* Here it should be mentioned that M. Ozawa, M. Tanaka and E. Teramoto (*J. Phys. Soc. Japan*, **18**, 551 (1963)) explained the linear relation between the T_m and the GC content of DNA on the basis of essentially the same idea as above but with a somewhat different expression—an experssion of statistical mechanics. The present writer's thermodynamic expression was first described at the 10th Nucleic Acid Symposium, Kanazawa, May, 1962.

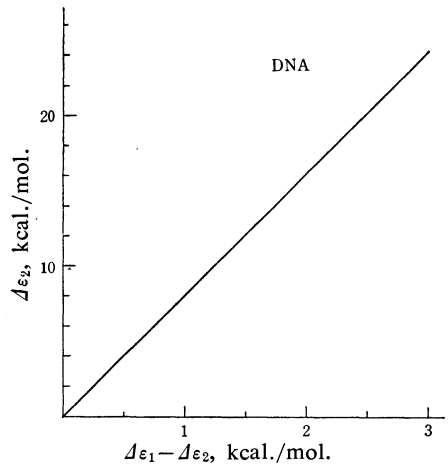

Fig. 4. Relation of $\Delta\varepsilon_2$ and $\Delta\varepsilon_1-\Delta\varepsilon_2$ for DNA in the solution with .0.15 mol./l. NaCl plus 0.015 mol./l. Na-citrate.

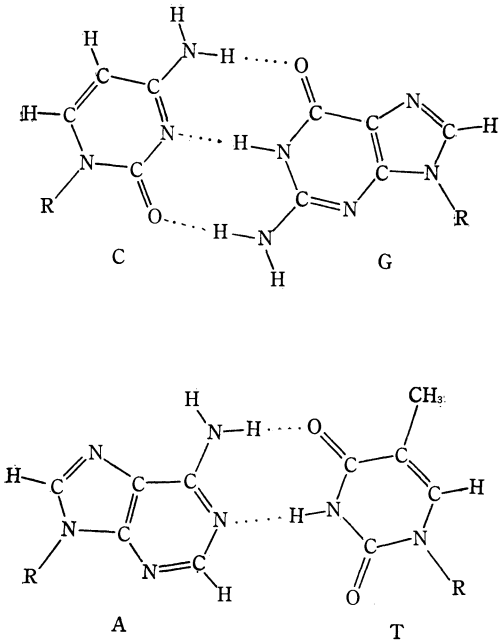

Fig. 5. Hydrogen bonds between cytosine (C) and guanine (G) residues and between adenine (A) and thymine (T) residues.[11]

of these values is fixed, all of these values can be determined by these relations. It has been pointed out[11] that, as is shown in Fig. 5, cytosine and guanine can form three hydrogen bonds, while adenine and thymine can form only two hydrogen bonds. If the stability of the helical conformation came solely from these hydrogen bonds, and if each of these hydrogen bonds made an equal contribution to the stability, $\Delta\varepsilon_2/(\Delta\varepsilon_1-\Delta\varepsilon_2)$ should be equal to 2. The actual value of 8.1 indicates that the third hydrogen bond in the cytosine-guanine bridge makes a relatively small contribution to the stability of the helix.

2. The Degree of Protonation and the Melting Temperature of Polyriboadenylic Acid

Polyriboadenylic acid (poly A) is known to form a two-stranded helical complex in its acidic solution.[12] It has been found that the melting temperature of this complex depends upon the degree of the protonation of the adenine residue. According to the experimental results obtained by Fresco and Klemperer,[12] the melting temperature is 90°C for a 0.88 degree of protonation (at pH 4.25) and 68°C for a 0.76 degree of protonation (at pH 4.86). At pH 4.25, the fraction (g_1) of the AH^+—AH^+ pair is about $0.88\times0.88=0.78$, the fraction (g_2) of the AH^+-A pair is about $0.88\times0.12=0.11$, and the fraction (g_3) of the A—A pair is about $0.12\times0.12=0.01$, where A and AH^+ indicate the adenine residue and protonated adenine residue respectively. At pH 4.86, the fraction (g_1) of the AH^+-AH^+ pair is about $0.76\times0.76=0.58$, the fraction (g_2) of the AH^+-A pair is about $0.76\times0.24=0.18$, and the fraction (g_3) of the A—A pair is about $0.24\times0.24=0.06$. Let the contribution of the AH^+-AH^+ pair to the helix stability be $\Delta\varepsilon_1$, that of the AH^+-A pair, $\Delta\varepsilon_2$, and that of the A—A pair, $\Delta\varepsilon_3$. Now we obtain the relation:

$$\Delta E=n(\Delta\varepsilon_1 g_1+\Delta\varepsilon_2 g_2+\Delta\varepsilon_3 g_3) \tag{9}$$

instead of Eq. 5, and the relation

$$g_1=\frac{\Delta S-\boldsymbol{R}\ln 0.5\,a}{n(\Delta\varepsilon_1-\Delta\varepsilon_2)}T_m-\frac{\Delta\varepsilon_2-(\Delta\varepsilon_2-\Delta\varepsilon_3)g_3}{\Delta\varepsilon_1-\Delta\varepsilon_2} \tag{10}$$

instead of Eq. 6. It is assumed that

$$\Delta\varepsilon_2-\Delta\varepsilon_3=\Delta\varepsilon_1-\Delta\varepsilon_2 \tag{11}$$

then Eq. 10 becomes

$$g_1-g_3=\frac{\Delta S-\boldsymbol{R}\ln 0.5\,a}{n(\Delta\varepsilon_1-\Delta\varepsilon_2)}T_m=\frac{\Delta\varepsilon_2}{\Delta\varepsilon_1-\Delta\varepsilon_2} \tag{12}$$

Thus we obtain

$$\frac{\Delta S-\boldsymbol{R}\ln 0.5\,a}{n(\Delta\varepsilon_1-\Delta\varepsilon_2)}=0.0114\ \text{deg}^{-1} \tag{13}$$

and

$$\Delta\varepsilon_2/(\Delta\varepsilon_1-\Delta\varepsilon_2)=3.4 \tag{14}$$

from the observed relation of g_1-g_3 and T_m (see Fig. 6). Therefore, it may be concluded that, very roughly, the AH^+-AH^+ pair gives $(3.4+1.0)/3.4=1.3$ times the contribution to

11) L. Pauling and R. Corey, *Arch. Biochem. Biophys.*, **65**, 164 (1956).

12) J. R. Fresco and E. Klamperer, *Ann. New York Acad. Sci.*, **81**, 730 (1959).

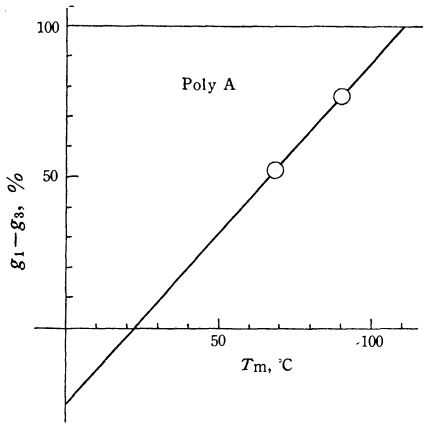

Fig. 6. T_m plotted against g_1-g_3 of poly A in the solution with 0.15 mol./l. NaCl.

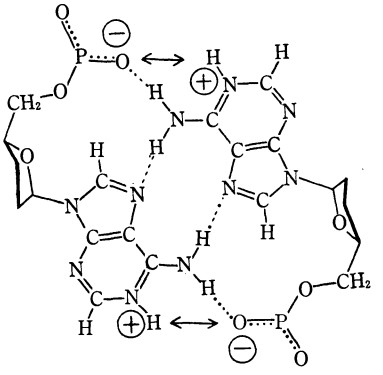

Fig. 7. Hydrogen bonds between two adenine residues.[13]

the helix stability given by the AH^+-A pair.

It has been pointed out[13] that two adenylic acid residues can form the four hydrogen bonds shown in Fig. 7, and that the additional stability of the protonated poly A may be attributed to an electrostatic force between the positively-charged $(N_1H)^+$ group of the protonated adenine residue in one of the two intertwined helices and the negatively-charged phosphate group in the other helix. The amount of this stability may be estimated from the difference between the pK values of poly A and adenosine. From the titration curve (at 25°C) of the poly A solution with 0.15 molal sodium chloride,[12] the pK of poly A may be estimated as about 5.5. On the other hand, Levene and Simms[14] reported the pK for adenosine to be 3.5. This means that protonated poly A needs more free energy for deprotonation than does protonated adenosine. The difference is:

$$(\boldsymbol{RT}/\log_{10} e)(5.5-3.5)=2.8 \text{ kcal./mol.}$$

where T is the absolute temperature of the solution and e is the base of the natural logarithm. This difference may be attributed mostly to the additional stability of the protonated poly A because of the above-mentioned electrostatic force. If we assume, on this basis, that

$$\Delta\varepsilon_1-\Delta\varepsilon_2=2.8 \text{ kcal./mol.}$$

then the values of $\Delta\varepsilon_1$, $\Delta\varepsilon_2$, $\Delta\varepsilon_3$, and $(\Delta S-\boldsymbol{R}\ln 0.5\,a)/n$ are calculated by Eqs. 11, 13, and 14 as follows:

$$\Delta\varepsilon_1=12.2 \text{ kcal./mol.}$$

$$\Delta\varepsilon_2=9.4 \text{ kcal./mol.}$$

$$\Delta\varepsilon_3=6.6 \text{ kcal./mol.}$$

$$(\Delta S-\boldsymbol{R}\ln 0.5\,a)/n=32 \text{ e.u.}$$

3. The Effect of Salt Concentration

The melting temperature of nucleic acid is greatly influenced by the ionic strength of the solution. Marmur and Doty[10] showed this to be the case for E. coli K-12 DNA heated in various concentrations of potassium chloride. It was found that, when the salt concentration is raised, the T_m goes up in the manner shown in Fig. 8.

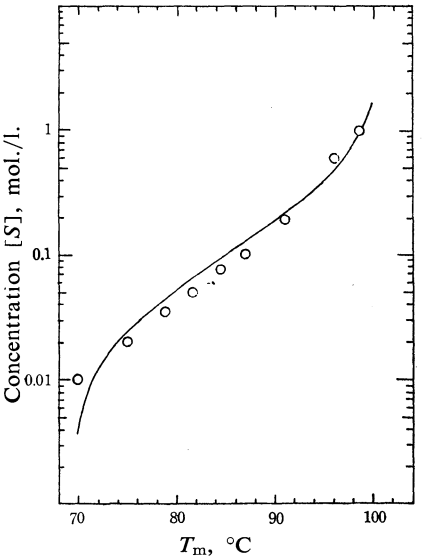

Fig. 8. T_m of E. coli K12 DNA plotted against the KCl concentration (in logarithmic scale) in the solution.

○: From the data given by Marmur and Doty.[10]

—: Theoretical curve on the assumption that $K'=10(\text{mol./l.})^{-1}$, $(\Delta S-\boldsymbol{R}\ln 0.5\,a)/\alpha N=0.0304 \text{ deg}^{-1}$, and $E_0/\alpha N=10.4$.

It would be expected that raising the salt concentration of the suspending medium would

13) A. Rich, D. R. Davies, F. H. C. Crick and J. D. Watson, *J. Mol. Biol.*, 3, 71 (1961).

14) P. A. Levene and H. S. Simms, *J. Biol. Chem.*, 65, 519 (1925).

produce a shielding of the repulsive forces of the charged phosphate groups of the DNA molecule, and that this would produce an additional stability of the helical form and, thus, a higher melting temperature. Let us assume that the shielding occurs through an adsorption of the cations by the DNA molecules at the PO_2^- groups, and that, for this adsorption, Klolz's equation,[15]

$$\frac{1}{r}=\frac{1}{K'N}\frac{1}{[S]}+\frac{1}{N} \qquad (15)$$

is valid. In Eq. 15, r is the average number of the cations in question adsorbed by one double-helical DNA molecule AB; N, the maximum number of the cations that can be adsorbed by one double-helical DNA molecule; $[S]$, the concentration of the cations free from the adsorption, and K', the equilibrium constant (at T_m) of each of the reactions:

$$\begin{aligned}&AB+S=AB\cdot S\\&AB\cdot S+S=AB\cdot S_2\\&AB\cdot S_2+S=AB\cdot S_3 \qquad (16)\end{aligned}$$

and

$$AB\cdot S_{N-1}+S=AB\cdot S_N$$

In the present case, ΔE in Eq. 4 may be given as

$$\Delta E=\Delta E_0+\alpha r \qquad (17)$$

where ΔE_0 is the enthalpy of the melting of DNA without cations, and α, the increase of ΔE caused by the adsorption of one cation. From Eqs. 4, 15 and 17, we obtain the relation,

$$(\Delta S-\boldsymbol{R}\ln 0.5a)T_m=\Delta E_0+\alpha NK'[S]/(1+K'[S]) \qquad (18)$$

The melting temperature of DNA is usually examined at a concentration of 20 μg./ml., i.e., about 6×10^{-5} mol. nucleotide per liter. In a solution with such a low concentration of DNA, the free cation concentration $[S]$ is practically equal to its total concentration ($10^{-2}\sim1$ mol./l.). Therefore, Eq. 18 is considered to give the T_m value as a function of the salt concentration ($\fallingdotseq[S]$). The equilibrium constant K' is a function of T_m, as

$$K'=\exp(\Delta S'/\boldsymbol{R})\exp(-\Delta E'/\boldsymbol{R}T_m) \qquad (19)$$

where $\Delta E'$ and $\Delta S'$ are, respectively, the enthalpy and the entropy of each of the reactions 16. If $\Delta E'$ is small, however, K' is practically constant over a small range of T_m (see Fig. 9). As will be mentioned below, this is actually the case for the adsorption of cations by the DNA molecules. It would be convenient to draw curves representing the relations between $[S]$ and $K'[S]/(1+K'[S])$ for various K' values, as in Fig. 10. The abscissa $K'[S]/(1+K'[S])$ should have a linear relation with the T_m in question, since, from Eq. 18,

$$K'[S]/(1+K'[S])=[(\Delta S-\boldsymbol{R}\ln 0.5a)/\alpha N]T_m-\Delta E_0/\alpha N \qquad (19)$$

A comparison of Fig. 8 and Fig. 10 shows that the observed effect of the KCl concentration of the T_m of DNA can be well explained by what has been presented and by assuming that

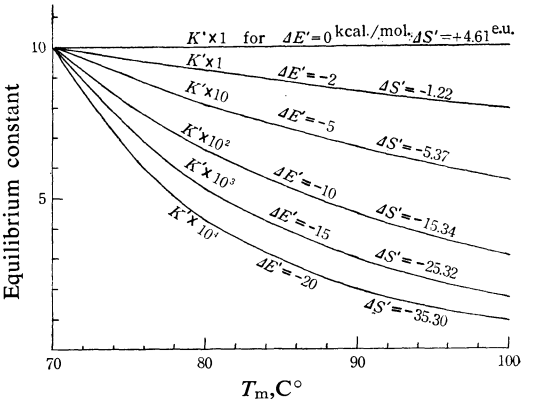

Fig. 9. Equilibrium constant K' plotted against the temperature in question (T_m). $\Delta E'$ and $\Delta S'$ are the enthalpy and entropy of the reaction in question (see Eq. 19 in the text).

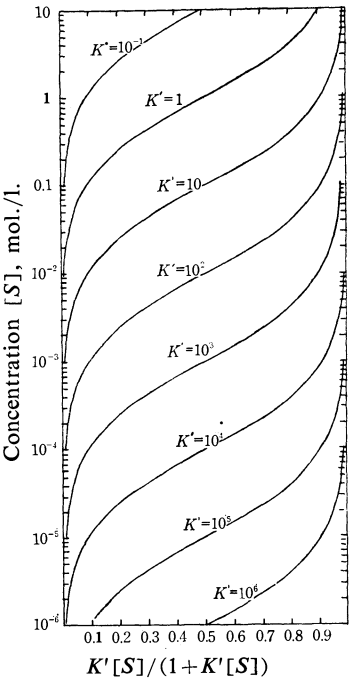

Fig. 10. Relations between $[S]$ (in logalithmic scale) and $K'[S]/(1+K'[S])$ for various K' values.

15) I. M. Klotz, "Protein Interactions" in H. Neurath and K. Bailey (ed.), "The Proteins," Academic Press, New York (1953).

$K'=10$ (mol./l.)$^{-1}$

$(\Delta S-\boldsymbol{R}\ln 0.5\,a)/\alpha N=0.0304$ deg^{-1}

and

$\Delta E_0/\alpha N=10.4$

It may be pointed out here that straight lines of T_m vs. GC-content observed by Marmur and Doty[10] at different salt concentrations are almost parallel to each other (see Fig. 2). The lines have the same slope but different intercepts. On the basis of Eq. 6, this means that, at different salt concentrations, the values of $(\Delta S-\boldsymbol{R}\ln 0.5\,a)/n(\Delta\varepsilon_1-\Delta\varepsilon_2)$ are equal to each other, but that the values of $\Delta\varepsilon_2/(\Delta\varepsilon_1-\Delta\varepsilon_2)$ are different from each other. This suggests that the stability of the helical form of DNA due to the base pairing is not affected (and that thus the $\Delta\varepsilon_1-\Delta\varepsilon_2$ value is not affected) by the salt concentration.

From the fact that the two straight lines, in question are parallel,[10] another interesting conculsion may be drawn: The $\Delta E'$ is very small for the adsorption of cations by the DNA molecules. The increase in T_m (denoted as ΔT_m) when the salt concentration is raised from "0.01 M PO_4+0.001 M versene" to "0.15 M NaCl+0.015 M Na citrate" should be proportional to the K' value on the basis of Eq. 18. If the $\Delta E'$ in question is -2 kcal./mol. or so, the K' (and therefore ΔT_m) should decrease appreciably when the T_m is raised from 70 to 90°C (see Fig. 9). The experimental results of Marmur and Doty[10] (given in Fig. 2) indicate that this is not actually the case, and that ΔT_m (and therefore K') remains constant at any T_m in the 70~90°C range. Thus, the absolute value of $\Delta E'$ is considered to be much smaller than 2 kcal./mol. If the absolute value of $\Delta E'$ is smaller than 1.6 kcal./mol. ($\Delta E>-1.6$ kcal./mol.) and if $K'=10$ (mol./l.)$^{-1}$, as has been given above, then $\Delta S'$ should be positive. The positive $\Delta S'$ obtained here may be interpreted as indicating that the adsorption of cations by the DNA molecules takes place through a hydrophobic bond.[16]

4. The Effect of Spermine

Spermine $NH_3^+(CH_2)_3NH_2^+(CH_2)_4NH_2^+\cdot(CH_2)_3NH_3^+$ is known to cause, when it is added to a DNA solution, an increase in the T_m of DNA.[4,17] This is considered to be due to the formation of complex molecules of spermine plus double-helical DNA, which are more stable than the double-helical DNA molecules free from spermine.

The binding reaction of spermine molecules, S, with double-helical DNA molecules, AB, may be expressed by Eqs. 15 and 16 of the preceding section. The enthalpy of melting the ΔE of such a spermine-DNA complex may be expressed by Eq. 17, and the melting temperature, T_m, may be given by Eq. 18. When T_m is plotted against $\log_{10}[S]$, a curve similar to those given in Fig. 9 is obtained. From a comparison of such a curve and those in Fig. 9, the K' value is estimated to be about 10^5 (mol./l.)$^{-1}$ in solutions with 0.03 mol./l. sodium chloride at 80°C, and about 10^3 (mol./l.)$^{-1}$ in solutions with 0.15 mol./l. sodium chloride at 90°C. Thus, it may be seen that the equilibrium constant, K', for spermine is much higher than that for potassium cation and that it depends greatly upon the salt concentration in the solution.

Mandel[4] examined the effects of spermine on the T_m values of solutions of DNA's obtained from a number of different sources and with different guanine-cytosine contents (GC-content). He observed that the extent of the increase in T_m (ΔT_m) becomes smaller with the increase in GC-content. Thus, $\Delta T_m=3.1$°C for a DNA with a GC-content of 26% ($T_m=81.3$°C), while $\Delta T_m=1$°C for a DNA with a GC-content of 58% ($T_m=95.8$°C). He concluded that ΔT_m is a function of the adenine-thymine content of the DNA sample. In the present writer's view, however, what he observed is mostly to be attributed to the effect of the temperature on the K' value; it is not to be directly correlated with the base composition of DNA.

As has been mentioned above, the interaction of the spermine molecule with the DNA molecule is very strong, and $\Delta E'$ for the present case may be as high as $-10\sim-20$ kcal./mol. or so. If it is -20 kcal./mol., for instance, the K' value at 95°C can be only one-third of that at 80°C (see Fig. 9). It is quite possible that such a lowering in K' value causes the lowering in ΔT_m value mentioned above. In addition, we have recently obtained[8] a bit of evidence which shows that the existence of the adenine-thymine base pairing in a nucleic acid is not a necessary condition for the interaction with spermine; the addition of only 0.0005 mol./l. of spermine produces a marked elevation of the T_m (from 58 to 90°C) of 1:1 complex polyriboinosinic acid plus polyribocytidylic acid, poly(I+C), which contains no adenine-thymine base pair.

There it remains much to be done before we can discuss the molecular structure of the spermine-DNA complex in the molecular structure of the spermine-DNA complex in detail. On the basis of what we have so far obtained,

16) See, for example, G. Némethy and H. A. Scheraga, *J. Phys. Chem.*, **66**, 1773 (1962).
17) H. Tabor, *Biochemistry*, **1**, 496 (1962).

however, the writer would like to present a possible model of that structure here.

Quite recently, Iitaka and Huse[18] have determined the crystal structure of spermine phosphate hexahydrate. The results suggest in a very interesting way how the spermine molecule may combine with the DNA molecule in the double-helix form.

In the crystal structure of spermin phosphate hexahydrate, there is a sheet which consists of HPO_4^{2-} ions and water molecules formed by the O-H···H hydrogen bonds. The sheet contains parallel chains of phosphate ions running along the a axis. The phosphate-phosphate distance along the a axis is 7.96 Å, while the chain-chain distance along the b axis (in the sheet) is 11.6 Å. As Iitaka and Huse[18] pointed out, there is a certain similarity between the arrangement of phosphate groups found in spermine phosphate and that found in crystalline DNA. Langridge et al.[19] have shown the arrangement of phosphate groups along the polynucleotide helices in the B-form of LiDNA. In this structure, two oxygen atoms of the phosphate group, which share one negative formal charge, are turned outwards and so are readily available for interaction with proteins, water, etc. (see Fig. 11).

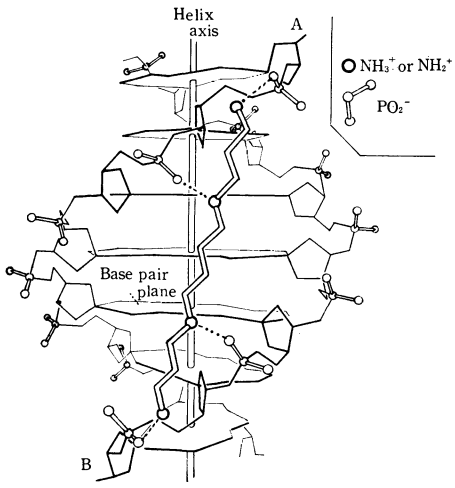

Fig. 11. A proposed model of spermine plus double-helical DNA.

The distance between successive phosphate groups along the helix is about 7.3 Å, which may be compared with the phosphate-phosphate distance, 7.96 Å, along the a axis in the phosphate chain in the spermine phosphate crystal. The perpendicular distance between two polynucleotide chains (chain A and B of the double-helix) across the shallow groove in LiDNA is about 13 Å, while in the spermine phosphate crystal the separation of the phosphate chains within the same sheet is found to be 11.6 Å, as has been given above. The spermine molecule in the spermine phosphate crystal is in the form of the fully-extended zigzag chain, and it is placed parallel to the phosphate-water sheet, forming an oblique bridge across the adjacent two phosphates chains in the same sheet. One of the two NH_3^+ groups makes a strong hydrogen bond with a phosphate group in the one chain, and the other NH_3^+ group makes a similar hydrogen bond with a phosphate group in the other chain. One of the two NH_2^+ groups makes a strong hydrogen bond with another phosphate group in the former chain, and the other NH_2^+ group makes a similar hydrogen bond with another phosphate group in the latter chain.

On the basis of what has been described above, it may be proposed that the spermine molecule combines with the double-helical NDA molecule, so that it forms an oblique bridge across the shallow groove between the two polynucleotide helices, A and B, as is shown in Fig. 11. A molecular model building shows that each of the NH_3^+ and the NH_2^+ groups on one end of a spermine molecule can form a strong hydrogen bond with one of the two adjacent phosphate groups in the DNA chain A, and that at the same time both the NH_3^+ and the NH_2^+ groups on the other end of the spermine molecule can form a similar hydrogen bond with one of the two adjacent phosphate groups in the DNA chain B. In this way, the spermine molecule may function as a clamp for binding two chains (A and B) together, and thus for stabilizing the double-helical structure of DNA.[20]

5. The Effect of Actinomycin D

The effect of actinomycin D on the T_m of DNA has recently been examined by Tsuboi et al.[5] Of what has been observed, the following two facts are to be pointed out here: First, only a very small amount (2.5×10^{-5}

18) Y. Iitaka and Y. Huse, This Bulletin, 37, 437 (1964); *Acta Cryst.*, in press.

19) R. Langridge, D. A. Marvin, W. E. Seeds, H. R. Wilson, C. W. Hooper, M. H. F. Wilkins and L. D. Hamilton, *J. Mol. Biol.*, 2, 38 (1960).

20) Iitaka and Huse (Ref. 18) showed that, in tne spermine phosphate hexahydrate crystal, the phosphate chains of the adjoining sheets as well as of the same sheet are bound together strongly by the spermine molecules. Likewise, a spermine molecule may function not only as a clamp for binding two polynucleotide helices together but also as an "adhesive" for binding two double-helical DNA molecules. It was found (Ref. 4) that, at concentrations of spermine in excess of 0.005 mol./l., visible aggregation of the DNA strands occurs. This fact may be interpreted as due to the above-mentioned "adhesive" function of the spermine molecule.

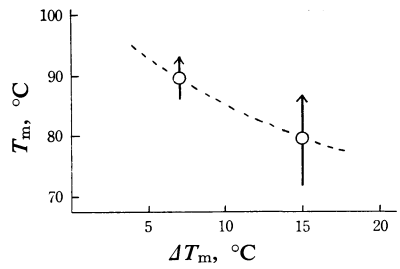

Fig. 12. Amount of elevation of T_m(ΔT_m) of calf-thymus DNA caused by addition of actinomycin D, plotted against the T_m of the solution.

mol./l.) is necessary to cause a marked elevation of T_m (72°C to 87°C). Secondly, the amount of elevation, ΔT_m, depends upon the original T_m value; ΔT_m is lower in a DNA solution with high a T_m (see Fig. 12).

On the basis of what has been discussed in this paper, the first fact may be interpreted as indicating that actinomycine D molecules are bound by the helical DNA molecule with a very high K' value and/or a very high α value. The second fact may be interpreted as indicating that the K' value depends greatly upon the temperature of the solution, because there is a high $\Delta E'$ value in each of the binding reactions, Eqs. 16.

6. The Effect of Caffeine, etc.

Ts'o, Helmkamp, and Sander[3] observed that the T_m's of polyriboadenylic acid (poly A) and DNA are lowered when caffeine, nucleosides, and related compounds are added to the solutions. Ts'o and Lu[21] found, on the other hand, that caffeine, for example, is bound by the random coil poly A with $K'=5.8$ (mol./l.)$^{-1}$ at 5°C, while it is much less strongly bound by the helical poly A ($K'<(1$ mol./l.)$^{-1}$ at 5°C). As they mentioned, the lowering of T_m may be related to the fact that caffeine (for example) interacts more strongly with the coil form of nucleic acids than with the helical form.

Also, for the present problem, Eqs. 17 and 18 are considered to be valid provided that the meanings are somewhat different of α, r, N, K' and $[S]$. α is now a negative value and represents the decrease in ΔE caused by the binding of caffeine to the coil form poly A. K' is the equilibrium constant (at T_m) of each of the reactions:

$$\begin{aligned} &A+S=AS \\ &AS+S=AS_2 \\ &AS_2+S=AS_2 \end{aligned} \qquad (20)$$

and

$$AS_{N-1}+S=AS_N$$

r is the average number of caffeine molecules bound by one random-coil poly A molecule (A); N, the maximum number of caffeine molecules that can be bound by one random-coil poly A molecule (A), and $[S]$, the concentration of the caffeine molecules free from poly A (which is practically equal to the total concentration of caffeine in the present case). From Eq. 18, the amount of the lowering of T_m ($-\Delta T_m$) due to the addition of $[S]$ of caffeine, etc., to the solution is expressed as:

$$\Delta T_m=\frac{\alpha K'[S]/(1+K'[S])}{(\Delta S-\boldsymbol{R}\ln 0.5\,a)/N} \qquad (21)$$

By the use of this expression, and by the use of the data obtained by Ts'o et al.[3,21] (plotted in Fig. 13 by circles) an attempt has

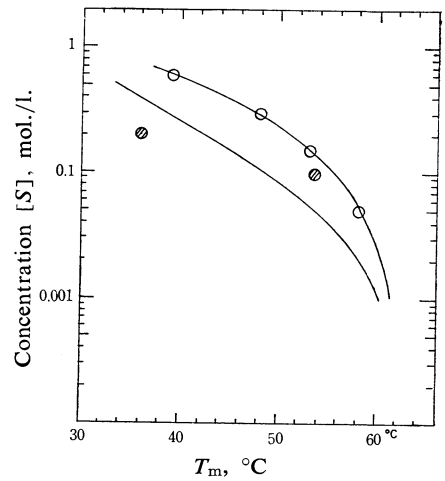

Fig. 13. T_m of poly A at pH 4.85 plotted against the concentration of caffeine (black circles) and purine (white circles) added to the solution.[3] Curves were obtained by a calculation based upon Eq. 21, and by assuming that $\alpha=1.2$ kcal./mol. and $K'=5.8$ (mol./l.)$^{-1}$ for purine and that $\alpha=1.3$ kcal./mol. and $K'=2$ (mol./l.)$^{-1}$ for caffeine. $(\Delta S-\boldsymbol{R}\ln 0.5\,a)/N$ was assumed to be 32 e.u. for both cases.

been made to estimate the α value for the case of caffeine plus poly A and also for the case of purine plus poly A. In both of these cases, $(\Delta S-\boldsymbol{R}\ln 0.5\,a)/N$ for poly A is assumed to be 32 e.u., which is equal to the value of $(\Delta S-\boldsymbol{R}\ln 0.5\,a)/n$ of poly A given in the last paragraph of section 2. Because the hydrophobic forces are considered to play a predominant role in the interaction of caffeine (or purine) with random-coil poly A,[3] the enthalpy of binding $\Delta E'$ for the present cases would be small. Therefore, K' value for caffeine plus

21) P. O. P. Ts'o and P. Lu, *Proc. Nat. Acad. Sci. (U. S. A.)*, **51**, 17 (1964). Their nK corresponds to K' in this paper.

poly A is assumed to be 5.8 $(\text{mol./l.})^{-1}$ not only at 5°C but also in the vicinity of T_m (40～60°C). The data given in Fig. 13 suggest that the K' value is slightly lower for the case of purine plus poly A than that for the case of caffeine plus poly A; it is assumed to be 2 $(\text{mol./l.})^{-1}$ for the former case. Therefore, the α value is calculated to be −1.2 kcal./mol. for the case of caffeine plus poly A and −1.3 kcal./mol. for the case of purine plus poly A. By these values of α, the date given in Fig. 13 can be well explained (see the theoretical curves in the figure). Thus, it may be concluded that the binding of one caffeine or purine molecule to the random-coil poly A casuses a lowering of the ΔE (enthalpy of melting) by 1.2～1.3 kcal./mol.

Summary

The mass action law has been applied to the "melting" process of nucleic acids and also to the binding process of small ions or molecules. On the basis of previously-obtained data on the variation of the melting temperature of nucleic acids caused by interaction with small ions and molecules, some of the enthalpy, entropy, and free energy changes involved in the processes have been estimated. A model has been proposed of how the spermine molecule may interact with the deoxyribonucleic acid molecule to stabilize the double-helical conformation of the latter molecule.

The Stability of Calcium Complexes of Purely-separated Polyphosphate

By Masaji MIURA and Yoshiki MORIGUCHI

(Received May 12, 1964)

The complex formation of linear-chain polyphosphates with various metals has been studied by several authors.[1-5] Their studies, however, have dealt with polyphosphates with molecular weight distributions. The investigation of complexes of purely-separated polyphosphates, except pyrophosphate and triphosphate, has not yet been undertaken. This is probably in part due to the difficulty of separating individual polyphosphates from their mixture in sufficient quantities and in part to their low stability for a hydrolytic degradation.[6] As their stability decreases with decrease in the pH of the solution, the measurements of the stability constants of polyphosphate complexes must be carried out at as high a pH as possible, and so it is difficult to apply such an usual method as pH titration.

The purpose of this study is twofold, namely, 1) to investigate the effect of the thain length of purely-separated polyphosphates on the stability of their calcium complexes, and to compare the present results with those given by Irani et al. and others[1,2] and 2) to investigate the effect of the ionic strength on the structure of calcium complexes of polyphosphates with various chain lengths from the point of view that polyphosphate is a kind of polyelectrolyte.

Experimental

The Synthesis and Separation of Polyphosphates.[6,7] — A polyphosphate glass was prepared by the pyrolysis of a mixture of sodium dihydrogen phosphate and disodium hydrogen phosphate containing ^{32}P at 800°C for 5 hr. Each linear-chain polyphosphate with a chain length of 4—8 phosphorus atoms was separated from the mixture of polyphosphates by anion-exchange chromatography using the H-form of Dowex 1X4 (100~200 mesh).

7) W. Wieker, *Z. Elektrochem.*, **64**, 1047 (1960).

An aqueous solution of sodium chloride was used as an eluent. Each polyphosphate was precipitated from the effluent by adding benzidin, and the precipitate was repeatedly washed with distilled water until the filtrate was free from chloride ions.

The benzidin polyphosphates thus obtained were transformed into tetramethylammonium polyphosphates by adding an aqueous solution of tetramethylammonium hydroxide. The isolated benzidin was separated from the polyphosphate solution by extraction with chloroform.

The pH of tetramethylammonium polyphosphate solutions was kept over 10 by adding tetramethylammonium hydroxide, and the solutions were stocked in a refrigerator to avoid hydrolytic degradation.

The G. R.-grade pyrophosphate and triphosphate were repeatedly crystallized from water and an ethanol-water mixture respectively.[8] Both of them were transformed into free acids by the use of cation-exchange resin.[1]

The concentration of each polyphosphate was determined by a radio tracer technique, while those of pyrophosphate and triphosphate were determined by means of pH titration.

Reagents.—The tetramethylammonium hydroxide and bromide were both G. R.-grade reagents and were used without further purification. The calcium solutions used as titrants were $5.01_2\times10^{-2}$, $1.02_9\times10^{-1}$ and $2.05_8\times10^{-1}$ M calcium nitrate standardized with disodium ethylenediaminetetraacetate at a pH of 13 in the presence of a calcon indicator.[9]

Apparatus and Procedure. — The nephelometer used in the present work was an A. K. A. spectrophotometer, which was reconstructed so we could keep the temperature in a cell-room constant and could stir a sample solution in a cell by means of a micromotor.

The solutions of polyphosphate and of oxalic acid as a precipitating agent were pipetted into a cell. The total ionic strength of the solution was adjusted to either 0.1 or 1.0 by adding a 3 M solution or crystals of tetramethylammonium bromide. Distilled water was added to the solution until its volume was 30~33 ml., and then the pH of the solution was kept at 10~12 by adding an aqueous solution of tetramethylammonium hydroxide.

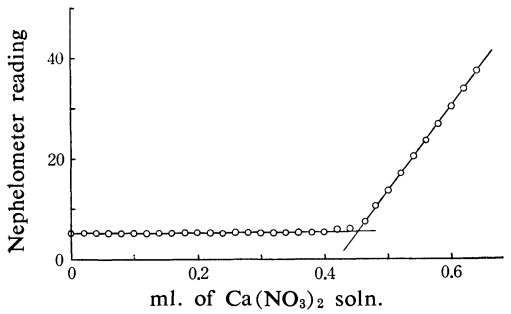

Fig. 1. An example of nephelometric titrations for the calcium-oxalate-polyphosphate system.

8) R. N. Bell, *Anal. Chem.*, **24**, 1997 (1952).

9) C. A. Goetz and R. C. Smith, *Iowa State J. Sci.*, **34**, No. 1, 81 (1959).

The nephelometric titration was carried out at 25±0.5°C under a nitrogen atmosphere by adding a standard solution of calcium nitrate through a calibrated microburet. The solution was vigorously stirred during the titration. At five-minute intervals titrant shots were taken. This procedure was proved by a preliminary test to avoid supersaturation and to give equilibrium values. An example of the results of the titration is shown in Fig. 1.

It was verified by ion-exchange chromatography and paper chromatography that the degradation of polyphosphate did not occur during the titration.[6,10]

The Treatment of Date

The evaluation of the stability constants of the calcium polyphosphate complexes was performed by a method similar to that reported by Irani et al.[1] Assuming that a polyphosphate chain consists of some sites, $L(\theta)$, which can bind a calcium ion to θ phosphorus atoms,* that these sites are mutually independent, and that the concentration of free calcium ions is negligibly small at the end-point compared with that of the calcium complex, the stability of the calcium complex at pH over 10 can be evaluated by means of the following equation:

$$\beta=\left(\frac{L_tA}{\theta yz}-1\right)\frac{K_{sp}}{[C_2O_4]_t} \qquad (1)$$

where β is the dissociation constant of the complex given by Eq. 2; L_t, the total concentration of the polyphosphate expressed by moles of phosphorus per liter; A, the total volume of the sample solution at the end-point; y, the number or ml. of z M calcium solution added until the end-point; $[C_2O_4]_t$, the concentration of oxalic acid, and K_{sp}, the solubility product of calcium oxalate expressed by Eq. 3. The literature values of K_{sp} are 1.32×10^{-8} and 7.80×10^{-8} at the ionic strengths of 0.1 and 1.0 respectively.[1]

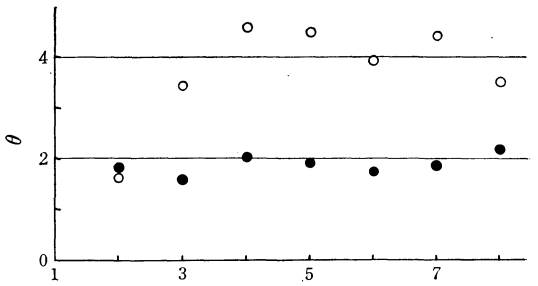
$$\beta=\frac{[Ca]\,[L(\theta)]}{[CaL(\theta)]} \qquad (2)$$

$$K_{sp}=[Ca]\,[C_2O_4] \qquad (3)$$

Thus, β can be calculated from Eq. 1 if θ is known. θ can be evaluated by the measurements at two different concentrations of oxalic acid, if the temperature, ionic strength and pH are kept constant. Namely, if y_1 and y_2 are obtained at two different concentrations of oxalic acid, $[C_2O_4]_{t_1}$ and $[C_2O_4]_{t_2}$, the elimination of β from Eq. 1 gives Eq. 4:

10) H. Grunze and E. Thilo, *Sitz. ber. deut. Akad. Wiss. Berlin Kl. Math. u. allgem. Naturw.*, **1953**, No. 5.

* The θ does not always indicate a so-called "co-ordination number," since it has not yet been clarified whether or not the bond between polyphosphate and calcium ions is a definite co-ordination one.



$$\theta=\frac{(L_{t_1}A_1/y_1z_1)\,[C_2O_4]_t-(L_t\,A_2/y_2z_2)\,[C_2O_4]_{t_1}}{[C_2O_4]_t-[C_2O_4]_{t_1}} \quad (4)$$

Charges on the ions in Eqs. 1—4 were omitted for purposes of simplification.

Results and Discussion

The nephelometric titration data are summarized in Table I. The θ values are plotted against the chain lengths of polyphosphate in Fig. 2. From this figure, the values of θ at an ionic strength of 0.1 are found to be about 2 regardless of the chain length, while the corresponding values at an ionic strength of 1.0 vary between 2 and 4 with the number of phosphorus atoms per chain. This may be due to an effect on the configuration of the polyphosphate chain of the supporting electrolyte added in order to adjust the ionic strength. As the polyphosphate is a kind of polyelectrolyte, the presence of the supporting electrolyte may cause the polyphosphate chain to coil up as a result of the decrease in electrostatic repulsion on the chain.[11] The coiled chain with an appropriate configuration may easily assume a value of θ higher than two.

The negative logarithms of the dissociation constants, β, of calcium polyphosphate complexes are summarized in Table II, along with the results of Irani et al., and they are plotted against the chain length in Fig. 3. As for the value of θ used to evaluate β from Eq. 1,

Number of phosphorus atoms per chain

Fig. 2. Relation between the number of phosphorus atoms bound by a calcium ion and the chain length of the polyphosphate. Ionic strength; ●: 0.1, ○: 1.0.

an 2, 3 or 4 integer, near the value shown in Fig. 2, was used. The values of θ reported by Irani et al. are independent of the ionic strengths and take the same values at the ionic strengths of both 0.1 and 1.0 (θ; 2, 3 and 4 for the chain lengths of 2, 3 and 6 phosphorus atoms respectively), whereas in this paper, the values of θ at an ionic strength of 0.1 are different from those at 1.0, except for pyrophosphate. Therefore, the stability constants given by Irani et al. were recalculated using the same values of θ as those used in the present study; the results are shown in Table II.

As may be seen in Fig. 3, the stability of calcium polyphosphate complexes increases with the chain length at the ionic strengths

of both 0.1 and 1.0 and levels off at the chain length of 6—7 phosphorus atoms when the ionic strength is 0.1, though not yet when it is 1.0. The increase in the stability with the chain length was also reported by Irani et al. and by Van Wazer et al.[12] This phenomenon is probably in part due to an increase in the charge density on a polyphosphate chain and in part to an effect of the chain configuration on the complex formation.

A comparison of the present results with those of Irani et al. shows that the stability constant of unfractionated polyphosphate with an average chain length of 6 phosphorus atoms agrees with that of purely-separated hexaphosphate in this work within the range of experimental error. From this result, it seems reasonable to conclude that the stability constant of the calcium complex of any polyphosphate is equivalent to that of a mixture of polyphosphates with the same average chain length, if the mixture does not contain ortho- or pyrophosphate. It has been verified by means of ion-exchange chromatography that ortho- and pyrophosphate are not present in the polyphosphate mixture prepared by the method described above.

It raises some questions that Irani et al. carried out the nephelometric titration using the precipitating agent not only at the same concentrations as ours, but at higher concentrations up to about eight times that of polyphosphate. As the stability constant of the calcium oxalate complex is considerably large, i. e., 10^3,[13] the dissolution of the complex can not be disregarded when the concentration of oxalic acid is too high compared with that of polyphosphate. This is supported by the fact that the dissociation constant of the triphosphate complex tends to decrease with an increase in the concentration of oxalic acid (e. g., β; 3.84, 1.22 and 1.06×10^{-6} for the 1.33, 2.00 and 2.67×10^{-2} M concentrations of oxalic acid respectively, at the ionic strength of 0.1).

The assumptions for the site in the derivation of Eq. 1 still remain to be discussed in more detail with regard to the structure of such polyelectrolyte complexes as calcium polyphosphate; these questions will be clarified in due course.

Summary

The formation of calcium complexes of purely-separated linear chain polyphosphates

with chain lengths of 2～8 phosphorus atoms has been studied by means of nephelometric titration at 25°C, pH values of 10～12, and ionic strengths of 0.1 and 1.0. The following results have been obtained: 1) The number of phosphorus atoms bound to a calcium ion is about 2, regardless of the chain length at an ionic strength of 0.1, while it varies from 2 to 4 according to the chain length at an ionic strength of 1.0; 2) The stability of calcium polyphosphates increases with the chain length at both ionic strengths and levels off at a chain length of 6～7 when the ionic strength is 0.1, though not yet when it is 1.0; and 3) The stability constant of a calcium complex of any long-chain polyphosphate is almost equal to that of a mixture of polyphosphates with the same average chain length.

The authors wish to thank Dr. Sadaichi Otani for his helpful advice relating to the synthesis and separation of polyphosphates.

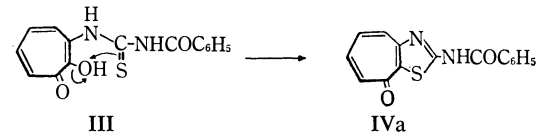
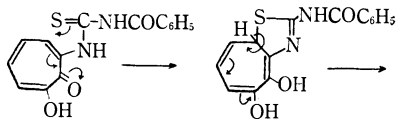
Cycloheptathiazole Derivatives. III. The Synthesis of Cycloheptathiazol-8-one and Its Derivatives

By Shuichi SETO and Kyozo OGURA

(Received May 15, 1964)

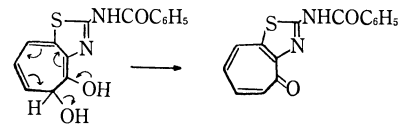


In the preceding papers of this series,[1,2] the syntheses of 7-hydroxycycloheptathiazol-6-one (I) and its 2-substituted derivatives were reported.



I

These series of compounds are interesting from the point of view of biological action and pharmacology, so the present authors have made a further investigation of the syntheses of another type of cycloheptathiazoles. This paper will describe the synthesis of cycloheptathiazol-8-one and its allied compounds.



The reaction of 3-aminotropolone (II) with benzoylisothiocyanate gave *N*-tropolon-3-yl-*N'*-benzoylthiourea (III), which was easily dehydrated by the action of acid or alkali, or merely by heating, to afford a cyclization product (IV). The ultraviolet and infrared absorption spectra suggested that IV might be a tropone derivative with a fused ring. The fact that the oxidation of IV with potassium permanganate gave 2-benzamidothiazole-4, 5-dicarboxylic acid (V), which had been previously synthesized in an authentic route,[1] showed that IV should have a thiazole ring. Therefore, the product is likely to be 2-benzamidocycloheptathiazol-8-one (IVa). However, another type of cyclization product, cycloheptathiazol-4-one derivative (IVb) could not be excluded, since abnormalities have often been found in the cyclization reaction of troponoid compounds.[1,3]

III IVa

III

IVb

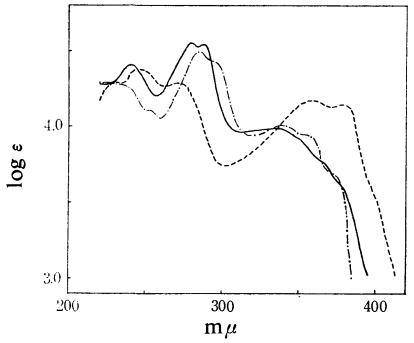
The following facts, however, exclude the structure IVb. 3-Aminotropolone (II) reacted smoothly with thiobenzoylthioacetic acid in the presence of alkali to give directly a cyclization product VI whose ultraviolet spectrum was similar to that of IV but quite different

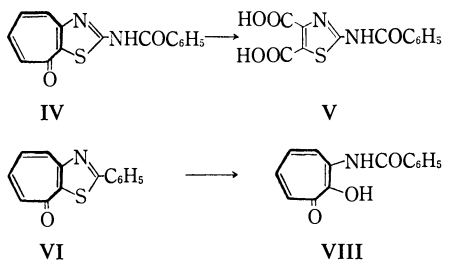
1) S. Seto, Y. Nishiyama and K. Ogura, This Bulletin, 35, 1998 (1962).

2) S. Seto, K. Ogura and Y. Nishiyama, ibid., 36, 173 (1963).

3) T. Nozoe, S. Seto, S. Matsumura and T. Asano, *Proc. Japan Acad.*, 32, 339 (1956); T. Nozoe et al., "Daiyukikagaku," Asakurashoten, Tokyo (1960), p. 182, etc.

from that of the 2-phenylcycloheptathiazol-4-one (VII) synthesized by Nozoe et al.[4] (Fig. 1). When VI was treated with alkali, 3-benzamidotropolone (VIII) was obtained. These facts show that VI must be 2-phenylcycloheptathiazol-8-one; consequently, IV probably has the structure IVa.





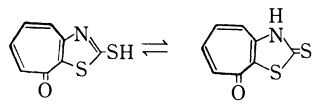


Fig. 1. Ultraviolet absorption spectra of IV (——), VI (·—·—·—·) and 2-phenylcycloheptathiazol-4-one[4] (------) in methanol.

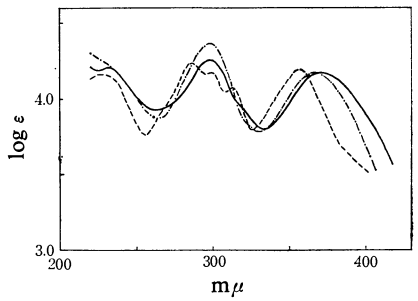
IV V

VI VIII

The 2-benzamido derivative IV is stable to alkali, and the fission of the thiazole ring does not occur, even when it is heated in an alkaline solution, but a stable salt is formed. The warming of IV in concentrated sulfuric acid gave 2-aminocycloheptathiazol-8-one (IX). When 3-aminotropolone (II) was treated with carbon disulfide in the presence of alkali, yellow crystals of $C_8H_5ONS_2$ (X), were obtained in a good yield. This substance is sparingly soluble in organic solvents and is fairly acidic. The infrared absorption spectrum exhibits multiplet absorption bands in the 2700~3100 cm^{-1} region due to its associated NH group, and the strongest absorption band corresponding to the carbonyl group shifted to a longer wave length region (1540 cm^{-1}) compared with those of IV and VI. The ultraviolet absorption spectrum of X is also markedly different from those of IV and VI. These facts indicate that X is probably 2-mercaptocycloheptathiazol-8-one, which exists as the thiazoline form Xb predominantly. This situation

Xa Xb

is quite similar to that of 2-mercaptobenzothiazole, which was tentatively investigated by Bellamy and Rogasch.[5] The ultraviolet absorption curve of X in methanol seems to correspond mainly to a stable anion formed by dissociation in the diluted solution, since the addition of acid causes a large hypsochromic shift, while the addition of alkali changes the spectrum only a few millimicrons.



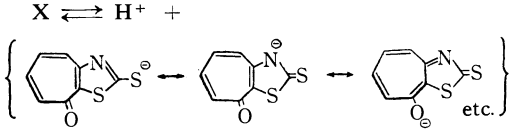


Fig. 2. Ultraviolet absorption spectra of X in methanol (——), in 0.1 N NaOH (·—·—·) and in 0.24 N HCl-MeOH (------).

The reaction of X with methyl iodide, benzyl chloride and monochloroacetic acid in the presence of alkali afforded *S*-methyl (XI), *S*-benzyl (XII) and *S*-carboxymethyl (XIII) derivatives respectively. All these compounds show ultraviolet absorptions of the same type as in the case of IV and VI. The treatment of X with thionyl chloride gave 2-chlorocycloheptathiazol-8-one (XIV), which was converted to 2-amino derivative (IX) by reaction with liquid ammonia. By this fact the relation between these compounds was established as is summarized in scheme 1. Finally, cycloheptathiazol-8-one (XV) was obtained by the treatment of X with hydrogen peroxide in *t*-butanol. The infrared absorption spectrum is shown in Fig. 4. Bis(cycloheptathiazol-8-on-2-yl)-disulfide (XVI) was also obtained by the reaction of X with hydrogen peroxide under rather mild conditions.

It is interesting to note that the ultraviolet absorption spectra of both XIV and XV are

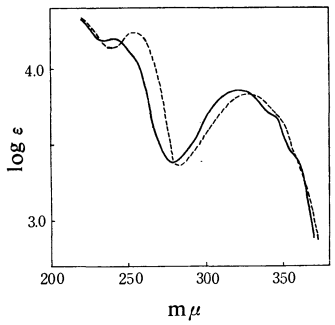

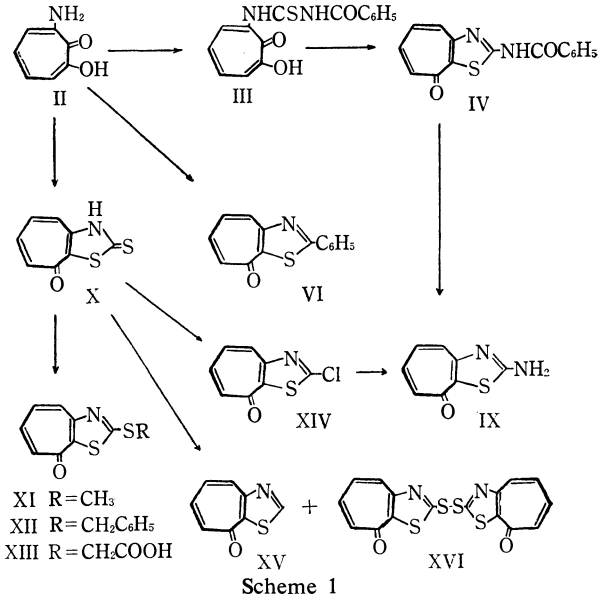

Fig. 3. Ultraviolet absorption spectra of XIV (------) and XV (——) in methanol.

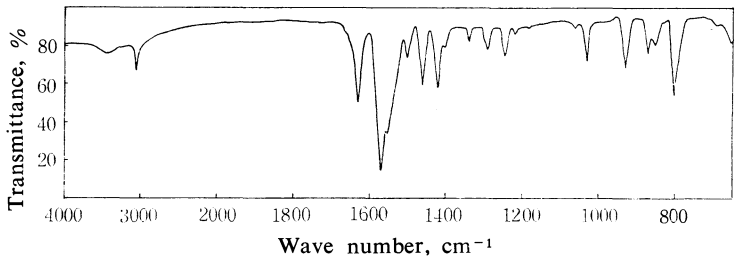
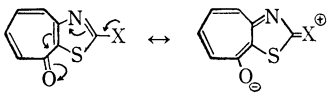
of the tropone type and quite different from those of cycloheptathiazol-8-one derivatives replaced at the 2-position by an electron-releasing group. This seems to imply that the contribution of the conjugation between the

Scheme 1





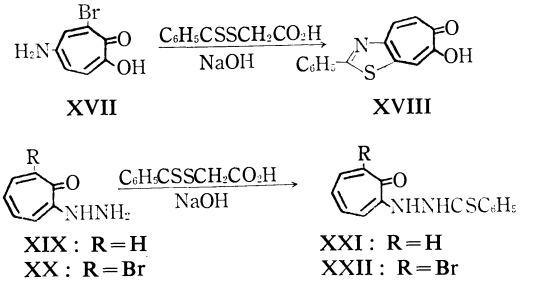


Fig. 4. Infrared absorption spectrum of XV in KBr disk.

electron-releasing group and the carbonyl group is very significant.

The reaction of thiobenzoylthioacetic acid with 3-bromo-5-aminotropolone (XVII) was also examined; it was found that the reaction proceeded easily in the presence of alkali at room temperature, furnishing 2-phenyl-7-hydroxycycloheptathiazol-6-one (XVIII) in the same manner as has been described in the preceding paper.[1] The elucidation of the structure was made by a comparison of its spectral data with those of the corresponding 7-hydroxycycloheptathiazol-6-one derivatives studied previously.[1] 2-Aminotropone did not react with thiobenzoylthioacetic acid, while 2-hydrazinotropone and its 7-bromo derivative reacted with the reagent to give *N*-thiobenzoyl derivatives, XXI and XXII respectively, which failed to be converted into any cyclization product.

Scheme 2

Experimental*

***N*-Tropolon-3-yl-*N'*-benzoylthiourea (III).**—A solution of II (100 mg.) and benzoylisothiocyanate (160 mg.) in ethanol (2 ml.) was stirred at 50~60°C for 1 hr. The yellow crystals that precipitated were collected and washed with methanol. This substance showed double melting point, 145~150°C and 260°C. Yield, 130 mg.

* All melting points are uncorrected. The microanalyses were carried out by Misses Yōko Endo and Yukiko Endo of this Institute, to whom the authors are indebted.

λ_{max}^{MeOH} mμ (log ε) : 268 (4.62), 380 (4.07).

Found : C, 60.30 ; H, 3.81 ; N, 9.08. Calcd. for $C_{15}H_{12}O_3N_2S$: C, 60.00 ; H, 4.03 ; N, 9.33%.

2-Benzamidocycloheptathiazol-8-one (IV). — a) When III (450 mg.) was stirred in a 50% aqueous sodium hydroxide solution (10 ml.), an orange precipitate was formed immediately. When this precipitate was gradually dissolved while being stirred at room temperature, yellow crystals soon separated out. After it had been stirred for 1 hr., the mixture was acidified with diluted hydrochloric acid, and the crystals were collected and recrystallized from ethanol to afford colorless crystals, m. p. 285~287°C (decomp.). Yield, 400 mg.

λ_{max}^{MeOH} mμ (log ε) : 240 (4.41), 279 (4.55), 289 (4.54), 340 (3.99).

Found : C, 63.10 ; H, 3.37 ; N, 9.81. Calcd. for $C_{15}H_{10}O_2N_2S$: C, 63.83 ; H, 3.57 ; N, 9.93%.

b) A solution of III (40 mg.) in concentrated sulfuric acid (0.5 ml.) was allowed to stand at room temperature overnight. The colorless precipitate that separated upon the addition of cracked ice to the solution was collected and recrystallized from ethanol. Yield, 30 mg.

c) A suspension of III (40 mg.) in ethanol (10 ml.) was refluxed for 30 min. ; the yellow prisms that separated out when it was cooled to room temperature were collected. Yield, 20 mg.

The Oxidation of IV with Potassium Permanganate.—To a solution of IV (40 mg.) in a 10% aqueous sodium hydroxide solution (1 ml.), a potassium permanganate solution (potassium permanganate, 100 mg. ; water, 2 ml.) was added ; this mixture was stirred at room temperature for 3 hr. After the decomposition of the excess permanganate by the addition of formalin, manganese dioxide was removed by filtration. The acidification of the filtrate with diluted hydrochloric acid, adjusted to pH 1, caused the precipitation of colorless crystals, which were identified with an authentic specimen of 2-benzamidothiazole-4, 5-dicarboxylic acid by a comparison of their infrared and ultraviolet spectra.[6]

2-Phenylcycloheptathiazol-8-one (VI).—A solution of II (100 mg.) and thiobenzoylthioacetic acid (180 mg.) in a 10% aqueous sodium hydroxide solution (1 ml.) was allowed to stand overnight ; the colorless needles which separated were then collected and recrystallized from ethanol to give colorless prisms, m. p. 138~139°C. Yield, 25 mg.

λ_{max}^{MeOH} mμ (log ε) : 240 (4.25 sh.), 285 (4.50), 295 (4.43 sh.), 340 (4.00).

Found : C, 70.60 ; H, 3.45 ; N, 5.70. Calcd. for $C_{14}H_9ONS$: C, 70.29 ; H, 3.79 ; N, 5.86%.

The Reaction of VI with Alkali. — When a mixture of VI (20 mg.) in a 30% aqueous potassium hydroxide solution (1 ml.) was heated on a water bath for a few minutes, a yellow precipitate appeared. After it had been cooled, the mixture was acidified with diluted hydrochloric acid, and the precipitate was collected. Recrystallization from ethanol gave pale yellow needles of m. p. 142~144°C, undepressed on admixture with 3-benzamidotropolone.

2-Aminocycloheptathiazol-8-one (IX). — A solution of IV (400 mg.) in concentrated sulfuric acid (4 ml.) was heated at 110°C for 4 hr. The brownish-yellow solution thereby obtained was poured into cracked ice and neutralized with a saturated sodium bicarbonate solution, and the precipitate was collected. The acidification of the filtrate gave colorless crystals of benzoic acid. The precipitate collected was recrystallized from methanol to afford yellow prisms, m. p. 225~245°C (decomp.). Yield. 100 mg.

λ_{max}^{MeOH} mμ (log ε) : 244 (4.10), 280 (4.38), 290 (4.32 sh.), 322 (3.91), 335 (3.91).

Found : C, 53.56 ; H, 3.68 ; N, 14.53. Calcd. for $C_8H_6ON_2S$: C, 53.93 ; H, 3.40 ; N, 15.73%.

2-Mercaptocycloheptathiazol-8-one (X).—A mixture of II (400 mg.), carbon disulfide (2 ml.) and ethanol (2.4 ml.) in a 10% aqueous sodium hydroxide solution (3 ml.) was stirred at room temperature for 2 hr. After the removal of the ethanol and the excess carbon disulfide under reduced pressure, the residual solution was acidified with diluted hydrochloric acid and adjusted to pH 3 ; the yellow precipitate thereby formed was collected and recrystallized from ethanol to give yellow scales, m. p. 255~300°C (decomp.). Yield, 550 mg.

λ_{max}^{MeOH} mμ (log ε) : 231 (4.21), 299 (4.25), 372 (4.16).

Found : C, 49.42 ; H, 3.17 ; N, 7.49. Calcd. for $C_8H_5ONS_2$: C, 49.24 ; H, 2.58 ; N, 7.18%.

2-Methylthiocycloheptathiazol-8-one (XI).—When a mixture of X (50 mg.), potassium carbonate (80 mg.) and methyl iodide (40 mg.) in water (1.5 ml.) was stirred at room temperature for 1.5 hr., a colorless precipitate appeared. This precipitate was collected and recrystallized from ethanol to give pale yellow prisms, m. p. 112~113°C. Yield, 40 mg.

λ_{max}^{MeOH} mμ (log ε) : 230 (4.20), 284 (4.36 sh.), 293 (4.38), 330 (3.96).

Found : C, 51.16 ; H, 3.15 ; N, 6.19. Calcd. for $C_9H_7ONS_2$: C, 51.68 ; H, 3.37 ; N, 6.76%.

2-Benzylthiocycloheptathiazol-8-one (XII).—A mixture of X (50 mg.), potassium carbonate (80 mg.) and benzyl chloride (40 mg.) in water (1.5 ml.) was stirred at 40°C for 2 hr. The precipitate thereby formed was collected and recrystallized from methanol to give pale yellow needles, m. p. 138~140°C. Yield, 40 mg.

λ_{max}^{MeOH} mμ (log ε) : 230 (4.26), 285 (4.33 sh.), 294 (4.37), 336 (4.00).

Found : C, 63.18 ; H, 3.88 ; N, 4.79. Calcd. for $C_{15}H_{11}ONS_2$: C, 63.16 ; H, 3.89 ; N, 4.91%.

2-Carboxymethylthiocycloheptathiazol-8-one (XIII).—A mixture of X (20 mg.), sodium carbonate (80 mg.) and monochloroacetic acid (30 mg.) in water (0.5 ml.) was stirred at room temperature for 1.5 hr. The solution thereby obtained was acidified with diluted hydrochloric acid and adjusted to pH ca. 2, and the precipitate was collected by filtration. Recrystallization from ethanol afforded pale yellow crystals, m. p. 233~235°C. Yield, 10 mg.

6) Y. Nishiyama and Y. Ikegami, *Bull. Chem. Res. Inst. Non-Aqu. Solns., Tohoku Univ.*, **12**, 43 (1963).

λ_{max}^{MeOH} mμ (log ε) : 235 (4.34), 285 (4.36 sh.), 295 (4.38), 338 (4.01).

Found : C, 47.93 ; H, 3.48 ; N, 5.73. Calcd. for $C_{10}H_7O_3NS_2$: C, 47.44 ; H, 2.79 ; N, 5.53%.

2-Chlorocycloheptathiazol-8-one (XIV). — To a solution of X (40 mg.) in dry benzene (0.5 ml.), thionyl chloride (0.3 ml.) was added, and the mixture was allowed to stand at room temperature for 1.5 hr. After the evaporation of benzene and the excess thionyl chloride, the residue was neutralized with an aqueous sodium bicarbonate solution and extracted with benzene. The combined benzene solution was evaporated and the residue was sublimed at 110°C under reduced pressure (3 mmHg). Recrystallization of the sublimate from benzene-petroleum ether gave colorless needles, m. p. 125~128°C. Yield, ca. 5 mg.

λ_{max}^{MeOH} mμ (log ε) : 255 (4.24), 332 (3.82).

Found : C, 48.58 ; H, 2.59 ; N, 7.19. Calcd. for C_8H_4ONSCl : C, 48.16 ; H, 2.02 ; N, 7.09%.

The Reaction of XIV with Liquid Ammonia.—A solution of XIV (10 mg.) in liquid ammonia (15 ml.) was allowed to stand at room temperature for 2 days. After the evaporation of the liquid ammonia, water (2 ml.) was added to the residue and the precipitate was collected and recrystallized from methanol to give yellow prisms, which were identified with 2-aminocycloheptathiazol-8-one (IX) by a comparison of their infrared absorption spectra.

Cycloheptathiazol-8-one (XV).—A mixture of X (50 mg.) and 30% hydrogen peroxide (0.2 ml.) in *t*-butanol (2 ml.) was heated at 90°C for 2 hr. Then the color of the precipitate gradually faded, and finally all the precipitate was dissolved. After the evaporation of the solvent under reduced pressure, the residue was neutralized with sodium carbonate and extracted with ether. The combined ether solution, after being dried over sodium sulfate, was passed through a column of alumina. The evaporation of the eluate left colorless needles, which were collected and recrystallized from benzene-petroleum ether to give colorless needles, m. p. 134~138°C. Yield, 10 mg.

λ_{max}^{MeOH} mμ (log ε) : 240 (4.20), 320 (3.85).

Found : C, 58.26 ; H, 3.29 ; N, 8.18. Calcd. for C_8H_5ONS : C, 58.90 ; H, 3.09 ; N, 8.59%.

Bis(cycloheptathiazol-8-on-2-yl) disulfide (XVI).—A mixture of X (50 mg.) and 30% hydrogen peroxide (0.2 ml.) in *t*-butanol (2 ml.) was warmed while being stirred at 80°C for 10 min. The colorless crystals thereby formed were collected and washed with hot methanol, m. p. 200~203°C. Yield, 20 mg.

Found : C, 49.22 ; H, 2.40 ; N, 7.10. Calcd. for $C_{16}H_8O_2N_2S_4$: C, 49.46 ; H, 2.08 ; N, 7.21%.

2-Phenyl-7-hydroxycycloheptathiazol-6-one (XVIII).—A solution of XVII (100 mg.) and thiobenzoylthioacetic acid (100 mg.) in a 2 N sodium hydroxide solution (0.8 ml.) and water (2 ml.) was allowed to stand at room temperature for 30 min. A yellow precipitate began to separate out after about 10 min. After the mixture had been neutralized with diluted sulfuric acid and adjusted to pH 2, the precipitate was collected and recrystallized from acetone-methanol to give pale yellow crystals, m. p. 220~222°C. Yield, 120 mg. The filtrate contained one atom equivalent of bromide ions.

λ_{max}^{MeOH} mμ (log ε) : 268 (4.54), 380 (4.35).

Found : C, 65.70 ; H, 3.34 ; N, 5.40. Calcd. for $C_{14}H_9O_2NS$: C, 65.88 ; H, 3.55 ; N, 5.49%.

***N*-(Tropon-2-yl)-*N'*-thiobenzoylhydrazide (XXI).**—When a mixture of 2-hydrazinotropone (50 mg.) and thiobenzoylthioacetic acid (50 mg.) in a 5% sodium hydroxide solution (2 ml.) was stirred for 1 hr., orange crystals appeared. After the neutralization of the mixture with diluted hydrochloric acid, the crystals were collected and recrystallized from ethanol to give yellow needles, m. p. 169~170°C. Yield, 50 mg.

λ_{max}^{MeOH} mμ (log ε) : 234 (4.46), 457 (4.38).

Found : C, 65.27 ; H, 4.73 ; N, 10.70. Calcd. for $C_{14}H_{12}ON_2S$: C, 65.62 ; H, 4.72 ; N, 10.93%.

***N*-(7-Bromotropon-2-yl)-*N'*-thiobenzoylhydrazide (XXII).**—When a mixture of 2-hydrazino-7-bromotropone (50 mg.) and thiobenzoylthioacetic acid (50 mg.) in a 5% sodium hydroxide solution (2 ml.) was stirred at room temperature for 1 hr., orange scales appeared. The crystals were collected and acidified with diluted hydrochloric acid to yield a yellow powder, which was collected by filtration and recrystallized from methanol to afford orange scales, m. p. 272~273°C. Yield, 50 mg.

Found : C, 50.06 ; H, 3.33 ; N, 7.85. Calcd. for $C_{14}H_{11}ON_2SBr$: C, 50,15 ; H, 3.31 ; N, 8.36%.

An Electron Spin Resonance Study of Irradiated Polymethylacrylate

By Hiroshi YOSHIDA*, Toshiyuki KODAIRA, Kozo TSUJI, Koichiro HAYASHI and Seizo OKAMURA

(Received May 20, 1964)

The decaying behavior of free radicals in irradiated polymers has been studied by the electron spin resonance (ESR) method with polymethylmethacrylate,[1,2] polyvinylchloride,[3,4] polyvinylalcohol,[5] polyoxymethylene[6] and polypropylene.[7] In most cases, free radicals follow a first-order or a second-order decay reaction, depending on the polymer and temperature range studied. It has been reported, in addition, that free radicals in many irradiated polymers, such as polyethylene,[8] polyvinylalcohol,[5,9] polytrifluorochloroethylene[8] and polycarbonate,[10] decay readily near the glass transition temperature. In order to study the decaying behavior of free radicals, the glass transition temperature should thus be taken into account.

For the convenience of experimental procedures, polymethylacrylate (PMA), with the glass transition temperature of +3°C, was used in the present investigation. First, ESR spectra of irratiated PMA were recorded at various temperatures and then interpreted. Irradiated methacrylate and polyethylacrylate were also studied for the sake of comparison. Quantitative studies of the decaying behavior of the free radicals in PMA were made below and above the glass transition temperature. The results obtained were then discussed in terms of molecular motion in the polymer and in terms of the structure of the free radicals.

Experimental

The PMA samples were prepared by the bulk polymerization of commercial methylacrylate after the usual purification. The polymer obtained was precipitated twice from an acetone solution with water and dried in vacuo.

The irradiations were carried out with 1.5 MeV. electrons from a Van de Graaff accelerator (dose rate: 1.5×10^5 rad./sec.) at −196°C. The PMA samples were irradiated in glass tubes which were sealed under a vacuum better than 10^{-4} mmHg.

ESR spectra were observed with a reflection-type x-band spectrometer using low-frequency field modulation (80 c. p. s.). Most observations were made at −196°C or at 12°C, using a TE_{011} cylindrical and a TE_{102} rectangular sample cavity respectively.

Results and Discussion

Observed Spectra and Their Interpretation.— PMA, irradiated and measured at −196°C, gave ESR spectra of the shape shown in Fig. 1 (a), with the irradiation dose of 3×10^7 rad. The spectra had no distinct hyperfine structure. With successive warming of the samples to −78°C, −45°C, −10°C and +18°C, the spectra changed from a singlet with the half-height width of 36 oerst. into a triplet, as Fig. 1 shows. Irradiated PMA gave the triplet spectrum at 12°C shown in Fig. 2 (a) immediately after warming to that temperature. This spectrum is the same as that reported by Ormerod and Charlesby.[2] The separation of the triplet

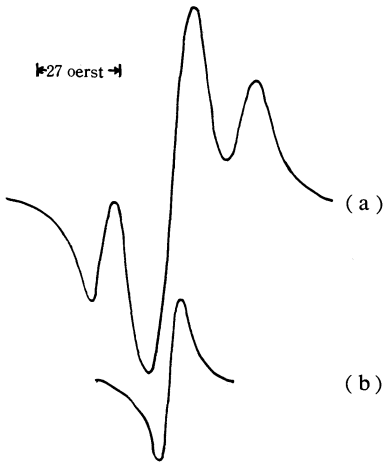

Fig. 2. ESR spectra of PMA irradiated at −196°C with the dose of 3×10^7 rad. and observed at 12°C: (a) immediately after warming to 12°C, (b) after 20 hr. at 12°C.

hyperfine components was 22 oerst. The central peak was a little more intense than the expected intensity distribution of 1 : 2 : 1. This may be due to an overlapping with a singlet spectrum, which showed ΔH_{mse} of 22 oerst. and was still observed after standing 20 hours at room temperature. The change of the spectra from a singlet at a low temperature to a triplet at room temperature was irreversible.

For comparison with the triplet spectra of irradiated PMA mentioned above, the ESR spectra of irradiated methylacrylate and irradiated polyethylacrylate were also studied.

Methylacrylate (MA) was solidified at −196°C and was irradiated at the same temperature under a vacuum. Irradiated MA gave a triplet spectrum with a separation of 22 oerst. at −196°C, as Fig. 3 shows. With an increase in the temperature, the spectrum became weaker, without changing its shape, until it disappeared completely below −78°C. On the other hand, MA which had been irradiated at −196°C with 5×10^7 rad. and warmed to −78°C gave white precipitates when dissolved at −78°C in petroleum ether. Apparently

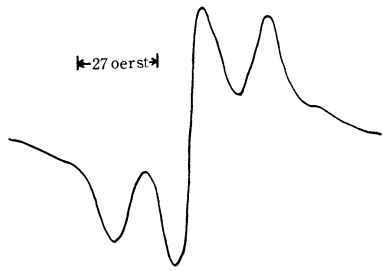

Fig. 3. ESR spectrum of methylacrylate irradiated and observed at −196°C, with the dose of 5×10^7 rad.

polymerization occurs in MA irradiated at −196°C and warmed to −78°C. It is probable that the free radicals giving a triplet spectrum are propagating end groups which disappear with the termination of the propagating chains.

Polyethylacrylate (PEA) was prepared, and its spectra were examined in the same way as those of PMA. PEA irradiated at −196°C gave the quintet spectrum shown in Fig. 4 (a), as has been reported previously.[2] With an increase in the temperature the spectrum changed irreversibly, to a triplet with the separation of 22 oerst. The triplet spectrum of irradiated PEA was much less stable than that of PMA.

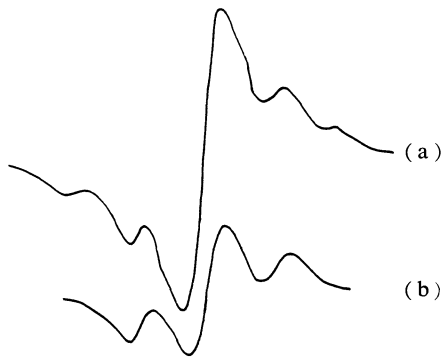

Fig. 4. ESR spectra of PEA irradiated at −196°C with the dose of 3×10^7 rad.: (a) observed at −196°C without warming, (b) observed at about −26°C immediately after warming to this temperature.

It has been reported that propagating radicals in vinyl polymerizations give triplet spectra.[11-15] It is not unreasonable to interpret the triplet spectrum of irradiated PMA as being due to propagating radicals, ~~~~$-CH_2-\dot{C}H(COOCH_3)$, as in the case of irradiated MA. With both PMA and MA, the separation between triplet hyperfine components was the same.

An alternative interpretation would be that the triplet spectrum of PMA is due to the radical structure, $-CH_2-CH(COO\dot{C}H_2)-CH_2-$, but this is not probable because irradiated PEA gave the same triplet.

The Formation and Decay of Free Radicals in PMA.—The concentration of free radicals in PMA increased with the irradiation dose, as

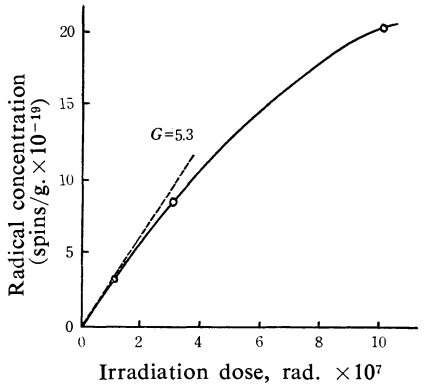

Fig. 5. Formation of free radicals in PMA irradiated at −196°C with the dose rate of 1.5×10^5 rad./sec. and observed at the same temperature.

is shown in Fig. 5. Irradiations and measurements were carried out at −196°C. From the initial slope of the curve in Fig. 5, the G value is calculated to be 5.3, with reference to the formation of free radicals which are stable at −196°C. The absolute value is correct within a 50% range of experimental error, and it is in accordance with that reported by Ormerod and Charlesby.[2]

Figure 6 shows the decaying behavior of free radicals in irradiated PMA when warmed

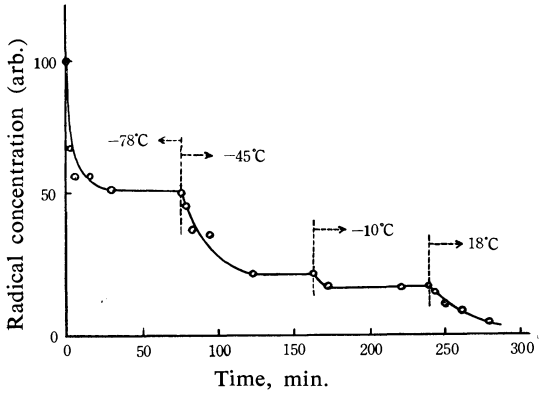

Fig. 6. Decay of free radicals in PMA irradiated at −196°C with the dose of 3×10^7 rad. with successive warming at several temperatures.

successively to a series of temperatures. At temperatures below the glass transition point of PMA, the radical concentration decreased rapidly at the beginning of warming, but it readily attained a final value at each temperature. At temperatures of transition point, the free radicals disappeared following a 2nd order decay process.

The same decaying behavior as that observed for PMA below the glass transition temperature was also reported for polymethylmethacrylate.[2] A possible interpretation for the behavior—in rigid PMA below its glass transition point—is that the thermal activation process which causes the disappearance of free radicals has a wide distribution of activation energies. A similar interpretation was applied by Semenov to the decaying behavior of free radicals in a mixture of *n*-octylalcohol, water and hydroperoxide which was solidified and irradiated at −196°C.[16]

The decay of free radicals in PMA was examined at different temperatures above the glass transition point. As Fig. 7 shows, the observed results fitted well to a 2nd-order decay process, $-d[R\cdot]/dt=k[R\cdot]^2$, except at the beginning of warming. Free radicals which disappeared in this range of warming temperature gave a triplet spectrum. The deviation from the 2nd-order decay at the beginning may be caused by free radicals which disappeared at the transient temperature from −196°C to each warming temperature. The rate constant, k, was obtained from the diagram

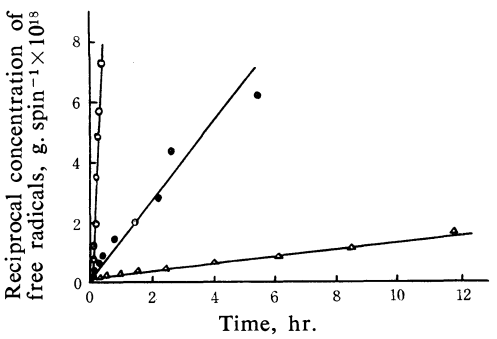

Fig. 7. Decay of free radicals in PMA, irradiated at −196°C with the dose of 3×10^7 rad. and measured at different temperatures.
○ 30°C ● 20°C △ 12°C

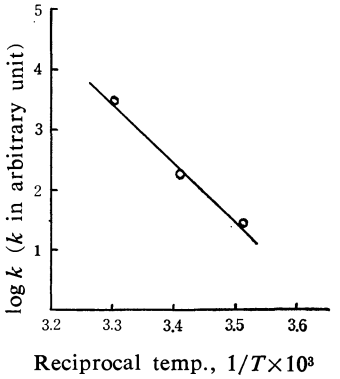

Fig. 8. Rate constants for radical recombination vs. reciprocal temperatures.

16) N. Semenov, Private communication (1962).

in Fig. 7; it is plotted as a function of the reciprocal temperatures in Fig. 8. The activation energy for k was 44 kcal./mol.

The activation energy for segmental motion in PMA has been reported to be 40 kcal./mol. from mechanical dispersion measurements.[17] The good agreement between the activation energies obtained from the mechanical measurements and from the decay of free radicals suggests that the free radicals in PMA giving a triplet spectrum disappear through recombination caused by segmental motion in the polymer. The assignment of the triplet spectrum as being due to the radical structure ~~~~$-CH_2-\dot{C}H(COOCH_3)$ is not in contradiction to the previously-discussed decaying mechanism of the free radicals.

The Structure of Glassy Carbon

By Tokiti NODA and Michio INAGAKI

(Received May 22, 1964)

It has already been reported that the properties of glassy carbon are remarkably different from those of usual electrographitized carbons.[1,2]

In this work, the structure of glassy carbon will be investigated by determining the interlayer spacing, the crystallite size, the disorganized carbon content and the radial distribution function of glassy carbon by means of X-ray diffraction techniques, and a structural model of glassy carbon will be proposed.

Experimental and Results

Two groups of glassy carbon, A and B, were used as the samples in this work. The samples of both groups were heat-treated at temperatures ranging from 500° to 3000°C.

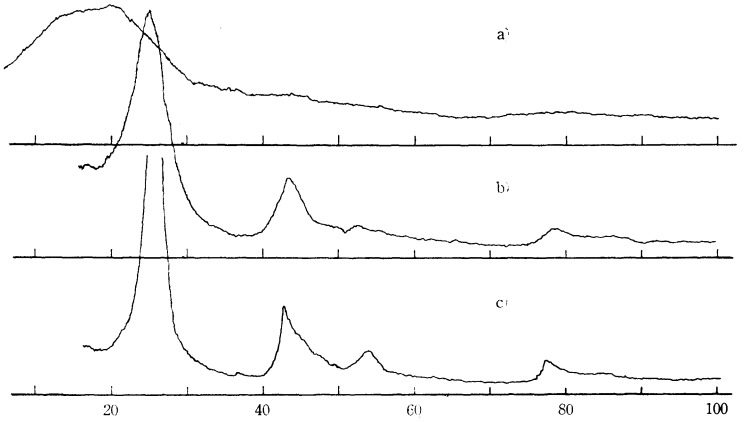

Fig. 1. X-Ray diffraction patterns of glassy carbon treated at a) 500°C, b) 1500°C, and c) 3000°C.

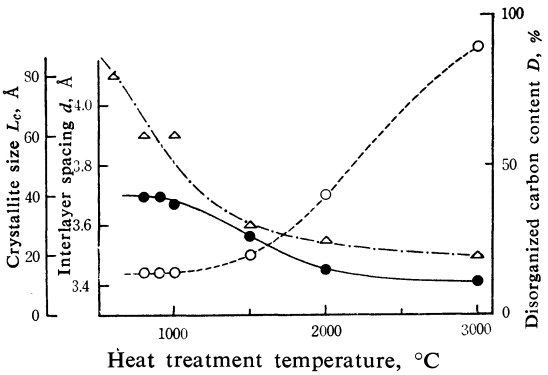

Fig. 2. Variations in the interlayer spacing d, the crystallite size L_c and the disorganized carbon content D with the heat-treatment temperature.
●: Interlayer spacing d
○: Crystallite size L_c
△: Disorganized carbon content D

The X-ray diffraction patterns are shown for the samples in the A group in Fig. 1. In Fig. 2, the variations of the interlayer spacing, d, the crystallite size, L_c, and the disorganized carbon content, D, are shown as functions of the heat-treatment temperature. The interlayer spacing and the crystallite size were measured from the observed (002) diffraction profile. With the sample heat-treated at 3000°C, the lattice constants, c_0 and a_0, and the crystallite sizes, L_c and L_a, were measured from (002) and (10) diffractions using an extra-pure silicon powder as an inner standard. It was found that $c_0=6.810$Å, $a_0=2.418$Å, $L_c=82$Å and $L_a=39$Å. The content of disorganized carbon, which did not participate in the graphite-like layer structure, was determined using the same method as Franklin.[3] The method consists of the determination of the most pertinent D value which makes the I'-profile symmetrical. For the glassy carbon heat-treated at 1500°C, the original I-profile and the symmetrical I'-profile, which corresponds to the D value of 30%, are shown in Fig. 3. The value of I' is calculated from Eq. 1:

$$I'=\frac{s^2}{0.0606}\cdot\frac{I-D}{1-D} \qquad (1)$$

where $s=2\sin\theta/\lambda$

$$I=\frac{I_{obs}-I_{Inc}}{I_{co}}$$

In the above equation, I_{co} and I_{Inc} are the intensities of the coherent and incoherent scattering of carbon respectively. The observed intensity, I_{obs}, of (002) diffraction had

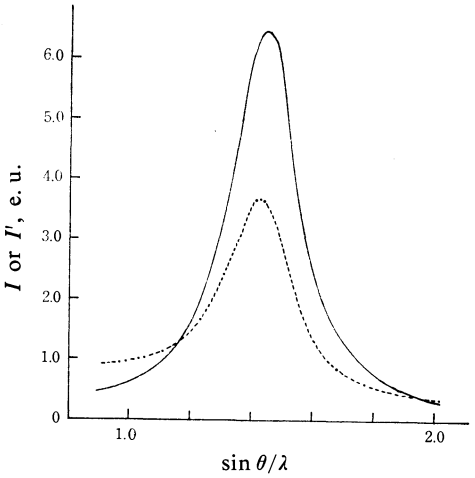

Fig. 3. Determination of the disorganized carbon content D.
……: I-profile, ——: I'-profile which corresponds to the D value of 30%.

been corrected for the various intensity factors, such as absorption and Lorentz-polarization factors, and then normalized to electron units by fitting the theoretical and experimental intensities in the range of s from 1.00 to 1.20Å^{-1}. The measurement of the diffraction intensity was made by means of point-by-point fixed counting at an angular interval of 0.5° and using CuK_α radiation.

