitro-2-thenyl chloride (IV) in carbon tetrachloride at 60 Mc.

4) K. Takahashi, T. Sone, Y. Matsuki and G. Hazato, This Bulletin, 36, 108 (1963).

5) Data obtained from the NMR spectra of some thenyl chlorides will be published later.

remainder may be explained as follows. The doublet (J=5.7 c. p. s.) centered about 350 c. p. s., with reference to cyclohexane, is clearly due to one[6] of the two ring protons of 3-nitro-2-thenyl chloride (III), while the doublet (J=1.6 c. p. s.) on the lowest field side is due to the proton at the 5-position of 4-nitro-2-thenyl chloride (IV).[7] Among the seven peaks in the 367.5 c. p. s.~373.2 c. p. s. region, the two peaks at the two outermost sides are due to one[6] of the two ring protons of III, while the other five peaks are related to the proton at the 3-position of IV; the overlapping of two triplets, which is caused by the coupling of the proton at the 3-position with both that at the 5-position and with the neighboring methylene protons, forms five peaks with an estimated intensity of 1 : 2 : 2 : 2 : 1, and the observed coupling constants (J_{35}=1.7 c. p. s. and J_{2CH_2-3}=0.8 c. p. s.) are in accord with the expected ones. The signals correspond well with those of authentic IV (b. p. 105~107°C/2 mmHg, n_D^{20} 1.6065, d_4^{20} 1.4825. Found: C, 33.89; H, 2.02; N, 7.52. Calcd. for $C_5H_4ClNO_2S$: C, 33.81; H, 2.27; N, 7.88%) prepared by the chloromethylation of 3-nitrothiophene, although attempts to isolate IV, itself or as a derivative, from the nitration product were unsuccessful.

The NMR spectrum of the product in the nitration of 2-thenyl acetate also suggests the formation of the 4-nitro derivative as a by-product.[8]

The authors wish to thank Mr. Kensuke Takahashi for his NMR spectral measurements and for his many helpful suggestions on the spectra.

The Chemical Research Institute of Non-Aqueous Solutions
Tohoku University
Katahira-cho, Sendai

6) At present, it is not possible to determine which of the doublets should be assigned to the proton at the 5-position or to that at the 4-position.

7) The agreement of the spacing both at 40 Mc. and at 60 Mc. assures the assignment of this doublet to one of the two ring protons of the 4-substituted isomer coupling with the other proton.

8) 4-Nitro isomer: J_{35}=1.5 c.p.s. and J_{2CH_2-3}=0.6 c.p.s. In a preceeding paper,[3] two peaks on the lowest field side in the NMR spectrum (40 Mc.) were ascribed to the dinitro isomer.

Electron Spin Resonance Studies of Deuterated Borate Glasses Irradiated with Gamma Rays at Liquid Nitrogen Temperature

By Yasuo NAKAI

(Received June 4, 1964)

The present investigation was undertaken with the expectation that paramagnetic absorption measurements would yield information regarding the hydrogen atoms produced in the radiolysis of B–O–H–O–B or H_2O in borate glass.

For the purpose of examining the effect of water or B–O–H–O–B in glass, borate glass, B_2O_3, was deuterated. The deuterated B_2O_3 glass used was made from the melting of D_3BO_3 prepared by the hydrolysis of trimethyl borate with D_2O.

The infrared spectrum of the deuterated B_2O_3 glass is shown in Fig. 1. The components of the hydrogen and deuterium atoms in the glass seem to be H : D = 1 : 1.

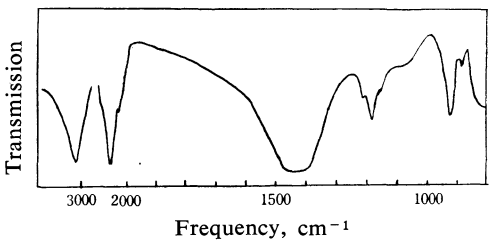

Fig. 1. The IR spectrum of deuterated borate glass.

The sample was irradiated at liquid nitrogen temperature with Co^{60} gamma rays (1×10^6 r). Derivative curves were obtained with a Varian 4501 ESR spectrometer at liquid nitrogen temperature employing a modulation frequency of 100 kc./sec.

The first derivative curve of the spectrum is shown in Fig. 2. The derivative peaks denoted by P_2, P_3, P_4 and P_5, and P_b (Bray's symbol) were found to be the same as have been reported previously.[1] The observed spectrum at 77°K appears to display other new derivative peaks. The additional peaks will be denoted by H_1 and H_2 for the outer pair, and D_1, D_2 and D_3 for the inner lines.

The paramagnetic resonance spectra of a free atomic hydrogen (S = 1/2, I = 1/2) would be expected to consist of a doublet with a

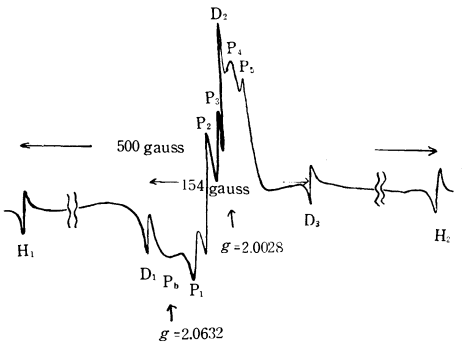

Fig. 2. The ESR spectrum obtained from γ-ray irradiated (1×10^6 r) deuterated borate glass.

separation of 506 gauss, while those of a free atomic deuterium (S = 1/2, I = 1) would consist of a triplet with a separation of 156 gauss between outer components.[2]

Therefore, H and D resonances seem to arise from the hydrogen atom center, H^0 of interstitial vacancy produced by the radiolysis of B–O–H–O–B or H_2O in glass. The derivative peaks denoted by D_1, D_2 and D_3 cannot be observed in nondeutrated samples.

At room temperature, hydrogen atoms may diffuse to form hydrogen molecules or BOH. Thus, no paramagnetic resonance absorption due to H^0 and D^0 centers can be observed.

Aminocyclitols. IV. The New Synthesis of Inosamine

By Tetsuo SUAMI and Seiichiro OGAWA

(Received June 4, 1964)

In a previous paper[1] of this series, the displacement of the mesylate group of the 2-amino-1, 3-cyclohexanediol derivative with an azide ion has been described. The replacement of the mesylate group of *myo*-inositol by an azide ion will be studied and the synthesis of inosamine will be described in the present communication.

IV Ac N_3
V Ac NHAc
VI H NHAc
VII H $NH_3^+Cl^-$

The starting material for the synthesis is a known (±)-1, 4, 5, 6-tetra-*O*-acetyl-*myo*-inositol (I).[2] By treating I with one mole of methanesulfonyl chloride in pyridine, (±)-1, 4, 5, 6-tetra-*O*-acetyl-3-*O*-mesyl-*myo*-inositol (II), m. p. 207~208°C, is obtained in 72% yield. II is further acetylated with acetic anhydride and pyridine to give (±)-3-*O*-mesyl-*myo*-inositol pentaacetate (III), m. p. 159~161°C, in 88% yield. It is found that III is different in melting point and in infrared spectra from 2-*O*-mesyl-*myo*-inositol pentaacetate, m. p. 190~192°C which is prepared from 1, 3, 4, 5, 6-penta-*O*-acetyl-*myo*-inositol[3] by the ordinary procedure of mesylation. Since tosyl chloride attacks an equatorial hydroxyl group rather than an axial one in the *myo*-inositol derivative,[4] the attacking of mesyl chloride might take place in a similar manner; therefore, the assignment of the attaching point of the mesylate group to C-3 (or C-1) in II seems to be reasonable. This is further confirmed by the NMR spectrum of III, which reveals a sharp signal at 7.00 τ, as is expected from the protons of an equatorial mesylate group.[5]

When II is then treated with sodium azide in boiling aqueous 2-methoxyethanol for 15 hr., an oily product is obtained. As it has been partially deacetylated during the reaction with sodium azide, this product is acetylated with acetic anhydride and pyridine to yield IV, which shows the characteristic infrared absorption of an azide group at 2115 cm^{-1}. IV is reduced with hydrogen in the presence of Raney nickel. The reduction product shows the infrared absorption of an amide group at 1645 and 1570 cm^{-1}; accordingly, a migration of the acyl group from O to N must have occurred[6] during the course of the reduction. Further treatment with acetic anhydride and pyridine gave hexaacetyl-inosamine (V), m. p. 205~205.5°C in 43% yield from II.

V is also obtained from III by the procedure mentioned above.

The selective deacetylation of V with ammonia in methanol yields *N*-acetyl-inosamine (VI), m. p. 224~225°C. The hydrolysis of VI with 6 N hydrochloric acid gives inosamine hydrochloride (VII), which shows a single spot of R_f 0.18 in ascending paper chromatography in an ethyl acetate - pyridine - acetic

acid - water (5 : 5 : 3 : 1) system[7] at 20°C (R_f of D-glucosamine hydrochloride : 0.25).

Not enough examples of the reactions of the sulfoxylate group with sodium azide have been accumulated to predict the stereochemistry of the reaction product, but there are three possible configurations for V: hexaacetyl-*myo*-inosamine-(1),[8] *rac*-inosamine-(2),[9] and *muco*-inosamine-(1).[10] The melting point of V and the R_f value of VII are different from those of the former two. Therefore, hexaacetyl-*muco*-inosamine-(1) seems to be the most probable structure for V.

Sensitized Luminescence of Tb^{3+}

By Hideo MIZUNO and Mutsuo MASUDA

(Received June 8, 1964)

Recently rare earth-activated phosphors have been studied in order to develop new laser materials. It is well known that rare earth-activated phosphors show line absorption spectra and line emission spectra, and that the intensities of these spectra are weak because the absorption and emission are due to $f-f$ forbidden transitions. Some experiments have been made to sensitize the luminescence of rare earth ions.[1] The authors have found that the emission of Tb^{3+} could be sensitized by heavy metals, such as Cu^+ and Tl^+.

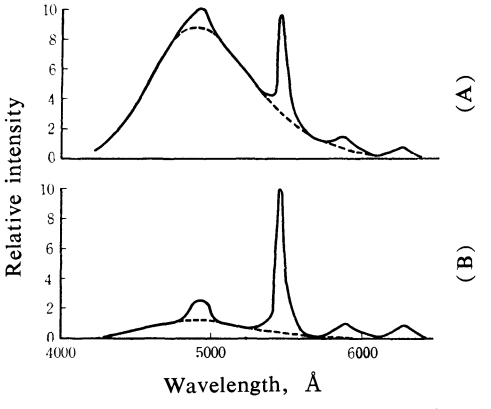

Fig. 1. Emission spectra of Cu and Tb activated phosphors.
(A) $Sr_{2.5}Mg_{0.3}(PO_4)_2$: 0.024 Cu, 0.01 Tb
(B) $Sr_{2.5}Mg_{0.3}(PO_4)_2$: 0.024 Cu, 0.1 Tb

Phosphors of the composition $Sr_{2.5}Mg_{0.3}(PO_4)_2$ activated with Tb^{3+} or the combination of Tb^{3+} with a heavy metal were fired in N_2 or mixed gas (10% H_2+90% N_2) for two hours at 1200°C. The emission spectra were measured at room temperature with a Kipp and Zonen double monochromator. The phosphors activated with Cu^+ and Tb^{3+} show the broad emission spectrum of Cu^+ with a maximum at 4900Å and the line emission spectrum of Tb^{3+} with peaks at 4900, 5460, 5880 and 6250Å, as is shown in Fig. 1. With an increasing Tb^{3+} content, the intensity of the Cu^+ emission decreases while that of the Tb^{3+} emission increases. The phosphor activated only with Tb^{3+} shows a weak emission under 3650Å radiation, but no emission under 2537Å radiation.

When Tb^{3+} coexists with Cu^+ in the host crystal, a strong emission of Tb^{3+} appears under 2537Å radiation. The excitation spectra were measured at room temperature by a Xe-lamp. The excitation spectrum for the Tb^{3+} emission of the phosphors was measured for the 5460Å line in the Tb^{3+} emission spectrum, which was separated from the Cu^+ emission by filters. As is shown in Fig. 2, the excitation spectrum for the Cu^+ activated phosphor is a broad band with a maximum at 3000Å, while the one for the Tb^{3+} activated phosphor is a line spectrum with a complicated structure and with a peak near 3700Å. The excitation spectrum for the Tb^{3+} emission in

1) W. W. Holloway, Jr., M. Kestigian and R. Newman, *Phys. Rev. Letters*, **11**, 458 (1963).

the phosphors activated with Cu^+ and Tb^{3+} shows the broad band corresponding to the excitation spectrum of Cu^+-activated phosphors. From these results it may be concluded that the Tb^{3+} emission is sensitized by Cu^+. It is reasonable to consider that the energy absorbed by Cu^+ is transferred to the $^5D_4$ level of Tb^{3+} by resonance transfer, and that the four lines of the Tb^{3+} emission spectrum with peaks at 4900, 5460, 5880 and 6250Å correspond to the transitions from $^5D_4$ to $^7F_6$, $^7F_5$, $^7F_4$ and $^7F_3$ of the Tb^{3+} energy levels respectively.[2]

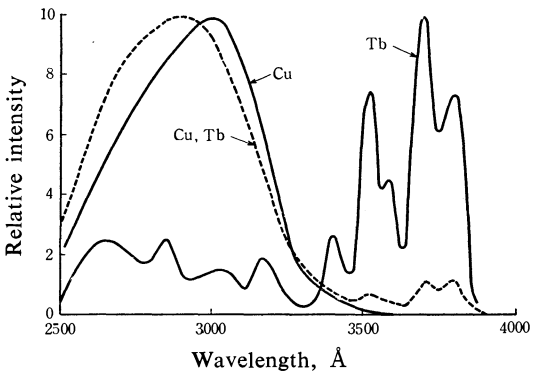

Fig. 2. Excitation spectra of $Sr_{2.5}Mg_{0.3}(PO_4)_2$: 0.1 Tb and $Sr_{2.5}Mg_{0.3}(PO_4)_2$: 0.024 Cu, 0.1 Tb.
Tb : Excitation spectrum for the Tb activated phosphor
Cu : Excitation spectrum for the Cu activated phosphor
Cu, Tb : Excitation spectrum for the Tb emission in the phosphors activated with Cu and Tb

Following the same procedure, it was found that the Tb^{3+} emission is sensitized by Tl^+ in the phosphors activated with Tl^+ and Tb^{3+}. Under 2537Å radiation the phosphors activated with Tl^+ and Tb^{3+} show the broad spectrum of Tl^+ with two maxima at 3400 and 3900Å, as well as the line spectrum of Tb^{3+}, which includes four new peaks at 3840, 4150, 4380 and 4570Å, in addition to the four peaks already described above. Therefore, it is reasonable to consider that, under 2537Å radiation, in the phosphors activated with Tl^+ and Tb^{3+} the energy absorbed by Tl^+ is transferred to the $^5D_3$ level of Tb^{3+} by resonance transfer, and that the former four peaks correspond to the transitions from the $^5D_3$ level, while the latter ones correspond to the transitions from the $^5D_4$ level, to which the energy is transferred from the $^5D_3$ level by radiationless transition.

In the present investigation it has been found that the Tb^{3+} emission is sensitized by such heavy metal ions as Cu^+ and Tl^+, and that Tb^{3+} is excited to the $^5D_4$ level by the sensitizer with an emission peak at about 4900Å, while Tb^{3+} is excited to the $^5D_3$ level by the sensitizer with an emission peak at about 3400～3800Å. In the line spectrum of Tb^{3+}, the 5460Å line is strongest. This emission corresponds to the transition from a $^5D_4$ to a $^7F_5$ level, which is located 2000 cm^{-1} above the ground state $^7F_6$. Consequently, it may be considered that these materials can be used as laser materials by creating a negative temperature state between the $^7F_5$ and $^5D_4$ levels.

Effects of Basic Substances on the Rate and Equilibrium of the Tautomeric Reaction between Anthrone and Anthranol

By Hiroaki BABA and Takeshi TAKEMURA

(Received June 8, 1964)

The rate and equilibrium of the keto-enol tautomeric reaction in solution between anthrone and anthranol are known to be strongly dependent upon the solvent employed.[1] In hydrocarbons the reaction is so slow that it requires several days to reach the equilibrium, starting from one of the tautomeric pair. This makes it practically impossible to determine the equilibrium constant, K, in such inert solvents. We have recently observed spectroscopically, however, that the tautomeric reaction in hydrocarbon solvents is markedly affected both in rate and in equilibrium by the presence of basic substances.

The absorption spectrum of anthrone in benzene is shown in Fig. 1, together with the spectrum of the equilibrium mixture of anthrone and anthranol. The equilibrium was established by the addition of a small amount of triethylamine to the benzene solution, the concentration of the amine being only 10^{-4} mol./l. Triethylamine of this low concentration sufficiently accelerates the keto-enol transformation, the rate being increased by a factor of 10^3, but it exerts almost no influence on the equilibrium itself. Consequently, from an analysis of the absorption spectra, the equilibrium constant could be determined to be $K=0.0025$ at 20°C in benzene. In the same way we obtained $K=0.0021$ at 20°C in isooctane. Furthermore, the temperature dependence of the K values led to the following ΔH values: $\Delta H=2.6$ kcal./mol. in benzene and $\Delta H=3.3$ kcal./mol. in isooctane. Both the K and ΔH values indicate that the keto form is more stable than the enol form in hydrocarbons. The present experimental data will be useful in dealing with the problem of keto-enol tautomerism in general.[2,3]

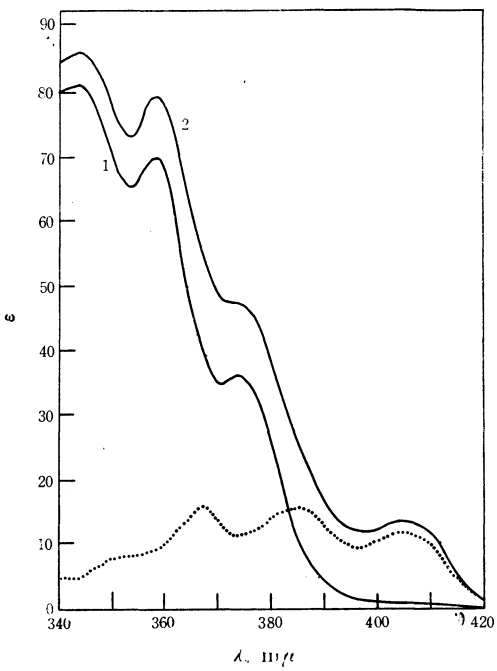

Fig. 1. Absorption spectra of anthrone and the equilibrium mixture of anthrone and anthranol in benzene at 20°C. Solid curve 1, anthrone; solid curve 2, the equilibrium mixture; dotted curve, difference of absorptions 2 and 1, corresponding to the absorption due to anthranol.

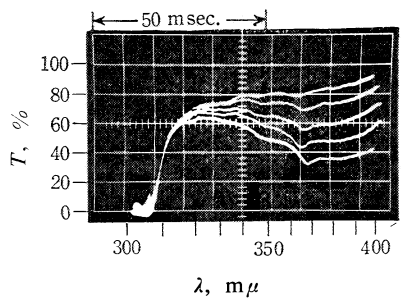

Fig. 2. Spectrophotometric tracing of the base-catalyzed transformation reaction from anthrone to anthranol. The spectra from top to bottom are at 1.5, 4.5, 10, 20, and 120 sec., respectively, after mixing of isooctane solution of anthrone and the same solution of triethylamine. The concentrations of anthrone and triethylamine at the beginning of the reaction are, respectively, 6.1×10^{-4} and 0.9 mol./l. The cell length is 11 mm. and the temperature is 24°C.

1) Y. Bansho and K. Nukada, This Bulletin, **33**, 579 (1960); K. Nukada and Y. Bansho, ibid., **26**, 454 (1953).

3) A. Streitwieser, "Molecular Orbital Theory for Organic Chemists," John Wiley and Sons, New York (1961), pp. 248-255.

The equilibrium between anthrone and anthranol is affected by the amine with higher concentrations. It is noticeably displaced to the side of the enol form with an increasing concentration of added amine. Thus, for the amine concentration of 1 mol./l., the enol form amounts to about 10 per cent of the keto form. This phenomenon can be satisfactorily interpreted as due to the formation of a hydrogen bond between the enol form and the amine. When the concentration of triethylamine is of the order of 10^{-1} to 1 mol./l., the tautomeric equilibrium is reached in isooctane within one or two minutes. The keto-enol reaction was traced by the use of a rapid-scan spectrophotometer[4] constructed recently in our laboratory; this spectrophotometer can display transmission curves on a cathode-ray tube for the wavelength region from 220 to 650 mμ, with a scanning time of 0.3 sec. The results are given in Fig. 2, from which it can be seen that the reaction is of the first order.

Several other basic compounds have also been investigated. Pyridine has essentially the same effect as in the case of triethylamine on both the reaction rate and the equilibrium. Dioxane produces no appreciable change in the reaction rate, but it has a definite effect on the keto-enol equilibrium. Details of the work will be published later.

On a New Type of Cyclododecatriene - Silver Nitrate Complex

By Shunsuke KURIBAYASHI, Noritake YASUOKA, Toshiko MITSUI, Hiroshi TAKAHASHI and Muneaki YAMAGUCHI

(Received June 19, 1964)

In the course of X-ray work on the cyclododecatriene - silver nitrate complex, we have found a new type of complex.

Zakharkin and Korneva reported[1] that *trans, trans, cis*-cyclododecatriene-1, 5, 9 (abbreviated *t, t, c*-CDT) forms a complex with silver nitrate and gave it the formula $(C_{12}H_{18})AgNO_3$ (m. p. 166~167°C). This complex crystallizes as a platelet. In the course of a structure analysis by X-ray diffraction, we found a few needle-like crystals among them. These needles gave X-ray diffraction patterns different from those of platelets. We cite below the former (needles) as the β-type and the latter (platelets) as the α-type. The β-type crystal melts at 149°C and was found by elementary analyses to be of the formula $(C_{12}H_{18})_2AgNO_3$. (Found: C, 58.37, 58.67; H, 7.33, 7.27; Calcd. C, 58.30; H, 7.34%.) Crystallographic data of both complexes are shown in Table I.

The infrared absorption spectra of *t, t, c*-CDT and of both complexes are shown in Fig. 1. The absorption maximum at 970 cm^{-1}, which is assigned to an out-of-plane bending of the CH bond related to the trans C=C bond, is shifted to 990 cm^{-1} in the case of the α-type.

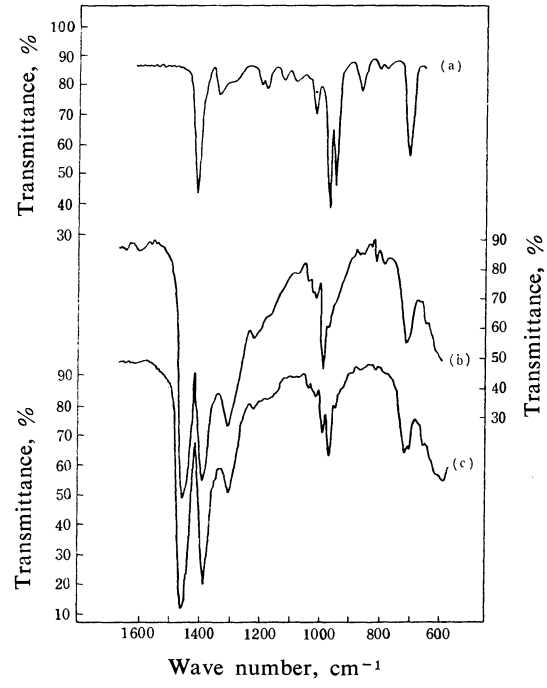

Fig. 1. Infrared spectra of
(a) *trans, trans, cis*-Cyclododecatriene,
(b) α-Type complex in Nujol and
(c) β-Type complex in Nujol.

1) L. I. Zakharkin and V. V. Korneva, *Doklady Akad. Nauk. S.S.S.R.*, 132, 1078 (1960).

TABLE I. CRYSTALLOGRAPHIC DATA OF *trans, trans, cis*-CYCLODODECATRIENE-SILVER NITRATE

	Crystal system	a (A)	b (A)	c (A)	Probable space groups from missing reflections
α-Type	Orthorhombic	15.72	17.62	9.66	$Cmc2_1$, $Cmcm$, $C2cm$
β-Type	Orthorhombic	5.35	15.34	29.80	$Pbcn$

On the other hand, in the case of β-type crystals, the absorption band at 970 cm^{-1} still remains, and that at 990 cm^{-1} is also observed. The absorption at 720 cm^{-1}, assigned to an out-of-plane bending of the CH bond related to the cis C=C bond, remains unchanged in both cases.

These facts suggest that both of the two trans C=C bonds of the α-type coordinate to the Ag^+ ion, but that only one of them does in the case of the β-type and that the cis C=C bond remains free in both cases.

Preliminary X-ray work supports these conclusions. Details of the results of our X-ray crystal structure analysis will be reported in the near future.

The Far Infrared Spectra of Trimethylaluminum

By Teiichiro OGAWA, Kozo HIROTA and Kunio FUKUSHIMA

(Received June 23, 1964)

The peculiar structure and the high reactivity of trimethylaluminum has provided a very interesting subject for chemists. The vibrational spectra of this molecule have been measured by several authors. Hoffmann,[1] for instance, has published his extensive investigation of the infrared and Raman spectra in the region above 400 cm^{-1}. The infrared measurement was extended to the region from 400 to 120 cm^{-1} by the present authors.[2] Recently Gray,[3] and Onishi and Shimanouchi[4] have described the infrared spectra in the region above 280 cm^{-1}.

As to the assignments of the spectra, however, Hoffmann and Gray gave contradictory views; therefore, in order to settle the problem, observation in the far infrared region has had to be carried out. In the present communication, the far infrared spectra of

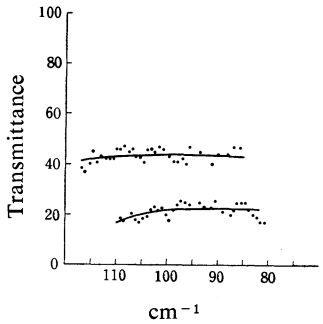

Fig. 3. The far infrared spectra of trimethylaluminum in the 120 to 85 cm^{-1} and 110 to 80 cm^{-1} region. Any band is not observed.

trimethylaluminum will be reported.

Commercial trimethylaluminum (Ethyl Corporation, New York) was purified by vacuum distillation and then transferred into a liquid cell made of two polyethylene films 0.5 mm. thick. This cell was then kept by itself in a vacuum of about 10^{-2} mmHg for several days. The infrared spectra in the 700~270 cm^{-1} region were measured by a Perkin-Elmer Model 221 spectrophotometer with CsBr optics, and the spectra in the 500~65 cm^{-1} region, by a Perkin-Elmer Model 201C far infrared spectrometer. The spectra in the region above 400 cm^{-1} were also measured by a Nippon Bunko Model DS402G spectrometer and found to be similar to those described in the literature.[1,3]

The observed spectra are shown in Figs. 1, 2 and 3. The thickness of the sample is not the same in all measurements but greater in the longer-wavelength region. Two absorption bands were found at 367 cm^{-1} and 175 cm^{-1} in the observed far infrared region.

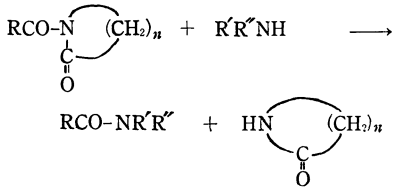
The Acyl-Exchange Reactions of N-Acyl Lactams with Amines. A Novel Synthesis of N-Substituted Amides

By Hisaya TANI, Nobuki OGUNI and Takeo ARAKI

(Received October 23, 1963)

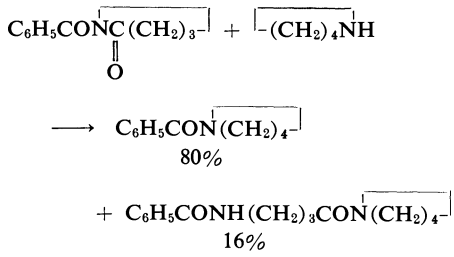
The *N*-acylated lactam has two carbonyl groups in each molecule, so two types of nucleophilic reaction are possible. If an amine attacks the ring carbonyl, a ring-opening reaction may be expected to occur, while if it attacks the acyl carbonyl, an acyl-exchange reaction will occur.



The hydrolysis of the acyl lactam has been investigated,[1] but its aminolysis has not yet been reported. Of various amides, on the other hand, acylimidazole has been successfully used as an acylating reagent in the synthesis of peptides, and it is thought to be an active amide.[2,3]

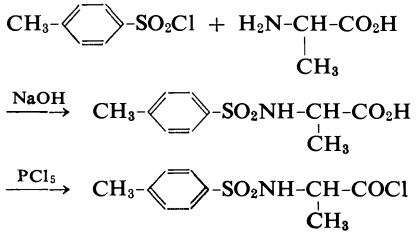
The present paper is concerned with the aminolysis of some acyl lactams, i. e., the *N*-acetyl or *N*-benzoyl derivatives of 2-pyrrolidone, 2-piperidone and ε-caprolactam. The reactions were studied by means of product isolation techniques; it was found that *N*-acyl lactams generally exchange their *N*-acyl groups readily with a hydrogen atom of the amines, thus producing corresponding amides in good yields. The results obtained indicate that *N*-acyl lactams can be considered as a kind of active amides.

Results and Discussion



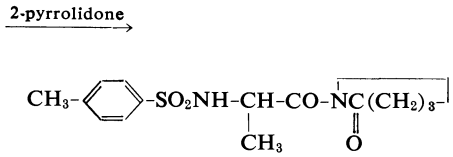
The general procedure for the aminolysis of *N*-acyl lactams was as follows: a tetrahydrofuran solution of an *N*-acyl lactam and an amine (aniline, benzylamine, *n*-butylamine, diethylamine, pyrrolidine or piperidine) was sealed in a glass tube and kept standing for a predetermined length of time in a bath. The temperature of the bath was about 50°C in the case of *N*-benzoyl lactams and about 90°C in the case of *N*-acetyl lactams, varying with the reactivity of the series of lactams.

All of the acetyl lactams used readily reacted with amines and gave corresponding amides in good yields. *N*-Benzoyl lactam also reacted with amines and gave satisfactory results. These results are summarized in Tables II and III.

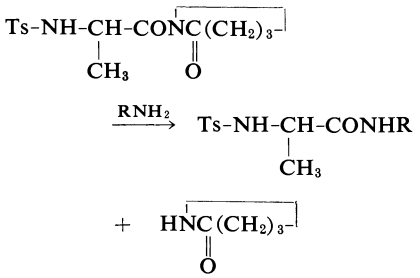


The chemical behavior of the acyl lactams described above indicates that these compounds are good acylating reagents and may be regarded as active amides.

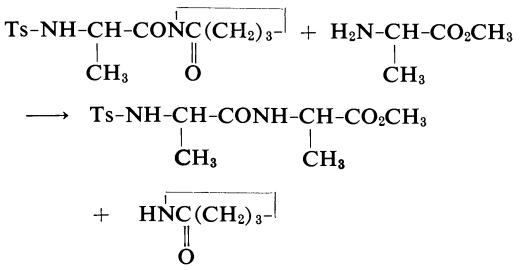
It is noteworthy that small amounts (ca. 20%) of ring opened products were obtained by the reaction of *N*-benzoyl-2-pyrrolidine with such secondary amines as diethylamine, pyrrolidine and piperidine. In the other cases studied, however, no ring-opened product was obtained.



On the other hand, the results of alkaline hydrolysis by potassium hydroxide (Table IV) indicate that the ring-opened products were always obtained, along with lactams, regardless of the number of carbon atoms in the lactam rings. The reason why secondary amines attack the carbon atom of the ring carbonyl of *N*-benzoyl-2-pyrrolidone in an exceptional manner is an interesting but as yet unclarified problem.



Applications: The novel acyl-exchange reaction presented above was applied to peptide synthesis. *N*-Tosyl-DL-alanyl-2-pyrrolidone was synthesized by the following route.



1) A. R. Battersby and J. C. Robinson, *J. Chem. Soc.*, 1956, 2076.
2) G. W. Anderson and R. Paul, *J. Am. Chem. Soc.*, **80**, 4423 (1958).
3) R. Paul and G. W. Anderson, ibid., **82**, 4596 (1960).

Tosyl-DL-alanyl-2-pyrrolidone was converted almost quantitatively to tosyl-DL-alanine *N*-benzylamide by reaction with benzylamine, or to tosyl-DL-alanine *N*-(*n*-butyl)amide by reaction with *n*-butylamine. The results are listed in Table V.

The extension of this reaction to dipeptide synthesis seemed to be interesting. In fact, when the alanine methyl ester was allowed to react with *N*-(tosyl-DL-alanyl)-2-pyrrolidone, the normal acyl-exchange reaction occurred and gave a dipeptide in a good yield:

Experimental

Materials.—*N*-Acetyl lactams were prepared by the acylation of corresponding lactams with acetyl or benzoyl chloride in benzene containing triethylamine. Crude *N*-acyl lactams were purified by fractional distillation or repeated recrystallization. The *N*-acyl lactams used are listed in Table I.

Solvent.—Tetrahydrofuran (THF) was purified by the usual method.

The Reaction of *N*-Acyl Lactams with Amines.—*General Procedure.—i) Reaction*: An *N*-acyl lactam 0.01~0.04 mol. (1 part) and 0.02~0.08 mol. of an amine were dissolved in THF (10~70 ml.). The mixture was then heated in a sealed tube for 16~48 hr. at temperatures ranging from 50 to 90°C.

ii) Methods of Fractionation: The solvent and the unreacted amine were removed under reduced pressure. When the residue solidified, it was purified by recrystallization from suitable solvents (procedure A). When the residue was oily, it was purified by distillation under reduced pressure (procedure B). When the oily residue could not be distilled, two methods were used. One was to dissolve the residue in ethyl acetate and to wash the solution first with 0.5 N hydrochloric acid and second with water, and then to dry it with anhydrous sodium sulfate (procedure C); the other was column chromatography on activated alumina (procedure D). The results are tabulated in Tables II and III, together with the experimental conditions and the methods of purification.

The Hydrolysis of *N*-Benzoyl Lactams.—*General Procedure.*—An *N*-benzoyl lactam (1.9 g.) was dissolved in 20 ml. of dioxane containing 20 ml. of 0.5 N potassium hydroxide and an excess of water (10 ml.). After the mixture had been allowed to stand for half an hour at 14°C, the solution was concentrated in vacuo to one-third of its volume. After the concentrate had been extracted twice with 10 ml. of ethyl acetate, the water layer was acidified (pH 3) with 3 N hydrochloric acid and extracted five times with petroleum benzine (150 ml.). By evaporating the petroleum extract, benzoic acid (m. p. 120~121°C) was obtained. The water layer of the extraction was re-extracted with ethyl acetate. After the ethyl acetate had been removed, the corresponding *N*-benzoyl-*ω*-amino acid was obtained; this was then recrystallized from ethyl acetate. The corresponding *N*-benzoyl-*ω*-amino acids were thus obtained. The results are listed in Table IV.

Tosyl-DL-alanine.—Into a solution of DL-alanine (0.7 mol.) dissolved in 330 ml. of 2 N sodium hydroxide and 400 ml. of water, tosyl chloride

a) See text of the reactions of *N*-acyl lactam with amines. b) *N*-(Tosyl-DL-alanyl)-2-pyrrolidone 0.003 mol. and amine 0.01 mol. were used with 20 ml. of THF. Reaction was continued for overnight at 60°C c) Recrystallized from ethyl acetate. d) *N*-(Tosyl-DL-alanyl)-2-pyrrolidone 0.005 mol. and amine 0.03 mol. were used with 20 ml. of THF, at 60°C for overnight. e) Recrystallized from ether. f) *N*-(Tosyl-DL-alanyl)-2-pyrrolidone 0.003 mol. and DL-alanine methyl ester 0.006 mol. in 10 ml. of THF were used, at 60°C for overnight. g) Recrystallized from the mixture of acetone and petroleum ether.

(1 mol.) was stirred; the stirring was then continued for 5 hr. at room temperature. After the reaction had been completed, the reaction mixture was extracted with benzene in an adjusted basic media (pH 9). The residue was acidified to pH 3 by adding 3 N hydrochloric acid. A crystalline material precipitated. It was recrystallized from ethyl acetate, m. p. 136～137°C. Yield, 72.5%.

Tosyl-DL-ananyl-2-pyrrolidone.—Eighteen grams of phosphorus(V) chloride were added to the solution of 19.2 g. of tosyl-DL-alanine in 280 ml. of ether, and the mixture stirred for half an hour. After the removal of the ether, colorless needles were obtained. They were then dissolved in 240 ml. of THF, and the solution was cooled to 0°C. Fifty milliliters of THF solution containing 2-pyrrolidone (16 ml.) and triethylamine (8.8 g.) was then added drop by drop to the tosylalanyl chloride solution. The precipitate was separated off, and the THF was removed. The residue was dissolved in 100 ml. of ethyl acetate. The solution was washed with a 5% solution of potassium bicarbonate, a 5% solution of hydrochloric acid, and then with water, and dried with sodium sulfate. After the ethyl acetate had been removed, a crystalline material was obtained. It was recrystallized from ethyl acetate, m. p. 133～134°C. Yield, 76%.

Found: C, 54.05; H, 5.78; N, 8.95. Calcd. for $C_{14}H_{18}O_4N_2S$: C, 54.18; H, 5.58; N, 9.03%.

The Reaction of *N*-(Tosyl-DL-alanyl)-2-pyrrolidone with Amines.—The procedure was the same as that in the reaction of *N*-acyl lactams with amines. The results are listed in Table V.

Summary

N-Acetyl and *N*-benzoyl lactams consisting of a five-to-seven-membered ring were found to be good acylation reagents. Several amines were acylated with these reagents to give the corresponding amides in good yields.

When *N*-benzoyl-2-pyrrolidone was used, ring-opened by-products were obtained by the reaction with a secondary amine, such as pyrrolidine and piperidine.

Tosylalanyl-2-pyrrolidone reacted with primary amines to produce the corresponding tosylalanine amides. The alanine methyl ester reacted as a primary amine with tosylalanyl-2-pyrrolidone to afford a dipeptide.

The authors are indebted in some parts of their experiments to Mr. Sigeru Tanaka, Mr. Hiroshi Kagawa and Mr. Hajime Yasuda; grateful acknowledgment is hereby made to these persons.

Studies in the Equilibrium Dyeing of Cotton with Direct Dyes: The Determination of the Activity and Affinity of Direct Dyes for Cellulose

By E. H. DARUWALLA and G. G. KULKARNI

(Received December 7, 1963)

The three main theories which have been put forth to explain the effect of dye and salt concentration and temperature on the equilibrium dyeing of cellulosic fibres with direct dyes are those suggested by Hanson, Neale and Stringfellow,[1] by Willis, Warwicker, Standing and Urquhart,[2] and by Peters and Vickerstaff.[3] Peters and Vickerstaff are of the opinion that the driving force during dyeing can be best represented by the Gibbs free energy changes involved; they obtained a quantitative measure of the tendency of dye to pass from the aqueous phase to the fibre phase, which they termed as "affinity." These workers in the development of the treatment were faced with the great difficulty of expressing the activity of dye in the fibre phase, as no precise information was available regarding the saturation values of cellulose with regard to direct dyes. They were, therefore, compelled to introduce a term for the volume of cellulosic fibres, the values of which were deduced arbitrarily from the results of the adsorption of Chrysophenine G by cellulosic fibres, which gave linear plots of unit slope when the logarithm of ionic products in fibre and in the solution at equilibrium were plotted. Recently, Daruwalla and D'Silva[4] developed a new thermodynamic approach in which the activity of dye in cellulosic fibre substances is expressed in terms of the fraction of total sites occupied at a particular stage of dyeing. On the basis of this thermodynamic approach, they obtained consistent values of affinity for three direct dyes under different experimental conditions.

The present work was undertaken with a view of seeing whether the thermodynamic treatment of Daruwalla and D'Silva could be applied to other direct dyes, dyes with different chemical structures and aggregation tendencies. Attempts have also been made to test the validity of this treatment in explaining the behaviour of Chlorazol Sky Blue FF and Chrysophenine G during dyeing from a mixed dyebath.

Experimental Procedure

Materials.—The cellulosic fibre substance used was 20^s yarn made from Indian cotton and from which, by suitable treatments, impurities other than cellulose in the fibre substance were removed. Pure samples of Congo Red (C. I. Direct Red 28), Benzopurpurine 4B (C. I. Direct Red 2), Benzopurpurine 10B (C. I. Direct Red 7), Chloramine Purple 10BC (C. I. Direct Red 61), Chlorazol Corinth GW (C. I. Direct Red 10), Benzocorinth B (C. I. Direct Violet 21), Diazol Violet R (C. I. Direct Violet 43), Chlorazol Blue B (C. I. Direct Blue 6), Chlorazol Blue G (C. I. Direct Blue 10), Durazol Blue 2R (C. I. Direct Blue 71) and Chlorazol Orange RN (C. I. Direct Orange 8) were obtained from commercial dyes by purification, using the technique recommended by Robinson and Mills,[5] the purity of the samples was determined from an analysis of the elements present. All the other chemicals used were of Analar quality.

The Determination of the Heat of Dyeing.—The determination of the heat of dyeing was carried out by a technique similar to that described by Gilbert,[6] in which a fibre containing a constant amount of a dye is brought to equilibrium at different temperatures with solutions containing different amounts of dye. The details of the determination are the same as those mentioned by Daruwalla and D'Silva.[4]

The Determination of the Fibre Degradation of NaOCl-treated Dyed Cotton.—A definite weight of dyed or undyed cotton was treated with a 50 ml. sodium hypochlorite solution (3 g./l. available chlorine) buffered to pH 7 at 30°C for 3 min. The oxidised sample was washed thoroughly, antichlored, washed, and dried; the fluidity of the solution containing oxidised sample dissolved in a cuprammonium hydroxide solution was then determined according to A. S. T. M. Standards specifications.[7]

For the determination of the values of $[D_\phi]$, the amount of dye in the fibre phase (g. ions/kg.) and $[D_\sigma]$, the amount of dye in the solution (g. ions/l.) in equilibrium at different temperatures, the desorption technique for attaining equilibrium was used. This method of approach for obtaining the values of $[D_\phi]$ and the corresponding values of $[D_\sigma]$ at different temperatures was preferred to the

normal method of obtaining these values from adsorption experiments because, in the latter case, longer times are required for the establishment of equilibrium, with a risk of the decomposition of dyes and changes in the structure of the cellulosic fibres. It was found that the affinity values calculated from the appropriate values of $[D_\phi]$ and $[D_s]$ obtained from desorption experiments were close to those recorded in the literature where the adsorption technique for attaining equilibrium conditions between the dye in the fibre substance and the dye in the bath was employed.

Results and Discussion

For the direct dyes studied, the results of the present investigation indicate that, except for the initial low concentration of adsorbed dye, the values of the heat of dyeing remain constant over a fairly wide range of dye concentration in the fibre, and that, beyond a critical dye concentration, the values tend to decrease continuously as the amount of adsorbed dye in the fibre is increased (Figs. 1–3). The critical dye concentration beyond which the values decrease is peculiar to each dye studied (Table I). In view of the fact that the cellulose-water system is not homogeneous, the sorption affinity of dye will not be identical over all the surface with which dye may come in contact, with the result that the values of the heat of dyeing associated with different portions of cotton will be different. The values of the heat of dyeing generally indicate overall changes in the heat content of the system, but to some extent these values may also be considered to indicate the energy of the association of a particular dye with cellulose. The fact that constant values of the heat of dyeing over a sufficiently wide range of adsorbed dye are obtained in the present study goes to show that, within this range, the dye

is likely to form a monomolecular layer in the substrate. With further absorption of dye, multimolecular layers are likely to be formed; moreover, because the energy released in sorbate-sorbate interaction is generally lower than that released in the sorbate-solvent interaction, the values of the heat of dyeing show a tendency to decrease as soon as multimolecular layer formation commences. The critical concentration beyond which the values of the heat of dyeing tend to decrease may, therefore, be taken as a stage of the completion of the formation of a monolayer of a particular dye in a cellulosic fibre substance. Although it is not possible to indicate very conclusively whether or not, up to the stage of constancy in the values of the heat of dyeing, a monomolecular layer of the dye is formed in the substrate, indirect evidence in support of this concept is available from the results of the density measurements of dyed cellulose[4] and from the results of the oxidation of cellulose containing different amounts of dye with a sodium hypochlorite solution. As did Daruwalla and D'Silva, the present authors found that, in the case of cotton containing increasing amounts of dye (Chloramine Purple 10BC, Chlorazol Orange RN and Chlorazol Blue B), catalytic oxidation is very rapid, but that beyond a critical dye concentration in the fibre, the extent of oxidation does not change appreciably (Fig. 4). This critical dye concentration is analogous to the stage beyond which the values of the heat of dyeing tend to decrease. Thus, because of the formation of a monolayer of dye in cellulose, the dye which is in close proximity to cellulose is more effective in increasing cellulose oxidation than when additional dye going into the fibre gets adsorbed on the monolayer of the dye present in the substrate. Furthermore, as will be discussed later, when these critical concentrations of dyes are considered to be saturation values and when the activity of dye in the fibre and the subsequent affinity values are calculated on the basis of a mechanism of the adsorption of dye anions on specific sites, plots correlating the activity of dye in the fibre with that in solution at equilibrium are linear with slopes close to unity and affinity values are fairly consistent over a wide range of dye concentration in the bath at different dyebath temperatures. Direct evidence is also available from the results of the present study regarding the saturation value of a direct dye for cotton when the reciprocals of the dye in the fibre to that in solution are plotted at different temperatures of dyeing (Fig. 5). These curves are linear, indicating a Langmuir type of adsorption, and the intercept on the $1/[D_\phi]$ axis corresponds to a figure very close to that obtained for monolayer formation from the experiments of the heat of dyeing measurements (Table II).

TABLE II. COMPARISON BETWEEN THE SATURATION VALUES OBTAINED FROM HEATS-OF-DYEING MEASUREMENTS AND THOSE OBTAINED FROM ADSORPTION MEASUREMENTS

Dye	Saturation values obtained from heats of dyeing, mmol./kg. dry fibre	Saturation values obtained from adsorption, mmol./kg. dry fibre
Congo Red	18.67	17.86
Benzopurpurine 4B	17.96	20.83
Chloramine Purple 10BC	19.61	18.52
Chlorazol Blue B	7.24	8.30
Chlorazol Blue G	5.78	6.17

The amounts of dye required for the formation of a monolayer as obtained from the heat of dyeing measurements vary between 6 and 19 mol./kg. of cotton for the different dyes studied. When a comparison is made between the saturation values of different dyes studied, it appears that there is not much difference between dyes of similar structure (namely dye nos. 1–4), but when large sulphonic acid groups are introduced in the dye molecule, as

in the case of Chlorazol Blue B and Chlorazol Blue G, the saturation values drop appreciably (Table I).

With most of the dyes studied, at a low dye concentration the values of the heat of dyeing are always higher than the normal values, indicating that there exist a limited number of sites in cotton for which dye has high affinity and that, when dye is adsorbed on these highly-active sites, dyeing on the less active and more plentiful sites takes place. These observations are in agreement with those of Gnehm and Kaufler,[8] and Jackson and Turner,[9] who found that the last traces of direct cotton dyes could not be removed by repeated washing or by extraction with an aqueous solution of pyridine, and with those of Mann and Marrinan,[10] who observed that, during the rehydrogenation of deuterated groups in cellulose, a few of these groups were very resistant to rehydrogenation. Very recently, Daruwalla and Shet,[11] who studied the kinetics of the rate of the removal of primary adsorbed water in different cellulosic fibres, observed that the rate of removal during the last stages was extremely low compared with the rate of the removal of primary adsorbed water. No correlation was observed between the nitrogen content of the fibre substance or free-COOH groups in the fibre and the amount of dye in the fibre substance where high values of the heat of dyeing are obtained. It appears that the high energy of association between

dye and fibre at low concentrations may be due both to adsorption on sites of high activity and to steric factors which prevent the dye molecules trapped in the network of cellulose from passing from the fibre phase to the solution phase.

When the affinities of direct cotton dyes for cellulose are to be determined, the main parameters required are the activity of dye in the fibre and in the dyebath. Affinity can be represented by the equation:

$$-\Delta G^\circ = RT \ln a_\phi - RT \ln a_\sigma \qquad (1)$$

where R is the gas constant; T, the absolute temperature of dyeing; a_ϕ, the activity of dye in fibre, and a_σ, the activity of dye in an aqueous solution. If the dye is assumed to be completely ionised in a solution and if the activity coefficient is considered to be unity, the activity of the dye in solution can be represented by the product of the ionic concentration of the dye anions and sodium ions in the solution, and

$$-\Delta G^\circ = RT \ln a_\phi - RT \ln [D_\sigma] [Na_\sigma]^z \qquad (2)$$

where $[D_\sigma]$ and $[Na_\sigma]$ are the ionic concentrations of dye anions and sodium ions in the solution at equilibrium (g. ions/l.) and z is the valency of the dye. For assigning a value to the activity of dye in the cellulose phase, a choice of a suitable function to represent the activity will depend on the mechanism of dyeing which is postulated. If the dye is assumed to be completely ionised in the substrate, the activity of dye in the fibre will vary depending on which of the following three thermodynamic mechanisms is operative during the dyeing:

A. Both the dye anions and sodium ions are adsorbed on specific sites in the fibre in a monomolecular layer and are not subjected to interference, either electrical or otherwise, from the adjacent adsorbed anions.

B. Only the dye anions are adsorbed on specific sites, while the sodium ions are diffusely adsorbed.

C. Both the dye anions and sodium ions are attracted to the fibre-solvent interphase and there is a possibility of formation of a multimolecular layer. Vickerstaff[12] has considered these three thermodynamic approaches for expressing the activity of dye in the fibre phase and has developed appropriate equations for the calculation of activity in the fibre and of affinity values for each of these mechanisms.

Until now only mechanism C could be considered and tested because in the other two mechanisms it was essential to know the exact amount of dye required to form a monolayer in the fibre substance. Peters and Vickerstaff[3] adopted the mechanism of diffused adsorption for both dye anions and gegenions; this mechanism necessitated the use of the volume term V, which represents the volume of the surface of the fibre substance which takes part in the dyeing. The validity of this term has, however, been questioned by Preston, Mhatre and Narasimhan,[13] by Nishida[14] and by Horiki[15]. It was, therefore, thought desirable to test the alternative approach of expressing the activity of a direct dye in a fibre substance as the fraction of the total sites occupied at a specific stage of equilibrium dyebath adsorption. From the knowledge of the saturation value of a direct dye for cotton obtained with

precision from the determination of the heat of dyeing at different concentrations of adsorbed dye in the fibre, the two mechanisms, A and B, could be investigated. When mechanism A is applied to the results of the present study, it is found that it is not valid, the slopes of the plots correlating $(z+1)\log\theta_D/(1-\theta_D)$, where θ_D is the fraction of total sites occupied by dye anions, with $\log[D_\sigma][Na_\sigma]^z$ are far from unity (Table III), and the calculated affinity values are not at all consistent. This is because the dyebath contains both dye and electrolyte; therefore, the total number of sodium ions present in the fibre would not only be equal to those required for maintaining electrical neutrality but would also be equal to the sum of sodium ions surrounding dye anions in an equivalent number and to those arising from the electrolyte present in the fibre phase in equilibrium with the solution phase, according to the Donnan membrane equilibrium.

When mechanism B is considered in connection with the results of the present sudy, under different temperatures and conditions of dye concentration in the bath, plots correlating $\log\theta_D/(1-\theta_D)\cdot[Na_\phi]^z/V^z$ with $\log[D_\sigma][Na_\sigma]^z$ are linear, except for Chlorazol Blue B, Chlorazol Blue G and Chlorazol Orange RN, with slopes close to unity (Figs. 6–8 and Table III), and the affinity values are consistent (Tables IV–VI). $[Na_\phi]$ is the ionic concentration of dye anions in the fibre phase (g. ions/kg.); it can be determined by means of the Donnan equilibrium between sodium ions and chloride ions in the fibre and in the external solution according to the equation derived by Peters and Vickerstaff.[3] V is the surface volume in l./kg. dry fibre, which is taken to be 0.3 l./kg. for cotton. In the case of Congo Red, Benzopurpurine 4B and Benzopurpurin 10B, the plots correlating the activity of dye in the fibre to that in the solution are closer to unity, and the affinity values agree more closely with one another when mechanism B is considered than is the case when the treatment of Marshall and

Peters[16] is considered (mechanism C). The affinity values obtained from the results of dyeing equilibria at different temperatures and the values of the heat dyeing determined from the slopes of the linear plots correlating $\Delta G^\circ/T$ with $1/T$ are given in Table I. It can be seen that the values of the heat of dyeing obtained are close to those obtained from the desorption experiments mentioned earlier, where the method of determining the heat of dyeing does not involve the expression of the activity of the dye in the fibre phase.

The following are the main points which serve to show that the mechanism based on the adsorption of dye anions on specific sites and sodium ions being diffusely adsorbed is more probable for dyeing equilibria with direct dyes on cellulose than that developed by earlier workers based on diffused adsorption for both the ions.

(1) The saturation values which are used to calculate the total number of sites available for dye adsorption in order to determine the activity of the dye in the cellulose substrate are actually obtained from experimental data rather than arbitrarily accepting the volume term, V, to fit the experimental results with the postulated theory.

(2) Plots correlating the logarithm of the activity of the dye in the fibre to that in the solution are linear, with slopes approaching unity.

(3) The calculated values of the affinity of a dye are consistent with one another under different conditions of dye concentrations in the bath at each of the dyebath temperatures studied.

(4) Plots correlating $\Delta G^\circ/T$ against $1/T$ are linear, and the values of the heats of dyeing obtained from the slopes of these curves are very close to those obtained from desorption experiments where the treatment used does not involve the expression of the activity of the dye in the fibre.

The Adsorption of the Dye Mixture.—Boulton, Delph, Fothergill and Morton,[17] Neale and Stringfellow[18] and Derbyshire and Peters[19] have shown that, with binary mixtures of Chrysophenine G and Chlorazol Sky Blue FF, the equilibrium adsorption of either of the two dyes was reduced when the other dye was present in the dyebath. The main factors which are likely to influence the adsorption of direct dyes from mixtures are competition between different dye anions for available sites in the fibre substance, the effect of each dye in contributing to the surface charge of the cellulose and sodium ion concentrations in the fibre, and interaction between dyes in the solution. As the fibre at a low concentration of adsorbed dye is very far from being saturated, however, competition for available sites is not likely to have much effect. According to Neale and Stringfellow,[18] the effect of each dye on the charge on the fibre surface and on the sodium ion concentration in the fibre is inadequate to explain the reduced adsorption from the mixed dyebath. Thus, the main contribution to the reduction in the dye uptake from a mixed dyebath appears to arise from the interaction of dyes in the solution.

Horiki[15] could explain satisfactorily in a quantitative way the adsorption of Chrysophenine G and Chlorazol Sky Blue FF from a mixed dyebath at 90°C by a cellophane sheet, assuming the formation of 1 : 1 complex and adopting the thermodynamic treatment of Marshall and Peters[16] for equilibrium dyeing. At higher concentrations of Chrysophenine G in the dyebath, however, he could not explain the adsorption behaviour on the basis of the 1 : 1 complex.

In the present study, in order to explain the behaviour of Chrysophenine G and Chlorazol Sky Blue FF when applied from a mixed dyebath, the data given by Horiki[15] have been considered and the saturation values and affinity values for these two dyes in cellophane have been determined by the desorption experiments mentioned before. Assuming that the thermodynamic treatment mentioned before is valid in the case of mixtures also, the effective dyebath concentration of each dye which would effect a specific equilibrium adsorption on cellophane can be calculated from the equation:

$$-\Delta G^\circ = RT \ln \theta_D/(1-\theta_D) \cdot [Na_\phi]^z/V^z - RT \ln [D'_\sigma] [Na_\sigma]^z \quad (3)$$

where $[D'_\sigma]$ is the effective dyebath concentration of a particular dye (g. ions/l.), when the affinity values of the dyes at a particular temperature and the saturation values of cellophane for these dyes are known. From the knowledge of the effective dyebath concentration of each dye under different concentrations of combinations and at different temperatures, the amount of each dye in the mixture which is ineffective in dyeing can be obtained and the types of complexes of these two dyes likely to be formed under different conditions can be predicted. These results for the dyeing temperatures of 70 and 90°C have been

recorded in Table VII, where F_ϕ and G_ϕ represent the concentrations of Chlorazol Sky Blue FF and Chrysophenine G in cellophane at equilibrium (g. ions/kg.), F_σ and G_σ are the equilibrium dyebath concentrations of Chlorazol Sky Blue FF and Chrysophenine G in a mixture dyebath (g. ions/l.), F'_σ and G'_σ are the effective dyebath concentrations of Chlorazol Sky Blue FF and Chrysophenine G (g. ions/l.) as calculated from Eq. 3 and F_c and G_c are the dyebath concentrations of Chlorazol Sky Blue FF and Chrysophenine G ineffective in adsorption because of the interaction of dyes in the mixture (g. ions/l.) (they correspond to $(F_\sigma - F'_\sigma)$ and $(G_\sigma - G'_\sigma)$ respectively). The affinity values of Chlorazol Sky Blue FF for cellophane at 70 and 90°C have been calculated as 8.9 and 7.9 kcal./mol. respectively; the corresponding figures for Chrysophenine G are 6.0 and 5.6 kcal./mol. The saturation values of Chlorazol Sky Blue FF and Chrysophenine G for cellophane as obtained from the measurements of the heats of dyeing are 0.01512 g. ions/kg. dry cellophane and 0.02647 g. ions/kg. dry cellophane respectively. V, the volume term of the cellulose phase in cellophane, is considered to be 0.45 l./kg., a figure also used by Marshall and Peters[16] for the calculation of affinity values.

It can be seen from the results of Table VII that the experimental data for the adsorption of these dyes from a mixed dyebath at 70 and 90°C can be explained on the basis of the formation of a 1 : 1 complex between these two dyes up to the stage where the ratio of the amount of Chlorazol Sky Blue FF to that of Chrysophenine G is less than 1 : 2, but at higher concentrations of Chrysophenine G, complexes other than 1 : 1 (namely, 1 : 2, 1 : 3 and 1 : 4) appear to be formed in the dyebath. The types of complexes formed for the same ratio of Chlorazol Sky Blue FF to Chrysophenine G as starting dyebath concentrations appear to be the same at both 70 and 90°C. These results are in agreement with those recorded by Derbyshire and Peters,[19] who, from calorimetric measurements of the magnitude of the heats of interaction between Chrysophenine G and Chlorazol Sky Blue FF, have indicated the possibility of the formation of a considerable proportion of complexes richer in Chrysophenine G in the presence of an excess of this dye in an aqueous solution. These workers have also shown that the adsorption spectrum of a mixture of these two dyes in an aqueous solution is not the same as the sum of the spectra of its constituents and that, even at 90°C, the formation of a 1 : 1 complex takes place in the aqueous solution to an appreciable extent. In agreement with the deductions obtained in the present study from the equilibrium adsorption measurements of these two dyes from a mixed dyebath and the subsequent calculation of the effective dyebath concentration, these workers showed that, when an excess of Chrysophenine G was present in the dyebath, for a constant proportion of Chlorazol Sky Blue FF, the absorption maxima of Chlorazol Sky Blue FF shifted to longer wavelengths, this shows that the formation of higher complexes does take place to a certain extent under these dyebath conditions.

In conclusion, from the results of the present study it may be noted that the thermodynamic treatment developed by Daruwalla and D'Silva[4] is valid for a number of direct cotton dyes with different chemical constitutions and different aggregation behaviours. The affinity values obtained with the present treatment with all the dyes studied are higher than those obtained by adopting the treatment of Marshall and Peters.[16] It is rather difficult, however, to state which of these two sets of values may be considered to represent the true values. Nevertheless, it appears that the values obtained by adopting the thermodynamic treatment developed in the present study, values which are based on experimentally-determined value for the activity of dye in the fibre as calculated from the fraction of the total sites occupied, are likely to be more representative. Futhermore, the thermodynamic treatment used in the present study also explains in a semiquantitative way the equilibrium adsorption behaviour on cellulose of Chrysophenine G and Chlorazol Sky Blue FF when they are applied from mixed dyebaths.

*The Synthesis of Methylacetylene by the Pyrolysis of Propylene. I. The Effect of Pyrolysis Conditions on Product Yields**

By Yasumasa SAKAKIBARA

(Received February 5, 1964)

Methylacetylene would be a valuable material in the field of synthetic chemistry. For example, it is known that methylacetylene is carbonylated with carbon monoxide to give methacrylate,[1] just as acetylene gives acrylate. Although various methods have been reported for the synthesis of methylacetylene, however, there is no economically attractive one. The present author was interested in obtaining methylacetylene by the pyrolysis of light hydrocarbons, especially by the direct dehydrogenation of propylene.

Rice et al.[2] were the first to report the synthesis of methylacetylene and allene, both being isomeric and equilibrated thermo-catalytically,[3] by the pyrolysis of isobutylene. In many investigations[4-14] of the pyrolysis of propylene, methylacetylene has not been detected in the products, while Szwarc[15] alone has found allene as a main product. He pyrolyzed propylene at temperatures ranging from 680 to 870°C and at pressures from 2 to 15 mmHg; there was a low conversion of 0.01 to 2 per cent. Recently, in the course of this study, it has been announced (U. S. Pat.[16]) that allene and methylacetylene were produced by contacting propylene with a metal filament heated over 900°C, at low pressure and with a short contact time. The purpose of the present investigation is to determine suitable conditions for the production of methylacetylene and allene by the pyrolysis of propylene and to obtain data on the distribution of the pyrolysis products.

Experimental

Materials.—Propylene was prepared by the vapor phase dehydration of isopropyl alcohol, using activated clay as a catalyst. After it had been washed with about a 15% solution of sodium hydroxide, it was stored in a 25 l. water-gas holder. Gas chromatographic analysis showed that the purity was better than 99.0 mol. % and that the principal impurities were hydrogen, methane, ethylene, and propane. Cylinder nitrogen of 99.9 mol.% purity was used as a reference gas, a known amount (about one-fourth of the propylene volume) being added to the propylene. The change in the volume (rate of expansion) of the reactant gas upon pyrolysis was calculated from the change in the concentration (mol.%) of the nitrogen.

Apparatus and Procedure. — The apparatus is shown in Fig. 1. The reactant gas, consisting of about 80 vol.% propylene and 20 vol.% nitrogen, was introduced into a silica (or porcelain) reaction tube from the gas holder through a water bubbler, a drying tower containing calcium chloride, and a needle valve. The gas pressure in the gas holder was always kept at atmospheric pressure by allowing water to run into it. To carry out experiments over a wide temperature range, various silica reaction tubes, from 2.9 to 11.0 mm. in inside diameter, and two different types of electric furnaces, one 30 cm. long (furnace I) and the other 10 cm. long (furnace II), were employed. Furnace II, having been constructed from a spiral "Siliconit" heating element,* was used mainly for heating to 1100°C and above. The reaction tube was suspended in the center of another silica tube, which extended through the furnace. The exhausted gas from the reaction tube was rapidly cooled with running water at the exit of the tube; it then passed through a trap immersed in ice-water to remove any liquid products and then through a 300-ml. glass gas-sampling flask, which was attached to a

bypass. The gas leaving the flask passed through a microscrew clamp and was continuously pumped out by an oil pump. The reactant-gas feed and the pressure, measured at the entrance of the reaction tube and at the exit of the sampling flask, were regulated to the desired grades by means of the needle valve before the reaction tube and the microscrew clamp.

The temperature was measured by a Pt-Pt·Rh thermocouple tied to the external wall of the reaction tube. The total volume of the reaction tube was measured, and a section, 20 cm. long in furnace I and 7 cm. long in furnace II, was assumed to be heated to the recorded temperature. The volume of the reaction zone, calculated on the basis of the above assumption, was used in the calculation of the contact time by means of the formula:

$$\text{Contact time (sec.)} = V_R/F$$

where V_R = the volume of the reaction zone (ml.)
F = the flow rate of the reactant gas corrected to the temperature and pressure of the reaction zone (ml./sec.)

The pyrolysis was performed under conditions varying over the following wide range: temperature, 800~1400°C; contact time, 4.4×10^{-4}~2.3 sec.; pressure, 50~200 mmHg (partial pressure of propylene, about 40~160 mmHg).

Analysis.—All hydrocarbon products through C_4 were analyzed, using mainly an 11.0-wt.% β,β'-oxydipropionitrile on silica gel column (1.0 or 2.4 m.) at 60°C and a 30-wt.% dioctyl phthalate column (2.4 m.) at room temperature and with hydrogen as the carrier gas. Although the β,β'-oxydipropionitrile-modified silica gel column was found by the present author to give a good separation of air and most of hydrocarbons through C_4 at temperatures below 70°C, the dioctyl phthalate column appeared to be more suitable for the rapid analysis of small quantities of methylacetylene and allene in the pyrolyzed gas. In practice, the latter column was used for the analysis of allene, methylacetylene, the isobutene-1-butene pair, and the 2-butenes-butadiene pair. For the sake of convenience, the overlapped peaks of isobutene-1-butene and 2-butenes-butadiene were adopted as those of 1-butene and butadiene respectively, because in most cases, the amounts of isobutene and 2-butenes formed were negligible (particularly of the former) or, at most, slight. For the quantitative analysis, relative gas volume response factors which had been measured for a series of hydrocarbons for hydrogen were used. The factors (per unit chromatographic peak area, propylene=1.00) used for methylacetylene and allene were 1.07 and 1.10 respectively. Hydrogen was analyzed using the above β,β'-oxydipropionitrile-modified silica gel column and using nitrogen as the carrier gas. In a gas-sampling procedure for gas chromatography, the gas sample of reduced pressure in the sampling flask was introduced into one to five milliliters glass sample tubes using a vacuum system.

In several cases, acetylenic hydrogen of methylacetylene and acetylene was determined chemically by a concentrated silver nitrate solution.[17] The results were in full accord with those of gas chromatography.

Results and Discussion

The conversion of propylene (per cent of propylene pyrolyzed) and the yield of each product (moles per 100 mol. of propylene pyrolyzed) to be given below were obtained by the formulas:

$$\text{Conversion} = \{(a-b\cdot f)/a\}\times 100$$

$$\text{Yield} = \{p\cdot f/(a-b\cdot f)\}\times 100$$

where a, the volume percentage of propylene in the reactant gas; b, the volume percentage of propylene in the pyrolyzed gas; f, the rate of the expansion of the reactant gas by pyrolysis; the ratio of the volume percentage of nitrogen before to that after pyrolysis; and p, the volume percentage of the product.

In the composition of the pyrolyzed gas, the volume percentage was calculated on the basis of gases from hydrogen through C_4 hydrocarbons, though C_5 and higher hydrocarbons were present to a slight degree. Such treatment is possible without distorting the conversion and yield, because they are determined only on the basis of the ratio of each component to nitrogen. Furthermore, since methylacetylene and allene are equilibrated rapidly over catalysts,[3] the total yield was used to evaluate conditions for the synthesis of methylacetylene. In order to examine the hydrogen and carbon balance,

* Furnace I was used.

the percentages of hydrogen and carbon accounted for in gaseous products through C_4 hydrocarbons were calculated from their yields.

Concerning pyrolysis products, no ethane was detected in any experiment, except in those at 200 mmHg pressure, in which a trace of ethane was found. Propane was disregarded, because the reactant gas was contaminated with a small amount (0.4%) of propane and its amount decreased with increasing conversion until it showed only a trace at conversion levels above about 20%. Also, the total of butadiene and 2-butenes, the latter being much smaller than the former, was given as butadiene, as was described in the analytical procedure section.

The Effect of Temperature on Product Yields. —The results obtained in the conversion range from 8 to 14% are shown in Table I and Fig. 2. The yields of both methylacetylene (M-C_3H_4) and allene (A-C_3H_4) increased with an increase in the temperature in the range investigated, from 800 to 1400°C; the total yield [(M+A)-C_3H_4] ranged from 10 mol. at 800°C up to 37 mol. at 1300°C. Although the total yield increased rapidly in the lower part of the temperature range, it was almost constant (36 to 37 mol.) at high temperatures, ranging from 1200 to 1400°C. Thus, a high temperature of 1200 to 1300°C was found to be suitable for the synthesis.

The main products through C_4 hydrocarbons, except for methylacetylene and allene, were methane, ethylene, hydrogen, acetylene, 1-butene, and butadiene. The approximate decreasing order of yield is as just listed. The yields of methane and ethylene, formed in the ratio of about 1 to 1, decreased with an increase in the temperature from about 50 mol. to 40 mol. Contrarily, the yields of hydrogen and acetylene increased regularly with an increase in the temperature, reaching 26 mol. and

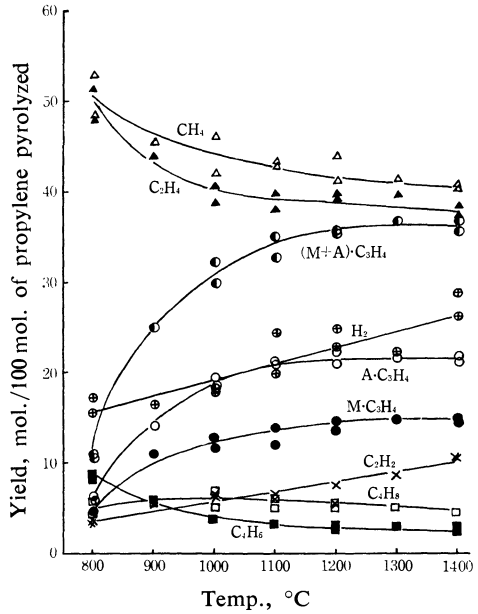

Fig. 2. Effect of temperature on product yields. Conversion, 9 to 14%

10 mol. respectively at 1400°C. The amount of 1-butene was nearly constant at about 5 mol., while that of butadiene fell from 8 mol. at 800°C to 3 mol. at 1400°C.

Some amounts of higher hydrocarbons (C_5 and higher) and coke appeared to be formed. In Table I, the deficiencies of the hydrogen and carbon accounted for in the gaseous products (in hydrogen and in hydrocarbons through C_4) must be explained in terms of the formation of higher hydrocarbons, and of them and coke respectively, when these deficiencies are not due to experimental error. Thus, the

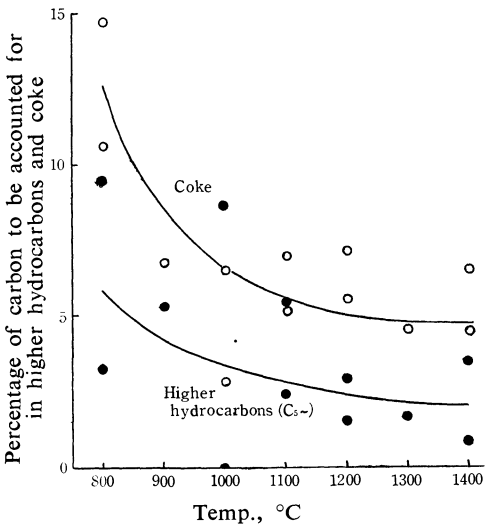

Fig. 3. Estimated amounts of higher hydrocarbons and coke.

percentage of carbon to be accounted for in the higher hydrocarbons and coke (Fig. 3) was derived from the deficiencies of the hydrogen and carbon, on the assumption of an average ratio of carbon to hydrogen of 3:4 in the higher hydrocarbons (probably olefins, cycloolefins, aromatics etc.[14]) formed. On the whole, the estimated amounts (in percentages of carbon) of both higher hydrocarbons and coke, though a part of their values are scattered, fall at a considerable rate with an increase in the temperature.

The Effect of Contact Time (Conversion) on Yields. — The results of the pyrolysis at 100 mmHg pressure and 1200°C, which was a suitable temperature for the synthesis, are shown in Table II (Run No. 36—52) and Fig. 4. The

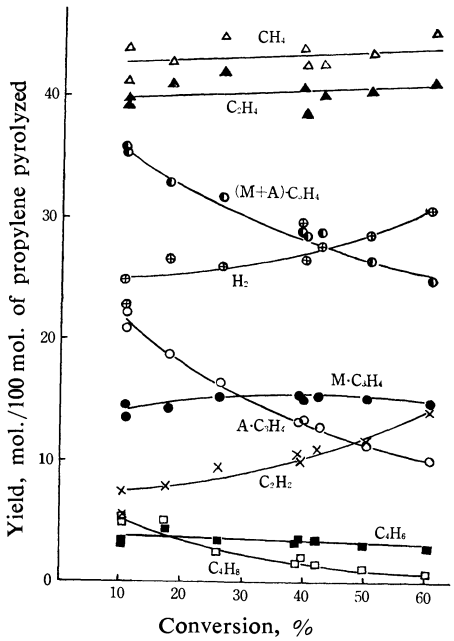

Fig. 4. Effect of contact time (conversion) on product yields. Temp., 1200°C

total yield of methylacetylene and allene decreased with the increasing conversion, ranging from 36 mol. at 10% conversion down to 25 mol. at 60% conversion. In this connection, the yield of allene fell at a considerable rate as the conversion was increased, while that of methylacetylene was fairly constant at 13 to 15 mol. over the wide conversion range studied. Thus, taking account of an equilibrium relation between methylacetylene and allene, it seems probable that methylacetylene is not a primary but a secondary product of the isomerization of allene. On the other hand, the yields (in moles per 100 mol. of entering propylene) of methylacetylene and allene increased with the increasing conversion, being 9 mol.

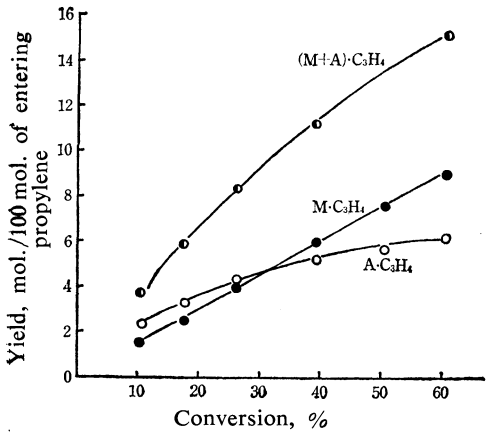

Fig. 5. Variation of yields (in moles per 100 mol. of entering propylene) of methylacetylene and allene with conversion. Temp., 1200°C

and 6 mol. respectively (total 15 mol.) at the highest conversion, 60% (Fig. 5).

The yields of both methane (42~44 mol.) and ethylene (39~41 mol.) hardly varied over the conversion range investigated. The yields of hydrogen and acetylene, however, increased fairly rapidly with the increasing conversion, being 31 mol. and 14 mol. at 60% conversion respectively. In the conversion range, butadiene, formed probably by the secondary decomposition of 1-butene, was obtained in a constant yield of about 3 mol., while the yield of 1-butene decreased with the increasing conversion from 5 mol. to 1 mol. The percentage of hydrogen and carbon accounted for in the gaseous products decreased with an increase in the contact time (conversion). Admittedly, the decrease of hydrogen means that the formation of higher hydrocarbons becomes striking. Furthermore, in view of the results that the yield of methylacetylene-allene, because it is unstable as compared with propylene, decreased fairly rapidly with the increasing contact time, it may be supposed that they react easily with propylene or various radicals, e.g., allyl, to form higher hydrocarbons.

The variations in the yields of methylacetylene and allene, and in the total yield with conversion at 1100°C and 1300°C, in addition to that at 1200°C, are shown in Fig. 6. In the cases of 1100°C and 1300°C, the variation in their yields with conversion was almost the same as that at 1200°C, except that it was somewhat lower at 1100°C.

The Effect of Pressure on Yields.—In addition to the experiments made at 100 mmHg pressure (partial pressure of propylene, about 80 mmHg), a number of experiments were carried out at 50 and 200 mmHg pressure (partial pressure of propylene, about 40 and 160 mmHg respectively). The results are shown in Table II. Also, Fig. 7 shows the effect of pressure on the yields of methylacetylene and allene, as well as the total yields. When yields at fixed conversions are compared, the total yields and also each yields are found to increase with a decrease in the pressure. The differences in the total yields between different pressures were larger at higher conversions. The highest

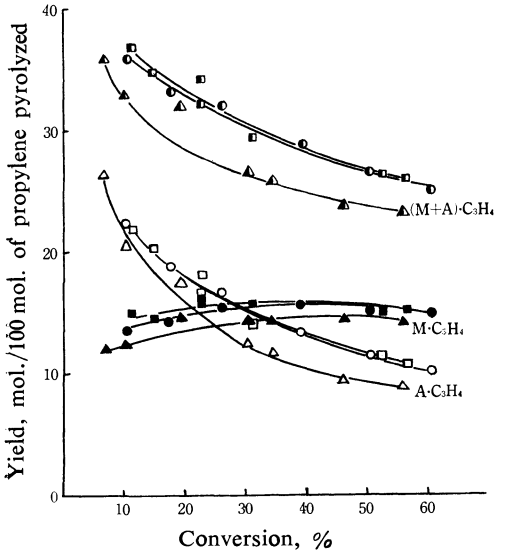

Fig. 6. Variation of yields of methylacetylene and allene with conversion at various temperatures.

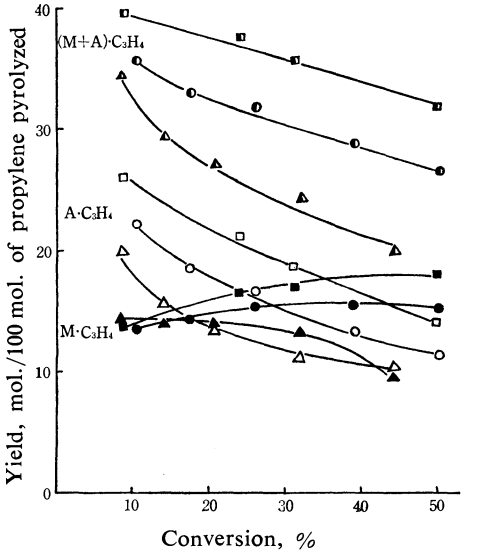

Fig. 7. Effect of pressure on yields of methylacetylene and allene.
Triangles, 200 mmHg; Circles, 100 mmHg; Squares, 50 mmHg.

total yield of 40 mol. was obtained when the pressure (50 mmHg) and the conversion (9.0%) were the lowest studied. It is noticeable that, with 100 mmHg pressure, the yield of methylacetylene is fairly constant over the conversion range, while with 50 mmHg pressure the yield increases with the increasing conversion.

The yields of other gaseous products varied slightly with pressure over the range investigated. Namely, with a decrease in the pressure the yields of methane and ethylene decreased slowly, while reversely, that of acetylene increased. On the other hand, the yields of 1-butene and butadiene almost did not vary at all with the pressure. The percentage of hydrogen and carbon accounted for in the gaseous products increased with the decrease in the pressure from 88% and 75% at 200 mmHg pressure (44% conversion) to 95% and 88% at 50 mmHg pressuse (50% conversion) respectively. On the basis of the above variation in the distribution of pyrolysis products with pressure, it is assumed that the formation of higher hydrocarbons by the additions to propylene of propylene, allene, and methylacetylene (as molecules or radicals derived from them) is diminished as the pyrolysis pressure is decreased, and that, consequently, the yield of methylacetylene-allene is increased.

Summary

Propylene has been pyrolyzed in a flow system over a wide range of conditions (temperature, 800~1400°C; contact time, 4.4×10^{-4} ~2.3 sec.; pressure, 40~160 mmHg) to find suitable conditions for producing methylacetylene (and allene) and for obtaining data concerning the distribution of pyrolysis products. Under proper conditions, the pyrolysis occurred without any appreciable production of tarry and carbonaceous materials. High temperatures (1200~1300°C), short contact times (millisecond order; conversions below 30%), and low pressures (below 100 mmHg) were found to required for the good production of methylacetylene-allene. A methylacetylene-allene yield of 38 mol. per 100 mol. of propylene pyrolyzed was realized at 1200°C, 50 mmHg pressure (partial pressure of propylene, 40 mmHg), and 24% conversion (contact time, 1.7 msec.). The other gaseous products were found to be methane, ethylene, hydrogen, acetylene, 1-butene and butadiene, in decreasing order.

The author wishes to express his thanks to Professor Sango Kunichika of Kyoto University for his helpful advice and kind encouragement throughout this work.

The Synthesis of Methylacetylene by the Pyrolysis of Propylene. II. The Mechanism of the Pyrolysis[*1]

By Yasumasa SAKAKIBARA

(Received March 23, 1964)

Previously,[1] when the present author investigated the pyrolysis of propylene with the object of finding suitable conditions for the production of methylacetylene-allene,[*2] he found that high temperatures (1200~1300°C), low pressures (below 100 mmHg), and short contact times (conversion below 30%) were required for good results. In this paper the mechanism for the pyrolysis will be reported on.

The distribution of the products of the pyrolysis varies considerably with pyrolysis conditions, and on the basis of observed results several mechanisms have been suggested in recent years. Ingold and Stubbs,[2] investigating the pyrolysis at temperatures from 570 to 650°C and at pressures from 50 to 500 mmHg, proposed a series of molecular

rearrangement reactions. At higher temperatures, however, it is quite possible that a radical mechanism may predominate. Szwarc,[3] who used higher temperatures (680~870°C), lower pressures (2~15 mmHg), and very low conversions (0.01~2%), found that allene, methane, ethylene, and hydrogen were the main products; he suggested a free-radical chain mechanism for the primary decomposition reaction. Another radical mechanism was proposed by Laidler and Wojciechowski,[4] who reinvestigated the pyrolysis under conditions similar to those used by Ingold and Stubbs and found a considerable amount of higher hydrocarbons but did not detect any allene. The mechanism was partly different from the Szwarc mechanism; namely, a step in the Szwarc method, $CH_2=CH-CH_2\cdot \rightarrow CH_2=C=CH_2 + H$, was replaced by the reaction, $CH_2=CH-CH_3 + CH_2=CH-CH_2\cdot \rightarrow$ higher hydrocarbons + H.

In the present investigation, an effort was made to clarify the mechanism for the pyrolysis at higher temperatures (800~1400°C). Special attention was given to the development of mechanisms for the formation of allene and methylacetylene and for their subsequent decomposition, mechanisms by which we can account for the experimental results. In order to obtain information about secondary reactions involving allene, the pyrolysis of allene itself also was investigated under conditions similar to those of propylene.

Experimental

The Pyrolysis of Propylene. — A large number of experimental results have already been described.[1] The present additional experiments were carried out similarly.

The Pyrolysis of Allene. — The experimental methods were the same as those for propylene.

Allene was prepared by the debromination of 2,3-dibromopropene with zinc.[5] The crude allene was passed through two wash bottles, containing a 10% sodium hydroxide solution and a 3 M silver nitrate solution, and a cooled trap at −20°C, and was then condensed in an ethanol-dry ice trap. It was distilled roughly and stored over a saturated sodium chloride solution in a 25 l. gas holder. Gas chromatographic analysis showed that the purity was about 93 mol. %, the remainder being almost all propylene.

Results and Discussion

The Pyrolysis Products of Propylene. — The primary gaseous products were determined by extrapolating the products to zero conversion (the zero conversion method). With low conversion data obtained at 1100°C and 80 mmHg pressure, the extrapolation was easily treated (Fig. 1). From the figure it may be concluded that hydrogen, methane, ethylene, allene, and 1-butene are the primary products, and that methylacetylene, acetylene, and butadiene are the secondary products. Of the primary products, allene and 1-butene, which are less stable to heat than the original material, would undergo considerable subsequent decomposition, even at low conversion levels, to produce such secondary products as methylacetylene and butadiene respectively.

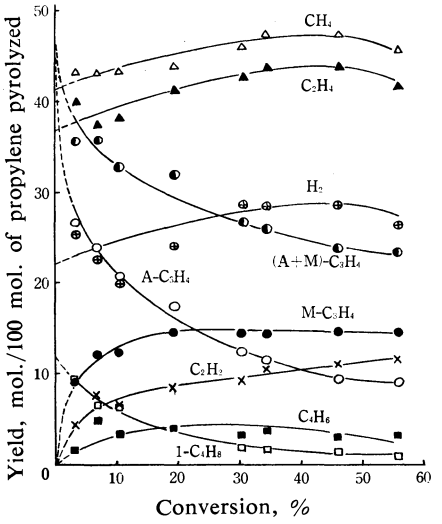

Fig. 1. Extrapolation of gaseous products from propylene to zero conversion (1100°C): A-C_3H_4, allene; M-C_3H_4, methylacetylene.

The formation of acetylene appears to be due to the decomposition of methylacetylene rather than to that of ethylene and methane, particularly at low conversion levels, in view of the results of the pyrolysis of allene described below. The effects of temperature (800~1400°C) and pressure (40~160 mmHg) on the product yield are shown in Tables I and II respectively.

Some higher hydrocarbons (C_5 and higher) and carbonaceous matter appeared to be formed, though they were not identified. Their amounts formed under the present conditions had previously been[1] estimated on the basis of the deficiencies of the percentage of hydrogen and carbon accounted for in the gaseous products (Table I). Laidler and Wojciechowski[4] obtained such liquid products as benzene, cyclopentadiene, cyclohexadiene, etc.

The Pyrolysis of Allene.—The data of the

pyrolysis of allene,*3 particularly at high temperatures and low pressures, were necessary for clarifying the mechanisms for the secondary reactions involving allene, in the pyrolysis of propylene. The results of the pyrolysis at temperatures of 800 to 1200°C and at a pressure of about 80 mmHg are shown in Table III. Allene was much less stable than propylene, as is shown by the relative stability of propylene and allene (Table V). At high temperatures, the isomerization to methylacetylene occurred predominantly, though lower temperatures favor polymerization rather than isomerization or decomposition (see footnote *3). Methylacetylene was a main gaseous product; much smaller amounts of hydrogen, methane, ethylene, and acetylene were found, together with a trace of C_4 hydrocarbons. At 800°C, the isomerization of allene

*3 Although a few investigations have been reported, none of them was applied to the conditions under which the pyrolysis of propylene was studied by the present author. Cf. R. N. Meinert and C. D. Hurd, *J. Am. Chem. Soc.*, 52, 4540 (1930); A. T. Blomquist and J. A. Verdol, ibid., 78, 109 (1956).

* Furnace I was used for Run Nos. 2—9 and furnace II for the others (See Ref. 1).

** The values were calculated in taking account of the amount of propylene contained in the reactant gas. The minus values shown in parentheses mean that propylene was pyrolyzed in the ratio of these values to 100 mol. of allene pyrolyzed.

to methylacetylene was incomplete. Judging from the low percentages of hydrogen and carbon accounted for in the gaseous products, considerable amounts of polymerized products appeared to be formed. On the other hand, at 1200°C and low conversion levels, other reactions than isomerization were considerably suppressed and the isomerization was performed efficiently. With increasing contact time (conversion), the yields of methylacetylene decreased rapidly. The methylacetylene/allene ratio, however, slowly approached the value of a theoretically calculated equilibrium constant for the allene $\rightleftarrows$ methylacetylene isomerization as was to be expected from the equilibrium relation (Table IV).

TABLE IV. EQUILIBRIUM CONSTANT FOR THE ISOMERIZATION OF ALLENE*
(CH_2=C=CH_2 $\rightleftarrows$ CH_3-C≡CH)

Temp., °K	800	1000	1200	1400	1500
$K_p=\frac{[CH_3\text{-}C\equiv CH]}{[CH_2=C=CH_2]}$	4.53	3.75	3.15	2.94	2.77

* The values were calculated on the basis of the $\Delta G°/T$ given in "Landolt-Börnstein Zahlenwerte und Funktionen" (6 Aufl. II Bd. 4 Teil, 453 (1961)); see also J. F. Cordes and H. Günzler, *Chem. Ber.*, **92**, 1055 (1959).

The main gaseous products other than methylacetylene, though they were found in much smaller quantities than those of methylacetylene, varied remarkably with the temperature and the rate of conversion. Figures 2 and 3 show the distribution of main gaseous products, exclusive of methylacetylene, and the methylacetylene/allene ratio at 800 and 1200°C. The conversion and yield described in these figures were those calculated by regarding both allene and its isomerization product, methylacetylene, as unreacted allene. The results of the zero conversion method suggest that ethylene is the primary product (Figs. 2 and 3).

This is supported also by the fact that, at both 800 and 1200°C, the yield of ethylene decreased with the increase in the methylacetylene/allene ratio which resulted from the isomerization of allene. Furthermore, it is reasonable that the decrease was rapid in the case of 1200°C, at which temperature the ratio increased rapidly with the increasing conversion. Hydrogen also appears to be a primary product. On the other hand, methane and acetylene are the secondary products, as determined by the zero conversion method. In the case of 1200°C, it should be noted that the yields of methane and acetylene were about the same, and that they increased rapidly with the increase in the methylacetylene/allene ratio. From these facts, it may be concluded that methane and acetylene are the decomposition products of methylacetylene, which is itself the isomerization product of allene.

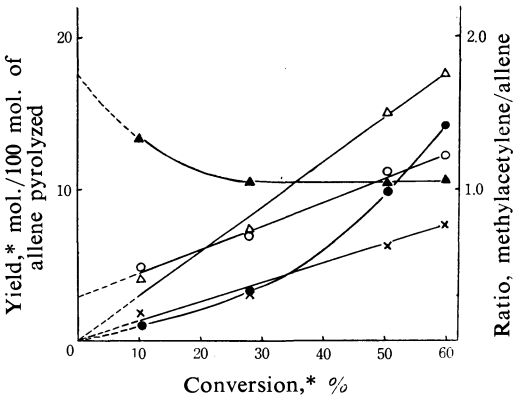

Fig. 2. Yields of main gaseous products (exclusive of methylacetylene) from allene pyrolysis at 800°C: ○, hydrogen; △, methane; ×, acetylene; ▲, ethylene; ●, methylacetylene/allene ratio.
* These values were calculated by regarding both allene and its isomerization product, methylacetylene, as unreacted allene.

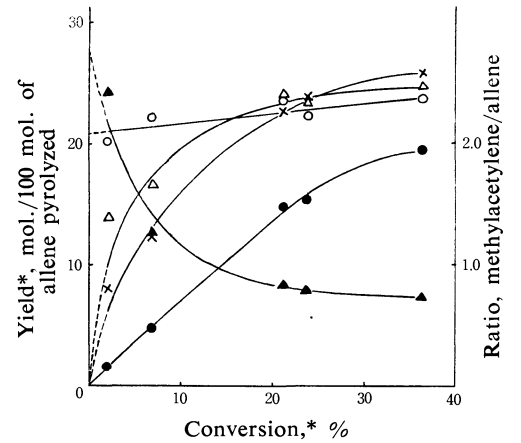

Fig. 3. Yields of main gaseous products (exclusive of methylacetylene) from allene pyrolysis at 1200°C: ○, hydrogen; △, methane; ×, acetylene; ▲, ethylene; ●, methylacetylene/allene ratio.
* See footnote* to Fig. 2.

Mechanism.—On the basis of the experimental results, a mechanism for the pyrolysis of propylene may be proposed. This mechanism may be developed by observing the following restrictions. Even at low conversions, secondary reactions involving such unstable products as allene and methylacetylene are considered to be important and are thus included. However, secondary reactions involving stable

TABLE V. RELATIVE STABILITY OF PROPYLENE AND ALLENE

	(0.10)	(8.2×10^{-3})	(8.1×10^{-4})	(1.5×10^{-3})
Ratio of contact time, propylene/allene	24	3.5	4.3	5.5
	(21)	(1.6)	(2.4)	(2.0)

* Contact times for fixed conversions were obtained from the curves of the contact time vs. the conversion.

** The values shown in parentheses are those of cases in which conversion was calculated by regarding both allene and its isomerization product, methylacetylene, as unreacted allene.

pyrolysis products are disregarded. The order of the decreasing stability of methane and light olefins is as follows: methane>ethylene >propylene>2-butene> 1-butene > isobutene.[6] Judging from the relative stability of propylene and allene, it may be said that allene is much less stable than propylene, especially at the lower temperatures investigated (Table V).

Although higher hydrocarbons (C_5 and higher) formed in the pyrolysis would readily undergo subsequent decomposition, these reactions are disregarded.

With the above restrictions in mind, the following mechanism was developed:

Primary reactions

$$CH_2{=}CH{-}CH_3 \rightarrow CH_2{=}CH{-}CH_2\cdot + H \quad (1)$$

$$CH_2{=}CH{-}CH_3 + H \rightarrow CH_2{=}CH{-}CH_2\cdot + H_2 \quad (2)$$

$$CH_2{=}CH{-}CH_3 + H \rightarrow CH_3{-}CH_2{-}CH_2{}^*\cdot \quad (3)$$

$$CH_3{-}CH_2{-}CH_2{}^*\cdot \rightarrow C_2H_4 + CH_3\cdot \quad (4)$$

$$CH_2{=}CH{-}CH_3 + CH_3\cdot \rightarrow CH_2{=}CH{-}CH_2\cdot + CH_4 \quad (5)$$

$$CH_2{=}CH{-}CH_3 + CH_2{=}CH{-}CH_2\cdot \rightarrow \text{higher hydrocarbons(HHC)(A)} + H(CH_3\cdot) \quad (6)$$

$$CH_2{=}CH{-}CH_2\cdot \rightarrow CH_2{=}C{=}CH_2 + H \quad (7)$$

$$CH_2{=}CH{-}CH_2\cdot + H \rightarrow CH_2{=}CH{-}CH_3 \quad (8)$$

$$CH_2{=}CH{-}CH_2\cdot + CH_3\cdot \rightarrow CH_2{=}CH{-}CH_2{-}CH_3 \quad (9)$$

Secondary reactions involving allene and methylacetylene

$$CH_2{=}C{=}CH_2 \rightleftarrows \begin{matrix} CH_2{=}C{=}CH\cdot \\ \updownarrow \\ \cdot CH_2{-}C{\equiv}CH \end{matrix} + H \rightleftarrows CH_3{-}C{\equiv}CH \quad (10)$$

$$CH_2{=}C{=}CH_2 + CH_2{=}CH{-}CH_2\cdot \rightarrow \text{HHC(B)} + H \quad (11)$$

$$CH_2{=}C{=}CH\cdot \leftrightarrow \cdot CH_2{-}C{\equiv}CH$$

$$+ CH_2{=}CH{-}CH_3 \rightarrow \text{HHC(C)} + H \quad (12)$$

$$CH{\equiv}C{-}CH_3 + CH_2{=}CH{-}CH_2\cdot \rightarrow \text{HHC(D)} + H \quad (13)$$

$$CH{\equiv}C{-}CH_3 + H \rightarrow C_2H_2 + CH_3\cdot \quad (14)$$

involving 1-butene

$$CH_2{=}CH{-}CH_2{-}CH_3 \xrightarrow{\text{(or by radicals R)}} CH_2{=}CH{-}\dot{C}H{-}CH_3 + H(RH) \quad (15)$$

$$CH_2{=}CH{-}\dot{C}H{-}CH_3 \rightarrow CH_2{=}CH{-}CH{=}CH_2 + H \quad (16)$$

(The asterisks indicate a hot radical which decomposes easily into C_2H_4 and $CH_3\cdot$.)

The known frequency factors and activation energies for the elementary reactions 1 to 9 are shown in Table VI. Those shown in parentheses are less certain values assumed by Laidler and Wojciechowski,[4] and by Amano and Uchiyama.[7]

In this mechanism, part of the primary decomposition reaction (reacitons 1–9) is a

TABLE VI. KINETIC PARAMETERS (AT 1000°K) FOR ELEMENTARY REACTIONS*

chain process. Reaction 1 is the chain initiation, reactions 2-6, 2-7, 3-4-5-6, and 3-4-5-7 are four chain propagation processes, and, finally, reactions 8 and 9 are the chain termination. Reactions 10 to 16 are the main secondary reactions, chiefly involving allene and methylacetylene.

The compatibility of the proposed mechanism with the observed experimental data can now be examined.

Products and Processes of Formation.—All the primary gaseous products, hydrogen, ethylene, methane, allene, and 1-butene, are formed by reactions 2, 4, 5, 7, and 9 respectively. Reaction 6, proposed by Laidler and Wojciechowski[4] for the formation of higher hydrocarbons, is also included in this mechanism, because considerable amounts of higher hydrocarbons appeared to be formed at the lower part of the temperature range investigated. In reaction 6, instead of hydrogen atoms, the splitting of methyl radicals would also be possible in view of the fact that C_5 olefins, such as cyclopentene,[8] cyclopentadiene,[4] and pentadiene,[9] were formed in the early stage of the pyrolysis of propylene or in that of the reaction of allyl radicals with propylene. Reaction 9 is included as a termination reaction in addition to reaction 8, though Szwarc,[3] and Laidler and Wojciechowski[4] adopted only reaction 8. This is a result of the fact that 1-butene was obtained as the primary product and the observation by Dominey and Danby[9] that the formation of butyl radicals by the addition of methyl radicals to propylene occurred only at temperatures below 400°C. In addition, it has been shown, most recently by Amano and Uchiyama,[7] that in the reaction $CH_3\cdot + C_3H_6 \rightarrow$ butyl, the equilibrium ratio of [methyl]/[butyl] is 10^3 at 1000°K by calculation from thermodynamic data; therefore, the reverse reaction is faster.

Of secondary reactions, those involving allene and methylacetylene may be presumed to be predominant in view of the relative stability of propylene and allene (Table V). Allene isomerizes to methylacetylene according to reaction 10, and the allene/methylacetylene ratio approaches the equilibrium constant. It has been shown by Collin and Lossing[10] that the loss of a H atom from allene results in the formation of a C_3H_3 radical which has a propagyl rather than an allenyl configuration and that the $CH{\equiv}C{-}CH_2\cdot$ and $\cdot CH{=}C{=}CH_2$ forms are probably resonance hybrids. Furthermore, they have presented the bond dissociation energies of 82.8 kcal./mol. for $CH{\equiv}C{-}CH_2{-}H$ and 81.2 kcal./mol. for $CH_2{=}C{=}CH{-}H$. The formation of higher hydrocarbons from allene and methylacetylene, which would clearly be responsible for the loss of allene—methylacetylene, may be ascribed to the reactions with allyl radicals (reactions 11 and 13) as in the case of propylene and to the reaction of propagyl radicals, produced from allene and methylacetylene, with propylene (reaction 12). Acetylene is probably produced by the reaction of methylacetylene with hydrogen atoms (reaction 14), in view of the experimental data of the pyrolysis of allene (Fig. 2 and 3). Considering the relative stability of ethylene and propylene,[6a] another process for the production of acetylene, the dehydrogenation of ethylene, appears to be less important in the early stage of the pyrolysis of propylene. Butadiene is probably produced by the dehydrogenation of 1-(and 2-)butene (reactions 15 and 16).

The Rates of the Formation of Products and Yields.—According to this mechanism, whenever an ethylene molecule is produced by reaction 4 a methyl radical is formed; this radical may give rise to a methane molecule by reaction 5 or, in a lesser degree, a 1-butene molecule by reaction 9. Therefore, the ethylene/(methane+1-butene) ratio must be 1:1. The experimental data seem to confirm this 1:1 ratio, considering that some amounts of methane are produced also from the methyl radicals formed by reaction 6 and by secondary reaction 14 (Fig. 1 and Table I).

The hydrogen/ethylene ratio should be independent of the pressure of propylene, since reactions 2 and 3, the latter followed by reaction 4 leading to the formation of ethylene, are the same reaction of propylene with hydrogen atoms. This is consistent with the experimental data (Table II). On the other hand, since the activation energies for both reaction processes are small (both 1.5 kcal./mol.), the hydrogen/ethylene ratio should be nearly independent of the temperature. The experimental data seem to confirm this requirement, and the experimental ratios are in fairly good agreement with the values (about 0.4) calculated from kinetic parameters (Table I).

Inspections were also made of allene and methylacetylene, whose production is an important object of this series of investigations. According to this mechanism, allyl radicals, which give allene by the elimination of a hydrogen atom, are produced by reactions 2

and 5, together with reaction 1. The allyl radicals disappear in any one of four reaction processes, 6, 7, 8, and 9. Of these processes, the last two, which are the chain-terminating reactions, are disregarded if the chain is long. In fact, however, it appears to be very short in view of the amount of 1-butene and the chain length estimated by Szwarc.[3]

First, the rates of the formation of higher hydrocarbons by reaction 6 (v_6) and of allene by reaction 7 (v_7) will be compared. Table VII shows the v_6/v_7 ratio, at various temperatures and at a 80 mmHg pressure, as calculated on the basis of the kinetic parameters shown in Table VI. From the calculated values, it follows that at 900°C the rate of reaction 7 is more rapid than that of reaction 6 and that reaction 6 may be practically disregarded above 1000°C.

TABLE VII. RATIO OF THE RATES OF REACTIONS 6 AND 7

Temp., °C	800	900	1000	1100
v_6/v_7	5.0	0.40	0.062	0.013

Next, assuming that the chain reaction is terminated only by reaction 9, it can be shown via the steady-state approximation method, that the yield (in moles per 100 mol. of propylene pyrolyzed) of allene is calculated by the following equation:

$$\text{Yield of allene}=\frac{L(1+C_1)}{(L+1)(2+C_1)(1+C_2)+LC_2(1+C_1)}\times 100$$

where L=chain length
C_1=ratio of rates of reactions 2 and 3, v_2/v_3
C_2=ratio of rates of reactions 6 and 7, v_6/v_7

Figure 4 compares the experimental yields of allene-methylacetylene (in 9~13% conversion) and the calculated yields of allene at various temperatures. The calculated values are those obtained by assuming that $L=5$, $C_1=0.50$, and $C_2=$ the values shown in Table VII. The results of the calculation (calculated yields I) show that the temperature has a remarkable effect on the yield of allene, as was observed in the experiments (Table I), and that high temperatures are suitable for the production of allene. Furthermore, considering that the values of kinetic parameters for elementary reactions 6 and 7 are uncertain and that allene undergoes secondary reactions readily, the experimental yields are in fair agreement with the calculated ones. The experimental yields however, can reasonably be accounted for on the basis of the yields of allene calculated by assuming $E_7-E_6=50$ kcal./mol., which is lower by 5 kcal./mol. than the value estimated by Laidler-Wojciechowski.[4] The second calculated yields (calculated yields II) are shown in Fig. 4 to be comparable with the experimental

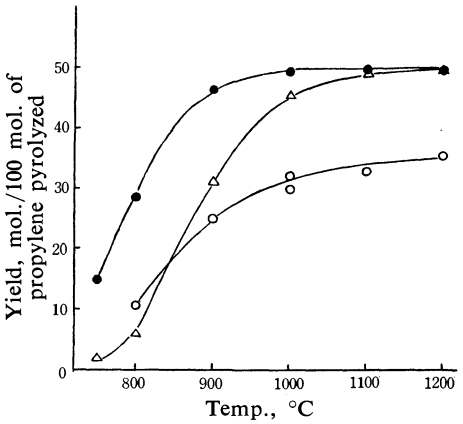

Fig. 4. A comparison of the experimental yields of allene-methylacetylene and the calculated yields of allene: ○, experimental yields; △, calculated yields I; ●, calculated yields II.

yields of allene-methylacetylene. The experimental values are considerably lower than the calculated ones. This may be supposed to be due to the loss of allene-methylacetylene by secondary reactions, probably by reactions 10 to 14, which proceed considerably even at low conversion levels. Furthermore, judging from the fact that the stability of allene-methylacetylene approaches that of propylene fairly rapidly with the increase in the temperature (Table V), it may be concluded that the degree of the loss by secondary reactions decreases with the increasing temperature and that, therefore, at high temperatures, for example, at 1100°C, allene-methylacetylene is obtained in yields comparatively close to the calculated yields.

The rapid decrease in the yield of allene-methylacetylene with the increase in conversion may be supposed to be due to the loss of allene, methylacetylene, and propylene, probably by various secondary reactions involving reactions 10 to 14. The variation in the methylacetylene/allene ratio with conversion can be accounted for by the equilibrium relation between the two. Namely, the experimental ratio (1.6 at 56% conversion) approached the calculated equilibrium constant (3.0 at 1100°C) with the increasing conversion (Fig. 1).

The decrease in the pressure of propylene

suppresses secondary reactions 11 to 14, by which means allene, methylacetylene, and propylene are lost; moreover, reaction 6 leads to the formation of higher hydrocarbons. Therefore, it may be expected that low pressures give better yields of allene-methylacetylene. The experimental data seem to confirm this (Table II).

Summary

A study has been made of the mechanism of the pyrolysis of propylene at high temperatures (800~1400°C). Of the gaseous products, hydrogen, methane, ethylene, allene, and 1-butene, obtained in the yields of 25, 43, 40, 27, and 9 mol. per 100 mol. of propylene pyrolyzed (3% conversion) respectively, have been found to be the primary products, while methylacetylene, acetylene, and butadiene, obtained in the yields of 9, 4, and 2 mol. respectively, have been found to be the secondary products. In view of the results of the pyrolysis of allene itself, even at a low conversion of 3%, allene appears to undergo considerable secondary reactions, such as isomerization to methylacetylene, addition to propylene and allyl radicals, and decomposition, for example, to acetylene and methane via methylacetylene. On the basis of the observed results, free-radical mechanisms have been proposed for the primary reactions and main secondary reactions. The mechanism for the primary decomposition reaction is a chain process in which the chain is initiated by the reaction $C_3H_6 \rightarrow C_3H_5\cdot$ (allyl radical) + H, and is, via the chain-propagating step, terminated by two types of reactions, $C_3H_5\cdot + H \rightarrow C_3H_6$ and $C_3H_5\cdot + CH_3\cdot \rightarrow 1\text{-}C_4H_8$. The formation of allene-methylacetylene has been satisfactorily explained by considering secondary reactions.

The author wishes to express his thanks to Professor Sango Kunichika of Kyoto University for his helpful advice and kind encouragement throughout this work.

The Separation of Potassium by Solvent Extraction

By Tadashi IWACHIDO and Kyoji TÔEI

(Received February 12, 1964)

Very few investigations of the solvent extraction of potassium have been made because potassium is highly ionic and so it is difficult to extract it by an ordinary solvent immiscible with water. This paper will describe the extraction of the potassium ion in an aqueous solution by nitrobenzene. The potassium ion is extracted in the form of potassium dipicrylaminate (DPA-K) and is stripped from the nitrobenzene layer by shaking it with a hydrochloric acid solution. The potassium ion is then determined gravimetrically with sodium tetraphenylborate (TPB-Na).

Experimental and Discussion

Reagents.—A dipicrylaminate aqueous solution, 0.1 M, was made by dissolving Hexyl Natrium (Mitsubishi Kasei Co., Ltd.) in water, while a 0.05 M dipicrylaminate nitrobenzene solution was prepared by dissolving Hexyl Natrium in nitrobenzene. The potassium chloride and the other reagents were of the analytical grade.

Organic Solvent. — To find out a suitable solvent, one immiscible with water and one which extracts potassium dipicrylaminate from an aqueous solution, the following solvents were tested: nitrobenzene, cyclohexanone, butylacetate and *o*-nitrotoluene. Among these solvents, nitrobenzene was best in extractability, and so it was used in all the extraction procedures.

Extraction. — As is shown in Fig. 1, two procedures were used in this experiment:

Procedure 1: The extraction by nitrobenzene from a solution containing deposited crystals of DPA-K formed by adding the reagent aqueous solution.

Procedure 2: The extraction from a solution containing potassium by adding the reagent nirobenzene solution which is almost saturated

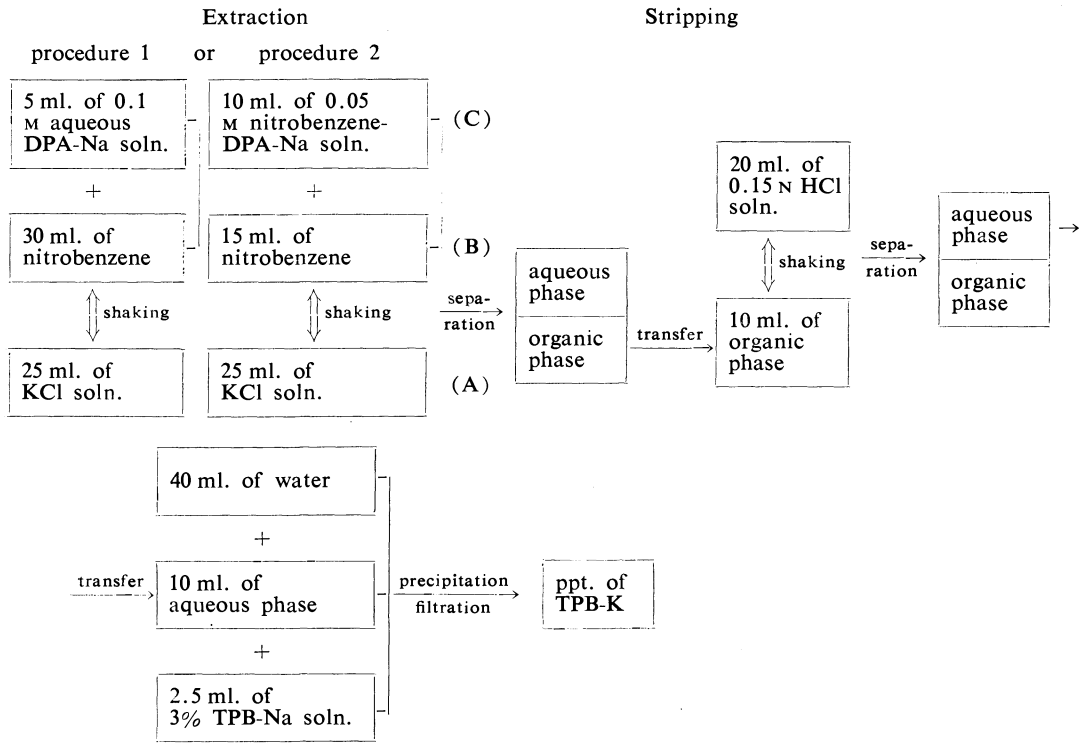

Fig. 1. Scheme of standard procedure.

with DPA-Na (0.05 M).

The molarity of the reagent was kept twice that of potassium throughout this experiment; the concentration of potassium chloride was also kept constant at 0.01023 M, corresponding to the potassium concentration of sea water.

Twenty-five milliliters of an aqueous potassium chloride solution were pipetted into a 100-ml. separatory funnel. In procedure 1, adequate amounts of the reagent aqueous solution and nitrobenzene were added to the potassium solution, or in procedure 2, the reagent nitrobenzene solution and nitrobenzene were added to the solution. After having been shaken for one or two minutes, this solution was allowed to stand overnight in order to separate it completely into two layers. The nitrobenzene solution was drained into a 100-ml. beaker.

Stripping Procedure.—Ten milliliters of the organic phase containing potassium dipicrylaminate was again pipetted into a 100-ml. separatory funnel, and then 20 ml. of 0.15 N hydrochloric acid were added. The two solutions were mixed well by shaking them until the color of the organic phase turned from orange-red to yellow. After the mixture had been allowed to stand for 2 hr., 10 ml. of the colorless aqueous solution was transferred into a 100-ml. beaker.

The Determination of the Potassium.[1]—The aqueous solution was diluted to 50 ml. with water, and then a 3 per cent solution of sodium tetraphenylborate (Kalibor, Dojindo & Co., Ltd.) was added drop by drop, with a gentle swirling. After the solution had cooled for 20 to 30 min. in a refrigerator, the precipitate was filtered through a No. 4 or 5 porosity glass filter, washed well with distilled water, and dried at 125°C for 1 hr. This was cooled in a desiccator and weighed. The precipitate was dissolved in acetone in Soxhlet's apparatus. The amount of potassium was calculated from the loss of weight. All the procedures are shown schematically in Fig. 1.

After 25 ml. of a potassium chloride solution (0.01023 M) had been shaken with the same volume of nitrobenzene, the amount of potassium was determined gravimetrically by means of the above method. The weight of TPB-K was always 0.8 mg. smaller than the calculated value. This negative error is due to the very small amount of TPB-K in a dilute solution (ca. 40 mg./50 ml.).[2]

Extractability. — The extractability, E, was calculated from the following equation, taking the above correction into consideration:

1) K. Tamaoku, *J. Japanese Chem.* (*Kagaku-no-Ryoiki*), 17, 39 (1963).
2) K. Sporek and A. F. Williams, *Analyst*, 80, 347 (1955).

$$E=D/(D+V_a/V_o)$$

where D is the distribution ratio, and V_o and V_a are the volumes of the organic and the aqueous layers respectively.

The Effect of the Volume Ratio, V_o/V_a.—Procedures 1 and 2 were compared in extractability under various volume ratios (Fig. 2).

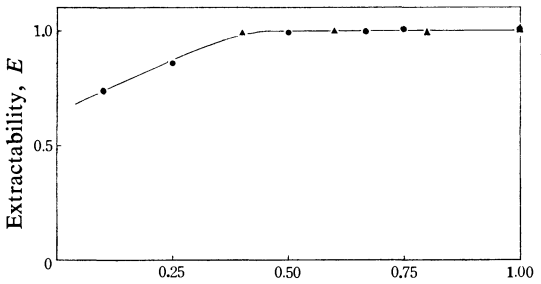

Fig. 2. Dependence of the volume ratios of organic to aqueous phase on extractability.
Sample: 0.01023 M KCl soln.
Procedure:
procedure 1 ($V_o/V_a=1.00$, (A)=25.0 ml.; $V_o/V_a=0.75\sim0.25$, (A)=50.0 ml.): ●
procedure 2 ($V_o/V_a=1.00\sim0.60$, (A)=25.0 ml.; $V_o/V_a=0.40$, (A)=50.0 ml.): ▲

Figure 2 shows that there is no appreciable difference between the two procedures; moreover, in the range of $V_o/V_a>0.5$, the extraction is almost perfect. In the range of $V_o/V_a<0.5$, however, somewhat lower values were obtained.

The Effect of pH. — Sodium in sodium dipicrylaminate will be displaced by hydrogen rather than by potassium in an acidic solution, so the experiment was carried out in a neutral or alkaline solution. The desired basicity was obtained by adding a small amount of a sodium hydroxide solution; the concentration of potassium was kept constant at 0.01023 M. The extractability decreased with the increase in pH, as is shown in Fig. 3. From the results, it must be concluded that the extraction is best in a neutral solution.

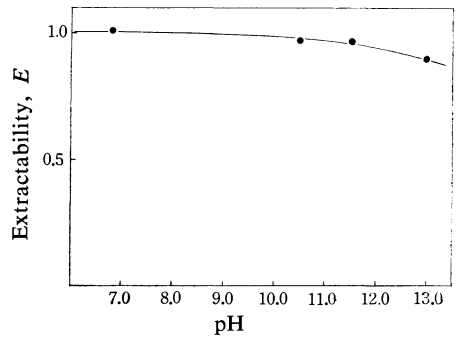

Fig. 3. Effect of pH.
Sample: 0.01023 M KCl soln. (+NaOH)
Procedure: standard procedure 1

The Effect Sodium Ions.—When an aqueous solution containing only potassium chloride was extracted by the reagent nitrobenzene solution, no turbidity was found in the organic phase, but in the presence of both sodium and potassium ions in a solution, the organic phase was turbid, even after standing overnight. In order to eliminate this turbidity, the solution was filtered through a dry filter paper or centrifuged at 2000 r. p. m. for 10 min. These two methods were compared in extractability by varying the time of standing in the stripping procedure. In these experiments, it was found that the extractability does not depend upon the stripping time; moreover, no significant difference between these two procedures was observed.

From Table I and Fig. 4, it is clear that the extractability decreases with the increase in the ratio of sodium to potassium ions, and that, thus, the co-existence of sodium hydroxide should similarly decrease the extractability (Fig. 3). The turbidity in the organic phase increases with the quantity of sodium ions.

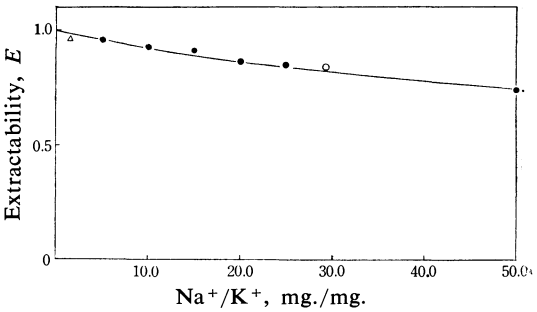

Fig. 4. Effect of sodium ion.
Sample: {Mixture of KCl and NaCl: ●; Bittern: △; Sea water: ○}
Procedure: procedure 2

For rapidity and convenience of experimentation, procedure 2 and the method of the elimination of turbidity by filtration were adopted for the following experiments.

The Separation of Potassium from Sea Water and Bittern by Solvent Extraction.—The extractabilities obtained with bittern (Table II) and sea water are shown in Table III. In Fig. 4, these values are plotted with open symbols against the ratio of sodium to potassium ions.

From Table III it may be concluded that, among all the ions which disturb the extraction, sodium ion has the most undesirable effect, but the co-existence of even a large

amount of magnesium ions has a negligible effect on the extractability.

In conclusion, by solvent extraction using sodium dipicrylaminate and nitrobenzene, the quantitative separation of potassium was not attained when sodium ions were also present. When sodium ions are absent, however, potassium can be quantitatively separated from the other ions.

The authors are very grateful to the Society of Salt Science, Japan, for its financial support, and also to Dr. Syozo Sato (Mitsubishi Kasei Co., Ltd.) for his generous gifts of Hexyl Natrium.

Chlorination by Sulfuryl Chloride. III.[1] *The Reactivities of the C–H Bond to Sulfuryl Chloride*

By Mannosuke ARAI

(Received March 16, 1964)

In a previous paper,[2] the author established that the action of sulfuryl chloride, in the presence of peroxide, on aromatic aldehydes with various nuclear substituents other than hydroxyl, resulted in the replacement of aldehydic hydrogen by chlorine, giving the corresponding acid chlorides.

$$ArC\overset{H}{\underset{O}{\diagdown}} + SO_2Cl_2 \xrightarrow[Bz_2O_2]{} ArC\overset{Cl}{\underset{O}{\diagdown}} + HCl + SO_2$$

Aliphatic hydrocarbons and the side chain of aralkyl hydrocarbons have also been established by Kharasch and Brown[3] to undergo a similar chlorination reaction. In order to establish the reactivity of various types of C–H bonding in relation to that of aldehydic hydrogen, the competitive chlorination of benzaldehyde and aralkyl and alicyclic hydrocarbons has now been carried out using sulfuryl chloride. The results are presented in this paper.

Experimental

Materials and Reagents.—Toluene, cyclohexane, cumene and *t*-butyl benzene (all reagent grade) were purified in advance by fractional distillation, and the purified materials were redistilled before use.

Benzaldehyde (reagent grade) was purified by vacuum distillation under a nitrogen atmosphere; freshly-distilled middle-cut was used for the experiment.

Sulfuryl chloride (first grade) was fractionally distilled, stored in a bottle wrapped with aluminum foil, and kept in a desiccator.

General Procedure for Chlorination.—The materials to be chlorinated competitively were placed in a 100 ml. round-bottomed flask equipped with a stirrer, a dropping funnel, and a reflux condenser, to which a calcium chloride tube was attached. After the air in the system had been replaced by dry nitrogen, benzoyl peroxide (0.1% of the weight of the sulfuryl chloride used) was added to the flask and the system was heated to 80±1°C. When sulfuryl chloride was gradually added through the dropping funnel, the evolution of gas was observed after some induction period. Heating was continued until the gas evolution ceased. After cooling, the hydrogen chloride formed was driven off by passing nitrogen through.

Analytical Procedures.—The reaction mixture obtained by the method descrived above was weighed. Any loss of weight during the reaction was distributed to each starting material according to the relative ratio of the vapor pressure.

The total chlorine content was determined by Rauscher's method[4] the reaction mixture (2 ml.) was heated with sodium in xylene for 2 hr. under reflux. *n*-Butanol was used to accelerate the reaction in place of amyl alcohol, which has been reported to contain halogens as impurities.[5] The sodium chloride obtained was determined by Mohr's method, using silver nitrate.

In order to determine the amount of benzoyl chloride produced, the reaction mixture (2 ml.) was decomposed by 80% ethanol at room temperature for 3 hr., thus forming hydrochloric acid, which was then titrated with sodium hydroxide potentiometrically. This method was established by experimentation using known amounts of benzoyl chloride and benzyl chloride in a mixture of toluene and benzaldehyde. It is also known that 2-chloro-2-phenylpropane, the chlorination product of the α-position of cumene, is decomposed quantitatively by 80% ethanol.[6]

Results and Discussion

The relative reactivity of toluene to benzaldehyde was first determined by means of competitive chlorination, using ca. 1/10 mol. of sulfuryl chloride. Under these conditions, the formation of dichlorocompounds can be ignored. The results are shown in Table I.

The relative reactivity is determined by the following scheme, using benzaldehyde as a standard:

$$RH + \cdot SO_2Cl \xrightarrow{k} R\cdot + HCl + SO_2$$

$$BzH + \cdot SO_2Cl \xrightarrow{k'} Bz\cdot + HCl + SO_2$$

$$\frac{k}{k'} = \frac{\log([RH]_{Int}/[RH]_{fin})}{\log([BzH]_{Int}/[BzH]_{fin})}$$

TABLE I. COMPETITIVE CHLORINATION OF BENZALDEHYDE AND TOLUENE AT 80°C[a]

Reactant	mol.	mol.
Benzaldehyde	0.280	0.171
Toluene	0.253	0.326
Sulfuryl chloride	0.040	0.034
Product		
Total chlorides	0.0398	0.0338
Benzoyl chloride	0.0308	0.0211
Benzyl chloride[b]	0.0090	0.0127
Benzaldehyde[c]	0.249	0.150
Toluene[c]	0.244	0.313
Reactivity of toluene	0.305	0.310
Mean	0.31	

a) In the presence of benzoyl peroxide
b) Total chlorides minus benzoyl chloride
c) Initial quantity minus the amount substituted and the amount vaporized

where $[\ ]_{int}$ and $[\ ]_{fin}$ denote the initial and the final concentration respectively.

Table I shows the reactivity of toluene to be 0.31 that of benzaldehyde.

Similar experimentation on and calculations of cyclohexane and benzaldehyde lead to the results listed in Table II, which shows the reactivity of cyclohexane to be 3.64 times that of benzaldehyde.

TABLE II. COMPETITIVE CHLORINATION OF BENZALDEHYDE AND CYCLOHEXANE AT 80°C[a]

Reactant	mol.	mol.
Benzaldehyde	0.248	0.339
Cyclohexane	0.261	0.245
Sulfuryl chloride	0.043	0.042
Product		
Total chlorides	0.0416	0.0421
Benzoyl chloride	0.0091	0.0123
Chlorocyclohexane[b]	0.0325	0.0298
Benzaldehyde[c]	0.239	0.327
Cyclohexane[c]	0.228	0.215
Reactivity of cyclohexane	3.65	3.62
Mean	3.64	

a) In the presence of benzoyl peroxide
b) Total chlorides minus chlorocyclohexane
c) Initial quantity minus the amount substituted and the amount vaporized

From the relative reactivity (0.31) of toluene to benzaldehyde, the value of 11.8 was derived as that of cyclohexane vs. toluene. The value thus derived indirectly is somewhat smaller than the value (13.1) obtained by Russell and Brown through the competitive chlorination of cyclohexane and toluene at 80°C directly.[6]

Next, the relative reactivity of cumene vs. benzaldehyde was examined. Since cumene has two kinds of hydrogen—a tertiary hydrogen at the α-position and six primary hydrogens at the β-position—all of which can be subjected to abstraction, it is of interest to determine each of the isomers formed and to see the relative reactivity of these two different hydrogens. Cumene was reacted at 80°C with ca. 1/10 mol. of sulfuryl chloride and benzoyl peroxide; the total amounts of chlorides and α-chloride (2-chloro-2-phenylpropane) in the product were determined separately, the amount of β-chloride (1-chloro-2-phenylpropane) being obtained as the difference between these two figures. The ratio of the isomers in the product is summarized in Table III.

TABLE III. ISOMER DISTRIBUTION OF CUMENE BY CHLORINATION AT 80°C[a]

Reactant	mol.	mol.
Cumene	0.334	0.496
Sulfuryl chloride	0.034	0.062
Product		
Total chlorides	0.0334	0.0622
α-Chloride	0.0270	0.0544
β-Chloride[b]	0.0044	0.0078
α-Chloride/β-Chloride	6.59	7.00
Mean	6.80	

a) In the presence of benzoyl peroxide
b) Total chlorides minus α-chloride

The ratio, 6.80, of α-chloride to β-chloride gives 40.8 per hydrogen at both positions. This value is rather close to the figure obtained by Kharasch[3] in 1939 from a similar reaction

TABLE IV. COMPETITIVE CHLORINATION OF BENZALDEHYDE AND CUMENE AT 80°C[a]

Reactant	mol.	mol.
Benzaldehyde	0.182	0.154

Cumene-α-chloride[d]	0.0231	0.0258
Benzoyl chloride[e]	0.0115	0.0096
Benzaldehyde[f]	0.170	0.144
Cumene[f]	0.248	0.348
Reactivity of cumene	1.51	1.23
Mean	1.37	

a) In the presence of benzoyl peroxide
b) The amount of HCl by hydrolysed with 80% EtOH, —— cumene-α-chloride and benzoyl chloride
c) Total chlorides minus (HCl)
d) 6.80 times β-chloride
e) (HCl) minus α-chloride
f) Initial quantity minus the amount substituted and the amount vaporized

in benzene, but it is different from the value, 2.13, derived from the photochlorination using chlorine.[7]

The competitive chlorination of benzaldehyde and cumene was realized, after a consideration of the isomer distribution. The ratio of the reactivity of cumene to that of benzaldehyde is shown to be 1.37 (Table IV); that is, the ratio is 4.43 to toluene. Our direct comparison of the reactivities of cumene and toluene is summarized in Table V.

Table V shows that the cumene vs. toluene ratio is 4.33, which is in good agreement with the value obtained indirectly in Table IV.

TABLE V. COMPETITIVE CHLORINATION OF TOLUENE AND CUMENE AT 80°C[a]

7) G. A. Russell and H. C. Brown, ibid., 77, 4031 (1955).

The results of a similar reaction of benzaldehyde and *t*-butyl benzene are summarized in Table VI, which shows that the reactivity of the latter is 25% that of the former. The relative value of *t*-butyl benzene to toluene is found from this value to be 0.80, which is again in good agreement with Russell's value,[6] 0.81, derived from the direct competitive reaction.

The results obtained above are summarized in Table VII and in Fig. 1.

TABLE VII. RELATIVE REACTIVITY ON A MOLECULAR AND BOND BASIS

	Molecule[a] A	Molecule[a] B	C-H Bond[b]

t-Hydrogen			11.6
prim-Hydrogen			0.28
t-Butylbenzene	0.25	0.80 (0.81)[c]	0.27
Cyclohexane	3.64	11.8 (13.2)[c]	2.9

a) Reactivity per molecule
b) Reactivity per C-H bond
c) The numerical values in parentheses are based upon the competitive reaction with toluene

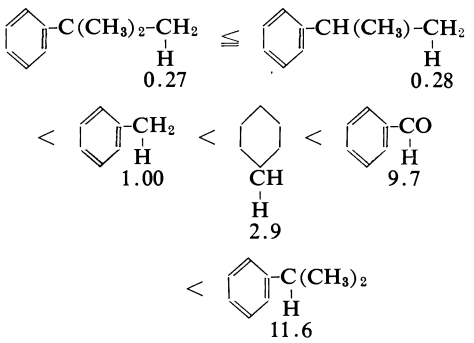

Fig. 1

The results of the chlorination by sulfuryl chloride are listed in Table VIII; those obtained by other halogenation reagents are shown for the sake of comparison.

The reaction with sulfuryl chloride is similar to the photochlorination using chlorine, but it has a higher selectivity. The hydrogen abstraction from the C-H bond in toluene would be expected to be accelerated by the formation of a stable benzyl radical in comparison with the case of cyclohexane, where no such acceleration can be expected. However, the reverse has been found to be the case

TABLE VIII. COMPARISON OF RADICAL HALOGENATION AGENTS

in the present study. This phenomenon can be rationalized, following Russell's explanation in his photochlorination, in terms of the inductive effect of the phenyl group in toluene. The aldehydic hydrogen in benzaldehyde has, as is shown in Table VII, a higher relative reactivity. This may be explained, together with the case of the tertiary hydrogen in cumene, by the greater stability of the radical formed in its transition state and by the weaker polar effect. However, more extensive studies are necessary before any definite conclusion can be drawn on this point.

The ratio of isomer formation in the chlorination of cumene (*tert/prim*) is 6.80, as has been described, which is far different from the ratio, 3.13, in photochlorination. This difference is of interest and is meaningful in connection with the reaction mechanism of the chlorination by sulfuryl chloride. Two mechanisms have hitherto been proposed for the radical chlorination by the reagent. One is that the chlorosulfonyl radical produced by the initiator decomposes to form the chlorine atom, which is the actual reacting species (equilibrium 1 and reaction 2).

$$SO_2Cl\cdot \rightleftarrows SO_2+Cl\cdot \quad (1)$$

$$RH+Cl\cdot \rightarrow R\cdot+HCl \quad (2)$$

$$RH+SO_2Cl\cdot \rightarrow R\cdot+SO_2+HCl \quad (3)$$

$$R\cdot+SO_2Cl_2 \rightarrow RCl+SO_2Cl\cdot \quad (4)$$

The other, alternative mechanism is that the chlorosulfonyl radical itself is responsible for the hydrogen abstraction (reaction 3). The latter mechanism has been established in the peroxide-catalyzed reaction of sulfuryl chloride with olefins.[8,9] Therefore, the different isomer distributions in the products obtained from cumene by photochlorination and by sulfuryl chloride chlorination is assumed to be based upon the difference between the actions of the chlorine atom and the chlorosulfonyl radical.

Russell[10] has concluded that, as a result of the solvent effect in the radical chlorination reaction, sulfuryl chloride reacts as does chlorosulfonyl radical in the presence of aliphatic solvents, while in aromatic solvents solvated chlorine atoms are the reacting species, as in the case in photochlorination. Since the isomer ratio in the chlorination products of cumene is supported experimentally by Kharasch,[3] an active hydrogen such as tertiary hydrogen in cumene is assumed to be abstracted by the chlorosulfonyl radical, which has greater selectivity than the chlorine atom, even in the aromatic solvent, contrary to Russell's explanation.

The author wishes to express his gratitude to Professor Mamoru Yamaguchi of Tohoku University for his constant guidance in the course of this work.

Isomerization of cis-Azobenzene in the Solid Phase

By Morizo TSUDA and Kenji KURATANI

(Received March 18, 1964)

Various solid phase reactions have been studied by many authors, but there have been few studies concernd with the simplest case, that is, with

$$A(solid) \rightarrow B(solid)$$

reaction. The isomerization and phase transformation belong to this case; the thermal isomerization of crystalline *cis*-azobenzene to *trans*-azobenzene will be considered as an example. The isomerization rate of *cis*-azobenzene in several solvents or in the liquid phase has been studied by Hartley[1] and Le Févre,[2] and it has been concluded that the thermal isomerization rate in these cases is expressed as a first order reaction. Along with the thermal change, the photo-isomerization in the various solvents has been studied by Zimmerman[3] and Birnbaum[4], and the results have been explained well by the reversible zeroth order reaction scheme. However, there has been no information about the solid phase, and, therefore, it appears that it would be valuable to learn of the effect of the crystalline lattice on the isomerization procsses.

Experimental

Materials.—*cis*-Azobenzene was prepared from the commercial reagent of G. R. grade, according to Hartley's method.[1]

trans-Azobenzene was recrystallized from an alcohol solution after having been boiled for several hours in a dark room. The melting points of cis- and trans-isomers, measured by the capillary method, were 69.0~71.5°C, and 66.0~68.0°C respectively.

Apparatus and Procedure.—The infrared absorption spectra of these crystals were measured by the KBr disk method in the range of 600~4000 cm^{-1}, using a Perkin-Elmer Model 112 spectrometer equipped with a NaCl prism. KBr disks were prepared under the pressure of 10 ton/cm^2 in vacuo, and were 12 mm. in diameter. The concentration of azobenzene in the disk was 0.7 mg./300 mg. KBr. In order to observe continuously the spectral intensity change of the disk at a constant temperature, a thermostat-cell was made and placed in front of the entrance slit of the spectrometer. A KBr disk was located at the center of the cell, and the radiation from the globar was transmitted through it. The medium circulating through the thermostat was liquid paraffin, while the temperature fluctuation of the thermostat-cell was ±0.2°C throughout the long run at nearly the middle point of the disk.

A calibration curve for the determination of the fractional isomerization, α, was prepared according to the following procedure; it is shown in Fig. 1.

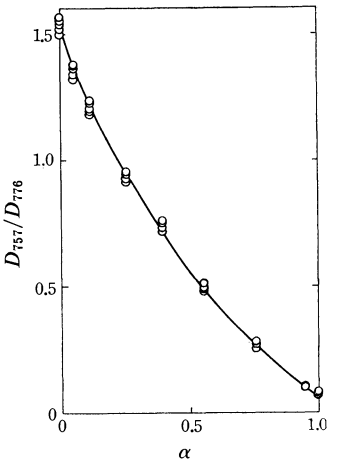

Fig. 1. Calibration curve for fractional isomerization.

Several lots of KBr disks having different mixing ratios of cis- and trans-isomers were prepared from the mechanical mixtures of isomers. Then the ratio of the optical density of the sharp band at 757 cm^{-1} to the that of 776 cm^{-1} was measured with these disks,* and was plotted against the isomeric mixing ratio, which was supposed to be equivalent to the fractional isomerization. In order to examine the reliability of the experimental process, the thermal isomerization rate of a 3 wt.% *cis*-azobenzene solution in cyclohexane at 50°C was measured according to a similar calibration curve. The reaction rate in solution was of the first order, as had been expected, and the rate constant at 50°C was 2.7×10^{-3} sec^{-1}. This value agrees well with the findings of Le Févre and Northcott.[2]

Poor reproducibility was found when the isomerization rate was measured with disks made from different lots of a KBr-azobenzene mixture, mean-

ing that the isomerization rate is affected a little by the degree of the crystal grinding, since the azobenzene crystal used for preparing disks was always of the same lot. However, the grinding condition was rather difficult to control. In order to overcome this difficulty, the following procedure was adopted: several disks were prepared at one time from the same lot of the KBr-azobenzene mixture, and the isomerization rates at different temperatures were then measured spectroscopically with these disks. The quantitative discussion of the experimental results was limited to the data obtained from the disks of the same lot.

Results

Appropriate Expression for Kinetics. — The thermal isomerization rates were measured at 36, 50 and 58°C. The change with time in the fractional isomerization α is shown as sigmoid curves in Fig. 2. This figure shows that three

stages in the isomerization process can be distinguished, the induction, acceleration and decay periods. In the present case, the induction period is relatively short, and our interest is concentrated on the acceleration period. Jacobs and Tompkins have written an excellent review of the kinetics equations of solid reactions and have deduced some theoretical expressions.[5] To know which of these equations is the most suitable for the present case, experimental results have been plotted according to these equations. Most of them, such as:

$$\log \alpha = k_3 t + c$$

$$\log(1-\alpha) = kt + c$$

$$1-(1-\alpha)^{1/2} = kt$$

$$1-(1-\alpha)^{1/3} = kt$$

$$\alpha = 1/2(k_2 t/a)^3 - 3/16(k_2 t/\alpha)^2$$

do not adequately represent the characteristics of experimental results.

However, the acceleration period in Fig. 2 can be represented by the following two equations. In the range of $\alpha = 0 \sim 0.6$, the Prout-Tompkins law,

$$\log[\alpha/(1-\alpha)] = k_3 t + \text{const.} \quad (1)$$

is a good approximation, while in the little narrower range of $\alpha = 0.03 \sim 0.5$, the power law,

$$\log \alpha = n \log t + \text{const.} \quad (2)$$

appears to be also applicable.

Figure 3 shows the relation between $\log[\alpha/(1-\alpha)]$ and the reaction time, and Fig. 4 shows the relation between $\log \alpha$ and $\log t$. However, the value of n in Eq. 2, which was estimated by the method of the least square, varied at random with the reaction temperature (i.e., it was 2.35 at 58°C, 3.00 at 50°C and 2.20 at 36°C), and no significant correlation

between n and reaction temperature could be found. This suggests that the power law is not applicable for the present reaction kinetics.

The Effect of the Pre-irradiation. — Prout-Tompkins' equation 1 is derived according to the assumptions that the nucleus formation is completed at a comparatively early stage of the reaction, that the nucleus branches into chains as the reaction proceeds, and that these chain branchings of reaction sites cause an increase in the chemical reaction rate. The termination of the branching by the interaction between growing nuclei should also be considered. The relation between the probabilities of chain branching, k_3, and of termination, k_4, is assumed to be $k_4=k_3(\alpha/\alpha_i)$, where α_i is the fractional isomerization at the points of inflection, which is approximated as 0.5. These circumstances are confirmed by the following pre-irradiation effect.

Pre-irradiation with a mercury lamp shortens the apparent induction period, and the Prout-Tompkins plots with the *cis*-azobenzene disks pre-irradiated for 0.5, 5, and 10 min. are parallel to that obtained with the non-irradiated pure *cis*-azobenzene disk. These plots are shown in Figs. 5a and 5b. This result can be explained if the influence of the irradiation is concerned only with the increase in the number of potential nucleus-forming sites or with that of the nuclei themselves. In the present case, the latter may occur, since the initial values of α_0 observed with the pre-irradiated disks are nearly 0.02 to 0.04. Therefore, the increase in the initial number of nuclei formed by the pre-irradiation makes the branching and termination steps predominant at the early stage of the thermal treatment, and the induction period is reduced significantly. Moreover, the irradiation does not affect the branching and termination rate constants; therefore, the slopes of Prout-Tompkins' plots are independent of the irradiation, as may actually be observed in Figs. 5a and 5b. The lateral shift of these plots is due to the difference in the initial value of α_0 or in the initial number of nuclei produced by the pre-irradiation.

The Effect of Grinding.—As has been previously described, the reaction rates observed with the disks from the different lots are not the same. This discrepancy is due to the difference in the degree of crystal grinding among the different lots of the KBr-azobenzene mixture. Two series of data are illustrated in Fig. 6. One series of data is obtained with disks made from one lot of the mixture, while the other series is observed with disks of the other lot. The reaction rates of the disks with different histories are not the same, even at the same temperature, and the reaction rate constants are also different. However, the activation energies in the rate constant, k_3, are nevertheless similar in these two series. This finding is not unreasonable considering the relation between the grinding action and the increase in the points of crystal defects. In fact, the same effect of grinding was revealed in the thermal decomposition of potassium and silver permanganates.[6,7]

Photo-isomerization. — The photo-isomerization of azobenzene in the solid state by prolonged irradiation with a mercury lamp (Toshiba SHL-100 UV) was observed at 12°C. The results are shown in Fig. 7; in contrast

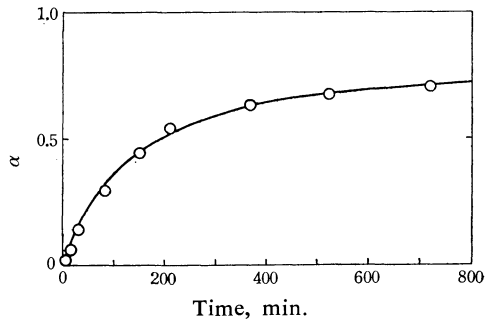

Fig. 7. Photo-isomerization of crystalline *cis*-azobenzene.

to the thermal process, there is no induction period. A similar contrast between the photo and thermal processes in the solid phase was observed in the case of the decomposition of barium azide.[8] The photo-decomposition of barium azide is more complicated than in the present case. That is, it proceeds linearly after some duration of the deceleration period, and there is also no induction period before the onset of the decomposition. However, the thermal decomposition of barium azide starts after the induction period, and the length of this induction period is effectively reduced by pre-irradiation with ultraviolet light.

Another striking characteristic of the solid-phase photo-process is that the photo-isomerization from trans to cis isomer does not occur in the solid-phase, as it does in the liquid-phase, (The photo-isomerization process in various solutions is utilized in preparing cis-azobenzene.) Pre-treatment, such as X-ray or γ-ray irradiation, in which an increase in the number of nucleus-forming sites can be expected, does not alter this characteristic. This behavior may be explained by assuming the stabilization of *trans*-azobenzene molecules by the crystalline lattice field.

Discussion

In the present study, it is important to establish the non-existence of the liquid phase, since partial melting often occurs in the course of the thermal reaction, especially in the case of organic compounds. The crystal of single isomeric azobenzene does not melt at temperatures lower than 68°C. However, mixing with the other isomer lowers its melting point to 41°C, i. e., to the eutectic point.[1] If the isomerization proceeds at temperatures lower than the eutectic point, the isomerization can be recognized as a perfect solid-state reaction. However, no reliable kinetics data could be obtained in the temperature range lower than 30°C, since the reaction rate became too slow. In order to avoid this difficulty, the reaction rates were measured at temperatures higher and lower than the eutectic point, i. e., in the range of 36~58°C; it was found that the kinetics at any temperature in this range could be treated with the same reaction mechanism, i, e., with Prout-Tompkins' law.

From the reaction kinetics obtained with the pure *cis*-azobenzene at the temperatures of 36, 50 and 58°C, the values of k_3 were estimated by the least-square method, and their logarithmic values were plotted against the reciprocal of the reaction temperature. This plot gives a straight line, as is shown in Fig. 8. This finding certifies that, even at the tem-

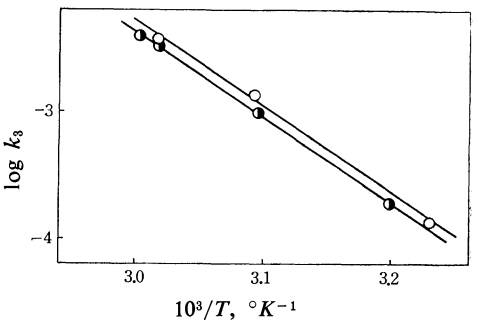

Fig. 8. Relationship between log k_3 and reaction temperature; ○ : lot A, ◑ : lot B. (cf. Fig. 6).

perature of 58°C, no partial melting occurred throughout the isomerization process. This conclusion is supported by the considerations that, if the liquid phase existed in the course of the thermal isomerization at temperatures highe than the eutectic point, the values of log k_3 at 50 and 58°C would not lie on a single straight line with the value at 36°C, and that the activation energy in the temperature range lower than the eutectic point would be larger than that in the higher temperature range.

This is confirmed further by another series of thermal isomerization studies, i. e., at the temperatures of 64, 58, 50 and 38°C. The relationship between $\log[\alpha/(1-\alpha)]$ and the reaction time at the temperatures of 58 and 50°C is shown in Fig. 6, while the Arrhenius plot of k_3 is given in Fig. 8, together with the results of the first series.

Following the Prout-Tompkins' reaction scheme, the activation energy of k_3 is found

8) J. G. N. Thomas and F. C. Tompkins, *Proc. Roy. Soc.*, **A209**, 550 (1951); **A210**, 111 (1951).

to be 31.3±0.3 kcal./mol. This value is reasonable, because Hartley has shown that the activation energy of the cis→trans isomerization of liquid-phase azobenzene is 23 kcal./mol. Because of the strain energy which exists on the interface of *cis*- and *trans*-azobenzene lattice, the activation energy in the solid-phase reaction must be larger than the one in the liquid-phase isomerization.

Summary

The thermal and photo-isomerizations of crystalline *cis*-azobenzene have been studied by infrared spectrophotometry in the temperature range of 36~58°C, It has been found that the thermal isomerization follows Prout-Tompkins' law, and the values of k_3 at 36, 50 and 58°C have been estimated. The Arrhenius plot of K_3 is linear, and the activation energy of k_3 is 31.3±0.3 kcal./mol. Pre-irradiation with a mercury lamp shortens the induction period, but it does not change the value of k_3. On the other hand, the value of k_3 is affected by the degree of grinding of azobenzene crystals. In this case, the activation energy is not altered by crystal grinding.

The photo-isomerization at 12°C, in contrast to the case of thermal isomerization, has no induction period. However, the trans→cis photo-isomerization does not occur even if the crystal is treated by X-ray or by γ-ray pre-irradiation.

The authors wish to thank Mr. Soji Tsuchiya for his helpful discussions throughout this work and Mr. Takuji Sakai for his assistance in preparing the apparatus.

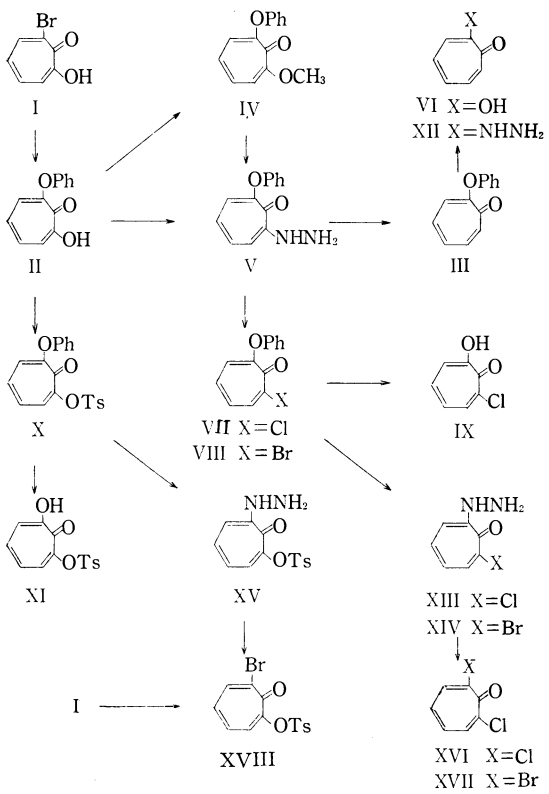
3-Phenoxytropolone and 2-Phenoxytropone

By Kahei TAKASE

(Received March 19, 1964)



It has been reported[1] that the reaction of 3-bromotropolone (I) and sodium phenoxide affords 3-phenoxytropolone (II) and that its phenoxyl group is not hydrolyzed by heating it with concentrated hydrochloric acid, as in diphenyl ether. In order to make clear the behavior of the phenoxyl group attached to the tropone or tropolone ring, in comparison with diphenyl ether, 2-phenoxytropone (III) and its derivatives were prepared from II and the reactivities of the phenoxyl group in the phenoxytropones toward some nucleophilic reagents, especially dilute alkali and hydrazine, were examined.

The heating of 3-bromotropolone (I) with 2~3 molar equivalents of sodium phenoxide in phenol, in the presence of a catalytical amount of copper acetate, gave 3-phenoxytropolone (II) in a good yield while in the absence of copper acetate the yield of II was low. The reaction did not proceed at all when only one molar equivalent of sodium phenoxide was used. The tropolonic nature of II was shown from the facts that II was soluble in aqueous alkali hydroxide solution, turned red in chloroform with a ferric chloride solution, and formed a pale green copper chelate. The prolonged heating of II which acid or alkali did not produce any change.

The methylation of II with diazomethane gave a crystalline methyl ether (IV), together with an oily substance. When IV was treated with hydrazine, it gave a hydrazinotropone derivative (V), in which the methoxyl was replaced by hydrazine. The oxidative decomposition of V by heating it with copper sulfate in acetic acid afforded phenoxytropone (III), which was easily hydrolyzed by heating it with dilute alkali to give tropolone (VI) and phenol. This result shows that III is 2-phenoxytropone and that IV and V are 7-methoxy- and 7-hydrazino-2-phenoxytropone respectively; consequently, it was concluded that the phenoxyl group of II was located in the 3-position of the tropolone ring. From this evidence, it was clear that the reaction of I and sodium phenoxide under these conditions was not accompanied by an abnormal substitution reaction such as was observed in the case of alkali hydroxide.[1]

1) Y. Kitahara, *Sci. Repts., Tohoku Univ.*, I, **39**, 265 (1956).

The oxidative decomposition of V by heating it with copper sulfate in concentrated hydrochloric acid or hydrobromic acid afforded 7-chloro- (VII) or 7-bromo-2-phenoxytropone (VIII), respectively. When VII or VIII was heated with dilute alkali, the phenoxyl group was easily hydrolyzed to give 3-chloro-[2,3] (IX) or 3-bromotropolone (I) respectively. The treatment of II with *p*-toluenesulfonyl chloride afforded a *p*-toluenesulfonate (X), in a quantitative yield; this gave a hydrolyzed product (XI) when heated with dilute alkali. From its reddish coloration with a ferric chloride solution and its ultraviolet absorption spectrum, which was similar to those of tropolones, XI was assumed to be 3-(*p*-tolylsulfonyloxy)tropolone; consequently, X was assumed to be 7-(*p*-tolylsulfonyloxy)-2-phenoxytropone.

The phenoxyl group in II remains unchanged upon treatment with acid or alkali; this behavior is similar to that of diphenyl ether. On the contrary, as has been mentioned above, the reactivities of the phenoxyl groups in 2-phenoxytropones (III, VII, VIII and X) differ greatly from that in II, and they are easily hydrolyzed with alkali. In order to make clear the different behavior of the phenoxyl group in 2-phenoxytropones and 3-phenoxytropolone, the reaction with hydrazine was examined. 2-Phenoxytropone (III) easily reacted with hydrazine to form 2-hydrazinotropone (XII). The phenoxyl group of VII, VIII and X were also replaced by hydrazine to give 7-chloro- (XIII), 7-bromo- (XIV)[4] and 7-(*p*-tolylsulfonyloxy)-2-hydrazinotropone (XV) respectively. The structure of XIII was confirmed through the formation of the known 2, 7-dichloro- (XVI) and 2-bromo-7-chlorotropone (XVII)[3] by oxidative decomposition with copper sulfate in concentrated hydrochloric or hydrobromic acid. The structure of XV, which afforded an acetate and an isopropylidene derivative, was also comfirmed by its derivation, when heated with copper sulfate in concentrated hydrobromic acid, to 2-bromo-7-(*p*-tolylsulfonyloxy)tropone (XVIII), which was also obtained by the tosylation of I.

From the foregoing experiments, it was found that the phenoxyl group of 2-phenoxytropones, rather than the halogen or the *p*-tolylsulfonyloxyl group, was replaced easily by hydrazine, as in the case of alkaline hydrolysis. This bavarior is rather interesting when compared with the behavior of 7-methoxy-2-phenoxytropone (IV) toward hydrazine, in which not the phenoxyl but methoxyl group is replaced. From these findings, the substituents at the 2- (or 7) position of the tropone ring may be arranged in the order of ease (methoxyl, phenoxyl, *p*-tolylsulfonyloxyl and halogen), with which they are replaced by a nucleophile.

When II was heated with hydrazine in ethanol, not the phenoxyl but the hydroxyl group was replaced to give V. This is interesting since tropolones in general do not react with ketonic reagents, and only specific tropolone derivatives, such as, 5-nitroso- and 5-arylazotropolones,[5] which can exist in the tautomeric diketone form, are known to react with ketonic reagents. It is also known that 3-carboxy- and 3-cyanotoropolone react with hydrazine to form 2-hydrazinotropones; this is considered to be due to the electron-attracting nature of the carboxyl or cyano group.[6] 3-Phenoxytropolone (II) cannot take the diketone structure; consequently, the replacement of the hydroxyl group by hydrazine must be due to the electron attraction of the phenoxyl

group, which renders the tropolone ring more liable to the attack of nucleophilic reagents.

Experimental[7]

3-Phenoxytropolone (II).—A mixture of 3-bromotropolone (I) (20.1 g.), sodium phenoxide (35 g.) and copper acetate (0.2 g.) in phenol (80 ml.) was heated at 135~140°C for 5 hr. The reaction mixture was then dissolved in a mixture of benzene (100 ml.) and water (100 ml.), acidified with 6 N sulfuric acid, and extracted with benzene. After being dried over sodium sulfate, the solvent was evaporated and the phenol was distilled off under reduced pressure. The residue was recrystallized from methanol to give II (18.3 g.) as colorless prisms, m. p. 106~107°C; reported 105~105.5°C.[1]

Copper Chelate.—M. p. 320°C; pale green crystals.

Found: C, 64.23; H, 3.89. Calcd. for $(C_{13}H_9O_3)_2Cu$: C, 63.73; H, 3.07%.

In this reaction, when copper acetate was not used, 30% of I was recovered and II was formed in a 49% yield after heating for 20 hr.

7-Methoxy-2-phenoxytropone (IV).—Into a cooled suspension of II (1.07 g.) in ether (15 ml.), an ethereal solution of diazomethane (10 ml.) was stirred. After the mixture had been allowed to stand overnight, the crystals which had formed were collected by filtration to give IV (0.41 g.), m. p. 92~95°C. Recrystallization from a mixture of benzene-petroleum ether gave colorless needles, m. p. 95°C.

λ_{max}^{MeOH} mμ (log ε); 242 (4.44), 325 (4.00), 353 (3.99).

Found: C, 73.55; H, 5.58. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

From the mother liquor, an oily substance was obtained. This oil failed to form a picrate and blackened with hydrazine.

7-Hydrazino-2-phenoxytropone (V).—*a) From IV.*—A mixture of IV (200 mg.) and 80% hydrazine hydrate (0.2 ml.) in ethanol (0.2 ml.) was warmed at 80°C for a few minutes to give V (140 mg.), m. p. 198°C (decomp.). Recrystallization from ethanol gave yellow prisms, m. p. 199°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 250 (4.32), 340 (4.12), 412 (4.04).

Found: C, 68.50; H, 5.17; N, 12.53. Calcd. for $C_{13}H_{12}O_2N_2$: C, 68.41; H, 5.30; N, 12.27%.

Acetate.—M. p. 189~190°C, pale yellow prisms (from methanol).

λ_{max}^{MeOH} mμ (log ε); 252 (4.31), 335 (4.12), 395 (3.99).

Found: C, 66.92; H, 4.77; N, 10.15. Calcd. for $C_{15}H_{14}O_3N_2$: C, 66.65; H, 5.22; N, 10.37%.

Isopropylidene Derivative.—M. p. 156~157°C, yellowish orange prisms (from acetone).

λ_{max}^{MeOH} mμ (log ε); 267 (4.36), 357 (4.33), 418 (4.20).

Found: C, 71.50; H, 5.82; N, 10.48. Calcd. for $C_{16}H_{16}O_2N_2$: C, 71.62; H, 6.01; N, 10.44%.

b) From II.—A mixture of II (1.00 g.) and a 50% ethanolic solution of hydrazine (1.5 ml.) was refluxed for 5 hr. to give V (0.77 g.) as yellow scales, m. p. 197°C. When the reaction period was short, the hydrazine salt of II was obtained as yellow needles m. p. 148°C (decomp.).

Found: C, 63.09; H, 5.65; N, 11.17. Calcd. for $C_{13}H_{14}O_3N_2$: C, 63.40; H, 5.73; N, 11.38%.

2-Phenoxytropone (III).—To a hot solution of V (500 mg.) in a mixture of glacial acetic acid (7.5 ml.) and water (3.5 ml.), a hot solution of copper sulfate (1.2 g.) in water (3 ml.) was added in one lot. After being heated for 5 min., the mixture was cooled, diluted with water (30 ml.), and extracted with chloroform. The solvent was then evaporated and the residue passed through a short alumina column, as with the benzene solution. The eluted substance was distilled under reduced pressure at 150°C to give III (320 mg.) as a colorless oil, which solidified on being allowed to stand, forming colorless crystals, m. p. 43~45°C.

λ_{max}^{MeOH} mμ (log ε); 228 (4.41), 322 (3.98).

Found: C, 79.19; H, 5.17. Calcd. for $C_{13}H_{10}O_2$: C, 78.77; H, 5.09%.

The Hydrolysis of III.—A mixture of III (100 mg.), ethanol (2 ml.) and a 2 N potassium hydroxide solution (2 ml.) was refluxed for 5 hr. and then acidified with 6 N hydrochloric acid and extracted with benzene. The benzene extract was shaken with 2 N sodium carbonate solution, and the aqueous layer was acidified and extracted with benzene. The evaporation of the solvent from the extract left crystals (60 mg.), m. p. 45~49°C; these crystals and its picrate, m. p. 81~83°C, shown no depression of melting point on admixture with tropolone (VI), m. p. 50°C, and its picrate, m. p. 83°C respectively.

7-Chloro-2-phenoxytropone (VII).—To a heated suspension of V (500 mg.) in concentrated hydrochloric acid (10 ml.), a hot solution of copper sulfate (3 g.) in water (7 ml.) was added in one lot. After it had been heated for 5 min., the mixture was cooled, diluted with water, and extracted with benzene. The benzene extract was passed through a short alumina column to give VII (480 mg.), m. p. 137~140°C. Recrystallization from cyclohexane afforded colorless prisms, m. p. 141~142°C.

λ_{max}^{MeOH} mμ (log ε); 242 (4.44), 328 (3.99), 355 (3.91).

Found: C, 67.33; H, 4.13. Calcd. for $C_{13}H_9O_2Cl$: C, 67.11; H, 3.90%.

7-Bromo-2-phenoxytropone (VIII).—When heated suspension of V (500 mg.) in concentrated hydrobromic acid (10 ml.) was treated with an aqueous copper sulfate solution as in the above experiment, VIII (320 mg.), m. p. 139~142°C, was obtained. Recrystallization from cyclohexane afforded colorless prisms, m. p. 142~143°C.

λ_{max}^{MeOH} mμ (log ε); 252 (4.33), 330 (3.98), 355 (3.91).

Found: C, 56.61; H, 3.37. Calcd. fo $C_{13}H_9O_2Br$: C, 56.34; H, 3.27%

3-Chlorotropolone (IX): The Hydrolysis of VII.—When VII (200 mg.) was treated with a 2 N potassium hydroxide solution, as in the experiment concerning the hydrolysis of III, it afforded crystals

7) All melting poins are uncorrected.

(80 mg.), m. p. 98~103°C, Sublimation at reduced pressure and recrystallization from ethanol gave colorless prisms, m. p. 103~104°C, this melting point was undepressed on admixture with an authentic specimen.[3]

λ_{max}^{MeOH} mμ (log ε); 248 (4.51), 324 (3.89), 379 (3.76), 398 (3.38).

3-Bromotropolone (I): The hydrolysis of VIII. —The treatment VIII (100 mg.) as in above experiment afforded I (40 mg.), m. p. 106~107°C.

7-(*p*-Tolylsulfonyloxy)-2-phenoxytropone (X).—Into a cooled solution of II (630 mg.) in pyridine (1.5 ml.), *p*-toluenesulfonyl chloride (600 mg.) was stirred; the mixture was then stirred for an additional hour and allowed to stand overnight. Water (20 ml.) was added, and the crystals (1.05 g.), m. p. 119~123°C, thereby obtained were recrystallized from methanol to give X (980 mg.), m. p. 114~116°C. Further recrystallization from methanol gave colorless prisms, m. p. 127~128°C.

λ_{max}^{MeOH} mμ (log ε); 228 (4.52), 325 (3.95), 350 (3.90).

Found: C, 64.96; H, 4.54. Calcd. for $C_{20}H_{15}O_5S$: C, 65.22; H, 4.26%.

3-(*p*-Tolylsulfonyloxy)tropolone (XI).—A mixture of X (370 mg.), ethanol (1 ml.) and a 2 N potassium hydroxide solution (1 ml.) was heated for 10 min. and then acidified. The crystals (240 mg.), m. p. 83~115°C, so obtained were recrystallized twice from benzene to give XI (70 mg.) as colorless needles, m. p. 169~170°C.

λ_{max}^{MeOH} mμ (log ε); 232 (4.43), 328 (3.85), 375 (3.76), 400 (3.54).

Found: C, 57.68; H, 4.10. Calcd. for $C_{14}H_{12}O_5S$: C, 57.54; H, 4.14%.

2-Hydrazinotropone (XII): The Reaction of III with Hydrazine. — A mixture of III (100 mg.), ethanol (0.5 ml.) and 80% hydrazine hydrate (0.05 ml.) was heated for 2 min., diluted with water, and extracted with chloroform. The chloroform extract was washed with a 2 N sodium hydroxide solution and evaporated to dryness, leaving crystals (60 mg.), m. p. 90~93°C, which were then recrystallized from benzene to give XII as yellow needles, m. p. 92~93°C.

λ_{max}^{MeOH} mμ (log ε); 247 (4.37), 238 (4.09), 406 (4.05).

7-Chloro-2-hydrazinotropone (XIII).—To a suspension of VII (230 mg.) in ethanol (1 ml.), 80% hydrazine hydrate (0.06 ml.) was added, and the mixture was heated for 2 min., affording XIII (160 mg.) as yellow needles, m. p. 165°C (decomp.), after recrystallization from ethanol.

λ_{max}^{MeOH} mμ (log ε); 255 (4.35), 342 (4.07), 416 (4.05).

Found: C, 49.43; H, 4.28; N, 16.32. Calcd. for $C_7H_7ON_2Cl$: C, 49.28; H, 4.14; N, 16.42%.

Acetate.—M. p. 205°C (decomp.), yellow needles (from ethanol).

λ_{max}^{MeOH} mμ (log ε); 255 (4.40), 338 (4.08), 404 (4.07).

Found: C, 50.89; H, 4.39; N, 13.02. Calcd. for $C_9H_9O_2N_2Cl$: C, 50.83; H, 4.27; N, 13.18%.

7-Bromo-2-hydrazinotropone (XIV). — To a suspension of VIII (140 mg.) in ethanol (0.5 ml.), 80% hydrazine hydrate (0.03 ml.) was added, and the mixture was heated for 1 min. to give XIV (100 mg.), m. p. 150°C. Recrystallization from ethanol afforded yellow needles, m. p. 156°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 253 (4.26), 345 (4.03), 418 (4.07).

Found: C, 38.99; H, 3.17; N, 12.84. Calcd. for $C_7H_7ON_2Br$: C, 39.10; H, 3.28; N, 13.02%.

Acetate. — M. p. 196°C (decomp.), pale yellow, silky needles (from ethanol).

λ_{max}^{MeOH} mμ (log ε); 258 (4.35), 3.40 (4.04), 406 (4.07).

Found: C, 41.42; H, 3.47; N, 10.58. Calcd. for $C_9H_9O_2N_2Br$: C, 42.04; H, 3.53; N, 10.90%.

Isopropylidene Derivative.—M. p. 101~103°C, pale orange prisms (from ethanol).

λ_{max}^{MeOH} mμ (log ε); 272 (4.38), 358 (4.23), 428 (4.31).

Found: C, 47.44; H, 4.39; N, 10.83. Calcd. for $C_{10}H_{11}ON_2Br$: C, 47.08; H, 4.35; N, 10.98%.

Neither the acetate nor the isopropylidene derivative of XIV showed any depression of the melting point on admixture with the respective derivative prepared from authentic 7-bromo-2-hydrazinotropone.[4]

7-(*p*-Tolylsulfonyloxy)-2-hydrazinotropone (XV). —To a suspension of X (630 mg.) in ethanol (4 ml.), 80% hydrazine hydrate (0.4 ml.) was added, and the mixture was heated for 2 min. to give XV (520 mg.) as yellow microneedles, m. p. 204°C.

λ_{max}^{MeOH} mμ (log ε); 230 (4.37), 250 (4.31), 340 (4.05), 412 (4.10).

Found: C, 55.44; H, 4.35; N, 9.30. Calcd. for $C_{14}H_{14}O_4N_2S$: C, 54.89; H, 4.61; N, 9.15%.

Acetate.—M. p. 187~188°C (decomp.), pale yellow prisms (from ethanol).

λ_{max}^{MeOH} mμ (log ε); 230 (4.38), 335 (4.00), 402 (4.09).

Found: C, 55.52; H, 4.86; N, 8.29. Calcd. for $C_{16}H_{16}O_5N_2S$: C, 55.16; H, 4.63; N, 8.04%.

Isopropylidene Derivative. — M. p. 165~166°C, yellow prisms (from ethanol).

λ_{max}^{MeOH} mμ (log ε); 227 (4.37), 267 (4.34), 353 (4.19), 422 (4.29).

Found: C, 58.94; H, 5.23; N, 8.09. Calcd. for $C_{17}H_{18}O_4N_2S$: C, 58.90; H, 4.93; N, 8.19%.

2,7-Dichlorotropone (XVI).—To a hot solution of XIII (100 mg.) in concentrated hydrochloric acid (2 ml.), a 25% aqueous copper sulfate solution (2 ml.) was added; the mixture was then heated for 2 min. Water was added and the crystals thereby obtained were collected and sublimed at reduced pressure to give XVI (90 mg.), m. p. 127~129°C. Recrystallization from benzene-cyclohexane afforded colorless needles, m. p. 130~131°C.

λ_{max}^{MeOH} mμ (log ε); 248 (4.46), 328 (3.92).

Found: C, 48.29; H, 2.53. Calcd. for $C_7H_4OCl_2$: C, 48.04; H, 2.30%.

2-Bromo-7-chlorotropone (XVII). — When a suspension of XIII (100 mg.) in concentrated hydrobromic acid (2 ml.) was treated with a copper sulfate solution as in the foregoing experiment, XVII

(100 mg.), m. p. 148~150°C, was obtained. Recrystallization from benzene-cyclohexane afforded pale yellow plates, m. p. 150~151°C.

λ_{max}^{MeOH} mμ (log ε) ; 220 (4.04), 253 (4.29), 337 (3.87).

Found : C, 38.65 ; H, 2.05. Calcd. for $C_7H_4OBr\cdot Cl$: C, 38.73 ; H, 1.79%.

2-Bromo-7-(*p*-tolylsulfonyloxy)tropone (XVIII). — *a) From XV.* — To a hot solution of XV (460 mg.) in concentrated hydrobromic acid (10 ml.), a 30% aqueous copper sulfate solution (10 ml.) was added ; the mixture was then heated for 1 min. The reaction mixture was diluted with water and extracted with chloroform. When the residue obtained after the evaporation of the solvent was passed through a short alumina column, as with the benzene solution, XVIII (250 mg.), m. p. 114~116°C, was obtained. Recrystallization from methanol afforded colorless needles, m. p. 117~118°C.

λ_{max}^{MeOH} mμ (log ε) ; 227 (4.35), 248 (4.27), 325 (3.87).

Found : C, 47.30 ; H, 3.03. Calcd. for $C_{14}H_{11}\cdot O_4SBr$: C, 47.33 ; H, 3.12%.

b) From 3-Bromotropolone (I). — Into a cooled solution of I (200 mg.) in pyridine (1 ml.), *p*-toluenesulfonyl chloride (200 mg.) was stirred. The mixture was then stirred for 3 hr., diluted with water (20 ml.), and allowed to stand, thus giving XVIII (150 mg.), m. p. 113~115°C. Recrystallization from methanol afforded colorless needles, m. p. 117~118°C.

The author wishes to express his deep gratitude to Professor Tetsuo Nozoe for his kind guidance and to Professor Yoshio Kitahara for for his valuable suggestions. Thanks are also due to Miss. Kuni Kato and Miss. Ayako Iwanaga for their elemental analyses.

The Reaction of 3-Carboxy- and 3-Cyanotropolone with Hydrazine

By Tetsuo NOZOE, Yoshio KITAHARA, Kahei TAKASE and Ichiro MURATA

(Received on March 19, 1964)

It has been known that tropolones generally do not react with the ketonic reagents, with a few exceptions, such as nitro-,[1] nitroso-[2,3] and arylazotropolone[3]. In our previous studies, however, it has been found that 3-carboxytropolone reacts with *o*-phenylenediamine to form cyclohepta[b]quinoxaline (benzo[b]tropazine).[4] The present authors have now carried out some studies of 3-carboxy- and 3-cyanotropolone and found that these tropolones react easily with hydrazine to give hydrazinotropone derivatives. Furthermore, 2-cyano- and 2-carboxytropone have been derived from 3-cyanotropolone by utilizing this reaction.

When 3-carboxytropolone (I) was heated with hydrazine in ethanol, 2-hydrazinotropone (II)[5] was obtained. Since tropolone itself does not react with hydrazine under these conditions, it is clear that the formation of II from I is not due to the reaction of hydrazine on tropolone, which would be formed by the decarboxylation of I, but to the decarboxylation of 2-carboxy-7-hydrazinotropone (III) (or its isomer; 3-carboxy-2-hydrazinotropone) formed as an intermediate.

3,5-Dibromo-7-carboxytropolone (IV)[6] also reacted with hydrazine, but no decarboxylation occurred in this case; 3,5-dibromo-7-carboxy-2-hydrazinotropone (V) (or its isomer, 5,7-dibromo-3-carboxy-2-hydrazinotropone) was obtained. The structure of V was confirmed from its analytical value, the similarity of its ultraviolet spectrum to that of II, and the formation of IV by its hydrolysis with 75% sulfuric acid.

In the reaction of 3-cyanotropolone (VI) and hydrazine in ethanol, the hydrazine salt of VI was first formed; this was changed by heating to afford a hydrazinotropone derivative (VII). The ultraviolet spectrum of VII is similar to that of II. The hydrolysis of VII with concentrated hydrochloric acid afforded

XV : R=$NHNHCOC_6H_5$

VI, and the oxidative decomposition of VII in acetic acid with cupric sulfate afforded 2-cyanotropone (VIII).[7] This evidence suggests that VII is 7-cyano-2-hydrazinotropone. The methylation of VI with diazomethane afforded two methyl ethers, 2-cyano-7-methoxytropone (IXa) and 3-cyano-2-methoxytropone (IXb); one of these, IXa, gave VII when treated with hydrazine, thus establishing the structures of these methyl ethers. When VII was oxidatively decomposed in concentrated hydrochloric acid with cupric sulfate, 2-chloro-7-cyanotropone (X) was obtained.

The above-mentioned results show that the tropolonic hydroxyl group of I and VI is substituted with hydrazine to the hydrazino group. This is, presumably, due to the electron-withdrawing nature of the carboxyl or cyano group, by which the tropolone nucleus is more liable to the attack of hydrazine than is usual tropolone.

The hydrolysis of 2-cyanotropone (VIII) by heating it in 75% sulfuric acid gave 2-carboxytropone (XI) in a good yield. The isomeric 4-carboxytropone (XII) has only been synthesized by Johnson et al.;[8] therefore, the XI obtained here is of interest as one of the fundamental troponoids. Its ultraviolet absorption spectrum in methanol (maxima at 231 and 316 mμ; log ε, 4.25 and 3.85 respectively) is similar to those of the usual tropones, and its pK_a value, 3.73,[9] is smaller than those of acetic acid or benzoic acid. The bromination of XI afforded an oily substance which gave 2, 7-dibromotropone[10] when heated. Methylation with diazomethane gave an oily methyl ester (XIII), while treatment with thionyl chloride afforded an unstable acid chloride. *p*-Toluidide (XIV) and benzoylhydrazide derivative (XV) of the acid XI were derived through this methyl ester or acid chloride.

Experimental[11]

The Reaction of 3-Carboxytropolone (I) with Hydrazine.—A mixture of I (330 mg.) and 80% hydrazine hydrate (300 mg.) in ethanol (10 ml.) was refluxed for 5 hr. The solvent was then evaporated, and the residue sublimed under reduced pressure. The sublimate (130 mg.) was recrystallized from benzene to give yellow needles (110 mg.); m. p. 92~93°C, which was undepressed on admixture with 2-hydrazinotropone (II).[5] λ_{max}^{MeOH} mμ (log ε); 246 (4.37), 338 (4.09), 406 (4.05).

3, 5-Dibromo-7-carboxy-2-hydrazinotropone (V).—A mixture of 3, 5-dibromo-7-carboxytropolone (IV) (160 mg.) and 80% hydrazine hydrate (50 mg.) in ethanol (20 ml.) was refluxed for 24 hr. The removal of the solvent and recrystallization from ethanol afforded V (150 mg.) as yellow needles, m. p. 216°C (decomp.)

λ_{max}^{MeOH} mμ (log ε); 268 (4.37), 352 (4.05), 431 (3.96).

Found: N, 8.29. Calcd. for $C_8H_6O_3N_2Br_2$: N, 8.55%.

The hydrolysis of V by heating it with 75% sulfuric acid afforded IV in a good yield.

2-Cyano-7-hydrazinotropone (VII).—*From 3-Cyanotropolone (VI).*—To a hot solution of VI (600 mg.) in ethanol (20 ml.), 80% hydrazine hydrate (800 mg.) was added; hydrazine salt of VI was then crystallized out as yellow needles, m. p. 166~168°C (Found: N, 23.27. Calcd. for $C_8H_9O_2N_3$: N, 23.45%). This mixture was refluxed for 3 hr., and the crystals thereby obtained were recrystallized from ethanol to give VII (550 mg.) as orange needles, m. p. 205°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 214 (4.22), 252 (4.14), 268 (4.08), 355 (3.87), 438 (4.24). Found: C, 59.52; H, 4.71; N, 26.13. Calcd. for $C_8H_7ON_3$: C, 59.62; H, 4.38; N, 26.08%.

11) All melting points are uncorrected.

From 2-Cyano-7-methoxytropone (IXa). — To a suspension of IXa (150 mg.) in methanol (10 ml.), 80% hydrazine hydrate (100 mg.) was added; when the mixture was then allowed to stand for 2 hr. at room temperature, it gave VII (110 mg.) as orange needles, m. p. 205°C (decomp.).

The heating of VII in concentrated hydrochloric acid for 3 hr. gave VI.

The Acetate of VII; m. p. 260°C, yellow needles (from ethanol).

λ_{max}^{MeOH} mμ (log ε); 215 (4.12), 247 (4.22), 273 (4.12), 345 (3.87), 430 (4.27).

Found: C, 59.32; H, 4.73; N, 20.69. Calcd. for $C_{10}H_9O_2N_3$: C, 59.10; H, 4.46; N, 20.68%.

2-Cyanotropone (VIII).—To a hot solution of VII (200 mg.), in a mixture of glacial acetic acid (6 ml.) and water (6 ml.) a 10% cupric sulfate solution (12 ml.) was added in one lot. After it has been heated for 15 min., the mixture was diluted with water and extracted with chloroform. The solvent was removed, the residue was sublimed under reduced pressure at 130°C, and the sublimate (60 mg.), m. p. 132~137°C, was recrystallized from benzene to give VIII as yellow needles, m. p. 136~137°C (decomp.), which was identified by mixed melting point and by a comparison of its infrared spectrum with that of an authentic specimen.[7] λ_{max}^{MeOH} mμ (log ε); 238 (4.32), 305 (3.71), 320 (3.73), 340 (3.70).

2-Cyano-7-methoxytropone (IXa) and 3-Cyano-2-methoxytropone (IXb).—Into a suspension of VI (2.0 g.) in methanol (40 ml.), an ethereal solution of diazomethane was added under cooling; the mixture was then allowed to stand overnight. The crystals which separated out were collected by filtration and recrystallized from water to give IXa (530 mg.) as pale yellow needles, m. p. 173.5~174.5°C.

λ_{max}^{MeOH} mμ (log ε); 250 (4.31), 311 (3.68), 327 (3.73).

Found: C, 66.54; H, 4.45. Calcd. for $C_9H_7O_2N$: C, 67.07; H, 4.38%.

The crystalline material (1.53 g.) obtained by the removal of the solvent from the mother liquor was dissolved in benzene and chromatographed on an aluminum column. From the first effluent, IXb was obtained as pale yellow scales, m. p. 141~142°C, after recrystallization from methanol.

λ_{max}^{MeOH} mμ (log ε); 234 (4.23), 331 (3.82).

Found: C, 66.89; H, 4.69. Calcd. for $C_9H_7O_2N$: C, 67.07; H, 4.38%.

7-Chloro-2-cyanotropone (X).—To a mixture of VII (500 mg.) and concentrated hydrochloric acid (6 ml.), a 30% cupric sulfate solution (6 ml.) was added in one lot, the mixture was then heated for 5 min. The crystals which were precipitated were collected and sublimed under reduced pressure to give X (410 mg.), m. p. 155~158°C, which was recrystallized from ethanol to afford yellow needles, m. p. 162~162.5°C.

Found: C, 58.13; H, 2.86; N, 8.79. Calcd. for C_8H_4ONCl: C, 58.02; H, 2.43; N, 8.46%.

2-Carboxytropone (XI).—A mixture of VIII (220 mg.) and 75% sulfuric acid (2 ml.) was heated for 1 hr. at 120~125°C and then poured into ice-water and extracted with chloroform. The solvent was removed, and the residue was recrystallized from benzene to give XI (200 mg.) as cream-colored needles, m. p. 149°C (decomp.).

Found: C, 63.78; H, 4.19. Calcd. for $C_8H_6O_3$: C, 64.00; H, 4.03%.

The Bromination of XI.—To a solution of XI (50 mg.) in glacial acetic acid (2 ml.) bromine (160 mg.) was added; the mixture was then stirred for 1 hr. The addition of water and extraction with chloroform gave an oily substance. This oil was heated in glacial acetic acid for 1 hr., and then the mixture was diluted with water, affording crystals. Recrystallization from benzene afforded 2, 7-dibromotoropone as pale orange plates (m. p. 169~170°C), identified by admixture with an authentic specimen.[10]

Methoxycarbonyltropne (XIII).—To a solution of XI (100 mg.) in methanol (1 ml.), an ethereal solution of diazomethane was added under cooling. The removal of the solvent gave an oily XIII. λ_{max}^{MeOH} mμ (log ε); 228 (4.18), 305 (3.77).

A mixture of XIII *p*-toluidine and methanol was heated for 1 hr. The removal of the solvent and recrystallization from benzene gave a *p*-toluidide derivative (XIV) as colorless plates, m. p. 152~153°C.

Found: N, 5.70. Calcd. for $C_{15}H_{13}O_2N$; N, 5.85%.

The Reaction of XI with Thionyl Chloride.—A mixture of XI (100 mg.) and thionyl chloride (100 mg.) in dry benzene (2 ml.) was refluxed for 3 hr.; the removal of the solvent then gave acid chloride, m. p. 155~156°. To a solution of this acid chloride in benzene (2 ml.), a solution of benzoylhydrazide (200 mg.) in benzene (5 ml.) was added, and the new mixture was refluxed for 30 min. The crystals thereby obtained were recrystallized from methanol to give a benzoylhydrazide derivative (XV) (200 mg.) as yellow prisms, m. p. 191~192°C.

Found: N, 10.78. Calcd. for $C_{15}H_{12}O_3N_2$: N, 10.44%. λ_{max}^{MeOH} mμ (log ε); 235 (4.44), 305 (3.86).

The expenses of the present series of experiments were defrayed by a grant-in-aid for Scientific Research from the Ministry of Education, to which the authors' thanks are due.

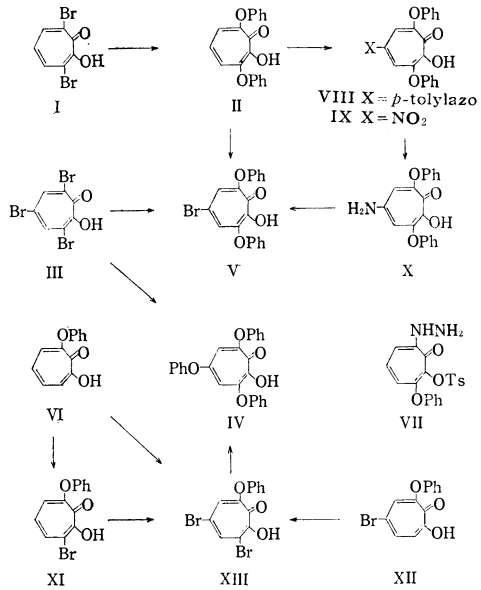
The Synthesis and Some Reactions of Polyphenoxytropolones



By Kahei TAKASE

(Received March 24, 1964)

In a previous paper,[1] it was described how the bromine of 3-bromotropolone was easily replaced with a phenoxyl group by heating it with sodium phenoxide, affording 3-phenoxytropolone. This reaction has now been extended to polybromotropolones, such as 3, 7-dibromotropolone and 3, 5, 7-tribromotropolone, in order to obtain polyphenoxytropolones, which are expected to be interesting from the point of view of synthetical studies in troponoid chemistry. In this paper, the synthesis of polyphenoxytropolones and some of their reactions will be reported.

The heating of 3,7-dibromotropolone (I) with an excess of sodium phenoxide in phenol, in the presence of a catalytic amount of copper acetate, gave 3, 7-diphenoxytropolone (II), in which both bromine atoms were replaced with a phenoxyl group. However, even with one or two molar equivalents of sodium phenoxide, no monosubstituted product was obtained. Similarly, when heated with an excess of phenoxide, 3, 5, 7-tribromotropolone (III) afforded 3, 5, 7-triphenoxytropolone (IV), while heated with three molar equivalents of phenoxide, a diphenoxy compound (V) was obtained. By analogy with the formation of 3-phenoxytropolone from 3-bromotropolone,[1] the phenoxyl groups of II and IV are assumed to be located at the 3 : 7 and positions 3 : 5 : 7 respectively. The structure of V was established as 5-bromo-3, 7-diphenoxytropolone from the fact that the bromination of II also afforded V.

These polyphenoxytropolones, like the common tropolones, are soluble in alkali, are colored red in chloroform with a ferric chloride solution, and give methyl ethers with diazomethane and tosylates with *p*-toluenesulfonyl chloride. When heated with hydrazine, II did not give any hydrazinotropone derivative as 3-phenoxytropolone (VI) did,[1] but only hydrazine salt. By heating in acid, the tosylate of II was hydrolyzed to reproduce II, but it gave a resinous substance in alkali. When the tosylate of II was heated with hydrazine, one of the phenoxyl groups was replaced with hydrazine to give a hydrazino derivative (VII). From the similarity of its ultraviolet absorption curve to that of 2-hydrazinotropone, VII may be assumed to be 7-hydrazino-3-phenoxy-2-(*p*-tolylsulfonyloxy)tropone. The methyl ether of II, however, afforded only a resinous product with hydrazine.

The azo-coupling of II with *p*-tolyldiazonium chloride gave a *p*-tolylazo compound VIII in a good yield. The treatment of II with sodium nitrite in acetic acid did not give any nitroso compound, but it did give a nitro compound IX. The catalytic reduction of both VIII and IX gave the same amino compound, X, which then afforded 5-bromo-3, 7-diphenoxytropolone (V) by Sandmeyer reaction. This evidence indicates that VIII, IX and X are 5-(*p*-tolylazo)-, 5-nitro- and 5-amino-3, 7-diphenoxytropolone respectively.

The bromination of 3-phenoxytropolone (VI) in methanol afforded a monobromo derivative (XI), which is different from the 5-bromo-3-phenoxytropolone (XII)[2] obtained from 5-amino-3-phenoxytropolone. On the other hand, the bromination of VI in acetic acid, in the presence of sodium acetate, afforded a dibromo compound XIII, which was also obtained by the bromination of both XI and XII in acetic acid. The treatment of XIII with

1) K. Takase, This Bulletin, 37, 1288 (1964).

2) K. Takase, ibid., 37, 1298 (1964).

sodium phenoxide gave 3, 5, 7-triphenoxytropolone (IV). From this evidence, XI and XIII may be considered to be 7-bromo-3-phenoxytropolone and 5, 7-dibromo-3-phenoxytropolone respectively.

The above-mentioned results show that bromine atoms of bromotropolones are easily replaced by phenoxide and that the chemical natures of polyphenoxytropolones thereby obtained are similar to those of common tropolones. That is, they are acidic, show positive in ferric chloride tests, give ethers or esters, and are capable of the electrophilic substitution reaction at the 3-, 5- and 7-positions. It is interesting that a nitro compound IX was produced in place of a nitroso compound by the action of nitrous acid. This unexpected result is considered to result from the action of nitrogen dioxide, or its equivalent, formed in the reaction medium.

Experimental[3]

3, 7-Diphenoxytropolone (II). — A mixture of 3, 7-dibromotropolone (I) (2.00 g.), dried sodium phenoxide (4.00 g.), copper acetate (50 mg.) and phenol (8 ml.) was heated at 135～140°C for 5 hr. The reaction mixture was then dissolved in a mixture of benzene and water, acidified with 6 N hydrochloric acid, and extracted with benzene. All the benzene extracts were combined, the benzene and phenol were distilled under reduced pressure, and the residue was recrystallized from methanol, affording II (1.95 g.) as colorless prisms, m. p. 138～139°C.

λ_{max}^{MeOH} mμ (log ε) ; 255 (4.39), 332 (3.95), 375 (3.79), 405 (3.64).

Found : C, 69.39 ; H, 4.28. Calcd. for $C_{32}H_{24}O_7S$: C, 69.56 ; H, 4.38%.

b) From 5, 7-Dibromo-3-phenoxytropolone (XIII). When a mixture of XIII (370 mg.), dried sodium phenoxide (350 mg.), copper acetate (10 mg.) and phenol (1 g.) was treated as described in a), IV (310 mg.) was obtained as pale yellow microprisms, m. p. 162～163°C.

5-Bromo-3,7-diphenoxytropolone (V).—*a) From 3, 5, 7-Tribromotropolone (III).*—A mixture of III (720 mg.), dried sodium phenoxide (720 mg.), copper acetate (10 mg.) and phenol (2 g.) was heated at 135～140°C for 5 hr. The reaction mixture was treated as described in the above experiment, and V (370 mg.), m. p. 138～139°C was obtained. Recrystallization from methanol afforded pale yellow prisms, m. p. 140～141°C.

λ_{max}^{MeOH} mμ (log ε) ; 258 (4.40), 350 (4.06), 425 (3.81).

Found : C, 59.22 ; H, 3.45. Calcd. for $C_{19}H_{13}O_4Br$: C, 59.24 ; H, 3.40%.

b) The Bromination of 3, 7-Diphenoxytropolone (II).—To a suspension of II (30 mg.) and sodium acetate (140 mg.) in glacial acetic acid, a solution of bromine (160 mg.) in the same solvent (0.5 ml.) was added ; the mixture was then stirred under cooling for 4 hr. The reaction mixture was diluted with water and extracted with chloroform. After the solvent had been removed from the extract, the residual oil was solidified by the addition of methanol, affording V (220 mg.) as pale yellow prisms, m. p. 140～141°C.

c) The Sandmeyer Reaction of 5-Amino-3, 7-diphenoxytropolone (X).—A solution of X (110 mg.) in dioxane (1 ml.) containing 6 N sulfuric acid (0.3 ml.) was diazotized by the addition of a solution of sodium nitrite (30 mg.) in water (0.3 ml.) at 0～5°C over a 40 min. period. This diazotized mixture was then stirred into a solution of cuprous bromide (200 mg.) in concentrated hydrobromic acid (2 ml.) at room temperature. After being stirred for a further 2 hr., the mixture was diluted with water, and the copper chelate thereby formed was collected and dried. Into a suspension of this copper chelate in chloroform, hydrogen sulfide gas was passed, and the copper sulfide thereby formed was filtered off. The removal of the solvent from the filtrate and the recrystallization of the residue from methanol gave V (80 mg.) as pale yellow prisms, m. p. 140～141°C.

7-Hydrazino-3-phenoxy - 2 -(*p* - tolylsulfonyloxy)-tropone (VII).—A mixture of the tosylate of II

3) All melting points are uncorrected.

(100 mg.), 80% hydrazine hydrate (0.2 ml.) and ethanol (2 ml.) was heated for 1 min., affording VII (80 mg.) as yellow micro-needles, m. p. 194°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 228 (4.34), 260 (4.41), 343 (3.95), 404 (4.13).

Found: C, 60.32; H, 4.60; N, 6.81%. Calcd. for $C_{20}H_{18}O_5N_2S$: C, 60.30; H, 4.55; N, 7.03%.

5-(*p*-Tolylazo)-3, 7-diphenoxytropolone (VIII).—A *p*-tolyldiazonium chloride solution prepared from *p*-toluidine (110 mg.), 6 N hydrochloric acid (0.5 ml.) and sodium nitrite (80 mg.) was stirred into a solution of II (300 mg.) in pyridine (4 ml.). After it had stirred for 2 hr., water was added, and the crystals thereby formed were collected and washed with methanol to give VIII (400 mg.), m. p. 194~197°C. Recrystallization from ethyl acetate afforded orange silky needles, m. p. 200~201°C.

λ_{max}^{MeOH} mμ (log ε); 307 (4.22), 414 (4.36), 462 (4.30).

Found: C, 73.37; H, 4.49; N, 6.92. Calcd. for $C_{26}H_{20}O_4N_2$: C, 73.57; H, 4.75; N, 6.60%.

5-Nitro-3, 7-diphenoxytropolone (IX).—Into a cooling suspension of II (200 mg.) in glacial acetic acid (3 ml.), a solution of sodium nitrite (150 mg.) in water (0.5 ml.) was stirred. After it had been stirred for a further 3 hr., the mixture was diluted with water, giving yellow crystals (120 mg), m. p. 172°C (decomp.). Recrystallization from methanol gave IX (80 mg.) as yellow silky needles, (m. p. 188°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 220 (4.38), 404 (4.23).

Found: C, 64.77, 64.91; H, 3.52, 3.90; N, 3.64. Calcd. for $C_{19}H_{13}O_6N$: C, 64.96; H, 3.73; N, 3.99%.

5-Amino-3, 7-diphenoxytropolone (X).—*a) The Hydrogenolysis of VIII.*—A suspension of VIII (200 mg.) in methanol (5 ml.) was shaken with hydrogen in the presence of platinum oxide (5 mg.); 27 ml. of hydrogen gas was absorbed in a period of 1.5 hr. The catalyst was then filtered off, and the filtrate was concentrated to a small volume to give X (110 mg.), m. p. 235~239°C. Recrystallization from methanol afforded yellow plates, m. p. 240~241°C.

λ_{max}^{MeOH} mμ (log ε); 258 (4.45), 353 (4.15), 410 (3.94).

Found: C, 70.82; H, 4.63; N, 4.41. Calcd. for $C_{19}H_{15}O_4N$: C, 71.02; H, 4.71; N, 4.36%.

N-Acetate: M. p. 216~217°C, pale yellow micro-needles (from ethanol.)

λ_{max}^{MeOH} mμ (log ε); 465 (4.42), 348 (4.11).

Found: C, 68.68; H, 4.39; N, 3.91. Calcd. for $C_{21}H_{17}O_5N$: C, 69.41; H, 4.72; N, 3.86%.

b) The Hydrogenolysis of IX.—A suspension of IX (90 mg.) in methanol (3 ml.) was skaken with hydrogen in the presence of platinum oxide (5 mg.); 23 ml. of hydrogen gas was absorbed in a period of 1 hr. After the removal of the catalyst and the solvent, the residue was recrystallized from methanol, affording X (60 mg.) as yellow plates, m. p. 240~241°C.

7-Bromo-3-phenoxytropolone (XI).—Into a cooling suspension of 3-phenoxytropolone (VI) (640 mg.) in methanol (10 ml.), a solution of bromine (530 mg.) in methanol (1 ml.) was stirred. After the mixture had been stirred for 1 hr., the removal of the solvent gave an oily material, which was chromatographed through a column of silica gel as a solution in benzene. From the second effluent, the evaporation of the solvent gave crystals (220 mg.), m. p. 91~94°C, which were then recrystallized from cyclohexane, affording XI as pale yellow needles, m. p. 98~99°C.

λ_{max}^{MeOH} mμ (log ε); 260 (4.45), 335 (3.96), 415 (3.89).

Found: C, 53.32; H, 3.23. Calcd. for $C_{13}H_9O_3Br$: C, 53.26; H, 3.10%.

5, 7-Dibromo-3-phenoxytropolone (XIII).—*a) The Bromination of 3-Phenoxytropolone (VI).*—To a suspension of VI (210 mg.) and sodium acetate (240 mg.) in glacial acetic acid (1 ml.), bromine (320 mg.) was added. After the mixture had been stirred for 2 hr., water was added and the crystals thereby formed were collected to give XIII (340 mg.), m. p. 136~138°C. Recrystallization from methanol afforded pale yellow needles, m. p. 140~141°C.

λ_{max}^{MeOH} mμ (log ε); 262 (4.50), 350 (4.14), 435 (3.97).

Found: C, 42.17; H, 2.29. Calcd. for $C_{13}H_8O_3Br_2$: C, 41.99; H, 2.17%.

b) The Bromination of 7-Bromo-3-phenoxytropolone (XI).—To a suspension of XI (30 mg.) and sodium acetate (10 mg.) in glacial acetic acid (0.5 ml.), bromine (20 mg.) was added. After it had been stirred for 2 hr., the mixture was treated as described in a) and XIII (30 mg.) was obtained as pale yellow needles, m. p. 140~141°C.

c) The Bromination of 5-Bromo-3-phenoxytropolone (XII).—When XII (60 mg.) was brominated as in a), XIII (40 mg.) was obtained, m. p. 140~141°C.

The author wishes to take this opportunity to express his sincere gratitude to Professor Tetsuo Nozoe for his kind guidance throughout the course of this work, and to Professor Shuichi Seto and Professor Yoshio Kitahara for much helpful advice. Thanks are also due to Miss Kuni Kato and Miss Ayako Iwanaga for their elementary analyses.

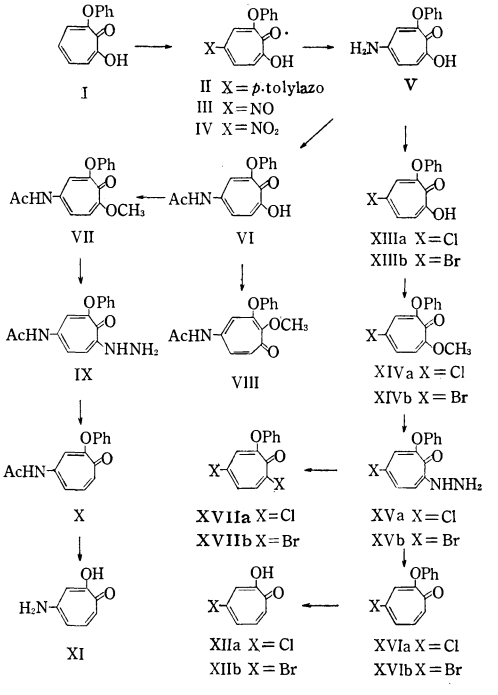
The Synthesis of 4-Substituted Tropolones from 3-Phenoxytropolone

By Kahei TAKASE



(Received March 24, 1964)

In a previous paper,[1] it was described how 2-phenoxytropone has been synthesized from 3-phenoxytropolone through a hydrazinotropone derivative. This reaction has now been extended to 5-substituted 3-phenoxytropolones in order to synthesize some 4-substituted tropolones, such as 4-amino-, 4-chloro- and 4-bromotropolone, which are fundamental compounds in troponoid and are interesting in their chemical natures.

The azo-coupling of 3-phenoxytropolone (I)[1] with *p*-tolyldiazonium chloride afforded a *p*-tolylazo compound (II). On the other hand, the nitrosation of I with sodium nitrite in acetic acid afforded a nitroso compound (III), and the nitration of I with fuming nitric acid afforded a nitro compound (IV). By catalytic reduction all of these compounds (II, III and IV) gave the same amino compound (V.) From the general tendency in the electrophilic substitution of tropolones, which suggests that azo and nitroso groups are located at the 5-position of the tropolone ring,[2] II and III are assumed to be 5-(*p*-tolylazo)- and 5-nitroso-3-phenoxytropolone respectively; consequently, IV and V are 5-nitro- and 5-amino-3-phenoxytropolone respectively.

The acetylation of V gave a monoacetate (VI), which is assumed to be 5-acetamido-3-phenoxytropolone from its acidic nature, its positive color reaction with ferric chloride, and its infrared spectrum, which shows an absorption at 1683 cm^{-1} (C=O of amide). The methylation of VI with diazomethane afforded two methyl ethers (VII and VIII.) When heated with hydrazine, one of these methyl ethers, VII, gave a hydrazinotropone derivative (IX,) in which the methoxyl group was replaced with hydrazine. The oxidative decomposition of IX with copper sulfate in acetic acid afforded a dehydrazinated compound (X,) which is assumed to be 4-acetamido-2-phenoxytropone from its infrared spectrum, which shows absorptions at 1704 cm^{-1} (C=O of amide) and 827 cm^{-1}.[3] The alkaline hydrolysis of X afforded an amino compound, which was identical with the 4-aminotropolone (XI) obtained from 4-acetyltropolone by a Schmidt reaction[4] or from 3-iodotropolone by an abnormal substitution reaction in liquid ammonia.[4] On the basis of these results, it is established that IX and X are 4-acetamido-7-hydrazino-2-phenoxytropone and 4-acetamido-2-phenoxytropone respectively, and that, consequently, methyl ether VII and VIII are 4-acetamido-7-methoxy-2-phenoxytropone and 5-acetamido-2-methoxy-3-phenoxytropone respectively.

4-Chlorotropolone (XIIa) and 4-bromotropolone (XIIb) were synthesized from 5-amino-3-phenoxytropolone (V) as described in the following sequence. By a Sandmeyer reaction, V was converted to 5-chloro-3-phenoxytropolone (XIIIa) and 5-bromo-3-phenoxytropolone (XIIIb), which in turn gave crystalline methyl ethers, 4-chloro-7-methoxy-2-phenoxytropone (XIVa) and 4-bromo-7-methoxy-2-phenoxytropone (XIVb) with diazomethane respectively. The heating of methyl ethers, (XIVa and XIVb) with hydrazine afforded

2) T. Nozoe, *Fortsh. Chem. org. Naturstoffe*, 13, 273 (1956).
3) 2,4-Disubstituted tropones show the characteristic absorption in the 810~840 cm^{-1} range (T. Nozoe, K. Takase and M. Yasunami, to be published).
4) K. Doi, This Bulletin, 34, 497, 501 (1961).

4-chloro-7-hydrazino-2-phenoxytropolone (XVa) and 4-bromo-7-hydrazino-2-phenoxytropone (XVb) respectively, in both of which the methoxyl group was replaced with hydrazine. The oxidative decomposition of hydrazino compounds, (XVa and XVb,) with copper sulfate in acetic acid afforded 4-chloro-2-phenoxytropone (XVIa) and 4-bromo-2-phenoxytropone (XVIb), the alkaline hydrolysis of which gave the known 4-chlorotropolone (XIIa)[6] and 4-bromotropolone (XIIb)[5,6] respectively. By the oxidative decomposition of hydrazino compounds, (XVa and XVb,) with copper sulfate in concentrated hydrochloric acid or hydrobromic acid, 4, 7-dichloro-2-phenoxytropone (XVIIa) and 4, 7-dibromo-2-phenoxytropone (XVIIb) were obtained. The above-mentioned results confirm that 4-substituted tropolones were synthesized from 3-phenoxytropolone.

Experimental[7]

5-(*p*-Tolylazo)-3-phenoxytropolone (II).—Into a solution of 3-phenoxytropolone (I) (420 mg.) in a N potassium hydroxide solution (10 ml.), *p*-tolyldiazonium chloride solution prepared from *p*-toluidine (240 mg.) was stirred. The mixture was then stirred for a further 2 hr. and acidified with 6 N hydrochloric acid. The crystals (640 mg.) m. p. 141~143°C, so obtained were recrystallized from benzene, affording II (520 mg.) as red needles, m. p. 156~157°C.

λ_{max}^{MeOH} mμ (log ε) ; 232 (4.32), 300 (4.11), 402 (4.38).

Found: C, 72.43; H, 5.10; N, 8.52. Calcd. for $C_{20}H_{16}O_3N_2$: C, 72.28; H, 4.85; N, 8.43%.

5-Nitroso-3-phenoxytropolone (III).—To a stirred solution of I (4.28 g.) in glacial acetic acid (28 ml.), a solution of sodium nitrite (4.0 g.) in water (8 ml.) was added over a 1 hr. period at 0~5°C. The mixture was stirred for a further hour, and then allowed to stand overnight in an ice-box. The crystals thereby obtained were collected by filtration and washed with water, affording III (3.57 g.), m. p. 198°C (decomp.). Recrystallization from a large amount of ethanol afforded yellowish orange rhombo prisms, m. p. 202°C (decomp.).

λ_{max}^{MeOH} mμ (log ε) ; 250 (3.93), 298 (4.05), 460 (3.50).

Found: C, 64.07; H, 3.68; N, 5.64. Calcd. for $C_{13}H_9O_4N$: C. 64.20; H, 3.73; N, 5.76%.

5-Nitro-3-phenoxytropolone (IV).—To a solution of I (210 mg.) in glacial acetic acid (2 ml.), fuming nitric acid (0.05 ml.) was added under cooling, and the mixture was then stirred for 1 hr. The addition of water to the mixture gave IV (70 mg.) as yellow crystals, m. p. 139~142°C, which were recrystallized from methanol, affording yellow needles, m. p. 143~144°C.

λ_{max}^{MeOH} mμ (log ε) ; 245 (4.25), 390 (4.17), 432 (4.25).

Found: C, 60.03; H, 3.60; N, 5.54. Calcd. for $C_{13}H_9O_5N$: C, 60.23; H, 3.50; N, 5.40%.

5-Amino-3-phenoxytropolone (V).—*a) From 5-(p-Tolylazo)-3-phenoxytropolone (II).*—A suspension of II (150 mg.) in methanol (10 ml.) was shaken with hydrogen in the presence of 5% palladium on carbon (20 mg.) ; 23 ml. of hydrogen (23°C, 760 mmHg) was absorbed during 5 hr. The catalyst was then removed and the solvent evaporated, affording a mixture of crystals and an oily substance. Benzene was added to this mixture, and soluble part was decanted off. The residue was recrystallized from methanol to give V (70 mg.) as yellow needles, m. p. 90~94°C, which showed the same melting point upon further recrystallization from the same solvent.

λ_{max}^{MeOH} mμ (log ε) ; 235 (4.38), 358 (4.24).

Found: C, 65.03, 64.88; H, 5.52, 5.34; N, 5.57, 5.54. Calcd. for $C_{13}H_{11}O_3N \cdot CH_3OH$: C, 64.36; H, 5.79; N, 5.36%.

b) From 5-Nitroso-3-phenoxytropolone (III).—When a suspension of III (2.43 g.) in methanol (40 ml.) was hydrogenated in the presence of 5% palladium on carbon (200 mg.), 490 ml. of hydrogen (20°C, 760 mmHg) was absorbed during 1 hr. The catalyst was then filtered off and the filtrate concentrated to give V (1.91 g.) as yellow needles, m. p. 92~94°C.

The hydrogenolysis of III in the presence of platinum oxide also gave V.

c) From 5-Nitro-3-phenoxytropolone (IV).—When a solution of IV (60 mg.) in methanol (5 ml.) was hydrogenated in the presence of platinum oxide, V (30 mg.) was obtained as yellow needles, m. p. 90~93°C, after the treatment described in b).

5-Acetamido-3-phenoxytropolone (VI).—When a mixture of V (1.86 g.) and acetic anhydride (3.7 ml.) was heated for 5 min. and then cooled, it afforded VI (1.55 g.) as yellow needles, m. p. 190~191°C.

λ_{max}^{MeOH} mμ (log ε) ; 242 (4.38), 348 (4.18).

Found: C, 66.76; H, 4.94; N, 5.10. Calcd. for $C_{15}H_{13}O_4N$: C, 66.41; H, 4.83; N, 5.16%.

4-Acetamido-7-methoxy-2-phenoxytropone (VII) and 5-Acetamido-2-methoxy-3-phenoxytropone (VIII).—To a stirred suspension of VI (1.35 g.) in a mixture of ether (2.5 ml.) and ethyl acetate (5 ml.), an ethereal solution of diazomethane (10 ml.) was added under cooling with ice-water. After the mixture had been stirred for a further 6 hr., the crystals (940 mg.), m. p. 191~194°C, so obtained were collected by filtration and recrystallized from methanol, affording VII (540 mg.) as pale yellow prisms, m. p. 216~218°C.

λ_{max}^{MeOH} mμ (log ε) ; 245 (4.34), 343 (4.15), 368 (4.12).

Found: C, 67.31; H, 5.68; N, 4.80. Calcd. for $C_{16}H_{15}O_4N$: C, 67.36; H, 5.30; N, 4.91%.

All the filtrates were combined, the solvent was removed, and the residue was dissolved in ethyl acetate and chromatographed through and alumina column. The first effluent gave crystals (470 mg.), m. p. 120~124°C, which were then recrystallized

7) All melting points are uncorrected.

from ethyl acetate, affording VIII as yellow scaels, m. p. 126~127°C.

λ_{max}^{MeOH} mμ (log ε); 245 (4.35), 340 (4.18).

Found: C, 67.48; H, 5.27; N, 4.86. Calcd. for $C_{16}H_{15}O_4N$: C, 67.36; H, 5.30; N, 4.91%.

From the second effluent, VII (250 mg.) was obtained, m. p. 214~216°C after recrystallization from methanol.

4-Acetamido-7-hydrazino-2-phenoxytropone (IX).—A mixture of VII (540 mg.), ethanol (1.5 ml.) and 80% hydrazine hydrate (0.2 ml.) was warmed for 2 min. and then cooled to give IX (460 mg.) as yellow needles, m. p. 210°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 258 (4.37), 360 (4.27), 428 (3.99).

Found: C, 63.13; H, 5.13; N, 15.10. Calcd. for $C_{15}H_{15}O_3N_3$: C, 63.15; H, 5.30; N, 14.73%.

Acetate: M. p. 247°C (decomp.), pale yellow needles (from ethanol).

λ_{max}^{MeOH} mμ (log ε); 252 (4.39), 355 (4.29), 410 (4.01).

Found: C, 62.17; H, 5,01; N, 12.59. Calcd. for $C_{17}H_{17}O_4N_3$: C, 62.37; H, 5.24; N, 12.84%.

4-Acetamido-2-phenoxytropone (X).—A solution of IX (200 mg.) in a mixture of glacial acetic acid (3 ml.) and water (1 ml.) was heated at about 100°C; to this, a 30% copper sulfate solution (1.2 ml.) was added in one lot and heating was continued for 2 min. The reaction mixture was then diluted with water (15 ml.) and extracted with chloroform, and the chloroform solution was passed through a short alumina column. The evaporation of the solvent from the effluent left crystals (130 mg.), m. p. 168~171°C, which were recrystallized from a mixture of chloroform and ethyl acetate to give X as colorless needles, m. p. 174~175°C.

λ_{max}^{MeOH} mμ (log ε); 268 (4.25), 358 (4.05).

Found: C, 70.16; H, 5.45; N, 5.47. Calcd. for $C_{15}H_{13}O_3N$: C, 70.58; H, 5.13; N, 5.49%.

4-Aminotropolone (XI).—A mixture of X (120 mg.) in ethanol (2 ml.) and a 2 N potassium hydroxide solution (1 ml.) was heated under reflux for 2 hr. and then neutralized to pH 7 with 2 N hydrochloric acid and extracted with chloroform. After the evaporation of the solvent, the residue was sublimed in vacuo and recrystallized from methanol to give XI (40 mg.) as colorless needles, m. p. 187~188°C, which showed no depression of melting point on admixture with an authentic specimen.[4]

N-Acetate: M. p. 167°C; pale brown prisms (from ethanol).

λ_{max}^{MeOH} mμ (log ε); 267 (4.56), 335 (3.75), 365 (3.85).

Found: C, 60.51; H, 5.00; N, 7.74. Calcd. for $C_9H_9O_3N$: C, 60.33; H, 5.06; N, 7.82%.

5-Chloro-3-phenoxytropolone (XIIIa).—To a stirred mixture of V (920 mg.) in 50% aqueous dioxane (10 ml.) containing concentrated sulfuric acid (0.6 ml.), a solution of sodium nitrite (360 mg.) in water (1 ml.) was added over a 30 min. period at 0~5°C. After being stirred for an additional hour, the mixture was stirred into a solution of cuprous chloride (1.4 g.) in concentrated hydrochloric acid (7.5 ml.); stirring was then continued for one hour. Water was added, and the copper chelate thereby obtained was collected by filtration and dried. Into a suspension of this copper chelate in chloroform, hydrogen sulfide gas was passed, and the copper sulfide thereby formed was filtered off. The evaporation of the solvent from the filtrate gave XIIIa (710 mg.), m. p. 100~103°C, which was recrystallized from methanol, affording pale yellow prisms, m. p. 106~107°C.

λ_{max}^{MeOH} mμ (log ε); 248 (3.40), 342 (4.09), 385 (3.77), 416 (3.68).

Found: C, 62.95; H, 3.96. Calcd. for $C_{13}H_9O_3Cl$: C, 62.79; H, 3.65%.

5-Bromo-3-phenoxytropolone (XIIIb).—A diazotized solution of III (920 mg.), as in the above experiment, was treated with a solution of cuprous bromide (1.4 g.) in concentrated hydrobromic acid (7.5 ml.). The copper chelate so obtained was treated with hydrogen sulfide gas to give XIIIb (870 mg.), m. p. 93~96°C. Recrystallization from methanol afforded pale yellow needles, m. p. 100~101°C).

λ_{max}^{MeOH} mμ (log ε); 250 (4.42), 342 (4.17), 390 (3.75), 416 (3.79).

Found: C, 53.34, H, 2.09. Calcd. for $C_{13}H_9O_3Br$: C, 53.26; H, 3.10%.

4-Chloro-7-methoxy-2-phenoxytropone (XIVa).—To a stirred suspension of XIIIa (950 mg.) in ether (8 ml.), an ethereal solution of diazomethane (6.5 ml.) was added while it was being cooled with ice-water; then the mixture was stirred for 3 hr. and allowed to stand overnight. The crystals so obtained were collected by filtration and recrystallized from ethanol, affording XIVa (430 mg.) as pale yellow needles, m. p. 133~134°C.

λ_{max}^{MeOH} mμ (log ε); 248 (4.37), 330 (4.05), 362 (3.91).

Found: C, 63.96; H, 3.99. Calcd. for $C_{14}H_{11}O_3Cl$: C, 64.01; H, 4.23%.

The removal of the solvent from the filtrate gave an oily substance, which was then dissolved in benzene and chromatographed through an alumina column. The first effluent gave an oily substance (300 mg.), while the second effluent gave XIVa (100 mg.).

4-Bromo-7-methoxy-2-phenoxytropone (XIVb).—The same treatment of XIIIb (1.03 g.) with diazomethane as in the above experiment and recrystallization from ethanol afforded XIVb (470 mg.) as pale yellow needles, m. p. 155~156°C.

λ_{max}^{MeOH} mμ (log ε); 428 (4.42), 330 (4.05), 360 (3.94).

Found: C, 54.92; H, 3.09. Calcd. for $C_{14}H_{11}O_3Br$: C, 54.74; H, 3.61%.

The filtrate was chromatographed as in the above experiment, giving an oily substance (300 mg.) and XIVb (70 mg.).

4-Chloro-7-hydrazino-2-phenoxytropone (XVa).—When mixture of XIVa (400 mg.) in ethanol (2 ml.) and 80% hydrazine hydrate (0.2 ml.) was warmed for 2 min., XVa was obtained as yellow needles, m. p. 205°C (decomp.).

λ_{max}^{MeOH} mμ (log ε) ; 256 (4.22), 352 (4.14), 430 (3.92).

Found : C, 59.64 ; H, 3.98 ; N, 10.48. Calcd. for $C_{13}H_{11}O_2N_2Cl$: C, 59.43 ; H, 4.23 ; N, 10.68%.

Acetate : M. p. 155～157°C ; pale yellow needles (from methanol).

λ_{max}^{MeOH} mμ (log ε) ; 255 (4.32), 348 (4.12), 398 (3.94), 414 (3.96).

Found : C, 59.09 ; H, 4.13 ; N, 9.01. Calcd. for $C_{15}H_{13}O_3N_2Cl$: C, 59.12 ; H, 4.33 ; N, 9.19%.

4-Bromo-7-hydrazino-2-phenoxytropone (XVb).—The treatment of XIVb (400 mg.) with hydrazine, as in the above experiment, afforded XVb (340 mg.) as yellow needles, m. p. 199°C (decomp.).

λ_{max}^{MeOH} mμ (log ε) ; 258 (4.19), 355 (4.09), 430 (3.80).

Found : C, 50.69 ; H, 3.74 ; N, 8.90. Calcd. for $C_{13}H_{11}O_2N_2Br$: C, 50.83 ; H, 3.61 ; N, 9.12%.

Acetate : M. p. 185～186°C, yellow needles (from ethanol).

λ_{max}^{MeOH} mμ (log ε) ; 255 (4.33), 348 (4.22), 395 (3.93), 412 (3.95).

Found : C, 51.74 ; H, 3.65 ; N, 7.79. Calcd. for $C_{15}H_{13}O_3N_2Br$: C, 51.59 ; H, 3.75 ; N, 8.02%.

4-Chloro-2-phenoxytropone (XVIa).—A solution of XVa (180 mg.) in a mixture of glacial acetic acid (2 ml.) and water (1 ml.) was heated at about 100°C ; to this, a 30% copper sulfate solution (1.5 ml.) was added in one lot and heating was continued for 15 min. The mixture was then diluted with water and extracted with chloroform, and the chloroform solution was passed through a short alumina column. The removal of the solvent from the effluent left crystals (110 mg.), m. p. 80～83°C, which were recrystallized from a mixture of benzene and cyclohexane to give XVIa as colorless prisms, m. p. 85～86°C.

λ_{max}^{MeOH} mμ (log ε) ; 238 (4.37), 332 (3.95).

Found : C, 66.52 ; H, 3.61. Calcd. for $C_{13}H_9O_2Cl$: C, 67.11 ; H, 3.90%.

4-Bromo-2-phenoxytropone (XVIb). — The same treatment of XVb (210 mg.) with a copper sulfate solution, as in the above experiment, and recrystallization from a mixture of benzene and cyclohexane afforded XVIb (100 mg.) as colorless prisms, m. p. 94～95°C.

λ_{max}^{MeOH} mμ (log ε) ; 242 (4.37), 332 (4.00).

Found : C, 56.40 ; H, 3.23. Calcd. for $C_{13}H_9O_2Br$: C, 56.34 ; H, 3.27%.

4-Chlorotropolone (XIIa).—A solution of XVIa (70 mg.) in a mixture of ethanol (1 ml.) and a 2 N potassium hydroxide solution (1 ml.) was heated under reflux for 2 hr. and then acidified with 6 N hydrochloric acid and extracted with benzene. The benzene layer was shaken with a 2 N potassium carbonate solution, and the carbonate layer was acidified and extracted with chloroform. The removal of the solvent from the extract and the sublimation of the residue in vaccuo afforded colorless crystals, m. p. 68～71°C. Recrystallization from ethanol gave XIIa, m. p. 79～80°C, as colorless needles, which showed no depression of melting point on admixture with an authentic specimen.[6]

4-Bromotropolone (XIIb). — The hydrolysis of XVIb (70 mg.), as in the above experiment, afforded colorless crystals (40 mg.), m. p. 80～83°C. Recrystallization from ethanol gave XIIb, m. p. 87～88°C, as colorless needles, which showed no depression of melting point on admixture with an authentic specimen.[5,6]

4, 7-Dichloro-2-phenoxytropone (XVIIa).—A suspension of XVa (100 mg.) in concentrated hydrochloric acid (2 ml.) was heated at about 100°C ; to this, a 20% copper sulfate solution (2 ml.) was added in one lot, and heating was continued for 2 min. The mixture was then diluted with water and extracted with chloroform. The solvent was evaporated, and the residue was passed through a short almina column in a benzene solution to give XVIIa (70 mg.), m. p. 112～115°C. Recrystallization from methanol afforded colorless needles, m. p. 115～116°C.

λ_{max}^{MeOH} mμ (log ε) ; 248 (4.42) ; 340 (3.99).

Found : C, 58.19 ; H, 3.08. Calcd. for $C_{13}H_8O_2Cl_2$: C, 58.45 ; H, 3.02%.

4, 7-Dibromo-2-phenoxytropone (XVIIb). — The treatment of XVb (100 mg.) in concentrated hydrobromic acid with a copper sulfate solution, as in the above experiment, afforded XVIIb (50 mg.), m. p. 112～114°C. Recrystallization from methanol afforded pale yellow needles, m. p. 117～119°C.

λ_{max}^{MeOH} mμ (log ε) ; 262 (4.33), 345 (3.99).

Found : C, 43.68 ; H, 2.75. Calcd. for $C_{13}H_8O_2Br_2$: C, 43.54 ; H, 2.26%.

The author wishes to take this opportunity to express his sincere gratitude to Professor Tetsuo Nozoe for his kind guidance throughout the course of this work, and to Professor Shuichi Seto and Professor Yoshio Kitahara for much helpful advice.

*Spectroscopic Studies of the Complex Produced by Trimethylaluminum and Diphenylamine**

By Makoto KAWAI, Teiichiro OGAWA and Kozo HIROTA

(Received March 19, 1964)

In order to make clear the polymerization mechanism of lower olefins and epoxides by the use of a Ziegler-type catalyst, it is most important to know the chemical and physical nature of the catalyst. In our previous work, the structure of trialkylaluminum was studied by infrared spectroscopy.[1] The present papar will report on the structure of the complex obtained by the reaction of trimethylaluminum and diphenylamine. Since trimethylaluminum is the lowest member of the trialkylaluminum series, this compound has been well investigated in spite of its low reactivity toward lower olefins. Until recently only a few compounds of $R_2Al\text{–}NR'_2$ type have been reported.

Formerly Brown and Davidson studied a trimethylaluminum and dimethylamine complex.[2] Then Fetter and Bartocha reported on the reaction of trimethylaluminum with various methyl hydrazines.[3] Hoffmann and Tornau described the compound $(Et_2Al\text{-}NC_9H_8)_2$[4] and Murahashi et al. investigated the polymerization of methyl methacrylate by an $EtAl\text{-}N(C_6H_5)$ catalyst.[5] In the publication mentioned above, it was concluded that most of the compounds a covalent aluminum-nitrogen bond was formed by a general reaction scheme:

$$AlR_3 + R'_2NH \rightarrow R_3Al : NHR'_2$$
$$\rightarrow R_2Al\text{–}NR'_2 + HR$$

The compound of the $R_2Al\text{–}NR'_2$ type has been suggested as associating to form a dimer through nitrogen bridges.[2,3] As the complex was sensitive both to air and to moisture, the reaction and subsequent manipulation were carried out under a high vacuum.

Experimental

Materials. — Trimethylaluminum (Ethyl Corp.) was transferred to several break-sealed ampoules in a dry nitrogen atmosphere and then distilled into storage ampoules under a high vacuum. Diphenylamine was recrystallized from alcohol, and was dried and degassed in vacuo before use. Cyclohexane (optical grade) was dried with calcium hydride and evaporated sodium film and then distilled in vacuo into break-sealed storage ampoules.

Reaction. — The reaction was carried out in a conventional high-vacuum system. Trimethylaluminum was transferred to a cold reactor (−196°C) containing diphenylamine. By warming the reactor toward room temperature, some gas was gradually evolved indicating the commencement of the reaction. After the mixture had been heated to the melting point of the product so as to complete the reaction, the excess trimethylaluminum and evolved gas were pumped out. The product was solid at room temperature and liquid at an elevated temperature. Cyclohexane was distilled into the reactor so as to dissolve the product. Then the solution was led into an NMR tube and a break-sealed capsule (for ultraviolet absorption measurements) previously attached to the reactor. Both NMR tube and break-sealed capsule were sealed and removed from the vacuum line.

Apparatus and Measurements.—The evolved gas was analyzed by a Hitachi Model RMU-5B mass-spectrometer installed at the Institute for Protein Reserch of Osaka University. Measurements of the ultraviolet spectra were made with a Hitachi Model EPS-2 spectrometer using 1-cm. quartz cells at room temperature. Samples were prepared under a high vacuum in a U-tube attached to the ampoule (Fig. 1). At first, the break-sealed capsule was broken, the cyclohexane in the ampoule was then transferred to the capsule, and the solution was introduced into the cell. The sample was diluted by distilling cyclohexane into the cell. The proton resonance spectra were obtained with a Varian Model A-60 high-resolution NMR spectrometer at 60 Mc. The sweep rate was about 1 p.p.m./min. For the measurement of the temperature dependence of the rate of methyl group exchange in the system of trimethylaluminum and the complex, the standard equipment of the spectrometer was used. The solvent was used as an internal reference (8.56 p.p.m. in τ value).

Results and Discussion

The ultraviolet spectra of diphenylamine, diphenylammonium ion and the complex are shown in Fig. 2. The long wavelength bands of diphenylammonium ion and the complex show the vibrational structure characteristic of weakly-perturbed benzene rings. The spectrum of the complex resembles the spectra of polyphenyl compounds, which have no lone electron pair at the central atom directly bonded to phenyl radicals (for example $(C_6H_5)_3PO$).[6] The long wavelength band of the complex (274 mμ) is located between the corresponding bands of the diphenylammonium ion (255 mμ) and of diphenylamine (285 mμ). Hence, it may be concluded that the several phenyl rings in the complex are not appreciably conjugated with one another and that, therefore,

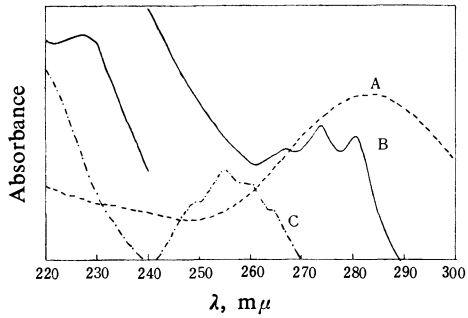

Fig. 2. Ultraviolet absorption spectra.

A: Diphenylamine in cyclohexane
B: The complex in cyclohexane
C: Diphenylammonium ion in water

the nitrogen atom in the complex will take approximately a hybride sp^3 orbital.

The proton magnetic resonance spectrum of the complex (Fig. 3) shows two groups of peaks, with chemical shifts (in τ value) of 2.90 p.p.m. and 10.58 p.p.m. The unresolved low field peaks represent all the protons of the phenyl rings. This group of peaks occurs at a lower field position than that of diphenylamine (3.20 p.p.m.). Groenewege et al. have reported a value of 10.67 p. p. m. for the outer methyls in trimethylaluminum dimer and 9.53 p. p. m. for the bridge methyls.[7] Hoffmann has described a shift of 10.54 p. p. m. of the outer methyls in a dimethylaluminum tertiary-butoxyl dimer.[8] Compounds of the $(Me_2AlX)_2$ type (with X=OR, NR_2,$\cdots$) form bridges only across X. However, their spectra do not yield the outer-methyl signal position of the trimethylaluminium, because the inductive and co-ordinative influences of the X substituents separately alter the effective electronegativity of the molecule residue.

Me_2Al〈. Negative polarizing substituents which asociate through a lone electron pair (X=OR, NR_2) show the sum of both influences. Thus, the sharp high field peak was assigned to methyl protons in the complex. The intensity ratios of both peaks were found to be approximately 5 : 3 by integration. This suggests that the ratio of phenyl groups to methyl groups in the complex is 1 : 1. The gas evolved in the course of the reaction was found to be methane.

From these observations of the complex, as well as from the results of previous works, the reaction of trimethylaluminum with diphenylamine may be expressed by Eq. I.

$$Al_2Me_6 + 2(C_6H_5)_2NH \rightarrow [(C_6H_5)_2NAlMe_2]_2 + 2CH_4 \quad (I)$$

The structure of the complex may be a dimer through nitrogen bridges, which are perpendicular to the plane of four methyl groups.

(II)

The dimer shown in formula II may be called a aluminum diphenylamide complex. In order to confirm this structure of the complex, the NMR spectra of the mixtures of the complex and trimethylaluminum at various ratios were measured in cyclohexane. Figure 4 shows methyl group signals of mixtures at room temperature. The molar ratios of the complex to trimethylaluminum are about 1 : 1 and 1 : 3.2.

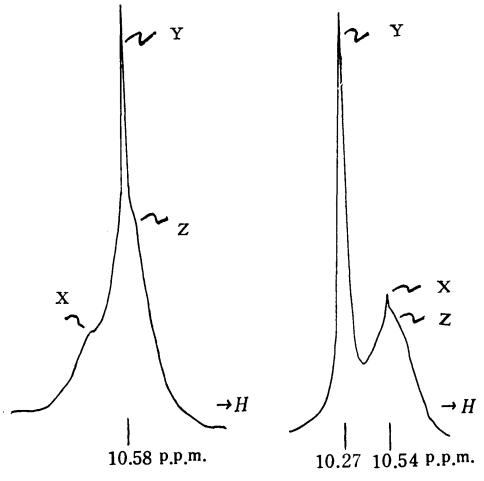

Fig. 4. NMR spectra of mixtures at the molar ratio of (a) 1 : 1 and (b) 1 : 3.2 (the complex : trimethylaluminum) at room temperature.

In the molar ratio 1 : 1, there is no sharp methyl group signal of trimethylaluminum at 10.29 p.p.m., but a sharp methyl group signal (X) and broadened signals are superposed. The position of the former signal coincides with that of the complex. In the mixture, (1 : 3.2) there are two broad and one sharp signals of the methyl group, as is shown in Fig. 4(b). A broad signal with a chemical shift of 10.27 p.p.m. (Y) and a sharp signal (X) with one of 10.54 p.p.m. are assigned to trimethylaluminum and the complex respectively. The broadened signals in those systems show that some exchange takes place in the system.

Each sample was measured at various temperatures to make clear the mechanism of this exchange. The temperature dependences of the NMR spectra of the mixture of the complex and trimethylaluminum in the molar ratios of 1 : 1 and 1 : 3.2 are shown in Fig. 5 and Fig. 6 respectively. The figures illustrate the broadening and coalescence of NMR peaks when they pass through the transition region between slow and fast exchange.

All the results and assignments are summarized in Table I. In the mixture, (1 : 3.2) two broadened signals (Y and Z) at room temperature move together as the temperature rises and coalescence into a single peak (T) at about 50°C. The sharp signal (X) decreases

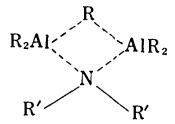
its intensity as the temperature is elevated and finally disappears at about 70°C. At 90°C, the spectrum becomes sharp and narrow. Figure 5 shows the same behavior of methyl group signals in mixture (1 : 1). These results reveal behavior of methyl group signals in the mixture (1 : 1). These results reveal the presence of three chemical species in the system.

The dimer structure of the complex suggested above permits us to interpret the three species and also these exchange phenomena by assuming the following reaction:



i.e. $B_2 + A_2 \rightleftharpoons 2AB$

where A stands for $AlMe_2N(C_6H_5)$ and B, for $AlMe_3$. The broad signal (Z) is assigned to the outer methyl groups of the mixed dimer AB. The existence of the three species could not be explained by a monomer structure. There are five different sites which can be occupied by the methyl groups. In the previous study of trimethylaluminum by proton resonance, it was concluded that the exchange between B_2 and B_2 (including intramolecular exchange) was fast at room temperature.[8] At room temperature, the NMR spectrum of Fig. 5 shows a sharp methyl group signal at 10.58 p.p.m. (X) corresponding to A_2 and broadened methyl group signals, which originate from a slow exchange between AB and B_2 and between AB and AB. At 50°C the rate of this exchange is probably fast enough for the two broadened peaks to coalescence into a single peak (S), as is shown in Fig. 6. A sharp methyl group signal (X) corresponding to A_2 decreases with the increasing temperature and disappears at 90°C. This shows that reaction III proceeds toward the right side with the increasing temperature. At 90°C, therefore, AB is the predominant species in the system and shows a sharp signal (S), which indicates a fast exchange between AB and AB. This observation shows that the rate of the three exchanges between B_2 and B_2, between AB and AB, and between AB and A_2 are in the observable region of proton resonance.

Using the value, 10.40 p.p.m. of AB and 10.29 p.p.m of B_2, the τ-value of the mixture (1 : 3.2) at 90°C was calculated** shown in Table I. The agreement of the observed and the calculated τ-values for the mixture (1 : 3.2) at 90°C supports the present assignment of proton magnetic resonance spectra.

Ziegler et al. reported that the mixtures of dialkylaluminum amide $(R_2AlNR'_2)_2$ and trialkyl aluminum do not polymerize ethylene, and that a mixed dimer of the type

** This τ-value was the weighted average of the τ-values of B_2 and AB, assuming that reaction III proceeded completely towards the right side at 90°C.

(IV)

is not produced in the system.[9]

The results of the present NMR study clearly show the existence of the mixed dimer (IV) in the present case. A similar system was reported to polymerize methyl methacrylate.[5] Aliphatic amines and aromatic amine might be different in activity in forming a complex.

Summary

The reactive complex produced by the reaction of trimethylaluminum with diphenylamine has been studied by the ultraviolet absorption and proton magnetic resonance methods. The ultraviolet absorption of the complex has shown two bands, at 228 mμ and 274 mμ, in cyclohexane. Proton magnetic resonance spectrum of the complex has been shown to consist of two groups of peaks, with an intensity ratio of approximately 5 : 3 and with chemical shifts of 2.90 p.p.m. and 10.58 p.p.m. These shifts have been assigned to phenyl protons and methyl protons respectively. In the mixture of trimethylaluminum and the complex, an exchange of methyl groups occurs. The structure of the complex has been concluded to be dimeric through two nitrogen bridges, as is shown in formula II.

The authors wish to express their thanks to Professor Heimei Yuki (Faculty of Engineering Science, Osaka University) for his helpful discussions in the course of this study.

*Infrared Spectra of Adsorbed Formic Acid**

By Teiichiro OGAWA, Kosaku KISHI and Kozo HIROTA

(Received May 4, 1964)

In order to investigate the mechanism[1] of the catalytic decomposition of formic acid, the infrared spectra of adsorbed formic acid have been already studied by Hirota, Kuwata and Nakai,[2] and by others[3]. Hirota et al. found new bands at 1590 cm^{-1} and 1360 cm^{-1} for the silica-supported zinc catalyst[2] and assigned these bands to the chemisorbed formate anion.

The adsorbent hitherto investigated have, however, been confined to the metal oxides and supported metals, and their spectral region has usually been in the range from 2000 cm^{-1} to 1250 cm^{-1}.[2] In order to clarify the reaction mechanism, a spectroscopic study of the adsorbed state on pure metals and an extension of the wavelength region have to be carried out. In the present report, a new cell for infrared measurement is devised and adsorbed states on evaporated metal films are investigated in the four ranges from 4000 cm^{-1} to 400 cm^{-1}.

Experimental

The cell was made of hard glass, on which windows of polyethylene films 0.5 mm. thick were stuck with a small amount of glyptal resin, as is shown in Fig. 1. Similar films 0.1 mm. thick were set in the cell as substrata for the evaporated metal film. The cell was then degassed and kept under about 10^{-2} mmHg for several days. The use of polyethylene as optical windows made it possible to measure the 4000 cm^{-1}~3100 cm^{-1}, 2500 cm^{-1}~1500 cm^{-1}, 1250 cm^{-1}~750 cm^{-1} and below 700 cm^{-1} regions. Zinc metal could easily be evaporated on the thin polyethylene films by heating it externally with a gas-burner.

The spectra were recorded with a Nippon Bunko Model DS402G spectrometer. Polyethylene films and a wire netting were inserted in the reference beam during the measurement. Formic acid was dried by anhydrous cupric sulfate.

Results and Discussion

The spectrum of the evaporated zinc film was measured first, and then formic acid was introduced into the cell at about 30 mmHg. The two spectra are shown in Fig. 2 by a dotted and a solid line respectively. Successive evacuation and spectral measurements were carried out; one of such spectra is shown in the figure by a dot-dash line.

The observed bands are summarized in Table I. The bands which disappeared after ten minutes' evacuation were assigned to formic acid in the vapor state. The two band which remained after an hour's evacuation were considered to arise from the chemisorbed species and were assigned to the adsorbed formate anion on the basis of a comparison of them with the spectra of the zinc formate and the formate anion in solution.

The effects of polyethylene or glyptal resin on the adsorbed state were checked; no band of the formate anion or others was observed without the metal film after ten minutes' of pumping. The saturated hydrocarbon as polyethylene is chemically inactive and is considered to have less influence on the adsorbed states than does a silica or alkali halides crystal. The present method, therefore, not only makes it possible to find a new band at 770 cm^{-1}, but also reveals the less unperturbed adsorbed states.

Summary

The infrared spectra of adsorbed formic acid on zinc have been measured. Two bands have been found at 1570 cm^{-1} and 770 cm^{-1} and assigned to the adsorbed formate anion.

High-kinetic Energy Fragment Ions from Organic Compounds under Electron Impact. IV. Methanol

By Toshikazu TSUCHIYA

(Received March 24, 1964)

It has long been known[1,2] that fragment ions formed from polyatomic molecules under electron impact often have excess kinetic energy,* and studies of KE fragment ions from hydrocarbons have been reported.[1-7] Hustrulid et al.[1] suggested that these ions with a high kinetic energy result from the dissociation of doubly-charged ions formed by electron impact. Mohler et al.[3] computed the repulsive energies of ions fromed from various compounds on this assumption.

In the present ariticle, some findings on the KE fragment ions from methanol will be reported, and a mechanism of the production of the KE ions will be suggested according to the proposal made by Hustrulid and Mohler.

Measurement

Methanol was a special-grade reagent obtained from the Nippon Rikagaku Shiyaku Co. and was purified by distillation. It was found to be mass-spectroscopically pure. The procedure for the measurement of KE ions has previously been reported.[6]

The results of measurement are given in Table I. Column two gives the kinetic energy, E, of the KE ions CH_2^+, CH_3^+ and OH^+, while columns three and four give the intensity of the KE ion, I_k, and that of TE ion, I_t, respectively in arbitrary units. The last column gives the lowest electron energy, A, at which the KE ions could be detected. In each instance, the given result is the mean value of four measurements. The reproducibility of E values was ± 0.2 eV. The + mark in the I_k column indicates the presence of a weak peak.

Table I. Ions of high kinetic energy in the mass spectrum of methanol

m/e	E, eV.	I_k	I_t	A, eV.
14		+		
15	2.7	0.7	74.3	37
17	1.9	1.3	2.0	36

E, kinetic energy
I_k, intensity of the high kinetic-energy peak,
I_t, intensity of the thermal energy peak,
A, minimum electron energy at which the kinetic-energy peak was observed.
+ indicates the presence of a weak peak.

Discussion

KE peaks appear at m/e 14, 15 and 17, which indicate CH_2^+, CH_3^+ and OH^+ ions respectively. The kinetic energy of the CH_2^+ ion could not be measured, as its intensity was too small. CH_3^+ and OH^+ KE ions may be produced individually or simultaneously from methanol by one or more of the following reactions:

$$CH_3OH \rightarrow CH_3OH^+ \rightarrow \begin{cases} CH_3^+ + OH & 19.2 \quad (1) \\ CH_3^+ + O + H & 23.6 \quad (2) \\ OH^+ + CH_3 & 21.0 \quad (3) \\ OH^+ + CH_2 + H & 24.5 \quad (4) \\ OH^+ + CH + 2H & 28.8 \quad (5) \\ OH^+ + C + 3H & 31.2 \quad (6) \end{cases}$$

$$CH_3OH \rightarrow CH_3OH^{2+} \rightarrow CH_3^+ + OH^+ \qquad 31.5 \quad (7)$$

The figures after each formula indicate the energy of formation in eV. computed from the measured kinetic energy in Table I and from other appropriate data,[8] assuming the conservation of the momentum of fragments.

Since the intensities of KE ions were rather weak over a fairly wide range of electron energies, the precise values of the appearance potentials could not be estimated. A comparison of the tangent of the ionization efficiency curves of the ions with that of neon indicates that the appearance potentials of the KE ions are somewhat lower than the minimum electron energy given in Table I. Hence, in the following discussions, we will confine our

investigation to these reactions that require energies larger than about 30 eV. Thus, reactions 1—4 were discarded, assuming the produced fragments are not in excited states.

The peak height of the OH^+ KE ion is larger than that of the CH_3^+ KE ion, as may be seen from Table I. As both ions are focused at about the same ion acceleration voltage, their "sensitivities" are considered to be approximately equal.[9] Under the present experimental conditions, the number of ions produced in the ion source is considered to be proportional to the area of the recorded ion peak rather than to the height of the peak, and it is expected that the higher the initial kinetic energy of the ions, the larger the recorded ion peak width.[10] Even taking such circumstances and the amount of kinetic energies of the OH^+ ion and the CH_3^+ ion in Table I into consideration, the number of CH_3^+ ions of high energy is considered to be smaller than that of the OH^+ ion. Since, by reaction 7, CH_3^+ and OH^+ are expected to be produced in the same amount, reactions 5 and 6, which should produce the OH^+ KE ion only, must be considered. In the investigation described above, the possibility of a simultaneous production of CH_2^+ and OH^+ KE ions was disregarded, as the intensity of CH_2^+ was very small.

The CH_3^+ KE ion is expected to be produced only by reaction 7, which involves the disruption of a doubly-charged ion proposed by Hustrulid[1] and Mohler[3]. On this base, the two ions produced simultaneously are expected to have the same momentum. From the measured kinetic energies given Table I, the momenta of CH_3^+ and OH^+ are computed to be proportional to 9.2 and 8.0 respectively. Even taking into account the experimental errors, these two values are not expected to coincide with each other. The discrepancy may be explained as follows. Hitherto we have assumed that the two fragments produced in reaction 7 have only translational energies. However, the circumstances are quite different if we suppose that the OH^+ KE ion can carry away energy in some other form, such as rotational energy, because of the particular molecular structure of the mother substance.