In the variations of the interlayer spacing, the crystallite size and the disorganized carbon content with heat treatment, no remarkable difference was found between the samples in the A and B groups.

For each sample, the radial distribution

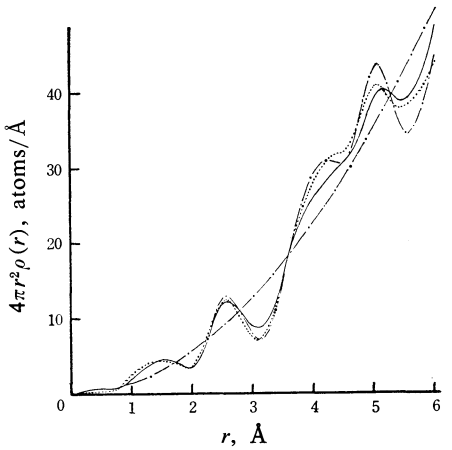

Fig. 4. Radial distribution curve of glassy carbon.
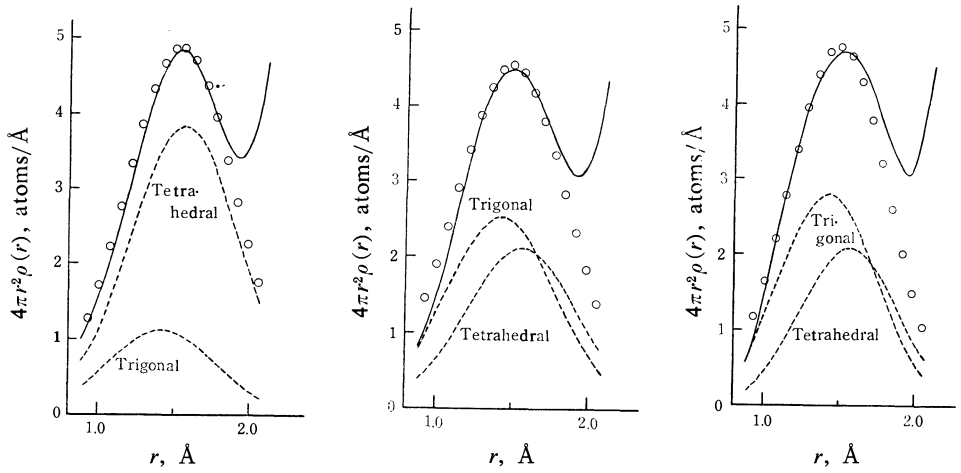
——: Treated at 900°C
……: Treated at 1500°C
-·-·-: Treated at 2000°C
—·—: Mean electron density $4\pi r^2\rho_0$

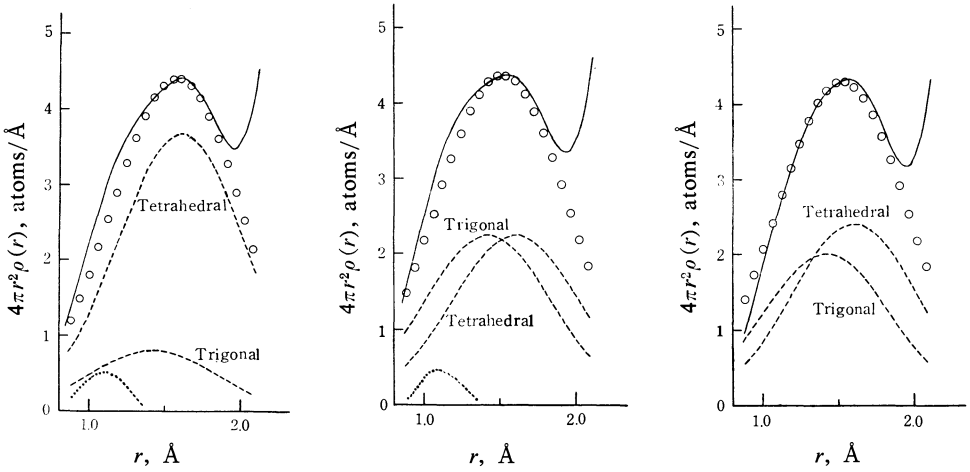
3) R. E. Franklin, *Acta Cryst.*, 3, 107 (1950).



function, $4\pi r^2\rho(r)$, was calculated by means of the summation of Eq. 2:

$$4\pi r^2\rho(r) = 4\pi r^2\rho_0 + 8\pi r \sum_{s=0.08}^{1.60} s\cdot i(s)\cdot e^{as^2}\cdot \sin(2\pi rs)\Delta s \quad (2)$$

where $s = 2\sin\theta/\lambda$



$$i(s) = \frac{I_{obs} - (I_{co} + I_{inc})}{I_{co}}$$

In the above equation, the value of ρ_0 was calculated as 0.113 atoms/Å^3 using the theoretical density of graphite of 2.25 g./cm^3. The interval, Δs, of the above summation was 0.02 Å^{-1}. The factor e^{-as^2} was the artificial temperature factor, and the value of a in this factor was determined as 0.90 so that the value of this factor would be equal to 0.10 at the upper limit of s. The observed intensity, I_{obs}, had been corrected for the various intensity factors and then normalized to electron units on the basis of the range of s from 1.50 to 1.60 Å^{-1}. The measurement of the diffraction intensity was made by means of point-by-point fixed counting and using CuK_α radiation in the range of s from 0.08 to 1.20 Å^{-1} and by using MoK_α radiation in the range of s from 1.20 to 1.60 Å^{-1}. The radial distribution curves for three samples of the B group are shown in Fig. 4.

Fig. 5. Separation of the first peak of the radial distribution curve into component curves with the glassy carbons in the A group.
——: Observed curve ------: Component curve ○○○○: Composite curve

a) 800°C-treated b) 1500°C-treated c) 2000°C-treated

Fig. 6. Separation of the first peak of the radial distribution curve into the component curves with the glassy carbons in the B group.
——: Observed curve ------: Component curve
○○○○: Composite curve ·····: Remainder curve

The first peak of the radial distribution curve, whose position corresponds to the distance to the nearest neighbour atoms, is represented by the solid line in Figs. 5 and 6. Since the mean co-ordination number obtained from the area under the observed curve was in the range of 3~4 and since the first peak was located at around 1.5~1.6Å, it was assumed that glassy carbon is mainly composed of two types of carbon atoms, one having a tetrahedral relation to its neighbours, like diamond, and the other having a trigonal relation to its neighbours, like graphite. In this paper, these two types of carbon atoms are called tetrahedral and trigonal carbon atoms respectively. Therefore, the first observed peak was separated into two component curves corresponding to trigonal and tetrahedral carbon atoms on the assumption that the curve for each carbon atom had the Gaussian form. For example, the first observed peak for the glassy carbon heat-treated at 850°C could be separated with a negligible remainder when the two component curves were expressed as follows:

For tetrahedral carbon atom

$$\frac{9.6}{\sqrt{2\pi}} \cdot \exp\left\{-\frac{1}{2} \cdot \left(\frac{r-1.56}{0.36}\right)^2\right\}$$

For trigonal carbon atom

$$\frac{2.8}{\sqrt{2\pi}} \cdot \exp\left\{-\frac{1}{2} \cdot \left(\frac{r-1.42}{0.36}\right)^2\right\}$$

The separated curves are shown by the broken lines in the figures. With several samples of the B group, particularly with samples heat-treated at low temperatures, the remainder between the observed curve and the composite curve was not negligible, as is shown by the dotted line in Fig. 6.

Discussion

The X-ray diffraction pattern for glassy carbon is very similar to that for a carbon black. The interlayer spacing decreases and the crystallite size increases with an increase in the heat treatment temperature. These variations are also similar to the variations with heat treatment for usual carbon materials. It can be said that graphitization, that is to say, the developments of a graphite-like layer structure, proceeds in glassy carbon. The deduction that the graphite-like layer structure is developed in glassy carbon with heat treatment could be drawn from the variations in other properties,[2,4] such as electrical resistivity and the Hall coefficient, with heat treatment. However, glassy carbon is a typical non-graphitizing carbon because the progress of its graphitization is very little in comparison with that of graphitizing carbons, as can be seen in Fig. 2. The degree of graphitization for the glassy carbon heat-treated at 3000°C was almost the same as that for the petroleum coke heat-treated at about 1900°C. With the glassy carbon heat-treated at low temperatures such as 500~600°C, the (002) diffraction was not well-defined, and the disorganized carbon content was as large as 80%. The glassy carbon heat-treated at a low temperature should be called an organic solid. The radial distribution curve for the glassy carbon heat-treated at 500°C converged to the mean electron density, $4\pi r^2\rho_0$, beyond $r=4$Å. With an increase in the heat treatment temperature, the values of r at the maxima on the observed radial distribution curves approach those for graphite; that is to say, $r=1.4$, 2.6, 4.0 and 5.0 Å. This result is consistent with the variations in the interlayer spacing, the crystallite size and the disorganized carbon content with the heat treatment temperature.

With the samples of the A group, the curve which is composed of two component curves, corresponding to trigonal and tetrahedral carbon atoms, coincides quite well with the observed curve. The content of the tetrahedral carbon atom was calculated from the mean co-ordination numbers of the component curves, taking into consideration the fact that the theoretical co-ordination numbers for tetrahedral and trigonal carbon atoms are 4 and 3 respectively. It was found that the calculated content of the tetrahedral carbon atom is in good coincidence with the disorganized carbon content. With the samples of the B group, particularly with the samples heat-treated at low temperatures, the coincidence between the observed curve and the composite curve was not as complete as with the samples of the A group. A small number of carbon atoms with another relation to their neighbours may also exist in glassy carbon. From the remainder curve, which is located at around 1.1Å, the carbon-hydrogen bond can be expected. However, the carbon-carbon triple bond and the carbon-oxygen double bond might be assumed because such a separation procedure of the first peak is not very accurate.

As has been described above, the graphite-like layer structure was developed in glassy carbon with heat treatment, and no diffraction line which corresponds to that of the other structures was detected in the X-ray diffraction pattern of glassy carbon. Therefore, it can

4) T. Yamaguchi, *Carbon*, **1**, 47 (1963).

be assumed that the trigonal carbon atoms form the graphite-like layer structure and that the tetrahedral carbon atoms form no regular structure. From these results, a structural model of glassy carbon can be proposed, in which tetrahedral carbon atoms form the main part of the criss-cross linkages which link the graphits-like layers in a random way. Furukawa[5] has proposed a somewhat different structural model of glassy carbon, a three-dimensional irregular network configuration of carbon atoms without assuming a significant graphite-like layer structure.

The reason why the structure of glassy carbon is somewhat different in the A and B groups has not yet been made clear. However, it can be said that the conditions of the production of glassy carbon may have a certain effect on its structure. Yamaguchi[4] also used two types of glassy carbon, one impermeable to gas and the other rather porous.

Summary

The structure of glassy carbon has been investigated by determining the interlayer spacing, crystallite size and disorganized carbon content, and by an analysis of the radial distribution function.

Glassy carbon has been found to be a typical non-graphitizing carbon. From the analysis of the first peak of the radial distribution curve, it has been assumed that not only trigonal but also tetrahedral carbon atoms exist in glassy carbon. A structural model of glassy carbon has been proposed; in this model tetrahedral carbon atoms form the main part of the criss-cross linkages which link graphite-like layers in a random way.

The authors wish to thank Dr. Yoshihiro Sumiyoshi, Miss Yukiko Matsunaga and Mr. Motohiro Yamamoto for their assistance in the calculation of the radial distribution function. Thanks are also due to the Tokai Electrode Mfg. Co. for supplying the samples.

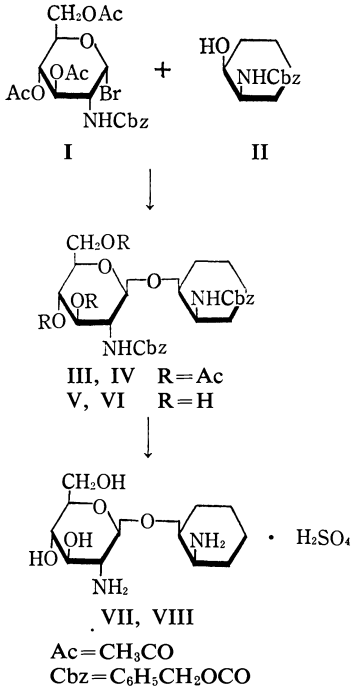
Studies on Antibiotics and Related Substances. XIX. The Synthesis of cis-2-Aminocyclohexyl D-Glucosaminide



By Tetsuo SUAMI, Seiichiro OGAWA, Teruo YOSHIZAWA and Sumio UMEZAWA

(Received May 30, 1964)

Previous studies of the synthesis of *trans*-2-aminocyclohexyl D-glucosaminide[1] have stimulated our interest in the synthesis of *cis*-2-aminocyclohexyl D-glucosaminide. In the present paper, the synthesis of two diastereomers of *cis*-2-aminocyclohexyl D-glucosaminide will be described.

The starting compound, *dl-cis*-2-aminocyclohexanol, was prepared by the following two method: the hydrogenation of *o*-acetamidophenol,[2] and the inversion reaction of *dl-trans*-2-aminocyclohexanol.[3] An attempt to resolve the racemic *cis*-2-aminocyclohexanol with tartaric acid or di-*O*-benzoyl tartaric acid did not yield a satisfactory result. Therefore, *dl-cis*-2-aminocyclohexanol was treated with carbobenzyloxy chloride to yield *N*-carbobenzyloxy-*dl-cis*-2-aminocyclohexanol (II) in 86% yield. The condensation of II with α-1-bromo-3, 4, 6-tri-*O*-acetyl-*N*-carbobenzyloxy-D-glucosamine (I)[4] in the presence of mercuric cyanide gave a mixture of glucosaminides (III and IV), which was then separated by fractional recrystallization to III, m. p. 155°C, $[\alpha]_D^{12}$ +25.2° and IV, m. p. 138°C, $[\alpha]_D^{28}$ −36.5°. Considering their optical rotations and elemental analyses, III and IV might be identified as *N*-carbobenzyloxy-*d-cis*-2-aminocyclohexyl 3, 4, 6-tri-*O*-acetyl-*N*-carbobenzyloxy-β-D-glucosaminide and *N*-carbobenzyloxy-*l-cis*-2-aminocyclohexyl 3, 4, 6-tri-*O*-acetyl-*N*-carbobenzyloxy-β-D-glucosaminide respectively. The deacetylation of

3) A. C. Cope, E. Ciganek and J. Lazar, ibid., **82**, 2591 (1962).
4) J. C. Jruine, D. McNicoll and A. Hynd, *J. Chem. Soc.*, **1911**, 250; L. Zervas and S. Konstas, *Chem. Ber.*, **93**, 435 (1960).

III and IV with methanol saturated with ammonia gave V, $[\alpha]_D^{20}$ +20.6° and VI, $[\alpha]_D^{25}$ −59.2° respectively. The catalytic hydrogenolysis of V and VI, followed by neutralization with sulfuric acid, yielded crystalline sulfate, VII $[\alpha]_D^{15}$ +10.2° and VIII, $[\alpha]_D^{15}$ −50.8° respectively. The designation of VII and VIII as β-anomers is based on their optical rotations, which are less dextrorotatory than those of α-anomers in an analogous compound,[5] and on their infrared spectra.[6]

Experimental

All melting points are corrected. The infrared spectra were recorded in potassium bromide pellets.

***dl-cis*-2-Aminocyclohexanol Hydrochloride.**—a) *dl-cis*-2-Aminocyclohexanol hydrochloride was prepared from *o*-acetamidophenol by the method of Carter et al.[2] in 14% yield.

b) *dl-cis*-Isomer was obtained from *dl-trans*-2-aminocyclohexanol by the method of Cope et al.[3] in 50% yield.

***dl-cis*-2-Acetamidocyclohexanol Acetate.**—A two gram portion of *dl-cis*-2-aminocyclohexanol was treated with a large excess of acetic anhydride for 48 hr. at room temperature. The mixture was then evaporated under reduced pressure, and the residue was distilled in vacuo to yield 2.5 g. (72%) of a viscous oil, b. p. 140~155°C/4 mmHg. After it had stood for three months at room temperature, it crystallized completely. The product was recrystallized twice from benzene and petroleum ether to give the melting point of 71~73°C.

Found: C, 60.58; H, 8.76; N, 7.11. Calcd. for $C_{10}H_{17}NO_3$: C, 60.28; H, 8.66; N, 7.03%.

The Kunz hydrolysis[7] of the product indicated that one acetyl group (1.05) was bound in an ester and another one in an amide form.

***N*-Carbobenzyloxy-*dl-cis*-2-aminocyclohexanol (II).**—*dl-cis*-2-Aminocyclohexanol hydrochloride was treated with carbobenzyloxy chloride in the presence of an excess of sodium bicarbonate to give II, m. p. 72~73°C in 85.5% yield (lit.[8] m. p. 72~73°C).

***N*-Carbobenzyloxy-*cis*-2-aminocyclohexyl 3, 4, 6-Tri-*O*-acetyl-*N*-carbobenzyloxy-β-D-glucosaminide (III and IV).**—A mixture of 8.0 g. of I and 8.0 g. of II in 100 ml. of anhydrous benzene was heated under reflux while being mechanically stirred for 7 hr. with 8.0 g. of mercuric cyanide. The mixture was then filtered to remove any insoluble substance. The filtrate was diluted with 230 ml. of chloroform and washed with a 10% sodium chloride solution and cold water. The solvent was removed under reduced pressure to give a semicrystalline residue. The residue was dissolved in 23 ml. of absolute ethanol and kept in a refrigerator to yield 1.4 g. of the product, m. p. 150~165°C. The crude product was repeatedly recrystallized from methanol-water (2 : 1) to yield 0.87 g. of needles (III), m. p. 154~155°C. $[\alpha]_D^{12}$ +25.2° (*c* 1.63, chloroform).

Found: C, 61.04; H, 6.25; N, 4.11. Calcd. for $C_{34}H_{42}N_2O_{16}$: C, 60.88; H, 6.31; N, 4.18%.

The alcoholic mother liquor was added to ether to give 3.0 g. of the product, m. p. 66~68°C. The crude product was fractionally recrystallized from methanol-water (2 : 1) to yield 1.2 g. of needles (IV), m. p. 136~138°C. $[\alpha]_D^{28}$ −36.5° (*c* 1.07, chloroform).

Found: C, 61.07; H, 6.48; N, 4.25. Calcd. for $C_{34}H_{42}N_2O_{16}$: C, 60.88; H, 6.31; N, 4.18%.

Further recrystallizations of III and IV did not raise their melting points or optical rotations.

***N*-Carbobenzyloxy-*d*-*cis*-2-aminocyclohexyl *N*-Carbobenzyloxy-β-D-glucosaminide (V).**—III (0.7 g.) was suspended in 30 ml. of methanol saturated with ammonia at 5°C. After it had been kept overnight in a refrigerator, the solution was evaporated under reduced pressure to yield a colorless syrup. The product was washed with a small amount of water and then repeatedly recrystallized from acetone-ether to yield 0.35 g. of the amorphous product (61.6%), m. p. 114~116.5°C, $[\alpha]_D^{20}$ +20.6° (*c* 1.92, methanol).

Found: C, 61.60; H, 6.59; N, 5.07. Calcd. for $C_{28}H_{36}N_2O_9$: C, 61.75; H, 6.66; N, 5.14%.

***N*-Carbobenzyloxy-*l*-*cis*-2-aminocyclohexyl *N*-Carbobenzyloxy-β-D-glucosaminide (VI).**—IV (0.6 g.) was treated by being placed in a refrigerator overnight with 30 ml. of methanol saturated with ammonia. The solution was treated similarly with III to yield 0.4 g. of crystals (89%), m. p. 160.5~162°C, $[\alpha]_D^{25}$ −59.2° (*c* 0.92, methanol).

***d-cis*-2-Aminocyclohexyl β-D-Glucosaminide Sulfate (VII).**—A solution of V (1.09 g.) in 25 ml. of absolute methanol was hydrogenated for 40 hr. at room temperature in a hydrogen stream over palladium black (400 mg.). The mixture was then filtered to remove the catalyst, and the filtrate was evaporated under reduced pressure to dryness. The crude product (0.57 g.) was obtained after drying it over phosphorus pentoxide. $[\alpha]_D^{20}$ −12.6° (*c* 2.85, methanol). The crude free base (0.55 g.) was neutralized with 0.1 N sulfuric acid to pH 7, and the solution was filtered to remove a small amount of insoluble substance. Then the filtrate was evaporated under reduced pressure to yield 1 ml. of a residual solution. The addition of absolute ethanol to the solution gave 253 mg. of colorless needles (34%) melting at 275°C (decomp.). $[\alpha]_D^{15}$ +10.2° (*c* 2.64, water).

Found: C, 38.76; H, 6.82; N, 7.56; S, 8.23. Calcd. for $C_{12}H_{24}N_2O_5 \cdot H_2SO_4$: C, 38.49; H, 7.00; N, 7.48; S, 8.56%.

IR: 883 cm^{-1} (type 2b of β-D-glucopyranoside).

***l-cis*-2-Aminocyclohexyl β-D-glucosaminide Sulfate (VIII).**—A 0.33 g. portion of VI was treated in a manner similar to that described above for V to give 140 mg. of crystals (31.4%) melting at 270°C (decomp.). $[\alpha]_D^{15}$ −50.8° (*c* 3.27, water).

Found: C, 38.34; H, 7.11; N, 7.37; S, 8.27. Calcd. for $C_{12}H_{24}N_2O_5 \cdot H_2SO_4$: C, 38.49; H, 7.00; N, 7.48; S, 8.56%.

IR: 887 cm^{-1} (type 2b of β-D-glucopyranoside).

Paper Chromatography.—VII and VIII showed a single spot of R_f 0.38 and 0.26 respectively, in an ascending development at 22.5°C in an ethyl acetate-pyridine-acetic acid-water (5 : 5 : 1 : 3) system[9] (R_f of D-glucosamine hydrochloride: 0.29) on Toyo filter paper No. 50. The spots were detected by means of a spray of ninhydrin in pyridine.

Bioassays. — VII and VIII showed almost no antimicrobial activity against E. coli when examined with a paper-disk method.

The authors are indebted to Mr. Saburo Nakada for his microanalysis, to Mrs. Setsuko Iriyama for her bioassays, to Miss Sunao Ohata for her infrared spectra, and to Mr. Kenji Yabe, Mr. Kiyoshi Imoto and Miss Sumiko Uchida for their assistance in analytical experiments. This research has been in part supported by the Asahi Glass Foundation for Contributions to Industrial Technology.

*Electronic Spectrum of Fluorenone**

By Akira KUBOYAMA

(Received June 2, 1964)

Heretofore the electronic spectra of fluorenone and its derivatives have been reported on by many authors. Though fluorenone is a fundamental substance in organic chemistry, there have been few papers in which these spectra have been studied in detail either theoretically or experimentally. In this work, the electronic spectrum of fluorenone in various solvents will be measured, and from these results and from the results calculated with the simple MO[1] method for the π-electronic system of fluorenone the nature of each absorption band of fluorenone will be studied. It will be shown that the weak absorption band near 380 mμ, which has been heretofore regarded as an $n\rightarrow\pi^*$ band,[2-5] is really a $\pi\rightarrow\pi^*$ band.

Experimental and Results

Materials. — Commercially-available fluorenone was purified by means of vacuum sublimation (m. p. 83~84°C). All the solvents used in the present study were of special grade. Ethanol (99.5 vol.%) was distilled. Chloroform was washed several times with water, dried with calcium chloride, and distilled. Carbon tetrachloride was dried with calcium chloride and distilled. Dioxane and

Measurements. — The absorption spectra were measured with a Cary 14M recording spectrophotometer with the fused quartz cells of 1 and 5 cm. path.

Results.—The absorption spectra obtained are given in Figs. 1—3.

Method of Calculation

It is thought that, in the calculations with the MO method for the π-electronic system of unsaturated carbonyl compounds such as fluorenone, the effect of the configuration interaction in explaining the low energy electronic spectra qualitatively is not indispensable as in quinones,[7,8] and so, that the results obtained with the simple MO method are useful to some extent in this case. Therefore, in this work we used results obtained with the simple MO method.

Though the molecular dimensions of fluorenone have never been established, considering the molecular dimensions of fluorene studied by X-ray analysis[9] it is thought that fluorenone is planar or almost so, and that in the calculations with the simple MO method the Coulomb and the exchange integrals used in quinones can reasonably be applied to fluorenone. In *o*- and *p*-benzoquinones,[8] in order to make the MO's in the simple MO method simulate those obtained with the SCF MO method, including electronic interaction, the Coulomb integral (α_i) of the oxygen atom should be far smaller (in β units) than those generally used; the exchange integral (β_{ij}) of the conventional single bond also should be smaller (in β units) than those generally used. These new integral values are thought to be better than those generally used. The integral values used with this in mind are shown in Chart 1(a). The dependence of the orbital energy levels upon the Coulomb integral of

the oxygen atom of fluorenone was also calculated. Furthermore, the calculations with the integral values used in our previous studies[10] of quinones were also carried out for the sake of comparison. These integral values are shown in Chart I(b).

Calculated Results and Discussion

As may be seen in Figs. 1—3, it appears that fluorenone has three absorption bands (near 380 mμ, 300 mμ, and 250 mμ, respectively) in the near-ultraviolet region. Unfortunately, the vibrational structure of the 380 mμ band is not clear. The 380 mμ band shifts considerably toward longer wavelengths from *n*-heptane to carbon tetrachloride, chloroform, and ethanol. In chloroform and ethanol the 380 mμ band is at almost the same position and seems to be at a little longer wavelengths than in carbon tetrachloride. The shift of the center of the 380 mμ band from *n*-heptane to chloroform and ethanol is estimated at ca. 8 mμ. As for the 300 mμ band, in *n*-heptane, the intervals (ca. 770 cm^{-1}) in the three peaks on the longer wavelength side (at 319 mμ, 311.5 mμ and 304 mμ, respectively) are far smaller than that (1470 cm^{-1}) between the two peaks on the shorter wavelength side (at 291 mμ and 281 mμ). The former peak group shifs ca. 10 mμ toward longer wavelengths from *n*-heptane to ethanol, while the latter one shifts only ca. 1.5 mμ toward longer wavelengths. The orders of the magnitude of the red-shift[11] of the former and the latter peak groups in various solvents are ethanol>chloroform>carbon tetrachloride and chloroform>carbon tetrachloride>ethanol respectively.

These differences in vibrational structure and solvent effect between the two peak groups show that the two peak groups originate in different eletronic transitions. The 250 mμ band shifts only ca. 1 mμ toward longer wavelengths from *n*-heptane to ethanol, and the order of the magnitude of the red-shift is chloroform>ethanol, as in the 290 mμ band. The interval (1235 cm^{-1}) between the two peaks (at 255 mμ and 247 mμ) of the 250 mμ band in *n*-heptane also almost agrees with that of the 290 mμ band in *n*-heptane. From the facts mentioned above it may be concluded that fluorenone has four absorption bands in the near-ultraviolet region (near 380 mμ, 310 mμ, 290 mμ, and 250 mμ respectively). The facts about the vibrational structure and solvent effect mentioned above may show that the excited electronic states of the 290 mμ and 250 mμ bands are substantially similar and different from that of the 310 mμ band.

Considering that, as a proton-donor in the hydrogen-bond formation, ethanol is stronger than chloroform and that *n*-heptane and carbon tetrachloride are not proton donors, the large red-shift of the 310 mμ band in ethanol and chloroform is thought to be mainly due to hydrogen-bond formation between the carbonyl oxygen atom of fluorenone and these solvents. On the other hand, the polarizability of solvents is generally thought to be almost equally effective for the red-shifts of all absorption bands of solutes. The order of the magnitudes of the polarizability of various solvents, as a bulk effect, agrees with that of the refractive indices of the solvents. The refractive indices[12] (for the sodium D line at 20°C) of chloroform and carbon tetrachloride (1.445 and 1.463 respectively) are considerably larger than those[12] of ethanol and *n*-heptane (1.361 and 1.388 respectively). Therefore, from the facts mentioned above, it may reasonably be concluded that, for the red-shift of the 310 mμ band, the hydrogen-bond formation mentioned above is far more effective than the polarizability of the solvents and that, for the red-shifts of the 290 mμ and 250 mμ bands, the hydrogen-bond formation mentioned above is less effective than the polarizability of the solvents. As for the 380 mμ band, for its red-shift the hydrogen-bond formation mentioned above is thought to be effective.

The 310 mμ, 290 mμ, and 250 mμ bands may be safely regarded as $\pi\rightarrow\pi^*$ bands. The 380 mμ band has, heretofore, been described as an $n\rightarrow\pi^*$ band. As has been pointed out by Blealey and Kasha,[13] however, $n\rightarrow\pi^*$ bands shift toward longer wavelengths with hydrogen-bond formation between hetero-atoms in solutes, participating in the $n\rightarrow\pi^*$ transition, and solvents. Therefore, the solvent effect for the 380 mμ band shows that this band should be a $\pi\rightarrow\pi^*$ band. The maximum molar absorption coefficient of the 380 mμ band (ca. 250) seems too large for $n\rightarrow\pi^*$ bands of planar unsaturated carbonyl compounds. It is well known that $n\rightarrow\pi^*$ bands shift toward shorter wavelengths with the substitution of electron-donating groups, such

10) A. Kuboyama, This Bulletin, **31**, 752 (1958); **32**, 1226 (1959).

11) In this paper the terms "shifts of absorption bands toward longer wavelengths and toward shorter wavelengths" are abbreviated as a "red-shift" and "blue-shift", respectively.

TABLE I. POSITIONS OF THE CENTER OF THE 380 mμ BAND

	Solvent	λ(mμ)	Lit.
Fluorenone	*n*-Heptane	~377	
Fluorenone	Ethanol	~385	
2-Methylfluorenone	Isooctane	~395	Ref. 2
3-Methylfluorenone	Isooctane	~375	Ref. 2
2-Dimethylaminofluorenone	Heptane	~485	Ref. 18
2-Dimethylaminofluorenone	Ethanol	~520	Ref. 18
2-Hydroxyfluorenone	Dioxane	~425	Ref. 18
3-Methoxyfluorenone	Isooctane	~365	Ref. 19

as alkyl, hydroxyl, and amino groups.[14-17] In Table I, the center positions of the 380 mμ bands of several, electron-donating-group substituted fluorenones in various solvents are shown. The solvent effects by *n*-heptane and isooctane are thought to be nearly the same. From this table it may be seen that the 380 mμ band shifts toward longer wavelengths with "2"-substitution and more or less toward shorter wavelengths with "3"-substitution respectively. This "2"-substitution effect also shows that the 380 mμ band should be a $\pi\rightarrow\pi^*$ band. All the experimental facts mentioned above show that the 380 mμ band should be a $\pi\rightarrow\pi^*$ band. Therefore, the 380 mμ band will henceforth be so regarded. Since the position of the $n\rightarrow\pi^*$ band of fluorenone is thought to be not far from that of the 380 mμ band, the former band is probably hidden in the latter one because of its low intensity. The blue-shift of the 380 mμ band with the "3"-substitution of electron-donating groups will be explained later on the basis of the π-electronic structure of fluorenone.

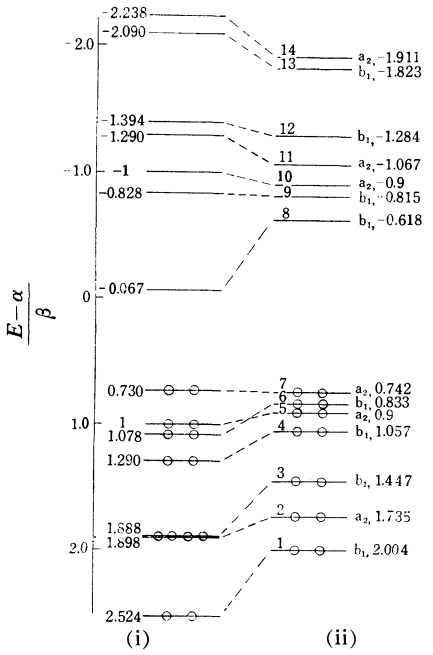

Fig. 4a. Orbital energy levels of fluorenone.

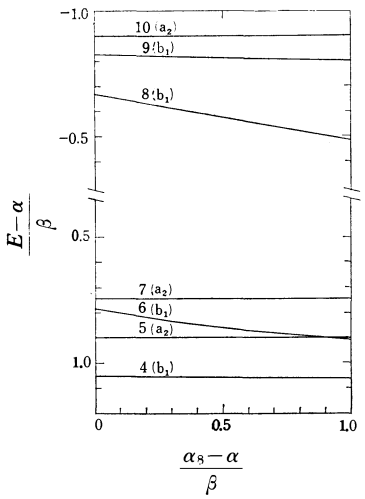

Fig. 4b. Dependence of orbital energies upon Coulomb integral of oxygen atom.

The calculated orbital energy levels of fluorenone and the dependence of energy upon the Coulomb integral of the oxygen atom of fluorenone are shown in Figs. 4a and 4b, respectively. The energy levels in Fig. 4a(i) were obtained with the integral values in Chart I(b). The MO's are classified according to their symmetry properties in the symmetry group C_{2v}. Considering Figs. 4a and 4b together, the transitions which may reasonably be assigned to the 380 mμ band are thought to be safely limited to the three transitions (7→8, 6→8, and 5→8) on the basis of the magnitude of transition energy. It is reasonable to expect that, with the hydrogen-bond formation between fluorenone and solvents, the Coulomb integral of the oxygen atom of fluorenone becomes larger (in β unit). In Fig. 4b it may be seen that, with the increase in the Coulomb integral of the oxygen

atom, the energies of the transitions (7→8 and 5→8) become smaller to a larger extent than that of the transition (6→8). Therefore, from the solvent effect the 380 mμ band may favorably be assigned to either of the two transitions (7→8 or 5→8), both ($A_1 \rightarrow B_2$). Similarly, from the solvent effect, the 310 mμ band also may be assigned to either of these two transitions.

The blue-shift of the 380 mμ band with the "3"-substitution of electron-donating groups is explained as follows. Generally, in a transition ($m \rightarrow n$) in a π-electronic system, where m and n denote orbital energy levels in the simple MO method, the change in the transition energy with the substitution of electron-donating groups in the j-th atom position of the π-electronic system depends upon C^2_{mj} and C^2_{nj} in the approximation of the perturbation method,[17] where C_{ij} denotes the coefficient of the j-th atomic orbital of the LCAO MO of the i-th orbital energy level. If $C^2_{mj} \gtrsim C^2_{nj}$, the transition energy decreases with the substitution, and if C^2_{mj} is considerably smaller than C^2_{nj}, we may expect that the transition energy will rather increase with the substitution. In Table II, the C^2_{ij} values of fluorenone ($i=5, 6, 7, 8$; $j=2, 3$) are shown. In Table II, in all the cases ((a), (b), and (c)), the relative magnitudes of C^2_{ij} are similar; on the basis of them, only the transition (7→8) ($A_1 \rightarrow B_2$) can reasonably be assigned to the 380 mμ band in consideration of the substitution effect mentioned before; therefore, the transition (5→8) ($A_1 \rightarrow B_2$) may be assigned to the 310 mμ band. According to this assignment, from Table II the blue-shift of the 310 mμ band with the "2"-substitution of electron-donating groups may be expected, but, unfortunately, we have no available data about this point. In fluorenone only two kinds of electronic transition ($A_1 \rightarrow B_2$ and $A_1 \rightarrow A_1$) are possible. Therefore, the assignment of the 290 mμ and 250 mμ bands to the transition ($A_1 \rightarrow A_1$) is thus favorable.[20] The directions of the polarization of the transitions ($A_1 \rightarrow B_2$ and $A_1 \rightarrow A_1$) are perpendicular to and along the C–O bond axis of fluorenone respectively.

TABLE II. VALUES OF C^2_{ij}

(1)

	C^2_{52}	C^2_{62}	C^2_{72}	C^2_{82}

(b)	0	0	0.160	0.031
(c)	0	0	0.159	0.017

(2)

	C^2_{53}	C^2_{63}	C^2_{73}	C^2_{83}
(a)	0.125	0.116	0.027	0.070
(b)	0.125	0.114	0.027	0.065
(c)	0.125	0.084	0.021	0.068

Note: In (a) and (c) integral values in Charts I(a) and I(b) respectively were used. In (b) the integral values in Chart I(a) were used except that $\alpha_8=\alpha+\beta$.

Summary

The electronic spectrum of fluorenone in various solvents has been measured; from these results and from the results obtained with the simple MO method for the π-electronic system of fluorenone, the nature of each absorption band of fluorenone has been studied. It has been concluded that fluorenone has four $\pi \rightarrow \pi^*$ absorption bands (near 380 mμ, 310 mμ, 290 mμ, and 250 mμ respectively) in the near-ultraviolet region. The assignments of the 380 mμ and 310 mμ bands to the transition ($A_1 \rightarrow B_2$) and the 290 mμ and 250 mμ bands to the transition ($A_1 \rightarrow A_1$) are favorable in view of the obtained results.

The author wishes to express his thanks to Mr. Kōichi Wada of the Yokohama Customs House for his kind assistance.

*Semiconductivity of Phenanthrene Single Crystals**

By Shoichi MATSUMOTO and Tomomichi TSUKADA

(Received June 6, 1964)

Extensive studies have been made of the electrical properties of the anthracene single crystal,[1-4] which is now regarded as a model substance for the investigation of the semiconductive properties of aromatic hydrocarbons.

In order to elucidate the mechanism of electronic conduction in organic solids, it is also important to accumulate reliable data on the electrical properties of other relatively simple hydrocarbons. However, on phenanthrene, a structural isomer of anthracene, the available experimental results are quite limited.[5]

In the present work, the electrical conductivity and its anisotropy will be studied in detail on phenanthrene single crystals, and the results will be compared with the related behavior of anthracene.

Experimental

Material.—Powdered phenanthrene of a chemical-purpose grade obtained from the Eastman Kodak Company was purified by recrystallization from an ethanol solution, followed by vacuum sublimation. Each purification process was carefully repeated more than four times.

In the fluorescence spectrum of the resultant flaky and colorless sample, there was no peak other than those of phenanthrene reported in the literature,[6] except for a slight variation in the intensity. This variation may be due to the difference in the crystalline state.

Crystal Growth.—Crystals of purified phenanthrene with a melting point of 103°C were grown by means of a modified Bridgeman method.

In the electrical furnace applied here, the upper part was maintained at a temperature a little higher than the melting point of the sample, and the bottom part, at a temperature lower; there was a large temperature gradient, about 10°C/cm., in the middle part.

The powdered sample was sealed under a 10^{-3}~10^{-4} mmHg vacuum into a cylindrical glass tube, the bottom of which was sharpened like a pencil. The tube was lowered at the rate of 1~2 mm. per hour through the center of the furnace.

In this process, the crystal grew its ab plane perpendicular to the isothermal plane in the furnace.

Crystals of about 8×8×15 mm. could thus be made, but in most cases, cracks developed along the ab plane soon after the preparation. Therefore, only uncracked portions were cut out from them to use for the electrical measurement.

Specimen Cell.—An electrical conductivity cell of the sandwich type was prepared on a Teflon block, as is schematically shown in Fig. 1.

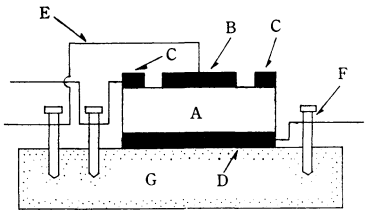

Fig. 1. The conductivity cell of sandwich type.
A: Crystal, B: Front electrode
C: Guard-ring electrode
D: Back electrode, E: Lead wire
F: Terminal, G: Teflon block

The cell had a guard-ring electrode which was grounded in order to prevent an effect of the surface current.

Silver paste (Ecco Bond), which was found to make ohmic contact with this sample, as will be described in the following paragraph, was applied as electrodes. The following two kinds of cells were used to measure the electrical resistivity in two crystallographic directions: the ⊥ab plane and the // ab plane.

(1) The ⊥ab cell, the electrodes of which were painted on both sides of the ab plane of a crystal in order to evaluate the electrical resistivity perpendicular to this plane ($\rho_{\perp ab}$).

(2) The //ab cell, the electrodes of which were attached on both sides of the plane perpendicular to the ab plane in order to observe the electrical resistivity parallel to the ab plane ($\rho_{/\!/ ab}$).

Measurements.—The measuring apparatus consisted of a vibrating reed electrometer (Takeda TR-88).

The current-voltage characteristics were examined in an atmosphere of air and nitrogen gas in order to find the effect of an ambient atmosphere on the electrical conductivity of the sample. The measurement of the temperature dependence of the electrical resistivity was made over the temperature range

from 24 to 75°C for both increasing and decreasing temperatures.

Results and Discussion

The current-voltage characteristics of the specimen //ab cell in air and in nitrogen gas at room temperature are shown in Fig. 2.

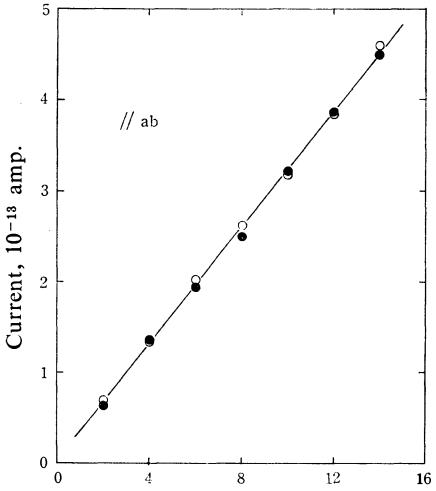

Fig. 2. The current-voltage characteristics of phenanthrene.
○ in air
● in nitrogen gas

There was no difference between the current in air and that in nitrogen gas within the range of experimental error. Therefore, the observation of the temperature dependence of the electrical resistivity was made in air.

As is exemplified by the same figure, the current-voltage relation was linear up to 1600 V. per cm. A similar result was obtained for the specimen ⊥ ab cell.

As has been reported in many papers on the semiconductive property of organic compounds, the observed temperature dependence of the electrical resistivity of phenanthrene is, for both increasing and decreasing temperatures, in good agreement with the following expression, as is shown in Fig. 3.

$$\rho = \rho_0 \exp(\Delta\varepsilon/2kT)$$

where ρ is the electrical resistivity, $\Delta\varepsilon$ is the thermal activation energy, k is the Boltzmann constant, and T is the abolute temperature. The values of $\Delta\varepsilon$, ρ_0, and the resistivity at 15°C, ρ_{15}, are given in Table I. The last value was estimated by extrapolation from the observed temperature dependence.

There is no anisotropy in the value of the activation energy. An anisotropy can be found, however, in the value of the electrical

** From H. Inokuchi et al.

resistivity; the electrical resistivity measured on the ab plane ($\rho_{//ab}$) is lower by a factor of about twenty-five than that perpendicular to this plane ($\sigma_{\perp ab}$).

The electrical conductivity (σ) can be expressed as $\rho = |e|n\mu$, where n is the concentration of the charge carrier and μ, the mobility of the carrier.

Since no anisotropy is found in the activation energy, it is not likely that the concentration of the charge carrier varies according to the direction of the electric field. Therefore, it seems that the observed anisotropy in the electrical conductivity results from the difference in the mobility of the charge carrier. This assumption has been affirmed by the mobility anisotropy in anthracene obtained through a pulsed photoconductivity technique[3] and tight-binding band calculations.[4]

The conductivity anisotropy observed with a

phenanthrene crystal is, however, larger than that of anthracene reported by Mette and Pick,[1] who have found that in the anthracene crystal, the conductivity on the ab plane is a few times higher than that in the direction perpendicular to the plane. Such a difference might be due to the difference in the band structures between phenanthrene and anthracene.

As the molecules in a phenanthrene crystal are arranged so that the molecular planes are nearly perpendicular to the ab plane,[7,8] the overlapping of π-orbitals are largest in the direction parallel to the ab plane. The resistivity is lowest in this direction, as has been found to be true in anthracene[1] and other substances.[9]

There is an appreciable difference between phenanthrene and anthracence in the absolute values of $\Delta\varepsilon$ and ρ_{15}, as is shown in Table I. A similar result has been reported also by Rust et al. as a result of their experiment with powder specimens.[5]

Therefore, we must conclude that while phenanthrene and antheacene are structural isomers and have similar crystallographic characters,[7,8,10] the electrical properties of the two substances are markedly different.

Summary

Phenanthrene single crystals have been grown by means of a modified Bridgeman method. The electrical conductivity has been measured for two crystallographic directions, $\perp$ ab and $/\!/$ab.

The electrical resistivity is not affected appreciably by ambient oxygen. The temperature dependence of electrical resistivity can be described as $\rho=\rho_0\exp(\Delta\varepsilon/2kT)$, where the activation energy ($\Delta\varepsilon$) is 1.14 eV. for $\perp$ab and 1.15 eV. for $/\!/$ ab; the two values agree well. A large anisotropy has been found in the resistivity at 15°C. The resistivity is 4.8×10^{15} Ω cm. and 1.9×10^{14} Ω cm. for $\perp$ ab and $/\!/$ab respectively.

It has been concluded that, although phenanthrene is an isomer of anthracene, the electrical properties of phenanthrene differ considerably from those of anthracene.

The authors wish to thank Dr. Haruo Kuroda for many valuable discussions and suggestions, Dr. Toru Matsushita for his helpful advice on the growth of crystals, and Dr. Yoshiro Fukao for his X-ray analysis.

Studies of the Synthetic Inorganic Ion Exchanger. IV.[1] *The Separation of the Fission Product and Uranium by Means of a Stannic Phosphate Cation Exchanger*

By Yasushi INOUE, Shin SUZUKI and Hidehiro GOTO

(Received May 6, 1964)

The separation of uranium and fission products is one of the main parts of the reprocessing of irradiated nuclear fuels. In such a process it is better to use the unit processes which can be applied to the remote handling operations and which are not interfered with by the irradiation of the high dose of ionized radiation. In this respect, the ion exchange method employing the stannic phosphate cation exchanger which has been developed in this laboratory is considered to be one of the most promising methods.

Stannic phosphate, besides its resistivity against ionized radiation, has various other excellent characteristics and was applied to the separation of fission products in the preceding study of this series.[2] Using various concentrations of nitric acid and ammonium chloride

1) Y. Inoue, This Bulletin, **36**, 1324 (1963).

2) Y. Inoue, ibid., **36**, 1316 (1963).

solutions as the eluants, the separation was achieved on small columns in a relatively simple operation. It had, however, a shortcoming in that some of the rare earths was eluted with cesium.

The purpose of this study is to modify the method for the mutual separation of fission products in order to prevent the contamination of cesium and to establish a method for the separation of uranium from the fission products.

Experiment

Reagents.—*Ion Exchanger.*—The stannic phosphate used was prepared by the method described previously.[2]

Radioactive Isotopes.—They were the same as those of the last paper of this series.[1]

All the other reagents, such as uranyl nitrate, nitric acid, phosphoric acid, acetic acid, sodium carbonate and ammonium chloride, were of the highest grade of purity.

Apparatus.—All the absorption measurements were made with a Hitachi spectrophotometer, model EPU-2, with 1 cm. silica transmission cells. The pH meter, radiation measurement instruments and fraction collector were those described in the foregoing report.

Procedure.—*The Determination of Uranium.*—In the presence of phosphate, the thiocyanate-spectrophotometric method[3] cannot be used because of the strong interference from phosphate. In this case, the sodium carbonate-hydrogen peroxide-sodium hydroxide method[4] was employed. The calibration curves were made in the presence of the same amount of phosphoric acid as in the sample solution in order to eliminate the interference from phosphate. The procedure was as follows: After less than 10 ml. of the sample solution had been placed in a 100 ml. beaker, the volume was brought to about 10 ml. with distilled water. The pH of the solution was adjusted with sodium hydroxide, and then it was transfered into a 25 ml. volumetric flask. Five milliliters of 5% sodium carbonate, 1 ml. of 10% sodium hydroxide and 2 ml. of 3% hydrogen peroxide solutions were added succesively. After this new solution had been diluted to the 25 ml. mark, the absorbance of the solution was measured against a corresponding blank at the wavelength of 370 or 400 mμ. The concentration of uranium was calculated from the relationship between the absorbance and the concentration represented in Table I.

TABLE I. RELATIONSHIP BETWEEN ABSORBANCE AND CONCENTRATION OF URANIUM IN THE PRESENCE OF PHOSPHORIC ACID

Concn. of H_3PO_4, M	(μg./ml.)/unit absorbance	
	370 mμ	400 mμ

10^{-1}	185.2	238.6
2×10^{-1}	196.5	244.8
4×10^{-1}	232.5	276.6
1.0	281.8	333.2

3) E. B. Sandell, "Colorimetric Determination of Traces of Metals," Interscience Publishers, New York (1959), p. 916.
4) Ibid., p. 915.

The Determination of the Distribution Coefficients.—The distribution coefficients were determined by equilibrating 500 mg. of the ion exchanger in a thermostat at 25°C with 50 ml. of suitable solutions for two or three days. This was followed by the filtration of the mixture and by the analysis of the filtrate. If necessary, the pH of the filtrate was measured. The metallic ion content of the exchanger after equilibrium was estimated from the difference between the total initial and final concentrations of metal present in the solution.

The distribution coefficients were calculated by means of the usual relationship:

$$K_d=\frac{\left(\begin{array}{c}\text{Amount of cation in exchanger/}\\ \text{Wt. of exchanger in g.}\end{array}\right)}{\left(\begin{array}{c}\text{Amount of cation in solution/}\\ \text{Vol. of solution in ml.}\end{array}\right)}$$

Cerium was carrier-free ^{144}Ce, and the concentration of uranium was 10^{-3} M. They were determined radiochemically and spectrophotometrically respectively.

Column Operation.—The column was prepared as follows. To 2 g. of a dried exchanger in the hydrogen form (100~200 mesh), sufficient distilled water was added to allow a mixing thorough enough to expel any adhering air bubbles. After this mixing, the slurry was poured into a glass column, 7 mm. in internal diameter, using glass wool as a column support. The column thus prepared had a height of 40 mm. The flow rate of the influent was controlled according to the rate of exchange for each experiment and is described in figures of the elution curve. For making elution curves, effluents were received in polyethylene test tubes in suitable amounts; their radioactivities were measured with a well-type scintillation counter, and their uranium contents were determined by the method described above. When beta-rays were used for the measurement of the radioactivity, one drop of solution from every 2 g. of the effluents was placed on an aluminum dish, and their radioactivities were measured by a G. M. counter in the usual manner.

Results

The Modification of the Separation Method of a Fission Product Solution.—In the mutual separation of fission products, cesium was not obtained in a radiochemically pure state when it was eluted by a 3 M ammonium chloride solution as has been described previously. When this eluant was applied to the fission product solution containing uranium, rare earths and also uranium were eluted by this eluant, as will be shown later. This is perhaps

because of the partial elution of rare earths and uranium by the hydrogen ions which are replaced from the column by the action of concentrated ammonium ions. This is supported by the fact that this objectionable phenomenon is less pronounced when the exchanger is treated with a sufficient amount of 3 M ammonium chloride beforehand. Even with this pretreatment, however, the exchanger was not completely converted to the ammonium form. (This was clearly indicated by the fact that when an ammonium carbonate solution came in contact with the exchanger, bubbles of carbon dioxide were generated.) Moreover, even if the exchanger were completely converted to the ammonium form, the contamination of cesium would not be eliminated, as the presence of some acid in the eluant is needed for the complete elution of strontium, which is completed before the elution of cesium. Therefore, at all events, it is essential to devise a procedure by which cesium can be eluted in a radiochemically pure state.

It is conceivable that the interfering effect of the remaining hydrogen ions can be eliminated by the treatment of the column with a neutral solution before the elution of cesium. As one such reagent, ammonium acetate was chosen, and, as is shown in Fig. 1, a clear-cut elution curve was obtained. It was confirmed by the radiochemical analyses of several representative aliquots of the effluents that no contamination of cerium occurred in the cesium fraction.

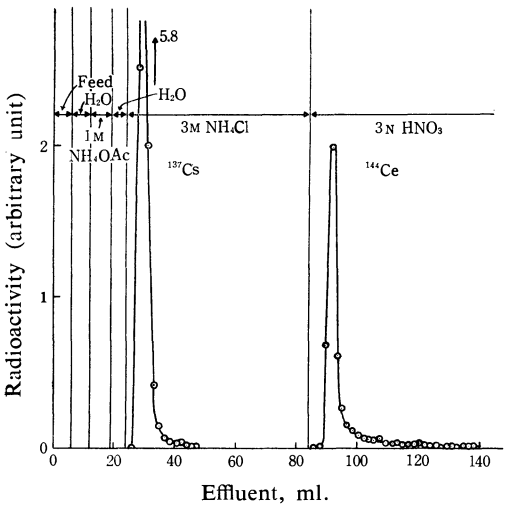

Fig. 1. Separation of ^{144}Ce and ^{137}Cs. Flow rate: 0.5~0.6 ml./min.

Furthermore, this procedure did not affect at all the elution processes after that of 3 M ammonium chloride.

The Distribution Coefficients of Uranium in a Nitric Acid Solution.—To contribute to the establishment of the method of separation, the distribution coefficients of uranium were determined in a nitric acid medium, as is shown in Table II. For the purpose of comparison, the values for nuclides present in fission products are cited in the table quoted from the preceding report. The distribution coefficients of uranium decrease with an increase in the acidity and resemble those of rare earths. From these results, it is expected that the separation of uranium from rare earths by nitric acid is very difficult, while that from other nuclides is easy. First the conditions for the mutual separation of uranium and individual nuclides in fission products were determined; then the separation of uranium and gross fission products was carried out.

The Separation of ^{89}Sr and Uranium.—The separation of ^{89}Sr and uranium was carried

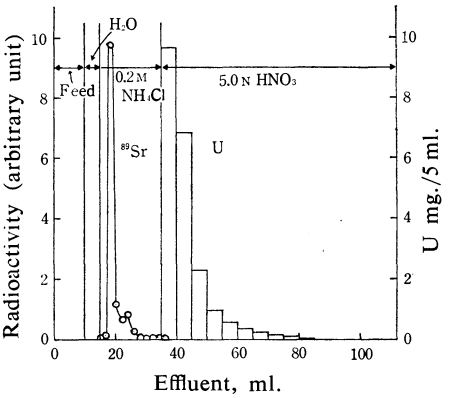

Fig. 2. Separation of ^{89}Sr and uranium. Flow rate: 0.5~0.6 ml./min.

out by the hydrogen-form exchanger. Ten milliliters of a sample solution containing a 10^{-2} M uranyl nitrate and carrier-free ^{89}Sr were passed through the column, and then 0.2~0.5 M ammonium chloride and 5 N nitric acid solutions were passed through in order to elute strontium and uranium successively. The separation went well, as is shown in Fig. 2. When an ammonium-form exchanger was used, it was necessary to use an eluant containing some acid in order to make a complete elution of strontium. A part of the uranium was also eluted by this reagent; therefore, an ammonium-form exchanger cannot be used in the separation of these elements.

The Separation of ^{137}Cs and Uranium.—When the hydrogen-form exchanger was used, uranium was eluted partly in 3 M ammonium chloride, as in the case of rare earths, as is shown in Fig. 3. The treatment of the column with a 1 M ammonium acetate solution before the elution of cesium made it possible to prevent the contamination of uranium, and separation was satisfactory, as is shown in Fig. 4.

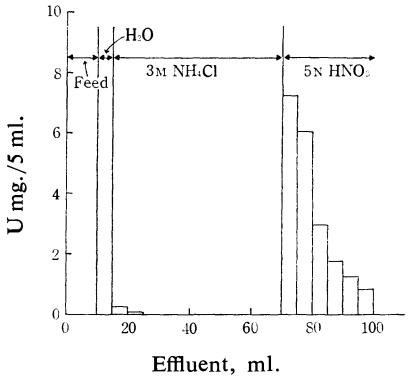

Fig. 3. Elution of uranium from hydrogen form exchanger.
Flow rate: 0.5~0.6 ml./min.

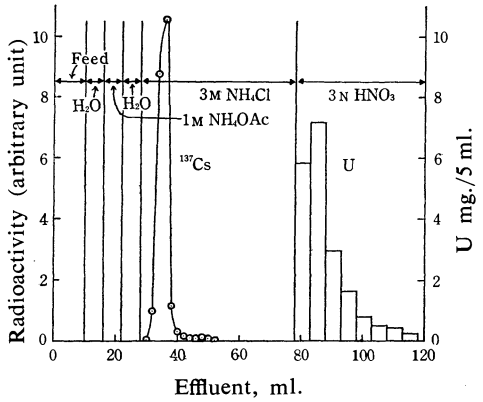

Fig. 4. Separation of ^{137}Cs and uranium.
Flow rate: 0.5~0.6 ml./min.

The Separation of ^{144}Ce and Uranium.—These two elements cannot be eluted by ammonium chloride, and separation by nitric acid seems to be very difficult, as is indicated by the results of Table II. This was also confirmed experimentally by the detailed investigation of the elution curves of uranium using various concentrations of nitric acid as eluants. Therefore, it is necessary to search for the other eluants. For this purpose, various concentrations of ammonium carbonate, ammonium carbonate-ammonium acetate, ammonium carbonate-ammonium chloride, ammonium carbonate-acetic acid-ammonium acetate, sulfuric acid, potassium sulfate, acetic acid-sodium acetate and phosphoric acid were investigated. Among these, ammonium carbonate-ammonium chloride and phosphoric acid looked promising and were investigated in detail.

The Ammonium Carbonate-Ammonium Chloride System.—The distribution coefficients of uranium and cerium measured in this system are presented in Table III. The distribution coefficients of uranium decreased with a decreasing pH, while those of cerium increased. As was described in the foregoing report, this exchanger is unstable at high pH values, so that possibly a low pH is preferable. With 5×10^{-2} M ammonium carbonate-3 M ammonium chloride, the differences between their distribution coefficients were very large, and the pH of the solution was low enough. Consequently, this condition seems to be quite suitable for the separation of these elements. According to this principle, the elution of uranium and cerium was conducted by using 5×10^{-2} M ammonium carbonate-3 M ammonium chloride and 1 N nitric acid as the eluants respectively. Uranium exhibited a sharp elution peak, but it showed considerable tailing and the yield was only 40% with an initial 150 ml. of eluants (Figs. 5 a and b). In other words, although it was possible to remove cerium from uranium

completely, the yield was very low, so this method of separation was by no means suitable.

The Phosphoric Acid System.—The distribution coefficients of uranium and cerium in various concentrations of phosphoric acid solutions are shown in Table IV. The distribution coefficients of uranium decreased monotonously with an increase in the acid concentration, and scarcely any uranium was adsorbed from phosphoric acid solutions above 1 M. On the contrary, although the distribution coefficients of cerium showed a maximum value between 0.1 and 0.5 M acidity and then rather decreased with an increase in the acidity, still it showed a fairly high value of about 3600 in 1 M phosphoric acid; it thus differed considerably from the uranium, and so it may be

presumed that the condition is suitable for use. Ten milliliters of a sample solution containing 10^{-3} M uranium and carrier-free ^{144}Ce were poured into a hydrogen-form exchanger bed; when the level of the solution reached the top of the exchanger bed, 5 ml. of water, 60 ml. of 1 M phosphoric acid, 6 ml. of water and 50 ml. of 3 N nitric acid were passed through the column succesively. One of the examples is shown in Fig. 6. The elution curve showed

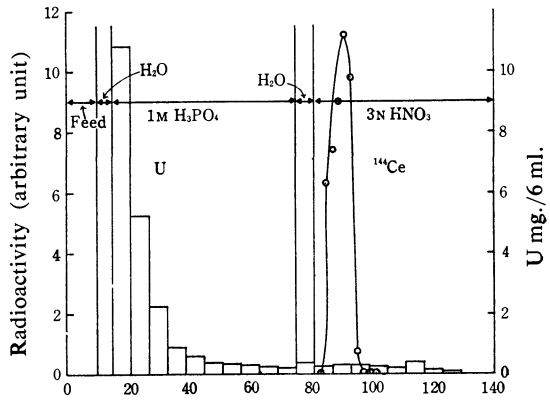

Fig. 6. Separation of uranium and ^{144}Ce.
Flow rate: 1 M H_3PO_4, 0.2 ml./min.; 3 N HNO_3 0.5~0.6 ml./min.

tailing to some extent, and the yield of uranium was about 92%. The use of a larger volume of phosphoric acid improves the yield, but it is not practical, as can be predicted from the shape of the elution curve. In any case, it is easy to recover over 90% of uranium without any contamination of cerium. The unfavorable tailing results from the slow rate of exchange.

The Behavior of Zirconium and Niobium.—The behavior of ^{95}Zr and ^{95}Nb in equilibrium was also investigated. As these nuclides were eluted partly by 1 M phosphoric acid, there was fear of contaminating uranium. As has been described previously, uranium was quantitatively eluted by nitric acid above 1 N but

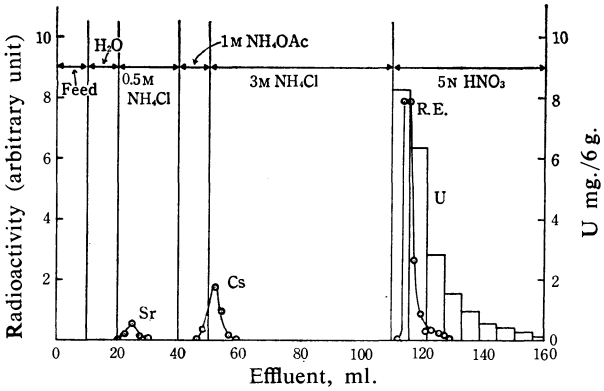

Fig. 7a. Separation of uranium and fission product.
Flow rate: 0.5~0.6 ml./min.

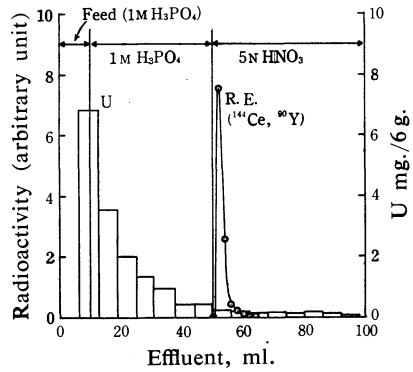

Fig. 7b. Separation of uranium and rare earths.
Flow rate: 1 M H_3PO_4, 0.2 ml./min.; 5 N HNO_3; 0.5~0.6 ml./min.

zirconium and niobium were not eluted at all. Therefore, the separation of uranium and a zirconium-niobium mixture was achieved by means of 3 N nitric acid.

The Separation of Uranium and the Fission Product.—Putting the above results together, the best conditions for the separation of uranium and the fission product were decided upon. To the sample solution, 5 ml. of concentrated perchloric acid were added; this was boiled until a yellow color had appeared once and then diminished. (It is advisable to lead the distillate into water in order to prevent any health hazard.) Then the residual solution was evaporated almost to dryness on a hot plate. After it had cooled, 1 ml. of 1 N nitric acid was added; the mixture was heated to dissolve the residue and then diluted to 10 ml. with water. This was poured into an exchanger bed; when the level of the solution reached the top of the exchanger bed, 10 ml. of water (by which no adsorbable form of zirconium and niobium could be washed out), 20 ml. of 0.5 M ammonium chloride (the elution of strontium), 10 ml. of 1 M ammonium acetate, 100 ml. of 3 M ammonium chloride (the elution of cesium), and 100 ml. of 5 N nitric acid (the elution of uranium and rare earths) were passed through the column successively. The 5 N nitric acid effluent was heated on a hot plate until the metastannic acid had coagulated completely. After the effluent had been cooled and diluted enough to prevent any destruction of filter paper, it was filtered to remove the metastannic acid (no uranium is lost by this procedure), and then the filtrate was evaporated almost to dryness. After it had cooled again, 10 ml. of 1 M phosphoric acid was added, and heated to dissolve the residue. This was poured into another exchanger bed, and, after the level of the solution had reached the top of the exchanger bed, 1 M phosphoric acid was percolated in until the yellow color of the column faded. A 5 N nitric acid solution was also passed through to elute rare earths. The elution curves are shown in Figs. 7a and b. The yields of uranium and beta and gamma decontamination factors are summarized in Table V. It goes without saying that if the fission product is cooled long enough to provide the decay of zirconium-95, radiochemically pure uranium can be collected in the 1 M phosphoric acid effluant which is inserted between 3 M ammonium chloride and 5 N nitric acid in the above procedure. This is shown in Fig. 8.

TABLE V. YIELD AND DECONTAMINATION FACTOR OF URANIUM
(uranium added; 23.81 mg.)

Uranium recovery		Decontamination factor	
Found (mg.)	%	β	γ
22.22	93.3	2.4×10^3	2.0×10^3
22.22	93.3	1.1×10^3	7.0×10^2
21.46	90.0	2.3×10^3	1.7×10^3

The Enhancement of the Yield of Uranium.—As can be seen from Table V, the yield of uranium was 90% or so; for the improvement of the recovery of uranium it is necessary to use a larger volume of eluant; the large volume of the eluant and the time needed make it impractical in all respects. If the saturation of a column by uranium does not affect the adsorption of rare earths, the column can be used for the uptake of rare earths until the break-through capacity for them is saturated. If a uranium solution contains only a low concentration of rare earths, such as a

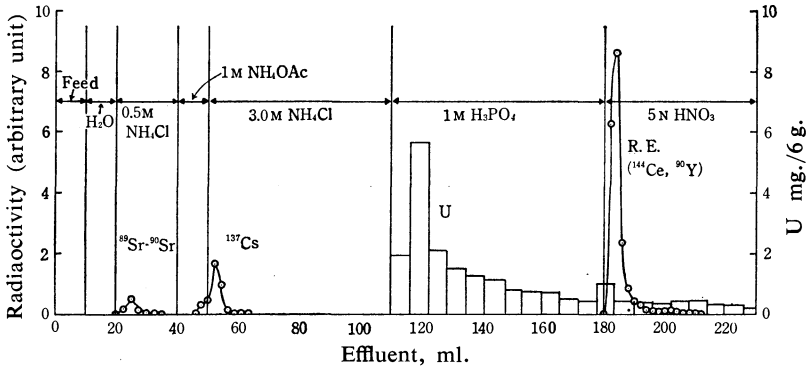

Fig. 8 Separation of uranium and fission product (in the absence of ^{95}Zr-^{95}Nb). Flow rate : 0.5~0.6 ml./min. except with 1 M H_3PO_4 (0.2 ml./min.)

carrier-free concentration, the perfect recovery of rare earth-free uranium can be accomplished by such a simple method as passing the solution through a column previously treated with a uranium solution, and this column could be used to an almost unlimited extent. When a 1 M phosphoric acid solution saturated with cerium ions was used, the column quantitatively adsorbed cerium from 26 ml. of the solution and then started to break through. This corresponded to about 0.2 meq. of cerium(III).

Summary

The separation of fission products and uranium has been carried out by means of a stannic phosphate cation exchanger. By using various concentrations of nitric acid and ammonium chloride solutions as eluants, the separation of uranium-strontium and uranium-cesium has been easily performed, but that of uranium-rare earths is very difficult. Among the various reagents investigated, a 1 M phosphoric acid solution is most suitable for the separation of uranium from rare earths. In view of the above results, the separation of uranium and gross fission products has been carried out; the resultant yield of uranium is more than 90%, and the decontamination factor is $(2\sim3)\times10^3$.

Part of the expenses for this investigation have been defrayed by a grant-in-aid by the ministry of education.

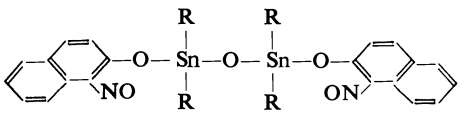
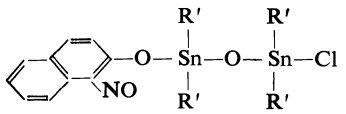
NOTES



The Reaction of Dialkyltin Dichlorides with α-Nitroso-β-naphthol

By Toshio TANAKA, Ryuhei UE-EDA, Masanori WADA and Rokuro OKAWARA



(Received March 4, 1964)

Dialkyltin dichlorides react with 8-hydroxyquinoline at the mole ratio of 1:2 to give dialkyltin bis(8-hydroxyquinolinates),[1,2] and with 2,2'-bipyridyl and 1,10-phenanthroline at the mole ratio of 1:1 to give dialkyltin(2,2'-bipyridyl) dichlorides and dialkyltin(1,10-phenanthroline) dichlorides[2,3] respectively. From these facts, bidentate ligand molecules, KeH, with protonating hydrogen had been expected to react with dialkyltin dichlorides to give the compounds of the R_2SnKe_2 type, compounds which might have the chelate structure containing a hexa-coordinated tin atom.

Such an expectation does not, however, seem to be true in the case of α-nitroso-β-naphthol, which reacted with dimethyltin dichloride under similar conditions to give tetramethyl-1,3-bis(α-nitroso-β-naphthoxy)distannoxane, $[(C_{10}H_6NO_2)(CH_3)_2Sn]_2O$ (Ia), but not dimethyltin bis(α-nitroso-β-naphtholate), $(CH_3)_2Sn(C_{10}H_6NO_2)_2$. Diethyltin dichloride also gave the corresponding distannoxane (Ib). On the other hand, under similar conditions, di-*n*-propyltin and di-*n*-butyltin dichlorides gave tetraalkyl-1-(α-nitroso-β-naphthoxy)-3-chlorodistannoxanes, $(C_{10}H_6NO_2)R'_2SnOSnR'_2Cl$ (II).

(Ia) $R=CH_3$
(Ib) $R=C_2H_5$

(IIa) $R'=n\text{-}C_3H_7$
(IIb) $R'=n\text{-}C_4H_9$

The infrared spectra of these distannoxanes I and II in the potassium bromide region are shown in Fig. 1, together with that of α-nitroso-β-naphthol. It was previously found by the present authors and by others that a

broad band near 600 cm^{-1} would be associated with the Sn–O–Sn stretching vibration in dimeric distannoxanes (III).[4,5] Although this

(III)

characteristic band has here been observed in the two compounds shown in I, the Sn–O–Sn stretching vibration in the compounds of II was observed at a lower frequency and with a different shape. Considering these spectra, the association of the latter two compounds in the solid state may be different from that of the former. The presence of the chelate structure in these compounds is, however, not yet obvious from the results of the present investigation.

Experimental

Materials.—Dialkyltin dichlorides supplied by the Nitto Kasei Company were purified either by sublimation or by recrystallization from ligroin or petroleum ether. α-Nitroso-β-naphthol was obtained commercially and checked with the melting point.

The Reaction of Dialkyltin Dichlorides with α-Nitroso-β-naphthol.—Into a solution of 1.0 g. (0.006 mol.) of α-nitroso-β-naphthol and 0.66 g. (0.003 mol.) of dimethyltin dichloride in 25 ml. of methanol, 6 ml. of 1 N ammonium hydroxide in methanol was slowly stirred in over a period of about one hour. During an additional three hours of stirring, a yellow precipitate gradually appeared, and the solution changed from dark green to brown. The precipitate was then filtered off, repeatedly washed with benzene, and dried under reduced pressure. Yield, 90%. M. p.>230°C. Found: C, 44.09; H, 3.73; Sn, 35.84. Calcd. for $[(C_{10}H_6NO_2)(CH_3)_2Sn]_2O$: C, 43.82; H, 3.68; Sn, 36.08%. This compound Ia was also obtained in almost the same yield by the reaction of dimethyltin dichloride with α-nitroso-β-naphthol at the mole ratio of 1 : 1. Similarly, diethyltin dichloride reacted with α-nitroso-β-naphthol to give a yellowish green precipitate. Recrystallization from a methanol-chloroform mixture (volume ratio 2 : 1) gave a dark brown crystalline compound (Ib). Yield, 70%. M. p. 163°C. Found: C, 47.04; H, 4.47; Sn, 32.92. Calcd. for $[(C_{10}H_6NO_2)(C_2H_5)_2Sn]_2O$: C, 47.11; H, 4.52; Sn, 33.25%. By a similar procedure with di-*n*-propyltin dichloride, a yellowish brown precipitate was obtained. Recrystallization from a dichloromethane-ligroin mixture gave a dark brown crystalline material (IIa). Yield, 40%. M. p. 159~160°C. Found: C, 41.60; H, 5.41; Sn, 37.61. Calcd. for $(C_{10}H_6NO_2)(C_3H_7)_2SnOSn(C_3H_7)_2Cl$: C, 41.72; H, 5.41; Sn, 37.48%. Di-*n*-butyltin dichloride gave a yellowish precipitate, which was recrystallized from methanol (IIb). Yield, 50%. M. p. 140~141°C. Found: C, 45.22; H, 6.04; Sn, 34.39. Calcd. for $(C_{10}H_6NO_2)(C_4H_9)_2SnOSn(C_4H_9)_2Cl$: C, 45.29; H, 6.14; Sn, 34.43%. The same compound was also prepared by the neutralization of the mixture of tetra-*n*-butyl-1,3-dichlorodistannoxane, $[(C_4H_9)_2ClSn]_2O$, and α-nitroso-β-naphthol at the mole ratio of 1 : 2 in methanol with 1 N ammonium hydroxide. This compound was identified by mixed melting point determination with the compound derived from di-*n*-butyltin dichloride.

Even when di-*n*-propyl and di-*n*-butyltin dichlorides were treated with a large excess of α-nitroso-β-naphthol and then neutralized, only the corresponding compounds of type II were obtained, not the compounds of type I.

Infrared Spectra.—The infrared spectra were taken in mulls in Nujol by a Hitachi EPI-2G grating infrared spectrophotometer.

The Crystal Structure of Tohdite

By Goro YAMAGUCHI, Hiroaki YANAGIDA and Shuitiro ONO

(Received March 12, 1964)

The synthetic procedure and some crystallographic data of a new alumina hydrate, Tohdite $5Al_2O_3 \cdot H_2O$, were reported in a previous paper.[1] The crystallographic data are summarized in Table I. In the present work we will attempt to determine the crystal structure of Tohdite from the X-ray powder diffraction data.

Experimental

Crystals of Tohdite can be prepared by the hydrothermal treatment of boehmite with a small amount of some mineralizer. They occur in a variety of forms, such as hexagonal plates and needles. They are not, however, suitable for the

measurement of the relative X-ray diffraction intensities, since the specimens always show preferred orientations. A new method for preparation has been found as follows. Eta-alumina was obtained from a dehydration, at 800°C in air, of bayerite $Al(OH)_3$ which had been prepared by neutralizing an aluminum chloride aqueous solution with ammonia. The eta-alumina was inverted to a microcrystalline tohdite when treated hydrothermally under a water vapor pressure of about 200 atm. at 460°C. Tohdite prepared by this method was used for the intensity measurement, since it showed no preferred orientation.

The X-ray diffraction data for Tohdite in Table II were recorded on a diffractometer using Cu$K\alpha$-radiation. A set of I_o experimental intensities relative to 202 was obtained by measuring the areas under the diffraction peaks.

Structure Analysis

In the following discussion, we will disregard the contribution of the two hydrogen atoms of the formula $5Al_2O_3 \cdot H_2O$ to the diffraction intensities and will instead pay attention to the arrangement of the 10 aluminum atoms and 16 oxygen atoms in the unit cell.

The unit cell of Tohdite is clearly related to those of kappa- and beta-alumina. (Kappa-alumina is the dehydrated product of Tohdite.) The lattice constants of Tohdite and these aluminas based on orthohexagonal lattices[2] are compared in Table III.

TABLE III. ORTHOHEXAGONAL LATTICE CONSTANTS OF TOHDITE AND KAPPA- AND BETA-ALUMINA (IN Å)

Kappa-alumina	$a=16.80$	$b=9.71$	$c=17.85$
Beta-alumina	$a=5.56$	$b=9.65$	$c=22.55$
	$3a=16.70$		
Tohdite	$a=5.58$	$b=9.66$	$c=8.77$
	$3a=16.73$		$2c=17.54$

The crystal structures of kappa- and beta-alumina were studied by Saalfeld[2] and Beevers[3] respectively. The similarity between the unit cell of Tohdite and those of the above-mentioned aluminas indicates that in the Tohdite structure the layers of oxygen and aluminum atoms lie alternatively in sheets perpendicular to the c-axis and that the unit cell of Tohdite is formed by the close stacking of 4 oxygen layers, each layer containing 4 oxygen atoms. The high density and refractive index of Tohdite also imply a close-packed arrangement of oxygen atoms.

For the arrangement of aluminum atoms, it is well known that there are two types of aluminum positions, that is, octahedral sites

2) H. Saalfeld, *N. Jb. Abh.*, **95**, 1 (1960).
3) C. A. Beevers and M. A. S. Ross, *Z. Krist.*, **97**, 59 (1937).

and tetrahedral sites. In this case, since the 10 aluminum atoms in the unit cell are distributed over 4 aluminum layers, it can easily be assumed that two aluminum layers contain 2 aluminum atoms each, while the other two layers contain 3 atoms each.

With the above-mentioned extinctions the following space groups are possible; P31c, $P\bar{3}1c$, $P6_3mc$, $P\bar{6}2c$ and $P6_3/mmc$. The latter two of them, however, must be rejected, because the arrangement of the reflection planes and axial glide planes characteristic of these groups causes an unreasonable arrangement of aluminum atoms. $P\bar{3}1c$ characterized by centers of symmetry and axial glide planes is also improbable for a similar reason. Therefore, Tohdite must belong to the P31c or $P6_3mc$ group. Since there is no evidence of trigonal symmetry, the more highly symmetrical space group, $P6_3mc$, may be assumed for Tohdite.

First the sequence of the oxygen layers can be determined as:

$$\dot{A}BAC\dot{A}BA\dot{C}A, \text{ etc.}$$

(following theusual nomenclature),

since the unit cell contains a screw hexads, 6_3, in the [001]-direction. The vertical dashes denote the boundaries of the unit cells in the [001]-direction. Second, the arrangement of aluminum atoms must be taken into consideration. Since there are two types of aluminum positions, as has been mentioned above, we were able to assume several trial arrangements. These arrangements were examined and rejected bacause of the poor agreement of the calculated with the observed intensities. The best result was obtained by placing aluminum atoms at (1/6 1/3 3/8), (2/3 1/3 1/8) (octahedral sites) and (1/3 2/3 μ) (tetrahedral sites). μ is approximately 0.068.

Results

The atomic parameters are given in Table IV. A set of relative intensities for these atomic positions, I_c, was calculated by means of the following equation:

$$I_c = KnD\frac{1+\cos^2 2\theta}{\sin^2\theta\cdot\cos\theta}|F|^2$$

where θ is the Bragg angle; F, a structure factor; n, the multiplicity; D, a temperature factor for $B=1.62$ Å^2, and K, a scale factor. They give the agreement factor

$$\frac{\sum_{hkl}(I_o\sim I_c)}{\sum_{hkl}I_o}$$

of 0.26, where the unobserved reflections marked * were excluded.

Futher refinements on the basis of the data of the powder diagram are hardly possible. It, therefore, remains conceivable that the atoms may be slightly displaced from these special positions of $P6_3mc$ and that a less symmetrical space group should be taken for this crystal. However, it is sure that the structure given covers the principal features of the Tohdite lattice.

Table IV. Position parameters

Atom	x/a	y/a	z/c	Number of equivalent positions
O(1)	0	0	0	2
O(2)	1/2	0	0	6
O(3)	1/3	1/6	1/4	6
O(4)	1/3	2/3	1/4	2
Al(1)	1/6	1/3	3/8	6
Al(2)	2/3	1/3	1/8	2
Al(3)	1/3	2/3	0.068	2

Figure 1 shows a unit cell of Tohdite. In this structure four-fifths of the aluminum atoms are in octahedral sites, and the rest, in tetrahedral sites. Interatomic distances calculated from the atomic positions in Table IV are given in Table V. There are two different atomic distances for tetrahedral bonds, since the aluminum atoms in tetrahedral sites are not placed at the centers of the tetrahedra.

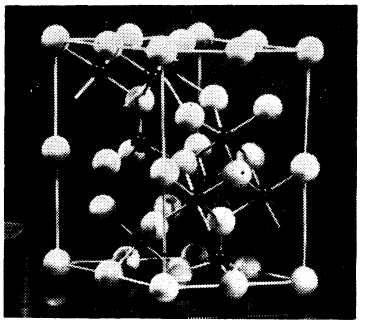

Fig. 1. The unit cell of the Tohdite structure. Oxygen atoms are shown as large and aluminum atoms as small spheres.

Table V. Interatomic distances (in Å)

O-O (I)	within a layer	2.79
O-O (II)	between layers	2.72
Al-O (I)	octahedral bond	1.95
Al-O (II)	tetrahedral bond	1.72 1.60

*Harze aus Formaldehyd. LXXXI. Anlagerungen von mono- und difunktionellen Thiolen, Thiolsäuren und Dioxim an Methylenbisacrylamid**

Von Minoru IMOTO, Koichi KONDO und Kiichi TAKEMOTO

(Eingegangen am 22. April, 1964)

Die Umsetzung von Acrylonitril mit Formaldehyd ist bisher schon von einigen Forschern untersucht worden. Bei der Umsetzung in Anwesenheit von Schwefelsäure gewinnt man als Hauptprodukt Hexahydro-1, 3, 5-*s*-triazin[1] oder Methylenbisacrylamid[2] je nach ihrer Menge und Konzentration. Im Laufe von unseren Untersuchungen über die Polymersynthese durch Polyaddition hat es uns interessiert, die Reaktionsfähigkeit dieser an beiden Enden vinylgruppenhaltigen Verbindung, Methylenbisacrylamid (abgekürzt MBAA), weiter zu erforschen, über die bisher noch keine Angaben vorliegen. Wir haben gefunden, dass Thiolen und Thiolsäuren an die Vinylgruppen des MBAAs sehr anlagerungsfähig sind, und ausserdem, dass die zweifunktionellen Verbindungen wie Dithiolen und Dithiolsäuren auf dieselbe Weise durch Wasserstoffübertragung zu polymeren Substanzen führen.

Experimentelle Ergebnisse

Anlagerung von Thiolen oder Thiolsäuren an MBAA.—Über die Anlagerungen von Thiolen an Olefinen ist schon viel berichtet worden. Es ist bekannt, dass Thiolen unter alkalischer Bedingung leicht an α,β-ungesättigten Carbonylverbindungen, Acrylnitril und auch an Acrylamid anlagern.[3] Dass die Anlagerung von Thiolen und Thiolsäuren an C=C Bindungen glatt verläuft, ist wohl auch bei den Umsetzungen an dehydrochloriertes Polyvinylchlorid bestätigt worden.[4]

Die Anlagerung von Thiolen und Thiolsäuren an MBAA wurde in Dioxanlösung bei Raumtemperatur durchgeführt. Äthylmercaptan und Thiophenol wurden als Thiolen, und Thiobenzoesäure und Thioessigsäure wurden als Thiolsäuren benutzt. Als Katalysator wurden bei der Umsetzung von Thiobenzoesäure Schwefelsäure, und in allen anderen Fällen Natriumalkoxyd benutzt. Die Umsetzungen verlaufen bei allen Fällen schon bei Raumtemperatur exothermisch sehr glatt, und die Anlagerungsprodukte waren als farblose Substanzen ausgeschieden. Bei erhöhter Temperatur war vorwiegend nur die thermische Polymerisation von MBAA verlaufen, und es gab keine Addukten.

Die Tabelle I zeigt die Ergebnisse der Umsetzungen.

TABELLE I. ANLAGERUNGEN VON THIOLEN UND THIOLSÄUREN AN MBAA (bei Raumtemperatur, in Dioxan)

RSH	Katalysator	Schmp. des Produktes °C	Ausbeute %
CH_3CH_2SH	C_2H_5ONa	183～184	46
C_6H_5SH	t-C_4H_9ONa	186～187	82
CH_3COSH	C_2H_5ONa	171～172.5	40
C_6H_5COSH	H_2SO_4	205～206	90

$$2RSH + CH_2=CHCNHCH_2NHCCH=CH_2 \longrightarrow RSCH_2CH_2CNHCH_2NHCCH_2CH_2SR$$

Bei der Umsetzung mit Thiophenol unter Zugabe von Natriumäthylat war die Ausbeute sehr klein, und das gewonnene Produkt zeigte keinen scharfen Schmelzpunkt. Bei der Umsetzung mit Thioessigsäure wurde eine unschmelzbare, durchaus unlösliche Substanz gewonnen, wenn Schwefelsäure als Katalysator gebraucht wurde.