Lyman,[11] in a study of the band spectrum of the hydroxyl radical produced by a discharge through water vapor, pointed out that a part of the OH radical exhibits "abnormal rotation." Many authors have studied the abnormal rotation of the hydroxyl radical,[12-15] and similar phenomena have been reported in a study of water vapor bombarded by electrons.[14,15] This phenomenon has been explained as follows. A water molecule has the equilibrium form of an isosceles triangle at the ground state, two hydrogen atoms bonding with an oxygen atom at about 105°. When a water molecule is excited to an unstable excited state by vacuum discharge or electron bombardment, however, one of the two hydrogen atoms will fly off in a direction normal to the line joining the initial position and the oxygen atom, leaving the other to rotate about the oxygen atom. The amount of the abnormal rotational energy is reported to be about 0.4 eV.[14] in this event. A similar abnormal rotation of OH is also observed in the case of ethanol.[13]

More recently Chupka,[16] in a study of appearance potentials, has pointed out that appreciable excess rotational energy may be present where the dissociation into fragments with excess kinetic energy occurs in a direction not along the line connecting the centers of the mass of the two fragments.

The molecular structure of methanol is shown in Fig. 1,[17] the C–O–H angle is about 108°. If it is assumed that, according to the mechanism proposed by Hustrulid and Mohler, at first two electrons are removed from the methanol molecule, leaving a positive charge on the CH_3 and OH groups, and that then the doubly-charged molecular ion dissociates into CH_3^+ and OH^+ KE ions by means of the Coulomb repulsion, a part of the Coulomb

energy may be considered to be transferred to the rotational energy of the fragment ions. Because of the structure of the parent ion, OH^+ rather than CH_3^+ is expected to obtain rotational energy in the main. If OH^+ is assumed to carry away energy by rotational motion, we may judiciously elucidate the phenomenon that the momenta of the two fragment ions in reaction 7 differ greatly, the OH^+ ion having the smaller momentum.

The difference between the sum of the measured kinetic energies of the two fragments and the total energy computed from the kinetic energy of the CH_3^+ ion is 0.5 eV. If it is assumed that the CH_3^+ ion has only a translational energy, and that vibrational motion of OH^+ is only slightly excited, a value of 0.5 eV. may be assigned to the rotational energy of the OH^+ ion. This value is considered to be compatible in order of magnitude with the value reported for the abnormal rotational energy of the OH molecule from water,[14] taking the accuracy of the present experiment into account. According to Mohler et al., the distance between two charges in the present case is estimated to 2.8 Å. However, since nothing is known about the actual distance between the charges in CH_3OH^{2+}, the postulate given above cannot be corroborated from this point of view, although the assumed distance would not be unacceptable. If the CH_3^+ ion has additional excitation energy, a smaller distance may be assumed.[3]

Summary

Fragment ions with high kinetic energies have been produced from methanol by electron impact, as in the cases of many hydrocarbons. Assuming that a fragment has a rotational energy of the order of 0.5 eV. most of the high-energy ions from methanol can be ascribed to a doubly-charged molecule ion that dissociates into two singly-charged fragments.

The author wishes to express his thanks to Mr. Mikitake Nakayama for his assistance in purifying the sample and to Mr. Ryuzo Shiota for his kind discussions and survey of the manuscript.

An Application and Modification of the Freeze-out Technique by Quiram and Biller for the Determination of Pollutants in the Atmosphere by Mass Spectrometry

By Hiroko HOSHINO, Nobuhide WASADA and Toshikazu TSUCHIYA

(Received March 24, 1964)

Many works[1-5] have reported on concentrating air pollutants in a cold trap in order to analyze the concentrates by mass spectrometry. It has long been known that water can be passed through an ordinary in-seal trap at the temperature of liquid air,[6] even though its vapor pressure is almost 10^{-26} mmHg at these temperatures. Extremely small frozen particles are formed at these low temperatures, and these fine crystals are carried into the gas stream through the trap. Contaminants contained in air, other than water, may also pass more or less through a trap in a similar manner. To collect from air sufficient pollutants for subsequent analysis, Shepherd et al.[1] and Quiram and Biller[5] used a cold trap of glass wool or one of silica gel. To compensate the passover of the pollutants, Shepherd et al. took a large amount of the air sample. Quiram's method, on the other hand, requires only 3 l. NTP of air. In his method, by handling glass stop cocks manually, a part of the air sample was introduced into the trap and was then left in contact with the glass wool for about 30 sec. in order to improve the condensation efficiency of the pollutants; then the air sample in the trap was evacuated off.

2) P. P. Mader, M. W. Heddon, R. T. Lofberg and R. H. Koehler, ibid., **24**, 1899 (1952).
3) E. R. Quiram, S. J. Metro and J. B. Lewis, ibid., **26**, 352 (1954).
4) K. Suzuki, S. Araki and S. Hirano, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **61**, 26 (1958).
5) E. R. Quiram and W. F. Biller, *Anal. Chem.*, **30**, 1166 (1958).
6) M. Shepherd and A. Martin, *J. Res. Natl. Bur. Standards*, **2**, 1145 (1929).

This procedure was repeated about 50 times until the air in the 3 l. sample bottle was exhausted. By this method they improved the collection efficiency and could collect sufficient hydrocarbons contained in the atmosphere above 10 p.p.m. for subsequent analysis with a mass spectrometer. Though excellent in its capacity of collection, the method of Shepherd et al. is somewhat unhandy to apply in field work, while in that of Quiram and Biller it is very troublesome to handle the stopcocks.

We have employed the method of Quiram and Biller, investigating its usefulness for several pollutants, notably for a trace of mercury vapor in air. Since the results proved to be satisfactory, as will be described below, we have slightly improved the freeze-out technique by automatically circulating the air sample through a glass-wool trap instead of handling the stopcocks manually. Synthetic air samples were analyzed by this procedure, and the results checked.

Experimental

The assembly of the sample-collecting apparatus is shown schematically in Fig. 1. The apparatus is essentially the same as that employed by Quiram and Biller, but it was modified by the addition of

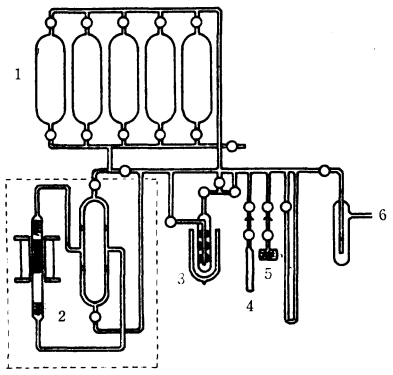

Fig. 1. Sample collecting manifold.

1 Sample bottles
2 Circulation pump
3 Glass-wool trap
4 Contaminant concentration thimble
5 Drying agent
6 To vacuum pump

a magnetic circulating pump, which is shown in Fig. 1, encircled with a dotted line. The volume of the gas-collecting bottle was about 3 l. Five gas-collecting bottles were assembled in order to prepare synthetic blended samples by a dilution technique using these bottles successively. Blends of appropriate concentrations in the bottles were diluted with air, and could be used immediately to get a calibration curve.

The magnetic circulation pump was equipped with only one solenoid. The principal features of the pump have been reported by Livingston.[7] The 2000-turn coil driving the piston was of enamel wire, 1.5 mm. in diameter. The solenoid was activated by an electronic timer obtained from the Sakashita Factory. When adjusted to an optimum stroke, the pump circulated air at atmospheric pressure at the rate of 3 l./min. with a power consumption of about 50 W. When necessary, the pump can be shunted out from the gas sample manifold by stop cocks. Under these conditions, the method of Quiram and Biller was tested.

The procedure of manual operation for the freezing out of the contaminants from the air sample was the same as that reported by Quiram and Biller. In the mercury analysis, a mercury manometer in the gas-handling manifold of the mass spectrometer was demounted in order to eliminate the mercury background.

In the circulation method, the air sample was repeatedly circulated from a sample bottle through a cold trap for an appropriate period. The other operations were the same as in Quiram and Biller's method. Carbon dioxide was not removed from the collected contaminants in the present experiment, however. Rather, the amount of carbon dioxide in the room air itself was determined beforehand using argon as the internal standard, and in the subsequent analysis of the various components in the collected pollutants, carbon dioxide, collected simultaneously, was used as the internal standard, since one of the main components of the substance frozen-out from the air itself of the room was carbon dioxide, and the same air was introduced into the sample bottle containing an appropriate amount of blended materials in order to prepare the air sample.

In order to determine the appropriate circulating time, the carbon dioxide in the room air was collected under various circulating times, ranging from 5 to 60 min. The amount of carbon dioxide collected was then determined, using argon as the internal standard. Table I shows the result. Since a 10-min. circulation was found to be sufficient to attain a maximum, an almost constant collection efficiency in the case of carbon dioxide, all the samples were circulated for 10 min. in the following determinations.

The gases used to prepare the samples were standard gases obtained from the Takachiho Chemicals Co. Anhydrous magnesium perchlorate, the

drying agent, was a guaranteed reagent obtained from the Toyama Kagaku Co. A Consolidated Electrodynamics Corp. mass spectrometer, type 21-103C, was used.

Results and Discussion

Mercury Determination. — Table II shows the mean deviation of the determination of the mercury vapor in the air by Quiram and Biller's method. The samples were prepared as follows. An evacuated 3 l. sample bottle containing a drop of mercury was immersed in water, which was kept at a constant temperature. The atmosphere in the bottle was found to come to an equilibrium with liquid mercury in about an hour. After 3 hr. of immersion, the mercury drop was removed from the bottle containing the mercury vapor corresponding to the temperature of the water; then, by opening a cock, the bottle was filled with room air. The pressure of mercury in the sample bottle was estimated from the Table recording vapor pressure versus temperature.[8] The samples in Table II and Table III were obtained by successively diluting the air prepared by the procedure. The data in Table III indicate the known content of mercury and the ratio of the mercury found to the known content. The rather low value of the ratio is probably due to poor collection efficiency, since little memory effect was observed in the mass spectrometer. For analysis we used a working curve. Figure 2 indicates such a working curve. A synthetic air sample containing 1.7×10^{-2} p.p.m. of mercury vapor was analyzed by the method. The result was 2.0×10^{-2} p.p.m., which is 20% over the blended value. As much mercury vapor contained in atmosphere as the maximum allowable tolerance, i.e., about 1/100 p.p.m., may be determined by this method, with a mean deviation of about 20% (Table II), whereas, according to our experiment, with hydrocarbons contained in the air, the detection limit of the present technique was 1 p.p.m.*

is not recovered. Figure 3 shows the relation between the amount of blended compounds and the amount collected. As may be seen in the figure, the working curves of various compounds coincide remarkably in this range of concentration. This is not surprising, however, as these pollutants are physically, rather than chemically, adsorbed on glass-wool. When samples of the same composition were analyzed several times, the reproducibility of the analysis was found to be about ±10%. Blended samples of various compositions were analyzed, but no interference effect among components was observed.

In the range of 10~100 p.p.m., about 90% of each of the pollutants was recovered. With the object of seeing the whereabouts of the uncollected pollutants, the remaining air of the once-freezed-out sample containing *n*-butane was treated afresh. By this treatment, about 10% of the original amount of *n*-butane was collected. From this result it seems that the uncollected portion of the pollutants is not lost in the process, but remains in the gas phase.

The compounds in the lowest concentration blend tested, which contained about 10 p.p.m. of each of the compounds, gave peak heights of 20~80 divisions of the recorder chart of mass spectrometer, according to their sensitivities. Since a difference of one division has significance under favorable circumstances, a one- or two-fold decrease in concentration, depending on the compounds, may be tolerated in analyzing a sample of air of this size. The time necessary for the sample manipulation, including mass spectrometric recording, is about 3 hr. per sample.

The merit of the present procedure is that it requires only mechanical operations, no mental concentration. The method has, however, a few limitations. One of these concerns the fact that some contaminants which are often encountered, such as carbon monoxide, methane and hydrogen, cannot be collected by this technique. Those substances which dissolve or attack vacuum grease, such as benzene or boronfluoride, also do not give reliable results when one uses ordinary greased stopcocks. For a similar reason, a drying agent may also limit the usefulness of the method.

Summary

Quiram and Biller's freeze-out method, originally devised to determine hydrocarbons contained in air above 10 p.p.m. and using a mass spectrometer, was tried on a trace (down to 1/100 p.p.m.) of mercury vapor in atmosphere; it was proved to give satisfactory results. The freeze-out procedure was then slightly modified. To collect the pollutants, the air sample was circulated automatically for ten minutes through the freezing-out trap instead of repeatedly handling the stopcocks. By this procedure, a blended air sample containing various pollutants above 10 p.p.m. have been analyzed. The precision is about ±10%.

The authors would like to express their thanks to Dr. Shun Araki for his advice and to Mr. Ryuzo Shiota for his valuable discussions and survey of the manuscript.

The Spectrophotometric Determination of a Small Amount of l-Ascorbic Acid with the Iron(III)-1, 10-Phenanthroline Reagent

By Isao ONISHI and Tadashi HARA

(Received March 24, 1964)

Though several methods[1-4] have been reported for the spectrophotometric determination of ascorbic acid on the basis of the oxidation-reduction reaction between *l*-ascorbic acid and the coloring agents, they seem to be either complicated or unreliable because the absorptivity of the colored solution varies with time. The purpose of the present study is to establish a simple and accurate spectrophotometric method, which is indispensable for the investigation of the catalytic effects of metal complexes on the autoxidation of *l*-ascorbic acid.

It is well known that the iron(II) - 1, 10-phenanthroline complex shows an intense red color and is more stable than the corresponding ferric complex over a wide pH range. On the other hand, the ferric complex has been found by the authors to be quantitatively reduced to the ferrous complex by *l*-ascorbic acid. Use is made of these facts for the present purpose. Because of the instability of the colored solution, no report has been presented for the determination of *l*-ascorbic acid using the ferric complex as a coloring agent. The instability of the colored solution seems to be caused by the photo-reduction of the ferric complex, because the iron(III) - 1,10-phenanthroline solution gradually shows a red color in visible light.[5]

The photo-reduction of the ferric complex, however, has been avoided by adding a chelating agent such as ethylenediaminetetraacetic acid (EDTA) to mask excessive ferric iron after the color development. The method has been further applied to the measurement of the catalytic activities of metal complexes for the autoxidation of *l*-ascorbic acid.

Experimental

Apparatus.—Absorbance mearurements were made with a Shimadzu spectrophotometer, Model QR-50, using 1 cm. glass cells.

Reagents. — *l-Ascorbic Acid Solution.* — For the determination, 0.2 g. of l-ascorbic acid manufactured by Merck & Co. is dissolved in water, and the solution is diluted to 100 ml. A 10 ml. portion is pipetted out and diluted to 500 ml. For the catalytic reaction, 0.2 g. of *l*-ascorbic acid is directly dissolved in 500 ml. of water. These solutions are freshly prepared for every use.

1,10-Phenanthroline Solution.—Prepared by dissolving 1.4401 g. of 1,10-phenanthroline hydrochloride in water, and by diluting this to 1000 ml. with water.

Ferric Iron Solution. — Prepared by dissolving 0.9858 g. of ferric ammonium sulfate in 1000 ml. of water.

EDTA Solution.—Prepared by dissolving 9.2555 g. di-sodium salt of EDTA in water, and by diluting it to 500 ml.

Metal Salt Solutions.—Prepared as 10^{-4}M solutions.

Buffer Solution.—Prepared by mixing each of 1 M acetic acid and sodium acetate solution at a moderate ratio.

Water.—Prepared by redistilling ordinary distilled water with an all-glass-jointed Pyrex glass apparatus, and by saturating it with purified air.

Procedure. — Take 5.0 ml. each of iron(III) and buffer solutions in a 50 ml. measuring flask, add a sample solution containing *l*-ascorbic acid, and, then 5.0 ml. of the 1,10-phenanthroline solution. Add 1.0 ml. of the EDTA solution after 1 min., dilute to the mark with water, and measure the absorbance of the colored solution at 514 mμ against a reagent blank solution within an hour.

Results and Discussion

Absorption Spectra.—The absorption spectra of the blank, iron(II)- and iron(III)-complexes are shown in Fig. 1. The maximum absorbances for both A and B in Fig. 1 are observed at 514 mμ, where the blank shows a slight absorption. The shapes of the absorption spectra are quite similar for A and B, and the λ_{max} gives a good agreement with the values reported in the literature.

The Effect of pH. — The absorbance of the mixture of 5.0 ml. each of iron(III) and 1, 10-phenanthroline solutions and of 10 ml. of a *l*-ascorbic acid solution was measured at various pH values. The results obtained are shown in Fig. 2. The absorbances of the colored solutions are almost the same at pH 3.6~5.8.

B: Fe(II) + (1,10-phenanthroline)
C: Fe(III) + (1,10-phenanthroline)

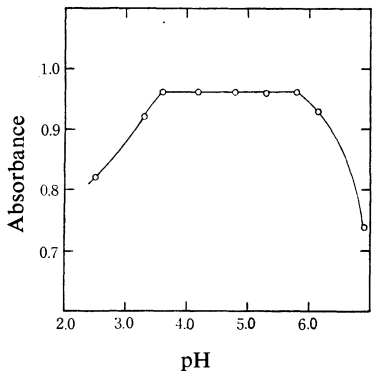

Fig. 2. Relationship between pH and absorbance of the colored solution.

The Stability of the Colored Solution.—The relations between the absorbance and the time after the color development are shown in Fig. 3. It is apparent from Fig. 3 that the absorbance of the colored solution increases with time in the absence of a chelating agent, while it is almost constant in the presence of a moderate amount of EDTA or phosphoric acid. The increase in the absorption mentioned above seems to be due to the photo-reduction of the ferric complex, because the mixed solution of iron(III) and 1,10-phenanthroline easily turns red under sunlight, and the stable coloration seems to be based on the masking of the excessive iron(III) with EDTA or phosphoric acid. The coloration is stable for at least an hour in the presence of a chelating agent.

Calibration Curve. — Solutions containing various amounts of *l*-ascorbic acid were treated by the preceding procedure; the results are plotted in Fig. 4. As can be seen from Fig. 4,

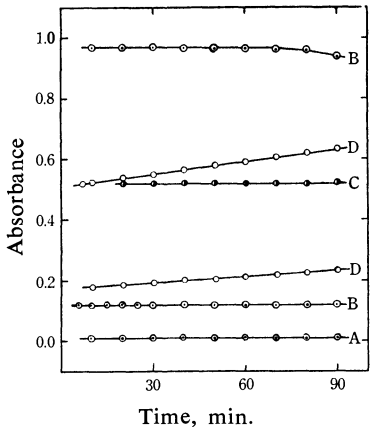

Fig. 3. Stability of the colored solution.

A: Fe(III) + (1,10-phenanthroline) + (1 ml. of 0.05 M EDTA)
B: Fe(III) + (1,10-phenanthroline) + (different amount of *l*-ascorbic acid) + (1 ml. of 0.05 M EDTA)
C: Fe(III) + (1,10-phenanthroline) + (*l*-ascorbic acid) + (1 ml. of 0.15 M H_3PO_4)
D: Fe(III) + (1,10-phenanthroline) + (*l*-ascorbic acid)

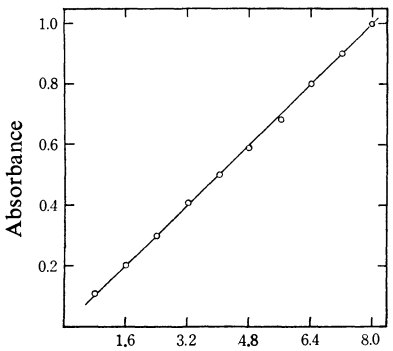

Fig. 4. Calibration curve for *l*-ascorbic acid at 514 mμ.

up to 8.0 p.p.m. *l*-ascorbic acid obeys Beer's law.

Diverse Ions.—The method is interfered with not only strong oxidizing or reducing agents, but also by small amounts of cations. The effects of metal ions on the catalytic oxidation of *l*-ascorbic acid were measured by the following procedure: Take a definite amount of metal ions in a test-tube fitted with a glass-stopper, adjust the pH to 4.3 with the acetate buffers, and dilute to 90 ml. with water. Take an aliquot volume of an *l*-ascorbic acid solution in another test-tube. Stopper both tubes and place them in a thermostat held at 25±0.1°C for about two hours. Pipette out 10 ml. of the *l*-ascorbic acid solution, add it to the other

test-tube, mix, and let it stand in the thermostat. Pipette a 10 ml. portion out of the solution as soon as possible, and estimate the amount of *l*-ascorbic acid in it by the preceding method, where the time is regarded as zero. The residual amounts of *l*-ascorbic acid in the mixed solution are determined by the same treatment after a definite interval.

The values of $\log C_0/C$ are plotted against the time, "t," and the rate constant, "k," is calculated from the equation, $k=(2.303/t)\times\log C_0/C$. The results obtained are shown in Table I and in Fig. 5. The catalytic effects of various metal ions are compared by the k values, the order of which is as follows:

$$\text{Cu(II)} \gg \text{Fe(II)} > \text{Cd} > \text{Zn} > \text{Al} > \text{Fe(III)}$$

Among these, copper(II) is the most active, followed by iron(II), iron(III), cadmium, zinc and aluminum. The other metal ions, such as silver(I), cobalt(II), mercury(II), magnesium, manganese(II), nickel(II), lead(II), palladium and chromium(III), do not show any remarkable activity. Since the linear relationships as shown in Fig. 5 are obtained between $\log C_0/C$ and t with regard to the active ions, the oxidation is consider to proceed as of the first order with respect to the ascorbic acid. The reaction rate of *l*-ascorbic acid against various pH values in the presence of a definite amount of copper(II) is shown in Fig. 6. Judging from the reaction mechanism reported in the literature,[6,7] the following conditions seem to be at least necessary for the catalytic oxidation of *l*-ascorbic acid with metal ions: (1) the coordination of *l*-ascorbic acid to the metal ions, and (2) the valency change of the metal ion by the coordination. Since the complex formation proceeds witd the pH increase, the results shown in Fig. 6 are understandable.

According to Mellor and Maley,[8] the stability of bivalent metal complexes is ordered as follows:

TABLE I. OXIDATION RATE OF *l*-ASCORBIC ACID IN THE PRESENCE OF VARIOUS KINDS OF METAL IONS
(25 ± 0.1°C, pH=4.3, metal ion: 5×10^{-6} M/l.)

Metal ion	Salt	Rate constant k, $\times10^3$ min^{-1}
—	—	3.14
Ag	$AgNO_3$	3.14
Cd	$Cd(NO_3)_2$	6.90
Co	$Co(CH_3COO)_2$	3.03
Cu	$CuSO_4$	33.7
Fe	$FeSO_4(NH_4)_2SO_4$	7.32
Hg	$Hg(NO_3)_2$	2.68

7) A. Weissberger and J. E. LuValle, ibid., **66**, 700 (1944).
8) D. P. Mellor and L. Maley, *Nature*, **159**, 370 (1947); **161**, 436 (1948).

$$Pd > Cu > Ni > Pb > Co > Zn > Cd > Fe > Mn > Mg$$

In view of this stability series and the reversibility of the valency change, the order of the catalytic activity is also understandable, except for iron(III). The inactivity of iron(III) seems to be closely related to the hydrolysis at pH 4.3. The inactivity of palladium is considered to be based on the irreversibility of its valency, since palladium(II) is easily reduced to palladium(0).

Summary

A simple and accurate spectrophotometric method with the iron(III) - 1, 10-phenanthroline reagent has been established for the determination of a small amount of *l*-ascorbic acid; it has been applied to the measurement of the catalytic effects of metal ions on the autoxidation of *l*-ascorbic acid.

The authors wish to express their heartly thanks to Miss Mikiko Kobata and Miss Masako Onishi for their skillful technical assistance.

The Catalytic Effects of Copper Complexes on the Oxidation of l-Ascorbic Acid

By Isao ONISHI and Tadashi HARA

(Received March 24, 1964)

In the preceding paper,[1] the catalytic effects of metal ions on the oxidation of *l*-ascorbic acid were examined, and copper(II) was found to be the most active among them. The present study has been carried out in order to determine the relationship between the catalytic acitivity of various kinds of copper(II) complexes and the stability of the complexes. Though the discussions have often been made qualitatively with regard to the relationship between the catalytic activity of metal complexes and their stability, no quantitative relationship has been reported. The catalytic activity of copper(II) decreases more or less in the presence of the chelating agent, which forms a stable complex with copper(II). Since the decrease in the catalytic activity changes depending on the kinds of chelating agents and on the mole ratios of copper to the chelating agents, the stability constants of copper complexes can be calculated by measuring the rate constant with the solutions of the same composition as the copper(II) complexes. The results obtained by this method will be compared with those obtained by the polarographic method, etc. As for the relationship between k and the stability constant, K_s, k will be found to be inversely proportional to the $\log(1+K_s\cdot[Y]^n)$, in which [Y] means the concentration of the dissociated chelating agent.

1) I. Onishi and T. Hara, This Bulletin, 37, 1314 (1964).

Experimental

Apparatus and Reagents.—The same apparatus and reagents were used as in the preceding paper except for the following. For the measurement of the polarogram, a Yanagimoto polarograph, Model PR-2, was used. Each chelating agent was prepared as $n\times10^{-4}$ M solution by taking the mole ratio, n, of the chelating agent to copper into consideration.

Procedure.—Take a definite amount of metal ions or an additional chelating agent in a test-tube fitted with a glass-stopper, adjust the pH to either 4.3 or 6.0 with an acetate buffer, and dilute to 90 ml. with water. Take an aliquot volume of an *l*-ascorbic acid solution in another test-tube. Stopper the test-tubes, place in the thermostat held at 25±0.1°C, and treat in a manner similar to that described in the preceding paper.

Results and Discussion

The Relation between the Amount of Copper(II) and *k*.—The rate constant, k, for the oxidation of *l*-ascorbic acid was measured in

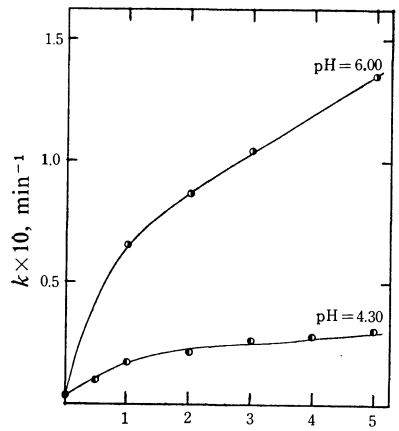

Fig. 1. Relations between the amount of Cu^{2+} and k.

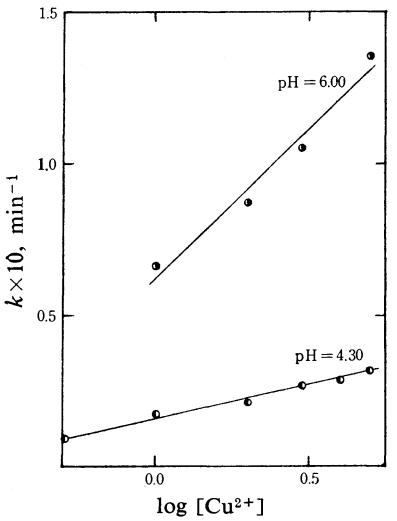

Fig. 2. Relations between log $[Cu^{2+}]$ and k.

the presence of various amounts of copper(II) and with an accuracy of within 5%. The results obtained are shown in Fig. 1. By taking the logarithm of the copper concentration in Fig. 1, Fig. 2 is obtained. As can be seen from Fig. 2, there are two straight lines, and the relations between the amount of copper(II) and k are generally given by Eq. 1;

$$k=a\log[Cu^{2+}]+b \qquad (1)$$

Since a and b are constant under the limited conditions and since their numerical values may easily be estimated from Fig. 2, Eq. 1 is replaced by Eq. 2 or 3 respectively:

$$\text{at pH}=4.3 \quad k_{4.3}=0.023\log[Cu^{2+}]+0.0155 \qquad (2)$$

$$\text{at pH}=6.0 \quad k_{6.0}=0.100\log[Cu^{2+}]+0.064 \qquad (3)$$

By measuring the value of $k_{4.3}$ or $k_{6.0}$ and by substituting them into Eq. 2 or 3, log $[Cu^{2+}]$ is easily found.

The Effects of Chelating Agents on k.—The rate constant for the oxidation of *l*-ascorbic acid was measured in the presence of various kinds of chelating agents, which were added to copper(II) in the same ratios as with copper complexes. The results obtained are shown in Table I. It is apparent from Table I that the values of k vary with the chelating agents, but no definite relation exists between the stability constant and k. The relation between k and the mole ratio of EDTA to copper(II) is

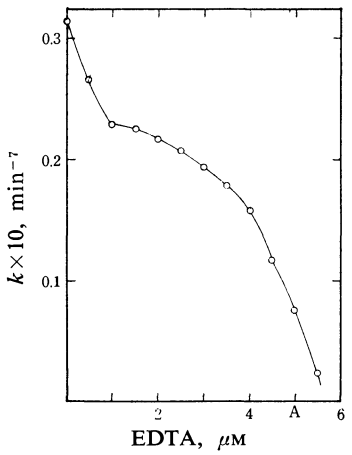

Fig. 3. Relation between k and the mole ratio of EDTA to Cu^{2+}.
Cu^{2+}: 5 μM, A: equivalence point

shown in Fig. 3. As can be seen from Fig. 3, the value of k decreases with an increase in the mole ratio of EDTA to copper(II). Therefore, the catalytic activity of the copper-EDTA system is considered to be due to the free copper ion alone. This was later confirmed by the agreement between the experimental and the theoretical results.

The Estimation of the Stability Constant.—The stability constants of copper(II) complexes are calculated on the basis of the assumption that the catalytic activity of copper(II) complexes are due to the free copper ions which have been liberated from the copper(II) complexes at equilibrium.

If Cu is made to react with n mol. of dissociated chelating agents, Y, to form CuY_n, the formation reaction is expressed by Eq. 4. (Here, the charges on the ions are omitted for the sake of simplicity.)

$$Cu + nY \rightleftarrows CuY_n \tag{4}$$

$$K = [CuY_n] / [Cu]\,[Y]^n \tag{5}$$

If the initial concentration of Cu, $[Cu]_0$, is known,

$$[CuY_n] = [Cu]_0 - [Cu] \tag{6}$$

Similarly, Eq. 7 is derived:

$$[Y]_t = [Y]_0 - n[CuY_n] = n[Cu] \tag{7}$$

where $[Y]_0$: initial concentration of chelating agent,

$[Y]_t$: total concentration of unbound chelating agent at equilibrium.

$[Y]$ is calculated from $[Y]_t$ by the following process. The dissociation of the chelating agent, H_mY, is given by Eq. 8:

$$\begin{aligned} &H_mY \rightleftarrows H^+ + H_{m-1}Y \\ &\qquad K_{d_1} = [H^+]\,[H_{m-1}Y] / [H_mY] \\ &H_{m-1}Y \rightleftarrows H^+ + H_{m-2}Y \\ &\qquad K_{d_2} = [H^+]\,[H_{m-2}Y] / [H_{m-1}Y] \\ &\qquad \cdots\cdots\cdots\cdots \\ &H_2Y \rightleftarrows H^+ + HY \\ &\qquad K_{d_{m-1}} = [H^+]\,[HY] / [H_2Y] \\ &HY \rightleftarrows H^+ + Y \quad K_{d_m} = [H^+]\,[Y] / [HY] \end{aligned} \tag{8}$$

$[Y]_t$ is also given by Eq. 9:

$$[Y]_t = [H_mY] + [H_{m-1}Y] + \cdots\cdots + [HY] + [Y] \tag{9}$$

The terms, $[H_mY] \sim [HY]$ in Eq. 9 are given by rewriting Eq. 8;

$$\begin{aligned} &[HY] = [H^+]\,[Y] / K_{d_m} \\ &[H_2Y] = [H^+]^2\,[Y] / K_{d_m} \cdot K_{d_{m-1}} \\ &[H_mY] = [H^+]^m\,[Y] / K_{d_m} \cdot K_{d_{m-1}} \cdots \\ &\qquad \cdot K_{d_2} \cdot K_{d_1} \end{aligned} \tag{10}$$

By substituting Eq. 10 into Eq. 9, Eqs. 11 and 12 are obtained:

$$[Y]_t = \frac{[H^+]^m\,[Y]}{K_{d_1} \cdot K_{d_2} \cdot \cdots \cdot K_{d_m}} + \frac{[H^+]^{m-1}\,[Y]}{K_{d_2} \cdot K_{d_1} \cdot \cdots \cdot K_{d_m}} + \cdots \frac{[H^+]\,[Y]}{K_{d_m}} + [Y] \tag{11}$$

$$[Y] = [Y]_t / \left(\frac{[H^+]^m}{K_{d_1} \cdots K_{d_m}} + \cdots + \frac{[H^+]}{K_{d_m}} + 1 \right) \tag{12}$$

If k is measured in the presence of a copper-complex, $\log [Cu]$ is found by Eq. 2 or 3, followed by the calculation of $[CuY_n]$ and $[Y]_t$ by Eqs. 6 and 7. $[Y]$ is also calculated by Eq. 12, and the stability constant is finally calculated by Eq. 5. The results obtained by this method are shown in Table II, along with those obtained by the polarographic method, etc. The results agree well with those obtained by other methods.

Table II. The stability constants of copper complexes calculated from k (pH=4.3, 25±0.1°C, ionic strength=0.2)

Chelating agent	lok k_s from rate constant	lok k_s from polarographic method*	lok k_s from literature
EDTA	15.2	15.1	18.80[2]
NTA	12.1	13.8	12.96[3]
1, 10-Phenanthroline	12.9	—	12.45[4]
α, α'-Dipyridyl	14.1	12.3	—
Oxine	25.4	—	26.22[5]
Oxalic acid	10.4	—	10.3[6]

* Calculated from the shifts of half-wave potentials.

Correlation among k, K_s and Y.—Figure 4 is obtained by plotting k against $\log (1 + K_s \cdot [Y]^n)$. As can be seen from Fig. 4, k is inversely proportional to $\log (1 + K_s [Y]^n)$. This relationship may also be derived theoretically. Eq. 5 is expressed by Eq. 13:

$$K_s = ([Cu]_0 - [Cu]) / [Cu]\,[Y]^n \tag{13}$$

By rewriting Eq. 13,

$$[Cu] = [Cu]_0 / (1 + K_s [Y]^n) \tag{14}$$

By taking a logarithm and combining it with Eq. 1,

$$k = a \log [Cu]_0 - a \log (1 + K_s [Y]^n) + b \tag{15}$$

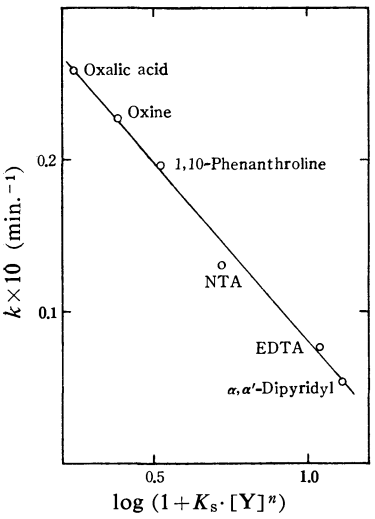

Fig. 4. Relation between k and $\log(1+K_S[Y]^n)$ (pH=4.3, ionic strength=0.2, 25±0.1°C)

Since the first term on the right-hand side is thought to be a constant, Eq. 16 is glven:

$$k = -a \log(1+K_s[Y]^n) + b' \qquad (16)$$

According to Fig. 4, the value of k for a given copper-complex at a definite pH can be estimated by the use of the values for K_S and Y. It is expected that Eq. 16 generally holds for the various kinds of reactions which proceed as of the first order.

Summary

The stability constants of various kinds of copper complexes have been estimated on the basis of the decrease in the catalytic activity of copper(II) in the presence of chelating agents. The rate constant, k, has been found to be inversely proportional to $\log(1+K_s[Y]^n)$.

The authors wish to express their hearty thanks to Mr. Shozo Fukui and Miss Keiko Yamamoto for their skillful technical assistance.

*The Effect of the Type of Radiation on the Radiation-Induced Addition of Acetaldehyde to Cyclohexene**

By Akira SHINGYOUCHI, Motoyoshi HATADA and Kozo HIROTA

(Received February 21, 1964)

An earlier report[1] studied the gamma-ray-induced addition of acetaldehyde to cyclohexene; cyclohexyl ketone was the main product. The products were different from those when ultraviolet irradiation was carried out.[2] Since such a discrepancy might be caused by the difference in irradiation sources, the effect of the type of radiation will be investigated in the present report by comparing the results obtained by use of gamma-rays,[1] ultraviolet light, and electron beams.

* Chain-Telomerization Induced by Radiation. VII. Presented at the Annual Meeting of the Chemical Society of Japan, April, 1963.

1) M. Hatada, J. Takezaki and K. Hirota, This Bulletin, 37, 1661 (1964).

2) P. de Mayo, I, B. Stothers and W. Templeton, *Can. J. Chem.*, 39, 488 (1961).

Experimental

Materials.—Acetaldehyde was prepared by the method which has previously been described in the present series of studies. Commercial cyclohexene was used after distillation. Commercial DPPH was used without any further purification.

Irradiation Procedures.—For electron-beam irradiations, spot electron beams (1.5 MeV., 50 μamp) from a Van de Graaff accelerator were used. Figure 1 shows the apparatus for the irradiation. The sample (40 ml.) was irradiated in a vessel equipped with a magnetic stirrer, A, and an aluminum window, B, through which the electron beams penetrated into the vessel. During the irradiation, the sample was cooled with an ice water bath.

The dose rate was estimated to be 0.77×10^{20} eV./sec. by the use of a cerric-cerrous dosimeter in

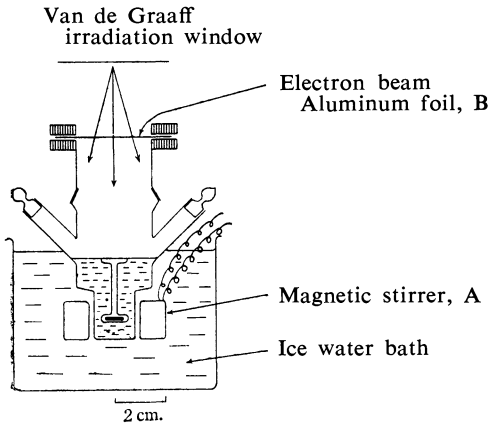

Fig. 1. Apparatus for electron beam irradiation.

the vessel used for the irradiation of the mixture. Details of the dosimetry will be described elsewhere.[3]

For the irradiation with an ultraviolet light, a high-pressure mercury lamp (Toshiba H400 P type) was used as the irradiation source. The sample (8 ml.) was degassed and distilled into a quartz tube under vacuum. Having been sealed off, the tubes were then subjected to the irradiation at 17°C for 5 hr.

Analysis. — After irradiation, the samples were subjected to gas chromatographic analyses, the conditions of which were as follows:

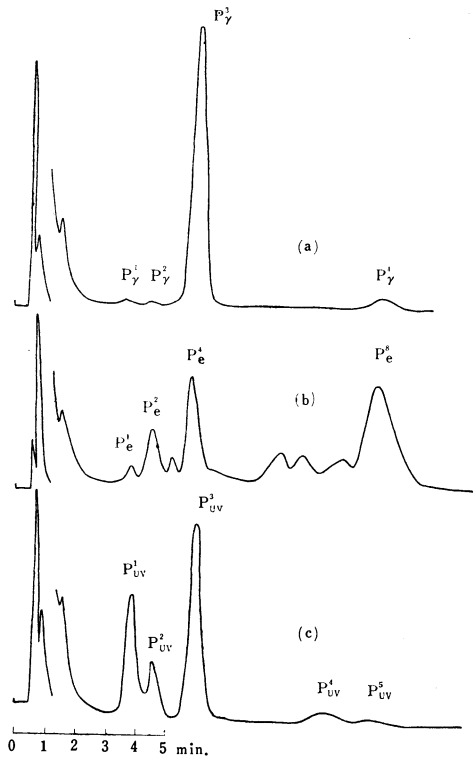
Column, P. E. G. 6000; column length, 3.0 m; carrier gas, He; flow rate, 60 ml./min.; column temperature, 180°C; apparatus; Shimadzu GCIB.

For the identification of the peaks which appeared in the gas chromatograms, a mass spectrometer (Hitachi RMU-5) and an infrared spectrometer (Shimadzu AR275) were used.

Results and Discussion

Identification of the Irradiation Products.— Typical gas chromatograms of the irradiated samples with γ rays,* electron beams, and ultraviolet are shown in Figs. 2a, 2b, and 2c respectively. The peaks which appeared in the gas chromatograms are designated as P^i_γ, P^i_e and P^i_{UV} respectively, where the subscripts denote the type of radiations while the superscripts, $i=1, 2, 3,\ldots\ldots$ denote the order in which the peaks appeared in the gas chromatograms.

By a comparison of the retention times of the peaks obtained by different irradiation sources, some of the products may be assumed to be the same. They may be grouped in parentheses as follows:



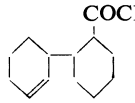


Fig. 2. Gas chromatograms of irradiated mixtures.
a) with γ-rays, b) with electron beams from the Van de Graaff accelerator, and c) with ultraviolet light from the high pressure mercury lamp.
Column: Polyethylene glycole 6000, 3.0 m.
Column temp.: 180°C
Carrier gas: He 60 cc./min.

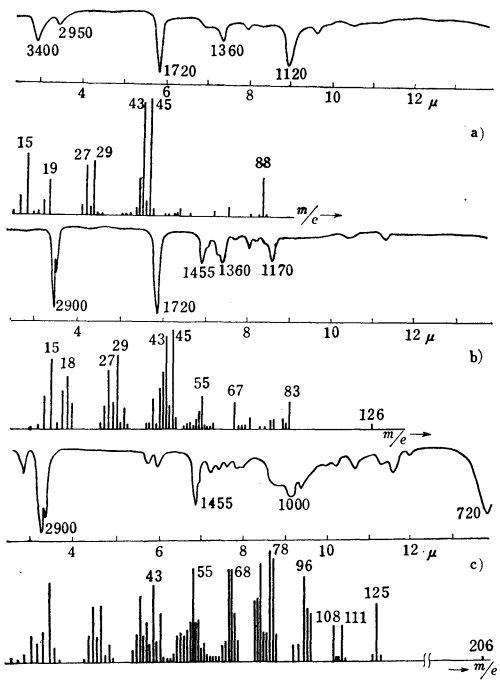
$$A(P^1_\gamma, P^1_e, P^1_{UV}),\ B(P^2_\gamma, P^2_e, P^2_c),$$
$$C(P^3_\gamma, P^4_e, P^3_{UV}),\ D(P^4_\gamma, P^8_e, P^5_{UV})$$

The mass spectra and the infrared spectra of these fractions, A, C and D, are shown in Figs. 3a, 3b and 3c respectively, but the spectra of the fraction B were difficult to obtain because of its small yield as well as because of lack of a standard samples. The fraction A, which gives the same mass spectrum, infrared spectrum and retention time in the gas chromatogram as acetoin, $CH_3\overset{O}{\overset{\|}{C}}-\overset{OH}{\overset{|}{\underset{H}{\underset{|}{C}}}}-CH_3$, is identified as this compound. The fraction C is assigned to be methyl cyclohexyl ketone (McHK) from the mass and infrared spectra shown in Fig. 3b. The D fraction is estimated to be 1-acetyl-2(3-cyclohexenyl)-cyclohexane,

in the mass spectrum and from

3) Y. Nakai et al., Annual Meeting of the Physical Society of Japan, 1963.

* Almost all the data on γ-ray irradiations in this report are reproduced from a former report[1] for the sake of comparison.



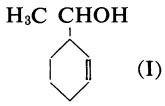


Fig. 3. Mass spectra and infrared spectra of fractions corresponding to the peaks appeared in the gas chromatogramms:
a) P^1_γ, P^1_e, P^1_{UV}, b) P^3_γ, P^4_e, P^3_{UV} and
c) P^4_γ, P^8_e

the absorptions of ν_{CH_2,CH_3} (2900~2950 cm^{-1}) and ν_{CO} (1720 cm^{-1}) in the infrared spectrum in Fig. 3c.* Although the identification of this product is not so definite as the former two, it will be supported by the experimental results below.

(I)

In the present experiment, 1-cyclohex-2'-enylethan-1-ol(I) was not found as has been reported by Mayo[2], even when ultraviolet was used as the irradiation source. Since the separating factor of the column used in this experiment is not as large as that of Mayo's, there may be some ambiguity concerning the separation of (I) from McHK. However, this ambiguity is reduced to some extent by the fact that the absorption of ν_{OH} is not found in the infrared spectrum of this fraction. At any rate further experiments using higher resolution colums will be needed to elucidate this problem.

* The absorption band at ν_{OH}~3300 cm^{-1} appeared in the IR spectrum of the fraction C. This band seems to be attributed to a trace of water condensed in the fraction collector from the atmosphere, and it seems to become significant when the fraction is difficult to collect effectively because of its lower vapor pressure.

The Effect of the Irradiation Time on the Yields. — The amounts of the products are plotted against the irradiation time in Figs. 4-1 and 4-2, practically giving a linear increase of the amount of the products. However in the region of higher doses, the rates of formation decrease because of the decomposition of the products as a result of irradiation.

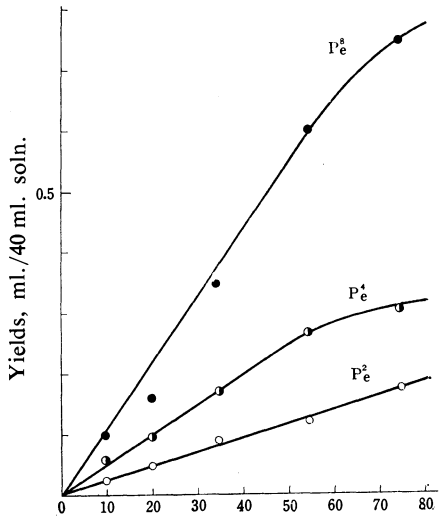

Fig. 4-1. The yields of products vs. irradiation time (electron beam irradiation).
Cyclohexene: 35 ml., Acetaldehyde: 5 ml.
Irradiation temp.: 0°C
Electron accelerating voltage: 1.5 MeV.
Electron beam current: .50 μA.

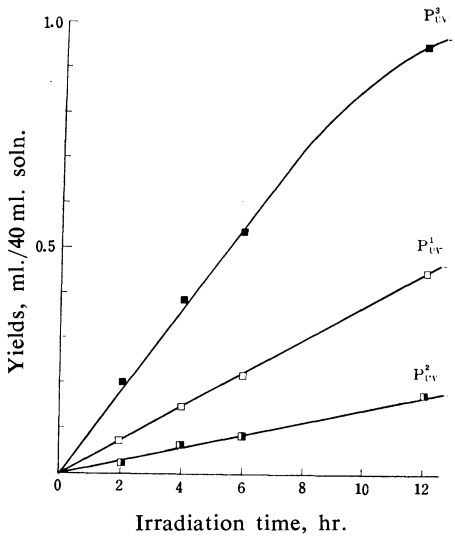

Fig. 4-2. The yields of products vs. irradiation time (ultra-violet light irradiation).
Cyclohexene: 2 ml., Acetaldehyde: 6 ml.
Irradiation temp.: 17°C

The Effect of the Compositions of the Feed on the Yields.—The results are shown in Fig. 5, where the yields of the products are plotted against the volume percent of cyclohexene. For the methyl cyclohexylketone formation, the concentration of that cyclohexene in the feed which gives a maximum yield of McHK seems to depend on the type of radiation. It reaches its highest value at 40% in the electron

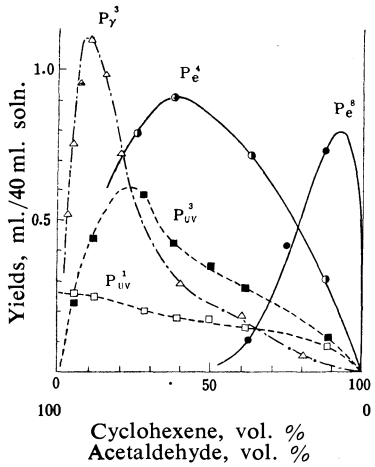

Fig. 5. The yields of products vs. cyclohexene in the feed.

irradiation, at 25% in ultraviolet irradiation, and at 10% in the γ-ray irradiation.

Acetoin was produced most favorably in pure acetaldehyde. The yield of 1-acetyl-2-(3-cyclohexenyl)cyclohexane reaches a maximum in the cyclohexene-rich mixture (ca. 90%). These relations between the yields and the cyclohexene fraction in the feed seem to be reasonable judging from the structure of the product molecules.

The Temperature Dependencies on the Yields.—The yield of McHK increases with the rise in irradiation temperature in the case of ultraviolet irradiation, as Fig. 6 shows. The Arrhenius plot for the McHK formation gives an overall activation energy of 3.5 kcal./mol., which is approximately equal to that obtained in the γ-ray irradiation. This coincidence indicates that the mechanism of the McHK formation is the same in both systems.

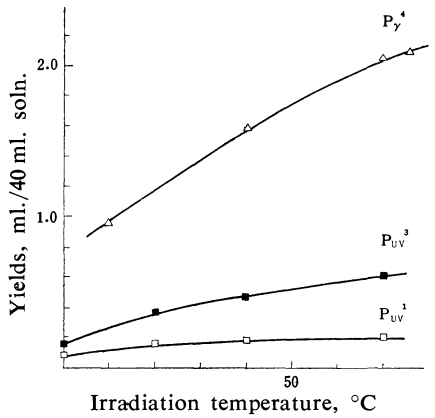

Fig. 6. The yields of products vs. irradiation temperature.

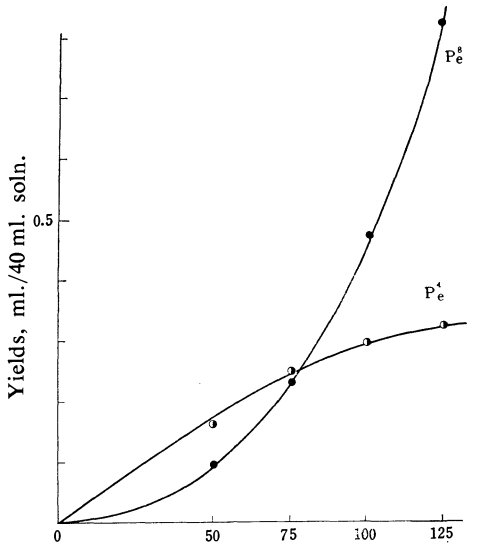
The Effect of the Dose Rate on the Yields.—The effects of the dose rate of the electron beams on the formation of McHK and 1-acetyl-2-(3-cyclohexenyl)cyclohexane are shown in Fig. 7. The yield of McHK is proportional to 1/2 power of the beam current, while that of 1-acetyl-2-(3-cyclohexenyl)cyclohexane is proportional to 1. The reason for this will be discussed below.



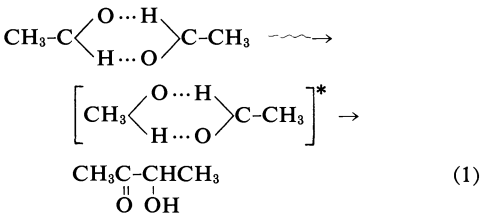


Fig. 7. The yields of products vs. electron beam current.
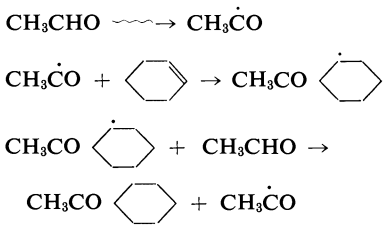
Cyclohexene: 30 ml., Acetaldehyde: 10 ml.
Irradiation time: 20 min.
Irradiation temp.: 0°C
Accelerating voltage: 1.5 MeV.

The Effect of Additives.—When ultraviolet was used as the irradiation source, the peaks P^1_{UV} and P^2_{UV} in the gas chromatogram were not affected by the addition of DPPH, but P^3_{UV} decreased markedly. However, when the electron beams were used as the irradiation source, the peaks P^1_e, P^2_e and P^3_e were not changed, while P^4_e and P^8_e decreased markedly upon the addition of DPPH.



The Reaction Mechanism of Acetoin Formation.—Acetoin was formed by ultraviolet and electron beam irradiations in the acetaldehyde-rich mixture, but it was formed in only a small quantity by the γ-ray irradiation. As

has been mentioned above, the formation of acetoin was not inhibited by the addition of DPPH. These facts indicate that acetoin was formed via a bimolecular process 1 which involves the excitation of the acetaldehyde dimer thus, forming a chelate ring. This reaction does not proceed via a chain mechanism, so it plays only a minor role in the case of the γ-ray irradiation, where the dose rate is significantly lower than in the other.

$$CH_3C(=O)CH(OH)CH_3 \quad (1)$$

Methyl Cyclohexylketone.—McHK was formed by γ-ray, electron beam and ultraviolet irradiations. Its formation was inhibited by the addition of DPPH, and its rate of formation depends on the 1/2 power of the dose rate. On the basis of these results, McHK formation may be attributed to the following radical chain process, as was suggested in a previous report:[1]

Fraction C (1-Acetyl-1-(3-cyclohexenyl)-cyclohexane).—This productwas formed only when a cyclohexene-rich mixture was irradiated with electron beams. The formation of this compound was inhibited by the addition of DPPH, and its rate of formation depends on the first power of the dose rate. Consequently, this fraction was formed by a recombination reaction of the two radicals, probably  * and  .

The fact that this product is formed in only a small amount in the two types of radiation other than that of electron beams may stem from the situation that the radicals which react to form this fraction are not produced effectively in the case of ultraviolet irradiation because cyclohexene does not absorb the ultraviolet light of this wavelength region, and that the concentrations of these radicals are small in the case of γ-ray irradiation because of its low dose rate.

Summary

Several kinds of products have been found to be formed from mixtures of cyclohexene and acetaldehyde by the irradiation of γ-rays, electron beams, and ultraviolet. Both the yields and the kind of product seem to depend on the type of radiation because of their dose rate and bond-dissociating power.

Studies on Organic Catalytic Reactions. II. The Hydration of Nitriles to Amides with Nickel Catalysts

By Ken-ichi WATANABE

(Received March 23, 1964)

In a preliminary note,[1] it was reported that nitriles are hydrated to the corresponding amides by the catalytic action of nickel. It is notably important that the hydration of nitriles is effected in water without any acid, alkali or hydrogen peroxide and that it is generally stopped at the amide stage. This paper will describe and discuss the results of further investigation of the hydration of nitriles.

In general, aromatic nitriles are hydrated to the corresponding amides, the yields of amides range from 30 to 90 per cent of the nitriles used except in special cases. The reaction of aliphatic nitriles is somewhat complicated and is different from that of aromatic ones: the yield of the amides is comparatively lower than that from aromatic nitriles, and the hydration reaction is accompanied by side reactions forming some acidic compounds. The catalysts used are Urushibara nickel (U-Ni),[2] Raney nickel, "stabilized nickel"[3] and related substances. The general procedure for the hydration is completed by refluxing a nitrile for five to ten hours in water with a suitable amount of a nickel catalyst. During the reaction, a small quantity of ammonia is generated; this can be detected with litmus. After the reaction, the catalyst is filtered off, and the solution is evaporated to a solid mass which consists of a crude amide.

In a few cases, a very small quantity of the corresponding acid is obtained by hydrolysis. However, benzamide itself is hardly ever hydrolyzed to benzoic acid, even when it is refluxed for a long time with a newly-prepared nickel catalyst. Amines are obtained in some cases because of the hydrogenation of the nitrile with hydrogen adsorped on the nickel catalyst. The yield of amines increases largely when a solvent other than water, especially ethanol, is used. In some cases, the formation of a metal complex is observed by a presumable side reaction between the nitrile and the catalyst. In general, the hydration to an amide is predominant over the other side reactions mentioned above if the condition of the reactions is suitable: the features of this metal-catalyzed hydration are peculiar and are unlike those of acid- or base-catalyzed hydration.

The Effect of the Nature and the Position of the Substituents in Substituted Benzonitriles.— The results of experiments on the hydration of various nitriles with U-Ni-B in water are given in Table I. As is shown in the table, the hydration of substituted benzonitriles is governed largely by the nature and the position of the substituent in the benzene nucleus. It is rather remarkable that amides can not be obtained from *p*-hydroxybenzonitrile (Exp. 6), ethyl *o*- and *p*-cyanobenzoates (Exp. 13 and 14) or *p*-cyanobenzaldehyde (Exp. 16). On the other hand, a complex-formation between the nitrile (or intermediate) and the catalyst metal is observed with *p*-hydroxybenzonitrile (Exp. 6), *p*-nitrobenzonitrile (Exp. 7), *o*- and *p*-aminobenzonitriles (Exp. 9 and 10), mesitonitrile (Exp. 11), ethyl *o*- and *p*-cyanobenzoates (Exp. 13 and 14) and *p*-cyanobenzaldehyde (Exp. 16). The yield of the complexes varies with the kind of nitrile.

It has been found that there are two types of complexes, one containing zinc and the other containing nickel. Zinc complexes are obtained from *p*-cyanobenzoic acid, ethyl *o*- and *p*-cyanobenzoates and *p*-hydroxybenzonitrile. Nickel complexes are obtained from *p*-nitrobenzonitrile, *o*- and *p*-aminobenzonitriles and *p*-cyanobenzaldehyde. The former is easily decomposed to the corresponding carboxylic acids with acid or aqueous alkaliliberating ammonia. On the other hand, the latter is very stable to acid, alkali and oxidizing agents. As a whole, electron-releasing substituents retard the hydration reaction and electron-attracting substituents effect the formation of metal complexes. 3-Cyanopyridine gives rise to a very high yield of the amide, the nitrogen in the pyridine nucleus having an important electron-attracting effect on the cyano group.

A remarkable ortho effect is observed in this hydration reaction, which has been similarly recognized in the case of acid or alkaline hydration. The yield of amides is

more or less diminished with ortho-substituted benzonitriles, such as *o*-tolunitrile (Exp. 2), *o*-methoxybenzonitrile (Exp. 4), *o*-nitrobenzonitrile (Exp. 7), *o*-aminobenzonitrile (Exp. 9), mesitonitrile (Exp. 11), ethyl *o*-cyanobenzoate (Exp. 13) and α-naphthonitrile (Exp. 17), the largest effect being observed with mesitonitrile. The reaction velocity becomes slower, and often a considerable quantity of the starting materials is recovered unchanged. In some cases, unfavorable side reactions are alternated.

The Effect of the Nature of the Catalyst.— When *o*-nitrobenzonitrile was hydrogenated with a nickel catalyst in either the liquid[4] or the vapor phase, it was reported that a considerable quantity of *o*-aminobenzamide was formed by the hydration of the nitrile group.[5] It has been presumed that the hydrogenating activity of the nickel catalyst is largely depressed by poisoning with the amino group produced by the reduction of the nitro group,[6] and that the nitrile group is hydrated with water produced by the hydrogenolysis of the nitoro group or originally present in the solvent. The present investigation shows that such is the case, since the ability of nickel catalysts to effect the hydration of nitrile group has been proved. Ordinary nickel catalysts for

hydrogenation are generally available for the hydration of nitriles.

In this connection, precipitated nickel, precipitated copper, nickel oxide, cupric oxide and Urushibara copper (U-Cu) were also tested with relation to the hydration of benzonitrile. The results of representative experiments are shown in Table II. The highest yield of benzamide was given with U-Ni-B, followed by those with U-Ni-A, Raney nickel and stabilized

* Sample as Exp. I, Table I

nickel. The other substances mentioned above gave poor results as catalysts for the hydration, and they sometimes caused unexpected side reactions.

It should be noted that the procedure for the preparation of U-Ni may be simpler for the hydration than for hydrogenation. Common city water serves well enough for preparing the catalyst, and it does not matter if the catalyst is exposed to air during the preparation. To prepare Raney nickel (W-4) for the hydration, caution is unnecessary with regard to the temperature, air and water. The stabilized nickel and the reduced nickel catalysts are less active than the U-Ni's and Raney nickel. It was found that the precipitated nickel or copper is of no use at all for the hydration of nitriles to amides, a large amount of complexes of corresponding amines and zinc being formed.

The results of the experiments indicate that the hydrating activity of the nickel catalysts depends on the size of the crystallites of the catalysts. It is known that the approximate sizes of the crystallites of U-Ni-A, U-Ni-B, U-Ni-BA, U-Cu and reduced nickel are 40 Å 40 Å, 120 Å, 260 Å and 350 Å respectively. The yields of benzamide obtained with these catalysts follows the above-mentioned order. If too small a quantity of a catalyst is used, or if the reaction time is insufficient for the hydration, the nitrile is sometimes recovered unchanged in a considerable quantity. Gas chromatographic research shows that about 90 per cent of benzonitrile is changed after five hours with a U-Ni-B catalyst. When the catalyst is not so active, a large quantity is necessary for a satisfactory hydration, as is shown by Exp. 15 and 16 in Table II.

In the previous experiments, any specific behavior of thiophene or pyridine as a promoter of the catalyst was examined, and it was shown shat a small quantity of thiophene or pyridine exhibited no promoter action in an ethanolic solution but, rather, had an unfavorable effect. In the present investigation, however, some different information was put forward on this subject. It is noteworthy in Table I that nitriles of basic character, such as 3-cyanopyridine and *p*-aminobenzonitrile, give good yields of amides, whereas those of an acidic character, such as *p*-hydroxybenzonitrile and *p*-cyanobenzoic acid, give no hydration products. The aliphatic nitriles, some of which are hydrolyzed to acids during the reaction, also give unfavorable results, as in the normal hydration. From these results, it may be inferred that the hydration of nitriles is due to the catalytic action of the basic contact sites (active center) of the nickel catalysts.

It is assumed that a nickel catalyst acts in two different ways, exhibiting acidic and basic functions. It has been suggested that the catalytic hydrogenation of nitriles and nitro groups is due to the acidic contact sites of the catalyst,[7] as is the reductive dehydroxymethylation of primary alcohols.[8] On the other hand, the catalytic hydrogenation of carbonyl groups[9] and the dehydroxylation of alcohols are attributed to basic sites.[8] In the hydration of nitriles, acidic substances or acidic parts of the nitrile molecules may cover the basic sites of the catalyst, resulting in the depression of the hydration reaction. Ammonia, generated by the hydrogenolysis of nitriles during the reaction, and basic parts of the nitrile molecules may cover the acidic sites of the catalyst and accentuate the catalytic activity of the basic sites to realize a favorable hydration. According to the studies of the reaction mechanism of the hydrolysis of nitriles with acid or alkali, the hydration has been assumed to be initiated at the carbon atom of a nitrile group, endowed with a carbonium character. In the catalytic hydration of nitriles, the reaction may be similarly initiated at the carbon atom attached to the basic sites of the catalyst. Our preliminary test for the effects of pyridine and thiophene on the hydration of benzyl cyanide proved that the former increases the yield of the amide, while the latter decreases it. This will be discussed in a subsequent report of this series.

The Effect of Solvents:—Methanol, ethanol, 1-butanol, dioxane and water were examined for as possible solvents for the catalytic hydration of benzonitrile. Water was proved to be the most excellent of all. When any other solvent than water is used, the nitrile group is hydrogenated more or less by hydrogen adsorped on the catalyst; sometimes undesirable side reactions are caused. The reactions in water generally give good yields of amides. The results of the experiments are listed in Table III, while the results of the hydration in water and ethanol are compared in Table II. It is noteworthy that water suppresses the catalytic activity for hydrogenation and emphasizes the catalytic activity for hydration.

dust in a 1000 ml. Erlenmeyer flask, a small quantity of was added, and the mixture was heated to boil. In another vessel, 40 ml. of a nickel chloride solution containing 16 g. of $NiCl_2 \cdot 6H_2O$ was heated to 60°C and then added to the zinc dust with vigorous shaking. A violent exchange reaction took place, depositing nickel on the surface of the zinc. When the generation of hydrogen had ceased, about 640 ml. of 13% acetic acid, prepared from 83 ml. of CH_3COOH and 560 ml. of water and heated to about 70°C in advance, was added gradually while the mixture was shaken well, lest the contents should overflow as a results of the vigorous generation of hydrogen. The whole was occasionally shaken for about twenty minutes, until the liquid turned slightly green; then the mixture was diluted with cold water. The acid solution was decanted off, and the residue was washed with water several times by decantation until the washing became neutral to litmus. The catalyst thus prepared was used directly for the reaction in water. For use in other solvents, it was collected by filtration and pressed between filter paper before adding it to the solvents. The catalyst thus obtained contains about 3 g. of nickel.

U-Ni-B.—For the preparation of U-Ni-B, 640 g. of a sodium hydroxide solution (70 g. of sodium hydroxide and 570 ml. of water) were used to digest the precipitated nickel. The procedure was the same as for U-Ni-A in other respects. The finished catalyst was repeatedly washed with water until the washing became neutral to phenolphthalein paper. The U-Ni-B thus obtained contains 4 g. of nickel and is more voluminous than U-Ni-A.

U-Ni-BA.—To 20 g. of aluminum grains of 40~80 mesh in a 1000 ml. Erlenmeyer flask, a small quantity of hot water was added, and then 40 ml. of a hot nickel chloride solution containing 16 g. of $NiCl_2 \cdot 6H_2O$ was added. The whole was occasionally shaken until the reaction mixture became slushy. The exchange reaction was controlled by either cooling with cold water or heating with hot water. The precipitate was washed with cold water by decantation, and 500 g. of a 20% sodium hydroxide solution (100 g. of sodium hydroxide and 400 ml. of water), heated to about 60°C in advance, was gradually added. Because of the vigorous exothermic reaction, the contents were shaken well. The aluminum dissolved completely in a short time. The solution was decanted off, and the residue was washed three or four times with cold water by decantation until the washings became neutral to phenolphthalein. The catalyst thus obtained contains about 4 g. of nickel.

U-Cu.—U-Cu was prepared by almost the same procedure as that used for U-Ni, cupric chloride being used instead of nickel chloride. The precipitated copper could not be digested well with aqueous alkali, but it was digested well with aqueous acetic acid.

Precipitate Nickel (or Copper).—The precipitated nickel (or copper), prepared from nickel (or copper) chloride and zinc dust, was used directly after being washed with only water. The catalyst is very voluminous and contains much more adsorbed hydrogen.

Stabilized Nickel.—This is a kind of reduced nickel supported on kieselguhr and stabilized by treatment with carbon dioxed. The KSY-6 FC type (Nikko Shokai, Tokyo) was used for the hydration of benzonitrile.

The Hydration of Nitriles.—The procedure for the hydration of benzonitrile to benzamide with U-Ni-B (Exp. I, Table I) is shown as an example. The nickel catalyst (containing 4 g. of nickel) in 80 ml. of water was placed in a 200 ml. round flask, and 5 g. of benzonitrile was added. The flask was fitted with an Allihn condenser. The mixture was refluxed vigorously for about eight hours until the oil drops of benzonitrile on the water disappeared. The catalyst was separated by filtration while hot and washed with hot water and ethanol. The filtrate, admixed with the washings, was evaporated on a water bath. Benzamide was obtained in white crystals. The yield was 4.5 g. (78%). The crude amide, although it was fairly pure, was recrystallized from hot water with a small quantity of active charcoal. M. p. 127~128°C. It was identified by hydrolyzing to benzoic acid with alkali.

The author wishes to express his hearty thanks to Professor Kazuo Hata for his kind advice.

The Mechanism of the Thermal Decomposition of Hexamminecobalt(III) Chloride

By Nobuyuki TANAKA and Michio NANJO

(Received March 28, 1964)

The thermal decomposition of hexamminecobalt(III) complexes has been extensively studied by several researchers,[1-6] and the stoichiometric relation,

$$6[Co(MH_3)_6]Cl_3(s) \rightarrow 6CoCl_2(s) + N_2(g) + 6NH_4Cl(s) + 28NH_3(g)$$

has been proposed for the complete decomposition.[6] Its mechanism, however, is not fully understood. In the course of a reinvestigation of the thermal decomposition of metal complexes in this laboratory, some preliminary results suggested that the decomposition of cobalt(III) complexes was often initiated by the electron transfer from either a ligand atom or an outer-sphere ion to the central cobalt(III) atom, forming a less stable cobalt(II) complex. These results have been confirmed by polarographic and infrared spectroscopic measurements of the thermal decomposition product of hexamminecobalt(III) chloride, as well as by the measurement of the infrared spectra of the complex at elevated temperatures. The results will be briefly presented in this paper. A similar conclusion has been obtained by Wendlandt and Smith[7] from the thermomagnetic measurement of cobalt(III) ammine complexes.

Experimental

Hexamminecobalt(III),[8] hexamminecobalt(II)[9] and hexamminechromium(III)[10] chlorides were prepared by the methods given in the literature cited; they were identified by the measurement of their infrared absorption spectra.

The thermogravimetric curves were recorded with an automatic-recording thermobalance, Shimadzu Thermano Balance Type RT-2, in a nitrogen atmosphere. A 400-mg. sample was used in each measurement unless otherwise stated. The furnace heating rate was approximately linear with the time at about 3°C per min. The particle sizes of the samples ranged between 100 and 200 mesh.

Polarograms were recorded with a Yanagimoto PR-2 Polarorecorder equipped with an automatic potential scanner. The samples which had been taken out of the furnace were dissolved in supporting electrolyte solutions containing 1 M ammonium chloride, 1 M ammonium hydroxide and 0.005% gelatin. The dropping mercury electrode used had an m value of 2.06 mg./sec. and a drop time, t_d, of 3.72 sec., when measured at −0.80 V. vs. SCE in the same supporting electrolyte solution.

A Hitachi EPI-2G double-beam instrument with a KBr foreprism and gratings was used for the measurement of the infrared absorption spectra. The KBr disk method was employed unless otherwise stated.

Results and Discussion

The thermogravimetric curves of hexamminecobalt(III), hexamminecobalt(II) and hexamminechromium(III) chlorides are reproduced

Polarograms of heated samples of hexamminecobalt(III) chloride are given in Fig. 2, where, for convenience of comparison, the current is represented with a value for one millimolar

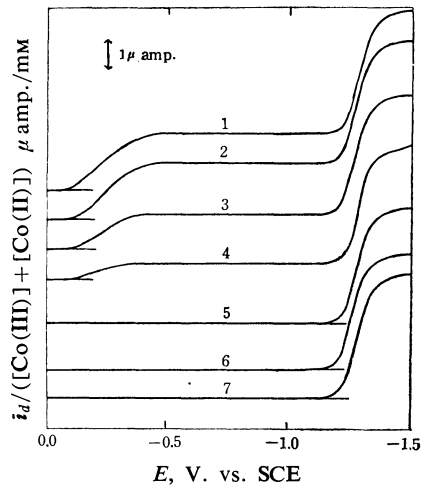

Fig. 2. Polarograms of the $[Co(NH_3)_6]Cl_3$ subjected to the thermal treatment, being recorded in 1 M NH_4Cl - 1 M NH_4OH containing 0.005% gelatin: The numbers represent the sample numbers given in Table I. Polarograms are corrected for the residual currents and the current is represented with the value for one millimolar of the total concentration of Co(III) and Co(II).

of the total concentration of cobalt(III) and cobalt(II). The temperatures at which the samples were taken out of the furnace are given in Table I. On curves 1 to 4, the first wave starts around −0.1 V. vs. SCE, which corresponds to the reduction of cobalt(III) to cobalt(II). The change in the limiting current with various heights of the mercury reservoir shows that the limiting current is diffusion-controlled. The second wave can be attributed to the reduction of cobalt(II) to cobalt(0). The height of the first wave decreased with an increase in the temperature at which the samples were treated. This indicates that the amount of cobalt(III) in the sample is less when treated at a higher temperature. Curve 5, which was obtained with the sample taken out of the furnace at 305°C, shows that the cobalt(III) was completely reduced to cobalt(II). Percentages of the decrease in weight and cobalt(III) content are given in Table I.

2	170	0	0
3	285	11.9	35
4	295	22.8	76
5	305	30.7	100
6	340	37.6	100
7	475	48.6	100

* Temperatures at which the samples were taken out of the furnace.

Infrared spectra of hexamminecobalt(III) chloride treated at various temperatures are given in Fig. 3. The absorption band due to the NH_3 symmetric deformation vibrations at 1320 cm^{-1} and that due to the NH_3

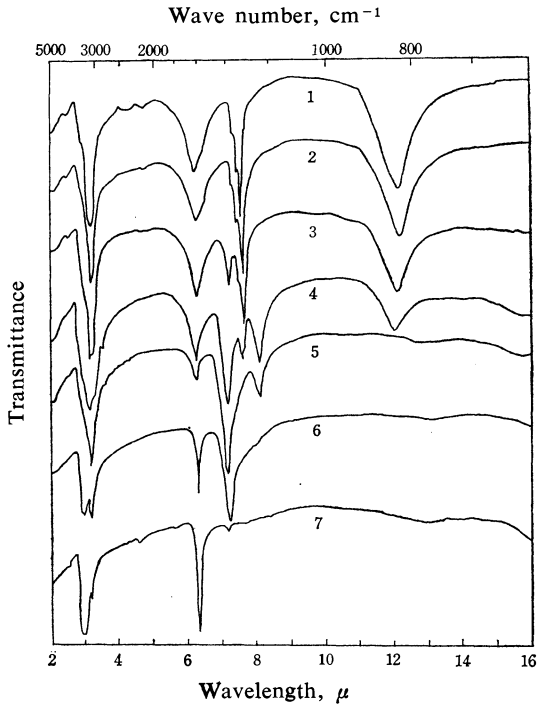

Fig. 3. Infrared absorption spectra of the $[Co(NH_3)_6]Cl_3$ subjected to the thermal treatment: The numbers represent the sample numbers given in Table I. Transmittance scale displaced arbitrarily.

rocking vibrations at 830 cm^{-1} decrease in intensity as temperature increases until they disappear at 340°C. A new absorption band appears at 1400 cm^{-1}; this is assigned to the ν_4 vibration of NH_4^+ ions. In samples 6 and 7, the NH_3 degenerate deformation band at 1608 cm^{-1} overlaps with a sharp ν_4 band of free ammonia molecules. These changes in the infrared absorption spectra may indicate a decrease in cobalt(III) content as well as

the formation of ammonium ions and free ammonia molecules. These experimental results indicate that, at higher temperatures, cobalt(III) in a hexammine complex is reduced to cobalt(II) to form a less stable cobalt(II) ammine complex, which then immediately dissociates ammonia molecules and undergoes decomposition, as may be seen from the thermogravimetric curve of hexamminecobalt(II) chloride in Fig. 1. Mori and Tsuchiya[6] have proposed that the thermal decomposition of hexamminecobalt(III) chloride proceeds according to the reaction,

$$[Co(NH_3)_6]Cl_3(s) \rightarrow [CoCl(NH_3)_5]Cl_2(s) + NH_3(g)$$

However, they also found the formation of ammonium chloride at temperatures higher than 170°C. This result seems to indicate that the decomposition reaction is not so simple as they proposed.

In this connection, the infrared absorption spectra of hexamminecobalt(III) chloride which were recorded at elevated temperatures by means of the potassium chloride disks should be noted (Fig. 4). The NH_4^+ band at 1400 cm^{-1}

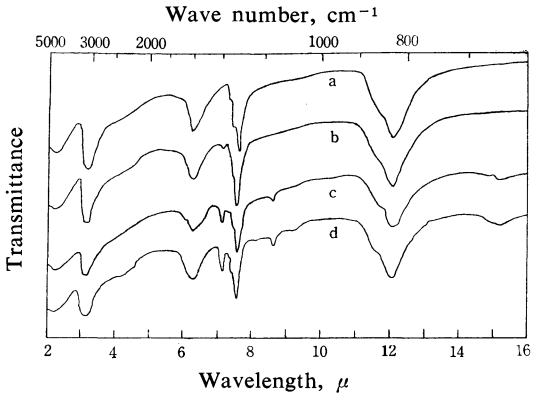

Fig. 4. Infrared absorption spectra of the $[Co(NH_3)_6]Cl_3$ in KCl disks at (a) room temperature, (b) 200°C, (c) 260°C and (d) after cooling of (c). Transmittance scale displaced arbitrarily.

appears on the spectra obtained at 200°C and higher. At temperatures higher than 260°C, two new absorption bands are observed, at 1160 cm^{-1} and 655 cm^{-1}; these are considered to be due to the NH_3 symmetric deformation vibration and the NH_3 rocking vibration of cobalt(II) ammine complexes respectively. Cobalt(III) in the hexammine complex is reduced to cobalt(II) by accepting an electron from either a ligand molecule or an outer-sphere ion to form a cobalt(II) ammine complex. Since the complex is kept in the potassium chloride disk, it retains its structure without dissociating all of the ammonia molecules and gives the absorption bands characteristic of the cobalt(II) ammine complex.

It has been known that the Co–N bond in cobalt(III) ammine complexes is stronger than the Cr–N bond in chromium(III) ammine complexes.[11] This seems to contradict the result obtained from the thermogravimetric measurement, that hexamminecobalt(III) chloride does not decompose more easily than hexamminechromium(III) chloride (see Fig. 1). This contradiction may be explained by considering that the decomposition of hexamminecobalt(III) chloride is initiated by the electron transfer from either a ligand or an outer-sphere ion and that the decompositions of these two complexes, consequently, proceed according to entirely different mechanisms.

Summary

The thermal decomposition of hexamminecobalt(III) chloride has been investigated by thermogravimetric, polarographic and infrared spectroscopic method. The results indicate that the reaction is initiated by the electron transfer from either a ligand molecule or an outer-sphere ion to the central cobalt atom, forming a less stable cobalt(II) complex, which immediately dissociates ammonia molecules and undergoes decomposition.

The measurements of infrared absorption spectra were carried out by Mr. Mitsuo Shoji. The authors wish to thank the Ministry of Education for the financial support granted for this research.

The Solvent Extraction and Spectrophotometric Determination of Uranium using Benzoyltrifluoroacetone as the Chelating Reagent

By Tsunenobu SHIGEMATSU, Masayuki TABUSHI and Masakazu MATSUI

(Received April 9, 1964)

It has been generally known that β-diketones are useful chelating reagents in analytical chemistry, chelate chemistry and radiochemistry. Fluorinated β-diketones such as TTA are especially useful in the solvent extraction of metals, because a fluoromethyl group increases the acidity of the enol form.[1]

As do many other metals, uranium reacts with β-diketones to form extractable chelates, which are widely utilized for the separation of the metal. The present authors have studied the chelates of uranium with acetylacetone (AA),[2] dibenzoylmethane (DBM)[3] and trifluoroacetylacetone (TFA),[4] and have developed methods for the extraction separation and the photometric determination of uranium using these β-diketones.

An extraction using benzoyltrifluoroacetone (BTFA), a fluorinated β-diketone, might have some advantages: Quantitative extraction can be expected at a lower pH range from the lower pK_D value of the reagent;[5] high extractability can be anticipated from its low solubility in water, and the extraction may be facilitated by the shielding effect of the phenyl group against hydration to the central metal.

From this view-point, the authors have investigated the solvent extraction of uranium as a BTFA chelate and will propose a procedure for the separation and the spectrophotometric determination of the element.

Experimental

Apparatus. — Spectrophotometric measurements were made with a Shimadzu automatic recording spectrophotometer, model UV-50, and a Hitachi photoelectric spectrophotometer, model EPU-2A, using 1 cm. transmission cells. Radioactivity countings were performed with a Kobe Kogyo NaI(Tl) (4.45 cm.×5.08 cm.) well-type scintillation counter, model PS-300, connected to a transistorized scaler, model SA-230, and a Metro automatic decatron scaler, model D-5, using a Philips halogen-quenched G-M tube 1905. A Hitachi-Horiba glass electrode pH meter, model P, was used for the pH measurements.

The Standard Solution of Uranium, 100 μg./ml. — A stock solution was prepared by dissolving $UO_2(NO_3)_2 \cdot 6H_2O$ with water; the concentration was determined gravimetrically as U_3O_8. The stock solution was diluted to make the standard solution.

The Benzoyltrifluoroacetone Solution, 1 M. — 4.3232 g. of BTFA was dissolved and diluted to 20.0 ml. with acetone.

The EDTA-Ca Solution. 0.2 M.

Acetic acid. 1 M.

Boric acid. 1 M.

The Lutetium-177, Zirconium-Niobium-95 and Fission Products Solution. — The radioisotopes were obtained from ORNL. Lutetium and zirconium-niobium were converted to sulfate by fuming them with sulfuric acid. These sulfates and fission products solution were diluted to give a 1~5 μc./ml. solution.

Organic Solvents. — Chloroform was purified by washing it with a diluted sodium hydroxide solution, water, diluted hydrochloric acid, and three portions of water, followed by distillation. Butyl acetate was washed with water and distilled. Reagent-grade benzene was used without further purification. All the other reagents used were reagent-grade materials.

Results and Discussion

Absorption Spectra. — The absorption spectra of the uranium BTFA chelate were obtained by the following procedure. To the solution containing 100 μg. of uranium, the pH of which adjusted to 5~6, 0.1 ml. of a 1 M BTFA acetone solution was added. The solution was then diluted to 10 ml. and shaken with 10.0 ml. of benzene, chloroform or butyl acetate. The organic layer was separated, and the absorption was measured against the reagent blank.

Figure 1 shows the absorption curve of the uranium chelate in butyl acetate. The absorption curve exhibits a maximum at 380 mμ; that is almost the same as in the case of benzene or chloroform. For practical purposes, however, it seems suitable to make the measurements at a longer wavelength such as 385

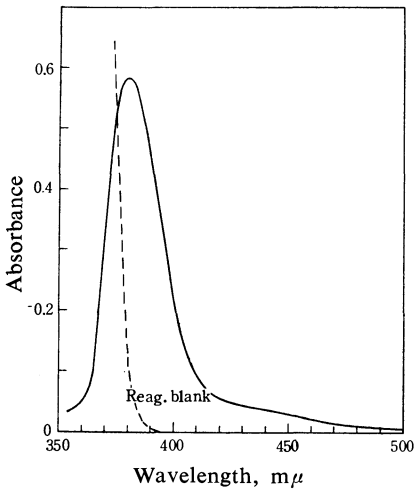

Fig. 1. Absorption spectrum of uranium BTFA chelate.
Solvent: butyl acetate U: 10.0 p.p.m
BTFA: 1×10^{-2} M

mμ, because of the quite high absorption of the reagent blank found around and below 380 mμ. Measurements were therefore performed at 385 mμ and 400 mμ in the following experiments.

The Effect of pH. — The effect of the pH value on absorbance and, consequently, on the extraction of uranium was studied by extracting 100 μg. of uranium with 10.0 ml. of an organic solvent from 10 ml. of an aqueous solution, which had a variable pH value and which contained 0.1 ml. of 1 M BTFA and sodium chloride or acetic acid at and below pH 7, or boric acid above pH 7 in the final concentration of 0.1 M. The influence of EDTA was also studied by using a solution containing 0.02 M EDTA-Ca and 0.1 M acetic acid.

The absorption of the reagent blank extracted from an acidic or neutral solution is independent of the pH value, but it is affected by the pH when the extraction is made from an alkaline solution. In the latter case absorbances of the reagent blank in benzene or chloroform media decreased, while that in a butyl acetate medium increased, with an increase in the pH value. Accordingly, the effect of pH in an alkaline solution was examined by measuring absorbances at 400 mμ but not at 385 mμ.

The results are shown in Figs. 2, 3 and 4.

These figures reveal that butyl acetate is convenient as an extracting solvent for the uranium BTFA chelate, because the absorbance is kept constant over a wider pH range and the acetate buffer hardly affects the extraction, as may be seen in Fig. 4. The phenomenon that butyl acetate is superior in the extraction of the uranium β-diketone chelate has previously been recognized in the acetylacetone and dibenzoylmethane systems.

Analytical Procedure and Calibration Curve. —From the above experimental results, a procedure for the spectrophotometric determination of uranium was designed as follows.

To a sample solution containing 5~150 μg. of uranium, add 1 ml. of a 1 M acetic acid and 0.2 M EDTA-Ca solution. Dilute the solution to about 10 ml., adjust the pH to 5.5~6.0, and add 0.1 ml. of a 1 M BTFA acetone solution. After it has been left standing for 10~15 min., extract the uranium chelate with 10.0 ml. of butyl acetate and then measure the absorbance at 385 mμ or 400 mμ against the reagent blank.

W^{6+}	2	59.2	60.7	
V^{5+}	5	26.8	26.5	
	1	99.6	100.9	
Zn^{2+}	10	100.0	100.0	

Diverse Ions. — To investigate the influence of several metal ions, the measurements were made on a solution containing a proper amount of foreign cations with 100 μg. of uranium. The results are presented in Table I.

Silver, chromium(III), iron(III), tin(IV), titanium and large amounts of aluminum interfere because of the formation of hydroxide; a few milligrams of copper precipitate when the chelating reagent is added and a milligram or more of tungsten and vanadium-(V) gives a negative error.

The Extraction Recovery of Uranium. — Extractability was estimated by determining uranium remaining in the aqueous layer by means of the DBM method.

Uranium was extracted as the BTFA chelate by the above procedure, and the aqueous layer was washed with 10 ml. of butyl acetate. The pH value of the solution was adjusted to 6.5, and 0.5 ml. of a 5% DBM acetone solution was added. The uranium DBM chelate was extracted with 10.0 ml. of butyl acetate, and the absorbance was measured at 410 mμ or 420 mμ against the reagent blank.

The extraction recovery of the uranium BTFA chelate was found to be more than 99.9 per cent.

The Separation from Lutetium-177, Zirconium-Niobium-95 and Fission Products.—Extractions were carried out on a solution containing

TABLE II. DECONTAMINATION FACTORS OF LUTETIUM-177, ZIRCONIUM-NIOBIUM-95 AND FISSION PRODUCTS

Nuclide	Decontamination factor (1)*	(2)*
Lutetium-177	1.2×10^{3}	2.5×10^{3}
Zirconium-niobium-95	4.0×10^{3}	6.3×10^{3}
Fission products (gross γ)	1.7×10^{2}	2.4×10^{2}
Fission products (gross β)	1.1×10^{2}	1.6×10^{2}

*(1) Radioactivities were measured on organic and aqueous solution obtained by the described procedure.
(2) Measurements were made after organic layers were washed with 10 ml. of aqueous solution, which had the composition similar to the extraction condition.

TABLE III. COMPARISON OF FOUR β-DIKETONE METHODS

β-Diketone	pK_D*	Concn.** (M)	pH***	Molar extinction coef. and wavelength
Trifluoroacetylacetone	8.7	2×10^{-2}	4～7.5	4690 at 358 mμ
Benzoyltrifluoroacetone	9.2	1×10^{-2}	3.5～8.5	14000 at 385 mμ
Acetylacetone	12.7	5×10^{-2}	6～7.5	2640 at 365 mμ
Dibenzoylmethane	13.7_5	1×10^{-2}	5～9	20300 at 400 mμ

* The pK_D values were obtained in 74.5 vol. per cent dioxane (Ref. 5).
** Concentration in organic layer after distribution.
*** In the absence of EDTA-Ca.

100 μg. of uranium and 1～5 μc. of lutetium-177, zirconium-niobium-95 or mixed fission products. One milliliter of the counting samples pipetted out from the solvent and from each of the aqueous layers, and γ- and β-activities were measured with a well-type NaI(Tl) scintillation counter and a G-M counter respectively.

The decontamination factors summarized in Table II indicate that the extraction procedure recommended for the determination of uranium can be successfully applied to the separation of uranium from rare earth elements, zirconium and mixed fission products.

In Table III, the method proposed in this paper is compared with the methods using AA, TFA, and DBM as the reagents.

The order of the minimum pH value for the complete extraction do not agree with that of the pK_D value; AA and DBM, and TFA and BTFA, are reversed. This may be due to the difference in solubility in water and to the shielding effect of the phenyl group.

As is shown in Table III, the uranium BTFA chelate can be extracted at the lowest pH value and from the widest pH range among the chelates of these four β-diketones. Therefore, the BTFA method is most suitable for the extraction of uranium, although it is less sensitive than the DBM method with regard to the spectrophotometric method.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

The Vacuum Ultraviolet Absorption Spectra of Aniline and Some of Its N-Derivatives

By Katsumi KIMURA,* Hiroshi TSUBOMURA* and Saburo NAGAKURA

(Received April 10, 1964)

Concerning the effect of substituent groups upon the electronic spectrum of benzene, a number of theoretical and experimental studies have already been carried out.[1-17] This effect may be discussed from two different viewpoints: one of them is the wavelength shift and the intensity change of the bands pertinent to the benzene molecule, and the other is the appearance of an additional new band caused by the charge-transfer interaction between the

substituent groups and the benzene ring. The latter band is called an intramolecular charge-transfer or electron-transfer band. Since 1954, the latter phenomenon has been studied by one of the present authors and Tanaka, by Longuet-Higgins and Murrell and by others;[11-15] the intramolecular charge-transfer band has been observed with such substituted benzenes as nitrobenzene, benzoic acid, and *p*-nitroaniline.

Concerning aniline, Nagakura and Tanaka[10] first pointed out the possibility of an intramolecular charge-transfer band for the 235 mμ band. Murrell[12] studied this problem theoretically in detail and assigned the 235 mμ band to an intramolecular charge-transfer band whose transition is accompanied by an electron transfer from the amino group to the benzene ring. In addition, several authors have made quantum mechanical considerations of this problem by various kinds of approximate methods.

Their results are not always consistent with each other in the interpretation of the 235 mμ band of aniline. For instance, some authors interpret this band as the shifted band of the 200 mμ band of benzene. In order to determine which of the two interpretations is correct and, moreover, in order to obtain accurate knowledge about the π-electron structure of aniline, the experimental data of vacunm ultraviolet absorption spectra corresponding to higher-energy transitions are undoubtedly important. In spite of this, only a few experiments of absorption spectra in the vacuum ultraviolet have hitherto been carried out with aniline and its derivatives, although Klevens and Platt have measured absorption spectra for aniline, *N*-methylaniline and *N*, *N*-dimethylaniline in heptane solutions in the 1700~2300 Å region.[18]

Under these circumstances, we undertook to extend absorption measurements down to 1500 Å for aniline and some members of its *N*-derivatives in the vapor phase, using a recording vacuum ultraviolet spectrophotometer. In doing so, we succeeded in finding some new absorption bands in the vacuum ultraviolet region and in confirming the appearance of the intramolecular charge-transfer band. Furthermore, we could obtain more reliable knowledge than before about the π-electron structures of aniline and its derivatives by combining the present experimental results with theoretical considerations.

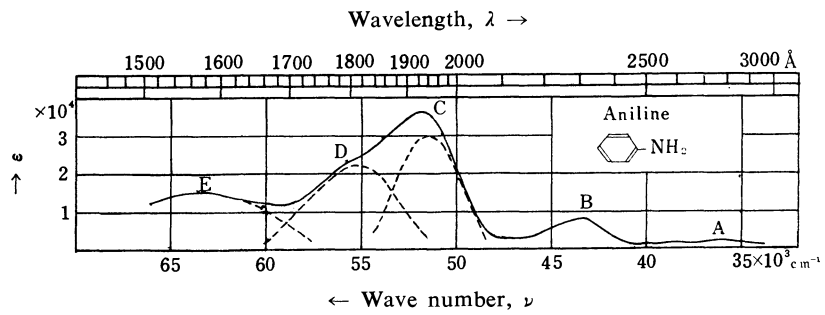
18) H. B. Klevens and J. R. Platt, *J. Am. Chem. Soc.*, 71, 1714 (1949); Technical Report of the Laboratory of Molecular Structure and Spectra, Department of Physics, University of Chicago (1954-1955).

Experimental

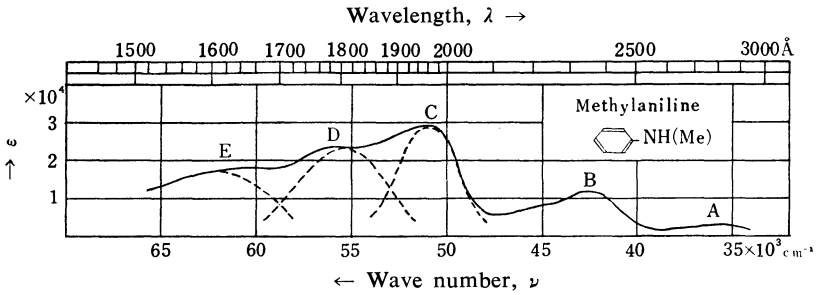
Absorption measurements for aniline and its *N*-derivatives were carried out in the vapor phase at room temperature. A recording vacuum ultraviolet spectrophotometer constructed in our laboratory was used for the measurements in the region from 1500 to 2200 Å, the apparatus using a Bausch and Lomb concave grating with a radius of 995.4 mm. The details of this apparatus have been published elsewhere.[19] Gas cells with paths 10 and 30 mm. long and with lithium fluoride windows were used.

The compounds studied were aniline, *N*-methylaniline, *N*-ethylaniline, *N*, *N*-dimethylaniline, *N*, *N*-diethylaniline, and *N*-*n*-butylaniline. The commercial materials of these compounds were fractionally distilled in a vacuum glass line, and the vapor of the purified samples was transferred through it into the gas cell for absorption measurements. The vapor pressure was measured with an accuracy of ±0.02 mmHg by using a mercury manometer with a travelling microscope attached. Spectra were carefully measured for different vapor pressures under the same optical conditions. Absorption measurements in the quartz region over 1900 Å were also carried out with a Cary spectrophotometer Model 14 M, a gas cell 10 cm. long being used. A comparison between the absorption spectra taken with the two apparatus in the overlap region of wavelength gave us an opportunity to check the accuracy of the intensity measurements made by means of our vacuum ultraviolet spectrophotometer.

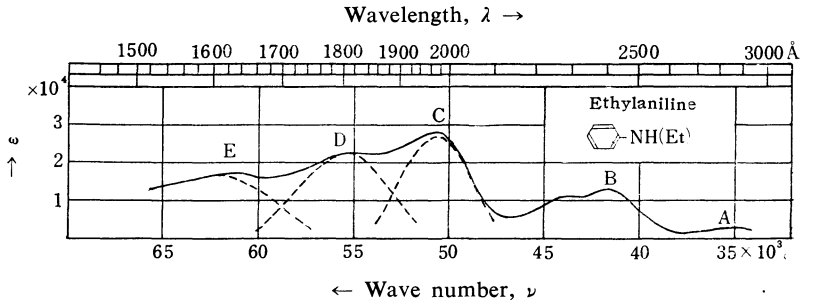
The vapor phase spectum of benzene was also taken in the region over 1500 Å; it gives reference data for interpreting the electronic spectra of the anilines reported here. The *N*-*n*-butylaniline spectrum was measured only in the region over 2000 Å, because its vapor pressure at room temperature is too low to measure a vacuum ultraviolet spectrum with the gas cells employed in the vacuum apparatus.



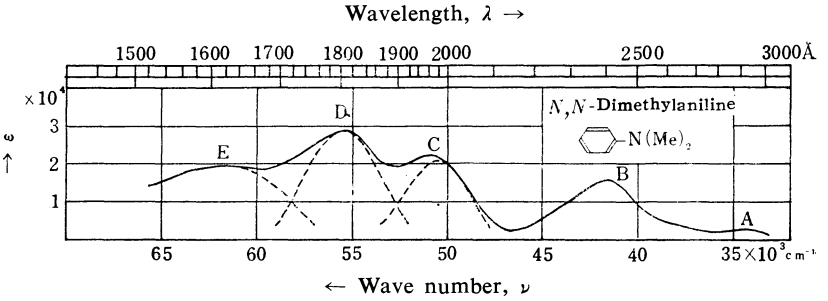
Experimental Results



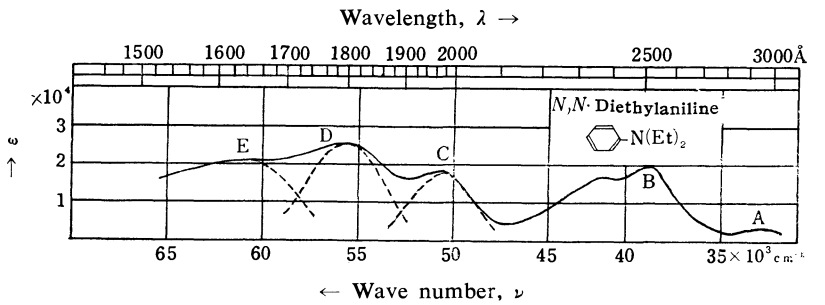
Our measurement for benzene indicated that the wavelengths of the three absorption peaks in the vapor phase are: 1776 Å (6.98 eV.) for the $^1A_{1g} \rightarrow {}^1E_{1u}$ transition, 2008 Å (6.17 eV.) for the $^1A_{1g} \rightarrow {}^1B_{1u}$ transition, and 2534 Å (4.89 eV.) for the $^1A_{1g} \rightarrow {}^1B_{2u}$ transition,[20] with oscillator strengths of 1.035, 0.126, and 0.01 respectively.



The absorption spectra of the anilines observed in the present work are shown in Fig. 1. The spectra show five characteristic bands near



19) H. Tsubomura, K. Kimura, K. Kaya, J. Tanaka and S. Nagakura, This Bulletin, 37, 417 (1964).



20) The $A_{1g} \rightarrow B_{1u}$ and $A_{1g} \rightarrow B_{2u}$ absorptions are accompanied with vibrational structures. The above-mentioned peak wavelength values for these absorptions were taken from the position of the strongest maximum for each absorption. Klevens and Platt[18] determined the $A_{1g} \rightarrow E_{1u}$, $A_{1g} \rightarrow B_{1u}$ and $A_{1g} \rightarrow B_{2u}$ transition energies to be 6.74, 6.14, and 4.89 eV. respectively by measuring the benzene spectrum in a heptane solution.

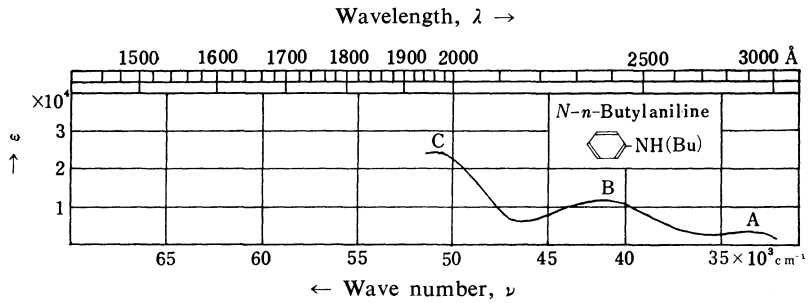

Fig. 1. Ultraviolet absorption spectra of aniline, *N*-methylaniline, *N*-ethylaniline, *N*, *N*-dimethylaniline, *N*, *N*-diethylaniline, and *N*-*n*-butylaniline. The A and B bands of aniline have vibrational structures which are neglected in this figure.

2850, 2350, 1950, 1800, and 1600 Å; they are designated as A, B, C, D and E respectively. Among these bands, the C and D bands are superposed to a considerable extent. The resolution of these two bands is made under the assumption that the curves of these bands are approximately of the Gaussian type and that the C bands and the D bands have the same half-widths.

The experimental oscillator strengths, f, were computed from the integral areas under the curves by the following equation:

$$f=4.32\times10^{-9}\int\varepsilon d\nu \qquad (1)$$

where ε is the molar extinction coefficient and ν is the frequency in cm^{-1}. Table I summarizes the experimental results concerning the peak wavelengths, the molar extinction coefficients, the transition energies, and the oscillator strengths for the anilines.

It may be seen from Fig. 1 and Table I that the spectral feature changes in the following order:[21]

$$\text{Ph-NH}_2,\ \text{Ph-NH(Me)},\ \text{Ph-NH(Et)},$$
$$\text{Ph-N(Me)}_2,\ \text{Ph-N(Et)}_2 \qquad (2)$$

The A and B bands show red shifts and increasing f values in the above order, from aniline to *N*, *N*-diethylaniline. On the other hand, the C and D bands, roughly speaking, shift to a small extent to longer wavelengths with appreciably decreasing f values and the differences in the absorption intensity between the C and D bands decrease going from aniline to *N*, *N*-diethylaniline. It should also be noticed that the E bands are commonly broad for all the compounds under consideration. This may conceivably show that the E bands are composed of two closely overlapping bands. The above interpretation is supported by the present theoretical consideration, details of which will be described below.

21) Ph-NH(*n*-Bu) is located at next to Ph-NH(Et) so far as its spectral data in the quartz region is concerned.

Theoretical

The present method of calculating the π-electron structures of the anilines is essentially based on that presented by Longuet-Higgins and Murrell,[12] in particular, on that of the calculation of aniline by Murrell,[12] in which the interaction between the two fragments of the benzene ring and the amino group is taken into account by configurational interaction among the ground, charge-transfer and locally excited configurations.

Although no detailed structural data of the anilines, even of the aniline molecule itself, have yet been reported, we assumed in the present theoretical treatment that the molecules are coplanar and belong to the symmetry group C_{2v}. In actual calculations, we took seven electron configurations; that is to say, besides the ground configuration, two charge-transfer configurations and four locally-excited configurations. The wave functions and energies for the locally excited configurations corresponding to the $A_{1g}\rightarrow B_{2u}$, $A_{1g}\rightarrow B_{1u}$, $A_{1g}\rightarrow E_{1u}$ excitations of benzene are as follows:

Wave function	Energy, eV.	
$\psi_{B_{1u}}=2^{-1/2}\{(\phi_3^{-1}\phi_5)-(\phi_2^{-1}\phi_4)\}$	4.89	
$\psi_{B_{1u}}=2^{-1/2}\{(\phi_3^{-1}\phi_4)+(\phi_2^{-1}\phi_5)\}$	6.17	
$\psi_{E_{1u}}=2^{-1/2}\{(\phi_3^{-1}\phi_5)+(\phi_2^{-1}\phi_4)\}$	6.98	
$\psi_{E_{1u}'}=2^{-1/2}\{(\phi_3^{-1}\phi_5)-(\phi_2^{-1}\phi_5)\}$	6.98	(3)

where the ϕ_i's are the molecular orbitals of benzene expressed in terms of the six carbon $2p\pi$ atomic orbitals.[22] The energy values given

22) The six molecular orbitals of benzene are:
$\phi_1=6^{-1/2}(\chi_1+\chi_2+\chi_3+\chi_4+\chi_5+\chi_6)$
$\phi_2=12^{-1/2}(2\chi_1+\chi_2-\chi_3-2\chi_4-\chi_5+\chi_6)$
$\phi_3=2^{-1}(\chi_2+\chi_3-\chi_5-\chi_6)$
$\phi_4=2^{-1}(\chi_2-\chi_3+\chi_5-\chi_6)$
$\phi_5=12^{-1/2}(-2\chi_1+\chi_2+\chi_3-2\chi_4+\chi_5+\chi_6)$
$\phi_6=6^{-1/2}(\chi_1-\chi_2+\chi_3-\chi_4+\chi_5-\chi_6)$.

here are taken from the electronic absorption spectrum data of benzene measured by the present authors. Taking an elelctron from the nonbonding π-orbital of the amino group (θ), and putting it into the lowest vacant orbitals of benzene (ϕ_4 and ϕ_5), we could obtain the two charge-transfer configurations, which might be represented by[23];

$$\psi_{CTa}=(\theta^{-1}\phi_5) \text{ and } \phi_{CTb}=(\theta^{-1}\phi_4) \quad (4)$$

the corresponding energies being

$$E_{CTa}=I-A-Q_1 \text{ and } E_{CTb}=I-A-Q_2 \quad (5)$$

Here I is the ionization potential of the substituent, A the electron affinity of benzene, Q_1 and Q_2 the electrostatic energies given by;

$$Q_1=1/3\{(C_1C_1/NN)+1/2(C_2C_2/NN)+1/2(C_3C_3/NN)+(C_4C_4/NN)\}$$
$$Q_2=1/2\{(C_2C_2/NN)+(C_3C_3/NN)\} \quad (6)$$

The two-center integrals (CC/NN) were calculated by the use of a quadratic equation with the atomic distance r_{CN}:

$$(CC/NN)=0.1922r_{CN}^2-2.502r_{CN}+10.83 \quad (7)$$

which was derived in the way suggested by Pariser and Parr.[24]** Concerning atomic distances, it was assumed that the C–C distances are the same in benzene (i. e., $r_{CC}=1.397$ Å[25]), and that the distance of the C–N bond is equal to that in 2, 5-dichloroaniline determined recently by an X-ray crystal analysis technique (i. e., $r_{CN}=1.407$[26]). From this geometry, Q_1 and Q_2 were calculated to be 5.44 and 5.00 eV.

Off-diagonal matrix elements of the total electron Hamiltonian were evaluated by the method of Longuet-Higgins and Murell[12] and also by that of Pople[27] as follows:

$$H_{G.CTa}=-\frac{2}{\sqrt{6}}(\beta-\beta')$$
$$H_{CTa.B_{1u}}=-\frac{1}{\sqrt{6}}(\beta+\beta')$$
$$H_{CTa.E_{1u}}=\frac{1}{\sqrt{6}}(\beta+\beta')$$
$$H_{CTb.B_{2u}}=\frac{1}{\sqrt{6}}(\beta+\beta')$$
$$H_{CTb.E_{1u}'}=-\frac{1}{\sqrt{6}}(\beta+\beta') \quad (8)$$

where β is the resonance integral between two atomic orbitals belonging to the nitrogen and adjacent carbon atoms, and β' is that belonging to the nitrogen and ortho-position carbon atoms. The ratio of β' to β was assumed to be equal to that of the corresponding overlap integrals, $\beta'=\beta(S'/S)=0.116\beta$, where S and S' are the overlap integrals corresponding to β and β'. The inclusion of β' is one of the characteristics of the present calculation. This seems to be necessary in order to improve the coincidence between the observed and theoretical transition energies. This point will be discussed later in some detail.

In the present calculations, β and β' were assumed to be parameters common to all the compounds under consideration, and the $(I-A)$ values were regarded as pertinent to the individual molecules. We determined these parameters in such a way that the calculated transition energies fit as well as possible to the experimental values of the anilines reported here by a trial-and-error method. The secular equations were solved by the aid of a Facom 202 electronic computer for various sets of parameters; the β value ranges from -1.4 to -2.6 eV., with an interval of 0.2 eV., and the $(I-A)$ values, from 9.5 to 12.5 eV, with an interval of 0.1 eV. From the systematic comparison, it was found that the best values for β and β' are -1.94 and -0.25 eV. respectively.

The transition energies ΔW evaluated by the use of the above β and β' values are plotted against the $(I-A)$ values in Fig. 2, from which it may be found that the best $(I-A)$ values in eV units are: 11.34 for aniline, 11.04 for *N*-methylaniline, 10.94 for *N*-ethylaniline, 10.84 for *N*, *N*-dimethylaniline, and 10.64 for *N*, *N*-diethylaniline. Table II gives the energy levels and wave functions calculated with the best values for β, β' and $(I-A)$. Furthermore, the relation between the electron configurations used in the present calculation and the energy levels finally obtained is shown in Fig. 3, *N*, *N*-dimethylaniline being taken as an example.

The oscillator strengths were calculated by the use of the following equation:

$$f_{ih}=1.085\times10^{11}\nu_{ih}D_{ih}^2 \quad (9)$$

Where ν_{ih} and D_{ih} are, respectively, the transition energy (in cm^{-1}) and the transition moment (in cm.) for the $i\rightarrow h$ transition. In calculating theoretical oscillator strengths, we took the three following integrals into account:

** In the derivation of Eq. 7, data for the valence state ionization potentials and electron affinities for carbon and nitrogen were taken from the table recently given by G. Pilcher and H. A. Skinner (*J. Inorg. Nucl. Chem.*, **24**, 937 (1962)).

23) One is symmetric and the other is antisymmetric with regard to the symmetry plane vertical to the molecular plane; they are denoted with the letters "a" and "b" respectively,

24) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 767 (1953).

25) K. Kimura and M. Kubo, ibid., **32**, 1776 (1960).

26) T. Sakurai, M. Sundaralingam and G. A. Jefferey, *Acta Cryst.*, **16**, 354 (1963).

Discussion

As may be seen in Table I, we obtained an excellent agreement in the transition energies and oscillator strength values between the theoretical and the experimental results. It is interesting that the changes in the absorption spectra of the compounds can be well interpreted in terms of the change in the $(I-A)$ values or the energies of the charge-transfer configurations on the assumption that β and β' are constant for the series of compounds under consideration. The resuls on aniline obtained by other authors are compared with the present results in Table III. The results by Fischer-Hjalmars and by Murrell are similar to ours, although their results are somewhat different from ours in that the calculated transition energies for the three higher frequency transitions are considerably smaller than the observed values.

The most important point of our experimental results is that the five absorption bands were found in the wavelength region of 160 mμ to 300 mμ. On the basis of the absorption intensity and the shape of absorption curve, these bands can safely be assigned to the $\pi \rightarrow \pi^*$ transition bands. This means that some additional bands appear in the absorption spectra of the anilines, in addition to the shifted bands of the 180, 200 and 260 mμ bands of benzene. According to our interpretation, the additional bands are intramolecular charge-transfer bands caused by the interaction between the electron donor (NH_2, NHMe, etc.) and the electron acceptor (the benzene ring). The additional bands of this kind could not observed with phenol and toluene, as will be mentioned in a following paper. In other words, the absorption bands of these two compounds can be interpreted as the shifted bands of benzene. In this point the absorption spectra of the anilines exhibit a striking contrast to those of phenol and toluene. At any rate, it may be said that theoretical treatment[1-3,8] in which the substituent effect is considered to be only a weak perturbation to the energy levels of benzene itself, can not be applied to the anilines.

The transitions to the lowest excited states (W_1) which give rise to the A bands correspond mainly to the transition to the B_{2u} state of benzene. The contributions from the charge-transfer configuration in the W_1 state are 22% for aniline, 36% for *N*, *N*-diethylaniline, and so on. There is no doubt that the B bands appearing around 240 mμ, which are called intramolecular charge-transfer bands, are to be assigned to the transitions to the W_2 states to which the charge-transfer configurations are mainly contributed; for instance, their contributions are, respectively, 50% and 62% for aniline and *N*, *N*-diethylaniline.

According to the present experimental results, going from aniline to *N*, *N*-diethylaniline, the C and D bands show very small red shifts and the oscillator strengths of the C bands decrease appreciably. These phenomena can be well explaind by the present theoretical study. The decrease in the intensity of the C band may be due to the decreasing contributions of the E_{1u} locally excited configuration, going from aniline to *N*, *N*-diethylaniline.

The shortest wavelength band for each compound is most likely to be attributed to two transitions, $W_0 \rightarrow W_5$ and $W_0 \rightarrow W_6$, whose transition energies are almost equal to each other. This seems to be a reason for the broadness of the band. As is shown in Table II, the calculated results show that, going from aniline to *N*, *N*-diethylaniline, the fifth and the sixth bands both shift toward the longer wavelengths and, at the same time, their f values increase, with increasing contributions from the E_{1u} locally excited configuration of benzene. These features derived by the theoretical calculations agree well with those of the observed E bands.

As can be seen in Table II, the contributions of the charge-transfer configurations to the ground states are 5% for aniline, 6% for *N*, *N*-diethylaniline, and so on, while the calculated stabilization energies due to conjugation are 7.37 kcal./mol. for aniline, 8.29 kcal./mol. for *N*, *N*-diethylaniline, and so on. The conjugation energy of aniline coincides well with the extra resonance energy estimated empirically (6 kcal./mol.)[28]. This seems to establish that the present theoretical results on the conjugation effect in the ground states are reasonable.

As may be easily seen from Fig. 2, the present calculations indicate that the $(I-A)$ values decrease in the order of aniline > *N*-methylaniline > *N*-ethylaniline > dimethylaniline > *N*, *N*-diethylaniline. The changes in the $(I-A)$ values should be attributed to those in the ionization potentials of the substituents. In Fig. 4, the $(I-A)$ values of aniline, *N*-methylaniline and *N*, *N*-dimethylaniline are compared with the ionization potentials of ammonia and amines. It may be said that the differences in the $(I-A)$ values obtained for the anilines reflect a general tendency in th effect of methyl and ethyl substituents upon the ionization potential of ammonia.

Taking the value of I as equal to the ionization potential of ammonia, 10.25 eV., we can

estimate the electron affinity of benzene to be $A=-1.00$ eV. from the $(I-A)$ value of 11.25 eV. obtained for aniline. We have a few theoretical data on the electron affinity of benzene available for comparison with the present data; one is the -1.63 eV. given by Hedges and Matsen,[29] and the other, the -0.54 eV. given by Pople and Hush.[30] From the comparison of these values, it may be said that the present electron affinity value of benzene seems to be reasonable. Similar attempts to estimate the electron affinity of benzene from the $(I-A)$ values obtained for the aniline derivatives have been unsuccessful because of the large fluctuations among the experimental ionization potential data for amines (see Fig. 4.)

The present values of $\beta(CN)=-1.94$ eV. may be compared with the other data used in the theoretical calculations of aniline by several other authors. Murrell[12] has used $\beta(CN)=-1.60$ eV., and Fischer-Hjalmars[4] has used $\beta(CN)=-1.452$ eV. in her calculation using the Pariser-Parr-Pople method, while Bloor and Peradejordi's value[16] was $\beta(CN)=-2.74$ eV.

In the present calculations, it should be emphasized that taking β' (the resonance integral for the N···C(ortho) atom pair) into account leads to considerably better results than when it is disregarded. As can be seen from Eq. 8, β' $(=0.116\beta)$ makes the off-diagonal term, $H_{G.CTa}$, smaller by about 12%, while it makes all the other terms in Eq. 8 greater by about 12%. This effect brings about a lower transition energy value for the longest wavelength band; consequently, a good agreement between the theoretical and experimental results was obtained.

Furhermore, we checked the effect of the other electron configurations with higher energies upon the transition energies,[31] although we could well reproduce the observed spectra of the anilines by the above-mentioned calculation, taking the seven electron configurations into account. The results show that the effect is not important.

Extra peaks appearing at about 230 mμ for *N*-methylaniline, *N*-ethylaniline, and *N*-butylaniline, and at about 250 mμ for *N*, *N*-diethylaniline may be attributed to the $n \rightarrow \sigma^*$ transitions, since the ultraviolet absorption measurements with saturated amines have indicated that a relatively weak absorption band due to an $n \rightarrow \sigma^*$ transition appears around 200 mμ; for instance, for trimethylamine it appears at 212 mμ.[19]

Summary

The vacuum ultraviolet absorption spectra of anilne, *N*-methylaniline, *N*-ethylaniline, *N*, *N*-dimethylaniline, *N*, *N*-diethylaniline and *N*-*n*-butylaniline have been measured in the vapor phase by a recording vacuum ultraviolet spectrophotometer, with which the absorption measurements have been extended down to

29) R. M. Hedges and F. A. Matsen, *J. Chem. Phys.*, **28**, 950 (1958).
30) J. A. Pople and N. S. Hush, *Trans. Faraday Soc.*, **51**, 600 (1955).

31) We checked how the other electron configurations with higher energies affect the calculated results. In order to check this point, we tried to calculate by including several additional higher energy configurations of the following types:
$(\phi_2^{-1}\phi_6)$, $(\phi_3^{-1}\phi_6)$, $(\theta^{-1}\phi_6)$, $(\theta^{-1}w)$, $(\phi_2^{-1}w)$ and $(\phi_3^{-1}w)$ which correpond to transitions to the highest vacant orbital of benzene (ϕ_6) and to the $3p\pi$ atomic orbatal of nitrogen (w). Assuming roughly that all the diagonal elements of the new configurations are 9.0 eV., and that the resonance integral between the nitrogen $3p\pi$ orbital and the adjacent carbon $2p\pi$ orbital is -2.0 eV., we obtaind transition energies by solving 5th- and 8th-order secular equations built up with the thirteen configurations. The resulting transition energies (in eV.) for seven original configurations were found to be 4.97 (4.72) for the $W_0 \rightarrow W_1$ transition, 5.53 (5.42) for the $W_0 \rightarrow W_2$, 6.65 (6.42) for the $W_0 \rightarrow W_3$, 7.04 (6.86) for the $W_0 \rightarrow W_4$, 7.81 (8.04) for the $W_0 \rightarrow W_5$, and 8.18 (8.05) for the $W_0 \rightarrow W_6$; the values in parentheses indicate the corresponding energies listed in Table I.

1500 Å. Some new bands have been found in the vacuum ultraviolet region, and in total five $\pi \rightarrow \pi^*$ transtion bands with molar extinction coefficients larger than 1500 have been observed commonly for the anilines. In order to clarify the nature of these bands, a theoretical treatment has been made by considering the configuration interaction among the ground, locally excited and charge-transfer configurations. An excellent agreement has been obtained between the experimental and the calculated results. It has been concluded that the anilines studied here exhibit intramolecular charge-transfer bands characteristic of the electron transfer interaction between the substituents and the benzene ring.

The Szilard-Chalmers Reaction of Several Neutron-Irradiated Inorganic Phosphorus Compounds

By Kichizo TANAKA

(Received Appril 11, 1964)

In 1948, Williams[1] reported that, in the Szilard-Chalmers process, the longer the irradiation time in a reactor, the higher was the retention of the parent form for potassium ferrocyanide and antimony pentafluoride. This high retention for long irradiations was postulated as resulting from radiation annealing, particularly with gamma-rays.

In a series of studies by the author on the Szilard-Chalmers effects on several inorganic phosphorus compounds, such post-irradiation processes as thermal annealing[2] and gamma-ray annealing[3] were reported in the distribution of chemical species containing phosphorus-32 for several neutron-irradiated phosphates. In an experiment[4] concerned with the preparation of phosphorus-32 of a high specific activity by means of the (n, γ) reaction of phosphates, the recovery and enrichment factors were affected by the irradiation conditions.

In the present paper, studies will be made of the neutron irradiation of several phosphates under various irradiation conditions in order to find the optimum conditions of irradiation for the preparation of phosphorus-32 of a high specific activity. For the group separation of the chemical species of phosphorus-32, the results obtained by paper partition chromatography[5] will be compared with those obtained by the ion-exchange method and with those obtained by paper electrophoresis.[6-9] The effects of radiation in a reactor on the distribution of chemical species containing phosphorus-32 will also be discussed.

Experimental

Target Materials.—Guaranteed reagents were used without further purification. Hydrated salts were dehydrated, dried, and analyzed as previously reported.[2]

Neutron Irradiation.—Samples sealed in a polyethylene tube were irradiated in the holes of JRR-1 (operated at 40 kW.) or of JRR-2 (operated at 5 MW.). Thin gold foils were used as thermal neutron flux monitors, and thin aluminum foils and small nickel pellets, as fast neutron flux monitors. These monitors were irradiated by being placed in a capsule holding the target material. When irradiated in a glory hole of JRR-1 and in a vertical hole of JRR-2, the samples were sealed in a quartz tube which was then placed in an aluminum container. The samples were irradiated at ambient reactor temperatures.

Separation Procedure.—After irradiation, the samples were stored in a vessel cooled with dry ice. Each sample was then dissolved in water so that the concentration was made 0.1 M. The solution was submitted to one-dimenssional paper partition chromatography. Two different systems were used for the separation; one used *n*-butanol saturated with 2 N nitric acid as the developing agent, and the other, a mixture of 1 N ammonia, dioxane and *n*-butanol (1 : 1 : 1, volume ratio). The

TABLE I. THE DISTRIBUTION OF CHEMICAL SPECIES CONTAINING PHOSPHORUS-32 FOR DISODIUM HYDROGEN PHOSPHATE: COMPARISON OF THREE SEPARATION METHODS

By paper partition chromatography	%	By paper electrophoresis	%	By ion exchange method	%
Polyphosphates	46.1	Polyphosphates	45.0	Fraction absorbed with an aqueous chlorides solution	62.2
		Isohypophosphate and hypophosphate	18.4		
Orthophosphate	22.0	Orthophosphate	23.1	Fraction eluted with an aqueous chlorides solution	37.8
		Orthophosphite	9.9		
Reduced species (P(I)	32.0 2.9)	Hypophosphite	3.6		

procedure was the same as has previously been described.[2] The ion exchange method used to prepare phosphorus-32 of a high specific activity was also the same as in a previous paper.[4] When the sample solution in an equimolar mixture of 0.025 M potassium chloride and 0.025 M hydrochloric acid was passed through the column, orthophosphate, orthophosphite, and hypophosphite ions were eluted with an equimolar mixed solution of 0.025 M potassium chloride and 0.025 M hydrochloric acid, and the absorbed phosphorus-32 was completely eluted with 8 M hydrochloric acid. The distribution of the chemical species containing phosphorus-32 formed in phosphates by neutron irradiation was very complex; therefore, the distribution of the phosphorus oxy-acid species obtained by the two methods were compared with that obtained by paper electrophoresis. Recently, the usefulness of high voltage electrophoresis for the separation of a complex phosphate mixture has been recognized; in such an electrophoresis voltage gradients up to 80 V./cm. were attained. Lindner and Harbottle[10] applied this method to finding the distribution of the chemical species containing phosphorus-32 in neutron irradiated phosphates. In the present experiment, the sample was dissolved in 0.1 M lactic acid, and a 0.1 M lactic acid solution was used as the electrolyte. The voltage gradient was 80 V./cm. During development, the filter paper (Whatman 3 MM) was clamped between two glass plates, the upper plate being cooled with ice. The separation took about one hour.

Counting Procedure.—After separation, the filter paper was dried and cut into pieces 1 cm. wide. These pieces were placed on the bottom of a glass planchet (2.5 cm. in diameter) and counted with a gas-flow GM counter, an automatic sample changer made by the Tracer-Lab Inc. also being used. Each piece was counted at least ten days after neutron irradiation to avoid error arising from contamination by sodium-24 or potassium-42. The total count was 2^{10} counts for each piece. The sample in a solution was evaporated in a glass planchet (2.5 cm. in diameter) and counted with a thin end-window-type gas flow GM counter. The gamma-ray spectra were measured with a 256-channel scintillation spectrometer equipped with a NaI crystal (7.4 cm.×7.4 cm.).

The Chemical Analysis of Phosphorus.—Trace amounts of phosphorus were determined by colorimetry, as has been reported by Gaitanis.[11] For macroamounts, gravimetric determination was used after precipitating the phosphorus with ammonium molybdate.

Results and Discussion

The distribution of the chemical species containing phosphorus-32 was studied using the three different separation methods described above, and the distributions were compared with each other. Each sample was irradiated for 2 hr. in a pneumatic tube of JRR-1 (the nominal neutron flux, 0.64×10^{12} n./cm^2-sec). The results obtained for disodium hydrogen phosphate are shown in Table I. In all three separations the storage time was also the same. In the paper partition chromatography, three fractions, the polyphosphates, the orthophosphate and the reduced species, were separated. The polyphosphates and the reduced species consisted of mixed phosphorus oxy-acid species, as has previously been reported.[2] From the analysis of the R_f values, tripolyphosphate and pyrophosphate were observed in the chromatographic histogram for the polyphosphates. Hypophosphite was observed by separation with a mixture of 1 N ammonia, dioxane and *n*-butanol. As may be seen in the table, the percentages of phosphorus-32 in the polyphosphates and in the orthophosphate are the same as those obtained by the paper electrophoresis. On the other hand, the percentage of the reduced species is much larger than the sum of the orthophosphite and hypophospphite given by the paper electrophoresis. This difference corresponds exactly to the percentages of the isohypophosphate and hypophosphate in the paper electrophoresis.

In the ion exchange separation, the activities of the fractions which are absorbed on the anion exchange resin from the aqueous chloride

10) L. Lindner and G. Harbottle, "Proceedings of Chemical Effects of the Nuclear Transformations," Vol. I, IAEA, Prague (1961), p. 485.

11) M. J. Gaitanis, "Master Analytical Manual," Section 1-12 TID-7015 (1957).

solutions are higher than those of the polyphosphates obtained by the other separations. In the case of the ion exchange separation, the elutions were made successively with a potassium chloride solution, as has been reported by Weiser.[12] Appoximately one-half of the total activity of the absorbed fraction is found in pyrophosphate and tripolyphosphate; the remaining half is not identified. The percentages of the sum of the polyphosphates, isohypophosphate and hypophosphate in the paper electrophoresis were approximately equal to those absorbed on the anion exchange resin. For the neutron-irradiated orthophosphate salts treated with anion exchange resin, the eluted solution with 8 M hydrochloric acid was evaporated to near dryness by heating the solution and submitting it to one-dimenssional paper partition chromatography. Phosphorus-32 was observed in the orthophosphate and reduced species. Because orthophosphite and hypophosphite ions were eluted with an aqueous chloride solution, this provided other evidence that the reduced polyphosphate species were formed by the Szilard-Chalmers process of orthophosphate salts. These species were absorbed on the resin from the aqueous chloride solutions.

Several orthophosphate salts, sodium orthophosphite and sodium hypophosphite were irradiated in a pneumatic tube of JRR-1. The distribution of the chemical species containing phosphorus-32 which was obtained by paper partition chromatography is plotted in Fig. 1—3 as a function of the neutron irradiation time. For the orthophosphate salts, the shorter the irradiation time, the higher was the percentage of the reduced species, but the lower were those of the polyphosphates and orthophosphate. The fraction of orthophosphate is considerably reduced by irradiating it for shorter periods of time. However, the distribution of the phosphorus oxy-acid species contaianing phosphorus-32 was apparently independent of the irradiation time for sodium orthophosphite and sodium hypophosphite, although the fraction of hypophosphite in sodium orthophosphite slightly decreases when the sample is irradiated for longer periods of time.

The samples were irradiated at various locations in the reactor of JRR-1. The results obtained from these irradiations are shown in Table II. The thermal neutron fluxes measured with a thin gold foil by a calibrated ionization chamber are shown in the third column in Table II. The fast neutron fluxes in the fourth column were obtained from the induced activity of magnesium-27 by the $^{27}Al(n, p)^{27}Mg$ reaction, assuming that the cross section was 3.1 millibarns.[13] The energy distribution of the fast neutrons at any location in a reactor was assumed to be the same as that of the

fission neutrons.[14,15] The fast neutron fluxes obtained by this reaction were checked by those from other reactions, $^{27}Al(n,\alpha)^{24}Na$ and $^{58}Ni(n,p)^{58}Co$.

At the central position in the glory hole of JRR-1 at 40 kW. operation, the fast neutron flux obtained by this method agreed with other observations,[16] $1.2\sim1.5\times10^{12}$ n./cm²-sec. For the gamma-ray intensity in the reactor, the data shown by Nakadoi et al.[17] were used. When irradiated for the same period of time, the distribution of the chemical species containing phosphorus-32 was strongly dependent on the location where they were irradiated. For sodium dihydrogen phosphate, the reduced species obtained by irradiation in the glory hole considerably differed from those of the other locations. The reduced species in two different salts were compared. The percentages of the reduced species in the sodium dihydrogen phosphate salt and in the disodium hydrogen phosphate salt were approximately the same when irradiated in the vertical hole No. 12; however, the percentage of the reduced species in the disodium hydrogen phosphate salt was approximately twice that in the sodium dihydrogen phosphate salt when irradiated in the glory hole.

The orthophosphate salts were irradiated in a pneumatic tube of JRR-2 (operated at 5 MW). The distributions obtained by the chromatographic separation were compared with those of JRR-1 as shown in Table III. Low proportions of the reduced species were observed when they were irradiated at a high operating

power. This is due to the greater dose exposures in the reactor. Some of the orthophosphate salts were irradiated in a vertical hole of JRR-2 and subjected to ion exchange separation. Decreases in the recovery were observed for longer periods of irradiations, as Table IV shows. When the salts were neutron-irradiated for 72 hr. at ambient reactor temperatures up to 170°C in a vertical hole of JRR-2 for sodium dihydrogen phosphate and disodium hydrogen phosphate, the enrichment factor decreased to approximately unity. This can be explained by the thermal pyrolysis of the orthophosphate salts. The ambient reactor temperature was measured with a very thin (0.3 mmϕ) alumelchromel thermo-couple placed adjacent to the sample. The low fractions of the polyphosphates in Table IV are the results for irradiations at high ambient reactor temperatures. They can be attributed to the effects not only of radiation annealing but also of thermal annealing.

When the irradiation time was extrapolated to zero, the retention as orthophosphate approached approximately 8 to 15% for the orthophosphate salts studied. Although this retention was obtained for irradiation at ambient reactor temperatures of JRR-1, much difference was not seen between the retention estimated by the extrapolation of the irradiation time to zero and those obtained by irradiation cooled with liquid nitrogen for 2 hr.[18]. This suggests that the distribution of the chemical species containing phosphorus-32 at an irradiation time of zero, which is called the initial distribution, is independent of such post-irradiation effects as thermal and radiation annealing.[3]

As the chemical species were annealed by gamma irradiation, an attempt was made to analyze the variation of the distribution of the chemical species with the neutron irradiation time[1] in a reactor. On irradiation in JRR-1, the effect of radiation annealing would be the greatest cause of the variation of the distribution, because ambient reactor temperatures were not so high[19] that the thermal annealing was prominent for the variation of the distribution. Roughly speaking, if the rate of the annealing of the chemical species containing phosphorus-32 is proportional to the numbers of the chemical species present, the apparent rate constant is dependent on the intensity of radiation in a reactor; then

$$N_t = N_0 \frac{\lambda}{\lambda+k}\left[\frac{1-\exp\{-(\lambda+k)t\}}{1-\exp(-\lambda t)}\right]$$

where k is the apparent rate constant for the variation of the distribution, λ is the decay constant of phosphorus-32, and N_0 and N_t are the numbers of the chemical species at irradiation time zero and at irradiation time t respectively. For this analysis, the initial distribution was assumed to be independent of the post-irradiation effects. For the initial distribution, N_0, the extrapolated values at irradiation time zero for the reduced species were used. However, those for the polyphosphates and orthophosphate were estimated in a different way because these fractions increased with the increase of neutron irradiation time, and the sum of the increase of these two fractions corresponded to the decrease of the reduced species. At an infinitely long irradiation time, N_t approached a constant value; namely, $N_{t=\infty} = \lambda/(\lambda+k)$. If $k \gg \lambda$ were attained as expected from the results of the radiation-annealing experiment, this value might be assumed to be zero at a long irradiation time. The difference between the numbers of the polyphosphates obtained by a 5 hr.-neutron irradiation of JRR-1 and those of the fraction at irradiation time zero was assumed to be the initial distribution of the annealable species in the increase of the polyphosphates. The remaining fraction of the reduced species was then assigned to be the initial distribution of those in the increase of the orthophosphate.

The estimation of the apparent rate constants is based on the best fit of each experimental value, N_t at irradiation time t. The apparent rate constants are shown in Fig. 1, where the neutron irradiation time is shown on the absissa. The apparent rate constants thus

obtained for the variation of the reduced species vary with the neutron irradiation time; the shorter the irradiation time, the higher the apparent annealing rate. However, this is to be expected from the finding that the radiation annealing takes place by means of mixed processes for the reduced species, as was shown in a previous paper.[3] In the increase of the orthophosphate, however, the apparent rate constants seemed to be independent of the neutron irradiation time. The results shown in Table II and Table III were also analyzed for sodium dihydrogen phosphate and disodium hydrogen phosphate. The ratio between the apparent rate constants for the two salts is compared with different locations on irradiation. This is shown in Table V. The apparent rate constants change roughly with the pile factor, and the ratio of these constants for the two salts seemed to fluctuate independent of the irradiation conditions. The effects of fast neutrons in a reactor were probably suggested by the ratio of these rate constants among the salts in which the hydrogen content was a variable, because the effective dose was attributed to the hydrogen atoms in the salts. The does rates were estimated from the results of fast neutron fluxes obtained above. For this estimation, it was assumed that the energy distribution was the same as that of fission neutrons, and that all the energies of the scattered atoms were absorbed into the sample. It was approximately one-fourth of the gamma ray dose intensity for dihydrogen phosphate and one-twentieth of that for monohydrogen phosphate at the maximum (No. 1 hole of JRR-1). However, the ratio was not increased. Fast neutrons were probably less effective for the annealing process during irradiation in a reactor.

Summary

The distribution of the chemical species containing phosphorus-32 formed by the (n, γ) reaction has been studied for several phosphates as functions of the irradiation conditions in a reactor. The variation in the distribution has been discussed in connection with the radiation annealing process during irradiation, and a comparison of the distribution of the chemical species containing phosphorus-32 by three separation methods has been made.

By means of the analysis of the variation curves of the distribution of the chemical species containing phosphorus-32, the apparent rate constants have been estimated. It has been suggested that the variations in the distribution may be approximately expressed by radiation annealing processes, and that they are affected by pile factors.

The author wishes to express his appreciation to Professor Shizuo Fujiwara for his guidance and encouragement, and to Dr. Kenjiro Kimura for his valuable advice. His thanks are also due to Dr. Nagao Shibata and to Dr. Kenji Yoshihara for their discussions and valuable suggestions.

Radiolysis of n-Butane in the Gas, Liquid and Solid Phases

By Tetsuo MIYAZAKI, Shigeyoshi ARAI, Shoji SHIDA and Shiro SUNOHARA

(Received April 11, 1964)

Many investigations have been made of the radiolysis of alkanes in order to elucidate the radiolysis mechanism. Although the phase seems to influence the mechanism of the radiolysis, experimental studies of its effect have been few. A comparison of the gas phase with the liquid phase was made by Dewhurst[1] for the radiolysis of *n*-hexane. He reported that the vapor-phase radiolysis showed a much higher proportions of products which must ultimately result from C–C bond cleavage, while the liquid-phase radiolysis showed a higher proportion of product, which must result from C–H bond cleavage. Hamashima et al.[2] compared the radiolysis of neopentane in the gas and the liquid phases.

1) H. A. Dewhurst, *J. Am. Chem. Soc.*, **83**, 1050 (1961).

2) M. Hamashima, M. P. Reddy and M. Burton, *J. Phys. Chem.*, **62**, 246 (1958).

The present authors have studied the phase effect on the radiolysis of *n*-butane; it is the simplest hydrocarbon which contains two types of C–C bond and is easily liquefied. They found a clear difference between the C–C bond scissions in the gas and the condensed phases.

Experimental

Materials.—A commercial pure-grade *n*-butane, stated to be of 99.7% purity, was used without further purification. The gas chromatographic analysis of this material showed 0.036% isobutane and 0.130% isopentane, but no unsaturated impurities were detected.

Irradiation.—The radiolysis in the gas phase was carried out in a glass cylinder 1 liter in volume. The cell used for the liquid and solid radiolyses was a heavy-walled glass tube 1.5 cm. in diameter and 13 cm. long. The samples were irradiated with 1.5 MeV. electrons from a Van de Graaff accelerator with γ-rays from cobalt-60 of 200 c. and 16000 c. The gas samples were irradiated with electrons at room temperature. The hydrogen yield ($G(H_2)=1.3$) from irradiated ethylene at 100 mmHg was used as the measure of the gas dosimetry.[3] The liquid samples were irradiated with γ-rays and electrons at room temperature. The dose rate of γ-rays was 1.5×10^{19} eV./g. hr. and 3.1×10^{19} eV./g hr. Doses were determined by a Fricke dosimeter, taking $G(Fe^{+3})=15.5$. The solid radiolysis was carried out at −196°C.

Product Analysis. — After irradiation, non-condensable gas (a mixture of hydrogen and methane) at −196°C was transferred to a gas burette by a Toepler pump and then analyzed using a copper oxide furnace. Condensable gas was vaporized into a gas holder, an aliquot of which was subjected to gas chromatography. The columns used were of dimethyl sulfolane at room temperature for C_2–C_5 hydrocarbons, of silica gel at 40°C for ethane and ethylene, and of dinonyl phthalate at 80°C for C_6–C_8 hydrocarbons. For runs with iodine added, alkyl iodide products were analyzed by gas chromatography with a dinonyl phthalate column at 80°C.

Results and Discussion

***G*-Value.** — The amounts of the major irradiation products of liquid *n*-butane are plotted against the energy absorbed in Fig. 1 and Fig. 2.

The initial yield was calculated from the initial slopes of these curves, since the amount of olefin did not increase linearly with the energy absorbed.

The radiolytic yields obtained in the gaseous, liquid and solid phases are listed in Table I.

The *G*-values obtained for gaseous and liquid *n*-butane are in good agreement with those reported in the previous works.[4-7]

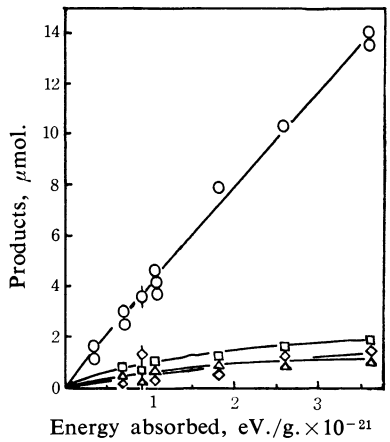

Fig. 1. Product formation in the liquid phase radiolysis as a function of the energy absorbed. Ordinates represent the yield from 1000 μmol. *n*-butane. The hydrogen yield in the electron bombardment was assumed to be equal to that in the γ-rays radiolysis.

C_6	0.38	0.38	—
C_7	0.09	0.05	—
C_{8A}	0.26	0.38	0.20

a) Results are the averages at the pressure of 50 and 100 mmHg. The total dose is 2.5×10^{21} eV./g.
b) The yields of hydrogen and lower hydrocarbons (C_1-C_4) were determined by extrapolation to zero dose. The yields of C_5-C_8 hydrocarbons represent the mean values of two runs at the total dose 3.7×10^{21} eV./g.
c) The mean values of three individual irradiations, that is, two runs at 3.7×10^{21} eV./g. and one run at 2.6×10^{21} eV./g.

Formation of C_2 and C_3 Products.—n-Butane has two types of C–C bonds, and the major products from these C–C bond scissions are C_1, C_2 and C_3 hydrocarbons. It is noted in Table I that the $G(C_2)$ of the liquid phase is approximately the same as that of the gas phase, while for $G(C_3)$ this is not the case.

Since the irradiation with 1.5 MeV. electrons and γ-rays gave the same yield (Fig. 1 and Fig. 2), the different $G(C_3)$ values cannot be ascribed to the different dose rate and, therefore, must be due to the different radiolysis mechanisms in the two phases.

Table II compares the radiolyses in the gas, liquid and solid phases, the vacuum ultraviolet photolysis (1470A and 1236A),[8,9] the mass spectral fragmentation[10] and the appearance potentials of ions from n-butane.[11]

The C_2/C_3 ratios in the radiolyses of liquid and solid butane are 4.2 and 5.7 respectively. These values are similar to the value of the photolysis, where only the cracking of neutral excited butane takes part, but not to that of mass spectral fragmentation. Since the parent ion in the mass spectral fragmentation is highly excited, the fragmentation of low excited ions which may take part in the condensed-phase radiolysis would be different from that in the mass spectroscopy. As may be seen in Table II, the appearance potential of $C_3H_7^+$ is lower than that of $C_2H_5^+$ and, accordingly, the low-excited ion produces C_3 products mainly; the C_2/C_3 in the fragmentation of the low excited ion should be less than 1.43. Therefore, the values of C_2/C_3 in the liquid and solid radiolyses cannot be explained, even by the fragmentation of such a low-excited butane ion.

On the contrary, the C_2/C_3 in the radiolysis of n-butane in the gas phase is analogous to that of mass spectral fragmentation, but not so that of the photolysis.

Bond Dissociation Energy.—In the radiolysis of liquid hydrocarbons, it has been shown that weaker bonds are preferentially broken.[12,13]

Since the difference between the gas and liquid radiolyses of n-butane obviously cannot be explained by the bond strength of the neutral molecule alone, the bond strength of the butane ion is also considered here.

The bond dissociation energies of n-butane and the butane ion are given below.

TABLE II. COMPARISON OF RADIOLYSIS OF n-BUTANE WITH OTHER CRACKING PROCESSES

	Solid	Liquid	Gas	Photolysis (1470A, 1236A)	Mass spectrum[b]	A. P. of ions from n-butane
C_2/C_3[a]	5.7	4.2	1.1	3-4	1.4	$C_4H_{10}^+$ 10.4 eV.
						$C_3H_6^+$ 11.0 eV.
						$C_3H_7^+$ 11.2 eV.
						$C_2H_4^+$ 11.6 eV.
						$C_2H_5^+$ 12.1 eV.

a) C_2 represents the sum of the yields of ethane and ethylene. C_3 represents the sum of the yields of propane and propylene.
b) The complementarity between ion and radical is assumed to hold in the mass spectral fragmentation.

8) M. C. Sauer and L. M. Dorfman, *J. Chem. Phys.*, **35**, 497 (1961).
9) H. Okabe and D. A. Becker, ibid., **39**, 2549 (1963).
10) American Petroleum Institute Research Project No. 44, Mass Spectral Data.
11) M. B. Loffel and R. A. Lad, *J. Chem. Phys.*, **16** 420 (1948).
12) H. Yamazaki and S. Shida, ibid., **32**, 950 (1960).
13) K. Fueki and K. Hirota, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 209 (1960).

	n-Butane molecule	ΔH (kcal./mol.)
$CH_3CH_2CH_2CH_3$	$\rightarrow CH_3 + C_3H_7$	84.0
	$\searrow 2\ C_2H_5$	81.0
	Butane ion	
$CH_3CH_2CH_2CH_3^+$	$\rightarrow CH_3 + C_3H_7^+$	3.5
	$\searrow C_2H_5 + C_2H_5^+$	30.2

The bond dissociation energies of the butane ion have been derived by assuming the heats of formation of C_4H_{10}, $C_3H_7^+$, $C_2H_5^+$, CH_3 and C_2H_5 to be 219, 190, 224, 32.4 and 25.2 kcal./mol. respectively.[14] In the butane molecule, the second bond is weaker than the first bond, while in the butane ion the first bond is much weaker than the second bond. Therefore, one may expect that C_2 products are more readily formed than C_3 products from the fragmentation of the butane molecule, while C_3 products become the major product from that of the butane ion.

Radical Detection by the Scavenger Method. —*n*-Butane saturated with iodine was irradiated with γ-rays in the gaseous and liquid phases. The yields of alkyl iodide, which represent the yields of the radical, and the decrement of each product upon the addition of DPPH are shown in Table III.

TABLE III. *G* VALUES OF RADICALS IN THE RADIOLYSIS OF *n*-BUTANE AND IODINE (or DPPH) MIXTURE[a]

b) The pressure of *n*-butane is 200 mmHg and that of I_2 is 0.3 mmHg.
c) The concentration of I_2 is 0.025 mol./l.
d) The concentration of DPPH is about 0.001 mol./l. ΔCH_4, ΔC_2 and ΔC_3 represent the difference between the initial yield and the molecular yield of methane, C_2-products and C_3-products respectively. This difference can be thought to represent the yield of radical.

The present data on liquid butane are not similar to the reported values.[15] The disagreement seems to be due to the different analytical techniques. McCauley et al. separated the alkyl iodides by fractional distillation, but in the present study iodides were analyzed by gas chromatography.

The yield of the propyl radical is only one-fifth of that of the methyl radical in the gas phase, while in the liquid phase the amounts of methyl and propyl radicals are approximately equal. From this result, it seems that in the liquid phase the homolytic dissociation of the butane molecule into two radicals occurs, while in the gas phase this mode of dissociation is of minor importance. From the mass spectral study, the scission of the first C–C bond of the butane ion is known to produce the propyl ion and the methyl radical, but not the propyl radical or the methyl ion. Since the yield of the methyl radical is extremely high as compared with that of the propyl radical in the gas phase radiolysis, the dissociation of the butane ion seems to occur in the gas phase.

Conclusion

From these discussions it seems that the fragmentation of butane ion is important in the gas phase radiolysis, but that in the condensed phases that of the butane molecule is important. The main reactions are as follows:

Solid and liquid radiolyses

$$n\text{-}C_4H_{10} \sim\sim\rightarrow n\text{-}C_4H_{10}' \rightarrow C_3H_7 + CH_3$$
$$\searrow 2\ C_2H_5$$
$$C_3H_7 + n\text{-}C_4H_{10} \xrightarrow[\text{solid, liquid}]{} C_3H_8 + C_4H_9$$
$$C_3H_7 + R \xrightarrow[\text{liquid}]{} C_3H_6, \text{ Products}$$

Gas radiolysis

$$n\text{-}C_4H_{10} \sim\sim\rightarrow C_4H_{10}^+ \rightarrow C_3H_7^+ + CH_3$$
$$\searrow C_2H_5^+ + C_2H_5$$
$$C_3H_7^+ + n\text{-}C_4H_{10} \longrightarrow C_3H_8 + C_4H_9^+$$
$$C_4H_9^+ + e \longrightarrow C_4H_8, \text{ Products}$$

N. B. C_4H_{10}' represents a neutral precursor of fragmentation.
R represents some radicals.

We wish to express our appreciation to Dr. Shin Sato for his very valuable suggestions and to Mr. Kiyoshi Furukawa and Mr. Tomoyoshi Kudo for their fruitful discussions. We appreciate also the help of the Japan Atomic Energy Institute in performing the irradiation.

A Method of Synthesizing Pure Violanthrene

By Junji Aoki

(Received April 28, 1964)

Zinc dust fusion is a convenient and excellent method for obtaining aromatic hydrocarbons from their quinones.[1] The preparation of violanthrene (III) from violanthrone (II) is a mere application of the above method, but little attention has been paid to the purity of violanthrone. This quinone as usually supplied is one of the condensation products obtained by the alkali fusion of benzanthrone (I). It is, therefore, unavoidable that by-products[2] are mixed in it as impurities. Among these by-products, violanthrone B and all the other substances except isoviolanthrone (IV) can be removed by means of the differences in their solubility and vattability, but the removal of isoviolanthrone is very difficult since isoviolanthrone is as vattable at 55~60°C and as difficult to dissolve in organic solvent as is violanthrone. Although the proportion of isoviolanthrone decreases as the temperature of alkali fusion is raised,[3] it has been found by the author that, even in a sample prepared under proper conditions, 6~7 per cent of the sample is isoviolanthrone.[4]

When the zinc dust fusion was applied to such a sample, isoviolanthrone was also reduced to isoviolanthrene (V). In consequence, a mixture of violanthrene and isoviolanthrene was obtained as the reduction product; the separation of these two hydrocarbons was also very difficult. It may, therefore, be asserted that, in seeking to obtain pure violanthrene, such material must not be used.

The reliable sample of pure violanthrene which had been prepared by the present author from pure violanthrone synthesized by Scholl's mothod[5] (Scheme 1) gave the absorption spectrum shown in Fig. 1. It has one high peak at 496 mμ, and the peak at 365 mμ is lower than that at 385 mμ. On the other hand, the absorption spectrum of isoviolanthrene has two high peaks, at 363 and 521 mμ (Fig. 1).

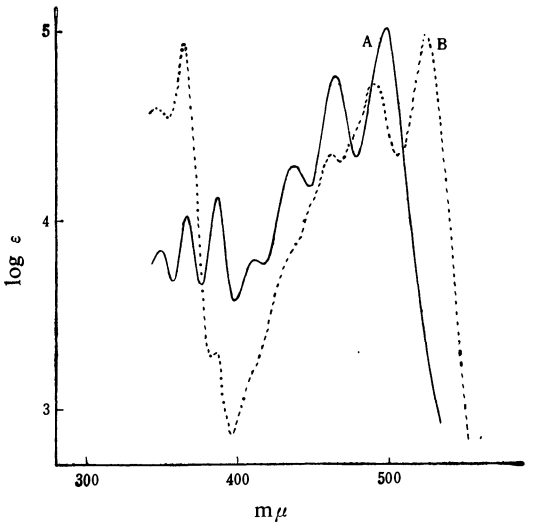

Fig. 1. Absorption spectra of violanthrene (A) and isoviolanthrene (B) (in 1,2,4-trichlorobenzene).

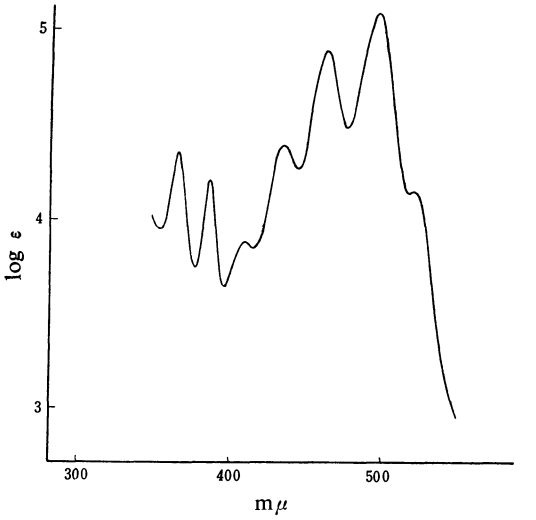

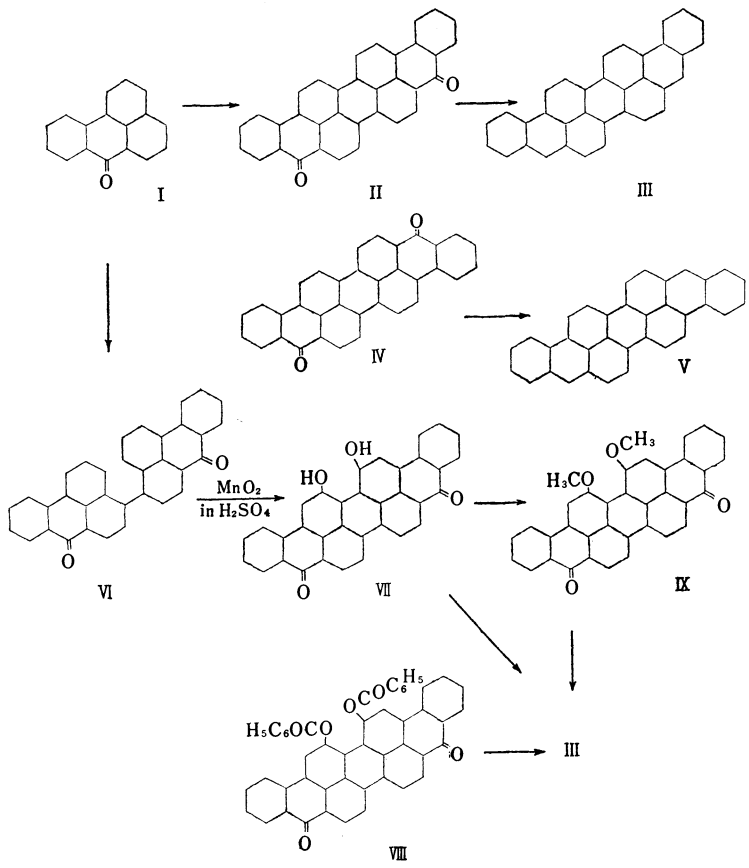

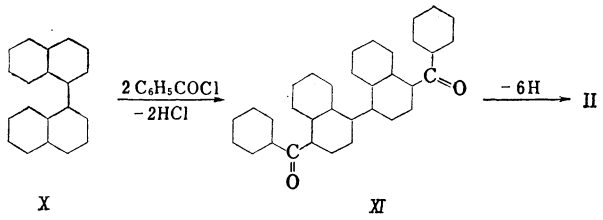

Fig. 2. Absorption spectrum of violanthrene contained isoviolanthrene (in 1,2,4-trichlorobenzene).

However, the absorption spectrum of the reduction product obtained from violanthrone containing isoviolanthrone was very characteristic, as is shown in Fig. 2. As a result of the

5) R. Scholl and Chr. Seer, *Ann.*, **394**, 171 (1912).

Scheme 1

presence of isoviolanthrene, it has a low peak at nearly 520 mμ, and the peak at nearly 365 mμ is unexpectedly higher than that at nearly 385 mμ. These facts confirm that violanthrone, the material needed to obtain pure violanthrene, must be supplied by means of Scholl's method, not by alkali fusion.

However, Scholl's method, which was devised for the determination of the structure of violanthrone, is not an adequate synthetic method, since it consists of many steps and contains processes difficult to perform.

The present author has found, however, that the zinc dust fusion of 16, 17-dihydroxyviolanthrone (VII),[6] its dibenzoate (VIII) and a dimethyl ether (IX) gives pure violanthrene. Since the dimethyl ether, 16,17-dimethoxyviolanthrone, is a component of "Indanthrene Brilliant Green FFB" and since 16, 17-dihydroxyviolanthrone is its intermediate product, these substances can be readily supplied.

Consequently, the above facts indicate an advantageous method of synthesizing pure violanthrene; the author especially recommends the use of the dibenzoate of 16, 17-dihydroxyviolanthrone, since this substance can be readily purified by recrystallization.

6) This substance should be prepared from 4, 4'-dibenzanthronyl (VI), as will be described below. Although it is obtained by the oxidation of violanthrone, the purity of the raw material is again questionable.

7) C. S. Schoepfle, *J. Am. Chem. Soc.*, **45**, 1569 (1924).

8) T. Maki and M. Maezawa, This Bulletin, **28**, 77 (1955).

In addition, judging from the facts that these materials are applied to obtain the pure sample of violanthrene, it may be considered that these substances contain little or no isomer of the isoviolanthrone type, because the cyclization of 4,4'-dibenzanthronyl is carried out by the action of manganese dioxide in a concentrated sulfuric acid, not by alkali fusion.

Experimental

Violanthrone (II) (Scholl's Method). — This material was synthesized in the steps shown in Scheme 1. Dinaphthyl (1,1') (X) was prepared from α-bromonaphthalene by the method described in Ref. 7. From this product, violanthrone was synthesized following Scholl's method.[5] The crude product was refluxed with 100 parts of chlorobenzene for 2 hr., and the soluble impurities were removed by hot filtration. Further purification was carried out by the vatting method. Thus pure violanthrone was obtained.

Yield: 0.6 g. of II from 1.0 g. of XI, 1.6 g. of XI from 2.5 g. of X, and 3.2 g. of X from 50 g. of α-bromonaphthalene.

16,17-Dihydroxyviolanthrone (VII). — The synthesis was carried out by the method described in Ref. 8.

Dibenzoate (VIII).—A mixture of 2.0 g. of VII, 2.0 g. of pyridine and 200 g. of *o*-dichlorobenzene was refluxed for 30 min. Then, 4.5 g. benzoyl chloride was added, and boiling was continued for 30 min. After standing overnight, the reaction mixture was filtered to remove the unchanged substance as the insoluble material (0.9 g.). The filtrate was slightly warmed and 100 ml. of alcohol added, giving fine black needles with a certain green brightness. Yield: 1.5 g.; m. p. higher than 400°C. This product, 16,17-dibenzoate, is soluble in an organic solvent; the solution shows a purple color with a strong red fluorescence. In addition, as a result of the examination of the above method, it was found that pyridine was indispensable for this reaction and that more of it was necessary than the mole ratio of benzoyl chloride,

Found: C, 82.58; H, 3.53. Calcd. for $C_{48}H_{24}O_6$ (VIII): C, 82.75; H, 3.47%.

16,17-Dimethoxyviolanthrone. — "Indanthrene Brilliant Green FFB" (Mitsui Chemical Industries Ltd.) was refluxed with 50 parts of 96, 60 and 20 % alcohol successively; the insoluble part was then collected, washed with water, and dried. This material, after the water-soluble substances had been removed, was finely powdered, refluxed with 100 parts of chlorobenzene for 2 hr. and the insoluble part used as the sample.

Zinc Dust Fusion (Violanthrene).—Violanthrone or its derivative was treated as in Ref. 9.

The sample of Fig. 2 was prepared from impure violanthrone (violanthrone 92.7, isoviolanthrone 7.3 %[10]); by comparing the absorption spectra, the amount of isoviolanthrene in this reduction product was estimated at about 10 per cent.

The author wishes to thank Mrs. Yasuko Usui for her assistance during the dibenzoate experiment.

10) This value was obtained from the absorption spectra in concentrated sulfuric acid. The details will be dealt with in a later report.

The Spectrophotometric Determination of Trace Amounts of Arsenate and Arsenite in Natural Waters with Special Reference to Phosphate Determination

By Ken SUGAWARA and Satoru KANAMORI

(Received April 6, 1964)

The current methods for the determination of arsenic,[1-5] in which molybdoarsenate or its reduction product, "*molybdenum blue*", is determined spectrophotometrically, are only applicable to microgram quantities of the element and are inconvenient for usual natural waters, the arsenic content of which is from several tenths to several micrograms per liter. It is a time-consuming and laborious work to concentrate the necessary liters of a sample. Furthermore, when the available amount of the sample is limited or the sample is extremely

1) N. W. Rakestraw and F. B. Lutz, *Biol. Bull.*, **65** 397 (1933).
2) S. Gorgy, N. W. Rakestraw and D. L. Fox, *J. Mar. Research*, **7**, 22 (1948).

diluted, the methods are useless.

The present authors have previously reported a spectrophotometric method for determining submicrogram quantities of orthophosphate in natural waters.[6] The principle was to isolate molybdophosphate by solvent extraction, to liberate molybdate by decomposition from the extracted molybdophosphate in which the molybdenum is coordinated to phosphate in the ratio of 1 : 12, and finally to determine the liberated molybdenum spectrophotometrically.

In the present work the authors have extended this principle so that it is possible to separately determine 0.01~1.00 μg. of phosphate-P, 0.02~2.00 μg. of arsenate-As, and 0.02~2.00 μg. of arsenite-As from a sample smaller than 250 ml.

The method consists of the following five steps: 1) Phosphate and arsenate are extracted as molybdophosphate and molybdoarsenate successively with the proper solvents. 2) The arsenite in the remaining solution is oxidized into arsenate. Then the arsenate is extracted according to step 1. 3) The three fractions, phosphate, arsenate and arsenite, are washed. 4) The respective heteropolymolibdate are stripped and subjected to decomposition, with the liberation of free molybdate. 5) The liberated molybdate is spectrophotometrically determined as thiocyanate for the respective fractions.

Experimental

Apparatus. — The absorbance is measured by the use of a Beckman spectrophotometer, type DU, with 10 mm. cells of Pyrex glass.

All glass vessels must be free from any contamination of arsenic. Especially, it is recommended that the 500 ml. separatory funnel for the extraction of molybdoarsenate be washed with hot mineral acid for several days.

Reagents. — All reagents should be of the analyzed reagent grade, and water distilled with copper still must be used.

Ascorbic Acid: a 0.05% aqueous solution.

Hydrochloric Acid: concentrated. One milliliter of methanol is added per liter of the acid to reduce the trace of chlorine.

n-Butanol, Chloroform and Acetone: distilled.

Solvent A: *n*-butanol and chloroform are mixed in a 4 : 6 proportion by volume.

Solvent B: *n*-butanol, chloroform and acetone are mixed in a 3 : 7 : 3 proportion by volume.

Ammonium Molybdate: a 10% aqueous solution.

Washing Solution A: 60 ml. of *n*-butanol and 40 ml. of concentrated nitric acid are dissolved to 1 l. with distilled water.

Washing Solution B: 60 ml. of *n*-butanol, 140 ml. of acetone, and 10 ml. of concentrated nitric acid are dissolved to 1 l. with distilled water.

Potassium Iodate: a saturated aqueous solution.

Sodium Hydroxide: a 1 N aqueous solution.

Ferrous Ammonium Sulfate: 1 g. of the hexahydrate is dissolved in 100 ml. of 0.2 N sulfuric acid.

Potassium Thiocyanate: a 10% aqueous solution.

Stannous Chloride: 10 g. of the dihydrate is dissolved in 100 ml. of 1 N hydrochloric acid.

Phosphate Standard Solution. — A stock solution containing 1 mg. of phosphate-P per ml. is prepared by dissolving 0.439 g. of potassium dihydrogen phosphate to 100 ml. with distilled water. The addition of a few drops of chloroform keeps the solution from a mold growth. The working standard solutions are prepared by properly diluting the stock solution.

Arsenite Standard Solution. — A stock solution containing 1 mg. of arsenite-As per ml. is prepared as follows, 0.132 g. of arsenic trioxide is dissolved in 10 ml. of a 1 N sodium hydroxide solution, slightly acidified with diluted hydrochloric acid and made up to 100 ml. This stock solution is properly diluted for the preparation of working standard solutions.

Arsenate Standard Solution. — One milliliter of an arsenite stock standard solution is evaporated up with 20 ml. of concentrated nitric acid and 1 ml. of concentrated hydrochloric acid on a water bath, and then the residue is dissolved in hot water and properly diluted.

Procedure. — *The Separation of Phosphate, Arsenate and Arsenite.* — Into a 500 ml. separatory funnel, 250 ml. of a sample water, 0.3 ml. of an ascorbic acid solution, 4 ml. of hydrochloric acid, 15 ml. of *n*-butanol, and 10 ml. of solvent A are taken; the funnel is then shaken for 3 min. to saturate the aqueous phase with solvent A. The addition of the ascorbic acid protects the arsenite from any possible oxidation, leaving the coexisting phosphate and arsenate untouched. The organic layer is replaced by a new 5 ml. of solvent A. After 2.5 ml. of the ammonium molybdate solution is added, the funnel is immediately shaken for 3 min. The extract is transferred to a 100 ml. separatory funnel. The extraction is repeated with another 5 ml. of solvent A. For the determination of phosphate, these two extracts of the phosphate-fraction are combined in a 100 ml. separatory funnel.

The remaining aqueous phase is again subjected to extraction by two or more 5 ml.-portions of the solvent A to remove the last trace of phosphate. Then 7.5 ml. of the ammonium molybdate solution and 35 ml. of acetone are added to the funnel and the arsenate is extracted by shaking the mixture for 3 min. with two 5 ml.-portions of solvent B. For the determination of arsenate, these two extracts of the arsenate fraction are combined in a 100 ml. separatory funnel.

The remaining aqueous phase is extracted with two or more 5 ml.-portions of solvent B to ensure the complete separation of the arsenate. Then 5 drops of a saturated potassium iodate solution are added to oxidize the arsenite to arsenate. The arsenate thus formed is extracted according to the step for the separation of arsenate described above,

6) K. Sugawara and S. Kanamori, This Bulletin, **34**, 258 (1961).

and the extracts of the arsenite fraction are combined in a 100 ml. separatory funnel.

*The Determination of Phosphate**. — The phosphate fraction separated above is shaken for 3 min. with 50 ml. of washing solution A to wash out any uncombined molybdate and any contaminative heteropolymolybdate other than molybdophosphate. The remaining organic layer is then transferred to a 50 ml. separatory funnel. After the addition of 10 ml. of the 1 N sodium hydroxide solution the funnel is shaken for 1 min. to strip the molybdophosphate completely from the oily phase, and then the organic layer is drawn off. Next, 3 ml. of concentrated hydrochloric acid, 1 ml. of the ferrous ammonium sulfate solution, 3 ml. of the potassium thiocyanate solution and 3 ml. of the stannous chloride solution are successively added. The molybdenum thiocyanate with an amber color is extracted with two small portions of solvent A. The extract is made up to 5 ml. in order to subject it to spectrophotometry at 475 mμ. Here, to protect the ferrous iron from oxidation, the addition of a few small crystals of stannous chloride to the joint extract is recommended.

The Determination of Arsenate. — The arsenate fraction is shaken with two 50 ml.-portions of washing solution B for 3 min. Through the washing process, only molybdoarsenate remains in the organic phase; the other molybdenum compounds contaminating the molybdoarsenate are washed out.

The organic layer is transferred to a 50 ml. separatory funnel in order to subject it to the stripping of molybdoarsenate with an alkali solution and to the final step of spectrophotometry, as has been described in the determination of phosphate.

The Determination of Arsenite. — The extract of the arsenite fraction is processed as described in the determination of arsenate.

Discussion

The Separation of Phosphate, Arsenate and Arsenite.—*The Extraction of Molybdophosphate.* —Figures 1 and 2 show the relation of the percent extraction of phosphate, arsenate, germanate and silicate as respective heteropolymolybdates to the acidity in hydrochloric acid and to the concentration of ammonium molybdate in the sample solution before extraction. When the concentration of ammonium molybdate is fixed at 0.08%, the extraction of molybdophosphate is practically complete at the acidity of higher more than 0.19 N and when the acidity is fixed at 0.19 N, it is complete at the concentration of ammonium molybdate of higher more than 0.08%. More-

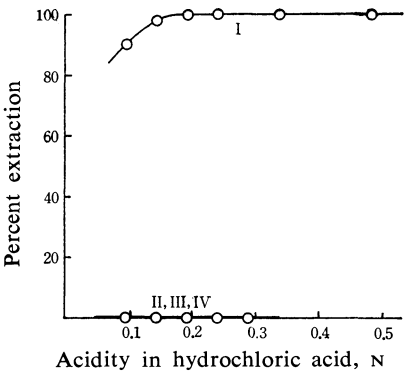

Fig. 1. Percent extraction of phosphate, arsenate, germanate and silicate and the acidity of aqueous phase before extraction.
I: Phosphate II: Arsenate
III: Germanate IV: Silicate
The concentration of ammonium molybdate: 0.08%

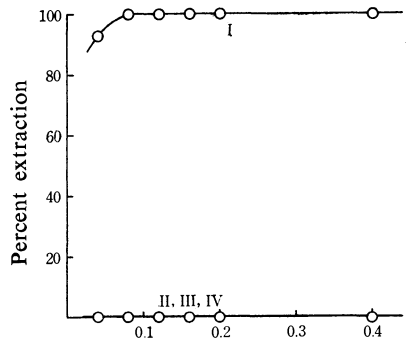

Fig. 2. Percent extraction of phosphate, arsenate, germanate and silicate and concentration of ammonium molybdate before extraction.
I: Phosphate II: Arsenate
III: Germanate IV: Silicate
The acidity in hydrochloric acid: 0.19 N

over the extraction of the other ions is less than 0.3% in the whole range examined and shows a tendency to increase with the acidity and the concentration of molybdate. Accordingly, the acidity of 0.19 N and the concentration of ammonium molybdate of 0.1% are chosen as the optimum conditions for the extraction of phosphate, under which conditions the other ions are extracted in percentages of less than 0.01%.

The Extraction of Molybdoarsenate.—Figures 3 and 4 show the relation of the percent extraction of arsenate, germanate and silicate as respective heteropolymolybdates to the acidity in hydrochloric acid and to the concentration of ammonium molybdate. When the concentration of ammonium molybdate is fixed

* When more than 2 μg. of phosphate-P is treated with, 2 ml. of the stannous chloride solution and 10 ml. of chloroform are added to the extract, which is then swirled to reduce the extracted molybdophosphate to the "molybdenum blue" completely. Then, 10 ml. of 1 N hydrochloric acid is added and the funnel is shaken for 1 min. to back-extract the "*molybdenum blue*" into the aqueous phase, which is subjected to spectrophotometry at 740 mμ.

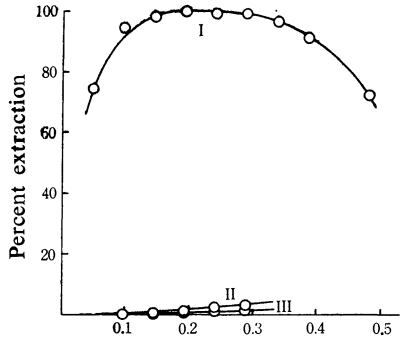

Fig. 3. Percent extraction of arsenate, germanate and silicate and acidity of aqueous phase before extraction.
I: Arsenate II: Germanate III: Silicate
The concentration of ammonium molybdate: 0.1%

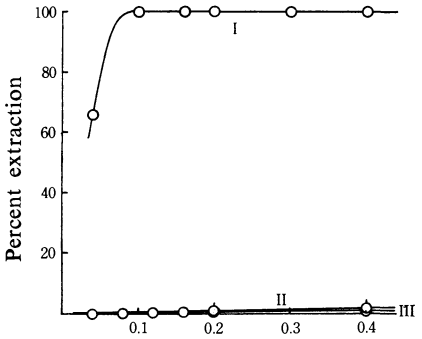

Fig. 4. Percent extraction of arsenate, germanate and silicate and concentration of ammonium molybdate in aqueous phase before extraction.
I: Arsenate II: Germanate III: Silicate
The acidity in hydrochloric acid: 0.19 N

at 0.1%, the extraction of arsenate is complete in the acidity range from 0.19 N to 0.24 N, and when the acidity is fixed at 0.19 N, it is complete at the concentration of ammonium molybdate of higher more than 0.1%. Moreover, the extraction of the other ions increases with the acidity and the concentration of molybdate up to 4 per cent. However, as will be shown later, a large amount of silicate interefers with the extraction of arsenate, because a considerable amount of molybdate is consumed by the silicate. Therefore, the acidity of 0.19 N and the concentration of ammonium molybdate of 0.4% are chosen as an appropriate conditions under which germanate and silicate are extracted in percentages as small as 1.5% and 0.5% respectively.

The Washing of the Extracts.—*The Washing of the Phosphate Fraction.*—Figure 5 shows the

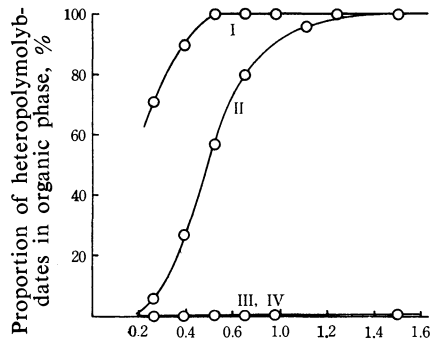

Fig. 5. Distribution of heteropolymolybdates of phosphate, arsenate, germanate and silicate and acidity of aqueous phase.
I: Molybdophosphate
II: Molybdoarsenate
III: Molybdogermanate
IV: Molybdosilicate

distribution of four heteropolymolybdates between 10 ml. of solvent A and 50 ml. of the 6% *n*-butanol aqueous solution at various acidities in nitric acid. The molybdophosphate remains completely in the organic phase at an acidity of higher more than 0.52 N, while almost all of the molybdogermanate and molybdosilicate is in the aqueous phase, and the proportion of molybdoarsenate in the organic phase increases with the increase in acidity. When the phosphate fraction of the extracts is washed with washing solution A (0.52 N in acidity), 57% of molybdoarsenate and less than 0.5% of the other heteropolymolybdates remain in the organic phase.

TABLE II. APPLICATION OF THE PRESENT METHOD TO NATURAL WATERS

Sample	Sample taken ml.	Added Phosphate -P μg.	Added Arsenate -As μg.	Added Arsenite -As μg.	Found Phosphate -P μg.	Found Arsenate -As μg.	Found Arsenite -As μg.
Ground water from a well on the campus of Nagoya University	250	0	0	0	11.3	0.08	0.03
	250	3.0	0.05	0.05	14.2	0.14	0.07
Sea water from the north-western Pacific Ocean (33°12'N; 139°53'E)	250	0	0	0	13.6	0.25	0.13
	250	2.0	0.50	0.50	15.8	0.76	0.63

of solvent B and 50 ml. of a washing solution containing 6% *n*-butanol and 14% acetone at various acidities in nitric acid is shown in Fig. 6. The molybdoarsenate remains completely in the organic phase at an acidity of higher more than 0.10 N, and a small proportion of the other ions remains in the organic phase, although this proportion increases with the acidity. At the acidity of 0.13 N in washing solution B, less than 1% of molybdogermanate and molybdosilicate remain in the organic phase. Usual natural waters contain several milligrams of dissolved silica per liter, and, therefore, duplicated washing is needed to get exact results for arsenate determination.

Standard Curve. — The standard curves for phosphate-P and arsenate-As are shown in Fig. 7.

The molecular extinction coefficients were measured as 15.5×10^3 for molybdenum thiocyanate and as 185×10^3 and 184×10^3 for phosphate- and arsenate-equivalents respectively. Therefore, the P/Mo and As/Mo ratios in the extracted chemical species are 12.0 and 11.9 respectively; this shows that both extracted molybdophosphate and molybdoarsenate are 12-acid.

As is shown in Fig. 7, the sensitivity of the present method is high enough to be applicable to natural waters with no need to concentrate samples previously.

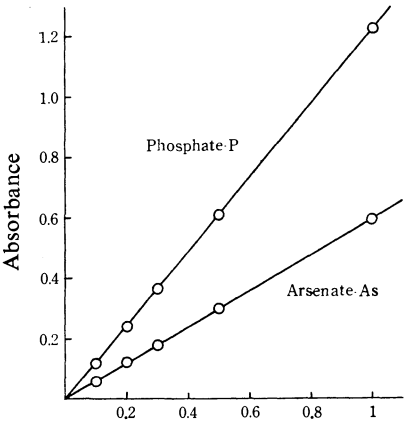

Fig. 7. Standard curves.

Interference

The detailed discussion of the successive isolation of phosphate, arsenate and arsenite

in the previous section suggests an applicability of the present method to the analysis of trace amounts of these ions in the presence of considerable amounts of germanate and silicate. This is also proved to be satisfactory by the results listed in Table I. Thus, 200 μg./l. each of arsenate-As and arsenite-As, 2 mg./l. of germanate-Ge, and 20 mg./l. of silicate-Si do not interfere with the determination of phosphate. One hundred micrograms of phosphate-P, 2 mg./l. of germanate-Ge, and 4 mg./l. of silicate-Si do not interfere with the determination of arsenate or arsenite, but 20 mg./l. of silicate-Si shows a marked negative interference; this is avoided by the extraction of molybdoarsenate at an increased concentration of ammonium molybdate (1.2%).

Large amounts of titanium(IV), vanadium(V) and tungsten(VI) interfere, but they are tolerated up to the concentrations of 20 μg./l., 20 μg./l. and 200 μg./l. respectively.

Sodium, potassium, calcium, magnesium, chloride, sulfate and nitrate cause no interference up to the concentrations found in sea water.

When a sample contains some oxidizing agent, there is danger that a part of the arsenite will be converted to arsenate during the process of analysis. The addition of a small amount of ascorbic acid will protect the arsenite from this oxidation.

Examples of the application of the present method to natural waters are listed in Table II.

The authors wish to thank Dr. Motoharu Tanaka for his many helpful discussions and suggestions during this work.

On the Study of the Copper Chelates of Ephedrine and Related Compounds. II. The Crystal Structure of the Bis-l-ephedrine Copper(II) Chelate Benzene Clathlate

By Yoshiharu AMANO, Kenji OSAKI* and Tokunosuké WATANABÉ**

(Received April 23, 1964)

As is well known, when a copper(II) salt is added to an aqueous solution of *l*-ephedrine in the presence of alkali hydroxide, the color of the solution changes to blue-violet. If the mixture is extracted with *n*-hexane or benzene, a reddish-violet solution is obtained; from it well-defined crystals can be obtained. In a previous paper,[1] it was concluded that the crystal consisted of bis-*l*-ephedrine copper(II) chelate (abbreviated as ephedrine copper chelate in the following), and that the copper atom had a square-planar coordination.

Ephedrine copper chelate exhibits peculiar properties. It reacts at room temperature with carbon tetrachloride of other halogenated hydrocarbons, yielding chloride ions and the oxidation products of ephedrine.[2] It dissolves easily in non-polar solvents such as *n*-hexane in spite of having hydrophillic groups in its molecule.

In order to clarify the above-mentioned peculiar properties of the ephedrine copper chelate, a crystal structure analysis of this compound was conducted; the experimental results obtained and a discussion based on the structure will be presented below.

Experimental

Efforts were made to prepare single crystals of the ephedrine copper chelate, crystals suitable for X-ray crystal structure analysis. From a benzene solution, hexagonal plates or prisms a deep violet in color were obtained. These crystals have a cleavage plane parallel to the hexagonal basal plane. The examination, by means of ultraviolet absorption, of the volatile components of the solution obtained by dissolving these crystals in *n*-hexane showed the presence of a benzene molecule in the crystal. The results of the elemental analysis also suggest that the crystal contained two benzene

(2) $(C_{10}H_{14}ON)_2 \cdot Cu \cdot 2/3C_6H_6$

molecules per three chelate molecules. The results of the elemental analysis are shown in Table I.

The unit cell dimensions were determined by precession photographs. These photographs show that the Laue symmetry of the crystal is $\bar{3}$m. There remain two possible space groups, P312 and P321, on the basis of the extinction rules and the Laue symmetry. In these two space groups, the mirror planes of the reciprocal lattice have different orientations with respect to the crystal axes. From the examination of the symmetry of the reciprocal lattice, it was found that .there are mirror planes parallel to the a*c* planes. Therefore, it was concluded that the space group is P321-D_3^2 and that the a-axis is a two-fold axis. The density as calculated from the composition, $(C_{10}H_{14}ON)_2 \cdot Cu \cdot 2/3C_6H_6$, as was suggested by the elemental analysis, agreed with the observed value.

The specimens for the intensity measurements were cut out along the a- and c-axes from hexagonal plates or prisms. The sets of intensities were obtained from equi-inclination Weissenberg photographs using both multiple-films and varying exposures, with copper $K\alpha$ radiation filtered through nickel foil. The zeroth to third layers about the a-axis and the zeroth layer about the c-axis were recorded.

The intensities were estimated by visual comparison with a calibrated intensity scale prepared with the same specimen and reduced to the same scale.

Corrections for Lorentz and polarization factors were applied in the usual way, but none were made for absorptions since μr is 0.37 for the a-axis specimen and 0.47 for the c-axis specimen. The preliminary scale factor and temperature factors were determined by Wilson's method and were further improved during the later stages of the refinements. The crystallographic data are shown in Table II.

The Determination of the Structure

The number of atoms in the unit cell gives the following information. The copper atoms must lie on the two-fold symmetry axis, so that the chelate molecule has the two-fold rotational symmetry. The center of the solvated benzene molecule lies on the three-fold axis.

Because the a-axis is shorter than the c-axis, we first attempted to proceed with a projection corresponding to the ($h0l$) reflections and to use the other layer-line spectra to confirm the structure. The sharpened Patterson synthesis using the ($h0l$) reflections showed that the copper atom was located at a position with $x=0$, $y=0.1935$, and $z=0$. This conclusion agreed with the results of the vector analysis.

A trial model was set up from this Patterson map using the vector convergence diagram method and also on the basis of the molecular packing. The solvated benzene molecules were disregarded at this stage.

On the basis of this trial model, the values of the $F(h0l)$ were calculated. From a comparison of these with the observed structure amplitudes, it was possible to deduce the signs of about one-third of all the $F(h0l)$ reflections obtained. Using these signs, the first Fourier synthesis was calculated. In this projection, there appeared, in addition to the expected peaks of the atoms of the copper chelate, an extended hill-like cluster almost perpendicular to the z-axis and symmetrically situated with respect to the three-fold axis. It was suggested that this hill-like cluster be the projected structure of the solvated benzene molecule. This was thought admissible because the space which the benzene molecule is to occupy corresponds to quite a large hole between the copper chelates. It was further suggested that the six carbon atoms of the benzene molecule are statistically distributed along the ring which has a radius of 1.39Å. Therefore, the effect of the benzene molecule was added in the following computations of the structure factor, where each carbon atom was assumed to lie at four equally-spaced positions with a weight of 1/4.

After several successive Fourier and difference Fourier refinements, the R values for 259 $F(h0l)$ and 49 $F(hk0)$ reflections became 26.5% and 18.8% respectively.

The Refinement of the Structure

The positional and thermal parameters were refined by the three-dimensional least-squares method using the $(h0l)$, $(h1l)$, $(h2l)$ and $(h3l)$ structure factors. The positional and isotropic individual thermal parameters were refined by disregarding the off-diagonal terms other than the x, y-interaction terms, to minimize the value of $\sum w||F_o|^2-|F_c|^2|^2$. The weights applied to the terms were:

$w = 30/|F_o|$ for $30 \leq |F_o|$

After each cycle of the refinements, the positional and thermal parameters of the atoms of the copper chelate were improved. Those of the carbon atoms of the benzene molecule, however, showed unreasonable shifts. Therefore, no shifts were applied to the parameters of the benzene molecule. After several cycles of least-squares, the R value was reduced to 16.3% for all the reflections used, including the non-observed reflections.

At this stage, we tried to see if any model of the structure with the benzene molecule at

a definite orientation would improve the structure factors. The structure factors were calculated by using the parameters obtained for the atoms of the copper chelate, and by adding the contribution of the benzene molecule in either of the four sets of coordinates listed in Table III. No significant differences were found in the R values among the four sets of the carbon atoms and the statistical model described earlier. However, the R value increased to 23.1% if we disregarded the contributions of the benzene molecule. The final set of positional and thermal parameters corresponding to the statistical model is listed in Table IV. The observed and calculated structure factors are reproduced in Table V.

A Description and Discussion of the Structure

The intermolecular bond lengths and angles of the copper chelate molecule as calculated on the basis of the above atomic parameters are shown in Fig. 1. Although the accuracy of the results is not still adequate to enable us to discuss the bond lengths and angles quantitatively, the overall stereochemical relation of the atoms in the copper chelate molecule and the mutual disposition of the copper chelates are clear.

Molecular Structure. — In a previously reported paper,[1] it was concluded that the hydrogen atom of the alcoholic hydroxyl group of the ephedrine molecule was replaced by the copper ion in the chelate formation, and also that the chelate ring was built by a four-coordinated square-planar configuration. The results of the X-ray crystal structure analysis not only confirmed the above prediction, but also led to useful information about the structure, as will be described below.

The copper atom lies on the two-fold rotational axis and is surrounded by two oxygen and two nitrogen atoms in a square configuration. These four atoms are almost coplanar with the copper atom, and there are no atoms

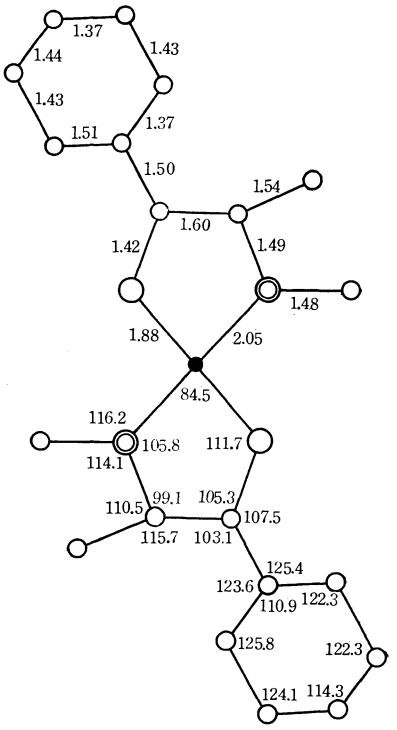

Fig. 1. Interatomic bond lengths and angles.

between the copper atoms in the adjacent unit cells in the direction perpendicular to the plane of the square. As is well known, however, the majority of cupric compounds, have distorted octahedral configurations, in agreement with the conclusions of the theory of Orgel[3] based on the Jahn-Teller effect.[4] In the ephedrine copper chelate, therefore, its configuration can be regarded as a limiting case of the usual distorted octahedral configuration with two ligands completely removed. This configuration of the copper chelate coordinated through the alcoholic hydroxyl group of the ephedrine molecule, without using two available orbitals, would be related to the peculiar property of the ephedrine copper chelate, namely, its reactivity with the halogenated hydrocarbons,[2] and also

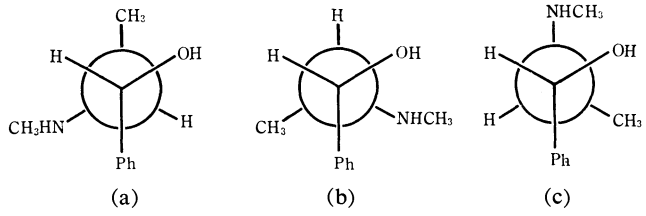

Fig. 2. Conformations of ephedrine molecule.

to its light absorption associated with copper-(II), which has its maximum at 518 mμ.

With respect to the ephedrine molecule, there are three possible conformations (cf. Figs. 2 (a), (b) and (c)). Conformation (a) has been proposed for the free ephedrine molecule by Close.[5] For the ephedrine molecule of the copper chelate, however, there remain two possible conformations, (b) and (c), bacause the nitrogen and oxygen atoms must be close together to form a chelate with the copper atom. The conformation of the ephedrine molecule of the copper chelate as found by present investigation is concluded to be the conformation (c), which is the same as that reported for ephedrine hydrochloride.[6]

Intermolecular Relation of the Chelate.— Although the positions of the hydrogen atoms were not determined, the existence of the hydrogen bonds can be inferred from the observed interatomic distances and from the possible distribution of the hydrogen atoms. In this crystal, three chelate molecules related by the three-fold symmetry form a trimer structure by means of six hydrogen bonds, as is shown in Fig. 3. In this trimer structure, the normals of the three square planes formed by the copper, oxygen and nitrogen atoms point to the three-fold symmetry axis. The distance between the two copper atoms in the trimer molecule is 4.07Å, which is the shortest copper-copper atom distance in this crystal. There will be no direct coupling between these copper atoms. The main force forming the trimer structure would be the six intermolecular hydrogen bonds of the NH···O type.

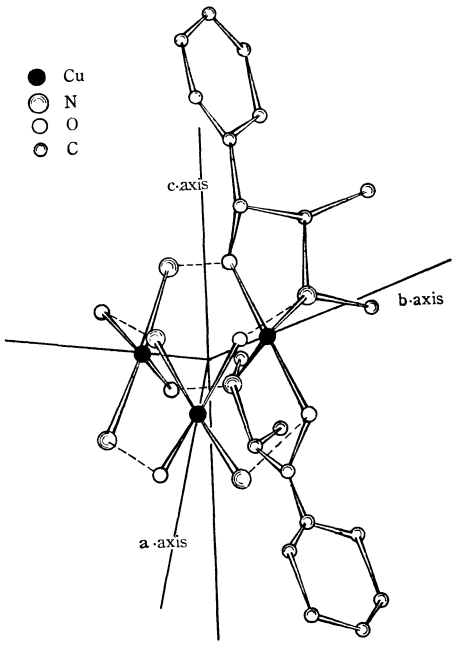

Fig. 3. Trimer structure of chelate molecule.

An infrared absorption spectrum of the crystal had already shown the presence of a hydrogen-bonded N–H stretching band, the type of molecular association which existed in the crystal had not yet been determined. This problem can now be interpreted, without any doubt, on the basis of the trimer structure of the chelate molecule described above. The observed absorption frequeny, 3130 cm^{-1}, in the infrared absorption spectrum agrees well with the value

obtained from the intermolecular N(H)–O bond length (2.87Å), using the table given by Nakamoto et al.[7]

The ephedrine copper chelate is easily soluble in non-polar solvents, such as *n*-hexane or benzene. This indicates that the ephedrine copper chelate still retains its trimer structure in these solvents, because it is hardly acceptable that the monomer chelate molecule with hydrophillic groups would dissolve in non-polar solvents. In fact, the absorption spectrum of the crystal is almost identical with the spectrum of its *n*-hexane or benzene solution in the visible region.

Molecular Packing.—The arrangement of the trimer chelate molecules in this crystal structure leaves two large cavities in the unit cell; the benzene molecules are enclosed in these cavities (Fig. 4 and Fig. 5). This crystal can, therefore, be considered to be a sort of clathlate compound. Namely, the trimer chelate is the host, and the benzene the guest molecule. It may be suggested that these benzene molecules are also responsible for holding together the trimer chelate molecules by virtue of the van der Waals attraction forces. It is highly probable that they rotate or are distributed statistically about the symmetry axis.

Throughout this study, the calculation of the structure factor, the Fourier summation and the least-squares method were carried out on the NEAC 2203 and the NEAC 2206 at the Computation Center of Osaka University, using partial modifications of programs originaly written by one of the authors (K. O.).

Studies of Crystal Hydrates. VII.[1] *The Dielectric Properties of Capillary Water in Single Crystals of* DL-$[Co(en)_3]Cl_3 \cdot nH_2O$*

By Hideaki CHIHARA, Setsuo OKAWA** and Syûzo SEKI

(Received May 1, 1964)

The molecules of water of crystallization in DL-$[Co(en)_3]Cl_3$ hydrate are packed in linear, four-lane array in cylindrical channels which extend in the direction of the crystallographic c axis of this hexagonal crystal.[2] The partial dehydration of the hydrate crystal does not produce any substantial change in its X-ray diffraction patterns; this suggests a zeolitic nature of the dehydration. The thermodynamic properties of the dehydration[3] are also consistent with the structural studies and, further, suggest that the water is in a state similar to capillary-condensed water, such as is found in zeolite minerals. Water molecules in zeolites are usually so mobile that they are detected by means of high-resolution nuclear magnetic resonance at room temperatures.[4] However, the structural studies of zeolites have not been successful in locating the water molecules in the crystal lattice, and even had this been done, the arrangement of water molecules would still be quite complex.

The water molecules in DL-$[Co(en)_3]Cl_3 \cdot nH_2O$, where n runs from 0 to 4, were located by the X-ray diffraction technique; a brief account of the structure and the arrangement of the water molecules has already been given in a previous paper.[3] An investigation into the extent to which these molecules are mobile in the crystalline channels was considered to be of interest; it was also thought that the dielectric absorption study would give us some clue to the mode of motion of the water molecules. A preliminary experiment on the dielectric absorption[3] has shown that a relaxation absorption occurs below room temperature in the radio frequency region; this merits more detailed systematic study.

Experimental

Material. — The powdered DL-$[Co(en)_3]Cl_3$ used was from the same source as has been described previously.[3] Single crystals were grown by slowly cooling the nearly-saturated solution from 40°C. at the rate of about 1°C/day. Hexagonal prism crystals about 1'' long and 3/4'' across were readily obtained; these were shaped with Emery powder and kerosene into disks about 1 mm. thick. Kerosene was washed with benzene, and the crystals were finally polished with a drop of water. The crystals were then stored over powdered DL-$[Co(en)_3]Cl_3 \cdot 3.6H_2O$ for at least a month prior to the measurements in order to secure a uniform water content throughout. In obtaining disks with (0001) faces, drops of water had to be used instead of Emery powder and kerosene because the crystal was readily cleaved parallel to the c axis.

Apparatus and Equipment. — Measurements of the dielectric constant and loss between 40 c./s. and 5 Mc./s. were made with a mutual-inductance bridge of the Cole type[5] (Ando Elec. Co., Model TR-1B), which works between 30 c./s. and 5 Mc./s. Oscillators were of the low-distortion type, General Radio 1301A and Ando Elec. GET-2. A Q-meter of the Yokogawa Elec. Works, Model QM-101, was used to determine rough estimates at higher frequencies in order to check the consistency.

The measuring electrodes were designed so as to chill the specimen close to 90°K and to secure good electrical contacts between the electrodes and the specimen at all temperatures by making allowance for the thermal expansion and contraction of the crystal. Several pieces of measuring apparatus of slightly different designs were constructed; the one which is illustrated in Fig. 1 is typical of them. Here, A is a bakelite base for an electron tube (type Z), C is the glass stem with six Ni lead wires fused in, D are mica-disk spacers, E is a brass electrode (high-impedance side) 5 mm. in diameter and 1 mm. thick, and H is the other electrode (low-impedance side) with a spring of music wire, G, underneath, one end of which is soft-soldered to the electrode, H, and the other end of which is soldered to the supporting brass plate, F. The lead wires J are brass rods 2 mm. thick and are connected to Ni wires at the upper ends with soft solder. The temperature of the crystal was measured with a copper-constantan thermocouple junction, I, which was attached to the lower electrode, H (electrically insulated).

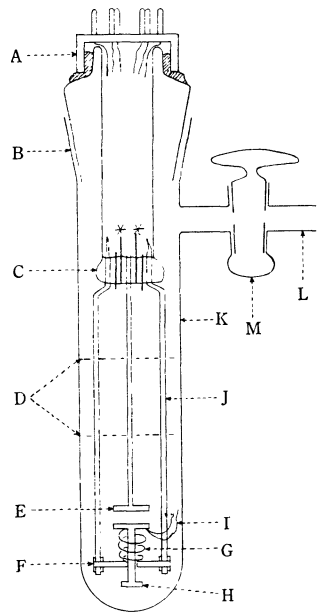

Fig. 1. Sample cell and electrodes for dielectric measurements.

The glass jacket, K, had a side tubing, L, which permitted control of the ambient pressure. The whole jacket was cemented to the six-legged base, A, with an Epoxy resin above the ground-glass joint, B. The apparatus was inserted in a Dewar vessel below the level of L and further placed in a shielded enclosure. To minimize the external disturbances, two of the fused lead wires (* marks in Fig. 1) and one of the thermocouple lead wires were electrically grounded.

Such construction of the apparatus, particularly the use of the base, A, proved to make the calibration procedure easy if a needle-and-mercury switch was employed to reduce the variation of the stray capacitance when the measuring cell was switched on and off.

Determination of the Cell Constants.—As there are no guard electrodes in the apparatus, the edge corrections had to be estimated experimentally. This was done in conjunction with the determination of the stray capacity by referring to the dielectric constant (5.30) of the (001) face of sodium chloride. The apparent total capacity of the cell was determined with single crystals of sodium chloride (aluminum foils of $1\times1\,cm^2$ on either side) of different thicknesses (between 0.99 and 1.37 mm.) inserted between the measuring electrodes. The apparent capacity, plotted against the reciprocal of the crystal thickness, gave a good straight line; the slope gave the cell constant, including the edge corrections, and the intercept gave the stray capacity. This was further checked favorably with a single crystal of potassium chloride ($\varepsilon'_{100}=4.41$).

Procedure and Determination of the Water Content of the Crystal in situ. — The specimen crystals were sandwiched, for the measurements, between aluminum foils $1\times1\,cm^2$ which were glued on the crystal with a very thin film of silicone grease. The thickness of the crystal was measured to within 0.01 mm. and was found to be uniform all over within these limits. The initial water content of the crystal was determined gravimetrically. The practical limit of the hydration of DL-$[Co(en)_3]Cl_3\cdot nH_2O$ is $n=3.6$ at room temperature, as may be seen from the sorption-desorption isotherm.[3] Crystals of a smaller degree of hydration were prepared in the dielectric apparatus. The side tubing (L in Fig. 1) was connected to a vacuum line through a trap with an appendix glass tube with narrow walls. The specimen having been placed, the glass jacket, K, was chilled with liquid nitrogen and evacuated. After the crystal had been warmed to room temperature, some water of crystallization was distilled into the trap cooled with liquid nitrogen for a variable length of time. The distilled water was then recollected in the appendix tube, which was then fused off and weighed. The same procedure was repeated in situ after dielectric measurements had

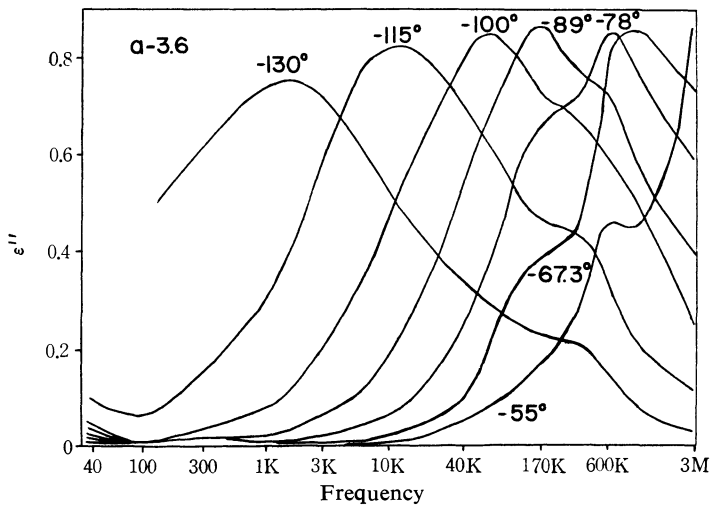

Fig. 2. Dielectric loss of specimen a-3.6.

been made at particular water contents, the final weight of the crystal being used to monitor the accuracy of the amounts of the water distilled between the successive series of dielectric measurements. Usually the total weight of the trapped water and the weight loss of the crystal agreed to within several parts per cent. Where the rate of dehydration is high (for a large n value) it was necessary to cool the crystal during the distillation. For crystals with (0001) flat faces, the distillation was slower than for those with $(10\bar{1}0)$ faces. After a certain amount of dehydration, the stopcock, M, was closed and the crystal was allowed to regain its transparency (quick dehydration often made the surface of the crystal opaque). It took about a week for a new equilibrium to be achieved. Dielectric measurements were made in most cases with a rising temperature at about 1 deg./min. from -170°C at a prefixed frequency. In one case, at -78°C, the apparatus was immersed in a dry ice-petroleum benzine mixture and the frequency was scanned from 40 c./s. to 3 Mc./s. in order to compare it with the other measurements.

Experimental Results and Discussion

The experimental results were converted to plots of ε' or ε'' as a function of the frequency at several selected temperatures; some of them are shown in Figs. 2 through 5, where a-3.6, for example, denotes that the external electric field was perpendicular to the $(10\bar{1}0)$ or a plane (i.e., perpendicular to the axis of the channel) and that the water content of the crystal was 3.6 mol. per formula unit of the salt.

The anomalous dispersion and absorption were found to depend on the water content of the crystal and are apparently associated with some motion of the water molecules in the channels. The wavelengths and the temperatures where the absorption is seen are low for the water of crystallization. This suggests considerable mobility in the water molecules. Thus, the frequency of the maximum absorption, when extrapolated to room temperature, comes very close to the critical frequency for liquid water.[3)]

There are two absorptions in the frequency range examined; one is larger than the other and is markedly displaced to higher frequencies at higher temperatures. The smaller peak (300 to 600 kc.) does not seem to move with the change in temperature, although it seems to change with the water content. This temperature-independent absorption is rather difficult to interpret.* Therefore, we will here consider only the temperature-dependent part of the dielectric absorption.

The anisotropy of the absorption is rather small. The only difference is in the additional large dielectric loss, which increases towards lower frequencies when the electric field is

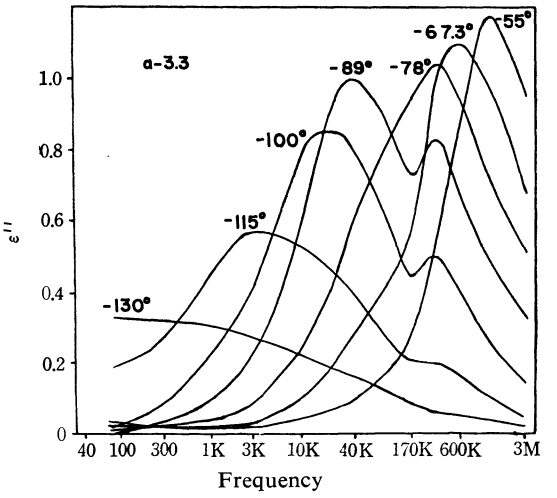

Fig. 3. Dielectric loss of specimen a-3.3.

parallel to the crystallographic c axis (see Fig. 5 for the results with c-3.6). This additional loss is most probably due to d.c. conductivity; it is also seen in a-2.7 and to a much smaller extent in a-3.6. The appearance of d.c. conductivity in the "a" specimens indicates that the crystal starts to fissure as the water of crystallization is successively removed. The d.c. conductivity would thus be due to the grain-boundary diffusion of water in the "a" specimens. The "c" specimens, on the other hand, shows a large d.c. conductivity, even with a good crystal; this may be reasonably accounted for by the ionic conduction due to proton jumps through the hydrogen bond between α and β sites in cooperation with the rotation of water molecules at both types of sites.

The shape of the absorption curve changes with the temperature, as Fig. 3 shows. It generally becomes sharper at higher temperatures; this tendency is more pronounced as the water content is decreased.

The main dielectric loss peak is the relaxation absorption due to the hindered rotation of the water molecules. The relaxation is

* On the basis of the crystal structure described previously,[3)] two possibilities which would give rise to the almost temperature-independent absorption were considered. One is the rotational isomerism between the two gauche configurations of ethylenediamine units that coordinate a Co^{3+} ion. However, such isomerism has to take place in synchronism at least among the three ethylenediamine molecules belonging to the same Co^{3+} ion. The other possibility is the rotation of the water molecules at the α sites about the axis of the hydrogen bond, O-H·····Cl^-. Because the other hydrogen atom of this water is only very weakly engaged in the O-H·····O hydrogen bond to a water molecule at a β site, such axial rotation would require a very small activation energy, which in turn might cause the absorption to be almost independent of the temperature. While this seems to be a plausible explanation, the frequencies at which the absorption is observed are too low for such a mechanism.

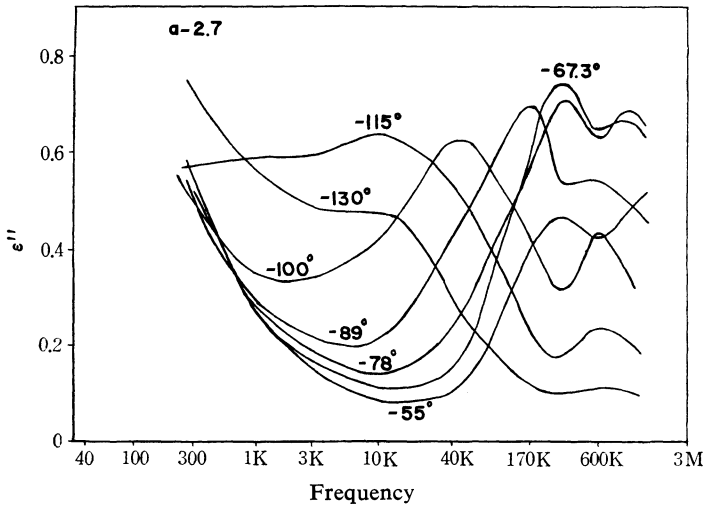

Fig. 4. Dielectric loss of specimen a-2.7.

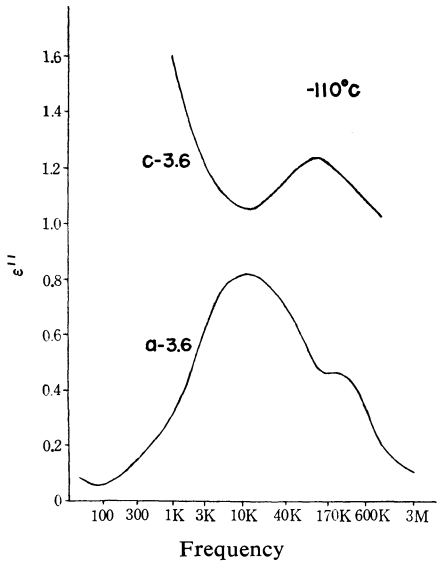

Fig. 5. Comparison of dielectric loss of specimens a and c.

not, however, that of a simple mechanism, as the shapes of the semi-circular Cole-Cole plots show in Figs. 6 and 7. Their asymmetric shape is, of course, partly due to the inclusion of the temperature-independent loss in the plots, but it also suggests a distribution of the relaxation times. The so-called activation plots of the log of the frequency that gives maximum ε'' versus $1/T$ are linear and the activation energies were obtained therefrom (Table I). The location fo the absorption maxima for a-2.7 was determined with difficulty; therefore, its activation energy may be in error by as much as 1 kcal./mol. It would be interesting to note a correlation between the activation energies and the differential heat of hydration or dehydration; either quantity shows a minimum or maximum between $n=2$ and 3. Generally these activation energy values are consistent with a mechanism of the molecular rotation of water accompanying the dissociation of several weak hydrogen bonds.

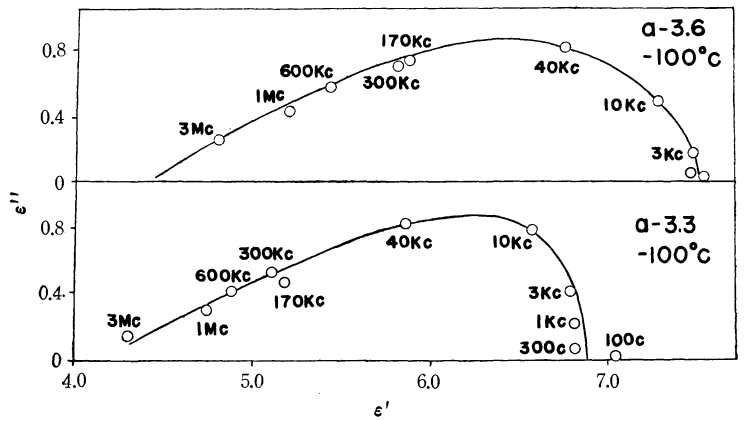

Fig. 6. Cole-Cole diagrams of specimens a.

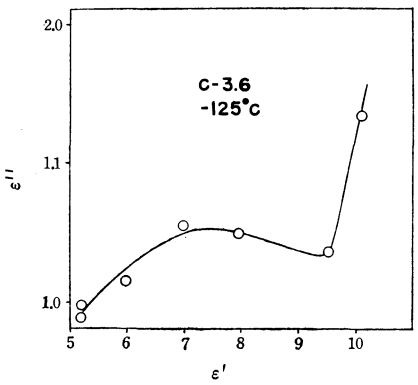

Fig. 7. Cole-Cole diagram of specimen c.

TABLE I. ACTIVATION ENERGIES (kcal./mol.)

a-3.6	7.3	c-3.6	5.6
a-3.3	7.9	c-2.9	4.9
a-2.7	4.7	c-0.43	5.5
a-0.9	6.8	c-0.27	8.3

There is one feature of interest in the temperature dependence of the maximum of ε'', as is most evident in Fig. 3. The maximum of ε'' increases with the temperature as the absorption becomes sharper; its rates of increase are different above and below about $-90°C$. Such differentce in behavior is also seen in the static dielectric constant, ε'_0 and these are compared in Fig. 8. There is a sharp break in ε'_0 at $-90°C$ as well as in ε''_{max} for the specimen a-3.3. In contrast, ε'_0 for the specimen a-3.6 decreases linearly as the temperature is raised with the same slope as does ε'_0 for a-3.3 above $-90°C$. Such a decrease is

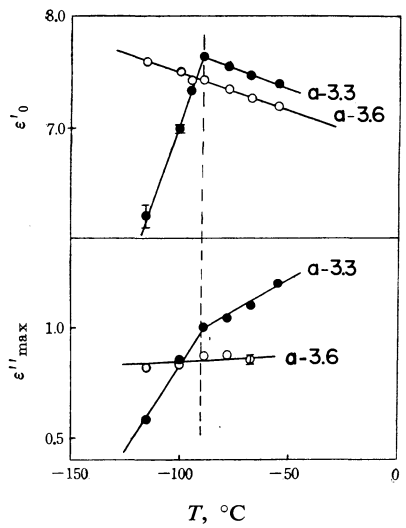

Fig. 8. Static dielectric constants and the loss maxima as a function of temperature.

due to thermal agitation opposing the static polarization. We shall now examine the structural mechanism in which a break point in ε'_0 appears with a-3.3. The two possible sites, α and β, for water molecules should have different potential energies; the β sites become stable only after the surrounding α sites have been occupied by water molecules. There must thus be an equilibrium partition of water molecules for a fixed total number of water molecules between the two types of sites, a partition governed by the Boltzmann distribution. The potential energy at a β site depends on the configuration of the environment and, therefore, has a certain distribution. At the lowest temperatures, the α sites will be almost filled if n is larger than 3, while a fraction of the β sites will remain vacant. Thus, the molecules are more or less fixed rigid, giving a small static polarization. As the temperature is raised, some molecules at the α sites would be vaporized into the β sites, leaving 'defects' behind at the α sites. When this occurs, an average β site molecule will see a potential field which is relaxed to some extent because of the defect formation. Thus the static dielectric constant will tend to increase until a critical temperature ($-90°C$ for $n=3.3$) is reached, at which the maximum possible number of O–H groups can be oriented in the direction of the applied electric field either through the dissociation of O–H··· O hydrogen bonds or through the rotation of water molecules and the reformation of the hydrogen bonds, the number being consistent with the equilibrium partition of molecules between the α and β sites.

Assuming that there are two different states of minimum potential energies, corresponding to different hydrogen bond schemes, we may estimate the difference in the potential energies by a formal application of a plot of $\log \varepsilon'' T$ against $1/T$.[6] Figure 9 shows the results thus obtained; this, however, should not be considered as representing the potential curve of a molecule but be regarded as the total potential energy of the assembly of water molecules. The potential energy difference of a-3.3 drops by about 0.7 kcal./mol. from 1.6 to 0.9 kcal./mol. at $-90°C$, at which kT_c amounts to about 0.4 kcal./mol.

When the water content is larger, say, when $n=3.6$, this critical temperature would be lowered because the number of vacant β sites is much smaller. This may be a reason for the failure to observe a break in ε'_0 for a-3.6. Such a mechanism of defect formation and the aquisition of molecular mobility is also

6) J. S. Dryden and R. J. Meakins, *Rev. Pure Appl. Chem.*, 7, 15 (1957).

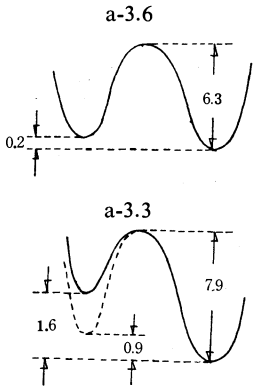

Fig. 9. Schematic potential energy curves for the assembly of water molecules.
—— Below −90°C, - - - Above −90°C

related to the results of thermodynamic investigation, in which an isothermal order-disorder phenomenon was observed in the differential heat and entropy of sorption of water by the anhydrous crystal.[3] It is possible that the transition phenomenon found here by the dielectric measurements may have some consequences on such other properties as the heat capacity of the partly hydrated crystal of this salt.

Summary

The dielectric constant and loss of single crystals of DL-$[Co(en)_3]Cl_3 \cdot nH_2O$ have been measured between −150°C and room temperature in the frequency range 40 c./s. and 3 Mc./s. The water content, n, was varied from 0.27 to 3.6. The anomalous dispersion and relaxation absorption due to the hindered rotation of water have been observed and they are strongly dependent on n. The activation energies for the relaxation absorption have been determined for different n values and for different orientations of the crystals. A molecular mechanism for the absorption has been presented on the basis of the zeolitic nature of the water molecules in the crystal as determined previously from structural[2] and thermodynamic[3] investigation.

The authors' thanks are due to Mr. Nobuo Nakamura for part of the measurements with an "a" specimen.

Electrical Conductivity of Organic Semiconductors at High Pressure

By Yoshiya HARADA, Yusei MARUYAMA, Ichimin SHIROTANI and Hiroo INOKUCHI

(Received May 22, 1964)

Recently, the effect of high pressure on the electrical conductivity of polycyclic aromatic hydrocarbons and quinones has been studied.[1] In each case, the observed conductivity increases by several orders of magnitude at high pressure. This behaviour seems to be closely associated with the increase in the amount of overlap between adjacent molecules.

In this report, we will attempt to calculate the band structure of the anthracene crystal at atmospheric pressure and also at 160 kilobars in order to see what differences may be expected in the electrical conductivity.

Following LeBlanc,[2] the treatment of the tight-binding approximation was used. In the calculation of the band energy for both electrons and holes, the interaction of the anthracene molecule, sited in the crystal with a monoclinic structure C_{2h}^5,[3] with twelve neighbour molecules was considered:

$$E(\boldsymbol{k}) = \text{const} + 2E_b \cos \boldsymbol{k}\boldsymbol{b} + 2E_c \cos \boldsymbol{k}\boldsymbol{c} \pm | 2E_{a/2\,b/2}[\cos \boldsymbol{k}(\boldsymbol{a}/2+\boldsymbol{b}/2) + \cos \boldsymbol{k}(\boldsymbol{a}/2-\boldsymbol{b}/2)] + 2E_{a/2\,b/2\,c}[\cos \boldsymbol{k}(\boldsymbol{a}/2+\boldsymbol{b}/2+\boldsymbol{c}) + \cos \boldsymbol{k}(\boldsymbol{a}/2-\boldsymbol{b}/2+\boldsymbol{c})] | \quad (1)$$

where $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$ denote the unit-cell vectors,

1) a) G. A. Samara and H. G. Drickamer, *J. Chem. Phys.*, 37, 474 (1962); b) H. Inokuchi, I. Shirotani and S. Minomura, This Bulletin, 37, 1234 (1964).

2) O. H. LeBlanc, Jr., *J. Chem. Phys.*, 35, 1275 (1961); G. D. Thaxton, R. C. Jarnagin and M. Silver, ibid., 66, 2461 (1962).

and E_b, E_c, $E_{a/2\,b/2}$ and $E_{a/2\,b/2\,c}$ represent intermolecular resonance integrals. These integrals were calculated*1 by the method used by LeBlanc, except that all of the two-centre interatomic integrals were considered for the evaluation of each intermolecular integral (Eqs. A10 and A11 given by LeBlanc have been corrected by Katz et al.[4]). Since the crystal structure of anthracene under pressure has not yet been determined, the resonance integrals at high pressure were calculated by assuming that the crystal is compressed isotropically without changes in the orientations of lattice vectors and molecules. From the relation between pressure and volume given by Samara and Drickamer,[1a] the lattice distances at 160 kilobars were estimated to be 88% of those at atmospheric pressure. Figure 1 shows the

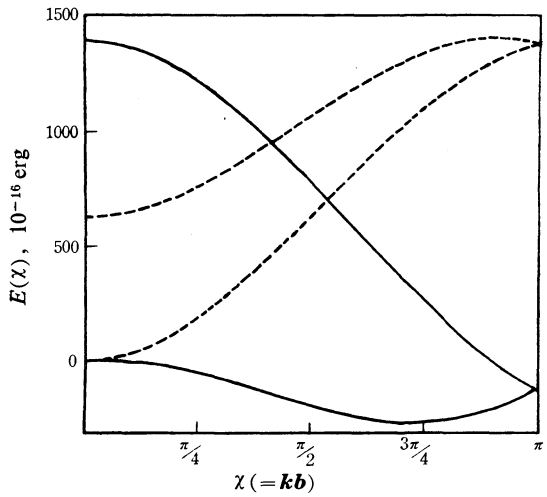

Fig. 1. Energy contours for both electrons (solid line) and holes (dashed line) in the $\boldsymbol{b}^{-1}$ direction at 160 kilobars. The origins of the energy scales have been arbitrarily chosen to make $E(0)$ the same for both bands.

contour of $E(\boldsymbol{k})$ for each band at 160 kilobars in the $\boldsymbol{b}^{-1}$ direction in the Brillouin zone. The total band widths of the electrons and holes at 160 kilobars are 1.65×10^{-13} erg and 1.39×10^{-13} erg, these values being 5.2 and 5.8 times as large as those calculated at atmospheric pressure. If we assume that the carrier-scattering can be described by the constant mean free time, $\tau(\boldsymbol{k})=\tau_0$, the mobility components are given by:

$$\mu_{ij}=e\tau_0<v_iv_j>/\boldsymbol{kT} \qquad (2)$$

where v_i is the i th component of the carrier velocity, $\mathbf{v}$, which is given by:

$$\mathbf{v}=(1/\hbar)\partial E(\boldsymbol{k})/\partial\boldsymbol{k} \qquad (3)$$

The quantity $<v_iv_j>$ is a statistical average over the band. The velocity components and the mean square velocities of both carriers in the a, b and c' directions are given in Table I.*2

Table I shows that the mobilities, on the whole, increase the magnitude by several tens times at 160 kilobars.*3 (The values of the c' components are incredible. In order to obtain reasonable results for this component, a refined treatment such as Katz et al.'s[4] is necessary.) The observed pressure effect on the conductivity of quaterrylene, $C_{40}H_{20}$, and violanthrone, $C_{34}H_{16}O_2$, is given in Table II,[1b] where the ratios of the number of carriers, $n_{160\text{ kb}}/n_{\text{atm}}$, and of the mobilities, $\mu_{160\text{ kb}}/\mu_{\text{atm}}$, are estimated from the $n\propto\exp(-\Delta\varepsilon/2\boldsymbol{kT})$ and $\sigma\propto n\mu$ relations. On the basis of this estimation, the sharp drop in the resistivity at a high pressure is attributed to the great increase in the concentrations of charge carriers, $10^3\sim10^4$ times, and to the increment of the mobilities, $10^1\sim10^2$ times, as is to be expected from the band theory treatment. When the electrical conductitvity of the anthracene crystal is compared with that of a larger aromatic hydrocarbon crystal, a similar behaviour is found. In the case of the circumanthracene ($C_{40}H_{16}$) crystal, it is found theoretically that the mobilities of the carriers are 2~3 times as large as those of the anthracene crystal.[5] On the other hand, the increase in the concentrations of charge carriers is estimated to be 10^7

*1 To faciliate the calculation, a digital computer, Facom 202, was programmed. About 20 sec. are required to compute a intermolecular resonance integral of the anthracene crystal.

4) J. I. Katz, S. A. Rice, S. Choi and J. Jortner, *J. Chem. Phys.*, **39**, 1683 (1963).

*2 Recently, Katz et al. (Ref. 4) refined the band calculation using the SCF carbon atomic orbital represented in the form of a linear combination of four Slater wave functions. The band widths calculated by their method are about five times larger than those found by LeBlanc. Although the present treatment is inadequate for the evaluation of the magnitude of the band widths and the velocity components, it might be useful for the estimation of the ratios of these values at a high pressure to those at atmospheric pressure. This is illustrated by the following table, which shows the mobility change due to the application of a pressure of 3000 atm.

Crystal direction	$\mu_{3000\text{ atm}}/\mu_{\text{atm}}$ Electron			Hole		
	Exp.[a]	Calcd.[b]	Calcd.[c]	Exp.[a]	Calcd.[b]	Calcd.[c]
a	1.4	1.1	1.2	1.4	1.0	1.2
b	1.3	1.2	1.3	1.4	1.1	1.3
c'	1.0	0.9	1.3	1.4	1.3	1.6

Quaterrylene	8.3×10^{-9}	0.61	1.4×10^{-4}	0.16	6×10^{3}	3
Violanthrone	4.3×10^{-11}	0.78	1.4×10^{-3}	0.20	8×10^{4}	400

a) $n_{160\text{kb}}$ and n_{atm} mean the concentrations of charge carriers at 160 kilobars and at atmospheric pressure, respectively.

times (anthracene, $\Delta\varepsilon=2.7$ eV.[6]; circumanthracene, $\Delta\varepsilon=1.8$ eV.[7]). Hence, in this case also, the increment of the conductivity may be due mostly to the great increase in charge carriers resulting from the lowering of the energy gap value.

Summary

In order to study the effect of high pressure on the electrical conductivity of organic semiconductors, the band structure of the anthracene crystal has been calculated at atmospheric pressure and also at 160 kilobars, using the treatment of the tight-binding approximation. The total band widths of both electrons and holes at 160 kilobars are 5~6 times as large as those at atmospheric pressure. Although the mobilities of both carriers, on the whole, increase in magnitude by several tens times at 160 kilobars, the sharp drop in the resistivity at high pressure may be due mostly to the great increase in the concentrations of the charge carriers (10^3~10^4 times).

NOTES

The Seebeck Effect in an Electrolytic Thermocouple Involving Ion-permselective Membranes

By Toshio IKEDA and Masao TSUCHIYA*

(Received March 30, 1964)

Several years ago, Tyrrell and his co-workers[1] reported on the Seebeck effect on the purely electrolytic thermocouple of the following system:

$$\underset{T}{\mathrm{Ag/AgX,\ MX}(m)}\ \Big|\ \underset{T}{\text{Ion exchanger in M}^+\text{ form (MR)}}\ \Big|\ \underset{T+\Delta T}{\mathrm{MX}(m)},\ \underset{T}{\mathrm{AgX/Ag}} \qquad (1)$$

Their purpose was to explain the thermal sensation of nerve systems. Recently, we have studied an electrolytic thermocouple of the following type:

$$\underset{T}{\mathrm{Hg/HgCl,\ KCl}(m^\circ)}\ \overset{\mathrm{D}}{\vdots}\ \underset{T}{\mathrm{KCl}(m)}\ \overset{\mathrm{D'}}{\vdots}\ \underset{T+\Delta T}{\mathrm{KCl}(m^\circ)},\ \underset{T}{\mathrm{HgCl/Hg}} \qquad (2)$$

where D and D' are ion-permselective membranes of an identical nature, but kept at different temperatures, T and $T+\Delta T$ respectively; the whole system is symmetrical in its construction, except for the temperature gradient applied to it.

As can easily be seen from the structure, the EMF of the cell 2 consists of two parts: one is the difference between the two isothermal membrane potentials arising at two membranes kept at different temperatures, T and $T+\Delta T$ respectively; the other is the difference between the two thermal diffusion potentials[2] which are revealed in opposite directions in two solution phases of different concentrations, m° and m. By taking the sign convention of EMF, ΔE, of the cell 2 to follow the sign of the calomel electrode on the hot side, we have, then, for the first approximation:

$$\boldsymbol{F}\Delta E=\frac{\partial}{\partial T}\left[\sum_k \frac{t_k'}{z_k}\boldsymbol{R}T\ln\frac{m_k\gamma_k}{m_k^\circ\gamma_k^\circ}\right]\Delta T - \frac{\partial}{\partial m}\left[\sum_k \frac{t_k Q_k^*}{z_k T}\Delta T\right](m-m^\circ) \qquad (3)$$

where $\boldsymbol{F}$ and $\boldsymbol{R}$ have their usual meanings; T is the absolute temperature; t_k and t_k' are the transport numbers of k-th ion species of z_k valency in the solution and membrane phases respectively; m_k and γ_k are the molality and the activity coefficient of k-th ion species on the molality scale, and the symbols with the superfix o refer to those in the outer electrolytic solution. Q_k^* is the ionic heat of transfer of k-th ion species. As judged from the Q_k^* values,[3,4] the second term on the right side of Eq. 3 can be ignored as compared with the first. Moreover, if a single 1, 1 valent electrolyte is used and if the membranes are perfectly permselective exclusively to one ion species (for example, to K^+), (i.e., in the case of $t'_{K^+}=1$, $t'_{Cl^-}=0$; accordingly, $\partial t'_{K^+}/\partial T=0$, $\partial t'_{Cl^-}/\partial T=0$), Eq. 3 can practically be approximated to $\boldsymbol{F}\mathrm{d}E/\mathrm{d}T = 2.303\boldsymbol{R}\log_{10}(m_{K^+}\gamma_{K^+}/m^\circ_{K^+}\gamma^\circ_{K^+})$, since the contribution from $\partial\ln\gamma_{K^+}/\partial T$ is very small, not exceeding 3% of the total in most cases.

Oxidized collodion membranes[5,6] prepared in a bag form, of nearly equivalent nature, were pasted with collodion to the nozzles of both terminal calomel electrodes. The membranes used were nearly completely permselective to cations, as judged from their apparent cation transport number being found to be about 0.97. Anion permselective membranes

were prepared by forming a resin in the cellophane matrix by diffusing formaldehyde and aniline hydrochloride in aqueous media from either side of a cellophane that was tied with cotton thread to the endings of the nozzeles of two terminal calomel electrodes. The apparent anion transport numbers of these membranes were found to be about 0.91. The electrode nozzles so prepared were inserted into the appropriate compartments of an H-shaped cell filled with an m molal potassium chloride sulution. The temperature of two legs of the H-cell was controlled by thermostated water in Dewar vessels, fixed on one side, while it was varied around the mean temperature of 25°C on the other side. The EMF of the cell 2 was measured by varying, for the sake of experimental convenience, the concentration, m, of the inner pottasium chloride solution, while that of the outer was fixed at a convenient value. The EMF was found, for all values of m, to be proportional to the temperature difference, ΔT, in the temperature range studied. In Fig. 1 the temperature coefficient, dE/dT, was plotted against $\log m\gamma_{\pm}$, where $\gamma_{\pm}$ is the mean ionic activity coefficient. A nearly linear relation with a slope of about 197 μV./deg. (which was very close to the theoretical value, $2.3\boldsymbol{R/F}$) was found there, well agreeing with the present theory and with Tyrrell's results for the system 1. Reverse phenomena were found when anion-selective membranes were used in place of cation-selective membranes. The slope was somewhat higher than the theoretical expectation; however, this might be due to some change in the chemical nature of the anion-selective membranes used here, because these membranes were found to exhibit a faster fading of the isothermal membrane potential at higher temperatures.

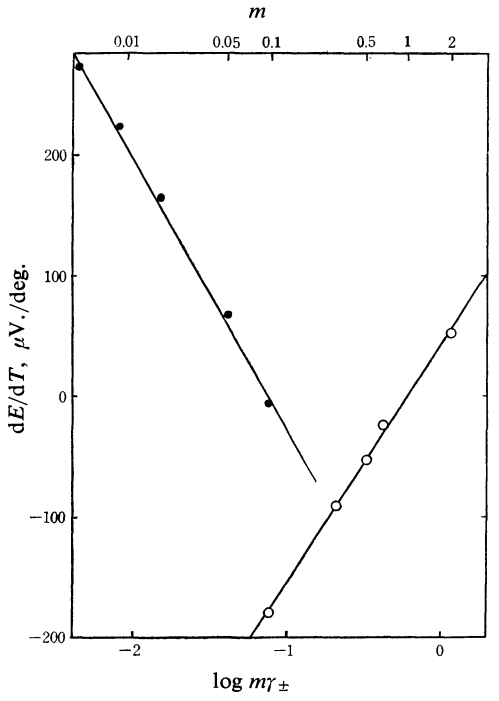

Fig. 1. Initial thermoelectric power dE/dT of the system 2.
○, for the system, oxidized collodion membranes being used, where m^o was fixed at 1 M.
●, for the system, aniline-formaldehyde resin membranes being used, where m^o was fixed at 0.1 M.

These facts indicate that the mechanism for the generation of EMF is perhaps the same in both systems, 1 and 2. The magnitude of dE/dT here obtained is in itself probably insufficient to explain why it is a stimulant in producing the thermal sensation, but several tens of nerve fibers would serve, if the cooperative function of the nerve fiber systems is taken into consideration.

The Direct Resolution of DL-*Aspartic Acid by the Use of an Optically Active Amine*[1]

By Kaoru HARADA

(Received April 9, 1964)

N-Acyl DL-amino acids have been used in most cases for the chemical and enzymatic resolution of DL-α-amino acids. However, for acidic amino acids, various other methods of resolution have been employed. DL-Glutamic acid was resolved by seeding,[2] by an optically-active amine[3] and by lysine[4] without using its *N*-acyl derivative. DL-Aspartic acid was resolved from its supersaturated copper complex solution by seeding it with L- or D-aspartic acid copper complexes.[5] DL-Aspartic acid was resolved by preferential crystallization with optically-active glutamic acid[6] and by the direct salt formation of optically-active lysine.[4] DL-Aspartic acid was also partially resolved on a starch column.[7]

In this report, the direct resolution of DL-aspartic acid by the use of optically-active α-methylbenzylamine[8] will be described. The optically-active amine has been used in several stereospecific syntheses of α-amino acids.[9-12] The use of D(−)α-methylbenzylamine ($[\alpha]_D^{27}=-40.6°$) resulted in the crystallization of L-aspartic acid D-amine salt ($[\alpha]_D^{27}=-9.7°$) from the reaction mixture. L(+)Amine ($[\alpha]_D^{27}=+39.3°$) resulted in D-aspartic acid L-amine salt ($[\alpha]_D^{27}=+10.9$). These salts were dissolved in water, and the pH was adjusted to about 2.8 to precipitate L- or D-aspartic acid. Optically-pure L-aspartic acid ($[\alpha]_D^{27}=+25.0°$) and almost pure D-aspartic acid ($[\alpha]_D^{27}=-23.0°$) were obtained. Optically-impure D- and L-aspartic acid (optical purity 50~60%) were isolated from the mother liquors of crystallization. D-Aspartic acid D-amine salt was prepared in order to compare it with its diastereomer. The solubility of the salt in the resolution solvent was much higher than that of its diatereomer. The optically-active amine could not be applied for the resolution of free DL-glutamic acid.

Experimental

Standard Aspartic Acid Amine Salts. — *(L-Aspartic Acid D-Amine) Salt.* — L-Aspartic acid (0.67 g., 0.005 mol.) was dissolved in a mixture of 2.0 ml. of water and 0.66 g. (0.005 mol.) of D(−)-methylbenzylamine ($[\alpha]_D^{27}=-40.6°$ in benzene). To this, 10 ml. of methanol and 5 ml. of acetone were added, and the mixture was kept in a refrigerator overnight. The (L-aspartic acid D-amine) salt crystallized; m. p. 260~263°C (decomp.), $[\alpha]_D^{27}=-9.9°$ (*c* 2.04, water). Found: C, 56.48; H, 7.34; N, 11.23. Calcd. for $C_{12}H_{18}N_2O_4$: C, 56.68; H, 7.13; N, 11.02%.

(D-Aspartic Acid L-Amine) Salt. — The salt was obtained from D-aspartic acid ($[\alpha]_D^{27}=-24.3°$) and L(+) amine, $[\alpha]_D^{27}=+10.5°$ (*c* 2.13 water). Found: C, 56.43; H, 7.14; N, 11.18%.

(D-Aspartic Acid D-Amine) Salt.—The salt did not crystallize under the above conditions, but it did crystallize upon the addition of an extra 10 ml. of acetone to the salt solution; m. p. 258~263°C (decomp.), $[\alpha]_D^{27}=+9.2°$ (*c* 1.04, water). Found: C, 56.66; H, 7.17; N, 10.92%.

The Resolution of DL-Aspartic Acid. — DL-Aspartic acid (6.65 g., 0.05 mol.) was dissolved in a mixture of 200 ml. of water and 6.10 g. (0.05 mol.) of D(−)α-methylbenzylamine ($[\alpha]_D^{27}=-40.6°$ in benzene) and filtered. To this, 50 ml. of methanol and 60 ml. of acetone were added, and the flask was rubbed with a glass rod (or preferably seeded with L-aspartic acid D-amine salt) and kept overnight in a refrigerator. The product, 4.70 g. (71%) of (L-aspartic acid D-amine) salt, was recrystallized by dissolving it in 12 ml. of water and precipitated with 15 ml. of methanol and 35 ml. of acetone. Pure salt (3.60 g.) was obtained; m. p. 260~263°C (decomp.), $[\alpha]_D^{27}=-9.7°$ (*c* 2.18, water). Found: C, 56.68; H, 6.97; N, 11.01. Calcd. for $C_{12}H_{18}N_2O_4$: C, 56.68; H, 7.13; N, 11.02%.

In the same way, (D-aspartic acid L-amine) salt was isolated by the use of L(+)-α-methylbenzylamine ($[\alpha]_D^{27}=+39.3°$ in benzene); 4.50 g. of salt was thereby isolated. After recrystallization, 3.48 g. of pure salt was obtained; m. p. 260~263°C

(decomp.), $[\alpha]_D^{27} = +10.9°$ (*c* 2.08, water). Found: C, 56.63; H, 7.03; N, 11.13%.

Optically-Active Aspartic Acid. — *L-Aspartic Acid.*—Three grams of (L-aspartic acid D-amine) salt was dissolved in 15 ml. of water, and the pH was adjusted to about 2.8 by the addition of 3 N hydrochloric acid. Then 15 ml. of ethanol was added, and the mixture was kept in a refrigerator overnight. The crystallized L-aspartic acid was filtered and washed with cold water and absolute alcohol. L-Aspartic acid (1.35 g.) was obtained; $[\alpha]_D^{27} = +25.0°$ (*c* 1.97, 6 N HCl). Found: C, 36.25; H, 5.39; N, 10.48. Calcd. for $C_4H_7NO_4$: C, 36.09; H, 5.30; N, 10.52%. From the mother liquor, optically-impure D-aspartic acid (1.50 g.) was obtained, $[\alpha]_D^{27} = -12.3°$ (*c* 1.07, 6 N HCl). Found: C, 36.21; H, 5.43; N, 10.34%.

D-Aspartic Acid. — D-Aspartic acid L-amine salt (1.20 g.) was treated in the way described above. D-Aspartic acid (0.53 g.) was isolated; $[\alpha]_D^{27} = -23.0°$ (*c* 2.30, 6 N HCl). Found: C, 35.88; H, 5.45; N, 10.37%.

A Tracer Study on the Source of Carbon Dioxide in the Chromic Acid Oxidation of Toluene and Fluorene

By Yoshiro OGATA and Hiroyoshi TABUCHI

(Received April 11, 1964)

In our previous reports[1,2] it has been found that the chromic acid oxidation of toluenes or fluorene in acetic acid gave carbon dioxide, together with benzoic acids or fluorenone respectively. The following mechanism was suggested to explain the second-order rate with chromium trioxide and the evolution of carbon dioxide:

$$C_6H_5CH_3 + 2CrO_3 \rightarrow$$

$$C_6H_5CH\left(\begin{matrix}O\\ \|\\ O\text{-}Cr\text{-}OH\\ \\ O\text{-}Cr\text{-}OH\\ \|\\ O\end{matrix}\right) \xrightarrow{2CrO_3} C_6H_5COOH$$

$$+ 2Cr_2O_3 + H_2O + 3O \quad (1)$$

In order to get more information on the source of carbon dioxide, the oxidations to toluene and fluorene were carried out under conditions similar to those described in the previous reports, using labeled acetic acid as the solvent. The liberated carbon dioxide was taken out as barium carbonate, and the radioactivity estimated. The radioactivity of only 18 cpm in barium carbonate obtained from the oxidation of toluene (No. 1 in Table I) shows that the carbon dioxide derived from the oxidation of acetic acid is only 2.5% ($18\times100/716$) of the total carbon dioxide evolved, where 716 cpm is the radioactivity of the solvent acetic acid. The values for fluorene (Nos. 4 and 5 in Table I) show that 1.7~2.8% of carbon dioxide is derived from acetic acid. Benzoic acid was found to be stable under the experimental conditions (No. 3 in Table I).

If the side chain of toluene is attacked, the reaction products should contain benzene, phenols, quinones and/or biphenyl. Only *p*-benzoquinone was detected by gas chromatography, however. It was found by visible spectrophotometry that the amount of quinone was very small. It was observed that quinone was easily oxidized to carbon dioxide and water by an acetic acid solution of chromic acid (No. 8 in Table I).

In conclusion, the benzene ring of toluene is probably completely broken by active oxygen to carbon dioxide; i.e., the side chain of toluene and/or benzoic acid is oxidized by the active oxygen produced from Eq. 1 to quinone, and then the quinone is further oxidized by chromic acid to carbon dioxide and water. However, the consumption of the starting material, toluene, by this attack of active oxygen is so small compared with that of chromium trioxide that there is no appreciable influence on the rate equation.

2) Y. Ogata and H. Akimoto, *J. Org. Chem.*, **27**, 294 (1962).

Table I. Chromic acid oxidations in acetic acid

Solvent, CH_3CO_2H : 15 ml. for Nos. 1—3 and 8 and 30 ml. for Nos. 4—7; CrO_3 : 4.15×10^{-3} mol. for Nos. 1—3 and 7.29×10^{-3} mol. for Nos. 4—7

No.	Substrate (10^{-3} mol.)	Temp. °C	Time hr.	Obtained $BaCO_3$ g.	Radioactivity CH_3CO_2H c.p.m.	Radioactivity $BaCO_3$ c.p.m.
1	Toluene (0.833)	70	3	0.211	716	18
2	None	70	3	0.065	0	0
3	Benzoic acid (0.833)	70	3	0.080	0	0
4	Fluorene (2.43)	40	2	0.218	358	10
5	Fluprene (2.43)	40	2	0.201	358	6
6	None	40	2	0.008	0	0
7	Fluorenone (2.43)	40	2	0.276	0	0
8	*p*-Benzoquinone (0.833)	70	3	0.682	0	0

Similar results were obtained in the tracer study of the chromic acid oxidation of fluorene in acetic acid-1-^{14}C (Nos. 4 and 5 in Table I); this indicates that the aromatic ring is completely broken by active oxygen to produce carbon dioxide.

Experimental

Materials.—All the materials were purified as in the previous papers.[1,2] Acetic acid-1-^{14}C was synthesized from labeled barium carbonate via the reaction with methyl magnesium iodide.[3] The radioactivity of all the radioactive materials were measured by a Geiger-Müller counter after their conversion to barium carbonate. The radioactivities of barium carbonate were measured by using layers of infinite thickness and corrected for their background.

Oxidation. — The carbon dioxide evolved was swept out by passing oxygen-free dry nitrogen gas through and then absorbed by aqueous barium hydroxide after passing it through aniline to eliminate the acetic acid.

The Gas Chromatography of the Oxidation Products.—The solution of the reaction product was added to sodium bicarbonate to neutralize acetic acid and benzoic acid and then extracted with ethyl ether. The extract was dried and analyzed by gas chromatography on a 1.5 m. copper column packed with Silicon DC 703 at a helium pressure of 21 p. s. i. at 70°C (for benzene), at 100°C (for quinone), at 170°C (for phenol) or at 190°C (for biphenyl). No indication of the presence of benzene, phenol or biphenyl was observed. *p*-Benzoquinone was identified by having the same peak as the authentic sample and also by color tests with sulfuric acid or sodium hydroxide.[4]

The Estimation of the Concentration of Quinone.—The reaction products was extracted with ether, the extract being analyzed spectrophotometrically at the wavelength of the absorption maximum, 430 mμ with 1 cm. cells. The reaction mixture was found to contain ca. 7×10^{-3} M benzoquinone, which was to be less 1/30 of the calculated concentration (240×10^{-3} M) on the assumption that one mole of toluene gave one mole each of carbon dioxide and quinone.

The authors wish to thank Dr. E. Nakano and Dr. Y. Izawa for their aid in performing these experiments.

*The Electrical Properties of the Poly(N-vinyl Carbazole)-Tetracyanoquinodimethane Charge Transfer Complex**

By Akimasa TANIGUCHI, Seiichi KANDA, Takeshi NOGAITO, Shigekazu KUSABAYASHI, Hiroshi MIKAWA and Kazuo ITO

(Received April 21, 1964)

Tetracyanoquinodimethane (abbreviated as TCNQ) forms a charge transfer complexes with various amines.[1] The electrical resistivity of these compounds is fairly low, and some of them show an ESR signal.[1,2]

It is to be expected that vinyl polymers with π-electron systems of aromatic amines will form charge transfer complexes with TCNQ and also that the complexes have conductive characteristics. Plasticity may also be expected to be retained in the product complex.

Charge transfer complexes derived from polyvinylanthracene,[3] polyethinylnaphthalene,[4] polyvinylpyridine,[5] polyvinylnaphthalene[6] and polyvinylmesitylene[6] have been reported.