Ausser Thiolsäuren und Thiolen wurden die Anlagerungen von Benzoesäure und Anilin an MBAA auch versucht, was uns aber nicht gelungen ist.

Polyaddition von Dithiolen und Dithiolsäuren an MBAA.—Die Umsetzung von MBAA mit Dithiolen und Dithiolsäuren wurde in der gleichen Weise in Dioxanlösung bei Raumtemperatur durchgeführt. Dithioglykol wurde als Dithiol, und Dithioterephthalsäure wurde als

Dithiolsäure gewählt. Als Katalysator waren bei diesem Fall Salzsäure oder Schwefelsäure, und bei jenem Fall Natriumäthoxyd gewählt. In beiden Fällen wurden polymere Substanzen gewonnen. Die Umsetzung kann wie folgt angenommen werden.

Das bei der Umsetzung mit Dithioglykol gewonnene Produkt ist unschmelzbar und auch unlöslich, verkohlt aber bei ungefähr 240°C. Das bei der mit Dithioterephthalsäure gewonnene Produkt ist auch unschmelzbar und in fast allen gewöhnlichen organischen Lösungsmitteln unlöslich,. ausser in Ameisensäure, Eisessig und in Dimethylsulfoxyd, wo es jedoch nur schwer löslich ist. Es verkohlt bei ungefähr 230°C.

Zum Unterschied von der Umsetzung mit Dithioglykol wurde bei der Umsetzung mit Äthylenglykol kein polymeres Anlagerungsprodukt erhalten.

Polyaddition von Dioxim an MBAA. — Die Polyaddition von MBAA mit Diäthylglyoxim wurde in Anwesenheit von Triton B als Katalysator in Dimethylformamid bei Raumtemperatur durchgeführt. Die Umfällung von gewonnenen Produckt aus Essigsäure/Äther wurde wiederholt, und eine farblose, amorphe polymere Substanz erhalten. Die Umsetzung kann wie folgt formuliert werden.

Dieses Produkt ist in gewöhnlichen polaren Lösungsmitteln wie Wasser, Alkohol und Eisessig löslich. Es schmelzt bei 217~235°C, und die Grenzviskosität war 0.036 in Eisessig bei 25°C. Aus diesem Wert kann man vermuten, dass das unter oben erwähnten Bedingungen gewonnene Produkt nicht sehr hochmolekular ist.

Experimenteller Teil

Ausgangsmaterialien. — Thiobenzoesäure wurde aus Benzoylchlorid,[5] und Dithioterephthalsäure wurde aus Terephthalsäurechlorid[6] hergestellt. Ausser diesen wurden nur handelsübliche Produkte benutzt. Dioxan, Eisessig und Dimethylsulfoxyd wurden nach der gewöhnlichen Vorschrift gereinigt. Die Grenzviskosität wurde mit einem Ubbelohde'schen Viskometer gemessen.

MBAA wurde nach der Vorschrift von Magat et al.[2] durch die Umsetzung von Acrylnitril mit 37%igen Formaldehydlösung in Anwesenheit von Hydrochinon bei 40°C dargestellt. Die Ausbeute war 80%. Farblose Nadeln, Schmp. 178~180°C (Lit., 185°C), Molekulargewicht, 159 (kryoskopisch) (Ber., 154%).

Anlagerung von Äthylmercaptan an MBAA.— Zu 4.1 g (0.066 mol.) Äthylmercaptan, die sich mit 12 ccm Dioxan und Natriumäthylat (C_2H_5OH 46 g, Na 0.1 g) in einem vierhalsigen Rundkolben (200 ccm.) befand, wurde bei 20°C 70 ccm Dioxanlösung von 5.1 g. (0.033 mol.) MBAA in 10 Min zugetropft. Die Temperatur stieg schnell bis auf 28°C und das Produkt wurde als farblose Substanz ausgeschieden. Nach weiterem dreistündigen Umrühren wurde es abfiltriert. Rohausbeute 4.2 g (46% d. T.). Die Kristalle wurden aus Äthanol-Wasser und Äthanol je zweimal umkristallisiert. Das so erhaltene Blättchen zeigte den Schmelzpunkt 183~184°C.

Gef.: C, 47.66; H, 7.96; N, 10.14; S, 22.21. Ber. für $C_{11}H_{22}N_2O_2S_2$: C, 47.45; H, 7.96; N, 10.06; S, 23.03.

Anlagerung von anderen Thiolverbindungen an MBAA. — Die Umsetzungen von MBAA mit Thiophenol unter Zugabe von Natrium-*t*-butylat, mit Thioessigsäure unter Zugabe von Natriumäthylat, und mit Thiobenzoesäure unter Zugabe von Schwefelsäure wurden in der gleichen Weise durchgeführt, und die erhaltenen farblosen Produkte wurden umkristallisiert.

Reaktionsprodukt mit Thiophenol;

Gef.: C, 61.01; H, 6.19; N, 7.30; S, 16.52. Ber. für $C_{19}H_{22}N_2O_2S_2$: C, 60.93; H, 5.92; N, 7.48; S, 17.12%.

Reaktionsprodukt mit Thioessigsäure;

Gef.: C, 43.47; H, 6.01; N, 9.34; S, 19.79. Ber. für $C_{11}H_{18}N_2O_4S_2$: C, 43.12; H, 5.92; N, 9.14; S, 20.93%.

Reaktionsprodukt mit Thiobenzoesäure;

Gef.: C, 58.68; H, 5.27; N, 6.78; S, 15.89. Ber. für $C_{21}H_{22}N_2O_4S_2$: C, 58.58; H, 5.15; N, 6.50; S, 14.89%.

Die IR-Banden von -CONHR- (bei 3300, 3070, 1655 und 1550 cm^{-1}) sind an jeden Reaktionsprodukten noch vorhanden, während die Banden von CH_2=CH- (bei 2975, 1620, 990 und 910 cm^{-1}) nicht mehr aufgetreten sind. Bei den Reaktionsprodukten mit Äthylmercaptan traten die neuen Banden von C-S-Bindung (bei 790 und 770 cm^{-1}) ausser den Banden von CH_3- und -CH_2- Bindungen,

5) P. Noble und D. S. Tarbell, "Org. Syntheses," Coll. Vol., 4, 924 (1962).
6) S. Sunner und T. Nilson, *Svensk. Kem. Tid.*, **54**, 163 (1942); *Chem. Abstr.*, **38**, 3249 (1944).

bei dem mit Thioessigsäure weiter die Bande von >C=O (bei 1690 cm^{-1}), und bei dem mit Thiophenol und Thiobenzoesäure die Banden der Phenylgruppe (bei 1580, 1120, 735 und 690 cm^{-1}) auf.

Polyaddition von Dithiol und Dithiolsäure an MBAA.—*Umsetzung von MBAA mit Dithioglykol.* —Zu 2.4 g (0.025 mol.) Dithioglykol, die sich mit 20 ccm Dioxan und Natriumäthylat (C_2H_5OH 92 g, Na 0.1 g) in einem vierhalsigen Rundkolben (200 ccm) befindet, wurde bei Raumtemperatur 70 ccm Dioxanlösung von 3.9 g (0.025 mol.) MBAA in 15 Min zugetropft, wobei das Produkt sogleich ausgeschieden wurde. Nach weiterem fünfstündigem Umrühren wurde es abfiltriert. Rohausbeute 2.3 g. Das erhaltene Produkt wurde wegen der Unlöslichkeit in allen Lösungsmitteln mit Wasser und Äthanol gewaschen und dann mit Wasser-Äthanol unter Rückfluss ausgekocht.

Umsetzung von MBAA mit Dithioterephthalsäure. —Zu 70 ccm Dioxanlösung von 2.6 g (0.016 mol.) MBAA wurde in Anwesenheit von 1.0 g konz. Salzsäure 3.1 g (0.016 mol.) Dithioterephthalsäure, das in 50 ccm Dioxan suspendiert worden ist, in 40 Min zugetropft, wobei die Mischung unter Bildung von Niederschlägen sogleich trüb wurde. Nach fünfstündigem Umrühren wurde sie abfiltriert. Farbloses Pulver mit der Ausbeute von 5.7 g. Es wurde aus Eisessig-Methanol zweimal umgefällt. Das Produkt färbt sich beim Stehenlassen.

Die IR-Banden dieser zwei Produkte traten auch bei 2900 cm^{-1} (-CH_2- Bindung) ausser der Bande von -CONHR- Bindung auf, während beim Reaktionsprodukt mit Dithioterephthalsäure noch weitere Banden der Phenylgruppe (bei 1150, 850 und 780 cm^{-1}) aufgetreten sind.

Anlagerung von Dioxim an MBAA.—Zu 40 ccm Dimethylformamidlösung von 2.0 g (0.013 mol.) MBAA wurde bei Raumtemperatur 10 ccm Dimethylformamidlösung von 1.5 g (0.013 mol.) Dimethylglyoxim in 15 Min zugetropft und nach einer halben Stunde wurde 3 ccm Triton B weiter zugesetzt. Das Reaktionsgegemisch wurde bei Raumtemperatur noch 2 Std umgerührt. Nach vierundzwanzigstündigem Stehenlassen wurde weiter eine kleine Menge Wasser zugesetzt, und der ganze Inhalt in überschüssigen Äther gegossen. Der Niederschlag wurde abgesaugt und wurde nach dreimaligen Umfällungen aus Eisessig-Äther getrocknet. Ausbeute 0.2 g.

Das gewonnene Produkt zeigte die IR-Banden von CH_3- (bei 1370 cm^{-1}) und CH_2=CH- (bei 900 und 990 cm^{-1}) ausser der Bande von -CONHR- Bindung.

Zusammenfassung

Thiolen und Thiolsäuren lagern sich leicht an Methylenbisacrylamid in Dioxanlösung unter Zugabe von katalytischer Menge Alkoxyde oder Mineralsäuren bei Raumtemperatur an. Bei den Umsetzungen von Dithiolen und Dithiolsäuren mit Methylenbisacrylamid wurden unschmelzbare und in allen gewöhnlichen organischen Lösungsmitteln unlösliche polymere Substanzen gewonnen, die bei ungefähr 230~240°C verkohlen. Aus der Umsetzung von Dimethylglyoxim mit Methylenbisacrylamid wurde eine in polaren Lösungsmitteln lösliche Substanz erhalten, deren Grenzviskositätswert aber nicht sehr gross ist.

Studies of the Behaviors of Carrier-free Radioisotopes. I. The Coprecipitation of Cadmium-115 with Ferric Hydroxide

By Fujio ICHIKAWA

(Received April 25, 1964)

It is well-known that some carrier-free radioisotopes are coprecipitated with ferric hydroxide. The mechanism of the coprecipitation is not always identical, however. There are four groups of elements which are coprecipitated with ferric hydroxide; the first, the cations which are precipitated as insoluble hydroxides when a macro quantity of the cation exists in the solution (rare earths, etc.); the second, the cations which are not precipitated as hydroxides (strontium, etc.); the third, the anions which form insoluble compounds with ferric ions in the solution of a macro concentration (phosphate, etc.); the last, the anions which do not form insoluble compounds with ferric ions (sulfate, etc.).

In the present paper, the coprecipitation behavior of carrier-free cadmium with ferric hydroxide will be studied.

Experimental

A mixture of cadmium-115g (53 h) and cadmium-115m (43 d) was used as a carrier-free tracer of cadmium. These radioisotopes were separated from the uranium target, which was bombarded with 50 MeV. protons by the synchrocycrorton at the

Institute for Nuclear Study, the University of Tokyo. The target was dissolved into a few milliliters of 8 N nitric acid, and the cadmium was separated from uranium and other fission products by means of ion-exchange and coprecipitation techniques. According to the γ-ray spectrum and the decay curve of the cadmium fraction, only cadmium-115m, cadmium-115g and its daughter, indium-115m, could be detected.

The cadmium-115 solution, the ferric chloride solution, and the carrier or hold-back carrier solution were mixed in a 10~15 ml. centrifugal tube; then a freshly-prepared ammonium hydroxide or sodium hydroxide solution was added to this tube, and the contents were centrifuged. The radioactivities of the initial and supernatant solutions were measured by a scintillation counter after the two days which were required to obtain radioequilibrium between cadmium-115g and indium-115m. The coprecipitation ratio was calculated from these data.

Results and Discussion

The coprecipitation ratio of cadimium was measured as a function of the ferric, cadmium, ammonium and other ion concentrations.

It is to be expected that cadmium will form stable ammine complex ions in the presence of ammonium ions and will not be coprecipitated with ferric hydroxide. However, when ammonium hydroxide was used as a precipitant, about half the amount of carrier-free cadmium was coprecipitated with 10 mg. ferric hydroxide. This ratio increased logarithmically with the amount of precipitate (cf. Fig. 1). The ratio depended also on the concentration of ammonium ions at a constant pH value. Figure 2 shows this relation and proves that the formation of an ammine complex causes a decrease in the coprecipitation ratio. The cadmium concentration varied from a carrier-free concentration (10^{-12} M) to 1 M. The coprecipitation ratio did not change in concentrations less than 10^{-7} M, whereas in higher concentrations it decreased rapidly, as is shown in Fig. 3.

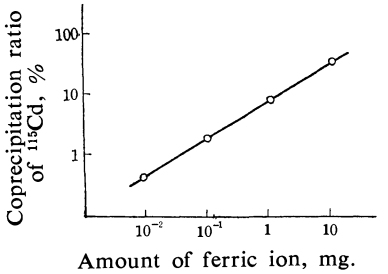

Fig. 1. Coprecipitation ratio of carrier-free cadmium with $Fe(OH)_3$ as a function of the amount of precipitate.

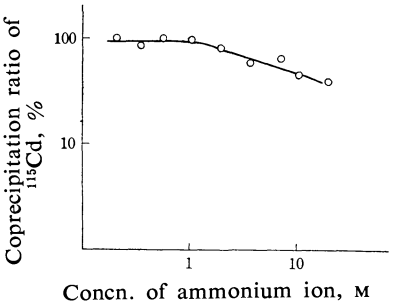

Fig. 2. Coprecipitation ratio of carrier-free cadmium with $Fe(OH)_3$ as a function of ammonium ion concentration.

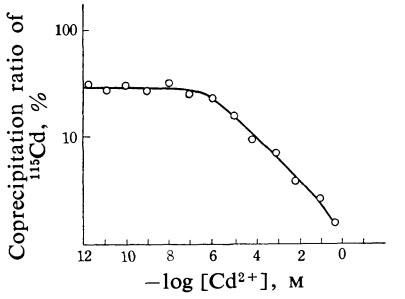

Fig. 3. Coprecipitation ratio of cadmium with $Fe(OH)_3$ as a function of cadmium ion concentration.

The existence of such ions as zinc, cobalt and copper, which form soluble ammine complexes, decreased the coprecipitation ratio of carrier-free cadmium. The addition of barium ions also depressed the coprecipitation.

When sodium hydroxide was used as a precipitant, the carrier-free cadmium was coprecipitated entirely with ferric hydroxide. These facts suggest that: 1) the coprecipitation of carrier-free cadmium is based upon the adsorption of cadmium ions and its ammine complex ions on the negatively-charged surface of ferric hydroxide, 2) the adsorption of ammine complex ions is less than that of simple ions, and 3) the cations which exist in the ammoniacal solution behave as hold-back carriers for carrier-free cadmium because of their occupation of the adsorption surface.

The author wishes to express his thanks to Dr. Haruo Natsume for his encouragement of this work and also to Mr. Tadashi Sato for experimental assistance.

Stability Order in Metal Chelate Compounds. III.[1] *4-Nitro- and 4-Chlorocatechol Complexes**

By Yukito MURAKAMI and Masasuke TOKUNAGA

(Received May 25, 1964)

In view of the relatively high stabilities of the zinc(II) chelates of the catechol derivatives,[2] it was decided to investigate the interaction of bivalent transition metal ions with other catechol derivatives. The ligands employed in the present work are 4-nitro- and 4-chlorocatechol. Since both the nitro and the chloro group, as well as the sulfonate and carboxylate groups, are known to act as electron-withdrawing substituents, the extent of the effects of these substituents on the chelate stability and on the dissociation of catechol protons is estimated.

Experimental

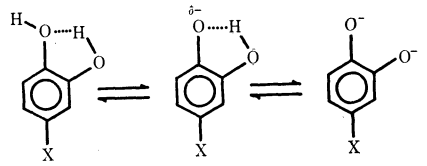
The preparation of metal solutions, and the apparatus and procedures for potentiometric titration, have been mentioned elsewhere.[2,3]

4-Nitrocatechol.[4] — Into a mixture of catechol and sodium nitrite dissolved in water was added 2.5 M sulfuric acid at 0°C with stirring. After the addition of sulfuric acid had been completed, the reaction mixture was treated with ether; the product was recovered from the ether extract. The yellow needle-like crystals were recrystallized from benzene and purified further by vacuum sublimation at 1 mmHg and 130~140°C; m. p.: found, 176~177°C; reported,[4] 172~174°C.

Found: C, 46.40; H, 3.15; N, 9.20. Calcd. for $C_6H_5O_4N$: C, 46.46; H, 3.25; N, 9.03%.

4-Chlorocatechol.[5]—Sulfuryl chloride was added gradually to an ether solution of catechol at nearly 0°C. The reaction mixture was stirred for approximately one hour at 0°C, and then the crude material was recovered as ether was removed from the solution under reduced pressure. This material was recrystallized from benzene as white crystals; m. p.: found, 87.2~88.2°C; reported,[6] 88°C.

Found: C, 50.03; H, 3.47. Calcd. for $C_6H_5O_2Cl$: C, 49.85; H, 3.49%.



Results and Discussion

Acid Dissociation Constants.—The dissociating catechol protons of both 4-nitro- and 4-chlorocatechol were found to behave in a manner similar to those of catechol derivatives reported previously.[2] The acid dissociation constants of the present catechols are summarized in Table I. It is obvious that the

TABLE I. ACID DISSOCIATION CONSTANTS OF THE CATECHOLS

4-Nitrocatechol	6.59	10.75
4-Chlorocatechol	8.43	11.54

nitro group situated at the 4-position has a profound electron-withdrawing effect on the dissociation of catechol protons, thus lowering both pK_{H_2L} and pK_{HL} values. Therefore, the dissociation of the protons of 4-nitrocatechol must take an alternative process to that assumed for the 4-sulfo and 4-carboxy derivatives,[2] as is shown in Chart 1. Meanwhile, since the chloro group exerts a greater electron-withdrawing effect at its meta position than at the para, 4-chlorocatechol must undergo the same dissociation as the nitro derivative.

X=NO_2, Cl

Chart 1. Dissociation process of catechol-protons.

Chelate Stability Constants. — The stability constants for the bivalent metal chelate compounds with the two catechol derivatives of the present study are summarized in Table II. Among the metal chelates of catechol derivatives studied in these laboratories, the following stability order with respect to a ligand was established:

Mn(II)	6.51	4.74		6.82	4.66	

4-nitrocatechol<catechol<4-chlorocatechol~4-carboxycatechol<4-sulfocatechol<Tiron.

There has been found no systematic relationship between the ligand basicity and the chelate stability, partly because of the difference between the dissociation process of the present ligands and that previously reported.[2] It is interesting to note that the 4-nitrocatechol chelates show relatively large stability constants for the lower basicity of the ligand. This is presumably due in part to the resonance contribution of the nitro group to the stabilization of the chelate ring.

The stability order among the transition metals treated in this work was found to be the same as that previously reported;[2] it follows the sequence:

manganese(II)<cobalt(II)~nickel(II)<zinc(II)<copper(II).

SHORT COMMUNICATION

*The Mechanism of the Photochromism and Thermochromism of 2, 2', 4, 4', 5, 5'-Hexaphenyl-1, 1'-biimidazolyl**

By Taro HAYASHI, Koko MAEDA and Midori MORINAGA

(Received August 4, 1964)

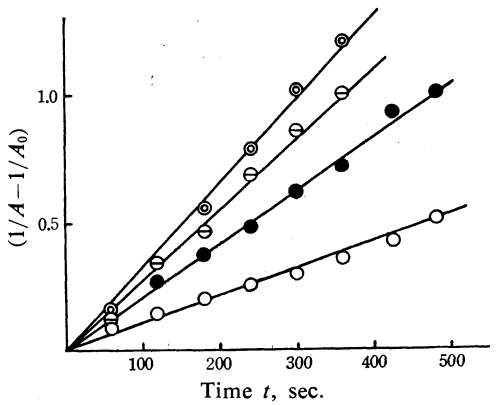
We previously found[1,2] that 2, 2', 4, 4', 5, 5'-hexaphenyl-1, 1'-biimidazolyl (I) ($C_{42}H_{30}N_4$, fine pale yellow prisms, m. p. 199~201°C (decomp.)) and its various substitution compounds exhibited photochromism and thermochromism in both a solution and a solid state. A pale yellow benzene solution of I showed an absorption maximum at 280 mμ (ε=28500) at 15°C, while the solution which turned reddish purple upon irradiation with sunlight at 15°C or upon heating on a water bath in the dark showed new absorption maxima at 347 mμ (ε=1100), 520 mμ (shoulder) and 554 mμ (ε=190) with a decrease in the absorbance of 280 mμ and was found to exhibit an electron spin resonance (g value: 2.003). When the solution irradiated was immediately placed in a dark room, the absorbance of 347 mμ and 554 mμ gradually decreased with the recovery of the absorbance of 280 mμ, an isosbestic point being shown at 309 mμ, and a decrease in the electron spin resonance was also found.

In a benzene solution of I (C=1.49×10^{-5} mol./l.) the absorbance of 347 mμ was measured in the dark at 19.0, 36.1, 45.5 and 50.5°C in order to measure the absorbance due only to thermochromism, A_1. In the same solution when irradiated for 3 min. with a mercury vapor lamp at the temperatures mentioned above, a decrease in the absorbance of 347 mμ, A_2, due both to photochromism and thermochromism with time, was measured beginning immediately after irradiation at the temperatures mentioned above. When the difference between A_2 and A_1 of the same temperature, which was the decrease in the absorbance due

* Presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

1) T. Hayashi and K. Maeda, This Bulletin, 33, 566 (1960).

2) T. Hayashi, K. Maeda, S. Shida and K. Nakada, *J. Chem. Phys.*, 32, 1568 (1960); T. Hayashi and K. Maeda, This Bulletin, 35, 2057 (1962).



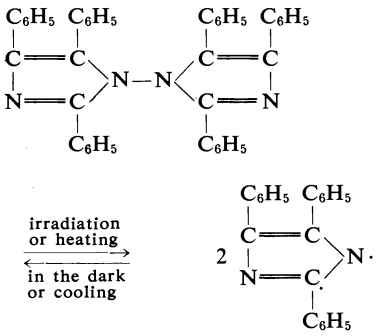


Fig. 1. The rate of the decrease of the absorbance A of 347 mμ in a solution ($C=1.49\times10^{-5}$ mol./l.) of hexaphenylbiimidazolyl.
$A_0 : A$ at $t=0$
—◎— 50.5°C —⊖— 45.5°C
—●— 36.1°C —○— 19.0°C

only to photochromism, A, was calculated, the reciprocal of A was found to decrease linearly with time, as is shown in Fig. 1. The linearity shows that the reaction which causes absorbance A to decrease obeys the rate law for a second-order reaction, since the absorbance of 347 mμ was confirmed to obey Beer's law in a benzene solution of a concentration lower than about 10^{-5} mol./l. at 15°C. This finding suggests that this reaction is a recombination of 2, 4, 5-triphenylimidazolyl radicals formed by the homolytic dissociation of I and that the mechanisms of the photochromism and thermochromism of hexaphenyl-biimidazolyl (I) may be represented by the following equation:

This mechanism was supported by the determination of the molecular weight in a benzene solution ($C=0.0124$ mol./l.) with a macro-cryoscopic method carried out in a dark room, which showed a decrease in molecular weight from 600 to 440 with irradiation. From the rate constants which were obtained from the measurements shown in Fig. 1, the activation energy for the recombination of 2, 4, 5-triphenylimidazolyl radicals was determined to be 7.3 kcal./mol. The equilibrium constants for the thermal homolytic dissociation of I were estimated to be approximately 3.1×10^{-4} (49.0°C), 4.7×10^{-4} (53.8°C) and 1.1×10^{-3} (60.4°C) from the absorbance of 554 mμ due to thermochromism by the mass action law and Beer's law and from the equilibrium constants, ΔH for this reaction was estimated to be about 23 kcal./mol.

Infinite Circular Gas Chromatographic Columns[1]

By Samuel SIDEMAN

(Received February 1, 1964)

The use of infinite circular columns in gas chromatography has been proposed by Martin[2] in his address, "Past, Present and Future of Gas Chromatography," before the first International Symposium on Gas Chromatography (ISA). He suggested that "if you have two columns and two substances that are very difficult to separate, you can arrange to drive the pair of substances into the first column and then, when it gets near one end, you connect it to the other column and you continue blowing until it's gone right into the second column, monitoring its passage with an extremely small detector, probably a katharometer in this case. When it is safely in the second column, you disconnect the first column and start blowing in the end of the second column and carry on until it's started into the first one again. And so you go on, round and round and round."

Porter and Johnson[3,4] utilized a circular column to obtain data for extractive distillation. Using a pump to circulate the gas into the column, they were thus able to use volatile liquids as partitioning solvents.

The search for a chromatographic column suitable for the separation of components with very small separation factors, such as nitrogen isotopes, has been going on in these laboratories for the last few years. Some of the very long columns used exhibited extremely high retention times (up to nine hours in some cases). Appreciable pressure drops were required, and a rapid decrease in the efficiency of the column occurred because of the evaporation of the liquid phase.

As these difficulties are obviously absent in circular infinite columns, it was of interest to study other characteristics of such systems. The effect of column length, i.e., the number of cycles, on the width of the peaks was examined, both by theory and experiment, and the feasibility of utilizing this technique for the separation of components was investigated.

4) R. S. Porter and J. F. Johnson, *Ind. Eng. Chem.*, **52**, 691 (1950).

Apparatus

Two mechanisms for circulating the sample gas in the column were compared.

A) An Infinite Column with Externally-supplied Carrier Gas.—Figure 1 illustrates the system used. Two short columns, with a thermal conductivity cell (T. C. C.) at each end, were connected head to tail. Two pairs of electrically-operated valves were used to direct the flow in a closed circuit. One of the valves of each pair was connected to the carrier gas cylinder, while the other vented to the atmosphere. Once the sample reached the end of one column, a signal from the T. C. C. energized one pair of valves and simultaneously de-energized the other pair. The sample was thus directed into the second half of the circuit, and vice versa. A delay-relay unit (Fig. 2) was incorporated in the system to ensure the delayed operation of the valves. This was achieved by deactivating a triggering micro-switch set in the recorder for the time

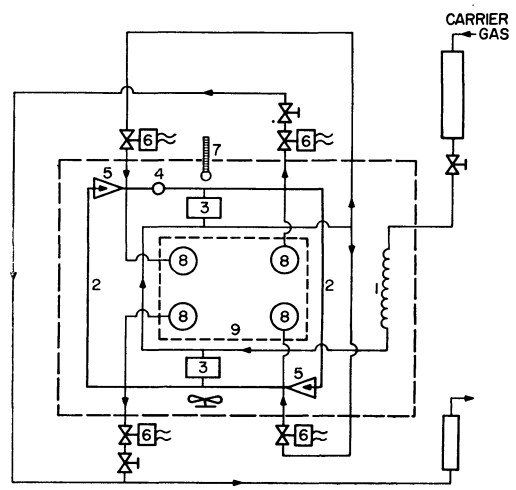

Fig. 1. Schematic diagram of an infinite circular gas chromatographic column of the "two half cycles" type.

needed for the sample to pass through the T. C. C. By this arrangement the leading peak in each half-cycle entering the T. C. C. triggered the micro-switch, which in turn alternated the electric valves.

Some experiments were conducted with one T. C. C. only. In this arrangement the two half-columns were so connected that the reference and sample sides of the T. C. C. alternated for each half cycle. The base line drift

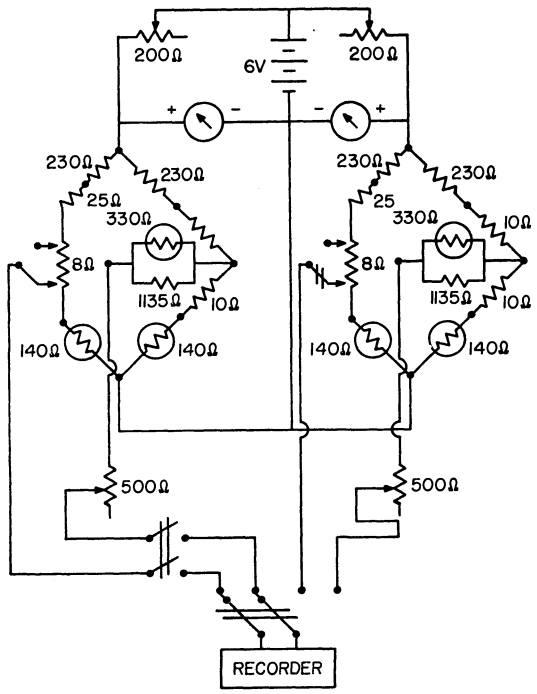

Fig. 3. Wiring diagram of the two T. C. C.s.

caused by peak broadening discouraged further work with this arrangement; therefore, two T. C. C.s were connected, one at the end of each half-circuit. Figure 3 illustrates the wiring of the two T. C. C.s.

B) An Infinite Column with Gas Circulation Pump.—The arrangement of the apparatus is illustrated in Fig. 4. Except for a short length of unpacked tubing which passed through the squeeze pump (a Sigmamotor type), the column and the T. C. C. were housed in an air-thermostat. The plastic tubing used was coated with polyvinyl alcohol to prevent losses of the compound tested by diffusion through the wall. A rotameter was used to calibrate the gas flow

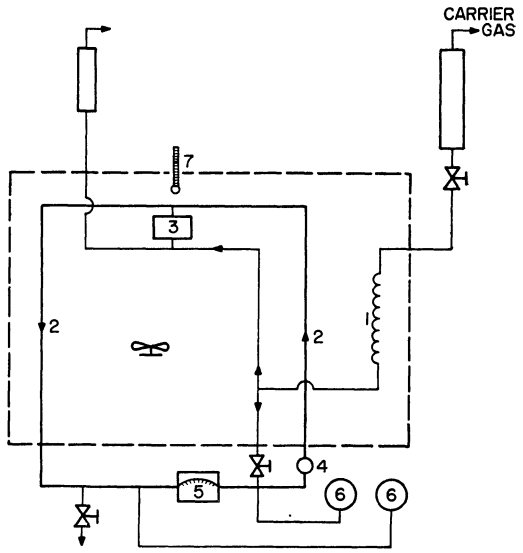

Fig. 4. Schematic diagram of an infinite circular gas chromatographic column of the "pump" type.
1 : Preheater coil 2 : Chromatographic column 3 : Thermal conductivity cell 4 : Sample injection block 5 : Squeeze pump 6 : Pressure gauge 7 : Thermometer

through the column. Pressure gauges across the pump provided pressure drop measurements. These were connected to the column through copper capillaries, thus ensuring a minimum voidage in the column. The rotameter was taken out of the system after the desired flow rate had been fixed. Variations in the flow caused by the removal of the rotameter were sufficiently small to be disregarded. By opening two needle valves (at the inlet and outlet of the pump), the apparatus could be used as a standard gas chromatograph.

Advantages and Disadvantages of the Above Mechanisms

The obvious advantage of the "half-cycle," method A, over the "pump" method, B, is

that there is no risk of mixing the sample, since it does not require an external pump and since it can be constructed with a minimum dead volume. The disadvantages, however, are discouraging. An elaborate apparatus is needed, and the control mechanism is rather complicated. A base line shift occurs when the valves are alternated at each half-cycle, and this has to be corrected for either manually or automatically. Moreover, pressure waves due to sudden pressure variation at each half-cycle cause the sample to contract in the gas-phase only, thus disturbing the equilibrium and broadening the peak. Under these conditions, no efficient separation seems feasible.

The main advantage of the pump technique is its simplicity. It is easy to operate at various absolute pressures. The main disadvantage is, of course, the mixing of the sample as it passes through the pump, which may result in undesired peak broadening.

The Effect of the Number of Cycles on Peak Width

Theoretical. — Under ideal conditions gas chromatographic peaks closely approach the normal distribution curve; i. e., the curve approaches the base-line (or zero concentration line) asymptotically. Thus, theoretically, the width of the peak is infinite. In practice, the width is measured at some convenient place. The common procedure is to measure the width between the intercepts of the tangents to the peak passing through the inflection points at the base-line. The width thus obtained is equal to 4σ, where σ is the standard deviation.

For the usual case where the volume of the sample S is negligible ($0.5 > S/v\sqrt{n}$), the width of the peak, W, has been shown (Van Deemter et al.[5]) to be:

$$W = 4v\sqrt{n} \qquad (1)$$

where v is the volume of one theoretical stage and n is the number of theoretical plates in the column. The retention volume, V_r, has also been shown to be:

$$V_r = vn \qquad (2)$$

The combination of these two equations enables us to determine the theoretical number of stages by the well-known relation:

$$n = 16(V_r/W)^2$$

where both W and V_r are measured in the same units (volume, time or length).

Assuming that the number of stages in the column is directly proportional to the length of the column, Eq. 1 can be written:

$$W = K'\sqrt{NL + L'} \quad \text{or:} \quad W^2 = K(NL + L') \qquad (3)$$

where K is a proportionality constant, N is the number of cycles (starting from the T. C. C.), L is the length of the column, and L' is the length of the fragment of the column from the injection block to the T. C. C. When the apparatus is so constructed that $L' = 0$

$$W^2 = KNL \qquad (3a)$$

or, when $L' = 1/2L$

$$W^2 = KL(N + 1/2) \qquad (3b)$$

Equation 3 indicates that the higher the number of cycles, the wider the peak becomes.

The assumption of the linear proportionality of n and L can be experimentally verified for non-overlapping peaks. Let subscript i represent the number of the consecutive peaks. Then, from Eq. 1, the ratio of the widths of two consecutive peaks is:

$$\frac{W_{i+1}}{W_i} = \frac{\sqrt{n_{i+1}}}{\sqrt{n_i}} = \frac{\sqrt{L_{i+1}}}{\sqrt{L_i}} \qquad (4)$$

Now, if L is expressed in half-cycles, i. e., $L_1 = (1/2)L(=L')$, $L_2 = (3/2)L$, $L_3 = (5/2)L$, etc., substitution in Eq. 4 gives:

$$\frac{W_{i+1}}{W_i} = \sqrt{\frac{2i+1}{2i-1}} \qquad (4a)$$

which is the theoretical value of the ratio of the widths of two consecutive peaks.

Experimental.—An example of the chromatograms obtained using the first mechanism is given in Fig. 5. No attempt was made to draw quantitative conclusions from these experiments.

Figure 6 shows a chromatogram obtained using the pump technique with a sample of ethyl methyl ketone. The column was 8 m. long, was packed with polyethylene powder, 50~70 mesh, which was coated with 15% glycerol. A polyethylene packing was chosen for this work because of its low pressure-drop characteristics. The column was flushed for about two hours with carrier gas before each

run to remove traces of material left over from previous experiments.

A set of measurements from an experimental run with a sample of *n*-heptane is given in Table I. Only the first three peaks could be measured with a fair degree of reliability. Once the peaks met head to tail, the base-line shifted upwards; consequently, accurate measurement was not possible.

Figure 7 was drawn according to Eq. 3b and shows good agreement between experiment and theory. Agreement is also evident in Fig. 8,

which shows the experimental versus theoretical width ratio of the consecutive peaks given in Table I.

Discussion and Conclusions

The characteristics and performance of infinite circular columns in gas chromatography have been studied. Two mechanisms for gas circulation in the column have been experimentally compared. The half-cycle-type mechanism proved to be rather unsuccessful because of intermittent pressure drops inherent in this mode of operation. The pump mechanism was found easy to operate and was used for most of the experimental work conducted. The separate effect of mixing due to pump action is yet to be studied. The theoretical relationship of the width to the number of cycles has been experimentally verified.

The results obtained in this study discourage the use of low-efficiency columns, with about 100 theoretical plates, for separation purposes. This is in agreement with our previous report[6] that separation is feasible only with high-efficiency columns, where the width of the peak is less than a half, and preferably a quarter, of the retention volume of the first peak. With the low-pressure, low-efficiency polyethylene column used in this work, head and tail mixing of the consecutive peaks occurred and no separation was feasible. Other packed columns with a higher number of theoretical plates could not be used with the given pump mechanism because of the higher pressure drops required. Nevertheless, the reported pump mechanism, though presently limited only to low-pressure, low-efficiency columns, may be used for some particular applications, where the following advantages may be utilized:

(1) The use of short circular columns instead of the usual long columns eliminates the high pressure differential between inlet and outlet.

(2) Absolute retention times can be read directly, with no need for dead volume corrections, sometimes even without pressure corrections.

(3) Volatile solvents can be used as column coating with practically no aging of the column.

(4) Uniform coating can be made in situ.

(5) The behaviour of ternary systems can be easily studied, and separation factors applicable to extractive distillation can be evaluated.

Thanks are due to Mr. B. Gal-Or for his co-operation in this work and to Messrs. Z. Chouri, J. Margalit, M. Marton, E. Kutzinsky and G. Hirsh, senior students in the Department of Chemical Engineering, Technion-Israel Institute of Technology, for carrying out part of the experimental work.

A Study of the Hydration of Calcium Orthoplumbate. III. The Behavior of Dehydration

By Masumi KOISHI

(Received March 7, 1964)

The following facts have been observed regarding the process and products of the hydration of calcium orthoplumbate at various temperatures in an atmosphere of nitrogen-water vapor:[1] i) In the hydration process, the mole ratio of CaO/PbO_2 in calcium orthoplumbate decreased linearly, while that of H_2O/CaO decreased step-by-step, with the increase in temperature. ii) The powder which appeared in the hydration process changed color parallel with the inversion rate of the anhydrous compound. iii) The composition and nature of completely-hydrated products at various temperatures were examined by X-ray diffraction analysis, thermobalance analysis, chemical analysis, differential thermal analysis, infrared absorption spectrum and electron microscopy. The results of all the methods showed good agreement.

In this paper, the dehydration of calcium orthoplumbate hydrates will be examined by a differential thermal analysis pattern, and the information thus obtained will be used for analyzing the dehydration behavior of the crystalline water and negative catalytic effects of calcium hydroxide. The results of present experiment will support the conclusion of the previous paper. The reaction order (n) and the frequency factor (A) of the dehydration stage will also be discussed.

Theoretical

The Determination of the Activation Energy (E) and the Frequency Factor (A). — The activation energy (E) was obtained from the variation in the peak temperature with the rate of heating.[2] Kissinger derived the following equation from the theoretical consideration:

$$\frac{d(\ln \phi/T_m^2)}{d(1/T_m)} = -\frac{E}{R} \qquad (1)$$

where ϕ(°C/min.) denotes the rate of heating; T_m (°K), the temperature of maximum deflection; R, the gas constant, and E, the activation energy. The variation in the peak temperature with the rate of heating is governed only by the activation energy. The plot of $-R\cdot\ln \phi/T_m^2$ vs. $1/T_m$ should give a straight line; the slope of this line will be E according to Eq. 1.

The reaction order (n) and the frequency factor (A) are calculated from Eqs. 2 and 3:

$$n(1-x)_m^{n-1} = 1 + (n-1)\cdot 2RT_m/E \qquad (2)$$

$$E\phi/RT_m^2 = A\cdot n(1-x)_m^{n-1}\cdot e^{-E/RT_m} \qquad (3)$$

where $(1-x)_m$ denotes the amount of material left unreacted and n, the empirical order of reaction.

The Estimation of the Reaction Order from the Peak Shape.—Kissinger proposed a "shape index (S)" to obtain the reaction order. When S is plotted against n^2, the points fall roughly on a straight line defined by

$$S = 0.63\cdot n^2 \qquad (4)$$

This expression was used to estimate the reaction order of the dehydration reaction from the differential thermal analysis data.

Experimental Procedure

Material.—*Calcium Orthoplumbate Hydrate-Calcium Hydroxide Mixtures.*—The mixture applied in this experiment was prepared by hydrating calcium orthoplumbate. The process of hydration was carried out at 30, 50, 80 and 100°C in an atmosphere of nitrogen-water vapor. The ratio of H_2O/Ca_2PbO_4 was 10 in the process. Hydration finished after 390 min. Hydrated mixtures were identified by X-ray diffraction patterns, differential thermal analysis curves, thermobalance, and chemical measurements.

Calcium Orthoplumbate Hydrate. — The Franke method[3] was applied in order to remove calcium hydroxide from hydrated mixtures. The Franke method (or the acetoacetic ester method) for the extraction of free calcium hydroxide in calcium orthoplumbate hydrate-calcium hydroxide mixtures gave good results.

The general formula $(2-N)CaO\cdot PbO_2\cdot mH_2O + N\cdot Ca(OH)_2$ was assigned to the completely-hydrated mixture in the preceding paper.[1]

The samples employed for thermal analysis are

TABLE I. MATERIALS USED FOR DIFFERENTIAL THERMAL ANALYSIS

Material	Composition: Hydrate $(2-N)$	Composition: Hydrate m	Composition: Free $Ca(OH)_2$ N	Condition of reaction: Temp. °C	Condition of reaction: Time min.
A	1.5	3.0	0.5	50	390
B	1.2	1.8	0.8	80	390
C	1.0	1.0	1.0	100	390
D	1.5	3.0	—	50	390
E	1.2	1.8	—	80	390
F	1.0	1.0	—	100	390
G	$Ca(OH)_2$: Extra pure reagent				
H	$Mg(OH)_2$: Extra pure reagent				

Formula: $(2-N)CaO \cdot PbO_2 \cdot mH_2O + NCa(OH)_2$

listed in Table I. Samples A, B and C were calcium orthoplumbate hydrate - calcium hydroxide mixtures. D, E and F were calcium orthoplumbate hydrate. Two chemical reagents, calcium hydroxide, and magnesium hydroxide, were employed as reference samples.

Apparatus and Procedure. — The apparatus of differential thermal analysis employed in this work consists of an analytical furnace, a transformer, and recording equipment. Specimen holders made of pure nickel have a diameter of 1/4 inch and a length of 1/2 inch.

A chromel-alumel thermocouple was used. The reference material was α-aluminum oxide. Each of the eight samples was run in differential thermal analysis at the rate of 3, 4, 5, 7, 9, 10 and 13°C per min. to determine the variation in the peak temperature with the rate of heating. The samples were ground to pass through a 250-mesh sieve. Specimen holders were filled loosely with 500 mg. of the sample, and a gentle tapping was carried out. The standard deviation of a single measurement was within 2.5°C. The thermobalance apparatus employed in this work was the same as that described in the preceding paper.[1] The loss in weight was recorded continuously as the furnace temperature increased. About 1 g. of the sample was used for each determination.

Results and Discussion

The loss in weight accompanying the heat treatment of calcium orthoplumbate hydrate and calcium orthoplumbate hydrate - calcium hydroxide mixtures in the thermobalance measurement is given in Figs. 1 and 2 respectively.

It is apparent from Figs. 1 and 2 that the dehydration of samples D, E and F proceeds in one stage, and that of A, B and C, in three

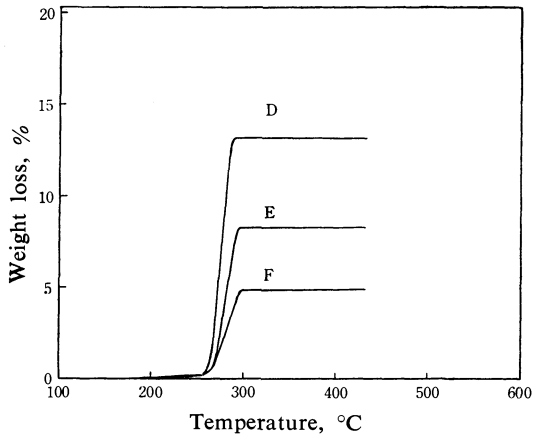

Fig. 2. Thermobalance results for calcium orthoplumbate hydrate.

stages. Stages I and II in Fig. 1 seem to show the first and second stage of the dehydration respectively; III may show the decomposition of calcium hydroxide.

The results of the differential thermal analysis experiments with samples A—H are listed in Table II. In the case of samples A, B and C the dehydration proceeded in two steps in the range of 316～370°C and 402～430°C when the rate of heating was varied from 3°C per min. to 13°C per min. On the other hand, in the case of the extracted hydrate (D, E and F), the dehydration proceeded in one step. The dehydration temperature was 303～382°C.

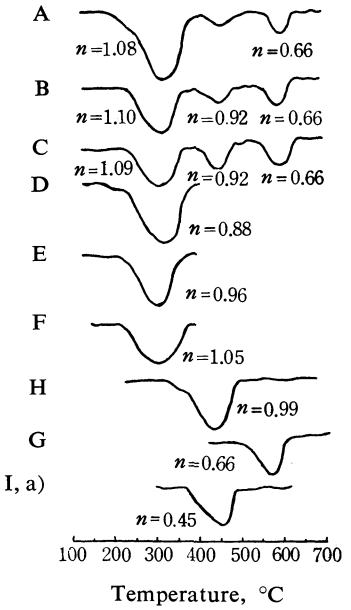

Fig. 3. Typical differential thermal analysis curves for the samples used in the present study.

It may be concluded from the comparison of the results of the thermobalance with those of the differential thermal analysis that the dehydration of the two-stage mechanism starts at a slightly higher temperature and proceeds over a wider range than does the one-stage dehydration.

This conclusion seems to show that the dehydration of the hydrated mixture is partially retarded by the presence of liberated calcium hydroxide. This negative catalytic

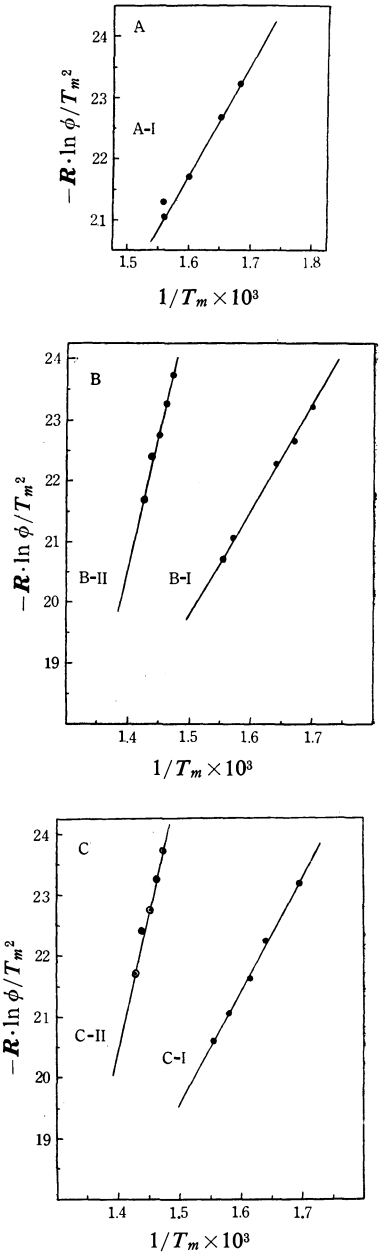

Fig. 4. Differential thermal analysis data obtained for samples A, B and C.

action of calcium hydroxide can reasonably be explained by the results of the reaction order (n) and the activation energy (E).

The shape of the endothermic peak associated with the thermal decomposition of these samples is depicted in Fig. 3. The corresponding values of n obtained from Eq. 4 are also given there. Each differential thermal analysis datum in Table II gives a straight line of $-R\cdot\ln\phi/T_m^2$ vs. $1/T_m$, thus enabling us to calculate the activation energy (E). The case of A is shown in Fig. 4 as an example. The values of n, A and E obtained are given in Table III.

TABLE III. KINETIC RESULTS BY DIFFERENTIAL THERMAL ANALYSIS METHODS

** Second dehydration step.
*** Liberated calcium hydroxide.
a) Kissinger's data by DTA method for Brucite.
b) Kissinger's data by isothermal weight-loss measurements for Brucite.

Gregg and Razouk reported that the reaction order of Brucite $Mg(OH)_2$ was 0.66 and the activation energy, 27.6 kcal. per mole. Kissinger[2] obtained the reaction order of 0.55~0.44 and the activation energy of 31.4 kcal. per mole from his differential thermal analysis, and the reaction order of 0.69 and the activation energy of 27.2 kcal. per mole, from the results of the isothermal reaction rate for the same compound. The value of the reaction order of magnesium hydroxide (0.99) reported in this paper (Table III) differs from those reported by Kissinger and by Gregg and Razouk, but the activation energy of 25.0 kcal. per mole is similar to their values in order of magnitude.

The values of the reaction order derived from the differential thermal analysis are nearly equal to unity in the cases of samples A, B and C. While the activation energies of the first dehydration were found to be 18.2, 18.0, and 18.0 kcal. per mole, those of the second dehydration were from 41.0 to 43 kcal. per mole. The second dehydration of sample A was not obtained exactly. The activation energies for D, E and F were

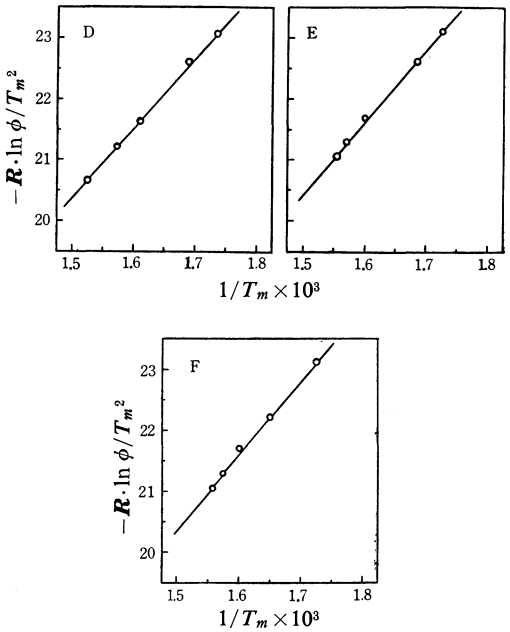

Fig. 5. Differential thermal analysis data obtained for samples D, E and F.

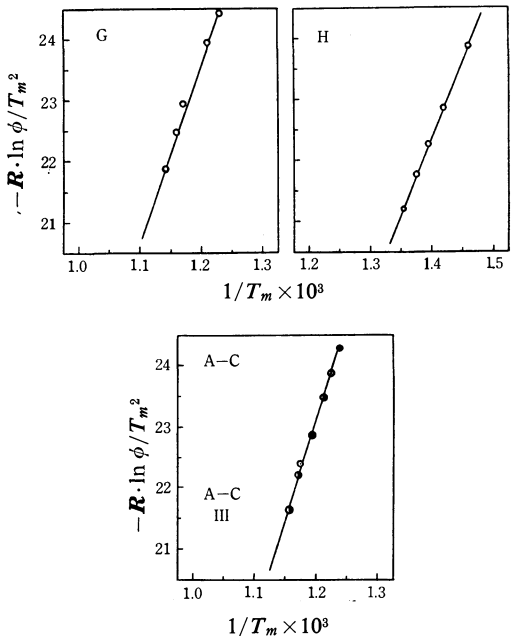

Fig. 6. Differential thermal analysis data obtained for samples A, B and C.
● 50°C; ○, 80°C; ◑, 100°C (temperature of hydration)

found to be 11.5, 11.5 and 12.1 kcal. per mole; the reaction orders of E and F were nearly equal to unity, while that of D was apart from unity, that is, 0.88. The lack of agreement in the case of the dehydration of sample D can not be explained. The difference in activation energy between the first and second dehydration processes indicates that the dehydration is influenced by the inhibitive action of the calcium hydroxide liberated; that is, the elevation of the activation energy of the second dehydration seems to arise from the fact that small particles of calcium hydroxide liberated in hydrate mixtures are firmly bound to the hydrate.

The behavior of the binding of calcium hydroxide to hydrate is considered to be as follows: a comparison of the electron micrograph reported in the preceding paper[1] with the above-mentioned results suggests that the crystals of calcium hydroxide produced by the hydration link together to form a three-dimensional network and that hydrated calcium orthoplumbate fills up the space existing in the calcium hydroxide network. The three-dimensional network of calcium hydroxide may be a linkage consisting of crystals of a spherical form, as suggested by the results of Sato,[4] because the values of the reaction order in this study agree with those of Sato.

4) N. Sato, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **76**, 862 (1955).

Summary

The behavior of the dehydration of a hydrate mixture of calcium orthoplumbate and calcium hydroxide and of the hydrate of calcium orthoplumbate has been studied with a thermobalance and by differential thermal analysis.

It has been shown that the dehydration of crystalline water in the hydrate mixture was retarded by the presence of the calcium hydroxide liberated; this conclusion has been based on both the activation energy of the hydrate and its loss of weight.

It seems that calcium orthoplumbate fills the space in a network consisting of calcium hydroxide particles.

The author wishes to express his gratitude to Professor Ayao Kitahara of Tokyo College of Science for his continuous encouragement and helpful discussions throughout this work.

A Semi-empirical MO Theory of σ Electron Systems. I. General Theory*

By Hidekazu HAMANO**

(Received March 10, 1964)

Most of the theoretical work on organic molecules that has been reported so far is connected with π electron systems; relatively little is known about the electronic states of the σ electrons. However, recent progress in experimental techniques such as nuclear magnetic resonance, nuclear quadrupole resonance, and electron spin resonance has made it desirable to obtain some more theoretical information about the electronic states of the σ electrons in organic molecules. The present paper constitutes an attempt in this direction.

* This work was supported by a grant from the U. S. Army Research Office (Durham) and the National Science Foundation to the University of Pennsylvania.

** On leave of absence from Tokyo Gakugei University, Tokyo, Japan.

It is obvious that any theoretical description of the σ electrons in organic molecules will be of an approximate nature. We plan to base our discussion on the SCF LCAO MO method as developed by Roothaan,[1] a method which has been successfully applied to small molecules. However, we will be forced to introduce some additional approximations, since a straightforward application of Roothaan's theory is not feasible for large organic molecules.

Let us consider a molecule with a closed-shell ground state. It is assumed that each doubly-occupied SCF LCAO MO may, in principle, be associated with either a lone pair or a localized σ bond, though in Roothaan's complete treatment each SCF LCAO

MO should, in principle, be represented as a linear combination of all available atomic orbitals in the molecule. In a first approximation we represent the SCF LCAO MO's that are associated with lone pairs or σ bonds as linear combinations of the corresponding atomic orbitals on the atoms. If we substitute the MO into the analogue of the Roothaan equations[1] and then solve them, we may anticipate one solution for each lone pair and two solutions for each bond; the solution with the lower energy will be called the bonding orbital, and the other solution, the anti-bonding orbital. In the following pages the expression "*to a first approximation*" refers to the above calculation. The first-order treatment is considerably less accurate than a complete SCF LCAO MO calculation would have been, but we may use its results as a starting point for a second-order treatment which will give results that are of an accuracy comparable with that of the solutions of the complete SCF LCAO MO calculations.

It is possible to construct molecular orbitals as linear combinations of the lone-pair, bonding and anti-bonding orbitals obtained above. This approach might be called the LCBO MO method (with molecular orbitals represented as linear combinations of bond or lone-pair orbitals). The coefficients in these linear combinations are unknown, but it may be assumed that in each case there is a major contribution from a lone-pair or a bonding orbital and that the coefficients of the anti-bonding orbitals are significantly smaller. Therefore, they may be determined by means of a perturbation method. In the following remarks we will use the expression "*to a second approximation*" as referring to the results of this perturbation treatment.

We will be forced to introduce some semi-empirical features into the theory, especially in connection with estimating the non-diagonal elements of the matrix that represent the interaction between different bonds or lone pairs, since a non-empirical evaluation of these quantities would be very tedious. This semi-empirical procedure supplies a convenient tool for dealing with large organic molecules.

The general theory will be developed in this paper; applications and some further details will be discussed in subsequent papers.

I. First Order Theory.—*General Considerations.*—In developing our theory we will basically follow Roothaan's method.[1] However, we will replace Roothaan's LCAO approximation by the LCBO approach. We will also consider a molecule with a closed-shell ground state. The inner electrons may be taken as being adequately represented by means of the inner-shell atomic orbitals; hence, only the valence electrons need to be taken into account.

The molecular $2N$-electron ground state wave function is represented as an antisymmetrized product of molecular spin orbitals:

$$\Phi=\{(2N!)\}^{-1/2}\sum_{\mathbf{P}}P\delta_{\mathbf{P}} \times\{\prod_{i}\phi_i(2i-1)\phi_i(2i)\alpha(2i-1)\beta(2i)\} \quad (1)$$

where the ϕ_i are suitable molecular orbitals, which are represented as LCAO in Roothaan's theory.[1] We may also write the MO as linear combinations of orbitals that are localized in specific bonds or lone pairs such as those proposed by Edmiston and Ruedenberg[2] or Lennard-Jones,[3] which are obtained by means of a unitary transformation. We will go one step further and take the orbitals as bond or lone-pair orbitals themselves. The validity of this procedure is not immediately obvious, however, and so it may be useful to clarify its theoretical basis and the relation between the LCAO and LCBO approximations.

We may represent the bond orbitals as linear combinations of valence atomic orbitals (LCVAO):

$$\varphi_p=a_p(A,p)+b_p(B,p) \quad (2)$$

where A, p and B, p are the valence AO of both atoms respectively, and each φ_p is normalized. The valence AO (A, p), (B, p) and lone-pair orbitals φ_f may be represented as linear combinations of the AO on the corresponding atoms:

$$A,p=\sum_{\lambda}d_{\lambda}^{p}\chi_{\lambda}^{A}, \qquad .\ \varphi_f=\sum_{\mu}d_{\mu}^{f}\chi_{\mu}^{A} \quad (3)$$

where χ_{λ}^{A} is the λth AO of atom A and d_{λ}^{p} is its coefficient in the pth bond orbital. This set of hybridized AO's belonging to the same atom may be taken as orthonormal and equivalent. Each bond orbital, φ_p, may be supposed to be obtained by solving an equation for bond p. Usually two different solutions are obtained, a bonding orbital, φ_p^+ and an anti-bonding orbital, φ_p^-; they are orthogonal to one another. In this way, we may replace a set of atomic orbitals by an equivalent set of valence orbitals and also replace the paired valence AO (A, p) and (B, p) by the bonding φ_p^+ and anti-bonding

3) J. Lennard-Jones, *Proc. Roy. Soc.*, **A198**, 1, 14 (1949). He called these orbitals "*equivalent orbitals.*"

φ_p^- orbitals. We may thus represent the MO's as linear combinations of bond or lone-pair orbitals instead of the LCAO approximation:

$$\psi_i = \sum_p c_{ip}\varphi_p \tag{4}$$

The variational procedure for minimizing the total energy of the molecule then leads to the following equation:

$$\boldsymbol{L}\boldsymbol{c}_i = \varepsilon_i \boldsymbol{S}\boldsymbol{c}_i \tag{5}$$

where $\boldsymbol{L}$ is the set of LCBO SCF Hamiltonian matrix elements which are given by:

$$\begin{aligned}\boldsymbol{L}_{pq}^{+-} &= \langle\varphi_p^+|\boldsymbol{H}|\varphi_q^-\rangle \\ &+ \sum_i [2\langle\psi_i(1)\varphi_p^+(2)|r_{12}^{-1}|\psi_i(1)\varphi_q^-(2)\rangle \\ &- \langle\psi_i(1)\varphi_p^+(2)|r_{12}^{-1}|\varphi_q^-(1)\psi_i(2)\rangle], \text{ etc.}\end{aligned} \tag{6}$$

The $\boldsymbol{H}$ is the Hamiltonian for the electrons in the combined potential field of the nuclei and inner-shell electrons. The column vectors, $\boldsymbol{c}_i$ represent the coefficients of the BO in the ith MO, ε_i is the eigenvalue of the MO, and $\boldsymbol{S}$ is an overlap matrix with elements $S_{pq}^{+-} = \langle\varphi_p^+|\varphi_q^-\rangle$, etc. Equation 5 is the secular equation for the SCF LCBO MO.

It would, however, be as difficult as in the LCAO approach to obtain a reliable solution of Eq. 5 from *ab initio* calculations; we therefore wish to solve the equation by introducing the following approach. The matrix elements, S_{pq}^{+-}, are usually smaller than the S_{pq}^{++} or S_{pq}^{--} since the signs of the coefficients, a_p or b_p, of the valence AO in the bond orbital defined by Eq. 2 are different for the bonding and anti-bonding orbitals, and since the overlap integrals between unpaired valence AO's are generally small (they are zero for the AO on the same atom). Since the delocalization of the σ electrons is considered to be small, we may also assume that the $\boldsymbol{L}_{pq}^{+-}$ are relatively small. They may be considered as small perturbations. We will discuss this in greater detail in the second order theory described in Section II. In the first order treatment these smaller terms may, therefore, be neglected. Equations 4 and 5 are then reduced to:

$$\psi_i^+ = \sum_p c_{ip}^+\varphi_p^+, \qquad \psi_i^- = \sum_p c_{ip}^-\varphi_p^- \tag{7}$$

$$\boldsymbol{L}^+\boldsymbol{c}_i^+ = \varepsilon_i^+\boldsymbol{S}^+\boldsymbol{c}_i^+, \qquad \boldsymbol{L}^-\boldsymbol{c}_i^- = \varepsilon_i^-\boldsymbol{S}^-\boldsymbol{c}_i^- \tag{8}$$

where the plus and minus signs refer to quantities connected with the φ_p^+ and φ_p^- respectively. In this approximation, the ψ_i^+ and ψ_k^- are determined from two independent sets of equations, representing the occupied and unoccupied MO respectively in the molecular ground state. We will only discuss the equations for the occupied orbitals, since the other equations are in every way equivalent. For the sake of brevity, we will omit the plus sign in the following remarks.

The non-orthogonality between the different BO's will cause some complications in the subsequent discussion; it is, therefore, convenient to introduce, according to Löwdin,[4] the following orthogonalized BO (OBO):

$$\varphi^\circ = \varphi(\boldsymbol{1}+\boldsymbol{S}^\circ)^{-1/2} \tag{9}$$

where $\boldsymbol{1}$ is a unit matrix and $\boldsymbol{S}^\circ$ is an overlap matrix with the elements:

$$S_{pq}^\circ = S_{pq} - \delta_{pq}, \quad \delta_{pq} = \begin{cases}1 & (p=q)\\ 0 & (p\neq q)\end{cases} \tag{10}$$

Equations 7 and 8 may, then, be written as:

$$\psi_i = \sum_p c_{ip}^\circ\varphi_p^\circ \tag{11}$$

$$\boldsymbol{L}\boldsymbol{c}_i^\circ = \varepsilon_i\boldsymbol{c}_i^\circ \tag{12}$$

where

$$\boldsymbol{c}^\circ = (\boldsymbol{1}+\boldsymbol{S}^\circ)^{1/2}\boldsymbol{c}$$

Since the matrix $\boldsymbol{c}^\circ$ is unitary, the molecular wave function, Φ°, and the electronic energy, W_e°, of the ground state may be written as:

$$\begin{aligned}\Phi^\circ = \{(2N)!\}^{-1/2}\sum_{\mathbf{P}}\boldsymbol{P}\delta_{\mathbf{P}} \\ \times\{\Pi_p\varphi_p^\circ(2p-1)\varphi_p^\circ(2p)\alpha(2p-1)\beta(2p)\}\end{aligned} \tag{13}$$

$$W_e^\circ = \sum_p \overline{W}_p = \sum_p [2\overline{H}_p + \sum_q (2\overline{J}_{pq} - \overline{K}_{pq})] \tag{14}$$

where the summation is to be performed over all the OBO's. The $\overline{H}_p$, $\overline{J}_{pq}$ and $\overline{K}_{pq}$ are core, Coulomb, and exchange integrals respectively with regard to OBO.

It would be a tedious procedure to use the OBO to perform calculations on large molecules. Fortunately, the overlap integrals between different BO's are usually much smaller than those between directly-bonded AO's. The possible consequences of the non-orthogonality of these orbitals have been discussed by Löwdin,[4] by means of OBO instead of non-orthogonal BO. They may, therefore, be neglected. In this approximation, the

4) P. O. Löwdin, *J. Chem. Phys.*, **18**, 365 (1950).

OBO's are reduced to the corresponding BO's. Equations 12, 13 and 14 may be rewritten as:

$$\boldsymbol{L}\boldsymbol{c}_i=\varepsilon_i\boldsymbol{c}_i \tag{15}$$

$$\Phi^\circ=\{(2N)!\}^{-1/2}\sum_{\mathbf{P}}\boldsymbol{P}\delta_{\mathbf{P}}\times\{\Pi_{\mathrm{p}}\varphi_{\mathrm{p}}(2p-1)\varphi_{\mathrm{p}}(2p)\alpha(2p-1)\beta(2p)\} \tag{16}$$

$$W_{\mathrm{e}}^\circ=2\sum_{\mathrm{p}}H_{\mathrm{p}}+\sum_{\mathrm{pq}}(2J_{\mathrm{pq}}-K_{\mathrm{pq}}) \tag{17}$$

Equations 16 and 17 show that the quantities in terms of the MO's may, instead, be expressed in terms of BO's in the first order treatment. Therefore, we may use the BO's instead of the MO's as a basis for the discussion of the first order theory. The method for determining the BO's will be discussed in the next subsection.

SCF Bond Orbital Approach. — Let us now proceed to determine the explicit form of the BO's which are represented by the variational function of Eqs. 2 and 3. Since we wish to make use of the SCF procedure, our method may be called the "*SCF BO approach.*"

Most σ electron systems of organic molecules contain some heteropolar bonds. It may be convenient to introduce the bond polarity parameter proposed by Mulliken:[5]

$$Q_{\mathrm{p}}=Q_{\mathrm{p}}^{\mathrm{A}}=b_{\mathrm{p}}^2-a_{\mathrm{p}}^2=(b_{\mathrm{p}}^2+a_{\mathrm{p}}b_{\mathrm{p}}S_{\mathrm{p}})-(a_{\mathrm{p}}^2+a_{\mathrm{p}}b_{\mathrm{p}}S_{\mathrm{p}})=-Q_{\mathrm{p}}^{\mathrm{B}} \tag{18}$$

where

$$S_{\mathrm{p}}=\langle\mathrm{A,p}|\mathrm{B,p}\rangle$$

The numerical evaluation of the various integrals involving atomic orbitals would be quite tedious. If we neglect the differential overlap between valence AO's in different BO's, we may simplify matters by making use of Mulliken's approximation:[5]

$$(\mathrm{A,p:B,p})\sim 1/2S_{\mathrm{p}}[(\mathrm{A,p:A,p})+(\mathrm{B,p:B,p})] \tag{19}$$

Nevertheless, the exchange integrals between the valence AO's on the same atom belonging to adjacent bonds or lone pairs need not necessarily be negligible; they have to be explicitly taken into account. Equation 17 may then be rewritten as:

$$\begin{aligned}W_{\mathrm{e}}^\circ=&\sum_{\mathrm{R,p}}(1-Q_{\mathrm{p}}^{\mathrm{R}})H_{\mathrm{R,p}}+2\sum_{\mathrm{p}}F_{\mathrm{p}}\gamma_{\mathrm{p}}\\&+1/4\sum_{\mathrm{R,pU,p}}(1-Q_{\mathrm{p}}^{\mathrm{R}})(1-Q_{\mathrm{p}}^{\mathrm{U}})J_{\mathrm{R,pU,p}}\\&+1/2\sum_{\mathrm{R,pT,q}}(1-Q_{\mathrm{p}}^{\mathrm{R}})(1-Q_{\mathrm{q}}^{\mathrm{T}})(J_{\mathrm{R,pT,q}}\\&-1/2\delta_{\mathrm{R,pT,q}}K_{\mathrm{R,pT,q}})+2\sum_{\mathrm{f}}H_{\mathrm{f}}\\&+2\sum_{\mathrm{fg}}(J_{\mathrm{fg}}-1/2\delta_{\mathrm{fg}}K_{\mathrm{fg}})\\&+\sum_{\mathrm{fR,p}}(1-Q_{\mathrm{p}}^{\mathrm{R}})(J_{\mathrm{fR,p}}-1/2\delta_{\mathrm{fR,p}}K_{\mathrm{fR,p}})\end{aligned} \tag{20}$$

where

$$F_{\mathrm{p}}=2a_{\mathrm{p}}b_{\mathrm{p}}=[-S_{\mathrm{p}}+\{1-(1-S_{\mathrm{p}}^2)Q_{\mathrm{p}}^2\}^{1/2}]/(1-S_{\mathrm{p}}^2) \tag{21}$$

$$\gamma_{\mathrm{p}}=H_{\mathrm{A,pB,p}}-1/2S_{\mathrm{p}}(H_{\mathrm{A,p}}+H_{\mathrm{B,p}}) \tag{22}$$

and where the R, p, U, p, etc., stand for the valence AO (A, p), (B, p), etc.; f and g refer to lone pair orbitals; $\delta_{\mathrm{R,pT,q}}$, etc., are taken as unity if the R, p and T, q are the valence AO's of the same atom in different bonds, otherwise they are zero.

The variational procedure leads to the following simultaneous equation:

$$\partial W_{\mathrm{e}}^\circ/\partial Q_{\mathrm{p}}=0 \tag{23}$$

$$\partial W_{\mathrm{e}}^\circ/\partial d_\lambda=0,\ \text{etc.} \tag{24}$$

In general, the explicit solutions of Eq. 24 may complicate the discussion; they correspond to the information on the atomic valence state. We may assume that the solutions of Eq. 24 have already been obtained implicitly and that they may then be inserted into Eq. 23. This does not mean that a calculation of the valence states of atoms in molecules is not important—their significance has already been emphasized by Moffitt[6-8]—, but only that it would be beyond the scope of this paper to discuss them here. Equation 23 may now be written as:

$$\begin{aligned}&(H_{\mathrm{B,p}}-H_{\mathrm{A,p}})-2Q_{\mathrm{p}}M_{\mathrm{p}}\gamma_{\mathrm{p}}+1/2(J_{\mathrm{B,pB,p}}\\&-J_{\mathrm{A,pA,p}})+Q_{\mathrm{p}}[1/2(J_{\mathrm{A,pA,p}}+J_{\mathrm{B,pB,p}})\\&-J_{\mathrm{A,pB,p}}]+\sum_{\mathrm{T,q}\neq\mathrm{p}}(1-Q_{\mathrm{q}}^{\mathrm{T}})[(J_{\mathrm{B,pT,q}}\\&-1/2\delta_{\mathrm{B,pT,q}}K_{\mathrm{B,pT,q}})-(J_{\mathrm{A,pT,q}}-1/2\delta_{\mathrm{A,pT,q}}\cdot\\&K_{\mathrm{A,pT,q}})]+2\sum_{\mathrm{f}}[(J_{\mathrm{B,pf}}-1/2\delta_{\mathrm{B,pf}}K_{\mathrm{B,pf}})\\&-(J_{\mathrm{A,pf}}-1/2\delta_{\mathrm{A,pf}}K_{\mathrm{A,pf}})]=0\end{aligned} \tag{25}$$

where;

$$M_{\mathrm{p}}=[1-(1-S_{\mathrm{p}}^2)Q_{\mathrm{p}}^2]^{-1/2}=1+1/2(1-S_{\mathrm{p}}^2)Q_{\mathrm{p}}^2+3/8(1-S_{\mathrm{p}}^2)^2Q_{\mathrm{p}}^4+\cdots\cdots \tag{26}$$

Since we are now considering electron pair bonds, even the small values of the polarity parameters may be of interest. By expanding M_{p} as above and by taking only the zeroth and first powers of Q_{p}, we obtain for Eq. 25:

5) R. S. Mulliken, ibid., **46**, 497, 675 (1949).

6) W. Moffitt, *Proc. Roy. Soc.*, **A202**, 534 (1950).
7) W. Moffitt, ibid., **A210**, 245 (1951).
8) W. Moffitt, *Reports Prog. Phys.*, **17**, 173 (1954).

$$Q_p = K_p [(\chi_{B,p} - \chi_{A,p}) + \sum_{\substack{T,q \\ (q \neq p)}} Q_p^T \{(J_{B,pT,q} - 1/2\delta_{B,pT,q} K_{B,pT,q}) - (J_{A,pT,q} - 1/2\delta_{A,pT,q} K_{A,pT,q})\}] \quad (27)$$

where;

$$K_p = [1/2(J_{A,pA,p} + J_{B,pB,p}) - J_{A,pB,p} - 2\gamma_p]^{-1} \quad (28)$$

$$\chi_{U,p} = \chi^\circ_{U,p} + \chi'_{U,p} \quad (29)$$

$$\chi^\circ_{U,p} = -\varepsilon^\circ_{U,pU,p} - 1/2 J^\circ_{U,pU,p} \quad (30)$$

$$\chi'_{U,p} = -H'_{U,p} - \sum_{\substack{T,q \\ (q \neq p)}} J'_{U,pT,q} - 2\sum_f J'_{U,pf} \quad (31)$$

$$\varepsilon^\circ_{U,pU,p} = H^\circ_{U,p} + \sum_{\substack{T,q \\ (q \neq p)}} (J^\circ_{U,pT,q} - 1/2 K^\circ_{U,pT,q}) + 2\sum_f (J^\circ_{U,pf} - 1/2 K^\circ_{U,pf}) \quad (32)$$

The superscripts small circle and prime refer to the corresponding one-center and two-center integrals respectively under the conditions $H^\circ_{U,p} + H'_{U,p} = H_{U,p}$, etc. $\varepsilon^\circ_{U,pU,p}$ is the Hartree-Fock energy parameter associated with U, p in the valence state of the atom U and generally not an eigenvalue of the hybridized AO. The $\chi_{U,p}$, $\chi^\circ_{U,p}$, and $\chi'_{U,p}$ may be defined as the "*intramolecular electronegativity of the atom U for the bond p*," "*the electronegativity of the atom U for the bond p*," *and* "*the induced electronegativity of the atom U for the bond p*," respectively; the second quantity is specific for the atom and is equivalent to the electronegativity scale defined by Moffitt;[9] the third quantity consequently also the first, depend on the interaction energy with the other atoms. We may approximate the $\chi^\circ_{U,p}$ as:

$$\chi^\circ_{U,p} \sim 1/2(I_{U,p} + E_{U,p}) \quad (33)$$

where the approximations $-\varepsilon^\circ_{U,pU,p} \sim I_{U,p}$, $J^\circ_{U,pU,p} \sim I_{U,p} - E_{U,p}$ are used; the $I_{U,p}$ and $E_{U,p}$ are the corresponding ionization potential and electron affinity respectively. This definition of electronegativity agrees with the one given by Mulliken.[10]

We may also give a different definition of the electronegativity scale without changing our conclusions. If we add the quantity $J_{A,pB,p}$ to the $-\chi'_{A,p}$ and $-\chi'_{B,p}$ respectively, we obtain the quantities $\varepsilon'_{A,pA,p} = -\chi'_{A,p} + J_{A,pB,p}$, etc., which are the neutral penetration energies and which are usually small. From these quantities, a different electronegativity scale may be defined:

$$\chi_{U,p} = -\varepsilon_{U,pU,p} - 1/2 J_{U,pU,p} \quad (34)$$

where

$$\varepsilon_{U,pU,p} = \varepsilon^\circ_{U,pU,p} + \varepsilon'_{U,pU,p} \quad (35)$$

Equation 34 corresponds to the generalized definition of Moffitt's electronegativity scale.[9] This procedure causes no changes in the results of Eq. 27, because we have $\chi'_{B,p} - \chi'_{A,p} = \varepsilon'_{A,pA,p} - \varepsilon'_{B,pB,p}$. These quantities are generally very small; they become important only if the quantity $(\chi^\circ_{B,p} - \chi^\circ_{A,p})$ is zero or very small, because the order of the magnitude of $(\chi'_{B,p} - \chi'_{A,p})$ may then become compatible with $(\chi^\circ_{B,p} - \chi^\circ_{A,p})$. This effect may, therefore be called the "*homopolar inductive effect or the quantum-mechanical inductive effect;*" it depends on the position of the bond in the molecule, but not on the polarities of the other bonds.

The K_p's are considered to be specific for the bond p, because the γ_p's are not supposed to depend on the adjacent atoms or bonds, as follows from their definition. They are also defined as:

$$K_p = \partial Q_p / \partial(\chi_{B,p} - \chi_{A,p}) \quad (36)$$

This suggests that the K_p may be called the "*auto-polarizability of the bond p*"; that is, the K_p measures the change of Q_p when the electronegativity difference is changed. The K_p may be approximated by:

$$K_p \sim [1/2\{I_{A,p} - E_{B,p}) + (I_{B,p} - E_{A,p})\} - J_{A,pB,p} - 2\gamma_p]^{-1} \quad (37)$$

The first term is the average energy of the ion pairs A^+B^- and A^-B^+ at infinite distances, and the second and third terms correspond to the average values of the Coulomb attraction and exchange repulsion energies of these ion pairs respectively. To a good approximation, therefore, K_p is regarded as an inverse of the average energy of the ion pairs A^+B^- and A^-B^+ at the equilibrium distance of bond p. We may conclude that the mobilities of the electrons in the bond decrease with an increase in the average energy of these two ion pairs. The sign of K_p is always positive, because the second and third terms of Eq. 28 have opposite signs and their sum—which corresponds to the interaction energy between atoms A and B—is small compared with the first term, which is always

9) W. Moffitt, *Proc. Roy. Soc.*, **A202**, 548 (1950).
10) R. S. Mulliken, *J. Chem. Phys.*, **2**, 782 (1934).

positive. This is important for the interpretation of the empirical rules, as will be shown later.

Now we wish to introduce the following inductive parameter:

$$\begin{aligned}\Pi_{pq} = K_p[&(J_{B,pA,q} - 1/2\delta_{B,pA,q}K_{B,pA,q}) \\ &- (J_{A,pA,q} - 1/2\delta_{A,pA,q}K_{A,pA,q}) \\ &- (J_{B,pB,q} - 1/2\delta_{B,pB,q}K_{B,pB,q}) \\ &+ (J_{A,pB,q} - 1/2\delta_{A,pB,q}K_{A,pB,q})] \\ \equiv &\delta_{\mathbf{P}+\mathbf{P}'}\Pi_{\mathbf{P}(B,pA,p)\mathbf{P}'(A,qB,q)} \\ &(q \neq p) \end{aligned} \tag{38}$$

where $\mathbf{P}$ and $\mathbf{P}'$ are the operators which represent the permutations of the orders of B, p, A, p, etc., and where $\delta_{\mathbf{P}+\mathbf{P}'}$ is unity when $(\mathbf{P}+\mathbf{P}')$ is even, and otherwise minus unity. Equation 27 may now be simplified as:

$$Q_p = Q_p^\circ + Q_p' \tag{39}$$

where

$$Q_p^\circ = K_p(\chi_{B,p} - \chi_{A,p}) \tag{40}$$

$$Q_p' = \sum_{q \neq p} \Pi_{pq}Q_q \tag{41}$$

It follows from these equations that the bond polarity, Q_p, consists of the following two parts: 1) Q_p°, the specific bond polarity of the bond p, which is determined by the electronegativity difference if we neglect the small homopolar inductive effect, and 2) Q_p', the induced bond polarity, which is induced by the polarity of the other bonds. These equations also give another definition of Π_{pq}:

$$\Pi_{pq} = \partial Q_p/\partial Q_q \tag{42}$$

This means that Π_{pq} is a measure of the change in Q_p when Q_q is changed; it may be defined as the "*mutual polarizability of the bond p to the bond q*" for $p \neq q$. For $p = q$, the quantity Π_{pp} is always unity and may be defined as the "*self-polarizability of the bond p.*" The Π_{pq}'s have the following additional properties:

$$\Pi_{pq}/\Pi_{qp} = K_p/K_q, \quad 0 < |\Pi_{pq}| < 1 \quad (q \neq p) \tag{43}$$

So far we have considered one specified bond p only. Equations 27 and 39, however, are in principle simultaneous equation. We will proceed to derive their explicit solutions. we obtain the explicit solution of Eq. 27 as:

$$\overline{Q}_p = \Delta_p/\Delta_n, \quad (p = 1, 2, 3, \ldots\ldots, n) \tag{44}$$

where;

$$\Delta_n = \det\{2\delta_{pq} - \Pi_{pq}\} \tag{45}$$

which is a determinant of n rows and columns; Δ_p is obtained from Δ_n by replacing the pth column of Δ_n by the column $(Q_1^\circ, Q_2^\circ, Q_3^\circ, \ldots\ldots, Q_n^\circ)$; n and p denote the total number of bonds in the molecule and the pth bond respectively and $\overline{Q}_p$ stands for the corresponding SCF value of Q_p.

Let us now define the following quantity:

$$\overline{\Pi}_{pq} = (-1)^{p+q}\Delta_n^{pq}/\Delta_n = \partial\overline{Q}_p/\partial Q_q^\circ \tag{46}$$

where Δ_n^{pq} is the determinant obtained by striking out from Δ_n the pth column and qth row. $\overline{\Pi}_{pq}(p \neq q)$ may be called the "*SCF mutual polarizability of the bond p to the bond q*" corresponding to Π_{pq}, and $\overline{\Pi}_{pp}$, "*SCF self-polarizability of the bond p*" corresponding to Π_{pp}. These definitions allow us to rewrite:

$$\overline{\boldsymbol{Q}} = \overline{\boldsymbol{\Pi}}\boldsymbol{Q}^\circ \tag{47}$$

where $\overline{\boldsymbol{Q}}$ and $\boldsymbol{Q}^\circ$ are column vectors whose components are given by Eqs. 44 and 40 respectively, and where $\overline{\boldsymbol{\Pi}}$ is a matrix with components that are given by Eq. 46. That is, these components are combined by the relation $Q_p = \sum_q \overline{\Pi}_{pq}Q_q^\circ$.

We have so far considered only the case where the bond polarities are small. In general, the quantity K_p may formally be written as:

$$\begin{aligned}K_p = [&1/2(J_{A,pA,p} + J_{B,pB,p}) \\ &- J_{A,pB,p} - 2M_p\gamma_p]^{-1}\end{aligned} \tag{48}$$

Apparently we obtain the general theory if we replace γ_p by $M_p\gamma_p$, as is indicated by Eq. 28. The extreme values for M_p are reached for $|Q_p| = 0$ (pure homopolar bond) as $M_p = 1$ and for $|Q_p| = 1$ (pure ionic bond) as $M_p = |S_p|^{-1}$. Since, in the interval $0 \leqq |Q_p| \leqq 1$, M_p is a monotonous and single-value function of Q_p, it will have all the values between 1 and $|S_p|^{-1}$. If Q_p is no longer small with respect to unity, it is necessary to solve Eq. 47 by means of an SCF procedure and by considering the explicit dependence of M_p on Q_p. This may become a very cumbersome problem. Since, in general, $\overline{Q}_p$ will not be very different from Q_p°, we may take to a first approximation the M_p value which corresponds to Q_p°. This will not affect the values of K_p very much.[11] The K_p may then be defined specifically for the bond p, and we may follow the the preceding argument just as it is.

11) Since the S_p values for σ bonds are usually around 0.5, M_p can only take values from 1 to 2. Therefore this may be a satisfactory approximation.

The SCF bond polarities, $\overline{Q}_p$, thus obtained enable us to determine the coefficients, a_p and b_p, of the valence AO as:

$$a_p^2=1/2(1-\overline{Q}_p-F_pS_p), \text{ and}$$

$$b_p^2=1/2(1+\overline{Q}_p-F_pS_p) \quad (49)$$

The corresponding values, $\overline{Q}_p^-$, for the anti-bonding orbital of the bond p may similarly be derived if it is borne in mind that $\overline{Q}_p^-=-\overline{Q}_p^+$ as a result of the orthogonality between the bonding and anti-bonding orbitals of the bond p.

We are now in a position to solve the secular equation 15 by taking the SCF BO as a basis. We will then be able to determine the first order SCF LCBO MO's and their eigenvalues. The method will be described in Section III in connection with the semi-empirical approach.

II. Second Order Theory.—In the first order treatment we neglected the interactions between bonding and anti-bonding orbitals. We will now proceed to a more accurate treatment in which these interactions are explicitly considered. Since they are usually small, they may be treated as perturbations. We may then take the above sets of the SCF LCBO MO's and their eigenvalues as a basis for developing the second order theory.