In the present work, the electrical and optical properties of the charge transfer complex between poly(*N*-vinyl carbazole) and TCNQ have been investigated. The photoconductive properties of poly(*N*-vinyl carbazole) and its sensitization with TCNQ and other compounds acting as acceptors have already been described.[7]

Preparation. — The poly(*N*-vinyl carbazole) used is Luvican M170 (Badische Anilin u. Soda Fabrik A. G.). TCNQ was prepared by the method described in the literature.[8]

Poly(N-vinyl Carbazole)-TCNQ Charge Transfer Complexes.—These complexes were prepared easily by dissolving both components in chloroform at room temperature. The dark green material thus obtained was fairly stable thermally, with a softening point between 210 ~270°C. It was possible to make a film of the complex by evaporating the solution containing the material.

In preparing the complex, the ratio between the amounts of the two components were changed as shown in Table I. The mole ratio between the carbazole monomer unit of poly(*N*-vinyl carbazole) and TCNQ in the various complexes obtained are shown in the table. The mole ratios of the components were estimated spectroscopically from the intensities of the absorption peaks at 330 and 400 mμ.

As reference substances, an *N*-ethyl carbazole-TCNQ complex and a carbazole-TCNQ complex were also prepaped.

N-Ethyl Carbazole-TCNQ Charge Transfer Complex.—One hundred ninty-five milligrams (10^{-3} mol.) of *N*-ethyl carbazole and 204 mg. (10^{-3} mol.) of TCNQ were mixed as a chloroform solution (100 ml.). The solution immediately turned dark green, and a crystalline solid separated. The solution was evaporated to half of its volume after one hour, and the precipitated crystalline complex was filtered. Dark green needles; sublimation temperature above 160°C; yield 270 mg.

Found: C, 77.10; H, 4.59; N, 17.73. Calcd. for a one-to-one complex $C_{26}H_{17}N_5$: C, 78.19; H, 4.26; N, 17.53%.

Carbazole-TCNQ Charge Transfer Complex.—One hundred sixty-seven milligrams (10^{-3} mol.) of carbazole and 204 mg. (10^{-3} mol.) of TCNQ were mixed as in the case of ethyl carbazole. Sublimations temperature, 210~250°C; yield, 310 mg.

Found: C, 76.70; H, 4.41; N, 19.54. Calcd. for a one-to-one complex $C_{24}H_{13}N_5$: C, 78.00; H, 3.24; N, 18.55%.

Spectroscopic Properties. — The absorption spectra of the charge transfer complex between poly(*N*-vinyl carbazole) and TCNQ are shown in Fig. 1. In chloroform the main bands are at 330, 400 and 620 mμ, of these, 330 mμ is the absorption due to poly(*N*-vinyl carbazole) itself and 400 mμ, that due to TCNQ. The 620 mμ band is, consequently, the so-called charge transfer band between the two components. The absorption spectra of the glassy solid film

of the complex are very similar to those of the chloroform solution, having maxima at 330, 400 and 600 mμ.

As a reference, the absorption spectrum of the *N*-ethyl carbazole - TCNQ complex was also measured. In the chloroform solution, a charge transfer band was observed around 560 mμ, as is shown in Fig. 1.

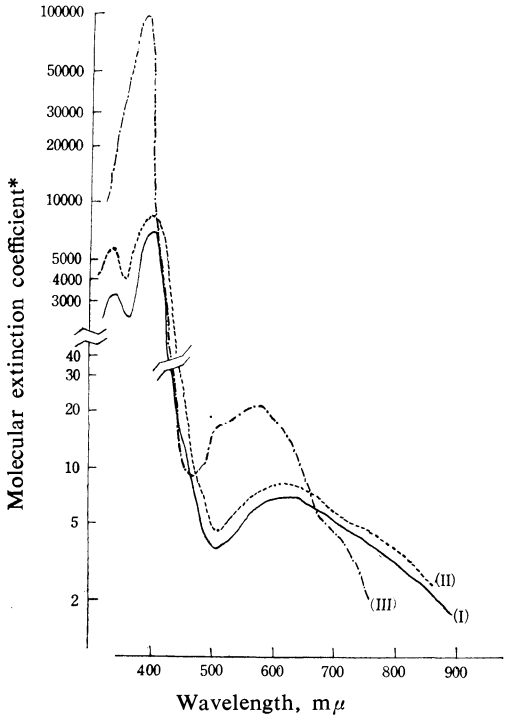

Fig. 1. Absorption spectra of some complexes.

(I) Poly(*N*-vinyl carbazole) and TCNQ were dissolved in chloroform in the ratio 10 : 1.
(II) Poly(*N*-vinyl carbazole) - TCNQ complex film (arbitrary unit).
(III) *N*-Ethyl carbazole - TCNQ complex in chloroform.
* This value is calculated by dividing the optical density of the solution as observed with the mol./l. concentration of the carbazole monomer units present in the solution.

Electrical Properties.—The electrical conductivity of the material was measured with a pellet made under 5000 kg./cm^2 pressure with a silver-paste electrode by the DC method, the applied voltage being 20~2000 V./cm. The relation between the current and the applied voltage obeyed Ohm's law in this range. The relationship between the logarithm of the resistivity and the reciprocal of the temperature is shown for the complexes in Fig. 2. The specific resistivity at room temperature and the band gap, ε, as calculated from the temperature dependence of the resistivity by the equation $\rho = \rho_0 \exp(\varepsilon/2kT)$ are tabulated in Table I. The specific resistivity of poly(*N*-vinyl carbazole) itself was above 10^{17} Ωcm. The conductivities of the *N*-ethyl carbazole - TCNQ complex and the carbazole-TCNQ complex are also listed in this table.

Summary

Poly(*N*-vinyl carbazole) (specific resistivity, above 10^{17} Ωcm.) gives a dark-green charge transfer complex with tetracyanoquinodimethane.

The specific resistivity of the complexes at room temperature is $10^{14}\sim10^{16}$ Ωcm. and the band-gap energy is 1.1∼1.5 eV. The film-forming property of poly(*N*-vinyl carbazole) is retained in the complex. The charge transfer band is observed at about 620 mμ.

The authors wish to thank Mr. Takuzo Fujino and Mr. Tsuneyo Shishido for their elementary analyses.

An Improved Fusion Method for the Synthesis of Purine Nucleosides. The Acid-catalyzed Reactions of $N_{(7)}$- or $N_{(9)}$-Acylpurines with Acylated Sugars

By Yoshiharu ISHIDO, Akira HOSONO, Sadanori ISOME, Akira MARUYAMA and Tetsuo SATO

(Received May 25, 1964)

In previous papers[1] from our laboratory, the acid-catalyzed fusion reaction of purines with acylated sugars has been reported. Recently, the method has been applied to the synthesis of nucleosides of D-xylose,[2a] 2-deoxy-D-ribose,[2b,3] and deoxyaminosugars.[3]

The extensive experiments on the acidic catalysts for this reaction made it clear that the compounds formulated as R-SO_3H, picric acid, and many inorganic acidic compounds were effective. It is of great interest that amphoteric acids, such as sulfanilic and sulfamic acids, showed fairly good catalytic effects.[4]

On the other hand, perspective observation of the reactivity of purine derivatives in the fusion reaction made us aware of the fact that there is no rational correlation between the reactivity of purines and the polar effect of their substituent groups on the reaction centers, though such correlation was confirmed in the fusion reaction of phenols with acylated sugars.[3] Accordingly, it was deduced that this fact was probably due to the fusibility of purine derivatives.[4b,c]

In fact, the reactions of purines with a high fusibility, such as 2, 6-dichloropurine (I) [m. p. 181°C (decomp.)[5]], halogenopurines, and theophylline, proceeded in a homogeneous state to yield the corresponding purine nucleosides, 2, 6-dichloro-9-(2', 3', 5'-tri-*O*-acetyl-β-D-ribofuranosyl)purine (II)[4b,c] {m. p. 158~159°C, $[\alpha]_D^{21.5}$ −5.7° (*c* 1.05, chloroform), λ_{max}^{EtOH} 253 mμ (ε, 6100) and 274.5 mμ (ε, 9800), λ_{min}^{EtOH} 258 mμ (ε, 5800)}, and others, generally in a good yield (40~80% yield of the theoretical yileds)[4]. On the other hand, amino- or hydroxypurines with extremely high melting points were usually hard to fuse on the reaction and were not practically reactive.[4] These results have led to the suggestion that easily-fusible purine derivatives might be favorable for the fusion reaction.

Thereupon, purines which are acylated at a nitrogen atom of the imidazole nucleus and have much lower melting points than those of the parent purines have been applied to the reaction.

Birkofer[6] prepared diacyladenines by refiuxing adenine with excess acid anhydrides. Montgomery[7] also obtained monoacethlyalogenopurines by refluxing diaminohalogenopyrimidines with ethyl orthoformate in acetic anhydride. He deduced from the infrared spectra that the acetyl group should be linked to a nitrogen atom of the imidazole moiety of the purine nucleus. The melting points of these acyl purines are much lower (30~200°C) than those of the parent purine.

We have newly obtained acyl derivatives of theophylline ($N_{(7)}$-acetyl, m. p. 156~157°C;

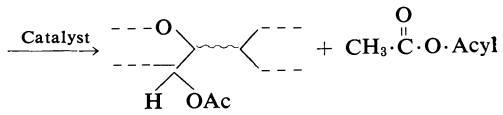
$N_{(7)}$-propionyl, m. p. 129~130°C; $N_{(7)}$-*n*-butyryl, m. p. 88~90°C), I ($N_{(9)}$-propionyl, m. p. 169~171°C; $N_{(9)}$-*n*-butyryl, m. p. 104~106°C), guanine (2-*NH*-, $N_{(9)}$-diacetyl, m. p. 261~263°C), and 5,6-dimethyl-benzimidazole (*N*-acetyl, m. p. 136~139°C), etc. The yields of these derivatives range from 70 to 90% of the theoretical yields.



Among these derivatives, the acetyl derivatives gave the best results on the reaction with 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose in the presence of sulfamic acid as the catalyst at a suitable temperature. Thus, 7-β-D-ribofuranosyltheophylline, II, 2-methylthioadenosine, adenosine, and guanosine were obtained in 82, 82, 57, 14, and 28% yield of the theoretical yields respectively. It was found that the yields of these nucleosides were raised by 10 to 30% compared with those reported previously.[1-4a,b]

The concomitant production of acid anhydrides in this modified fusion reaction was confirmed by infrared spectra, while acetic acid was formed in the reaction of free purines with acetylated sugars. This fact provides a further chemical proof of the interpretation[7] based on the infrared spectra of monoacetylhalogenopurines.

In view of the above facts, the most reasonable scheme of the modified reaction may be written as follows:

Acetylated sugars Acylpurines

Purine nucleoside acetates Acid anhydrides

A detailed investigation of the improved method and related matters will be reported in the near future.

Electric Conductivity and Electron Spin Resonance of Semiconductive Complexes of Polymer Species of Diphenylamine

By Keiji KUWATA, Yuzuru SATO and Kozo HIROTA

(Received July 14, 1964)

In a previous communication,[1] the formation of a stable polymer species from diphenylamine under an oxidative atmosphere with a vanadium pentoxide catalyst was reported, and the polymer structure composed of a structural unit was proposed as follows:

$n=3\sim17$

TABLE I. SPECIFIC RESISTANCE AND CONCENTRATION OF THE UNPAIRED ELECTRON FOR THE COMPLEXES AT ROOM TEMPERATURE (30°C)

* Mol. wt. (Rast) of the polymer, 1.3×10^{3}.
** Broad singlets for solids, but hf structures of five lines were observed for the benzene solutions of the complexes.

Molecular complexes of the polymer species of DPA, a good electron donor because of the structure shown above, with some electron acceptors were prepared, and their semiconductive properties and concentrations of the unpaired electron were measured.

For both measurements, a benzene solution of iodine, chloranil or tetracyanoethylene (TCNE) was mixed with a benzene solution of the polymer, because of its low solubility with other solvents, and the solvent was removed, finally under a vacuum.

A sample with a high specific resistance was measured by the use of a vibrating-reed-type millivoltmeter.*

The specific resistance and concentration of each complex are shown in Table I.

The relative amount of iodine strongly bound to the polymer was determined to be about one-fifth mole to a structural unit of the polymer by the elementary analysis of a complex, which was washed repeatedly with an aqueous potassium iodide solution until no more iodine was liberated into the solution.

This relative amount of iodine is somewhat lower than that obtained for the most conductive complex, i. e., one-and-a-half mole to a structural unit, and the excess amount of iodine, more than one-fifth, obviously increases the conductivity.

The highest concentration of the unpaired electron, however, is obtained for a complex with the different composition of one mole of iodine to three structural units (cf. Table I).

This complicated phenomenon seems to be caused by the excess amount of iodine bound weakly to the complex.

The Photochemical Rearrangement of Ethyl Phenyl Carbonate

By Chyongjin PAC and Shigeru TSUTSUMI

(Received July 31, 1964)

It has been reported that the migration of the acyl group in phenyl acetate occurs under the influence of ultraviolet light[1] in a manner similar to that of the Fries-reaction.[2] Such photochemical reactions of catechol acetate,[1] anilides,[3] phenyl benzoates[4] and *p-t*-butylphenyl benzoates[5] have been investigated and have supplied a convenient method for the preparation of a number of hydroxy or amino aromatic ketones.

The migration of the alkoxycarbonyl group, however, has been scarcely observed at all. In the course of the investigation of the reaction of ethoxycarbonyl radical in hydrocarbons,[6] it was found that the migration of the ethoxycarbonyl group took place in the photochemical reaction of ethyl phenyl carbonate (EPC), thus affording ethyl salicylate and ethyl *p*-oxybenzoate in fairly good yields.

I II

After the irradiation of EPC (13 g.) in 150 ml. of acetic acid for 120 hr. with a low pressure mercury arc (100 W.), the irradiated mixture was worked up as usual and gave ethyl salicylate, I (a 16% yield based on the EPC used), ethyl *p*-oxybenzoate, II (25%), and phenol (7~8%), while 26% of the EPC was recovered.

These products were identified by infrared spectroscopic and gas chromatographic measurements, mixed melting point tests with authentic samples, and elementary analyses.

In a similar way, the photochemical reaction of EPC in ethanol afforded I (17%), II (18%) and phenol (13%), while 23% of the EPC was recovered.

When ether was used as a solvent, a decrease in the yield was observed in I (8~10%) and II (10%), while phenol (13%) and EPC (39%) were also detected.

In non-polar solvents such as benzene or *n*-heptane, the wall of the light source was covered with polymeric products during the course of irradiation, and only trace amounts of the products or none at all were detected. However, it is not clear whether or not there were any solvent effects on the photochemical rearrangement of EPC.

On the basis of the results of mixed irradiation experiments,[7] it has been suggested that the migration of the acyl group is intramolecular, and Kobsa[5] showed that, upon the absorption of a light quantum, the ester decomposed into a pair of radicals in a solvent cage, which then underwent subsequent reactions.

Considering the above facts on the migration of the acyl group, the photochemical rearrangement of EPC may be expected to be intramolecular. The details of this reaction are now being investigated.

The Transfer Coefficient of a Redox Process at Varying pH Values as Determined by the Faradaic Rectification Method

By H. P. Agarwal

(Received September 21, 1961)

The periodic variation of an electrode potential about a mean potential when the electrode is polarized by a sinusoidal current is known as rectification by electrode reaction. This phenomenon, when first observed in a solution containing a redox couple, was named the "redoxokinetic effect,"[1] but it is now generally known as the Faradaic rectification.[2,3] The recent development of the Faradaic rectification allows us to study the kinetics of fast electrode processes conveniently.[4] The study can be divided into two parts. The first of them relates to the study at the mercury-aqueous solution interface by the method followed by Barker and his co-authors,[3] but corrections for the double-layer structure in the solution of the boundary-value problem and for the alternating voltage control across the Faradaic impedance at high frequencies are necessary, as has been pointed out by Matsuda and Delahay.[5] The second method previously adopted by the present author,[6] consists of studying the reaction at the platinum-aqueous solution interface, where the solution contains an equimolecular concentration of oxidant and reductant. The latter has the advantage that no correction for kinetic parameters, as suggested by Matsuda and Delahay, is necessary.

The hydrogen ion concentration of the medium used as the supporting electrolyte for the reactants has a tremendous influence on the electrode kinetics and the shift in mean potential, i. e., the redoxokinetic potential,[7] ψ; hence, the effect of pH on the transfer coefficient has been studied in the present work.

Experimental

The method for measuring a. c. voltage incident and the shift in mean potential was the same as has been described earlier.[6] The cell contained an 0.001 M solution of quinhydrone (A. R.) in a buffer solution of known pH. The pH of the buffer used varied from pH 1.4 to pH 8.1. For buffers of pH 1.4 to 4.62, sodium acetate (A. R.) and hydrochloric acid (A. R.) solutions were used; on the other hand, for buffers having pH 6.1 to pH. 8.1 solutions of disodium hydrogen phosphate (E. Merck) and potassium dihydrogen phosphate (E, Merck), the concentration of each being 1/15 M were mixed in suitable proportions to obtain a buffer of the desired pH. The exact pH of each solution was confirmed using a Leeds and Northrup pH-meter. The results obtained are given in Table I, which does not, however, include the results obtained with the buffer with pH 8.1 for want of reproducibility. For the sake of brevity, the readings of ψ obtained at 8 mV. of a. c. have not been included, as they were found to be exactly four

Table I. Shift in mean potential, ψ, at 4 mV. of A. C. of the buffer solutions of quinhydrone 0.001 M in relation to the frequency of A. C. and pH of the solutions*,**(29±0.05°C)

times those shown at 4 mV. of a. c. in Table I at the corresponding frequency.

Results and Discussion

It can be seen from Table I that ψ, the shift in the mean potential, is constant at a frequency of 200 c./sec. or above when the pH of the solution is 1.4 or 2.1. Below a frequency of 200 c./sec., ψ decreases, but to confirm whether it decreases with the square root of frequency, further work at frequencies below 100 c./sec. is necessary. With the increase in the pH of the solution, ψ becomes negative; it becomes constant at a frequency of 1000 c./sec. or above (columms of pH 4.62 and pH 6.1 in Table I). With a lowering of the frequency, ψ increases in magnitude and is not proportional to the square root of frequency; therefore, the determination of the standard rate constant in such solutions is not possible. If the pH of the supporting electrolyte increases beyond 6.1, no constancy in the value of ψ is attained, even at frequency of 2000 c./sec. (column of pH 7.1 in Table I). When the pH of the medium is increased further, say, up to 8.1, the entire system becomes unstable and no reproducible observations are possible. At pH 8.1 the quinhydrone system is unstable, and so the entire solution in the cell looks black or brownish. As the constancy in the mean potential is reached at higher frequencies in the pH range of the solution from 1.4 to 6.1, the values of the transfer coefficient α, at different pH values have been calculated from the theoretical equation[8] applicable at high frequencies:

$$\alpha = 0.5 - \frac{2\psi RT}{V^2 nF}$$

where R is the gas constant, T is the absolute temperature, n is the valency, F is the Faraday constant, and V is the a. c. voltage incident. The transfer coefficients of the quinhydrone system determined from the above equation at pH 1.4, 2.1, 4.62 and 6.1 are, respectively, 0.376, 0.389, 0.503 and 0.506 at 29°C. These results show that the transfer coefficient decreases rapidly with the lowering in the pH of the medium, but with the pH values above 4.62, the variation in the transfer coefficient is low. Further, the values of transfer coefficients lower than 0.5 indicate that, at higher hydrogen ion concentrations, the depolarising action of hydroquinone during the anodic half wave increases. When the transfer coefficient exceeds 0.5, which usually takes place at higher pH values, the conversion of quinone into hydroquinone during the cathodic half wave is favoured. Thus, the knowledge of the transfer coefficient of an electrode reaction at varying pH values helps us to understand the mechanism of electrode processes. It is interesting to note that, in buffers of higher pH values, ψ is tremendously affected in the lower frequency range.

8) K. S. G. Doss and H. P. Agarwal, *Proc. Indian Acad. Sci.*, **34**, 263 (1951); ibid., **35**, 45 (1952).

Summary

The transfer coefficient of 0.001 M quinhydrone in buffer solutions of various pH values has been determined by Faradaic rectification studies. The value of α at 29°C has been found to be 0.376 at pH 1.4, 0.389 at pH 2.1, 0.503 at pH 4.62, and 0.506 at pH 6.1. The transfer coefficients determined at various pH values, help us to understand the mechanism of electrode processes.

A Mass Spectrometric Investigation of Petroleum. III.[1] *The Determination of the Alkyl Side Chain Number on Aromatics in the High Boiling Range Fraction of Petroleum*

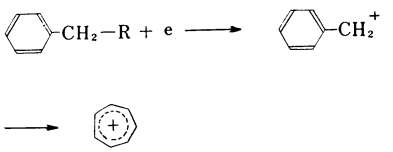
By Shozo Oshima

(Received October 1, 1963)

Hitherto, the alkyl side chain number on alkyl aromatics in the high boiling range fraction of petroleum has been determined by the infrared spectrometric assigment of the ratios of CH_2 and CH_3. However, the accuracy of this method is not satisfactory, and only a mean value is obtained when there are more than two types of co-existing compounds.

The present author has reported the total carbon number of the alkyl side chain as one of a series of studies of the petroleum fraction.[1,2] In this series of studies, the alkyl side chain number must be determined in order to ascertain the carbon number of each alkyl side chain.

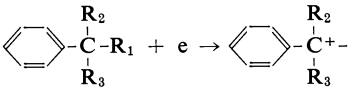
For this purpose, the cleavage mechanism of alkyl aromatics under electron impact was studied, and a method was devised by which the alkyl side chain number could be determined from the finding of the α and β cleavage characteristic of the aromatic ring. Thus mass spectrometry can determine the alkyl side chain numbers for different types of coexisting compounds.



Experimental

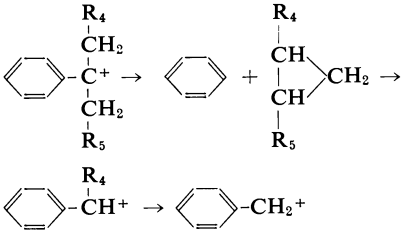
Several authentic aromatics were measured by a Hitachi-RMU 5B type mass spectrometer. Mass spectral data of other unavailable compounds were obtained from the literature.[3]

Theoretical



The Mass Spectra of Alkylbenzene.—Under electron impact *n*-alkylbenzene is stabilized as the tropylium ion according to the β bond cleavage.[4] Therefore, *m/e* 91 is a very intense peak in the spectrum.

However, branched alkylbenzene at the α-position cleaves itself to yield the *m/e* $(89+R_2+R_3)$ ion, and some of these ions decompose



m/e 91

into the *m/e* $(91+R_4)$ or the *m/e* $(91+R_5)$ ion, the *m/e* 91 ion are produced by further rearrangement.[5-7]

(R_2, R_3=hydrogen or alkyl chain)

Alkylbenzene with more than two alkyl substituents takes an α cleavage in addition to the β cleavage described above. When the substituent is longer than the propyl group, the cleavage of the β bond is observed, while the α cleavage is observed when it is the methyl or ethyl group.

Thus, monosubstituted alkylbenzenes give their most intense peak according to the β cleavage, while polysubstituted alkylbenzenes give intense peaks according to the β and α cleavages as well.

The following equation indicates the carbon number of the alkyl side chain on the ion produced according to the β cleavage:

$$b=a(n-1)/n+1 \qquad (1)$$

where

b: the total carbon number of the alkyl side chain on the ion produced;

a: the total carbon number of the alkyl side chain on the original molecule, and
n: the alkyl side chain number.

If the ion is formed according to the α cleavage, on the other hand, the equation will be;

$$b=a(n-1)/n \qquad (2)$$

Since the total carbon number of the alkyl side chain on the ion (b) is obtained from the most intense peak in the spectrum, the alkyl side chain number (n) can be obtained by determining the a value from the most intense peak in the spectrum.

The alkyl side chain number (n) was calculated from Eqs. 1 and 2 for 89 kinds of mass spectral data of authentic alkylbenzenes possessing from 3 to 12 carbons in the alkyl side chain and involving from 1 to 6 alkyl side chain numbers. Figure 1 indicates the relationship between the real side chain number and n from Eqs. 1 and 2. The n values which were derived from the β cleavage process agree with the real value when the chain number is small, but they differ when the chain number becomes more than three. On the other hand, the n from the α cleavage process shows good agreement with the real value when the chain number is large, but they differ greatly when the chain number is less than 4.

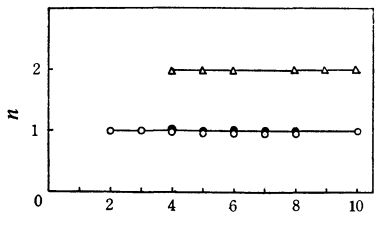

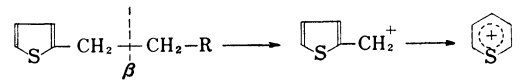

Fig. 2. Carbon number of alkyl radical and n at alkylthiophene.
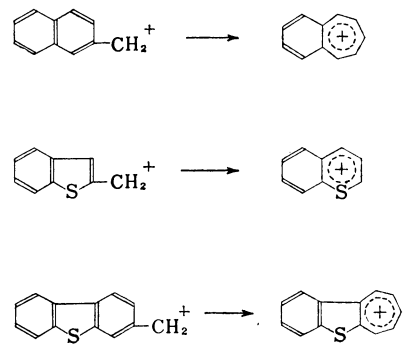
○ n-alkylthiophene
● iso-(2)-alkylthiophene
△ di-n-alkylthiophene



Alkylthiophene.—The most intense peak in the spectrum of alkylthiophene is generally due to the β cleavage of the alkyl side chain. This results from the hypothetical formation of the thiacyclohexatrienium ion, which is similar to the tropylium ion observed in alkylbenzene.

The n values calculated from Eq. 1 for 27 authentic alkylthiophenes showed good agreement with the real values. Figure 2 indicates the relationship between n and the carbon number of the alkyl side chain.

Miscellaneous Compounds.—The most intense peaks in the mass spectra of naphthalene, benzothiophene and dibenzothiophene also result from the β cleavage of alkyl side chains.

These ions are thought to be stabilized by the following process:

The Determination of *a*.—The a value of the high boiling range aromatic fraction in petroleum is determined by the following procedure. An aromatic mixture of petroleum is separated into small fractions by liquid chromatography in order to separate the coexisting compound types which overlap on the same mass numbers in the case of the low voltage ionization method. However, if the mass difference between the two aromatic rings is larger than b, overlapping compound types are permitted to coexist in the same fraction. When these isolated aromatic mixture are measured by the low voltage ionization method, the alkyl carbon number of the most abundant molecule is obtained according to the author's method.[2] Thus, the a value is determined.

The Determination of *b*.—When the isolated sample mentioned above is then measured under 50~100 eV. to obtain fragment ions, the most intense peak in the spectrum is b. On the other hand, in the presence of more than two types of compounds, the most intense

peak among the objective compounds has to be taken as b.

The Determination of n. — There are two procedures for determining n for alkylbenzenes. The first method is to multiply a correction value by n as calculated from Eq. 1, assuming β cleavage. Table I indicates the correction value. The other method is as follows; Eq. 1 is used where $n=1$ or 2, Eq. 2 is used where $n=5$ or 6, and the mean value between Eqs. 1 and 2 is used where $n=3$ or 4. Equation 1 is used for alkylthiophene, and it is also adopted for naphthalene, benzothiophene and dibenzothiophene in spite of the scarce calibration data about them.

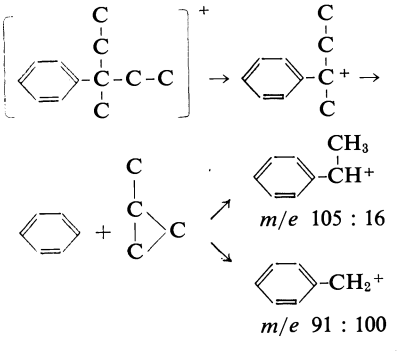


TABLE I. CORRECTION VALUES OF n

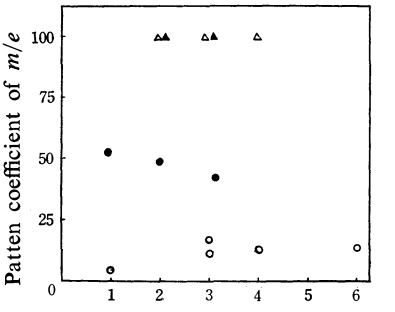
Chain number	1	2	3	4	5	6
Correction value	1	1	1.2	1.4	1.7	2.0

Discussion

If the most intense fragment peak in the spectrum is a factor determining the alkyl side chain number, the cleavage mechanism should not be influenced by the alkyl side chain number or by other structure requirements.

Monoalkylbenzenes should give the most intense peak on the same mass number. If α carbon has no side chain, monoalkylbenzenes actually give the most intense peak at m/e 91 without exception. Methylated (α) monoalkylbenzenes give the most intense peak at m/e 105 according to the β cleavage, and the ratio of m/e 105 to m/e 91 is about 10%. This value is unchanged even if the chain length is changed. Moreover, α-dimethyl monoalkylbenzenes give the most intense peak at m/e 119 and the ratio of m/e 119 to m/e 91 is about 40~60%, which is also independent of the length of the alkyl side chain. However, when ethyl or a longer alkyl group ($>C_3$) is attached to the α carbon, m/e 91 becomes a intense peak. For example, 3-ethyl-3-pentylbenzene is cleaved as follows:

Therefore, normal alkylbenzenes and branched alkylbenzenes having ethyl or a longer alkyl group ($>C_3$) on α carbon are cleaved to form the most intense peak at the same mass number. However, α-methyl monoalkylbenzenes cause an error, as is indicated in Fig. 3. Polysubstituted methyl or ethyl benzene produces α-cleavage rather than β-cleavage ions. Figure 4 shows the ratio of the α cleavage to the β cleavage in the case of dialkylbenzene. When the carbon number of the alkyl chain is C_1 or C_2, a large amount of α cleavage is observed; it would be expected



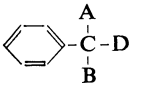


Fig. 3. Peak intensity of m/e 91 at monoalkylbenzene.

△ dipropylbenzene

that this inclination would become more marked as the benzene ring is substituted more. This means that an increase in the alkyl side chain number disturbs the determination of the alkyl side chain number from the β-cleaved ion. Accordingly, a correction value is required.

Figure 5 shows the effect of the carbon number of the alkyl chain. The n value from the α cleavage tends to decrease as the carbon number increases in n-alkylbenzene. Other alkylbenzenes, however, do not show this inclination. Therefore, the effect of the carbon number should not be considered excessive.

The following facts have been established about the sensitivity of β-cleaved ions. Monoalkylbenzenes are cleaved to form the hydrogen-rearranged m/e 92 ion as well as the m/e 91 ion, and there is a certain relationship between

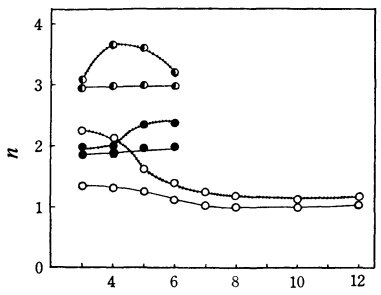

Fig. 5. Carbon number of alkyl radical and n at alkylbenzene.
○ radical number : 1
● radical number : 2
◐ radical number : 3
⫲ α-cleavage — β-cleavage

the molecular ion peak height and the summed peak height of m/e 91 and 92. The ratio of the molecular ion and the summed peak height (m/e 91+92) tends to decrease when the number of carbon which are lost as a neutral radical after β cleavage increases. On the other hand, when the number of carbons is within C_3 to C_5, this ratio becames constant.[8] This means that the number of β-cleaved ions is about the same within a certain size range of the alkyl chain. This makes it desirable to use the β cleavage process for the determination of the alkyl side chain number.

According to Fig. 1, the choice of Eq. 2 for the determination of the alkyl side chain number is preferable to the C_5 and C_6 of the side chain. However, considering the cleavage mechanism, the chance of error elsewhere is increased.

Alkylbenzenes in the high-boiling-range petroleum fraction are considered to include all kinds of alkylbenzenes. Because of the above reason, the calculated alkyl side chain number is, after all, the average value. Charlet reported that in almost all cases the alkyl side chain number is about 3 to 4 in the high boiling fraction of petroleum.[9] Alkyl side chain numbers (n) calculated from Eq. 1 and corrected according to Table I for alkylbenzene and naphthalene in the aromatic fraction isolated from light gas oil were 3 or 4, which agreed well with the findings of infrared spectrometry. It was clear that a and b could be determined by examining the same sample for which the n was determined.

According to a number of spectral data, it may be considered that the alkyl side chain number of alkylthiophene can be determined by Eq. 1, but much more data are required for naphthalenes, benzothiophenes, dibenzothiophenes and other aromatics.

Summary

The cleavage mechanism of alkylbenzene and other compounds under electron impact has been studied. The following facts are evident. If the ion from the aromatic compound is formed according to β cleavage under electron impact, the carbon number of the alkyl side chain on the compound may be indicated by the following equation;

$$b=a(n-1)/n+1 \quad (1)$$

where

b: the total carbon number of the alkyl side chain in the ion produced;
a: the total carbon number of the alkyl side chain in the original molecule, and
n: the alkyl side chain number.

If the ion is formed according to α cleavage, the equation will be:

$$b=a(n-1)/n \quad (2)$$

The effects of the alkyl side chain number and the structure upon n values from Eqs. 1 and 2 have also been studied. From the study, a method has been devised by which the alkyl side chain number of aromatics in the high-boiling-range fraction of petroleum can be determined from the total carbon number of the alkyl side chain in the molecule ion and the carbon number of the alkyl side chain in the peak showing the most intense peak in the spectrum.

The author wishes to express his hearty thans to Mr. Tsunehiko Kozuma for his kind guidance and to Mr. Kinya Fujii for his assistance.

Reaction of Tropone with 1,2,3,4-Tetrachlorocyclopentadiene. A Novel Rearrangement Reaction to Fulvenes[1]

By Yoshio KITAHARA,* Ichiro MURATA,* Makoto FUNAMIZU* and Takashi ASANO**

(Received December 20, 1963)

Sesquifulvalene (cycloheptatrienylidenecyclopentadiene),[2] one of the non-alternant hydrocarbons, is an interesting substance, both theoretically and chemically, which has been recently synthesized by Prinzbach and Rosswog;[3] some of its derivatives are also known, such as tetrabenzo-,[4] 1, 2, 3, 4-tetraphenyl-,[5] 1, 2-benzo-3-benzyl-,[6] 1-benzyl-,[3] and 1-(*p*-methoxybenzyl)-sesquifulvalene.[3] Attempts have been also made in this laboratory to synthesize sesquifulvalene, while syntheses of the quinone compounds, sesquifulvalene-1, 4-quinone and 2, 3-benzosesquifulvalene-1, 4-quinone,[7,8] have already been reported.

McBee[9] found that 1, 2, 3, 4-tetrachlorocyclopentadiene[9,10] (I) undergoes condensation with various aromatic aldehydes to form the corresponding fulvene derivatives, while Kitahara and Doi[11] found that tropone (II) undergoes condensation with malononitrile and the cyanoacetic ester to form 8, 8-dicyanoheptafulvene[11,12] and 8-cyano-8-ethoxycarbonylheptafulvene[11,12] respectively.

(III)

Considering these facts, it seemed possible to synthesize 1, 2, 3, 4-tetrachlorosesquifulvalene (III) by the reaction of I and II; examinations were therefore made on this point. A solution of I and II in a large volume of ethanol was allowed to stand at room temperature, and the ultraviolet absorption spectrum[13] of the solution, which gradually turned red, was measured in order to follow the progress of the reaction. The intensity of the absorption maximum of II, near 300 mμ, gradually decreased, and a new maximum appeared at 374 mμ. The ratio of the absorbances at 374 and 300 mμ, taken at definite intervals, gradually increased until the value remained constant at around 1.9 after 40 hr. From this reaction mixture, red prisms (IV), m. p. 116~117°C, were obtained. The analytical values of IV failed to agree with $C_{12}H_6Cl_4$ (III) but unexpectedly agreed with the formula, $C_{14}H_{11}OCl_3$. The infrared spectrum[14] of IV showed absorption bands at 1255 and 1043 cm^{-1} due to aromatic ether bonds, and the NMR spectrum[15] had a triplet at 8.55 τ and a quartet at 5.90 τ corresponding to the protons of an ethoxyl group. Elementary analysis and these spectra suggested that one of the chlorine atoms had been replaced by an ethoxyl group.

When the reaction of I and II in methanol was carried out in a thermostatic bath at 20°C, the absorbancy ratio at 374 and 300 mμ reached a constant value of 3.4 after about 40 hr. From this reaction mixture, two kinds of product were obtained: red prisms (V), m. p. 117~118°C, and reddish orange needles (VI), m. p. 77~78°C. Elementary analyses indicated that both V and VI had the molecular formula $C_{13}H_9OCl_3$. Since the infrared spectrum of V exhibited absorption bands at 1257 and 1026 cm^{-1}, due to aromatic ether bonds, and those of VI exhibited such bands at 1263 and 1025

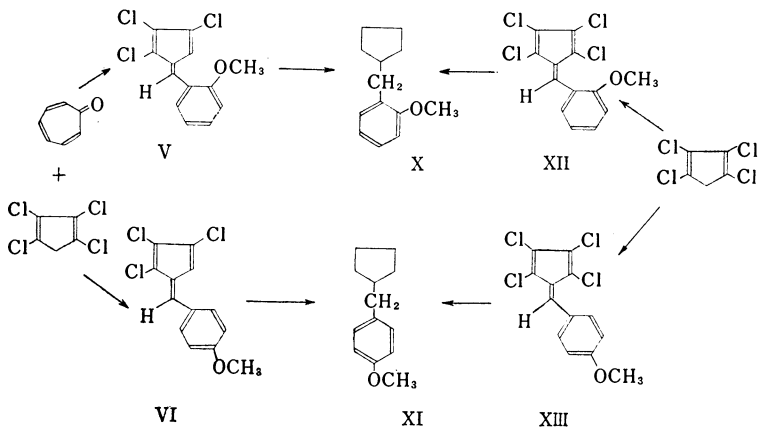
cm^{-1}, and since the NMR spectrum showed absorptions at 6.13 τ (singlet) for V and 6.19 τ (singlet) for VI, corresponding to the methoxyl protons, it appeared that a methoxyl group had been introduced by this reaction.

The reaction between II and 1, 2, 3, 4-tetrabromocyclopentadiene[16] (VII) followed an entirely analogous course; red plates (VIII), m. p. 128~129°C, and red prisms (IX), m. p. 90~91°C, were obtaind.

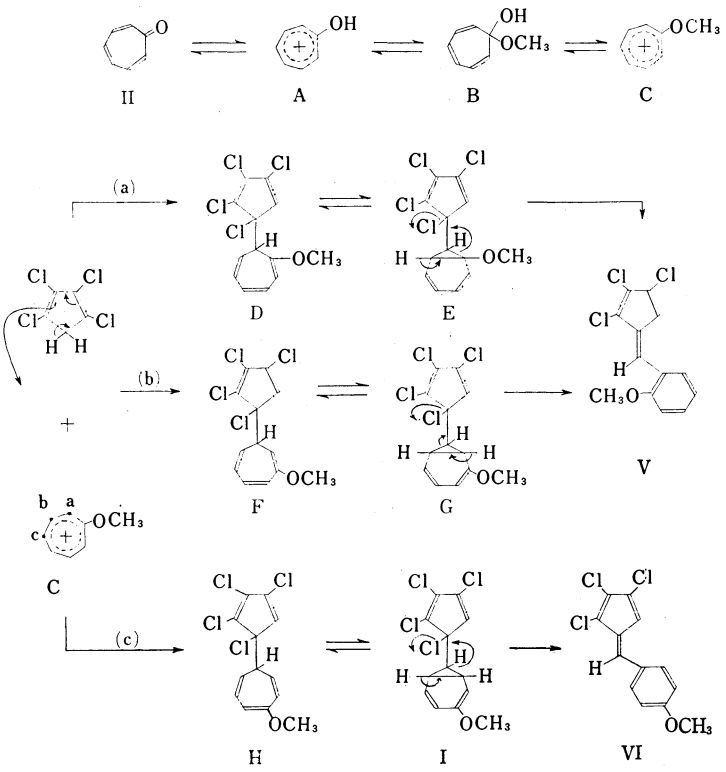
From the foregoing experimental evidence and the presence of an absorption maximum in the comparatively long wavelength region at 374 mμ in the ultraviolet spectra of the products (V, VI, VIII, IX), V and VI were assumed to be isomers formed by the replacement of one of the four chlorine atoms in III by a methoxyl group.

The examination of the infrared spectrum in the C–H out-of-plane region indicated the presence of an absorption corresponding to an *o*-disubstituted benzene at 749 cm^{-1} in V and that of a *p*-disubstituted benzene at 818 cm^{-1} in VI. The sharp absorption at 852 cm^{-1} in V and at 861 cm^{-1} in VI is considered to be due to the C–H of a tri-substituted double bond.



The catalytic reduction of V in methanol, in the presence of sodium acetate and using palladium-carbon as a catalyst, resulted in the absoption of 6 molar equivalents of hydrogen, and a colorless oil (X) was obtained. A similar reduction of VI also afforded a colorless oil (XI).

The infrared spectra of the reduction products, X and XI, indicated the absorption of an aromatic ether bond at 1247 and 1034 cm^{-1} in X and at 1253 and 1039 cm^{-1} in XI, absorptions which are practically unchanged from those of V and VI. If the methoxyl group had been present in the five-membered ring, the absorption of the ether bond in the reduction products (X and XI) would have shifted to about 1150~1060 cm^{-1}.[17] The absorption of the C–H out-of-plane vibration in the *o*-disubstituted benzene still apears at 752 cm^{-1} in X, and that of the *p*-disubstituted benzene, at 833 cm^{-1} in XI.



The ultraviolet absorption spectra of X and XI are very similar to that of anisole.[18]

From these considerations, it may be concluded that the structure of V and VI is not the anticipated sesquifulvalene skeleton, like III, but that the products are probably trichloro-6-(*o*-methoxyphenyl)fulvene and trichloro-6-(*p*-methoxyphenyl)fulvene for V and VI respectively.

In order to prove these structures, the condensation of I with *o*- and *p*-anisaldehyde respectively was carried out in ethanol. When the products thus obtained, 1, 2, 3, 4-tetrachloro-6-(*o*-methoxyphenyl)fulvene (XII), m. p. 166°C, and 1, 2, 3, 4-tetrachloro-6-(*p*-methoxyphenyl)-fulvene[9] (XIII), m. p. 123°C, were submitted to catalytic reduction over palladium-carbon in methanol, in the presence of sodium acetate; 7 molar equivalents of hydrogen were absorbed in each case to give two colorless oils (X′ and XI′). The ultraviolet and infrared spectra of X′ and XI′ were identical in all respects with those of X and XI.

17) L. F. Bellamy, "The Infra-red Spectra of Complex Molecules," Methuen Co., London (1958), p. 114.
18) R. A. Friedel and M. Orchin, "Ultraviolet Spectra of Aromatic Compounds", John Wiley and Sons Inc., New York (1951), Nos. 55, 56.

The results have afforded evidence of the structures assigned to V and VI, with the exception of the positions of three chlorine atoms. From the mechanism of this rearrangement reaction, it may be expected that the three chlorine atoms will be located at the 1-, 2- and 3-positions.

An examination of the physicochemical properties of tropone (II) has let us to consider it to have an ionic structure because of the contribution of six π electrons resulting from the polarization of the carbonyl group.[19,20] Consequently, an equilibrium exists, in methanolic solution of tropone, among the hydroxytropylium cation (A), hemiketal (B), and the methoxytropylium cation (C), as is indicated below, and the reaction may be considered to proceed via C. The attack of I on C may be possible at any of the three positions, a, b and c. If the attack occurs at a *o*-methoxy derivatives (V) will form from a norcaradiene type intermediate (E), and then be rearranged. If the reaction takes the b course, the rearrangement of the norcaradiene intermediate (G) will form V by the liberation of the proton adjacent to the methoxyl group. If the reaction follows the c course, the rearrangement of the intermediate (I) may be considered to form the VI by the liberation of the γ-proton of the methoxyl group. From such a rearrangement mechanism, the three chlorine atoms should be in the 1-, 2- and 3-positions in both V and VI.

The structures of V and VI were further confirmed from their NMR spectra. V had signals at 6.13 τ (singlet, OCH_3), 3.52 τ (doublet, J=1 c. p. s., 4-H), 2.37τ (partially resolved doublet, 6-H), and 3.3~2.5 τ (multiplet, four protons of the benzene ring). VI had signals

19) H. J. Dauben and H. J. Ringold, *J. Am. Chem. Soc.*, 73, 876 (1951).

20) W. von E. Doering and F. L. Detert, ibid., 73, 876 (1951).

21) The 4- and 6-protons was assigned by means of a comparison of their spectra with that of 1, 2, 3, 4-tetrachloro-6-(*p*-methoxyphenyl)fulvene (XIII). XIII lacked a signal in the 3.5 τ region, but the peaks due to the methoxyl- (6.18 τ, singlet) and A_2B_2-type absorptions (3.14 τ, doublet, J=9 c. p. s., 2.44 τ, doublet, J=9 c. p. s.) and the 6-proton (2.52 τ, singlet) were present. Therefore, the more shielded signals in V and VI (3.52 τ, 3.43 τ) can be assigned to a 4-proton, while the more deshielded signals (2.37 τ, 2.78 τ) can be assigned to a 6-proton.

at 6.19 τ (singlet, OCH_3), 3.43 τ (doublet, J=1 c. p. s., 4-H), 2.78 τ (partially resolved doublet, 6-H)[21], and at 3.14 τ and 2.55 τ (J=9 c. p. s.).

The doublet splitting pattern of the 4- and 6-protons (J=1 c. p. s.) can be interpreted only in the case of structures V and VI.[22]

The reaction of 1, 2, 3, 4, 5-pentabromocyclopentadiene (XIV) and tropylium bromide (XV) produced red needles, m. p. 79°C, which were identical with 1, 2, 3, 4-tetrabromo-6-phenylfulvene (XVI), which was obtained by the reaction, under McBee's conditions,[9] of 1, 2, 3, 4-tetrabromocylopentadiene (VII) and benzaldehyde. Since the reaction of XIV and XV, neither of which contains a methoxyl group, results in rearrangement, it seems certain that the liberation of a proton acts as the driving force of this rearrangement reaction.

The foregoing experimental facts have shown that the reaction of I and II in methanol results in an entirely new type of rearrangement reaction in which the methoxyl group enters the seven-membered ring (a six-membered ring after the rearrangement) and in which a chlorine atom in the five-membered ring is liberated.

Experimental

The Reaction of Tropone (II) 1, 2, 3, 4-Tetrachlorocyclopentadiene (I).—*Reaction in Ethanol.*— A solution of tropone (2.12 g.) and 1, 2, 3, 4-tetrachlorocyclopentadiene (4.08 g.) in ethanol (250 ml.) was allowed to stand at room temperature; the ultraviolet absorption spectrum of the reaction mixture was measured at definite intervals. The ratio of absorbances at 374 and 300 mμ became almost constant at 1.9 after about 40 hr.

The reaction mixture was then poured into ice water, and the red oil which separated was washed with water and dried over phosphorus pentoxide. This oil when treated with cyclohexane formed red crystals (0.6 g.), m. p. 110~115°C. Recrystallization from methanol gave IV as red prisms, m. p. 116~117°C.

Found: C, 55.42, 56.00; H, 3.65, 3.80. Calcd. for $C_{14}H_{11}OCl_3$: C, 55.74; H, 3.68%.

UV λ_{max}^{MeOH} mμ (log ε): 248 (3.80), 323 (4.11), 374 (4.27).

Reaction in Methanol.— A solution of tropone (10.0 g.) and 1, 2, 3, 4-tetrachlorocyclopentadiene (19.2 g.) in methanol (1200 ml.) was allowed to stand in a thermostatic bath at 20°C; the ultraviolet spectrum of the reaction mixture was measured at definite intervals. The ratio of absorbances at 374 and 300 mμ became constant at ca. 3.4 after about 45 hr. The methanol solution was evaporated under reduced pressure to one-half the original volume, and then poured into 1000 ml. of ice water and extracted thoroughly with petroleum ether (b. p. 36°C). The petroleum ether layer was washed with water, dried over magnesium sulfate, and evaporated. The oily residue crytasllized on the addition of a small amount of methanol; recrystallization from methanol gave 3.0 g. of crude V, melting at 116~118°C.

The recrystallization mother liquor of V was chromatographed over an alumina column (45×300 mm.). Elution with petroleum ether (600 ml.) gave 2.3 g. of crude V, m. p. 114~116°C, further elution with the same solvent (450 ml.) afforded 2.95 g. of crude VI, m. p. 72~75°C.

The recrystallization of crude V from methanol gave red prisms with a m. p. of 117~118°C.

Found: C, 54.41; H, 2.95. Calcd. for $C_{13}H_9OCl_3$: C, 54.29; H, 3.16%.

UV λ_{max}^{MeOH} mμ (log ε): 248 (3.84), 320 (4.11), 373 (4.27).

The Recrystallization of crude VI from ethanol afforded reddish orange needles, m. p. 77~78°C.

Found: C, 54.33; H, 3.16. Calcd. for $C_{13}H_9OCl_3$: C, 54.29; H, 3.16%.

UV λ_{max}^{MeOH} mμ (log ε): 250 (4.02), 374 (4.55).

The Reduction of 1, 2, 3-Trichloro-6-(*o*-methoxyphenyl)fulvene (V).—A solution of V (2.9 g.) in 100 ml. of methanol, with 5% palladium-carbon (0.1 g.) and anhydrous sodium acetate (2.5 g.), was shaken with hydrogen at an ordinary temperature and pressure; 6 molar equivalents of hydrogen were absorbed in about 1 hr. The solution was then filtered and evaporated. After the addition of water, the residue was extracted with petroleum ether, and the extract was dried over magnesium sulfate and then evaporated. The residual oil was submitted to distillation under reduced pressure gave 1.1 g. of a colorless oil, X.

Found: C, 81.49; H, 9.36. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.54%.

UV λ_{max}^{MeOH} mμ (log ε): 220 (3.86), 272 (3.32).

IR: 1609, 1592, 1247, 1034, 752 cm^{-1}.

The Reduction of 1, 2, 3-Trichloro-6-(*p*-methoxyphenyl)fulvene (VI).—The catalytic reduction of VI (2.9 g.) in methanol, under the same conditions as for V, afforded 1.2 g. of a colorless oil, XI.

Found: C, 82.09; H, 9.34. Calcd. for $C_{13}H_{15}O$: C, 82.06; H, 9.54%.

UV λ_{max}^{MeOH} mμ (log ε): 225 (4.08), 278 (3.16).

IR: 1618, 1590, 1520, 1523, 1039, 833 cm^{-1}.

1, 2, 3, 4-Tetrachloro-6-(*p*-methoxyphenyl)fulvene (XIII).— Synthesis according to the method of McBee yielded XIII as reddish orange needles, m. p. 122~123°C.

UV λ_{max}^{MeOH} mμ (log ε): 255 (3.98), 385 (4.38).

1, 2, 3, 4-Tetrachloro-6-(*o*-methoxyphenyl)fulvene (XII).—A solution of 1, 2, 3, 4-tetrachlorocyclopentadiene (4.1 g.) and *o*-anisaldehyde (2.72 g.) in ethanol (10 ml.) was refluxed on a water bath for 2~3 hr., and then cooled. The crystals which separated were collected by filtration. Recrystallization from ethanol gave red needles m. p. 165~166°C.

22) The long range 1, 3-spin-spin coupling of a vinylic proton with an allylic proton is a well-recognized phenomenon. S. Alexander, *J. Chem. Phys.*, **28**, 355 (1958); **32**, 1700 (1960); R. R. Fraser and D. E. McGreer, *Can. J. Chem.*, **39**, 505 (1961); E. B. Whipple, J. H. Goldstein and G. R. McClure, *J. Am. Chem. Soc.*, **82**, 3811 (1960); E. B. Whipple, *J. Chem. Phys.*, **35**, 1039 (1961); A. A. Bothner-By and C. Naar-Colin, *J. Am. Chem. Soc.*, **83**, 231 (1961); A. A. Bothner-By, C. Naar-Colin and H. Gunther, ibid., **84**, 2748 (1962).

Found: C, 58.55; H, 4.00. Calcd. for $C_{13}H_5OCl_4$: C, 58.08; H, 3.73%.

UV λ_{max}^{MeOH} mμ (log ε): 255 (3.84), 330 (4.06), 374 (4.19).

The Reduction of XII and XIII.—The catalytic reduction of XII and XIII under the same conditions as in the reduction of V and VI yielded two colorless oils, X′ and XI′. The ultraviolet and the infrared absorption spectra of X′ and XI′ were identical with those of X and XI respectively, indicating the identity of X and X′, and XI and XI′, respectively (*o*- and *p*-methoxybenzylcyclopentanes).

1, 2, 3, 4, 5-Pentabromocyclopentadiene (XIV).—A mixture of 1, 2, 3, 4, 5, 5-hexabromocyclopentadiene (21.5 g.) in ethanol was hydrogenated. One molar equivalent (900 ml.) of hydrogen was absorbed. Ether was added to the reaction mixture to dissolve the crystal which had separated, and the solution was then filtered and evaporated. The crystalline residue (14.9 g.) after recrystallization from petroleum ether afforded XIV as colorless needles (8.55 g.), m. p. 104°C.

Found: C, 13.17; H, 0.36. Calcd. for C_5HBr_5: C, 13.04; H, 0.22%.

1,2,3,4-Tetrabromo-6-phenylfulvene (XVI).—a) A suspension of tropylium bromide (0.34 g.) and 1, 2, 3, 4, 5-pentabromocyclopentadiene (0.92 g.) in carbon tetrachloride (3 ml.) was refluxed on a water bath for 2 hr.; a vigorous evolution of hydrogen bromide gas was observed during the reaction. The carbon tetrachloride was removed under reduced pressure, and the residual oil was heated for 4 hr. at 80°C to complete the evolution of hydrogen bromide. The oil was dissolved in a small amount of benzene, treated with activated charcoal, and then purified by alumina chromatography, using petroleum ether as an eluant. The crystals so obtained were recrystallized from ethanol to afford reddish-brown, silky needles XVI, m. p. 78~79°C.

Found: C, 30.73; H, 1.44. Calcd. for $C_{12}H_{16}Br_4$: C, 30.67; H, 1.29%.

UV λ_{max}^{MeOH} mμ (log ε): 280 (3.75), 343 (4.24).

b) A solution of 1,2,3,4-tetrabromocyclopentadiene (0.765 g.) and benzaldehyde (0.215 g.) in ethanol (2 ml.) was refluxed on a water bath for 10 hr. The solvent was then evaporated, and the residue was recrystallized from ethanol to give 0.42 g. of XVI, m. p. 78~79°C, which showed no depression on admixture with XVI obtained as in a).

Reaction of Tropone (II) and 1, 2, 3, 4-Tetrabromocyclopentadiene (IV).—A solution of tropone (0.65 g.) and 1, 2, 3, 4-tetrabromocyclopentadiene (2.30 g.) in methanol (150 ml.) was allowed to stand at room temperature for 6 hr. The solution was then concentrated under reduced pressure, and the crystals which formed were filtered off. Recrystallization from ethanol afforded VIII as red plates (0.75 g.), m. p. 128~129°C.

Found: C, 37.57; H, 2.34. Calcd. for $C_{13}H_9OBr_3$: C, 37.09; H, 2.13%.

UV λ_{max}^{MeOH} mμ (log ε): 250 (3.79), 330 (sh.), 375 (4.30).

The evaporation of the mother liquor from VIII, and the chromatography over alumina of the residue in petroleum ether, gave 0.83 g. of crude IX m. p. 85~87°C. Recrystallization from methanol afforded red prisms, m. p. 90~91°C.

Found: C, 37.51; H, 2.34. Calcd. for $C_{13}H_9OBr_3$: C, 37.09; H, 2.13%.

UV λ_{max}^{MeOH} mμ (log ε): 250 (3.94), 380 (4.54).

The Oxidation of Fe^{2+} by Ultrasound

By Satya PRAKASH, Jata Dhari PANDEY and Rajendra SINGH

(Received January 10, 1964)

Among the various unusual chemical effects produced by high frequency intense sound waves, much interest has been shown recently in the oxidation reactions of aqueous solutions of inorganic salts, e.g., the oxidation of iodide ions,[1-8] the oxidation of ferrous ions,[9-14] the oxidation of cerous ions,[13,14] and the reduction of acidified potassium permanganate[15] and neutral ferrocyanide.[14,15]

The present paper will report on a study of the oxidation of acidic ferrous ammonium sulphate by the intense ultrasonics of 1 Mc.

Experimental

In the present investigation, the source of ultrasonic power was a commercially-available ultrasonic generator, Mullard Type E-7562, which is meant for all purposes requiring high power ultrasonic waves at high frequencies. In addition to the generator, the other accessories were a suitable ultrasonic bath, a proper reaction vessel, and an easy procedure for the coupling of the reaction vessel with the transducer. The basic circuit of the oscillator is shown in Fig. 1. It consists of mainly a number of condensers (C), a tuning coil (L) which is of a variable type and which can be detached from the instrument and replaced by another coil designed for another frequency, and Mullard's silica envelop, triode-type TYS_4-500, which is used to generate radiofrequency power. The oscillator was self-biased, and meters were provided to read the cathode current up to 1 amp., high tension up to 3.500 V., and radiofrequency output voltage up to 10 kV. The transducer used was made of barium titanate ceramics with a frequency of 1 Mc. The

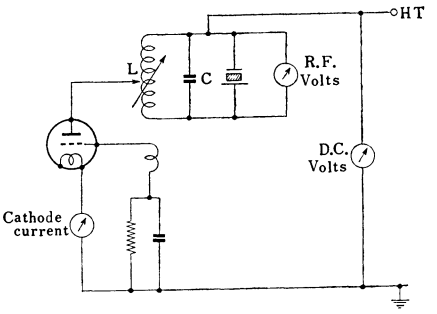

Fig. 1. Simplified oscillator circuit of ultrasonic generator.

major portion of the work was done at a fixed electrical output to the transducer, except when the effect of sonic intensity was to be studied. The reaction vessel was a 250-ml. flat bottomed jena glass battle with ground glass stopper. This reaction bottle was held vertically above the transducer in a water bath and the position so adjusted as to produce a maximum fountain inside the vessel when the ultrasound passed through. The other details of the experimental technique have already been described in previous communications.[16,17] The temperature was kept at 31.5 ± 0.1°C.

Materials. — A stock solution of 0.1 N ferrous ammonium sulphate (A. R., B. D. H.), acidified with A. R. sulphuric acid, was prepared in doubly-distilled water. A ceric sulphate solution of about 0.1 N was prepared from B. D. H.-quality salt by dissolving 34 g. of the salt in 50 ml. of 1 : 1 sulphuric acid (A. R. quality) and making it up to 500 ml. with doubly-distilled water. This solution was then standardised by titrating it against a standard ferrous ammonium sulphate solution, using N phenylanthranilic acid in alcohol as an indicator.

Results and Discussion

In a series of experiments, 25 ml. portions of ferrous ammonium sulphate solutions of known concentrations were placed in the reaction bottle and subjected to ultrasonic waves for different periods of time. The radiofrequency output voltage was kept constant, equal to 2.0 kV. (approx.). As a result of the ultrasonic exposure, the ferrous content of the solution changed to ferric; this was estimated

Initial concn. of $FeSO_4(NH_4)_2SO_4 \cdot 6H_2O$	$k_1 \times 10^3$ min^{-1}	
	$k_1 = (2.303/t) \cdot \log_{10}(a/(a-x))$*	Graphically from slopes (Figs. 2 and 3)
N/100	3.779	4.145
N/300	5.411	5.200
N/400	8.407	8.171
N/600	8.925	8.348
N/800	16.885	15.545
N/1000	18.520	19.969

* a Initial concentration
x Concentration at time t

volumetrically from time to time. The results are shown in Figs. 2 and 3. A study of the kinetics showed that the reaction is of the first order. The rate constant obtained is shown in Table I.

A perusal of the table will show that the order of the reaction does not change with the concentration and that the rate increases considerably at higher dilutions of ferrous ammonium sulphate. The values of k_1 as calculated from the equation and from the graph (Figs. 2 and 3) are approximately the same, with a maximum error of about 7 per cent. It can also be predicted that, when the concentration is decreased ten times, the values of k_1 increase by about five times, when the concentration of the solution is halved, k_1 is almost doubled, and so on.

We also investigated the effect of the intensity of ultrasound on the rate of reaction. The results are shown in Fig. 4, where the variation in the constants with acoustic power is given. At a fixed concentration (N/500) of ferrous ammonium sulphate, the kinetics of the reaction was studied by varying the R.F. output. The order velocity constants, as calculated both theoretically and graphically, are given in Table II.

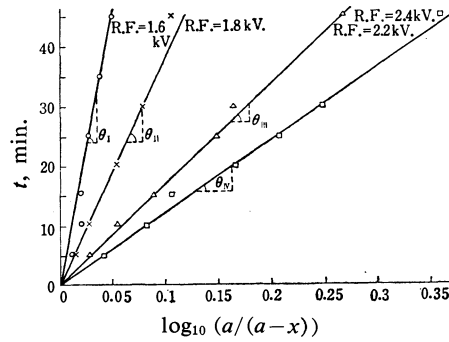

Fig. 4. The effect of ultrasonic intensity.

TABLE II. KINETICS OF REACTION AT DIFFERENT INTENSITIES OF ULTRASOUND

R. F. output kV.	$k_1 \times 10^3$ min^{-1}	
	$k_1 = (2.303/t) \cdot \log_{10}(a/(a-x))$	From graph (Fig. 4)
1.6	3.048	2.530
1.8	6.266	6.073
2.2	13.685	13.160
2.4	18.684	18.679

It is clear from the above data, as well as from Fig. 4, that the sonic intensity has a pronounced effect on the rate of reaction. The values of k_1 continuously increase with an increase in the R. F. output voltage. Further, it may also be concluded that the increase in k_1 values is slower at lower powers than at higher ones.

It is well known that chemical reactions do not occur at very low intensities. Nearly all the observed chemical effects of ultrasonic irradiation in liquid systems occur only at intensities sufficient to induce cavitation within the system. Cavitation is only initiated when and where the pressure amplitude is

greater than the cavitation threshold amplitude. Above this threshold value the reaction rate increases continuously. The increase in intensity will result in an increase in the cavitational intensity, which may be defined as the capability of cavities to bring about chemical reactions. It is evident that, as the number of cavitational holes increases, more and more cavities will form and collapse, resulting in an increase in the rate of the reaction. In the experimental procedure, it was found in most cases that the initial rate (k_1) was slightly higher than the rates during the progress of the reaction. The higher initial rate is most probably connected with the absence of scattering gas bubbles in the very beginning of the reaction.

The formation of hydrogen peroxide from water, when it is exposed to ultrasonic waves, is a complex process, involving many interrelated reactions. The most probable mechanism of the sonolysis of water is the free radical mechanism proposed recently by Weissler,[18] Lindström et al.,[19] Prudhomme et al.[20], and others.[14,21] They have all suggested the formation of H_2O_2 and some freee radicals, such as H, OH and HO_2. According to Weissler, the various steps involved may be written as:

$$H\cdot OH \rightarrow H + OH$$
$$H + H \rightarrow H_2$$
$$OH + OH \rightarrow H_2O_2$$
$$H + H_2O_2 \rightarrow H_2O + OH$$
$$OH + H_2 \rightarrow H_2O + H$$

In oxygenated solutions, additional hydrogen peroxide may be formed by a route involving, perhydroxyl (HO_2) radical:

$$H + O_2 \rightarrow HO_2$$
$$HO_2 + HO_2 \rightarrow H_2O_2 + O_2$$

When a solution of ferrous ammonium sulphate in water is exposed to ultrasonic waves, the formation of H, OH, HO_2 and H_2O_2, as has been described above, is the primary step. Since the cavitation bubbles collapse and those formed at the solid nuclei are weak, the direct decomposition of ferrous ammonium sulphate is doubtful. The presence of a gas[21-25] is always a necessary condition for the occurrence of cavitational chemical reactions. Most probably, the primary decompositions due to the cavitation take place in the gas phase inside the cavitation bubbles.[26,27] Therefore, the oxidation of potassium iodide or of ferrous ammonium sulphfate may be regarded as a secondary reaction brought about by the products of the primary reactions.

The major pioneering work introducing the concept of inorganic free radicals in the field of reaction kinetics was that of Haber and Weiss.[28-29] We have made use as follows of the steps suggested to explain the oxidation mechanism:

	Heat, kcal.
$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH$	
$\rightarrow Fe^{3+}\cdot OH^- + OH$	$-(5 \text{ to } 7)$
$Fe^{2+} + OH \rightarrow Fe^{3+} + OH^-$	$+42$
$Fe^{2+} + HO_2 \rightleftarrows Fe^{3+} + HO_2^-$	$+29$

The $Fe^{3+}\cdot OH^-$ radical may further combine as:

$$Fe^{3+}\cdot OH^- + OH \rightarrow Fe^{2+} + H_2O_2 \quad +(5 \text{ to } 7)$$

The heats of reaction are taken from Uri's review.[30]

The auto-oxidation of Fe^{2+} may also take place due to activated oxygen:

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^-$$

At a lower concentration the formation of chain carriers (H_2O_2, HO_2 and OH) is enhanced, resulting in an increase in the reaction rate.

Summary

With the help of Mullard's high frequency ultrasonic generator, type E-7562, with a barium titanate transducer with a frequency of 1 Mc, the oxidation of an acidic ferrous ammonium sulphate solution has been studied. The kinetics of the reaction, at six different concentrations of a ferrous ammonium sulphate solution and at four different ultrasonic intensities has been investigated. The reaction has been found to obey the first order kinetics. A probable mechanism based on the Haber-Weiss work has also been proposed.

Analysis of the Volatile Constituents of Hamanasu Absolute Oil

By Kiichi NISHIMURA, Tsutomu SAKAI, Mieko OGAWA and Yoshio HIROSE

(Received January 18, 1964)

Previously[1] three of the present authors presented detailed analytical data on the volatile constituents of commercial Hamanasu flower absolute oil and predicted the presence of a minute quantity of a component which is thought to be essential for the floral note of the Hamanasu flower. This report will present some additional data and observations which have been obtained in preliminary attempts to separate this characteristic ingredient.

Experimental

Preliminary Separation of the Materials. — To remove unnecessary non-volatile fractions, 100 g. of commercial Hamanasu absolute oil was steam-distilled; 65 g. of volatile oil was thereby obtained. Then, by treating this volatile oil three times with 5 g. of the Girard T reagent, 30 mg. of the carbonyl fraction was separated. As has been reported, the volatile fraction of Hamanasu absolute oil is composed mainly of phenylethyl alcohol, and it was desirable to separate the gross part of it in order to facilitate the further fractionation of minute components. For this purpose, a mixture of 62 g. of the volatile oil, 100 g. of phthalic anhydride, and 100 cc. of benzene was refluxed for 3 hr. on a water-bath. Acid phthalate and the excess phthalic anhydride were removed from the reaction mixture in the usual way, leaving 7.4 g. of unchanged oil. The same procedure was repeated to give 1.9 g. of an oil which was shown to contain only a few alcoholic compound by measuring its infrared spectrum. Alcoholic compounds regenerated from the acid phthalate by alkaline hydrolysis had a rather simple oder of phenylethyl alcohol and seemed to contain no characteristic ingredients.

Gas Chromatography.—Gas chromatography was carried out using a Shimadzu GC-2B type gas chromatograph: column; polyethylene glycol (25%) on celite, 3 m.; temp., 170°C; carrier gas, N_2.

Liquid Chromatography.—Mallinickrodt's silicic acid was used as the adsorbent, and a hexane solution of ether (3%, 5%, 10%, 30%), as the elute solvent.

Paper Chromatography. — 2,4-Dinitrophenylhydrazones were chromatographed, on a filter paper impregnated with *N,N*-dimethylformamide as the stationary phase, by developing it with cyclohexane saturated with *N,N*-dimethylformamide.

Results and Discussion

The final non-alcoholic oil was subjected to adsorption chromatography and separated into 18 fractions. Each fraction was analyzed by means of gas chromatography and infrared spectroscopy. The compounds identified are shown in Table I.

For illustration, the full composition of the volatile fraction of Hamanasu absolute oil is presented in Table II (in which the dotted items are newly added as a result of this study), together with the composition of Bulgarian rose oil, in which the content of every component was estimated in the authors' laboratory. Carbonyl compounds that could be identified only by paper chromatography are omitted from this table, as they will be discussed in a later part of this report.

It may safely be predicted that the effect of the combination of the constituents of Hamanasu oil is essentially the same as that of Bulgarian rose oil, although the proportions of some ingredients are quite different in these two species of rose. It is curious that there seems to be no organoleptic evaluation of rose oxide in the litrature. The authors reconstituted Hamanasu oil according to their complete analytical data and observed that rose oxide has a marked effect in adding freshness to the floral note. However, some other component is still missing, the floral tone itself; for the time being, this missing component is insufficiently substituted for by ionone or irone.

The carbonyl fraction, separated by the Girard T reagent, was treated with an acidic solution of 2,4-dinitrophenylhydrazine. The products were extracted with chloroform, concentrated to a small volume, and subjected to

** Fractions 13 to 18, were mainly phthalic acid diester.

paper chromatography. When the same procedure was followed as with Bulgarian rose oil, it was found that the chromatogram of the carbonyl fraction of Hamanasu oil is very simillar to that of Bulgarian rose oil. These results are shown in Table III.

Every spot of each chromatogram was cut into pieces and extracted with chloroform, and the ultraviolet adsorption of each extract was measured in neutral and basic solutions (Table IV).

When the deterioration of the peak at the end of one hour was observed, all spots except spot No. 2 from Bulgarian rose oil and spots No. 1 to 4 from Hamanasu oil developed an aliphatic aldehyde character. This would account for the well-known fact that lower homologs of aliphatic aldehyde occur frequently

in natural products as common ingredients and/or as degradation products in the course of processing.

The aliphatic aldehyde character was not shown by spot No. 2 from Bulgarian rose oil and spot No. 6 from Hamanasu oil, however, in spite of the fact that the R_f values of these spots correspond to those of acetaldehyde and butyraldehyde respectively. Neither spot corresponds to any simple ketones or aromatic aldehydes. After all, these rose oils probably contain some unknown compounds of an α,β-unsaturated aldehyde or polyfunctional ketone character.

In 1958, Panayotov and Ivanov[2] applied the paper chromatographic technique to the carbonyl fraction isolated by the extraction of Bulgarian rose oil with a sodium bisulfite solution; they thus identified eight components, including cinnamaldehyde, salicylic aldehyde and carvone, by merely referring to the R_f value of each spot. However, it was difficult for the authors of this paper to derive any positive evidence of the presence of those carbonyl compounds in either Bulgarian rose oil or Hamanasu oil, even by taking both liquid and paper chromatographic data into account.

Summary

The separation of the carbonyl fraction and the non-alcoholic fraction, by the Girard T reagent and phthalic anhydride respectively, from the principal constituent, phenylethyl alcohol, of Hamanasu flower absolute oil, and the successive analyses of each fraction have been carried out in order to elucidate the essential olfactory ingredient of the rose oil. The attempt resulted in adding some new components to those listed in the previous report: rose oxide, citronellyl acetate, geranyl acetate and methyleugenol.

The variety of the components has been proven to be essentially the same as in Bulgarian rose oil, although the proportion differs in some components.

Synthesis of Benzocyclobutene by Photochemical Desulfonylation

By Yoshinobu ODAIRA, Kenzo YAMAJI and Shigeru TSUTSUMI

(Received March 9, 1964)

As part of the investigation of the synthesis of cyclic compounds, studies of the decarbonylation of cycloalkanones[1,2] and the denitrogenation of diazo-cycloalkanones[3-8] by photochemical reaction have been extensively carried out by several groups of workers in recent years. Little attention has, however, been paid to the synthesis of cyclic compounds by the photo-desulfonylation of the cyclic sulfone; up to the present, no reports along this line have been made.

On the other hand, concerning the desulfonylation of cyclic sulfone, it has been shown in earlier papers[9,10] that a few cyclic compounds were produced by pyrolyses of the corresponding cyclic sulfones. On the whole, however, not only were the pyrolytic conditions employed in the above experiments very drastic, but also the yields of the resulting cyclic compounds were rather insignificant. For example, the pyrolysis of 1, 3-dihydroisothianaphthene-2, 2-dioxide in the molten state at temperatures between 280°C and 300°C[7] gave a mixture of *o*-xylene, benzocyclobutene and 1, 2, 5, 6-dibenzocycloöctadiene in yields as low as 3.2, 12.8 and 4.0% respectively.

It was well known that the aromatic compounds containing a sulfonyl group exhibit intense absorption in the ultraviolet region. Therefore, it might be expected that the desulfonylation of aromatic sulfone would be photochemically accelerated by the collisional transfer of vibrational energy from excited molecules to foreign molecules.

The present investigation was undertaken to confirm the feasibility of the synthesis of the benzocyclobutene ring system by the photolysis of 1, 3-dihydroisothianaphtene-2, 2-dioxide.

Results and Discussion

The results of the formation of benzocyclobutene by the decomposition of the sulfone are listed in Table I.

TABLE I. DECOMPOSITION OF 1, 3-DIHYDROISOTHIANAPHTHENE-2, 2-DIOXIDE[a]

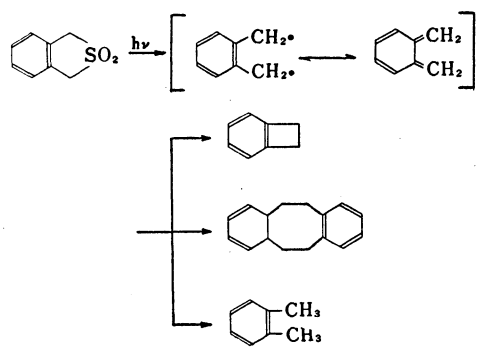
Expt. No.	Temp. °C	Irradiation	Benzocyclobutene yield,[b] %
1	200	−	2.6
2	200	+	4.0
3	250	−	17.5
4	250	+	24.9
5	300	−	30.7
6	300	+	39.2
7	350	−	42.0
8	350	+	53.2

a) Each experiment was carried out in the reduced pressure system.
b) Based on total amount of the sulfone used.

In each case, benzocyclobutene was obtained as the major product, together with small amounts of 1, 2, 5, 6-dibenzocycloöctadiene; in addition, the molar ratios of benzocyclobutene and 1, 2, 5, 6-dibenzocycloöctadiene were approximately between 3.9 and 4.1. In some cases, however, with irradiation (Expt. 4 and 6), the products were contaminated by a trace amount of *o*-xylene. From the above results, it may be concluded that the temperature change, within the range of 200~350°C, has an obvious effect on the conversion of the sulfone and that the irradiation considerably accelerates the desulfonylation of the sulfone. As has been described earlier, in every reaction under reduced pressure it has been observed that the ultraviolet-light has no remarkable effect on the molar ratio of benzocyclobutene and 1, 2, 5, 6-dibenzocycloöctadiene. On the other hand, in the reaction under the atmospheric pressure (Expt. 9), the formation of 1, 2, 5, 6-dibenzocycloöctadiene increases, while the formation of benzocyclobutene, on the contrary, decreases, the formation of a small amount of *o*-xylene being clearly observed, as is shown in Table II.

Although one would expect that, from the stand point of chemical equilibrium, reducing

TABLE II. EFFECT OF REACTION PRESSURE ON THE COMPOSITION OF PRODUCT



Expt. No.	Temp. °C	Press. mmHg	Yield,[a] %		
			Benzocyclobutene	Dibenzocyclooctadiene	*o*-Xylene
5	300	12~15	30.7	8.1	—
9[b]	300	760	7.8	28.3	2.0

a) Based on total amount of the sulfone.
b) In the absence of ultraviolet-light.

the pressure would accelerates the desulfonylation considerably, the total amount of the decomposition product was nearly equal to the amount of the reaction product under the reduced pressure. Moreover, in order to ascertain the thermal behavior of benzocyclobutene, a further experiment was carried out. When benzocyclobutene was heated under atmospheric pressure at 300°C for 2 hr., 1, 2, 5, 6-dibenzocycloöctadiene was formed in a 57.1% yield, along with a trace amount of *o*-xylene.

In view of the above facts, the most reasonable conclusions to be drawn are that the rate of desulfonylation is independent of the reaction pressure, and that the reaction pressure plays a very important role in the further reaction of the intermediate *o*-xylylene biradical generated by the desulfonylation of the sulfone. Namely, as soon as benzocyclobutene is formed by desulfonylation under reduced pressure, it is immediately removed from the reaction vessel without collision with the other. Consequently, the dimerization of benzocyclobutene was considerably suppressed.

It seems to be more reasonable to consider that the decomposition of 1, 3-dihydroisothianaphthene-2, 2-dioxide may proceed through the intermediate *o*-xylylene biradical, which may be a mesomeric species, and be generated by the desulfonylation of the above sulfone. The intramolecular cyclization of the biradical will lead to benzocyclobutene and the dimerization to 1, 2, 5, 6-dibenzocycloöctadine. Furthermore, it may perhaps be presumed that *o*-xylene is formed by the hydrogen abstraction of the intermediate biradical from the sulfone or the above cyclic products.

Further investigations into the photochemical desulfonylation of various cyclic sulfones are being carried out in this laboratory.

Experimental

Materials. — Forty grams of 1, 3-dihydroisothianaphthene, prepared according to the directions of Cava et al.,[10] were added drop by drop, over a period of 3.5 hr., into 11.3% peracetic acid (930 ml.) with stirring. The temperature was maintatined at 5~10°C during the addition of the sulfide, and after the addition was complete, the mixture was allowed to stand at room temperature for 1 day. After cold water (1000 ml.) had then been stirred into the above mixture, the crude sulfone was precipitated, collected by filtration, and dried. The concentration of the mother liquors in vacuo gave an additional sulfone. Three recrystallizations from benzene-petroleum ether gave 44.6 g. (90.3%) of 1, 3-dihydroisothianaphthene-2, 2-dioxide, m. p. 148.5 ~149.0°C.

Found: C, 57.08; H, 4.81. Calcd. for $C_8H_8O_2S$: C, 57.14; H, 4.80%.

Apparatus and Procedure.—The photolyses were conducted in a reaction vessel connected by a stopcock to a manometer, two traps and a vacuum pump. The reaction vessel, containing a thermometer and the low pressure mercury resonance lamp (100 W.), was a cylindrical glass cell, with an internal diameter of 8.0 cm. and a length of 25 cm.; it was coiled with the flexible heater and placed on the shaking machine. Pulverized 1, 3-dihydroisothianaphthene-2, 2-dioxide (5.0 g.) was placed in the reaction tube, and a considerable volume of glass-wool was stuffed into the output-part of the reaction vessel to avoid trouble due to the sublimation of the starting material. Before the reaction began, the system was swept by nitrogen gas and evacuated to 12~15 mmHg. The reactions, regardless of the presence or absence of the ultraviolet-light, were carried out at 200~350°C with shaking at the reduced pressure of 12~15 mmHg for 5 hr.

After the reaction was complete, the volatile product, which had been collected in traps cooled at −78°C by a dry-ice-acetone bath was, analyzed by gas chromatography, using a 3 m. tricresyl phosphate column at 110°C; it was thus confirmed to be usually composed of only one component, except for the rare case when that component is accompanied by a trace of *o*-xylene. The volatile product

was distilled under reduced pressure, giving a colorless benzocyclobutene, b. p. 52.0~52.5°C/22 mmHg, n_D^{21} 1.5405 (Lit.[11] b. p. 50.5~51.0°C/20 mmHg; n_D^{20} 1.5421). It showed infrared absorption bands at 1580, 1545, 1475, 778 and 717 cm^{-1} (*o*-disubstituted benzene); the ultraviolet spectrum of this compound was in full accordance with that described in the literature.

A mixture of 0.5 g. of benzocyclobutene and 0.6 g. of maleic anhydride in 1.5 ml. of benzene was heated in a sealed tube at 130°C for 30 hr. After the reaction mixture had been distilled under reduced pressure to remove any unchanged substances, the residual solid was sublimed at 150~165°C/3 mmHg. Recrystallization of the sublimate from benzene gave 0.55 g. of 1,2,3,4-tetrahydronaphthalene-*cis*-2,3-dicarboxylic anhydride as white needles, m. p. 188.0~188.5°C (Lit.[12] m. p. 189°C).

The brownish residue in the reaction vessel was extracted with a large amount of petroleum ether as completely as possible. The ethereal extract was then dried over anhydrous sodium sulfate, and the solvent was evaporated. The residue was dissolved in benzene - light-petroleum ether (1 : 10) and chromatographed over alumina. The evaporation of the solvent from the effluent left colorles crystals. Recrystallization from ethyl alcohol afforded 1,2,5,6-dibenzocycloöctadiene as white needles, m. p. 108°C (Lit.[10] m. p. 109~110°C).

Found: C, 92.38; H, 7.41. Calcd. for $C_{16}H_{16}$: C, 92.26; H, 7.74%.

It showed infrared absorption bands at 1595, 1585, 1485, 755 and 733 cm^{-1} (*o*-disubstituted benzene); and at 3000 cm^{-1} (=C-H). Moreover, in its ultraviolet spctrum, the maximum absorptions were present in 264.0 mμ ($\log \varepsilon$ 2.965) and 272.0 mμ ($\log \varepsilon$ 2.667) in 95% ethyl alcohol.

Summary

The synthesis of benzocyclobutene by the photochemical desulfonylation of 1,3-dihydroisothianaphthene-2,2-dioxide has been studied and the following results obtained; 1) The irradiation considerably accelerates the desulfonylation of the sulfone, while the ultraviolet-light has no remarkable effect on the molar ratio of the formed benzocyclobutene and 1,2,5,6-dibenzocycloöctadiene. 2) The rate of desulfonylation is independent of pressure, and the reaction pressure plays a very important role in the further reaction of the intermediate *o*-xylylene biradical produced by the desulfonylation.

The Complexometric Estimation of Ferric Iron

By Balwant SINGH, M. S. MANKOTIA and H. S. LAMBA

(Received March 17, 1964)

1, 2-Diaminocyclohexane-*N*, *N*, *N'*, *N'*-tetraacetic acid (CyDTA) forms a very stable 1 : 1 complex with ferric iron, and the complex serves as a basis for the complexometric determination of this metal. Přibil[1] used salicylic acid as an indicator for the complexometric determination of iron(III) with CyDTA (disodium salt). Martinez and Mendoza[2] suggested the use of sulphosalicylic acid, tiron and potassium thiocyanate as indicators for the determination of ferric iron with CyDTA at pH values from 2 to 5 and at a temperature of 50°C, but they found that the results were 1 to 5 per cent too high. Přibil and Sir[3] determined iron(III) in the presence of aluminium and titanium in a weakly alkaline pyridine solution by masking aluminium and titanium with a two per cent solution of ammonium fluoride. An excess of CyDTA was added and back titrated with zinc chloride or zinc sulphate, using Eriochrome Black T as an indicator. Martinez and Mendoza[4] have also determined ferric iron photometrically with CyDTA at pH 4. Koroz and Poczoc[5] estimated iron(III) in the presence of calcium and magnesium, with sulphosalicylic acid as an indicator, at pH values from 2 to 3 at 60°C.

No more evidence is available in the literature for the determination of ferric iron with

CyDTA. In the present work, an attempt has been made to determine ferric iron alone as well as in the presence of various metal ions by titration with CyDTA (disodium salt), using pyrocatechol violet at pH 3.09 or *p*-anisidine-thiocyanate at pH 4.2 as an indicator. The end point of the complexometric titration in both cases is very sharp, and there is no dragging of indicator colour near the end point. The titrations can be successfully made at room temperature.

Experimental

The Preparation of Standard CyDTA (Disodium Salt). — 0.05 M CyDTA (disodium salt) was prepared by dissolving 35.45 g. of CyDTA in 400 ml. of boiling 0.5 N sodium hydroxide and diluting it to two litres in metal-free distilled water. This was further diluted ten times to prepare 0.005 M CyDTA (disodium salt).

The Preparation of a *p*-Anisidine-thiocyanate Indicator Solution.[6]—9.7175 g. of potassium thiocyanate were dissolved in water, and the volume made to 50 ml. In ethyl alcohol 1.2315 g. of *p*-anisidine were dissolved and the total volume of the solution was made to 50 ml. The two solutions were then mixed together, and the mixture used as *p*-anisidine-thiocyanate indicator.

The Preparation of a Pyrocatechol Violet Indicator Solution.—0.1 g. of pyrocatechol violet was dissolved in distilled water, and its volume made to 100 ml.

Results

The Estimation of Ferric Iron in Presence of Other Metal Ions.—An aliquot of a ferric nitrate solution was taken in a conical flask containing 50 ml. of water, and then 2 to 3 drops of pyrocatechol violet or *p*-anisidine-thiocyanate were added to it. A sodium acetate and hydrochloric acid buffer was added to adjust the pH of the solution to 3.09 or 1.42 respectively. The mixture was titrated with 0.005 M CyDTA (disodium salt). The end

6) B. Singh, S. S. Sahota and M. S. Mankotia, *Z. anal. Chem.*, **173**, 275 (1960).

point was marked by a sharp colour change from blue to yellow in the case of pyrocatechol violet and from violet to yellow when *p*-anisidine-thiocyanate was used as the indicator. The titration was then performed in the presence of barium chloride, calcium chloride, strontium nitrate, chromium nitrate, mercuric nitrate, magnesium sulphate, thorium nitrate, sodium fluoride, ammonium oxalate, copper sulphate, nickel acetate, cobalt chloride and manganese chloride respectively. Some typical results are given in Table I.

From the data given in Table I it is evident that ferric iron, alone or in the presence of Ba^{2+}, Ca^{2+}, Sr^{2+}, Cr^{3+}, or Hg^{2+}, can be determined volumetrically by titrating it with a CyDTA (disodium salt) solution, using pyrocatechol violet or *p*-anisidine-thiocyanate as an indicator.

Thorium nitrate interferes in this titration, because CyDTA forms a 1 : 1 complex with thorium as well as with iron(III) ; the amount of CyDTA used is, therefore, double that required for the estimation of iron(III). In the presence of sodium fluoride and ammonium oxalate, there is no end point in the complexometric determination of ferric iron with CyDTA (disodium salt) because of the formation of stable complexes of iron fiuoride and iron oxalate respectively. Because of the presence of coloured compounds (copper sulphate, cobalt chloride and manganese chloride), no end point was detected in these titrations.

Summary

Ferric iron has been determined, alone or in the presence of Ba^{2+}, Ca^{2+}, Sr^{2+}, Cr^{3+} or Hg^{2+}, by titrating it with CyDTA (disodium salt), using pyrocatechol violet and *p*-anisidine-thiocyanate as indicators at pH 3.09 and 1.42 respectively. Th^{4+}, F^-, $C_2O_4^{2-}$, Cu^{2+}, Ni^{2+}, Co^{2+} and Mn^{2+} have been found to interfere in the complexometric estimation of ferric iron with CyDTA (disodium salt).

The authors wish to take this opportunity to thank the Council of Scientific and Industrial Research (India) for the award of Junior Fellowship to one of them (M. S. M.), thus enabling him to pursue the study of complexometric titrations.

The Kinetics of the Reaction of Aromatic Ketones with Nitrous Acid in Sulfuric Acid

By Yoshiro OGATA, Yoshiaki FURUYA and Masahiro ITO

(Received March 17, 1964)

The present authors have previously reported that the rate-determining step for the nitrosation of cyclohexyl aryl ketones in sulfuric acid (SNIA process) is the enolization of the ketone.[1] The present paper will describe the effect of the structure of alkyl phenyl ketones on the rate, where the alkyl groups are methyl, isopropyl and isobutyl. The rates were measured by means of ultraviolet spectrophotometry. The rate data, together with the observed reaction products, including gaseous products, were analyzed to get some information on the reaction mechanism.

Experimental

Materials.—Commercial acetophenone was purified by distillation; b. p. 195~196.5°C. *p*-Methylacetophenone (b. p. 117.5~118.1C/31 mmHg), *p*-chloroacetophenone[2] (b. p. 126~127.5°C/27 mmHg), propiophenone[3] (b. p. 108~109°C/23.5 mmHg) and isobutyrophenone[4] (b. p. 106~107°C/21.0 mmHg) were prepared by Friedel-Crafts reactions of the corresponding aromatics with the corresponding acid anhydrides or acyl chlorides. *m*-Nitroacetophenone[5] was prepared by the nitration of acetophenone and recrystallized from ethanol; m. p. 78.8~79.2°C.

Isonitrosoacetophenone[6] was obtained by the reaction of acetophenone with methyl nitrite in ethyl ether and was recrystallized from toluene, m. p. 127~128.5°C. Phenylglyoxal[7] was prepared

by the oxidation of acetophenone with selenium dioxide in dioxane; b. p. 94~96°C/24.8 mmHg.

The Reaction Products.—*From Acetophenone.*—A solution of 20 ml. of 2.0 M acetophenone in 98.0% sulfuric acid and a solution of 40 ml. of 1.5 M sodium nitrite in 98.0% sulfuric acid were mixed; the mixture was then kept standing at 70°C for 7 hr. The resulting solution was diluted with water and extracted with ether. The ethereal extract was treated with aqueous alkali, and the aqueous layer was then acidified with hydrochloric acid and filtered. Benzoic acid was obtained; 4.6 g. (93.0%); λ_{max}=228 mμ; m. p. and mixture m. p. 123~124.8°C.

From Propiophenone.—A mixture of propiophenone (4.0 g.) and sodium nitrite (2.8 g.) in 98% sulfuric acid was allowed to stand at 70°C for 6 hr. Benzoic acid was obtained; 3.6 g. (97%); m. p. and mixture m. p. 120.5~122°C.

From Isobutyrophenone.—A mixture of isobutyrophenone (7.2 g.) and sodium nitrite (4.2 g.) in 95% sulfuric acid was heated at 60°C for 4.5 hr. The obtained product contained benzoic acid (5.6 g. (94%); m. p. and mixture m. p. 123~124°C) and acetoxime (0.7 g. (20%); m. p. and mixture m. p. 60~61°C (lit.[8] m. p. 60°C)).

From Isonitrosoacetophenone.—Isonitrosoacetophenone (1 g.) in 98% sulfuric acid was heated for 4 hr. at 70°C, yielding benzoic acid (0.8 g. (97%); m. p. and mixture m. p. 122~123.5°C).

Ultraviolet Spectrophotometry and Chemical Analysis.—The conversion curves were prepared as has been previously described.[1] The following different extinctions were employed: acetophenone, (E_{228}—E_{241}) vs. (E_{241}—E_{280}); *p*-methylacetophenone (E_{237}—E_{252}) vs. (E_{252}—E_{280}); *p*-chloroacetophenone, (E_{237}—E_{250}) vs. (E_{250}—E_{280}); *m*-nitroacetophenone, (E_{217}—E_{256}) vs. (E_{217}—E_{300}); propiophenone, (E_{228}—E_{240}) vs. (E_{240}—E_{270}), and isobutyrophenone, (E_{228}—E_{241}) vs. (E_{241}—E_{270}).

A Typical Run for the Rate Measurements.—A solution of 5 ml. of 0.4 M acetophenone in 98.6% sulfuric acid in a stoppered flask was brought to temperature equilibrium at 70°C. Then the reaction was started by the addition of 0.5 M sodium nitrite (5 ml.) in 98.6% sulfuric acid at 70°C. Aliquots (0.5 ml. each) were taken out at appropriate time intervals, and each aliquot was diluted with methanol to a 10^{-4} M total concentration of aryl ketone plus aryl carboxylic acid. The conversion percentage was determined graphically.

Results and Discussion

Acetophenone.—The rate of the reaction of acetophenone in 98.6% sulfuric acid with an initial concentration of 0.2 M ketone and in 0.097~0.388 M nitrous acid at 70°C satisfied the second-order rate law (Table I):

$$v = k\,[\text{ketone}]\,[HNO_2]$$

Lowering the concentration of sulfuric acid resulted in an increase in the amount of by-products, including gas, and, hence, a deviation from the second-order rate law; e. g., with 86% sulfuric acid the yield of benzoic acid was poor (30%).

It has been known that isonitrosoacetophenone PhCOCH=NOH is isolable as an intermediate in the reaction of acetophenone with nitrosyl chloride in ethanolic pyridine.[9] The authors observed that isonitrosoacetophenone converted rapidly to benzoic acid in sulfuric acid at 70°C, the conversion slowing down with a decrease in the sulfuric acid concentration as measured spectrophotometrically. When the conversion was made in dilute sulfuric acid in the presence of nitrous acid, nitrous oxide was detected by gas chromatography (Table II), as reported in the reaction of isonitrosoacetophenone with nitrosyl chloride.[9] Phenyl glyoxal, which has been known as one of the other products in the reaction using nitrosyl chloride,[9] was converted to a tarry material in sulfuric acid.

TABLE I. THE RATE DATA OF NITROSATION OF ALKYL PHENYL KETONES IN 98.6% SULFURIC ACID

Ketone	Temp. °C	Initial concn. of ketone M	Initial concn. of HNO_2 M	First-order rate constant k sec^{-1}	Second-order rate constant k' $l.\,mol^{-1}\,sec^{-1}$

Propiophenone.—The reaction in 98.6% sulfuric acid at 60°C was first-order with both ketone and nitrous acid, as in the case of acetophenone (Table I). The product contained a quantitative amount of benzoic acid. Lowering the acidity of the solution resulted in the evolution of a gas which contained nitrous oxide and carbon monoxide (Table II).

Isobutyrophenone.—The rate law was different from those of acetophenone and propiophenone in that it obeyed the following first order equation (Table I):

$$v = k\,[\text{ketone}]$$

TABLE II. GAS CHROMATOGRAPHIC ANALYSIS OF EVOLUTION GASES FROM NITOSATION MIXTURES OF ACETOPHENONE, PROPIOPHENONE AND ISONITROSOACETOPHENONE IN 86.0% SULFURIC ACID AT 70°C

Column: Activated charcoal (30~60 mesh), 3 m.

$\Delta S^{\neq}$, e. u.	−4.3	−9.1	−10.5

ketone,[1] while the rate-determining step for acetophenone or propiophenone is an attack of nitrosonium ions.

$$HON{=}C\begin{matrix}R\\ \diagup\\ \diagdown\\ R'\end{matrix} \longrightarrow RCONHR' \text{ (or } R'CONHR) \quad (5)$$

Defining k and K as the rate and equilibrium constants for the subscripted steps, and S and E as ketone and enol respectively, the following equations are derived by means of the stationary-state method:

$$k_2[SH^+][B] = k_{-2}[E][BH^+] + k_3[E][NO^+] \quad (6)$$

The introduction of the relation:

$$[SH^+] = K_1[H^+](a-x)/(1+K_1[H^+]) \quad (7)$$

into Eq. 6 gives Eq. 8, where $(a-x)$ is the stoichiometric concentration of ketone.

$$[E] = \frac{K_1k_2[B][H^+](a-x)}{(k_{-2}[BH^+]+k_3[NO^+])(1+K_1[H^+])} \quad (8)$$

Therefore, assuming that step 4 is very fast, the rate of the formation of benzoic acid may be expressed as:

$$v = k[NO^+][E] = \frac{K_1k_2[NO^+][B][H^+](a-x)}{(k_{-2}[BH^+]+k_3[NO^+])(1+K_1[H^+])} \quad (9)$$

The observed results imply that $k_{-2}[BH^+] \gg k_3[NO^+]$ with acetophnone and propiophenone, while $k_{-2}[BH^+] \ll k_3[NO^+]$ with isobutyrophenone and cyclohexyl aryl ketone; i.e., the rate is determined by step 2. The deprotonation of the conjugate acid of isobutyrophenone is more difficult because of the steric hindrance, electron-releasing effect of the methyl group and also the decrease in the number of α-hydrogen atoms: therefore, step 2 may be slowed down to a rate-determining step. A slight increase in the first-order rate constant with an increase in the initial concentration of nitrous acid was observed with isobutyrophenone; this may be explained by a small tendency of the rate to be rather second-order.

Electron-attracting groups in acetophenone accelerate the reaction, probably because of their favorable effect on deprotonation step 2. The substituent effect was reversed for the bromination of acetophenone in 75% aqueous acetic acid.[10] The facts may be explained by the lower acidity of the latter reaction, by which protonation step 1 is affected by substituents, while ketones in sulfuric acid are completely protonated.

A direct attack of nitrosonium ions on the α-position of ketone may lead to the second-order rate law, but this electrophilc attack is less probable because of the strong electron-withdrawal of the carbonyl group. Moreover, the rate-determining decomposition of nitrosoketone (Eq. 4) is unconceivable, since it was observed that nitrosoketone in sulfuric acid decomposes much faster than the nitrosation of the ketone. The rate of step 4 increases with an increase in the acidity of the sulfuric acid solution; hence, the amount of by-product decreases.

Summary

The rates of the reaction of acetophenone, ring-substituted acetophenones, propiophenone and isobutyrophenone with nitrous acid in 98.6% sulfuric acid have been measured by means of spectrophotometry. The rates have been expressed as $v=k$[ketone][NO^+] with acetophenones and propiophenone, while they are $v=k$[ketone] with isobutyrophenone. The electron-attracting groups in acetophenone accelerate the reaction with Hammett's ρ value of +2.6. A probable mechanism has been suggested which involves a rate-determining nitrosation of enolized ketone for acetophenone and propiophenone, and a rate-determining enolization of ketone for isbutyrophenone.

Metal Complexes of Mononitrosochromotropic Acid. A Study of the Copper Complex and Its Chelometric Titrations

By Sachindra Kumar DATTA and Sachindra Nath SAHA

(Received March 17, 1964)

It appears that chromotropic acid forms two nitroso derivatives; mononitroso and dinitroso.[1] The dinitrosochromotropic acid has been used by Steigmann[2] for the detection of copper, nickel and palladium. Datta[3] used this compound for the complexometric and spectrophotometric determination of thorium. The mononitroso derivative has been utilised by various workers for the detection and determination of copper, cobalt and nickel. Since the two nitroso compounds of chromotropic acid give colour reactions with many metals, a thorough investigation of the colour complexes and their probable analytical applications has been undertaken by the present authors.[5] The following elements were found to give coloured products with mononitrosochromotropic acid: copper, palladium, cobalt, nickel, magnesium, manganese, vanadium, uranium, beryllium, iron(III), chromium, cerium(III), lanthanum, gold, thorium, zirconium, etc. Lead and cobalt(III) form a coloured precipitate. Methods for the detection of most of these and of fluoride ion on the spot plate and filter paper have already been developed.[6]

The present paper will deal with the copper complex of mononitrosochromotropic acid (abbreviated as MNCA) and will make a thorough study of its application in the complexometric determination of copper. This reagent has been used recently by Pande and Srivastava,[7] and later by Sen and Srivastava,[8] as an indicator in the titration of copper with EDTA. However, they carried out such titrations only in a pure solution, and the interference in the titration has not been studied in detail. The direct titration of copper with nitrosochromotropic acid carried out by Ansbacher and his co-workers[9] proved very unsatisfactory to the present authors. The method was also rejected as unsuitable by Conn et al.[10] in their determination of copper in milk. However, in all the works carried out by various workers, nitrosochromotropic acid was present in the solution in which it was prepared and that solution was employed as such, without isolating the pure product. The present authors prepared and isolated the compound in its pure form and used it for the experiments reported on here and earlier. The study of the copper complex by various physico-chemical methods and the spectrophotometric determination of copper with this reagent will be reported on shortly.

Experimental

Reagents and Chemicals.—*Copper Solution.*—A stock solution of A. R. copper sulphate pentahydrate was prepared in water containing a little sulphuric acid and was estimated with EDTA, using PAN as an indicator. The other copper salts were made from reagent-grade salts.

Reagent Solution.—Mononitrosochromotropic acid (MNCA) was prepared as has been reported earlier.[6] A 0.05% solution in water was used. Other indicator solutions: PAN, a 0.05% solution in ethanol; murexide, a saturated solution in water; pyrocatechol violet, a 0.1% solution in water, and Chrome Azurol S, a 0.4% solution in water.

EDTA. — Disodium dihydrogen ethylenediaminetetraacetate dihydrate (A. R.) was dissolved in water to make 0.05, 0.01 and 0.001 M solutions; it was estimated as usual by means of a standard calcium solution. The other reagents and chemicals used were also of reagent grade.

Apparatus. — A Beckman Model H-2 pH meter was used for the adjustment of the pH of the solutions.

Results

The Reaction of Copper with Mononitrosochromotropic Acid.—MNCA reacts with copper in a weakly acidic or weakly alkaline medium

to form a violet- or permanganate-coloured soluble complex. The formation of the copper complex with various copper salts has been studied. A few drops of an MNCA solution were added to 0.05 M solutions of different copper salts, which had previously been rendered almost neutral, and then the pH was raised by adding a 0.1 M ammonium hydroxide solution. The colour changes are noted in Table I. It appears that the same complex is formed with various copper salts and that the colour deepens only when the pH is raised.

TABLE I. REACTIONS OF MNCA WITH DIFFERENT COPPER SALTS

Copper salt	pH	Colour reactions
Copper sulphate	3.4	Pale pink
	8.0	Permanganate colour
Copper chloride	4.0	Pink
	7.8	Violet
Copper nitrate	4.2	Pink
	8.0	Violet
Copper acetate	5.5	Bluish violet
	7.8	Violet
Copper ammonium sulphate	5.2	Pale permanganate colour
	8.4	Violet
Copper ammonium chloride	3.5	Pink
	6.8	Violet
Copper oxalate	5.4	Violet colour on boiling
Copper citrate	3.4	Reddish pink
	7.3	Violet
Copper tartrate	3.2	Pale pink
	7.8	Pale violet
Copper perchlorate	3.8	Pink
	7.2	Violet
Copper glycinate	—	No colour formation at any pH
Copper iodate	4.4	Pink colour, intensifies on heating

Preliminary Studies of the Stability of the Copper Complex.—To 100 ml. of a 0.1 M copper sulphate solution, a solution of 1 M sodium acetate was added slowly until the pH became 5.6 to 6 and the volume had been diluted to 200 ml. To this mixture 50 ml. of 0.4 M MNCA was added, and the mixture was kept in a water bath at 40°C for 5 min. to complete the reaction. A deep-red-violet copper complex formed in the solution. The complex could not be isolated in the solid state or extracted by any organic solvent.

To 5 ml. of this complex solution, various substances (acids, alkalis, oxidizing agents, reducing agents, protective colloids, alcohols, ketones, amines, amino acids, polyhydroxy alcohols and other organic substances) were added in order to study the stability or instability of the copper complex in their presence. The results indicated are: The copper complex appears to be stable as such for about a week, and it remains stable in the presence of protective colloids, starch, gelatine, etc., for about a fortnight. The mineral acid decomposes it, and it breaks below pH 5. The colour intensifies with ammonium hydroxide, sodium hydroxide and potassium hydroxide, up to a pH of 9. No change is observed with ammonium carbonate. Among the oxidizing agents, a 0.1 M solution of potassium permanganate or dichromate at pH 5.6 to 5.8 discharges the colour of the complex slowly, but in the presence of acid, the decomposition is immediate. Hydrogen peroxide discharges the colour at once. Persulphates and periodates also decompose the complex. The reducing agents (ascorbic acid, hydroxylamine hydrochloride, hydroquinone in an alcoholic solution, sodium sulphite, etc.) break the complex, and the colour changes to yellow. With hydrogen sulphide, a black precipitate of copper sulphide forms. The complex is decomposed by thiosulphate, potassium iodide, ferro- and ferricyanides, and ammonium sulfocyanide, but it does not change with fluorides, molybdates, selenates, ammoniacal potassium iodide, or thiosulphate. The organic solvents, such as alcohols, ketones, esters, chloroform, carbon tetrachloride, and polyhydroxy alcohols, do not change the colour, nor can the complex be extracted in the organic phase. With acetylacetone, the complex breaks and the lower layer becomes blue because of the formation of copper acetylacetonate, while the upper layer becomes orange because of the liberation of the free reagent. Glycine and EDTA displaced copper from its complex.

The Titrimetric Determination of Copper with EDTA Using MNCA as an Indicator.—As the copper complex of MNCA is less stable than the copper-EDTA complex, the direct titration of copper with EDTA, using MNCA as an indicator, is possible. The end-point colour change is from a permanganate or violet colour to a greenish yellow or to an almost colourless state in a dilute solution. The optimum conditions for such titration have been developed from the study of various factors, such as pH, buffer solutions, the temperature, the dilution of the volume and the concentration and age of the indicator solution.

The Effect of pH and Buffer Solutions.—The titration of copper with EDTA has been carried out at various pH values in order to study the effect of hydrogen ion concentration in the titration employing this indicator. The effect of using different buffer solutions in fixing the pH has also been examined. One millilitre of a copper solution was mixed with 2 ml. of buffer solution, and the volume was diluted to about 30 ml. and 4 drops of an indicator solution (0.02%) were added. The

TABLE II. EFFECT OF pH AND BUFFER IN THE EDTA TITRATION OF COPPER
1 ml. of 0.1 M $CuSO_4$, taken 10 ml. of 0.01 M EDTA

Buffer used	pH	EDTA, reqd. ml.	Remarks on end point

	8.6	10.18	End point not sharp
	9.0	10.25	
	10.2	10.55	

mixture was then titrated with 0.01 M EDTA in the cold. Some of the results of this titration have been recorded in Table II and represented in Fig. 1.

The results indicate that pH range from 6.8 to 7 with a pyridine - hydrochloric acid buffer was suitable for the titration of copper. A sharp colour transition was obtained. Triethanolamine gave a little higher result, and the colour change at the end point was also not very sharp. An ammonium chloride - ammonia buffer gave good results from pH 7 to 8. A very sharp end point from a permanganate colour to pale yellow was obtained with this buffer. The titration at lower pH values, from 5.8 to 6.5, may also be carried out with a sodium acetate buffer, the end point colour transition is then sharp but not as good as that obtained with an ammonium chloride - ammonia buffer. Other buffers were not found suitable.

The Effect of Temperature.—Titration at different temperatures from 10 to 66°C showed that the complex is stable up to 40°C and that the titrations may be made at room temperature without any loss of accuracy.

The Effect of the Concentration of the Indicator.—In order to examine whether the concentration of the indicator solution has any effect on the titre value and on the sharpness of end point, titrations were carried out with different amounts of the indicator in 50 ml. of the titrant. It was seen that, in an ammonium chloride - ammonia buffer, when a few drops of a 0.05% indicator solution were gradually added to the pale blue copper solution, the blue colour gradually faded, the solution became almost colourless and then turned a pale permanganate colour, and, at the end point with EDTA, the colour changed to pale yellow or became nearly colourless. However, with a large ammount of indicator, the colour is deep yellow or orange, and with a larger amount of copper, the end point colour is a greenish-yellow. Too great an excess of the indicator obscures the end point. Good results are obtained with 0.2 to 0.5 ml. of a 0.05% indicator solution for a solution containing about 6 mg. of copper. The same results were

Curve D : 0.1 M $CuSO_4$ 0.7 ml., using triethanolamine buffer

obtained with a sodium acetate or pyridine buffer.

The Effect of the Dilution of Volume.—Titration was carried out by varying the volume of the titrant without changing the amount of indicator or copper. A 50 ml. volume gave good results. With a larger amount of copper, for instance, more than 10 mg., the volume should be about 100 ml. or larger.

The Age of the Indicator Solution.—The solution of the indicator is not very stable. A solution, once prepared, may be used for only a week with little loss of accuracy. It is desirable that the titrations always be carried out with solutions which are not older than two or three days, and such solutions should always be kept in amber-coloured bottles.

The Effect of Ketonic Solvents in the Titrant.—The sharpness of the end point of the titration has been found to improve slightly in the presence of some ketones, like acetone, diacetone alcohol or ethyl methyl ketone. The addition of about 10 ml. acetone per 50 ml. of volume was found to give good results.

Procedures Recommended for Pure Copper Solution.—a) Take 10 ml. of a nearly copper solution containing about 6~10 mg. copper in a 250 ml. conical flask, and add 2 ml. of 1 M ammonium chloride solution and 5 drops of 2 M ammonium hydroxide, 10 ml. of acetone and 4 drops of 0.05% indicator solution. Dilute the mixture to 50 ml. Adjust the pH to 7.2 to 7.4 with one or two more drops of ammonia. The solution then assumes a permanganate colour. Titrate in the cold with 0.01 M EDTA until the colour sharply changes to pale yellow. This method may be used for the determination of 2 to 30 mg. of copper in a solution.

b) To the above copper solution, add 1 ml. of pyridine and 4 drops of the indicator. Dilute to 50 ml. with water. The pH should be 7; if it is below, add 1 or 2 drops of a dilute pyridine solution (0.2%) in order to raise it to 7. The colour of the solution is violet. Titrate with EDTA. At the end point the colour changes from bluish-violet to greenish yellow or becomes almost colourless. This method is useful for the estimation of 2 mg. to 20 mg. of copper.

c) To an almost neutral copper solution, add 2 ml. of a sodium acetate solution, 10 ml. of acetone and 4 drops of the indicator. Dilute to 50 ml. with water. Adjust the pH to 6.2~6.6 with a few drops more of a sodium acetate solution and titrate it as before with EDTA until the colour changes from red-violet to light green. From 2 to about 60 mg. of copper may be determined by this method with accuracy. With more than 60 mg. of copper, the end point passes through a series of colour changes, from red-violet to blue-violet, bluish grey, grey, and, finally, yellowish green. Here the end point is a bit long-drawn and not sharp.

Some typical results of titrations in the lower range are recorded in Table III. The titration of copper was also carried out side by side by following the prescribed procedures but using other indicators (viz. PAN,[11] murexide,[12] pyrocatechol violet[13] and Chrome Azurol S[14]) for the sake of comparison. The results indicate that the new indicator, mononitrosochromotropic acid, is satisfactory, being as effective as the standard indicators mentioned above.

The Micro Titration of Copper.—Microgram quantities of copper may be determined with EDTA, using MNCA, with a fair degree of accuracy. The minimum quantity of copper that may be titrated by this procedure is about 7 μg.; with a lesser amount, a sharp

sharp. The titration may also be made by using a sodium acetate buffer, the pH is adjusted to 6.4 by adding a 0.2 M sodium acetate solution drop by drop, and the titration is carried out as before.

Titration in the Presence of Various Organic Substances.—It was observed that the copper complex of MNCA was stable in the presence of many organic compounds. The titration of copper with EDTA has been carried out in mixtures containing various organic amines and other complexing agents in order to examine whether the copper present in the solution becomes available to MNCA and, subsequently, to EDTA for its complexometric titration. The results of such titrations, under the conditions stated, are given in Table V. In the case of quinoline, 0.5 ml. of it was dissolved in a mixture of 15 ml. acetone and 10 ml. ethanol, the copper solution added, and the pH of the mixture raised to 7.4 with 2 ml. ammonium chloride and a few drops of 1 M ammonium hydroxide the mixture was then diluted to 50 ml. and titrated as before with EDTA.

The Effect of Masking Agents.—In order to examine the effect of masking agents on the indicator-copper complex and the possibility of using them as masking agents for the elimination of the interference of various metal ions, titrations of copper in the presence of some well-known masking substances have been carried out. The results are recorded in Table VI. It may be seen that a number of such complexing agents do not interfere with the titration, but that those which form strong complexes with copper itself, such as potassium cyanide and glycine, cannot be used. The copper-indicator complex does not form in the presence of those reducing agents which may also be used as masking agents, such as ascorbic acid, hydroquinone and hydroxylamine.

The Study of Interference by Diverse Ions in the Titration. — As the EDTA titration of copper is best carried out in a weakly alkaline medium, many cations (e. g., zinc, nickel, cobalt, calcium, magnesium, barium, lead, cadmium and the rare earths) interfere in the process. When the titration is done in an acetate buffer at pH 5.8 to 6.4, small amounts of calcium, barium and magnesium may be tolerated, and the addition of a little ammonium fluoride improves results. The interference of iron(II) and aluminium may be removed by using triethanolamine, sodium or ammonium fluoride in both ammoniacal and sodium acetate solutions. Mercury(II) may be masked by an ammoniacal potassium iodide solution. The addition of oxalic acid removes the interference of zirconium. The method is effective when copper is separated from the mixture of cations containing tartaric acid with thioacetamide or hydrogen sulphide and the EDTA titration is applied. Silver and alkali metals do not interfere. Table VII shows some of the results.

TABLE VII. EFFECT OF FOREIGN IONS ON TITRATION OF COPPER
Copper taken (0.1 M solution), 1~10 ml. of 0.01 M EDTA

Ions present	Quantity mg.	Buffer used	Masking agent	EDTA, reqd.

Zr	4.32	Na-acetate	Oxalic acid	10.10

Discussion and Summary

The copper complex of mononitrosochromotropic acid (MNCA) forms in a weakly acidic or a weakly basic solution, and the colour of the complex in solution deepens as the pH is raised (from pH 5 to 5.4 it is pink, from 5.4 to 6.6 it is red-violet, from 6.6 to 7.2 the colour is permanganate-violet, and at higher values pH up to 8.5, it is blue-violet). The complex decomposes at higher pH values. The same copper complex appears to form in all the above pH ranges. The complex is stable in the presence of many inorganic substances, but it is decomposed by oxidising and reducing agents and also by substances that form stronger complexes with copper. The copper complex, however, could not be extracted with any of the organic solvents commonly employed in solvent extraction methods. MNCA may be successfully used as an indicator in the complexometric titration of copper with EDTA.

The titrations carried out with this indicator, side by side with other indicators for copper, indicated that the new indicator may be placed in the same group as murexide, PAN, pyrocatechol violet or Chrome Azurol S with regard to the sharpness of the end point, colour contrast, accuracy, and precision in the titration of copper. The titration may be performed at different pH ranges using different buffer solutions: with sodium acetate at pH 5.8 to 6.5, with pyridine at pH 6.8 to 7, and with ammonium chloride and ammonia at pH 7 to 8. The change in the end point colour is from reddish-violet, bluish-violet or permanganate-violet to pale greenish yellow. Copper may be titrated in the macro range from 2 to 60 mg. of copper and in the micro-range down to 7 μg. by using this indicator.

The effect of various complexing agents, polyhydroxy alcohols, amines, amino acids and other masking agents, etc., on the EDTA titration of copper has also been studied; a number of them do not appear to interfere. The cations that form EDTA complexes in the same pH range as copper interfere in the titration, however. Iron and aluminium may be masked by triethanolamine or sodium fluoride, mercury(II), by ammoniacal potassium iodide, and zirconium, by oxalate. The alkali and alkaline earth metals do not interfere.

The authors express their thanks to M/S Dojindo & Co., Japan, for kindly supplying samples of pyrocatechol violet and Chrome Azurol S used in this work.

Structural Studies of the Gum Jeol Polysaccharide

By A. K. BHATTACHARYYA and A. K. MUKHERJEE*

(Received March 24, 1964)

Gum Jeol (Odina Wodier, Roxb) has been reported[1] to contain galactose, arabinose and galacturonic acid as constituent units. An aldobiuronic acid has also been reported. The constitution of the degraded gum obtained by the removal of the labile arabinose units has also been described.[2] This paper will report on the structural studies of the whole gum obtained by its repeated purification (equivalent weight 1150).

The supernatant liquid obtained during autohydrolysis was found by paper chromatography to contain a large proportion of L-arabinose, a trace of D-galactose, and an oligosaccharide having R_{gal} 1.36 in solvent G. The mixture was resolved on a cellulose column using solvent A, and the pure oligosaccharide obtained from fraction III was converted to a sirup. The molecular weight as determined by the alkaline hypoiodite method was 274, showing it to be a disaccharide of two pentose units. This was characterised as 3-*O*-L-arabofuranosyl-L-arabinose from hydrolysis and periodate oxidation studies (vide Experimental Section).

The purified gum was methylated[3-5] to a fully methylated polysaccharide showing no hydroxyl band in the infrared spectrum in the region of 3500~3600 cm^{-1}. It was soluble in chloroform and had $[\alpha]_D^{32}$ −37° (in chloroform). A portion of the methylated gum was subjected to methanolysis under conditions known to cause no cleavage of aldobiuronic acid. The methyl ester was hydrolysed with barium hydroxide,[6] and the acid fraction was separated by adsorbing it on Dowex 1-X4 (acetate-form) anion-exchange resin. The neutral glycosides were converted to a mixture of methyl sugars, which were separated on a cellulose column and identified through their crystalline derivatives (vide Experimental Section). These are shown in Table I.

The acid fraction was displaced from the resin column with 1 N sulphuric acid. Neutralisation, deionisation with Amberite IR-120(H) cation-exchange resin, and the evaporation of the resulting solution yielded a thick sirup with $[\alpha]_D^{32}$ +64° (in chloroform). This has been shown[2] to be 3-*O*-(2,3,4-tri-*O*-methyl-D-galactopyranosyluronic acid)-2,4-di-*O*-methyl-D-galactose, since, on reduction of the methyl ester methyl glycoside and subsequent hydrolysis, it afforded two methyl sugars, viz., 2,3,4-tri-*O*-methyl-D-galactose and 2,4-di-*O*-methyl-D-galactose in equimolecular proportions.

The mole proportions of these components were determined by weighing the different pure fractions obtained by column chromatography and by calculating the amounts of the pure components from the mixtures with the aid of specific rotations (vide Experimental Section). The hypoiodite method[6a] could not

TABLE I. ANALYSIS OF THE HYDROLYSATE OF THE METHYLATED GUM (NEUTRAL PART)

	Methyl sugar	R_g*	$[\alpha]_D$	Crystalline derivative	Mole proportion
1	2,3,5-Tri-*O*-methyl-L-arabinose	0.96	−40°	Amide	2.03
2	2,3,4,6-Tetra-*O*-methyl-D-galactose	0.89	+108°	Anilide	3.1
3	2,3,4-Tri-*O*-methyl-D-galactose	0.70	+114°	Anilide	1.0
4	2,4-Di-*O*-methyl-D-galactose	0.46	+86°	Anilide	1.94
5	2-*O*-Methyl-L-arabinose	0.40	+98°	Ph·hydrazone	1.05
6	2-*O*-Methyl-D-galactose	0.28	+79°	Anilide	1.1

be used since it was found difficult to separate the different components quantitatively on paper chromatogram.

From the above results, the following conclusions can be drawn. The characterisation of 2, 3, 5-tri-*O*-methyl-L-arabinose and 2, 3, 4, 6-tetra-*O*-methyl-D-galactose shows that both arabofuranose and galactopyranose residues are present as non-reducing end groups. The presence of 2, 3, 4-tri-*O*-methyl-D-galactose in the trimethyl fraction of the hexose units indicates that the main chain is 1→6 linked. The absence of a dimethyl arabinose indicates that arabinose is not present in the backbone chain of the molecule. The fact that the molecule is highly branched is supported by the characterisation of 2, 4-di- and 2-*O*-methyl-D-galactose and 2-*O*-methyl-L-arabinose. It is also clear that the galactose units which are singly-branched are linked through C_1, C_3 and C_6, while those which are doubly-branched are linked through C_1, C_3, C_4, C_6. The branched arabinose units are, however, linked through C_1, C_3, C_5.