The overlap integrals between the bonding and anti-bonding orbitals may be neglected even in this higher approximation, as has been discussed above. By making use of first and second order perturbation theories, we easily obtain the following perturbed MO's ψ_i, their eigenvalues, ε_i, and also the molecular electronic energy, W_e:

$$\psi_i=\psi_i^+-\sum_k[\beta_{ik}^{+-}/(\varepsilon_k^- -\varepsilon_i^+)]\psi_k^- \quad (50)$$

$$\varepsilon_i=\varepsilon_i^+-\sum_k(\beta_{ik}^{+-})^2/(\varepsilon_k^- -\varepsilon_i^+) \quad (51)$$

$$W_e=W_e^\circ-\sum_{ik}(\beta_{ik}^{+-})^2/(\varepsilon_k^- -\varepsilon_i^+) \quad (52)$$

where β_{ik}^{+-} is the component of the Hamiltonian matrix that represents the interactions between occupied and unoccupied MO's in a first order theory. The occupied MO's and their eigenvalues in the ground state only are described here. The corresponding quantities for unoccupied MO's are obtained in a similar fashion.

Since all the BO's are represented as linear combinations of the AO's, the LCBO MO's may finally be reduced to the LCAO's. These LCAO MO's may then be considered to be good approximations of Roothaan's SCF LCAO MO's. The localized MO's obtained from these MO's by means of a unitary transformation are now not strictly localized in the specific bonds or lone pairs, whereas in the first order theory the orbitals have been the BO's themselves. Therefore, the second order theory includes a consideration of the delocalization of bond or lone pair electrons, which is generally taken to be small for σ-electron systems. In our theory the delocalization is described in terms of the electron transfer from bonding to antibonding orbitals on different bonds.

III. Semi-empirical Approach.—Le us now set out to solve Eq. 15, which is the secular equation in the first order theory. By making use of the results obtained in Section I, we can easily estimate the values of the diagonal elements, L_{pp}, of the SCF LCBO Hamiltonian matrix. Since within the present approximation the matrix $\boldsymbol{c}$ is unitary, the L_{pp}^{++} may be rewritten as:

$$\begin{aligned}L_{pp}^{++}&=H_p+\sum_q(2J_{pq}-K_{pq})\\&=-1/2(\chi_{A,p}+\chi_{B,p})+1/2J_{A,pB,p}\\&\quad+1/4\overline{Q}_p(J_{B,pB,p}+J_{A,pA,p})-1/2\sum_{\substack{T,q\\(q\neq p)}}\overline{Q}_q^T\cdot\\&\quad[(J_{A,pT,q}-1/2\delta_{A,pT,q}K_{A,pT,q})\\&\quad+(J_{B,pT,q}-1/2\delta_{B,pT,q}K_{B,pT,q})]\\&\quad+(F_p+M_p\overline{Q}_p^2)\gamma_p \quad (53)\end{aligned}$$

and, for lone pairs:

$$L_{ff}^{++}=-\chi_{ff}-\sum_{R,p}\overline{Q}_p^R(J_{fR,p}-1/2\delta_{fR,p}K_{fR,p}) \quad (54)$$

where:

$$\begin{aligned}\chi_{ff}&=-H_f-2\sum_g(J_{fg}-1/2\delta_{fg}K_{fg})\\&\quad-\sum_{R,p}(J_{fR,p}-1/2\delta_{fR,p}K_{fR,p}) \quad (55)\end{aligned}$$

$\chi_{A,p}$, etc. are defined by Eq. 29. The corresponding L_{pp}^{--} values for the anti-bonding orbital of the bond p are similarly derived. However, we do not obtain the values for the non-diagonal elements, $L_{pq}(p\neq q)$, in this way because these quantities are not considered in the treatment described in Section I. Non-empirical calculations of these quantities are usually very tedious, especially for the large organic molecules that we wish to consider. Furthermore, even if Eq. 15 were solved, we would find the same difficulty in estimating the β_{pq}^{+-}, which will appear in the calculation of β_{ik}^{+-} in the second order theory. There-

fore, we wish to propose the following semi-empirical method:

1) The values of $\alpha_{pp}(\equiv L_{pp}$ including $L_{pp}^{--})$, etc. are determined non-empirically from Eq. 53 or 54.

2) The values of $\beta_{pq}^{++}(\equiv L_{pq}^{++})$, etc. are taken as empirical parameters, and Eq. 15 is then solved.

3) The values of β_{pq}^{+-} are also taken as empirical parameters. These assumptions enable us to perform perturbation calculations.

4) The results of the calculations are used to estimate the values of β_{pq}^{++}, β_{pq}^{+-}, etc., from the observed ionization potentials, spectroscopic data, etc.

The present semi-empirical method for σ-electron systems is very similar to the method developed by Pariser and Parr[12] for π-electron systems, as may be seen from our procedure for determining the α and β values. Since it is a relatively simple method, we expect it to be applicable to calculations of many properties of complex molecules.

IV. Inductive and Resonance Effects.—The concepts of "*inductive effect*" and "*resonance effect*," both of which are related to electron migration, have proved to be useful in organic chemistry. The inductive effect was originally defined as a classical electrostatic effect.[12,13] Even though several theoretical studies[13-18] of the inductive effect have been reported, we feel that its theoretical foundation has not yet been properly established. Therefore, we will try to discuss it on the basis of our theory.

In general, the inductive parameters, Π_{pq}, which were defined by Eq. 38 will be especially large if p and q are two adjacent bonds. If the adjacent bonds, p and q, are chosen in such a way that the A, p and A, q are AO's of the same atom, A, the sign of Π_{pq} should be negative and, therefore, Q_p and Q_q should have opposite signs, because the second term in the brackets of Eq. 38 is then dominant and K_p is positive. The intra-bond charge transfer in bonds p and q should, therefore, follow the direction of the arrows in Fig. 1. When this theorem is applied to

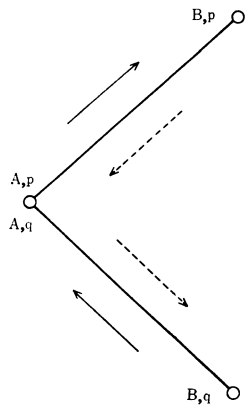

Fig. 1. Intra-bond charge transfers in the adjacent bonds p and q caused by the inductive effect.

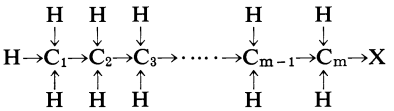

Fig. 2. Intra-bond charge transfers in the $C_mH_{2m+1}X$ molecule caused by the inductive effect.

the adjacent bonds of large molecules, for example, to the mono-substituted *n*-hydrocarbons, $C_mH_{2m+1}X$, the intra-bond electron transfers should follow the arrows in Fig. 2, since we take X to be more electronegative than the carbon. This conclusion agrees with that of the classical treatment[13] of the inductive effect. Equation 41 may thus be regarded as a quantum-mechanical representation of the inductive effect. The similarity between classical and quantum-mechanical results is confirmed by an inspection of the brackets of Eq. 38, which correspond to Coulomb interactions between the (A, p), (B, p), (A, q) and (B, q) if we take the (A, p) and (B, q) to be positive point charges and the (A, q) and (B, p) to be negative point charges or vice versa. It has thus been shown that the procedure for determining the bond polarity in the first order theory corresponds to a consideration of the inductive effect. Hereafter we will use the term "*inductive effect*" in this sense. The application of the inductive effect will be described in the second paper of this series.

The significance of the resonance effect for conjugated systems is well established; it is accompanied by a stabilization energy of the molecule which has been called "*resonance energy*" or "*conjugation energy*." On the other hand, for σ-electron systems, this effect is generally taken to be small. In our theory

it has been defined as the delocalization of σ-bond electrons in the second order theory. The resonance energy of molecules is then represented by the second term of Eq. 52. We will use the term "*resonance effect*" in the above sense.

We have thus defined the two effects separately on the basis of reasonable approximations; previous theories did not even distinguish between the two effects. The differences will become more obvious in the following considerations. In the first order theory, the electron density in each BO is equal to two, and the bond order[19] between different BO's is zero in our approximation. The inductive effect may then be defined as an intra-bond charge transfer; even then the electron density in each bond or lone pair is still two and the inter-bond orders are zero. On the other hand, the resonance effect corresponds to an inter-bond charge transfer from bonding to anti-bonding orbitals on different bonds.

Discussion

The present semi-empirical MO theory may not be as rigorous as the non-empirical SCF LCAO MO method but at least it makes it possible to deal satisfactorily with large molecules. Essentially based on the Hartree-Fock method, it is obtained by introducing some additional assumptions and approximations. However, it is impossible to avoid the deficiencies inherent in all one-electron methods; this causes the K_p to predict equal probabilities for the two possible ionic structures, A^+B^- and A^-B^+. This defect may be removed by considering the correlation between the paired electrons with opposite spins. This correlation problem has already been discussed by several authors.[20-25]

It may be valuable to compare our approach with previous theoretical work on the subject. Lennard-Jones[13] and his collaborators[26-28] have shown that the usual delocalized MO for saturated molecules may be replaced by a set of equivalent orbitals. However, their determination requires a knowledge of molecular symmetry. Recently Edmiston and Ruedenberg[2] proposed a method for determining more general localized MO's that do not follow from the molecular symmetry. The authors suggest that in a more precise theory each MO may be represented as a linear combination of the above localized orbitals. Although the localized orbitals are sometimes hard to determine, especially for large organic molecules, it is possible to overcome this difficulty by replacing the orbitals by the ordinary bond orbitals; this was done in the LCBO MO theory of Brown.[29] In this treatment the MO's are represented as linear combinations of bonding orbitals only, and the contributions of the anti-bonding orbitals are neglected. It was subsequently pointed out by Dewar and Pettit[30] that the contributions from the anti-bonding orbitals to the molecular energy, though small, are not negligible and that they ought to be taken into account. This delocalization effect of σ-electrons was also accounted for by Mulliken et al.[31] in terms of hyperconjugation.

The practical advantage of our theory is that it is closely connected with familiar chemical concepts such as inductive effect and electronegativity. This makes it possible to explain some previously proposed empirical rules. The details will be described in subsequent papers.

It is worth noting that the definitions of the absolute scale of electronegativity are independent of the different approaches. Our definition agrees with those obtained by Parks and Parr[20] or Oohata,[23] who used different approaches in which the correlation is taken into account; that is, all the results lead to the Moffitt scale.[9] This seems to support the validity of the absolute electronegativity scale. A detailed discussion of the electronegativity will be presented in a subsequent paper.

Summary

A semi-empirical MO theory is proposed for complex saturated molecules. In a first-order treatment, each MO is represented as a localized function that contains only the AO connected with one bond or atom. This enables us to define a set of bonding, anti-bonding and lone-pair orbitals. The molecular wave function is obtained as an anti-symmetrized product of the bonding and lone-pair orbitals.

19) The bond orders between BO are defined in the same way as for AO, the term "*inter-bond bond order*" is sometimes used in this paper.

In this approximate theory we discuss the definitions of the electronegativity scale and of the inductive effect; the electronegativity scales proposed by Moffitt and Mulliken are obtained as special cases. In a subsequent, more accurate second-order theory each MO is represented as a linear combination of all bonding, anti-bonding and lone-pair orbitals; this treatment is made by means of the perturbation theory. A semi-empirical approach is developed by taking the interactions between different bonds as empirical parameters. No applications of the general theory are presented here; they will be discussed in subsequent papers.

The author wishes to thank Dr. H. F. Hameka for his stimulating interest and encouragement and Professor R. G. Parr for his reading of the manuscript.

A Semi-empirical MO Theory of σ Electron Systems. II. Bond Polarity and Electronegativity*

By Hidekazu HAMANO**

(Received March 10, 1964)

In a previous paper,[1] we outlined a first and second order semi-empirical MO theory for σ electron systems. In the first order theory each σ bond is represented by a bonding orbital, and the wave function of a saturated molecule is obtained as an anti-symmetrized product of doubly-occupied bonding or lone-pair orbitals. We then discussed the polarity of the bond orbitals by introducing the bond polarity parameters, Q_p. It was shown that the bond polarity parameter is determined not only by the electronegativity difference but also by the inductive effect. This enables us to make theoretical predictions of experimental properties on the basis of bond polarity parameters. Many experimental quantities, such as dipole moments, nuclear quadrupole coupling constants,[2,3] and fluorine chemical shifts,[4,5] may be approximately calculated from the bond polarity parameters. In this paper we wish to apply our previous first order theory to a calculation of these properties for several organic molecules.

It has been shown that our definition of electronegativity includes the Moffitt[6] or Mulliken[7] scales as special cases. In addition, several other methods[3,8-11] have been proposed for obtaining the electronegativity constants from either experimental or theoretical atomic quantities. However the important question, why such a crude model based on atomic electronegativity constants can so successfully describe bond properties, has never been properly investigated theoretically. In this paper, we will attempt to answer this question by means of our first order theory. In connection with this problem, we will also investigate how the electronegativity scale of Pauling,[8] which was obtained empirically, fits into our theory.

I. The Electronegativity Scale and the Ionic Character of Bonds. — In this section we wish to discuss the connection between the various electronegativity scales and the ionic character of the bonds. We will take Eq. 39 of reference 1, $Q_p = Q_p^\circ + Q_p'$, as a starting point for this discussion. The Q_p° and Q_p' are the specific and induced bond polarities respectively

defined by Eqs. 40 and 41 of Ref 1. If we considered the bond polarities on the basis only of the atomic electronegativity differences, we could construct a crude model in which bond polarity is regarded as specific for the bond, independent of the surroundings. Fortunately, the contribution of the induced polarity, Q'_p, based on the inductive effect to total bond polarity, Q_p, will not change our conclusions significantly.[12] It has already been recognized empirically that such a seemingly crude approximation may lead to useful conclusions. Therefore, only each specific bond is discussed here; the inclusion of the inductive effect will be presented in the following section. In addition, since we will consider atomic electronegativities only, we may neglect the homopolar inductive effect,[1] which is generally small. We thus obtain the following simple relation:

$$Q_p = K_p(\chi^\circ_{B,p} - \chi^\circ_{A,p}) \qquad (1)$$

where $\chi^\circ_{B,p}$ and $\chi^\circ_{A,p}$ are defined as the Moffitt scale[6] of the electronegativity of atoms B and A respectively.

Let us now consider the bond polarity on the basis of of the atomic properties. Moffitt[6,13,14] has shown that this is roughly equivalent with the situation where the two atoms, A and B, are an infinite distance apart, but still in the same valence states as they would be at their equilibrium distance. If we adopt the approximation[15], $-\varepsilon^\circ_{A,pA,p} \sim I_{A,p}$, $J^\circ_{A,pA,p} \sim I_{A,p} - E_{A,p}$, etc., where the I and E are the corresponding ionization potential and electron affinity respectively, the Moffitt scale[6] of the electronegativity may then be reduced to the Mulliken scale[7] and the Q_p at the infinite distance may be written as:

$$Q^\infty_p = K^\infty_p(\chi^\circ_{B,p} - \chi^\circ_{A,p}) = K^\infty_p\,[1/2(I_{B,p} + E_{B,p}) - 1/2(I_{A,p} + E_{A,p})] \qquad (2)$$

where

$$K^\infty_p = 2\,[(I_{B,p} - E_{A,p}) + (I_{A,p} - E_{B,p})]^{-1} \qquad (3)$$

The Q^∞_p and K^∞_p refer to infinite internuclear separation. The values of Q^∞_p, K^∞_p and $|\chi^\circ_{B,p} - \chi^\circ_{A,p}|$ for various bonds are tabulated in Table I, and the relation between Q^∞_p and $|\chi^\circ_{B,p} - \chi^\circ_{A,p}|$ is illustrated in Fig. 1. The values of I and E used are taken from the tables of Pritchard and Skinner.[9] Equation 2 is similar to the definition of ionicity proposed by Wilmshurst[16] or by Hinze et al.[17] The curve in Fig. 1 is similar to the results obtained by

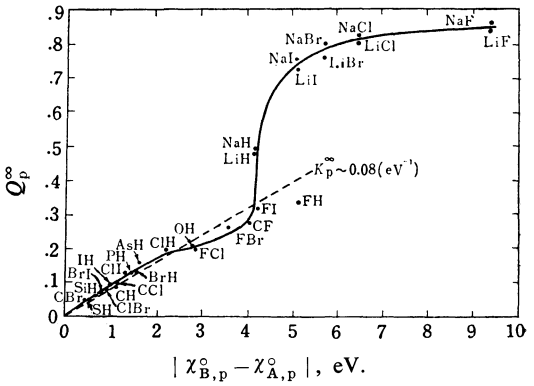

Fig. 1. Relalion between Q^∞_p and $|\chi^\circ_{B,p} - \chi^\circ_{A,p}|$.

Pauling[8] or by Dailey and Townes[18] except for the FH bond.

It may be seen from Table I and Fig. 1 that, for $|\chi^{\circ}_{B,p}-\chi^{\circ}_{A,p}|<4$ eV. or for $Q^{\infty}_{p}<0.3$, the K^{∞}_{p} are nearly constant. In this range, therefore, the Q^{∞}_{p} may be regarded as proportional to the electronegativity differences. The dotted line in Fig. 1 ($K^{\infty}_{p}\sim 0.08\,eV^{-1}$) seems to confirm this inference. We may say, therefore, that for all covalent bonds $K_{p}\sim 0.08\,eV^{-1}$. The fact that the point for the FH bond in Fig. 1 lies very closely to the dotted line seems to indicate that this bond is also essentially covalent. On the other hand, the bonds involving the alkali metals have to be regarded as strongly polar bonds. It follows from Table I that these great polarities are due not only to the large electronegativity difference but also to the large values of K_{p} which result from the small values of the ionization potentials and the electron affinities of the alkali metals. In general, however, the K_{p} seem to be insensitive to electronegativity differences. The reasons for this will now be discussed.

At first sight, it appears from Eq. 3 that the values of K_{p} depend on electronegativity differences. The K_{p} values, however, depend on the average sum of the energies of the ion pairs $A^{-}B^{+}$ and $A^{+}B^{-}$, and the electronegativity differences, on the difference between them. An inspection of the periodic table will reveal that most polar bonds are formed between metallic elements which have small electronegativities and non-metallic elements which have large electronegativities. Consequently, the average value of the energies of the ion pairs $A^{-}B^{+}$ and $A^{+}B^{-}$ is practically independent of the variations in electronegativity between the different metallic elements or between the non-metallic elements. We believe that the general validity and usefulness of the concept of electronegativity may be explained by the above considerations, and also by the fact that the homopolar inductive effect is usually small,[1] so that the differences in electronegativity depend on atomic quantities only.

We will now proceed to discuss the relation between our electronegativity scale and Pauling's scale.[8] Pauling's electronegativity scale has been defined as:

$$|X_{B}-X_{A}|=\sqrt{\Delta} \qquad (4)$$

where Δ is the "*ionic-covalent resonance energy*" in terms of eV. On the other hand, anticipating some results of the following paper,[19] we plan to show that, for bonds with small polarities, the ionic-covalent resonance energy, Δ_{p}, in our theory is given by:

$$\Delta_{p}=1/2K_{p}|\chi^{\circ}_{B,p}-\chi^{\circ}_{A,p}|^{2} \qquad (5)$$

If the two quantities, Δ and Δ_{p}, are equivalent, we obtain:

$$|X_{B}-X_{A}|=(1/2K_{p})^{1/2}|\chi^{\circ}_{B,p}-\chi^{\circ}_{A,p}| \qquad (6)$$

This leads to the following relation:

$$X_{P}=(1/2K_{p})^{1/2}\chi^{\circ}_{M} \qquad (7)$$

where X_{P} and χ°_{M} stand for Pauling[8] and Mulliken[7] scales of electronegativity in terms of eV. We then have

$$X_{P}/\chi^{\circ}_{M}=(1/2K_{p})^{-1/2}\sim 0.22\,(eV^{-1/2}) \qquad (8)$$

where the value $K_{p}\sim 0.08\,eV^{-1}$ has been substituted. This value is empirically known to be 0.32 or 0.36 ($eV^{-1/2}$).[9] The discrepancy between these values may partially be due to our definitions and approximations, especially to the crude evaluation of K_{p}. This difficulty has been discussed by Mulliken.[20] We will also try to explain it.

Differences in electronegativity are important, not the values themselves; we may thus add an arbitrary constant value to all electronegativities. Pauling's scale[21] has been arbitrarily determined by adjusting it to Eq. 4 under the arithmetic mean assumption, which may often be replaced by the geometrical mean.[22,23] On the other hand, the Mulliken scale may be regarded as an absolute scale of electronegativity. Consequently, the Pauling scale may not be adequately given by Eq. 7. The ionic-covalent resonance energy, Δ_{p}, in our theory may be defined adequately only for small bond polarities.[19] Therefore, it is not surprising that the value evaluated from Eq. 8 does not agree with the empirical value.

II. Some Applications of the Inductive Effect. —We will now proceed to discuss the case of polyatomic molecules by starting from the complete first order theory. Since this includes a consideration of the inductive effect, we may call it "*an application of the inductive effect.*" In this section, we wish to apply the inductive effect to two types of molecules, namely, MX_{n} and *n*-alkyl halide molecules (n-$C_{m}H_{2m+1}X$). We will take Eq. 47 of Ref. 1 as the basic equation for the discussion of this section:

18) B. P. Dailey and C. H. Townes, *J. Chem. Phys.*, **23**, 118 (1955).

19) Part III of this series, This Bulletin, **37**, 1592 (1964).
20) R. S. Mulliken, ibid., **3**, 573 (1935).
21) Pauling arbitrarily adopted $X_{H}=2.1$ and $X_{F}=4.0$.
22) T. L. Cottrell and L. E. Sutton, *Proc. Roy. Soc.*, **A207**, 49 (1951).
23) A. C. Hurley, ibid., **A218**, 333 (1953).

$$\overline{Q}_p = \sum_q \overline{\Pi}_{pq} Q_p^\circ \qquad (9)$$

where $\overline{Q}_p$ is the SCF bond polarity of the bond p and the $\overline{\Pi}_{pq}$ values are the SCF polarizabilities which are defined by Eq. 46 of Ref. 1.

A) MX_n-type Molecules.—Let us consider a molecule with n equivalent bonds MX. From Eq. 9, we obtain for the bond MX;

$$\overline{Q}_{MX} = Q_{MX}^\circ / [1-(n-1)\overline{\Pi}_{(MX,p)(MX,q)}] \qquad (10)$$
$$(p \neq q)$$

Since $\overline{\Pi}_{(MX,p)(MX,q)}$ is taken as negative here, it may be concluded that the bond polarities of the MX bonds in the MX_n-type molecules generally decrease with an increase in the number of MX bonds. We are led to believe, therefore, that the small CH bond polarity of methane is due not only to the original small polarity of the CH bond itself, but also to the inductive effect. This conclusion may also be extended to the CH_3 and CH_2 radicals of saturated hydrocarbons. Consequently, it follows that the CH bonds in saturated hydrocarbons may be almost homopolar, which is in agreement with the general opinion and all available experimental information. Another example we wish to consider is the series of the halomethanes, CH_3X, CH_2X_2, CHX_3 and CX_4 (X= halogen). It has been empirically shown that, in the above order, the dipole moments decrease, the magnitudes of halogen nuclear quadrupole coupling constants $|eQq_X|$ increase (as Table II shows), and the fluorine chemical shifts, δ_F,[24] increase as −21.00, −8.09, −1.82 and 0. By making use of the above conclusion together with the gradual decreasing s characters of the halogen bonding orbitals in the above order, which will be shown in the next subsection, apart from the induced polarity of the CH bonds,[25,26] the dipole moments may be explained by the decreasing CX bond moments,[27] and the eQq_X and δ_F values, by means of the Townes-Dailey[2] and Saika-Slichter[4,28] formulas respectively. These formulas are shown in Appendices A and B respectively.

The chlorine nuclear quadrupole coupling constants of some chloro-compounds which are listed in Table III may also be interpreted on this basis. The present conclusion agrees with previous findings.[29,30]

TABLE II. MOLECULAR DIPOLE MOMENTS μ AND HALOGEN NUCLEAR QUADRUPOLE COUPLING CONSTANTS $|eQq_X|$ OF HALOMETHANES

Molecule	μ, D[a]	$\lvert eQq_X\rvert$, Mc.[a,b]

garded as typical examples of the inductive effect. The numbers of each bond are defined as shown in Fig. 2: For the CX and CH bonds, the AO of the carbon atoms are taken as valence AO A_{CX} and A_{CH}, and those of the halogen and hydrogen atoms, as valence AO B_{CX} and B_{CH} respectively; for the CC bonds, the AO of the carbon atoms closer to the CX bond are taken as A_{CC}. For the sake of simplicity, the following assumptions are made:

1) It is assumed that $Q_2^\circ = Q_3^\circ = Q_4^\circ = \cdots\cdots = Q_n^\circ = 0$, which means that we take all bonds originally homopolar except for the CX bond.

2) Only the values of Π_{pq} between adjacent bonds are considered; the others are taken to be zero.

From Eq. 9 we then obtain:

$$ {}^m\overline{Q}_j = {}^m\overline{\Pi}_{j1} Q_1^\circ, \quad (j = 1, 2, 3, \cdots\cdots, n) \tag{11} $$

where the superscript m indicates the number of carbon atoms in each molecule, and ${}^m\overline{\Pi}_{j1}$ is given by:

$$ {}^m\overline{\Pi}_{j1} = (-1)^{j+1}\, {}^m\Delta_n^{j1} / {}^m\Delta_n \tag{12} $$

where ${}^m\Delta_n$ is the determinant of n rows and columns given by:

${}^m\Delta_n =$

$$

we consider that the first derivatives $d^m\overline{\Pi}_{11}/dm=(\partial^m\overline{\Pi}_{11}/\partial\rho_{m-1})(d\rho_{m-1}/dm)$, etc. Since $\Pi\ll1$,[31] we may limit ourselves to a consideration of the terms quadratic in Π. We then obtain :[32]

$$\partial^m\overline{\Pi}_{11}/\partial\rho_{m-1}\sim(-\Pi_{XC}\Pi_{CX})(e\rho_{m-1}+f)^{-2}<0 \quad (18)$$

$$\partial^m\overline{\Pi}_{21}/\partial\rho_{m-1}\sim(-\Pi_{CX}\Pi_{HC})(e\rho_{m-1}+f)^{-2}<0 \quad (19)$$

$$\partial^m\overline{\Pi}_{41}/\partial\rho_{m-1}\sim(\Pi_{CX})(e\rho_{m-1}+f)^{-2}>0 \quad (20)$$

Next let us examine the properties of the series ρ_m. From Eq. 17 we obtain the recurrent formula

$$d\rho_{m-1}/dm=(ad-bc)(c\rho_{m-2}+d)^{-2}d\rho_{m-2}/dm \quad (21)$$

We know, by considering Eq. 21 and the numerical values[31] of Π_{CC}, Π_{CH} and Π_{HC}, that the ρ_m and $(d\rho_{m-1}/dm)$ are monotonously decreasing and increasing functions of m respectively and that $\lim_{m\to\infty}(d\rho_{m-1}/dm)=0$. From the above results, we obtain the following:

$$d^m\overline{\Pi}_{11}/dm>0, \qquad d^m\overline{\Pi}_{21}/dm>0$$
$$d^m\overline{\Pi}_{41}/dm<0 \quad (22)$$

$$d^{2m}\overline{\Pi}_{11}/dm^2<0, \qquad d^{2m}\overline{\Pi}_{21}/dm^2<0$$
$$d^{2m}\overline{\Pi}_{41}/dm^2>0 \quad (23)$$

$$\lim_{m\to\infty}(d^m\overline{\Pi}_{11}/dm)=\lim_{m\to\infty}(d^m\overline{\Pi}_{21}/dm)$$
$$=\lim_{m\to\infty}(d^m\overline{\Pi}_{41}/dm)=0 \quad (24)$$

Since the signs of ${}^m\overline{Q}_1$, ${}^m\overline{Q}_2={}^m\overline{Q}_3$ and ${}^m\overline{Q}_4$ are positive, negative and negative respectively, it may be concluded that the polarity of the CX bonds increases with an increase in the number of carbon atoms and that the induced polarities of the CC and CH bonds increase and decrease with an increase in the number of carbon atoms respectively. If the number of carbon atoms becomes very large, all these quantities reach a saturation value asymptotically. It follows from Eqs. 18—20 that, in the present approximation, the ratios of the variations of the CX, CH and CC bond polarities are given by:

$$|d^m\overline{Q}_1/dm|:|d^m\overline{Q}_2/dm|:|d^m\overline{Q}_4/dm|$$
$$=\Pi_{XC}:\Pi_{HC}:1 \quad (25)$$

Equation 25 indicates that the variation in the induced polarity of the CC bond is most significant of all. Our conclusions may also be extended to the more distant CC and CH bonds, but they are not valid for the case of CH_3X molecules.

For CH_3X molecules, we have:

$${}^1\overline{\Pi}_{11}=[1-(3\Pi_{XH}\Pi_{HX})(1+2\Pi_{HH})^{-1}]^{-1} \quad (26)$$

$${}^1\overline{\Pi}_{21}=(-\Pi_{HX})(1+2\Pi_{HH}-3\Pi_{XH}\Pi_{HX})^{-1} \quad (27)$$

We will now attempt to compare the ${}^1\overline{\Pi}_{11}$ for CH_3X with the ${}^2\overline{\Pi}_{11}$ for C_2H_5X. The ${}^2\overline{\Pi}_{11}$ may be approximated by

$${}^2\overline{\Pi}_{11}\sim[1-(2\Pi_{XH}\Pi_{HX}+\Pi_{XC}\Pi_{CX})$$
$$\times(1+\Pi_{HH}-5\Pi_{CH}\Pi_{HC})^{-1}]^{-1} \quad (28)$$

By comparing the second terms of Eqs. 26 and 28, it may be concluded that ${}^2\overline{\Pi}_{11}>{}^1\overline{\Pi}_{11}$. Therefore, the previous argument is valid for all molecules of the series $C_mH_{2m+1}X$ except for the ${}^1\overline{\Pi}_{21}$.

So far we have disregarded changes in the valence states of the stoms, especially for the halogenes. In principle, a variation in the bond polarity is accompanied by a change in the hybridization of the corresponding AO. However, a complete calculation would be difficult, so we will discuss the problem qualitatively on the following assumptions:

1) All the valence AO of carbon atoms are assumed to be the usual sp^3 hybrids; only the hybridization of the valence AO of the halogens will be considered explicitly.

2) The s character in the halogen bonding orbitals is assumed to be small. The empirical data[2,3,18] on the nuclear quadrupole coupling constants of the halogens support this assumption.

3) The interaction between the halogen atom and the non-adjacent alkyl group may be accounted for by means of the CX bond polarity, $\overline{Q}_1$, only.

If the valence AO of the halogens are represented by Eqs. A-4 and A-5 in Appendix A, the electronic energy, W_e°, of these molecules may be written as:

$$W_e^\circ=a^2\Delta W(1-\overline{Q}_1)-\overline{Q}_1E_X+W_X(a=0)$$
$$+1/4(1-\overline{Q}_1)^2(J_{CC}+J_{X(b\sigma)X(b\sigma)})$$
$$+(1-\overline{Q}_1)H_C+2F_1\gamma_1+1/2(1-\overline{Q}_1^2)J_{CX(b\sigma)}$$
$$+4(1-\overline{Q}_1)J_{C\Pi}+(1+\overline{Q}_1)H'_{X(b\sigma)}$$
$$+4H'_\Pi+2H'_{X(b\sigma)}+R_r \quad (29)$$

where

$$W_X(a=0)=2I(s)+5I(p)+F^\circ(ss)+10F^\circ(pp)$$
$$-10/25F^2(pp)+10F^\circ(sp)-5/3G^1(sp) \quad (30)$$

31) The values calculated from simple Slater AO are $\Pi_{CC}=0.16$, $\Pi_{CH}=0.10$, $\Pi_{HC}=0.12$ and $\Pi_{HH}=0.08$, respectively so that this approximation seems to be reasonable.

32) In Eq. 20, we have also neglected the small term $2(\Pi_{CX}\Pi_{HH}-\Pi_{HX}\Pi_{CH})$.

$$\Delta W = I(\mathrm{p}) - I(\mathrm{s}) - F^{\circ}(\mathrm{ss}) - 4F^{\circ}(\mathrm{sp}) + 2/3G^{1}(\mathrm{sp}) + 5F^{\circ}(\mathrm{pp}) - 10/25F^{2}(\mathrm{pp}) \quad (31)$$

$$E_{\mathrm{X}} = -I(\mathrm{p}) - 2F^{\circ}(\mathrm{sp}) + 1/3G^{1}(\mathrm{sp}) - 5F^{\circ}(\mathrm{pp}) + 10/25F^{2}(\mathrm{pp}) \quad (32)$$

and where the subscripts 1, C and Π stand for the CX bond, the carbon AO associated with it, and the halogen Π orbitals respectively. The a^2 values describe the amount of s character in the halogen bonding orbitals. R_{r} is the energy of the alkyl group (except for the CX bond), including the interaction energy with the CX bond. $W_{\mathrm{X}}(a=0)$, ΔW and E_{X} are the valence state energy of the halogens for the configuration $(ns)^2(np\sigma)(np\Pi)^4V_1$, its promotion energy to the $(ns)(np\sigma)^2(np\Pi)^4 \cdot V_1$, and the electron affinity of halogens for the p orbital respectively. I, F and G are Slater parameters,[33] where s and p stand for the ns and np orbitals of the halogen respectively. The variational procedure for Eq. 29, neglecting small terms, yields:

$$\begin{aligned} a \sim & [(1+S_1)^{-2}S_{\mathrm{Cs}}\gamma_1 - F_1\{H_{\mathrm{Cs}} - 1/2S_{\mathrm{Cs}}(H_{\mathrm{X(b}\sigma)} + H_{\mathrm{C}})\}] - 1/2(1-\overline{Q}_1^2)(\mathrm{CC}\,|\,\mathrm{sp}) + (1-\overline{Q}_1 \\ & + F_1S_1)(\mathrm{C}:\mathrm{sp})/[[\Delta W(1-\overline{Q}_1) \\ & + 1/2(1-\overline{Q}_1)^2\{-F^{\circ}(\mathrm{pp}) - 4/25F^{2}(\mathrm{pp}) \\ & + F^{\circ}(\mathrm{sp}) + 2/3G^{1}(\mathrm{sp})\} + [(1+S_1)^{-2}S_{\mathrm{Cp}}\gamma_1 \\ & - F_1\{H_{\mathrm{Cp}} - 1/2S_{\mathrm{Cp}}(H_{\mathrm{X(b}\sigma)} + H_{\mathrm{C}})\}] \\ & - F_1S_1\{I(\mathrm{s}) - I(\mathrm{p})\}]] \end{aligned} \quad (33)$$

where

$$S_{\mathrm{Cs}} = \langle \mathrm{C}\,|\,\mathrm{s}\rangle, \qquad S_{\mathrm{Cp}} = \langle \mathrm{C}\,|\,\mathrm{p}\rangle$$

$$(\mathrm{CC}\,|\,\mathrm{sp}) = \langle \mathrm{C(1)s(2)}\,|\,r_{12}^{-1}\,|\,\mathrm{C(1)p(2)}\rangle$$

$$(\mathrm{C};\ \mathrm{sp}) = \langle \mathrm{s}\,|\,-1/r_{\mathrm{C}}\,|\,\mathrm{p}\rangle$$

The first terms of the numerator and denominator are both positive and greater than the following terms. From Eq. 33, neglecting small terms, we have

$$da^2/d\overline{Q}_1 \sim 2a^2/(1-\overline{Q}_1) \quad (34)$$

This shows that the variation of a^2 is less than that of $\overline{Q}_1$ and the corresponding derivative is positive.

Now we will consider the same relation from a different point of view. Clearly we hope that the results thus obtained agrees with Eq. 34. The variation in the electronegativity, $\chi_{\mathrm{X}}^{\circ}$, of the halogen as a function of a^2 is given by:

$$d\chi_{\mathrm{X}}^{\circ}/da^2 = \Delta W + Y \quad (35)$$

where

$$\begin{aligned} Y = & F^{\circ}(\mathrm{sp}) + 2/3G^{1}(\mathrm{sp}) - F^{\circ}(\mathrm{pp}) - 4/25F^{2}(\mathrm{pp}) \\ & + a^2[F^{\circ}(\mathrm{ss}) + F^{\circ}(\mathrm{pp}) + 4/25F^{2}(\mathrm{pp}) \\ & - 2F^{\circ}(\mathrm{sp}) - 4/3G^{1}(\mathrm{sp})] \end{aligned}$$

Since, for $a^2 \ll 1$, the Y value will generally be positive, Eq. 35 shows that $\chi_{\mathrm{X}}^{\circ}$ increases with an increase in the amount of s character. The ${}^{\mathrm{m}}\Pi_{11}$ are insensitive to variations in a^2 and are closed to unity, as may be seen from the definition. We have then

$$d\overline{Q}_1/da^2 \sim (dK_{\mathrm{CX}}/da^2)(\chi_{\mathrm{X}}^{\circ} - \chi_{\mathrm{C}}^{\circ}) + K_{\mathrm{CX}}(d\chi_{\mathrm{X}}^{\circ}/da^2) \quad (36)$$

where

$$dK_{\mathrm{CX}}/da^2 = K_{\mathrm{CX}}{}^2[-Y + d(J_{\mathrm{CX(b}\sigma)} + 2\gamma_1)/da^2] \sim -0.01Y(\mathrm{eV}^{-1}) \quad (37)$$

The second term of Eq. 37, which is connected with the strength of the bond, is much smaller than the first term, so it may be neglected and the approximate value, $K_{\mathrm{CX}} \sim 0.1$ $(\mathrm{eV}.^{-1})$, substituted. The substitution of Eqs. 35 and 37 into Eq. 36 yields

$$d\overline{Q}_1/da^2 \sim 0.1\Delta W + (0.06 \sim 0.1)Y \quad (38)$$

where the fact that $|\chi_{\mathrm{X}}^{\circ} - \chi_{\mathrm{C}}^{\circ}|$ is 4 eV. or less for all the halogens is used. Experimental data on ΔW are, unfortunately, not available, but the estimated values of Pritchard and Skinner[9] are F: 21 eV.; Cl: ~11 eV.; Br: ~11 eV.; I: ~8 eV. The exact values of Y are not known, but they are probably compatible with or less than ΔW. It follows, therefore, that the derivative of $\overline{Q}_1$ with respect to a^2 is always larger than unity. This agrees qualitatively with Eq. 34.

It may be concluded that both the polarity of the CX bond and the amount of s character in the bonding orbital of the halogen increase with an increase in the number of carbon atoms, but that the first effect is more important than the second. (For the CI bond, however, they are probably equally important.) The previous conclusion should, therefore, be modified as follows: The increasing polarities in the CX bonds are caused not only by the increasing polarizability, ${}^{\mathrm{m}}\overline{\Pi}_{11}$, but also by the increasing electronegativity, $\chi_{\mathrm{X}}^{\circ}$, in connection with the increasing amount of s character. Both the amount of s character and the polarities of the CX bonds reach saturation values if the carbon atoms become very numerous.

These conclusions may be extended to similar halogen compounds, for example, the halomethanes, because the behavior of molecules is accounted for only by the CX bond polarity here. This has already been shown in Subsection II-A).

It has been shown that the dipole moments of alkyl halides increase with an increase in the number of carbon atoms and that they also tend to a saturation value,[35] as Table IV shows. This fact may be interpreted as follows: Both the induced dipole moments of the CC bonds and the moments of the CX bonds increase with an increase in the number of carbon atoms, while the lone pair moment of the halogens behaves similarly. The CH bond moments decrease, and they oppose the increase in molecular dipole moments, but this effect is small.[25] The saturation of the dipole moment may be explained by the saturation of all the quantities involved.

Information on the CX bonds may also be obtained from a consideration of the molecular quadrupole coupling constants, eQq_X of the halogens. They show an oscillating decrease with an increase in the number of carbon atoms, as is listed in Table V. This behavior is caused by crystal fields; it may be explained by considering the different unit cells[35] for compounds with even and odd numbers of carbon atoms. The saturation effect may be obscured, especially by this influence. In this connection, it may be of interest to observe that the boiling points[36] of these molecules or paraffins increase monotonously with an increase in the carbon numbers, whereas the melting points[36] increase in an oscillatory fashion. We may expect, therefore, the eQq_X values for free molecules to decrease monotonously. This inference seems to be confirmed if they are interpreted by the Townes-Dailey formula in Appendix A.

Discussion

We have shown that the first order theory, which contains the electronegativity and the inductive effect, is particularly valuable for a discussion of the bond polarity; it makes it possible to give a qualitative interpretation of the experimental dipole moments, nuclear quadrupole coupling constants, etc. It may then be noticed that the SCF procedure is indispensable to the interpretation of the above experimental data. The physical meaning of the SCF procedure may be explained in connection with the inductive effect as follows: The polarities induced in the other bonds by a certain polar bond may also polarize the

35) A. Mueller, *Proc. Roy. Soc.*, **A120**, 437 (1928).

36) N. A. Lange, "Handbook of Chemistry," Handbook Publ. Inc., Ohio (1956).

original bond.[37] We can then determine the accurate charge distribution in the molecule by considering all the correlations among the intra-molecular bonds. This corresponds to the exact solution of the many-body problem on the assembly of charged particles; it corresponds to our SCF procedure also. In fact, the correspondence between the quantum-mechanical and classical inductive effects has been pointed out. A close inspection of the examples shown in Section II will confirm the above explanation. Furthermore, the theory may be extended even to infinite polymers, as has been shown in Subsection II-B). This suggests that the present theory may be applicable to very large molecules. Although in the present treatment, the second order theory has been omitted, it ought to be taken into account in the quantitative discussion; the delocalization of the lone pair electrons on the halogen atoms—they attribute to the highest occupied orbitals in saturated molecules—may be especially important.

In Section I, the validity of the electronegativity scale has been discussed on the assumption that the polarity of bonds may be inferred from the valence state of the atoms in the infinite separation. This seems to confirm the idea of "*atoms in molecules*" developed by Moffitt.[13,14] It is not true for the inductive effect; however, the valence state of atoms is important even then.

Summary

A previously proposed theory is applied to a study of the electronegativity scale and the ionic character of bonds. The general validity of the electronegativity scale and also the relation between the Mulliken and Pauling scales are discussed. The previously defined inductive effect is used as a basis for calculations on MX_n-type molecules and on *n*-alkyl halide molecule. The results are then used for the qualitative interpretation of the experimental dipole moments, nuclear quadrupole coupling constants and fluorine chemical shifts.

The author wishes to thank Dr. H. F. Hameka for his stimulating interest and encouragement, and Professor R. G. Parr for reading the manuscript.

Appendix A. The Derivation of the Townes-Dailey Formula.—The electronic contributions to the nuclear quadrupole coupling constants, eQq, for axially symmetric molecules are represented by:

$$eQq=eQ\langle\Phi^{o}|r^{-3}(3\cos^2\theta-1)|\Phi^{o}\rangle \qquad \text{(A-1)}$$

where e and Q are the electronic charge and the nuclear quadrupole moment of the coupled atom respectively; Φ^{o} is the molecular wave function which is given by Eq. 16 of Ref. 1. The contribution of the inner-shell electrons of the coupled atom may be neglected.[2,3,18] Because of the rapid decrease of the function r^{-3}, we will consider only the contribution of the coupled atom. In this approximation, we obtain

$$eQq=2eQ\sum_{p}\langle\varphi_p|r^{-3}(3\cos^2\theta-1)|\varphi_p\rangle \qquad \text{(A-2)}$$

where φ_p refers to the bonds connected with the coupled atom or its lone pairs.

Now let us consider the case of a halogen atom. For the MX bond (X=halogen), we have

$$\varphi_{MX}=c_M M+c_X X(b\sigma) \qquad \text{(A-3)}$$

where

$$X(b\sigma)=a(ns)+(1-a^2)^{1/2}(np\sigma) \qquad \text{(A-4)}$$

$$X(l\sigma)=(1-a^2)^{1/2}(ns)-a(np\sigma) \qquad \text{(A-5)}$$

The M refers to the AO of the atom M, and $X(b\sigma)$ and $X(l\sigma)$ are the bonding and lone pair orbitals respectively of the halogen with σ symmetry, together with the lone pair orbitals, $n\Pi$ and $n\overline{\Pi}$, with Π symmetry. The parameter a is the hybridization factor, and n can take the values 3, 4 and 5 for Cl, Br and I. The substitution of Eqs. A-3, A-4 and A-5 into Eq. A-2 yields:

$$eQq_X=(1-a^2)(-1+Q_{MX}-F_{MX}S_{MX})eQq_{np\sigma} \qquad \text{(A-6)}$$

If we neglect the overlap S_{MX}, we have the following simple formula:

$$eQq_X=-(1-a^2)(1-Q_{MX})eQq_{np\sigma} \qquad \text{(A-7)}$$

This is equivalent to the Townes-Dailey formula,[2] which was derived from a valence bond treatment. It may be rewritten:

$$eQq_X=-2/5eQ(1-a^2)(1-Q_{MX})\langle np|r^{-3}|np\rangle \qquad \text{(A-8)}$$

where the integral is the mean value of r^{-3} for the np orbital of the free halogen atom.

Appendix B. The Derivation of the Saika-Slichter Formula. — On the assupmtion that the second (paramagnetic) term in Ramsey's equation[38] is mainly responsible for the chemical shifts in fluorine, the chemical shift may be approximated by

$$\Delta\sigma=-(4/3\Delta E)(0|\sum_{jk}\boldsymbol{m}_j\boldsymbol{m}_k\boldsymbol{r}_k^{-3}|0) \qquad \text{(B-1)}$$

The various quantities in this formula are defined in Ramsey's paper.[38] In the same way as in Appendix A, we obtain

$$\Delta\sigma=-(2/3\Delta E)(e^2\hbar^2/m^2c^2)(1-a^2)(1-Q_{MF})\times\langle 2p|r^{-3}|2p\rangle \qquad \text{(B-2)}$$

This corresponds to the Saika-Slichter formula.[4] It resembles the Townes-Dailey formula given by Eq. A-8, as has already been predicted by Saika and Slichter.[4]

37) It is called "*reaction field*" in classical theory.

A Semi-empirical MO Theory of σ Electron Systems. III. The Bond Additivity Rule*

By Hidekazu HAMANO**

(Received March 10, 1964)

We have already established[1,2] that σ electron systems may usually be regarded as consisting of localized electron pairs, and that our first order theory corresponds to the localized bond model. This idea seems to be supported by the fact that many molecular quantities, such as heats of formation, dipole moments, and polarizabilities,[3] may be derived by means of bond additivity rules. At first sight, therefore, the empirical additivity rules seem to be based essentially on the localization of σ electrons. However, we have shown[2] in the first order theory how same bonds may vary in different molecules because of changes in the bond polarity which are due to the inductive effect. This suggests that the different bond quantities may be assigned to the bonds in different molecules and that the additivity rules do not necessarily hold.

On the other hand, some deviations from the additivity of bond properties due to the delocalization effects have been found. This has been accounted for in our theory as the second order approximation.[1] In spite of these facts, it appears that the empirical rules reveal a much more exact additivity of all the bond properties than should be expected. This problem for the additivity of bond energies has been discussed by several authors[4-7] using different approaches, but the additivity of bond moments in only a few molecules has been discussed.[8,9] We wish to discuss the additivity of bond energies and bond moments in general in this paper, including our second order theory, especially by taking the influence of the inductive effect into consideration.

I. The Bond Additivity of the Heat of Formation.—By making use of previous results[1] of the first and second order theory, we obtain the heats of the formation of molecules:

$$W=\sum_{\mathrm{p}}\overline{W}_{\mathrm{p}}^{-2}\sum_{\mathrm{ik}}(\beta_{\mathrm{ik}}^{+-})^2/(\varepsilon_{\mathrm{k}}^{-}-\varepsilon_{\mathrm{i}}^{+}) +1/2\sum_{\mathrm{lm}}Z_{\mathrm{l}}'Z_{\mathrm{m}}'/R_{\mathrm{lm}}-\sum_{\mathrm{a}}W_{\mathrm{a}}^{\circ} \quad (1)$$

where $\overline{W}_{\mathrm{p}}$ is the bond energy for each orthogonalized BO defined by Eq. 14 of Ref. 1; the second term is a resonance energy in terms of our second order theory; Z_{l}' and Z_{m}' denote the effective nuclear charges of the atoms l and m including the inner shell electrons, respectively; R_{lm} is the internuclear distance, and W_{a}° is the energy of the atom a at infinite separation, excluding the energy of the inner-shell electrons. The third term, which corresponds to the internuclear repulsion energy including inner-shell electrons, may be rewritten as:

$$\sum_{\mathrm{lm}}Z_{\mathrm{l}}'Z_{\mathrm{m}}'/R_{\mathrm{lm}}=\sum_{\mathrm{ab}}Z_{\mathrm{a}}'Z_{\mathrm{b}}'/R_{\mathrm{ab}}+\sum_{\mathrm{cd}}Z_{\mathrm{c}}'Z_{\mathrm{d}}'/R_{\mathrm{cd}} \quad (2)$$

where the a and b denote the directly-bonded atoms, and the c and d, the other pairs. The $\sum\overline{W}_{\mathrm{p}}$ may be expanded as a power series in S_{pq}:[10]

$$\sum_{\mathrm{p}}\overline{W}_{\mathrm{p}}=\sum_{\mathrm{p}}W_{\mathrm{pp}}-\sum_{\substack{\mathrm{pq}\\(\mathrm{q}\neq\mathrm{p})}}S_{\mathrm{pq}}W_{\mathrm{pq}}+\cdots\cdots \quad (3)$$

where

$$W_{\mathrm{pq}}=2H_{\mathrm{pq}}+(2-\delta_{\mathrm{pq}})\sum_{\mathrm{r}}[2\langle\varphi_{\mathrm{r}}(1)\varphi_{\mathrm{p}}(2)\cdot|r_{12}^{-1}|\varphi_{\mathrm{r}}(1)\varphi_{\mathrm{q}}(2)\rangle-\langle\varphi_{\mathrm{r}}(1)\varphi_{\mathrm{p}}(2)\cdot|r_{12}^{-1}|\varphi_{\mathrm{q}}(1)\varphi_{\mathrm{r}}(2)\rangle] \text{ etc.}$$

Since, in general, the overlap integrals, S_{pq}, between different BO are much smaller than the integrals, S_{p}, between directly-bonded

orbitals, only terms containing zeroth and first powers of S_{pq} in Eq. 3 may be considered. The first term, W_{pp}, may be regarded as the energy of the pth bond or lone pair; the sum is equivalent to the W_e° given by Eq. 17 or 20 of Ref. 1, whereas the second term, W_{pq}, is connected with the interaction energy between different bonds or lone pairs.

First let us examine the quantity W_e°. Since the discussion of the bond additivity may be restricted to the case of bonds with small polarities, we may use the approximation $F_p \sim (1+S_p)^{-1} - 1/2Q_p^2$.[1] Thus we obtain for W_e°:

$$W_e^\circ = \sum_a (W_a + W_a') + \sum_p{}' (E_p + \Delta_p) \tag{4}$$

where

$$\begin{aligned} W_a = {} & \sum_{R,\,p(a)} H^\circ_{R,p(a)} + 2 \sum_{f(a)} H^\circ_{f(a)} + \\ & 1/2 \sum_{\substack{R,\,p(a)\\ (q\neq p)}} \sum_{T,\,q(a)} (J^\circ_{R,p(a)T,q(a)} - 1/2K^\circ_{R,p(a)T,q(a)}) \\ & + 2 \sum_{f(a)R,p(a)} (J^\circ_{f(a)R,p(a)} - 1/2K^\circ_{f(a)R,p(a)}) \\ & + 2 \sum_{f(a)g(a)} (J^\circ_{f(a)g(a)} - 1/2K^\circ_{f(a)g(a)}) \end{aligned} \tag{5}$$

$$\begin{aligned} W_a' = {} & \sum_{R,p(a)} H'_{R,p(a)} + 2 \sum_{f(a)} H'_{f(a)} + 1/2 \\ & \sum_{\substack{R,p(a)T,q\\ (q\neq p)}} J'_{R,p(a)T,q} + \sum_{f(a)R,p} J''_{f,(a)R,p} \\ & + \sum_{R,p(a)f} J''_{R,p(a)f} + 2 \sum_{f(a)g} J''_{f(a)g} \end{aligned} \tag{6}$$

$$\begin{aligned} E_p = {} & (H^*_{A,p} + H^*_{B,p}) + 2(\sum_{f(A)} H^*_{f(A)} + \sum_{f(B)} H^*_{f(B)}) \\ & + 1/4(J^\circ_{A,pA,p} + J^\circ_{B,pB,p}) + 1/2(\sum_{\substack{B,q\\ (q\neq p)}} J^*_{A,pB,q} \\ & + \sum_{A,q} J^*_{B,pA,q}) + 2(\sum_{f(B)} J^*_{A,pf(B)} + \sum_{f(A)} J^*_{B,pf(A)}) \\ & + 4 \sum_{f(A)g(B)} J^*_{f(A)g(B)} + 1/2J^*_{A,pB,p} + 2\gamma_p(1+S_p)^{-1} \end{aligned} \tag{7}$$

$$\begin{aligned} \Delta_p = {} & \overline{Q}_p^2 \, [1/4(J_{A,pA,p} + J_{B,pB,p}) - 1/2J^*_{A,pB,p} \\ & - \gamma_p] + \overline{Q}_p [(H_{B,p} - H_{A,p}) + 1/2(J_{B,pB,p} \\ & - J_{A,pA,p}) + \sum_{\substack{T,\,q\\ (q\neq p)}} (1 - \overline{Q}_q^T)\{(J_{B,pT,q} \\ & - 1/2\delta_{B,pT,q}K_{B,pT,q}) - (J_{A,pT,q} - \\ & 1/2\delta_{A,pT,q}K_{A,pT,q})\} + 2\sum_f \{(J_{fB,p} - \\ & 1/2\delta_{fB,p}K_{fB,p}) - (J_{fA,p} - 1/2\delta_{fA,p}K_{fA,p})\}] \end{aligned} \tag{8}$$

and where $\sum_a$ and $\sum_p{}'$ denote summations over all atoms and over all bonds except lone pairs respectively; the parenthesis, (a), etc., of the AO refer to the atom, a etc., and the R, p, etc., stand for the valence AO A, p, B, p etc. The superscripts, small circle, asterisk and double prime of H, J, etc., denote the one-center integrals, two-center integrals between directly-bonded atoms and two-center integrals between the other paired atoms respectively under the conditions $H = H^\circ + H^* + H''$, etc. The symbol W_a represents the valence state energy of the atom a: the E_p and Δ_p correspond to the covalent bond energy and the ionic-covalent resonance energy of the bond p respectively. By using Eqs. 2, 3 and 4, Eq. 1 may be reduced to

$$\begin{aligned} W = {} & \sum_a \Delta W_a + [\sum_p{}' (E_p + \Delta_p) + 1/2\sum_{ab} Z'_a Z'_b / R_{ab}] \\ & + (\sum_a W'_a + 1/2\sum_{cd} Z'_c Z'_d / R_{cd}) - \sum_{\substack{pq\\ (q\neq p)}} S_{pq} W_{pq} \\ & - 2\sum_{ik} (\beta^{+-}_{ik})^2 / (\varepsilon^-_k - \varepsilon^+_i) \end{aligned} \tag{9}$$

where $\Delta W_a (= W_a - W_a^\circ)$ is the promotion energy of the atom a. If there are n_a bonds connected with the atom a, then its contribution to the bond energy for each bond separately may be estimated as $\Delta W_a / n_a$, because the empirical bond energy contains implicitly the energy of lone pairs and all hybridized AO are here considered to be equivalent to each other. As can be seen from Eq. 6, the third term of Eq. 9 may be approximated as

$$\sum_a W'_a + 1/2\sum_{cd} Z'_c Z'_d / R_{cd} \sim 0 \tag{10}$$

The fourth and fifth terms of Eq. 9 are related to interaction energies between different bonds or lone pairs; although actually they may not be assigned to specific bonds or lone pairs, nevertheless it is possible[11] to do this in a strictly formal sense. Since usually $S_{pq} > 0$ and $W_{pq} < 0$, the fourth and fifth terms may be taken to be positive and negative respectively. It follows that the two terms tend to cancel each other and that the contribution of these terms to the bond energies is small.

Let us now consider the influence of the inductive effect on the heats of formation.

11) The fourth term may be assigned to specific bonds or lone pairs as follows from Eq. 3. It was shown by Dewar and Pettit (M. J. S. Dewar and R. Pettit, *J. Chem. Soc.*, **1954**, 1625) that if all bond orbitals are degenerated or almost degenerated the fifth term may be approximated by

$$\sum_{ik} (\beta_{ik}{}^{+-})^2 / (\varepsilon_k{}^- - \varepsilon_i{}^+) \sim \sum_{\substack{pq\\ (p\neq q)}} (\beta_{pq}{}^{+-})^2 / (\varepsilon_q{}^- - \varepsilon_p{}^+)$$

where the p and q stand for bonding and antibonding orbitals respectively.

By using the results of Ref. 1, the Δ_p may be rewritten as:

$$\Delta_p = -1/2\, K_p^{-1}\, \overline{Q}_p^2$$
$$= -1/2K_p^{-1}\,[\overline{\Pi}_{pp}Q_p^{\circ 2} + 2\overline{\Pi}_{pp}Q_p^{\circ}\sum_{q\neq p}\overline{\Pi}_{pq}Q_q^{\circ} + (\sum_{q\neq p}\overline{\Pi}_{pq}Q_q^{\circ})^2] \quad (11)$$

The second and third terms correspond to the induced energy at the bond p, they are generally small compared with the first term, because the quantities Q° and $\overline{\Pi}_{pq}$ $(p\neq q)$ are smaller than unity and $\overline{\Pi}_{pp}$ is nearly equal to unity here.[1,2] For an essentially covalent bond ($Q_p^\circ = 0$), the third term is important, but it is still small. It follows that the influence of the inductive effect on resonance energies is insignificant. Equation 11 also shows that the Δ_p values are negative and that their absolute values increase with an increase in the bond polarity; this has already been included in Pauling's theory.[12]

It may be difficult to predict the influence of the inductive effect on the fourth and fifth terms of Eq. 9; however, it can be inferred as follows: Electron transfer by the inductive effect occurs, as in Fig. 1 of Ref. 1, so that the induced energy in the term $S_{pq}W_{pq}$ tends to be cancelled and the induced energies in the paired quantities, $(\beta_{pq}^{+-})^2$ and $(\beta_{qp}^{+-})^2$, which appear in the quantities $(\beta_{Ik}^{+-})^2$ also tend to cancel each other.[13] It seems, therefore, that the influence of the inductive effect on the heat of formation is very small. For example, in the series CH_3X, CH_2X_2, CHX_3 and CX_4 (X=Cl, Br, I), by taking the CH bond energies to be 90.4 kcal./mol.,[14] the C–Cl bond energies are empirically obtained as 71, 70, 70 and 69.6 kcal./mol.,[14] the C–Br bond energies, as 57, 57, 58 and 58 kcal./mol.,[14] and the C–I bond energies, as 43, 43 and 43 kcal./mol.[14] respectively. As has been shown in Ref. 2, however, the polarities of the CX bonds in these series are all changed by the inductive effect. Nevertheless, these bond energies and also the CH bond energies appear to be almost constant. This seems to confirm our inference. The bond energy, D_p, of the bond p, therefore, may be obtained as:

$$D_p = |\Delta W_A/n_A + \Delta W_B/n_B + E_p + Z'_A Z'_B/R_{AB} - 1/2K_p^{-1}\, Q_p^{\circ 2} + \lambda_p| \quad (12)$$

Since the variation in the promotion energy, ΔW, from molecule to molecule is generally small, at least for similar molecules, as has been discussed in Ref. 2, each term of Eq. 12 except the last term may be regarded as specific for the bond p. The λ_p is a small correction term which is mainly due to the interaction energy between the bond p and its adjacent bonds or lone pairs. However, this term is implicitly included in the empirical bond energy. Actually, for the branched isomers of hydrocarbons, small deviations in the empirical bond energies have been reported.[15] For a series of similar molecules such as hydrocarbons, however, this relative variation may be expected to be quite small, because the λ_p values are nearly constant. The D_p may thus be regarded as the empirical bond energy. To an even cruder approximation, the D_p may be rewritten as

$$D_p \sim |\Delta W_A/n_A + \Delta W_B/n_B + 1/4(J_{A,pA,p} + J_{B,pB,p}) + (B:A,\ pA,\ p) + (A:B,\ pB,\ p) + 1/2J_{A,pB,p} + 2\gamma_p(1+S_p)^{-1} - 1/2K_pQ_p^{\circ 2} + \lambda_p| \quad (13)$$

In this approximation, it is shown that the lone pairs on both the atoms A and B make no contributions to the bond energy except indirectly. The bond energy is then regarded as specific for the bond only.

Another necessary condition for bond additivity is that the length of one particular bond be the same in different positions or molecules. This condition is satisfied for saturated compounds, but it is well known that the bond lengths in nonsaturated compounds may vary considerably. It may thus be concluded that bond energies are not only additive but also remain constant for different molecules in saturated compounds.

II. The Bond Additivity of the Dipole Moment.—If nuclei and inner-shell electrons are regarded as point charges, the molecular dipole moment, μ, may be given by:

$$\mu = e\,[\langle \boldsymbol{r}_e\rangle - \sum_a Z'_a \boldsymbol{R}_a] \quad (14)$$

where

$$\langle \boldsymbol{r}_e\rangle = \langle \Phi^* |\ \boldsymbol{r}_e\ | \Phi\rangle$$

The $\boldsymbol{R}_a$ and $\boldsymbol{r}_e$ are the radius vectors which represent the position of the nucleus of the atom a and the electrons respectively, and Φ is the molecular wave function given by Eq. 1 of Ref. 1. By using the previous results,[1] we obtain

$$\langle \boldsymbol{r}_e\rangle = 2\sum_I [\boldsymbol{r}_I^+ - 2\sum_k \boldsymbol{r}_{Ik}^{+-}\ \beta_{Ik}^{+-}/(\varepsilon_k^- - \varepsilon_I^+)$$

$$+\sum_{kl} \boldsymbol{r}^{-}_{kl}\ \beta^{+}_{ik}{}^{-}\beta^{+}_{il}{}^{-}/(\varepsilon^{-}_{k}-\varepsilon^{+}_{i})\ (\varepsilon^{-}_{l}-\varepsilon^{+}_{i})] \tag{15}$$

where

$$\boldsymbol{r}^{+}_{ik}{}^{-}=\langle\psi^{+}_{i}\,|\boldsymbol{r}_{e}|\,\psi^{-}_{k}\rangle, \qquad \boldsymbol{r}^{+}_{i}\equiv\boldsymbol{r}^{+}_{ii}{}^{+}, \text{ etc.}$$

The subscript i refers to the unperturbed filled MO, and the subscripts k and 1, to the unperturbed empty MO respectively. The last term is relatively small; it will, therefore, be neglected. According to a discussion similar to that of the previous section, we obtain[10]

$$\sum_{i}\boldsymbol{r}^{+}_{i}=\sum_{p}\overline{\boldsymbol{r}}_{p}=\sum_{p}\boldsymbol{r}_{p}-\sum_{\substack{pq\\(p\neq q)}}S_{pq}\boldsymbol{r}_{pq} \tag{16}$$

where the $\overline{\boldsymbol{r}}_{p}$ and $\boldsymbol{r}_{p}$ are the corresponding quantities for OBO p and BO p respectively. Equation 15 may now be reduced to:

$$\langle\boldsymbol{r}_{e}\rangle=2\sum_{p}\boldsymbol{r}_{p}-2\sum_{\substack{pq\\(p\neq q)}}S_{pq}\boldsymbol{r}_{pq} -4\sum_{ik}\boldsymbol{p}^{+}_{ik}{}^{-}\ \beta^{+}_{ik}{}^{-}/(\varepsilon^{-}_{k}-\varepsilon^{+}_{i}) \tag{17}$$

The first term may be assigned to a specific bond or a lone pair, but this is not necessarily true for the other terms. By using Eqs. 18 and 21 of Ref. 1, $\boldsymbol{r}_{p}$ may be represented as:

$$\begin{aligned}\boldsymbol{r}_{p}&=1/2\,[(1-\overline{Q}_{p}-F_{p}S_{p})\boldsymbol{r}_{A,p}+(1+\overline{Q}_{p}\\&\quad-F_{p}S_{p})\boldsymbol{r}_{B,p}+2F_{p}\boldsymbol{r}_{A,pB,p}=1/2\,[(\boldsymbol{R}_{A}+\boldsymbol{R}_{B})\\&\quad+(\boldsymbol{r}^{x}_{A,p}+\boldsymbol{r}^{x}_{B,p})+\overline{Q}_{p}(\boldsymbol{R}_{p}+\boldsymbol{r}^{x}_{B,p}-\boldsymbol{r}^{x}_{A,p})\\&\quad-F_{p}\boldsymbol{V}_{p}]\end{aligned} \tag{18}$$

where

$$\boldsymbol{V}_{p}=S_{p}(\boldsymbol{r}_{A,p}+\boldsymbol{r}_{B,p})-2\boldsymbol{r}_{A,pB,p}$$

$$\boldsymbol{r}_{U,p}=\boldsymbol{R}_{U}+\boldsymbol{r}^{x}_{U,p} \qquad (U=A, B)$$

The $\boldsymbol{R}_{U}$ and $\boldsymbol{r}^{x}_{U,p}$ stand for the radius vector for the nucleus of the atom U and the atomic dipole vector of AO U, p respectively. $\boldsymbol{R}_{p}$ is the vector pointing from nucleus A to nucleus B along the bond p with the distance R_{AB} as its magnitude. In a similar way, we have for lone pairs:

$$\boldsymbol{r}_{f(a)}=\boldsymbol{R}_{a}+\boldsymbol{r}^{x}_{f(a)} \tag{19}$$

We thus obtain:

$$\begin{aligned}2\sum_{p}\boldsymbol{r}_{p}&\equiv2(\textstyle\sum'_{p}\boldsymbol{r}_{p}+\sum'_{f}\boldsymbol{r}_{f})=\sum_{a}Z'_{a}\boldsymbol{R}_{a}+\sum_{a}\boldsymbol{r}^{x}_{a}\\&\quad+\textstyle\sum'_{p}\overline{Q}_{p}(\overline{\boldsymbol{R}}_{p}+\boldsymbol{r}^{x}_{B,p}-\boldsymbol{r}^{x}_{A,p})-\sum'_{p}F_{p}\boldsymbol{V}_{p}\end{aligned} \tag{20}$$

where

$$\boldsymbol{r}^{x}_{a}=\sum_{U,p(a)}{}'\boldsymbol{r}^{x}_{U,p(a)}+2\sum_{f(a)}{}'\boldsymbol{r}^{x}_{f(a)} \tag{21}$$

$\sum'_{p}$ and $\sum'_{f}$ denote summations over bonds and lone pairs exclusively, and U, p(a) stands for the AO belonging to the atom a and the bond p. Since the valence AO of the atom a may be an equivalent set in the present treatment, the total atomic dipole of the atom a given by Eq. 21 may be rewritten as

$$\boldsymbol{r}^{x}_{a}=\sum_{f(a)}{}'\boldsymbol{r}^{x}_{f(a)} \tag{22}$$

This shows that the total atomic dipole vanishes except for the lone pair dipole. By using Eqs. 17, 20 and 22, the molecular dipole moment, μ, may now be written as

$$\begin{aligned}\mu=e\,[&\textstyle\sum'_{f}\boldsymbol{r}_{f}+\sum'_{p}\overline{Q}_{p}(\boldsymbol{R}_{p}+\boldsymbol{r}^{x}_{B,p}-\boldsymbol{r}^{x}_{A,p})-\sum'_{p}F_{p}\boldsymbol{r}_{p}\\&-2\sum_{\substack{pq\\(p\neq q)}}S_{pq}\boldsymbol{r}_{pq}-4\sum_{ik}\boldsymbol{r}^{+}_{ik}{}^{-}\beta^{+}_{ik}{}^{-}/(\varepsilon^{-}_{k}-\varepsilon^{+}_{i})]\end{aligned} \tag{23}$$

If we restrict ourselves to the case of small bond polarity, apart from the last two terms of Eq. 23, which may not be specific for localized bonds or lone pairs, the bond moment, μ_{p}, may be defined by:

$$\begin{aligned}\mu_{p}=e\,[\{&(\textstyle\sum_{f(A)}{}'\boldsymbol{r}^{x}_{f(A)})_{p}+(\sum_{f(B)}{}'\boldsymbol{r}^{x}_{f(B)})_{p}\}-\boldsymbol{V}_{p}/(1+S_{p})\\&+\overline{Q}_{p}(\boldsymbol{R}_{p}+\boldsymbol{r}^{x}_{B,p}-\boldsymbol{r}^{x}_{A,p})+1/2\overline{Q}_{p}\boldsymbol{V}_{p}\}]\end{aligned} \tag{24}$$

where $e(\sum_{f(A)}{}'\boldsymbol{r}^{x}_{f(A)})_{p}$ and $e(\sum_{f(B)}{}'\boldsymbol{r}^{x}_{f(B)})_{p}$ are the components of the lone pair moments of the atoms A and B respectively in the direction of the bond p. The first term, therefore, is the part of the atomic dipole due to the lone pairs; it vanishes for atoms such as tetrahedral carbon. It follows that in the atomic dipoles only the lone pairs contribute to the bond moments if we neglect the indirect contributions from the other terms of Eq. 24. This conclusion agrees with previous works,[9,16,17] and the significance of the lone pair dipole has been emphasized by several authors.[9,16-19] The second term is the homopolar dipole moment which is especially significant for homopolar bonds, and the third term is the heteropolar dipole, which is due to the bond polarity. In Mulliken's approximation[20] the homopolar dipole term vanishes; in addition, if the atomic dipole is neglected, we obtain

$$\mu_{p}=e\overline{Q}_{p}\boldsymbol{R}_{p} \tag{25}$$

The bond moment, μ_{p}, then coincides with the

corresponding empirical quantity.[6] This approximation, however, is generally not correct. The significance of the homopolar dipole has also been stressed by several authors.[8,18,19,21-23] For instance, the actual calculation[8,17,23] of the bond moment of the CH bond, which is regarded as nearly homopolar, yields a large value for this term, even if the atomic dipole is neglected. In spite of these facts, the concept of bond moments as given by Eq. 25 has proved to be a useful tool in the interpretation of experimental dipole moments.

The quantum mechanical theory does not seem to be in agreement with this. However, the discrepancy may be interpreted as follows: A vector summation over the whole molecule of the atomic dipoles and homopolar dipoles of Eq. 24 may tend to cancel some of the terms that cause the discrepancies. This statement may not have a general validity, but it seems to be correct for many organic compounds where all the bonds connected to one central atom usually point in opposite directions. The same inference may be true for the last two terms of Eq. 23; they also tend to cancel each other. In fact, the empirical bond moments are usually much smaller than those given by Eq. 24; sometimes their directions are even opposite to the theoretical ones.[23] In addition, if it is borne in mind that the empirical bond moments are not uniquely defined and that it is permissible to omit the quantities which are cancelled in summing over the whole molecule as long as this sum reproduces the total molecular dipole moment, it is not surprising that the theoretical and empirical bond moments are not in agreement with one another.

We will now consider the influence of the inductive effect on the bond moment. Since the Q_p consists of the specific Q_p° and induced Q_p' polarities,[1] if follows from Eq. 24 that the induced bond moment is nearly proportional to the induced polarity, Q_p'. The intra-bond electron transfers caused by the inductive effect occur as in Figs. 1 or 2 of Ref. 1, so the vector sum of the induced bond moment throughout the molecule may be additive. Besides, each bond moment is sensitive to variations in the hybridization. The bond moment, μ_p, may thus be defined as different in different molecules, and the molecular dipole moments may depend greatly on the inductive effect. The dipole moments of the series of CH_3X, CH_2X_2 and CHX_3 (X=halogens), which are tabulated in Table II of Ref. 2, seem to support this argument; if the CX and CH bond moments in these series were constant, the CH_2X_2 molecules would have the larger dipole moments and the CH_3X and CHX_3 molecules would have the same smaller moments. The experimental data, however, show that the dipole moments of these series decrease in the above order. This discrepancy has already been discussed in the preceding paper.[2] Another example has also been shown in Ref. 2. The assumption of a uniform bond moment, therefore, may be a poor approximation when the inductive effect is taken into consideration. Bond moments do not remain constant for different molecules, whereas for bond energies they do.

The previous argument assumes again that all bond lengths are constant; the validity of this assumption has already been discussed in the previous section.

Discussion

In the present treatment, it has been shown that the bond additivity is valid only if the delocalization of the bond electrons in σ electron systems is small. At first sight, therefore, it appears that the bond additivity is based only on the localization of the electrons in their bonds. The justification of the bond additivity, however, is essentially due to the following: If the BO are taken as a basis, such physical quantities as heats of formation and dipole moments may be represented by the matrices of the corresponding operators with respect to the BO. By means of a unitary transformation these matrices may be diagonalized; the heat of formation or the dipole moment of the molecule is then obtained as the trace of the matrix. After the transformation, each diagonal element may formally be assigned to one specific bond. However, since the trace of the matrix remains invariant,[24] we may also take the diagonal elements of the original matrix as each describing a separate bond. Their sum will then correctly represent either the total heat of formation or the dipole moment of the molecucle, even though the diagonal elements bofore and after the unitary transformation are not necessarily the same.[25] For bond

21) R. S. Mulliken, *J. Chem. Phys.*, 3, 573 (1935).
22) C. A. Coulson and M. T. Rogers, ibid., 35, 593 (1961).
23) H. Hamano, ibid., 34, 1678 (1961).

24) Actually this is true only for the localized MO, but since the orbitals are sufficiently localized in each specific bond or lone pair, it is a reasonably good approximation for the BO also.

25) This is equivalent with the principle of spectroscopic stability as introduced by Born et al. (M. Born, W. Heisenberg and P. Jordan, *Zeits. f. Physik*, 35, 557 (1926)). In fact, the theoretical background for many semi-empirical models in physical and chemical problems, especially for sum rules, is due to this principle; the details and some examples appear in Van Vleck's book (J. H. Van Vleck, "Electric and Magnetic Susceptibilities," Oxford Univ. Press, London (1932)), in connection with the principle of spectroscopic stability.

energies this was discussed in Ref. 1; for bond moments it is shown in Eq. 16.

The validity of the concept of bond additivity is due not only to the facts above, but also to the accidental cancellations when summing over the whole molecule. These cancellations occur in different ways for different quantities and then determine whether the bond quantities are constant or not from molecule to molecule, the former case for bond energies and the latter for bond moments. These facts often make the empirical bond quantities appear to be different quantities from those obtained quatum-mechanically.[26] This is especially true for bond moments. In practice, if the bond quatities are constant for different molecules, we say that the bond additivity rule holds. In this sense, dipole moments do not follow the additivity rule.

Chemists have often discussed the physical quantities of molecules by using the "*chemical bond*" concept. At first sight it seems to follow from our considerations that this concept is not meaningful theoretically because the bond orbitals are not eigenfunctions and molecular-observable quantities should be derived as expectation values of the molecular wave function. The present argument, however, shows that the chemical bond is a reasonable concept as long as it is used to discuss properties belonging to the total molecule. The situation is the same for the valence AO's of atoms; they are also equivalent orbitals which are not eigenfunction. The concept of these localized orbitals is thus very useful for chemists, even though it does not have physical significance. It is also worth noting that the concept of bond is not directly connected with the empirical bond additivity rules, as has been discussed above.

26) The contribution of lone pairs then vanishes in the approximation of Eq. 13 for heats of formation and does not vanish for dipole moments, its influence is implicitly accounted for by adjusting the empirical value for the bond quantity.

Summary

The aditivity rules for bond energies and bond moments are discussed on the basis of a previously-proposed theory. The results show that the apparent additivities are partially caused by accidental cancellations when summing over the molecule and essentially by the invariance of the trace of the matrix representing the molecular quantity. Bond energies are then constant in different molecules, whereas bond moments are not, mainly because of the inductive effect.

The author wishes to thank Dr. H. F. Hameka for his stimulating interest and encouragement, and Professor R. G. Parr for his reading the manuscript.

*The Homolytic Methoxylation of Aromatic Compounds by the Anodic Oxidation of Methanol**

By Tadao INOUE, Kikuhiko KOYAMA and Shigeru TSUTSUMI

(Received April 11, 1964)

In a previous paper,[1] we have described how the anodic oxidation of methanol in the presence of alkylated aromatic hydrocarbons produces α-methoxy derivatives, which might be formed by the reaction of a methoxyl radical generated by the electrolysis of methanol as an intermediate.

The present study was undertaken to provide additional information about the anodic methoxylation of aromatic compounds. Thus, diphenylmethane, indan and tetralin, which are known as compounds with hydrogen atoms reactive towards autoxidation[2] or other free-radical reactions,[3] were chosen as the aromatic compounds.

* Reported at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

Results and Discussion

The electrolyses were carried out using two platinum foil electrodes at 15~20°C, and the current density was kept approximately 8.3 amp./dm², according to the procedure described earlier.[1] The anodic oxidation of methanol containing sodium methoxide in the presence of tetralin afforded α-methoxytetralin (I) as a main product (current yield: 10~13%) and a small amount of formaldehyde, which was identified as its 2,4-dinitrophenylhydrazone, but the formation of the other isomeric methoxytetralin or of the dimeric product was not observed. When indan or diphenylmethane was used instead of tetralin, α-methoxyindan (II) (current yield: 8%) or α-methoxydiphenylmethane (III) (current yield: 2.9~3.6%) was obtained as the main product in each case. The experimental results obtained are summarized in Tables I, II and III. These products were analyzed by gas chromatography and infrared spectroscopy.

From these results, it can be considered that the methoxylated products are produced through a mechanism involving the attack of methoxy radicals upon the hydrocarbons; this hypothesis is based on the following reasons:

(A) The Position of Substitution: The reaction products clearly indicated that the methoxyl group was introduced in the α-position of the hydrocarbons, at which the hydrogen abstraction took place by ordinary free-radical reactions.[3-5]

(I) (II) (III)

(B) The Reactivity of the Aromatic Compounds: The relative reactivities were obtained by the following calculations: A/BC, where A: the yield (mol.) of α-methoxylated products; B: amp. hr. and C: the number of active hydrogen atoms.

TABLE IV. THE RELATIVE REACTIVITY OF THE AROMATIC HYDROCARBONS

Hydrocarbon	Product	A/B	A/BC
Diphenylmethane	III	6.7×10^{-4}	3.3×10^{-4}
Indan	II	14.4×10^{-4}	3.6×10^{-4}
Tetralin	I	23.1×10^{-4}	11.6×10^{-4}

The data given in Table IV indicate that the reactivity of these compounds in these electrolyses increases in the following order:

4) J. A. Meyer, V. Stannett and M. Szwarc, *J. Am. Chem. Soc.*, **83**, 25 (1961).
5) G. A. Russell, ibid., **78**, 1047 (1956); A. L. Williams, F. A. Oberright and J. W. Brooks, ibid., **78**, 1190 (1956).

diphenylmethane < indan < tetralin

This increasing order of the reactivities of these hydrocarbons is also observed in other free-radical reactions involving ROO·, *t*-BuO· and CH_3· radicals.[4,5]

The results obtained here, however, show a remarkable contrast to the observations that a methoxyl radical formed by the decomposition of peroxides reacts with the aromatic hydrocarbons to give high yields of methanol and benzylic dimers, but no methoxylated products.[6,7] Such an anomalous reaction in these electrolyses can be explained as follows:

(a) Since the environment around the electrode might have a particularly high concentration of the methoxyl radical, the benzylic radicals resulting from the hydrogen abstraction by the methoxyl radical would be expected to react preferentially with the methoxyl radical and, consequently, not to give the dimeric products.

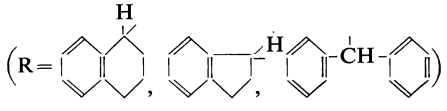
(b) As another possible rationalization, the following reaction path may be considered:

$$R\cdot \xrightarrow[\text{anode}]{-e} R^+ \xrightarrow{CH_3O^-} ROCH_3$$

Recently, Bonner and Mango[8] reported that electrolytically-generated benzyl radicals in the Kolbe electrolysis were oxidized with greater ease. Thus, the possibility that the free radical might be oxidized to carbonium ions to give solvolysis product can not be excluded in the present case.

Therefore, it may be assumed that the α-methoxylated products would be produced by the following course:

$$CH_3ONa \longrightarrow CH_3O^- + Na^+$$



$$CH_3O^- \xrightarrow[\text{anode}]{-e} CH_3O\cdot$$

$$CH_3O\cdot + RH \longrightarrow CH_3OH + R\cdot$$

$$CH_3O\cdot + R\cdot \longrightarrow ROCH_3$$

or

$$R\cdot \xrightarrow[\text{anode}]{-e} R^+ \xrightarrow{CH_3O^-} ROCH_3$$

Experimental

All melting points and boiling points illustrated in the report are uncorrected. Electrolyses were carried out with the apparatus previously described.[1]

Materials.—When commercial tetralin was treated with solid sodium hydroxide and distilled from sodium, a fraction (b. p. 81.5~83°C/14 mmHg, $n_D^{20}=1.5380$) was collected. Indan was prepared by the reduction of α-chloroindan[9] with lithium aluminum hydride in a dry ethereal solution; b. p. 176~177°C (lit.,[10] b. p. 177°C), $n_D^{20}=1.5382$. Diphenylmethane was obtained commercially and was carefully distilled from sodium; b. p. 122~123°C/10 mmHg, $n_D^{20}=1.5767$. Methanol was purified in the manner described earlier.[1] These materials were confirmed to be pure by gas chromatography.

The Anodic Oxidation of Methanol in the Presence of Tetralin.—The reaction conditions and the yields of the product I are summarized in Table I.

R-3 is exemplified as follows: Metallic sodium (0.5 g., 0.022 mol.) was dissolved in 75 g. of absolute methanol, and then 45 g. of tetralin (0.34 mol.) was added to the mixture. After dry nitrogen had been bubbled through the mixture for about 1 hr., the mixture was electrolyzed at 12°C for 78 hr. and a current was maintained at nearly 0.5 amp. During the course of the electrolysis, tetralin was gradually dissolved and the electrolyzed solution turned brown in color. The reaction mixture was worked up in a manner similar to that used in an experiment described earlier.[1] After the ether had been removed, the oily residue (44.5 g.) was distilled under diminished pressure to give the following fractions:

Fraction	B. p., °C/mmHg	Weight, g.
1	40~62/1~2	29.3
2	62~83/1~2	8.3
3	83~120/1~2	1.6
4	Residue	2.0

By gas chromatographic analysis (conditions: column, P. E. G. 6000 and P. E. DA, 3 m.; column temperature, 160°C; carrier gas, H_2), it was shown that every fraction except fraction 4 was a mixture of unreacted tetralin and α-methoxytetralin, and that the total amount of this product was 13.1 g. Fraction 2 was chromatographed over silica gel (2.5×58 cm.). Elusion with benzene led to the isolation of unreacted tetralin, and α-methoxytetralin; b. p. 80~82°C/2 mmHg, $n_D^{15}=1.5363$.

Found: C, 81.22; H, 8.60. Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

The infrared spectrum of the latter compound showed the characteristic absorption band at 1092 cm^{-1} (C-O-C of aliphatic ether) and was identical with that of an authentic sample prepared as described below.

The Synthesis of α-Methoxytetralin.—α-Methoxy-β-bromotetralin was prepared by the reaction of α, β-dibromotetralin with methanol according to the procedure of Braun;[11] b. p. 118~120°C/2~3 mmHg (lit., b. p. 151~152°C/13 mmHg). α-Methoxytetralin was prepared by the reduction of α-methoxy-β-bromotetralin with lithium aluminum hydride in dry ether and was purified by the column chromotography (column; silica gel, 2.5×58 cm.; eluted with

benzene). B. p. 80~81.5°C/1~2 mmHg, $n_D^{15}=1.5371$.

The Anodic Oxidation of Methanol in the Presence of Indan. — To a solution of sodium methoxide (0.5 g., 0.022 mol.) in 75 g. of absolute methanol, 45 g. (0.38 mol.) of indan was added. This new solution, after dry nitrogen had been bubbled through, was electrolyzed for 93 hr. under the following initial conditions: current, 0.5 amp.; volt, 15 V.; temperature, 12°C; current density, 8.3 amp./dm². During the course of the reaction, both electrodes were mutually exchanged at intervals to avoid the deposition of resinous materials. When the electrolyzed solution was treated in a manner similar to the experiment described earlier,[1] it gave the following fractions:

Fraction	B. p., °C/mmHg	Weight, g.
1	~50/1~2	24.5
2	50~82/1~2	7.9
3	82~100/1~2	3.0
4	Residue	3.5

Gas chromatographic analysis (column, P. E. G. 6000 and P. E. DA, 3 m.; column temperature, 159°C; carrier gas, H_2) showed that fractions 1, 2 and 3 were mixtures of unreacted indan and α-methoxyindan, and that the total amount of this product was 6.8 g.