The isolation and characterisation of 2, 4-di-*O*-methyl and 2, 3, 4-tri-*O*-methyl-D-galactose from the aldobiuronic acid fraction of the methylated gum, after reduction and subsequent hydrolysis, indicate clearly that the reducing galactose moiety of the aldobiuronic acid is a part of the main chain and that the uronic acid is present as a single-unit side chain.

From these results and from our knowledge of the structure of the repeating unit of the degraded gum,[2] a possible structure of the repeating unit of the whole gum polysaccharide may be as in Fig. 1.

where Galp = a D-galactopyranosyl unit, Galp A = a D-galactopyranosyluronic acid unit, and Araf = a L-arabofuranosyl unit.

It should be pointed out here that, from the results obtained above, it is not possible to assign the exact sequence of the different groups shown. This repeating unit, however, explains the products obtained from the hydrolysate of the whole gum. It also explains the change in the molar ratio of the compounds of the hydrolysates of the methylated whole gum and of methylated degraded gum shown in Table II.

TABLE II. CHANGE IN THE MOLAR RATIO OF THE METHYL SUGARS IN METHYLATED DEGRADED GUM AND METHYLATED WHOLE GUM

Methyl sugar	Methylated degraded gum	Methylated whole gum
2, 3, 5-Tri-*O*-methyl-L-arabinose	—	2
2, 3, 4, 6-Tetra-*O*-methyl-D-galactose	3	3
2, 3, 4-Tri-*O*-methyl-D-galactose	2	1
2, 4-Di-*O*-methyl-D-galactose	1	2
2-*O*-Methyl-L-arabinose	—	1
2-*O*-Methyl-D-galactose	1	1
Methylated aldobiuronic acid	2	2

During autohydrolysis, the labile arabofuranose units are cleaved out and the degraded gum shows the above behaviour.

The above structure, however, does not explain why the supernatant liquid from autohydrolysis should give only one kind of disaccharide, 3-*O*-L-arabofuranosyl-L-arabinose, and not the other, 5-*O*-L-arabofuranosyl-L-arabinose, which could not be obtained. This may, however, be due to the preferential cleavage of the 1→5 glycosidic bond to the 1→3 bond.

The results of the methylation studies were supported by the data obtained from the periodate oxidation of the gum using periodic acid.[7-9] It was found that the gum consumed 7.58 mol. of the oxidant in 30 hr. (constant), liberating 3.40 mol. of formic acid in 25 hr. (constant) per equivalent of the gum. Considering the facts that (1) a non-reducing galactopyranose unit or galactopyranosyluronic acid unit and a 1→6 linked galactopyranose unit of the backbone chain consume 2 mol. of periodic acid, liberating one mole of formic acid, that (2) galactopyranose units linked through C_1, C_3 and C_6 or C_1, C_3, C_4 and C_6 cannot react with periodic acid, that (3) each non-reducing arabofuranose unit should consume one mole of periodic acid without liberating any formic acid, and, that (4) the arabinose units linked through C_1, C_3, and C_5 do not react at all with periodic acid, the consumption of periodic acid and the liberation of formic acid per equivalent of the gum (assuming the above structure) works out as 7.30 and 3.13 mol. respectively.

The periodate oxidised gum, after reduction with sodium borohydride[10] and the usual

subsequent treatment, was precipitated with ethanol. The product on hydrolysis gave D-galactose 38.45% and L-arabinose 5.33% (as anhydrosugars). These values are good agreement with the values (36.7% anhydro galactose and 5.98% anhydro arabinose) calculated from the above structure.

The molecular weight of the methylated gum as determined by the light-scattering method was found to be 1.68×10^5. The molecular weight of one repeating unit of the methylated gum, on the basis of the proposed structure, is 2724. Hence, the D.P. of the gum-polysaccharide works out to be 62.

Experimental

Chromatographic separations were carried out using a descending technique with Whatman No. 1 filter papers. The solvent systems employed were: (A) ethyl acetate : pyridine : water (8 : 2 : 1); (B) *n*-butanol : acetic acid : water (4 : 1 : 5) upper layer; (C) *n*-butanol : ethanol : water (40 : 11 : 19); (D) *n*-butanol : ethanol : water (5 : 1 : 4) upper layer; (E) ethyl methyl ketone - water azeotrope; (F) ethyl acetate : acetic acid : water (9 : 2 : 2), and (G) ethyl acetate : acetic acid : water (3 : 1 : 3) upper layer. Aniline oxalate and ammoniacal silver nitrate spray reagents were used in developing the paper chromatograms.

Evaporations were carried out under reduced pressure at bath temperatures of 35~40°C. All the values of specific rotations are at equilibrium.

The isolation and purification of the gum have already been described in details.[2] The purified gum had 8.8% moisture; 0.79% ash; $[\alpha]_D^{30}$ −44° (*c* 0.5, 4% sodium hydroxide solution); equivalent wt., 1150 (acidimetry); 14.5% anhydro uronic acid;[11] 21.7% pentosan;[12] no nitrogen; and 0.51% methoxyl.[13] The gum on hydrolysis gave D-galactose (63.7%) and L-arabinose (19.5%) as estimated by the periodate method.[14]

The Examination of the Supernatant Liquid Obtained during the Autohydrolysis of the gum.—The procedure for the autohydrolysis of gum Jeol has been discussed before.[2] After the precipitation of the degraded gum, the supernatant liquid was collected and concentrated to a small volume. This, on paper chromatographic separation, indicated the presence of arabinose, a trace of galactose and an oligosaccharide (R_{gal} 1.36 in solvent G). The mixture (ca. 500 mg.) was fractionated on a cellulose column (60×3.5 cm.), using solvent A and cutting 20 ml. portions in each tube. The eluate, after paper chromatographic examination, was separated into three fractions.

Fraction I (380 ml.) containing only L-arabinose, was evaporated (410 mg.) and then crystallized from methanol; m. p. and mixed m. p. 152~154°C (with L-arabinose), $[\alpha]_D^{30}$ +108° (*c* 0.8, water). Fraction II (60 ml.) contained a mixture of galactose (trace) and the oligosaccharide (fraction III) (12 mg.) and was not examined further. Fraction III (160 ml.), containing chromatographically-pure oligosaccharide and with $[\alpha]_D^{32}$ +90° (*c* 0.5, water), was evaporated to a sirup (52.6 mg.). The oligosaccharide, on hydrolysis with 1 N sulphuric acid followed by the usual treatment, gave spot of only arabinose on a paper chromatogram. The molecular weight, as determined by the alkaline hypoiodite method, was 274 (calculated for a disaccharide of two pentose units, 282). The sirup (ca. 31.5 mg.) was oxidised with a sodium metaperiodate solution (3 M, 1 ml.) in an acetate buffer (pH 3.7, 49 ml.) in the dark at 0°C. The consumption of periodate became constant in two-and-a-half hours, amounting to 2.08 mol. per mole of the disaccharide.

The Methylation of the Gum.—The purified gum (10 g.) was methylated with dimethylsulphate and sodium hydroxide[3] (four times) and then by Purdie's method[4] (four times), following the method of Falconer and Adams.[5] The fully-methylated gum was a light yellow solid (7.5 g.) with $[\alpha]_D^{32}$ −37° (*c* 0.9, chloroform) and 42.2% methoxyl; it showed no hydroxyl band in the infrared spectrum.

The Methanolysis and Hydrolysis of the Methylated Gum. An Examination of the Neutral Part.—A portion of the methylated gum (2 g.) was refluxed with 2.5% dry methanolic hydrogen chloride (50 ml.) for 16 hr. (constant rotation). The solution was then neutralised (silver carbonate), filtered, and evaporated to a sirup. The sirup was heated with an aqueous barium hydroxide[6] solution (2%, 30 ml.) on a boiling water bath for 4 hr. at 80°C. The solution was neutralised (carbon dioxide gas) and then centrifuged. The resulting solution was deionised with Amberlite IR-120(H), and the acidic component was quantitatively adsorbed on Dowex 1-X4 (acetate) resin. The column was thoroughly washed with water to collect the neutral fraction, which was concentrated to a sirup (5 ml.) and then hydrolysed with 1 N sulphuric acid (50 ml.) at the temperature of a boiling-water bath for 14 hr. (constant rotation). The solution was neutralised (barium carbonate), filtered, deionised, and concentrated to a sirup. The paper chromatographic examination of the sirup using solvents C and D indicated the presence of 2,3,5-tri-*O*-methyl-L-arabinose, 2,3,4,6-tetra-, 2,3,4-tri-, 2,4-di-*O*-methyl-D-galactose 2-*O*-methyl-L-arabinose, and 2-*O*-methyl-D-galactose.

The mixture of methyl sugars (1.0 g.) was resolved on a cellulose column (80×3.5 cm.) using solvent E and collecting 10 ml. in each tube in an automatic fraction-collector. The eluates after chromatographic examination were separated into ten fractions and separately evaporated to sirups. Table III shows the various fractions so obtained.

The Examination of the Fractions and Characterisation of the Methyl Sugars.—*Fraction 1.*—The sirup, $[\alpha]_D^{30}$ −40° (*c* 1, water), was chromatographically pure. The sugar was converted to 2,3,5-tri-*O*-methyl-L-arabonamide through its lactone

TABLE III. THE NEUTRAL FRACTIONS OBTAINED AFTER METHANOLYSIS AND HYDROLYSIS OF THE METHYLATED GUM

Fraction	Tube No.	Sugars detectable by paper chromatography	Sugar given on demethyltion[15]	R_g*	-OCH_3 %	$[\alpha]_D$	Yield mg.
1	34—40	2,3,5-Tri-*O*-methyl-L-arabinose	Arabinose	0.96	48.24	−40°	138.2
2	41—44	2,3,5-Tri-*O*-methyl-L-arabinose and 2,3,4,6-Tetra-*O*-methyl-D-galactose	Arabinose and Galactose	—	—	+39°	67.0
3	45—54	2,3,4,6-Tetra-*O*-methyl-D-galactose	Galactose	0.89	51.8	+108°	265.1
4	55—58	2,3,4,6-Tetra-*O*-methyl-D-galactose, 2,3,4-Tri-*O*-methyl-D-galactose and probably Di-*O*-methyl-arabinose (trace)	Galactose and Arabinose	—	—	+111°	51.0
5	59—66	2,3,4-Tri-*O*-methyl-D-galactose	Galactose	0.70	41.9	+114°	81.0
6	74—89	2,4-Di-*O*-methyl-D-galactose	Galactose	0.46	29.0	+86°	145.3
7	90—99	2,4-Di-*O*-methyl-D-galactose and 2-*O*-methyl-L-arabinose	Galactose and Arabinose	—	—	+90°	54.2
8	100—109	2-*O*-Methyl-L-arabinose	Arabinose	0.40	18.3	+98°	50.2
9	110—117	2-*O*-Methyl-L-arabinose and 2-*O*-methyl-D-galactose	Galactose and Arabinose	—	—	+86°	13.5
10	118—136	2-*O*-Methyl-D-galactose	Galactose	0.28	15.8	+79°	80.5

* R_g values are with reference to 2,3,4,6-tetra-*O*-methyl-D-glucose in solvent C.

m. p. and mixed m. p. 134~136°C (lit. 136~138°C), $[\alpha]_D^{31}$ +18° (*c* 0.5, water), lit. +20°.[16]

Fraction 2.—The sirup (67 mg.) had $[\alpha]_D^{30}$ +39° (*c* 1, water) and was found by paper chromatography to be a mixture of 2,3,6-tri-*O*-methyl-L-arabinose and 2,3,4,6-tetra-*O*-methyl-D-galactose. On demethylation, the sirup gave galactose and arabinose. From the specific rotation value of the mixture, the amounts of the trimethyl arabinose and tetramethyl galactose were found to be 31.2 mg. and 35.8 mg. respectively.

Fraction 3.—This fraction, with $[\alpha]_D^{30}$ +108° (*c* 1.05, water), was chromatographically pure. The 2,3,4,6-tetra-*O*-methyl-D-galactose was characterised through the crystalline *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-galactosylamine, m. p. and mixed m. p. 187~189°C,[17] $[\alpha]_D^{30}$ +36° (*c* 0.5, acetone), lit. +39°.[18]

Fraction 4.—The sirup, with $[\alpha]_D^{30}$ +111° (*c* 0.8, water), was found by paper chromatography to be a mixture of 2,3,4,6-tetra- and 2,3,4-tri-*O*-methyl-D-galactose and a trace of methyl arabinose. On demethylation, it gave spots of galactose and arabinose (faint). Disregarding the trace amount of methyl arabinose, the amounts of the tetra- and trimethyl galactose were calculated to be 32.1 and 18.9 mg. respectively from the specific rotation value.

Fraction 5.—The chromatographically-pure fraction had $[\alpha]_D^{30}$ +114°C (*c* 1, water) and was proved to be 2,3,4-tri-*O*-methyl-D-galactose by preparing its aniline derivative, m. p. and mixed m. p. 163~164°C.[19] The melting point depressed on admixture with the aniline derivative of 2,4,6-tri-*O*-methyl-D-galactose.

Fraction 6.—The sirup, with $[\alpha]_D^{30}$ +86° (*c* 1.2, water), was chromatographically pure. On trituration with ether, followed by drying in vacuo, the sirup was converted into a crystalline solid which, on crystallisation from a small volume of ethanol, yielded crystals with an m. p. and mixed m. p. of 98~100°C (with 2,4-di-*O*-methyl-D-galactose monohydrate), lit. 98~99°C.[20] It was further characterised through the crystalline *N*-phenyl-2,4-di-*O*-methyl-D-galactosylamine; m. p. and mixed m. p. 214~215°C, lit. 216°C.[20]

Fraction 7.—The sirup (54.2 mg.), with $[\alpha]_D^{29}$ +90° (*c* 0.6, water), gave galactose and arabinose on demethylation. The mixture, on paper chromatographic examination, indicated the presence of 2,4-di-*O*-methyl-D-galactose and 2-*O*-methyl-L-arabinose. By comparing the specific rotation values of the mixture and of its components, the amounts of dimethyl galactose and monomethyl arabinose were found to be 36.1 and 18.1 mg. respectively.

Fraction 8.—The chromatographically-pure fraction had $[\alpha]_D^{31}$ +98° (*c* 0.9, water) and was identified as 2-*O*-methyl-L-arabinose by conversion to the crystalline phenyl hydrazone; m. p. and mixed m. p. 111~112°C, lit 114°C.[21]

Fraction 9.—The fraction (13.5 mg.) had $[\alpha]_D^{28}$ +86° (*c* 0.5, water) and gave, on demethylation, spots of galactose and arabinose, along with other partially-methylated sugars on a paper chromatogram. The mixture had components which had

the same R_g values as those of 2-*O*-methyl-L-arabinose and 2-*O*-methyl-D-galactose; from the specific rotation value, their amounts were found to be 5.0 and 8.0 mg. respectively.

Fraction 10. — This pure fraction, with $[\alpha]_D^{26}$ +77° (*c* 1.02, water), was proved to be 2-*O*-methyl-D-galactose by converting it to crystalline *N*-phenyl--2-*O*-methyl-D-galactosylamine; m. p. and mixed m. p. 158~159°C, lit. 165°C.[22]

The Examination of the Acid Fraction. — The acid fraction was displaced from the column of Dowex 1-X4 (acetate) resin with 1N sulphuric acid. The neutralisation, deionisation and evaporation of the resulting solution yielded a thick sirup (495 mg.) which had $[\alpha]_D^{32}$ +64° (*c* 1.05, chloroform). A portion of the sirup (ca. 340 mg.) was converted to the methyl ester methyl glycoside by Fischer's method, reduced with lithium aluminium hydride in dry ether,[23,24] and then hydrolysed with 1N sulphuric acid. The hydrolysate, after the usual treatment, was converted to a sirup (264 mg.) which, on paper chromatographic examination using solvents C and D, revealed the presence of 2,3,4-tri-*O*-methyl-D-galactose and 2,4-di-*O*-methyl-D-galactose, with a trace amount of tetramethyl galactose. The mixture (125 mg.) was separated on Whatman No. 3MM filter paper using solvent D. The first fraction (56 mg.) had $[\alpha]_D^{32}$ +107° (*c* 1.1, water) and was identified[2] as 2,3,4-tri-*O*-methyl-D-galactose by preparing the crystalline *N*-phenyl-2,3,4-tri-*O*-D-galactosylamine, m. p. and mixed m. p. 164~166°C, $[\alpha]_D^{31}$ +38° (*c* 0.5, acetone). The second fraction (52 mg.) had $[\alpha]_D^{31}$ +84° (*c* 1.05, water) and was characterised[2] as 2,4-di-*O*-methyl-D-galactose by preparing its aniline derivative, m. p. and mixed m. p. 218~219°C. The amounts of the two components obtained after separation indicate that they are in an equimolecular proportion.

Periodate Oxidation Studies of the Gum.—The gum (110.9 mg.) was dispersed in water (50 ml.) and was treated with a 0.2 M periodic acid solution in water (50 ml.). The oxidation was conducted by shaking the reaction mixture in the dark at 15°C. The liberated formic acid and the periodic acid consumption during the reaction were estimated in the usual way[25] at regular intervals of time. The liberation of formic acid became constant after 25 hr., corresponding to 3.40 mol. (after correction for the titratable acidity of the gum and periodic acid), while the periodate uptake became constant after 30 hr., corresponding to 7.58 mol. per equivalent of the gum.

The periodate-oxidised gum (102.5 mg.) was neutralised (barium hydroxide) and filtered, and to the clear solution sodium borohydride (150 mg.) was added. The reduction was then allowed to proceed for 4 hr. at room temperature. After the usual treatment, the resulting solution was poured into ethanol to precipitate the periodate-oxidised reduced gum, which was triturated with ethanol and then by dry ether and finally dried in vacuo at 40°C. Yield, 62.2 mg. The precipitated polysaccharide (ca. 40 mg.) was hydrolysed with 2N sulphuric acid at the temperature of a boiling-water bath for 24 hr. The amounts of galactose and arabinose left unattacked by periodic acid, as estimated by using D-ribose as a reference sugar, were found (as anhydro sugars) to be 38.45% each.

The Determination of the Molecular Weight of the Methylated Gum.—All measurements of the intensity of scattered light for the molecular weight determination of the methylated gum were carried out with a Brice-Phoenix light-scattering photometer (Model OM 1000 A), using a semi-octagonal cell. The concentrations used were over a range of $(1\sim7)\times10^{-3}$ g./ml., and the working standard method was used to calculate the turbidity, τ. The molecular weight was found to be 1.68×10^5, as calculated by the dissymmetry method[26] assuming the particle-scattering factor of P 90°[27,28] for the random coil.

Summary

The polysaccharide obtained from gum jeol has been shown to be composed of D-galactose, L-arabinose, and D-galacturonic acid. The hydrolysis of the fully-methylated gum yielded 2, 3, 5-tri-*O*-methyl-L-arabinose (2.03 mol.), 2,3, 4, 5-tetra-*O*-methyl-D-galactose (3.1 mol.), 2, 3, 4-tri-*O*-methyl-D-galactose (1 mol.), 2,4-di-*O*-methyl-D-galactose (1.94 mol.), 2-*O*-methyl-L-arabinoses (1.05 mol.) and 2-*O*-methyl-D-galactose (1.1 mol.) in the neutral fraction of the hydrolysate. The reduced acidic fraction gave 2, 3, 4-tri-*O*-methyl-D-galactose (2 mol.) and 2, 4-di-*O*-methyl-D-galactose (2 mol.). The structural significance has been discussed from the above results and from the results of periodate oxidation studies of the gum. The molecular weight of the methylated gum has also been determined by the light-scattering method.

The Reduction of Isothiocyanato-ammine Complexes of Chromium(III) at the Dropping Mercury Electrode

By Nobuyuki TANAKA, Tasuku ITO and Reita TAMAMUSHI

(Received March 24, 1964)

The polarographic behavior of some isothiocyanato complexes of chromium(III) has been reported. Maki, Shimura and Tsuchida[1] investigated the polarographic behavior of several isothiocyanato chromium(III) complexes in neutral unbuffered solutions. The electrode process of hexaisothiocyanatochromate(III) was studied by Fischerová and Fischer,[2] and the polarographic behavior of some isothiocyanato-ammine chromium(III) complexes in Divers' liquid was reported by Ichniowski and Clifford.[3] Meanwhile, an extremely high adsorbability of isothiocyanato complexes on the mercury electrode has been demonstrated.[4] A systematic study of the electrode processes of a series of isothiocyanato chromium(III) complexes seems, therefore, to be worthwhile and desirable.

In this paper, the reduction of isothiocyanato-ammine chromium(III) complex ions, $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ ($p=0, 1, 2, 4$ and 6), at the dropping mercury electrode has been studied by the measurement of the direct current, the alternating current and the Kalousek polarograms. The electrode processes of these complexes have been discussed on the basis of other chromium(III) complexes which were previously studied.[5-8]

Experimental

Materials.—$[Cr(NH_3)_6]Cl_3$,[9] $[Cr(NCS)_2(NH_3)_4]Cl$,[10] $NH_4[Cr(NCS)_4(NH_3)_2]\cdot 2/3H_2O$[11] and $K_3[Cr(NCS)_6]\cdot 4H_2O$[12] were prepared according to the procedures described in the literature. $[Cr(NCS)(NH_3)_5]Cl_2$ was prepared by a modification of the procedure of Werner and Halben.[13] The complexes were identified by the measurement of the absorption spectra and by the determination of the nitrogen and chromium contents. The nitrogen content was determined by the usual method, and the chromium content by a method which has previously been reported.[7] The analysis gave the following results:

$[Cr(NH_3)_6]Cl_3$
Calcd.: Cr, 19.9; N, 32.2%
Found: Cr, 19.0; N, 31.3%
$[Cr(NCS)(NH_3)_5]Cl_2$
Calcd.: Cr, 19.5; N, 31.6%
Found: Cr, 19.4; N, 31.8%
$[Cr(NCS)_2(NH_3)_4]Cl$
Calcd.: Cr, 19.1; N, 30.9%
Found: Cr, 18.5; N, 30.1%
$NH_4[Cr(NCS)_4(NH_3)_2]\cdot 2/3H_2O$
Calcd.: Cr, 14.9; N, 28.2%
Found: Cr, 14.6; N, 27.6%
$K_3[Cr(NCS)_6]\cdot 4H_2O$
Calcd.: Cr, 8.82; N, 14.2%
Found: Cr, 8.55; N, 14.2%

All the chemicals used were of a guaranteed reagent grade.

Apparatus and Procedure.—Direct-current (d. c.) and alternating-current (a. c.) polarograms were recorded with a Yanagimoto Model PR-2 pen-recording polarograph and a Yanagimoto Galvarecorder Y-GR 2 respectively. The Kalousek circuit and the cell equipments used were the same as have been reported previously.[7] The dropping mercury electrode (DME) employed had an m value of 1.62_5 mg./sec. and a drop-time, t_d, of 5.21 sec. when measured in an air-free solution containing 0.9 M potassium chloride, 0.1 M acetate buffer and 0.005% gelatin at -0.5 V. vs. SCE and at 50 cm. of height of the mercury reservoir. The potential of DME was referred to the saturated calomel electrode (SCE). The cell temperature was maintained at 25°C by means of a water thermostat. The dissolved oxygen in the electrolytic solution was removed by bubbling pure nitrogen gas through the solution.

All the measurements were carried out in the solution of ionic strength 1.0 containing 0.1 M acetate buffer (pH 4.7) and 0.005% gelatin or 2×10^{-5} M LEO (polyoxyethylene lauryl ether) unless otherwise stated. As the complexes are not stable in an aqueous solution, each solution for the electrolysis

was made freshly from the dry crystalline chromium-(III) complexes, and polarographic measurements were made as soon as possible after the removal of the dissolved oxygen.

Results

It has been shown in a previous study[6] that isothiocyanato-ammine complex ions of chromium(III), $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$, give no well-defined polarographic reduction wave in unbuffered neutral solutions, but do in acetate buffer or acid solutions. As typical examples of the current-potential curve, the polarograms of isothiocyanatopentamminechromium(III) ion, $[Cr(NCS)(NH_3)_5]^{2+}$, are given in Figs. 1 and 2. The maximum appears when the solution does not contain a sufficient amount of maximum suppressor and this can be attributed to the high adsorbability of the complex ions which have thiocyanate coordinated.[4] The addition of 0.005% gelatin or 2×10^{-5} M LEO suppresses this maximum.

The current-potential curves were obtained at various concentrations of the complex ions and at various heights of the mercury reservoir. The limiting current, $\bar{i}_l$, is proportional to the concentration of the complex ion in the range from 0.2 mM to 2.5 mM. Table I presents the linear relationship between the limiting current and the square root of the effective height of the mercury reservoir. These two relationships hold in every case and this indicates clearly that the limiting currents are diffusion-controlled.

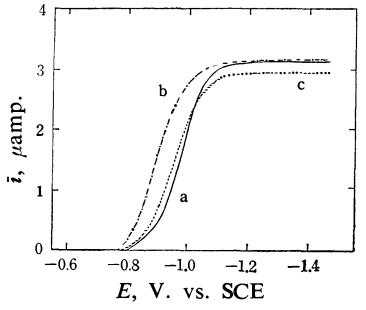

Fig. 1. Polarograms of 1.0 mM $[Cr(NCS)(NH_3)_5]Cl_2$ in 0.9 M KCl (a), 0.9 M KSCN (b) and 0.3 M Na_2SO_4 (c) solutions containing 0.1 M acetate buffer and 0.005% gelatin.

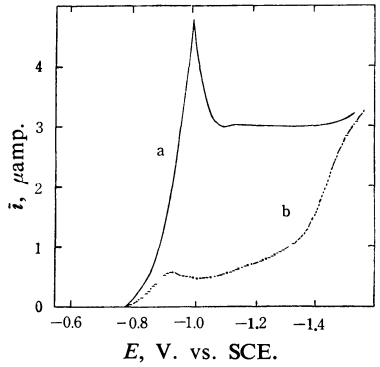

Fig. 2. Polarograms of 1.0 mM $[Cr(NCS)(NH_3)_5](NCS)_2$ in 0.9 M KCl + 0.1 M acetate buffer without maximum suppressor (a) and in 1 M KCl + 0.005% gelatin (b).

The half-wave potentials and the diffusion current constants, which were obtained in the solutions of ionic strength 1.0 containing various kinds of supporting electrolytes, are given in Table II. The reduction potentials of these complexes have been found to be affected to a great extent by the kind of supporting electrolyte.

Kalousek and a. c. polarograms were recorded to examine the polarographic reversibility of the electrode processes of the complexes. Typical Kalousek polarograms are reproduced in Fig. 3. The effect of the supporting electrolyte on Kalousek and a. c. polarograms is significant.. Nevertheless, all the

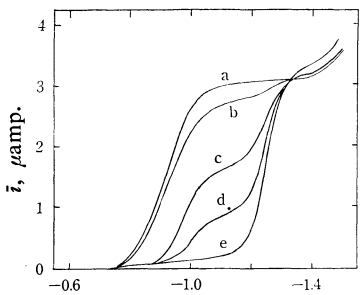

Fig. 4. D. c. polarograms of 1.0 mM $[Cr(NCS)_2(NH_3)_4]Cl_2$ in 0.9 M KSCN, 0.1 M acetate buffer and 0.005% gelatin without (a) and with 0.1 mM (b), 0.5 mM (c), 0.75 mM (d) and 5.0 mM (e) of EDTA.

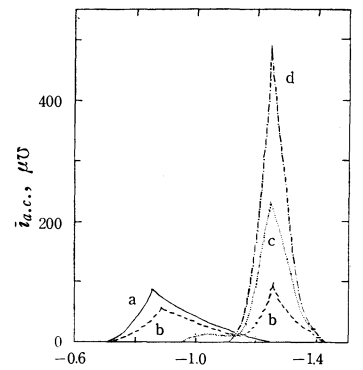

Fig. 5. A. c. polarograms of 1.0 mM $[Cr(NCS)_2(NH_3)_4]Cl_2$ in 0.9 M KSCN, 0.1 M acetate buffer and 0.005% gelatin without (a) and with 0.2 mM (b), 0.5 mM (c) and 5.0 mM (d) of EDTA.

complexes investigated gave similar Kalousek polarograms in a given supporting electrolyte solution.

The measurements of d. c. and a. c. polarograms of $[Cr(NCS)_2(NH_3)_4]^{+}$ were also made in the presence of EDTA (Figs. 4 and 5). The addition of EDTA causes a decrease in the limiting current over some potential range, as seen in Fig. 4. On a. c. polarograms, upon the addition of EDTA, the original wave decreases in height and a new wave appears at −1.25 V.; this wave increases in height with an increasing concentration of EDTA.[14] These phenomena were observed with all of the complexes investigated.

Discussion

One of the distinctive characteristics of the isothiocyanato-ammine complex ions, $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$, is their specific adsorption on the mercury electrode,[4] and this is well reflected in their polarographic behavior. The maximum wave shown in Fig. 2 seems to be due to the high adsorbability of the isothiocyanato complexes. The ligand NCS^- is coordinated with the central chromium atom through the nitrogen atom[4,15,16], and consequently the sulfur atom turns to the surface of the electrode.

As is shown in Table II, the supporting electrolyte has an important effect on the half-wave potential. The difference in the ease with which one electron enters in the reacting chromium(III) seems to be changed by some factors determined by the supporting electrolyte used. In potassium chloride or sodium sulfate solutions, the half-wave potential shifts to less negative potentials with an

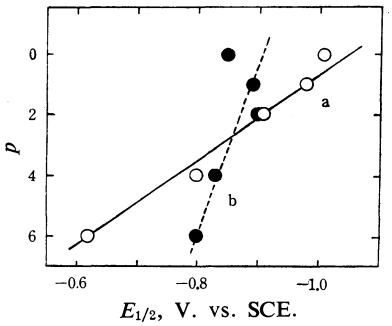

Fig. 6. Relation between p of $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ and the half-wave potential: Half-wave potentials were observed in 0.1 M acetate buffer solutions containing 0.9 M KCl and 2×10^{-5} M LEO (a), and those containing 0.9 M KSCN and 0.005% gelatin (b).

increase in the number of the thiocyanate group coordinated in $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$. On the other hand, no such tendency holds in potassium thiocyanate or potassium iodide solutions. Fig. 6 gives the relations between the p value of $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ and the half-wave potential in potassium chloride and potassium thiocyanate solutions. The linear relation in the potassium chloride solution (curve a in Fig. 6) may indicate that the number of the coordinating thiocyanate is one of the important factors in determining the reduction potential. In the potassium thiocyanate solution, the half-wave potentials of the complex cations are at less negative potentials than in the potassium chloride solution, whereas those of the complex anions are at more negative potentials (curve b in Fig. 6). Similar shifts of the half-wave potentials were also observed in potassium iodide solutions.

It seems that the above-mentioned observations can be explained by considering the specific adsorption of thiocyanate ions (or iodide ions) and that of the complex ions, and the electrostatic interaction between the electrode surface and the complex ions. At the concentration of the experimental conditions, a large amount of thiocyanate ions (or iodide ions) is specifically adsorbed at the surface of the DME at the potentials where the complex ions are reduced. The negative charge on the surface of the DME, therefore, is so large that $[Cr(NH_3)_6]^{3+}$, a tervalent cation, is attracted to the electrode surface, whereas $[Cr(NCS)_6]^{3-}$, a tervalent anion, is repelled. This causes the shifts of the reduction potential toward the opposite directions.

However, there is an alternative explanation of this potential shift. Isothiocyanato complexes are very adsorptive at the mercury electrode and seem to be reduced in the adsorbed state. The specific adsorption of the complexes with more NCS^- coordinated are partially disturbed when the adsorptive electrolyte is used. This results in the shift of the half-wave potential to more negative potentials. On the other hand, the reduction of the complex ions with less NCS^- coordinated, e.g., $[Cr(NH_3)_6]^{3+}$, is accelerated by the effect of the adsorbed supporting electrolyte SCN^-, as is the case in the polarographic reduction of Ni^{2+},[17] Zn^{2+} [18] and In^{3+}.[19] The acceleration effect caused by adsorbed SCN^- is seen in the Kalousek and the a. c. polarograms.

In most cases, the log-plot gave no straight line but two straight-line segments or curved lines, except in the case of $[Cr(NH_3)_6]^{3+}$ in a potassium chloride solution. Fig. 7 shows the plots of $\log i/(i_d-i)$ vs. E for the reduction waves of $[Cr(NCS)(NH_3)_5]^{2+}$ in the supporting electrolyte solutions indicated. It should be noted that the steeper portion of the slope comes at less negative potentials in a potassium thiocyanate solution, but at more negative potentials in a potassium chloride solution. This was observed with all of the complexes investigated.

As is seen in Fig. 3, the reversibility of the reduction of chromium(III) to chromium(II) at the dropping mercury electrode varies to some extent with the supporting

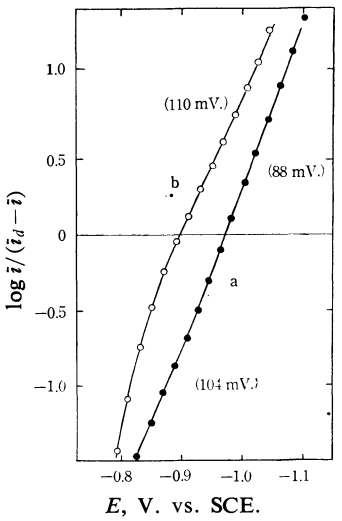

Fig. 7. Log-plots for the reduction waves of 1.0 mM $[Cr(NCS)(NH_3)_5]Cl_2$ in 0.9 M KCl (a) and 0.9 M KSCN (b) solutions containing 0.1 M acetate buffer and 0.005% gelatin.

electrolyte used. The Kalousek polarograms of $[Cr(NH_3)_6]^{3+}$ obtained in potassium chloride and sodium sulfate solutions (curves a and c in Fig. 3), where the anodic waves are clearly separated from the cathodic ones, indicates that the reduction proceeds irreversibly. The corresponding a.c. peaks are as small as that for Ni^{2+} ion, which is known to be of a typical irreversible nature.[7] In a potassium thiocyanate solution (curve b in Fig. 3), however, the polarographic reversibility increases.

The value of $i_p/(n\bar{i}_d\sqrt{t_d})$ represents the degree of the polarographic reversibility of the electrode reaction, where i_p is the peak current of the a.c. wave (in μU), $\bar{i}_d$, the average diffusion current of the corresponding d.c. polarograms (in μamp.), and n, the number of electrons involved in the electrode process[20]. Table III shows the $i_p/(n\bar{i}_d\sqrt{t_d})$ values for the reduction of the complex ions.

TABLE III. VALUES OF $i_p/(n\bar{i}_d\sqrt{t_d})$ (U amp^{-1} sec$^{-1/2}$)

	In 0.9 M KSCN, 0.1 M acetate buffer and 0.005% gelatin	In 0.9 M KCl, 0.1 M acetate buffer and 2×10^{-5} M LEO
$[Cr(NH_3)_6]^{3+}$	16.7	8.1
$[Cr(NCS)(NH_3)_5]^{2+}$	9.9	4.4
$[Cr(NCS)_2(NH_3)_4]^{+}$	14.1	2.6
$[Cr(NCS)_4(NH_3)_2]^{-}$	27.8	10.8
$[Cr(NCS)_6]^{3-}$	44.3	9.3

The a.c. wave height became higher with an increasing p value of $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ in a potassium thiocyanate solution. The reversibility revealed by the a.c. polarography accords well with that revealed by the measurement of the Kalousek polarograms.

All experimental results indicate that no preceding chemical reaction takes place prior to the electron transfer process, which is always followed by a rapid aquation of the divalent species, and that the aquation reaction may contribute to the polarographic reversibility.

From their detailed investigation of the polarographic reduction of $[Cr(NCS)_6]^{3-}$ in a potassium thiocyanate solution, Fischerová and Fischer concluded that the reversibility increased at higher concentrations of potassium thiocyanate.[2] Furthermore, Ichniowski and Clifford, who recently investigated the polarographic behavior of isothiocyanato-ammine complexes of chromium(III) in Divers' liquid, reported that the reduction proceeds reversibly.[3] These facts may suggest that the polarographic reduction proceeds reversibly under conditions where the following chemical reaction does not or hardly occurs.

The effect of EDTA on the reduction waves of $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ is interpreted in the same way as the effect of ethylenediammine on the polarograms of $[Co(NH_3)_6]^{3+}$ which was reported by Laitinen and Kivalo.[21]

The complex ion $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ is reduced at the electrode to form $[Cr(NCS)_p(NH_3)_{6-p}]^{(2-p)+}$, which in turn reacts with EDTA:

$$[Cr(NCS)_p(NH_3)_{6-p}]^{(2-p)+} + EDTA = Cr(II)\text{-}EDTA + pNCS^- + (6-p)NH_3$$

Because of the lability and the relative stability of these divalent chromium complexes, the reaction proceeds rapidly to the right. The Cr(II)-EDTA thus formed may or may not be oxidized at the electrode to the Cr(III)-EDTA complex, depending on the electrode potential. If the oxidation takes place, the oxidation current cancels the reduction current of $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ and the limiting current of the $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ wave decreases. The wave which appears at more negative potentials corresponds to the oxidation-reduction wave of the Cr(II)-EDTA and $[Cr(H_2O)(edta)]^-$ system. The effect of EDTA on the a.c. polarographic wave can be explained in the same way. A detailed study of the d.c. and the a.c. polarography of $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ in the presence of EDTA will be reported elsewhere.

Summary

The reduction of a series of isothiocyanatoammine chromium(III) complexes $[Cr(NCS)_p(NH_3)_{6-p}]^{(3-p)+}$ at the dropping mercury electrode has been studied. The direct current, the alternating current and the Kalousek polarograms of these complexes have been measured in various supporting electrolyte solutions. The nature of the reduction waves, corresponding to the one-electron reduction of chromium(III) to chromium(II), has been discussed.

*The Reduction of Indium(III) in Thiocyanate Solutions at the Dropping Mercury Electrode**

By Nobuyuki TANAKA, Takashi TAKEUCHI and Reita TAMAMUSHI**

(Received June 4, 1964)

The effects of adsorbed ions or molecules on the rate of electrode processes have recently received considerable attention from many investigators. Frumkin was the first to point out the effect of adsorbed cations on the reduction wave of persulfate ions at the dropping mercury electrode. He discussed the dependence of the kinetics of the electrode processes on the surface layer structure.[1] Tamamushi et al. reported the apparent reversibility of the reduction of zinc(II), which increased with the increasing concentration of halide ions in the solution.[2,3]

The reduction wave of indium(III) at the dropping mercury electrode is irreversible and very much drawn-out in sodium nitrate or sodium perchlorate solutions. In potassium thiocyanate or potassium iodide solutions, on the other hand, indium(III) produces a reversible three-electron reduction wave in the potential region between -0.5 and -0.9 V. vs. saturated calomel electrode. Shirai[4,5] found that the polarographic behavior of an indium(III)-thiocyanate system was very peculiar; on the direct current (d.c.) polarogram of the system a minimum appeared at relatively negative potentials, and on the alternating current (a.c.) polarogram a negative admittance was observed in the potential region where the minimum appeared on the d.c. polarogram. However, she gave no explanation of the effect of thiocyanate ions on the reduction process of indium(III) at the electrode.

In the present paper, the acceleration effect of thiocyanate ions on the reduction of indium(III) at the dropping mercury electrode is presented, and the most plausible mechanism to explain the effect is proposed.

Experimental

D.c. and a.c. polarograms were obtained with a pen-recording polarograph, Yanagimoto Galvarecorder Y-GR 2 equipped with an automatic potential scanner. In the more accurate measurement of d.c. polarograms, a manual apparatus similar to that of Kolthoff and Lingane[6] was used. Current-time curves during the life of a mercury drop were recorded with a mechanical oscillograph, Yokogawa type N-6.[7] The faradaic impedance was determined by an impedance bridge used in the previous study.[8] The attachment of the bridge and the electrolysis cell were the same as described previously.[8] The impedance of the cell circuit was measured at the moment immediately before the detachment of the mercury drop. The electrode potential of the dropping mercury electrode (DME) was measured against a saturated calomel electrode (SCE), which was connected to the electrolytic solution through an agar-agar bridge containing 1 M potassium nitrate. In the impedance measurement, a Pt-spiral electrode of a large surface area was used as an auxiliary electrode. The rate of flow of mercury and the drop time of the DME used were 1.14 mg./sec. and 6.71 sec. respectively, being measured in an air-free 0.5 M sodium perchlorate solution containing 1×10^{-6} M polyoxyethylene lauryl ether (LEO) under an applied pressure of 50 cm. of mercury at open circuit. The dissolved oxygen in the electrolytic solution was removed by passing pure nitrogen gas through the solution for about 30 min. All measurements were carried out at 25.0 ± 0.1°C.

A standard solution of indium(III) was prepared by dissolving a known amount of pure indium metal (Kanto Chemical Co. purity 99.99%) in a concentrated nitric acid. All the other chemicals were of an analytical reagent grade. Redistilled water was used for the preparation of solutions. Proper amounts of nitric acid were added to the electrolytic solutions (pH 2.7 to 3.7) to prevent indium(III) ions from the hydrolysis.

* This was partly presented at the 18th International Congress of Pure and Applied Chemistry, Montreal (1961), under the title of "Minimum on the Current-potential Curve in Polarography," and also at the First Australian Conference on Electrochemistry, Sydney and Hobart (1963), under the title of "Effect of Adsorbed Ions and Molecules on the Rates of Electrode Processes at the Dropping Mercury Electrode."

Results

D. c. polarograms of 1 mM of indium(III) which were obtained in the solutions containing various amounts of thiocyanate ions are given in Fig. 1, where $\bar{i}$ means the average current

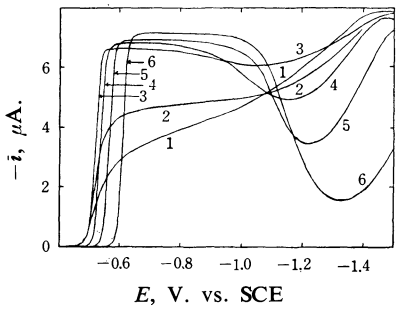

Fig. 1. Direct current polarograms of 1.0 mM $In(NO_3)_3$ in the solutions of ionic strength 1.0 (with $NaNO_3$) containing various concentrations of KSCN and 1×10^{-5} M LEO. The concentrations of KSCN are: (1) 0, (2) 0.0001, (3) 0.002, (4) 0.04, (5) 0.20, (6) 1.00 M.

during the life of a mercury drop.* The ionic strength of the solution was adjusted to be 1.0 with sodium nitrate. In a sodium nitrate solution, the reduction wave of indium(III) was very much drawn-out, and a relatively small cathodic current was observed in the potential region of −0.5 to −0.9 V. vs. SCE (curve 1 in Fig. 1). The cathodic current in this potential region, however, was greatly increased by the addition of a minute amount of thiocyanate ions (curves 2 and 3 in Fig. 1).

The ionic species of indium(III) in the bulk of the solution do not change appreciably by the addition of such a small amount of thiocyanate ions.[9] Therefore, it is suggested that the effect of thiocyanate ions on the reduction of indium(III) at the dropping mercury electrode is mainly due to the change in the state of the electrode surface by the adsorption of thiocyanate ions. When the concentration of thiocyanate ions was larger than 0.02 M, a reversible three-electron reduction wave of indium-(III) was completely developed in the potential region mentioned above. The half-wave potential $E_{1/2}$ of the reduction wave of indium(III) shifted to negative potentials with the increase in the concentration of potassium thiocyanate. Fig. 2 shows the relation between the $E_{1/2}$ and the logarithm of the concentration of potassium thiocyanate. The number of thiocyanate ions coordinated with an indium(III) ion was determined from the slope of this relation, with the result that two thiocyanate ions were coordinated in a 0.3 M potassium thiocyanate solution and four in a 0.8 M potassium thiocyanate solution.

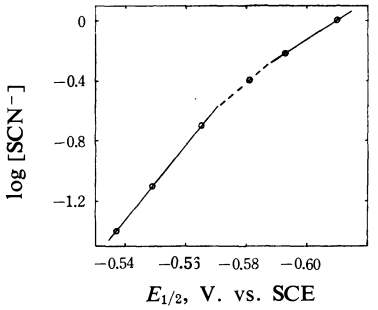

Fig. 2. Half-wave potentials of In(III)-SCN complexes as a function of the logarithm of the thiocyanate concentration.

At more negative potentials, a remarkable minimum appeared on the d. c. polarogram. It should be noticed that, in the In(III)-KSCN system, the minimum was observed in solutions of relatively high ionic strength. Therefore, the appearance of the minimum was unable to be explained on the basis of a simple electrostatic repulsion between the electrode surface and the depolarizing species.[10,11]

The current-time curves during the life of a mercury drop given in Fig. 3 were recorded

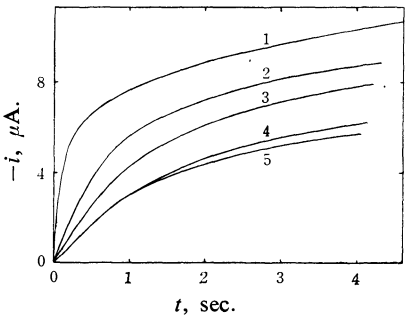

Fig. 3. Current-time curves of 1.0 mM $In(NO_3)_3$ in 0.4 M KSCN obtained at (1) −0.80, (2) −1.10, (3) −1.15, (4) −1.23, (5) −1.29 V. vs. SCE.

with 1.0 mM indium(III) at 0.4 M potassium thiocyanate at various potentials in the region where the minimum appeared on the d. c. polarogram. These current-time curves were approximately represented by the relation:

$$\log|i| = k + \beta \log t$$

* In this study, the sign of the cathodic current is taken as negative.

where i is the instantaneous current and k, the constant. The values of β were found to be beween 1/6 and 2/3. This suggests that the current in this potential region is partly controlled by some process of a kinetic nature.

An example of a. c. polarograms of 1.0 mM of indium(III) obtained in a 0.4 M potassium thiocyanate solution is shown in Fig. 4 (curve 1). A remarkable negative admittance was observed in the potential region where the d. c. current began to decrease. Such anomalies on the a. c. polarogram were also reported by Shirai for the In(III)-KSCN, Ni(II)-KSCN and Cu(II)-NH_4NO_3 systems.[3] The negative admittance suggested the unique mechanism

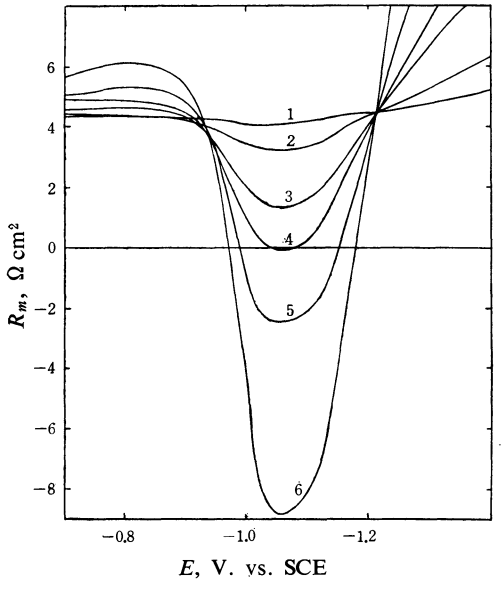

Fig. 5. The resistance component R_m of DME/ 1.0 mM $In(NO_3)_3$−0.4 M KSCN as a function of the electrode potential obtained at frequencies of (1) 1000, (2) 500, (3) 300, (4) 250, (5) 200 and (6) 150 cycles/sec.

of the electroreduction of indium(III) at the electrode surface.

The accurate measurement of the impedance of the electrode-solution interface, which was assumed to be represented with a series combination of the resistance, R_m, and the capacitance, C_m, was carried out by means of an impedance bridge. Fig. 5 shows the relation between the resistance component R_m of the impedance and the electrode potential. At relatively low frequencies, negative values of the resistance component were obtained in the potential region where the negative admittance was observed on the a. c. polarogram. The capacitance component C_m of the impedance was found to be almost the same as that of the supporting electrolyte solution in the whole potential region measured. From those measurements, it can be said that the anomalous negative admittance on the a. c. polarogram results from the negative value of the resistance component of the impedance.

Discussion

The electrical equivalent circuit of a polarizable electrode-solution interface can be represented with the circuit as shown in Fig. 6. If the

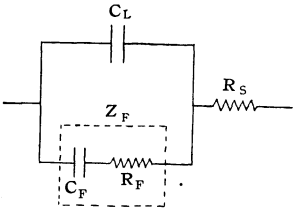

Fig. 6. Equivalent circuit of electrolytic system: C_L, double layer capacity; R_S, resistance of the cell; Z_F faradaic impedance; R_F, polarization resistance; C_F, electrolytic capacitance.

impedance of the electrolytic cell is measured by an impedance bridge with the corresponding arm composed of the resistance R_m and the capacitance C_m in series, R_m is represented as follows:

$$R_m - R_s = \frac{C_F^2 R_F}{\omega^2 C_L^2 C_F^2 R_F^2 + (C_F + C_L)^2} \qquad (1)$$

where ω is the angular frequency of the superimposed alternating current. In order to explain the experimental result that R_m is smaller than the resistance of the solution R_s, the polarization resistance R_F should be negative. The expression of R_F has been presented by Grahame[12,13], and the simplest

12) D. C. Grahame, *J. Electrochem. Soc.*, **99**. C 370 (1952).
13) P. Delahay, "New Instrumental Methods in Electrochemistry," Interscience Publishers, New York (1954), p. 146.

expression is given as follows:

$$R_F = \left(\frac{\partial E}{\partial i}\right)(1+\kappa) \tag{2}$$

$$\kappa = \frac{1}{\sqrt{2}\, nFA\omega^{1/2}D^{1/2}}\left(\frac{\partial i}{\partial C_R} - \frac{\partial i}{\partial C_O}\right) \tag{3}$$

where D is the common diffusion coefficient of the oxidant and the reductant; A, the surface area of the electrode; C_O and C_R, the concentrations of the oxidant and the reductant at the electrode surface respectively; n, the number of electrons involved in the eletron-transfer process, and F, the faraday. Generally, the term $(1+\kappa)$ is positive because the sign of the cathodic current is taken as negative, and consequently the sign of R_F is the same as that of $(\partial E/\partial i)$.

The faradaic current, i, is represented as,

$$i = -nFA(k_c C_O - k_a C_R) \tag{4}$$

where k_c and k_a are the cathodic and the anodic rate constants, respectively. At sufficiently negative potentials compared to the standard potential of the system, the cathodic rate constant k_c is much larger than the anodic one k_a of the electrode reaction. At such potentials the current is given by the equation,

$$i = -nFAk_c C_O \tag{5}$$

Differentiating with respect to the electrode potential E,

$$\left(\frac{\partial i}{\partial E}\right)_{C_O} = -nFA\left(\frac{\partial k_c}{\partial E}\right)C_O \tag{6}$$

is obtained. Eq. 6 indicates that the sign of R_F depends on that of $(\partial k_c/\partial E)$.

As has been described above, it is considered that adsorbed thiocyanate ions on the electrode surface accelerate the reduction of indium(III) at the DME. This may be justified by the fact that the acceleration effect of the thiocyanate ion decreases and the minimum appears on the d.c. polarogram at potentials more negative than about -1.0 V. vs. SCE where thiocyanate ions desorb from the mercury electrode surface.* Therefore, the overall eletrode reaction under the influence of the adsorbed thiocyanate ions may be assumed to consist of two simultaneous processes in parallel:

$$O + ne + Hg(n) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} R \tag{I}$$

$$O + ne + Hg(c) \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} R \tag{II}$$

The reaction through path I proceeds at the naked part of the electrode surface, Hg(n), while the reaction through path II proceeds at the electrode surface which is covered with the adsorbed thiocyanate ions, Hg(c); k_1 (or k_{-1}) and k_2 (or k_{-2}) are the reduction (or the oxidation) rate constants of reactions through paths I and II respectively.

If it can be assumed that the reduction of indium(III) through one path proceeds independently of the other, the overall reduction rate constant k_c can be given by a linear combination of k_1 and k_2:

$$k_c = (1-\theta)k_1 + \theta k_2 \tag{7}$$

where θ is the degree of coverage of the electrode surface by thiocyanate ions. Thiocyanate ions are electrocapillary active and are adsorbed on the mercury surface, particularly at the potentials in the positive branch of the electrocapillary curve, whereas, at relatively negative potentials in the negative branch of the electrocapillary curve, they markedly decrease in the degree of adsorption, and the electrode surface is gradually covered with some other species, such as water molecules or the hydrated cations present in the solution. In the region where thiocyanate ions are specifically adsorbed on the electrode surface, the contribution of the reaction at the covered surface to the overall process is so large that the electrode reaction of indium(III) virtually proceeds at the covered surface only. This explains the experimental result that, when the concentration of thiocyanate ions is greater than approximately 0.02 M, a reversible reduction wave is developed.

The contribution of the reaction at the naked electrode, however, is expected to increase as the potential becomes more negative. This results in the gradual decrease in the overall cathodic rate constant k_c with the increase in the negative potential; k_c might be comparable to, or smaller than, the rate of diffusion of the oxidant in a certain negative potential region. It is expected that, in this potential region, the actual d.c. current becomes smaller than that which would be expected for the diffusion-controlled current. When the potential is extremely negative, the electrode reaction of indium(III) proceeds only through path I. The decrease in the d.c. current at potentials more negative than -1.0 V. vs. SCE is considerable; the larger the decrease, the greater the concentration of thiocyanate ions in the solution is. This is probably due to the fact that the species of indium(III) in the bulk of the solution depends on the concentration of thiocyanate ions.

The shape of the current-time curve during the life of a mercury drop shown in Fig. 5

* Detailed studies of the adsorption of thiocyanate ions on the mercury electrode will be reported elsewhere.

suggests that the cathodic current of indium(III) in a potassium thiocyanate solution at the negative potentials where the minimum appears on the d. c. polarogram is partly controlled by some processes of a kinetic nature. This is understandable if the rate of change in the state of the electrode surface during the life of a mercury drop is considered. The adsorption equilibrium of simple ions such as thiocyanate ions at the mercury surface is established almost instantaneously. The coverage θ of the electrode surface with the adsorbed ions is constant over the whole period of the life of a mercury drop, i. e.,

$$\left(\frac{\partial\theta}{\partial \ln t}\right)_E = 0 \quad \text{and} \quad \left(\frac{\partial k_c}{\partial \ln t}\right)_E = 0$$

At the potentials where k_c is smaller than the rate of diffusion, the characteristics of the current-time curve would be similar to those of the usual irreversible process, as is shown in Fig. 5.

The experimental result that the a. c. polarogram of the In(III)-KSCN system gives a negative admittance in a certain potential region can be explained as follows. As has been discussed earlier, this negative admittance results from the negative value of the polarization resistance R_F, the sign of which is opposite to that of $\partial k_c/\partial E$ in the potential region where the anomaly is observed. At such negative potentials, $\partial k_c/\partial E$ can be expressed from Eq. 7 as follows:

$$\frac{\partial k_c}{\partial E} = (k_2 - k_1)\frac{\partial\theta}{\partial E} + (1-\theta)\frac{\partial k_1}{\partial E} + \theta\frac{\partial k_2}{\partial E} \quad (8)$$

In Eq. 8, both the second and the third term of the right-hand side have generally negative values, whereas the first term is considered to be positive because the condition,

$$k_2 - k_1 > 0 \quad \text{and} \quad \frac{\partial\theta}{\partial E} > 0 \quad (9)$$

may be satisfied in the present case. Therefore, the negative value of R_F and, in consequence, the negative admittance are expected when the relation:

$$\left|(k_2-k_1)\frac{\partial\theta}{\partial E}\right| > \left|(1-\theta)\frac{\partial k_1}{\partial E} + \theta\frac{\partial k_2}{\partial E}\right| \quad (10)$$

is statisfied. In the In(III)-KSCN system, it is plausible to assume that both k_2-k_1 and $\partial\theta/\partial E$ are so large that the relation of Eq. 10 holds in the potential region where the anomaly is observed on the a. c. polarogram.

Summary

The reduction process of indium(III) at the dropping mercury electrode in thiocyanate solutions has been investigated by direct current polarography, alternating current polarography and faradaic impedance measurements. The reduction current in the potential region between −0.5 to −0.9 V. vs. saturated calomel electrode is greatly increased by the addition of minute amounts of thiocyanate ions, when a remarkable minimum is observed on the diffusion current plateau at relatively negative potentials. On the alternating current polarogram, indium(III) in a potassium thiocyanate solution gives a negative admittance in the potential region where the minimum appears on the direct current polorogram. The analysis of impedance measurements has shown that the resistance component has a negative value in that potential region. The experimental results have been explained by assuming that the overall electrode process is composed of two simultaneous reactions, one of which proceeds at the naked electrode surface, and the other at the electrode surface covered with adsorbed thiocyanate ions, and by assuming that thiocyanate ions accelerate the reduction of indium(III) at the surface of the electrode.

Magneto-chemical Studies of Some Organo-Silicon Compounds Containing Si–O Bonds

By R. L. MITAL

(Received March 23, 1964)

The environmental role of the diamagnetic susceptibilities has been recently studied in detail in the case of some aliphatics,[1-5] and it has been established beyond doubt that the environments do affect the magnetic values. A similar phenomenon appears in silicon chemistry, where there is a much controversy over the atomic susceptibility value of silicon; values ranging from 20.7 to −3.01 have been reported.[6-7]

In two different homologous series of organo-silicon compounds, Pascal's law holds good only if different values are assigned to χ_{Si} in each series.[6] This opens a new era in the magneto-chemical studies of organo-silicon compounds. With this in view, the present paper will deal with the magnetic susceptibilities of a few silicon compounds with different numbers of Si–O bonds, and the results will be discussed from the structural point of view.

Experimental

The substances used were of A. R. quality. Before the magnetic measurements were taken, the purity of the samples was checked by standard methods. The diamagnetic susceptibility of the compounds was measured with the help of a very sensitive microbalance devised by Neogy and Lal.[8] This balance has the capacity of correctly measuring the total susceptibility of the order of 0.5×10^{-12} c.g.s. e.m.u.

This balance essentially consists of a quartz fibre stretched between two pins, one attached to a torsion head and the other to the chuck. The ends of the quartz fibre are fused to two thin quartz rods which are fitted to the brass pins. This system ensures a perfect returning to the zero position of the balance beam for every set of readings. A mirror is attached at the centre of the beam, and a small circular coil of thin copper wire is clamped to the beam at the centre, with its horizontal plane. The two leads of the coils are taken out of the box along the quartz fibre to ensure minimum resistance to the rotation of the beam. In order to reduce the oscillations of the beam, a damping vane is also provided. The coil is connected to a voltage source, lead accumulators in series with a number of rheostats, in order to control the current, and with a standard one ohm resistance, the terminals of which are connected to the test terminals of a potentiometer. The balance is mounted on a sturdy wooden bench above the pole pieces. The constant field gradient is secured by attaching the pole shoes on the pole faces, making an angle of 6° with the pole surface.

The organo-silicon compound is placed in a capsule. This capsule is then suspended from one end of the beam. When the field is switched on, the whole capsule experiences a force, which is measured by sending a current through the copper coil and by measuring the potential drop across the standard one ohm resistance with the help of a high-precision portable pye potentiometer capable of measuring 0.05 mV. For determining the susceptibility of silicon compounds, the push on the capsule filled with the sample is compared with that on the same capsule filled with pure benzene, the mass susceptibility[9] of which was taken to be -0.7081×10^{-6} c.g.s. e.m. units. The results are shown in Table I.

Discussion

From Table I we see that the mean value of χ_{Si} in this series of the compounds is 17.0, while in individual members it varies from 14.4 to 19.1. χ_{Si} has been calculated from the molecular susceptibilities of the compounds and by subtracting from χ_M the atomic susceptibilities of hydrogen (2.0)[10,11] and of oxygen (5.3)[10] and the group susceptibilities of methyl (13.45)[12] and of χ_{CH_2} (11.68[12] units). It is interesting to note that as the number of Si–O bonds increases, the value of χ_{Si} decreases. The observed force constants[13] for the Si–O bond in a number of molecules are all higher than the value calculated by using Siebert's formula, while the Si–O bond is shorter than the sum of the relevant atomic radii.[14] All these observations are consistent with a significant contribution by $p\pi$-$d\pi$ interactions to

TABLE I. MOLECULAR DIAMAGNETIC SUSCEPTIBILITIES OF CERTAIN ORGANO-SILICON COMPOUNDS (-10^6 c.g.s. units)

Compound	χ_M (Observed)	χ_{Si}	χ_{Si} (Mean value)	Previously recorded value of χ_{Si} in these compounds
Trimethyl-silanol	66.3	18.6		
Trimethyl-methoxy-silane	78.2	19.1		
Ethoxytri-methylsilane	89.5	19.1		
Dimethyl-dimethoxy-silane	81.6	17.2		
Dimethyldi-ethoxysilane	104.7	17.0	17.0	12.50[7]
Methyldi-ethoxysilane	92.8	17.3		12.75[7]
Di-*n*-propyldi-ethoxysilane	150.8	16.4		
Dimethyl-silanediol	58.4	16.9		
Diethylsilane diol	81.0	16.1		
Methyl-trimethoxy-silane	85.6	15.9		
Methyltri-ethoxysilane	120.3	16.8		12.03[7]
Tetraethoxy-silane	134.5	14.4		12.06[7]

the Si–O bond in organo-silicon compounds. Such interactions decrease the Pauli's diamagnetic term in the well-known van Vleck's quantum mechanical equation:

$$\chi_M = \frac{-Ne^2}{6mc^2}\sum\bar{r}^2 + \frac{2}{3}N\sum_{n'\neq n}\frac{|m_0(n,n')|^2}{h\nu(n',n)}$$

The symbols have the usual significance. This decrease lowers the value of χ_{Si} in the compounds containing Si–O bonds. Thus, the magnetic studies add to the evidence that silicon is capable of forming π bonds with ligands by the use of d-type orbitals involving $p\pi$-$d\pi$ transactions. Such transactions have been beautifully discussed in some detail by Eaborn.[15]

In tetraalkyl silanes, $p\pi$-$d\pi$ bonding is not so specious as in alkoxy silanes, so the value of χ_{Si} in tetraalkyl substituted silanes will be conclusively higher than that in the alkoxy silicon derivatives.

Summary

The diamagnetic susceptibilities of a few organo-silicon compounds have been measured with the help of a very sensitive and accurate microbalance, with an accuracy of the order of 0.5×10^{-12} c.g.s. e.m.u. The mean value of χ_{Si} in these compounds containing Si–O bond is 17.0. The environmental role of Si–O liaisons on the value of χ_{Si} has been discussed from the structural point of view.

The author wishes to express his sincere thanks to Dr. S. Dayal for the gift of organo-silicon compounds; to Professor A. Mookherji, University Professor and Head of the Physics Department, Burdwan University, for allowing him to use laboratory facilities and for giving valuable suggestions, and to Professor R. C. Mehrotra for his encouragement.

Preferential Ion Transport in Electrodialysis through Ion-exchange Resin Membranes

By W. G. B. MANDERSLOOT

(Received March 24, 1964)

In electrodialysis through ion-exchange resin membranes, different ionic species of the same charge sign are usually transported at different rates.[1-4] Even early in the development of practical permselective membranes, suggestions were made for ion separations by means of electrodialysis.[5] In electrodialytic water treatment, the preferential ion transport has implications with respect to meeting the product specifications (the desired product being either the partially-desalted water or the simultaneously-produced concentrated brine), e. g., with respect to the maximum allowable concentration of precipitate-forming ions in the brine.

Preferential ion transport through permselective membranes can be described from first principles,[6-10] but, as will be shown, the inherent difficulties allow only qualitative conclusions and predictions to be made, particularly in practical systems.

Theoretical Considerations

The migrating counterions are transported consecutively (Fig. 1) through the bulk solution being electrodialysed by electric and convective transport, through the diffusion layer on the respective membrane by electric and diffusional transport, across the solution/membrane interface, through the membrane and across a second membrane/solution interface, and through a second diffusion layer into the bulk of the brine.

Transport through the Membrane.—The electrical transport ratio of two counterions, i and j, in an ion-exchange resin membrane is given by:

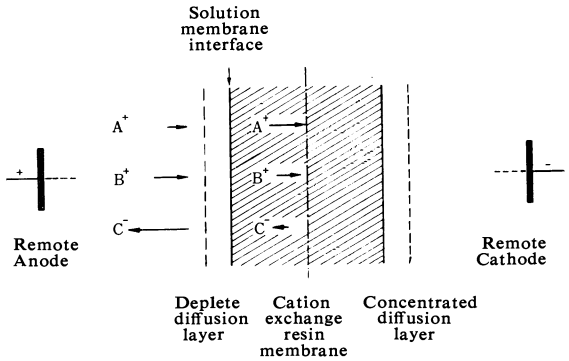

Fig. 1. Preferential ion transport through a single (cation) exchange membrane.

$$\frac{\bar{t}_i}{\bar{t}_j} = \frac{\bar{u}_i \bar{X}_i}{\bar{u}_j \bar{X}_j} \qquad (1)$$

in which t is the transport number, u, the electrical mobility, and X, the fractional contribution of one counterion to the total counterion content; the barred symbols refer to the resin phase.

The mobility of each counterion in the membrane phase is determined by the restricting forces acting on that (hydrated) counterion, by the electrostatic and other binding forces exerted by the fixed ionic groups in the resin, and by the frictional forces encountered. Equation 1 holds for local values; however, ion-exchange resins are known to have some heterogeneity in their crosslinking or pore structure,[11-14] and only average values for $\bar{u}$ and $\bar{X}$ can be measured.

Furthermore, the mobilities of the counterions in the resin are not independent,[15] there occurs some interaction, which can be detected from the non-linearity of a plot of the resin conductance versus the equivalent counterion

composition in the resin.[16-19] The deviation from linearity is sometimes negligible;[1,20] it can be expected, that the interaction will be strong in highly-crosslinked ion-exchange resins with a high concentration of fixed ions.

From published data,[21-26] it is apparent that the electrical mobilities of the counterions are governed by much the same factors as those which play an important part in ion-exchange equilibria, namely, the charge and size of the hydrated counterion and the nature and concentration of the fixed ions. Consequently, when a pressure-volume effect is not determining, the preferentially-absorbed counterion often has a relatively low mobility in the resin. It is, therefore, not surprising that some ion-exchange resin membranes specially prepared to have a specific affinity for a certain counterion[27,28] show little specific transport of that ion *across* that membrane. The effect of the preferential absorption of the counterion is then counteracted by the strong binding of that ion. This counteraction can be so strong that, for example, very little Ba^{2+} is transported across a sulphonic acid resin membrane placed in a mixed sodium chloride/barium chloride solution.[29]

When the preferential absoption of one counterion in the resin is caused by the specific exclusion of the other counterion, then the preferentially-absorbed ion may have a relatively high mobility in the resin which enhances the preferential transport of that ion across the membrane.

Transport Across the Solution/Membrane Interface. — The concentration ratio, $\bar{X}_i/\bar{X}_j$, inside the membrane depends on the uptake of the ions from the solution on the membrane surface, which has a different composition from the bulk solution because of polarisation, which is caused by the fact that the transport number in the membrane of the joint counterions is close to 1. It has been pointed out by Dibenedetto[9] that the ion-exchange equilibrium on the interface is hardly affected at all by the current density because the (electrical) transport velocities of the ions are small in comparison with their velocities because of Brownian motion.

If we define the relative affinity coefficient, K_j^i, by:

$$K_j^i \equiv \left(\frac{X^*_j}{\bar{X}_j}\right)^{z_i}\left(\frac{\bar{X}_i}{X^*_i}\right)^{z_j} \qquad (2)$$

in which z is the electrovalency of each counterion and * refers to the solution on the membrane surface, then:

$$\frac{\bar{X}_i}{\bar{X}_j} = \bar{X}_j^{(z_i/z_j-1)} \cdot (K_j^i)^{1/z_j} \cdot \frac{X^*_i}{(X^*_j)^{z_i/z_j}} \qquad (3)$$

It has been shown[19] that K_j^i is the sum of a number of terms and is far from constant when i and j are of unequal valency; K_j^i is, then, dependent on the total external electrolyte concentration and on $\bar{X}_j$ (or X_j). In electrodialytic processes, both the total electrolyte concentration and X_j change with either time or place.

An interesting development is the layered membranes in which a highly conductive ion-exchange resin membrane has been covered on both sides with a thin layer of a less conductive but very highly crosslinked ion-exchange resin,[30] the special properties of this thin layer of resin determining the uptake of counterions from the adjacent solution. The thin layer on the other side of these membranes has been applied for mechanical reasons, but it may simultaneously serve to eliminate the effect of possible polarisation at the first resin/resin interface.

Transport Across the Depleted Diffusion Layer. —If only one electrolyte is present, the system can be described in terms of a diffusion layer with a linear concentration gradient.[8,31,32] In systems with two electrolytes sharing the ion which has the same sign as the fixed ions in the resin membrane, it has been assumed[6-8] that two systems, each with one electrolyte and a linear concentration gradient, can be superimposed (Fig. 2) to arrive at a relation between X^*_i/X^*_j and X_i/X_j. This leads, however, to an inconsistency. With two superimposed linear gradients, t_i/t_j varies in

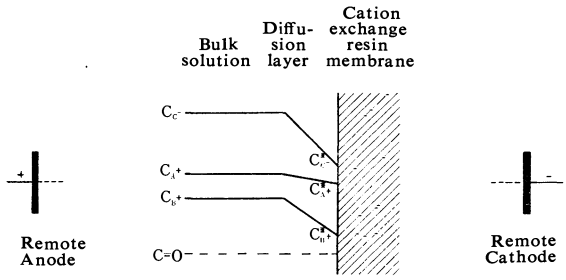

Fig. 2. Concentration gradients across a diffusion layer in a dialysate compartment.

the diffusion layer with the distance from the membrane, because the ratio of the concentrations of the two ions varies (anywhere: $t_i/t_j = u_iC_i/u_jC_j$). Therefore the diffusion fluxes of i and j should also vary across the diffusion layer, but this requires non-linear concentration gradients.

In practical electrodialysis, the effect of polarisation is counteracted by the forced convection of the electrolyte solution towards the membrane surface through the use of convection-inducing devices placed in the path of the solution.[33-36] This makes it virtually impossible to relate X and X^*. The limit to preferential transport for the zero current density may, however, be estimated from

$$\frac{\bar{t}_i}{\bar{t}_j} = \bar{X}_j^{(z_i/z_j-1)} \cdot (K^i_j)^{1/z_j} \cdot \frac{\bar{u}_i X_i}{\bar{u}_j (X_j)^{z_i/z_j}} \qquad (4)$$

while at high current density $\bar{t}_i/\bar{t}_j$ approaches t_i/t_j.

Overall Transport. — More complicating factors are introduced in practical electrodialysis because a number of processes occur simultaneously (Fig. 3). The membranes are not ideally (charge-) selective, and co-ion transport takes place, together with a certain amount of salt diffusion and also osmosis in the opposite direction. The preferential ion transport measured by the analysis of the desalting or the concentrating stream is the total effect of all the processes taking place.

From the considerations given above, it will be clear that a description of the preferential ion transport from first principles is very unattractive and that an empirical approach is to be preferred. Fortunately, the process can be described, under certain conditions, as a separation process with a constant separation factor[6,37] denoted s:

$$\frac{dC_i}{dC_j} = s\frac{C_i}{C_j} \qquad (5)$$

When an amount of saline water is demineralised from concentrations C_i' and C_j' to concentrations C_i'' and C_j'', the integration of Eq. 5 gives:

$$\ln \frac{C_i''}{C_i'} = s \ln \frac{C_j''}{C_j'} \qquad (6)$$

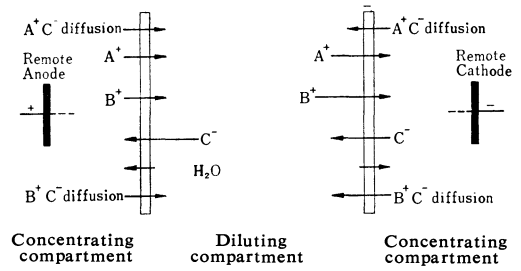

Fig. 3. Transport processes occurring simultaneously in a dialysate compartment.

Experimental

A batch of 10 l. mixed electrolyte solution, contained in an aspirator with a calibrated-level glass for volume measurements, was circulated by a pump through the parallel desalting (or "dialysate") compartments of a membrane pack containing ten such compartments alternating with eleven concentrating (or "brine") compartments (Fig. 4). Samples

of the batch, which was thoroughly mixed by a fast flow through a by-pass of the membrane pack, were analyzed at regular intervals, while the total electrolyte content was indicated by a conductivity meter. The vertical compartments with upward flow were formed by the cut-away rectangular centre section of asbestos " steam-jointing " gaskets, 1/32 inch thick, which were filled with perforated corrugated spacers, each compartment having a surface area of 128 cm^2. The first and last brine compartments were connected to calomel electrodes, so that the voltage drop across the membrane pack could be measured by a vacuum-tube voltmeter with a high input resistance. The voltage on these electrodes was kept constant in each experiment. The current-carrying electrodes, having the same surface area as the compartments in the pack, were placed in electrode compartments adjacent to the end brine compartments. A separate electrode rinse solution was circulated through the electrode compartments.

A batch of brine, with the same initial composition as the initial dialysate, though usually double the concentration, was circulated through the brine compartments in parallel. The total electrolyte concentration of the brine, measured with a conductivity cell, was kept approximately constant during each experiment by continuous dilution with distilled water. The flow velocities in the brine and dialysate compartments were 10 cm./sec. All the solutions were thermostatically controlled. Further details on the experimental set-up are given elsewhere.[38]

The following membrane pairs were used:

C. S. I. R. parchment-base-type PS (cation exchange) and G (anion exchange)
Permaplex[39]—C20 and A20
T. N. O.[40]—C60 and A60
A. M. F.[41]—3129 B56 and 96

Results and Discussion

The reasonably general validity of Eq. 6 is illustrated for cation transfer and anion transfer in Figs. 5 and 6 respectively, in which results obtained with a variety of membrane combinations and on different initial water compositions have been brought together. The results of the investigation of the effect of compartmental voltage with T. N. O. membranes and Permaplex membranes are shown in Figs. 7 and 9 respectively.

The results obtained with parchment-base membranes (lines A and in Fig. 5 and line K

Volt per compartment pair

Fig. 8. The separation factors (from Fig. 7) versus compartmental voltage.

in Fig. 6), which were of an early type not highly efficient in sea water, indicate that Eq. 6 holds well even if the detrimental transfer processes indicated in Fig. 3 constitute a considerable portion of total ion transfer.

That the separation factor is independent of the initial composition is indicated by line H in Fig. 5, which represents two experiments with the same membrane pair, the same electric potential drop per compartment pair, and the same flow velocity in the compartments, but on water with a completely different composition, namely, synthetic sea water with a sodium : calcium equivalent ratio of 45 : 2, and a total electrolyte concentration 0.6 N, and a mixed sodium chloride/calcium chloride solution, 0.5 N in Cl^-, with a sodium : calcium equivalent ratio of 1 : 1.

That Eq. 6 holds even when a very small amount of one ion is present is demonstrated by line D in Fig. 5, which represents the removal of a small amount of K^+ from a natural brackish well water. A strong deviation from linearity was found for the separation of Cl^- and SO_4^{2-}, as is indicated in line J in Fig. 6. This will be discussed separately.

The Effect of Compartmental Voltage (Current Density).—This effect is illustrated by the different slopes of lines H and I in Fig. 5, representing identical experiments but run at 1.0 V. and 0.75 V. per compartment pair respectively. It should be noted that during the runs the current density, i, decreases with the electrolyte concentration in the dialysate C, approximately according to[38] $i=\frac{E}{a+b/C}$, in which E is the compartmental voltage and a and b are constants.

The effect of the compartmental voltage drop, which is a measure of the degree of polarisation at a constant flow velocity, was investigated in more detail, using T. N. O. C60 and A60 membranes at 30°C with initial electrolyte concentrations in the dialysate of 0.25 N Cl^- (0.125 N Na^+ and 0.125 N Ca^{2+}), a constant total brine concentration of 0.5 N, and compartmental voltage drops, constant in each run, from 0.2 to 1.0 V. The separation factors derived from the slopes of the lines in Fig. 7 are plotted in Fig. 8 versus the voltage.

Similar experiments have been carried out with Permaplex membranes, but the range of voltages used was higher (0.2 to 1.5 V. per compartment pair) because the higher resistance of these membranes caused the current densities to be 10~20% lower at equal voltages. The non-linearity of the preferential ion transport data, as given in Fig. 9, can be attributed to polarisation, which increases with a decrease in the electrolyte concentration in the dialysate. It is interesting that the lines in Fig. 9 tend to approach the same slope at low concentrations. It was not possible to measure the polarisation in terms of an increase in the electric resistance of the membrane pack. Preferential ion transfer could thus be used as a very sensitive, though rather impractical, measure of the degree of polarisation. Because of the curved lines in Fig. 9, only the separation factors corresponding to the *initial* slopes

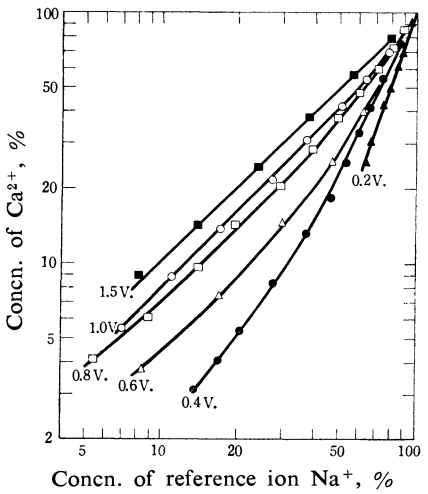

Fig. 9. Preferential cation transport through Permaplex A 20 and C 20 membranes at various compartmental voltages.

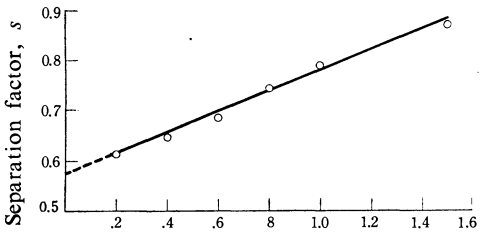

Fig. 10. The separation factors (from initial slopes in Fig. 9) versus compartmental voltage.

have been plotted versus the voltage in Fig. 10. The separation factors in Fig. 10 are approximately the same as in Fig. 9. The values for K_{Ca}^{Na} were also reasonably close for the two types of membranes.[19]

The Effect of the Nature of the Membrane. —Heterogeneous membranes (ground ion-exchange resin embedded in a sheet-forming binder) appear to cause less separation than homogeneous membranes when used under comparable conditions, as is evident from the results shown in Figs. 5 and 6 and in Figs. 7 and 9. This can be explained by the fact that a portion of the ion transport through the heterogeneous membranes is through a liquid path;[44,45] moreover, as has been mentioned in the previous section, the polarisation on these membranes is stronger.[46]

A comparison of the data in Fig. 7 with lines H (1.0 V.) and I (0.75 V.) in Fig. 5 shows that the preferential transport of Ca^{2+} through the homogeneous AMF membranes, which have a high internal concentration of fixed ions, is much more marked than through the T. N. O. membranes, which have a relatively low internal concentration.[19] This can be attributed to the higher affinity of the AMF membranes for calcium ions at intermediate loadings.[19]

The Cl^-/SO_4^{2-} Separation. — In Fig. 6 a strong deviation from linearity is found for the Cl/SO_4 separation using AMF membranes (line J). At high concentrations there is hardly any SO_4^{2-} transport. It increases considerably, however, below a total electrolyte concentration of 0.15 N. This is a reflection of the strong increase in affinity for SO_4^{2-} relative to Cl^- at concentrations below 0.15N;[19] later experiments have shown that this phenomenon is quite general with membranes which are efficient at concentrations above 0.15 N, particularly if the membranes are highly crosslinked.

The Order of Preference.—The order of the preferential transport of common ions at total electrolyte concentrations below 1 N, using highly efficient ion-exchange resin membranes and preventing serious polarisation, as found by us agrees well with most data reported by other workers.[2,16,29,37,41,42,47-54] For cations the general order is $Ca^{2+}>Mg^{2+}>K^+>Na^+>Li^+$, and for anions, $Cl^->SO_4^{2-}>CO_3^{2-}\cdot(HCO_3^-)$ and $NO_3^->Cl^->F^-$. These orders compare very well with those observed in ion exchange equilibria; the relative affinity coefficient, K_j^i, appears to be the determining factor unless the mobility in the membrane of one counterion is greatly reduced by very strong binding forces (e. g., ionpair formation).

Summary

Because of the great difficulties encountered when describing preferential ion transport in

electrodialytic demineralisation from first principles, an empirical approach is more attractive. Preferential ion transport can be described as a simple separation process with a separation factor which is constant for a certain membrane pair under certain conditions, namely, a constant voltage drop per compartment pair at a constant flow velocity in the compartments, high enough to avoid any serious polarisation. Exceptions occur when one counterion is immobilised to a great extent in the resin, when specific strong binding forces are operative (e.g., ionpair formation), and also when the preferential absorption of a counterion is based on the preferential exclusion of the other counterion. The latter appears to be the case in the separation of Cl^- and SO_4^{2-} at high total electrolyte concentrations.

The order and magnitude of preference are, in the first instance, governed by the same factors which govern ion-exchange equilibrium. The separation of ions has been shown to decrease with an increase in the applied electric potential (current density). It has been demonstrated that heterogeneous membranes cause a concentration polarisation at lower current densities than homogeneous membranes and that this early polarisation can be detected from the preferential ion transport data before it can be measured in terms of the resistance of the membrane pack.

The author is indebted to Mr. J. Venlet for his assistance in the experimental work and in the evaluation of the results.

*The Addition Reactions of Propanol-2 to Ethylene Induced by Gamma-ray Irradiation in the Gaseous Phase**

By Tadashi KURIHARA and Hiroshi HOTTA

(Received March 26, 1964)

It is known that the α-*C*-alkylation of primary and secondary alcohols results from their peroxide- and light-induced reactions with olefins.[1] Similar reactions are also induced by gamma-ray irradiation. The addition reactions of propanol-2 to ethylene in the liquid phase have been studied with gamma-rays by Hirota and Hatada.[2] It would be interesting to study if some differences are found between the liquid and gaseous phases. Therefore, in the present study, the samples were prepared with care so as to prevent them from condensing at the reaction temperatures.

Experimental

Materials.—Propanol-2 was purified by column distillation after refluxing it over calcium oxide. Ethylene (99.8%) was purified repeatedly by vacuum distillation at −196°C. No impurities were found by gas chromatography after these purifications. The samples were collected by vacuum distillation in a hard-glass tube (about 40 ml.).

Irradiation. — The samples were irradiated at 2.2×10^4 r./hr. of cobalt-60 gamma-rays while being kept within ±1°C of the given temperature in a controlled electric heater. The absorbed energy, *E*, is estimated by the equation:

$$E=87.7\times tD(\sum\rho_i m_i) \quad \text{(erg.)} \qquad (1)$$

where t=irradiation time (hr.)
D=dose rate measured by the Fricke dosimeter (r./hr.)
ρ=relative electron density to air
m=mass of the reactant (g.)

The relative electron densities, ρ, are 1.11 and 1.13 for ethylene and propanol-2 respectively.

The experiments were carried out under the conditions listed in Table I.

Analytical.—After irradiation, the total amounts of the gases in the tube and of the non-condensable gases at −196°C were measured. The latter compositions were analyzed by the mass-spectrum method in order to determine the amounts of hydrogen and methane produced. Then the condensed liquids were analyzed immediately by gas chromatography, using a column of PEG 6000 at 70 and 150°C.

2) K. Hirota and M. Hatada, This Bulletin, **34**, 1644 (1961).

Results

Non-condensable Gases.—The results of experiments 1—5 (Table I) are shown in Fig. 1 against the irradiation time for the decrement of ethylene (△) and the amount of the non-condensable gases produced (⊙). The *G*-values of hydrogen and methane, based on the total absorbed energy in the mixture, were found to be 4.2 and 3.8 from mass-spectrometric analysis. The corresponding values are 2.77 and 1.65 for the gamma-ray radiolysis of pure propanol-2 at room temperature,[3] and 1.28 and 0.21 for the 2 MeV. electron-radiolysis of ethylene of 150 mmHg at 25°C.[4] These facts suggest that the hydrogen abstraction reactions by hydrogen atoms and methyl radicals are of minor importance in the present chain process.

Condensable Products.—Compared with the retention time of propanol-2, the gas chromatography gave the twenty-one peaks of the shorter retention time at 70°C and the sixteen peaks of the longer one at 150°C. Among these the identified products are listed in the order of their retention times in Table II. Some results of experiments 1—5 (Table I) are shown in Fig. 2 against the irradiation time for the amounts of acetone (●), 2-methylbutanol-2 (⊙), 2-methylhexanol-2 (△) and 2-methyloctanol-2 (⊡).

Hexanol-2	11
2-Methyloctanol-2 (1 : 3 telomer)	25.5

* From the results of the Experiment 3 (Table I).

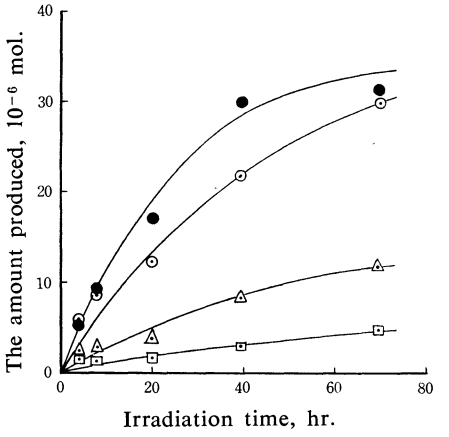

Fig. 2. The amounts of products as a function of irradiation time (experiments 1—5); acetone (●), 2-methylbutanol-2 (1 : 1 telomer) (⊙), 2-methylhexanol-2 (1 : 2 telomer) (△), and 2-methyloctanol-2 (1 : 3 telomer) (⊡).

Although a large number of the products could not be identified, the peak area, A_i, is proportional to the mole concentration, M_i, independent of the materials of the related compounds, as is shown in Fig. 3. Therefore, even if there are some unknown products, the

3) J. D. Strong and J. G. Burr, *J. Am. Chem. Soc.*, **81**, 776 (1959).

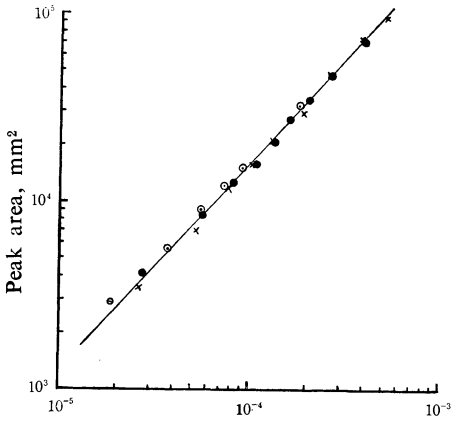

Fig. 3. Peak areas of various materials for gas chromatography at 100°C as a function of their mole concentration; acetone (●), propanol-2 (×) and 2-methylbutanol-2 (⊙).

mole concentration of the respective products, M_i, can be estimated from the gas chromatograph chart by the equation:

$$M_i = M_p \times \frac{A_i}{\sum A_i} \qquad (2)$$

where M_p is the mole concentration of the parent reactant, propanol-2. The $\sum A_i$ is the sum of all the peak areas, including that of propanol-2. Therefore, the G-value is obtained by the equation:

$$G_i = 1.1 \times 10^{12} \times \frac{M_p A_i}{tD(\sum \rho_i)(\sum A_i)} \qquad (3)$$

The G-values, estimated by Eq. 3 from the results of experiment 3 (Table I), are shown in Table II. For this case, the G-value of all the products is 815, judging from the sum of the peak areas, including those for the unidentified products. On the other hand, the G-value of the consumed ethylene is 1800 (cf. Fig. 1). This means that 2.2 ethylene molecules are apparently combined with a propanol-2 molecule.

Discussion

The Overall Reaction Scheme.—A part of the reaction scheme can be assumed to be as shown in Table III from the identified products in Table II, where PH is propanol-2, and, E, ethylene. This indicates that all the radicals which can be expected from propanol-2 are present as precursors. These precursor radicals, I—V (Table III), are formed not only by the reactions shown in Table III, but also by various reactions between propanol-2 and various radicals.

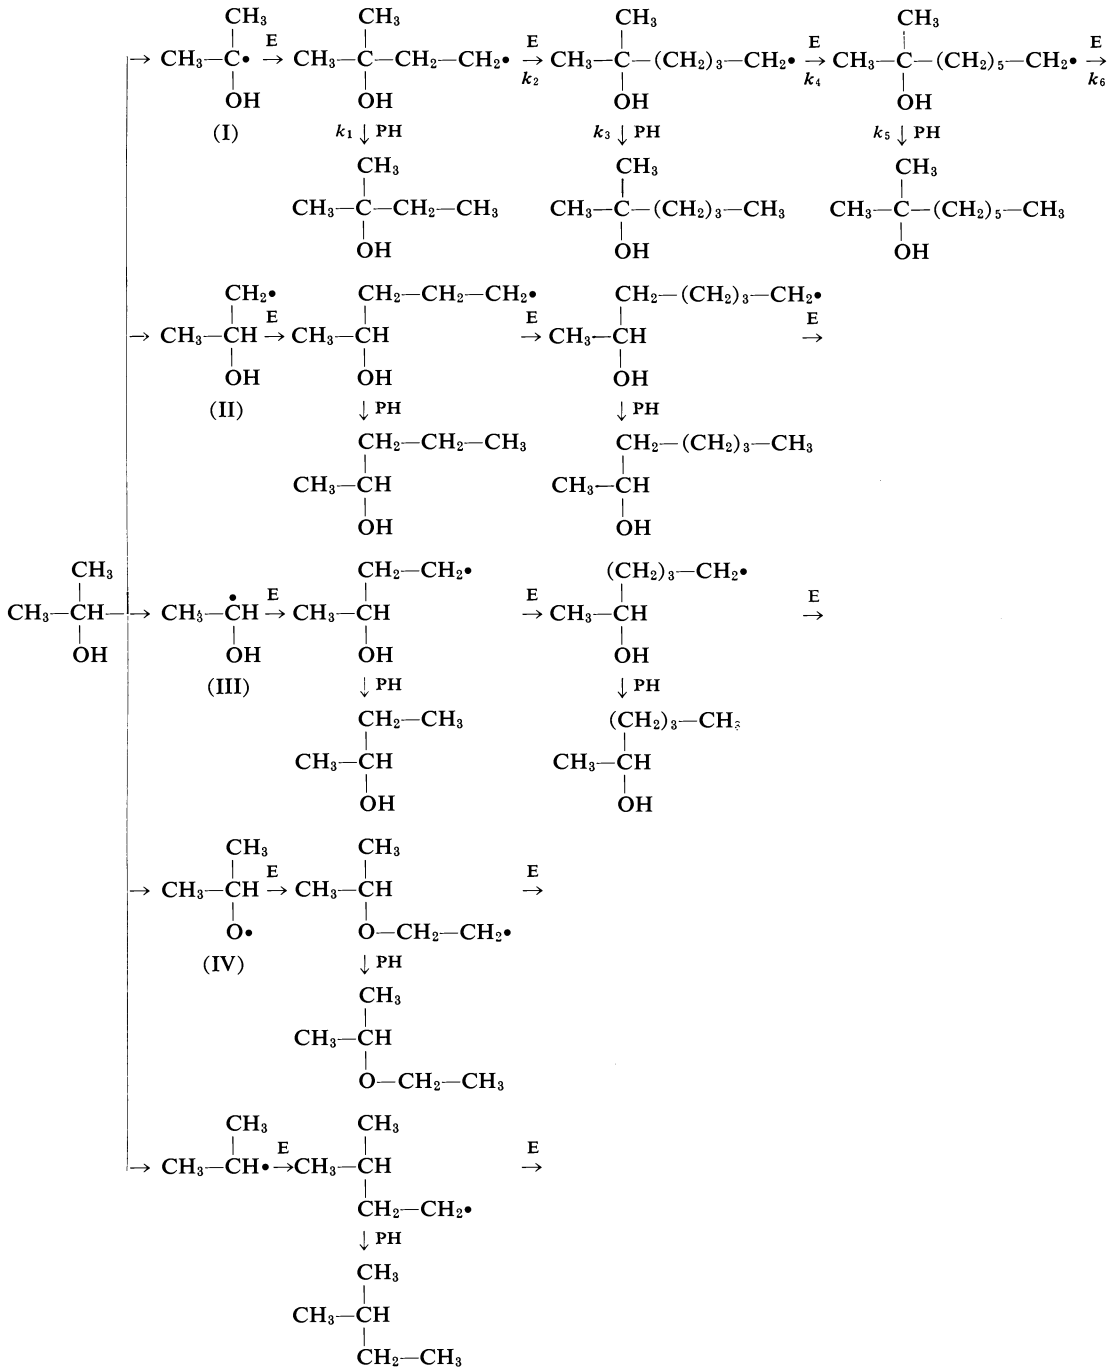
The API's mass-spectral data[5] show that almost all the propanol-2 molecules lose not a hydrogen atom but a methyl radical by ionization. On the other hand, the present findings indicate that the major precursor radical is 1-hydroxyisopropyl, as is to be expected from the radical mechanism. This indicates that the present processes are radical and not ionic, even if initiated by irradiation, namely, ionization and excitation.

The present finding in the gaseous phase is in contrast with the finding in the liquid phase, reported by Hirota and Hatada,[2] that almost all the products were from the 1-hydroxyisopropyl radical, although the mole fraction of ethylene in that experiment was different from that in the present experiments. This may show that the addition reaction is predominant in the liquid phase; it will be shown later that the chain transfer constant is smaller than that in the gaseous phase. In other words, the products produced only in the gaseous phase may perhaps be attributed to the radical transfer reaction of radicals with propanol-2 molecules.

Acetone and Acetaldehyde.—The G-values of acetone and acetaldehyde are nearly equal to those from the radiolysis of gaseous propanol-2 (experiment 10, Table I) and are independent of the mole fraction of ethylene (experiments 3, 11—15, Table I). Therefore, they are assumed to be formed independently of ethylene.

1-Hydroxyisopropyl Radical.—The 1-Hydroxyisopropyl radical (radical I, Table III) is the most important precursor radical formed from propanol-2, as is indicated by the G-value of the telomers in Table III. This radical might react variously with propanol-2 by means of radical transfer reactions as well as by the hydrogen transfer reaction.

It may not necessarily be concluded that acetone is formed through this radical, for the yield of acetone is independent of the ethylene content, which is indispensable for the formation of this radical. Although the molecular detachment of hydrogen from propanol-2 is sometimes assumed for the excited molecule of radiolysis or photolysis and for the thermal formation on the special solid catalysts, this may be supposed not to be the present case.



According to Mellow and Burton,[6] the addition reactions, started from this precursor radical, P, shown in Table III, are expressed by the following rate relations:

$$\frac{(\text{P–E–H})}{(\text{P–E–E–H})} = \frac{k_1(\text{PH})}{k_2(\text{E})} + \frac{k_1 k_4}{k_2 k_3} \qquad (4)$$

5) Mass Spectral Data of American Petroleum Institute Research Project 44, Carnegie Inst. Techn., Pittsburgh (1957).

6) F. W. Mellow and M. Burton, *J. Phys. Chem.*, **66**, 2164 (1962).

TABLE III. REACTION SCHEME

and

$$\frac{(\text{P-E-E-H})}{(\text{P-E-E-E-H})}=\frac{k_3(\text{PH})}{k_4(\text{E})}+\frac{k_3k_6}{k_4k_5} \qquad (5)$$

where the symbols are as represented in Table III. The yields of these telomers depend on the ethylene content in the results of experiments 11—15 (Table I). The chain transfer constants, $c_1=k_1/k_2$, $c_2=k_3/k_4$, and $c_3=k_5/k_6$, are estimated by the use of Eqs. 4 and 5 to be 0.62, 0.55±0.05 and 0.50±0.05 from these results.

On the other hand, according to Walling,[7] the chain transfer constants, c_i, can be expressed by the equation:

7) C. Walling, "Free Radicals in Solution," John Wiley and Sons, New York (1957), p. 246.

$$F_i=\frac{c_iR}{\Pi(c_iR+1)} \qquad (6)$$

where F_i is the mole fraction of the i'th telomer to the whole telomers, and R, the mole ratio of the reactants, (PH)/(E). The mole fraction of the respective telomers, F, is plotted against the R in Fig. 4 on the basis of the results of experiments 11—15.

The chain transfer constants, obtained from the curves in Fig. 4 using Eq. 6, are plotted as the function of the R in Fig. 5. On the other hand, the constants in the liquid phase obtained by this method are $c_1=0.062$, $c_2=0.056$, and $c_3=0.073$ at $R=18$;[2] these values are smaller than the present values in the gaseous phase.

The 1-Hydroxyethyl Radical.—The 1-Hydroxyethyl radical, (radical III, Table III) is considered to be one of the precursor on the basis of the presence of hexanol-2, as is shown in Table III. However, butanol-2 could not be identified by gas chromatography, for this peak

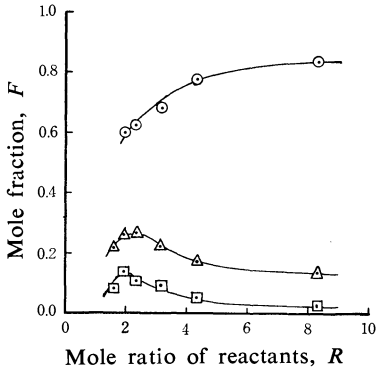


Fig. 4. The mole fractions of the telomers produced, F, as a function of the mole ratio, (propanol-2)/(ethylene), R (experiments 11—15). Marks are the same as in Fig. 2.

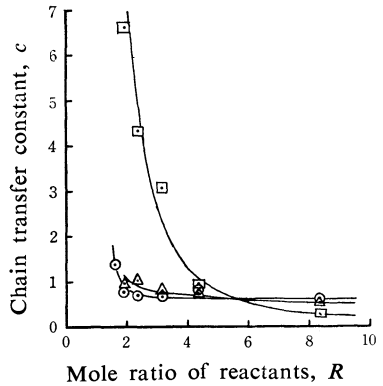

Fig. 5. The chain transfer constants, c, estimated by Eq. 6 as a function of mole ratio, (propanol-2)/(ethylene), R (experiments 11—15); c_1 (⊙), c_2 (△) and c_3 (⊡).

was covered by the tail of 2-methylbutanol-2. Ethanol might be formed by the reaction with propanol-2, but this product could also not be identified because of the large peak of propanol-2. Therefore, the G-value of this precursor radical cannot be estimated quantitatively. However, this is not so important as in the mass-spectrum.

Other Precursor Radicals. — As Table III shows, the 2-hydroxypropyl, isopropoxyl and isopropyl radicals are also assumed to be precursors on the basis of the presence of the identified products. The G-value of heptanol-2, expected from the 2-hydroxypropyl radical, seems to be small.

The Temperature Dependence of the Yields.—The results of experiments 3, 6—9 (Table I) showed that the yields of the products, including the unidentified ones, decreased with a decrease in the temperature, except for the telomers of radical I in Table III, and that the twenty-two products could not be found by gas chromatography from the samples at 100 and 125°C. The amounts of some of the products produced are plotted in Fig. 6 against the reciprocal of the absolute reaction temperature. As is shown by the dotted lines in Fig. 6, the yield of telomers increased also at lower temperatures. This is either due to the condensation of some part of the propanol-2 on the wall of the tube, thus suppressing the radical transfer reactions or disproportionation reactions and promoting the addition reactions in the liquid phase, as has been discussed already, or to such conditions at a lower temperature, even if it is not condensed. This seems to support the latter assumption that a large number of the products are not

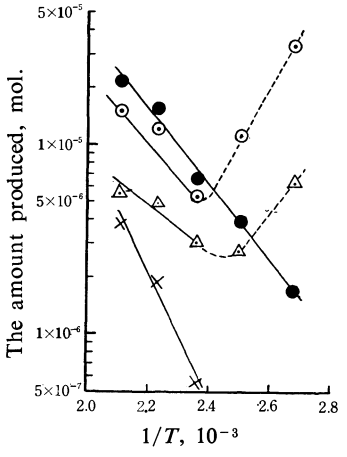

Fig. 6. The amounts of products as a function of the reciprocal of absolute reaction temperature (experiments 3, 6—9); acetone (●), 2-methylbutanol-2 (⊙), 2-methylhexanol-2 (△), and ethyl isopropyl ether (×).

formed at lower temperatures, as has been pointed out above.

The apparent activation energies of the formation of 2-methylbutanol-2, 2-methylhexanol-2, acetone and ethyl isopropyl ether are 8.40, 5.75, 9.19 and 15.7 kcal./mol. respectively, judging from the slope of the curves at higher temperatures in Fig. 6. The value of 2-methylbutanol-2 in the liquid phase is 6.3 kcal./mol. according to Hirota and Hatada.[2] On the other hand, the activation energy of the hydrogen abstraction reaction from propanol-2 by the methyl radical is 7.3 kcal./mol. according to Trotman-Dickenson and Steacie.[8]

Summary

When a mixture of propanol-2 and ethylene was irradiated in the gaseous phase by cobalt-60 gamma-rays at 100°C to 200°C, thirty-seven products were found by gas chromatography from the samples above 150°C in addition to the telomers already reported, while fifteen products were found at 100°C. While the yield of these products increased with an increase in the temperature, the yield of the telomers increased not only with an increase in the temperature but also with a decrease in the temperature below 125°C. The identified products show that all the kinds of radicals, which were expected from propanol-2 are present as the precursors of these products. It has been concluded from these facts that the various radical transfer reactions and disproportionation reactions occur in the gaseous phase, especially above 150°C, although the addition reactions are predominant in the liquid phase at lower temperatures. On the other hand, although 1-hydroxyethyl radical ions are predominant in the electron impact of propanol-2, the 1-hydroxyisopropyl radical is predominant among the precursor radicals. This shows that the present processes are radical and not ionic.

The authors wish to express their thanks to Dr. Hideo Kon, NAIG, for his kind advice.

The Solvent Extraction of Ruthenium with 8-Hydroxyquinoline

By Toyoaki KATO

(Received March 30, 1964)

Because of the difficulty of separating it, ruthenium has prompted studies of a simple and effective method for separation; various isolation schemes for radioactive ruthenium from a fission product mixture have already been reported.[1-5]

The solvent extraction of radioruthenium was accomplished; ruthenium was transferred as its tetroxide into carbon tetrachloride,[4] as perruthenate into pyridine[5] or as its thiocyanate complex into various organic solvents.[6]

On the other hand, numerous organic reagents which can react with ruthenium have been employed for the colorimetric determination, but heating is generally required to develop the color.[7-15]

It has also been stated that in an acetate medium 8-hydroxyquinoline forms a green complex with ruthenium(III) which is extractable

with chloroform,[16] but the experimental conditions of the complex formation, as well as its extraction behavior, are not known in detail.

In the present work, the investigation of the solvent extraction hehavior of ruthenium with 8-hydroxyquinoline was carried out using radioactive ruthenium, ruthenium-106, as a tracer.

Extraction can also be applied for the removal of the tracer amounts of ruthenium that are ordinarilly met with in the radiochemical separation.

Experimental

Ruthenium Stock Solutions.—A hydrochloric acid solution of ruthenium(IV) was prepared by dissolving "ruthenium trichloride" obtained from the Yokosawa Chem. Co. in 6 M hydrochloric acid.[17] The ruthenium content of this solution was determined as 1.93 mg. Ru/ml. by the method of Taimni.[18]

A nitric acid solution of ruthenium(IV) of a known ruthenium content (1.6 mg. Ru/ml.) was prepared by absorbing gaseous ruthenium tetroxide into 1 N nitric acid containing 3% hydrogen peroxide followed by heating it at 40°C for 30 min. The ruthenium tetroxide was prepared according to Kambara's method,[19] in which "ruthenium trichloride" was oxidized with lead peroxide in a sulfuric acid medium.

A more dilute solution containing 10 μg. Ru/0.1 ml. was prepared by diluting the stock solutions just before use; in every extraction experiment, a 0.1 ml. aliquot of this solution was used.

Radioactive Ruthenium. — Ruthenium-106 as "trichloride" in 8 M hydrochloric acid, with a radiochemical purity of about 99%, was imported from the Radiochemical Centre, Amersham, England. A part of this was diluted with 0.1 M hydrochloric acid to make its radioactivity about 5×10^4 c. p. m./0.1 ml.; this was used as a tracer of ruthenium(IV) in hydrochloric acid. Another part of this was converted into a nitrate solution in the same manner as was described for inactive ruthenium nitrate. This was used as a tracer of the corresponding ruthenium(IV) nitrate after proper dilution with 0.1 M nitric acid, also with a radioactivity of about 5×10^4 c. p. m./0.1 ml.

8-Hydroxyquinoline and Other Chemical Reagnts. — Commercial 8-hydroxyquinoline of guaranteed grade, with the observed melting point of 72.5~74.5°C, was used.

The organic solvents and other reagents were all guaranteed grade reagents. Redistilled water was used.

Apparatus.—For the measurement of the radioactivity, a well-type scintillation counter, Model RSP-1, made by the Kōbe Kôgyô Co., Japan, was employed. For measuring the pH of the aqueous phase, a glass electrode pH meter, Model EHM-1, made by the Hitachi Co., Japan, was employed.

Experimental Procedure.—The procedure for the extraction experiment was, unless otherwise stated, as follows: To an aliquot of 8-hydroxyquinoline dissolved in *n*-propanol or in 10 M acetic acid in a test tube, an aqueous buffer and, if needed, another reagent solution were added to adjust the pH value of the solution, and the total volume was made up to 6 ml. with water. A 0.1 ml. portion of each ruthenium-106 and ruthenium solution (Ru : 10 μg.) was added, and the mixture was kept at an elevated temperature (60°C in most cases) in a constant temperature bath for a time.

After having been cooled in running water, the contents were transferred into a separatory funnel, and the 8-hydroxyquinolate formed was extracted with a suitable aliquot of an organic solvent (2 or 5 ml.) like *n*-butanol or benzene by shaking it for 1 min. An excess quantity of 8-hydroxyquinoline was employed in every extraction system; viz., 2 ml. of 0.05 M 8-hydroxyquinoline (100 μeq.) in *n*-propanol or 1 ml. of 1 M 8-hydroxyquinoline (1 meq.) in a 10 M acetic acid solution was used.

In all extractions, both the organic and aqueous phases, after having been disengaged in a separatory funnel, were drained into two test tubes. The respective ruthenium contents were then estimated by gamma counting, and the percentage extraction was computed as a ratio of the counting rate of the organic extract to the sum of the counting rates of the two phases. The pH of the aqueous phase after extraction was also measured.

Results and Discussion

The Formation of 8-Hydroxyquinolate. — In the preliminary study of the extraction of ruthenium as 8-hydroxyquinolate, it was found that the rate of the formation of 8-hydroxyquinolate, as well as of the extraction, was quite slow at room temperature when an aqueous solution containing ruthenium was shaken with 8-hydroxyquinoline in chloroform, even at relatively high pH values (pH 4~6) and at a high concentration of the reagent (1 M). The formation of the 8-hydroxyquinolate, however, was accelerated when an aqueous solution was kept at an elevated temperature in the presence of an excess reagent as its *n*-propanol solution, so the following equilibrium extraction might be achieved rapidly by shaking it with an additional organic solvent such as chloroform.

As is shown in Fig. 1, the extraction of 8-hydroxyquinolate with 2 ml. of chloroform or *n*-butanol from an aqueous phase under various conditions was accomplished after the aqueous system had been kept at 60°C for 1 hr.

Ruthenium(IV) nitrate was used in this experiment; it will also be used hereafter unless otherwise indicated.

Extraction Solvent. — The ruthenium 8-hydroxyquinolate formed in an aqueous acetate medium of pH 6 in the manner described above was extracted with each 2 ml. portion of various organic solvents. As is shown in Table I, more than 99% of the original ruthenium is transferred into various organic solvents, except isopropyl ether. *n*-Butanol is especially efficient in retaining 8-hydroxyquinolate.

TABLE I. EXTRACTION BY VARIOUS SOLVENTS

Solvent	% Extracted
n-Butanol	99.3
Isoamyl alcohol	96.4
Cyclohexanone	97.0

Isopropyl ether	84.0
Isoamyl acetate	92.1
Benzen	93.0
Carbon tetrachloride	90.1
Chloroform	94.8

Extraction Curves. — The determination of the pH range where the extraction of ruthenium has to be successful was carried out.

The shape of the extraction curve is generally affected by the buffer component employed to adjust the pH of an aqueous phase, thereby emphasizing the importance of the proper selection of the buffer component and its concentration in a system.[20-22]

First, extraction with 2 ml. of *n*-butanol from an aqueous acetate system composed of 0.33 M sodium acetate or ammonium acetate was carried out, varying the pH values with additional dilute nitric acid, acetic acid, or aqueous ammonia. The extraction curve thus obtained is illustrated in Fig. 2, from which the extraction of ruthenium of either tracer (ruthenium-106, carrier-free) or ordinary micro amounts (Ru : 10 μg.) may be found to be almost complete by using 2 ml. of *n*-butanol at the pH value of 4~6.

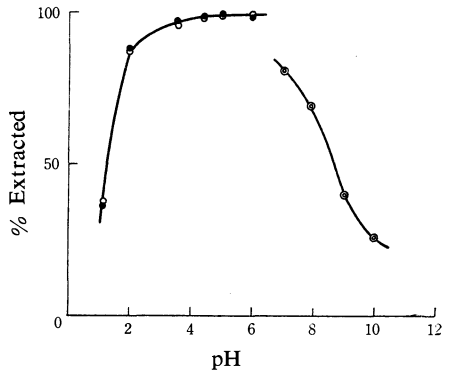

Fig. 2. Effect of pH on the extraction from acetate buffers.
● Ru : carrier-free
○, ◎ Ru : 10 μg.

In an aqueous ammonia - ammonium acetate system, extractability is reduced by an interfering action of the ammonium ion, as will be described later on. Hence, the discontinuity of the extraction curve appeared at about pH 6.

Next, the relation between the percentage extraction of ruthenium and the pH of the aqueous solution containing various buffer components, viz., 0.03 M phthalate, 0.1 M citrate, 0.03 M or 0.1 M phosphate, or an aqueous ammonia - ammonium chloride mixture was investigated. An aqueous solution of sodium hydroxide was used to give the aqueous solution higher pH values. Extraction was also carried out with 2 ml. of *n*-butanol.

The results are illustrated in Fig. 3. In the phthalate system, as well as in the case of acetate, an almost complete extraction was achieved at the pH range of 4~6, but in this pH region extraction is considerably reduced in the presence of citrate. Phosphate and ammonium salts were also unfavorable as buffer components.

Coexisting Substances. — The effects of the coexistence of inorganic salts and organic acids or their salts are given in Table II. With large amouts of chloride, nitrate, sulfate and borate, no significant interferences were observed, but with oxalate and other organic substances, severe interferences resulted.

The Amount of Ruthenium.—The concentration dependence of ruthenium on the extractability was determined in an extremely low

concentration, from a tracer amount to 2.5×10^{-3} M, in an original aqueous solution. In this experiment, a definite amount of ruthenium(IV) was added to an aqueous solution containing a carrier-free ruthenium-106 tracer, and extraction with 2 ml. of *n*-butanol was carried out at pH 5.6 after heating the solution with an excess reagent, as has been described above.

As is shown in Table III, as much as 99% of the original ruthenium(IV) could be transferred into *n*-butanol as its 8-hydroxyquinolate.

The Extraction of Ruthenium Added as "Trichloride." — As the course of the extraction seemed to consist of the formation of 8-hydroxyquinolate in aqueous - *n*-propanol - acetate systems and its distribution into the organic solvent, the effect of the heating time, the concentration dependence of ruthenium and the pH range for complete extraction were also investigated when both of ruthenium and ruthenium-106 solutions were added as "trichloride" in hydrochloric acid. The results presented in Figs. 4, 5 and 6 show that the percentage extraction reaches a limiting value upon one hour's heating at 60°C and that the value is held constant over a wide concentration range of ruthenium; almost complete extraction can be achieved in the pH range of 4~6 by 2 ml. of *n*-butanol. This behavior is closely similar to that observed in the case of nitrate, in which the oxidation state of ruthenium is quadrivalent.[23] As is shown in Table II. extraction was, however, reduced to an appreciable extent in the presence

of hydroxylamine hydrochloride, which reduces ruthenium(IV) to tervalent.[24] It has been mentioned that ruthenium(III) in hydrochloric acid is fairly air-oxidized to the ruthenium(IV) state; hence, a commercial water-soluble ruthenium trichloride is usually composed, at least in part, of ruthenium(III) salt.[25]

Indeed, when "ruthenium trichloride" was dissolved in 6 M hydrochloric acid, its absorption spectrum was characterized by intense peaks at 385 and 254 mμ, together with a minor peak at 476 mμ corresponding to that of the chloro-ruthenium(IV) species; according to Wehner's paper,[26] this was defined as $Ru(OH)_2Cl_4^{2-}$. Air-oxidation occurred to both inactive and radioactive ruthenium; therefore, the extraction behavior of 8-hydroxyquinolate has to be identical with that of ruthenium(IV).

The Improvement of the Extraction System. — Thus the extraction of ruthenium in *n*-butanol as 8-hydroxyquinolate is completed from an aqueous *n*-propanolic solution, but the back extraction of ruthenium from an organic extract composed of a *n*-propanol - *n*-butanol mixture can not be performed because of the water-miscible property of this solvent mixture. Therefore, it is desirable to modify an extraction system so as to produce a favorable separation of ruthenium from the organic extactants. On the other hand, it is also desirable to make the rate of approach to the extraction equilibrium higher than has been observed in previous parts. Consequently, the behavior was further examined in a system involving the formation of 8-hydroxyquinolate with a still larger amount of the reagent and subsequent extraction with an almost water-immiscible solvent such as benzene.

Hereafter, ruthenium(IV) nitrate was again used, and the aqueous phase was prepared by adding an acetic acid solution of 8-hydroxyquinoline (up to 1 meq.) and adjusting the pH of the resulting solution to 4 with an additional 1 ml. portion of 2 M sodium acetate, as has been described in the Experimental section.

The effect of heating time on the extractability is shown in Fig. 7, where the percentage extraction in an equilibrium extraction with 2 ml. of *n*-butanol reaches a constant value of 99.3% with 1 meq. of the reagent after being heated for 30 min. at 60°C or for 10 min. at 80°C. In these cases, 99.0% of the ruthenium

is extracted with 5 ml. of benzene. It may also be seen that the formation of 8-hydroxyquinolate at room temperature is unfavorably slow. The percentage extraction reached 78% after the aqueous phase had stood for about 40 hr. In the presence of 100 μeq. of the reagent, the extraction by 2 ml. of *n*-butanol was somewhat reduced to 97%.

Shaking Time.—With a large amount of the reagent, it is to be expected from the extraction rate that the equilibrium can be readily achieved by directly agitating both phases without heating. Therefore, an aqueous acetate system containing 1 meq. of the reagent was mixed with each 5 ml. portion of *n*-butanol or benzene. The effect of the shaking time on the extractability is given in Fig. 8, where the equilibrium extraction can not be attained even by a shaking of up to 2 hr. Because it requires a longer time for equilibration, the formation of the extractable 8-hydoxyquinolate in an aqueous system by heatnig should be followed by the extraction.

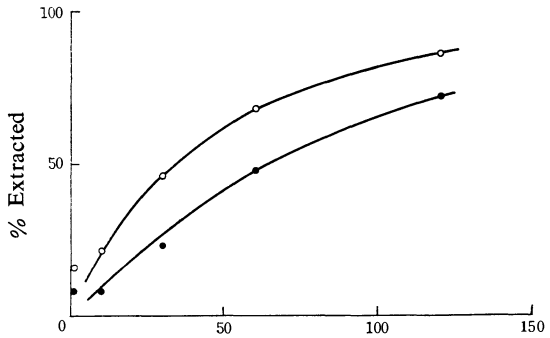

Fig. 8. Effect of shaking time on the extraction
○ *n*-Butanol
● Benzene

It may also be concluded that the complex formation in the aqueous phase is the limiting step in this separation method.

The Presence of a Water-Miscible Solvent.—Although the benzene extraction was sufficient for the extraction of ruthenim, the enhancement of extractability was recognized with *n*-butanol as the extracting solvent and, morever, with *n*-propanol present in an aqueous system.

The fairly water-miscible solvents seemed to be efficient for the formation and subsequent extraction of 8-hydroxyquinolate. It has been discussed now, in a chelate extraction system, a good extraction can be attained by the effect of a mixed solvent.[27,28] On the basis of these considerations, further investigation was carried out with such solvents to produce some different media for the formation of 8-hydroxyquinolate. First, the 8-hydroxyquinolate was formed in 6.2 ml. of the aqueous solution containing 1 ml. of a water-miscible solvent, such as *n*-propanol, methyl cellosolve, ethylene glycol, dioxane and pyridine, and then the extraction was carried ont with 2 ml. of benzene. As is shown in Table IV, the percentage extraction is greater to a minor, but appreciable, extent in the presence of any of the solvents excepting pyridine, than in their absence. No simple relation can be found between the solvent character and the extractability, as the extractability does not reach its highest point even with dioxane, which has the lowest dielectric constant among the solvents. In the presence of *n*-butanol, the highest result was attained, and by the later *n*-butanol extraction, the extractability might be enhanced remarkably: a combination of 2 ml. of *n*-propanol and 5 ml. of *n*-butanol resulted in the 99.9% extraction of ruthenium.

extraction of ruthenium was not attained appreciably with the various back extractants listed in Table V except for concentrated mineral acid.

8-Hydroxyquinolate, once formed, retains its extractable property, even in a range of extremely low pH values where the excess reagent is transferred into the aqueous phase as a protonated form of 8-hydroxyquinoline, H_2Ox^+.[29] Washing a benzene extract with 1 N mineral acid, almost all the excess reagent can be removed with as little a loss of ruthenium as 1.5%. 8-Hydroxyquinolate is released by contact with more concentrated hydrochloric or sulfuric acid, and 95% of the ruthenium is found in concentrated hydrochloric acid after 10 minutes' agitation.

The Application of Solvent Extraction. — Ruthenium(IV) 8-hydroxyquinolate is greenish-yellow in color. The absorption spectrum of the benzene solution, shown in Fig. 10, is characterized by an intense peak at 437 mμ and a broad maximum at about 700 mμ in the visible range.[30] The colorimetric determination of a minute amount of ruthenium can be attained directly in the organic extract; the experimental conditions for this purpose will be described in detail elsewhere.

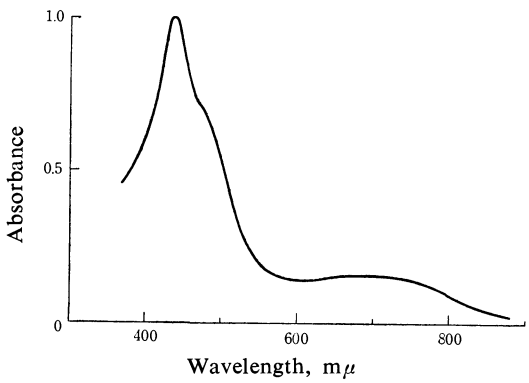

Fig. 10. Absorption spectrum of ruthenium(IV)-8-hydroxyquinolate in benzene extract.

Next, the elements in mixed fission products were tested for their extractable properties by this method. Each pure nuclide in a carrier-free state[31] was subjected individualy to the experimental procedure; extraction with 5 ml. of benzene from an aqueous acetate solution of pH 4 containing 1 meq. of the reagent, and back extraction with an equal volume of 1 N nitric acid. Table VI shows 86.6% of the original zirconium-niobium-95 is accompanied by ruthenium-106 in the benzene extract but is completely separated by the following acid washings. The decontamination from the nuclides tested is complete. Ruthenium-103, 106 of a high radiochemical purity can be obtained from the mixed fission products by this extraction method.

Table VI. Behavior of some fission product nuclides

Nuclide	% Found in benzene extract	% Found in 1 N nitric acid*

Summary

The solvent extraction behavior of ruthenium(IV) with 8-hydroxyquinoline has been investigated in detail using ruthenium-106 as a tracer.

The complex formation in the aqueous phase is fairly slow and is the limiting step in the procedure, but it can be enhanced by heating. Complete extraction is attainable with *n*-butanol, benzene and other organic solvents after 8-hydroxyquinolate has been formed by one hour's heating at 60°C with the excess reagent in an aqueous acetate medium of pH 4~6. *n*-Propanol, especially when combined with *n*-butanol, is an efficient extraction solvent. The presence of ammonium salts, organic

acids or their salts causes interference. 8-Hydroxyquinolate, once formed, remains extractable even at very low pH values. The stripping of ruthenium from the benzene extract is accomplished by contact with concentrated hydrochloric acid.

This solvent extraction is applicable to the colorimetric determination of minute amounts of ruthenium and to the isolation of ruthenium activities in mixed fission products.

The author wishes to express his hearty thanks to Professor Yoshinaga Oka for his kind suggestions and fruitful discussions in the course of this work.

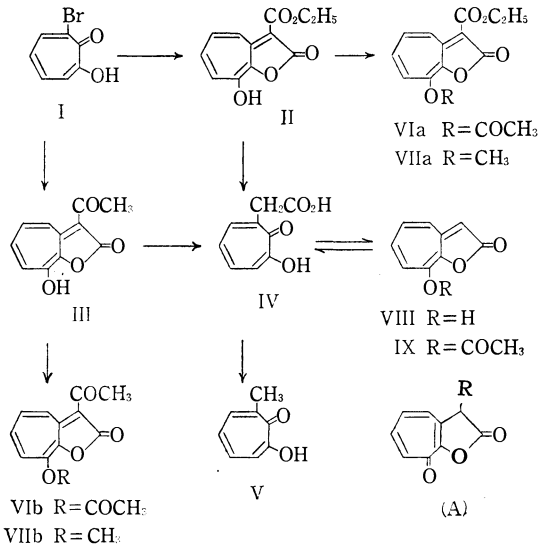
The Synthesis of 8-Hydroxy-1-oxaazulan-2-one and Its Derivatives by the Condensation of 3-Bromotropolones with Diethyl Malonate and Ethyl Acetoacetate

By Kahei TAKASE

(Received April 11, 1964)



During studies of the C-alkylation of tropolones by anionoid substitution reaction, it has been found that the reaction of 3-bromotropolones and diethyl malonate or ethyl acetoacetate afforded as condensation products 8-hydroxy-1-oxaazulan-2-one (8-hydroxy-2H-cyclohepta[b]furan-2-one) derivatives. The alkyl derivatives of these condensation products have also been obtained by the extension of this reaction to alkyl derivatives of 3-bromotropolone. Moreover, 8-hydroxy-1-oxaazulan-2-one itself and 3-carboxymethyltropolones have been derived from these condensation products. In this paper, the synthesis and some reactions of 8-hydroxy-1-oxaazulan-2-ones will be described.

Hartley[1] reported that *o*-bromobenzoic acid reacted with diethyl malonate or ethyl acetoacetate, in the presence of a copper catalyst, to give condensation products. This reaction has now been extended to 3-bromotropolone (I). The heating of I with diethyl sodiomalonate, in the presence of copper acetate, gave an acidic compound (II), $C_{12}H_{10}O_5$ (one OC_2H_5), in a good yield. Under the same conditions, ethyl sodioacetoacetate also gave an acidic compound (III), $C_{11}H_8O_4$ (no OC_2H_5). These condensation products were soluble in alkalis, but they did not show any coloration with a ferric chloride solution. When heated in concentrated hydrobromic acid, II afforded an acidic compound IV while evolving carbon dioxide. The heating of II in a sodium hydroxide solution also gave IV. Acid IV is a dibasic acid with pK_a, 4.52 and 8.77,[2] and showed a green color with a ferric chloride solution. The heating of IV in pyridine gave 3-methyltropolone (V)[3] while carbon dioxide was evolved.

These results indicate that the acid IV is 3-carboxymethyltropolone and that, consequently, II is a condensation product possessing the malonic ester group at the 3-position of the tropolone nucleus. The lactone structure (A) may also be assumed for II from the analytical values and the negative ferric chloride test, which suggests that the hydroxyl group of tropolone is masked. However, II is a monobasic acid with pK_a, 3.57,[4] which value would be due to the enolic hydroxyl, not to the opening of the lactone ring. Furthermore, the acetylation of II with acetic anhydride gave a neutral monoacetate (VIa), and the methylation of II with diazomethane gave a neutral monomethyl derivative (VIIa). The ultraviolet absorption spectra of both VIa and VIIa are similar to those of 1-oxaazulan-2-ones,[5] as Fig. 2 shows. The ultraviolet absorption spectrum of II, as is shown in Fig. 1, is also similar to those of 1-oxaazulan-2-ones, although its maxima show a slight hypsochromic shift.

Japan Acad.*, **27**, 646 (1951); T. Nozoe, T. Mukai, M. Kunori, T. Muroi and K. Matsui, *Sci. Repts. Tohoku Univ.*, I, **35**, 242 (1952).
4) The dissociation constants were measured by Mrs. Toshiko Kurosawa of the Chemical Laboratory, Faculty of Science, Tohoku University; to her the author's thanks are due.
5) S. Seto, *Sci. Repts. Tohoku Univ.*, I, **37**, 367 (1953).

From this evidence, II is assumed to be 3-ethoxycarbonyl-8-hydroxy-1-oxaazulan-2-one, and VIa and VIIa, to be 3-ethoxycarbonyl-8-acetoxy- and 3-ethoxycarbonyl-8-methoxy-1-oxaazulan-2-one respectively.

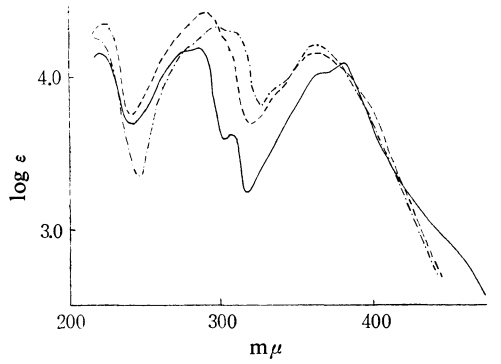

Fig. 1. UV spectra of II (------), III (-·-·-) and VIII (——) in methanol.

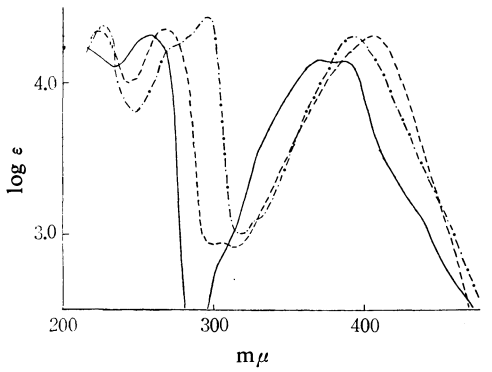

Fig. 2. UV spectra of VIa (------), VIIa (-·-·-) and IX (——) in methanol.

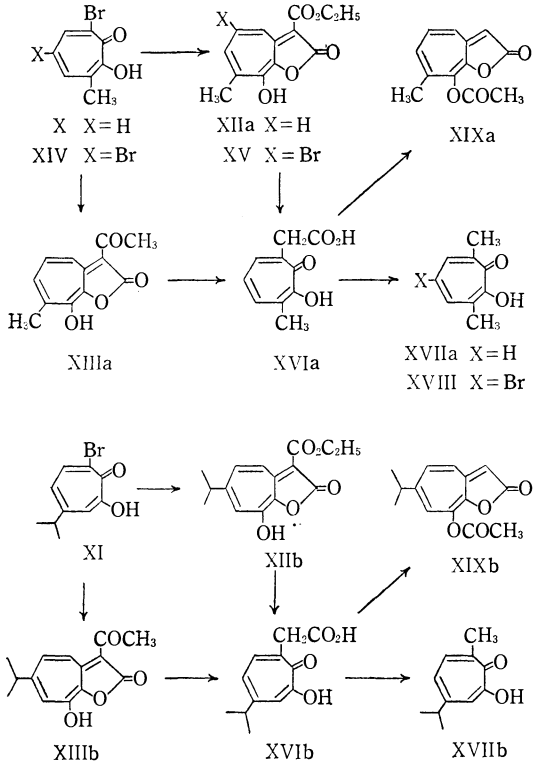
The condensation product (III) is assumed to be 3-acetyl-8-hydroxy-1-oxaazulan-2-one, similar to II, from the following evidence. This compound III is a monobasic acid with pK_a, 3.44,[4] and gave a neutral monoacetate VIb and a neutral monomethyl ether VIIb. The ultraviolet absorption spectra of III and of its acetate VIb and methyl ether VIIb are similar to those of II and of its derivatives, VIa and VIIa, respectively. The heating of III in concentrated hydrobromic acid afforded IV as well as liberated acetic acid.



The parent compound, 8-hydroxy-1-oxaazulan-2-one (VIII) was obtained as orange crystals by dissolving IV in concentrated sulfuric acid and then pouring the mixture into ice-water. Its ultraviolet absorption curve is similar to those of 1-oxaazulan-2-ones, as Fig. 1 shows. When heated in an aqueous solvent, VIII was easily hydrolized to IV. The acetylation of VIII gave an acetate IX, which was also obtained from IV by heating it with acetic anhydride. The ultraviolet absorption spectrum, as shown in Fig. 2, indicates that IX is 8-acetoxy-1-oxaazulan-2-one. The hydrolysis of IX by heating with acids gave IV.

Alkyl derivatives of 8-hydroxy-1-oxaazulan-2-ones were obtained by the extension of this condensation reaction to alkyl derivatives of 3-bromotropolone. When heated with diethyl sodiomalonate or ethyl sodioacetoacetate, both 3-bromo-7-methyltropolone (X)[6] and 3-bromo-6-isopropyltropolone (XI)[7] gave corresponding condensation products, XIIa, b and XIIIa, b, respectively. All of these compounds are acidic and gave neutral monoacetate. The ultraviolet absorption spectra of these compounds and their acetates are closely similar to those of 8-hydroxy-1-oxaazulan-2-ones (II and III) and their acetates respectively. From this evidence, the condensation products, XIIa, b and XIIIa, b, are assumed to be 3-ethoxycarbonyl-7-methyl-, 3-ethoxycarbonyl-6-isopropyl-, 3-acetyl-7-methyl- and 3-acetyl-6-isopropyl-8-hydroxy-1-oxaazulan-2-one respectively. 3, 5-Dibromo-7-methyltropolone (XIV)[6] also reacted with diethyl sodiomalonate to give a condensation product XV. The structure of XV was established from the facts that its ultraviolet absorption spectrum is similar to those of 8-hydroxy-1-oxaazulan-2-ones and that its catalytic debromination gave XIIa.

When heated in concentrated hydrobromic acid, both XIIa and XIIIa afforded 3-carboxymethyl-7-methyltropolone (XVIa) and both

6) K. Takase, *Bull. Chem. Research Inst. Non-Aqueous Solns. Tohoku Univ.*, **13**, 169 (1964).

7) T. Nozoe, T. Mukai and K. Takase, *Proc. Japan Acad.*, **26** (8), 19 (1950); T. Nozoe, E. Sebe, S. Mayama and S. Iwamoto, *Sci. Repts. Tohoku Univ.*, I, **36**, 184 (1952).

XIIb and XIIIb afforded 3-carboxymethyl-6-isopropyltropolone (XVIb). The decarboxylation of XVIa and XVIb by heating in pyridine afforded 3, 7-dimethyltropolone (XVIIa)[3] and 6-isopropyl-3-methyltropolone (XVIIb)[3] respectively. The bromination of XVIIa gave 5-bromo-3, 7-dimethyltropolone (XVIII). When XVIa and XVIb were treated with acetic anhydride, they gave 7-methyl-8-acetoxy- (XIXa) and 6-isopropyl-8-acetoxy-1-oxaazulan-2-one (XIXb) respectively. The ultraviolet absorption spectra of XIXa and XIXb are similar to those of 1-oxaazulan-2-ones. Acetoxy derivatives XIXa, b were easily hydrolized by heating them in concentrated acid or dilute alkalis, affording carboxymethyltropolones (XVIa, b).

These condensation reactions did not proceed without the use of copper acetate. 5-Bromotropolone did not react with diethyl malonate and ethyl acetoacetate under these conditions, while 3, 7-dibromotropolone afforded resinous substances.

Experimental[8]

3-Ethoxycarbonyl-8-hydroxy-1-oxaazulan-2-one (II).—To a solution of diethyl sodiomalonate prepared by dissolving sodium (12.0 g.) in a mixture of diethyl malonate (100 ml.) and dry dioxane (200 ml.), 3-bromotropolone (I) (20.0 g.) and copper acetate (200 mg.) were added; the mixture was then refluxed for 6 hr. After the addition of water (200 ml.), the mixture was shaken with ether (200 ml.) and the aqueous layer was acidified with 6 N hydrochloric acid and allowed to stand overnight. The crystals thereby formed were collected and washed with chloroform to give II (17.6 g.), m. p. 208°C (decomp.). Recrystallization from acetone afforded yellow needles, m. p. 225°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 222 (4.35), 290 (4.43), 357 (4.15).

Found: C, 61.60; H, 4.52; OC_2H_5, 19.22. Calcd. for $C_{12}H_{10}O_5$: C, 61.54; H, 4.30; OC_2H_5, 19.20%.

3-Acetyl-8-hydroxy-1-oxaazulan-2-one (III).—To a solution of ethyl sodioacetoacetate prepared by dissolving sodium (12.0 g.) in a mixture of ethyl acetoacetate (90 g.) and dry dioxane (160 ml.), I (20.0 g.) and copper acetate (400 mg.) were added; the mixture was then refluxed for 18 hr. The reaction mixture was treated as described in the above experiment to give III (19.0 g.), m. p. 278°C (decomp.). Recrystallization from a large amount of acetone gave yellow silky needles, m. p. 285°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 294 (4.32), 361 (4.19).

Found: C, 64.82; H, 4.26. Calcd. for $C_{11}H_8O_4$: C, 64.70; H, 3.95%.

3-Carboxymethyltropolone (IV).—*a) From II.*—A mixture of II (3.95 g.) and concentrated hydrobromic acid (30 ml.) was heated at 130~140°C for 2 hr. The mixture was poured into ice-water (50 g.) and adjusted to pH 3 with a potassium hydroxide solution, the crystals thereby obtained were collected by filtration, affording IV (1.14 g.), m. p. 170°C (decomp.). From the mother liquor, further crops of IV (1.38 g.), m. p. 171°C (decomp.), were obtained by continuous extraction with ether for 20 hr. Recrystallization from dimethylformamide afforded pale yellow needles, m. p. 174°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 243 (4.26), 329 (3.94), 391 (3.91).

Found: C, 59.67; H, 4.66. Calcd. for $C_9H_8O_4$: C, 60.00; H, 4.48%.

b) From III.—A mixture of III (4.0 g.) and concentrated hydrobromic acid (30 ml.) was treated as in a), affording IV (2.70 g.) as yellow needles, m. p. 170°C (decomp.).

c) The Heating of II in Alkali.—A solution of II (200 mg.) in a 2 N sodium hydroxide solution (3 ml.) was heated for 5 hr. The mixture was then acidified with 6 N hydrochloric acid and continuously extracted with ether for 5 hr., affording IV (100 mg.) as pale yellow needles, m. p. 170°C (decomp.).

3-Methyltropolone (V).—A mixture of IV (5.00 g.) and pyridine (15 ml.) was heated under reflux for 3 hr. After the addition of water, the mixture was acidified with 6 N hydrochloric acid and extracted with chloroform. The solvent was evaporated, the residue was sublimed at 110~120°C under reduced pressure, and the sublimate was recrystallized from cyclohexane to give V (3.32 g.) as colorless plates, m. p. 49~50°C, which showed

8) All melting points are uncorrected.

no depression of melting point on admixture with an authentic specimen.[8]

3-Ethoxycarbonyl-8-acetoxy-1-oxaazulan-2-one (VIa).—A mixture of II (1.00 g.) and acetic anhydride (2.5 ml.) was heated at 140°C for 1 hr. Water was added, and the crystals thereby formed were collected and recrystallized from ethanol to give VIa (1.00 g.) as yellow needles, m. p. 135~136°C.

λ_{max}^{MeOH} mμ (log ε); 223 (4.33), 265 (4.34), 402 (4.29).

Found: C, 60.91; H, 4.71. Calcd. for $C_{14}H_{12}O_6$: C, 60.87; H, 4.38%.

The heating of VIa in concentrated hydrobromic acid at 140°C for 1 hr. gave IV.

3-Acetyl-8-acetoxy-1-oxaazulan-2-one (VIb).—A mixture of III (1.00 g.) and acetic anhydride (1 ml.) was treated as described in the above experiment, affording VIb (1.00 g.) as orangish yellow needles, m. p. 168~169°C, after recrystallization from ethanol.

λ_{max}^{MeOH} mμ (log ε); 225 (4.47), 277 (4.41), 416 (4.38).

Found: C, 63.67; H, 4.05. Calcd. for $C_{13}H_{10}O_5$: C, 63.41; H, 4.09%.

3-Ethoxycarbonyl-8-methoxy-1-oxaazulan-2-one (VIIa).—Into a suspension of II (460 mg.) in ethyl acetate (10 ml.), an ethereal solution of diazomethane (3.5 ml.) was stirred while it was being cooled. The mixture was then stirred for 10 hr., and the crystals thereby formed were collected and recrystallized from ethanol to give VIIa (310 mg.) as yellow needles, m. p. 142~143°C.

λ_{max}^{MeOH} mμ (log ε); 225 (4.38), 295 (4.43), 392 (4.31).

Found: C, 62.83; H, 4.87. Calcd. for $C_{13}H_{12}O_5$: C, 62.90; H, 4.87%.

The heating of VIIa in concentrated hydrobromic acid at 140°C for 1 hr. gave V.

3-Acetyl-8-methoxy-1-oxaazulan-2-one (VIIb).—III (410 mg.) was treated with diazomethane as described in the above experiment, affording VIIb (320 mg.) as orangish yellow needles, m. p. 231~232°C (decomp.) after recrystallization from ethanol.

λ_{max}^{MeOH} mμ (log ε); 228 (4.39), 258 (4.08), 300 (4.47), 404 (4.35).

Found: C, 66.02; H, 4.68; OCH_3, 14.21. Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62; OCH_3, 14.05%.

8-Hydroxy-1-oxaazulan-2-one (VIII).—A solution of IV (400 mg.) in concentrated sulfuric acid (1 ml.) was poured into ice-water to give VIII (220 mg.), m. p. 220°C (decomp.). Recrystallization from a mixture of dioxane and dimethylformamide gave orangish yellow prisms, m. p. 223°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 220 (4.16), 275 (4.17), 285 (4.18), 305 (3.62), 380 (4.09).

Found: C, 66.41; H, 3.87. Calcd. for $C_9H_6O_3$: C, 66.67; H, 3.73%.

8-Acetoxy-1-oxaazulan-2-one (IX).—*a) From IV.*—A mixture of IV (1.00 g.) and acetic anhydride (2 ml.) was heated at 140°C for 2 hr. After the addition of water (30 ml.), the mixture was extracted with benzene and the benzene solution was passed through a short column of silica gel, affording IX (930 mg.), m. p. 140~150°C. Recrystallization from methanol gave orange prisms or needles, m. p. 151~152°C.

λ_{max}^{MeOH} mμ (log ε); 257 (4.30), 369 (4.14), 387 (4.14).

Found: C, 64.63; H, 4.00. Calcd. for $C_{11}H_8O_4$: C, 64.70; H, 3.95%.

The heating of IX in concentrated hydrobromic acid at 140°C for 1 hr. gave IV.

b) From VIII.—A mixture of VIII (100 mg.) and acetic anhydride (0.5 ml.) was treated as in a), affording IX (100 mg.), m. p. 151~152°C.

3-Ethoxycarbonyl-7-methyl-8-hydroxy-1-oxaazulan-2-one (XIIa).—To a solution of diethyl sodiomalonate prepared by dissolving sodium (600 mg.) in a mixture of dioxane (10 ml.) and diethyl malonate (6 ml.), 3-bromo-7-methyltropolone (X) (1.07 g.) and copper acetate (50 mg.) were added; the mixture was then heated under refluxing for 15 hr. The reaction mixture was diluted with water and acidified with 6 N hydrochloric acid. The crystals thereby formed were collected and recrystallized from acetone to give XIIa (1.02 g.) as yellow silky needles, m. p. 201°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 227 (4.29), 295 (4.46), 355 (4.13).

Found: C, 63.08; H, 4.88. Calcd. for $C_{13}H_{12}O_5$: C, 62.90; H, 4.87%.

Acetate: m. p. 146~147°C, yellow needles (from methanol).

λ_{max}^{MeOH} mμ (log ε); 230 (4.43), 267 (4.40), 408 (4.40).

Found: C, 62.12; H, 4.83. Calcd. for $C_{15}H_{14}O_6$: C, 62.06; H, 4.86%.

3-Ethoxycarbonyl-6-isopropyl-8-hydroxy-1-oxaazulan-2-one (XIIb).—To a solution of diethyl sodiomalonate prepared by dissolving sodium (3.0 g.) in a mixture of dioxane (40 ml.) and diethyl malonate (25 ml.), 3-bromo-6-isopropyltropolone (XI) (6.0 g.) and copper acetate (100 mg.) were added; the mixture was then heated under refluxing for 15 hr. The reaction mixture was treated as described in the above experiment to give XIIb (5.28 g.) as yellow needles, m. p. 214~215°C, after recrystallization from acetone.

λ_{max}^{MeOH} mμ (log ε); 230 (4.46), 290 (4.50), 355 (4.26).

Found: C, 65.47; H, 5.72. Calcd. for $C_{15}H_{16}O_5$: C, 65.21; H, 5.84%.

Acetate: m. p. 116~117°C, yellow needles (from methanol).

λ_{max}^{MeOH} mμ (log ε); 230 (4.43), 270 (4.34), 410 (4.38).

Found: C, 64.26; H, 5.61. Calcd. for $C_{17}H_{18}O_6$: C, 64.14; H, 5.70%.

3-Acetyl-7-methyl-8-hydroxy-1-oxaazulan-2-one (XIIIa).—To a solution of ethyl sodioacetoacetate prepared by dissolving sodium (600 mg.) in a mixture of dioxane (10 ml.) and ethyl acetoacetate (5 ml.), X (1.07 g.) and copper acetate (50 mg.) were added; the mixture was then heated under refluxing for 20 hr. The reaction mixture was treated as described in the above experiment to give XIIIa (980 mg.) as yellow silky needles, m. p.

265°C (decomp.), after recrystallization from acetone.

λ_{max}^{MeOH} mμ (log ε); 225 (4.25), 295 (4.41), 362 (4.12).

Found: C, 66.19; H, 5.12. Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62%.

Acetate: m. p. 200~201°C, orange prisms (from methanol).

λ_{max}^{MeOH} mμ (log ε); 230 (4.37), 275 (4.25), 421 (4.30).

Found: C, 64.74; H, 4.56. Calcd. for $C_{14}H_{12}O_5$: C, 64.61; H, 4.65%.

3-Acetyl-6-isopropyl-8-hydroxy-1-oxaazulan-2-one (XIIIb).—To a solution of ethyl sodioacetoacetate prepared by dissolving sodium (3.0 g.) in a mixture of dioxane (40 ml.) and ethyl acetoacetate (22 ml.), XI (6.0 g.) and copper acetate (100 mg.) were added; the mixture was then heated under refluxing for 15 hr. The reaction mixture was treated as described in the above experiment to give XIIIb (5.60 g.) as yellow needles, m. p. 253°C (decomp.), after recrystallization from acetone.

λ_{max}^{MeOH} mμ (log ε); 230 (4.30), 293 (4.38), 367 (4.16).

Found: C, 68.31; H, 5.72. Calcd. for $C_{14}H_{14}O_4$: C, 68.20; H, 5.73%.

Acetate: m. p. 105~106°C, yellow needles (from methanol).

λ_{max}^{MeOH} mμ (log ε); 230 (4.43), 278 (4.33), 420 (4.39).

Found: C, 66.85; H, 5.39. Calcd. for $C_{16}H_{16}O_5$: C, 66.66; H, 5.59%.

5-Bromo-3-ethoxycarbonyl-7-methyl-8-hydroxy-1-oxaazulan-2-one (XV).—To a solution of diethyl sodiomalonate prepared from sodium (100 mg.), dioxane (4 ml.) and diethyl malonate (0.9 ml.), 5,7-dibromo-3-methyltropolone (XIV) (400 mg.) and copper acetate (50 mg.) were added; the mixture was then heated under refluxing for 20 hr. After the addition of water (5 ml.), the sodium salt thereby formed was collected, dissolved in hot water and acidified with 6 N hydrochloric acid to give XV (310 mg.) as yellow needles, m. p. 275°C (decomp.), after recrystallization from dioxane.

λ_{max}^{MeOH} mμ (log ε); 240 (4.36), 300 (4.49), 363 (4.14).

Found: C, 48.05; H, 3.54. Calcd. for $C_{13}H_{11}O_5Br$: C, 47.73; H, 3.39%.

The Debromination of XV.—When a solution of XV (160 mg.) and sodium acetate (100 mg.) in water (5 ml.), in the presence of palladium-carbon (10 mg.), was shaken with hydrogen, 13.3 ml. of hydrogen was absorbed during a 3.5 hr. period. The catalyst was then filtered off and the filtrate acidified with 6 N hydrochloric acid to give XIIa as yellow needles, m. p. 201°C (decomp.), after recrystallization from acetone.

3-Carboxymethyl-7-methyltropolone (XVIa).—*a) From XIIa.*—A mixture of XIIa (490 mg.) and concentrated hydrobromic acid (3 ml.) was heated at 130~140°C for 45 min. The reaction mixture was then diluted with water and adjusted to pH 3 with a potassium hydroxide solution, and the crystals thereby formed were collected and recrystallized from glacial acetic acid to give XVIa (360 mg.) as pale yellow needles, m. p. 177°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 242 (4.49), 320 (3.81), 355 (3.78), 370 (3.81).

Found: C, 61.97; H, 5.20. Calcd. for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%.

b) From XIIIa.—A mixture of XIIIa (320 mg.) and concentrated hydrobromic acid (3 ml.) was heated at 130~140°C for 2 hr.; the crystals thereby formed were collected by filtration to give dark green needles, m. p. over 300°C (110 mg.).

λ_{max}^{MeOH} mμ; 227, 312, 355, 450.

Found: C, 57.91; H, 3.76%.

The filtrate was adjusted to pH 3 with a potassium hydroxide solution, affording XVIa (160 mg.) as yellow needles, m. p. 177°C (decomp.), after recrystallization from glacial acetic acid.

3-Carboxymethyl-6-isopropyltropolone (XVIb).—*a) From XIIb.*—A mixture of XIIb (500 mg.) and concentrated hydrobromic acid (6 ml.) was heated at 130~140°C for 2 hr. After it had cooled, the mixture was poured into water (20 ml,) to give XVIb (360 mg.), m. p. 158°C (decomp.). Recrystallization from chloroform afforded colorless needles, m. p. 160°C (decomp.).

λ_{max}^{MeOH} mμ (log ε); 245 (4.47), 335 (3.84), 368 (3.81).

Found: C, 64.50; H, 6.23. Calcd. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

b) From XIIIb.—A mixture of XIIIb (500 mg.) and concentrated hydrobromic acid (6 ml.) was treated as in a), affording XVIb (340 mg.) as colorless needles, m. p. 160°C (decomp.), after recrystallization from chloroform.

3,7-Dimethyltropolone (XVIIa).—A mixture of XVIa (200 mg.) and pyridine (2 ml.) was heated under refluxing for 6 hr. After the addition of water (5 ml.), the mixture was acidified with 6 N hydrochloric acid and extracted with chloroform. The solvent was evaporated, the residue was sublimed at about 100°C under reduced pressure, and the sublimate was recrystallized from petroleum ether to give XVIIa (80 mg.) as colorless plates, m. p. 68~70°C, which was undepressed on admixture with an authentic specimen.[3]

λ_{max}^{MeOH} mμ (log ε); 243 (4.53), 320 (3.79), 355 (3.77), 370 (3.81).

6-Isopropyl-3-methyltropolone (XVIIb).—A mixture of XVIb (500 mg.) and pyridine (1 ml.) was heated under refluxing for 5 hr. After the addition of water (5 ml.), the mixture was acidified with 6 N hydrochloric acid and extracted with chloroform. The removal of the solvent left an oil, which was then distilled under reduced pressure to give XVIIb (330 mg.) as a pale yellow oil. The *p*-tolylazo derivative of this oil showed no depression of melting point on admixture with the known 5-(*p*-tolylazo)-6-isopropyl-3-methyltropolone.[3]

5-Bromo-3,7-dimethyltropolone (XVIII).—To a solution of XVIIa (30 mg.) in methanol (2 ml.), bromine (30 mg.) was added; the mixture was then stirred for 2 hr. Water was added, and the crystals thereby formed were recrystallized from methanol to give XVIII (40 mg.) as colorless plates, m. p. 136~137°C.

λ_{max}^{MeOH} mμ (log ε) ; 245 (4.48), 330 (3.97), 368 (3.64), 387 (3.64).

Found : C, 47.51 ; H, 4.14. Calcd. for $C_9H_9O_2Br$: C, 47.19 ; H, 3.96%.

7-Methyl-8-acetoxy-1-oxaazulan-2-one (XIXa).—A mixture of XVIa (120 mg.) and acetic anhydride (0.4 ml.) was heated at 140°C for 2 hr. Water was added, and the crystals thereby formed were recrystallized from methanol to give XIXa (120 mg.) as orange prisms, m. p. 127~128°C.

λ_{max}^{MeOH} mμ (log ε) ; 228 (4.31), 257 (4.35), 392 (4.22).

Found : C, 66.00 ; H, 5.08. Calcd. for $C_{12}H_{10}O_4$: C, 66.05 ; H, 4.62%.

6-Isopropyl-8-acetoxy-1-oxaazulan-2-one (XIXb).—A mixture of XVIb (1.00 g.) and acetic anhydride (2 ml.) was treated as described in the above experiment to give XIXb (880 mg.) as orange prisms, m. p. 101~102°C, after recrystallization from methanol.

λ_{max}^{MeHO} mμ (log ε) ; 228 (4.23), 255 (4.29), 373 (4.22), 388 (4.23).

Found : C, 68.47 ; H, 5.56. Calcd. for $C_{14}H_{14}O_4$: C, 68.27 ; H, 5.73%.

The author wishes to express his gratitude to Professor Tetsuo Nozoe for his kind and unfailing guidance throughout the course of this work. He is also indebted to Messrs. Masaru Ogata and Hiromoto Ishiyama for their technical cooperation, and to Miss Ayako Iwanaga for her elementary analyses.

*Syntheses of Peptides Related to the N-Terminal Structure of Corticotropin. III. The Synthesis of L-Histidyl-L-phenylalanyl-L-arginyl-L-tryptophan, the Smallest Peptide Exhibiting the Melanocyte-stimulating and the Lipolytic Activities**

By Hideo OTSUKA and Ken INOUYE

(Received April 13, 1964)

This investigation was undertaken to find out the minimum structure required for the two extra-adrenal activities of corticotropin as a melanocyte-stimulating hormone (MSH) and a lipolytic agent.

There have been reports on the relationship between these hormonal activities and the chemical structure. Hofmann and Yajima,[1] for instance, concluded from their synthetic studies that two things were essential for the MSH activity, the sequence His-Phe-Arg-Try-Gly (positions 6 to 10) in the corticotropin and in the α-MSH molecules and the presence of the histidine and the tryptophan residues at their respective positions. Pickering and Li[2] reached the same conclusion from their studies of synthetic peptides.

Concerning the activity as lipolytic or adipokinetic agents, Raben et al.[3] first reported that a peptide, H-Ser-Tyr-Ser-Met-Glu(NH_2)-His-Phe-Arg-OH, which corresponded to the γ-amide derivative of the *N*-terminal octapeptide sequence of the corticotropin and α-MSH molecules, was inactive, when it was lengthened at the carboxyl end to a decapeptide, H-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Try-Gly-OH, the activity was encountered. Tanaka, Pickering and Li[4] also reported that the smallest peptide which was active in rat adipose tissue was the *N*-terminal decapeptide, whereas a pentapeptide, H-His-Phe-Arg-Try-Gly-OH, was still active in the rabbit.

It has not yet been examined whether or not the glycine next to the tryptophan (position 9) is essential to these activities. Therefore, we synthesized a tetrapeptide, L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophan, and assayed it for MSH activity by the in vitro frog skin method.[5] It was found that the peptide exhibited the same level of potency

(3.6×10^4 units per gram) as pentapeptides, L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine[6,7] and its D-phenylalanine analog.[8] This may show that the glycine is not only not essential for the activity, but that it is not so stimulating, as is the case with a hexapeptide, H-Gly-His-Phe-Arg-Try-Gly-OH,[9] in which the *N*-terminal glycine shows a tenfold increase in potency as compared with the pentapeptide without the *N*-terminal glycine. The tetrapeptide was also active as a lipolytic agent at a dose of 1000 μg. in rabbit perirenal adipose tissue. This potency is comparable to that reported for the pentapeptide.[4] From this finding, it may be concluded that the glycine is not essential also for the lipolytic activity.

One of the difficulties in the synthesis of the tetrapeptide is that the tryptophan resides at the carboxyl end of the molecule. The saponification of the tryptophan ester was accompanied by the fission of the peptide bonds. We have failed also in an attempt to prepare the *t*-butyl ester of tryptophan which may be removed by a mild acid solvolysis. Therefore, it appeared most promising to employ the benzyl ester, which could be removed by means of catalytic or chemical reduction. In order to minimize the racemization which occurs during peptide synthesis, a step-by-step procedure, by which a peptide chain is extended from the carboxyl end, may be recommended. However, all the intermediate products that we have tried so far, namely, the various derivatives of N^G-tosyl(or nitro)-L-arginyl-L-tryptophan and L-phenylalanyl-N^G-tosyl(or nitro)-L-arginyl-L-tryptophan, failed to crystallize. Because of this disadvantage, it was very difficult to remove the impurities[10] which were produced during the repeated treatment of the tryptophan peptide in order to remove its amino-protecting group with such an acid reagent as hydrogen bromide-acetic acid or trifluoroacetic acid. Fortunately, we could obtain the hydrazide of *t*-butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginine in a crystalline state. As is well known, the azide coupling procedure is free from racemization.[11] Therefore, the procedure for the synthesis of the tetrapeptide was designed as follows:

The crystalline N^G-tosyl-L-arginine methyl ester (III, free base) was coupled with *t*-butyloxycarbonyl-L-phenylalanine by the *N*, *N'*-dicyclohexylcarbodiimide (DCCI) method.[12] The resultant protected dipeptide (VII) was converted into the crystalline hydrazide (IX). The coupling of the azide (derived from compound IX) with L-tryptophan benzyl ester gave the protected tripeptide, *t*-butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginyl-L-tryptophan benzyl ester (XI). The amino-protecting group of compound XI was removed by treatment with trifluoroacetic acid,[13] affording the tripeptide ester, L-phenylalanyl-N^G-tosyl-L-arginyl-L-tryptophan benzyl ester. This tripeptide ester was next condensed with N^α, N^{Im}-dicarbobenzoxy-L-histidine[14] by the DCCI procedure to obtain the protected tetrapeptide, N^α, N^{Im}-dicarbobenzoxy-L-histidyl-L-phenylalanyl-N^G-tosyl-L-arginyl-L-tryptophan benzyl ester (XII). Then, the reduction of compound XII in sodium in liquid ammonia was performed in order to remove all the protecting groups, namely, the two carbobenzoxy, one tosyl and one benzyl ester, groups. The resultant free tetrapeptide (XIII) was purified on a carboxymethyl cellulose column. The purified product was then submitted to paper chromatography in a solvent system consisting of *n*-butanol - acetic acid - water (4 : 1 : 2), and to electrophoresis on paper at pH 3.8, 6.6 and 11.1; these tests indicated that it behaves as a homogeneous substance. Moreover, the tetrapeptide obtained was found to be completely digestible by leucine aminopeptidase to give an amino acid composition in molar ratios which are consistent with the theoretical values.

The azide-coupling procedure has never before been employed when the nitroarginine residue has been included in the carboxyl moiety to be activated, because the nitroguanidino function may be decomposed by the action of hydrazine.[15] As is shown above, it is a valuable advantage that the N^G-tosyl-arginine is entirely free from this trouble. In the step of coupling Phe-Arg with Try for the preparation of compound XI, the DCCI method was also tried in place of the azide procedure, but the product had a low optical rotation ($[\alpha]_D^{25}$ $-4.4°$ (methanol)). This means that some racemization occurred in the arginine residue.

In connection with these studies, we have next achieved an improved synthesis of the tetrapeptide; this synthesis consists of the catalytic hydrogenation of a derivative with low solubility, N^{α}, N^{Im}-dicarbobenzoxy-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophan benzyl ester (m. p. 167~168°C decomp., $[\alpha]_D^{24.5}$ −12.3° (dimethylformamide)). This compound was obtained from crystalline N^{α}, N^{Im}-dicarbobenzoxy-L-histidine *p*-nitrophenyl ester (m. p. 112~113°C, $[\alpha]_D^{24.5}$ −15.0° (ethyl acetate))[16] and L-phenylalanyl-nitro-L-arginyl-L-tryptophan benzyl ester, which was synthesized in a step-by-step manner from the carboxyl end by the use of the *t*-butyloxycarbonyl group[19,20] as an amino-protecting element in conjugation with the DCCI procedure. This improved procedure for the synthesis of the protected tetrapeptide gave an over-all yield, based on L-tryptophan benzyl ester, of approximately 50%. The details of these experiments will be published elsewhere.

Experimental

All melting points are uncorrected.

N^{G}-Tosyl-L-arginine Monohydrate (I).—To 15 g. of crystalline N^{α}-carbobenzoxy-N^{G}-tosyl-L-arginine (m. p. 102~106°C),[21] 130 g. of 25% (w/w) hydrogen bromide in acetic acid was added; the mixture then stood at room temperature for 30 min., after which time the solvent was removed at 40~45°C in vacuo. The oily residue was dissolved in 60 ml. of water and shaken with 60 ml. of ethyl acetate. The aqueous layer was washed further with ethyl acetate, cooled in an ice-bath, and neutralized to pH 8.6~8.8 by the addition of 28% aqueous ammonia to separate colorless crystals. After refrigeration overnight, the crystals were collected, washed with cold water, and dried; yield, 10.33 g. (92.1%); m. p. 142~147°C. Recrystallization from water gave lustrous crystals; recovery 94%, m. p. 145~149°C, $[\alpha]_D^{23.5}$ −3.9±1° (*c* 2.435, methanol), $[\alpha]_D^{24}$ +18.1±0.8° (*c* 2.518, N HCl); lit.[21]: m. p. 146~150°C, $[\alpha]_D^{25}$ −5.5° (*c* 1.3, methanol).

Found: C, 45.36; H, 6.41; N, 16.46; S. 9.11; H_2O, 5.18. Calcd. for $C_{13}H_{20}O_4N_4S \cdot H_2O$: C, 45.07; H, 6.40; N, 16.17; S. 9.26; H_2O, 5.20%.

N^{α}-Carbobenzoxy-N^{G}-tosyl-L-arginine Methyl Ester (II).—To 50 ml. of anhydrous methanol which had previously been cooled below −10°C, 1.20 ml. (0.0165 mol.) of thionyl chloride and 6.93 g. (0.015 mol.) of N^{α}-carbobenzoxy-N^{G}-tosyl-L-arginine were added. The solution was stirred for 4 hr. and then let stand overnight at 0°C. After the removal of the solvent in vacuo the resulting sirup was dissolved in 50 ml. of ethyl acetate, washed with water, 5% sodium bicarbonate and with water, and dried over sodium sulfate. The evaporation of the solvent gave a foamy residue, which was then dried over phosphorus pentoxide in vacuo; yield, 6.59 g. (92.2%), colorless amorphous powder, $[\alpha]_D^{25.5}$ −8.7±0.4° (*c* 4.972, methanol). A single spot was visible in thin-layer chromatography on silica gel in ethyl acetate (R_f =0.43).

Found: C, 55.39; H, 6.36; N, 11.15; S, 6.28. Calcd. for $C_{22}H_{28}O_6N_4S$: C, 55.45; H, 5.92; N, 11.76; S. 6.73%.

N^{G}-Tosyl-L-arginine Methyl Ester (Free Base) (III).—Compound II (15.00 g.) was dissolved in 97 g. of 38% (w/w) hydrogen bromide in acetic acid, and the reaction mixture was allowed to stand at room temperature for 60 min. and evaporated in vacuo at 40~45°C. The residue was dissolved in 40 ml. of water and washed three times with 50 ml. portions of ethyl acetate to afford an aqueous solution of the ester hydrobromide, which gave a single ninhydrin reactive spot (R_f=0.63) on paper in the *n*-butanol-acetic acid-water (4:1:2) system.

To the aqueous solution of the hydrobromide obtained above, 60 ml. of methylene chloride was added, the mixture was then shaken with 30 ml. of ice-cold 50% (w/v) potassium carbonate at 0°C. The aqueous phase was extracted again with methylene chloride, and the combined extract was dried over anhydrous sodium sulfate and evaporated in vacuo at 30°C to afford a gummy residue, which crystallized upon being dissolved in a small volume of methylene chloride. After the addition of ether, the mixture was refrigerated overnight and the crystals were filtered off, washed with ether and dried; yield, 9.71 g. (94.6% based on compound II used); m.p. 97°C (soften over 93°C). Recrystallization from the same solvent gave a sample for analyses; m. p. 98.5°C (soften over 95°C), $[\alpha]_D^{25}$ +14.8±1° (*c* 2.424, methanol).

Found: C, 48.78; H, 6.48; N, 15.92; S, 9.66. Calcd. for $C_{14}H_{22}O_4N_4S$: C, 49.11; H, 6.48; N, 16.36; S, 9.36%.

***t*-Butyloxycarbonyl-L-phenylalanine Dicyclohexylamine Salt (VI).**—*By t-Butyl p-Nitrophenyl Carbonate.*[19]—The free acid was synthesized by almost the same procedure as that described by Anderson and McGregor.[19] The product was ultimately crystallized from ethyl acetate and a large volume of petroleum ether as colorless fine needles. Since the isolation of the crystals was rather troublesome, the product was isolated and estimated as dicyclohexylamine salt.[22]

To an ethereal solution of the sirupy product (4.72 g.), which was obtained from 3.30 g. (0.02 mol.) of L-phenylalanine and 7.18 g. (0.03 mol.) of *t*-butyl *p*-nitrophenyl carbonate, a solution of 3.23 g. (0.018 mol.) of dicyclohexylamine (DCHA) in ether was added at 0°C. The DCHA salt which

separated soon was filtered off, washed with ether, and dried; yield, 7.86 g. (88.0% based on L-phenylalanine used); m. p. 209~214°C decomp., $[\alpha]_D^{27}$ +29.2±2° (*c* 1.025, methanol).

Found: C, 70.13; H, 9.67; N, 6.36. Calcd. for $C_{26}H_{42}O_4N_2$: C, 69.92; H, 9.48; N, 6.27%.

By t-Butyl Azidoformate.[20]—The amorphous free acid, which was obtained by the method of Schwyzer et al.[23] from 8.3 g. (0.05 mol.) of L-phenylalanine and 14.3 g. (0.10 mol.) of *t*-butyl azidoformate,[24] was converted into the DCHA salt as described above; yield, 17.43 g. (78.2% based on L-phenylalanine used); m. p. 210~212°C decomp., $[\alpha]_D^{25.5}$ +28.9±0.5° (*c* 1.048, methanol).

Found: C, 71.09; H, 9.70; N, 6.37. Calcd. for $C_{26}H_{42}O_4N_2$: C, 69.92; H, 9.48; N, 6.27%.

L-Tryptophan Methyl Ester (V).—*L-Tryptophan Methyl Ester Acetate.*—A crude sample of L-tryptophan methyl ester hydrochloride[25] was converted into the acetate for purification. A mixture of the hydrochloride dissolved in a small volume of water and ether was shaken with 50% (w/v) potassium carbonate at 0°C. The ether phase was dried over sodium sulfate, to which an appropriate amount of glacial acetic acid was added to separate L-tryptophan methyl ester acetate as colorless thin needles; m. p. 106~108°C, $[\alpha]_D^{24.5}$ +15.3±1° (*c* 2.615, water).

Found: C, 60.50; H, 6.67; N, 10.09: Calcd. for $C_{12}H_{14}O_2N_2 \cdot CH_3COOH$: C, 60.42; H, 6.52; N, 10.07%.

Free Ester (V).—A suspension of 1.67 g. (6.0 mmol.) of the ester acetate obtained above in 20 ml. of methylene chloride was shaken with 5 ml. of ice-cold 50% (w/v) potassium carbonate in an ice-salt bath. The aqueous phase was then extracted again with methylene chloride. The combined organic extract was, after having been dried over sodium sulfate, evaporated at 25°C in vacuo to afford a sirupy residue, which crystallized easily from ether-petroleum ether; yield, 1.28 g. (97.8%); m. p. 90~91°C, $[\alpha]_D^{23.5}$ +36.3±1° (*c* 2.577, methanol).

Found: C, 66.12; H, 6.54; N, 12.92. Calcd. for $C_{12}H_{14}O_2N_2$: C, 66.04; H, 6.47; N, 12.84%.

L-Tryptophan Benzyl Ester (VI).—*L-Tryptophan Benzyl Ester p-Toluenesulfonate.*—A mixture of 20.42 g. (0.1 mol.) of L-tryptophan and 20.9 g. (0.11 mol.) of *p*-toluenesulfonic acid monohydrate in 150 ml. of benzyl alcohol was stirred at 90~100°C under a slow stream of nitrogen. After 6 hr. anhydrous ether (750 ml.) was introduced, and the precipitates (the salt of unesterified tryptophan) was filtered off (14.94 g.). From the filtrate the crystalline *p*-toluenesulfonate of the benzyl ester separated slowly in the form of needles; yield, 25.15 g.; m. p. 171~173°C.

Found: C, 64.59; H, 5.73; N, 6.22. Calcd. for $C_{25}H_{26}O_5N_2S$: C, 64.36; H, 5.62; N, 6.00%.

Free Ester (VI).—To 3.50 g. (7.5 mmol.) of the *p*-toluenesulfonate obtained above, 10 ml. of water and 30 ml. of ether were added. The mixture was then shaken with 10 ml. of 50% (w/v) potassium carbonate. The aqueous phase was extracted again with ether. The combined extract was dried over sodium sulfate and evaporated in vacuo to give a solid residue, which was then recrystallized from ether-petroleum ether; yield, 1.97 g. (89.4%); m. p. 71°C, $[\alpha]_D^{26.5}$ +12.8±1° (*c* 2.067, methanol); lit.[26] m. p. 71~72°C.

Found: C, 73.47; H, 6.22; N, 9.63. Calcd. for $C_{18}H_{18}O_2N_2$: C, 73.45; H, 6.16; N, 9.52%.

***t*-Butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginine Methyl Ester (VII).**—To a suspension of 3.125 g. (7.0 mmol.) of compound IV in 70 ml. of 50% ethanol, 7 ml. (wet volume) of Dowex-50W×8 (H^+-form) was added; the mixture was then shaken at room temperature for 30 min. After the removal of the resin, the filtrate was evaporated in vacuo at 40~45°C. The resulting sirup was dissolved in ether, and the solution was, after having been dried over anhydrous sodium sulfate, evaporated again to obtain *t*-butyloxycarbonyl-L-phenylalanine in an essentially quantitative yield.

The acyl amino acid obtained above was dissolved in methylene chloride; to the mixture 2.40 g. (7.0 mmol.) of compound V and a methylene chloride solution of 1.45 g. (7.0 mmol.) of *N*, *N'*-dicyclohexylcarbodiimide (DCCI) were then added at 0°. The reaction mixture (total volume 25 ml.) was let stand at 0°C overnight and then filtered to remove the separated urea (1.49 g., 95.2%). The filtrate was evaporated to afford a sirupy residue, which was redissolved in 40 ml. of ethyl acetate, washed successively with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate, water and finally with saturated sodium chloride, and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was dissolved in 7 to 8 ml. of acetonitrile, cooled at 0°C for 30 min., and then filtered to remove a slight amount of the urea. The evaporation of the solvent gave a foamy residue which was dried over phosphorous pentoxide; yield, 4.13 g. (100%); m. p. 93~98°C, $[\alpha]_D^{25}$ −5.9±0.5° (*c* 4.647, methanol). Thin-layer chromatography on silica gel in ethyl acetate gave a single spot reactive to ninhydrin when previously treated with concentrated hydrochloric acid.

Found: C, 56.78; H, 7.01; N, 11.82; S. 5.55. Calcd. for $C_{28}H_{39}O_7N_5S$: C, 57.03; H, 6.67; N, 11.88; S, 5.44%.

***t*-Butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginine (VIII).**—To a solution of 3.245 g. (5.5 mmol.) of compound VII in 16 ml. of methanol, 5.5 ml. of 2 N sodium hydroxide was added. The mixture was shaken at room temperature for 30 min. and then neutralized at 0°C by the addition of 11.0 ml. of ice-cold N hydrochloric acid and 20 ml. of water. The product thus precipitated was extracted three times with ethyl acetate. The combined organic phase was washed twice with

23) R. Schwyzer, P. Sieber and H. Kappeler, *Helv. Chim. Acta*, **42**, 2662 (1959).

24) *t*-Butyl carbazate, the key intermediate to the azide, was also easily obtained from *t*-butyl *p*-nitrophenyl carbonate[19] in a 90% yield.

25) R. A. Boissonnas, St. Guttmann, R. L. Huguenin, P.-A. Jaquenoud and Ed. Sandrin, *Helv. Chim. Acta*, **41**, 1867 (1958).

water and shaken with 15 ml. of M sodium bicarbonate and twice with water. The aqueous extracts were combined, washed three times with ethyl acetate, and then acidified at 0°C with ice-cold 4 N hydrochloric acid in the presence of 30 ml. of ethyl acetate. The aqueous phase was extracted twice with ethyl acetate. The combined ethyl acetate solution was washed once with ice-cold N hydrochloric acid and once with water until the washing became almost neutral; it was then dried over sodium sulfate and evaporated in vacuo at 30°C to afford a colorless, foamy residue which was dried over phosphorus pentoxide; yield, 3.05 g. (96.4%); m. p. 100~110°C, $[\alpha]_D^{24}$ +1.0±0.5° (*c* 4.226, methanol). A sample was treated with an-anhydrous trifluoroacetic acid at room temperature for 60 min. and then chromatographed on paper in the *n*-butanol - acetic acid - water (4 : 1 : 2) system to give a single ninhydrin reactive spot with R_f =0.80.

Found: C, 56.04; H, 6.78; N, 11.43; S. 5.81. Calcd. for $C_{27}H_{37}O_7N_5S$: C, 56.33; H, 6.48; N, 12.17; S, 5.57%.

***t*-Butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginine Hydrazide (IX).**—Compound VII (4.86 g., 8.25 mmol.) was dissolved in 48 ml. of anhydrous ethanol, and then 4.05 ml. of hydrazine hydrate was added at 0°C. The mixture was allowed to stand at 0°C for 3 days and then, after the addition of 50 ml. of water, concentrated to about 40 ml. in vacuo at 40°C. The sirupy precipitate was extracted three times with ethyl acetate, and the organic extracts were combined, washed twice, with water and with saturated sodium chloride, and dried over sodium sulfate. The crystalline hydrazide, which separated during the concentration of the ethyl acetate solution, was collected, washed twice with ice-cold ethyl acetate, and dried; yield, 4.58 g. (94.1%); m. p. 110~114°C. Recrystallization from methanol - ethyl acetate did not alter the melting point; $[\alpha]_D^{24}$ −6.3±1° (*c* 2.440, methanol).

Found: C, 55.22; H, 7.19; N, 16.61; S, 5.50. Calcd. for $C_{27}H_{39}O_6N_7S$: C, 54.99; H, 6.67; N, 16.63; S, 5.44%.

***t*-Butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginyl-L-tryptophan Methyl Ester (X).**—*A) By the Carbodiimide Method.*—Compound VIII (2.88 g., 5.0 mmol.) and 1.09 g. (5.0 mmol.) of L-tryptophan methyl ester (V) were dissolved in 15 ml. of acetonitrile; to this solution was added under ice-cooling 1.03 g. (5.0 mmol.) of DCCI dissolved in a small volume of acetonitrile. The reaction mixture was then allowed to stand at 0°C overnight. After the removal of the separated urea (1.04 g., 92.5%), the filtrate was evaporated in vacuo at 35°C. The resulting sirupy residue was dissolved in 30 ml. of ethyl acetate, and the solution was washed with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate, and water, and dried over anhydrous sodium sulfate. The evaporation of the solvent gave a foamy residue which was dried over phosphorus pentoxide in vacuo; yield, 3.68 g. (94.8%). The crude acyltripeptide ester (1.20 g.) obtained above was dissolved in 10 ml. of ethyl acetate, and the solution was passed through a column of dry silica gel (about 200 g.) with more ethyl acetate. The 3 ml.-fractions were collected, and those of tube Nos. 41—146, which contained the desired compound, were pooled and evaporated to dryness in vacuo to give an amorphous solid; wt. 0.86 g. (recovery 71.5%), m. p. 110~120°C, $[\alpha]_D^{25}$ −3.4±0.5° (*c* 4.546, methanol). Thin-layer chromatography on silica gel in ethyl acetate gave a single Ehrlich reactive spot. The single spot was also visible when the plate was heated after having been treated with sulfuric acid.

Found: C, 60.13; H, 6.66; N, 12.03; S, 4.33. Calcd. for $C_{39}H_{49}O_8N_7S$: C, 60.37; H, 6.37; N, 12.64; S, 4.13%.

B) By the Azide Method.—To a solution of 2.95 g. (5.0 mmol.) of compound IX in dimethylformamide (12 ml.), which had previously been cooled below −10°C, 25 ml. of ice-cold N hydrochloric acid and 2.75 ml. of ice-cold 2M sodium nitrite were added; the mixture was then stirred at −10°C for three min., after which time 20 ml. of ice-cold saturated sodium chloride was introduced. The separated azide was then extracted three times with 20 ml.-portions of cold ethyl acetate. The organic extract was washed with 20 ml. of ice-cold M sodium carbonate and 20 ml. of ice-cold saturated sodium chloride, and dried over anhydrous sodium sulfate. To this ethyl acetate solution 1.07 g. (4.85 mmol.) of L-tryptophan methyl ester (V) was then added, and the mixture was allowed to stand at 0°C. After 47 hr. the reaction mixture was washed with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate, water and, finally, saturated sodium chloride, and dried over sodium sulfate. The evaporation of the solvent gave a foamy residue which was dried over phosphorus pentoxide in vacuo; yield, 3.41 g. (90.8%). The crude product obtained above was purified on a silica gel column in almost the same way as has been described in A) to afford 2.80 g. (recovery 82.2%) of the pure tripeptide derivative, which was homogeneous in thin-layer chromatography; m. p. 110~120°C $[\alpha]_D^{26}$ −3.2±0.5° (*c* 4.417, methanol).

Found: C, 59.31; H, 6.60; N, 12.08; S, 4.10. Calcd. for $C_{39}H_{49}O_8N_7S$: C, 60.37; H, 6.37; N, 12.64; S, 4.13%.

***t*-Butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginyl-L-tryptophan Benzyl Ester (XI).**—*t*-Butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginine azide (prepared from 2.95 g. (5.0 mmol.) of the hydrazide (IX) as described above) and 1.47 g. (5.0 mmol.) of L-tryptophan benzyl ester (VI) were coupled in a ethyl acetate solution, almost as in case of the corresponding methyl ester (X), to give 3.24 g. (76.2%) of the crude peptide. A 3.14 g.-sample of the crude product was purified on silica gel (150 g.) as in the case of compound X; wt., 2.70 g. (recovery 86%), $[\alpha]_D^{24.5}$ −6.6±0.5° (*c* 4.095, methanol).

Found: C, 63.31; H, 6.42; N, 11.12; S, 3.68. Calcd. for $C_{45}H_{53}O_8N_7S$: C, 63.44; H, 6.27; N, 11.51; S, 3.76%.

The carbodiimide procedure was also employed in coupling compound VIII with L-tryptophan

benzyl ester (VI), as in the case of compound X, to obtain the same tripeptide derivative. The product was homogeneous in chromatography, but it had a low optical rotation; $[\alpha]_D^{25}$ $-4.4\pm0.6°$ (*c* 2.428, methanol).

N^{α}, N^{Im}-Dicarbobenzoxy-L-histidyl-L-phenylalanyl-N^{G}-tosyl-L-arginyl-L-tryptophan Benzyl Ester (XII).—Compound XI (2.45 g., 2.88 mmol.) was dissolved in 7.0 ml. of anhydrous trifluoroacetic acid at 0°C, and the solution was let stand at room temperature for 1 hr. under nitrogen. To this solution was then introduced about 100 ml. of anhydrous ether under ice-cooling. The resulting precipitates were collected, washed thoroughly with anhydrous ether, and dried to give 2.34 g. (94.0%) of L-phenylalanyl-N^{G}-tosyl-L-arginyl-L-tryptophan benzyl ester trifluoroacetate.

The ester trifluoroacetate (0.866 g., 1.0 mmol.), which had been dissolved in 15 ml. of ethyl acetate, was shaken with 10 ml. of ice-cold 50% (w/v) potassium carbonate at 0°C. The organic phase was then washed with saturated sodium chloride, dried over sodium sulfate, and evaporated in vacuo at 30°C under nitrogen to afford a foamy residue (0.86 g.) The free tripeptide ester thus obtained was then dissolved in 10 ml. of acetonitrile, along with 0.423 g. (1.0 mmol.) of N^{α}, N^{Im}-dicarbobenzoxy-L-histidine.[14] To this solution was added 0.206 g. (1.0 mmol.) of DCCI dissolved in a small volume of acetonitrile; the mixture was allowed to stand at 0°C for 20 hr. After the separated urea had been removed by filtration, the filtrate was evaporated in vacuo at 35°C. The sirupy residue was redissolved in ethyl acetate, washed with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate and water, and dried over sodium sulfate. The evaporation of the solvent gave an amorphous solid residue; yield, 1.15 g. (99.3%). The crude product (1.15 g.), which was dissolved in 10 ml. of ethyl acetate, was applied onto a column of silica gel (60 g.) which had been previously stabilized with ethyl acetate; it was then eluted with the same solvent. The fractions containing the desired compound were pooled and evaporated to afford an amorphous solid residue; wt. 0.81 g. (recovery 70%); m. p. 97~105°C, $[\alpha]_D^{24.5}$ $-10.9\pm1°$ (*c* 1.825, methanol). Thin-layer chromatography on silica gel in ethyl acetate gave a single spot, which was reactive to the Ehrlich but not to the Pauly reagent.

Found: C, 64.26; H, 5.85; N, 11.94; S, 2.97. Calcd. for $C_{62}H_{64}O_{11}N_{10}S$: C, 64.34; H, 5.57; N, 12.10; S, 2.77%.

L-Histidyl-L-phenylalanyl-L-arginyl-L-tryptophan Monoacetate Dihydrate (XIII).—The protected tetrapeptide XII (500 mg.) was dissolved in 170 ml. of liquid ammonia which had been distilled from sodium; small pieces of sodium were then added over an interval of 20~25 min. until a blue color persisted. After the addition of 0.18 ml. of acetic acid, most of the ammonia was allowed to evaporate spontaneously; the rest was removed in vacuo to dryness over an ice-bath. The residue was dissolved in 40 ml. of 0.1 N acetic acid, and the solution was filtered through a Celite pad to remove any insoluble precipitates. The filtrate was passed through an Amberlite CG-50 column (wet vol. 14 cc.) in order to desalt it.[27] The column was washed with 700 ml. of 0.25% acetic acid and 50 ml. of water, and the peptide was then eluted with a solution consisting of pyridine-acetic acid-water (30 : 4 : 66 by volume). The eluate was evaporated in vacuo at 45°C, and the residue was dissolved in about 10 ml. of 0.1 N acetic acid. The lyophilization of this solution gave the crude tetrapeptide; yield, 306 mg. (95.8%). The crude product (230 mg.) was dissolved in about 20 ml. of a 0.025 M ammonium acetate buffer (pH 6.45), and this solution was added to a column (1.33×43 cm.) of carboxymethyl cellulose (Serva, 0.6 meq./g.) which had been equilibrated with the same buffer. The column was then eluted successively with the following ammonium acetate buffers (pH 6.45): 0.025 M (250 ml.), 0.0375 M (700 ml.), 0.05 M (350 ml.), and 0.075 M (1050 ml.). Individual fractions (7.5 ml. each) were collected at a flow rate of approximately 2 ml. per min. Absorbancy measurements at 280 mμ revealed the presence of one major and at least four minor components in the chromatogram. The fractions corresponding to the major peak, which was eluted with the 0.075 M buffer at the end, were pooled, the bulk of water was removed in vacuo, and the rest was lyophilized repeatedly to a constant weight; wt., 122 mg. (50.8% based on the protected peptide). The purified sample behaved as a single ninhydrin, Pauly, Ehrlich and Sakaguchi reactive spot in paper chromatography in the *n*-butanol-acetic acid-water (4 : 1 : 2) system (R_f = 0.52~0.55), and in paper electrophoresis at pH 3.8, 6.6 and 11.1. λ_{max}^{HCl} 280.5 mμ (ε 5100), 288 mμ (ε 4250); $[\alpha]_D^{24.5}$ $-5.4\pm2°$ (*c* 0.947, N HCl). Amino acid ratios[28] in acid hydrolysate: His 1.00, Phe 1.00, Arg 1.03, (Try 0.79, decomposed partially with acid) (recovery 92.2%); amino acid ratios[28] in leucine aminopeptidase digest[29]: His 1.00, Phe 1.03, Arg 0.97, Try 0.98 (recovery 92.5%).

Found: C, 55.32; H, 6.71; N, 18.02. Calcd. for $C_{32}H_{40}O_5N_{10}\cdot CH_3COOH\cdot 2H_2O$: C, 55.12; H, 6.53; N, 18.91%.

Summary

1) A tetrapeptide, L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophan, corresponding to the amino-acid sequence of positions 6 to 9 in the corticotropin and α-MSH molecules has been synthesized.

2) This synthetic tetrapeptide has been found to exhibit an MSH potency of 3.6×10^4 units per gram in the in vitro frog skin assay, and it is also active on lipolysis in rabbit perirenal adipose tissue. These results may confirm that the glycine at position 10

29) LAP Lot No. 5930, Worthington Biochemical Corporation, Freehold, New Jersey, U. S. A.

in the molecules of corticotropin and α-MSH is not essential for these biological activities.

3) It has been shown that the azide-couling procedure can be employed successfully for the synthesis of arginyl peptides provided it is used in combination with the N^G-tosyl-arginine.

4) The preparation of N^G-tosyl-L-arginine and some of the relevant compounds has been described.

The authors wish to express their sincere thanks to Professor Choh Hao Li, Hormone Research Laboratory, University of California, for his courtesy in supplying a standard preparation of α-MSH. The authors are also indebted to Dr. Akira Tanaka for his assay of the lipolytic activity, Dr. Mitsuo Ebata for his amino acid analyses, Dr. Kaoru Kuriyama for his optical rotation measurements, Dr. Satoshi Mizukami for his elementary microanalyses, and Miss Yoshiko Jono and Mr. Makoto Kanayama for their able technical assistance.

Syntheses of Peptides Related to the N-Terminal Structure of Corticotropin. IV. The Synthesis of the Amino Acid Sequences, Lys-Pro-Val-Gly and Lys-Pro-Val-Gly-Lys

By Hideo OTSUKA, Ken INOUYE and Yoshiko JONO

(Received May 29, 1964)

In the course of our synthetic studies of corticotropin peptides, the tetra- and penta-peptide derivatives, which have amino acid sequences corresponding to positions 11 to 14 and 11 to 15 respectively of the corticotropin molecule, have been obtained. The ε-amino function of the lysine residues, which were incorporated in these peptides, was protected by the introduction of the *t*-butyloxycarbonyl group after the procedure described by Schwyzer and Rittel.[1] In the coupling steps throughout the synthesis, the *N*,*N'*-dicyclohexylcarbodiimide (DCCI) method[2] was used in combination with the carbobenzoxy-protecting group for α-amino functions. Both of these peptides were built up in a step-by-step procedure from their carboxyl terminals, and at the same time alternative routes of preparing the tripeptide intermediates were also tried. The details of these syntheses will be described in this paper. Synthetic procedures were summarized in Figs. 1 and 2.

The Synthesis of the Lys-Pro-Val-Gly-Lys Sequence.—N^{ε}-*t*-Butyloxycarbonyl-L-lysine[1] was converted as usual into N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysine, which was isolated in the form of the crystalline dicyclohexylamine salt (I). The free acid from compound I was then treated with diazomethane to prepare the diacyl-L-lysine methyl ester (II), which was obtained in a crystalline state (m. p. 62~63°C). The catalytic hydrogenation of compound II in methanol containing acetic acid gave crystalline N^{ε}-*t*-butyloxycarbonyl-L-lysine methyl ester acetate (III). The free ester derived from compound III was coupled with carbobenzoxyglycine to obtain carbobenzoxyglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine methyl ester (IV). Compound IV was hydrogenated, and the resultant dipeptide ester was condensed with carbobenzoxy-L-valine, thus affording carbobenzoxy-L-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine methyl ester (VII). The prolonged hydrogenation of compound IV yielded a large amount of a diketopiperazine like side product, even in the presence of excess acetic acid. The coupling of carbobenzoxy-L-proline with the hydrogenation product of compound VII gave a tetrapeptide derivative, carbobenzoxy-L-prolyl-L-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine methyl ester (VIII). The crystalline tetrapeptide ester (free base) (IX) was yielded by the catalytic hydrogenation of compound VIII. The hydrogenation was accelerated considerably by the addition of acetic acid; otherwise it proceeded very slowly. Compound VIII was then united with the free acid from compound I to obtain the crystalline

pentapeptide derivative, N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-L-prolyl-L-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine methyl ester (X), which could be converted into the corresponding crystalline hydrazide (XI).

The tripeptide intermediate, compound VII, was prepared also by the condensation of the free ester of compound III with carbobenzoxy-L-valylglycine (VI), which was derived from the preceding methyl ester (V) by saponification. Maclaren[3] has described how the saponification of carbobenzoxy-L-leucylglycine ethyl ester is accompanied by a side reaction, producing a cyclic compound with a hydantoin structure, when excess alkali is used. We have observed that the crystalline product, which was obtained by the saponification of compound V, had a little higher nitrogen content and a little lower carbon content than the theoretical values calculated for compound VI. This fact may suggest that the crude sample of compound VI was contaminated, even when an exactly equivalent amount of alkali was used on the saponification, by a small amount of such a side product as is shown below. The pure sample could, however, be isolated after recrystallization from ethanol-water in a moderately high yield.

The Synthesis of the Lys-Pro-Val-Gly Sequence. — Carbobenzoxy-L-valylglycine methyl

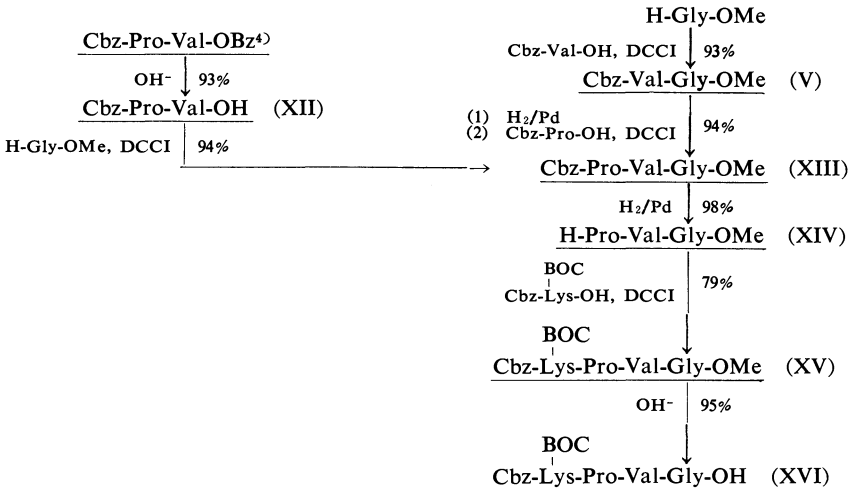

Fig. 2. Procedures for synthesis of the Lys-Pro-Val-Gly sequence. Cbz, carbobenzoxy; BOC, *t*-butyloxycarbonyl; Me, methyl; Bz, benzyl; DCCI, *N,N'*-dicyclohexycarbodiimide. Underline indicates that the compound was obtained in a crystalline form.

ester (V) was hydrogenated, and the resultant dipeptide ester was coupled with carbobenzoxy-L-proline to obtain a tripeptide intermediate, carbobenzoxy-L-prolyl-L-valylglycine methyl ester (XIII). This compound was also prepared through another procedure, consisting of the condensation of glycine methyl ester with carbobenzoxy-L-prolyl-L-valine (XII), which was derived from the crystalline benzyl ester[4] in a 90% yield by saponification. The corresponding methyl ester was, however, saponified to obtain compound XII in only a 50% yield.[5,6] This fact may indicate that the steric effect of the isopropyl side group in the valine methyl ester is more remarkable than that in the case of the benzyl ester.

The catalytic hydrogenation of compound XIII gave a crystalline tripeptide ester (XIV); this was next coupled with the free acid from compound I affording the crystalline tetrapeptide, N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-L-prolyl-L-valylglycine methyl ester (XV), from which the corresponding acid XVI was derived by saponification.

Experimental

All melting points are uncorrected. The catalytic hydrogenation was carried out in a closed vessel connected with another small one, filled with soda lime, in which the evolved carbon dioxide was to be absorbed.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysine Dicyclohexylamine Salt (I). — An 8.62 g.-sample (0.035 mol.) of N^{ε}-*t*-butyloxycarbonyl-L-lysine[1] (m. p. 226~227°C (decomp.), $[\alpha]_D^{25}$ +6.5±2° (*c* 1.085, 2 N ammonia)) and 6.0 g. of sodium bicarbonate were dissolved in 70 ml. of N sodium hydroxide and 30 ml. of water. The mixture was covered with 20 ml. of ether, and to this was added drop by drop 6.58 g. (0.0385 mol.) of benzyl chloroformate while it was being vigorously stirred at 0°C. The reaction mixture was stirred at 0°C for 30 min. and then at room temperature for 2 hr. After the ether phase had been removed, the aqueous solution was washed with ether and acidified to pH 2 at 0°C with ice-cold 4 N hydrochloric acid. The ensuing sirupy precipitates were taken up into cold ethyl acetate, and the organic solution was washed twice with water, dried over anhydrous sodium sulfate, and evaporated to dryness in vacuo. The resultant foamy residue was dissolved in ether, and the solution was mixed with an ethereal solution of 7.0 ml. (0.035 mol.) dicyclohexylamine (DCHA) and kept in a refrigerator overnight. The separated crystals were then collected, washed with ether, and dried; yield, 18.59 g. (94.8%); m. p. 148~149°C (sintering over 135°C). Recrystallization from methanol-ether gave 14.95 g. of colorless needles (recovery 80.5%); m. p. 153~155°C, $[\alpha]_D^{26}$ +5.5± 0.5° (*c* 4.564, methanol).

Found: C, 66.28; H, 9.43; N, 7.39. Calcd. for $C_{19}H_{28}O_6N_2 \cdot C_{12}H_{23}N$: C, 66.28; H, 9.15; N, 7.48%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysine Methyl Ester (II).—A suspension of 11.23 g. (0.02 mol.) of compound I in 160 ml. of 60% ethanol was shaken at room temperature for 30 min. in the presence of 20 ml. (wet volume) of Dowex-50W ×8 (H^+ form). After the resin had been removed by filtration, the filtrate was evaporated in vacuo at 40°C. The resultant oil was dissolved in ether and dried over anhydrous sodium sulfate. To this solution was added an ethereal solution of diazomethane at 0°C until the yellow color persisted; the mixture was then kept at 0°C for 10 min., after which time a few drops of acetic acid were

added to decompose the excess diazomethane. The solution was next washed successively with water, 5% sodium bicarbonate and water, dried over anhydrous sodium sulfate, and evaporated in vacuo, affording a dense oil which crystallized from ethyl acetate - petroleum ether; yield, 7.70 g. (97.7%); m. p. 60~61.5°C. Recrystallization from the same solvent system gave a sample for analyses; m. p. 62~63°C, $[\alpha]_D^{26}$ −9.3±1° (*c* 2.045, acetone). Lit. oil, $[\alpha]_D^{26}$ −10.6±0.5° (*c* 1.90, acetone);[1] m. p. 57°C, $[\alpha]_D$ not given.[7]

Found: C, 61.22; H, 7.59; N, 7.10. Calcd. for $C_{20}H_{30}O_6N_2$: C, 60.90; H, 7.67; N, 7.10%.

N^{ε}-*t*-Butyloxycarbonyl-L-lysine Methyl Ester Acetate (III).—Compound II (1.972 g., 5.0 mmol.), which was dissolved in 20 ml. of methanol and 0.5 ml. of acetic acid, was hydrogenated over a palladium black catalyst for 2 hr. After the catalyst had been filtered off, the solvent was removed in vacuo. The sirupy residue was dissolved in ether, and the solution was kept in a refrigerator overnight to afford the ester acetate in the form of needles; yield, 1.465 g. (91.4%); m. p. 78~79°C, $[\alpha]_D^{26}$ +17.0±1° (*c* 2.134, methanol).[8]

Found: C, 52.46; H, 8.86; N, 8.77. Calcd. for $C_{12}H_{24}O_4N_2 \cdot CH_3COOH$: C, 52.48; H, 8.81; N, 8.74%.

Carbobenzoxyglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine Methyl Ester (IV).—To a solution of 0.802 g. (2.5 mmol.) of compound III in 1 ml. of water were added 15 ml. of methylene chloride and 5 ml. of ice-cold 50% (w/v) potassium carbonate, and the mixture was shaken vigorously at 0°C. The aqueous phase was extracted again with cold methylene chloride. The organic extracts were pooled, dried over anhydrous sodium sulfate, and evaporated in vacuo at a both temperature of 25°C. The resultant oily residue was dissolved in methylene chloride together with 0.523 g. (2.5 mmol.) of carbobenzoxyglycine, and to this was added a methylene chloride solution of 0.517 g. (2.5 mmol.) of *N,N'*-dicyclohexylcarbodiimide (DCCI) at 0°C. The reaction mixture (total volume ca. 20 ml.) was then kept in a refrigerator overnight. After the separated *N,N'*-dicyclohexylurea had been removed by filtration (0.545 g., 97.2%), the filtrate was evaporated in vacuo. The sirupy residue was dissolved in ethyl acetate, and this solution was washed successively with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate and water, dried over anhydrous sodium sulfate, and evaporated in vacuo to give a sirup, which crystallized during storage in a refrigerator; yield, 1.013 g. (90.0%); m. p. 71~73°C. These crystals were recrystallized from ethyl acetate-petroleum ether, affording lustrous thin needles in a recovery of 92.5%, m. p. 74~75°C, $[\alpha]_D^{24.5}$ −8.04±0.5° (*c* 3.136, methanol).

Found: C, 58.58; H, 7.44; N, 9.60. Calcd. for $C_{22}H_{33}O_7N_3$: C, 58.52; H, 7.37; N, 9.31%.

Carbobenzoxy-L-valylglycine Methyl Ester (V).—Carbobenzoxy-L-valine (10.05 g., 0.04 mol.) and 3.56 g. (0.04 mol.) of freshly-distilled glycine methyl ester were coupled in the presence of 8.26 g. (0.04 mol.) of DCCI in a methylene chloride solution, almost as in case of compound IV. After the removal of the urea, the crystalline product was isolated from the filtrate during concentration; yield, 11.99 g. (93.2%); m. p. 159~161°C. Recrystallization from 40 ml. of chloroform and 160 ml. of ether gave 11.45 g. of needles (recovery 95.7%); m. p. 161~161.5°C, $[\alpha]_D^{23}$ −28.6±1° (*c* 2.205, methanol).

Found: C, 59.45; H, 6.83; N, 8.70. Calcd. for $C_{16}H_{22}O_5N_2$: C, 59.61; H, 6.88; N, 8.69%.

Carbobenzoxy-L-valylglycine (VI).—To a suspension of 3.224 g. (0.01 mol.) of compound V in 25 ml. of methanol was added 10.0 ml. of N sodium hydroxide; the mixture was then shaken at room temperature for 60 min. The resultant solution was diluted by the addition of 20 ml. of water and then acidified with N hydrochloric acid at 0°C. The precipitates were taken into ethyl acetate, and the organic solution was evaporated in vacuo affording a crystalline residue, which was redissolved in 40 ml. of ethyl acetate and extracted three times with 5% sodium bicarbonate. The aqueous extracts were combined and acidified again with 4 N hydrochloric acid at 0°C. The resultant precipitates were extracted with ethyl acetate and crystallized from ethyl acetate - ether; yield, 3.04 g. (98.5%); m. p. (130~132°C) 147~148°C, $[\alpha]_D^{24}$ −23.5±1° (*c* 2.032, methanol).

Found: C, 56.47; H, 6.36; N, 9.66. Calcd. for $C_{15}H_{20}O_5N_2$: C, 58.43; H, 6.54; N, 9.09%.

A 2.37 g.-sample of the crude product obtained above was recrystallized from ethanol-water (1 : 7) to give 2.03 g. of needles with a m. p. of 141~142°C. Recrystallization from the same solvent system gave a sample for analyses; m. p. 141~142°C, $[\alpha]_D^{25}$ −24.9±1° (*c* 2.474, methanol); lit.[9] m. p. 146°C, $[\alpha]_D^{22}$ −24.2±0.2° (*c* 5, methanol).

Found: C, 58.14; H, 6.52; N, 9.03. Calcd. for $C_{15}H_{20}O_5N_2$: C, 58.43; H, 6.54; N, 9.09%.

Carbobenzoxy-L-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine Methyl Ester (VII).—*A) By Val plus Gly-Lys.*—A 3.05 g.-sample (6.75 mmol.) of compound IV dissolved in 30 ml. of methanol and 1.5 ml. of acetic acid was hydrogenated over palladium for 2.25 hr. After the catalyst had been removed, the filtrate was evaporated in vacuo at 30°C. The ensuing oily residue was dissolved in 25 ml. of water, and the solution was washed twice with ethyl acetate and concentrated to about 10 ml. at 35~40°C in vacuo. To this concentrate was introduced 40 ml. of methylene chloride; the mixture was then shaken with 20 ml. of ice-cold 50% (w/v) potassium carbonate in an ice-bath. After the aqueous phase had been extracted twice more with cold methylene chloride, the organic extracts were combined, dried over anhydrous sodium sulfate, and evaporated in vacuo to give the dipeptide ester as a sirup in a quantitative yield.

The dipeptide ester obtained above and 1.70 g. (6.75 mmol.) of carbobenzoxy-L-valine were coupled, using 1.395 g. (6.75 mmol.) of DCCI in a methylene chloride solution in the same manner as has been

8) The value of $[\alpha]_D^{25}$ +19.0±1.0° (*c* 1.09, methanol) was given for the corresponding hydrochloride.[1]

9) W. Grassmann and E. Wünsch, *Chem. Ber.*, **91**, 449 (1958).

described above. After the separated urea had been filtered off, the solvent was removed in vacuo to give a crystalline solid mass, which was redissolved in 10 ml. of hot ethyl acetate; then, after the addition of 20 ml. of ether, the solution was kept in a refrigerator overnight. Crystalline precipitates were collected, washed with ether and dried; yield, 3.51 g. (94.5%); m. p. 128.5~129°C. Recrystallization from acetonitrile gave colorless needles with a m. p. of 130~131°C, $[\alpha]_D^{24.5}$ −12.2 ±1° (*c* 2.483, methanol).

Found: C, 59.22; H, 7.83; N, 10.17. Calcd. for $C_{27}H_{42}O_8N_4$: C, 58.89; H, 7.69; N, 10.18%.

B) By Val-Gly plus Lys.—Compound VI (0.772 g., 2.5 mmol.) and N^{ε}-*t*-butyloxycarbonyl-L-lysine methyl ester (prepared from 0.802 g. (2.5 mmol.) of compound III as described in case of compound IV) were coupled in the presence of 0.517 g. (2.5 mmol.) of DCCI in a methylene chloride solution. The reaction mixture was treated as described in A) to obtain the tripeptide; yield, 1.29 g. (93.7%), m. p. 130~131°C. These crystals were recrystallized from ethyl acetate-ether in a recovery of 94.8%, m. p. 131~132°C, $[\alpha]_D^{25.5}$ −12.1±0.5° (*c* 3.151, methanol).

Found: C, 59.16; H, 7.87; N, 10.19. Calcd. for $C_{27}H_{42}O_8N_4$: C, 58.89; H, 7.69; N, 10.18%.

Carbobenzoxy-L-prolyl-L-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine Methyl Ester (VIII).—Compound VII (6.61 g., 0.012 mol.) was dissolved in 60 ml. of methanol and hydrogenated over palladium black for 2.5 hr. After the catalyst had been removed, the filtrate was evaporated in vacuo at a bath temperature of 30°C to afford the tripeptide ester as a colorless foam. The tripeptide ester obtained above and 2.99 g. (0.012 mol.) of carbobenzoxy-L-proline were coupled by the use of 2.48 g. (0.012 mol.) of DCCI in methylene chloride in the same manner as above. After the urea had been removed (2.57 g., 95.5%), the evaporation of the solution gave a foamy residue, which crystallized from ethyl acetate-ether; yield, 7.31 g. (94.1%), m. p. 142~143°C. Recrystallization from ethyl acetate gave a sample for analyses, m. p. 143~144°C, $[\alpha]_D^{23}$ −50.6±1° (*c* 2.558, methanol).

Found: C, 59.47; H, 7.79; N, 10.64. Calcd. for $C_{32}H_{49}O_9N_5$: C, 59.33; H, 7.62; N, 10.81%.

L-Prolyl-L-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine Methyl Ester (IX).—Compound VIII (0.972 g.), which was dissolved in 15 ml. of methanol containing 0.5 ml. of acetic acid, was hydrogenated in the presence of a palladium black catalyst for 2 hr. The catalyst was removed by filtration, and the filtrate was evaporated in vacuo to give a colorless and clear oil. The oily residue was dissolved in 5 ml. of water, and the aqueous solution was, after being washed with ethyl acetate, mixed with 10 ml. of methylene chloride. The mixture was then shaken vigorously with 5 ml. of 50% (w/v) potassium carbonate at 0°C and the aqueous phase was extracted again with methylene chloride. The organic extracts were combined, dried over anhydrous sodium sulfate, and evaporated in vacuo to give a crystalline solid mass, which was washed with ether and dried; yield, 0.700 g. (90.9%), m. p. 98~102°C. Recrystallization from methanol-ether gave needles with a m. p. of 104~106°C, $[\alpha]_D^{24.5}$ −34.4±1.5° (*c* 1.762, methanol).

Found: C, 56.13; H, 8.49; N, 13.71. Calcd. for $C_{24}H_{43}O_7N_5$: C, 56.12; H, 8.44; N, 13.64%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-L-prolyl-L-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine Methyl Ester (X).—N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysine (prepared from 0.528 g. (0.94 mmol.) of the DCHA salt (I) as described in the preparation of compound II) and 0.483 g. (0.94 mmol.) of the crystalline tetrapeptide ester (IX) were condensed by the use of 0.194 g. (0.94 mmol.) of DCCI in methylene chloride in the same manner as has been described above. After the urea (0.190 g., 90.4%) had been removed, the methylene chloride solution was washed successively with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate and finally with water, dried over anhydrous sodium sulfate, and concentrated in vacuo. Gelatinous precipitates separated upon the addition of ether; yield, 0.728 g. (88.5%), m. p. 98~103°C. The amorphous solid crystallized in needles with a 90.0% recovery during the slow evaporation of the acetone solution in a cold room; m. p. 105~107°C, $[\alpha]_D^{25}$ −55.2±1° (*c* 2.126, methanol).

Found: C, 58.92; H, 7.98; N, 11.14. Calcd. for $C_{43}H_{69}O_{12}N_7$: C, 58.95; H, 7.94; N, 11.19%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-L-prolyl-L-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-L-lysine Hydrazide (XI).—A mixture of 0.876 g. (1.0 mmol.) of compound X and 0.5 ml. of hydrazine hydrate in 10 ml. of methanol was heated under reflux at a bath temperature of 90~95°C. The crystalline hydrazide started to separate in about one hour. After 2 hr. the bath was removed; the reaction mixture was allowed to stand at room temperature overnight and then refrigerated. The crystals were filtered off, washed with ice-cold methanol-ether (1 : 2) and with ether, and dried to give 0.615 g.; m. p. 194~195°C. The concentration of the mother liquor afforded an additional quantity of crystals; 0.084 g., m. p. 190~191.5°C. The total yield amounted to 0.699 g. (79.9%). The recrystallization of these crystals from methanol gave fine needles with a m. p. of 194~195°C in a recovery of 92.5%; $[\alpha]_D^{24.5}$ −31.3±1° (*c* 1.949, dimethylformamide).

Found: C, 57.58; H, 7.87; N, 14.28. Calcd. for $C_{42}H_{69}O_{11}N_9$: C, 57.58; H, 7.94; N, 14.39%.

Carbobenzoxy-L-prolyl-L-valine (XII).—To a solution of 8.77 g. (0.02 mol.) of carbobenzoxy-L-prolyl-L-valine benzyl ester (m. p. 91~92°C), which had been prepared as described previously,[4] in 50 ml. of methanol, 20 ml. of 2 N sodium hydroxide was added, and the mixture was shaken at room temperature for 60 min. The resultant solution was neutralized at 0°C with 40 ml. of ice-cold N hydrochloric acid, concentrated to about 50 ml. at 35°C in vacuo, and extracted three times with ethyl acetate. The organic extracts were combined and then shaken three times with M sodium bicarbonate. The pooled aqueous solution was, after being washed twice with ethyl acetate, acidified with 4 N hydrochloric acid. The oily precipitate was then taken into ethyl acetate. The ethyl acetate extracts were combined, washed twice with water, dried over anhydrous sodium sulfate, and evaporated at 35°C in

vacuo to afford a crystalline mass, which was dissolved in hot ethyl acetate and precipitated by the addition of petroleum ether; yield, 6.48 g. (93.0%), m. p. 136~137°C. A sample for analyses was obtained by recrystallization from ethyl acetate - ether (2 : 5) in the form of needles; m. p. 136.5~137.5°C, $[\alpha]_D^{22.5}$ $-56.1\pm1°$ (*c* 2.140, methanol.). Lit. m. p. 134~135°C, $[\alpha]_D^{18}$ $-58°$ (*c* 2.8, methanol);[5] m. p. 136°C, $[\alpha]_D^{25}$ $-57.8°$ (*c* 1.2, methanol).[6]

Found: C, 62.34; H, 7.15; N, 7.95. Calcd. for $C_{18}H_{24}O_5N_2$: C, 62.05; H, 6.94; N, 8.04%.

Carbobenzoxy-L-prolyl-L-valylglycine Methyl Ester (XIII). — *A) By Pro plus Val-Gly.* — Carbobenzoxy-L-valylglycine methyl ester (V) (3.22 g., 0.01 mol.), which was suspended in 30 ml. of methanol containing 2 ml. of 20% hydrogen chloride in methanol, was hydrogenated in the presence of palladium black for 2.5 hr. After the catalyst had been removed, the filtrate was evaporated in vacuo at 30°C. The resultant foamy residue was dissolved in 10 ml. of water, and the solution was washed twice with ethyl acetate. To this aqueous solution was added 20 ml. of methylene chloride and solid sodium chloride to the point of saturation. The mixture was then shaken with 10 ml. of ice-cold 50% (w/v) potassium carbonate at 0°C. The aqueous phase was then extracted twice more with cold methylene chloride. The organic extracts were combined, dried over anhydrous sodium sulfate, and evaporated at 25°C in vacuo to give the dipeptide ester as an oil. The obtained dipeptide ester and 2.49 g. (0.01 mol.) of carbobenzoxy-L-proline were coupled using 2.06 g. (0.01 mol.) of DCCI in a methylene chloride solution in the same manner as has been described above. After the removal of the separated urea, the filtrate was washed successively with N hydrochloric acid, water, 5% sodium bicarbonate and water, dried over anhydrous sodium sulfate, and evaporated in vacuo to give a foamy residue which crystallized from acetone-ether; yield, 3.92 g. (93.6%), m. p. 131~132°C (sintering over 127°C). The recrystallization from the same solvent system gave a sample for analyses; m. p. 131~132°C, $[\alpha]_D^{23.5}$ $-91.6\pm1°$ (*c* 2.130, methanol).

Found: C, 60.13; H, 6.89; N, 10.13. Calcd. for $C_{21}H_{29}O_6N_3$: C, 60.13; H, 6.97; N, 10.02%.

B) By Pro-Val plus Gly.—Compound XII (6.10 g., 0.0175 mol.) and 1.56 g. (0.0175 mol.) of freshly-distilled glycine methyl ester were coupled in the presence of 3.62 g. (0.0175 mol.) of DCCI in methylene chloride as above. The reaction mixture was then treated in the manner described in A) to obtain the tripeptide; yield, 6.85 g. (93.5%); m. p. 132~133°C. Recrystallization from acetone-ether did not alter the m. p.; $[\alpha]_D^{25}$ $-91.0\pm1°$ (*c* 2.158, methanol). Lit. m. p. 111~112°C, $[\alpha]_D^{25}$ $-90.4°$ (*c* 1.6, methanol);[10] amorph., m. p. 125~127°C, $[\alpha]_D^{24}$ $-89.7°$ (*c* 1.05, methanol).[11]

Found: C, 60.23; H, 7.03; N, 10.36. Calcd. for $C_{21}H_{29}O_6N_3$: C, 60.13; H, 6.97; N, 10.02%.

L-Prolyl-L-valylglycine Methyl Ester (XIV). — Compound XIII (5.25 g., 0.0125 mol.) was dissolved in 80 ml. of methanol and then hydrogenated over a palladium black catalyst for 1.5 hr. After the catalyst had been removed, the solvent was evaporated at 30°C in vacuo. The crystalline solid residue was recrystallized from methanol - ether - petroleum ether to give fine needles; yield, 3.475 g. (97.6%), m. p. 150°C, $[\alpha]_D^{25}$ $-76.8\pm1°$ (*c* 1.987, methanol); lit.[10] m. p. 140~142°C, $[\alpha]_D$ not given.

Found: C, 54.86; H, 8.17; N, 14.69. Calcd. for $C_{13}H_{23}O_4N_3$: C, 54.72; H, 8.12; N, 14.73%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-L-prolyl-L-valylglycine Methyl Ester (XV).—Compound XIV (2.85 g., 0.01 mol.) and N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysine (derived from 5.62 g. (0.01 mol.) of the DCHA salt (I)) were united by the use of 2.06 g. (0.01 mol.) of DCCI in a methylene chloride solution in the same manner as has been described above. The urea was then filtered off (1.99 g., 89.0%), and the filtrate was evaporated in vacuo to afford a foamy residue. The residue was dissolved in ethyl acetate, and the solution was washed successively with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate and water, and dried over anhydrous sodium sulfate. Gelatinous precipitates (5.70 g., 88.1%), which separated during the concentration of the ethyl acetate solution, crystallized from acetone in needles; yield, 5.13 g. (79.2%); m. p. 125~127°C. Recrystallization from acetone afforded thin lustrous needles as a sample for analyses; m. p. 128~129°C, $[\alpha]_D^{24.5}$ $-80.4\pm1°$ (*c* 2.035, methanol).

Found: C, 59.65; H, 7.70; N, 10.70. Calcd. for $C_{32}H_{49}O_9N_5$: C, 59.33; H, 7.62; N, 10.81%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-L-prolyl-L-valylglycine (XVI). — To a solution of 3.24 g. (0.005 mol.) of compound XV in 12 ml. of methanol, 5.0 ml. of 2 N sodium hydroxide was added at 0°C; the mixture was then shaken at room temperature for 60 min., after which time the solution was cooled in an ice-bath, diluted with 25 ml. of water, and then neutralized with 10.0 ml. of N hydrochloric acid. The resultant sirupy precipitates were taken into ethyl acetate and the organic solution was evaporated in vacuo to remove the methanol. The residue, which was dissolved again in ethyl acetate, was washed with cold water containing a few drops of N hydrochloric acid and with saturated sodium chloride, dried over anhydrous sodium sulfate, and concentrated in vacuo. The addition of twice as much ether gave gelatinous precipitates slowly. These precipitates were washed with ether and dried; yield, 2.87 g. (95.3%), m. p. 107~117°C, $[\alpha]_D^{24.5}$ $-79.6\pm1°$ (*c* 2.593, methanol); lit.[7] m. p. 116~118°C, $[\alpha]_D^{20}$ $-81.4\pm2°$ (*c* 1, methanol).

Found: C, 58.34; H, 7.55; N, 11.02. Calcd. for $C_{31}H_{47}O_9N_5$: C, 58.75; H, 7.48; N, 11.05%.

Summary

The amino acid sequence Lys-Pro-Val-Gly-Lys, which corresponds to positions 11 to 15 of the corticotropin molecule, has been synthesized in the form of a crystalline derivative,

The Behavior of Silicon, Aluminum, Iron, Magnesium, Calcium, Sodium and Potassium in Fumarolic Gas at the Mihara Volcano, Japan

By Hiroshi KAMIYA

(Received April 13, 1964)

The studies by Day and Shepherd[1,2] of gases evolved from the lava lake at Kilauea and by Allen and Zies[3,4] from the fumaroles at Valley of Ten Thousand Smokes are well known among the many investigations of volcanic gases. Recently Ellis[5] and Matsuo[6-8] also discussed the chemical equilibria in highly volatile components.

Krauskopf[9] has reviewed the possibility of vapor transport in the course of ore deposition. Observation of materials deposited in fumaroles shows that low volatile elements have been deposited directly from gases. In volcanic gases, water is the most abundant component, although the water content is variable. Morey[10,11] believes that water vapor would be able to dissolve and transport many elements of a low volatility at a high temperature and a high pressure. In some cases the vapor transport of relatively low volatile components, either as dissolved or gaseous compounds, is considered to account for the compositional differences in minerals and rocks of volcanic origin.[12,13]

According to White,[14] the vapor transport plays an important part in feeding various kinds of chemical species into hot spring water which has brought a great amount of the elements to the earth's surface. It is evident that water in either a gas or a liquid state would be an efficient transporting agent of many elements.

The principal purpose of this paper is to investigate the behavior of low volatile components in fumarolic gas at relatively high temperatures.

A Description of the Mihara Volcano

The Mihara Volcano on Izu-Oshima Island, situated 120 km. south of Tokyo, is one of the most active volcanoes in Japan. Geological, mineralogical and chemical studies on Mt. Mihara have been made in detail by Tsuboi,[15] Iwasaki,[16] Tsuya,[17] Kuno[18] and many other investigators.[19-21]

Since the eruption in 1957, however, the volcano has been dormant; recently only a small amount of ashes is sometimes ejected from the crater. There are many fumaroles along the cracks on the scoria cone in the southwestern part of the crater. The highest

temperature of the fumaroles was over 400°C in 1959. The temperature of these fumaroles, however, gradually decreased, until in 1961 the highest fell to 350°C.

Unlike the fumarolic gases in many other volcanoes, the gases at this volcano are admixture, with a great amount of air.[22] Excluding the air, the major constituents of the gas are carbon dioxide, hydrogen halides and sulfur compounds, water being extremely dominant. The fact that sulfur dioxide and free sulfuric acid, but no hydrogen sulfide, are detected in those fumarolic gases would account for a lack of free sulfur deposits at the orifice of the fumaroles. Deposits from gases and such decomposition products of ash and scoria as anhydrite, opal and clay minerals have been found at the orifices.[23-25] A map of the crater is shown in Fig. 1.

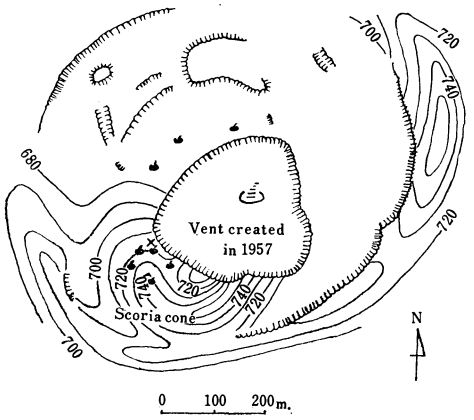

Fig. 1. Crater of Mihara Volcano.

Numerals in map represent meter above the sea-level.
× Position where condensed water was collected.
(≡) Fumarole
This was published by Oshima observatory of the Japan Meteorological Agency, on 20th in June, 1961.

Experimental

The Sampling of Condensed Water.—One end of a hard glass tube 2.5 cm. in diameter, bent at a right angle, was inserted into a fumarole, and the other end was connected with a 5 m. glass tube to which a 5 m. polyvinyl-chloride tube was attached. A 1 l. polyethylene bottle was fitted with the end of the polyvinyl-chloride tube in order to collect any water condensed by air cooling (Fig. 2). By this means, the elements transported in gases for the most part come to dissolve in the condensed water.

From one of the many fumaroles, thirty-eight samples of condensed water were collected during the period from April to September, 1959, and fifty samples, from May to July, 1961.

The orifice temperature of the fumarole was measured by an alomel-chromel thermocouple and an electric-resistance thermometer with an attached recorder.

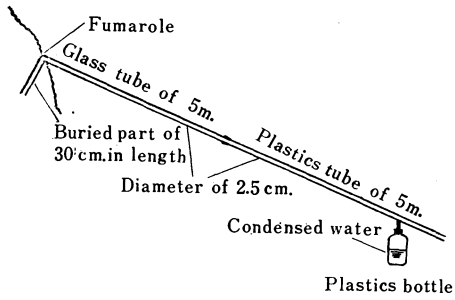

Fig. 2. Equipment for collecting condensed water from a fumarole.

The Analytical Method.—The condensed water was analyzed for acidity and for sulfate, chloride, silicon, aluminum, iron, calcium, magnesium, sodium and potassium.

1) Acidity.—The determination of acidity was carried out by titration with a sodium hydroxide solution using methyl orange as an indicator.

2) SO_4^{2-}.*—The sulfate was measured by means of the barium sulfate turbidity developed with a barium chloride gelatin solution.

3) Cl^-.—The chloride was determined by Mohr's method.

4) Silicon.—The silicon was determined colorimetrically by a molybdenum blue method.**

5) Aluminum.—The determination of aluminum was made by measuring the optical density of the red color of the complex formed with aluminon after extraction of iron with cupferron into chloroform.

6) Iron.—The determination of iron was carried out by reducing with hydroxylamine all the iron to a ferrous state, and then by making a colorimetric measurement of the absorbance of the red color developed with α,α'-bipyridyl or *o*-phenanthroline.

7) Calcium and Magnesium.—The sum of calcium and magnesium was determined by titrating them with an EDTA solution in the presence of Eriochrome Black T at pH 10. The calcium was independently determined by titration with an EDTA solution in strong alkaline media using Dotite NN as an indicator. The amount of magnesium was

* In the condensed water samples which were transferred to the laboratory, neither sulfur dioxide nor hydrogen sulfide was detected.
** By this method only the dissolved or less coagulated silica can be determined. However, no difference was found between the results of the above direct determination and those of the total silica determination.

calculated by subtracting the amount of calcium from the sum.

8) Sodium and Potassium. — The sodium and potassium were determined by means of flame photometry.

Results and Discussion

The Variation in the Concentration of the Components in Condensed Water. — Figure 3 shows the variations in the orifice temperature of the fumarole, the acidity of the condensed waters and the concentrations of the nine components (i.e., sulfate, chloride, silicon, aluminum, iron, calcium, magnesium, sodium and potassium), in the period from April to September, 1959, and from May to July, 1961.

In 1959 the measurement of the orifice temperature was discontinued because the thermometer was damaged. However, the continued gradual decrease in the temperature was assured by interpolation.

As may be seen in Fig. 3, the concentrations of the components in the condensed waters changed markedly, even in a short

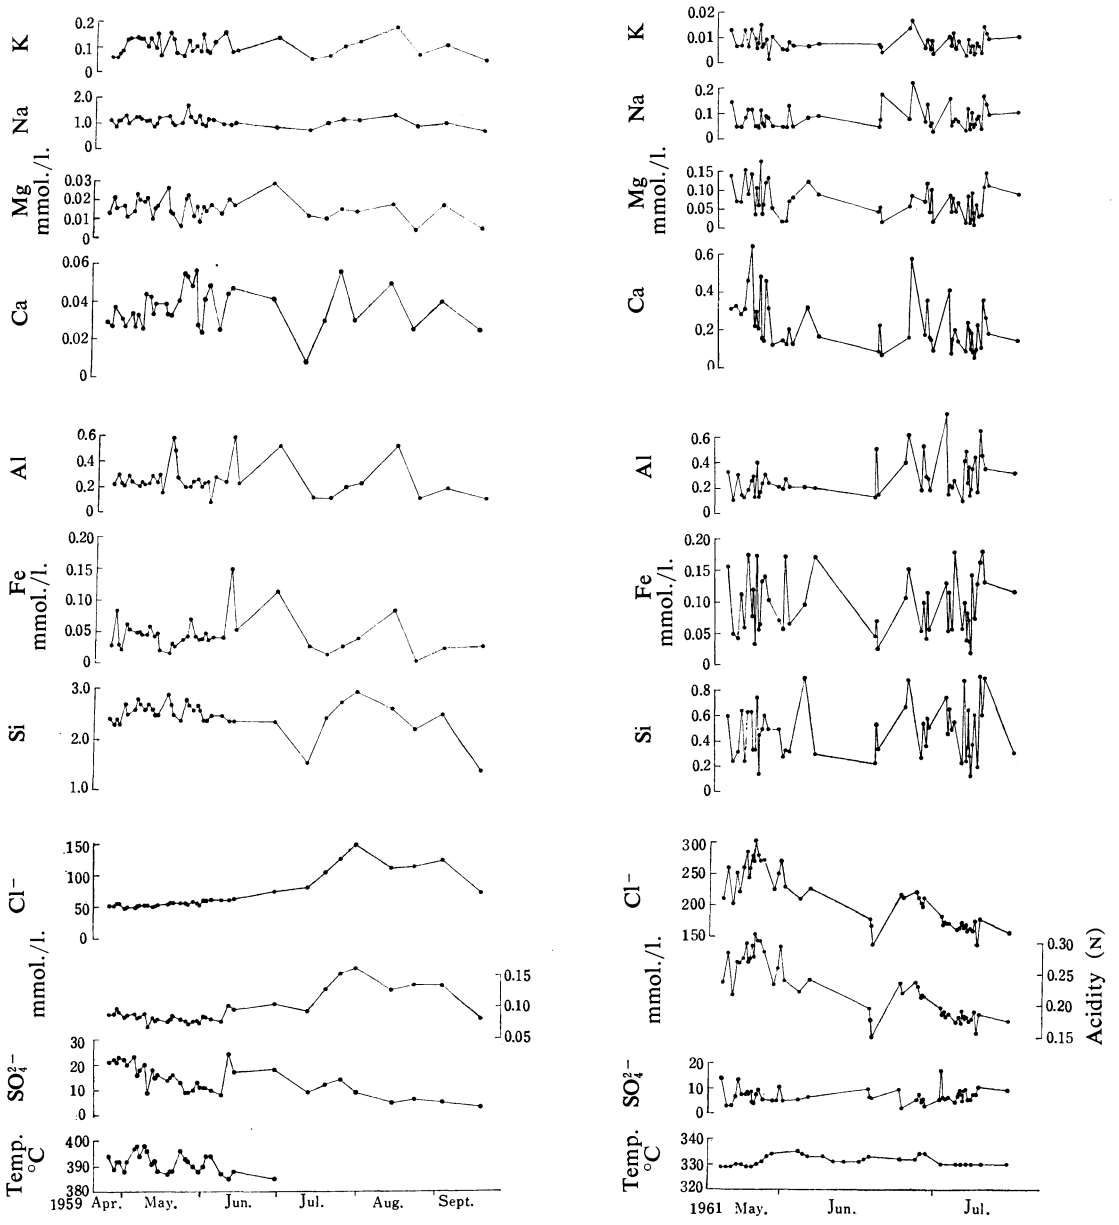

Fig. 3. Variation of orifice temperature of fumarole, acidity of condensed water and concentrations of components in condensed water in 1959 and 1961.

TABLE I. AVERAGE CONCENTRATION, ITS STANDARD DEVIATION AND VARIATION COEFFICIENT OF NINE COMPONENTS IN CONDENSED WATER, AND RATIO OF AVERAGE CONCENTRATION IN 1961 TO THAT IN 1959

	In 1959			In 1961			
	Average concn. mmol./l.	Standard deviation	Std. Dev. / Av. Concn. (ratio)	Average concn. mmol./l.	Standard deviation	Std. Dev. / Av. Concn. (ratio)	Av. Concn. ('61) / Av. Concn. ('59) (ratio)
Si	2.5	0.29	0.12	0.47	0.21	0.45	0.19
Al	0.27	0.12	0.46	0.28	0.15	0.53	1.0

interval. Mizutani and Matsuo[26] have observed similar variations in calcium and magnesium concentrations in condensed waters drawn from a fumarole at the Showa-shinzan Volcano.

On the basis of thermodynamic calculations, Ellis[5] and Matsuo[6-8] have shown that the chemical composition of volcanic gases should change in accordance with the temperature, the pressure and the type of magma. Some volcanologists even anticipate that eruptions can be predicted by measuring such a compositional change of gases.[26-29]

Table I gives the average concentrations, the standard deviations of the concentrations and the ratios of the standard deviations to the average concentrations denoting the variation coefficient, in both 1959 and 1961.

As given by the variation coefficients in Table I, the low volatile components differ considerably in their modes of variation in 1959; for example, the variation of silicon is the smallest, and that of iron the largest. In 1961, however, no marked differences exist among variation coefficients, which are generally larger than those in 1959. As for the highly volatile components, the variation of sulfate was much the same in both 1959 and 1961, while that of chloride in 1961 was much smaller than in 1959.

A Comparison between the Average Concentrations in 1959 and 1961.—The ratios of the average concentrations in 1961 to those in 1959 are shown in the final column of Table I.

The decrease in the orifice temperature, 390°C in 1959 to 330°C in 1961, resulted in the threefold increase in the chloride concentration; on the other hand, it also reduced the sulfate concentration by half.

The titrated acidity almost corresponds to the total gram-equivalent of the determined chloride and sulfate ions, as may be seen in Fig. 4. This means that chloride and sulfate ions are present in condensed water for the most part as free acid; in other words, the condensed water is practically a mixture of hydrochloric and sulfuric acids because of the small contribution of cations other than hydrogen ions (Table I).

The much stronger acidity in 1961 than in 1959 may be attributed to the increase in chloride (Fig. 4).

As for the low volatile components, in 1961 the average concentrations of sodium, potassium and silicon became lower; on the other hand, those of calcium, magnesium and iron became higher, while that of aluminum remained constant, as compared with those in 1959. This cannot be explained as a results of a simple vaporization of such a compound as metal chloride with a relatively high vapor pressure. As has been pointed out by Krauskopf,[9] coexistent water vapor and sulfur compounds should also be taken into consideration.

It will be evident that the amount of heat supplied by gas determines the orifice temperature of a fumarole.[30] Unfortunately, since neither the flow rate of the fumarolic gas nor the condensation rate of the water vapor was measured, it is uncertain whether the decrease

• Sample in 1959 ○ Sample in 1961

in the orifice temperature can be attributed to the decrease in the gas temperature itself or to the decrease in the flow rate.

Assuming that the water vapor content in the fumarolic gas changes according to the environmental conditions, it seems likely that the variation in the ratio of the content of a certain component to that of water vapor in gas, i. e., the variation in the concentration of a chemical component in condensed water, differs by chance. Therefore, a simple comparison of two average concentrations of a component for the two periods (1959 and 1961) would not decisively indicate the increase or decrease in the content of a chemical component in gas.

The Transport of the Low Volatile Components in the Fumarolic Gas.—While the gas is ascending from magma to the earth's surface through conduits with a decreasing temperature and a decreasing pressure gradient, the low volatile components in the gas might be partly deposited and so removed from the gas in the course of its ascending. The chemical composition of the condensed water should, therefore, be considered to be the result of various reactions during the ascending process.

Table II gives the mole percentages of the seven components, i. e., silicon, aluminum, iron, magnesium, calcium, sodium and potassium, in the lava of this volcano[19] and in the condensed water, and the ratio of the mole percentage of each component in the condensed water to that in the lava. The ratio may be considered to be a measure of the ease with which a chemical component is transported in gas. The ratio for the seven components may be concluded to be in the following order:

Na>K>Si>Al>Fe and Ca>Mg in 1959

and

Na>Ca>K>Al>Mg, Si and Fe in 1961.

Sodium was the most mobile component in both 1959 and 1961. Silicon was relatively mobile in 1959, but it turned out to be one of the least mobile components in 1961. On the contrary, calcium was one of the least mobile components in 1959, but the most mobile one after sodium in 1961.

The great mobility of sodium, potassium and silicon in 1959 corresponds to the conclusions by Kennedy,[31,32] Moery[10] and White.[14] According to them, many alkali chlorides and silica are transported in water at sufficiently high temperatures and pressures.

As may be noticed in Table II, the mole percentages of the seven components in condensed waters, i. e., in gases, are considerably different from those in lava. If such gases

are formed and separated out of a magma, compositional changes in the residual magma may be expected.

The writer wishes to express his indebtedness to Professor Kimio Noguchi for having been good enough to read the manuscript and for his helpful advice, and also to Mr. Minoru Yamamoto for his help in analyzing samples.

The Thermal Membrane Potential as a Function of the Apparent Ionic Transport Number of Membranes

By Toshio IKEDA, Masao TSUCHIYA* and Masaru NAKANO**

(Received April 20, 1964)

Some aspects of the "thermal membrane potential" (TMP) have previously been reported by one of us[1,2] in relation to its general properties and the theoretical basis for it. TMP is an EMF that appears at an ion-selective membrane, M, placed between two identical electrolytic solutions of the same concentration, m, in contact with one another, the two solutions are, however, kept at different temperatures, T and $T + \Delta T$. TMP can be measured by the the following cell system:

$$\underset{T}{\mathrm{Hg/HgCl}},\ \underset{T}{\mathrm{RX}(m)}\ \vdots\ \underset{T+\Delta T}{\mathrm{RX}(m)},\ \underset{T}{\mathrm{HgCl/Hg}} \quad (1)$$
$$\qquad\qquad\qquad\qquad\quad \mathrm{M}$$

where R represents the cation species, and X, the anion species, reversible to the electrodes of insoluble mercurous salt, HgX. On the other hand, the EMF of cell 1, and consequently the TMP, is very sensitive to the ionic permeability of the membrane used. The purpose of the present work is to find experimentally the relation between the EMF or its temperature coefficient (i. e., the thermoelectric power) and the ionic permeability of the membrane used in the cells of type 1, where the apparent ionic transport number of the membrane was adopted to represent the degree of the ionic permselectivity of the membrane.

Experimental

Materials. — GR chemicals were used without further purification in most cases. Ordinary distilled water was used in preparing the solutions. The mercury used for the calomel electrodes was purified by vacuum distillation after making the usual chemical refinements. Mercurous chloride, which was washed in advance by repeated decantation with the same solution of potassium chloride as that used for the meaurements, was used for the preparation of calomel electrodes. A pair of calomel electrodes was prepared after the usual manner in an identical way by the use of the same solution of potassium chloride as that used for the measurements of the TMP. Prior to the use of these calomel electrodes, they were let stand at least for five days in order to age them.

The Preparation of Membranes.—*Cation Permeable Membranes.* — An "oxidized" collodion membrane, according to Gregor and Sollner,[3] is advantageous because of its high cationic selectivity even with low electric resistance. The "oxidized" collodion membranes used in the present work were prepared according to the method found by one of us for getting membranes of graded cationic permeability.[4]

Anion Permeable Membranes. — A weak base-type cellophane matrix membrane of aniline-formaldehyde resin was prepared in the following way. A piece of cellophane membrane was cleaned by washing it with ether and water and was then tied with cotton thread at the end of a beaker cut off at its bottom. The beaker thus provided with a cellophane bottom was immersed in aqueous 1 M aniline hydrochloride, and a 5% aqueous formaldehyde solution acidified with a small amount of hydrochloric acid was placed on the cellophane membrane to let aniline-formaldehyde resin form in the membrane phase by means of diffusion. The most convenient temperature for the practical control of the resin-forming process was about 30°C. After about half an hour the membrane became yellowish orange as the result of the formation of the aniline-formaldehyde polymer. This cellophane

polymer matrix was washed with water overnight and stored for ready use in the electrolytic solution to be used for the experiment. Membranes prepared in such a way were found to be permselective to anions, exhibiting an anionic transport number of about 0.9 or less for the chloride ions. On the other hand, the anionic transport number of membranes of this type gradually diminishes down to about 0.6 in about two months when they are stored in aqueous media, presumably because of hydrolysis, but the rate of its change is so slow that this change will not practically disturb measurements that can be performed within a short time (about half an hour). This characteristic is, in a reverse sense, rather convenient for getting a serial run of measurements for different values of transport numbers; the same membrane can even be used if an appropriate interval is allowed for.

Cell System.—The cell system used in the present work was nearly the same as that reported on in a previous paper,[2] but some improvements were made in it. The cell is divided into two symmetrical compartments by a water-tight membrane which was placed between the brims of these two cell parts, sandwiched between two rubber sheets. This cell is suited also for measuring the isothermal membrane potential with the same membrane as was used for measuring the TMP. The cell used in the present work is sketched in Fig. 1. Here,

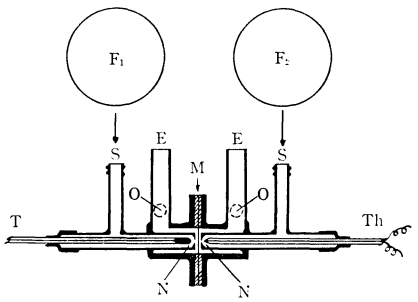

Fig. 1. Cell system.

M is the membrane, N is a fixed nozzle about 1 mm. in diameter at its orifice, S is the inlet for the solution by means of a siphon, and O is the outlet for the solution if it overflows. E is the connection for the terminal calomel electrode. F_1 and F_2 are flasks of about 3 l. which contain identical solutions. F_1 was kept at room temperature, while F_2 was kept in a bath whose temperature was controlled by a weak electric heater. F_2 was provided with an effective reflux condenser. These two solutions, identical but controlled at different temperatures, were let flow from F_1 and F_2 into the respective cell compartments through the respective nozzle, N, by means of polyvinyl chloride tube siphons at a rate above 50 cc./min. (This rate was the lowest limit for producing a stationary value of the EMF of the cell used; the flow rate employed by us was between 50 and 120 cc./min.). The solutions were then let spout against the respective sides of the membrane, M, to produce a clear-cut temperature gradient at the membrane. T is a mercury thermometer with 0.1°C divisions to be used for reading the temperature of the solution of F_1 at the instant immediately before it runs out of the orifice of the left-side nozzle to strike the left side of the membrane. On the other hand, Th is a thermister of the pencil type, which is convenient for reading the instantaneous variation in temperature of the solution of F_2 immediately before it runs out of the orifice of the right-side nozzle to strike the right side of the membrane.

To eliminate the heterogeneous thermocell effect, two calomel electrodes were kept at the same, constant temperature by placing them together in moderately running service water, whose temperature fluctuation did not exceed even ± 0.1°C per hour. TMP is substantially so small that every care must be taken not to introduce stray EMF's such as that coming from the drift of the electrode potentials due to a mechanical shock imposed accidentally upon the calomel electrodes, and such as those due to some thermoelectric effects of any sort which happen to occur in the system.

TMP was measured to a precision down to 0.1 μV. with a Yokogawa P-7-type potentiometer for low-voltage use by the aid of a highly sensitive galvanometer as a zero indicator. Here, we have adopted the convention for marking the EMF of this cell positive when the sign of the hot-side electrode is more positive. The apparent transport number of the membrane was detrermined from the isothermal membrane potentials observed at a concentration ratio of 0.05 M potassium chloride/0.1 M potassium chloride immediately before or after the TMP measurements.