Fraction 2 was chromatographed over silica gel and eluted with benzene to give following fractions:

Fraction	B. p., °C/mmHg	Weight, g.
a	55~57/10	1.5 $n_D^{20}=1.5380$
b	65~66/1~2	6.1 $n_D^{17}=1.5312$

Fraction a was identified as unreacted indan by gas chromatographic and infrared spectroscopic analysis.

Fraction b was identified as α-methoxylated indan, since the infrared spectrum of fraction b was identical with that of an authentic sample prepared by the following method and since it exhibited a characteristic absorption band at 1087 cm^{-1} (assigned to aliphatic ether C-O-C).

Found: C, 80.83; H, 8.39. Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16%.

The Synthesis of α-Methoxyindan.—α-Chloroindan was prepared by the reaction of indene with dry hydrochloric acid at 0~−10°C according to the procedure of Weissgerber.[9] B. p. 104~105°C/21~22 mmHg. α-Methoxyindan was prepared by the reaction of α-chloroindan with sodium methoxide in a methanol solution; b. p. 65~66°C/1~2 mmHg, $n_D^{17}=1.5312$.

The Anodic Oxidation of Methanol in the Presence of Diphenylmethane. —Metallic sodium (0.5 g.) was dissolved in 100 g. (3.1 mol.) of methanol, and then 50 g. (0.27 mol.) of diphenylmethane was added. The mixture was electrolyzed for 88 hr. under the following electrolytic conditions: current, 0.2 amp.; volt, 25 V.; temperature, 33°C; current density, 3.3 amp./dm². The reaction mixture was worked up in a manner similar to that used in an experiment described earlier.[1] From the ethereal layer, the following fractions were obtained:

Fraction	B. p., °C/mmHg	Weight, g.
1	102~111/2~3	39.3
2	111~126/2~3	2.5
3	126~152/2~3	1.1
4	Residue	4.5

By gas chromatographic analysis (conditions: column, P. E. G. 6000, 3 m.; column temperature, 192°C; carrier gas, H_2), it was also shown that every fraction except fraction 4 was a mixture of unreacted diphenylmethane and α-methoxydiphenylmethane, and that the total amount of this product was 1.8 g.

Fractions 2 and 3 were submitted to preparative gas chromatography (column, P. E. G. 6000, 6 m.; column temperature, 190°C; carrier gas, N_2), and the pure α-methoxydiphenylmethane was isolated; b. p. 120~121°C/2~3 mmHg, $n_D^{20}=1.5658$.

Found: C, 84.79; H, 7.19. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

The infrared spectrum of this product showed a strong C-O-C band at 1092 cm^{-1} and was identical with that of a sample prepared by the methylation of benzhydrol (0.015 mol.) with methyl iodide (0.09 mol.) and silver oxide (0.035 mol.); b. p. 120~121°C/2~3 mmHg, $n_D^{20}=1.5653$.

*The Synthesis of Methacrylic Esters by Carboxylation Reaction of Methylacetylene. I. Methyl Methacrylate; Reaction Conditions and Products**

By Yasumasa SAKAKIBARA

(Received May 7, 1964)

In previous papers[1,2] the present author has reported the synthesis of methylacetylene by the pyrolysis of propylene. In this connection, it is of great interest to synthesize methacrylic esters, especially methyl methacrylate, by the carboxylation reaction of methylacetylene.

Numerous investigations have been made of the synthesis of acrylic esters by the carboxylation of acetylene;[3] the following three processes are known:

The stoichiometric process

$$4CH{\equiv}CH + Ni(CO)_4 + 4ROH + 2HCl \rightarrow 4CH_2{=}CHCO_2R + NiCl_2 + H_2$$

The catalytic process

$$CH{\equiv}CH + CO + ROH \xrightarrow{\text{Catalyst}} CH_2{=}CHCO_2R$$

Catalyst: Nickel halides, triphenylphosphine nickel complexes, etc.

The semicatalytic process**

The stoichiometric process plus

$$CH{\equiv}CH + CO + ROH \xrightarrow{Ni(CO)_4} CH_2{=}CHCO_2R$$

Concerning the carboxylation of methylacetylene, however, very little has been published. One article by Yakubovich and Volkova[4] and one patent[5] have described the synthesis of methacrylic acid and its lower alkyl esters by the stoichiometric process (low yields). Recently, it has been reported by another patent[6] that aminoalkyl methacrylates were synthesized in fairly good yields from methylacetylene by the semicatalytic process. Jones et al.,[7] investigating the carboxylation of various monosubstituted acetylenes by the stoichiometric process, obtained ethyl α-butylacrylate in a 50% yield from butylacetylene. This paper will describe the synthesis of methyl methacrylate by the carboxylation reaction of methylacetylene. In this investigation the reaction will be examined by both the stoichiometric and catalytic, including the semicatalytic, processes.

Experimental

Materials. — Methylacetylene was prepared by the dehydrobromination of propylene bromide with potassium hydroxide.[8] The crude methylacetylene was purified by fractional distillation through a Podbielniak-type low-temperature column (80 cm. × 1.5 cm.); b. p. −23∼−22°C. The purity was higher than 98.5 mol.%; allene was shown to be the principal impurity by gas chromatographic analysis.

Carbon monoxide (99.7 mol.% pure) was purchased from the Takachiho Chemical Co.

Metal Carbonyls. — Nickel tetracarbonyl,[9] chromium hexacarbonyl,[10] and dicobalt octacarbonyl[11] were prepared by the usual methods.

Nickel tetracarbonyl: a colorless, transparent liquid; b. p. 42∼43°C (lit. 43°C).

Chromium hexacarbonyl: colorless crystals; m. p. 153∼155°C (lit. 152∼155°C).

Dicobalt octacarbonyl: dark-brown crystals; m. p. 51°C (lit. 51°C).

Nickel Halides and Triphenylphosphine Nickel Bromide Complexes.—Anhydrous nickel bromide and

nickel iodide were prepared by drying their hydrates at 140°C.[12]

Bis(triphenylphosphine)nickel dibromide, $(Ph_3P)_2NiBr_2$, was prepared by Yamamoto's procedure.[3e] It was a deep green solid; m. p. 218~220°C (lit. 221~222°C) (Found: C, 58.57; H, 4.31%).

Bis(triphenylphosphine)nickel dibromide *n*-butyl bromide, $(Ph_3P_2)_2NiBr_2BuBr$, was prepared by Reppe's procedure.[13] It was a bluish green solid; m. p. 178°C (lit. 178°C) (Found: C, 54.62; H, 4.71%).

Carboxylation. — *Stoichiometric Process.* — Two methods were employed. A) In a 200 ml., four-necked flask equipped with a mercury-sealed stirrer, a gas inlet, a dropping funnel, a thermometer, and a reflux condenser, methanol, concentrated hydrochloric acid, and hydroquinone were placed. The condenser was the same one as that of Jones et al.[14] and contained a mixture of dry ice-ethanol kept at about −20°C. The air in the flask was replaced completely by nitrogen while the flask was heated on a water bath. About 1 ml. of nickel carbonyl was added, and methylacetylene or a gas mixture of methylacetylene and acetylene was bubbled continuously through the solution while it was vigorously stirred. When the reaction began, as shown by a rise in the temperature and, in some cases, by a transient brown coloration, the remainder of the nickel carbonyl was added drop by drop at such a rate that the temperature remained constant. After dropping all amounts of nickel carbonyl, gas was introduced until the absorption stopped practically.

B) A 100 ml. electromagnetic stirring-type autoclave was charged with methanol, concentrated hydrochloric acid, nickel carbonyl, and hydroquinone. The vessel was then cooled to about −40°C and the air was replaced completely by nitrogen. After evacuation, methylacetylene was added by distillation. The vessel was heated slowly to about 80°C, at which temperature a vigorous reaction began; when a marked rise in the temperature was observed, the heating was stopped or weakened. After the mixture had cooled to room temperature, the remaining gas was discharged and collected in a gas holder for the analysis.

Catalytic Process. — A 100 ml. electromagnetic stirring-type autoclave was charged with methanol, a catalyst, hydroquinone, and methylacetylene in the same manner as in the above Process-B. Carbon monoxide was added to give a pressure of 15~25 atm. in most cases. The vessel was then heated to 150~290°C. During the period of reaction, when the partial pressure of carbon monoxide fell to about 10 atm. (at 170°C, about a 30 atm. pressure resulted from a mixture of methanol (20 ml.) and methylacetylene (8 g.)), carbon monoxide was added repeatedly to maintain a partial pressure of 10~40 atm. at the reaction temperature. In most cases, the reaction was continued until the absorption of carbon monoxide stopped practically. After the mixture had cooled to room temperature, the remaining gas was discharged through two traps cooled with ice-water (trap 1) and with dry ice-ethanol (−60°C, trap 2). The condensate in trap 2 was composed mainly of methyl ether and unreacted methylacetylene.

The Separation and Identification of Reaction Products.—*Waste Gases.* — These were analyzed by gas chromatography using the following three different columns: (1) a molecular sieve 5A column (2.4 m.) for hydrogen, nitrogen, methane, and carbon monoxide at 60°C, (2) a 30% (by weight) dioctyl phthalate column (4.7 m.) at room temperature, and (3) an 8.0% β, β'-oxydipropionitrile on silica gel column (2.5 m.) at 70°C for other gaseous substances.

Nickel Carbonyl.—In several cases, the nickel carbonyl, unchanged or formed from nickel-containing catalysts, was determined by a slight modification of the method of Jones et al.[7b]

Liquid Products.—The reaction mixture was poured into dilute sulfuric acid and extracted with methylene chloride. Acetone and esters were determined by gas chromatographic analysis of the extract. Two columns, a 2.4 m. column of 23% β, β'-oxydipropionitrile and a 2.4 m. column of 25% squalane, were used at 70°C, with a flow rate of 50 ml./min. of hydrogen as a carrier gas; *p*-xylene and toluene were selected as the internal standard substances respectively. The retention times measured under these conditions are shown in Table I.

TABLE I. RETENTION TIMES

Compound	Retention time, min.	
	β, β'-Oxydipropionitrile	Squalane
Methylene chloride	4.9	2.5
Methanol	7.3	1.0
Acetone	8.5	1.8
Methyl isobutyrate	8.7	8.9
Methyl propionate	9.1	5.5
Methyl acrylate	10.4	4.9
Methyl *n*-butyrate	14.6	12.6
Toluene	14.7	26.3
Methyl methacrylate	14.9	11.5
Water	17.2	2.0
p-Xylene	24.0	64.8
Methyl *trans*-crotonate	33.8	18.2

The above extract was washed thoroughly with a 7% sodium hydrogen carbonate solution, and the neutral and acidic fractions were separated. The alkaline solution was acidified with dilute sulfuric acid and extracted with methylene chloride. This extract was then condensed and flash-distilled at reduced pressure. The distillate was analyzed by gas chromatography to determine the carboxylic acids. The analysis was performed by a 2.4 m. column of 21% dioctyl sebacate +4% sebacic acid[15]

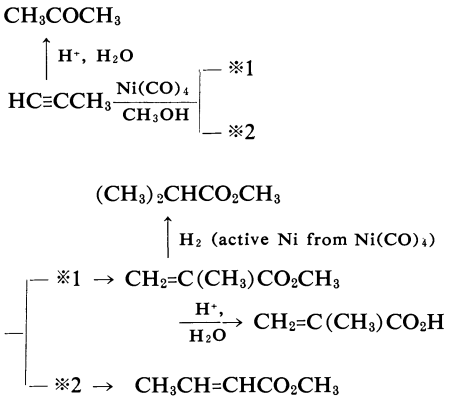
at 140°C, using chlorobenzene as an internal standard substance. On the other hand, the neutral fraction was condensed and flash-distilled at reduced pressure to give an ester fraction (~80°C/150 mmHg), a high-boiling fraction (60~100°C/50 mmHg), and a residue. In most cases of experiments which were carried out by the catalytic process, the extract, without separating the neutral and acidic fractions, was worked up like the above neutral fraction. The high-boiling fraction was analyzed by gas chromatography to determine the carboxylic acids.

By fractionating low-boiling fractions collected from several runs, the following compounds were isolated and identified:

Acetone; b. p. 56~57°C: 2,4-dinitrophenylhydrazone; m. p. 125°C (Found: N, 23.62%).



Methyl methacrylate; b. p. 47~48°C/112 mmHg, n_D^{20} 1.4149, d_4^{20} 0.947 (Found: C, 60.04; H, 8.25%).

Methyl *trans*-crotonate; b. p. 57~58°C/84 mmHg, n_D^{20} 1.4248, d_4^{20} 0.944 (Found: C, 59.85; H, 8.36%).

Results and Discussion

Stoichiometric Process.—*Carboxylation under Atmospheric Pressure.*—The carboxylation reaction was performed by introducing methylacetylene into a solution of methanol and concentrated hydrochloric acid with nickel carbonyl. The results are shown in Table II. By this method methylacetylene was not carboxylated so rapidly as acetylene. Even at a temperature of 73~76°C, no obvious reaction occurred, and methyl methacrylate was obtained in only a slight yield (3.6%, based on the methylacetylene consumed); about one half of the methylacetylene was recovered (Run 61). In this run, although the greater part (70%) of the nickel carbonyl used was consumed, most of carbon monoxide resulting from its decomposition was found in the waste gas as free carbon monoxide without having reacted with methylacetylene. When *n*-butanol was used instead of methanol, the reaction appeared to proceed slowly at 72~76°C after an induction period of several minutes, but the yield of butyl methacrylate was low (16%, Run 59). The addition of acetylene accelerated the reaction considerably. When a gas mixture of methylacetylene and acetylene in a 1 to 2:1 volume ratio was employed, a vigorous exothermic reaction occurred after a short induction period. The rate of the reaction became slower when the ratio of methylacetylene to acetylene is increased, and in the case of the 3:1 ratio, the reaction proceeded slowly under continuous heating (Run 57). In the case of the 2:1 ratio, the total yield of methyl methacrylate and methacrylic acid was 45%, the best yield in these three runs (Runs 56–58), while the total yield of methyl acrylate and acrylic acid produced from acetylene was 66%. The total yield of the carboxylation products (monomeric) of methylacetylene was always much lower than that of acetylene, and the residue (expressed as Rd in Table II) increased with an increase in the ratio of methylacetylene in the gas mixture. In view of these results, it is likely that, compared with acetylene, methylacetylene is difficult to carboxylate, but it can be polymerized and/or added to olefinic compounds such as methyl methacrylate, methyl acrylate, etc., under the conditions of the carboxylation reaction.

In addition to methyl methacrylate and methacrylic acid, methyl *trans*-crotonate, methyl isobutyrate, and acetone were obtained from methylacetylene as by-products in small amounts. The routes of formation of these substances are presumed to be as follows:

It should be noted that methyl isobutyrate, formed by the hydrogenation of methyl methacrylate, was obtained in much lower yields than was the methyl propionate formed by the hydrogenation of methyl acrylate, especially in Run 57, where the methylacetylene/acetylene ratio is 3:1.

Carboxylation under Pressure.—As the carboxylation reaction of methylacetylene did not proceed smoothly under atmospheric pressure, the reaction was examined by heating the reactants in an autoclave. By this method the carboxylation was achieved readily. The results are shown in Table III. In all cases, when the reaction temperature attained about 80°C a vigorous reaction took place, as was evidenced by a sudden marked rise in the temperature and a fall in the pressure. For example, in Run 16, the reaction temperature rose rapidly from 80 to 105°C, and a maximum pressure, at 14 atm., was reached at 82°C. In Run 63, where an excess of methylacetylene was used, 1.23 times the theoretical amount of methylacetylene (based on the nickel carbonyl used) was absorbed, and methyl

a) The values shown in parentheses are the yields based on the nickel carbonyl used.

b) This value is the ratio of the amount of methylacetylene absorbed to the theoretical amount based on the nickel carbonyl used.

methacrylate was obtained in a 45% yield, together with methacrylic acid in a 5% yield. On the other hand, the best total yield of methyl methacrylate and methacrylic acid, based on nickel carbonyl, was 66% (Run 15).

In all runs, considerable amounts of high-boiling materials (b. p. 87~92°C/47 mmHg, n_D^{20} 1.4760 in Run 15), in addition to small amounts of methyl crotonate, methyl isobutyrate, and acetone, were obtained as by-products. Although the high-boiling materials appeared to be C_7 olefinic esters formed by the dimerization of methylacetylene and the subsequent carboxylation and/or by the addition of methylacetylene to methyl methacrylate, no further study was made. In the stoichiometric reaction, one mole of hydrogen per mole of nickel carbonyl must be formed, if the reaction formula is correct. In reality, however, most of the hydrogen formed appeared to react with unsaturated substances. For example, in Run 63, only 16% of the theoretical amount of hydrogen was found in the waste gas (1920 ml.) as free (4 ml.) or combined hydrogen, that is, as hydrogen which added to methylacetylene to give propylene (227 ml.), as is shown in Table IV. Furthermore,

Table IV. Composition of waste gas

Nickel carbonyl	0.9	3.1
Others	6.6	3.5

in view of the fact that the yield of methyl isobutyrate was also small, it may be concluded that most of the hydrogen must be added to unsaturated high-molecular substances. This was observed similarly in Run 57, carried out under atmospheric pressure. In this case, only 7% of the theoretical amount of hydrogen was accounted for by the presence of free or combined hydrogen in the waste gas (Table IV), while 21% and 3% were accounted for by the formation of methyl propionate and methyl isobutyrate respectively.

Catalytic Process.—*Nickel Halide and Triphenylphosphine Nickel Bromide Complex Catalysts.*—The results are shown in Table V. Generally, in the presence of these catalysts

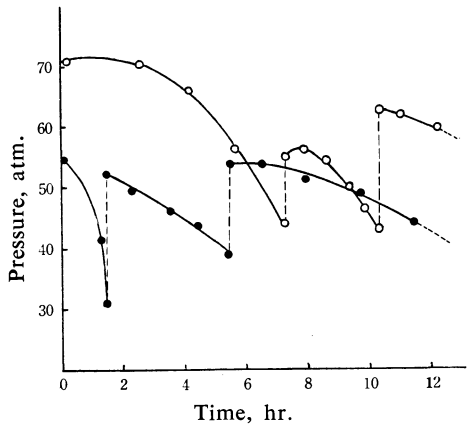

Fig. 1. Variation in total pressure with the reaction time-I*: ●, Run 41; ○, Run 44.
* The vertical broken lines show the added pressure of carbon monoxide.

the reaction proceeded fairly smoothly at a temperature of 170~180°C and under about a 10 atm. partial pressure of carbon monoxide, as is illustrated by the variation in total pressure shown in Fig. 1. A high pressure of carbon monoxide gave a slow rate of reaction. For example, in the case of about a 75 atm. partial pressure of carbon monoxide (total pressure, 105 atm.), the decrease in pressure during a reaction time of 10 hr. was only two atms. The induction period appeared to be reduced with the decrease in the partial pressure of carbon monoxide when other conditions were the same.

Triphenylphosphine nickel bromide and triphenylphosphine nickel bromide butyl bromide complexes gave better results than those obtained by nickel bromide and iodide, though these complexes have been reported to decompose with the separation of triphenylphosphine in methanol.[3a,3e] The total yield of methyl methacrylate and methacrylic acid was, however, unsatisfactory (best yield: 47% in Run 44), and a fairly long reaction time was required for the completion of the reaction.

The low yield appeared to be due chiefly to the loss of methylacetylene by polymerization leading to the formation of high-molecular substances (expressed as HBM and Rd in Table V). Particularly, large quantities of high-molecular substances were formed in cases where a vigorous exothermic reaction occurred in the early stages of the reaction, as shown by a marked fall in pressure (Run 41 in Table V and Fig. 1). Such a vigorous reaction was often encountered when the reaction was carried out at a low pressure of carbon monoxide (partial pressure below about 10 atm.) in the presence of the complex catalysts; it was observed that, at that time,

a) See footnotes a) and b) in Table V. The values in parentheses show initial pressure (in first addition) of carbon monoxide at room temperature.
b) The maximum yields of methyl isobutyrate and crotonic acid were 1.0% (Run 24) and 1.7% (Run 30), respectively.

most of the methylacetylene was consumed in reacting with much smaller amounts of carbon monoxide. This implies that methylacetylene is liable to polymerize under the conditions, as might be supposed from the reports of Reppe and Schweckendiek,[16] and Meriwether et al.,[17] who have investigated the polymerization of acetylenes by triphenylphosphine nickel bromide and triphenylphosphine nickel carbonyl complexes. Thus, the yield of the carboxylation products would be improved by adopting a continuous method, because the addition of methylacetylene suppresses the polymerization of methylacetylene. Furthermore, a continuous addition of carbon monoxide at optimum partial pressure (about 10 atm.) would reduce the reaction time.

Acetone was formed in considerable yields (3~24%) by the reaction of methylacetylene with water, which is formed by the formation of methyl ether from methanol. The ratio of methyl crotonate to methyl methacrylate was about 1 to 5; this ratio was much higher than that of the stoichiometric process where the reaction proceeded at lower temperatures (Table III). In all cases, methyl ether was formed in considerable quantities (10~50%, based on the methanol used).

The nickel halides and triphenylphosphine nickel bromide complexes used as catalysts changed considerably in the reaction. In all cases nickel carbonyl was formed, probably by the following reaction: $NiBr_2+2CH_3OH+5CO \rightarrow Ni(CO)_4+2CH_3Br+H_2O+CO_2$. In Run 42 nickel carbonyl was obtained in a 20% yield (based on the nickel complex used). The nickel carbonyl formed may be supposed to participate in the carboxylation reaction, in view of the catalytic action of nickel carbonyl which will be mentioned below. In certain cases the formation of nickel hydroxide as fine precipitates was observed.

Metal Carbonyl Catalysts.—The results are shown in Table VI. In the case of the nickel carbonyl catalyst, all experiments, except Runs 22 and 31, were carried out in the presence of one-fourth of the theoretical amount of nickel carbonyl (based on methylacetylene). Runs 23–25 are examples of experiments which were carried out semi-catalytically. The total yield of methyl methacrylate and methacrylic acid was low (35%) under these conditions. The results, however, suggest the possibility that this process, especially in a continuous method, may be so developed as to become a good process for the synthesis of methyl methacrylate from methylacetylene, as in the case of the carboxylation of acetylene. Concerning the occurrence of the reaction, it was observed that the reaction required a high temperature when a high initial pressure of carbon monoxide was applied. The relation between the reaction temperature (lowest) and the pressure of carbon monoxide is shown in Fig. 2. However, in this figure the reaction temperature (80°C) in the case of the stoichiometric process was taken as that for zero atm. pressure of carbon monoxide.

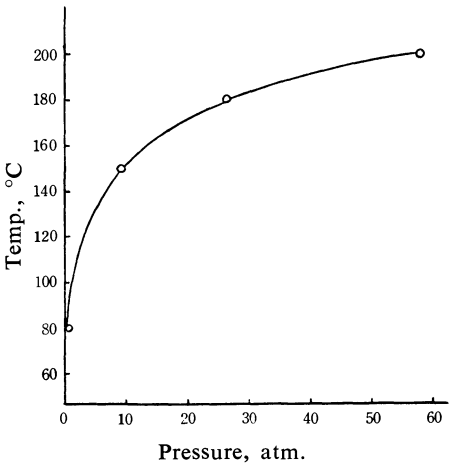

Fig. 2. Relation between the reaction temperature and the pressure (at room temp.) of carbon monoxide.

The reaction was similarly examined in the absence of hydrochloric acid. In cases where the acid was not added, scarcely any methyl methacrylate was formed at 180~195°C (Run 22), and it was obtained in a low yield (12%) at 200~205°C (Run 27). When water was present, the carboxylation reaction proceeded without the addition of any acid. This is an interesting fact, since it is generally known that nickel carbonyl without the addition of acid is not capable of forming acrylic esters from acetylene. The temperature at which the reaction occurred became lower as the amount of water was increased (Runs 26, 31, and 30). The reaction proceeded more readily in Run 30 (15 ml. methanol+5 ml. water) than in Run 23 (20 ml. methanol+1.7 ml. concentrated hydrochloric acid). The total yield of methyl methacrylate and methacrylic acid was better in the presence of water than in the presence of hydrochloric acid, and the best total yield was 46% (Run 30). Fortunately, by the use of water instead of hydrochloric acid, the formation of acetone (below 2%) and of methyl ether was suppressed.

In most cases, the greater part of the nickel

* The vertical broken lines show the added pressure of carbon monoxide.

carbonyl used as a catalyst was decomposed to give nickel chloride (in the presence of hydrochloric acid) or nickel hyroxide as fine precipitates. The decomposition was especially marked in cases where such a vigorous reaction as consumed, in a moment, all the carbon monoxide in the reaction vessel, occurred in the early stages of the reaction. Run 23 is given as an example of such cases in Fig. 3, which shows the variation in the total pressure of the reactants with the reaction time. In this run, the reaction stopped after the pressure fell rapidly, probably because of the decomposition of all the amounts of nickel carbonyl (compare with Run 31 in Fig. 3). Furthermore, it is noteworthy that such a vigorous reaction as has been described above appeared to result from two reactions of the carboxylation reaction and of the polymerization (inclusive of addition) reaction of methylacetylene, and that the latter reaction was probably a main cause of the poor yield of the carboxylation products. Thus, it may be supposed to be necessary, for keeping a long life of nickel carbonyl as a catalyst and for obtaining a better yield of methyl methacrylate, to add methylacetylene under controls. The performance of the carboxylation reaction by a semicontinuous method will be reported on in a subsequent publication.

Dicobalt octacarbonyl and chromium hexacarbonyl were not effective as catalysts for the carboxylation of methylacetylene (Runs 65—69). In the case of chromium hexacarbonyl, methyl methacrylate was obtained in only a slight yield (5%) in the presence of water and at the high temperature of 280～290°C (Run 69).

Summary

The synthesis of methyl methacrylate (MMA) by the carboxylation reaction of methylacetylene has been investigated.

Stoichiometric process: The carboxylation reaction was carried out under atmospheric pressure by premixing a 25～50 vol.% of acetylene in methylacetylene and under pressure (heating to 80°C). The total yields of MMA and MAA (methacrylic acid) were 45% (based on the methylacetylene consumed) under atmospheric pressure and 49% (66% (based on the nickel carbonyl used)) under pressure. Small amounts of methyl *trans*-crotonate, methyl isobutyrate, acetone, etc., were obtained as by-products, together with considerable amounts of high-boiling materials (not investigated).

Catalytic process: The reaction proceeded comparatively smoothly at 170～180°C and under about a 10 atm. partial pressure of carbon monoxide when triphenylphosphine nickel bromide complexes and nickel carbonyl-concentrated hydrochloric acid were used as catalysts. A triphenylphosphine nickel bromide catalyst, $(Ph_3P)_2NiBr_2$, gave the best total yield, 47%. It was found that, without the addition of acid, nickel carbonyl exhibits a catalytic action in the presence of water at 170～180°C. The total yield of MMA and MAA by this method was 46%. Fortunately, scarcely any acetone or methyl ether were formed. In view of this series of experimental results, it may be supposed that the poor total yield of MMA and MAA is chiefly due to the loss of methylacetylene by polymerization.

The author wishes to express his thanks to Professor Sango Kunichika of Kyoto University for his helpful advice and kind encouragement throughout this work. Also, the author wishes to thank Mrs. Toshiko Ikegami of Kyoto University for her microanalysis.

The Coprecipitation of Yttrium with Calcium Oxalate

By Tsunenobu SHIGEMATSU, Masayuki TABUSHI and Masakazu MATSUI

(Received May 7, 1964)

The coprecipitation method has been widely used for the chemical concentration or enrichment of trace elements from such extremely dilute solutions as natural water and for the chemical separation of radioisotopes.

There are two typical distribution laws in the coprecipitation mechanism. One, called the homogeneous distribution law, has been employed by Chlopin[1] and Henderson and Kracek[2]; it is expressed as follows:

$$\left(\frac{\text{tracer}}{\text{carrier}}\right)_{\text{crystal}} = D\left(\frac{\text{tracer}}{\text{carrier}}\right)_{\text{solution}} \quad (1)$$

where D is the homogeneous distribution coefficient and is constant for a given system. It represents a state of true thermodynamic equilibrium, in which the crystal phase has been digested enough for it to reach a homogeneous concentration.

The other law, offered by Doerner and Hoskins,[3] is called the logarithmic distribution law; it is expressed as follows:

$$\log\left(\frac{\text{initial quantity}}{\text{quantity left in soln.}}\right)_{\text{tracer}} = \lambda \log\left(\frac{\text{initial quantity}}{\text{quantity left in soln.}}\right)_{\text{carrier}} \quad (2)$$

where λ is the logalithmic distribution coefficient, which is constant for a given system. This law is obeyed when the rate of precipitation is slow enough to establish a replacement equilibrium on each layer of the crystal. A crystal formed in such circumstances retains a radial concentration gradient in which the tracer component is distributed throughout in a logalithmic manner. If λ is larger than unity, the tracer component is enriched in the crystal and the concentration of the tracer component is at a maximum at the center of each crystal and decreases gradually toward the outer part of the crystal; when λ is smaller than unity, the reverse is true.

It is of interest to study the coprecipitation from a homogeneous solution, because the crystals formed are large and more perfect, and because the precipitation process is more reproducible. Feibuch, Rowly and Gordon[4] reported that the coprecipitation of pairs of rare earth oxalates from homogeneous systems obeyed the logarithmic distribution law.

Calcium oxalate is often used as a coprecipitant,[5] and Purkayastha and Bhattacharyya[6] showed that the coprecipitation of yttrium and europium with calcium oxalate also followed the logarithmic distribution law. In our previous research,[7] it was observed that the coprecipitation of scandium with calcium oxalate was influenced by the conditions of the reacting solutions; in the pH range between 2.0 and 3.5, the system followed the logarithmic distribution law, whereas with a rise in pH value, it deviated gradually from the law until it began to obey the homogeneous distribution law near pH 4. The limiting distribution coefficient,[8] the value of distribution coefficients extrapolated to zero per cent of the calcium precipitated, changed with the pH value of the reacting solutions from 1.10 at an initial pH of 4.67 to about 18 at an initial pH of 2.43.

In this research the coprecipitation of yttrium with calcium oxalate was investigated. The effects of the pH value, the tracer component to the carrier ratio, the concentration of the buffer solution and several other variables on the distribution coefficient were investigated, using yttrium-91 as a tracer.

Experimental

Apparatus and Reagents. — Radioactivity countings were made with a Phillips halogen-quenched G-M tube connected to a Metro dekatron scaler, Model D-5. A Hitachi-Horiba glass electrode pH meter, Model M-3, was used for the pH measurements.

Yttrium-91 was supplied as chloride in hydrochloric acid by The Radiochemical Centre, Amersham, England, and was diluted to make a solution of 1 μc./ml. Reagent-grade dimethyl oxalate was

purified by recrystallizing it from dry methanol and was stored in a dry atmosphere to prevent the hydrolysis upon contact with moisture. The yttrium solution was prepared by dissolving reagent-grade yttrium oxide in hydrochloric acid. Calcium solution (2 M) was prepared by dissolving dry calcium carbonate in hydrochloric acid and diluting it with water. The EDTA solution (0.01 M) containing a EDTA-Mg complex was standardized by means of a calcium standard solution.

The other chemicals were chemically pure or reagent-grade materials.

Procedure. — An aliquot of a calcium chloride stock solution and a yttrium-91 solution with an appropriate amount of inactive yttrium is placed in a 250-ml. Erlenmeyer flask. A suitable volume of 10 N acetic acid or formic acid (as a buffer solution), a 10 N sodium hydroxide solution and a known weight of dry dimethyl oxalate in distilled water are added, the resulting solution is diluted to 200 ml., and then the pH value is measured. The flask with a reflux condenser is placed in a thermostat, and the solution is stirred continuously with a mechanical stirrer to prevent supersaturation.

When the temperature of the solution rises to a certain value, 2 ml. of the solution is pipetted out into a glass-counting dish 25 mm. in diameter. After calcium begins to precipitate with the oxalate ions released from dimethyl oxalate, 2.0 ml. of the solution is pipetted out from the reacting solution through a sintered glass filter into a counting dish at appropriate intervals of time.

The yttrium-91 activity of the liquid sample in the dish is measured in order to determine the amount of yttrium in the filtrate. The solution is then washed with hydrochloric acid into a beaker, dried slowly, and ashed by fuming it with concentrated perchloric acid on a hot plate. After adding water and a buffer solution, the calcium ions are titrated with a 0.01 M EDTA standard solution containing its magnesium chelate, using Eriochrome Black T as an indicator. The homogeneous and logarithmic distribution coefficients, D and λ, are calculated from Eqs. 1 and 2.

Results and Discussion

The Effect of the pH Value on the Coprecipitation.—The percentages of yttrium coprecipitated and of calcium precipitated in the fraction of calcium oxalate at several pH values are plotted in Figs. 1 and 2.

Figures 1 and 2 show that yttrium is enriched in the precipitate in the pH range investigated, and that the extent of enrichment increases as the pH decreases. The distribution coefficients were also calculated; a few typical examples are shown in Table I. The distribution of yttrium on the calcium oxalate obeys the logarithmic distribution law; this agrees with Purkayastha and Bhattacharyya's results,[6] which were obtained in a 3 N acetate medium. As has been previously reported,[7] the pH value of the reacting solution influenced

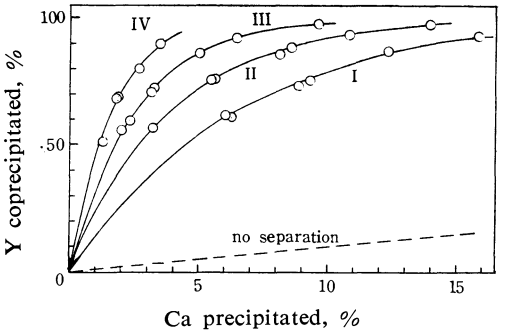

Fig. 1. Coprecipitation of yttrium with calcium oxalate in an acetate buffer solution. pH: I, 4.62; II, 4.20; III, 3.97; IV, 3.67; Y: 1.12×10^{-6} M, Ca: 0.2 M, dimethyl oxalate: 0.1 M, acetate: 1 M, temp.: 60°C. vol.: 200 ml.

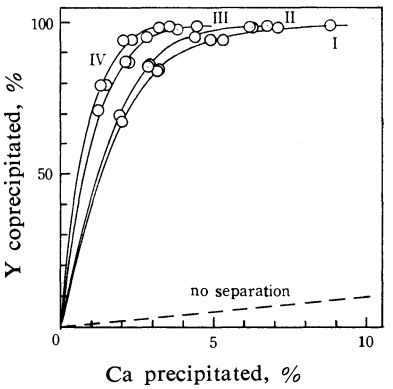

Fig. 2. Coprecipitation of yttrium on calcium oxalate in formic buffer solution. pH: I, 4.08; II, 3.42; III, 3.01; IV, 2.62; formic acid: 1 M. Others are same to in Fig. 1.

not only the distribution coefficient, but also the type of the distribution in a scandium-calcium system. In this yttrium system, however, the logalithmic distribution law is obeyed regardless of the pH value in the given range, although the coefficient increases with a decreases in the pH value.

The logarithmic distribution coefficient, λ, is plotted against the initial pH of the solution in Fig. 3. The limiting distribution coefficient of the scandium-calcium system is also shown for the sake of comparison.

There is a difference between the distribution curves obtained in acetate and in formate buffer solutions; this may be due to the property of the complex compounds of yttrium and calcium ions with acetate or formate.

The Effect of the Yttrium Concentration on the Distribution Coefficient.—The calcium oxalate was precipitated in the solutions, containing 3.37×10^{-6} M to 1.12×10^{-4} M yttrium;

TABLE I. COPRECIPITATION OF YTTRIUM WITH CALCIUM OXALATE

Ca: 0.2 M, Y: 1.12×10^{-6} M, dimethyl oxalate: 0.1 M, temp.: 60°C

Reaction time min.	Ca pptd. %	λ

195	4.45	93.4
	Average	98.7

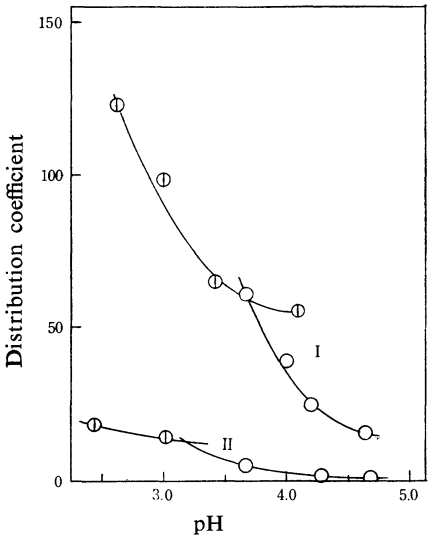

Fig. 3. The effect of pH on the distribution coefficient.
I: Y-Ca system, II: Sc-Ca system. -ⓘ-: 1 M formate solution, -○-: 1 M acetate solution.

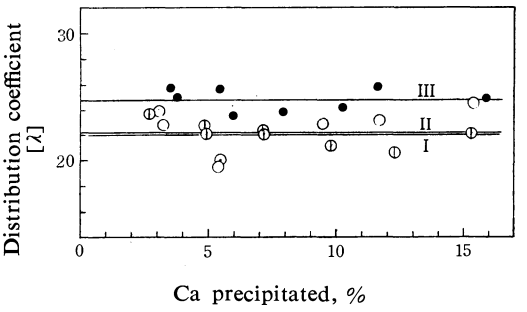

Fig. 4. The effect of yttrium concentration on distribution coefficient. pH: 4.24, I -ⓘ-: $Y=3.37\times10^{-6}$ M, $\lambda=22.0$; II -○-: $Y=3.37\times10^{-5}$ M, $\lambda=22.1$; III -●-: $Y=1.12\times10^{-4}$ M, $\lambda=24.9$.

the effect of the yttrium concentration is indicated in Fig. 4. No significant change in the logarithmic distribution coefficient is observed, and the mean value of λ is also in good agreement with the value ($\lambda=23$) as estimated from the curve in Fig. 3 (yttrium concentration: 1.12×10^{-6} M), at pH 4.23. This is in contrast with the scandium system, where the limiting distribution coefficient decreases as the concentration of the tracer component increases.

The Effect of the Rate of Precipitation.— Because the rate of precipitation depends upon the concentration of the dimethyl oxalate at a given pH, the effect of the latter was studied in order to examine the effect of the former.

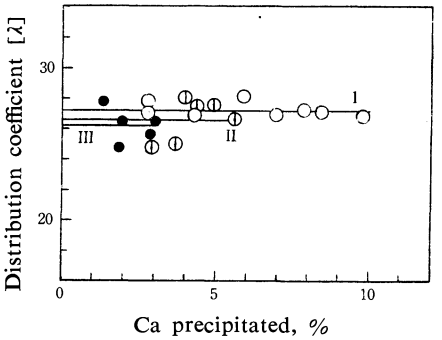

Fig. 5. The effect of the concentration of dimethyl oxalate. pH: 4.16, I -○-: 0.05 M ester, $\lambda=27.2$; II -ⓘ-: 0.02 M ester, $\lambda=26.5$; III -●-: 0.01 M ester, $\lambda=26.5$.

Figure 5 shows that the logarithmic distribution coefficient (measured at pH 4.16) is almost constant, even when the concentration of the ester changes from 0.01 M to 0.05 M, values which correspond to 1/20 and 1/4 of the stoichiometric quantity necessary to complete the precipitation of calcium ions. The value of λ obtained at pH 4.16 in Fig. 3 (ester

concentration: 0.1 M) is 26.5, which is approximately the same as the value in Fig. 5. The time required to precipitate 3 per cent of the calcium ion was about 1540, 450, 200 and 90 min. when the concentration of the dimethyl oxalate was 0.01, 0.02, 0.05 and 0.1 M respectively.

The Effect of Acetate Ion Concentration on the Coefficient.—The effect of the acetate concentration was examined with solutions containing 1.0 M, 0.5 M and 0.25 M of acetate; the results obtained at pH 4.10 are represented in Table II. The logarithmic distribution law is obeyed, but the value of the distribution coefficient is remarkably influenced by the acetate concentration. The mean values of λ were 30 at 1.0 M, 70 at 0.5 M and 186 at 0.25 M of acetate.

When the acetate concentration decreases and, consequently, the buffer action weakens, the pH-drift during the precipitation process is not negligible. However, the fact that the differences in the distribution coefficients of Experiments A, B and C are much larger than the fluctuation of data in each experiment can not be explained by such a pH-drift. It is reasonable to assume that acetate ions affect the enrichment of yttrium into the solid phase because of their complex formation.

As has been mentioned above, the distribution coefficient increases monotonically with a decrease in the pH value (see Fig. 3). One of the reasons, perhaps the major, might be also the complex formation of metal ions with acetate or formate, which dissociate more as the pH rises, although such complicated questions as the formation of a hydroxocomplex should also be taken into consideration.

It is interesting to compare the yttrium-calcium system with the scandium-calcium system. There are distinct differences between them. Firstly, in the yttrium-calcium system, the logarithmic distribution law is followed regardless of the pH in the given range, while the distribution of scandium changes gradually from logarithmic to homogeneous with an increase in the pH. Secondly, the molar ratio of the tracer component to the carrier affects the distribution coefficient in the scandium system, but not in the yttrium system. Lastly, under similar conditions yttrium gives larger distribution coefficients than does scandium.

A strict discussion is difficult, because a tervalent element coprecipitates with bivalent calcium as an oxalate and because the properties of the crystal are not clear. However, the results described above seem to show that yttrium is more stable than scandium in the calcium oxalate crystal. This may be caused by the fact that the ionic radius of bivalent calcium is nearer to that of tervalent yttrium than to that of tervalent scandium.

*Nuclear Magnetic Resonance Spectra of Polymethyl Methacrylate in Solution. I. An Attempt to make Stereoregularity Measurements**

By Yoshinori KATO and Atsuo NISHIOKA

(Received May 12, 1964)

Recent studies by Bovey et al.[1-3] of polymethyl methacrylate have demonstrated that high resolution nuclear magnetic resonance methods are applicable to the determination of the stereochemical configurations of polymer chains. The stereoregular polymerizations of methacrylic acid esters have been investigated[4,5] since 1958. The crystal structure of isotactic polymethyl methacrylate was proposed by Stroupe et al.[6] on the basis of the X-ray fiber pattern, and in order to measure the degree of stereoregularity of the polymer, an infrared spectrometer was employed by several workers.[7-10] The latter method gave a rather qualitative description of the chain structure. By the use of this method, however, we can not find out the difference between the syndiotactic and the atactic polymers. For this purpose, the nuclear magnetic resonance method would be the most powerful one, because new information about the stereochemical configuration of the polymer chains can be obtained from the spectra.

An attempt is made in this paper not only to estimate the tacticity of the polymer but also to find out the relation between the polymer and the polymerization mechanism by means of an analysis of the spectra.

Experimental

Since a detailed description of the polymerization was given by Watanabe et al.,[4,11] only a brief summary of the methods will be given here.

Free Radical Polymerization.—Each polymerization from −35°C to 0°C was carried out in a flask containing 8.0 ml. of methyl methacrylate in 20 ml. of toluene and 2.0 g. of benzoin by means of photosensitization by ultraviolet light. Dry nitrogen was introduced into the flask during the polymerization. Benzoyl peroxide (B.P.O.) was used as the initiator between 20°C and 70°C. Together with amounts of methyl methacrylate and toluene the same as those mentioned above, 0.1 g. of B.P.O. was sealed in a reaction vessel which had previously been flushed with nitrogen. Then the vessel was kept turning round in a constant temperature bath. At temperatures higher than 100°C, thermal polymerizations were employed. After an appropriate reaction time, the polymerization was stopped and the polymer products were poured into methanol. Then the precipitates were reprecipitated from an acetone solution and was dried in vacuo at about 50°C.

Polymerization Using Grignard's Reagent Catalysts.—*n*-Butylmagnesiumbromide and isobutylmagnesiumbromide were prepared as solutions in

toluene. For the former, for instance, polymerization was carried out by adding it (along with 2.54×10^{-3} mol. of bromine) to a mixture of 40 ml. of toluene and 20 ml. of methyl methacrylate at $-50°C$. A similar polymerization was made using di-*n*-butylmagnesium as a catalyst to examine the effect of the chemical components of the catalyst on the structure of the polymer. The polymerization conditions of methyl methacrylate are shown in Table I.

NMR Spectra.—The instrument employed for these measurements was a Varian Model V-4300-C spectrometer operating at 56.4 Mc./s. Spectra were taken at 20°C, using about 0.5 ml. of the solution of the polymer in ethanol-free chloroform (3% W/V). Since tetramethylsilane as an internal standard was not available, the scale of the abscissa of Fig. 1 is expressed in parts per million, with reference to the peak due to the methoxy group ($-OCH_3$). Three characteristic peaks at the right of the spectrum are assigned to α-methyl groups of the polymer. Since their relative intensities play an important role in our discussion, the spectra were exactly traced on section paper and were decomposed into three symmetrical peaks one by one, while the total area of the three peaks was kept unchanged. These trials should be repeated until a satisfactory similarity among the corresponding isolated peaks of all spectra is attained. Once a reasonable decomposition is accomplished for one spectrum, the results may be applied to another. It seems that for our spectra the values of the relative area thus obtained are more accurate than those measured with a planimeter.

Results and Representation

Some examples of the results are shown in Fig. 1. There are remarkable changes in both the $-CH_2$ and α-CH_3 regions. Especially, the relative intensities of the three peaks at the right vary with the conditions of polymerization, while their peak positions remain unchanged. As one of the authors[2,4] and other workers[1,3] have already mentioned, these changes in spectra are caused by an magnetic anisotropy effect of the ester carbonyl groups in combination with the conformation and stereochemical configuration of these polymer chains. Every monomer unit in a polymer chain of methyl methacrylate has an asymmetric carbon atom, and its placement may be designated as *d* or *l*. For the sake of convenience, they will be replaced in this paper by 0 and 1 respectively. It doesn't matter whether an arbitrary monomer unit in the polymer chain is represented by 0 (or 1). Assuming that any one of these monomer units corresponds to 0 (or 1), all the other monomer units may be classified without ambiguity. Assume two operators "$\oplus$" and "$\ominus$", similar to logical symbols, as follows:

a	b	$\oplus\{ab\}$,	$\ominus\{ab\}$
0	0	0	I
0	1	1	D_1
1	0	1	D_2
1	1	0	S

where the letters *a* and *b* represent either 0 or 1, and *ab* represents two consecutive digits formed in a binary sequence of 0's and 1's. The bottom row of this table, for instance, means that every pair of 1's (.... 1 1 ....) in the binary sequence must be replaced by 0 after the operation "$\oplus$." Therefore, a binary sequence of ten digits long (for example,

$$A=1\,1\,0\,0\,0\,1\,0\,1\,0\,0),$$

is transformed into:

$$B=\oplus\{A\}=0\,1\,0\,0\,1\,1\,1\,1\,0,$$

where A denotes the sequence A, the length of which is always reduced by one digit after the operation. In a like manner, every pair of 1's in the binary sequence must be changed to S by the operation "$\ominus$." When the above-mentioned meaning of 0 and 1 is taken into account, the binary sequence A may be recognized as a partial model of the polymer chains we are concerned with, and sequence B represents the states of the bonds of the monomer units which together construct the polymer chain. Applying operation "$\ominus$" to the sequence B yields a sequence

$$C=\ominus\{B\}=\ominus\oplus\{A\}=D_1D_2ID_1SSSD_2,$$

where D's are the units which break I- or S-sequences. We have called them "ditactic" (or di-syndiotactic) units in the meaning of the sequence A, because they themselves alone are constructed to the sequence as follows:

..... 1 1 0 0 1 1 0 0 1 1 0 0 .....

D-units as defined here are exactly the same as Bovey's h-units,[1] which were called "heterotactic configurations" (i.e., *ldd*, *dll*, *ddl*, or *lld*). It is apparent that in the sequence $\ominus \oplus \{A\}$, D_1's and D_2's appear in couples, sometimes by turns, and sometimes at both ends of I- or S-subsequences. Therefore, in an infinite sequence, both D_1 and D_2 should have the same probability of occurrence. In addition to this, it may be pointed out that even D's appear between two I- or S-subsequences, while odd D's are allowed to exist between I- and S-subsequences.

The facts that the α-methyl peak in general splits into three peaks and that the relative intensitites vary noticeably, suggest that every successive three-monomer unit in the polymer chains contributes to their peak intensities. From the viewpoint of nuclear magnetic resonance phenomena, the α-methyl group of any monomer unit is not affected very much by the other monomer units, except by the nearest neighbors on both sides. From the same point of view, we may explain that D_1- and D_2-units are essentially the same and that the α-methyl groups of polymethyl methacrylate are now classified into three species symbolized by I, D and S. It is conceivable that there exists a close relationship between these three species of α-methyl groups and the three α-methyl peaks in Fig. 1. The much useful information[4,5,12] so far obtained about the polymerization of methyl methacrylate leads to the following conclusion: The three α-methyl peaks are due to I-, D- and S-units, from left to right, respectively. The relative area of each peak is proportional to the ratio of the corresponding units to the whole polymer chain. Figure 1 shows that the left peak, ascribed to I-units, is very high in the spectrum of polymers using isobuthylmagnesiumbromide as a catalyst. On the contrary, for samples prepared with free radical initiators, the other two peaks are moderately high, and a tendency towards decreasing S-units can be observed as the polymerization temperature increases. The spectrum of the sample polymerized with di-*n*-butylmagnesium is a typical one; in it these three peaks are competitively high. It should be noticed that the D-unit of the polymer chains has been detected for the first time; no method except high resolution NMR is available at present for the direct measurement of the unit.

In order to facilitate the representation of the fractions of three units which appear in a sequence $\ominus \oplus \{A\}$, a ternary diagram as shown in Fig. 2 was employed. Any point plotted in

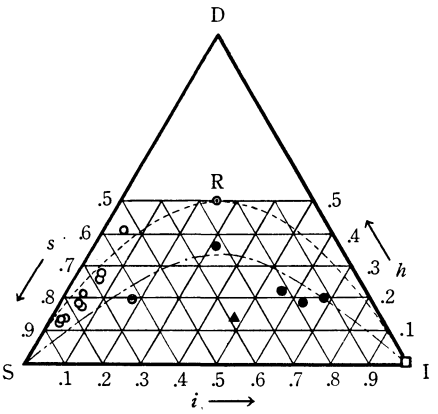

Fig. 2. Ternary diagram illustrating the stereochemical configuration of molecular chains of polymethyl methacrylate.

the ternary diagram represents only one type of stereochemical configuration of the polymer chain, because the corresponding I-, D- and S-units are always unique in their proportions. The apex at the top of the diagram is assumed to correspond to the configuration of polymer chains including only D-units; the others give, respectively, the configurations of pure isotactic and syndiotactic polymer chains in the meaning of Natta.[13] Making use of a geometrical theorem, the relation:

$$i+h+s=1 \qquad (1)$$

is valid for any point in the ternary diagram, where i, h and s represent the probabilities of finding I-, D- and S-units respectively in a sequence $\ominus \oplus \{A\}$. The dotted curve, SRI, and the point, R, will be discussed in the following section. Table II presents the results of quantitative measurements of the relative contributions due to three α-methyl peaks of the polymers prepared in various polymerization conditions. They correspond to the plots shown in Fig. 2.

For the methylene peaks of polymethyl methacrylate, a striking difference is found between the spectra of isotactic and syndiotactic polymethyl methacrylates. A quartet

13) G. Natta, *J. Polymer Sci.*, **34**, 3 (1959).

due to the methylene protons of the polymer can be observed in the former, while there is only a single, though rather broad peak in the latter. This point may be explained on the basis of the NMR spectrum of AB system.[14] Two protons of a methylene group are thought to be non-equivalent when they are just on the "0" bond in an infinite sequence, $\oplus\{A\}$. They, therefore, give rise to absorption lines which consist of a pair of doublets. In case they are on the "1" bond, they are equivalent and yield a single absorption peak. The values of the chemical shift, $(\delta_A-\delta_B)$, and the coupling constant, J_{AB}, as estimated from the spectrum of sample 11 in Fig. 1, are 37.0 c/s and 15.5 c/s respectively. These values are well in accordance with those obtained by Bovey et al.[1,3] In view of the above discussion, it is apparent that the configuration of the polymer chains can be determined in this case, not in the meaning of the sequence $\ominus\oplus\{A\}$, but in that of the sequence $\oplus\{A\}$. That is, the information about *D*-units can not be obtained, at least explicitly, by the analysis of the methylene peaks in the NMR spectrum of polymethyl methacrylate.

Polymer Characterization

In the preceding section, a short description was given of how the *D*-units behave in the sequence $\ominus\oplus\{A\}$. The sequence without a *D*-unit represents an isotactic or syndiotactic polymer chain, which is essentially the same as defined by Natta. In this case, the number of isotactic or syndiotactic sequences is only one, and its length is two units shorter than that of the original sequence, *A*; in other words, the number of the units in the sequence is less by two than that of the monomer units in the polymer chain. When any *D* is contained in the sequence, the situation is quite different. Some of the units belonging, in a sense, to the isotactic or syndiotactic part are counted this time in the sequence of *D*-units. This apparently indicates that a molecular chain in which isotactic and syndiotactic parts both exist contains one *D*-unit or more. A stereoblock polymer may be defined as one for which *h*, the proportion of *D*'s in the sequence $\ominus\oplus\{A\}$, is properly small in contrast with the large proportion of both *I*'s and *S*'s. As a general rule, the larger the proportion of *D*'s, the shorter the average length of *I*- and *S*-sequences becomes. Each average length of sequences is a characteristic measure of the polymer chain. On some assumptions in the polymerization steps, let us consider two cases:

Case 1. A Polymer with a Probability of a Specified Bond.—As was explained in the previous section, the states of bonds may be specified by two digits, "0" and "1", in the meaning of the sequence $\oplus\{A\}$. Let us assume that the probability of the occurrence of 0-digits in the sequence $\oplus\{A\}$ is designated by *p*. In terms of polymerization, it may be defined as the probability that the monomer unit at the end of a growing chain will add another monomer of the same designation, that is, of the same placement. The expected number of times that a sequence $\ominus\oplus\{A\}$ of the length *N* will contain the subsequence of *I*-units of the length *k* is given by:

$$\overline{X}_{I,k}=(N-k-1)p^{k+1}(1-p)^2+2p^{k+1}(1-p) \tag{2}$$

for $k\leqq N-1$, and

$$\overline{X}_{I,N}=p^{N+1} \tag{3}$$

which are easily derived from the calculation of the number of times that a binary sequence $\oplus\{A\}$ of the length $(N+1)$ includes consecutive 0-digits of the length $(k+1)$. Hence, the number of *I*-units in the sequence $\ominus\oplus\{A\}$ is:

$$\begin{aligned}[I] &= \sum_{k=1}^{(N+1)p-1} k\{(N-k-1)p^{k+1}(1-p)^2 \\ &\quad +2p^{k+1}(1-p)\}=p(1-p)\{(N-1)(1-p) \\ &\quad +2\}\sum_{k=1}^{(N+1)p-1} kp^k-p(1-p)^2\sum_{k=1}^{(N+1)p-1} k^2p^k\end{aligned} \tag{4}$$

The number of successive *I*-units of the length *k* included in the sequence $\ominus\oplus\{A\}$ is also given by:

$$\begin{aligned}[\{I\}] &= \sum_{k=1}^{(N+1)p-1} \{(N-k-1)p^{k+1}(1-p)^2 \\ &\quad +2p^{k+1}(1-p)\}=p(1-p)\{(N-1)(1-p) \\ &\quad +2\}\sum_{k=1}^{(N+1)p-1} p^k-p(1-p)^2\sum_{k=1}^{(N+1)p-1} kp^k\end{aligned} \tag{5}$$

When *N* is very large, Eqs. 4 and 5 are approximated as follows:

$$[I]\approx p(1-p)^2N\sum_{k=1}^{\infty} kp^k=p^2N \tag{6}$$

$$[\{I\}]\approx p(1-p)^2N\sum_{k=1}^{\infty} p^k=p^2(1-p)N \tag{7}$$

For an infinite sequence, it is necessary to take the limit of Eqs. 4 and 5. Thefore, the average length of successive *I*-units in the sequence $\ominus\oplus\{A\}$ is given by

$$\langle I\rangle=\lim_{N\to\infty}\frac{[I]}{[\{I\}]}=\frac{1}{1-p} \tag{8}$$

14) H. J. Bernstein, J. A. Pople and W. G. Schneider, *Can. J. Chem.*, 35, 65 (1957).

In like manner, results are obtained for *S*-units:

$$[S] = (1-p)^2 N \tag{9}$$

$$\langle S \rangle = 1/p \tag{10}$$

The summations, however, of even and odd *D*'s must be taken separately, since even *D*'s come into existence only between two *I*- or *S*-subsequences, while odd *D*'s come into existence between *I*- and *S*-subsequences. Thus, the number of *D*-units can be obtained straightforwardly:

$$\begin{aligned}[D] = {} & \{p^3+(1-p)^3\}\sum_{k=1}^{(N+1)p-1}\{2k(N-2k-1)p^k(1-p)^k\} \\ & +2\{p^2+(1-p)^2\}\sum_{k=1}^{(N+1)p-1}2kp^k(1-p)^k \\ & +2p(1-p)\sum_{k=1}^{(N+1)p-1}\{(2k-1)(N-2k)p^k(1-p)^k\} \\ & +2\sum_{k=1}^{(N+1)p-1}(2k-1)p^k(1-p)^k \end{aligned} \tag{11}$$

and

$$\begin{aligned}[\{D\}] = {} & \{p^3+(1-p)^3\}\sum_{k=1}^{(N+1)p-1}(N-2k-1)p^k(1-p)^k \\ & +2\{p^2+(1-p)^2\}\sum_{k=1}^{(N+1)p-1}p^k(1-p)^k \\ & +2p(1-p)\sum_{k=1}^{(N+1)p-1}\{(N-2k)p^k(1-p)^k\} \\ & +2\sum_{k=1}^{(N+1)p-1}p^k(1-p)^k \end{aligned} \tag{12}$$

where it is assumed that $p \leqq 1/2$. For $p > 1/2$, the results do not differ from Eqs. 11 and 12 except that p and $(1-p)$ replace each other. Taking the limit of the summations in Eqs. 11 and 12 gives the final results:

$$[D] \approx 2p(1-p)N \tag{13}$$

$$[\{D\}] \approx p(1-p)N \tag{14}$$

It is very interesting that the average length of successive *D*-units becomes equal to two units; that is,

$$\langle D \rangle = 2 \tag{15}$$

If we divide the number of units of each species by the total number of units in the sequence, we get the probability of the occurrence of the unit in the sequence; therefore, for this case Eqs. 6, 9 and 13 give:

$$i = p^2 \tag{16}$$

$$s = (1-p)^2 \tag{17}$$

$$h = 2p(1-p) \tag{18}$$

where i, s and h are the same probabilities that appeared in Eq. 1. Eliminating the parameter, p, from Eqs. 16 to 18, we find that

$$h/2 = \sqrt{i \cdot s} \tag{19}$$

This relationship can be seen in Fig. 2 as a dotted locus *S R I*. When the probability of making a 0-digit in a sequence $\oplus\{A\}$ is given, the structure of the sequence $\ominus \oplus \{A\}$ is always represented by one of the points just on the locus *S R I*. In terms of our experiments, this may be explained as follows. If the manner of the monomer addition, that is, the state of the bond, is specified by a single probability, p, the α-methyl groups of the polymethyl methacrylate so obtained give a spectrum which can be represented by a point on the curve *S R I*. The point "*R*" in the ternary diagram is of great interest because the value of p just equals one-half. This means that it exactly corresponds to the so-called random polymerization, and that, if the above mentioned probability is applicable, it may be considered as a special case of this model.

Case 2. The Stereoblock Polymer.—It is very difficult to put bounds to "stereoblock" polymers. According to the designation of the placements, they are composed of two kinds of blocks, such as 00000 and 111, which are formed alternately in the polymerization steps. When the lengths of these subsequences are rather too short, the polymer is no longer a stereoblock one. In all cases, however, the sequence lengths of *D*-units in the sequence $\ominus \oplus \{A\}$ should remain short. For the sake of simplicity, it is assumed that any *D*-unit appears "solo" throughout this section; two special cases, corresponding to two different mechanisms of polymerization, will be treated below.

First, we assume an infinitely long polymer chain in which isotactic and syndiotactic blocks appear "alternately" and in which the number of monomer units in the blocks varies from three to infinity. As an example, all sequences of "specified bonds" including any single 0-digit, such as

..... 1 1 1 1 0 1 1 1 .....

are excluded, since it is transformed by the operator "$\ominus$" into:

..... *I I I D D I I* .....

Then, for the *I*- and *S*-parts of the stereoblock polymer chain, it is found that

$$[\{I\}] = [\{S\}] = (i+s)N\sum_{k=1}^{\infty}\left(\frac{i}{i+s}\right)^{k}\left(\frac{s}{i+s}\right)^{2} = \frac{is}{i+s}N \tag{20}$$

for the very large integer, N, which equals the number of monomer units contained in the polymer chain. The other notations in Eq. 20 are exactly the same as those mentioned in the preceding section. By using the relation:

$$[\{I\}] + [\{S\}] = [\{D\}] \tag{21}$$

which holds for infinite sequences, the number of subsequences of D-units is given by:

$$[\{D\}] = \frac{2}{1/i + 1/s}N \tag{22}$$

which leads to:

$$h = \frac{2}{1/i+1/s} \tag{23}$$

since it is assumed that $[D] = [\{D\}] = hN$. $\langle I\rangle$ and $\langle S\rangle$ in this case can be represented by i, h and s:

$$\langle I\rangle = 2i/h \tag{24}$$

$$\langle S\rangle = 2s/h \tag{25}$$

The chain curve plotted in Fig. 2 exhibits the relation among i, h and s given by Eq. 23. If we accept the above model, this curve represents the spectra of the α-methyl groups of the methyl methacrylate polymer chains which would be formed in a manner that alternations from an isotactic chain growth to a syndiotactic one and vice versa occur quite at random.

In the second place, let us discuss the polymer chain designated by the following sequence:

$$\overbrace{\text{..... } D\,I\,I \text{ ..... } I\,I}^{\langle I\rangle}\ D\ \overbrace{S\,S \text{ ..... } S}^{\langle S\rangle}\,D \text{ .....}$$

in which isotactic blocks of length $\langle I\rangle$ and syndiotactic blocks of length $\langle S\rangle$ are formed alternately, leaving single D-units at every change. Then, we have

$$i = \langle I\rangle/(\langle I\rangle + \langle S\rangle + 2) \tag{26}$$

$$s = \langle S\rangle/(\langle I\rangle + \langle S\rangle + 2) \tag{27}$$

$$h = 2/(\langle I\rangle + \langle S\rangle + 2) \tag{28}$$

and Eqs. 24 and 25 again hold. In this case, if the values of $\langle I\rangle$ and $\langle S\rangle$ are given, Eqs. 26 to 28 correspond to the definite plot in the ternary diagram.

Discussion

We have now reached the point where we can discuss the relation between our models and the experimental results.

If a polymerization of methyl methacrylate occurs quite at random in the meaning of stereochemical placements of the monomer units, the polymers so obtained give the spectrum of α-methyl groups which may be represented by the point R in Fig. 2. All the experimental results, however, are scattered far from the point. This apparently indicates that the random polymerization in the strict sense can not be achieved, even if a free radical polymerization at a high temperature is employed. We may also conclude from Fig. 2 that essentially different mechanisms of polymerization give polymers of different structures. For polymers prepared with free radical initiators, the model described in the previous section (see Case 1) seems to be applicable. The probability, p, can be calculated by Eq. 17; the results are shown in Table II. It is conceivable that p depends almost entirely upon the polymerization temperature of the sample.

Table II. Characteristic parameters of free radical polymethyl methacrylate as a function of the polymerization temperature

Sample No.	Proportion of α-methyl peak area			p	$\langle I\rangle$	$\langle S\rangle$*
	i	h	s			
1	0.02	0.13	0.85	0.08	1.1	14.1
2	0.02	0.14	0.84	0.08	1.1	13.0
3	0.03	0.14	0.83	0.09	1.1	12.9
4	0.05	0.18	0.77	0.12	1.1	9.6
5	0.04	0.19	0.77	0.12	1.1	9.1
6	0.04	0.21	0.75	0.13	1.1	8.1
7	0.06	0.26	0.68	0.18	1.2	6.2
8	0.05	0.28	0.67	0.18	1.2	5.8
9	0.05	0.41	0.54	0.27	1.4	3.6

* Calculated from Eq. 34.

According to the procedure of Fordham,[15] the probability, p, may be written in the form:

$$p = \frac{k_i}{k_i + k_s} \tag{29}$$

where k_i and k_s are the rate constants for the addition of monomer units to the chain to form isotactic and syndiotactic placements respectively. We have, then,

$$\frac{k_i}{k_s} = \frac{p}{1-p} = \exp\{\Delta(\Delta S)/R\}\exp\{-\Delta(\Delta H)/RT\} \tag{30}$$

where $\Delta(\Delta S) = \Delta S_i - \Delta S_s$ and where $\Delta(\Delta H) = \Delta H_i - \Delta H_s$, which are the differences in activation entropies and in activation enthalpies

15) J. W. L. Fordham, *J. Polymer Sci.*, **39**, 321 (1959).

respectively between an isotactic placement and a syndiotactic one. Equation 30 shows that the logarithm of $p/(1-p)$ is linear in reciprocal temperature and that the values of $\Delta(\Delta H)$ and $\Delta(\Delta S)$ can be found from the slope and the intercept at $1/T=0$ respectively. In Fig. 3 are plotted the results from which we obtain:[11]

$$\Delta(\Delta H) = (1.58\pm0.07)\,\text{kcal.}$$

and $\Delta(\Delta S) = (0.67\pm0.24)$ e. u.

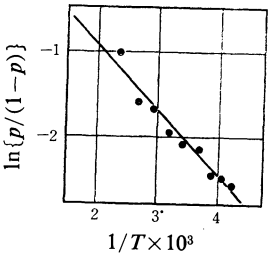

Fig. 3. $\ln\{p/(1-p)\}$ vs. $1/T$ for polymethyl methacrylate prepared in free radical polymerization.

These results are considerably larger than those obtained by other workers.[16,17] Substituting these values into Eq. 30, we find

$$\frac{k_i}{k_s} = 1.95\exp(-1580/\boldsymbol{RT}) \tag{31}$$

so that from Eqs. 17 and 29, the proportion of S-units will be:

$$s = \left\{\frac{1}{1+1.95\exp(-1580/\boldsymbol{RT})}\right\}^2 \tag{32}$$

Since the melting point of toluene is −95°C, Eq. 32 shows that the proportion of S-units attainable in practice in the polymer chain is less than 95 per cent. On the other hand, the random polymerization could be obtained, if it were possible, at about 1000°C. As a matter of fact, however, the polymerization would occur only below the ceiling-temperature[18] of the system.

Even the polymer made at room temperature contains fairly long sequences of S-units. The average sequence lengths of I- and S-units can be calculated from the equations given below:

$$\langle I\rangle = 1+h/2s \tag{33}$$

$$\langle S\rangle = 1+2s/h \tag{34}$$

The results are shown in Table II.

As we have seen in Fig. 2, the mechanism of anionic polymerization can not be explained by the model used for free radical polymerization. Let us now consider the applicability of the two models developed in the previous section for the stereoblock polymer. Of course, there are a few points to be clarified beforehand. First, it is very difficult to define the term "stereoblock" exactly, but no further discussion is needed here. Secondly, the polymer prepared with an anionic initiator might consist of molecular chains formed in several polymerization mechanisms, which could each perhaps be described in the same manner as the free radical polymers. The observations, however, on the difference in activation energies between isotactic and syndiotactic placements of a monomer-unit would not seem to support this assumption. The distribution range in the ternary diagram is too narrow to cover the cases of anionic polymerization. In case a sample is a mixture of polymer chains of different tacticities, its apparent i, h and s values can be calculated from these values of the componenents. In terms of the ternary diagram, this may be explained as follows. Just on each point of the ternary diagram we assume a material particle of the same mass as the corresponding component. Then, the overall structure of the sample can be represented by the center of gravity for the system of these material particles. It seems, therefore, impossible to deduce the plots for anionic polymerization products from the experimental results for free radical polymers.

As has been mentioned earlier, two models developed in the previous section for stereoblock polymers are special ones, because of their assumption that $\langle D\rangle=1$. One is a random-sequence-length model for its I- and S-parts, while the other is a constant-sequence-length model. The former is represented by the chain curve in Fig. 4. Some of the experimental results seem to satisfy Eq. 23 approximately when Bovey's data[1] are taken into account. One of our plots, however, deviates considerably from the curve. This may be partly due to the separation of three

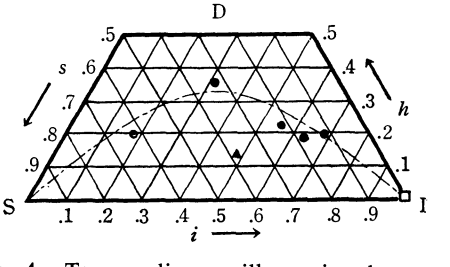

Fig. 4. Ternary diagram illustrating the stereochemical configuration of methyl methacrylate polymers prepared with anionic initiators: sample 10 ◓, sample 11 □, and sample 12 ▲, Bovey's data ●.

rather poorly resolved α-methyl peaks, since it is attended with a little difficulty. Mainly, however, it seems to arise from the fact that the mechanism of polymerization is more complicated.

For the latter model, the avrerage sequence lenghths $\langle I \rangle$ and $\langle S \rangle$ are introduced as the parameters, but as yet we have not sufficient information to evaluate them. Using the values of samples 10 and 12, we obtain $\langle I \rangle = 1.8$ and $\langle S \rangle = 6.2$ for the former and $\langle I \rangle = 7.5$ and $\langle S \rangle = 5.8$ for the latter. We might say that the steric hindrance for each stereochemical configuration of molecular chains would be one of the origins that make blocks of a constant length. It seems, however, rather improbable that such a long and constant sequence length as calculated above could be ascribed to this origin. On the contrary, it seems possible that in anionic polymerizations the behavior of metallic counterions brings us stereoblock polymers.[1] One example is that a metallic counterion contributes to the isotactic chain growth for a certain period, and then leaves from the chain end for the following period, allowing the syndiotactic chain growth. Alternation between these two states yields a stereoblock polymer chain, but this case would preferably be included in our former model. In actual fact, the mechanism of anionic polymerization is beyond our depth because of its complexity.

In the course of the decomposition of spectra, we found that, at room temperature, the *I* part of methyl methacrylate polymer chains gives a somewhat narrower resonance peak of α-methyl groups than that ascribed to the *S* part. Recently, at a higher temperature, we have observed the inversion of apparent peak heights between *I*- and *S*-peaks in some of the stereoblock polymers. This probably corresponds to the remarkable difference in glass temperature between isotactic and syndiotactic polymethyl methacrylates.[7] The detailed investigation of these problems must be the subject of future research.

Summary

The NMR spectra of polymethyl methacrylates prepared with various initiators have been examined. Three resonance peaks of α-methyl protons observed with an increasing magnetic field correspond to three species of the monomer units, i. e., *I*-, *D*- and *S*-units respectively. The proportion of each peak area may be used to characterize the stereoregularity of the polymer chain. A ternary diagram has been proposed to represent the stereochemical configuration of the polymers. Together with the average sequence lengths of the units, the possible polymerization mechanisms are considered. Free radical polymers of methyl methacrylate seem to be describable with a single parameter which depends only on the polymerization temperature. Some polymers prepared with anionic initiators show a stereoblock character. The polymerization mechanism has also been discussed in some idealized cases.

We are grateful to Dr. Haruaki Watanabe for materials used in this work and for many helpful suggestions. We are also much indebted to Dr. Akibumi Danno of the Japan Atomic Energy Research Institute for permitting us to use the NMR spectrometer.

Proton Magnetic Resonance Spectra of Polypropylene in Solution

By Yoshinori KATO and Atsuo NISHIOKA

(Received June 1, 1964)

During recent years, high resolution nuclear magnetic resonance spectroscopy has been applied to the study of polymers. In some cases, however, the polymer is not fully soluble to the required concentration, so that a well-resolved spectrum can not be obtained. When we use this method, there are a few restrictions on both the polymer and the solvent. First of all, a polymer solution of an appropriate concentration, say at least five per cent or so, is necessary for a detailed analysis of the NMR spectrum. On the other hand, the resonance peaks due to the solvent itself should not disturb those of the polymer.

In the case of ordinary polypropylene, the molecular weight is so high that we can scarcely obtain a well-resolved spectrum even at elevated temperatures. We have applied, therefore, a "weak" controlled thermal degradation to polypropylene in order to reduce the molecular weight and increase the solubility. The thermal degradation employed was so weak that it did not give rise to any significant change in the infrared absorption spectrum of the sample. By making use of this technique, an attempt is made in this paper to measure the degree of stereoregularity of polypropylene. A further object of the work is to study a saturated polymer with small difference in chemical shift.

So far as we know, few investigations[1-3] using high resolution NMR spectrometers have been made of polypropylene. This probably arises from the complexity of the spectrum because of the small difference in chemical shift. Very recently, a spin decoupling technique has been successfully employed to observe the stereochemical configurations of the molecular chains of some polymers.[4,5] This technique, as well as the use of partially-deuterated polymers, will be an effective means to overcome the complexity of the spectrum.

Experimental

Several kinds of commercial polypropylene were used in this work. The limiting viscosity numbers of the original samples, $[\eta]$, are shown in Table I.

TABLE I. LIMITING VISCOSITY NUMBER AND DENSITY OF ORIGINAL SAMPLE

Original sample	$[\eta]$*	Density
A	1.28	0.9126
B	1.71	0.9095
C-1	1.35	0.9080
C-2	1.52	

* Obtained at 135°C in tetraline.

For the sample, C-2 NMR measurements were carried out without any preliminary treatment. The other samples were first extracted with boiling *n*-heptane. The solvent had been renewed every three hours until no precipitate could be seen when it was poured into methanol. Then, the residue was separated by filtration and dried at 60°C in a vacuum. This was used as the sample termed "*n*-heptane-insoluble" in Table II. On the other hand, the extracted polymers were precipitated in a large amount of methanol; after filtration, they were dried in vacuo at 40°C. Then they were extracted with ether to give the *n*-heptane-extracted and the ether-soluble samples in the table. The acetone-extracted sample (sample 10) was obtained from an atactic polypropylene (C-3) by extraction with boiling acetone; again the residue was extracted with ether to prepare the ether-extracted sample (sample 2). The thermal degradation of the samples was carried out in vacuo. The conditions are shown in Table II. For samples 3, 5, 7 and 9 the processes of extraction were omitted and the thermal degradation technique immediately employed, while for samples 1, 2 and 10 only the former processes were employed. Finally, the other samples were obtained by thermal degradation of the residues remaining after the extraction with *n*-heptane.

All spectra were obtained with a Varian DP-60 spectrometer at about 140°C, except for the spectrum of the polypropene-1,1-d_2 sample. For this sample a nuclear magnetic resonance spectrometer, Mullard SL44 Mk. II, operating at 40 Mc/s was employed. Each 10% sample in *o*-dichlorobenzene was sealed in a glass tube together with a 0.2% antioxidant and 0.4% tetramethylsilane as internal standards. The peak positions were determined by using the sideband technique and were expressed by "the τ-scale."[6]

* An atactic polypropylene.

Results and Discussion

The Study of Each Spectrum.—Typical spectra are shown in Fig. 1, except for that of sample 1, from which we could not obtain well-resolved spectrum by any means.

Several points of interest have come to light during the course of the measurements. First, the spectrum of sample 10 is somewhat different from those of the others, and it doesn't change in the temperature range 23~140°C. Contrary to our result, the corresponding spectrum given by Satoh et al.[1] (their sample 2) exhibits a prominent peak at 8.75 τ. This is probably due to the fact that their sample was polymerized by a Ziegler-type catalyst, while ours were not. That is, the peak at 8.75 τ may be ascribed to some *n*-paraffins or polyethylenes. This fact may be of interest, but it will not be gone into further here. Secondly, the difference between the spectrum of sample 2 and that of sample 8 has attracted our great interest. Especially, the remarkable change in the middle region of the spectra seems to suggest the possibility of the stereoregularity measurement of the polymer chains. According to Natta, the ether soluble sample consists of molecular chains with an atactic configuration. Therefore, the spectrum of sample 2 shown in Fig. 1 may be decomposed into two parts, one isotactic and one syndiotactic. On the other hand, the *n*-heptane-insoluble fraction contains mainly isotactic molecular chains. Therefore, the spectrum of sample 8 must be very similar to that of a purely isotactic polymer. This point will be discussed in detail later.

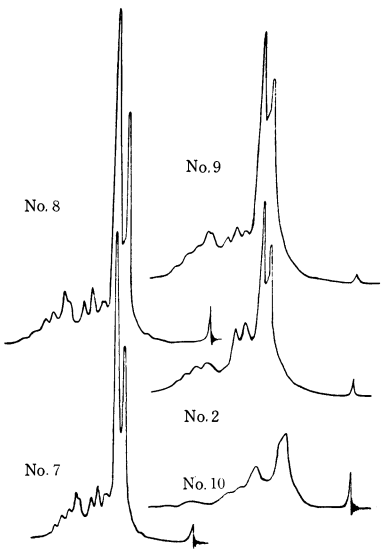

Fig. 1. NMR spectra of the samples shown in Table II.

The physical properties of each sample after the preliminary treatments are also given in Table II. A comparison of the spectra in Fig. 1 leads to the conclusion that the solubility of polypropylene roughly depends on the value of $[\eta]$. However, in the case of sample 9, a rather well-resolved spectrum was obtained regardless of the large value of $[\eta]$. This result is probably due to the fact that the sample consists of molecular chains with less isotactic configurations. As was mentioned in the previous section, the extraction procedure always preceded the thermal degradation when both were needed. In contrast, when the thermal degradation was carried out before the extraction, all the *n*-heptane-insoluble samples gave poorly-resolved spectra, though their final values of $[\eta]$ were much the same as those of the samples shown in Table II. This implies that the extraction procedure depends on both the stereoregularity of the polymer chains and the molecular weight distribution. At the present stage, it seems difficult to foretell which thermal degradation

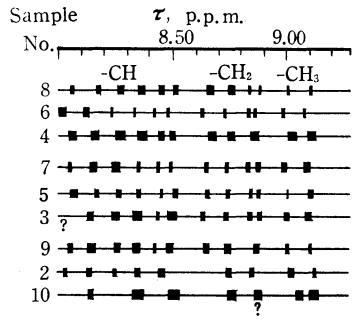

Fig. 2. Values of chemical shift for the samples given in Table II.

—— Isotactic P. Pr.
--- Atactic P. Pr.

condition is adequate to a certain polypropylene. In any case, however, the thermal degradation must be carried out as mildly as possible.

Figure 2 shows the values of the chemical shift for each sample. We can not find out any difference among the samples separated from various brands of polypropylene except for that between samples 2 and 10. The resonance peaks between 8.95 τ and 9.15 τ are ascribed to the methyl groups. It is found that the methyl resonance of atactic polypropylene shows a slight shift towards a higher magnetic field than that of isotactic polypropylene. Unfortunately, however, the shift is not large enough to be employed for the stereoregularity measurements. Very recently, this small shift has been independently confirmed more accurately by Nukada et al.[3]

Normalized spectra of atactic and isotactic polypropylenes, i. e., samples 2 and 8, are shown in Fig. 3. Vertical solid and broken lines separate the whole area of each spectrum into three parts in the ratio of 1 : 2 : 3 from left to right. These three parts roughly correspond to the α-proton, methylene and methyl resonances respectively. As we have already pointed out, the central parts corresponding to the methylene resonance are markedly different from each other. Especially, the resonance region of the methylene groups in the isotactic part of the polymer chains seems to be much broader than that in the syndiotactic part. We can not observe any noticeable change in any α-proton resonance region.

Now, let us assume that the ideal spectrum of either isotactic or syndiotactic polypropylene is available, and that the stereochemical configuration of the polymer chain is homogeneous; all the observed spectra can then be separated straightforwardly into isotactic and syndiotactic components, so that the degree of stereoregularity of each sample may be determined. The homogeneity of the configuration will be realized to a considerable extent by the extraction of the sample with a suitable solvent. Thus, not only the preparation of an absolutely isotactic polymer but also a theoretical approach to the ideal spectrum is a matter of importance for the measurement of stereoregularity. It is known that isotactic polypropylene can be easily obtained as the residue of extraction with *n*-heptane from the commercial sample, whereas it is rather difficult to obtain syndiotactic polypropylene. However, even the former will not give the ideal spectrum in the strict sense. We believe that the analysis of spectra is the shortest way at present to obtain the ideal spectrum.

For the sake of convenience, we have introduced the following value, X, as a measure of the stereoregularity of the polymer chain:[7]

$$X=\frac{\left(\begin{array}{c}\text{Relative intensity of}\\ \text{the peak at } 8.87\,\tau\end{array}\right)}{\left(\begin{array}{c}\text{Average relative intensity of}\\ \text{the peaks at } 9.0\,\tau \text{ and } 9.1\,\tau\end{array}\right)}$$

At first, we used apparent peak heights instead of the peak areas to evaluate the X-value; we found that the X-value varies from 0.15 to 0.50 in accordance with the stereochemical configuration of the polymer chain. On such occasions, however, not the peak height but the peak area should be used if possible. Therefore, our next problem was to separate each peak in order to measure the relative area. In case the spectrum is not so well resolved, it is very important to have some knowledge concerning the relative intensities of the peaks as well as the peak positions of the ideal spectrum. Therefore, we shall try to calculate the theoretical spectra due to the methylene groups of polypropylene.

7) Y. Kato and A. Nishioka, paper presented at the 3rd Symposium on Nuclear Magnetic Resonance Spectroscopy, Osaka, November, 1963.

ABC_2 and A_2B_2 Spectra. — In some vinyl polymers, the "backbone" methylene protons will approximately give rise to the NMR spectra of the ABC_2 (or A_2B_2) system in the notation of Bernstein et al.[8] Let us assume that the electron-coupled spin-spin nuclear magnetic interaction between any two hydrogen nuclei can be disregarded if more than two carbon-carbon bonds separate the nuclei. For the sake of simplicity, we will consider first a molecular chain with a planar zigzag conformation. Then, together with the neighboring α-protons, the metylene protons in the isotactic part can be regarded as an ABC_2 spin system, where the α-protons refer to C_2, while in the syndiotactic part they all together constitute a A_2B_2 spin system, where the methylene protons refer to A_2. This is the case with polypropylene if the spin-spin coupling constants between the methylene and the methyl protons are very small. For isotactic polypropylene the individual polymer molecules assume "gauche" rather than "trans" configurations and are, therefore, frozen in helical conformations, that is, the three-monomers one-turn helix. If the helical conformation is preserved even in the solution, the methylene resonance would be expected to give an A_2B_2 spectrum, contrary to the case of a planar zigzag conformation.

The basic functions and the complete matrix for the A_2B_2 spin system have been given by Pople et al.[9] In this system there are two electronic screening constants, σ_A and σ_B, together with four different spin coupling constants, J_{AA}, J_{AB}, J'_{AB}, J_{BB}. The chemical shift difference, δ_{AB}, is given by $\sigma_A-\sigma_B$.

By evaluation of the matrix elements one finds that the secular determinant factors into one 4×4, five 2×2, and two 1×1 submatrices. A total of twenty-eight transitions have to be considered in this case.

Next, the complete set of wave functions and all the elements of the matrix of the spin Hamiltonian for the ABC_2 system have been written by Cohen et al.[10] However, their analysis has been applied only to the ABX_2 case, where the resonance of the nucleus C is well removed from those of the A and B nuclei. In general, the ABC_2 spin system involves seven different constants, σ_A, σ_B and σ_C, and J_1, J_2, J_3 and J_4. However, because of disregarding all the spin-spin coupling constants between any two α-protons, the parameter J_4 vanishes in the present case, as is shown in Fig. 4.

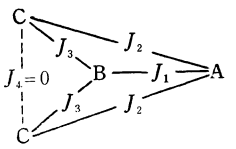

Fig. 4. Spin-spin coupling constants for the ABC_2 case, where $J_4=0$.