Results and Discussion

The plots of EMF against T are shown in Figs. 2 and 3 for membranes with different degrees of ionic permselectivity. The EMF of cell 1 under the isothermal conditions is not always zero; it differs from run to run, presumably because of the asymmetry of the conditions of the two terminal electrodes. However, as long as such an asymmetric potential maintains itself at a constant value during the measuring run, it will not interfere with the present purpose of determining the thermoelectric power, dE/dT. The EMF, E, of cell 1 was found to be practically linear with the temperature difference, ΔT, and to respond well to the change in temperature of the solutions on either side of the membrane, irrespective of the degree of ionic permselectivity of the membrane used. When the flows of the solution on either side of the membrane were stopped, TMP returned immediately to the original isothermal value, but it promptly recovered its proper value when the flow of the solution was resumed. If these conditions could not be satisfied, the attempt to observe EMF was abandoned as not possible. The other properties were entirely the same

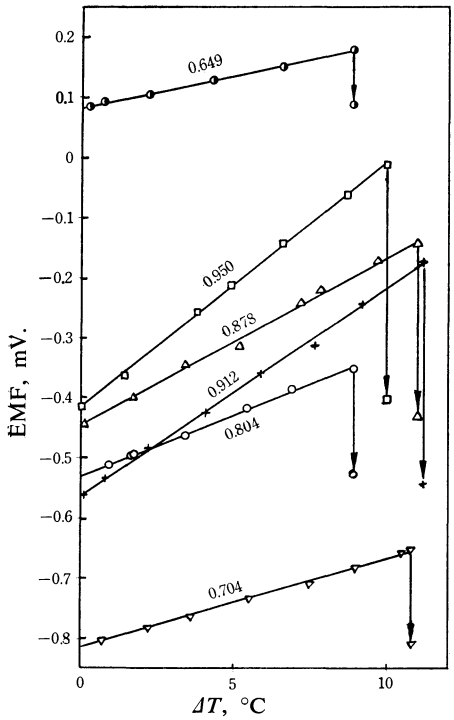

Fig. 2. EMF for oxidized collodion membranes in 0.1 M KCl. Figure attached to each line represents the apparent cationic transport number, t'_+, of the membrane applied. Vertical arrows show the return of potential to the isothermal value on stopping the flow.

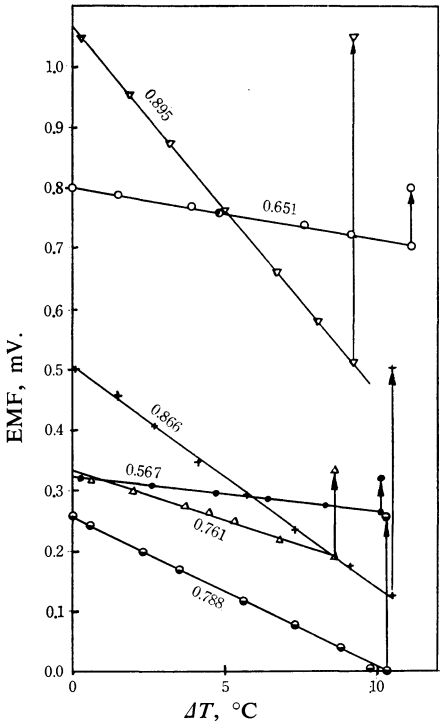

Fig. 3. EMF for aniline-formaldehyde resin-cellophane matrix membranes in 0.1 M KCl. Figure attached to each line represents the apparent anionic transport number, t'_-, of the membrane applied. Vertical arrows show the return of the potential to the isothermal value on stopping the flow.

as those found in previous works,[1,2] so the details are omitted here.

In Figs. 4 and 5 the values of dE/dT were plotted against the apparent ionic transport number, t'_+ or t'_- of the membranes. Here we found that the dE/dT values were characteristic of the nature of the membrane used, with negative signs for positive membranes ($t'_- > 0.5$), and positive signs for negative membranes ($t'_+ > 0.5$). In either negative or positive membranes, the absolute value of dE/dT is reduced practically to zero by the extrapolation at $t'_- = 0.5$ (or at $t'_+ = 0.5$) ; it gradually increases when the degree of the ionic permselectivity of the membrane is increased, and it precipitously reaches the highest limit characteristic of the nature of the membane at the extreme transport numbers of $t'_- = 1$ (or $t'_+ = 1$). In general, the absolute value of dE/dT for positive membranes was found always to be much higher than that for negative membranes at the equivalent values of the degree of the ion permselectivies of these two membranes.

According to our theory on the TMP,[2] dE/dT should be linear with the apparent transport number, t'_K, of the membrane used,

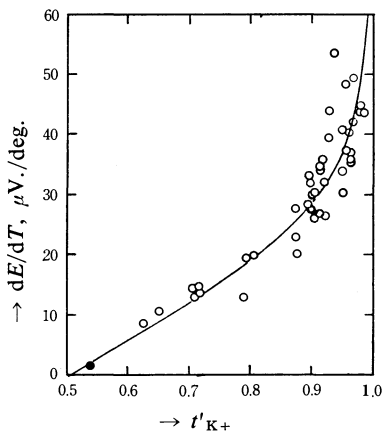

Fig. 4. Relation between thermoelectric power and apparent cationic transport number of oxidized collodion membranes in 0.1 M KCl. Black circle indicates the value for cellophane.

provided that the heats of the transfer of ions in the membrane phase are constant. However, as is clear in Figs. 4 and 5, this is not the case. This fact might indicate that the heats of the transfer of ions in the membrane phase

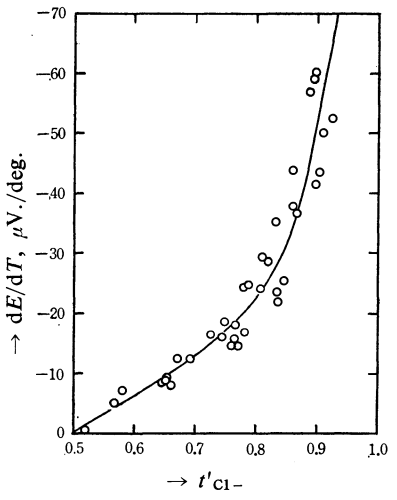

Fig. 5. Relation between thermoelectric power and apparent anionic transport number of aniline-formaldehyde resin-cellophane matrix membranes in 0.1 M KCl.

should be a function of the apparent ionic transport number of that membrane. This conclusion is very plausible; since the heats of the transfer of ions are substantially of a kinetic nature, accordingly the value of ionic heats of transfer in the membrane phase should depend on the membrane structure or on its measure, such as the apparent ionic transport number of the membrane. The relation between the ionic heat of transfer in the membrane phase and the apparent ionic transport number of the membrane has not yet been clarified, but it should be studied.

Summary

The thermal membrane potential (TMP) has been studied as a function of the apparent ionic transport number of ionselective membranes. The temperature coefficient of TMP, the thermoelectric power, has been found to be a continuously increasing function of the apparent ionic transport number of the membranes used, starting from zero at the neutral point, where the membrane exhibits no selectivity for ions, and approaching with acceleration when the ionic transport number of the membrane is increased until it reaches its highest limit at the perfect ion permselectivity. The sign of the thermoelectric power has been found to be positive for negative membranes, and negative for positive membranes. The absolute value of the thermoelectric power is higher for positive membranes than for negative membranes at equivalent degrees of ion permselectivity.

Transported Entropies and Conventional Eastman Entropies of the Transfer of Some Univalent Ions in Aqueous Solutions at 25°C

By Toshio IKEDA

(Received April 25, 1964)

An absolute estimation of the transported entropies* of individual ions was carried out previously by the present writer.[1,2] However, recently Turner and his co-workers[3] have reported reliable, and perhaps final, values of the Soret coefficient for a number of 1 : 1-electrolytes by using a conductivity method, and since the data of the Soret coefficients used in our previous calculations were less reliable than Turner's values, and since much the same thing can be said of the data on initial thermoelectric powers used previously, it is worthwhile to recalculate the transported entropies of single ions by using the most accurate data now available.

General. — The transported entropy for a single ion can be calculated exclusively from the experimental data on the initial thermoelectric power of the thermocell and the Soret coefficient without making any conventional

* The term "entropy of transfer" as defined by De Groot was used in the previous work and indicated with the symbol S^*, which is quite identical with the "transported entropy" used here with the symbol $\bar{\bar{S}}$. However, the usage of the former is undesirable, because such use causes confusion with the Eastman entropy of transfer, S^*, defined by Q^*/T, where Q^* is the heat of transfer at the absolute temperature, T.

assumption other than postulating the additivity for the partial molar ion entropies as well as for the ionic entropies (or heats) of transfer, though this property is now commonly acceptable, particularly in dilute solutions. The basic relations for calculating the transported entropies of individual ions are just the same as those used in the previous works.[1,2] In the simpler case, where the electrolyte contains a single salt giving two kinds of univalent ions, they are:[1,2,4]

$$\overline{\overline{S}}_+=-\boldsymbol{F}\varepsilon_0-\overline{\overline{S}}_{el}+\Delta S^\circ{}_M-2t_-\boldsymbol{RT}B\sigma \quad (1)$$

and

$$\overline{\overline{S}}_-=\boldsymbol{F}\varepsilon_0+\overline{\overline{S}}_{el}-\Delta S^\circ{}_M-2t_+\boldsymbol{RT}B\sigma+(S_++S_-) \quad (2)$$

when the initial thermoelectric power for thermocells with cation-reversible electrodes is available, and

$$\overline{\overline{S}}_+=-\boldsymbol{F}\varepsilon_0-\overline{\overline{S}}_{el}+\Delta S^\circ{}_R-2t_-\boldsymbol{RT}B\sigma+(S_++S_-) \quad (3)$$

and

$$\overline{\overline{S}}_-=\boldsymbol{F}\varepsilon_0+\overline{\overline{S}}_{el}-\Delta S^\circ{}_R-2t_+\boldsymbol{RT}B\sigma \quad (4)$$

when the ε_0 for thermocells with anion-reversible electrodes is available. Here, $\boldsymbol{F}$ is the Faraday constant. $\overline{\overline{S}}_k$ represents the transported entropy of k ion species in an m molar solution; it is defined by $\overline{\overline{S}}_k=S_k+S_k{}^*$, where S_k and $S_k{}^*$ are the absolute partial molar entropy and the absolute molar Eastman entropy of the transfer of k ion species respectively. The latter $S_k{}^*$, the Eastman entropy of the transfer of k ion species, is related to the Soret coefficient, σ, as follows: for a 1 : 1- electrolyte it is

$$\sigma=-\frac{\mathrm{d}\ln m}{\mathrm{d}T}=-\frac{S_+{}^*+S_-{}^*}{2\boldsymbol{RT}B},\quad B=\left(1+\frac{\mathrm{d}\ln\gamma_\pm}{\mathrm{d}\ln m}\right)_T \quad (5)$$

where $\boldsymbol{R}$ is the gas constant; T is the absolute temperature and $\gamma_\pm$ is the mean ion activity coefficient on the molality scale at the molality of m. $\overline{\overline{S}}_{el}$ denotes the transported entropy of electrons in the metallic leads of the thermocell concerned. t_+ and t_- are, respectively, the transport numbers of cations and anions. Finally, $\Delta S^\circ{}_M$ and $\Delta S^\circ{}_R$ refer to the contributions from the changes in the standard molar entropies of the electrode materials of the thermocells for the electrode reactions per Faraday. They differ with the electrode system; their practical forms are: $\Delta S^\circ{}_M=1/2\,S^\circ{}_{H_2}$ for a hydrogen electrode; $\Delta S^\circ{}_R=S^\circ{}_{Ag}-S^\circ{}_{AgX}$ for electrodes of silver/silver halide; $S^\circ{}_{Hg}-S^\circ{}_{HgCl}$ for mercury/calomel electrodes and $1/2(S^\circ{}_{Hg}-S^\circ{}_{HgO}-S^\circ{}_{H_2O})$ for mercury/mercuric oxide electrodes when alkali hydroxide is used as an electrolyte.

Calculations. — The salt entropy, (S_++S_-), was calculated in a formal manner by:

$$S_++S_-=S^\circ{}_++S^\circ{}_--2\boldsymbol{R}\ln m\gamma_\pm-2\boldsymbol{RT}\,\mathrm{d}\ln\gamma_\pm/\mathrm{d}T$$

where $S^\circ{}_+$ and $S^\circ{}_-$ are, respectively, the

standard partial molar entropies of cations and anions; their conventional values are given by Latimer and his co-workers.[5] The salt entropy is independent of the convention adopted in assigning its ion constituents; its absolute value is given on the basis of the third law. The other values of the standard entropies may be available in NBS service.[6] The values of B in 5 were obtained graphically from the mean ion activity coefficients.[7] The temperature coefficients of the mean ion activity coefficients can rarely be obtained by direct observation, so in most cases they were estimated by differentiating the Debye-Hückel equation. The transported entropy of electrons, $\overline{\overline{S}}_{el}$, in the metallic leads of thermocelles was approximated by the entropy of electrons; e. g., 0.04 e. u. for copper, and 0.05 e. u. for silver.[2] The other numerical data necessary for the calculations are listed in Table I, except for the ε_0 values, which are listed in Table II. All the data cited in the tables were taken at 25°C and 0.01 M. The σ values listed in Table I are those of Snowdon-Turner, but they have been corrected to 25°C at a rate[8] of $0.01\times10^{-3}\cdot deg^{-1}$ per degree of deviation in the mean temperature, at which the Soret coefficients were measured, from 25°C, since their original values were determined at mean temperatures slightly different from 25°C, ranging from 24.8°C to 25.4°C.

Upon applying these new data regarding σ and ε_0 as listed in Tables I and II to Eqs. 1—4, we get the transported entropies of individual ion species, i. e., $\overline{\overline{S}}_+$ and $\overline{\overline{S}}_-$. The results are listed in Table II. The single-ion transported entropies, $\overline{\overline{S}}_+$ and $\overline{\overline{S}}_-$, here obtained have been found to have their proper values characteristic of the nature of ions; they are nearly independent of the other ions present in the solution and of the type of the thermocells participating. This consequence is very important in yielding the transported entropies

TABLE III. MEAN AND SELF-CONSISTENT VALUES OF "REDUCED" TRANPORTED ENTROPIES, $\bar{\bar{S}}^{\circ}_{k}$, AND CONVENTIONAL EASTMAN ENTROPIES OF TRANSFER, S_k^*, (IN cal./deg./mol.), AND HEATS OF TRANSFER, Q_k^*, (IN cal./mol.) FOR INDIVIDUAL IONS AT 25°C AND 0.01 M

The value in parentheses was adopted as the standard for estimating the self-consistent values of $\bar{\bar{S}}^{\circ}_{k}$.

Ion	$\bar{\bar{S}}^{\circ}_{k}$ mean	$\bar{\bar{S}}^{\circ}_{k}$ selfcon.	S°_{k}(con) Ref. 5	S_k^*(con) Eq. 8	Q_k^*(con)
H^+	4.99±0.15	5.00	0	5.00	1490
Li^+	−0.68±0.11	−0.54	4.7	−5.24	−1562
Na^+	10.98±0.18	11.06	14.0	−2.94	− 878
K^+	20.43±0.10	20.59	24.2	−3.61	−1077
Rb^+	26.00	26.08	28.7	−2.62	− 782
Cs^+	29.33	29.30	31.8	−2.50	− 745
OH^-	16.56±0.01	16.06	−2.49	18.55	5530
Cl^-	18.73±0.10	(18.73)	13.5	5.23	1560
Br^-	25.16±0.02	25.01	19.7	5.31	1584
I^-	28.97±0.13	28.83	25.3	3.53	1052

as an absolute (not conventional) partial molar quantity without making any conventional assumptions. It would be desirable, if possible, to split $\bar{\bar{S}}_k$ into its two constituents, the absolute partial molar entropy, S_k, and the absolute molar Eastman entropy of transfer, S_k^*; however, we have no basis for doing so as yet.

On the other hand, it would be convenient to use a "reduced" quantity defined by ($\bar{\bar{S}}^{\circ}_{k} \equiv S^{\circ}_{k} + S_k^*$), which is equivalent to ($\bar{\bar{S}}_k - \boldsymbol{R} \ln m\gamma_k - \boldsymbol{RT} \mathrm{d} \ln \gamma_k / \mathrm{d}T$), in comparing $\bar{\bar{S}}_k$ values given at different concentrations, since $\bar{\bar{S}}_k$ depends greatly upon the concentration. To do this, $\gamma_+ = \gamma_- = \gamma_\pm$ was assumed for uni-univalent electrolytes. Calculated values of $\bar{\bar{S}}^{\circ}_{k}$ for cation and anion species are listed on the last two columns in Table II.

By using the calculated values of $\bar{\bar{S}}^{\circ}_{k}$ in Table II we have determined self-consistent values of $\bar{\bar{S}}^{\circ}_{k}$ for individual ion species by the following process: the most probable value of the "reduced" transported entropy of one ion species, for example, of the chloride ion (because so much data on it is available in the present case), was used as the standard for the estimation of the "reduced" transported entropies of its conjugate cations by subtracting it from $\bar{\bar{S}}^{\circ}_{MCl}$, the "reduced" transported entropy of any chloride MCl, which is calculable as the sum of the standard entropy and the Eastman entropy of transfer for one mole of the chloride MCl. Then the value of $\bar{\bar{S}}^{\circ}_{M^+}$, the "reduced" transported entropy of the cation, M^+, here determined was subtracted from $\bar{\bar{S}}^{\circ}_{MX}$, the "reduced" transported entropy of the other electrolyte, MX, with a common cation, M^+, to yield a self-consistent value of $\bar{\bar{S}}^{\circ}_{X^-}$ for any anion species, X^-. The process may then be extended.

The agreements between the self-consistent values thus determined and the simple average of $\bar{\bar{S}}^{\circ}_{k}$ for individual ion species from Table II are found in Table III to be fairly good, except for the hydroxide ion; the lack of agreement here may be due to the fact that the Soret coefficients of the hydroxides observed by Snowdon and Turner were somewhat lower. At any rate, the fact that such a good harmony was found might indicate, in other words, that the values of the Soret coefficient measured by Snowdon and Turner were quite proper.

Entropies of Transfer Based on the Convention of $\bar{\bar{S}}^{\circ}_{H^+}$(con)≡0. — The relation between the absolute (abs) and the conventional (con) standard molar entropies for k ion species of the ionic valency z_k can be written as follows:

$$\left.\begin{aligned} S^{\circ}_{H^+}(\mathrm{con}) &\equiv 0 \\ S^{\circ}_{k}(\mathrm{con}) &= S^{\circ}_{k}(\mathrm{abs}) - z_k S^{\circ}_{H^+}(\mathrm{abs}) \end{aligned}\right\} \quad (6)$$

We may define further the absolute and the conventional molar Eastman entropies of transfer respectively by the following equations:

$$S_k^*(\mathrm{abs}) = \bar{\bar{S}}^{\circ}_{k} - S^{\circ}_{k}(\mathrm{abs}) \quad (7)$$

and

$$S_k^*(\mathrm{con}) = \bar{\bar{S}}^{\circ}_{k} - S^{\circ}_{k}(\mathrm{con}) \quad (8)$$

By taking 6 into account, we have the alternative expression for S_k^*(con) as follows:

$$S_k^*(\mathrm{con}) = S_k^*(\mathrm{abs}) + z_k S^{\circ}_{H^+}(\mathrm{abs}) \quad (9)$$

or

$$Q_k^*(\text{con}) = Q_k^*(\text{abs}) + z_k T S^\circ_{H^+}(\text{abs}) \quad (10)$$

Equation 9 gives a definite basis for the conventional Eastman entropy of transfer as defined by 8 to be based on the same convention as that adopted in assigning the ion entropy: the convention of $S^\circ_{H^+}(\text{con}) \equiv 0$ for an aqueous hydrogen ion of one molal activity at 25°C and 1 atm.

Now, if only $S^\circ_{H^+}(\text{abs})$ were known, all the absolute values of S_k^* could be known from Eq. 9; however, the absolute values of $S^\circ_{H^+}$ estimated so far by some authors[9-12] are not sufficient as yet to realize such a purpose. Consequently, only the conventional values of S_k^* and Q_k^* (as based on the convention of zero for the hydrogen ion, not for the chloride ion as adopted by most authors) were calculated; they are listed in the last two columns in Table III. These conventional values may be converted easily into absolute ones by the aid of Eq. 9 or 10, when $S^\circ_{H^+}(\text{abs})$ is available. The values of $S_k^*(\text{con})$ or $Q_k^*(\text{con})$ in Table III may be used conveniently for predicting unknown Soret coefficients by means of a combination of the ions indicated in the table.

Summary

Absolute ionic transported entropies, conventional ionic Eastman entropies of transfer, and conventional ionic heats of transfer, using the same convention ($S^\circ_{H^+} \equiv 0$) as that adopted in assigning conventional standard ionic entropies, have been recalculated for ten univalent ions from the most accurate data now available on the initial thermoelectric powers and the Soret coefficients.

The Potential Constants of Phosphorus Trihalide and Phosphoryl Halides

By Yasuo NAKAI and Kumiko MORI

(Received May 2, 1964)

The Raman and infrared spectra of phosphorus trihalides and phosphoryl halides in the solid, liquid and vapor phases have previously been obtained.[1a,1b] The normal vibrations of PCl_3 and PBr_3 have been calculated on the basis of the general quadratic potential function derived by Howard and Wilson.[2] Using the mean square amplitudes of vibration obtained from gaseous electron diffraction experiments, together with the normal vibration frequencies, Iwasaki and Hedberg attempted to get a reasonable set of potential constants of the general quadratic function where the interaction terms between bond stretching and angle deformation are included.[3] On the other hand, no detailed studies of the potential constants of phosphoryl halides have yet been tried.

It is necessary to undertake a theoretical treatment of the experimental data on the vibrational spectra of phosphorus compounds in order to obtain reasonable potential constants which are transferable among phosphorus compounds.

At first the normal vibrations of pyramidal-type molecules, such as PCl_3 and PBr_3, were calculated by means of a modified Urey-Bradley force field (UBFF), and then phosphoryl halides, $OPCl_3$ and $OPBr_3$ were calculated by

means of a Urey-Bradley-Shimanouchi force field (UBSFF). It was found that there exists a relationship between the potential constants of the PCl_3, PBr_3, $OPCl_3$ and $OPBr_3$ compounds and the constants for the mixed halogen phosphorus compounds, PCl_2Br, $PClBr_2$, $OPCl_2 \cdot Br$ and $OPClBr_2$.

Normal Coordinate Treatment and Results

The Calculation of the Potential Constants of PCl_3 and PBr_3.—The Raman spectra of PCl_3 and PBr_3 reported by Delwaulle were used for the calculation of the potential constants in the present study. PCl_3 and PBr_3 have the pyramidal-type structure with C_{3v} symmetry.

As a potential function, the following modified UBFF was used:

$$V=\sum K'_{t0}\Delta r_{t0}+1/2\sum K_{t0}(\Delta r_{t0})^2 + \sum H'_{t0f}(r_{t0}r_{f0})^{1/2}\Delta\phi_{t0f}+1/2\sum H_{t0f}r_{t0}r_{f0}\cdot (\Delta\phi_{t0f})^2+\sum F'_{tf}\Delta q_{tf}+1/2\sum F_{tf}(\Delta q_{tf})^2 + \sum k_{tf}(\Delta r_{t0})(\Delta r_{f0}) + \sum h_{ijk}(r_{i0}r_{j0})^{1/2}(r_{j0}r_{k0})^{1/2}(\Delta\phi_{t0f})(\Delta\phi_{j0k}) \quad (1)$$

where K, H and F are the potential constants for bond stretching, angle deformation and interaction between non-bonded atoms respectively; k and h are the interaction terms between two bond-stretching coordinates and between two angle-deformation coordinates respectively. The following symmetry coordinates were used:

$$S_1(A_1)=3^{-1/2}(\Delta r_{01}+\Delta r_{02}+\Delta r_{03})$$
$$S_2(A_1)=3^{-1/2}(\Delta\phi_{102}+\Delta\phi_{203}+\Delta\phi_{301})$$
$$S_3(E)=2^{-1/2}(\Delta r_{02}-\Delta r_{03})$$
$$S_4(E)=2^{-1/2}(\Delta\phi_{301}-\Delta\phi_{102})$$
$$S_3^*(E)=6^{-1/2}(2\Delta r_{01}-\Delta r_{02}-\Delta r_{03})$$
$$S_4^*(E)=6^{-1/2}(2\Delta\phi_{203}-\Delta\phi_{301}-\Delta\phi_{102})$$

The secular equation, $|GF-E\lambda|=0$, is set up according to Wilson's method.[4]

An IBM model 7090 digital computer was used for the numerical computations involved in the normal coordinate treatment.

In the calculations using the simple UBFF, where k and h are assumed to be zero and F' is $-F/10$, the stretching, K_{AS}, and deformation, H_{AS}, potential constants of PCl_3 (and PBr_3) against F were determined from the two frequencies observed at 510 cm^{-1} and 257 cm^{-1} (380 cm^{-1} and 162 cm^{-1}) belonging to the A_1 species; also K_{ES} and H_{ES} were determined from the 480 cm^{-1} and 190 cm^{-1} (400 cm^{-1} and 116 cm^{-1}) belonging to the E species. A convenient representation of the relationship among the potential constants is obtained by plotting K and H against F in Figs. 1 and 2.

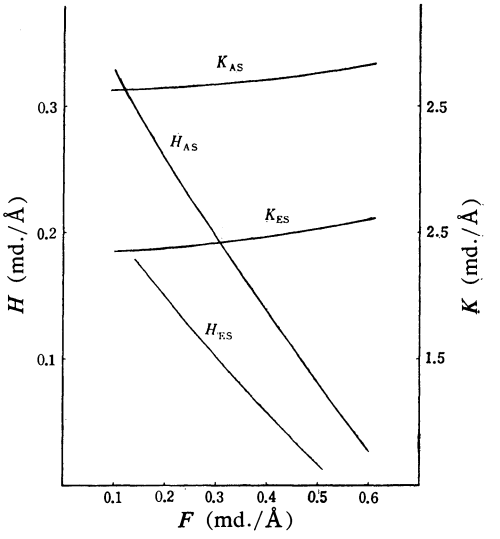

Fig. 1. The correlation of potential constants for PCl_3.

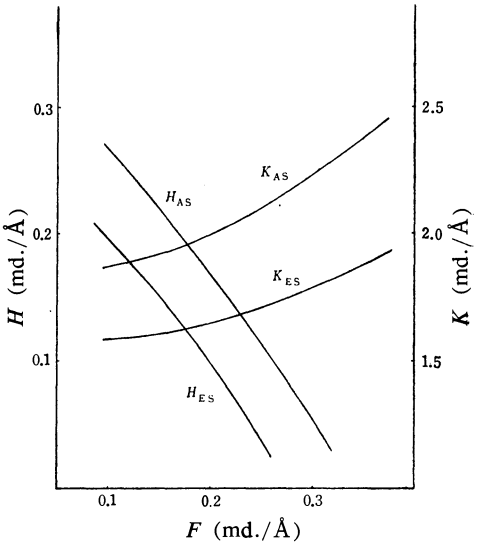

Fig. 2. The correlation of potential constants for PBr_3.

All the combinations of the K and H potential constants for the A_1 species are incompatible with those of the E species. We could not find any common values for the potential constants of the two symmetry species.

Therefore, we used a modified UBFF in our calculations. The relationship between the potential constants, K and H, of the simple UBFF and those of the modified UBFF may be expressed as follows:

4) E. B. Wilson, Jr., ibid., 7, 1047 (1939); 9, 76 (1941).

Table I. Potential constants (md./Å) and molecular parameters of phosphorus chloride

	K	H	k	h	F_{calcd}	r, Å	ϕ(degree)
PCl_3	2.182	0.168	0.217	0.036	0.244	2.039	100° 27′

* The potential constants of the Vth group elements were calculated by the same method.

Table II. Molecular parameters of phosphoryl chloride and bromide

	r_{01}	r_{02}	ϕ_{102}	ϕ_{203}
$OPCl_3$	1.45 Å	1.99 Å	115° 16′	103° 6′
$OPBr_3$	1.45 Å	2.18 Å	117°	101°

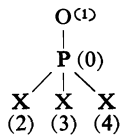

Table III. Potential constants of phosphoryl chloride and bromide (md./Å)

	$OPCl_3$			$OPBr_3$	
	Set 1	Set 2		Set 1	Set 2
$K_{P=O}$	9	9.85	$K_{P=O}$	9	9.50
K_{P-Cl}	2.2	2.54	K_{P-Br}	1.9	1.9
$F_{O\cdot\cdot(P)\cdot\cdot Cl}$	0.13	0.25	$F_{O\cdot\cdot(P)\cdot\cdot Cl}$	0.10	0.10
$F_{Cl\cdot\cdot(P)\cdot\cdot Cl}$	0.27	0.27	$F_{Br\cdot\cdot(P)\cdot\cdot Br}$	0.25	0.25
H_{OPCl}	0.2	0.286	H_{OPBr}	0.15	0.28
H_{ClPCl}	0.2	0.12	H_{BrPBr}	0.1	0.1
χ(md. Å)	0.06	0.06	χ(md. Å)	0.04	0.04

$$K=1/3(K_{AS}+2K_{ES}) \qquad k=1/3(K_{AS}-K_{ES})$$
$$H=1/3(H_{AS}+2K_{ES}) \qquad h=1/3(H_{AS}-H_{ES})$$

where K_{AS} and H_{AS}, and K_{ES} and H_{ES} are the stretching and deformation constants obtained from the A_1 and E species respectively, using the simple UBFF. The repulsive potential constants, $F_{Cl\cdot\cdot(P)\cdot\cdot Cl}$ and $F_{Br\cdot\cdot(P)\cdot\cdot Br}$, are estimated from the interatomic forces between Ar··Ar atoms and also from those between Kr··Kr atoms on the basis of the Lennard-Jones potential.[5] The potential constants, K, H, k and h, can be calculated from the observed frequencies by using the modified UBFF.

The potential constants and molecular parameters[6] are shown in Table I.

The Calculation of the Potential Constants of $OPCl_3$ and $OPBr_3$.—In order to investigate the relationship between the potential constants of phosphoryl halides and phosphorus trihalides, the normal vibrations of $OPCl_3$ and $OPBr_3$ were also calculated on the basis of the UBSFF. For this type of molecule, the internal tension, due to the redundancy among six angles is introduced.[7]

The following set of linear combinations of internal coordinates was chosen as the symmetry coordinates:

For the A_1 type:

$$S_1=\Delta r_{01}$$
$$S_2=3^{-1/2}(\Delta r_{02}+\Delta r_{03}+\Delta r_{04})$$
$$S_3=(3A^2+3B^2)^{-1/2}[B(\Delta\phi_{102}+\Delta\phi_{103}+\Delta\phi_{104}) - A(\Delta\phi_{304}+\Delta\phi_{402}+\Delta\phi_{203})]$$
$$S_4=(3A^2+3B^2)^{-1/2}[A(\Delta\phi_{102}+\Delta\phi_{103}+\Delta\phi_{104}) + B(\Delta\phi_{304}+\Delta\phi_{402}+\Delta\phi_{203})]$$

(S_4 is redundant.)

$$A=2ab(c-1)^2 \qquad B=2d(c-1)(a^2-c)$$
$$a=\cos\phi_{102}, \quad b=\sin\phi_{102}, \quad c=\cos\phi_{203}, \quad d=\sin\phi_{203}$$

For the E type:

$$S_5=6^{-1/2}(2\Delta r_{02}-\Delta r_{03}-\Delta r_{04})$$
$$S_6=6^{-1/2}(2\Delta\phi_{102}-\Delta\phi_{103}-\Delta\phi_{104})$$
$$S_7=6^{-1/2}(2\Delta\phi_{304}-\Delta\phi_{402}-\Delta\phi_{203})$$
$$S_5^*=2^{-1/2}(\Delta r_{03}-\Delta r_{04})$$
$$S_6^*=2^{-1/2}(\Delta\phi_{103}-\Delta\phi_{104})$$
$$S_7^*=2^{-1/2}(\Delta\phi_{402}-\Delta\phi_{203})$$

TABLE IV. OBSERVED AND CALCULATED FREQUENCIES (IN cm^{-1})

a) $OPCl_3$

	ν_{obs}	ν^1_{calcd}	Δ^1	ν^2_{calcd}	Δ^2
A_1 species	1292	1231	− 4.7	1292	0
	486	444	− 8.6	480	−1.2
	268	265	− 1.1	256	−4.5
E species	582	542	− 7.0	587	+0.9
	337	269	−20.0	339	+0.6
	191	218	+14.1	191	0

b) $OPBr_3$

	ν_{obs}	ν^1_{calcd}	Δ^1	ν^2_{calcd}	Δ^2
A_1 species	1260	1225	− 2.8	1259	−0.1
	340	336	− 1.2	342	+0.6
	173	166	− 4.0	176	+1.7
E species	488	446	− 8.6	486	+0.2
	267	217	−18.7	266	−0.4
	118	122	+ 3.4	122	+3.4

Δ: Percent deviation $100(\nu_{calcd}-\nu_{obs})/\nu_{obs}$

The molecular parameters[8] used in the calculations are given in Table II.

The potential constants of set 1 (Table III) were estimated from those of PX_3. Then the potential constants of set 2 (Table III) were selected to yield a better agreement between the observed and calculated frequencies for $OPCl_3$ and $OPBr_3$, except for $F_{Cl\cdot\cdot(P)\cdot\cdot Cl}$ and $F_{Br\cdot\cdot(P)\cdot\cdot Br}$, which were estimated from the Lennard-Jones potential as in the case of PX_3-type molecules. The calculated frequencies are compared with the observed frequencies in Table IV.

The Potential Constants of Mixed Halides of Phosphorus Compounds: PCl_2Br, $PClBr_2$, $OPCl_2Br$ and $OPClBr_2$.—Delwaulle and others[9] have shown that the mixing of PCl_3 and PBr_3 yields PCl_2Br and $PClBr_2$.

The normal vibrations of PCl_2Br and $PClBr_2$ were calculated. The values of the stretching-potential constants, K_{PCl} and K_{PBr}, were transferred from those of PCl_3 and PBr_3, while those of the deformation constant, H_{ClPBr}, and the repulsive constant, $F_{Cl\cdot\cdot(P)\cdot\cdot Br}$, for PCl_2Br and $PClBr_2$ were assumed to be the harmonic mean of those for PCl_3 and PBr_3 as follows:

$$k_{ij}=2\,[k_{ii}k_{jj}/(k_{ii}+k_{jj})]$$

The derivation of the values of the $[h]$ constants, for example, $h_{ClPBr\cdot BrPBr}$ may be shown as follows:

$$h_{ClPBr\cdot BrPBr}=2\,[h_{ClPBr}\cdot h_{BrPBr}/(k_{ClPBr}+h_{BrPBr})]$$

where

$$h_{ClPBr}=2\,[h_{ClPCl}\cdot h_{BrPBr}/(h_{ClPCl}+h_{BrPBr})].$$

Those potential constants of PCl_2Br and $PClBr_2$ are shown in Table V. The arithmetic mean was taken for the value of molecular parameters. Table VI compares the observed and calculated frequencies for PCl_2Br and $PClBr_2$.

The normal vibrations of $OPCl_2Br$ and $OPClBr_2$ were calculated by the same method as was used for PCl_2Br and $PClBr_2$.

TABLE V. POTENTIAL CONSTANTS OF MIXED HALOGEN COMPOUNDS (md./Å)

The calculated frequencies are compared with those obtained by Delwaulle et al.[10] in Table VII.

The agreement between the observed and calculated frequencies is satisfactory. Therefore, it is reasonable to assume the transferability of the potential constants among the compounds.

Discussion

The modified UBFF shown in Eq. 1 may be applied to such pyramidal molecules as PCl_3 and PBr_3, and the UBSFF, to such unsymmetric tetrahedral molecules as $OPCl_3$ and $OPBr_3$. Different force fields were used for the PX_3-type and OPX_3-type molecules in the present paper. However, the potential constants may involve physically significant common values among them.

The repulsion terms between the nonbonded halogen atoms for PCl_3 and PBr_3 are estimated from the interaction forces between atoms, on the basis of the Lennard-Jones potential. The K, H, k and h potential constants are the functions of the repulsion constant, F. On the other hand, the potential constants for $OPCl_3$ and $OPBr_3$ have been selected to produce the best agreement between the observed and calculated frequencies.

It was found that the values of K and H of OPX_3 are nearly the same as those of pyramidal molecules, PX_3. This result shows that there is a correlation between the potential constants of phosphoryl and phosphorus halogenides.

In the case of fluorine compounds, the potential constants are not transferable. A further investigation will be necessary in order to estimate the potential constant of $F\cdots F$ nonbonded repulsion.

The k and h potential constants may rise from the resonance energy because of the interaction between the unpaired electron of the P atom and the electrons existing in the PX bond and on the ẌPX plane.

In the calculation of the normal vibrations of mixed trihalogen phosphorus and phosphoryl compounds as well as of dihalogenide carbonyl, better results were obtained by the use of a harmonic mean than by the use of an arithmetical or geometric mean in the estimation of the potential constants. When the values calculated using the harmonic mean are compared with the values which are selected to produce the best agreement between the observed and calculated frequencies, the difference between the observed and calculated frequencies are of nearly the same order for both cases of phosphoryl halides.

Bell et al.[11] have shown that there is a linear correlation between the phosphoryl-absorption wavelength in phosphoryl halides

and the sum of the Pauling electronegativity constants of the halogens. In our present investigation, it was found that a linear correlation is obtained by plotting the phosphoryl potential constants in phosphoryl halides against the sum of the Pauling electronegativity, as is shown in Fig. 3. The value of the

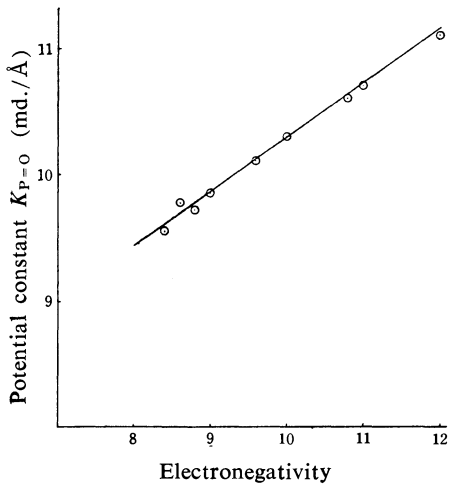

Fig. 3. The correlation between the P=O stretching constant and the sum of electronegativity.

	Sum of electronegativity	Potential constant
$OPBr_3$	8.4	9.5
$OPClBr_2$	8.6	9.77
$OPCl_2Br$	8.8	9.72
$OPCl_3$	9.0	9.85
$OPFBr_2$	9.6	10.10
$OPFCl_2$	10.0	10.30
OPF_2Br	10.8	10.60
OPF_2Cl	11.0	10.70
OPF_3	12.0	11.10

phosphoryl-stretching constant rises higher as the sum of the Pauling electronegativity increases. The effects of various substituents upon the P=O-stretching constant in many types of phosphoryl compounds may be due to an induced polarization. It may be interpreted that in the P-oxide the electronic structure can be represented as resonance hybrids: $R_3P^+-O^- \leftrightarrow R_3P=O$.

Summary

It is important to calculate the potential constants of phosphorus compounds systematically in order to determine physically meaningful potential constants.

First the normal vibrations of such pyramidal-type molecules as PCl_3 and PBr_3 have been calculated by the use of a Urey-Bradley force field as supplemented by the interaction terms between two bond-stretching coordinates and between two angle-deformation coordinates, and then such phosphoryl halogenides as $OPCl_3$ and $OPBr_3$ have been calculated by the use of a Urey-Bradley-Shimanouchi force field.

The repulsion terms between nonbonded halogen atoms have been estimated from the interaction forces between inert atoms based on the Lennard-Jones formula.

The force fields used for the PX_3-type and OPX_3-type molecules in the present paper are different. However, it has been found that a relationship exists between the potential constants of such compounds as PCl_3, PBr_3, $OPCl_3$ and $OPBr_3$, and those for mixed halogen phosphorus compounds, such as PCl_2Br, $PClBr_2$, $OPCl_2Br$ and $OPClBr_2$.

The additional potential terms used for the PX_3 type may arise from the resonance energy because of the interaction between the unpaired electrons of the P atom and the electrons existing in the PX bond and on the XPX plane.

In our present investigation, a linear correlation has been found to exist between the phosphoryl potential constants in phosphoryl halides and the sum of the Pauling electronegativity constants of the halogens.

Radiation-Induced Selective Main-chain Scission in Polyvinyl Alcohol

By Yutaka HIRANO*

(Received May 2, 1964)

The overall effect of high energy radiation on organic substance is generally accepted to be the production of main-chain scission, with a corresponding decrease in the molecular weight and/or a crosslinking which finally forms an insoluble three-dimensional network structure.[1-4] This behavior on irradiation has been correlated with the chemical structure of a repeating monomer unit in polymers and/or with their physicochemical properties just under irradiation.[5-7] As a general rule, those polymers which have at least one hydrogen atom on every carbon atom become crosslinked, while those which have one quarternary carbon atom in a monomer unit are degraded.[6]

Several papers[8-10] have already been presented on the radiation-induced changes in polyvinyl alcohol. It is generally accepted that the irradiation of the polymer produces the main-chain scission and carbonyl group at the end of the chain fractured and/or in the main-chain.

This paper is concerned with the effect of such structural variations as head-to-head linkage on the radiation-induced main-chain scission of polyvinyl alcohol.

There are two types of chemical structures in the main-chain of polyvinyl alcohol.[11] One is the regular, predominant head-to-tail structure, in which the monomer substituent OH occurs on alternate carbon atoms of the chain. Another is the anomalous structure in which a pair of substituents is situated on consecutive carbon atoms. The latter arises from the head-to-head addition of vinyl acetate, which gives a mother polymer for polyvinyl alcohol. This anomalous structure occurs on the average in every several tens of monomer units in the "usual" polymer.

Another paper[12] has briefly suggested that the main-chain scission of polyvinyl alcohol on irradiation might occur at one part of this anomalous structure, i.e., the 1,2-glycol structure. In the present investigation, polyvinyl alcohols which are different in the proportion of the 1,2-glycol structure to the main-chain have been irradiated. A more complete picture of the experimental evidence for the selective main-chain scission at the special chemical structure in the polymer will be given here. The mechanism of the selective main-chain scission will also be discussed.

Experimental

The Preparation of Polyvinyl Alcohols for Irradiation Studies. — Vinyl acetate monomers, freshly distilled in a stream of nitrogen, were polymerized under various conditions, as is indicated in Table I. The resulting mixture of polymers and unreacted monomers was dissolved in benzene, from which the polymer was precipitated by the addition of an excess of petroleum ether. The polymers were then converted to polyvinyl alcohol by stirring, for 1 hr. at room temperature, a 3% solution of the polymer in methanol containing

0.05 mol. sodium hydroxide per liter. The precipitated product was dissolved in water containing a small amount of alkali in order to make the conversion more complete. After the solution had been left standing for 1 hr., polyvinyl alcohol was precipitated by pouring it into an excess of methanol. The product was purified by extraction with methanol, using a Soxhelt extractor. Then it was dried in a vacuum to a constant weight and stored in a desiccator over calcium chloride.

Polyvinyl alcohol containing no 1,2-glycol structure in the main-chain was obtained by the oxidation of "usual" polyvinyl alcohol with sodium periodate, which selectively attacks the 1,2-glycol structure.[13] "Usual" polyvinyl alcohol was dissolved in water in a 4% solution, and five times as much reagent as was consumed was added as an aqueous solution. The oxidation reaction was conducted at 30°C for 1 hr. with a constant stirring. It was thus established that all the 1,2-glycol structures in polymer are severed under these experimental conditions. The reaction mixture was then poured into an excess of cooled methanol. It was necessary to use cooled methanol for carrying out the precipitation without a substantial loss of the oxidized polymer, because the degree of polymerization of the oxidized polymer was very low. The precipitated polymer was filtered off and then washed well with cooled methanol until the filtrate did not show the presence of IO_3^- and IO_4^- ions any more. Most of the end groups of this oxidized polyvinyl alcohol are supposed to be of a chemical structure such as $-CH_2CHO$ judging from the analogous reaction between monomeric glycols and $NaIO_4$. For the reduction of this aldehyde-type end group to the alcohol-type, the oxidized polymer was treated with $NaBH_4$. A reagent (0.8 g.) was mixed with 100 cc. of the oxidized polymer solution containing 4 g. of polymer. After the solution had stood for 48 hr. while being occasionally stirred at room temperature, the reduced polymer was precipitated into methanol, cooled, and acidified with acetic acid. It was then filtered off and washed with methanol until no borate ions could be detected in the filtrate by flame reaction. Finally it was dried in a vacuum at room temperature.

The water-containing polyvinyl alcohol sample was prepared from the 30% aqueous solution of the polymer by moulding it into a rod-like shape, 3~4 m./m. in diameter and 7~8 cm. long. This water-containing sample was dried at room temperature over a long period of time to the desired extent of water concentration. The mole percent of the 1,2-glycol structure in various polymer samples was computed from the degree of degradation with sodium periodate by the use of Flory's method.[11] Table I lists the preparation and characterization data for the polymers.

The Irradiation of Samples. — Polymer samples (1.5~2.0 g.) were weighed in hard glass tubes for the irradiation in a Co-60 γ-ray source at the Japan Atomic Energy Research Institute. An ambient temperature of about 20°C was maintained during the irradiation.

Each tube containing a dry powder sample for the irradiation was evacuated to the pressure of 10^{-4} mmHg. In all casses, the vacuum was retained overnight, indicating that there was no significant amount of precipitant or solvent left in the polymer; then each tube was sealed under a vacuum. Each tube containing the water containing polymer was then sealed in the presence of air and irradiated.

Molecular Weight Measurement.— The solution viscosities of the irradiated polymer samples were measured in water at 30°C using an Ostwald-type viscometer. Three or four concentrations of each of the irradiated polymers were run, and the plots of both the viscosity number, η_{sp}/c, and the logarithmic viscosity number, $\ln(\eta_r/c)$, versus the concentration were extrapolated to zero concentration in order to determine their limiting viscosity number, $[\eta]$. The limiting viscosity numbers of polymers which are irradiated and subsequently oxidized with sodium periodate were obtained from the single-concentration viscosity data at a concentration sufficiently low to obviate the extrapolation of $\ln(\eta_r/c)$ to infinite dilution. Five times as much reagent as was consumed was added to a 10 cc. portion of the irradiated polymer solution containing around 0.13 g. of the polymer. After this mixture had stood for 30 min. at 30°C, the viscosities were measured. Polymer concentrations were computed from the known concentration of the initial aqueous solution and the total volume after the reagent was added. Molecular weights were computed from the following relationship;[14]

$$[\eta] = 6.66 \times 10^{-4} M^{0.64}$$

where $[\eta]$ is expressed in deciliters/gram.

Results and Discussion

The Irradiation of Water-containing Polyvinyl Alcohol. — The viscosity changes in the irradiated water-containing polyvinyl alcohol before and after oxidation with $NaIO_4$ are shown in Fig. 1. It is found that a sudden gel formation occurs in the irradiated polymer, although the molecular weight of the polymer decreases gradually during the initial period of irradiation. This behavior on irradiation is very similar to that of the irradiated polypropylene.[15] The minimum radiation dose necessary to produce a gel is estimated to be about 23 Mr.

On the other hand, the limiting viscosity number of the polymer which is irradiated and subsequently oxidized with $NaIO_4$ steadily increases with the radiation dose.

Figure 2 illustrates schematically the main-chain scission and/or crosslinking of polyvinyl

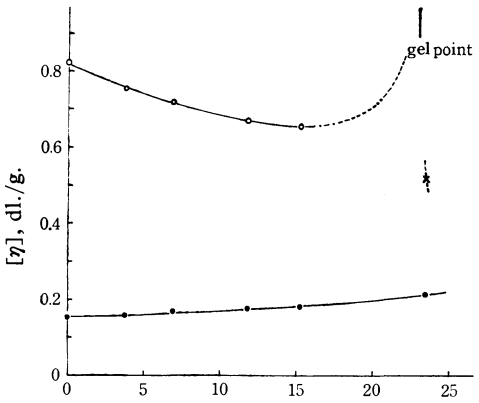

Fig. 1. Viscosity changes of irradiated water-containing polyvinyl alcohol (δ=1.54 mol.%) before and after oxidation with sodium periodate: Water content 6.7% (w/w). Intensity 4×10^4 r./hr. (○) before oxidation, (●) after oxidation, (×) viscosity of the soluble fraction (99.2%) of irradiated sample.

alcohol subjected to irradiation and/or chemical degradation with $NaIO_4$.

According to the theory of radiation-induced simultaneous degradation and crosslinking as developed by Saito,[16] the changes in the limiting viscosity number of the irradiated polymer are expressed as follows:

$$\eta(R)/\eta(0)=1+\{\alpha(\alpha+2)(\alpha+7)/6-\alpha\lambda\}(cuR)+[\alpha(\alpha+1)\{(\alpha+2)(\alpha+3)(\alpha+7)(\alpha+14)/90-(\alpha+2)(\alpha+7)\lambda/3+\lambda^2\}](cuR)^2+\cdots\cdots \quad (1)$$

where λ is ratio of the probability of the main-chain scission, r, and crosslinking, c, of monomer unit per unit of radiation dose; $\eta(0)$ and $\eta(R)$ are the limiting viscosity numbers of the polymer at zero dose and at radiation dose, R, respectively; u is a measure of the initial number average molecular weight, and α is the exponent of the relation between the viscosity and the molecular weight. This formula predicts that, if λ and α are the same in polymers, plots of $\eta(R)/\eta(0)$ versus uR of each of polymers can be superposed one upon the other by translation along the abscissa.

Provided that there are no differences in λ between the 1,3-glycol structure and the 1,2-glycol structure, the λ of *o*-PVA in Fig. 2 is equal to that of the "usual" PVA. Thus, *o-i*-PVA should decrease in viscosity with the radiation dose, since *i*-PVA decreases in viscosity during the initial period of irradiation. The treatment of this *o-i*-PVA with $NaIO_4$ might produce a further decrease in viscosity, if there exist 1,2-glycol structures formed by radiation-induced crosslinking. Furthermore, the degree of main-chain scission and crosslinking produced in this *o-i-o*-PVA is just the same as that in *i-o*-PVA, as is shown in Fig. 2.

The above-mentioned discussion leads us to the consideration that the viscosity of the "usual" PVA which is irradiated and subsequently oxidized with $NaIO_4$ should decrease with the radiation dose. This is inconsistent with the results shown in Fig. 1. The steady increase in the viscosity of irradiated and subsequently oxidized "usual" PVA would suggest that λ in a polymer which contains no 1,2-glycol structure is lower than that in a polymer which contains a 1,2-glycol structure in the main-chain. This discrepancy is considered to be partly due to the selective main-chain scission at a chemical structure such as a 1,2-glycol type on irradiation.

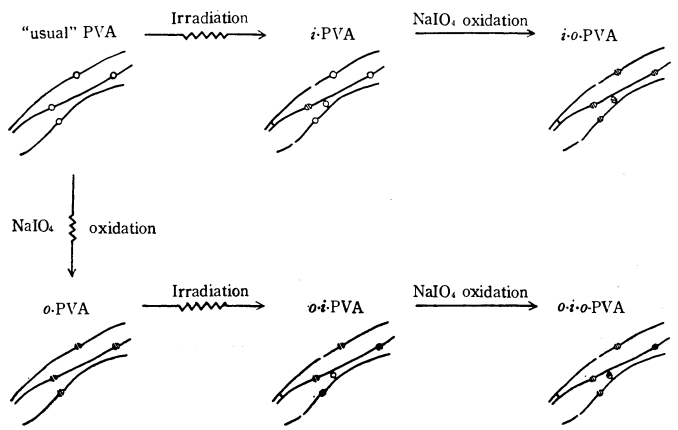

Fig. 2. Schematic main-chain scission and crosslinking of polyvinyl alcohol: —— 1,3-glycol structure, ○ 1,2-glycol structure.

The Irradiation of Polyvinyl Alcohols Which are Different in the Proportion of the 1, 2-Glycol Structure. — Figure 3 illustrates the results of the irradiation of "usual" polyvinyl alcohol as the reciprocal degree of the polymerization versus the radiation dose, R. A monotonous decrease in the molecular weight, but no gel formation, was observed for this dry specimen up to 130 Mr., which is in contrast with water-containing specimen. The main-chain scission process is predominant and does not depend on the radiation intensity in the range covered. No color has been detected in any irradiated specimens in a vacuum in contrast with the yellow coloration which appears upon irradiation in air.

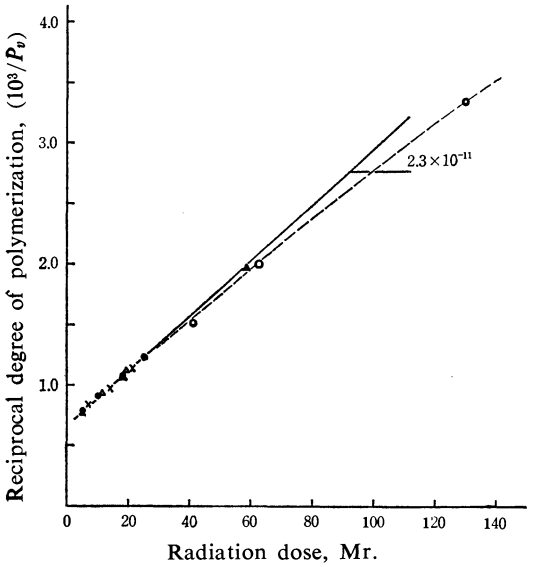

Fig. 3. Changes in the reciprocal degree of polymerization of irradiated polyvinyl alcohol ($\delta=1.54$ mol.%) with radiation dose: (×) 10^6 r./hr., (●) 6.4×10^5 r./hr., (△) 5.8×10^5 r./hr., (○) 2.8×10^4 r./hr.

Similar plots for the various polyvinyl alcohols which are different in the proportion of the 1, 2-glycol structure in the main-chain are shown in Figs. 4 and 5. The linearity of the curves obtained shows that the number of the main-chain scission produced is proportional to the radiation dose.

Pure random radiation-induced main-chain scission of the polymer reduces the initial molecular weight distribution to the most probable one and, then, predicts linear plots between $1/P_v$ and R. The relation is:[1]

$$(1/P_v)=(1/P_{v_1})+w(KNE_d)^{-1}(R_2-R_1) \quad (2)$$

where P_{v_1} and P_{v_2} are the viscosity average degree of polymerization of the polymer at radiation doses R_1 and R_2 ($R_1<R_2$) respectively, N is Avogadro's number, E_d is the average energy absorbed in eV. per main-chain scission produced, 1 r.$=5.81\times10^{13}$ eV./g., w is the molecular weight of structural unit, and K is the ratio of the viscosity average degree of polymerization to the number average one, which is given by $K=\{\Gamma(\alpha+2)\}^{1/\alpha}$.

For polyvinyl alcohol with $w=44$ and $\alpha=0.64$, we may, therefore, calculate $E_d=2.32\times10^{-9}$ eV./slope for various specimens from Figs. 4

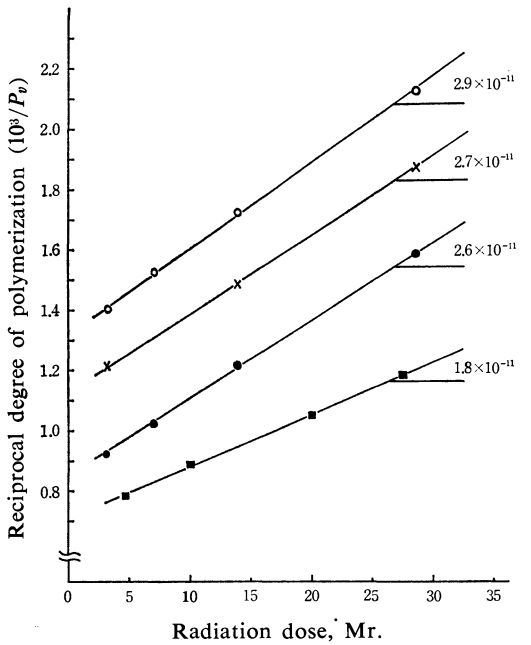

Fig. 4. Changes in the reciprocal degree of polymerization of polyvinyl alcohol samples with radiation dose: 1,2-glycol structure content, (○) 3.00, (×) 2.81, (●) 2.61, (■) 1.17 mol.%. Intensity 6.4×10^5 r./hr.

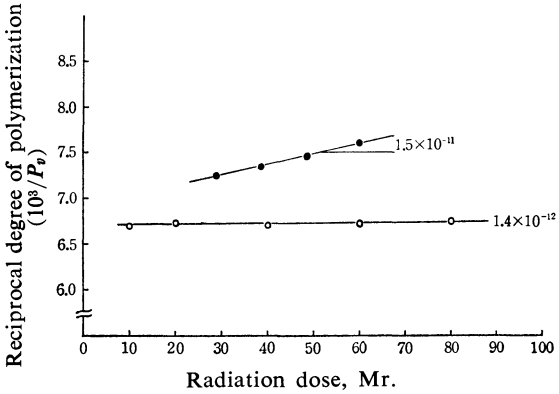

Fig. 5. Changes in the reciprocal degree of polymerization of polyvinyl alcohol samples with radiation dose: 1,2-glycol structure content, (○) 0.00, (●) 1.11 mol.%. Intensity 6.4×10^5 r./hr.

TABLE II. VARIATION IN E_d AND G_d WITH 1,2-GLYCOL STRUCTURE CONTENT

δ, mol. %	E_d, eV.	G_d
0.0	1670	0.06
1.11	154	0.65
1.17	128	0.78
1.54	100	1.00
2.61	88	1.13
2.81	85	1.17
3.00	79	1.26

and 5. In Table II the results are given as a function of the 1,2-glycol structure content, δ, in the polymer chain. The difference in G value for main-chain scission between $\delta=0$ mol.% specimen and $\delta=1.11$ mol.% one, which have nearly identical original degrees of polymerization, is beyond the range of experimental error. This fact definitely shows the predominant radiation-induced main-chain scission at a special part, such as the 1,2-glycol structure in the polymer chain.

Since it is not unreasonable to assume that the 1,2-glycol structures are distributed at random throughout the polymer, the molecular weight distribution of the irradiated polymer will approximate the most probable distribution, even if only these anomalous structures are selectively fractured on irradiation. This selectivity will, however, reduce the number of these structures on irradiation. Consequently, the average absorbed energy needed to produce a main-chain fracture varies as a function of the radiation dose and must increase gradually with an increase in the radiation dose. The departure from the linear relation between $1/P_v$ and R at high radiation doses in Fig. 3 may be ascribed to this specificity.

The Mechanism of Radiation-Induced Main-chain Scission.—A rapid approach to a certain value of G_d was observed with the increase in the 1,2-glycol content in the polymer chain (Table II and Fig. 6). It may, therefore, be suggested that a transfer of energy occurs from the 1,3-glycol structure to the 1,2-glycol structure along the polymer chain and that the latter part suffers a sacrificial damage. On the basis of the random distribution of the 1,2-glycol structure in the polymer chain, it is possible to deduce, from the G_d dependence on δ, the range of energy transfer offered by the 1,2-glycol structure. For this purpose let M represent the 1,3-glycol structure, I, the 1,2-glycol structure, and n, the number of units as a measure of the maximum range of energy transfer from M to I.

The relative probability of some configurations about a given M will be considered to be a function of the mole fraction of the 1,2-glycol structure, δ in the polymer chain. The

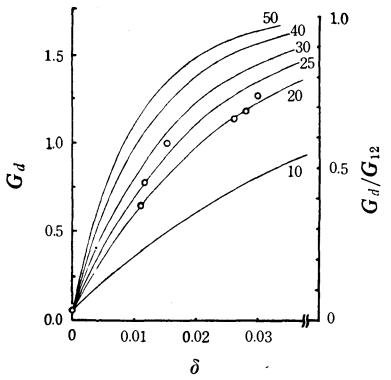

Fig. 6. G value for the main-chain scission plotted against the mole fraction of 1,2-glycol structure. Figures on the curve are the numbers of the monomer units in which the transfer of absorbed energy occurs.

probability of such a configuration when none of I is present within its n nearest neighbors on either side of M will be given as $(1-\delta)^{2n}$. In this configuration M can not lose its energy by transferring it to I and consequently, will be fractured with the probability of bond rupture per unit radiation dose, r_{13}. On the other hand, the probability of such a configuration when one or more I's are in existence within its n nearest neighbors on either side is equal to $1-(1-\delta)^{2n}$. In this case the energy transfer will occur from a given M to I. M will be protected against the bond ruputure by I. The released energy from M, however, will migrate and be "trapped" in one of the nearest neighboring I's. Therefore, this will give rise to a bond rupture of I, the probability of which is r_{12}. In other words, the 1,2-glycol structure may serve as an "energy sink" and draw off energy from the 1,3-glycol structure and dissipate it with the subsequent, sacrificial bond rupture. Thus, the total number of main-chain scissions, dS, produced with the radiation dose, dR, will be given by the equation:

$$dS=N(1-\delta)(1-\delta)^{2n}r_{13}dR+N(1-\delta)\times\{1-(1-\delta)^{2n}\}r_{12}dR+N\delta r_{12}dR \qquad (3)$$

where N is the total number of units in the irradiated system.

By rewriting Eq. 3, we obtain:

$$(1/N)(dS/dR)=r=r_{12}-(r_{12}-r_{13})(1-\delta)^{2n+1} \qquad (4)$$

The term on the left-hand side of Eq. 4 indicates the average probability for the main-chain scission of the polymer during irradiation. Thus, we obtain, by the use of the G_d value:

$$(G_d/G_{12})=1-\{1-(G_{13}/G_{12})\}(1-\delta)^{2n+1} \qquad (5)$$

As $G_{13}=0.06$, G_{12} was evaluated as about 1.7 from Fig. 5 by the extrapolation of experimental results to $\delta=100$ mol.%.

A plot of (G_d/G_{12}) versus δ is shown in Fig. 6, along with the calculated curves for several values of n. It may be seen in the figure that the experimental points, although scattered, lie between two curves for which n is 20 and 25. For $n=20$, it is estimated that the range of energy transfer is about 60 Å along the zigzag chain of the polymer.

The phenyl group is known to have a protecting effect against radiation-induced changes in various co-polymer systems.[17-20] The energy transfer process is also postulated, and a value of $n=1\sim6$ for its range is estimated. The evaluated value, $n=20$, for polyvinyl alcohol is quite large. However, a transfer of energy over distances of 50 Å or more is estimated in scintilater systems.[21,22]

Summary

Polyvinyl alcohols which are different in the mole fraction of the head-to-head structure, in which two of -OH substituents are situated on consecutive carbon atoms, have been irradiated with Co-60 gamma rays in a vacuum at room temperature in order to investigate the effect of this anomalous structure on the radiation-induced main-chain scission of the polymer. The selective main-chain scission in polyvinyl alcohol has been observed at such positions as the head-to-head structure. The average absorbed energy necessary to produce a main-chain scission, i.e., E_d, is about 1700 eV. for polyvinyl alcohol containing no head-to-head structure, while E_d is 100 eV. for polyvinyl alcohol containing a 1.54 mol.% head-to-head structure. A rapid increase up to a certain value in G_d, the number of chain scissions produced per 100 eV. of energy absorbed by the polymer, has been observed with the increase in the head-to-head structure content in the polymer chain. Thus, it has been postulated that there is a transfer of radiation energy from the head-to-tail structure to the head-to-head structure. An estimation has been made on the range of energy transfer from the G_d dependency on the concentration of the head-to-head structure.

The Electronic Structures of the Protonated Benzoic Acid and the Related Ions

By Haruo HOSOYA and Saburo NAGAKURA

(Received May 8, 1964)

There are two possible positions of the protonation of the carboxyl group: one of them, the oxygen atom of the carbonyl group, and the other, the oxygen atom of the hydroxyl group. In a previous paper[1] we studied the structures of protonated benzoic acid and mesitoic acid by the aid of various spectroscopic methods, such as ultraviolet, infrared and Raman spectra. Consequently, we succeeded in obtaining direct evidence that, in strongly acidic media, a proton attacks the carbonyl oxygen atom of benzoic acid, giving the (ion benzoic acidium ion):

(I)

Stewart and Yates[2] indirectly induced the

same conclusion from ultraviolet absorption measurements showing that the relative magnitudes of the basicities of the benzoic acid derivatives are well correlated with those of the corresponding benzaldehyde and acetophenone derivatives.

Furthermore, it was shown in the previous paper that the ultraviolet absorption spectrum of benzoic acid changes considerably upon the protonation. This reveals that the distribution and energy of the π-electrons of benzoic acid are greatly affected by the protonation. In order to obtain deeper knowledge on this point, we have undertaken to calculate the electronic structures of the benzoic acidium ion (I) and of such related ions as α-hydroxylbenzyl cations.

Method of Calculation

Only π-electrons were explicitly taken into account in the present calculations. Furthermore, the ion was considered to be composed of an electron donor and an acceptor: for example, the benzoic acidium ion (I) was considered to be composed of the two hydroxyl groups serving as an electron donor and the benzyl cation, as an electron acceptor. The ground and the lower excited states of I can be expressed as a linear combination of the ground, locally excited and charge-transfer configurations.[3] The locally excited configurations can be caused by the local excitation within the benzyl cation, and the charge-transfer configurations, by the electron transfer from the hydroxyl groups to the benzyl cation. Calculations of this kind have already been shown to give reliable results for the interpretation of electronic spectra of various unsaturated compounds.[4]

Component MO's. — Roothaan's LCAO-SCF molecular orbitals (φ_1, φ_2,……, φ_7) of the benzyl cation were calculated by Hanazaki et al.[5] on the assumptions that all the C–C bond lengths are 1.39 Å and that all the bond angles are 120°. These MO's are expressed as linear combinations of the Slater-type atomic orbitals with different effective nuclear charges (Z's), the magnitudes of which are, considering the assumed relation between Z's and the net charge densities, q's, self-consistent with the calculated q's on the respective carbon atoms. Symmetric (φ_s) and antisymmetric (φ_a) group orbitals were constructed from the two $2p\pi$ atomic orbitals, (χ^1_{OH} and χ^2_{OH}) of the hydroxyl oxygen atoms. The nine above-mentioned component molecular orbitals are given in Table I.

The Configurations and Their Energies. — In addition to the ground configuration, singlet and singly excited configurations with energies lower than 7 eV. were taken. In Table II they are grouped into symmetric (S) and antisymmetric (A) configurations with respect to the σ_V plane shown in Fig. 1. ψ_P and ψ_Q are, respectively, symmetric and antisymmetric charge-transfer configurations, in which an electron migrates from the oxygen atoms to the benzyl cation. ψ_β, ψ_γ and ψ_δ, and ψ_α, ψ_ε and ψ_ζ are symmetric and antimagnetric locally excited configurations respectively. The energies of ψ_α (2.75 eV.) and ψ_β (3.74 eV.) were taken to be equal to the lowest two transition energies of the benzyl cation observed by Hanazaki et al.[5]

b) Charge-transfer

c) Local excitation

d) Calculated values (Ref. 5)

e) Observed values (Ref. 5)

The energies of the other locally excited configurations were those calculated by them. The energies of the two charge-transfer configurations were estimated to be the difference between the ionization potentials of methanol (10.85 eV., observed[6]) and the benzyl radical (7.73., calculated[7]).[8]

Configuration Interaction. — The above-mentioned configurations interact with one another through the core and electronic repulsion parts in the total electronic Hamiltonian H:

$$H=\sum_i H^{\text{core}}(i)+\sum_{i>j}e^2/r_{ij}$$

$$H^{\text{core}}(i)=H^{\text{core}}_{\text{benzyl}}(i)+H^{\text{core}}_{\text{OH}}(i)$$

The antisymmetrized product wave functions, $\lvert k\bar{l}m\bar{n}\cdots\cdots\rvert$ and $\lvert k'\bar{l}'m'\bar{n}'\cdots\cdots\rvert$, interact with each other through the above Hamiltonian. The interaction energies can be degraded under the zero-differential overlap approximation[9,10] into the atomic integrals as follows:

(i) $\langle\varphi^*_k(i)\lvert H^{\text{core}}(i)\rvert\varphi_{k'}(i)\rangle=H^{\text{core}}_{kk'}$

if $k\neq k'$, $l=l'$, $m=m'$, $n=n'$, ……,

where

$H^{\text{core}}_{kk'}=0$, if k and k' are pertinent to the same composite,

$H^{\text{core}}_{kk'}=C_{kp}C_{k'q}\beta_{pq}$, if k and k' are pertinent to the two different composites which are jointed together through the bond between the p and q atoms,

C_{kp}: the LCAO coefficient for the p-th atom in the k-th MO, and

β_{pq}: the core resonance integral for the p—q bond.

(ii) $\langle\varphi^*_k(i)\varphi^*_l(j)\lvert e^2/r_{ij}\rvert\varphi_{k'}(i)\varphi_{l'}(j)\rangle$
$=(kk'\lvert ll')_{\text{MO}}$
$=\sum_{p,q}C^*_{kp}C_{k'p}C^*_{lq}C_{l'o}(pp\lvert qq)_{\text{AO}}$

if $k\neq k'$, $l\neq l'$, $m=m'$, $n=n'$,……

(iii) $\langle\varphi^*_k(i)\varphi^*_m(j)\lvert e^2/r_{ij}\rvert\varphi_{k'}(i)\varphi_{m'}(j)\rangle$
$=(kk'\lvert mm')_{\text{MO}}-(km'\lvert mk')_{\text{MO}}$
$=\sum_{p,q}(C^*_{kp}C_{k'p}C^*_{mq}C_{m'q}$
$-C^*_{kp}C_{m'p}C^*_{mq}C_{k'q})(pp\lvert qq)_{\text{AO}}$

if $k\neq k'$, $l=l'$, $m\neq m'$, $n=n'$,……

(iv) 0 otherwise.

Consequently, the non-zero off-diagonal matrix elements were obtained as follows:

$$H_{GP}=\sqrt{2}\langle\varphi_4H\varphi_s\rangle=2C_{41}\beta_{CO}=1.3974\beta_{CO}$$

$$H_{\beta P}=-\langle\varphi_2H\varphi_s\rangle=-\sqrt{2}C_{21}\beta_{CO}=-0.6337\beta_{CO}$$

$$H_{\beta\delta}=2(24\lvert 35)_{\text{MO}}-(23\lvert 45)_{\text{MO}}$$
$$=2\times0.4438-0.1736=0.7140\text{ eV.}$$

$$H_{p\gamma}=-\langle\varphi_1H\varphi_s\rangle=-\sqrt{2}C_{11}\beta_{CO}=-0.4827\beta_{CO}$$

$$H_{\gamma\delta}=2(14\lvert 35)_{\text{MO}}-(13\lvert 45)_{\text{MO}}$$
$$=-2\times0.3134+0.6004=-0.0264\text{ eV.}$$

$$H_{\alpha\zeta}=2(25\lvert 34)_{\text{MO}}-(23\lvert 45)_{\text{MO}}$$
$$=-2\times0.3954-0.1674=-0.9582\text{ eV.}$$

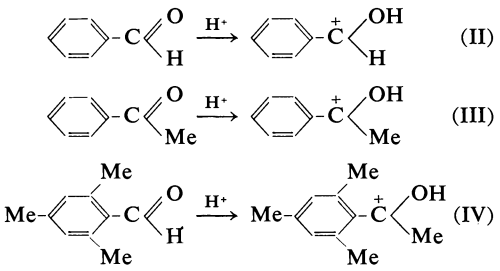
7) N. S. Hush and J. A. Pople, *Trans. Faraday Soc.*, **51**, 600 (1955).



8) In this calculation, the interaction between the two lone-pair π-electrons on the different oxygen atoms of the $-\overset{+}{C}\overset{OH}{\underset{OH}{<}}$ group is not taken into account. Furthermore, the difference in the electrostatic interaction energies before and after the electron transfer was estimated to be small and was, therefore, disregarded.

9) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 466, 767 (1953).

10) J. A. Pople, *Trans. Faraday Soc.*, **49**, 1375 (1953); *Proc. Phys. Soc.*, **A68**, 81 (1955).

The LCAO MO coefficients C's and the Coulomb repulsion integrals of the type $(pp|qq)_{AO}$ were calculated by Hanazaki et al.[5] using Pariser and Parr's approximation.[9]

Matrix Elements for the Related Ions. — Similar calculations were performed for the benzaldehydium ion (II), the acetophenonium ion (III) and the 2, 4, 6-trimethylbenzaldehydium ion (IV), which are, respectively, the monohydroxyl derivatives of the benzyl, α-methylbenzyl and 2, 4, 6-trimethylbenzyl cations. These ions are known to be produced, presumably from benzaldehyde, acetophenone and mesitaldehyde respectively, in strongly acidic media.

Each of these ions is separated into an electron donor (the hydroxyl group) and an electron accepter (the benzyl, α-methylbenzyl and 2, 4, 6-trimethylbenzyl cations for II, III and IV respectively). The interaction between the components is taken into account by means of the configurational interaction among the ground, locally excited and charge-transfer configurations. These three cations have only one hydroxyl group and, accordingly, one charge-transfer configuration,

$$\psi_O = 1/\sqrt{2}\{|1\bar{1}2\bar{2}3\bar{3}0\bar{4}| + |1\bar{1}2\bar{2}3\bar{3}4\bar{0}|\}$$

where 0 is the abbreviated representation of the $2p\pi$ atomic orbital, χ_O, of oxygen. The off-diagonal elements, H_{GO}, $H_{\beta O}$ and $H_{O\delta}$, with which the ψ_O configuration is related, are equal to $1/\sqrt{2}H_{GP}$, $1/\sqrt{2}H_{\beta P}$ and $1/\sqrt{2}H_{P\delta}$ respectively. The E_α (the energy of the α-locally excited configuration and E_β (the energy of the β-locally excited configuration) of III and IV were taken from the observed transition energies of the α-methylbenzyl (2.88 and 4.07 eV.) and 2, 4, 6-trimethylbenzyl (2.64 and 3.65 eV.) cations respectively.[5] The electron affinities of these parent ions were taken to be 7.43 eV. and 6.88 eV. respectively, by referring to the observed ionization potentials of the benzyl radical derivative[11] and methylbenzenes.[6,12,13]

Results and Discussion

Calculated Energy Levels and Wave Functions. —Calculations were performed, using the core resonance integral β as a parameter for each ion, by the aid of an electronic computer FACOM-202 in our institute. The calculated energy levels and wave functions are given in Fig. 2 and Table III, the cation I being taken as an example and the value of β_{CO} being taken to be equal to -2.0 eV., the optimal value for the energy level calculations.

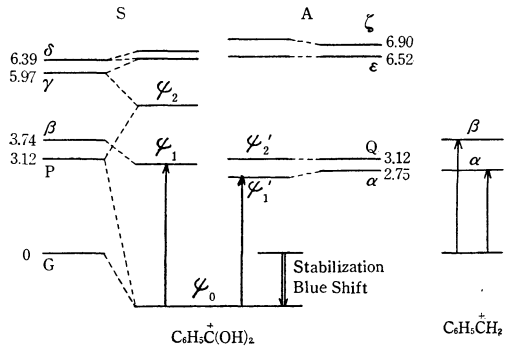


Fig. 2. Energy level diagram showing configuration interaction for the ion I.

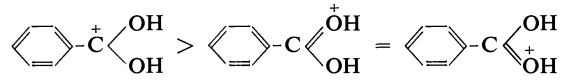
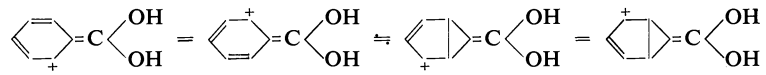
In order to obtain accurate experimental results on the absorption intensities, the ultraviolet absorption spectra of the ions I—IV in concentrated sulfuric acid were remeasured by the present authors, since most of the published data[14] for these ions have been concerned only with the location and peak intensity of the second longest wavelength band. Table IV summarizes the calculated and observed transition energies, ΔW, the calculated and observed oscillator strengths, f, the predicted directions of their transition moments, the half-widths of the second longest wavelength bands, $\nu_{1/2}$, the π-electronic stabilization energies due to the configuration interaction, ΔE, and the optimal β_{CO} values. The difficulty of the intensity calculation being kept in mind, it may be said that agreements between the calculated and observed values are good except for the oscillator strength of the $W_0 \rightarrow W_2$ transition of I.

11) A. G. Harrison, P. Kebarle and F. P. Lossing, *J. Am. Chem. Soc.*, **83**, 777 (1961).



12) It was assumed that the ionization potential of the α-methylbenzyl radical is nearly equal to that of the p-methylbenzyl radical (7.46 eV.).[11] Also, the difference between the ionization potentials of the 2, 4, 6-trimethylbenzyl radical and the benzyl radical was assumed to be equal to the difference between mesitylene (8.39 eV.)[6] and benzene (9.24 eV.)[6]. One methyl group substituted at these hydrocarbon species seems to be lower the ionization potential by about 0.3 eV.



13) Although the cations II, III and IV do not possess the C_{2v} symmetry properties, the secular equations for them were factorized into groups in the same manner as for the case of the cation I because of the nil value of the coefficient C_{31}. Therefore, the matrix elements other than the above-mentioned ones are equal to the corresponding elements for the case of I.

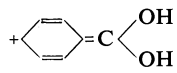
14) W. M. Schubert and R. E. Zahler, *J. Am. Chem. Soc.*, **76**, 1 (1954); R. Stewart and K. Yates, ibid., **80**, 6355 (1958); K. Yates and R. Stewart, *Can. J. Chem.*, **37**, 664 (1959).

Charge Densities and Stabilization Energies. —From the wave functions given in Table III, the π-electronic charge densities for the ground and two excited states of I were calculated as shown in Fig. 3, which also shows those of the ground state of the benzyl cation for purposes of comparison. The result on the protonated benzoic acid may be translated roughly into the valence bond method description as follows:

State — The degree of contribution of each resonance structure

Ground state (W_0) 

Excited state (W_1') 



Excited state (W_1)

a) The oscillator strengths were calculated by the following equations:

$f_{calcd}=4.704\times10^{-7}\tilde{\nu}Q^2$ ($\tilde{\nu}$ in cm^{-1}, Q in Debye)

$f_{obs}=4.32\times10^{-9}\int\varepsilon d\tilde{\nu}$ ($\tilde{\nu}$ in cm^{-1}, ε in $l.\cdot cm^{-1}\cdot mol^{-1}$)

b) Directions of the calculated transition moments (with respect to the long axis of the molecule).

c) All the observed values were obtained by the present authors.

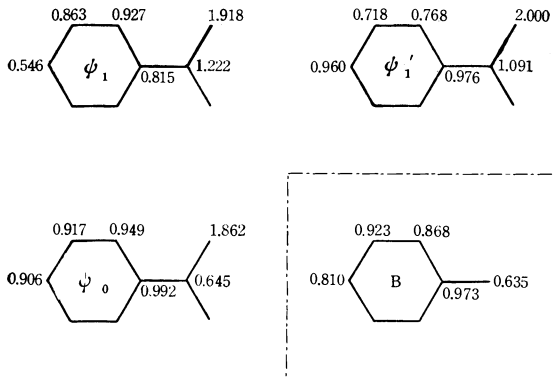

Fig. 3. π-Electronic charge-densities of the various states of the benzoic acidium ion (ψ_0, ψ_1', ψ_1) and of the ground state of the benzyl cation (**B**).

The π-electronic densities of the ground and excited states of the other ions are not very different from the corresponding values of I.

The stabilization energy, ΔE, due to delocalization of π-electrons amounts to 1.75 eV. for I, as is shown in Table IV. Most of this stabilization energy is brought about by the contribution of the charge-transfer configuration, ψ_P. Of the four ions concerned here, I is the most stable. According to our experiments, the ultraviolet absorption spectrum of benzoic acid in concentrated sulfuric acid does not change appreciably for more than ten days, while a gradual change is observed for the other ions. It may be expected that the hydroxyl groups stabilize the benzyl cation to some extent by their conjugation and steric hindrance effects. A similar stabilization effect is also found with the methyl group; the benzyl cation can not be stably produced under the usual conditions, while α- and/or ortho-methyl-substituted benzyl cations are stable enough for spectroscopic detection[15] because of the hyperconjugative and steric potencies of the methyl group.

The Shift of Bands of the Benzyl Cation by the Substitution.—The benzyl cation is characterized by its reddish color, while II is yellow and I is colorless, and their stabilities increase in just this order. These inclinations through less prominent, are also found for the α-methylated benzyl cations, which may be regarded as one of the most typical examples predictable of the unequivocal effect of hyperconjugation in ionic species.[5,15] The energy level diagram in Fig. 2 shows that the substitution of an electron donating group at the α-carbon atom of the benzyl cation, through the charge-transfer configuration, ψ_P, not only stabilizes the ion but also shifts the β-band ($\psi_G \rightarrow \psi_\beta$ transition) of the benzyl cation to blue. This is because the mixing of the charge-transfer configuration with the ground configuration, ψ_G, considerably lowers its energy, while the energy of the lowest excited configuration, ψ_β or ψ_P which had the same symmetry property as ψ_G, is little affected. Furthermore, because of the nil value of the coefficient C_{31}, α-substitution has no effect on the ψ_α configuration but makes the α-band ($\psi_G \rightarrow \psi_\alpha$ transition band) of the benzyl cation also shift to blue. On the other hand, as may be seen from the results of II and IV, the substitution of an electron-donating group at the benzene ring carbon atom (especially at the *o*- or *p*-position) is found to shift these characteristic bands to red. This phenomenon can be explained as resulting from the lowering of the ψ_α and ψ_β levels by the charge delocalization.

For the other ions the substitution effects on the absorption spectra are almost the same as those for I except for the second longest wavelength band. Because they have only one hydroxyl group, those ions have no ψ_Q configuration; therefore, unlike I, their second longest wavelength bands are not doubly degenerated. The observed half-widths of the second lowest bands seem to support this interpretation (see Table IV).

Charge-Transfer Complexes of Trinitrobenzene with Tetramethyl-p-phenylenediamine and p-Dimethoxybenzene

By Suehiro IWATA, Hiroshi TSUBOMURA* and Saburo NAGAKURA

(Received May 19, 1964)

Charge-transfer molecular complexes[1] between 1, 3, 5-trinitrobenzene (abbreviated hereafter to TNB) and some donor molecules have been studied very extensively.[2] For example, Foster and Thomson reported that the tetramethyl-*p*-phenylenediamine - TNB complex shows the charge-transfer absorption at 614 mμ in acetonitrile and at 583 mμ in cyclohexane, and that this complex is dissociated into ions in water and methanol.[3] Thus far, however, no quantitative consideration of the equilibrium constants and the heats of formation of this complex has been made.

In the present paper spectroscopic studies have been carried out with tetramethyl-*p*-phenylenediamine - TNB and *p*-dimethoxybenzene - TNB complexes, and the equilibrium constant and the heat of formation have been determined. Consequently, it has been found that the tetramethyl-*p*-phenylenediamine complex has the largest heat of formation and the longest wavelength charge-transfer absorption band among the TNB complexs studied so far.

Experimental

Materials. — TNB and *p*-dimethoxybenzene were purified by recrystallizing them from ethanol; their melting points were 120°C and 54.5°C, respectively. Tetramethyl-*p*-phenylenediamine (abbreviated hereafter to TMPD) was obtained by neutralizing its hydrochloride, and it was purified by vacuum sublimation.

n-Heptane was shaken with concentrated sulfuric acid, then washed with water, dried with calcium chloride and thereafter with sodium, and finally fractionally distilled.

Measurements.—A Cary recording spectrophotometer, model 14, was used for the measurements of the ultraviolet and visible absorption spectra. These spectra were measured by using cylindrical cells of 10 cm. light path length made of fused silica. The donor and the acceptor solutions, which were separately prepared, were mixed with each other just before the absorption measurements. For the experiments of the temperature dependence of the absorption intensity, we used a cell box with a heater, controlling the temperature with a thermister.

Results and Discussion

TMPD-TNB Complex.—The mixed solution of TMPD with TNB was violet. The absorption spectrum of this colored solution is shown in Fig. 1. The absorption maximum appears at 620 mμ (2.0 eV.). This absorption band may be thought to be Mulliken's charge-transfer band characteristic of the 1 : 1 molecular complex between TMPD as an electron donor and TNB as an electron acceptor. In order to make sure of this point and to evaluate the equilibrium constant for this system, Benesi-Hidebrand's equation[4] was applied.

Since, in the present experiments, the concentration of TMPD was much larger than that of TNB,[5] Benesi-Hildebrand's equation is applicable:

$$\frac{1}{\varepsilon^*}=\frac{C_a l}{D}=\frac{1}{K\varepsilon}\frac{1}{C_d}+\frac{1}{\varepsilon} \qquad (1)$$

where C_a and C_d are the initial concentrations

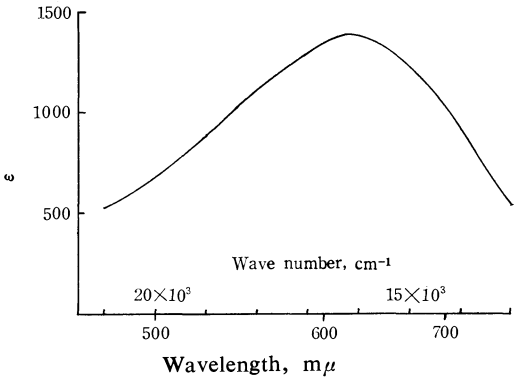

Fig. 1. The visible absorption spectrum of the molecular complex between TMPD and TNB in *n*-heptane (at 30°C).

4) H. A. Benesi and J. H. Hildebrand, *J. Am. Chem. Soc.*, **71**, 2703 (1949).

5) The initial concentrations of TNB and TMPD actually taken in the present experiment are $2.81\sim2.99\times10^{-4}$ mol./l. and $5\sim20\times10^{-3}$ mol./l. respectively.

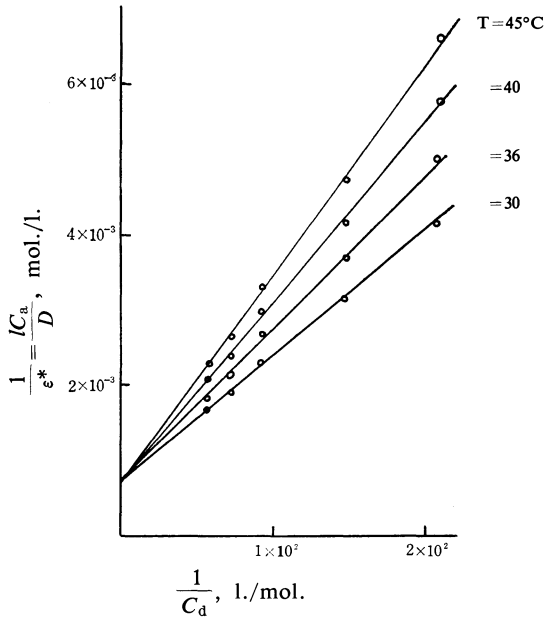

Fig. 2. Benesi-Hildebrand's plots for the TMPD-TNB system in *n*-heptane at various temperatures. Optical densities are measured at 620 mμ.

of the electron donor and acceptor respectively; K, the equilibrium constant for the 1 : 1 complex formation; D, the absorbancy; ε, the molar extinction coefficient, and l, the light path length of the cell. As may be seen in Fig. 2, a straight-line relationship is completely satisfied between $1/\varepsilon^*$ and $1/C_d$. This means that the 1 : 1 charge-transfer complex is formed between TMPD and TNB and that the charge-transfer band characteristic of the complex appears at 620 mμ. From the straight line obtained by the least-squares method, the equilibrium constant for the complex formation and the molar extinction coefficient of the charge-transfer band were determined by following the usual method.[4] The results obtained at 600, 620 and 640 mμ are given in Table I.[6]

Using the equilibrium constants at various temperatures given in Table I, we evaluated the heat of formation (ΔH) and the entropy change (ΔS) by the usual method.[7] The evaluated values are as follows:

$$\Delta H = -7.9 \text{ kcal./mol.} \qquad \Delta S = -18 \text{ e. u.}$$

These ΔH and ΔS values were the greatest of

Table I. The equilibrium constant (K in l./mol.) and the molar extinction coefficient (ε) of the TMPD-TNB complex evaluated at 600, 620 and 640 mμ

Temp. °C	K_{620}	K_{600}	K_{600}	Averaged	ε_{620}
30	44.4	42.8	44.4	43.9	1370
36	37.1	36.8	36.7	36.9	1340
40	29.3	30.0	29.2	29.5	1440
45	23.7	23.8	23.9	23.8	1520

the known TNB molecular complexes. This seems to be closely related with the fact that the TMPD-TNB complex has a smaller transition energy of the charge-transfer band ($h\nu_{CT}$ =2.0 eV.) than do the other TNB complexes.

Briegleb et al.[8] obtained the empirical formula of the relation between the ionization potentials (I) of the donor molecules and the transition energies of the charge-transfer bands ($h\nu_{CT}$) of TNB complexes:

$$h\nu_{CT} = I - 5.00 + \frac{0.70}{I - 5.00} \qquad (3)$$

From this relation and the observed $h\nu_{CT}$ value, the ionization potential of TMPD (I_{TMPD}) is evaluated to be 6.55 eV. A similar formula concerning chloranil complexes[8] leads to the I_{TMPD} value of 6.62 eV. It should be noticed that these two I_{TMPD} values are consistent with each other. Thus, it is concluded that TMPD has a small ionization potential and that in these two TMPD complexes the dative structure contributes largely to the ground state. This is related with the fact that TMPD complexes have a tendency to dissociate into ions in such polar solvents as methanol and acetonitrile.[3,9]

p-Dimethoxybenzene - TNB Complex. — The color of the mixed solution of *p*-dimethoxybenzene with TNB was yellow. The absorption spectrum ot this solution is given in

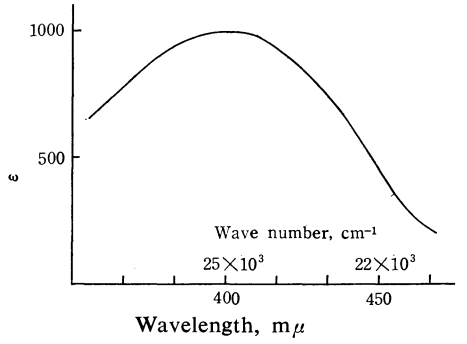

Fig. 3. The visible absorption spectrum of the molecular complex between *p*-dimethoxybenzene and TNB in *n*-heptane (at 22°C).

6) When, in the place of Eq. 1, the more precise Eq. 2 was used:

$$\frac{C_d}{\varepsilon^*} = \frac{lC_aC_d}{D} = \frac{1}{\varepsilon K} + \frac{1}{\varepsilon}(C_d + C_a) \qquad (2)$$

K=43.9 l./mol. and ε=1370 (at 620 mμ and 30°C) were obtained. These values are consistent with the corresponding values obtained by Eq. 1.

7) S. Nagakura, *J. Am. Chem. Soc.*, **80**, 520 (1958).

8) Chapter VI of Ref. 2.

9) W. Liptay, G. Briegleb and K. Schidler, *Z. Elektrochem.*, **66**, 331 (1962).

Fig. 3. The absorption band characteristic of the charge-transfer interaction between *p*-dimethoxybenzene and TNB appears at 400 mμ. By applying Eq. 1 to the absorbancy values measured at 420 mμ,[10] the equilibrium constant and the molar extinction coefficient were evaluated. The results are given in Table II.

From the temperature dependence of the equilibrium constants given in Table II, the heat of formation (ΔH) and the entropy change (ΔS) for the complex formation can be determined as follows:

$$\Delta H = -3.2 \text{ kcal./mol.}$$

$$\Delta S = -4.2 \text{ e. u.}$$

Furthermore, the molar extinction coefficient at the peak wavelength of the charge-transfer band could be evaluated as ~1000 by the aid of the equilibrium constant value obtained at 22°C.

TABLE II. THE EQUILIBRIUM CONSTANT (K) OF THE *p*-DIMETHOXYBENZENE-TEB COMPLEX EVALUATED AT 420 mμ

Temp., °C	19	22	25	28	31	36	40
K, l./mol.	3.5	3.3	3.1	2.9	2.8	2.5	2.3

By applying Eq. 3 to the peak wavelength of the charge-transfer band for the complex between *p*-dimethoxybenzene and TNB, the ionization potential of *p*-dimethoxybenzene could be obtained as 7.9 eV. This value is reasonable in view of the fact that the ionization potential of anisole has been determined as 8.2 eV. from the photoionization experiment of Watanabe.[11]

The Institute for Solid State Physics
The University of Tokyo
Azabu, Tokyo

10) The absorption maximum of the charge-transfer band is 400 mμ. In this wavelength region, however, there is a superposition of absorption due to TNB itself, so equilibrium constants are calculated by using the optical density at 420 mμ.

Ammonia-Synthesis Iron Catalysts Containing Magnesia as Their Principal Promoter. II. The Texture and Structure of the Catalysts[1]

By Hiroshi UCHIDA, Iwao TERAO,[2] Kiyoshi OGAWA and Masaaki OBA

(Received May 11, 1964)

The preceding paper[3] discussed the performances of the catalysts which were promoted singly by magnesia and doubly or triply by other oxides besides magnesia. The roles played by the individual promoters were discussed in terms of their effects on the specific activity per unit of specific surface area and on the extent of the specific surface area. The present investigation has been made to obtain a comprehensive picture of the texture and structure of these catalysts and to attain a further understanding of the effects of individual promoters on the catalyst performances from the structural point of view.

Experimental

The catalysts investigated were an unpromoted catalyst (cat. M-O), a couple of singly-promoted catalysts with different magnesia contents (cats. M-1 and -2), three doubly-promoted catalysts containing potash, lime, and silica as the respective second promoters (cats. M-3, -4 and -5, respectively), and two triply-promoted catalysts containing different amounts of magnesia but with fixed amounts of potash and silica (cats. M-7 and -8). For the sake of comparison, one of the catalysts of the alumina-promoted type (cat. A-102) was also investigated. Their promoter-compositions are illustrated in Table I.

The preceding paper[3] presented data on the bed density and the specific surface area of the samples after their use in the synthesis run. In the present study, the total pore volume, the average diameters of pores and particles, the fraction of the surface occupied by free iron, and so forth, all concerning the samples drawn from the same sources, have been determined. The total pore volume, V_{po} (cc./g.), was calculated from the difference between the volumes by the mercury and helium displacement methods, i. e., $V_{po}=V_{Hg}-V_{He}$. The bulk density of the catalyst granule, ρ_b(g./cc.), was given by a reciprocal of V_{Hg}, while the true density of the catalyst material, ρ_t(g./cc.), was given by a reciprocal of V_{He}. The catalyst porosity, or the void

fraction of a catalyst granule, was available from V_{po}/V_{Hg}. On the assumption of open-end cylindrical pores, the average pore diameter, $\bar{d}_{po}$ (cm.), was computed from the equation $\bar{d}_{po}=4V_{po}/S$, while, on the assumption that the catalyst granule consists of a loose packing of spherical or cubic particles, the average particle diameter, d_{pa}, was computed from the equation $\bar{d}_{pa}=6/(S\rho_t)$. In the above equations, S ($cm^2/g.$) stands for the specific surface area. Following the method of Emmett and Brunauer,[4] the fraction of surface occupied by free iron was expressed by the ratio of the carbon monoxide volume which was chemisorbed at −78°C, V_{CO}, to the nitrogen volume which formed a monolayer over the entire surface, V_m. The adsorption measurements were conducted by a conventional volumetric method. V_{CO} was determined from the difference between the total carbon monoxide adsorption at −196°C and the subsequent adsorption at this temperature after evaculation at −78°C, while V_m was determined by means of the BET equation applied to the nitrogen adsorption isotherm at −196°C.

In order to obtain additional information on the catalyst texture, the catalysts were examined by optical and electron microscopy. The oxide catalyst samples were polished on one surface by ordinary methods, finishing with a final buffing of soft cloth with wet alumina; they were then observed under an optical microscope before and after etching with hydrochloric acid. In some particular cases, the etched samples were reduced with hydrogn at temperatures between 380 and 500°C in a cell attached to a high-temperature microscope, and the structural changes in the surface with time of reduction were observed under a microscope. The hydrogen flow rate was approximately 5 l./hr. Electron microscopic observations were made by a JEM-6A electron microscope on replicas of the etched surfaces shadowed with chromium-carbon and also on finely ground powders of the catalyst samples before and after their use in the synthesis run. The samples were ground in castor oil.

X-Ray diffraction patterns were taken on powdered samples less than 200 mesh in size as well as on the samples after their use in the synthesis run, by means of a Geigerflex D-3F X-ray diffractometer. Fe $K\alpha$ radiation from a sealed-off X-ray tube equipped with berylium windows and with a manganese dioxide filter was used at 30 kV. and 7.5 mamp.

Results and Discussion

The Texture of Catalysts after Use in the Synthesis Run. — Table I summarizes the data on the mercury volume, mercury and helium densities, pore volume, porosity, average pore diameter, the fraction of the surface occupied by free iron, and the specific surface area. The comparison between the mercury volumes of cat. M-O and cat. M-1 shows that magnesia alone is already effective in preventing the catalyst granules from shrinking during the reduction process and subsequent synthesis run. The porosity values of the promoted catalysts fall in a narrow range from 0.43 to 0.50, all values being higher than the 0.36 of cat. M-O. In view of the fact cat. M-3 gives a higher porosity than cat. M-O, it is likely that the individual granule of the former catalyst consists of particles more loosely packed than those of the latter in spite of nearly the same extent of the specific surface area. In fact the average pore diameter is twice as large as that of cat. M-O. With regards to other catalysts, the average pore size depends mainly on the extent of the specific surface area, since their pore volumes are within the narrow range. The effects on the particle size of the addition of promoters will be described later in connection with the effects on the crystallite dimension.

The fraction of the surface occupied by the free iron of catalysts of the magnesia-promoted type, including the catalyst singly promoted by magnesia, is always small; this result is similar to that with catalysts of the alumina-promoted type. The result is, however, opposite to that of Kobosev et al.,[5] who stated that magnesia was entirely surface-inactive in the

TABLE II. LATTICE CONSTANT OF OXIDE CATALYST (a), CRYSTALLITE WIDTH OF REDUCED CATALYST (D), AND AVERAGE PARTICLE DIAMETER ($\bar{d}$)

Catalyst	M-O	M-1	M-2	M-3	M-4	M-5	M-7	M-8	A-102
a, Å	8.396	8.395	8.395	8.393	8.402	8.393	8.396	8.393	8.391
D, Å	560	300	310	640	280	250	300	290	390
$\bar{d}$, Å	6760	2640	1530	7950	1760	730	1790	920	1220

course of the reduction of an iron oxide. One explanation of these apparently different results may be that magnesia is surface-inactive in the earlier reduction stage, where the iron particles poduced by reduction remain extremely small in size, but that magnesia is apt to accumulate on the surface with the particle growth. This explanation is not contradictory to the facts that the reduction of cat. M-1 in the earlier stage takes place at a rate nearly as fast as the reduction of a pure magnetite, but that the last traces of oxygen can be removed only with difficulty.[3] The other promoters besides magnesia play scarcely any significant role in the change in the fraction; e. g., the fraction of cat. M-4 is of almost the same extent as that of cat. M-2.[6]

The Crystal Structure of the Catalysts before and after Use in the Synthesis Run.—The lattice constants of oxide catalysts were calculated on the basis of the α_1-line from the (553) or (731) plane of Fe_3O_4, the Bragg angle of which could be measured with a reasonable accuracy. The results are summarized in Table II. The addition of magnesia does not cause any changes in the lattice constant of a pure magnetite. This is quite different from the finding with the alumina addition by Westrik,[8] who pointed out that the lattice constant appears to decrease linearly with the ratio $Al^{3+}/(Fe^{3+}+Al^{3+})$ and who concluded that alumina is dissolved in the magnetite lattice. The linear relationship just referred to, on the other hand, can be interpreted in terms of the Vegard equation of $a=a_1M_1+a_2M_2$, where a is the lattice constant of the promoted catalyst, a_1 and a_2 are the lattice constants of Fe_3O_4 and Al_2FeO_4 spinel respectively, and M_1 and M_2 are the respective contents in mole fraction. Accordingly, Al_2O_3 and FeO in Fe_3O_4 combine to form the Al_2FeO_4 spinel, and the resulting spinel is in a solid solution with Fe_3O_4. If an identical mechanism is applied to the addition of magnesia, the lattice constant of cat. M-1 or cat. M-2 is expected to decrease with the magnesia content because the lattice constant of the $MgFe_2O_4$ spinel ($a=8.36$ Å) is smaller than that of pure magnetite. It is more likely, according to Goldschmidt,[9] that the Mg^{2+} ions cannot enter the lattice as substituents of the Fe^{2+} ions but that they can occupy the empty interstices in the magnetite lattice. Cat. M-4 gives the larger lattice constant, as can be expected from the larger size of Ca^{2+} ions.

From the broadening of the X-ray diffraction lines, which can be almost entirely accounted for by the occurrence of small crystallites,[10] the crystallite width of the samples after the synthesis run was calculated by means of the Scherrer formula: $D=C\lambda/B\cos\theta$. In this formula, D is the crystallite width, λ is the wave length of an X-ray radiation (1.937 Å for the Fe-K line), B is the true half-breadth (angular) of the diffraction line, θ is the Bragg angle, and C is 0.9. The graphs given by Jones[11] were used to make correction for the $\alpha_1\alpha_2$-doublet and to evaluate the true diffraction breadth on the basis of the experimental data. The calculations were made on the basis of the line from the (110) plane. The results are compared in Table II with those on the average particle diameter.

Apart from the results concerning cat. M-3, the crystallite widths of the catalysts of the magnesia-promoted type fall in a narrow range between 250 and 310 Å, whereas the average particle sizes of these catalysts fall in a far wider range from 700 to 2600 Å (cf. Table II). These facts indicate that the individual particles of these catalysts consist of from about 10 to several hundred crystallites and that the particle size is more strongly dependent on the promoter-composition than is the crystallite width. It is worthwhile to notice that not only the individual particles of cat. M-O but also those of cat. M-3 consist of more than 1000 crystallites. The comparison of the crystallite width and the particle size of cat. M-O with the respective values of cat. M-1 clearly

6) In connection with this finding, we want to call attention to the results of Hall et al.[7] who measured on this kind of catalyst the changes in the specific surface area and in the carbon monoxide chemisorption with the reduction progress in a hydrogen flow at atmospheric pressure and found a much higher value of the fraction after the complete reduction. The disagreement may perhaps be due to the different treatments to which the catalyst samples have been submitted.

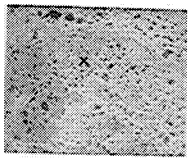
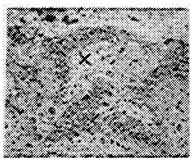
shows that the addition of magnesia largely contributes to a retardation of the growth of crystallites and particles, though not so much as does alumina (as for the particle growth, cf. Ref. 12), during the periods of reduction and synthesis. The effect is considerably pronounced when silica is added as the second promoter, but it is cancelled out in the presence of potash. Lime added as the second promoter scarcely affects the growth.

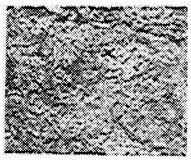
It is generally accepted[13] that the iron crystallites and particles probably unite quite easily to grow in size whenever they come in contact wihthout a barrier of promoter oxides. Marked growth, however, does not always take place because there is an interfacial layer of promoter oxides, as in the case of cat. M-3. Accordingly, the interfacial oxide layer capable of retarding the particle growth requires certain characteristics as regards the melting point of the oxide material; the crystallites are apt to combine more easily when the interfacial layer contains potash, which has a lower melting point than magnesia. The relatively small particle sizes of the triply-promoted catalysts, cats. M-6 and -8, are probably due to the fact (cf. Ref. 14) that silica acts to keep potash within the particles; as a consequence, the small fraction of potash coverage is established.



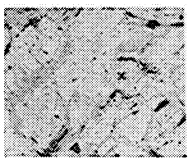
In view of the above picture of the catalysts, one might expect, at first glance, a lower specific activity per unit of the surface area, k' (atm.$^{0.5}$ ml./hr. m^2), with a larger size of the particles, for the particle growth is accompanied by the formation of crystallographic planes more closely packed than the (111) α-iron plane, whose specific activity is higher than that of any other planes. However, the situation is sometimes reversed; e. g., k' at 400°C of cat. M-3 (2.10×10^2), with a large particle size, is higher than that (2.4×10) of cat. M-5, with a much smaller particle size[3].



Microscopic and Electron Microscopic Structures of the Oxide Catalysts. — One can make easily finish the polishing of the catalysts of the magnesia-promoted type than those of the alumina-promoted type.[15] Photographs 1, 4 and 7 show the respective optical micrographs of the polished surfaces of cats. M-1, A-102 and M-7, while Phots. 2 and 5 show those after the etching of M-1 and A-102 catalysts. As is evident from the microphotographs, cats. M-1 and -7 of the magnesia-promoted type possess a larger number of holes and cavities than cat. A-102 of the alumina-promoted type, being more porous in structure. A close examination of Phots. 1 and 2 of cat. M-1 reveals that the etched figures are apt to appear in the region which is light gray on the polished surface. The etched figure appears to be a hill-and-valley structure on an electron micrograph (Phot. 8). Magnesia may be more concentrated in the light gray region, and it may give rise to the etching or the faster dissolution of the oxide material. In contrast, cat. A-102 gives an etched figure characterized by a mosaic structure of well-developed grains, across which a number of clear-cuts run in parallel (Phot. 5), and the individual grains consist btoh of a great many plate-shaped subgrains and a few single crystallites of the octahedral type (Phots. 9 and 10). Additional information on the shape of subgrains can be obtained from the respective electron micrographs (Phots. 11 and 12) taken of the finely ground powders of cats. M-1 and A-102. The powders from cat. M-1 are massive and irregular in shape, whereas the great majority of powders from cat. A-102 are plate-shaped. Cat. M-7 gives a polished surface which includes more pores and after the etching, shows grains of an irregular shape surrounded by narrow cracks. This catalyst gives both the plate-shaped and massive powders.[16]



The Change in the Structure of the Catalysts with the Progress of the Reduction.—In connection with our previous finding[3] that the reduction of the catalysts of the magnesia-promoted type in a current of synthesis gas at a high pressure proceeds more rapidly than that of cat. A-102 of the alumina-promoted type, the change in the surface of the etched samples with the progress of reduction was pursued for each catalyst under a high-temperature microscope. The rusults are exemplified in Phots. 3 and 6 for cats. M-1 and A-102 respectively.



As for cat. A-102, reduction takes place along the grain boundaries and sub-boundaries to result in the deeper grooves; hence, the reduction on the individual grains with only a few sub-boundaries proceeds at a very slow rate, probably because of the rapid accumulation of alumina on these surfaces. In contrast to this, the reduction of cat. M-1 starts at a great many domains scattered rather homogeneously over the whole surface, and a large number of small pores and narrow cracks appear before the reduction penetrates through the wall surfaces of the pores as well as of

the cracks into the interior. In this way, the reduction of cat. M-1 in the earlier stage proceeds more rapidly than that of cat. A-102. This finding gives additional support to Kobosev's view that magnesia is ineffective in retarding the reduction rate. Nevertheless, one must keep in mind the fact that magnesia acts as an effective stabilizer for the catalysts.

The Electon-microscopic Structure of the Catalysts after the Synthesis Run. — Electron microscopic investigations of the ammonia synthesis iron catalysts have been made by McCarty and Anderson[17] and more recently by Schaefer[18]. Their results are of much interest, because they gave us a direct concept of the catalyst structure. However, their results refer mainly to the pore structure of the catalysts after reduction under rather mild conditions at atmospheric pressure; they do not permit a detailed consideration of the particle structure of the catalysts in use at a high pressure. The present observations, therefore, have been made on finely ground powders from the catalyst samples after ammonia synthesis.[19]

The results are exemplified in Phots. 13 and 14 for cats. M-1 and A-102 respectively, revealing that the powders from cat. M-1 are massive and irregular in shape, whereas the powders from cat. A-102 are mainly thin-plated. The photographs, when compare with the corresponding photographs of the oxide catalysts (Phots. 11 and 12), indicate that the subparticles after the synthesis run can still retain their original shape. This finding seems to support the view of Westrik and

Zwietering[20] that both the habit and the orientation of the iron formed are very strongly affected by the oxide from which it has originated. For the plate-shaped subparticles, a thickness of 410 Å is calculated by means of the $\bar{d}_{pa}=2/\rho_t S$[21] formula, a value which is in good agreement with the crystallite width of 390 Å computed from the X-ray line broadening.

A highly active catalyst is usually furnished with both a moderately large specific surface area and a high specific activity per unit of the surface area.[22] However, the high specific activity is sometimes accompanied by a small extent of the specific surface area, and vice versa. In this connection, the above-mentioned finding suggests that a structure of the raw catalyst such as that revealed by the photographs of highly active cat. A-102 is favorable for establishing a large extent of the specific surface area of the high specific activity. The optical and electron microscopy of the catalysts may thus provide a convenient means for us to search for promoter-compositions which would be able to produce high-activity of catalysts.

Summary

This paper has presented data on such textures as the specific surface area, the pore volume, the average diameter of particles and pores, the fraction of the surface occupied by free iron and so forth, and on such structures as the lattice constant in the oxidic state and the crystallite width after the synthesis run of individual catalysts of the magnesia-promoted type, together with data on both a pure magnetite and a catalyst of the alumina-promoted type. It has also included the results of the examination of the catalysts by means of optical and electron microscopy.

Although the magnesia used as a promoter may be surface-inactive at the earlier stage of reduction, it tends at the later stage to cover the major portion of the particle surface and acts to retard the particle growth as well as the crystallite growth. The retarding effect on the growth is cancelled out when potash is added as the second promoter, but it is considerably pronounced in the presence of silica. Apart from the catalyst doubly promoted by magnesia and potash, the particle size of the promoted catalysts ranges from 700 to 2600 Å, but the crystallite widths lie in a far narrower range, between 250 to 390 Å. The specific activity per unit of the surface area is not always higher for the catalysts of the smaller particle sizes.

The lattice constant of a pure magnetite is not changed by the addition of magnesia, indicating that the Mg^{2+} ions occupy the empty interstices in the magnetite lattice.

The microscopic and electron-microscopic structures of the polished and etched surfaces of oxide catalysts of the magnesia-promoted type are very different from those of the alumina-promoted type. In view of the change in the microscopic structure of the surface with the reduction progress, an explanation in terms of the different reduction rates between the two types of catalysts is probable.

On the basis of the fact that the subparticles of the catalyst after the synthesis run still retain the original shape of the corresponding oxide catalyst, either plate-shaped or massive, the electron-microscopic as well as the microscopic observation of the polished and etched surface of the oxide catalyst can afford a means for predicting the promoter-composition which will produce a highly active catalyst.

21) On the assumption of plate-shaped subparticles, the thickness, $\bar{d}_{pa}$, is calculated from this formula.
22) Strictly speaking, the bed density should be taken into account, but it varies only a little among the catalysts under investigation.

On the Melting Temperature of Nucleic Acid in Solution

By Masamichi TSUBOI

(Received May 12, 1964)

Many natural and synthetic nucleic acids take doubly-stranded helical conformations in aqueous solutions at room temperature.[1] On raising the temperature of such a solution, a strand separation takes place, and the helical molecule turns to two single-stranded random coils. The process can be followed by the viscosity, the optical density (at 260 mμ), or the optical rotation measurement of the solution.[2] It is found that the transition occurs within a narrow temperature range. This transition is considered to be the "melting" of a one-dimensional "crystal." The temperature at the midpoint of the transition is denoted by T_m and may be called "the melting temperature." The melting temperature, T_m, of a nucleic acid in a solution varies according to the base composition of the nucleic acid, the salt concentration of the solution, and the pH of the solution. Some chemicals, such as caffeine,[3] spermine,[4] and actinomycin D,[5] when they are added to the solution, also affect the T_m value. This paper will present some discussion of these variations of T_m on the basis of a simple application of the mass action law to the strand-separation reaction.

Let us assume that, in a solution of a nucleic acid at a temperature in the vicinity of the melting temperature, there are only three kinds of molecules (see Fig. 1): the double-helix molecule (AB), and the two complementary single-stranded molecules (A and B), and that there is no molecule (such as C in Fig. 1) in which a half-way strand-separation takes place. This assumption is somewhat justified by the fact that in the CsCl density-gradient spectrum of partially heat-denatured deoxyribonucleic acid, no bands are observed corresponding to the molecules in which a half-way strand-separation takes place.[6]

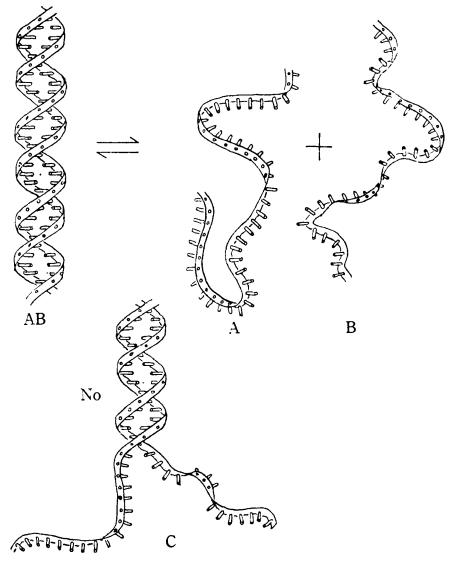

Fig. 1. A schematic representation of a transition of a doubly-stranded helix (AB) of a nucleic acid to two single-stranded random coils (A and B). The form C, where a half-way strand separation takes place, is not considered to exist.

Let us assume also that the melting of nucleic adid is essentially a reversible process, and that the irreversibility observed of deoxyribonucleic acid (DNA) is only an apparent one, an extremely long time being required for the complete "crystallization" (reformation of the perfect double-helix structure). This extremely low reaction rate is probably due to an extremely high activation entropy in the reformation reaction of DNA. As one can easily imagine, the chance is extremely low of any two complementary DNA chains to approach each other in such a way that the original proper base pairings can be reformed. The rate of double-helix reformation is quite high in a system where no such activation entropy is required. Thus, the melting of the double-helix molecule composed of 1:1 polydeoxyribothymidylic acid and polydeoxyriboadenylic acid, poly(dT+dA), was found to be completely reversible.[7] We have also observed

that, for the 1 : 1 complex of polyriboinosinic acid and polyribocytidylic acid, poly(I+C), the same optical density profile is obtained on heating and cooling.[8]

We can now consider that the "melting" problem is simply the problem of the dissociation equilibrium of the type:

$$AB \rightleftarrows A + B \qquad (1)$$

The equilibrium constant may be expressed as:

$$K=\frac{[A]\,[B]}{[AB]}=\frac{(1-f)^2}{f}a \qquad (2)$$

Here, f is the fraction of the double-helix molecules, and a is the total concentration of the nucleic acid in question. At the melting temperature, T_m, f equals[9] 1/2, and the equilibrium constant is given by:

$$K_m=\frac{1}{2}a \qquad (3)$$

The K_m is related to the enthalpy (ΔE) and the entropy (ΔS) of melting as:

$$-RT_m \ln K_m=\Delta E-T_m\Delta S \qquad (4)$$

1. The Guanine-Cytosine Content and Melting Temperature of DNA

The enthalpy of the melting of a deoxyribonucleic acid (DNA) may be given as:

$$\Delta E=n[\Delta\varepsilon_1 g+\Delta\varepsilon_2(1-g)] \qquad (5)$$

where $\Delta\varepsilon_1$ is the enthalpy of melting assigned to one cytosine-guanine bridge; $\Delta\varepsilon_2$, that assigned to one adenine-thymine bridge; g, the guanine plus cytosine content (GC content) of the DNA in question, and n, the mean number of bridges in the double-helix structure of the DNA in question. From Eqs. 3, 4 and 5, we obtain the relation:

$$g=\frac{\Delta S-R\ln 0.5a}{n(\Delta\varepsilon_1-\Delta\varepsilon_2)}T_m-\frac{\Delta\varepsilon_2}{\Delta\varepsilon_1-\Delta\varepsilon_2} \qquad (6)$$

If ΔS, $\Delta\varepsilon_1$, and $\Delta\varepsilon_2$ are assumed to be constants independent of T_m, then Eq. 6 shows that the melting temperature, T_m, should be a linear function of the GC content, g, of the DNA in question. This linear relation is just what was observed by Marmur and Doty.[10]* The straight lines obtained by them are reproduced in Fig. 2. The slope and intercept

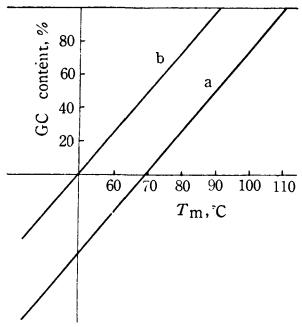

Fig. 2. Dependence of T_m on the guanine plus cytosine content of DNA.[10] The straight line a was obtained from the examination of the solution with 0.15 mol./l. NaCl plus 0.015 mol./l. Na-citrate, and the line b of the solution with 0.01 mol./l. PO_4 plus 0.001 mol./l. EDTA.

of the line for the solutions with 0.15 mol./l. sodium chloride are found to be respectively 1/42 and −8.1. Therefore, from Eq. 6, we obtain

$$\frac{\Delta S-R\ln 0.5\,a}{n(\Delta\varepsilon_1-\Delta\varepsilon_2)}=\frac{1}{42} \qquad (7)$$

and

$$\frac{\Delta\varepsilon_2}{\Delta\varepsilon_1-\Delta\varepsilon_2}=8.1 \qquad (8)$$

The 7 and 8 relations are given graphically in Figs. 3 and 4 respectively. At present the values of $\Delta\varepsilon_1$, $\Delta\varepsilon_2$, $\Delta\varepsilon_1-\Delta\varepsilon_2$, and $(\Delta S-R\times\ln 0.5\,a)/n$ are all unknown. However, if one

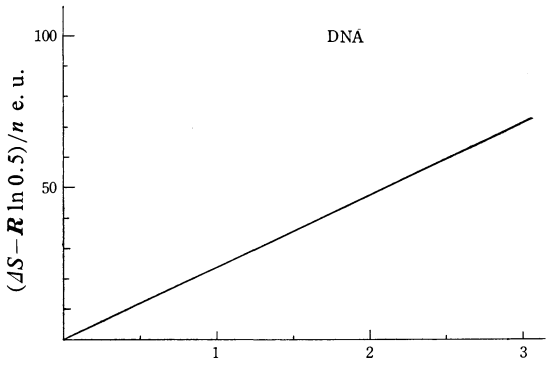

Fig. 3. Relation of $(\Delta S-R\ln 0.5\,a)/n$ and $\Delta\varepsilon_1-\Delta\varepsilon_2$ for DNA in the solution with 0.15 mol./l. NaCl plus 0.015 mol./l. Na-citrate.

9) It was pointed by J. Applequist (*J. Am. Chem. Soc.*, **83**, 3158 (1961)) that the hypochromism of nucleic acid at 260 mμ is not always proportional to f. Therefore, if the transition is followed by the measurement of the optical density at 260 mμ, the apparent midpoint of the transition does not always give the point where f=0.5. However, this does not seriously affect the present discussion, where T_m is required only as an operational quantity.