For this case the Hamiltonian operator is:

$$\mathscr{H} = \mathscr{H}^{(0)} + \mathscr{H}^{(1)} \quad (1)$$

Where:

$$\mathscr{H}^{(0)} = -\nu_A I_Z(A) - \nu_B I_Z(B) - \nu_C\{I_Z(C_1) + I_Z(C_2)\} \quad (2)$$

$$\mathscr{H}^{(1)} = J_1\boldsymbol{I}(A)\cdot\boldsymbol{I}(B) + J_2\boldsymbol{I}(A)\cdot\boldsymbol{I}(C_1) + J_2\boldsymbol{I}(A)\cdot\boldsymbol{I}(C_2) + J_3\boldsymbol{I}(B)\cdot\boldsymbol{I}(C_1) + J_3\boldsymbol{I}(B)\cdot\boldsymbol{I}(C_2) \quad (3)$$

where:

$\nu_1=\eta H_0(1-\sigma_1)$

H_0 is the external magnetic field,

η is a constant which converts magnetic units to energy units in cycles per second (c/s),

$\boldsymbol{I}$ is the nuclear spin vector, and

I_z is the Z component of the vector $\boldsymbol{I}$.

Adopting the notation of Pople et al.,[9] the complete set of basic functions and the matrix elements of the spin Hamiltonian is given in Table III. The diagonalization of the Hamiltonian involves the solution of one 4×4 matrix and two 3×3 matrices. In such a case, the numerical method must be used. In addition, the trial-and-error fitting procedure is so tedious that all the calculations were carried out with a digital computer, Musashino-1-β. Therefore, Tables III, IV and V are arranged so as to draw up a program for the electronic digital computer immediately. Table V lists both the resonance frequencies and the relative peak intensities; transitions are allowed only between the eigenfunctions of the same symmetry and with total spins differing by 1 from each other. Accordingly, thirty-four transitions in all are allowed in the ABC_2 case. Following Bernstein et al.,[8] each transition may be labeled as an A, B or C transition according to the change in spin, giving rise to the resonance line when the chemical shifts are much greater than the spin-spin coupling constants. When all the species of nuclei change their spin simultaneously, the line is labeled as a combination line.

Calculated Spectra.—The spectrum of syndiotactic polypropylene has been calculated by

E_{15}	a_{-1}	$a_{15,15}\Psi_{15}$

Satoh et al.[1] In this work we will calculate the spectrum due to methylene protons present mainly in the isotactic part of the polymer chains. However, it is assumed that the spectra can be analyzed in terms of the ABC_2 spin system.

Fortunately, while this calculation was being carried out, it was kindly pointed out to the authors by Mr. Yoshihito Komatsu that the NMR spectra of polypropene-2-d_1 and polypropene-2, 3, 3, 3,-d_4 had been examined by Stehling.[2] According to the results, the spectra of polypropene-2-d_1 samples are quite analogous to those of polypropene-2, 3, 3, 3-d_4 samples, except that an additional peak due to the methyl protons can be observed. Though the methyl groups in the isotactic part of the polymer chains are not equivalent to those in the syndiotactic part, both of them give rise to the same unresolved resonance peak. This probably proves that the spin-spin coupling constant between methylene and methyl protons of polypropylene is fairly small. Therefore, we can neglect it as an approximation to reduce the complicated spectrum due to the methylene protons to the ABC_2 or A_2B_2 case.

By means of an electronic computer, attempts were made to find some sets of the chemical shifts and the spin-spin coupling constants which fit the frequencies of the observed lines. In practice, three resonance peaks at 8.65 τ, 8.75 τ and 8.87 τ were used in order to judge whether or not the set of δ and J parameters fits the resonance frequencies of the observed

peaks. In the judgment a tolerence of ± 2 c/s was taken into account. We assumed in the first place that $\nu_A-\nu_C=40.5$ c/s, and that $\nu_B-\nu_C=13.5$ c/s, and we tried to obtain some sets of the other parameters which approximately fit the resonance positions. From the study of a series of acetylated sugars, it has been established by Lemieux et al.[11] that the spin-spin coupling constant for a pair of axial hydrogens on adjacent carbon atoms is in the 5~8 c/s range, that that for pairs of equatorial hydrogens is 3~4 c/s, and that that for axial and equatorial hydrogens is 2~3 c/s. Therefore, the parameters J_2 and J_3 were chosen within the range from -10 to $+10$ c/s. Since the simultaneous change of all signs of the spin-spin coupling constants does not affect the spectrum, the sign of J_1 was arbitrarily chosen as positive in each case. The absolute value of J_1 was varied progressively by 0.5 c/s within the 12~14 c/s.

The parameter J_1 was taken to be $+13.5$ c/s. The applicability of this value has also been confirmed by the spectra of polypropene-

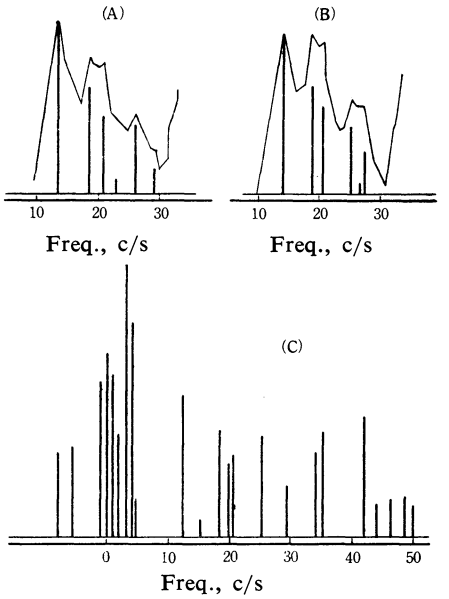

Fig. 5. ABC_2 spectra calculated with the sets of parameters; $\nu_A-\nu_C=40.5$ c/s, $\nu_B-\nu_C=13.5$ c/s, $J_1=13.5$ c/s and (A) $J_2=2.0$ c/s, $J_3=-7.0$ c/s; (B) $J_2=-3.0$ c/s, $J_3=-6.0$ c/s and (C) $J_2=-7.0$ c/s, $J_3=8.0$ c/s.

11) R. V. Lemieux, R. K. Kullnig, H. J. Bernstein and W. G. Schneider, *J. Am. Chem. Soc.*, **80**, 2237 (1958).

2, 3, 3, 3-d_4 obtained by Stehling. The two non-equivalent methylene protons give a typical spectrum of the AB system, and the value of J observed from the spectrum has been reported to be about 13.2 c/s.[2)]

For all the sets of parameters which fit the observed line positions, we calculated the peak intensities in order to compare them with the observed resonance peaks. It was found that only three sets fit the observed peaks moderately well. They are shown in Fig. 5. From the appearance of the above-mentioned three resonance peaks, especially that of the central one, we may conclude that the best fit at this stage is this set of parameters:

$$\nu_A-\nu_C=40.5 \text{ c/s}$$
$$\nu_B-\nu_C=13.5 \text{ c/s}$$
$$J_1=13.5 \text{ c/s}$$
$$J_2=-7.0 \text{ c/s}$$
$$J_3=8.0 \text{ c/s}$$

Furthermore, the electronic computer was used to revise the set of parameters so as to find a best fit. The revised parameters were:

$$\nu_A-\nu_C=39.0 \text{ c/s}$$
$$\nu_B-\nu_C=14.0 \text{ c/s}$$
$$J_1=13.5 \text{ c/s}$$
$$J_2=-6.0 \text{ c/s}$$
$$J_3=7.5 \text{ c/s}$$

From these values it may be concluded that the conformation of isotactic polypropylene in solution is somewhat different from that of the solid, that is, the helical conformation.

Further revision seems to be of little avail so long as we consider only the above-mentioned three peaks, because they are rather poorly resolved. Therefore, the information concerning the positions and intensities involves a slight ambiguity. The calculated spectrum for this set of parameters is illustrated in Fig. 6, where each resonance line in the central part has been replaced by an isosceles triangle with the same height as the line and a 4 c/s half-height peak width. By synthesizing the triangles, the theoretical spectrum for the methylene protons can be obtained. It should be noticed that resonance region of the methylene protons contained in isotactic polypropylene is very wide. Accordingly, great care must be taken in the analysis of the spectrum.

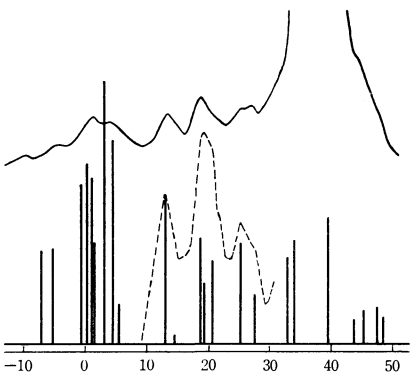

Fig. 6. Comparison between the experimental and the theoretical spectra of polypropylene. The parameters of the calculated spectrum are $\nu_A-\nu_C=39.0$ c/s, $\nu_B-\nu_C=14.0$ c/s, $J_1=13.5$ c/s, $J_2=-6.0$ c/s and $J_3=7.5$ c/s.

The Analysis of Observed Spectra. — In the preceding section, the theoretical spectrum of methylene protons in isotactic polypropylene was obtained. When the total intensity (or area) of the spectrum is normalized to unity, the relative intensities of the three resonance peaks at 8.65 τ, 8.75 τ and 8.87 τ are 0.0426, 0.0733 and 0.0437 respectively. For the sake of convenience, let us denote these three resonance peaks as A-, B- and C-peaks respectively. Both the B- and C-peaks contain more than two calculated resonance lines, whereas the A-peak has only one effective peak. Each one of the resonance lines contained in B- and C-peaks can be assigned as a combination line. This information is very important for decomposing each peak in the observed spectra as a means of measuring the degree of stereoregularity of the polymer chain.

As has already been explained, syndiotactic polypropylene gives rise to the resonance peaks due to the methylene groups, which can be interpreted in terms of a A_2B_2 spin system. Therefore, with the following constants:

$$\delta_{AB}=27.0 \text{ c/s}$$
$$J_{AA}=13.5 \text{ c/s}$$
$$J_{AB}=8.0 \text{ c/s}$$
$$J'_{AB}=6.0 \text{ c/s}$$
$$J_{BB}=0 \text{ c/s}$$

the spectrum of the methylene protons has been calculated. The result is shown in Fig. 7. In this case, however, the observed spectrum is very simple, as one can easily imagine from the spectrum of atactic polypropylene (sample 2). Hence, only two very similar resonance peaks due to the methylene protons will be available for revising the set of parameters. Therefore, there remain some ambiguities in the theoretical spectrum of syndiotactic polypropylene. However, it is a striking feature of the spectrum that no resonance peak can be observed in the vicinity of 8.65 τ. On this basis the degree

TABLE VI. ANALYSIS OF OBSERVED SPECTRA[a)]

Sample No.	Obsered peak intensity		Isotactic component			Estimated syndiotactic fraction at B and C peaks
	A	B+C	x[b)]	x'[c)]	x''[d)]	
2	0.020_9	0.22_0	0.49	0.46	0.38	0.31
5	0.036_4	0.13_4	0.85	0.91	0.90	0.21
7	0.038_0	0.12_6	0.89	0.96	0.95	0.18
8	0.040_2	0.12_4	0.94	0.97	0.96	0.19

a) The whole area is normalized.
b) Calculated from the fraction of A-peak.
c) Based on the assumption that the (B+C) fraction of the ideal spectrum of syndiotactic polypropylene equals 0.30_7.
d) Based on the spectrum shown in Fig. 7.

of stereoregularity of any given sample can be estimated if an well-resolved NMR spectrum is available. From the fraction of the A-peak in each spectrum, we calculated the proportion of the isotactic component, x, for the several samples given in Table II. Then, by using the sum of the fractions of the B- and C-peaks, the proportion of the syndiotactic component at the peak positions was estimated. The results are given in Table VI. The resolution of the spectrum of sample 9 was so poor that the estimation was not made. The values of x calculated above probably include some errors because it is difficult to separate a small A-peak. Therefore, we assumed that the fraction of the syndiotactic component at the B- and C-peak positions equals 0.30_7, which can be obtained from the results concerning sample 2 in Table VI. Then we calculated again the proportion of the isotactic component, x'. The results are listed in the next column of x in Table VI.

Finally, the spectrum of polypropene-1, 1-d_2 was obtained at 40 Mc/s. The results shown in Fig. 8 show a poorly-resolved spectrum because of the high molecular weight of the sample. However, a set of parameters:

$$\delta_{AB}=27.0\ \text{c/s}$$
$$J_{AB}=6.0\ \text{c/s}$$

for the AB_3 spin system fits the contour of the observed spectrum very well. Converting these parameters to the case of 60 Mc/s, it seems obvious that no overlap will be observed between the α-proton resonances of polypropylene and the methylene proton ones, except for the 8.40~8.55 τ region.

From Figs. 5, 6 and 7 the theoretical X-value for isotactic polypropylene has been found to be $X_I=0.13_7$, and that for syndiotactic polypropylene, $X_S=0.55$.

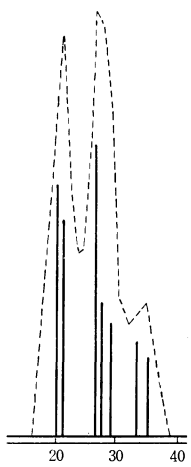

Fig. 7. The A_2 part of A_2B_2 type spectra with the parameters: $\delta_{AB}=27.0$ c/s, $J_{AB}=6.0$ c/s and $J'_{AB}=8.0$ c/s.

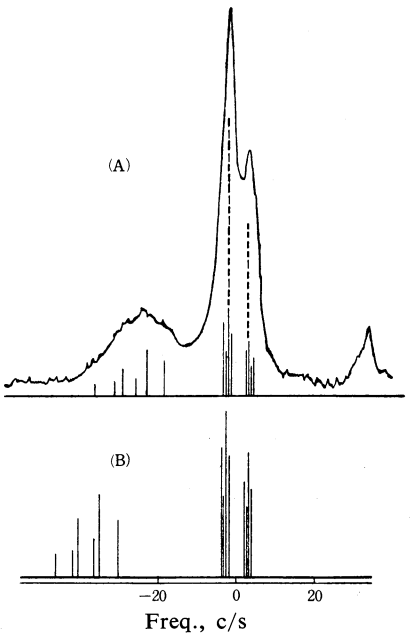

Fig. 8. NMR spectrum of polypropene-1,1-d_2 obtained at 40 Mc/s (A), together with the theoretical analysis at 60 Mc/s (B). The dotted line means the sum of each group of resonance lines.

As a conclusion, if an well-resolved NMR spectrum of a given polypropylene sample is available, the proportion of the isotactic part (x') can be evaluated by measuring only the fraction of the area of the B- and C-peaks (F_1). The formula for the evaluation is:

$$x' = \frac{0.307 - F_1}{0.190}$$

If the value of x' is close to unity, the following formula:

$$x' = \frac{F_0}{0.0426}$$

which is based entirely upon the theoretical spectrum of isotactic polypropylene, may be used, where F_0 means the fraction of the area of the A-peak.

In the near future the better resolution of individual resonance peaks will permit a more precise analysis of the stereoregularity of polypropylene.

Summary

The application of the NMR method to the study of commercial polypropylene seems to be restricted by some difficulties. A weak thermal degradation technique has therefore been employed to reduce the molecular weight of the polypropylene sample. However, the correspondence between the resultant molecular weight and the resolution of the spectrum is not always unique.

A remarkable difference between the NMR spectrum of isotactic polypropylene and that of atactic polypropylene can be found in the methylene resonance region. As an approximation, one may assume that the methylene groups of isotactic polypropylene give rise to the partial spectrum of an ABC_2 spin system, whereas those of syndiotactic polypropylene give rise to the partial spectrum of an A_2B_2 spin system. By means of an electronic computer, the best set of the δ and J parameters for the methylene resonance of isotactic polypropylene has been obtained. The results fit the observed spectrum fairly well. Using this information, the degree of stereoregularity (isotaxy) of a given polypropylene can be calculated. This method is applicable if an well-resolved NMR spectrum is available.

We are much indebted to Mr. Yoshihito Komatsu of the Daiwa Spinning Co., Ltd., for his sample preparation and preliminary treatment, and to Dr. Kô Abe for supplying a deuterated polymer sample. We are also indebted to Dr. Osamu Yamamoto and Mr. Teruo Suzuki of the Government Chemical Industrial Research Institute, Tokyo, for their measurements of NMR spectra. Thanks are due to Mr. Kôichi Mizuta of the Musashi Institute of Technology for his generous assistance in carrying out the numerical calculations.

*A High Resolution Nuclear Magnetic Resonance Study of the Styrene-Methylmethacrylate Copolymer**

By Yoshinori KATO, Nobuyuki ASHIKARI and Atsuo NISHIOKA

(Received June 9, 1964)

Since Bovey et al.[1] drew attention to the fact that new information about the configuration of polymer chains can be obtained from the high resolution nuclear magnetic resonance spectra, it has been a matter of great concern to us to find some direct evidence for the "copolymer structure" by means of the NMR method. In a preceding paper[2] it was shown that the microstructure of the methyl methacrylate polymer chains can be analyzed to a great extent by the aid of the NMR spectra. In that case the discovery of the *D*-unit (or the heterotactic unit) remarkably improved our knowledge about the stereo regularity of polymer chains. Especially by making use of the concept of the *D*-unit, the difference between

* This paper was read at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

random and stereoblock polymers can be difined more distinctly. Stereoreglar polymers may be regarded as a kind of copolymer in the sense that they consist of two different species of monomer placements, isotactic and syndiotactic. Therefore, some of the problems we considered in our previous study of polymethyl methacrylate may be applicable to the case of the copolymer.

On the other hand, it is well-known that a benzene ring placed in a magnetic field exhibits a long-range shielding effect which arises from the diamagnetic circulation of the π-electrons.[1,3] Therefore, in polymers such as polystyrene, which contains aromatic rings, some anomalies may be observed in the NMR resonance peaks of the α-protons, methylene protons, and the like. In such cases we may consider the aromatic ring as "a probe" to obtain some valuable information concerning the microstructure of the polymer. For these reasons we have studied the styrene-methyl methacrylate copolymer in solution by means of the NMR method.

At first we expected that the resonance peak due to α-methyl groups of methyl methacrylate would be separated into three peaks, as is the case with polymethyl methacrylate. If so, the dependence of the stereoregularity on the mole per cent of methyl methacrylate in the copolymer could have been obtained. Contrary to our expectations, however, the α-methyl peak does not separate explicitly, but quite a new anomaly can be found in the resonance region due to the methoxy groups.[4] A similar result could be obtained from the NMR spectra of the paraxylylene-methylmethacrylate copolymer.[5]

It is the purpose of this paper to interpret the NMR spectra of the styrene-methylmethacrylate copolymer in order to obtain some information concerning the copolymer structures Using this information it will be possible to study the kinetics of the radical copolymerization.

Experimental

Each sample was prepared in free radical polymerization at 40°C with triisopropylboron as a catalyst. Details of the polymerization conditions are listed in Table I. Proton magnetic resonance measurements were made at 20°C using a Varian V-4300-C spectrometer operating at 56.4 Mc/s. The concentration of the sample in carbon tetrachloride was varied within the range of 6~11% so as to make easy the observation of the minor component of each copolymer sample. The side band technique was employed to estimate the chemical shifts. However, since tetramethylsilane as an internal reference was not available, we could not express the peak positions in the τ-scale.

Results and Discussion

Figure 1 shows the NMR spectra of a polystyrene sample, a polymethyl methacrylate smple and of a mixture of these two polymers. The significance of these spectra is that we can not find any particular change in the NMR spectrum when these two polymers are mixed in the solution. The observed spectra of the copolymer samples are shown in Fig. 2. The sharp peaks at the extreme left may be due to a small quantity of an impurity such as benzene or chloroform. We examined this point and confirmed that the peak appears at the same position as the resonance peak of chloroform within the range of experimental error. Therefore, chemical shifts are expressed in parts per millon referred to this peak. The nearest peak to this is the aromatic proton resonance. In the spectra of samples 1 to 3 the phenyl resonance gives rise to a

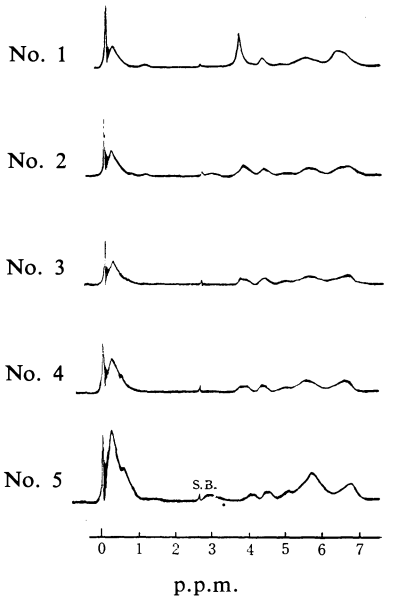

Fig. 2. NMR spectra of styrene-methylmethacrylate copolymers.

broad but single peak, whereas in the rest two separate peaks can be observed. A similar change of spectra has already been found by Bovey et al.[1] in their study of the styrene-butadiene copolymer. They attributed this change to the steric restriction of the phenyl groups. In the copolymer the average sequence length of styrene blocks may base short as several styrene monomer units. According to Bovey's criterion, these short styrene blocks give rise to a single resonance peak at 3.0 τ. However, if the average sequence length is longer than ten styrene units, the phenyl resonance always splits into two peaks. It was also confirmed by Bovey et al. that the smaller phenyl peak is due to the ortho-protons.

The comparison of the spectrum of sample 1 with that given in Fig. 1 (C) clearly shows that some remarkable changes have taken place in the resonance region of the methoxy groups contained in methyl methacrylate. For the sake of convenience, let us denote the three peaks at (3.8±0.2), (4.4±0.1) and 5.0 p.p.m. in our scale of the chemical shift as A-, B- and C-peaks respectively. It is then evident that the A-peak is due to the methoxy groups of methyl methacrylate, but that the relative peak area is considerably smaller than the corresponding peak of Fig. 1 (C). Here, we shall leave the B and C peaks untouched for the moment.

Next, the peak at about 5.6 p.p.m. can be assigned to the methylene protons. Since these protons are equally contained in styrene and methyl methacrylate, the relative area of this peak remains constant independently of the mole per cent of methyl methacrylate in the copolymer. Therefore, the normalization factor of the spectrum may be obtained as the reciprocal peak area of the methlene resonace. The peak at about 6.6 p.p.m. may be the α-methyl resonance. If so, the methyl peak area must be equal to that due to the methoxy groups of methyl methacrylate. The α-proton resonance of styrene is perhaps embedded on the left side of the methylene peak. In addition, the unknown peak C defined above overlaps with the methylene resonance. In order to settle these problems we measured the relative area of each peak. The results are shown in Fig. 3. In the measurement the α-proton peaks could not be separated from the methylene peaks explicitly. We separated them by remembering that the fraction

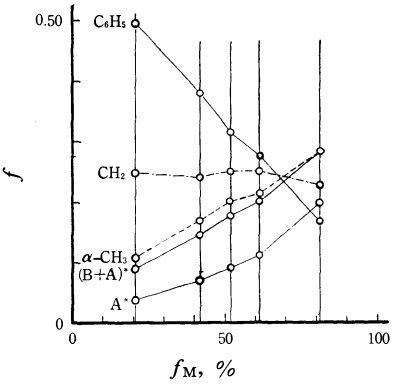

Fig. 3. Fraction of peak area (f_M) obtained from the NMR spectrum of styrene-methylmethacrylate copolymer plotted against mole per cent of methyl methacrylate charged (f).
* See text.

of the peak area of the methylene resonance is invariable. Therefore, the results may include small errors. However, it may safely be concluded from Fig. 3, that both the A- and B-peaks can be ascribed to the methoxy groups of methyl methacrylate. The sum of the A- and B-peak areas seems to be less than the peak area of the α-methyl resonance. This implies that there exist some other resonance peaks due to the methoxy groups. Judging from the possible configurations of the copolymer in connection with the long-range shielding effect of aromatic rings,[6,7] these unknown peaks may be found in the vicinity of the C-peak. Recently Bovey[8] has reported on this copolymer. Since his interpretations were based

on the well-resolved NMR spectra observed at 90°C, many interesting results have been obtained. Especially the change in the resonance region of methoxy groups with the mole per cent of methyl methacrylate in the monomer feed seems to offer a key to the analysis of the microstructure of the polymer chains. Introducing some assumptions, we may treat this problem in a way analogous to that used in the case of polymethyl methacrylate.[2]

In the case of this copolymer it is evident that not the stereoregular placement, but the placement of the styrene monomer unit referred to that of the neighboring methyl methacrylate unit is very important. On the assumption that any methyl methacrylate monomer unit in the copolymer chain can be classified only by its relative placement to the neighboring styrene monomer units on one or both sides, it may readily be seen that there are six configurations of three consecutive monomer units. In principle they may be expected to give rise to six different resonances of methoxy groups in the central methyl methacrylate units.

The configurations may be symbolically illustrated thus:

where S and M stand for styrene and methyl methacrylate monomer units respectively. A vertical line above (or below) the horizontal one represents a so-called *d*- or *l*-unit, and a broken line stands for one equivalent alternate. Perhaps the first configuration will give rise to a resonance at a higher magnetic field than the others. The resonance due to the second configuration will appear close to that due to the third. Though the fourth contains a styrene units at the each end, its resonance magnetic field may be very little different from those of the last two. The spectra of samples 3 to 5 shown in Fig. 1 seem to be in accordance with our interpretation, especially in the methoxy resonance region. However, because of the poor resolution, we can not discuss the problem further at present.

Another evidence of copolymer structure is provided by the interpretation of the chemical shifts. As is shown in Table II, the peak position of the α-methyl resonance shifts towards a higher magnetic field as the styrene component of the polymer chain increases. This is also in accordance with the results obtained by Bovey et al.[1,8] from the styrene-butadiene and methylmethacrylate-styrene copolymers. However, the exact stereochemical information which was available in the case of polymethyl methacrylate can no longer be obtained from this copolymer. In fact, only a slight change in the line shape of the α-methyl resonance can be observed. The same is true for the resonance line shapes of the styrene component.[9] In short, the methoxy resonance plays an important role in the NMR spectra of this copolymer.

As an example of a quantitative analysis of NMR spectra, the monomer reactivity ratio[10-13] was estimated from the measurements of the peak areas of both phenyl and α-methyl resonances. The copolymer composition curve is shown in Fig. 4.

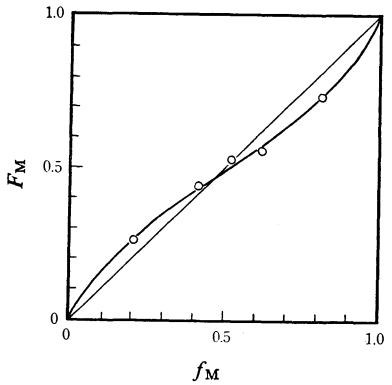

Fig. 4. Copolymer composition curve for the styrene-methylmethacrylate system. F_M, f_M are the mole fractions of MMA in copolymer and in monomer mixture. The heavy line is the theoretical curve for $r_1=0.56$, $r_2=0.50$; ○: experimental results.

The results,

$$r_1 \text{ (styrene)} = 0.56 \pm 0.01$$

$$r_2 \text{ (MMA)} = 0.50 \pm 0.03$$

are in good agreement with the values given by Lewis et al.:[14]

Monomer reactivity ratio	Polymerization temp. 60°C	131°C
r_1 (styrene)	0.52±0.026	0.590±0.026
r_2 (MMA)	0.46±0.026	0.536±0.026

Summary

The information concerning *D*-units in methyl methacrylate polymer chains has inproved our knowledge about the stereoregularity of the polymer.[2] As an extension of the study, we have examined styrene-methylmethacrylate copolymers prepared under various polymerization conditions. In these cases, the α-methyl resonance of methyl methacrylate does not change, except that the peak position shifts towards a higher magnetic field as the styrene component of the polymer chain increases. A direct evidence of the copolymer structure has been obtained by the analysis of the methoxy resonance. A total of six methoxy resonance lines can be observed if any methyl methacrylate monomer unit in the copolymer chain can be classified only in terms of its placement relative to the neighboring styrene monomer units.

Monomer reactivity ratios have been estimated from the NMR spectra. The results are r_1 (styrene) $=0.56\pm0.01$ and r_2 (MMA) $=0.50\pm0.03$.

The authors are indebted to Dr. Naohiro Hayakawa for his kind help in the NMR measurement.

Theoretical Studies of Light Scattering by Polydispersed Colloidal Systems of Spherical Particles[1)]

By Masayuki NAKAGAKI and Tsugiyo SHIMOYAMA

(Received May 13, 1964)

Recently light scattering has been widely used as a useful method to determine the size of colloidal particles. The method has become available as a result of the extensive improvement of experimental techniques and the development of theoretical information, at least, for monodispersed systems. Actual colloidal systems are, however, polydispersed, and their particle-size distribution is yet to be determined. For this purpose, it is, of course, desirable to determine the entire shape of the distribution curve experimentally, but that would require a great deal of experimental data of a very high precision. Therefore, one must often be satisfied with the determination of the values of a few parameters in an approximate presupposed equation and with the determination of a kind of average particle size. This approximate method is not unsatisfactory if the actual distribution curve has one maximum only. Heller et al. assumed a special shape of the distribution

1) Presented before the 14th Discussion of Colloid Chemistry, Ueda, October, 1961, and the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

function containing two parameters and studied the polarization ratio[2] and the turbidity.[3] Dettmar et al.[4] calculated the specific turbidity for the log-normal distribution of two parameters.

In the experiments of light scattering, however, the specific scattering intensity and the dissymmetry factor are frequently measured. Therefore, the effect of polydispersity on these quantities is of interest. The results obtained by using a three-parameter distribution function will be reported here.

Theoretical

Presupposed Distribution Curve.—If the distribution curve of the particle size has one maximum point, the distribution maximum, the width of the distribution and the dissymmetry of the distribution curve will be of main interest. A modified Gaussian curve containing the above-mentioned three parameters was used in the present experiment.

In the study of light scattering by colloidal spheres, the relative particle size:

$$\alpha=2\pi r/\lambda \tag{1}$$

is used, where r is the particle radius and λ is the wavelength of light in the dispersion medium. The particle-size distribution in weight, $W(\alpha)$, is assumed to have its maximum point at α_m, and for $\alpha<\alpha_m$ the function $W(\alpha)=W_1(\alpha)$ is a Gaussian function with the standard deviation of $\Delta\alpha_1$, and for $\alpha<\alpha_m$ the function $W(\alpha)=W_2(\alpha)$ is that with $\Delta\alpha_2$. Therefore, by using the average width of the distribution,

$$\langle\Delta\alpha\rangle=(\Delta\alpha_1+\Delta\alpha_2)/2 \tag{2}$$

and the dissymmetry of the distribution,

$$\Delta=\Delta\alpha_1-\Delta\alpha_2 \tag{3}$$

the distribution in weight will be;

$$\left.\begin{aligned} W_1(\alpha)&=(1/\langle\Delta\alpha\rangle)\phi(x_1)\\ x_1&=(\alpha-\alpha_m)/\Delta\alpha_1\end{aligned}\right\}\ \text{for}\ \alpha>\alpha_m \tag{4}$$

and

$$\left.\begin{aligned} W_2(\alpha)&=(1/\langle\Delta\alpha\rangle)\phi(x_2)\\ x_2&=(\alpha_m-\alpha)/\Delta\alpha_2\end{aligned}\right\}\ \text{for}\ \alpha<\alpha_m \tag{5}$$

where the function ϕ is the normalized Gaussian function;

$$\phi(x)=(1/\sqrt{2\pi})\exp(-x^2/2) \tag{6}$$

Mathematically, the function $W_2(\alpha)$ extends to the negative of α, and the $W(\alpha)$ given above by the combination of Eqs. 4 and 5 is normalized over the range from $-\infty$ to $+\infty$. Actually, however, the size distribution function should tend to zero when the α value approaches zero and should be meaningless for a negative value of α. Therefore, Eq. 5 is to be used only for $0<\alpha<\alpha_m$, and the functions of Eqs. 4 and 5 are to be re-normalized by dividing them with a factor $(\Delta\alpha_1/2\langle\Delta\alpha\rangle+f\Delta\alpha_2/2\langle\Delta\alpha\rangle)$, where

$$f=2\int_{-\alpha_m/\Delta\alpha_2}^{0}\phi(x)\mathrm{d}x \tag{7}$$

In this method, the value of $W_2(0)$ is not equal to zero. This discrepancy, is, however not serious in practice because the scattered light intensity rapidly decreases to zero when α decreases to zero.

Calculation of Mean Values. — The mean value, $\langle G\rangle$, of a quantity, G, for the presupposed distribution of the particle size can be calculated by the equation:

$$\langle G\rangle=(g_1+g_2)/(\Delta\alpha_1+f\Delta\alpha_2) \tag{8}$$

where

$$\left.\begin{aligned} g_1&=2\langle\Delta\alpha\rangle\int_{\alpha_m}^{\infty}GW_1(\alpha)\mathrm{d}\alpha\\ g_2&=2\langle\Delta\alpha\rangle\int_{0}^{\alpha_m}GW_2(\alpha)\mathrm{d}\alpha\end{aligned}\right\} \tag{9}$$

For the numerical calculation of g_1 and g_2 in this paper, the entire range of α is divided into equal intervals of $(\delta\alpha)=0.2$ and approximate summations instead of integrations were made because the numerical values of the scattered light intensity were available only at this interval of α. Therefore

$$\left.\begin{aligned} g_1&=2(\delta\alpha)\sum_{x_1=0}^{\infty}{}'G\phi(x_1)\\ g_2&=2(\delta\alpha)\sum_{x_2=0}^{\alpha_m/\Delta\alpha_2}{}'G\phi(x_2)\end{aligned}\right\} \tag{10}$$

In these summations, the terms for $x_1=0$ and $x_2=0$ were multiplied by 1/2 because the same term is included in both summations, g_1 and g_2.

The Specific Scattering Intensity and Dissymmetry Factor. — The quantities measured most often in the study of colloidal systems are the specific scattering intensity,[5] J_θ/I_0c, and the dissymmetry factor, z, where J_θ is the intensity per unit solid angle of the light scattered at the angle,[6] θ; I_0 is the intensity of the incident beam, and c is the concentration of the dispersed phase in g./100 ml. The

3) M. L. Wallach, W. Heller and A. F. Stevenson, *J. Chem. Phys.*, **34**, 1796 (1961).

4) H.-K. Dettmar, W. Lode and E. Marre, *Kolloid-Z.*, **188**, 28 (1963).

5) The value extrapolated to the infinite dilution should be compared with the theoretical value.

6) The scattering angle, γ, usually used in the case of a colloidal system according to Mie is related to the angle, θ, used here by the equation: $\gamma=180°-\theta$.

specific scattering intensity can be expressed theoretically by

$$J_\theta/I_0c=(N/c)(\lambda^2/4\pi^2)i_\theta \tag{11}$$

where N is the number of particles per unit of volume and i_θ is the function defined elsewhere.[7] If the system is polydispersed, the observed specific scattering intensity should be an average value defined by:

$$\langle J_\theta\rangle/I_0c=(\lambda^2/4\pi^2c)\langle Ni_\theta\rangle \tag{12}$$

or, by using Eq. 1;

$$\langle J_\theta\rangle/I_0c=(3/200\lambda\rho_2)\langle i_\theta/\alpha^3\rangle \tag{13}$$

where ρ_2 is the density of the dispersed phase. For the sake of the simplicity of numerical computation, a quantity, Y_θ, is used, which is to be determined experimentally by:

$$Y_\theta=(200/3)\lambda\rho_2\langle J_\theta\rangle/I_0c \tag{14a}$$

and computed theoretically by;

$$Y_\theta=\langle i_\theta/\alpha^3\rangle \tag{14b}$$

The dissymmetry factor, z, is:

$$z=Y_{45}/Y_{135}=\langle i_{45}/\alpha^3\rangle/\langle i_{135}/\alpha^3\rangle \tag{15}$$

Results and Discussion

Numerical Values of Y_θ and z.—Numerical values of Y_{45}, Y_{90}, Y_{135} and z for unpolarized light have been calculated according to Eqs. 8, 10, 14b and 15 for $m=1.20$ and $\alpha_m=0$ (0.2) 3.0, and for $\Delta\alpha_1=0$ (0.2) 1.0 and $\Delta\alpha_2=0$ (0.2) 1.0. For the calculations, the values of i_θ/α^3 were taken from the table published by Pangonis and Heller[8] for $\alpha=0$ (0.2) 7.0 for monodispersed systems. Some of the results of the computation are shown in the following figures.

Figure 1 shows the relation between Y_{90} and α_m when $\Delta=0$ and $\langle\Delta\alpha\rangle=0$ (0.2) 1.0. Each curve of Y_{90} vs. α_m has a maximum point at about $\alpha_m=1.6\sim1.7$; this curve becomes less steep as the $\langle\Delta\alpha\rangle$ value increases. The value of Y_{90} is mostly independent of $\langle\Delta\alpha\rangle$ at about $\alpha_m=0\sim1.0$ and $\alpha_m=2.3$. According to a figure (not shown here) designed to illustrate the relation between Y_{45} and α_m for $\Delta=0$ and $\langle\Delta\alpha\rangle=0$ (0.2) 1.0, it is concluded that the Y_{45} increases monotonously in the range of $\alpha_m=3.0$. The curves become less steep as the

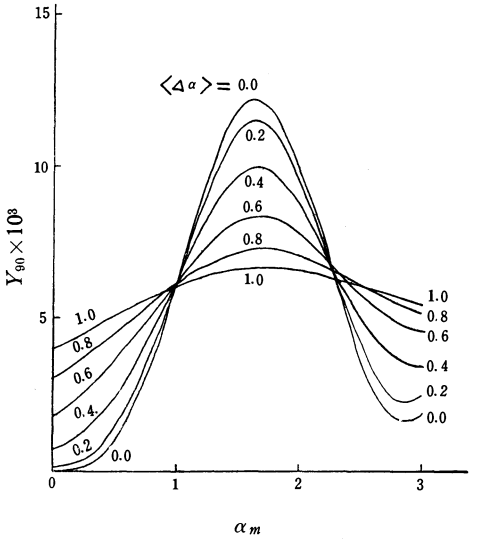

Fig. 1. Relation between Y_{90} vs. α_m for $m=1.20$, $\Delta=0$ and for various $\langle\Delta\alpha\rangle$ values.

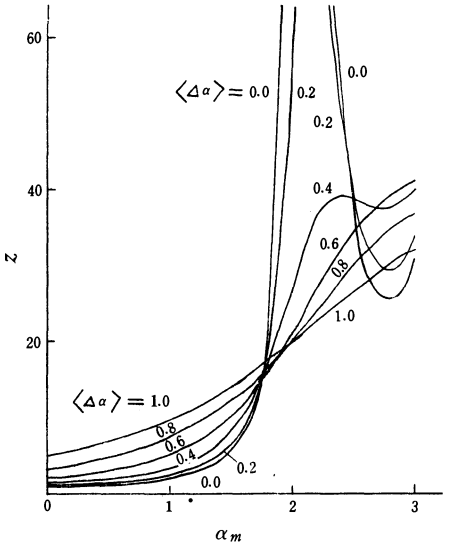

Fig. 2. Relation between z and α_m for $m=1.20$, $\Delta=0$ and for various $\langle\Delta\alpha\rangle$ values.

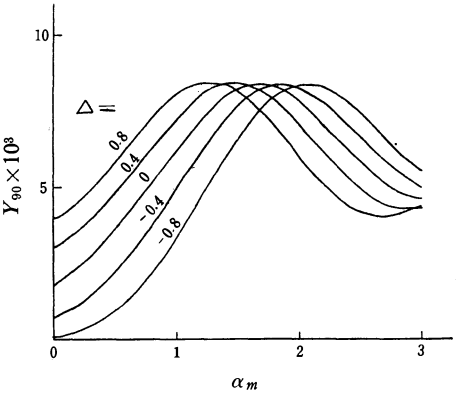

Fig. 3. Relation between Y_{90} and α_m for $m=1.20$, $\langle\Delta\alpha\rangle=0.6$ and for various Δ values.

7) E. g., W. Heller, M. Nakagaki and M. L. Wallach, *J. Chem. Phys.*, 30, 444 (1959).

8) W. J. Pangonis, W. Helleer. "Angular Scattering Functions for Spherical Particles," Wayne State University Press, Detroit, U. S. A. (1960).

$\langle \Delta\alpha \rangle$ values increase. The value of Y_{45} is mostly independent of $\langle \Delta\alpha \rangle$ at about $\alpha_m = 1.85$. According to a figure (not shown here) designed to illustrate the relation between Y_{135} and α_m for $\Delta = 0$ and $\langle \Delta\alpha \rangle = 0$ (0.2) 1.0, it is concluded that each curve of Y_{135} vs. α_m has a maximum point at about $\alpha_m = 1.3$, a minimum point at about $\alpha_m = 2.15$, and another maximum point at about $\alpha_m = 2.8$, when $\langle \Delta\alpha \rangle$ is not too large. The curves become less steep as the $\langle \Delta\alpha \rangle$ values increase. The values of Y_{135} at about $\alpha_m = 0.75$, 1.75, and 2.5 are mostly independent of $\langle \Delta\alpha \rangle$.

The dissymmetry factor, z, for $m = 1.20$ is shown in Fig. 2 for $\Delta = 0$ and $\langle \Delta\alpha \rangle = 0$ (0.2) 3.0. In the range of $\alpha_m = 0 \sim 3.0$, the z value has a maximum point at about $\alpha_m = 2.2$ and a minimum point at about $\alpha_m = 2.8$. The greater the $\langle \Delta\alpha \rangle$, the lower the maximum point becomes; at last the curve comes to increase monotonously with α_m when $\langle \Delta\alpha \rangle \geq 0.6$. The variation of z with $\langle \Delta\alpha \rangle$ is small at about $\alpha_m = 1.75$.

The change in the quantities due to the variation of $\Delta = -0.8(0.4) + 0.8$ were then studied. As is shown in Fig. 3, the curve of Y_{90} vs. α_m for $m = 1.20$ and $\langle \Delta\alpha \rangle = 0.6$ has one maximum in the range $\alpha_m = 0 \sim 3.0$; the curve is shifted to the left when $\Delta > 0$, and to the right when $\Delta < 0$, with the increase in $|\Delta|$. Similar shifts of curves were also observed in the cases of Y_{45} vs. α_m, Y_{135} vs. α_m and z vs. α_m (not shown here).

A Method to Determine the Parameter Values of the Distribution Functions. — The distribution function of the particle size presupposed previously had three parameters, α_m, $\langle \Delta\alpha \rangle$ and Δ. The three parameters can, in principle, be determined experimentally if three independent quantities, for example, Y_{90}, Y_{45}

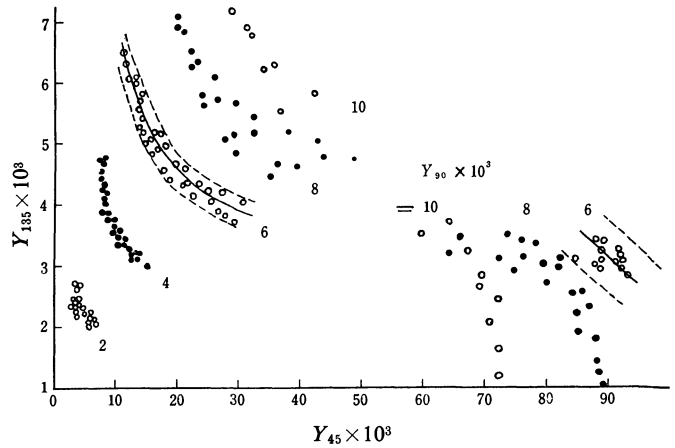

Fig. 4. Relation between Y_{45} and Y_{135} for various Y_{90} values of $m = 1.20$.

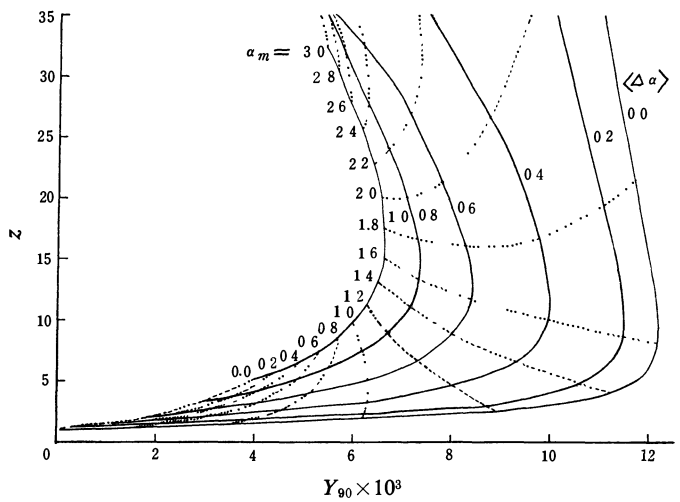

Fig. 5. Relation between z and Y_{90} for $m = 1.20$.

and Y_{135}, are measured with sufficient accuracy. In practice, however, the extent of the accuracy required for the procedure should be examined. In this connection, the values of Y_{45} and Y_{135} corresponding to several fixed values of Y_{90} are plotted[9] in Fig. 4 on the basis of the previously-computed values of Y_{90}, Y_{45} and Y_{135} for various α_m, $\langle\Delta\alpha\rangle$ and Δ values. The points for a given Y_{90} value are located in two separate regions, because the Y_{90} vs. α_m relation has a maximum. If the three quantities Y_{90}, Y_{45} and Y_{135} are entirely independent of each other and if all of three parameters α_m, $\langle\Delta\alpha\rangle$ and Δ can be determined experimentally, the points for a given Y_{90} value should be distributed over a sufficiently wide region on the $Y_{45}-Y_{135}$ plane. The actual distribution of the points, however, is not extended over a region, but is collapsed mostly on either one of two lines, as is shown in Fig. 4. If one assumes lines as drawn arbitrarily for the sake of illustration in Fig. 4, for example, for $Y_{90}=6\times10^{-3}$, one should be able to determine accurately the distance of points from these lines in order to be able to estimate the three parameter values experimentally. If the experimental errors of both Y_{45} and Y_{135} are as much as $\pm5\%$, the experimental values would be scatterd between the dotted lines in Fig. 4. This makes the experimental determination of the distance from the lines impossible when $\langle\Delta\alpha\rangle$ is smaller than 1.0 and $|\Delta|$ is smaller than 0.8. The accuracy of the experiment should be better than $\pm0.2\%$ in order to be able to determine three parameters with an accuracy of about $\pm4\%$.

If the accuracy of the experiment is not very good, as is described above, one must be satisfied with a distribution function of two parameters. The parameters to be adopted would be α_m and $\langle\Delta\alpha\rangle$ by assuming $\Delta=0$. This means that the distributsion of the particle radius is approximated by the usual Gaussian function. The two parameters, α_m and $\langle\Delta\alpha\rangle$, can be determined by measuring two independent quantities, for example, Y_{90} and z as in the usual light-scattering studies, on the basis of a chart such as Fig. 5 for $m=1.20$, constructed by using the results of the theoretical computation. The multivaluedness of α_m for a given Y_{90} value or the existence of a maximum point in the Y_{90} vs. α_m relation as shown in Fig. 1 or 3 does not make the analysis ambiguous if the maximum is only one or if the α_m value is less than 3.0, because the z values corresponding to the ascending and descending branches of the $Y_{90}-\alpha_m$ curve are different each other. In Fig. 5, the line for $\alpha_m=1.0$ is almost vertical because the dependence of Y_{90} on $\langle\Delta\alpha\rangle$ is small for this α_m value, and the line for $\alpha_m=1.8$ is almost horizontal because the dependence of z on $\langle\Delta\alpha\rangle$ is small for this α_m value, as has been described above.

Weight-averaged Particle Radius. — As a measure of the particle size, the α_m value corresponding to the most probable particle radius has been used so far. In light-scattering studies, however, the weight-average molecular weight is usually determined, especially for high polymer solutions. In the case of

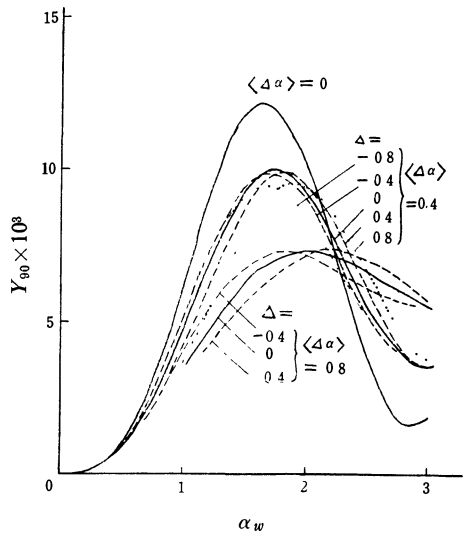

Fig. 6. Relation between Y_{90} and α_w for $m=1.20$.

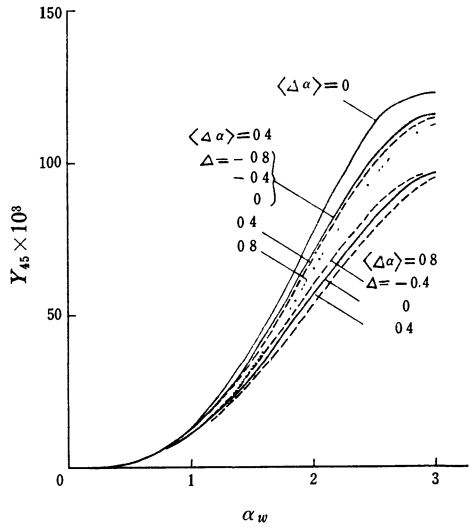

Fig. 7. Relation between Y_{45} and α_w for $m=1.20$.

9) A given value of Y_{90} corresponds to one or two (since Y_{90}-α_m relation has a maximum) values of α_m for each set of ($\langle\Delta\alpha\rangle$, Δ), and each set of (α_m, $\langle\Delta\alpha\rangle$, Δ) gives the corresponding Y_{45} and Y_{135} values.

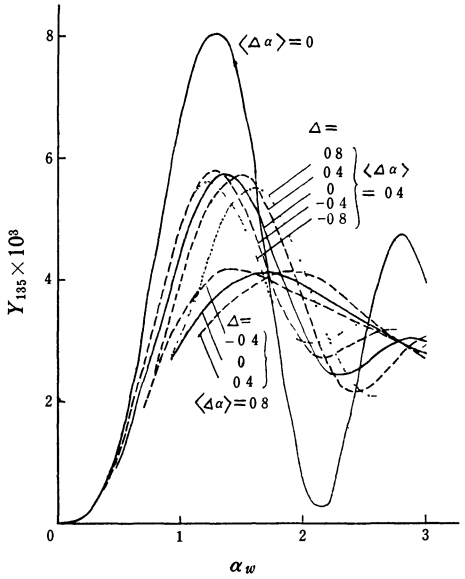

Fig. 8. Relation between Y_{135} and α_w for $m=1.20$.

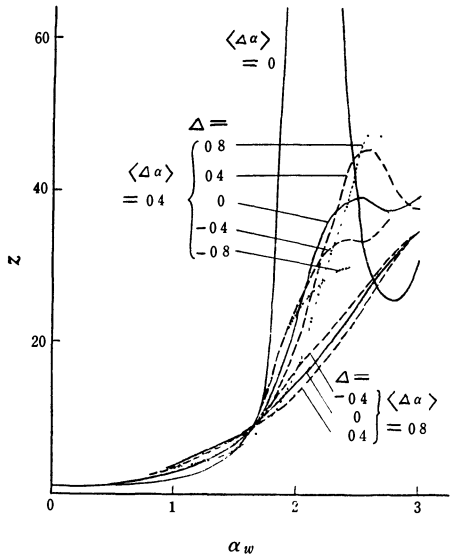

Fig. 9. Relation between z and α_w for $m=1.20$.

colloidal systems, too, the weight-averaged α^3 value may be preferable. Therefore, the cubic root of the weight-averaged α^3 value:

$$\alpha_w=\sqrt[3]{\langle\alpha^3\rangle} \tag{16}$$

may be used as a measure of the particle size of a polydispersed system. The theoretical value of $\langle\alpha^3\rangle$ for the presupposed distribution function was calculated according to Eqs. 8 and 10 for various α_m, $\langle\Delta\alpha\rangle$ and Δ values, and the previously discussed Y_θ and z vs. α_m relations were redrawn to Y_θ and z vs. α_w relations. The results of Y_{90} vs. α_w are shown in Fig. 6, those for Y_{45} vs. α_w in Fig. 7 those for Y_{135} vs. α_w in Fig. 8, and those for z vs. α_w in Fig. 9 for $m=1.20$ and for several combinations of $\langle\Delta\alpha\rangle$ and Δ. From these figures, it may be concluded: (1) the curves are mostly dependent on neither $\langle\Delta\alpha\rangle$ nor Δ if α_w is small. They coincide with the curve of $\langle\Delta\alpha\rangle=0$, although the deviation from the latter becomes the greater, the larger the α_w value; (2) the shape of the curves is determined mainly by the value of $\langle\Delta\alpha\rangle$; (3) the curves are shifted to either side when the Δ value comes to be different from zero, but the effect of Δ is not as great as that of $\langle\Delta\alpha\rangle$.

The fact that the curves coincide with each other when α_w is small is a natural consequence of Rayleigh's theory. Therefore, the value of α_{obs} obtained experimentally from the observed Y_θ values on the basis of the theoretical Y_θ vs. α relation of a monodispersed system is equal to α_w for a polydispersed system when the α_{obs} is smaller than about 0.6. When the value of α_{obs} is greater than about 0.6, however, another method is required to obtain the α_w value from the experimental Y_θ and z values.

An Empirical Method to Determine α_w.— When the Y_{90} value of a polydispersed system is measured, the values of α_{90} and z_{90} are determined where α_{90} and z_{90} are the α and z values of a monodispersed system having the same Y_{90} value as the polydispersed system.

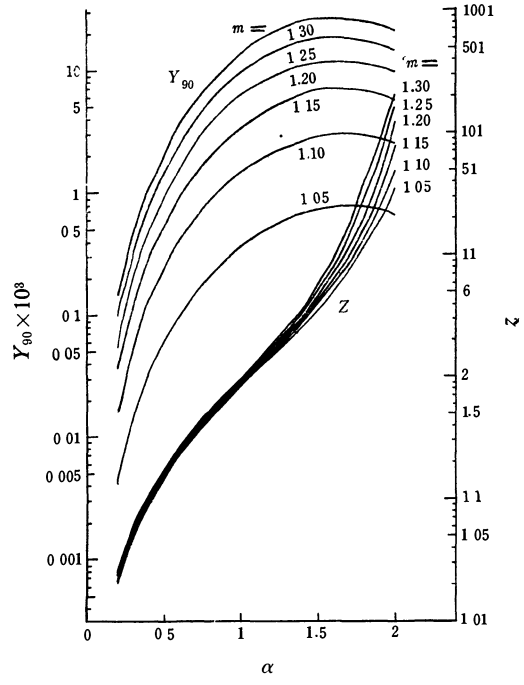

Fig. 10. Relations between Y_{90} and Z vs. α.

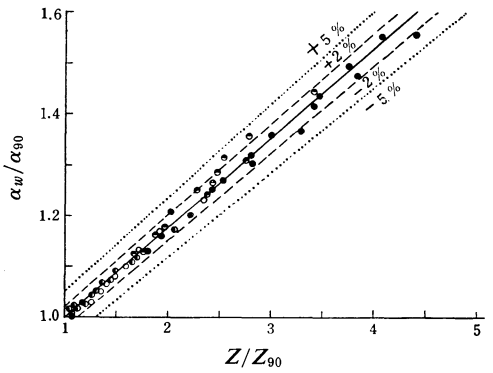

Fig. 11. Relation between α_w/α_{90} and Z/Z_{90} for $m=1.20$ and for $\langle\Delta\alpha\rangle=0.4$, $\Delta<0$ (◐), $=0$ (○), <0 (◓) and for $\langle\Delta\alpha\rangle=0.8$ (●).

For this purpose Fig. 10 may be used. In it the theoretical Y_{90} value is plotted on the left-side ordinate in a log scale, while the theoretical z value is plotted on the right-side ordinate in a $\log(z-1)$ scale, for various m-values of the monodispersed system. From Fig. 10, the values of α_{90} and z_{90} corresponding to the Y_{90}(obs) can be read off by using the curve for the m value of the system.

The Y_{90} and z values supposed to be measured for various polydispersed systems of $m=1.20$ can be obtained from the theoretical results described in the preceding paragraphs of this paper. By using these values and Fig. 10, it may be empirically concluded, as is shown in Fig. 11, that a linear relation holds approximately between α_w/α_{90} and z/z_{90}, at least within the range of $\langle\Delta\alpha\rangle$ and Δ values examined in this paper. Therefore, the following empirical equation:

$$\alpha_w/\alpha_{90}=1+k(z/z_{90}-1) \qquad (17)$$

is obtained with $k=0.176$ for $m=1.20$. This relation can then be used in order to determine the α_w value from the experimentally-determined Y_{90} and z values. In order to see the extent of the error arising in this method, the curves corresponding to errors of $\pm2\%$ and $\pm5\%$ are drawn on Fig. 11. Almost all points are located within the range of $\pm2\%$ precision. It was estimated, further, that the error was within 2% for $\alpha_w<1.2$ if $\langle\Delta\alpha\rangle=0.4$ and $\Delta=\pm0.8$ or if $\langle\Delta\alpha\rangle=0.8$ and $\Delta=\pm0.4$, and within 5% for $\alpha_w<1.5$ for the same $\langle\Delta\alpha\rangle$ and Δ values.

Similar studies have been made for other m values; the values of k thus obtained are shown in Table I. The error was not very dependent on the m values and was within 2% for $\alpha_w<1.5$ and within 5% for $\alpha_w<1.6$ if $\langle\Delta\alpha\rangle=0.4$ and $\Delta=0$.

Table I. Coefficients k for various m-values

m	k	m	k
1.05	0.207	1.20	0.176
1.10	0.192	1.25	0.172
1.15	0.182	1.30	0.169

Summary

In order to study the light scattering of polydispersed colloidal systems of spherical particles, a weight distribution function, $W(\alpha)$, of the relative particle radius α has been assumed to be a modified Gaussian function with three parameters: the most probable α-value, α_m; the width of the distribution, $\langle\Delta\alpha\rangle$, and the dissymmetry of the distribution, Δ. The values of Y_θ, which is proportional to the specific scattering intensity, for $\theta=45°$, 90° and 135°, and the dissymmetry factor, $z=Y_{45}/Y_{135}$, have then been computed.

In principle, it should be possible to determine three parameters of the particle size distribution, α_m, $\langle\Delta\alpha\rangle$ and Δ, from the observed values of three independent quantities, Y_{45}, Y_{90} and Y_{135}. It has, however, been concluded that practically the method requires very precise experiments. If one is satisfied with a distribution function of two parameters, α_m and $\langle\Delta\alpha\rangle$, the values of these parameters can be determined from the experimentally-obtained Y_{90} and z values on the basis of a chart constructed theoretically.

The value of α_w, which is the cubic root of weight-averaged $\langle\alpha^3\rangle$, is equal to the α value obtained from the measured specific scattering intensity by assuming that the system is monodispersed when α is small. If α is not small, the value of α_w can be obtained according to the empirical equation:

$$\alpha_w/\alpha_{90}=1+k(z/z_{90}-1)$$

The error will be within about 5% if $\alpha_w<1.5$.

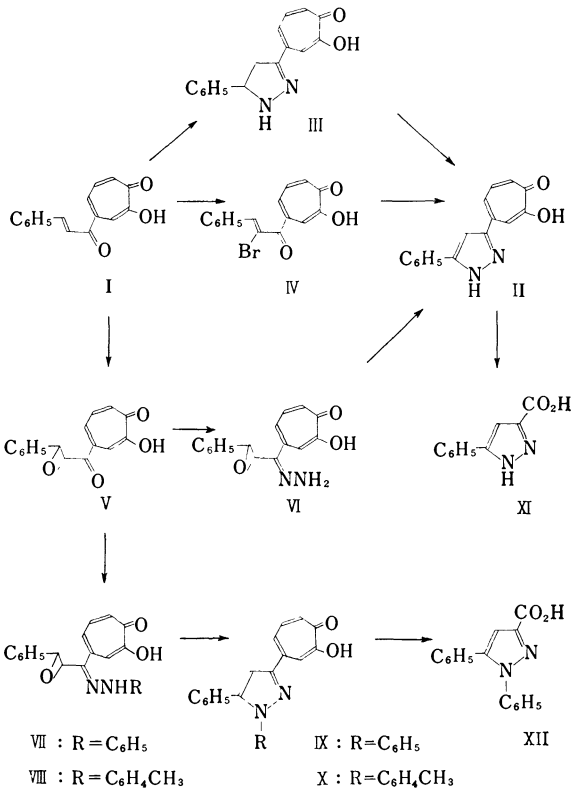
The Synthesis and Reactions of 4-(5-Phenyl-3-pyrazolyl)tropolones



By Tetsuo NOZOE, Kahei TAKASE and Yasuhiro MOCHIZUKI

(Received May 13, 1964)

Troponoid compounds containing a non-condensed heteroaromatic ring are expected to be interesting not only because of their chemical properties but also because of their potential biological properties. Because such compounds had never been synthesized, the present authors synthesized some pyrazolyltropolones, starting from 4-cinnamoyltropolone (I) obtained by the condensation of 4-acetyltropolone and benzaldehyde,[1] and investigated their chemical natures.

4-(5-Phenyl-3-pyrazolyl)tropolone (II), the structure of which was established as mentioned below, was synthesized by the following three routes: i) The dehydrogenation of 4-(4, 5-dihydro-5-phenyl-3-pyrazolyl)tropolone (III) obtained by a reaction of I with hydrazine (a 24% over-all yield from I). ii) The reaction of 4-(α-bromocinnamoyl)tropolone (IV),[2] obtained by the bromination of I, with hydrazine (a 22% yield from I). iii) The ring formation of the hydrazone (VI) of 4-(2, 3-epoxy-3-phenylpropionyl)tropolone (V),[2] obtained by the oxidation of I with alkaline hydrogen peroxide (a 40% yield from I). The third method seemed to be the best. In the same way, 4-(1, 5-diphenyl-3-pyrazolyl)-tropolone (IX) and 4-[5-phenyl-1-(*p*-tolyl)-3-pyrozolyl]tropolone (X) were also obtained from phenylhydrazone (VII) and *p*-tolylhydrazone (VIII) of epoxide (V) in 98% and 87% yields respectively. Compounds II, III, IX and X were all proved to be tropolone derivatives by the facts that they were soluble in alkali, reacted positively to the ferric chloride test and formed a greenish-yellow copper chelate. The alkaline permanganate oxidation of II and IX gave 5-phenylpyrazole-3-carboxylic acid (XI)[3] and 1, 5-diphenylpyrazole-3-carboxylic acid (XII)[4] in good yields. The compound, III, was presumed to be a pyrazoline rather than a hydrazone derivative because of its stability to acid. The structures of II, III, IX and X were established by these facts, as is shown in the scheme.

The azo-coupling of II with *p*-toluenediazonium chloride gave an orange-colored 5-(*p*-tolylazo) derivative, the position of the azo group being inferred from analogy with the azo-coupling reaction of the other tropolones.[5] The methylation of II and IX with diazomethane afforded two kinds of methyl ethers, XIIIa and XIIIb, and XIVa and XIVb respectively. The structures of these ethers were inferred from their infrared spectra, in which a strong absorption appeared at 819 for XIIIa, 815 for XIVa, 797 for XIIIb and 795 cm^{-1} for XIVb in Nujol mull. These data suggest that these ethers possess the structures shown.[6] Furthermore, it was interesting to note that the ultraviolet absorption spectra of 4-substituted 2-methoxytropones (XIIIa and XIVa)

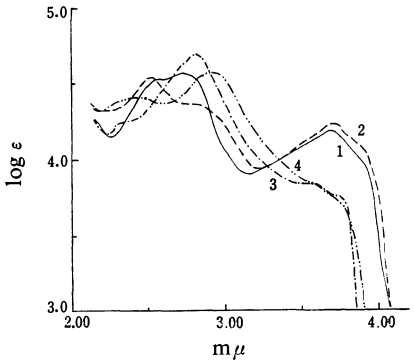
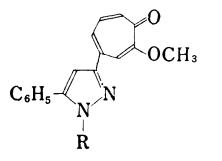
4) C. Bulow, ibid., 37, 2200 (1904).
5) T. Nozoe, *Fortschr. Chem. org. Naturst.*, 13, 233 (1956).
6) 2, 4-Disubstituted tropones show the characteristic absorption in the range 810~840 cm^{-1}, and 2, 6-disubstituted tropones show it in the range 770~800 cm^{-1}; T. Nozoe, K. Takase and M. Yasunami, to be published.

and 6-substituted isomers (XIIIb and XIVb) differed from each other remarkably in the long-wave region, as is shown in Fig. 1. Such was also the case in isomeric methyl ethers of styryltropolone[7] and in 3- and 4-phenyltropones,[8] this is probably due to the difference in the cross-conjugation system between the aromatic-ring and the unsaturated-ketone systems in a seven-membered ring.





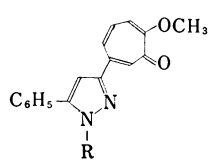


Fig. 1. Ultraviolet absorption spectra of
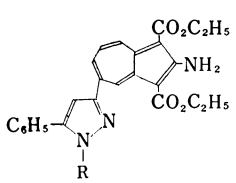
1: 2-Methoxy-4-(5-phenyl-3-pyrazolyl)tropone (XIIa),
2: 2-Methoxy-4-(1,5-diphenylpyrazolyl)tropone (XIVa),
3: 2-Methoxy-6-(5-phenylpyrazolyl)tropone (XIIIb) and
4: 2-Methoxy-6-(1,5-diphenylpyrazolyl)tropone (XIVb)
in methanol.



Methyl ethers (XIIIa, b and XIVa, b) were easily hydrolyzed to the original tropolones with alkali. They also gave, by the action of ethyl cyanoacetate in the presence of sodium ethoxide, pyrazolylazulene derivatives (XV, XVI and XVIIa),[9] the structures of which were inferred from their analytical data and their ultraviolet and infrared absorption spectra. These properties of pyrazolyltropolones, e.g., the formation of two kinds of reactive methyl ethers, were quite similar to those of usual monocyclic tropolones rather than those of tropolones fused with aromatic nuclei, e.g., benzotropolone[10a] or pyridotropolones.[10b]

Experimental[11]

4-(4,5-Dihydro-5-phenyl-3-pyrazolyl)tropolone (III).—A mixture of 4-cinnamoyltropolone (I) (500 mg.), ethanol (4 ml.), 80% hydrazine hydrate (0.2 ml.) and glacial acetic acid (5 drops) was heated under reflux for 5 min. The crystals thereby formed were collected and recrystallized from ethanol to give III (430 mg.) as yellow prisms, m.p. 132~133°C.

Found: C, 71.82; H, 4.91; N, 10.64. Calcd. for $C_{16}H_{14}O_2N_2$: C, 72.16; H, 5.30; N, 10.52%.

λ_{max}^{MeOH} mμ (log ε); 235 (4.29), 320 (4.31), 365~390 (4.15).

N-Acetate.—M.p. 181°C, pale yellow micro-needles (from ethanol).

Found: C, 69.32; H, 5.05; N, 8.96. Calcd. for $C_{18}H_{16}O_3N_2$: C, 70.11; H, 5.23; N, 9.09%.

4-(5-Phenyl-3-pyrazolyl)tropolone (II).—*a) From III.*—A mixture of III (270 mg.), chloranil (370 mg.), and glacial acetic acid (2 ml.) was heated under reflux for 3 hr. After the crystals (dihydrochloranil) which separated out on cooling had been filtered off, the solvent was removed from the filtrate and the residue was recrystallized from ethanol, affording II (80 mg.), m.p. 186~187°C. Further recrystallization from ethanol gave cream yellow silky needles, m.p. 190~191°C.

Found: C, 72.45; H, 4.65; N, 10.63. Calcd. for $C_{16}H_{12}O_2N_2$: C, 72.71; H, 4.58; N, 10.60%.

λ_{max}^{MeOH} mμ (log ε); 280 (4.61), 390 (3.93).

b) From 4-(α-Bromocinnamoyl)tropolone (IV).—To a suspension of IV (1.36 g.) in methanol (10 ml.), 80% hydrazine hydrate (0.4 ml.) was added, and the mixture was heated under reflux for 20 min. The crystals thereby formed were collected and recrystallized from ethanol to give II (655 mg.) as cream-yellow silky needles, m.p. 190~191°C.

c) From 4-(2,3-Epoxy-3-phenylpropionoyl)tropolone (V).—A mixture of V (1.54 g.), ethanol (50 ml.) and 80% hydrazine hydrate (0.5 ml.) was heated under reflux for 1 hr. and then cooled to give the hydrazone (VI) (820 mg.), m.p. 194°C (decomp.). Recrystallization from ethanol afforded yellow plates, m.p. 204°C (decomp.).

Found: C, 67.84; H, 5.07; N, 9.83. Calcd. for $C_{16}H_{14}O_3N_2$: C, 68.07; H, 5.00; N, 9.92%.

λ_{max}^{MeOH} mμ (log ε); 237 (4.23), 320 (4.33), 370 (4.12).

A mixture of the hydrazone (VI) (640 mg.), ethanol (50 ml.) and 6 N hydrochloric acid (3 drops) was heated under reflux for 1 hr. and then cooled to give II (470 mg.) as cream-yellow silky needles m. p. 190~191°C.

4-(1, 5-Diphenyl-3-pyrazolyl)tropolone (IX). — A mixture of epoxide (V) (1.35 g.), ethanol (40 ml.) and phenylhydrazine (0.8 ml.) was heated under reflux for 1 hr. and then concentrated to a small volume and allowed to cool to give the phenylhydrazone (VII) (1.69 g.), m. p. 199~201°C. Recrystallization from ethanol-dioxane afforded orange-yellow micro-needles, m. p. 207~209°C.

Found: C, 73.69; H, 4.94; N, 7.45. Calcd. for $C_{22}H_{18}O_3N_2$: C, 73.73; H, 5.06; N, 7.82%.

A mixture of the phenylhydrazone (VII) (1.69 g.), ethanol (70 ml.) and 6 N hydrochloric acid (10 drops) was heated under reflux for 40 min. and then concentrated to a small volume and allowed to cool to give IX (1.36 g.), m. p. 170~172°C. Recrystallization from ethanol afforded cream-yellow prisms, m. p. 171~172°C.

Found: C, 77.74; H, 4.56; N, 8.08. Calcd. for $C_{22}H_{16}O_2N_2$: C, 77.63; H, 4.74; N, 8.23%.

λ_{max}^{MeOH} mμ (log ε); 252 (4.45), 292 (4.50), 393 (3.91).

4-[5-Phenyl-1-(*p*-tolyl)-3-pyrazolyl]tropolone (X). — A mixture of epoxide (V) (270 mg.), ethanol (7 ml.) and *p*-tolylhydrazine (180 mg.) was heated under reflux for 40 min. and allowed to cool to give the *p*-tolylhydrazone (VIII) (350 mg.), m. p. 188~189°C. Recrystallization from ethanol-dioxane formed reddish orange prisms, m. p. 192~193°C.

Found: C, 73.74; H, 5.33; N, 7.36. Calcd. for $C_{23}H_{20}O_3N_2$: C, 74.17; H, 5.41; N, 7.52%.

A mixture of this *p*-tolylhydrazone (90 mg.), ethanol (5 ml.) and 6 N hydrochloric acid (1 drop) was heated under reflux for 1 hr. and then allowed to cool to give X (80 mg.), m. p. 166~168°C. Recrystallization from ethanol afforded cream-yellow needles, m. p. 169.5~170°C.

Found: C, 77.72; H, 4.97; N, 7.30. Calcd. for $C_{23}H_{18}O_2N_2$: C, 77.95; H, 5.12; N, 7.91%.

λ_{max}^{MeOH} mμ (log ε); 252 (4.45), 292 (4.46), 393 (3.90).

The Oxidation of II.—Into a solution of II (530 mg.) in a mixture of 6 N potassium hydroxide solution (2.5 ml.) and water (60 ml.), powdered potassium permanganate (2.80 g.) was stirred in small portions at room temperature; 2.56 g. of potassium permanganate were consumed rapidly. After stirring was continued for a further 3 hr., the excess permanganate was decomposed by the addition of methanol, the manganese dioxide which separated out was filtered off, and the filtrate was acidified to pH 2 with 6 N hydrochloric acid and extracted with ether. After the solution had been dried over anhydrous sodium sulfate, the solvent was removed from the extract to leave colorless crystals (330 mg.), m. p. 230~234°C. Recrystallization from aqueous methanol afforded 5-phenylpyrazole-3-carboxylic acid (XI) as colorless needles, m. p. 234~235°C (decomp.); it was identified by admixture with an authentic specimen[3] and also by a comparison of their infrared spectra.

Found: C, 63.42; H, 3.96; N, 14.47. Calcd. for $C_{10}H_8O_2N_2$: C, 63.82; H, 4.29; N, 14.89%.

The Oxidation of IX.—To a solution of IX (680 mg.) in a mixture of 6 N potassium hydroxide solution (5.5 ml.) and water (180 ml.), powdered potassium permanganate (2.95 g.) was added in small portions; the reaction mixture was treated in a manner similar to that above to give colorless crystals (430 mg.), m. p. 175~182°C. Recrystallization from aqueous methanol afforded 1,5-diphenylpyrazole-3-carboxylic acid (XII) as colorless needles, m. p. 183~184°C; it was identified by admixture with an authentic specimen[4] and by a comparison of their infrared spectra.

Found: C, 73.29; H, 4.96; N, 10.47. Calcd. for $C_{16}H_{12}O_2N_2$: C, 72.71; H, 4.58; N, 10.60%.

The *p*-Tolylazo Compound of II. — Into a solution of II (260 mg.) in pyridine (1.7 ml.), a solution of *p*-toluenediazonium chloride prepared from *p*-toluidine (120 mg.) by the usual method, was stirred under cooling. The mixture was then stirred for an additional 2 hr. and allowed to stand overnight. The crystals so obtained were collected by filtration and washed with a small amount of benzene to give 4-(5-phenyl-3-pyrazolyl)-5-(*p*-tolylazo)tropolone (250 mg.) as orange crystals, m. p. 220.5~221°C.

Found: C, 72.02; H, 4.47; N, 14.78. Calcd. or $C_{23}H_{18}O_2N_4$: C, 72.23; H, 4.74; N, 14.65%.

λ_{max}^{MeOH} mμ (log ε); 255 (4.57), 422 (4.50).

Methyl Ethers of II: 2-Methoxy-4-(5-phenyl-3-pyrazolyl)tropone (XIIIa) and 2-Methoxy-6-(5-phenyl-3-pyrozolyl)tropone (XIIIb).—To a solution of II (800 mg.) in ethyl acetate (150 ml.), an ethereal solution of diazomethane (13 ml.) was added. After additional stirring for 3 hr., the mixture was concentrated to a small volume to give crystals (690 mg.); m. p. 207~213°C. Recrystallization from methanol gave XIIIb (330 mg.) as cream-yellow needles, m. p. 252~253°C.

Found: C, 73.27; H,. 4.92; N, 9.71. Calcd. for $C_{17}H_{14}O_2N_2$: C, 73.36; H, 5.07; N, 10.07%.

λ_{max}^{MeOH} mμ (log ε); 280 (4.67).

The crystals, obtained from the mother liquor by the removal of the solvent, were fractionally recrystallized from methanol to give XIIIa (180 mg.) as cream-yellow plates, m. p. 235°C.

Found: C, 73.05; H, 4.99; N, 9.71. Calcd. for $C_{17}H_{14}O_2N_2$: C, 73.36; H, 5.07; N, 10.07%.

λ_{max}^{MeOH} mμ (log ε); 273 (4.55), 368 (4.17).

The heating of XIIIa or XIIIb with a dilute potassium hydroxide solution in aqueous ethanol gave II in a 60% yield.

Methyl Ethers of IX: 2-Methoxy-4-(1, 5-diphenyl-3-pyrazolyl)tropone (XIVa) and 2-Methoxy-6-(1, 5-diphenyl-3-pyrozolyl)tropone (XIVb).—Into a solution of IX (1.00 g.) in ethyl acetate (70 ml.), an ethereal solution of diazomethane (15 ml.) was stirred under cooling. After additional stirring for 4 hr., the mixture was allowed to stand overnight to give XIVb (440 mg.), m. p. 220~221°C, which was recrystallized from methanol as cream-colored needles, m. p. 223~224°C.

Found: C, 77.81; H, 4.88; N, 7.87. Calcd. for $C_{23}H_{18}O_2N_2$: C, 77.95; H, 5.12; N, 7.91%.

λ_{max}^{MeOH} mμ (log ε); 247 (4.40), 292 (4.56).

Removing the solvent from the mother liquor afforded crystals, from which XIVa (260 mg.) was obtained as pale yellow micro-needles, m. p. 168~169°C, after recrystallization from methanol.

Found: C, 77.71; H, 4.89; N, 7.94. Calcd. for $C_{23}H_{18}O_2N_2$: C, 77.95; H, 5.12; N, 7.91%.

λ_{max}^{MeOH} mμ (log ε); 252 (4.54), 370 (4.22).

The heating of XIVa or XIVb with a 2 N potassium hydroxide solution in aqueous ethanol afforded IX in a 60% yield.

Diethyl 2-Amino-5-(5-phenyl-3-pyrozolyl)azulene-1, 3-dicarboxylate (XV). — To a sodium ethoxide solution, prepared by dissolving sodium (300 mg.) in anhydrous ethanol (2 ml.), ethyl cyanoacetate (300 mg.) and then a solution of XIIIa (300 mg.) in anhydrous ethanol (50 ml.) were added. After having been allowed to stand for one day, the mixture was diluted with water (150 ml.) and extracted with benzene. The removal of the solvent from the extract left an oily substance, which was crystallized by the addition of a small amount of methanol, giving XV (170 mg.) as orange micro-crystals, m. p. 237~238°C.

Found: C, 69.92; H, 5.19; N, 9.36. Calcd. for $C_{25}H_{23}O_4N_3$: C, 69.91; H, 5.40; N, 9.76%.

λ_{max}^{MeOH} mμ (log ε); 259 (4.61), 343 (4.91), 462 (3.45). IR (KBr); 3420, 3290 (NH_2); 3200 (NH); 1667 (C=O) cm^{-1}.

Diethyl 2-Amino-5-(1, 5-diphenyl-3-pyrazolyl)azulene-1, 3-dicarboxylate (XVI) and 1, 3-Dicyano-2-hydroxy-5-(1,5-diphenyl-3-pyrozolyl)azulene (XVII). —Into a suspension of ethyl sodiocyanoacetate in ethanol, prepared from sodium (30 mg.), anhydrous ethanol (2 ml.) and ethyl cyanoacetate (250 mg.), a solution of methyl ether (a mixture of XIVa and XIVb) (250 mg.) in a mixture of anhydrous ethanol (15 ml.) and dry dioxane (10 ml.) was stirred. After having been allowed to stand for one day, the mixture was diluted with water and extracted with benzene. The removal of the solvent from the extract afforded XVI (190 mg.) as orange prisms, m. p. 179°C, after recrystallization from methanol.

Found: C, 73.89; H, 5.16; N, 8.18. Calcd. for $C_{31}H_{27}O_4N_3$: C, 73.64; H, 5.39; N, 8.31%.

λ_{max}^{MeOH} mμ (log ε); 253 (4.58), 346 (4.96), 462 (3.50). IR (KBr); 3440, 3310 (NH_2); 1658 (C=O) cm^{-1}.

An aqueous layer was acidified with 6 N hydrochloric acid and extracted with benzene. The solvent was removed from the extract and the residue was recrystallized from ethanol to give XVII (50 mg.) as orange micro-crystals, m. p. over 280°C.

Found: C, 78.64; H, 3.68; N, 13.22. Calcd. for $C_{27}H_{16}ON_4$: C, 78.60; H, 3.88; N, 13.59%.

λ_{max}^{MeOH} mμ (log ε); 233 (4.64), 345 (4.96), 393 (4.00), 470 (3.54). IR (KBr); 3010 (broad) (OH); 2210 (C≡N) cm^{-1}.

A part of the expenses for the present series of experiments were defrayed by a grant-in-aid from the Sankyo Co., Ltd., to which the authors' thanks are due.

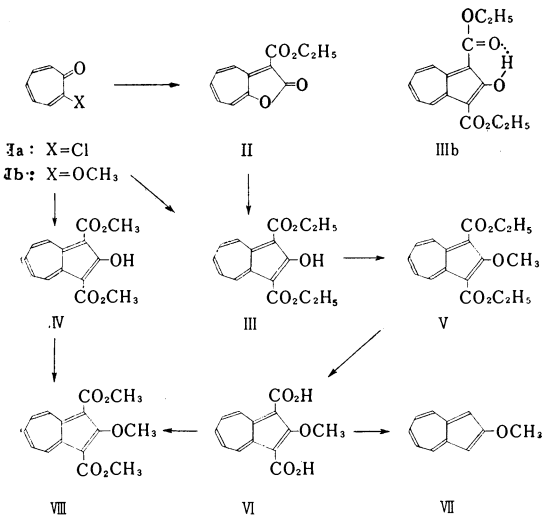
*The Synthesis of Diethyl 2-Hydroxyazulene-1, 3-dicarboxylate from Troponoids and Some Reactions of 2-Hydroxyazulene Derivatives**

By Tetsuo NOZOE, Kahei TAKASE and Noboru SHIMAZAKI

(Received June 15, 1964)



It has been reported that 2-chlorotropone and 2-methoxytropone react with ethyl cyanoacetate or malononitrile, in the presence of sodium ethoxide, to give azulene derivatives.[1] On the other hand, 1-oxaazulan-2-one (2*H*-cyclohepta[b]furan-2-one) derivatives have been obtained by the reaction of these tropone derivatives and diethyl malonate or ethyl acetoacetate.[2] We have reexamined these reactions with an interest in the azulene synthesis from troponoids and found that the reaction of 2-chlorotropone or 2-methoxytropone and malonic ester affords a new azulene derivative, 2-hydroxyazulene-1, 3-dicarboxylic ester. Some reactions of this azulene will be described here.

The reaction of 2-chlorotropone (Ia) and diethyl sodiomalonate in dry benzene gave 3-ethoxycarbonyl-1-oxaazulane-2-one (II), as has already been reported.[2] Furthermore, the reaction of 2-chlorotropone (Ia) or 2-methoxy

* Presented at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

2) S. Seto, *Sci. Repts. Tohoku Univ.*, I, **37**, 367 (1953).

tropone (Ib) diethyl malonate, in the presence of one or two molar equivalents of sodium ethoxide, in ethanol also gave II. However, when this reaction was carried out in ethanol by the use of an excess of sodium ethoxide, a yellowish-orange compound (III), $C_{16}H_{16}O_5$, was obtained in place of II. Further, the reaction of 2-methoxytropone with dimethyl malonate by the use of an excess of sodium methoxide in methanol afforded an orange compound (IV), $C_{14}H_{12}O_5$. These products are acidic and gave sparingly soluble sodium salts, red acetates and red *p*-nitrobenzoates. The ultraviolet absorption spectra of III and IV were similar to that of diethyl 2-aminoazulene-1,3-dicarboxylate,[1] as Fig. 1 shows. These findings suggest that III and IV are the diethyl and dimethyl esters of 2-hydroxyazulene-1,3-dicarboxylic acid respectively. The structures of III and IV were confirmed by the following

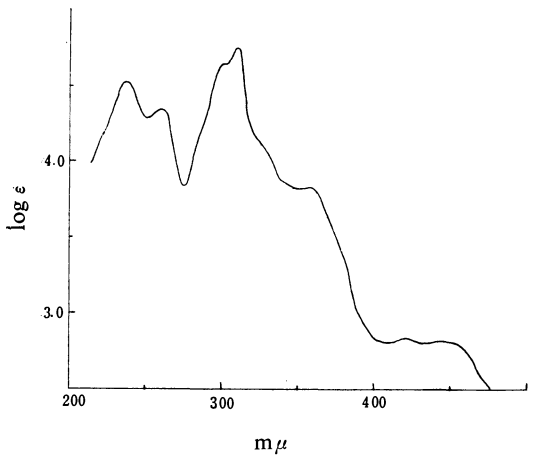

Fig. 1. The ultraviolet absorption spectrum of diethl 2-hydroxyazulene-1,3-dicarboxylate (III) in methanol.

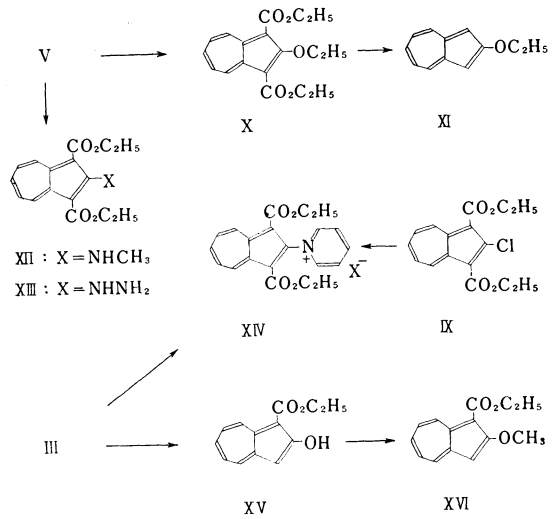
evidence. The methylation of III with diazomethane gave diethyl 2-methoxyazulene-1,3-dicarboxylate (V). The alkaline hydroysis of V, followed by the decarboxylation of the dicarboxylic acid (VI) thereby obtained, gave 2-methoxyazulene (VII).[3] On the other hand, the methylation of IV with diazomethane gave dimethyl 2-methoxy-azulene-1,3-dicarboxylate (VIII), which was identical with the dimethyl ester of dicarboxylic acid (VI).

The above mentioned experiments show without ambiguity that the reaction of 2-chloro- (Ia) or 2-methoxytropone (Ib) and the malonic ester affords the 1-oxaazulan-2-one derivative (II) or 2-hydroxyazulene derivatives (III) according to the amount of the ethoxide used. This evidence indicates that II is a reaction intermediate in the formation of azulene (III) from troponoids (I). This was confirmed by the finding that II easily reacted which diethyl malonate, in the presence of an excess of sodium ethoxide, to give III in a good yield.

It is known[3] that the chlorine atom of diethyl 2-chloroazulene-1,3-dicarboxylate (IX) is easily replaced by various anionoid reagents. In comparison with IX, the behavior of the methoxyl group of diethyl 2-methoxyazulene-1,3-dicarboxylate (V) towards some anionoid reagents was examined. The methoxy group of V was replaced by the ethoxyl group when heated with sodium ethoxide, affording diethyl 2-ethoxyazulene-1,3-dicarboxylate (X). The alkaline hydrolysis of X, followed by the decarboxylation of the dicarboxylic acid thereby obtained, gave 2-ethoxyazulene (XI).[4] When V was heated with alcoholic potassium hydroxide, the methoxy group was replaced by the ethoxyl group, along with the elimination of the ethoxycarbonyl group, to give XI directly. The methoxyl group of V was also replaced by methylamine and by hydrazine to give diethyl-2-methylaminoazulene-1,3-dicarboxylate (XII)[4] and diethyl 2-hydrazinoazulene-1,3-dicarboxylate (XIII)[4] respectively. Contrary to the case of IX,[3] V did not react with alcoholic ammonia, dimethylamine and aniline.



The efforts to replace the hydroxyl group of III with chlorine were unsuccessful; that is, III was recovered on treatment with thionyl chloride or phosphorous oxychloride. The tosylation of III with *p*-toluenesulfonyl chloride in pyridine gave pyridinium salt (XIV) in place of the *p*-tolylsulfonyloxy derivative. The picrate of XIV was identical with that of

3) T. Nozoe, S. Seto and S. Matsumura, This Bulletin, 35, 1990 (1962).

4) The compounds which have been derived from diethyl 2-chloroazulene-1,3-dicarboxylate (IX) have been reported[3] as oil.

the compound obtained by the treatment of IX with pyridine.[5] This is because the initially formed tosylate reacted with pyridine to give XIV.

Diethyl 2-aminoazulene-1, 3-dicarboxylate was brominated easily to give the 6-bromo derivative,[1] but the bromination of III ended only in its recovery. Nitrosation and azo-coupling reaction on III also recovered the starting material.

For the synthesis of 2-hydroxyazulene, the hydrolysis of III was examined. The alkaline hydrolysis of III gave ethyl 2-hydroxyazulene-1-carboxylate (XV), which afforded an acetate and a *p*-nitrobenzoate, along with an oily substance which changed to a black substance which was insoluble organic solvents. The methylation of XV gave ethyl 2-methoxyazulene-1-carboxylate (XVI). The acid hydrolysis of III gave only an insoluble black substance. The formation of these insoluble matters is assumed to be due to the polymerization of the unstable 2-hydroxyazulene which is formed. In the infrared spectra, III shows two absorptions (1675 and 1639 cm^{-1}) and due to an ester carbonyl, while its methyl ether (IV), shows only one absorption (1984 cm^{-1}). This evidence indicates that III exists as an intramolecular hydrogen-bonded structure (IIIa), which enhances the stability of this compound.

Experimental[6]

Diethyl 2-Hydroxyazulene-1, 3-dicarboxylate (III).—*a) From 2-Chlorotropone (Ia).*—To a sodium ethoxide solution prepared from sodium (700 mg.) and absolute ethanol (50 ml.), diethyl malonate (2.4 g.) and Ia (700 mg.) were added, and the mixture was allowed to stand for 40 hr. at room temerature; the reaction mixture then turned into a gelatinous orange mass. Water was added, and the sodium salts thereby separated out were collected and dissolved in glacial acetic acid. This solution was diluted with water and extracted with chloroform. The solvent was evaporated and the residue was recrystallized from ethanol to give III (700 mg.) as orangish yellow needles, m. p. 95~96°C.

Found: C, 66.60; H, 5.42. Calcd. for $C_{16}H_{16}O_5$: C, 66.67; H, 5.55%.

λ_{max}^{MeOH} mμ (log ε); 237 (4.53), 260 (4.34), 310 (4.75), 360 (3.83), 420 (2.84).

Acetate.—m. p. 129.5~130°C, red needles (from ethanol).

Found: C, 65.55; H, 5.67. Calcd. for $C_{18}H_{18}O_5$: C, 65.44; H, 5.49%.

λ_{max}^{MeOH} mμ (log ε); 235 (4.53), 270 (4.40), 300 (4.69), 335 (3.80), 365 (3.89), 480 (2.83).

p-Nitrobenzoate.—m. p. 180~181°C, red needles (from ethanol).

Found: C, 63.18; H, 4.59; N, 3.34. Calcd. for $C_{23}H_{19}O_8N$: C, 63.15; H, 4.38; N, 3.20%.

λ_{max}^{MeOH} mμ (log ε); 233 (4.59), 267 (4.53), 300 (4.81), 333 (3.91), 365 (3.93), 460 (2.88), 480 (2.91).

b) From 2-Methoxytropone (Ib).—To a sodium ethoxide solution prepared from sodium (11.6 g.) and absolute ethanol (300 ml.), diethyl malonate (48 g.) and Ib (13.6 g.) were added, and the mixture was allowed to stand for 40 hr. at room temperature. When the reaction mixture was then treated as in a), III (15.8 g.) was obtained as orangish yellow needles, m.p. 95~96°C.

c) From 2-Ethoxycarbonyl-1-oxaazulan-2-one (II).—To a sodium ethoxide solution prepared from sodium (230 mg.) and absolute ethanol (20 ml.), diethylmalonate (800 mg.) and II (500 mg.) were added. The mixture was treated as in a), and III (430 mg.) was obtained as organish yellow needles, m. p. (95~96°C).

Dimethyl 2-Hydroxyazulene-1, 3-dicarboxylate (IV).—To a sodium methoxide solution prepared from sodium (3.95 g.) and absolute methanol (85 ml.), dimethyl malonate (12 g.) and 2-methoxytropone (4.23 g.) were added, and the mixture was allowed to stand for 40 hr. at room temperature. The reaction mixture was treated as described in the above experiment, and IV (4.90 g.) was obtained as reddish orange needles or yellowish orange needles, m. p. 144~145°C, after recrystallization from ethyl acetate.

Found: C, 64.87; H, 4.49. Calcd. for $C_{14}H_{12}O_5$: C, 64.61; H, 4.65%.

λ_{max}^{MeOH} mμ (log ε); 238 (4.49), 260 (4.31), 310 (4.74), 356 (3.82), 450 (2.86).

Acetate.—m. p. 151~153°C, red needles (from ethyl acetate).

Found: C, 63.71; H, 4.75. Calcd. for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67%.

λ_{max}^{MeOH} mμ (log ε); [233 (4.52), [268 (4.40), 300 (4.70), 335 (3.81), 350 (3.78), 363 (3.89), 410 (2.55), 475 (2.85).

p-Nitrobenzoate.—m. p. 221~222°C, red needles (from dimethylformamide).

5) T. Nozoe and M. Oyama, to be published.
6) All melting points are uncorrected.

Found: C, 62.14; H, 3.60; N, 3.59. Calcd. for $C_{21}H_{15}O_8N$: C, 61.61; H, 3.69; N, 3.42%.

λ_{max}^{MeOH} mμ; 233, 266, 300, 363, 410, 470.

Diethyl 2-Methoxyazulene-1, 3-dicarboxylate (V).—To a suspension of III (1.50 g.), in ether (5 ml.), an ethereal solution of diazomethane (20 ml.) was added, and the mixture was stirred for 3 hr. while being cooled with ice-water. The solvent was evaporated and the oily residue was passed through a short column of amlumina with ether to give V (1.50 g.) as a red oil.

Found: C, 67.08; H, 5.98. Calcd. for $C_{17}H_{18}O_5$: C, 67.54; H, 6.00%.

λ_{max}^{MeOH} mμ (log ε); 235 (4.50), 265 (4.27), 305 (4.66), 345 (3.77), 480 (2.50).

2-Methoxyazulene-1, 3-dicarboxylic Acid (VI).—To a solution of V (600 mg.) in ethanol (8 ml.), a 2 N potassium hydroxide solution (6 ml.) was added, the mixture was then heated under reflux for 4 hr. The reaction mixture was acidified with 6 N hydrochloric acid to give VI (440 mg.) as orange micro crystals, m. p. 205~208°C.

Found: C, 63.50; H, 4.04. Calcd. for $C_{13}H_{10}O_5$: C, 63.41; H, 4.09%.

2-Methoxyazulene (VII).—The heating of VI (400 mg.) at about 200°C to effect decarboxylation, followed by sublimation under reduced pressure, gave a violet sublimate. This was recrystallized from methanol to give VII (80 mg.) as violet plates, m. p. 79~80°C; VII was identified with an authentic specimen[3] by admixture and by a comparison of the infrared spectrum.

Dimethyl 2-Methoxyazulene-1, 3-dicarboxylate (VIII).—*a) From Dimethyl 2-Hydroxyazulene-1,3-dicarboxylate (IV).*—To a suspension of IV (300 mg.) in ether (2 ml.), an ethereal solution of diazomethane (10 ml.) was added; the mixture was then stirred for 3 hr. while being cooled with ice-water. The residual oil obtained by the evaporation of the solvent was passed through a short column of alumina with ether and recrystallized from methanol to give VIII (280 mg.) as red needles, m. p. 69~70°C, reported[3] m. p. 61~62°C.

Found: C, 65.86; H, 4.91. Calcd. for $C_{15}H_{14}O_5$: C, 65.69; H, 5.15%.

λ_{max}^{MeOH} mμ (log ε); 235 (4.45), 267 (4.29), 305 (4.71), 340 (3.83), 410 (2.39), 470 (2.69).

b) From 2-Methoxyazulene-1,3-dicarboxylic Acid (VI).—To a suspension of VI (200 mg.) in ether (2 ml.), an ethereal solution of diazomethane (10 ml.) was added, and the mixture was stirred for 3 hr. while being cooled with ice-water. When the reaction mixture was treated as in a), VIII (150 mg.) was obtained as red needles, m. p. 69~70°C.

Diethyl 2-Ethoxyazulene-1, 3-dicarboxylate (X).—A mixture of V (400 mg.) and a 1 M sodium ethoxide solution (3 ml.) was heated under reflux for 3 hr. The reaction mixture was diluted with water and extracted with chloroform. The solvent was removed, and residue was passed through a short column of alumina with ether to give X (150 mg.) as red plates, m. p. 47~49°C.[4]

Found: C, 69.72; H, 6.51. Calcd. for $C_{18}H_{20}O_5$: C, 68.34; H, 6.37%.

2-Ethoxyazulene (XI).—*a) From Diethyl 2-Ethoxyazulene-1, 3-dicarboxylate (X).*—To a solution of X (200 mg.) in ethanol (4 ml.), a 2 N potassium hydroxide solution (2 ml.) was added, and the mixture was heated under reflux for 4 hr. The reaction mixture was acidified with 6 N hydrochloric acid to give 2-ethoxyazulene-1,3-dicarboxylic acid (150 mg.) as orange micro crystals, m. p. 200~205°C. This acid (130 mg.) was heated to effect decarboxylation and then sublimed at reduced pressure. The sublimate was passed through a short column of alumina with ether and recrystallized from ethanol to give XI (50 mg.) as violet plates, m. p. 76~77°C.[4]

Found: C, 83.61; H, 6.81. Calcd. for $C_{12}H_{12}O$: C, 83.69; H, 7.02%.

λ_{max}^{MeOH} mμ (log ε); 238 (4.08), 276 (4.78), 284 (4.85), 315 (3.77), 340 (3.58), 355 (3.75), 370 (3.69), 395 (2.67), 410 (2.64), 440 (2.44).

b) From Diethyl 2-Methoxyazulene-1,3-dicarboxylate (V).—To a solution of potassium hydroxide (400 ml.) in ethanol (10 ml.), V (600 mg.) was added, and the mixture was heated under reflux for 8 hr. The reaction mixture was diluted with water, neutralized with 6 N hydrochloric acid, and extracted with ether. The ether extract was chromatographed through an alumina column, and the evaporated of the solvent from the effluent left crystals, which were recrystallized from ethanol to give XI (100 mg.) as violet plates, m. p. 76~77°C.

Diethyl 2-(Methylamino)azulene-1, 3-dicarboxylate (XII).—A mixture of V (300 mg.), a 40% aqueous methylamine solution (2 ml.) and ethanol (2 ml.) was heated under reflux for 2 hr. The reaction mixture was diluted with water, neutrallized with 6 N hydrochloric acid, and extracted with chloroform. The solvent was evaporated and the residual oil was passed through a short column of alumina with ether to give XII (210 mg.) as orange plates, m. p. 48~50°C.[4]

Found: C, 68.16; H, 5.97; N, 4.29. Calcd. for $C_{17}H_{19}O_4N$: C, 67.76; H, 6.36; N, 4.65%.

λ_{max}^{MeOH} mμ (log ε); 230 (4.15), 255 (4.30), 280 (4.28), 324 (4.67), 410 (3.87), 460 (3.35).

Picrate.—m. p. 113~114°C, orange micro prisms (from ethanol).

Found: C, 52.32; H, 3.83; N, 10.38. Calcd. for $C_{23}H_{22}O_{11}N_4$: C, 52.07; H, 4.15; N, 10.56%.

Diethyl 2-(Hydrazino)azulene-1, 3-dicarboxylate (XIII).—To a solution of V (600 ml.) in ethanal (2 ml.), 80% hydrazine hydrate (2 ml.) was added, and the mixture was heated at 100°C for 3 min. The crystals thereby formed were collected and recrystallized from ethanol to give XIII (500 mg.) as yellow needles m. p. 108~109°C.[4]

Found: C, 63.67; H, 5.86; N, 9.29. Calcd. for $C_{16}H_{18}O_4N_2$: C, 63.56; H, 6.00; N, 9.27%.

λ_{max}^{MeOH} mμ (log ε); 246 (4.35), 273 (4.41), 316 (4.73), 363 (3.88).

Acetate.—m. p. 129~130°C (reported[3] m. p. 132°C), yellow needles (from methanol).

Found: C, 62.85; H, 5.58; N, 7.90. Calcd. for $C_{18}H_{20}O_5N_2$: C, 62.78; H, 5.85; N, 8.14%.

***N*-(1, 3-Diethoxycarbonylazulen-2-yl)pyridinium *p*-Toluenesulfonate (XIV).**—To a solution of III (600 mg.) in pyridine (3 ml.), *p*-toluenesulfonyl chloride (600 mg.) was added, and the mixture was stirred

for 3 hr. while being cooled with ice-water. The mixture diluted with water and extacted with chloroform. The solvent was evaporated, and the residue was recrystallized from ethanol to give XIV (680 mg.) as red needles, m. p. 184~185°C.

Found: C, 64.46; H, 4.81; N, 2.64. Calcd. for $C_{28}H_{27}O_7NS$: C, 64.48; H, 5.22; N, 2.69%.

λ_{max}^{MeOH} mμ (log ε); 228 (4.57), 269 (4.45), 296 (4.67), 320 (3.90), 356 (4.04), 470 (3.02).

***N*-(1, 3-Diethoxycarbonylazulen-2-yl)pyridinium Picrate.**—To a solution of XIV (50 mg.) in ethanol (2 ml.), a saturated alcoholic picric acid solution (1 ml.) was added to give picrate (60 mg.) as orange micro-prisms, m. p. 212~213°C.

Found: C, 55.75; H, 3.69; N, 9.59. Calcd. for $C_{27}H_{22}O_{11}N_4$: C, 56.05; H, 3.81; N, 9.68%.

Ethyl 2-Hydroxyazulene-1-carboxylate (XV).—A mixture of III (300 mg.) and a 2 N potassium hydroxide solution (2 ml.) in ethanol (8 ml.) was heated under reflux for 3 hr. The reaction mixture was then diluted with water, acidified with 6 N hydrochloric acid, and extracted with ether. The oily material obtained by the evaporation of the solvent was dissolved in benzene and chromatographed through a silica gel column. The evaporation of the solvent from the effluent left crystals, which were recrystallized from ethanol gave XV (150 mg.) as red needles, m. p. 75~76°C.

Found: C, 72.15; H, 5.64. Calcd. for $C_{13}H_{12}O_3$: C, 72.21; H, 5.59%.

λ_{max}^{MeOH} mμ (log ε); 293 (4.72), 304 (4.80), 350 (3.75), 450 (2.56), 490 (2.42).

p-Nitrobenzoate.—m. p. 191~193°C, reddish violet needles (from benzene).

Found: C, 66.06; H, 4.01; N, 3.74. Calcd. for $C_{20}H_{15}O_6N$: C, 65.75; H, 4.14; N, 3.83%.

Ethyl 2-Methoxyazulene-1-carboxylate (XVI).—To a suspension of XV (50 mg.) in ether, an ethereal solution of diazomethane (1 ml.) was added, and the mixture was stirred for 3 hr. while being cooled with ice-water. The solvent was evaporated, and the residue was passed through a short column of alumina with benzene to give XVI (50 mg.) as red needles, m. p. 64~65°C.

Found: C, 72.97; H, 5.66. Calcd. for $C_{14}H_{14}O_3$: C, 73.02; H, 6.13%.

A part of the expenses for the present series of experiments were defrayed by a grant-in-aid for Scientific Research from the Sankyo Co., Ltd., and from the Upjohn Co., Ltd. The infrared spectra were measured by using a Shimadzu infrared spectrophotometer IR-27 purchased by a grant-in-aid for Scientific Research from the Toyo Rayon Co., Ltd. The authors wish to express their deep gratitude for these contributions.

*The Mechanism of the Formation of Terephthalic Acid from Benzonitrile**

By Yoshiro OGATA, Yoshiaki FURUYA, Tadashi NOSHIRO and Tadahiro Go

(Received May 13, 1964)

It has been claimed by Henkel and Cie[1] that terephthalic acid can be obtained by the reaction of benzonitrile and potassium carbonate in either the presence or absence of a cadmium catalyst.

Although the reaction seems to proceed by way of benzoic acid, it is curious that the reaction proceeds even in the absence of a catalyst, since it has been known that benzoic acid cannot give an appreciable amount of terephthalic acid under the same conditions.

Moreover, the stoichiometry of the reaction and the cleaving bond in C_6H_5–C≡N are still not clear. The present paper will describe the results of our mechanistic study by means of a tracer study with radioactive carbonate and also the results of a study of reaction products together with the effect of conditions on the composition of the products.

Experimental

Typical Procedure for the Preparation of Terephthalic Acid from Benzonitrile. — An intimate mixture of benzonitrile (1.0 g., 0.01 mol.), finely powdered dry potassium carbonate (2.76 g., 0.02 mol.) and cadmium iodide (0.50 g., 0.00137 mol.) was placed in a sealed tube. The tube was enveloped with glass wool and placed in an autoclave together with toluene (ca. 30 ml.) in ordor to balance the internal pressure of the tube. The reaction was carried out at 360~500°C for 2.5~7 hr. The product was extracted with petroleum

ether (20 ml.), and the extract was analyzed to determine the benzonitrile and benzoic acid contents. The benzonitrile was identified by ultraviolet spectrography and by hydrolysis to benzoic acid; m. p. and mixture m. p. 122.5°C. Benzene was identified by ultraviolet spectrography and by nitration to *m*-dinitrobenzene; m. p. and mixture m. p. 88°C. The residual solid of the extraction was dissolved in hot water (100 ml.), filtered, acidified with hydrochloric acid, and again filtered while hot. The precipitate after drying gave terephthalic acid, which on esterification gave dimethyl terephthalate, m. p. and mixture m. p. 140°C. The filtrate was extracted with ether, the extract after the evaporation of the ether being washed with chloroform to extract benzoic acid alone, separating it from the residual isophthalic and terephthalic acids. The results are shown in Table I, together with the results of terephthalic acid formation from benzoic acid and benzamide.

The Estimation of Isophthalic and Terephthalic Acids in the Products.—Ultraviolet spectrophotometry was used. The reaction mixture was dissolved in hot water (100 ml.). The filtered solution was acidified and filtered after cooling. The precipitate after drying was analyzed for isophthalic and terephthalic acids contents by means of ultraviolet spectrophotometry by measuring the extinction at the wavelength of 284.7 mμ (for terephthalic acid) or of 280.5 mμ and 288.4 mμ (for isophthalic acid).[2] These data, shown in Table III, are of special interest in connection with the effect of potassium cyanate on the ratio of isophthalic acid to terephthalic acid in the product.

The Formation of Benzonitrile from Benzoic Acid and Potassium Cyanate. — A mixture of potassium benzoate (1.6 g., 0.01 mol.) and potassium cyanate (0.81 g., 0.01 mol.) was heated in a sealed tube at 470°C for 2.5 hr. Terephthalic acid (83.5 mg.) was obtained. The other products were analyzed by gas chromatography employing a Yanagimoto Model GCG-220 operated with a 1.3 m. column packed with Silicone D. C. 703 using helium with a flow rate of 28.4 ml./min. at 80°C for benzene (367 mg.) and of 31.25 ml./min. at 150°C for benzonitrile (13.8 mg., 1.4%). The retention times were 3.66 min. for benzene and 7.4 min. for benzonitrile. Quantitative determinations were made using the corresponding authentic sample as an internal standard.

The Formation of Terephthalic Acid from Benzamide.—A mixture of benzamide (1.21 g., 0.01 mol.), cadmium iodide and potassium carbonate was heated under the same conditions as above and worked up similarly. The results are shown in Table I.

Tracer Experiments.—Labeled carbon dioxide-^{14}C was evolved by hydrochloric acid from labeled barium carbonate obtained from the Isotope Center of Japan and absorbed in an aqueous solution of a calculated amount of potassium hydroxide. The solution was then evaporated to dryness in a vacuum, yielding labeled potassium carbonate. The method for the isolation of the product was the same as that given as a typical procedure above. The radioactivities of samples were expressed as those of the corresponding barium carbonates. All the data in Table II are averages of duplicate experiments; they have been calibrated for their background against standard barium carbonate.

Results and Discussion

The product from the cadmium salt-catalyzed reaction of benzonitrile with potassium carbonate was found to contain benzoic, isophthalic and terephthalic acids, together with benzene and potassium cyanate. Potassium was identified by converting it with aniline hydrochloride to phenylurea; m. p. and mixture m. p. 147°C.

2) N. Berman, C. H. Ruof and H. C. Howard, *Anal. Chem.*, 23, 1882 (1951).

It was confirmed by gas chromatography that potassium cyanate and benzoic acid can form a small quantity of benzonitrile. Therefore, the stoichiometric equation may be:

$$C_6H_5CN + K_2CO_3 \rightleftharpoons C_6H_5COOK + KOCN$$

$$2\,C_6H_5COOK \rightarrow p\text{- and } m\text{-}KOOC\text{-}C_6H_4\text{-}COOK + C_6H_6$$

Here, the first step is reversible, and the second step is a disproportionation of the benzoic acid formed which has been confirmed by a tracer study previously reported.[3]

However, it is still strange that the conversion of bonzonitrile to potassium terephthalate is possible without a cadmium catalyst. It is probable that the potassium cyanate formed behaves as a catalyst for the terephthalate synthesis, since it was observed that the added potassium cyanate possessed a slight catalytic ability to convert potassium benzoate to terephthalate (Table I).

It is apparent that potassium cyanate has the effect of increasing the ratio of isophthalic to terephthalic acid in the product (Table III). The meta : para ratio becomes exceptionally small in the presence of a cadmium catalyst (Table III).

The tracer experiments with cadmium iodide and $K_2{}^{14}CO_3$ indicated that only 1/10.72 of the original activity was incorporated in the terephthalate produced from normal benzonitrile. The extent of the incorporation was very close to the value (1/10.63) obtained in conversion of potassium benzoate to terephthalate with $K_2{}^{14}CO_3$ and CdI_2 in a sealed tube under the same conditions. Since radioactivities were

detected in the recovered benzoate in the cadmium-catalyzed conversion of benzonitrile or potassium benzoate to potassium terephthalate, the labeled carbon is introduced by the exchange of the carboxylate group in the benzoate.

In spite of the description of the pertinent Patent,[1] the yield of potassium terephthalate from benzamide at 490°C in a sealed tube under the same conditions was low; this implies that the reaction of benzonitrile to the terephtalate may not proceed via benzamide. The formation of terephthalic acid from benzamide, claimed in the patent,[1] may be the result of the formation of benzonitrile from benzamide by dehydration.

These facts suggest that the reaction of benzonitrile with potassium carbonate to form terephthalate is a conversion to potassium benzoate, followed by disproportionation. Here, the carboxylate group of benzoate may be exchanged with carbonate in the presence of a cadmium catalyst:

$$C_6H_5COOK \underset{(Cd^{2+})}{\overset{{}^{14}CO_3{}^{2-}}{\rightleftharpoons}} C_6H_5{}^{14}COOK$$

There seems to be no chance for the introduction of a carboxyl group from outside carbonate or carbon dioxide except at the exchange in benzoate. The extent of the exchange of carboxylate groups increases with an increase in the reaction temperature, and the exchange is catalyzed by cadmium salts. It is of interest to note that the exchange is impossible without a cadmium catalyst and that this situation is different from that of phthalate, where the exchange is possible without cadmium salt.[3a]

Summary

A mixture of benzonitrile, cadmium iodide and potassium carbonate has given, when heated in a sealed tube at 360~500°C, terephthalic acid (21~33%), together with a considerable amount of isophthalic acid. The

reaction was possible without a cadmium catalyst, but the yield of terephthalic acid was poorer (8.0%). The tracer study with $K_2{}^{14}CO_3$, as well as the identification of cyanate in the products, showed that the reaction proceeds by way of the conversion of benzonitrile to potassium benzoate and potassium cyanate, followed by the disproportionation of potassium benzoate to potassium terephthalate and isophthalate. Potassium cyanate seems to be a weak catalyst for the disproportionation.

Electron Spin Resonance of the Acenaphthylene Anion Radical

By Masamoto IWAIZUMI and Taro ISOBE

(Received May 16, 1964)

The electron spin resonance spectra of the anion radicals of an aromatic system provide much interesting information about these molecules. In particular, the approximate proportionality between the proton hyperfine constant and the π-electron spin density has yielded valuable information about the distribution of the unpaired electron, enabling one to test theoretical predictions.[1-11] However, some radicals produced by alkali metal reduction have been shown to exhibit some anomalous hyperfine structures, which can be attributed to the interaction of the radicals with the metal ions.[12-14]

The present investigation was undertaken to obtain more refined hyperfine coupling constants of the acenaphthylene anion radical than those previously reported and to examine the effects of the presence of metal ions on the hyperfine structure of this radical.

Experimental

To prepare the anion radical, both alkali metal reduction and electrolytic reduction methods were applied. In the former, the entire series of alkali metals, i.e., lithium, sodium, potassium, rubidium and cesium were used as reducing agents, with dioxane, tetrahydrofuran (THF), dimethoxyethane (DME), and dimethylformamide (DMF) as the respective solvents. In the latter, DMF, acetonitrile and a mixture of DMF and dioxane were used as solvents, tetra-*n*-propylammonium perchlorate as the supporting electrolyte, and the reduction was carried out in the electrolysis cell with a platinum anode and a mercury pool cathode, which was so designed that the electrolysis was possible within the microwave cavity. The ESR spectra were measured with a Hitachi X-band ESR spectrometer, model MPU-3B, employing field modulation at 100 kc./s. The preparation of the radicals and the measurement of the ESR spectra were carried out at room temperature (22.0~24.0°C).

Results and Discussion

The ESR Spectra and the Effect of Metal Ion Association on the Hyperfine Structures.— Figure 1 shows the ESR spectrum of the radical prepared with sodium in THF, together with the reconstruction based on the hyperfine coupling constants listed in Table I. As may be seen from this figure, the spectrum may be completely interpreted as arising from the coupling with four sets of two equivalent protons of the acenaphthylene anion radical. In the cases of the radicals other than those derived from the reduction with rubidium or cesium in DME, THF or dioxane, with lithium sodium or potassium in dioxane, and with potassium in THF respectively, the spectra show hyperfine splittings, similar to, though not strictly identical with, that given in Fig. 1. Figure 2, for example, shows the spectrum obtained from the radical prepared with sodium in DME: it should be compared with the spectrum given in Fig. 1.

In contrast, the spectra from the radicals prepared with rubidium or cesium in DME, THF or dioxane, with lithium, sodium or potassium in dioxane and with potassium in THF show more complicated hyperfine structures than those expected from the couplings with only the protons of the acenaphthylene anion radical. For examples, Figs. 3—5 show the spectra from the radicals prepared in dioxane with potassium, rubidium and cesium respectively. In the cases of the reduction with lithium, sodium or potassium in dioxane, and with potassium in THF, each line of the normal hyperfine pattern of the acenaphthylene radical is further split into four lines with equal intensities, while in the cases with cesium in DME, THF or dioxane, each line is further split into eight lines with equal intensities. These additional splittings can be explained by the interaction of the odd electron with each metal nucleus, viz., lithium, sodium or potassium of spin 3/2, and cesium of spin 7/2 respectively. In the cases of reduction with rubidium, too, we believe that the anomalous feature in the hyperfine structures is due to the interaction of the odd electron with two kinds of rubidium nuclei of spin 5/2 and 3/2, although the analysis of the spectra has not yet been completed.

The hyperfine coupling constants of the protons and the metal nuclei obtained from these spectra are listed in Table I. The assignment of the splittings to the respective proton positions was made on the basis of theoretical calculations for the odd-electron distribution. In a previous work,[1] the lack of resolution made it impossible to obtain a proton coupling at position 4 or to show a difference between positions 3 and 5.

All the spectra observed from the chemically- and electrolytically-produced radicals in the DMF solution agree with each other quite well and yield essentially the same coupling constants. However, in the other solvents, there is some small change in the proton hyperfine splittings as one goes from one metal to another. In the cases of electrolytically-produced radicals,

no appreciable variation of hyperfine structures with the solvents was observed. It may be considered, therefore, that the variation of the hyperfine splittings with the solvents or with alkali metals is caused by the association between the anion radical and metal ions.

As may be seen from Table I, the magnitude of the coupling of the cesium nucleus increases in the series of DMF-DME-THF-dioxane. In dioxane, which is nonpolar in nature, the splittings of all the alkali metals were observed. On the contrary, in the DMF solution no splittings due to any metal nuclei were observed. It may be concluded, therefore, that the association between the anion radical and metal ions increases in the series of DMF-DME-THF-dioxane solutions, and that the difference in the proton hyperfine coupling constants from those in the DMF solution is due to metal ion association.

In the dioxane solutions, the difference in proton hyperfine splittings from those in the DMF solutions is largest for the lithium-acenaphthylene anion radical; in going to the cesium-acenaphthylene anion radical it decreases. In view of studies by Mathius and others[15-17] on the optical absorption and reactivities of some radicals, it seems reasonable to consider that the lithium ion affects most strongly the proton hyperfine couplings of the anion radicals and that as the cationic radius increases the effect decreases. However, in the DME solutions, the difference in the proton hyperfine splitting from those in a DMF solutions is largest for the cesium-acenaphthylene radical and smallest for the lithium-acenaphthylene radical. We are not able to offer any explanation of this. However, leaving aside this question, it can be seen from Table I that the hyperfine coupling constants of the protons belonging to the six-membered ring increase by metal ion association, especially at position 3. However, the splitting constant at position 1 is not so affected; rather, it decreases in the case of the cesium-acenaphthylene anion radical.

Since the isotropic proton hyperfine splitting in the π-electron radicals has been shown to be linearly related to the π-lectron spin density,[18] the variation in the proton coupling constants observed here may be attributed to the redistribution of the π-electron spin densities caused by the cationic field of metal ions. According to the spin distribution predicted by McLachlan's method, the increase in the coupling constants at positions 2, 3 and 5 corresponds to the increase in the positive spin densities, and that at position 4, to the increase in the negative spin density.

The change in hyperfine coupling constants caused by metal ion association can be observed in some other aromatic anion radicals, but the magnitudes are not as large as those observed here. Furthermore, it is of interest to note that in the acenaphtylene anion radical the hyperfine coupling of the sodium nucleus is smaller than that of the lithium or potassium nucleus. In many cases reported previously larger couplings have been observed for the sodium nucleus than for the lithium or potassium nuclei.[7,14,19-22] Further work is in progress on the effect of metal ion association on the hyperfine coupling constants of the other aromatic anion radicals; a detailed discussion will be reported at a later date.

Calculated Hyperfine Coupling Constants and Spin Densities.—Table II shows the spin densities and hyperfine coupling constants calculated on the basis of the Hückel and McLachlan[3] methods. When these values are compared with the experimental values obtained in the DMF solution, the agreement seems rather good in spite of the neglect of the variation in the σ-π interaction parameter Q in McConnell's equation with bond angles. However, the total width of the spectrum is much larger than the usual values of 23~27 gauss. It may be considered, therefore, that negative spin densities possibly exist in the acenaphthylene anion radical, as may be expected from the calculations based on the McLachlan method.

TABLE II. CALCULATED HYPERFINE COUPLING CONSTANTS AND SPIN DENSITIES

Position	Hückel method*1		McLachlan method*2

Studies of Chemical Kinetics by Means of the Velocity of Sound. I. The Hydrolysis of Acetic Esters

By Tatsuya YASUNAGA, Nobuhide TATSUMOTO and Masaji MIURA

(Received May 22, 1964)

The velocity of sound is a function of the density and compressibility of fluids, and it is an important quantity in studying their physical properties. On the other hand, a chemical reaction in a solution causes a change in its compressibility because of the appearance and disappearance of molecular and ionic species. Therefore, the rate of chemical reactions can be determined by sound velocity measurements.

The ultrasonic velocity is one of a few physical quantities which can be determined with a very high degree of accuracy. One of the present authors[1] has determined the amount of ionic hydration and the critical micelle concentration of surfactants by means of a variable-path ultrasonic interferometer, the most accurate apparatus hitherto known for measuring the ultrasonic velocity. One disadvantage of this apparatus is, however, that it takes about one hour for one run of experiments in the velocity measurement. It is difficult, therefore, to trace thereby a rapid change in the sound velocity.

The sing-around method is a newly-develped technique in which the velocity is determined by the frequency measurement. Since the frequency can be determined quickly and precisely by means of the frequency counter, this method has the advantage over that of the interferometer when the velocity of sound varies with time.

In the present study, such chemical changes of a moderate rate as the hydrolysis of esters will be traced by means of the sing-around method.

Apparatus

The sing-around method, originally invented by Shepard and Knock,[2] has been developed recently by Greenspan and Tschieff.[3] The apparatus used in the present study was similar to that reported by the latter workers.

A schematic diagram of the circuit is given in Fig. 1. The principle of the operation of the circuit is as follows: The apparatus consists essentially of a pair of piezoelectric transducers, made of quartz crystals, mounted on both ends of a tube to form a sound path of a fixed length. An unmodulated pulse for starting the operation is generated by a pulse generator and fed to a sending transducer. The pulse received by a receiving transducer is then led to a high-gain pulse-shaping amplifier, and the amplified pulse retriggers the same pulse generator to emit the second pulse. By the repetition of this process, a train of repeated pulses is generated. When the path length is fixed, the frequency of the repeated pulses depends on the propagation velocity of the sound in the sample liquid and also on the circuit delays. The total time delay for a single cycle, τ, is given as:

$$\tau = 1/f = t_e + l/u \qquad (1)$$

where f is the frequency of the pulse repetition; t_e, the sum of electrical delays: u, the velocity of sound, and l, the path length.

The frequency was measured with a frequency counter. The time intervals of the gate for the frequency measurement were made as follows. First 5 Mc. continuous wave was generated by a temperature-controlled crystal oscillator, and then the frequency was lowered to 1 kc. by a multiplier circuit. The frequency of the 5 Mc. oscillator was monitored by the standard frequency of JJY. After it had been modified to the square wave, the 1 kc. wave

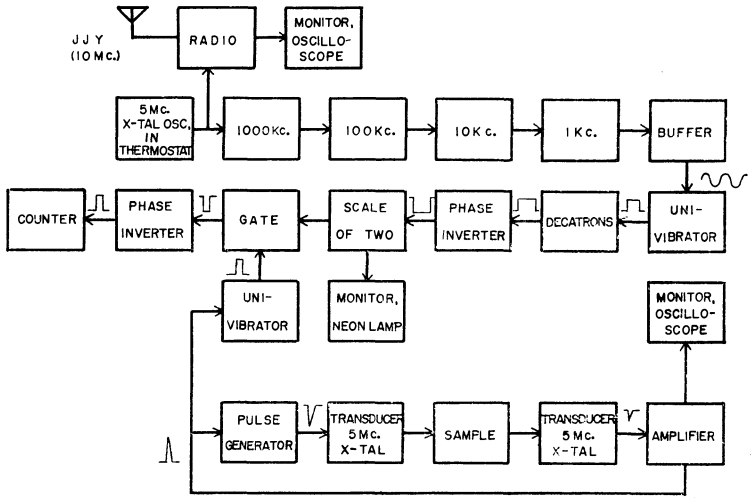

Fig. 1. Block diagram of sing-around velocimeter.

was fed to the decatron circuit to generate the 10 sec. intervals for the gate opening.

The repetition frequency was counted by the counter with six decatrons. The initiating pulse was generated by a blocking oscillator, using a pulse transformer with a ferrite core. The rise time of the pulse was less than 50 mμ sec., while the pulse width was about 200 mμ sec.

The cell shown in Fig. 2 was made of a pyrex tube, 16 mm. and 100 mm. in diameter and length respectively. The transducers, which had the 5 Mc. resonance frequency, were gold-plated x-cut crystals 20 mm. in diameter and 0.8 mm. thick. The grounding was made by thrusting the peripheries of the inner surfaces of transducers against brass rings on the ends of the glass tube. An epoxy resin was used to attach the transducers to the tube and also to protect the rings from the chemical attack.

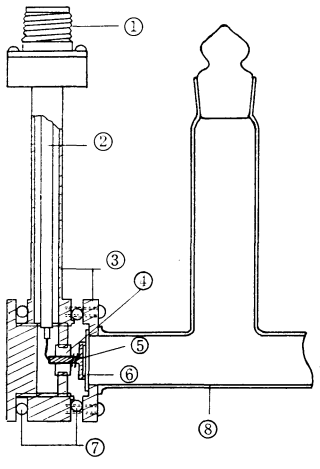

Fig. 2. Sectional diagram of one end of the cell, (1) connector, (2) coaxial cable, (3) brass, (4) polystyrene, (5) spring, (6) 5 Mc. quartz crystal, (7) neoprene O-ring, (8) pyrex tube.

The stability of the apparatus was examined by using water at 30±0.002°C for about thirty hours. The results given in Table I show that the sing-around velocimeter works steadily for a prolonged period with a high degree of accuracy. Since it requires only ten seconds to measure the sound velocity each time, slight and rapid changes in velocity in the solutions with respect to the reaction time can be traced continuously with a high degree of accuracy.

Table I. Change in the repetition frequency in water with time at 30±0.002°C

Experimental

Both methyl and ethyl acetates were used in this study. In one flask, an aqueous solution of a reactant was prepared and in the other a hydrochloric acid solution was placed, separately. After thermal equilibrium was reached, the two solutions were mixed together in one of the flasks, and then the counting of the reaction time was started. Then the mixture was transferred into a measuring cell immersed in advance in the same thermostat, and the change in the repetition frequency with the reaction time was traced by the frequency counter. The concentration of acetic acid in the

equilibrium mixture was determined by titration with dilute sodium hydroxide.

Chemically pure grade reagents were used without further purification.

Results and Discussion

In Figs. 3a and 3b, the pulse repetition frequencies during the reaction period are plotted against the reaction time. As may be seen from the figures, the frequency increases with time for ethyl acetate, while it decreases with time for methyl acetate.

These reactions can be expressed as follows:

$$CH_3COOR + H_2O \underset{k_2}{\overset{k_1}{\rightleftharpoons}} CH_3COOH + ROH \qquad (2)$$

and they are obviously bimolecular and reversible, although they can be treated as monomolecular in a dilute aqueous solution. The differential equation follows:

$$dx/dt = k_1(b-x)(w-x) - k_2x^2 \qquad (3)$$

where b is the initial concentration of an ester; x, the decrease in concentration after time t; w, the concentration of water, and k_1 and k_2, the velocity constants of hydrolysis and esterification respectively. Writing $k_2/k_1 = K$, the equilibrium constant, where:

$$K = (b-x)(w-x)/x^2 \qquad (4)$$

we can integrate Eq. 3 as:

$$\ln[\{A+(w+b)+2(K-1)x\}/\{A-(w+b)-2(K-1)x\}] = Ak_1t + \ln[\{A+(w+b)\}/\{A-(w+b)\}] \qquad (5)$$

where

$$A = \sqrt{(w+b)^2+4(K-1)wb}$$

If it is assumed that the change in the sound velocity is proportional to that in the concentration, the following expression results for ethyl acetate:

$$X \propto (u-u_0) \qquad (6)$$

where u_0 is the sound velocity at $t=0$. From Eq. 1, the difference in the sound velocities may be given as:

$$u-u_0 = l(f-f_0)/\{1-t_e(f+f_0)+ff_0t_e^2\} \qquad (7)$$

where f_0 is the repetition frequency at $t=0$. For the present apparatus, t_e, f and l are 4×10^{-8} sec^{-1}, 1.5×10^4 cycl./sec. and 10 cm. respectively, and the terms $t_e(f+f_0)$ and $ff_0t_e^2$ in Eq. 7 are both negligible in comparison with unity. The term $(u-u_0)$ is, therefore, proportional to $(f-f_0)$. Thus,

$$x = \alpha(f-f_0) \qquad (8)$$

where α is a constant. Consequently, Eq. 5 reduces to:

$$\ln[\{A+(w+b)+2\alpha(K-1)(f-f_0)\}/\{A-(w+b)-2\alpha(K-1)(f-f_0)\}] = Ak_1t + \ln[\{A+(w+b)\}/\{A-(w+b)\}] \qquad (9)$$

The left hand side of Eq. 9 is plotted against the reaction time in Fig. 4, and the value of

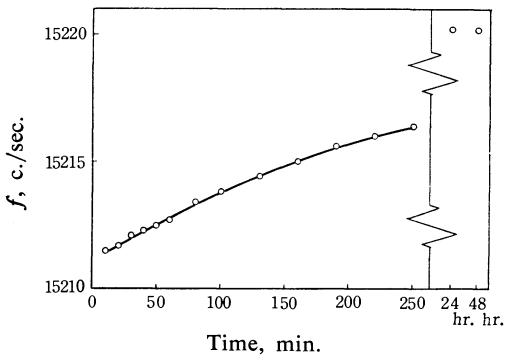

Fig. 3a. Change in velocity of sound with reaction time for ethyl acetate (25°C).

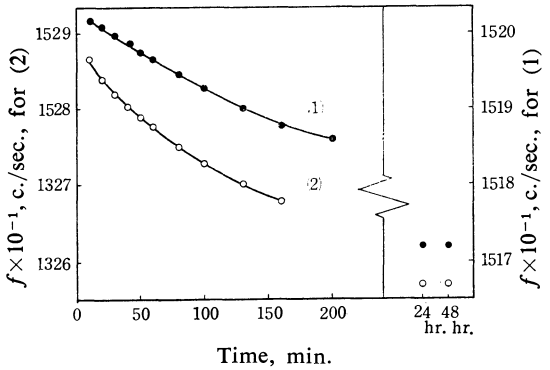

Fig. 3b. Change in velocity of sound with reaction time for methyl acetate, (1) 25°C, (2) 30°C.

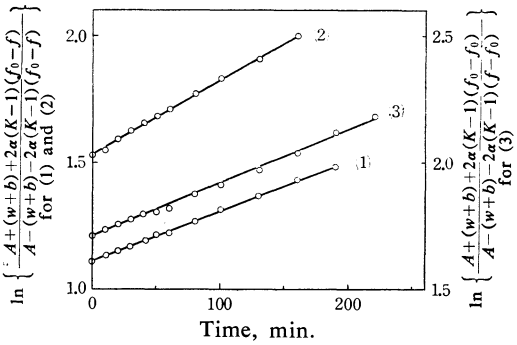

Fig. 4. The diagram of the hydrolysis of esters, (1) methyl acetate (25°C), (2) methyl acetate (30°C), (3) ethyl acetate (25°C).

f_0 is estimated by extrapolating f to $t=0$ in Figs. 3a and 3b. For methyl acetate the following equation holds instead of Eq. 8:

$$x=\alpha(f_0-f) \tag{10}$$

The value of α can be obtained from Eq. 11:

$$x_\infty=\alpha(f_\infty-f_0) \text{ or } x_\infty=\alpha(f_0-f_\infty) \tag{11}$$

where x_∞ and f_∞ are the concentration of products and the repetition frequency in the equilibrium state respectively. The measured points fall on a straight line for each one of the hydrolysis reactions studied in the present paper, as is shown in Fig. 4. The values of k_1 and k_2 obtained from the data given in Fig. 4 are listed in Table II, where those values reported by others are also included. As may be seen in the table, the values of the rate constant obtained in this study are in good agreement with those determined by other methods. The present results confirm that the sound velocity measurement by the sing-around method is applicable to the study of the chemical kinetics of such simple reactions as the hydrolysis of acetic esters. Further, it may also be expected that the present method can be extended to the study of faster reactions.

Ultrasonic Studies of the Hydration of Various Compounds in an Ethanol-Water Mixed Solvent. II. The Hydration of Organic Compounds

By Tatsuya YASUNAGA, Isamu USUI, Koichi IWATA and Masaji MIURA

(Received May 22, 1964)

In a previous paper,[1] it was reported that the degree of the hydration of inorganic electrolytes in a mixed solvent of ethanol and water can be determined by measuring the lowering of the ethanol concentration corresponding to the maximum point caused by the addition of the electrolytes in the plot of the sound velocity against the composition of the mixed solvent. A number of methods have been reported for the determination of the degree of hydration. Some of these methods are, however, applicable only to hydration of an electrostatic nature, and others, only to that of hydrogen bonding.

In the present study an attempt is made to determine, by the previous method, the degree of the hydration of such organic compounds as glucose, sucrose, glycine and gelatine.

ethanol are given in the table, together with the results measured for gelatine in our laboratory. They show that the mutual interaction between these compounds and ethanol is very small and may be disregarded without causing a serious error in the estimation of the hydration. Glucose, sucrose and glycine were guaranteed pure grade reagents and were used without further purification. Gelatine was purified by precipitation, with the addition of ethanol from its aqueous solution.

Results

The change in the velocity of sound when ethanol is added to the aqueous solutions of the compounds at various concentrations is presented graphically in Figs. 1—4. The amount of ethanol in the solution needed to give a maximum in the sound velocity decreases with the increasing concentration of the solute. The amount of hydration calculated from Eq. 1 in the previous paper[1] is shown in Fig. 5;

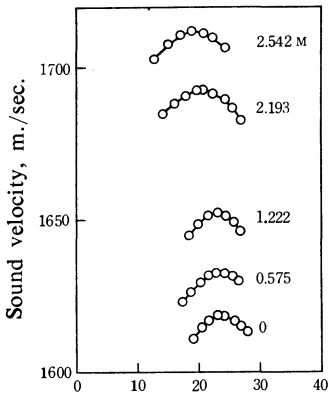

Fig. 1. Sound velocity in ethanol-water solution of glucose.

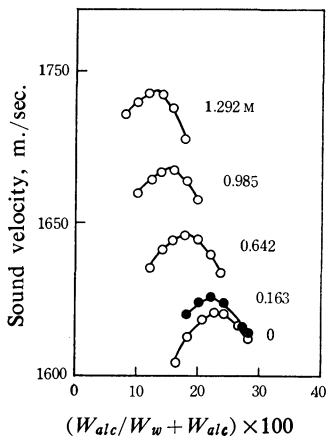

Fig. 2. Sound velocity in ethanol-water solution of sucrose.

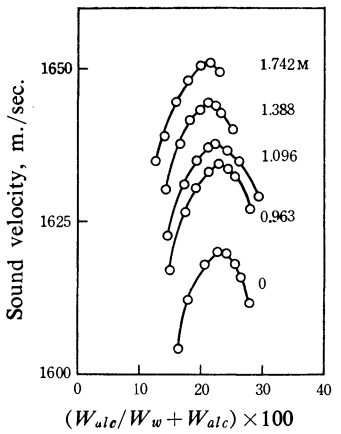

Fig. 3. Sound velocity in ethanol-water solution of glycine.

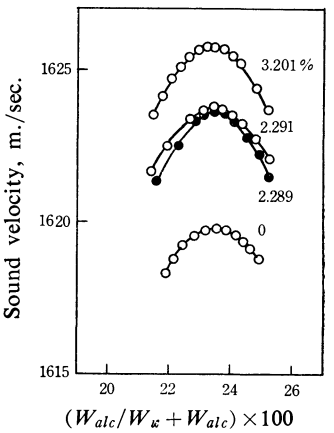

Fig. 4. Sound velocity in ethanol-water solution of gelatine.

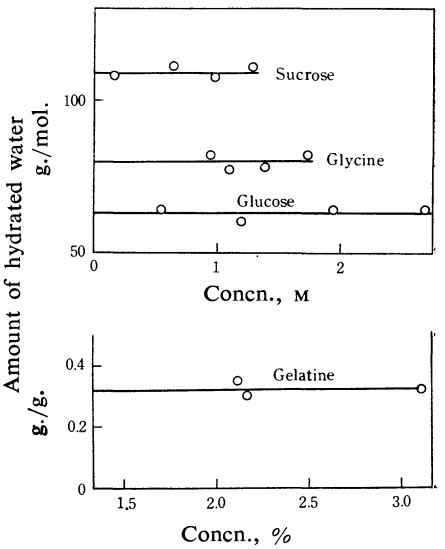

Fig. 5. Amount of hydration.

it is constant with respect to the concentration. The values for the degree of hydration at an infinite dilution, as calculated from Fig. 5, are given in Table II, together with those obtained by other experimental methods.

Table II. Comparison of the degree of hydration

Compound	This method mol./mol.	Activity method[4] mol./mol.	Sound velocity[5] mol./mol.
Glucose	3.5	2.0	3.5
Sucrose	6.1	4.8	3.8
Glycine	4.4		2.9[6]
Gelatine	0.32 g./g.		0.27 g./g.[7]

Discussion

The degree of the hydration obtained in the present study is constant and is independent of the concentration for all the compounds. This result is in good accord with the expectation from the principle of the calculation of the degree of hydration proposed in this paper. The numerical value of the degree of hydration also agrees well with those obtained by other workers, as is shown in Table II. These facts indicate that the findings concerning the degree of hydration given in the table are quite reasonable, as has been discussed in the previous paper, and that an acoustical structure of the solution of ethanol and water at the maximum velocity of sound is not affected by the presence of inorganic electrolytes or organic compounds.

As can be seen in Table II in this paper and from Table III in the previous paper, various methods have been used to determine different types of the degree of hydration. As has been shown in the previous report, the hydration for inorganic compounds is caused by the electro-static interaction between ions and water molecules, whereas the hydration for organic compounds, as reported in this paper, is mainly caused by hydrogen bonding.

The results in these two papers lead us to the conclusion that the present experimental method can be used to determine the degree of hydration of both types, electrostatic and hydrogen-bonded. Therefore, further developement of this method will facilitate the study of the hydration of polymers which are soluble in water and insoluble in ethanol.

Nature of the π-Electronic Spectra of Aromatic Compounds.[1] *I. Aromatic Hydrocarbons and Their Hydroxyl Derivatives*

By Kichisuke NISHIMOTO* and Ryoichi FUJISHIRO

(Received May 12, 1964)

It is very interesting, for several reasons, to carry out the systematic theoretical analysis of the π-electronic spectra of aromatic compounds in the visible and near-ultraviolet regions. First, the spectra of aromatic hydrocarbons show some remarkable regularities.[2,3] There is, for instance, a noticeable empirical relation, pointed out by Clar,[2] between the wavelengths of the weakest band and the strongest band in the spectrum of an aromatic hydrocarbon. Second, the effect of the substitution on the spectrum of the parent hydrocarbon depends largely upon the position at which the substituent is attached to the molecule.[4] Thirdly, the π-electronic spectrum of a *N*-heterocycle bears a noteworthy resemblance to that of the corresponding hydrocarbon,[4,5] although the replacement of –CH=

with -N= brings little change in the intensity and frequency of the spectrum of the parent hydrocarbon.

Recently, many excellent theoretical works on the π-electronic spectra of aromatic hydrocarbons have been published.[6-13] However, very few systematic theoretical studies of the nature of the π-electronic spectra of aromatic derivatives have been made, except for benzene derivatives.[14-20] In previous papers[21,22] we have studied the electronic spectra of phenol, α- and β-naphthols by the ASMO-CI method. Our theory expected that all the ^1L_b absorptions would be polarized in the direction perpendicular to their C–O bond axes. Our next interest has been to study the electronic spectra of more complicated derivatives, such as anthrols and nitroanthracenes. However, it is hard to study them by the ordinary ASMO-CI method.

The primary purpose of the present study is, therefore, to propose a theoretical procedure for the systematic study of the nature of π-electronic spectra of aromatic derivatives with a minimum of theoretical effort. The method is based on a limited LCMO approximation. It has been generally recognized that the Pariser-Parr's theory[11] is the best semi-empirical ASMO theory at present. However, the theory gives a rather unsatisfactory result for the transition energy of the benzene B_{2U} spectrum. This result is attributable to the estimation of two center-electron repulsion integrals, $\gamma_{\mu\nu}$. Recently, we have proposed an approximation[23] for the estimation of $\gamma_{\mu\nu}$ within the framework of zero differential overlap approximation, and we have successfully applied it to the SCF calculation of benzene *N*-heterocycles[23,24] and to the ASMO calculation of the electronic structure of some aromatic hydroxyl derivatives.[21,22,25]

In this paper, we will, first, study and elucidate the π-electronic spectra of several catacondensed hydrocarbons, whose general formula is $C_{4n+2}H_{2n+4}$, and will examine the existence of the Clar relation, by means of the ASMO-CI method. Next, we will study the effect of the substitution of a hydroxyl group on the nature of the π-electronic spectrum of the parent hydrocarbon. In subsequent papers, we will apply the present method to the aromatic nitro derivatives and the aromatic *N*-heterocycles.

Theoretical Procedure

The procedure of calculation may be summarized as follows: First, we calculate the eight lowest excited states, four of which are singlets and the others, triplets, of the parent hydrocarbon by means of the ASMO-CI method. The configurational wave function associated with a given electron configuration is represented by an antisymmetrized product of the Hückel molecular orbitals (HMO), which are obtainable in Ref. 26. The ground state wave function and the energy are described by the symbols Ψ_0 and H_0 respectively. The excited configurational function associated with the transition of one electron from an occupied orbital, ϕ_i, to a vacant orbital, $\phi_{k'}$, and the corresponding configurational energy are represented by $^1\chi_{ik'}$ and $^1H_{ik',ik'}$ or by $^3\chi_{ik'}$ and $^3H_{ik',ik'}$ respectively. (Here, the superscripts 1 and 3 indicate singlet and triplet respectively.)

It is interesting to note that the number of nodal planes, perpendicular to the molecular plane, of a given HMO is closely related to the orbital ring quantum number in the free electron theory.[6] It may, therefore, be closely connected with the selection rule for the transition. To a first approximation, it is, therefore, reasonable to assume that the "optical electrons" are those in the higher occupied orbitals, which have n nodal planes perpendicular to the molecular plane, and that the transitions from these orbitals to the lower vacant orbitals, which have $(n+1)$ nodal planes, are primarily responsible for the absorption spectrum in the longest wavelength regions.

For an aromatic hydrocarbon, there are two such higher occupied orbitals and two lower vacant orbitals, so that we can have four kinds of transitions from their combinations. In

order to discuss the spectra of aromatic compounds systematically, it will be convenient to use the following notation: 1) The higher one of the two higher occupied orbitals in a hydrocarbon is designated as ψ°_1, and the other as ψ°_2. 2) The lower one of the two lower vacant orbitals is designated as $\psi^\circ_{1'}$ and the other as $\psi^\circ_{2'}$. As Coulson-Rushbrook[27] and Longuet-Higgins[28] have pointed out, in an alternant hydrocarbon the molecular orbitals appear in pairs. Because of this peculiar property, the configurations $\chi_{12'}$ and $\chi_{21'}$ are degenerate. Therefore, we have the following relation:

$$H_{12',12'} = H_{21',21'} \tag{1}$$

In addition, because of the molecular symmetry, the configurations $\chi_{11'}$ and $\chi_{22'}$ combine together, as do as $\chi_{12'}$ and $\chi_{21'}$. As a result, the excited state should be divided into two classes, which may be expressed as follows:

$$\left.\begin{aligned} \Psi(\mathrm{L_a}) &= A\chi_{11'} + B\chi_{22'} \\ \Psi(\mathrm{B_a}) &= B\chi_{11'} - A\chi_{22'} \\ \Psi(\mathrm{L_b}) &= \frac{1}{\sqrt{2}}(\chi_{12'} - \chi_{21'}) \\ \Psi(\mathrm{B_b}) &= \frac{1}{\sqrt{2}}(\chi_{12'} + \chi_{21'}) \end{aligned}\right\} \tag{2}$$

where the letter in parenthesis is Platt's notation characterizing the nature of the excited state.

The interconfigurational energy, $H_{ik',jl'}$ which is given by

$$H_{ik',jl'} = \int \chi_{ik'} H \chi_{jl'} \mathrm{d}\tau \tag{3}$$

where H is the total Hamiltonian, is calculated by the method described in our previous paper.[25] The present calculations concern the interaction between only a few configurations, so it is not necessary to use a constant value of the semi-empirical parameter β_{CC}, which is a core integral over the neighboring carbon $2p\pi$AO's from molecule to molecule, since the β_{CC} value should depend more or less upon how many configurations are taken into account. As a matter of convenience, the value of β_{CC} is chosen here for each hydrocarbon to fit the observed absorption maxima of either the ^1B_b or ^1L_b species.

When the HMO's of the parent hydrocarbon are written as $\psi^\circ_{2n+1}, \cdots, \psi^\circ_1, \psi^\circ_{1'}, \cdots, \psi^\circ_{(2n+1)'}$ and those of the substituent, as $\theta_1, \cdots, \theta_m$, the HMO of an aromatic derivative, ψ_i, is exactly represented by the linear combinations of these unperturbed MO's:

$$\psi_i = \sum_k b_{ik}\psi^\circ_k + \sum_j b_{ij}\theta_j \tag{4}$$

However, since we are concerned with the electronic spectra of aromatic derivatives in the longest wavelength regions, we will be able satisfactorily to explain them by considering only the higher occupied and the lower vacant unperturbed MO's, which make the most important contribution to the lowest excited states of the molecule. From this point of view, we introduce a limited LCMO approximation and express ψ_i as:

$$\psi_i = C_{i2}\psi^\circ_2 + C_{i1}\psi^\circ_1 + C_{i1'}\psi^\circ_{1'} + C_{i2'}\psi^\circ_{2'} + C_{is}\theta_s + C_{is'}\theta_{s'} \tag{5}$$

where θ_s and $\theta_{s'}$ are the highest occupied and the lowest vacant HMO of a substituent respectively. C_{ij} is a coefficient to be determined by the variation principle, using appropriate parameters.

When the substituent is an auxochromic group, such as OH, NH_2, or $N(CH_3)_2$, there is no $\theta_{s'}$ (if we neglect the hyperconjugation effect). Therefore, in this case, ψ_i should be necessarily expressed by the linear combination of five unperturbed MO's:

$$\psi_i = C_{i2}\psi^\circ_2 + C_{i1}\psi^\circ_1 + C_{i1'}\psi^\circ_{1'} + C_{i2'}\psi^\circ_{2'} + C_{is}\theta_s \tag{6}$$

where θ_s is the lone pair orbital centered at the substituent. In the case of hydroxyl derivatives, we assume the conventional Coulomb integral, α_O, for the hydroxyl group to be:

$$\alpha_O = \alpha + 1.5\beta$$

and the conventional resonance integral to be:

$$\beta_{CO} = 0.7\beta$$

These are the values reported in our previous paper.[21]

The Hartree-Fock-like orbital energy associated with ψ_i is given by:

$$\bar{\varepsilon}_i = \int \psi_i F \psi_i \mathrm{d}\tau \tag{7}$$

where F is the Hartree-Fock operator, whose general expression has been given in Roothaan's article,[29] for the system. For the sake of simplicity, $\bar{\varepsilon}_i$ is estimated by the following approximation:

$$\begin{aligned} \bar{\varepsilon} = {} & (C^2_{i2} - C^2_{i2'})\bar{\varepsilon}^\circ_2 + (C^2_{i1} - C^2_{i1'})\bar{\varepsilon}^\circ_1 \\ & + C^2_{is}\bar{\varepsilon}^\circ_s + C^2_{is'}\bar{\varepsilon}^\circ_{s'} \\ & + 2C_{is}[(C_{i2} \pm c_{i2'})H_{2s} + (C_{i1} \pm C_{i1'})H_{1s}] \\ & + 2C_{is'}[(C_{i2} \pm C_{is'})H_{2s'} + (C_{i1} \pm C_{i1'})H_{1s'}] \end{aligned}$$

where the upper and lower signs are associated with the α- and β-substitution respectively.

29) C. C. J. Roothaan, *Revs. Modern Phys.*, **23**, 69 (1951).

Interaction energies, H_{2s}, H_{1s}, $H_{2s'}$ and $H_{1s'}$, are approximated by:

$$H_{2s}=\int \psi^{\circ}{}_2(1)H_{\mathrm{core}}(1)\theta_s(1)\mathrm{d}\tau$$

$$H_{1s}=\int \psi^{\circ}{}_1(1)H_{\mathrm{core}}(1)\theta_s(1)\mathrm{d}\tau$$

$$H_{2s'}=\int \psi^{\circ}{}_2(1)H_{\mathrm{cere}}(1)\theta_{s'}(1)\mathrm{d}\tau$$

$$H_{1s'}=\int \psi^{\circ}{}_1(1)H_{\mathrm{core}}(1)\theta_{s'}(1)\mathrm{d}\tau$$

$\bar{\varepsilon}^{\circ}{}_2$, $\bar{\varepsilon}^{\circ}{}_1$, $\bar{\varepsilon}^{\circ}{}_s$ and $\bar{\varepsilon}^{\circ}{}_{s'}$ are the Hartree-Fock-like orbital energies associated with $\psi^{\circ}{}_2$, $\psi^{\circ}{}_1$, θ_s and $\theta_{s'}$ respectively. Therefore, the configurational energy is given by;

$$^{1,3}H_{ik',ik'}=\bar{\varepsilon}_{k'}-\bar{\varepsilon}_i-[ii\mid k'k']+[ik'\mid ik'] \pm [ik'\mid ik'] \quad (9)$$

where

$$[ik\mid jl]=\int \phi_i(1)\phi_k(1)\frac{e^2}{r_{12}}\phi_j(2)\phi_l(2)\mathrm{d}\tau$$

The plus and minus signs are combined with the singlet and triplet configurations respectively. The interconfigurational energy is simply approximated by:

$$^{1,3}H_{ik',jl'}=-[ij\mid k'l']+[ik'\mid jl'] \pm [ik'\mid jl'] \quad (10)$$

This approximation means that a given configuration interacts with other configurations through only the electron repulsion term in the total Hamiltonian.

In the calculation of the molecular integrals of a hydroxyl derivative, we use the following approximation:

1) $\bar{\varepsilon}^{\circ}{}_s$ has a constant value of -11.649 eV., the value of the integral over the oxygen $2p\pi$ atomic orbital (AO) with respect to the Hartree-Fock Hamiltonian of phenol.[21]

2) The core integral over the neighboring carbon and oxygen $2p\pi$AO's is assigned a constant value of -1.664 eV., which is estimated as $0.7\times(\beta_{CC}$ of benzene).

3) The electron repulsion integrals over AO's are calculated by the method described in our previous papers.[21,25]

For convenience, we lay down the following rule for the numbering of the MO's of a derivative. We name the orbital which contains θ_s to the extent of more than 50%, ϕ_s, and the orbital which contains $\psi^{\circ}{}_2$ to the extent of more than 50%, ϕ_2, and so on. Using this rule, the excited state wave function for an aromatic derivative can be adequately given by the linear combination of six configurations:

$$\Psi_a=d_{a1}\chi_{11'}+d_{a2}\chi_{22'}+d_{a3}\chi_{12'}+d_{a4}\chi_{21'}+d_{a5}\chi_{s1'}+d_{a6}\chi_{1s'} \quad (11)$$

The coefficient d_{at} is to be determined by the variation principle.

In order to study the π-electronic spectra of aromatic compounds systematically, we use Platt's nomenclature[6] and set up the following somewhat artificial criterion for the assignment of the electronic transitions: we describe the excited state which is characterized by $d_{a1}>0$, $d_{a2}>0$ and $d^2{}_{a1}+d^2{}_{a2}>0.5$ as the L_a species. Here, d_{a1} is a coefficient which appeared in Eq. 11. The state which is characterized by $d_{a3}>0$, $d_{a4}>0$ and $d^2{}_{a3}+d^2{}_{a4}>0.5$, we designate as the B_b species. The criteria are arranged in Table I. In the table, C-T indicates an intramolecular charge transfer state. When we use these criteria, we will be able to assign theoretically the π-electronic excited states of a conjugated system without any trouble.

Table I. Assignment of the electronic transition in aromatic compounds

State	Characterization		
L_a	$d_{a1}>0$	$d_{a2}>0$	$d^2{}_{a1}+d^2{}_{a2}>0.5$
L_b	$d_{a3}>0$ or $d_{a3}<0$	$d_{a4}<0$ or $d_{a4}>0$	$d^2{}_{a3}+d^2{}_{a4}>0.5$
B_b	$d_{a3}>0$	$d_{a4}>0$	$d^2{}_{a3}+d^2{}_{a4}>0.5$
B_a	$d_{a1}>0$	$d_{a2}<0$	$d^2{}_{a1}+d^2{}_{a2}>0.5$
$(C\text{-}T)_1$		$d^2{}_{a5}>0.5$	
$(C\text{-}T)_2$		$d^2{}_{a6}>0.5$	

In the present calculations, the excited state wave function of a hydroxyl derivative is approximated by the linear combination of only four configurations, $\chi_{11'}$, $\chi_{22'}$, $\chi_{12'}$ and $\chi_{21'}$, for two reasons. First, ϕ_s is located deep

and apart from the others. Secondly, the interconfigurational energies between $\chi_{s1'}$ and the other configurations are relatively small.

The core structures and the molecular axes of hydrocarbons and their hydroxyl derivatives are shown in Fig. 1. Here, we assume that each molecular framework is made of the appropriate regular hexagon systems, with the constant bond length of 1.397 Å, the experimental carbon-carbon bond distance for benzene.[30]

The intensity of the absorption associated with the one-electron transition from Ψ_o to Ψ_a is calculated by:[31]

$$f=1.085\times10^{11}\tilde{\nu}_{oa}(D_{oa})^2 \qquad (12)$$

where $\tilde{\nu}_{oa}$ is the frequency of the transition in cm^{-1}. $\vec{D}_{oa}$ is the transition moment defined by:

$$\vec{D}_{oa}=\int \Psi_o \sum e_i r_i \Psi_a d\tau \qquad (13)$$

where e_i and r_i are the charge and the position vector of the i-th charged particle respectively. $\vec{D}_{oa}$ gives the direction of the polarization of the absorption band. Therefore, we usually use $\vec{D}_{oa}$ in assigning and classifying the electronic spectrum of a molecule.

Results and Discussion

The spectrum of a hydrocarbon in the visible and near ultraviolet regions usually contains four main absorptions. On the basis of a free electron model (perimeter model), Platt[6] classified these bands as ^1L_b, ^1L_a, ^1B_b and ^1B_a respectively. There is the following remarkable empirical relation, pointed out by Clar,[2] between the wavelength maxima of the weak ^1L_b band and the very strong ^1B_b band:

$$\lambda(^1L_b)/\lambda(^1B_b)=1.35 \qquad (14)$$

The calculated results of hydrocarbons are summarized in Table II, where they are also compared with the experimental data. The calculated interconfigurational energies are collected in Table III. The results are in satisfactory agreement with the experimental findings. The calculated $\lambda(^1L_b)/\lambda(^1B_b)$ values are given in Table IV. The results lead to this correlation equation:

$$\lambda(^1L_b)/\lambda(^1B_b)=1.36\pm0.06 \qquad (15)$$

That is, the present theory suggests approximately the existence of the Clar relation.

TABLE IV. CALCULATED RATIO OF THE WAVELENGTH OF ^1L_b SPECIES, $\lambda(^1L_b)$, TO THE WAVELENGTH OF ^1B_b, $\lambda(^1B_b)$

Molecule	$\lambda(^1L_b)/\lambda(^1B_b)$
Benzene	1.42
Naphthalene	1.41
Anthracene	1.35
Tetracene	1.29
Phenanthrene	1.28
Pyrene	1.39

Semi-empirically estimated β_{CC} values are collected in Table V. A plot of β_{CC} against n, the number of carbon atoms included in a given hydrocarbon, gives a good correlation, as is shown in Fig. 2. The correlation line is given by:

$$\beta_{CC}(n)=0.571\times10^{-0.0522n}+2.100\ \text{eV}. \qquad (16)$$

Alternant aromatic hydrocarbons can be broadly divided into two isomeric series: One is the linear series in which the rings are arranged linearly, as in anthracene. The other

TABLE V. SEMI-EMPIRICALLY ESTIMATED β_{CC} VALUES FOR HYDROCARBONS

Molecule	β_{CC} (in eV.)
Benzene	−2.3777
Naphthalene	−2.2310
Anthracene	−2.2062
Tetracene	−2.1673
Phenanthrene	(−2.2062)
Pyrene	−2.1863

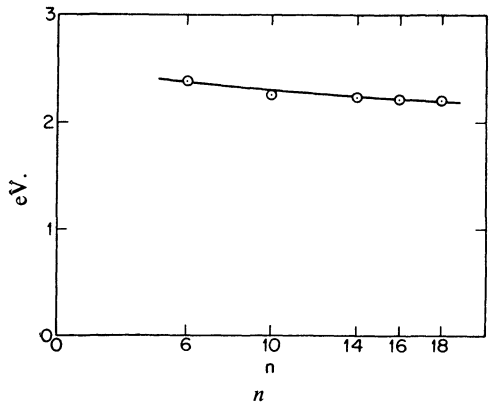

Fig. 2. A plot of β_{CC} against the number of carbon atom, n, contained in the hydrocarbon.

is the angular series, of which phenanthrene is the first member. As is shown in Fig. 4, in the linear series there is a steady displacement of the group of the maxima towards longer wavelengths with the increasing length of the conjugated system.

The molecules of the linear series have symmetry planes along both their short and long axes. The transition moments for allowed transitions can, then, be either perpendicular or parallel to the long axis of the molecule (x-axis in Fig. 1) or, alternatively, allowed transitions have either transverse or longitudinal polarization. The present calculation expects that the transitions from the ground state to $\Psi(^1L_a)$ or to $\Psi(^1B_a)$ will be polarized in the direction of the molecular y-axis, whereas the transitions from the ground state to $\Psi(^1L_b)$ or to $\Psi(^1B_b)$ will have the polarizations in the direction of the molecular x-axis. In assigning the spectrum of phenanthrene, there

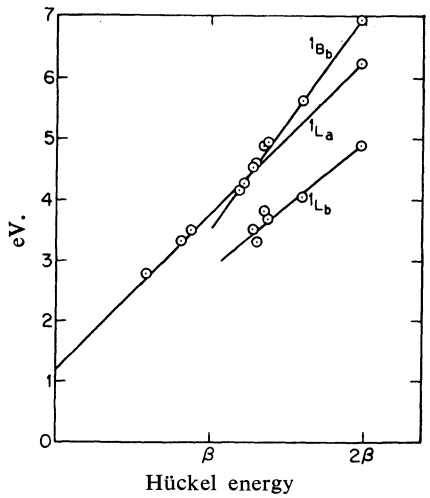

Fig. 3. A plot of the calculated singlet frequency against the corresponding Hückel energy.

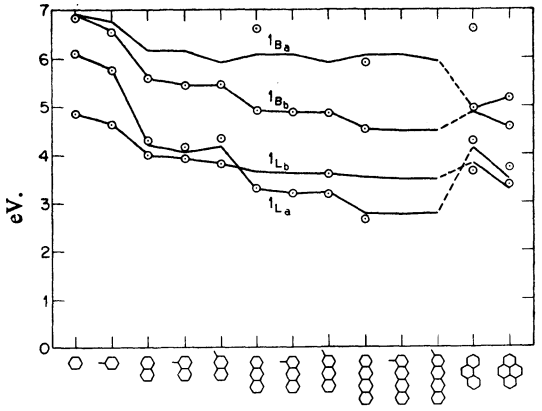

Fig. 4. Comparison of calculated and experimental singlet states. The experimental values are represented by circles.

is a puzzling question. We can treat it as a modified naphthalene spectrum. However, in the light of our theoretical results, it seems better to regard the spectra of phenanthrene and pyrene as modified biphenyl spectra. Their molecular axis should, therefore, be fixed as in Fig. 1 for the study of the electronic spectra. Unfortunately, with a few exceptions, the experimental polarizations are unknown.

The present calculation anticipates that the transition from the ground state to the $\Psi(^1L_b)$ will be forbidden if the molecule rests at the equilibrium configuration. However, the molecule continuously vibrates around the equilibrium positions with rather small amplitudes, and some of the vibrations may instantaneously break down the molecular symmetry. As a result, the forbidden ^1L_b absorption would barely appear through the coupling with such vibrations, accompanied by the vibrational fine structure as in the benzene 260 mμ absorption.

Our results show that the intensity of the ^1L_a absorption should increase with the length of the conjugated system. However, the observed oscillator strengths have practically the same value from molecule to molecule. Moreover, the calculated oscillator strength associated with the ^1B_b absorption seems somewhat larger than the observed values. The reason for this is probably to be found partly in the limited configuration interaction treatment and partly in the point charge approximation.

It is interesting to examine whether or not any interrelationships exist between the calculated frequency and the corresponding orbital energy difference in the Hückel theory. A plot of the calculated frequency against the corresponding Hückel energy gives a rather good correlation, as Fig. 3 shows.

Our approximation for two center electron

repulsion integrals seems to be adequate for the calculation of singlet states, but not for triplet states. There is a reason for this. Our approximation has been found from the benzene singlet spectrum by a trial and error procedure. As Linnett indicated in his book,[32] the electron correlation in the singlet state differs entirely from that in the triplet state. It is probable that our approximation implicitly includes the electron correlation in the singlet state, therefore, it perhaps does not explain the electron correlation in the triplet state.

In the present calculations, we have introduced the following two somewhat drastic approximations: for a molecule, the core integral, β_{CC}, has been fixed at a constant value, and only the four lowest excited configurations have been taken into account. The observed distances in a polyacene are usually not the same.[33] It is natural that the value of β_{CC} should vary with the variation in the bond distances. However, in this paper, we have used HMO's in which the bond dependence of the resonance integral has been neglected. Therefore, so far as we use HMO's in the theory, a constant β approximation may be reasonable. In order to improve the theory, we have to apply the SCF-MO theory with reference to the bond distance dependence of core integrals.

Next, we will consider the excited states of

the hydroxyl derivatives. Generally speaking, the absorption spectra of aromatic hydroxyl derivatives in the near ultraviolet regions closely resemble those of the parent hydrocarbons,[4,34] except that the absorption bands are usually shifted to somewhat longer wavelengths. However, in the polycyclic hydroxyl derivatives, not all the possible positions of substitution are identical, so the various groups of absorption bands (^1L_b, ^1L_a, ^1B_b and ^1B_a) are not always shifted to the same extent. For example, there is a noticeable difference between the spectral changes caused by the substitutions at the α- and β-positions. In this paper, the effect on the electronic spectrum of the substitution of a hydroxyl group at the α- or β-position of the parent hydrocarbon has been studied.

The calculated results of the hydroxyl derivatives are summarized in Table VI, where they are also compared with the experimental data. The calculated interconfigurational energies are collected in Table VII. The theoretical singlet frequencies are in satisfactory agreement with the experimental findings. It is suprising that the interconfigurational energies for α-hydroxyl derivatives are practically the same as those for the parent hydrocarbons. Their calculation is, however, an elaborate task, so it is convenient, for a first approximation, to use the latter in place of the former.

The substitution of a hydroxyl group on the parent hydrocarbon has the following effects: first, it breaks out the molecular symmetry of D_{2h} or D_{6h} and removes the peculiar degeneracy of the two configurations, $\chi_{12'}$ and $\chi_{21'}$. As a result, the theoretical oscillator strength of the ^1L_b absorption is not zero, but has a definite value. Furthermore, all the excited configurations will interact with each other. Secondly, a lone-pair orbital of the substituent conjugates with the π-electron system of the parent hydrocarbon. This usually results in something of a spectral red shift. Figure 4 shows the interrelation between the lower singlet states. The present theory suggests that the ^1L_a bands of the parent hydrocarbons are most sensitive for the α-substitution, whereas the β-substitution has no significant effect on them. On the other hand, the ^1L_b bands are

TABLE VIII. POLARIZATIONS OF THE ELECTRONIC TRANSITIONS IN AROMATIC DERIVATIVES

Molecule	Polarization $\Psi_0 \rightarrow \Psi(^1L_a)$	$\Psi_0 \rightarrow \Psi(^1L_b)$	$\Psi_0 \rightarrow \Psi(^1B_b)$	$\Psi_0 \rightarrow \Psi(^1B_a)$
Phenol	90°	180°	180°	90°
α-Naphthol	86°	180°	180°	89°
α-Anthrol	85°	180°	180°	89°

β-Naphthol	99°	115°	181°	78°
β-Anthrol	97°	72°	181°	79°
2-OH Tetracene	94°	41°	181°	80°

Note: Numerical value gives an angle between the transition moment vector and x-axis of the molecule.

34) H. Baba and S. Suzuki, This Bulletin, 34. 82 (1961); 35. 683 (1962).

remarkably affected by the β-substitution, while they are only slightly influenced by the α-substitution. It is interesting to note that the effect of substitution gradually decreases with the length of the parent conjugated systems.

We have a special interest in the effect of substitution on the direction of the polarization of the electronic transition of the parent hydrocarbon, because the nature of the electronic excited states of the molecule is frequently discussed on the basis of the polarization of the electronic transition.

The calculated results are summarized in Table VIII. Our calculations show that, in α-derivatives, in spite of the absence of D_{2h} or D_{6h} symmetry each absorption band should be polarized in the direction of the short or long molecular axis of the parent hydrocarbon systems. That is, the characteristics of the spectrum of the parent hydrocarbon are not changed in this case. On the other hand, in β-derivatives, the nature of the spectrum of parent hydrocarbons is considerably lost, because all the excited configurations interact strongly with each other. In β-naphthol, for example, the ^1L_b species contains a configuration $\chi_{11'}$ to the extent of about 26% and is polarized approximately in the direction perpendicular to the carbonoxygen bond. Moreover, the present theory expects that, if we try to assign the excited states of β-anthrol on the basis of the experimental polarization, it will be impossible to distinguish the ^1L_a and ^1L_b bands. Unfortunately, no experiments connected with the polarization of the electronic transition in the aromatic hydroxyl derivative have yet given us any results. In β-derivatives the direction of polarization moves gradually towards that of the parent hydrocarbon with an increase in the length of the conjugated system.

The calculated oscillator strength of the α-derivative exhibits a striking contrast to that of the β-derivative. Namely, by α-substitution, the ^1L_a absorption is intensified, whereas the ^1B_b absorption is slightly weakened. On the contrary, the β-substitution has the effects of intensifying the latter absorption and weakening the former absorption. Moreover, the ^1L_b absorption is considerably intensified by the β-substitution, while it is only slightly increased in intensity by the α-substitution. These results are in accord with the experimental data.[4]

The theoretical results for phenol, α- and β-naphthols in the present theory are in satisfactory agreement with those based on the ASMO-CI method.[21,22] This fact suggests that the present theory is reasonable and adequate for the purpose of making a systematic study of the electronic spectra of aromatic derivatives with a minimum of theoretical effort.

Summary

The π-electronic spectra of a number of aromatic hydrocarbons and their hydroxyl derivatives have been theoretically studied by the ASMO-CI method within the framework of a limited LCMO approximation. The calculated singlet frequencies are in satisfactory agreement with the experimental findings. The experimental Clar relation is obtained theoretically. The present theory suggests that the substitution of a hydroxyl group at the α-position of the parent hydrocarbon has effects of a substantial red shift in the ^1L_a band and a rather small shift in the ^1L_b band, but the band characteristics are practically the same as those of the parent hydrocarbon. On the other hand, the substitution at the β-position has the effect of mixing the ^1L_a species with the ^1L_b species to a considerable extent, so that the band characteristics of the parent hydrocarbon should be considerably modified by this type of substitution. In the light of the present theory, it is better to regard the spectra of phenanthrene and pyrene as modified biphenyl spectra. A plot of the calculated frequency against the corresponding Hückel energy gives a rather good correlation.

The authors wish to express their gratitude to Dr. Andrew D. Liehr, of the Mellon Institute, for his help with the manuscript.

*The Reactions of N-Substituted Thioamides with α-Halonitriles**[,1)]

By Hirohide CHOSHO, Kunihiro ICHIMURA and Masaki OHTA

(Received May 25, 1964)

In the previous papers of this series, it has been described how the meso-ionic compounds A and B are obtained by the treatment of carboxymethylmercapto derivatives (A′ and B′) with acetic anhydride,[2,3)] and how the treatment of cyanomethylmercapto derivatives of heterocyclic nitrogen compounds (C′) with acyl chloride gives compounds of the type C.[2)] The present paper will report the synthesis of non-condensed compounds of the type C by the reaction of *N*-substituted thioamides with α-halonitriles, since it is interesting to investigate the properties and the reactivities of this ring system.

As a preliminary stage in the formation of this ring system, thiobenzanilide was condensed

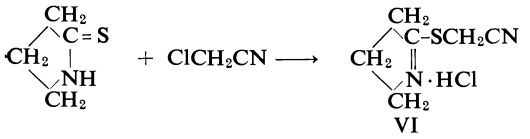
* This was identified as picrate.

with chloroacetonitrile in the presence of triethylamine to afford *S*-cyanomethylisothiobenzanilide (I). The treatment of this intermediate with hydrogen chloride in benzene or 2-propanol gave the expected product, "thiazone imine hydrochloride"[4] (II; X=Cl), the structure of which was deduced by an elementary analysis, by the absence of absorption due to the nitrile group in its infrared spectrum, and by the appearance of a band at 3250 cm^{-1} which may be due to the nitrogen-hydrogen stretching frequency. In addition, the hydrochloride (II; X=Cl) showed a characteristic band at 360 mμ ($\varepsilon=6.55\times10^3$) in its ultraviolet spectrum suggestive of the heterocyclic system. This ring formation seems to proceed as a result of the interaction of two polar groups, by a mechanism similar to that of sydnone imine salts.[5] The hydrochloride (II; X=Cl) was converted into the nitrate (II; $X=NO_3$) by the treatment with silver nitrate. On the treatment of I with a strong organic acid such as picric acid and *p*-toluenesulfonic acid, the ring formation took place to produce the thiazone imine salts of corresponding acid. The structure was confirmed by infrared spectra and by the fact that this picrate was identical with that obtained by the treatment of the thiazone imine hydrochloride (II; X=Cl) with picric acid.



Thiazone imine hydrochloride was converted into *N*-acyl derivatives III by the treatment with acid anhydride. The hydrochlorides of these *N*-acyl derivatives were also yielded by the treatment of I with the corresponding acyl chloride, as in the case of the compound C. The neutralization of the hydrochlorides of *N*-acyl compounds III gave free bases with high melting points, which could then be readily reconverted into the original hydrogen chlorides by the action of hydrogen chloride.

We attempted to prepare *S*-(α-cyanobenzyl)-isothiobenzanilide from thiobenzanilide and α-chlorophenylacetonitrile in the presence of triethylamine, which would be expected to form a 2, 3, 5-triphenylthiazone imine derivative, but only α, α'-dicyanostilbene resulted; this must be a condensation product of two moles of α-chlorophenylacetonitrile. It was, however, found that the hydrochloride (II; X=Cl) was also obtained by heating thiobenzanilide and chloroacetonitrile without a solvent or in biphenyl. This fact suggested that the other thiazone imine derivatives could also be obtained from the corresponding *N*-substituted thioamides and α-chloronitriles without isolating the intermediates. Actually, in a similar manner, some thiazone imine hydrochlorides were prepared from both components, as is shown in Table I. On the other hand, the reaction of thiopyrrolidone with chloroacetonitrile did not afford the expected heterocyclic compound, but alternatively formed *S*-cyanomethylisothiopyrrolidone hydrochloride (VI), the structural evidence for which is based on the elementary analysis and on its infrared spectrum.

The hydrochlorides of thiazone imines (II; X=Cl) decomposed in alkaline conditions, showing themselves incapable of existence as

4) This heterocyclic compound can be named "Ψ-4-imino-2, 3-diphenyl-3, 4-dihydrothiazole hydrochloride," according to Baker's proposal (*J. Chem. Soc.*, **1949**, 311), the symbol Ψ indicating the hybrid ionic structure. In the preceding paper the meso-ionic compound B was provisionally named "thiazone"; in the present paper the authors will refer to II derived from "thiazone" as salts of "thiazone imine" for the sake of simplification in naming.

5) P. Brookes and J. Walker, *J. Chem. Soc.*, **1957**, 4409.

a free base in contrast with the *N*-acylated free base IV. An acidic hydrolysis of the thiazone imine hydrochloride afforded an amide V, which was also produced by the acidic hydrolysis of the *N*-acetyl salt (III; R=CH_3) and *S*-cyanomethylisothiobenzanilide (I).

The reactivities of the compounds obtained above and the related derivatives containing other functional groups will be reported shortly.

Experimental

***S*-Cyanomethylisothiobenzanilide (I).** — Triethylamine (5 cc.) was added to a solution of thiobenzanilide (5 g.) and chloroacetonitrile (1.8 g.) in benzene (25 cc.), and the mixture was heated at 50°C for nine hours. After the mixture had stood overnight, the separated triethylamine hydrochloride was filtered off. The filtrate was evaporated to dryness under reduced pressure, and the residual crystals were collected. Recrystallization from ether-petroleum ether gave 3 g. of *S*-cyanomethylisothiobenzanilide as colorless needles; m. p. 68~69°C.

Found: C, 71.05; H, 4.83; N, 11.24. Calcd. for $C_{15}H_{12}N_2S$: C, 71.42; H, 4.76; N, 11.11%.

The Action of Hydrogen Chloride on I.—a) A 2-propanol solution of I (1 g.) was treated with 2-propanol saturated with hydrogen chloride. After the solution had stood, 2, 3-diphenylthiazone imine hydrochloride (II; X=Cl) precipitated; this was collected and washed with acetone. The yield was 0.8 g. It was purified by reprecipitation from an ethanolic solution with ether (see Table I).

b) The same hydrochloride was also obtained by passing dry hydrogen chloride into a benzene solution of I.

The Action of Picric Acid on I.—An ethanolic solution of I was treated with a solution of picric acid in ethanol to yield picrate (II; HX=picric acid) as yellow needles, which were recrystallized from 2-propanol, m. p. 177°C (decomp.).

Found: C, 52.23; H, 2.81; N, 14.47. Calcd. for $C_{21}H_{15}N_5O_7S$: C, 52.40; H, 3.21; N, 14.55%.

The Action of *p*-Toluenesulfonic Acid on I.—*p*-Toluenesulfonic acid (0.2 g.) in benzene was added to a benzene solution of I (0.1 g.). A yellow oil separated out. After the removal of the solvent, it was dissolved in methanol, and *p*-toluenesulfonate (II; HX=*p*-toluenesulfonic acid) was precipitated by adding ether drop by drop. This yellow needles (0.15 g.) melted at 197°C with decomposition.

Found: C, 62.28; H, 4.99; N, 6.60. Calcd. for $C_{22}H_{20}N_2O_3S_2$: C, 62.27; H, 4.75; N, 6.60%.

The Conversion of 2, 3-Diphenylthiazone Imine Hydrochloride (II; X=Cl) to Other Salts.—*Nitrate.*—Ten per cent aqueous silver nitrate was added to an aqueous solution of the hydrochloride (II; X=Cl) (1 g.). After the silver chloride had been filtered off, the filtrate was evaporated under reduced pressure and the residual crystals were collected by filtration. The yield was 0.9 g. Recrystallization from 2-propanol gave pure nitrate (II; X=NO_3) as yellow needles; m. p. 173.5°C (decomp.).

Found: C, 56.89; H, 4.19; N, 13.49. Calcd., for $C_{15}H_{13}N_3O_3S$: C, 57.14; H, 4.16; N, 13.33%.

Picrate.—The hydrochloride (II; X=Cl) in ethanol was treated with ethanol saturated with picric acid. Yellow needles; m. p. 177°C (unchanged by admixture with the picrate obtained above).

The Conversion of 2, 3-Diphenylthiazone Imine Hydrochloride (II; X=Cl) into *N*-Acetyl Derivatives (III and IV; R=CH_3).—When suspension of the hydrochloride (II; X=Cl) (2 g.) in acetic anhydride (10 cc.) was heated at 90°C for six hours, the reaction mixture turned into a clear solution. In about half an hour crystals precipitated, and the mixture was heated for a further two hours. The crystals were then filtered and washed with acetone. Yield, 2 g. Reprecipitation from an ethanolic solution with ether gave pure hydrochloride of *N*-acetyl-2, 3-diphenylthiazone imine (III; R=CH_3) as colorless needles; m. p. 290°C.

Found: C, 61.84; H, 4.76; N, 8.48. Calcd. for $C_{17}H_{15}N_2OSCl$: C, 61.50; H, 4.52; N, 8.47%.

This hydrochloride of the *N*-acetyl compound was treated with aqueous sodium hydrogen carbonate to yield 0.8 g. of its free base (IV; R=CH_3). Recrystallization from ethanol gave yellow needles; m. p. 198°C (decomp.).

Found: C, 69.55; H, 4.86; N, 9.59. Calcd. for $C_{17}H_{14}N_2OS$: C, 69.39; H, 4.76; N, 9.53%.

The Conversion of 2, 3-Diphenylthiazone Imine Hydrochloride (II; X=Cl) into an *N*-Benzoyl Derivative (IV; R=Ph).—A mixture of the hydrochloride (II; X=Cl) (2 g.) and the excess benzoic anhydride (4.9 g.) was heated at 150~160°C for one hour. The reaction mixture was then washed with hot benzene, and the crystals were collected. They were then suspended in water, treated with aqueous sodium hydrogen carbonate, filtered again, and washed with 2-propanol. Yield, 1.0 g. Recrystallization from ethanol gave a pure free base of an *N*-benzoyl compound (IV; R=Ph) as yellow needles; m. p. 211~212°C (decomp.).

Found: C, 73.95; H, 4.63; N, 7.87. Calcd. for $C_{22}H_{16}N_2OS$: C, 74.14; H, 4.53; N, 8.27%.

The Reaction of *S*-Cyanomethylisothiobenzanilide (I) with Acetyl Chloride.—*S*-Cyanomethylisothiobenzanilide (I) (1.0 g.) and acetyl chloride (0.32 g.) were heated in benzene at 60°C for three hours, and the precipitate was collected. An aqueous solution of the precipitate was treated with aqueous sodium hydrogen carbonate to yield yellow crystals. Recrystallization from ethanol gave the free base of an *N*-acetyl compound (IV; R=CH_3) as yellow needles; m. p. 198°C (decomp.), undepressed on admixture with a sample prepared from II with acetic anhydride.

The Reaction of *S*-Cyanomethylisothiobenzanilide (I) with Benzoyl Chloride.—The mixture of *S*-cyanomethylisothiobenzanilide (I) (1.0 g.) and the excess of benzoyl chloride was heated at 90°C for

one hour, and crystals were precipitated. The precipitate was then filtered and washed with benzene. The treatment of this precipitate with aqueous sodium hydrogen carbonate gave yellow crystals, which were filtered, washed with 2-propanol, and recrystallized from ethanol. The yield of the free base of an *N*-benzoyl compound (IV; R=Ph), m. p. 211~212°C (undepressed on admixture with a sample prepared from II with benzoic anhydride), was 1.0 g.

The Hydrolysis of *S*-Cyanomethylisothiobenzanilide (I).—A suspension of *S*-cyanomethylisothiobenzanilide (I) (0.5 g.) in 10% aqueous hydrochloric acid (5 cc.) was heated gently on a water bath for twenty minutes, and then the hydrolysate was crystallized by being left standing. The yield of hydrochloride of *S*-carbamoylisothiobenzanilide (V), m. p. 65~70°C, was 0.4 g. Recrystallization from chloroform raised the melting point to 85~88°C. Colorless crystals.

Found: C, 55.20; H, 5.38; N, 8.51. Calcd. for $C_{15}H_{15}N_2SOCl \cdot H_2O$: C, 55.46; H, 5.23; N, 8.62%.

The Hydrolysis of 2, 3-Diphenylthiazone Imine Hydrochloride (II; X=Cl).—The hydrochloride (II; X=Cl) (1 g.) in 10% aqueous hydrochloric acid was heated on a steam bath for a few minutes. Oil separated and solidified when the mixture was left standing. The solid was filtered and recrystallized from acetone. The yield was 1.0 g.; m. p. 85~88°C, undepressed by admixture with the above hydrolysate prepared from I.

The Hydrolysis of *N*-Acetyl-2, 3-Diphenylthiazone Imine Hydrochloride (III; X=CH_3).—The hydrochloride of the *N*-acetyl compound (1 g.) was hydrolysed with 10% aqueous hydrochloric acid in a manner similar to that above. The yield was 0.8 g.; m. p. 85~88°C, not depressed by admixture with the hydrolysate obtained above.

An Attempt to Prepare *S*-(α-Cyanobenzyl)-isothiobenzanilide. — Thiobenzanilide (5 g.) and α-chlorophenylacetonitrile (4 g.) were dissolved in benzene (40 cc.), triethylamine (10 cc.) was added, and the mixture was refluxed for two hours. After the mixture had stood overnight, triethylamine hydrochloride (3.5 g.) was filtered off, and the solvent was removed under reduced pressure from the filtrate. The residue crystallized by scratching. The crystals were collected and washed with methanol. Recrystallization from methanol gave *cis*-α, α-dicyanostilbene as colorless needles; m. p. 158°C (reported m. p. 160°C).[6]

Found: C, 83.46; H, 4.43; N, 11.87. Calcd. for $C_{16}H_{10}N_2$: C, 83.51; H, 4.35; N, 12.17%.

A General Procedure for Preparing Thiazone Imine Hydrochlorides.—a) *N*-Substituted thioamide and α-chloronitrile (a small excess) were heated on a steam bath, until the fused reaction mixture got more viscous with a rapid rise in the temperature. The cooled viscous product was then crystallized by rubbing it with acetone, filtered, and washed with acetone. Reprecipitation from an ethanolic solution with ether gave pure thiazone imine hydrochloride.

b) *N*-Substituted thioamide, α-chloronitrile, and biphenyl as a solvent were heated at about 120°C while being stirred. The reaction mixture was then cooled as soon as the temperature began to rise, and acetone was added in order to remove the biphenyl. The acetone-insoluble hydrochloride of the heterocyclic compound was then collected, washed with acetone, and purified by reprecipitation from an ethanolic solution with ether.

The Reaction of Thiopyrrolidone with Chloroacetonitrile.—A mixture of thiopyrrolidone (1 g.) and the excess chloroacetonitrile was heated. The reaction started suddenly in about fifteen minutes with the evolution of heat, but it was at once interrupted by cooling. The solid was washed with ethanol. Yield, 1.35 g. This *S*-cyanomethylisothiopyrrolidone hydrochloride (VI) was thoroughly washed with methanol in order to analyze it.

Found: C, 40.54; H, 5.23; N, 15.89. Calcd. for $C_6H_9N_2SCl$: C, 40.79; H, 5.10; N, 15.86%.

*Color Reactions of 3-Methyl-2-benzothiazolone Hydrazone with Phenol Derivatives. I. The Spectrophotometric Microdetermination of Catechol, Hydroquinone and Resorcinol**

By Eijiro KAMATA

(Received May 27, 1964)

Since Hünig and Fritsch[1] described the oxidative coupling of 3-methyl-2-benzothiazolone hydrazone (MBTH) with various organic compounds, MBTH has been used to detect and determine trace amounts of various types of organic compounds.[2-5]

In the present paper new spectrophotometric procedures for the determination of catechol, hydroquinone and resorcinol with MBTH will be reported.**

Experimental

Reagents.—*Standard Solutions of Catechol, Hydroquinone and Resorcinol (5 μg./ml.).*—Prepared freshly daily.

3-Methyl-2-benzothiazolone Hydrazone Hydrochloride.—The reagent is commercially available. A 0.4% aqueous solution and a 0.5% methanol solution of the salt were prepared.

Oxidants.—a) 1%(w/v) Ferric Chloride Solution. b) 2%(w/v) Potassium Ferricyanide Solution. — Prepared freshly daily.

Other Reagents.—Methanol. Acetone. Concentrated ammonia. (0.7+100) Ammonia. 8N Hydrochloric Acid. 10 %Mohr's Salt Solution.—Prepared within 10 min. before use.

Apparatus. — Beckman Model DK-II and DU spectrophotometers. Hitachi ESP-2 spectrophotometer. Coleman Model 14 spectrophotometer.

Results and Discussion

Preliminary Experiments. — The sensitivities and selectivities of the color reactions of catechol, hydroquinone and resorcinol with MBTH are largely dependent on the hydrogen ion concentration and on the conditions of oxidation.

In an ammoniacal medium (pH ~11.5) catechol gives a pink color with MBTH, dissolved oxygen acting as an oxidant for the oxidative coupling. In the same medium, hydroquinone gives a blue color, which fades into brown within 2 min. However, this blue color can be stabilized a further 3 min. by acetone. Resorcinol gives only a weak yellow color under these conditions, and its absorbance is negligibly low at the λ max. of the blue color obtained from hydroquinone.

In a weakly alkaline medium (pH 8~9), catechol, hydroquinone and resorcinol give a red or orange color with MBTH in the presence of ferricyanide. In this condition reproducible results are obtained only for resorcinol.

In the acidic ferric-ferrous redox buffer, catechol gives a violet color with MBTH. Under the same conditions hydroquinone and resorcinol give a weak red or orange color. Thus the medium is more selective for catechol than the ammoniacal medium.

In a higher hydrochloric acid solution (~1.2 N), catechol, hydroquinone and resorcinol give a red or orange color with MBTH in the presence of ferric chloride. These conditions are favorable for the determination of hydroquinone and resorcinol in a mixture of the two.

Taking these results and others into consideration, the following procedures have been elaborated:

TABLE I. SPECTROPHOTOMETRIC DETERMINATION OF DIHYDROXYBENZENE

Dihydroxybenzene	λ_{max} mμ	$\varepsilon \times 10^{-4}$	Color	Procedure
Catechol	510	2.8	Pink	1a
Catechol	550	2.4	Vioelt	1b
Hydroquinone	610	1.5	Blue	2
Resorcinol	495	5.2	Orange	4
Resorcinol	515	2.9	Orange	3

Recommended Procedures and The Effect of Various Factors

1) The Determination of Catechol.—a) In an Ammoniacal Medium. — To 2 ml. of a test

* A part of this paper was presented at the 14th Annual Meeting of the Chemical Society of Japan, Kyoto, 1961.

** Studies of the reaction mechanism of catechol, hydroquinone and resorcinol with MBTH are in progress. Applications of MBTH to the analysis of phenol derivatives will be published elsewhere.

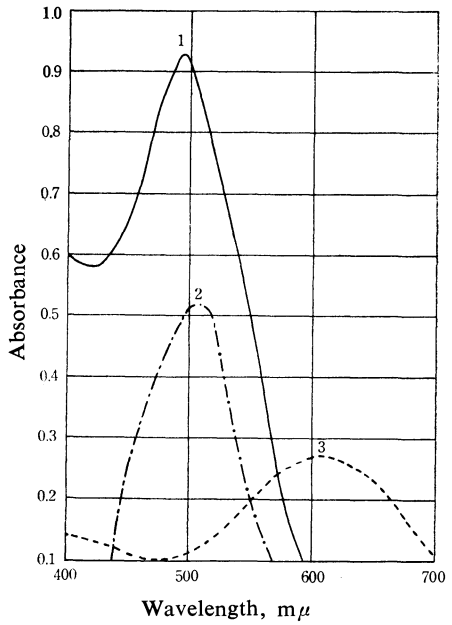

Fig. 1. Visible absorption spectra obtained in determination of catechol, hydroquinone and resorcinol in alkaline solution. 1. Resorcinol, 20 μg. (Procedure 4). 2. Catechol, 20 μg. (Procedure 1a). 3. Hydroquinone, 20 μg. (Procedure 2).

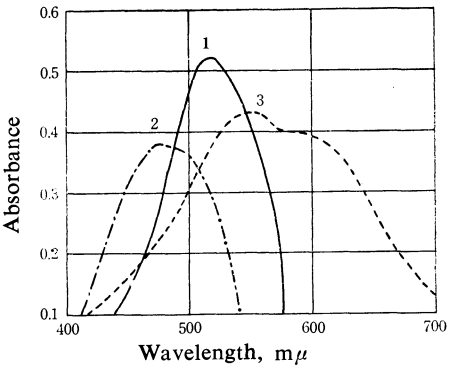

Fig. 2. Visible absorption spectra obtained in determination of catechol, hydroquinone and resorcinol in acid solution. 1. Resorcinol, 20 μg. (Procedure 3). 2. Hydroquinone, 20 μg. (Procedure 3). 3. Catechol, 20 μg. (Procedure 1b).

solution 4 ml. of a 0.5% MBTH methanol solution is added, and then 2 ml. of methanol and 2 ml. of concentrated ammonia. After the mixture has stood for 15 min., the absorbance is read at the wavelength of 510 mμ.

The Effect of Various Factors. — The absorbance reaches a maximum from 10 to 12 min. after the addition of ammonia. Very little change in the absorbance is noticed for a further 30 min. upon the addition of 2~3 ml. of concentrated ammonia. A lesser amount of concentrated ammonia is not sufficient to stabilize the product, and a decrease in the absorbance is observed after 25 min. upon the addition of 1 ml. of concentrated ammonia. The best results are obtainable with an MBTH hydrochloride concentration more than 0.2%. Beer's law is obeyed from 0 to 10 μg. of catechol. The molar absorptivity is 2.8×10^4 (Table I). The absorption spectrum is given in Fig. 1.

Derivatives of catechol give rise to a pink color. Hydroquinone and its derivatives and *p*-benzoquinone give rise to a brown color. The presence of less resorcinol than the equivalent amount of catechol does not interfere with the determination of catechol.

b) In the Medium of a Ferric-ferrous Salts Solution.—To 4 ml. of a test solution 2 ml. of a 0.4% MBTH aqueous solution is added, and then 1.6 ml. of a 10% Mohr's salt solution and 0.4 ml. of a 1% ferric chloride solution. After the mixture has stood for 5 min., 2 ml. of a acetone is added. The absorbance is read at the wavelength of 550 mμ within 30 min.

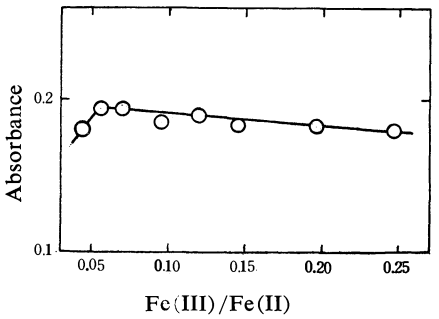

Fig. 3. Effect of Fe(III)/Fe(II) ratio on absorbance in procedure 1b. Catechol, 5 μg.

The Effect of Various Factors.—The absorbance reaches a maximum 4min. after the addition of the ferric chloride solution, and very little change in the absorbance is noticed for the next 6 min. The color is further stabilized for more than 30 min. by acetone. Best results are obtainable with a ratio Fe(III)/Fe(II) of about 0.06 (Fig. 3). The concentration of MBTH hydrochloride must be controlled below 0.1%; otherwise a turbid solution is obtained. The pH of the solution after the addition of all reagents is 3.0. At higher pH values the absorbance decreases and ferric hydroxide precipitates.

At lower pH values (pH 1~2) the violet color turns pink. In a solution containing ferric ions but not ferrous ions, catechol instantaneously gives a violet color with MBTH, and this color rapidly turns dark brown. In these two cases the reaction is no

TABLE II. DETERMINATION OF HYDROQUINONE AND RESORCINOL IN THE PRESENCE OF EACH OTHER

Hydroquinone, added μg.	Resorcinol, added μg.	Absorbance at 510 mμ	Net absorbance for resorcinol*	Calculated absorbance for resorcinol**	Recovery of resorcinol %
2.5	2.5	0.175	0.115	0.110	105
5.0	2.5	0.235	0.115	0.110	105
10	2.5	0.350	0.110	0.110	100
2.5	5.0	0.285	0.225	0.220	102
5.0	5.0	0.345	0.225	0.220	102
10	5.0	0.455	0.215	0.220	98

* Calculated from the following equation: Absorbance at 510 mμ − 0.024 × μg. of hydroquinone.
** Calculated from the calibration curve for resorcinol constructed by procedure 3.

longer selective for catechol, the sensitivities of the reaction of hydroquinone and resorcinol being comparable with that of catechol.

Beer's law is obeyed from 0 to 15 μg. of catechol. The molar absorptivity is 2.4×10^4 (Table I). The absorption spectrum is given in Fig. 2.

The presence of 2 μg. of hydroquinone or 5 μg. of resorcinol does not interfere with the determination of catechol. Derivatives of catechol give rise to a violet or blue color.

2) The Determination of Hydroquinone.—To 3 ml. of a test solution 3 ml. of a 0.5% MBTH methanol solution is added, and then 1 ml. of concentrated ammonia. After 1 min. 3 ml. of acetone is added to the solution. The absorbance is read at the wavelength of 610 mμ within 3 min.

The Effect of Various Factors. — The maximum absorbance is reached 40 sec. after the addition of ammonia, and very little change in the absorbance is noticed for the next 50 sec. The color is further stabilized for 3 min. by acetone. Acetone takes part also in making the solution clear. The absorbance is depressed in a methanol concentration more than 30%(v/v). Best results are obtainable with a 0.15% MBTH hydrochloride concentration and the addition of 1 or 2 ml. of ammonia. An increase or decrease in the concentration of MBTH or ammonia results in a decrease in the absorbance. Beer's law is obeyed from 0 to 10 μg. of hydroquinone. The molar absorptivity is 1.5×10^4 (Table I). The absorption spectrum is given in Fig. 1.

Catechol interferes with the reaction between hydroquinone and MBTH. Derivatives of hydroquinone and *p*-benzoquinone give rise to a blue color. The presence of resorcinol up to 100 μg. does not interfere with the determination of hydroquinone.

3) The Determination of Hydroquinone and Resorcinol in a Mixture of the Two. — To 4.5 ml. of a test solution 3 ml. of a 0.4% MBTH aqueous solution is added, and then 1.5 ml. of 8 N hydrochloric acid and 1 ml. of a 1% ferric chloride solution. Then the solution is heated for 2 min. in a water bath at 80°C. The solution is cooled in running tap water. Using a reagent blank as reference, the absorbance is read within 30 min. at the wavelength of 510 mμ, which corresponds to the sum of hydroquinone and resorcinol.

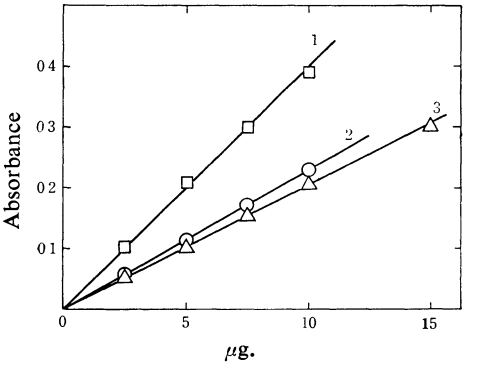

Fig. 4. Calibration curves for hydroquinone and resorcinol. 1. Resorcinol at 510 mμ (Procedure 3). 2. Hydroquinone at 510 mμ (Procedure 3). 3. Hydroquinone at 610 mμ (Procedure 2).

Refering to the content of hydroquinone previously determined by procedure 2 and to standard curves for resorcinol and hydroquinone constructed by this procedure (Fig. 4), the amount of resorcinol in mixtures with hydrquinone can be calculated by the following equation:

$$\mu g.\ \text{of resorcinol} = (\text{absorbance at } 510\ m\mu - 0.024\times \mu g.\ \text{of hydroquinone})\times 22.7$$

The Effect of Various Factors. — At room temperature the absorbance increases gradually, reaches a maximum, and decreases. After two minutes' heating in a water bath at 80°C, the reaction proceeds to completion, and no further change in absorbance is observed, even after the solution has stood for 30 min. at room temperature. The optimum range of the hydrochloric acid concentration is from 1.0 to 1.6 N for resorcinol and about 1.2 N for hydroquinone

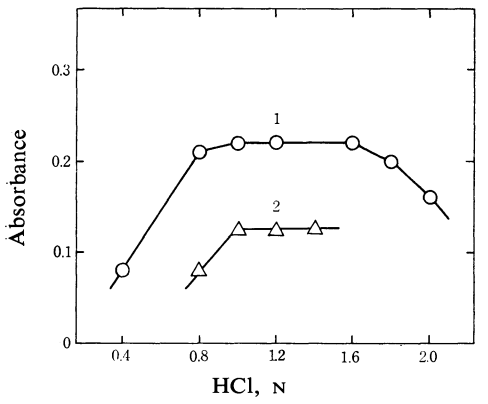

Fig. 5. Effect of acidity on absorbance in procedure 3. 1. Resorcinol, 5 μg. 2. Hydroquinone, 5 μg.

hydroquinone (Fig. 5). The optimum concentration of ferric chloride is from 0.10 to 0.14%. Best results are obtainable with an MBTH hydrochloride concentration more than 0.10%. Beer's law is obeyed from 0 to 7.5 μg. for resorcinol and from 0 to 10 μg. for hydroquinone. The molar absorptivity for resorcinol is 2.9×10^4 (Table I). Absorption spectra are given in Fig. 2.

Derivatives of dihydroxybenzene such as catechol give rise to an orange or red color.

Results of the recovery test for resorcinol in mixtures with hydroquinone are given in Table II. As is shown in the last column of the same table, the recoveries of resorcinol are from 98 to 105%.

4) The Determination of Resorcinol. — To 3 ml. of a test solution 0.5 ml. of a 0.5% MBTH methanol solution is added, and then 4.5 ml. of methanol, 1 ml. of (0.7+100) ammonia and 1 ml. of a 2% ferricyanide solution. The pH of the solution must be 8~9. The absorbance is read at the wavelength of 490 mμ within 30 min.

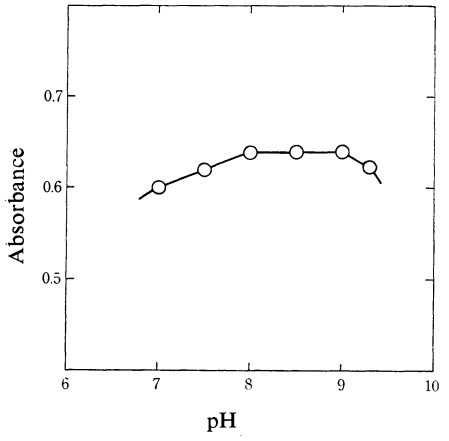

Fig. 6. Effect of pH on absorbance in procedure 4. Resorcinol, 10 μg.

The Effect of Various Factors.—The absorbance reaches a maximum a few minutes after the addition of the ferricyanide solution. Very little change in the absorbance is noticed for the next 30 min. The optimum range of the MBTH hydrochloride concentration is from 0.02 to 0.03% in the methanol concentration of about 50%(v/v). A turbid solution is obtained with a higher MBTH concentration. The optimum pH range is from 8 to 9 (Fig. 6). The use of an ammonia - ammonium chloride buffer is not recommended, the absorbance being depressed in the buffer. The concentration of potassium ferricyanide should be kept very close to 0.02%; otherwise precipitation occurs. Beer's law is obeyed from 0 to 10 μg. of resorcinol. The molar absorptivity is 5.2×10^4 (Table I). The absorption spectrum is given in Fig. 1.

Phenol derivatives give reddish colors.

Summary

New spectrophotometric procedures for determining microgram amounts of catechol, hydroquinone and resorcinol with MBTH have been described. The sensitivities and selectivities of the reactions are largely dependent on the pH and on the conditions of oxidation: 1) In an ammoniacal medium MBTH gives a stable pink color with catechol and, with hydroquinone, a blue color which is stabilized by acetone. Resorcinol gives only a faint color under these conditions. 2) When ferricyanide is used as an oxidant in a weakly alkaline solution, MBTH gives a sensitive orange color with resorcinol. 3) In an acidic ferric-ferrous redox buffer, MBTH gives a violet color with catechol. At pH 3 the reaction is selective for catechol. 4) Ferric chloride in 1.2N hydrochloric acid is favorable for the determination of hydroquinone and resorcinol in a mixture of the two.

We are grateful to Professor Motoharu Tanaka for his invaluable advice and criticism.

The Base-catalyzed Condensation of o-Nitroacetophenone. I. Some Properties of the Condensation Products

By Takeo SAKAN, Kousuke KUSUDA[1] and Toshio MIWA

(Received May 28, 1964)

The reaction of nitrobenzene with phenylmagnesium bromide is known to yield diphenylamine.[2] However, Newman and Smith[3] have found that *m*-nitrobenzaldehyde reacts smoothly with phenylmagnesium bromide at the low temperature of $-70°C$ to give *m*-nitrobenzhydrol, while the reaction gives only a tarry product at room temperature. This technique has been applied also to *o*-nitrobenzaldehyde.[4]

It seemed interesting to see what the reactions would be to the action of sodium acetylide upon *o*-nitroacetophenone at such a low temperature.

The treatment of *o*-nitroacetophenone with sodium acetylide in liquid ammonia at $-70°C$ yielded an orange-red crystalline compound, m. p. 171~172°C of a weak acidity (pK_a ca. 5.9) in a moderate yield, along with *o*-nitrobenzoic acid. A series of following papers will report on the elucidation of the structure and the reactions of this product, which will be referred to as compound A throughout this series.

The elementary analysis of compound A did not afford a constant result; rather, the results depended upon the kind of solvents from which it was recrystallized (see Experimental section). The analytical results agreed approximately with the $C_{17}H_{14}O_5N_2$ composition, which was supported by analyses of some of its derivatives (see below). The measrement of the *C*-methyl number gave a value of 0.72. The absence of a distinct absorption in the carbonyl region of the infrared spectrum of compound A suggests that the weak acidity of this compound may be due to an enolic group, to which a band near 3300 cm^{-1} can be assigned (Fig. 1). The absorption bands at 1535 and 1355 cm^{-1} correspond to the nitro group.

When compound A was treated with diazomethane or dimethyl sulfate and potassium carbonate, a yellow methyl ether, $C_{18}H_{16}O_5N_2$, was obtained. Similarly, the treatment of compound A with diethyl sulfate and potassium carbonate produced an ethyl ether, $C_{19}H_{18}O_5N_2$. These derivatives had lost the acidity as well as the absorption band near 3300 cm^{-1} of the original compound; these facts seem to support the speculation that the acidity of compound A may be attributed to an enolic function. The methyl ether has a weak absorption band at 3000 cm^{-1} which is shifted to 3250 cm^{-1} with an increase in its intensity in the carbon tetrachloride solution. Another conspicuous difference in the infrared spectrum of the methyl ether from that of compound A is the appearance of a new band, of a medium intensity, at 1616 cm^{-1}.

The ultraviolet spectra of compound A and its alkyl ethers possess a characteristic intense band near 380 mμ. The position of the band of compound A is shifted to ca. 400 mμ and the intensity of the band is increased when the compound is dissolved in aqueous alkali. On the other hand, such behavior is not observed in the case of its alkyl ethers.

The molecular formula of compound A, $C_{17}H_{14}O_5N_2$, was confirmed by elementary analyses of its alkyl ethers and by the determination of the molecular weight of the methyl ether by the Barger method. With this composition, compound A was assumed to be formed by the dehydrogenative condensation of three moles of *o*-nitroacetophenone with the simultaneous cleavage of one mole of *o*-nitrobenzoic acid.[5]

$$3\,C_8H_7O_3N \rightarrow C_{17}H_{14}O_5O_2+C_7H_6O_4N+H_2$$

If this condensation proceeds according to the stoichiometry of the equation and is terminated by the formation of the stable salts of both the products, the best yield compound A can be expected on the use of two gram atoms of sodium per three moles of *o*-nitroacetophenone;[6] this is indeed the case, as Table I

4) D. H. Hey and R. D. Mulley, *J. Chem. Soc.*, **1952**, 2276.

5) Although a pair of reagents, liquid ammonia and sodium, sounds like the conditions of the Birch reduction, the coexistence of a nitro compound and a strong base, sodium amide or acetylide, may produce oxidizing circumstances similar to those of the nitrobenzene and alkali pair.

6) Strictly speaking, the consumption of the nitro compound by reduction during the reaction is neglected.

TABLE I. BASE-CATALYZED CONDENSATION OF *o*-NITROACETOPHENONE

Per mole of *o*-nitroacetophenone		Compd. A	Compd. B	*o*-Nitrobenzoic acid	Recovered
Liq. NH_3 l.	Sodium g. atom	%[a]	%[b]	%[a,b]	%
1.3	0.57	37	—	121	49
2.1	0.63	54	—	31	30
1.0	0.67	50	—	70	c)
1.0	0.67	62	—	50	c)
3.2	1.04	34	—	53	45
6.6	3.45	—	26	71	58
1.0[d]	0.67	46	—	c)	c)
0.8[e]	0.67	45	—	c)	c)

a) The yield was calculated using the Eq. 1. The recovered ketone, if weighed, was reduced from the starting material on the calculation.
b) The yield of compound B was calculated by postulating that the compound had been formed according to the following equation:

$$2\ C_8H_7O_3N + NH_3 \rightarrow C_9H_{10}O_2N_2 + C_7H_5O_4N + H_2$$

c) The amount was not recorded.
d) Sodium amide was used in stead of sodium acetylide.
e) The reaction was carried out under an atmosphere of nitrogen.

shows. Without the introduction of acetylene, which might be unnecessary for the reaction, a comparative yield of compound A was obtained, and the reaction was rather violent. The fact that a similar result was obtained under an atmosphere of nitrogen excluded the possibility of the dehydrogenation by atmospheric oxygen.

When the condensation was carried out with a large excess of sodium, compound A was not formed, but a colorless product, $C_9H_{10}O_2N_2$, named compound B was obtained in a low yield.

The oxidation of compound A with alkaline hydrogen peroxide gave a weakly acidic substance, $C_{17}H_{12}O_5N_2$, m. p. 226~227°C. This compound was also obtained when the reaction mixture of the condensation had been allowed to stand in air for a long time before acidification. This substance is named dehydro-compound A.

Dehydro-compound A was methylated with dimethyl sulfate and potassium carbonate in a way similar to that used in the methylation of compound A to give a neutral methyl ether, $C_{18}H_{14}O_5N_2$. The methyl ether was obtained also by the oxidation of compound A

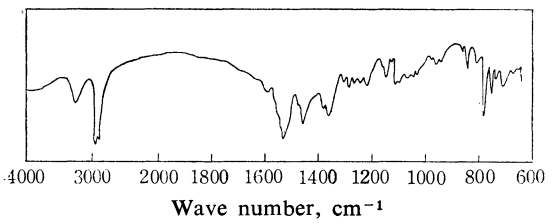

Fig. 1. Infrared spectrum of compound A (Nujol mull).

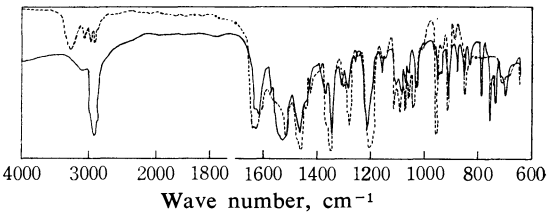

Fig. 2. Infrared spectrum of compound A methyl ether. (—— Nujol mull; ---- 0.06 M CCl_4 solution).

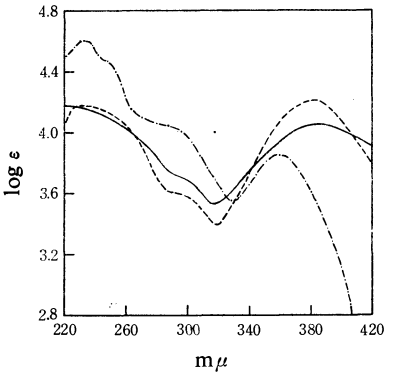

Fig. 3. Ultraviolet spectra (in ethanol) of compound A (——), compound A methyl ether (----) and dehydro-compound A (-·-·-).

methyl ether with periodic acid in dioxane. The ozonization of compound A ethyl ether produced a small amount of dehydro-compound A ethyl ether.[7] It should be pointed out that the dehydrogenation of compound A or its

7) See Part II: T. Sakan, K. Kusuda and T. Miwa, This Bulletin, 37, 1681 (1964).

alkyl ethers took place very readily with a variety of oxidizing agents.

In the ultraviolet spectra of dehydro-compound A and its methyl ether, the characteristic band near 380 mμ of the compound A series disappeared and a new band showed up near 350 m. This striking change in the spectrum suggests that a major reaction had occurred during the dehydrogenation.

Experimental[8]

The Condensation of *o*-Nitroacetophenone by Sodium Acetylide. *a) Compound A.*—Into 100 cc. of liquid ammonia saturated with acetylene, 1.5 g. (0.065 g. atom) of sodium was added in small pieces. After all the sodium had been added, 16.5 g. (0.1 mol.) of *o*-nitroacetophenone in 20 cc. of dry ether was stirred in one portion at −70°C. A violent exothermic reaction (the temperature of the reaction mixture reached −50°C) took place, giving a dark red mixture. The mixture was then kept at −50∼−60°C for one hour, 4.0 g. (0.075 mol.) of ammonium chloride was added, and the liquid ammonia was allowed to evaporate while about 50 cc. of ether was added. When the reaction mixture had reached the room temperature, a further amount of ether and some water were added. The separated ethereal solution was extracted with several portions of a 10% sodium hydroxide solution, and the aqueous extracts were added to the original aqueous layer. (From the ethereal solution, after concentration followed by distillation in vacuo, *o*-nitroacetophenone was recovered.) The combined aqueous solution, dark red in color, was washed with ether, acidified with hydrochloric acid, and extracted with ether. The ethereal solution was washed with a sodium bicarbonate solution until the washing became reddish.[9] The concentration of the ethereal solution gave orange-red needles, which, after recrystallization from ethanol, melted at 170∼171°C. Recrystallization from non-polar solvents gave somewhat yellowish crystals of the same melting point. The pK_a value (ca. 5.9) in an aqueous solution was not accurate because of the poor solubility of this compound in water. λ_{max} 382∼384 (4.05). ν_{max} 3286 (OH), 1535, 1355, 844 (NO_2).

Found: (a) From benzene-ligroin: C, 63.10; H, 4.46; N, 7.52. (b) From chloroform: C, 62.52; H, 4.22; N, 8.08. (c) From ethanol: C, 62.68; H, 4.17; N, 8.48. *C*-Methyl group[10]: 0.72. Calcd. for $C_{17}H_{14}O_5N_2$: C, 62.57; H, 4.32; N, 8.59%. The results of the condensation under various conditions, are listed in Table I.

b) Compound B.—*o*-Nitroacetophenone (10.0 g., 0.061 mol.) was subjected to condensation with sodium acetylide prepared from acetylene 5.0 g. (0.22 g. atom) of sodium in 400 cc. of liquid ammonia, and the reaction mixture was worked up in a way similar to that described in a). There was obtained 0.4 g. of a crystalline substance insoluble both in the ethereal and alkaline aqueous layers. From the neutral fraction, 5.8 g. of an oil boiling at 146°C/2.5 mmHg was obtained. The 2,4-dinitrophenylhydrazone of the oil, m. p. 166∼167°C, was identified as that of *o*-nitroacetophenone. The acid fraction gave 1.0 g. of crude *o*-nitrobenzoic acid. The insoluble material was dissolved in N hydrochloric acid, and the solution was treated with active carbon and then made alkaline with aqueous ammonia to give faintly brown plates decomposing at 236°C. λ_{max} 230 (4.18), 291 (3.92). ν_{max} 3280 (OH), 2860∼2500 (NH or OH[6]), 1672 (C=O).

Found: C, 60.82; H, 5.78; N, 15.69. Calcd. for $C_9H_{10}O_2N_2$: C, 60.66; H, 5.66; N, 15.72%.

Compound A Methyl Ether. — *a) With Diazomethane.*—A solution of 400 mg. (1.22 mmol.) of crude compound A in a little methanol was treated with an ethereal solution of diazomethane prepared from 4.0 g. (40 mmol.) of nitrosomethylurea. A benzene solution of the crude product was adsorbed on a small amount of active alumina. Benzene eluted 342 mg. (82%) of yellow crystals, which, after recrystallization from petroleum benzine, melted at 114∼115.5°C. λ_{max} 230 (4.17), 383 (4.21). ν_{max} 1533, 1347, 851 (NO_2).

Found: C, 63.58; H, 4.77; N, 8.36. Mol. wt. (Barger) 325±25. Calcd. for $C_{18}H_{16}O_5N_2$: C, 63.52; H, 4.74; N, 8.23%. Mol. wt. 340.

Elution with 50 cc. of benzene containing one drop of ethanol gave 44 mg. of dehydro-compound A methyl ether m. p. 127°C (see below).

b) With Dimethyl Sulfate and Potassium Carbonate.—A mixture of 1.6 g. (4.7 mmol.) of crude compound A, 1.0 g. (7.9 mmol.) of dimethyl sulfate, and 1.1 g. (8.0 mmol.) of potassium carbonate in 20 cc. of acetone was refluxed for 20 min. The insoluble substances were then removed by filtration, and the acetone was evaporated under reduced pressure to give a viscous oil.[11] The oil was purified in the way described in a) to give a quantitative yield of the methyl ether m. p. 113∼115°C and a trace of dehydro-compound A methyl ether, m. p. 127°C.

Compound A Ethyl Ether.—A mixture of 3.3 g. (10 mmol.) of crude compound A, 1.6 g. (10 mmol.) of diethyl sulfate, and 1.4 g. (11 mmol.) of potassium carbonate in 50 cc. of acetone was refluxed for one hour. The reaction mixture was worked out in a way similar to that described in methylation b). Chromatographic purification gave 3.4 g. (94%) of the ethyl ether, which was recrystallized from ether m. p. 117∼118°C.

8) All melting points are uncorrected. Unless otherwise noted, ultraviolet spectra were taken in ethanol and infrared spectra, in Nujol mull; Peak positions and intensities are expressed in λ_{max} mμ (log ε) and in ν_{max} cm^{-1}, respectively. The authors are much indebted to Mr. Jun'ichi Gōda and his associates for their elementary analyses and to Mrs. Michino Butsugan and Miss Hiromi Tokuda for their infrared determinations for this series of papers.

9) A considerable amount of compound A was extracted by aqueous sodium bicarbonate because of its acidity.

10) E. J. Eisenbraun, S. M. McElvain and B. F. Aycock, *J. Am. Chem. Soc.*, **76**, 607 (1954). The measurement was carried out by Dr. Akira Fujino, to whom the authors are indebted.

11) Superheating during the evaporation caused a severe resinification that made it impossible to obtain the methyl ether.

Found: C, 64.13; H, 4.89; N, 8.16. Calcd. for $C_{19}H_{18}O_5N_2$: C, 64.40; H, 5.12; N, 7.91%.

Dehydro-compound A.—To a warm solution of 4.0 g. (12 mmol.) of crude compound A in 150 cc. of a 2% sodium hydroxide solution was added 20 cc. of 30% hydrogen peroxide. The mixture was then stirred well and allowed to stand overnight to from a yellowish gel. The crystal-cake formed on acidification with 20% hydrochloric acid was crushed, collected by filtration, washed successively with water and ethanol, and then dried. Dehydro-compound A (3.5 g.) was recrystallized from chloroform and ligroin to give faintly grayish prisms melting at 226~227°C. This compound is rather unstable to light. λ_{max} 234 (4.60), 358 (3.85). ν_{max} 3145 (OH), 1675, 1600 (C=O), 1517, 1340 (NO_2).

Found: C, 63.44; H, 3.78; N, 8.79. Calcd. for $C_{17}H_{12}O_5N_2$: C, 62.96; H, 3.73; N, 8.64%.

Dehydro-compound A Methyl Ether.—A mixture of 470 mg. (1.44 mmol.) of dehydro-compound A, 0.2 g. (1.5 mmol.) of dimethyl sulfate, and 0.22 g. (1.6 mmol.) of potassium carbonate in acetone was refluxed for one hour. The removal of the insoluble material by filtration, followed by the evaporation of the solvent in vacuo, left crystals, which were then chromatographed on a short column of active alumina in benzene to give a quantitative yield of the methyl ether. After recrystallization from benzene-ligroin, it melted at 129.5~130°C. λ_{max} 230~231 (4.58), 285~287 (4.05), 350~352 (3.78). ν_{max} 1684, 1647 (C=O), 1534, 1355 (NO_2).

Found: C, 63.94; H, 4.25; N, 8.34. Calcd. for $C_{18}H_{14}O_5N_2$: C, 63.90; H, 4.17; N, 8.28%.

The Periodic Acid Oxidation of Compound A Methyl Ether.—A mixture of 500 mg. (1.47 mmol.) of compound A methyl ether, 380 mg. (1.42 mmol.) of sodium periodate, and 1.44 mg. of sulfuric acid in 9 cc. of dioxane was left to stand at room temperature for six days. The addition of water, followed by the evaporation of the solvent under reduced pressure, was repeated to remove the dioxane. The resulting aqueous solution was then extracted with ether-benzene, and the extract was washed with aqueous sodium bicarbonate and dried. The evaporation of the solvent under reduced pressure and the chromatography of the residue on active alumina gave 188 mg. of dehydro-compound A methyl ether, which, after recrystallization from benzene-ligroin, metled at 129.5~130°C. A mixed melting point determination with an authentic samle of the methyl ether showed no depression.

The Base-catalyzed Condensation of o-Nitroacetophenone. II. The Ozonolysis of Methyl Ether of Compound A, a Condensation Product, and the Structure of Compound B, Another Product

By Takeo SAKAN, Kousuke KUSUDA[1] and Toshio MIWA

(Received May 28, 1964)

The base-catalyzed condensation of *o*-nitroacetophenone has been reported to give an orange-red product, $C_{17}H_{14}O_5N_2$, named compound A.[2] In order to elucidate the structure of this compound, its methyl ether was ozonolyzed. The ozonolysis of compound A methyl ether yielded a colorless neutral compound, $C_{10}H_{11}O_3N$, along with *o*-nitrobenzoic acid, *o*-nitroacetophenone and formaldehyde.

The measurement of the *C*-methyl number of the C_{10}-compound gave a value of 0.64; a positive alkoxyl group test[3] showed the presence of an alkoxyl group. This compound gave negative reactions both with a ferric hydroxamate test[4] and with various carbonyl reagents, indicating the absence of either an ester or a keto function. On the other hand, it gave positive results with the Millon and Folin-Dennis reactions.[5] After hydrolysis,

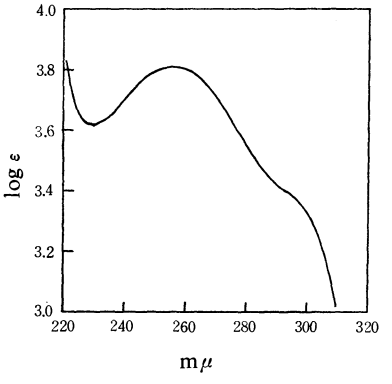
4) Ibid., p. 460.

5) Since the oxindoles with no hydrogen atom at their β-position had generally given a negative Folin-Dennis reaction, formula i was assigned to this compound (The 11th Annual Meeting of the Chemical Society of Japan,

(i)

Tokyo, April, 1958). Later this formula was found to be false by the confirmation of the presence of a *C*-methyl group. A color test with ammonium phosphomolybdate is more specific to the presence of the β-hydrogen of oxindole derivatives (T. Tokuyama, The 12th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1959); the C_{10}-compound gave a negative reaction with this reagent.

followed by diazotization and coupling with β-naphthol, it developed an orange color. The vapor of the zinc-dust distillation gave a violet spin-splinter reaction. These color reactions,[6] associated with the features of the ultraviolet spectrum[7] (Fig. 1), suggested the presence of an oxindole system in this compound. The carbonyl bond (1715 cm^{-1}) of the infrared spectrum of the compound can be assigned to the oxindole carbonyl. The *N*-unsubstituted oxindoles usually exhibit a broad band near 3200 cm^{-1}.[8] The absence of any bands above 3000 cm^{-1} of the infrared spectrum of the compound, except for a sharp band at 3410 cm^{-1}, indicated that the postulated oxindole nucleus can be substituted at the nitogen atom.



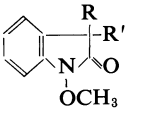


Fig. 1. Ultraviolet spectrum of the C_{10}-compound (I) in ethanol.

The acylation of the C_{10}-compound by acetic anhydride or *p*-nitrobenzoyl chloride in the presence of pyridine gave the corresponding *O*-acyl derivatives, as is indicated by their infrared spectra (see Experimental section). The disappearance of the 3410 cm^{-1} band in these spectra demonstrated that the band of the original compound should be attributed to a hydroxyl group.

On the basis of these results, the C_{10}-compound may be considered to be an *N*-substituted oxindole derivative with a hydroxyl, a methoxyl and a methyl group as substituents. The neutral property of the compound excluded the possibility that it might be a hydroxamic acid. Therefore, this compound was assumed to be 1-methoxy-3-methyldioxindole (I).

The treatment of the C_{10}-compound with thionyl chloride and pyridine produced a chloride II, which was hydrogenated in the presence of palladium-on-carbon and sodium acetate to a chlorine-free oil considered to be 1-methoxy-3-methyloxindole (III).

On the other hand, 1-methoxyoxindole (IV)[9] was formylated with ethyl formate in the presence of sodium ethoxide.[10] The formylation product, V, was hydrogenated over palladium-on-carbon to compound III. Both the compound from the ozonolysis and that from the synthetic path showed quite identical infrared spectra. The oily oxindole, III, was characterized by bromination to a crystalline monobromine atom of which was tentatively located at the position 5 of the oxindole system.

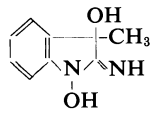
I, R=CH_3, R'=OH
II, R=CH_3, R'=Cl
III, R=CH_3, R'=H
IV, R=R'=H
V, R, R'=CHOH

Interestingly, the hydrogenation of V over Raney nickel caused a further reduction to 3-methyloxindole.

In order to confirm whether the *O*-methyl group of the C_{10}-compound had been introduced by the methylation of compound A, the ethyl ether of the latter was ozonolyzed. From ethyl ether of latter was ozonolyzed. From the neutral fraction two unknown compounds besides *o*-nitroacetophenone were isolated. One of the unkonwn compounds, $C_{19}H_{11}O_5N_2$, was supposed to be dehydro-compound A[2] ethyl ether on the basis of its ultraviolet spectrum.

The other unknown product, $C_{11}H_{13}O_3N$, was assigned the 1-ethoxyoxindole structure I (OEt for OMe) by analogy with the above-mentioned C_{10}-compound; this assignment was confirmed by its ultraviolet and infrared spectra, which were similar to those of the latter. Consequently, it is apparent that the hydroxyl group of weak acidity in compound A is not an enolic one, but one attached to a nitrogen atom, as in an oxime or in a hydroxamic acid. Hence, compound A contains an *N*-hydroxyindoline and an *o*-nitrophenyl moiety in its molecule.

The base-catalyzed condensation of *o*-nitroacetophenone using a large excess of sodium acetylide yielded no compound A, but formed a faintly yellow product, compound B.[2]



Contrary to the weakly acid compound A, this compound was basic and soluble in dilute hydrochloric and. It was recovered as precipitates from the acid solution when it was made alkaline with aqueous ammonia. It was insoluble in aqueous sodium bicarbonate. Hot aqueous alkali dissolved it gradually, with the

evolution of ammonia. The vapor of zinc-dust distillation gave a violet pine-splinter reaction, indicating the formation of the indole derivative. The green color developed with alcoholic ferric chloride quickly turned yellow. Aqueous ferric chloride gave the pale blue color characteristic of α-aminopyridine *N*-oxides.[11]

The attempted methylation of compound B by treatment with dimethyl sulfate and potassium carbonate afforded a compound melting at 134~135°C and with the evolution of ammonia. This compound was shown to be identical with the C_{10}-compound I obtained above by the ozonolysis of the compound A methyl ether.

On the basis of these results compound B may be represented by either of the following tautomeric structures, VIa or VIb:

VIa

VIb

Experimental[12]

The Ozonolysis of Compound A Methyl Ether. 1-Methoxy-3-methyldioxindole (I). — *a) Oxidative Decomposition.*—A solution of 1.31 g. (3.88 mmol.) of compound A methyl ether[2] in 40 cc. of ethyl acetate, which had been chilled in an ice-bath, was saturated with ozone and allowed to stand in an ice-bath overnight. The solvent was then removed by distillation under reduced pressure in the cold, and the remaining red oil was added to a mixture of 0.4 g. of sodium dichromate in 40 cc. of acetic acid to cause a violent reaction, with foaming. The mixture, diluted with water, was extracted continuously with ether, and the extract washed with aqueous sodium bicarbonate. The acid fraction (469 mg., 72%) was recrystallized from benzene-petroleum benzine to give crystal melting at 145~147°C. No depression was observed in a mixed melting point determination with *o*-nitrobenzoic acid.

The removal of the solvent in vacuo from the ethereal solution left a viscous oil, which deposited a small amount of crystals when left standing. The residue in benzene was adsorbed on active alumina. Four fractions taken with benzene gave a yellow oil weighing 61 mg., 60 mg., 63 mg. and 37 mg. respectively. The first three of them (184 mg. in total, 30%) showed identical infrared (ν_{max} 1695 (C=O), 1522, 1348 (NO_2)) and ultraviolet (λ_{max} 259) spectra. The combined oil was then converted to a 2,4-dinitrophenylhydrazone melting at 164~165°C, which was identified with that of *o*-nitroacetophenone by a mixed melting point determination.

Elution with benzene containing some ethanol yielded 38 mg. (5.1%) of crystals, which, after recrystallization from benzene-ligroin, melted at 134~136°C. λ_{max} 257 (3.81). ν_{max} 3410 (OH), 1715 (C=O).

Found: C, 62.37; H, 6.06; N, 7.47; *C*-methyl, 0.62. Calcd. for $C_{10}H_{11}O_3N$: C, 62.16; H, 5.74; N, 7.25%.

A solution of 5 mg. of the C_{10}-compound in one drop of pyridine was treated with about 5 mg. of *p*-nitrobenzoyl chloride under ice-cooling, and the mixture was allowed to stand overnight. The removal of the pyridine under reduced pressure, followed by washing successively with two portions of water, 5% aqueous sodium carbonate and water, gave a *p*-nitrobenzoate, which melted at 107~109°C after recrystallization from ethanol. ν_{max} 1745, 1730 (C=O).

A solution of 51 mg. of the C_{10}-compound in 15 drops of pyridine, cooled with ice, was treated with 4 drops of acetic anhydride. After being kept for 6 hr. at room temperature, the mixture was decomposed by the addition of water. The resulting oil was washed with N hydrochloric acid, water and aqueous sodium carbonate, and then taken into benzene. The benzene solution, after drying, was filtered through a short column of active alumina. The removal of the solvent left an oily acetate. ν_{max} 1745 (shoulder), 1739 (C=O).

b) Decompsition with Water. — Compound A methyl ether (623 mg., 1.83 mmol.), dissolved in ethyl acetate, was saturated with ozone. The resulting ozonide, as a solution, was decomposed by the addition of water. The organic layer was separated from the aqueous layer, which was extracted with ether. The extract, combined with the original organic layer, was worked out as described in a). The acid fraction gave 279 mg. (91%) of crude *o*-nitrobenzoic acid. The neutral fraction was adsorbed on alumina. A yellow oil (100 mg.) was eluted by benzene. Elution with benzene containing a small amount of ethanol gave 98 mg. (28%) of a crude C_{10}-compound.

c) Reductive Decomposition.—After a solution of 308 mg. (0.91 mmol.) of compound A methyl ether in 20 cc. of ethyl acetate had been saturated with ozone, the solution was shaken saturated sulfurous acid and worked out as described in a). From the acid fraction, 96.5 mg. (63.9%) of crude *o*-nitrobenzoic acid was obtained. The removal of the solvent from the neutral fraction immediately gave 124 mg. (71.1%) of crystals, which after, recrystallization from benzene-ligroin, melted at 136°C. The chromatography of the mother liquor of recrystallization gave a small amount of oil. It was assumed to be *o*-nitroacetophenone because of a positive reaction with 2,4-dinitrophenylhydrazine.

d) In Carbon Tetrachroride. — A solution of 429 mg. of compound A methyl ether in 80 cc. of carbon tetrachloride, chilled with ice, was saturated with ozone. After it had been allowed to stand overnight, the solution deposited a resinous material on the wall of the flask. The resinous material

12) All melting points are not corrected. Unless otherwise noted, ultraviolet spectra were taken in ethanol and infrared spectra in Nujol mull; they are expressed in λ_{max} mμ (log ε) and in ν_{max} cm^{-1}, respectively.

was dissolved by the addition of ethyl acetate, and the ozonide was decomposed by the addition of 70 cc. of water. The aqueous solution gave a positive reaction with 2,4-dinitrophenylhydrazine and chromotropic acid (formaldehyde).[13] The aqueous solution was then distilled, and 35 cc. of the distillate was treated with 12 cc. of a saturated aqueous methone solution and allowed to stand, thus depositing small needles melting at 183~185°C, which did not depress the melting point of the methone derivative of formaldehyde.

3-Formyl-1-methoxyoxindole (V). — Into a hot sodium ethoxide solution prepared from 1.0 g. (44 mmol.) of sodium and 13 cc. of dry ethanol was added a mixture of 4.4 g. (27 mmol.) of 1-methoxyoxindole[9] and 3.0 g. (40 mmol.) of ethyl formate, the reaction mixture solidifying into a pink cake with heat evolution. The cake was dissolved with 120 cc. of water, and the solution was acidified with hydrochloric acid to separate yellowish brown precipitates, which were collected by filtration, washed with 50% aqueous ethanol and recrystallized from ethanol to give 2.9 g. (56%) of V decomposing at 190°C. ν_{max} 2650 (OH), 1658 (C=O).

Found: C, 62.84; H, 4.75; N, 7.51. Calcd. for $C_{10}H_9O_3N$: C, 62.82; H, 4.75; N, 7.33%.

1-Methoxy-3-methyloxindole (III).—*a) From 1-Methoxy-3-methyldioxindole (I).*—A solution of 62 mg. (0.32 mmol.) of the C_{10}-compound in 1 cc. of pyridine was treated with 35 mg. (0.42 mmol.) of thionyl chloride. After being kept at room temperature for 18 hr., the mixture was diluted with ether and washed with water. The removal of the ether by distillation left 47 mg. of crystals, m. p. 78~102°C, which showed positive in a Beilstein test. The filtration of a benzene solution of the crystals through a short column of alumina gave 16 mg. of the chloride II. ν_{max} 1739 (C=O).

A solution of 45 mg. (0.21 mmol.) of the chloride II in ethanol was hydrogenated in the presence of 17.5 mg. (0.21 mmol.) of sodium acetate and 20 mg. of 5% palladium-on-carbon. Within 40 min. 7.9 cc. (14°C) of hydrogen was absorbed. After the removal of the catalyst by filtration, followed by the evaporation of the solvent in vacuo, the residue, as a benzene solution, was filtered through a short column of alumina to give 35 mg. of an oil. The oil showed an infrared spectrum (ν_{max} 1736~1721 (C=O)) quite identical with that of 1-methoxy-3-methyloxindole synthesized below.

b) From 3-Formyl-1-methoxyoxindole (V). — A solution of 170 mg. (0.89 mmol.) of the formylation product V in 10 cc. 95% ethanol was hydrogenated in the presence of 80 mg. of 5% palladium-on-carbon. Within 2 hr. 5.6 cc. (13°C) of hydrogen was absorbed. Work-up in a way similar to that described in a) gave III as an oil, which was characterized as a bromide. The elution of the alumina with benzene containing a little ethanol yielded crystals melting at little ethanol yielded crystals melting at 110~125°C. The hydrogenation of V over Raney nickel in ethanol also gave crystals, m. p. 118~120°C, as a sole product. They were assumed to be 3-methyloxindole (reported m. p. 123°C[14]).

5(?)-Bromo-1-methoxy-3-methyloxindole. — Into seven-tenths of a solution of 120 mg. (0.77 mmol.) of bromine and 140 mg. (1.54 mmol.) of potassium bromide in 5 cc. of water, 95 mg. (0.54 mmol.) of oily oxindole III was added, and the mixture was left to stand overnight. The mixture was then extracted with ether. The evaporation of the ether produced 94 mg. (48%) of pale yellow crystals, which, after filtration, as a benzene solution, through alumina, followed by recrystallization from benzene-ligroin, melted at 90~92°C.

Found: C, 46.91; H, 4.18; N, 6.21. Calcd. for $C_{10}H_{10}O_2NBr$: C, 46.89; H, 3.94; N, 5.47%.

The Ozonolysis of Compound A Ethyl Ether.—A solution of 492 mg. (1.39 mmol.) of the ethyl ether[2] in 36 cc. ethyl acetate was saturated with ozone, and the ozonide was decomposed with saturated aqueous sulfurous acid. Work-up in a way similar to that described in the ozonolysis of the methyl ether c) gave 125 mg. (54%) of *o*-nitrobenzoic acid and 260 mg. of the neutral fraction. The latter, dissolved in benzene, was adsorbed on alumina. The first crop eluted with benzene gave 27 mg. of an oil, which was identified with *o*-nitroacetophenone by derivation to its 2,4-dinitrophenylhydrazone. The second crop eluted with the same solvent gave 27.5 mg. of crystals, which, after recrystallization from benzene-ligroin, melted at 130~131°C. On the basis of the elementary analysis, the compound was assumed to be dehydro-compound A ethyl ether.

Found: C, 64.58; H, 4.56. Calcd. for $C_{19}H_{16}O_5N_2$: C, 64.77; H, 4.58%.

Elution with benzene containing a little ethanol yielded 79 mg. of crystals, which were recrystallized from benzene-ligroin; m. p. 80~81°C. λ_{max} 259 (3.59). ν_{max} 3344 (OH), 1704 (C=O).

Found: C, 63.51; H, 6:45; N, 6.97. Calcd. for $C_{11}H_{13}O_3N$: C, 63.75; H, 6.32; N, 6.76%.

The Attempted Methylation Compound B.—A mixture of 104 mg. of compound B, 5 cc. of acetone, 183 mg. of dimethyl sulfate and 200 mg. of potassium carbonate was heated under reflux for 5 hr. During the heating, the evolution of ammonia was observed (detected by the Nessler reaction and with litmus paper). After the removal of inorganic substances and of recovered compound B by filtration, followed by the evaporation of the solvent in vacuo, the remaining residue was dissolved in 100 cc. of benzene containing 3 drops of ethanol and the solution was filtered through a short column of alumina. The evaporation of the solvent left 37 mg. of crystals, which, after recrysallization from benzene-ligroin, melted at 134~135°C. This compound was identified with the 1-methoxy-3-methyldioxindole (I) obtained above by the ozonolysis of compound A methyl ether by a mixed melting point determination. By treating the insoluble material of the reaction mixture with water, 57 mg. of compound B remained undissolved.

Studies of the Hydration and the Structure of Water and Their Roles in Protein Structure. I. The Effective Volumes of 1-1 Electrolytes in Aqueous Solutions and the Electrostriction of Water[1)]

By Sachio Goto*

(Received May 29, 1964)

Recently several reports[2-8)] on the conformation of proteins have drawn attention to the properties and structure of water from the viewpoint of the stabilization of hydrophobic bonds. However, although there is a considerable literature on the properties and structure of water, there are still many problems to be solved.[7-15)]

In a series of studies, of which this is the first report, we propose to give information on the hydration and the structure of water and to elucidate the role of water in maintaining the conformation of proteins. As a basis for a consideration of these problems, the present paper is devoted primarily to the hydration of electrolytes.

There have been numerous investigations[16-25)] in different ways of the hydration of electrolytes in aqueous solutions. However, in all cases the results have been obtained in terms of various differing assumptions and there are large discrepancies between the results obtained.[17,18,26,27)] In addition, the state of the water of hydration is unknown. If the effective volumes of ions in aqueous solutions were known, various questions concerning the state and number of molecules of the water of hydration could be resolved. This problem is especially important in the case of uni-univalent (1-1) electrolytes.[23,28)] This paper will report on the effective volumes of ions and the magnitudes of the electrostriction of the solvent as analyzed from a measurement of their density at various concentrations in aqueous salt solutions. The state of the water around the ions will also be discussed.

The volumes of inorganic salts in aqueous solutions are apparently smaller than the volumes in their respective crystals, due to the contraction of the solvent by electrostatic attraction between ions and water dipoles. However, the volume of lithium iodide in solution is greater than that of its crystals.[29)] To obtain details on the magnitude of electrostriction, it is necessary to know the effective volumes of salts in solution rather than in crystals.

Calculation

The values for densities in aqueous salt solutions used in the calculations are quoted from the International Critical Table.

The reciprocal of the density (d_m) of a solution which contains m g. of the solute in 100 g. of the solution corresponds to the volume (V_m) of 1 g. of the solution. Therefore, the volume (V_c) of a solution containing 100 g. of water and c g. of solute can be written as follows:

$$V_c = \frac{100}{d_m} \times \frac{100}{100-m} \qquad (1)$$

$$=c\bar{v}+\frac{100}{d_o}-V^e{}_c \tag{2}$$

where $\bar{v}$ is the effective specific volume of salt in the solution; $V^e{}_c$, the volume of water decreased by electrostriction, and d_o, the density of pure water. c is given by:

$$c=\frac{100m}{100-m} \tag{3}$$

On changing the concentration, c, from c_i to c_j, we find:

$$\bar{v}_{i,j}=\frac{V_{ci}-V_{cj}}{c_i-c_j}=\frac{dV}{dc} \tag{4}$$

$$=\bar{v}-\frac{V^e{}_{ci}-V^e{}_{cj}}{c_i-c_j}=\bar{v}-\frac{dV^e}{dc} \tag{5}$$

where $\bar{v}_{i,j}$ corresponds to the apparent specific volume of the salt at a given concentration range. If $V^e{}_{ci}$ becomes equivalent to $V^e{}_{cj}$ with an increase in the concentration or if $dV^e/dc=0$, $\bar{v}_{i,j}$ will correspond to the effective specific volume of the salt in solution, because all the solvent water will be attracted by ions at a high concentration. In consequence, the volume of water (100 g.) may approach a constant ($100/d_o-V^e{}_{max}$) with an increase in the concentration of the solute, as is shown by curve B in Fig. 1.

Next, with regard to the correlation between V_c and the concentration of salt, the relation given in Eqs. 6 holds true empirically.

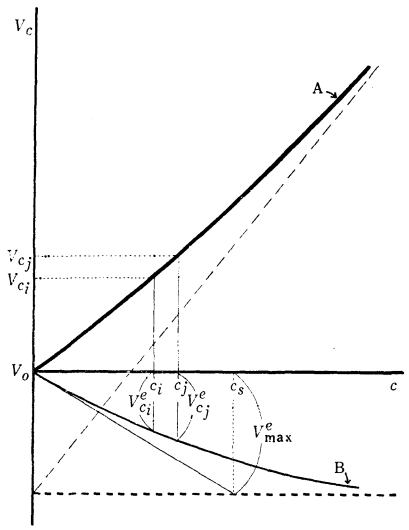

Fig. 1. Schematic representation of the volumes of the solution and the solvent plotted against the concentration of salt.
Curve A: volumes of solutions containing 100 g. of water.
Curve B: volumes of the solvent.
$V^e{}_{ci}$ and $V^e{}_{cj}$ represent the volumes of water decreased by electrostriction.

$$V_c=c\bar{v}+\frac{100}{d_o}-(1-e^{-kc})V^e{}_{max} \tag{6-a}$$

$$=c\bar{v}+\frac{100}{d_o}-(1-r^c)V^e{}_{max} \tag{6-b}$$

$$V_M=M\bar{v}_{mol}+\frac{1000}{d_o}-10(1-e^{-k'M})V^e{}_{max} \tag{6-c}$$

where M in Eq. 6-c indicates the molal concentration of salt and $\bar{v}_{mol}$ is the effective molar volume of salt in the solution. V_M is the volume of a solution containing 1000 g. of water and M moles of solute. The three parameters, $\bar{v}$, r and $V^e{}_{max}$, in Eq. 6-b were determined by the method of least squares on an electronic computer.

Further, from Eq. 5, the difference between $\bar{v}_{i,j}$ at an infinite dilution or the apparent specific volume, $\bar{v}_o$, of a salt, and its effective specific volume, $\bar{v}$, corresponds to the magnitude of electrostriction, v^e, per 1 g. of salt at an infinite dilution, which can be obtained from Eq. 8:

$$v^e=\bar{v}-\bar{v}_o \tag{7}$$

$$=kV^e{}_{max} \tag{8}$$

Results and Discussion

Figure 1 gives a schematic representation of the volumes of the solution and the solvent in the aqueous solution of a strong 1-1 electrolyte. The volume of the solution does not increase linearly with the concentration on account of the electrostriction of the solvent. This phenomenon may be due to the extremely rapid exchange reaction between hydrated and unhydrated water or to the overlap of hydrated water layers. In consequence, two curves, for the volumes of the solution (V_c) and of the solvent (V_s) respectively, are drawn under the following conditions;

$$\frac{dV_c}{dc}>0 \quad \text{and} \quad \frac{d^2V_c}{dc^2}>0$$

and

$$\frac{dV_s}{dc}<0 \quad \text{and} \quad \frac{d^2V_s}{dc^2}>0$$

Using Eq. 6-b, we analyzed these curves for the solutions of 1-1 electrolytes and determined the effective specific volumes, $\bar{v}$, of salt in an aqueous solution and the maximum volumes, $V^e{}_{max}$, of water decreased by the electrostriction; then, from Eqs. 7 and 8, the apparent specific volumes, $\bar{v}_o$, and the magnitudes of electrostriction, v^e, were calculated. The values obtained are listed in Table I.

For the least square calculation, we used the densities, d_m(*obeserved*), quoted from the

International Critical Table, of the solutions at the concentration, m, of salt from zero to that, m_c, described in Table I at intervals of 2 g. Within this concentration range, all the data, $d_m(observed)$, agree completely with the results, $d_m(calculated)$, calculated from Eqs. 6-b and 1 using the parameters obtained. As an example, the results calculated for a solution of sodium chloride are shown in Table II.

As may be seen from Table II, however, at very high concentrations $d_m(calculated)$ values deviate slightly from $d_m(observed)$ values. This phenomenon may be interpreted as follows.

Instead of Eq. 2, as a function of the molal concentration of salt Eq. 9 is obtained:

$$V_M = M\bar{v}_{mol} + \frac{1000}{d_o} - V^e{}_M \qquad (9)$$

The volume of water decreased by the electrostriction, $V^e{}_M(observed)$, at any given concentration of salt is obtained from Eq. 9; also, $V^e{}_M(calculated)$ can be calculated from Eq. 6-c as:

$$V^e{}_M = 10(1-e^{-k'M})V^e{}_{max} \qquad (10)$$

In Fig. 2, $V^e{}_M(observed)$ and $V^e{}_M(calculated)$ are plotted against the molal concentration of some 1-1 electrolytes in solutions taken as typical examples. As may be seen from this figure, $V^e{}_M(observed)$ deviates from $V^e{}_M(calculated)$ at high concentrations; this may be caused by the change in the effective volume of salt in a solution as a result of the formation of ion pairs. In consequence, $\bar{v}_{i,j}$ in Eq. 5 at high concentrations may approach the specific volume of salt in the crystal state. In fact, for most

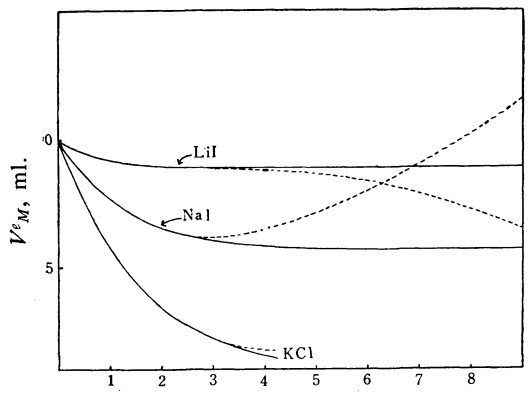

Fig. 2. Volume of water decreased by the electrostriction, V^e_M, plotted against the molal concentration of a few 1-1 electrolytes at 20°C as examples.
—— V^e_M(calculated)
- - - V^e_M(observed)

of the electrolytes calculated this expectation is realized.

On the other hand, if the hydration is related only to the shrinkage of the solvent due to electrostatic attraction, the lithium ion, which has the smallest ionic radius of all univalent cations, should have the largest electrostriction effect. However, in contrast, as may be seen from Fig. 3, which shows the curves for V^e_M(calculated) obtained from Eq. 10 plotted against the molal concentration of salt, and v^e_{mol} in Table III, which represents the magnitude of the molal electrostriction, the order of the molal electrostriction of univalent cations was found to be as follows:

$$Na^+ > K^+ > Rb^+ > Cs^+ > Li^+$$

Therefore, the behavior of the lithium ion in an aqueous solution seems to be unusual. It is well known that the lithium ion in an aqueous solution has an abnormal viscosity[19,22] and compressibility[16] compared with other univalent ions. Frank and Wen[20] and Kaminsky[22], therefore, suggested that there is a clathrate around the lithium ion; our results support this conception. One of these results is described in the present paper; the other will be reported in subsequent papers.

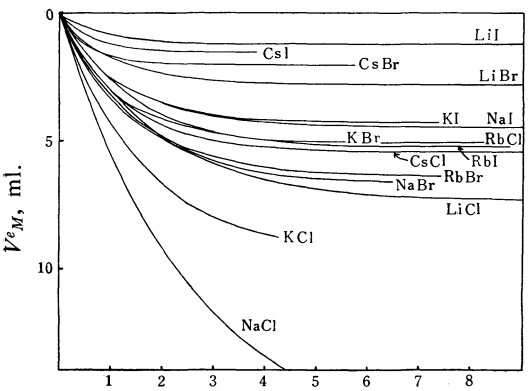

Fig. 3. Volume of water decreased by the electrostriction, V^e_M(calculated) obtained from Eq. 10, plotted against the molal concentration of the salt at 20°C.

There have been several reports on the clathrate structures of water around inert gases,[30,31] hydrocarbons[3,7,32,33] and ions[20,25,34-36]. A clathrate consists of water molecules bound mutually with hydrogen bonds and has a lower density than pure water.[7,8] If these conceptions are valid, then it becomes much easier to understand why v^e_{mol} and V^e_{max} are small for lithium salts. Hydration water seems to exist partly as a clathrate around the lithium ion, the density of which is low.

As may be seen from Table III, the effective molar volumes for various 1-1 electrolytes in aqueous solutions are stoichiometrically additive. The existence of this stoichiometric relation suggests that the results are accurate.

On the other hand, as may be seen from Fig. 3, the volume of the water of solutions

of lithium bromide and iodide decreases very little as a result of electrostriction. Thus, the difference in density between pure and hydrated water is apparently small. Therefore, the results support the theory that the hydration water around the lithium ion, perhaps in the secondary hydration shell, exists as a clathrate of a lower density.

Another point of interest shown in Fig. 3 is that the curves for V^e_M in rubidium salt and cesium salt solutions decreased very little, as in lithium salt solutions. This suggests very strongly that there is a clathrate around the rubidium and cesium ions, too. Further evidence for this conception will be given in subsequent papers in this series. Furthermore, Fig. 3 indicates the presence of a clathrate around the bromide and iodide ions, too.

Studies were made of the number of the molecules of the water of hydration of ions. The curve shown in Fig. 3 converges to the constant, V^e_{max}, which corresponds to the decrease in the volume of water when it is completely hydrated to the ions. Values for V^e_{max} for various electrolytes obtained from Eq. 6 are listed in Table I. As may be seen from Fig. 1, the tangent of curve B at an infinite dilution intersects the constant, V^e_{max}, at the concentration c_s. The relation between these is represented as follows:

$$\frac{V^e_{max}}{v^e} = c_s \tag{11}$$

$$\frac{100}{c_s} = H_s \tag{12}$$

where H_s is the weight (g.) of water hydrated to 1 g. of the solute. The value of c_s agrees with the reciprocal of k in Eq. 6-a. The number of the molecules of the water of hydration of ions, N, is obtained by the following equation:

$$N = \frac{H_s}{18} \times (\textit{molecular weight of solute}) \tag{13}$$

The values of N are listed in Table III. As may be seen from this table, the hydration numbers of ions are quite large, even though this estimation cause something of an error. The hydration number includes the primary hydration water molecules which are orientated towards the ions and affected by the electrostriction effect. However, the number is so great that it is not possible to explain the properties of 1-1 electrolytes by this effect alone. Therefore, there are probably clathrates around the ions.

In addition, it is of interest to draw attention to the significance of Pauling's model of the structure of water with regard to clathrate compounds.[13,15,37] In this model the number of water molecules per unit is about the same as the number of hydration of ions and the diameter acting as a cavity is the same as in a primary hydration shell.

The character of the clathrate formation of ions will be supported by experiments by means of nuclear magnetic resonance spectrometry and ultrasonic interferometry to be described in subsequent papers. The other strong evidence for the existence of a clathrate around ions is that of various reports[20,33-35] on the clathrate around tetraalkylammonium ions.

Summary

The effective volumes, the apparent volumes and the magnitudes of electrostriction for various 1-1 electrolytes in aqueous solutions have been determined from an analysis of the densities of solutions at various concentrations. The molar values thus obtained are stoichiometrically additive. The state of water molecules around ions and particularly the existence of clathrates around various univalent ions, such as lithium, rubidium, cesium, bromide and iodide, and the numbers of hydration water have also been discussed.

The author wishes to express his hearty thanks to Professor Toshizo Isemura for his kind guidance and encouragement, and to Dr. Yoshihiko Takada for his help in the electronic computer calculations.

Studies of the Hydration and the Structure of Water and Their Roles in Protein Structure. II. The Hydration of Electrolytes by Ultrasonic Interferometry and Its Temperature Dependence

By Toshizo ISEMURA and Sachio GOTO*

(Received May 29, 1964)

In a previous paper[1] of this series, we studied the effective volumes of ions, the magnitudes of electrostriction and the numbers of the hydration water of the ions of various 1-1 electrolytes. From the results we establisehd the existence of clathrates not only around the lithium ion, but also around the ions of rubidium, cesium, bromide and iodide, perhaps as a secondary hydration shell.

The present paper will primarily report on the numbers of hydration for various strong electrolytes as measured by the method of ultrasonic interferometry.

There are several methods to determine numbers of hydration, for example, by compressibility,[2] diffusion,[3] viscosity[4] or the dielectric constant[5]. Each is based on a different characteristic, and the significance of each character in relation to hydration is specific. Consequently, the numbers of hydration water calculated by these different methods are very different.

In the present work the method of compressibility was used. In this method there are mainly two ways to estimate the numbers of hydration water: (1), the compressibility of hydration water is assumed to be zero[2,6-13] and (2), it is assumed to be equal to that of ice.[14,15]

It is uncertain whether or not the compressibility of the solute is nearly zero. In reports on macromolecules, such as proteins, the compressibility of the solute has sometimes been disregarded[12,13] and sometimes not.[16,17] However, for small ions it may always be possible to neglect the compressibility of the solute.[2,6]

The Significance of the Compressibility of the Solution

If a part of the solvent (expressed in volume fraction), v_0, changes to v_2 as a result of hydration, the compressibility of the solution, β, may be derived as follows:

$$\beta = V_1\beta_1 + V_0\beta_0 - v_0\beta_0 + v_2\beta_2 \qquad (1)$$

where v_1, V_0 and V_2 are the volume fractions of the solute, solvent and hydrated water respectively, and β_1, β_0 and β_2 are the compressibilities of the solute, solvent and hydrated water respectively. The partial specific volume of the solute, $\bar{v}$, is given as $V_1/c=\bar{v}$, where c is the weight concentration of the solute. If it can be assumed that $v_0=v_2$, the following equation is obtained from Eq. 1 and is valid under the experimental conditions:

$$\frac{\beta_0-\beta}{c} - \bar{v}\beta_0 = \bar{v} - \beta_1 + \frac{v_2}{c}(\beta_0-\beta_2) \equiv K \qquad (2)$$

The adiabatic compressibility is determined experimentally by measuring the sound velocity, u, and the density, d, from the relation:

$$\beta = \frac{1}{u^2 d} \qquad (3)$$

Therefore, the left side of Eq. 2 can be determined experimentally.

Experimental

The sound velocity in the solution was measured with an ultrasonic interferometer at a frequency of 5 Mc./sec. Details of the method for measuring the wavelength have been given by Passynski.[2]

The values for the density of solutions were obtained by the pycnometer method developed by Lipkin et al.[18] The concentrations of the solutions were determined by measuring their densities. Measurements were made from 15 to 50°C at intervals of 5°C.

Results and Discussion

As may be seen from Eq. 2, to estimate the number of hydration it is necessary to assume the compressibilities of both the solute, β_1 and hydrated water, β_2. However, in aqueous solutions of strong electrolytes the compressibility of the solute is probably zero, as has been assumed by many authors.[2,6] Therefore, only the compressibility of hydrated water is uncertain in the calculation of the number of hydration from Eq. 2.

In an aqueous electrolyte solution, the strong electric field produced by the ion orientates the water molecules and causes the volume of the water to decrease. This is called the electrostriction effect.[19] This effect is probably exhibited mainly in the primary hydration shell of most 1-1 electrolytes. However, as has been described in the previous paper[1] of this series, there is a clathrate around the ions, perhaps as a secondary hydration shell. It is probably unreasonable to disregard the compressibilities of these water molecules in the secondary hydration shell or of those in the clathrate, which consists of water molecules bound mutually with hydrogen bonds. Shiio[14,15] considered the compressibility of all the hydrated water molecules in aqueous solutions of amino acids, proteins and saccharides to be the same as that of ice (18×10^{-12} cm^2/dyn.) in connection with a term, the iceberg of hydration.[20]

As has been described above, there are still some unsolved problems with regard to the compressibility of hydrated water. However, for the purpose of comparing different electrolytes, we temporarily assumed that the compressibilities of both solute and hydrated water were zero and determined the numbers of hydration on the basis of this assumption.

Figure 1 shows the numbers of hydration for various strong electrolytes in aqueous solutions and their dependence on the temperature. These numbers were obtained using Eq. 2, while the values for the partial specific volume, v, of 1-1 electrolytes are from the previous paper. In the case of 1-2 electrolytes, the apparent partial specific volumes were used. Figure 1 shows that in all these electrolyte solutions the numbers of hydration decrease with an increase in the temperature. In solutions of 1-1 electrolytes, the numbers

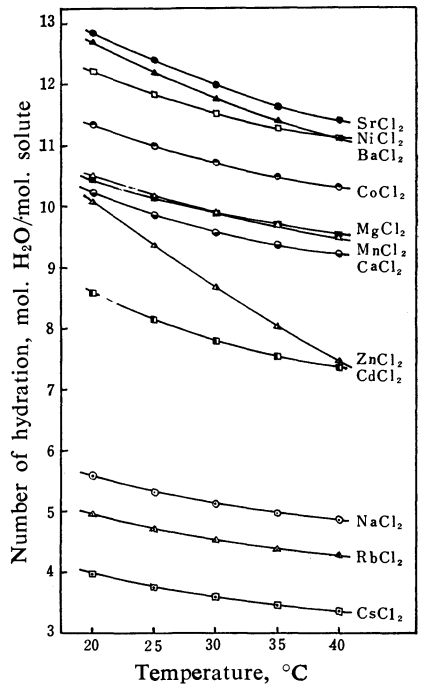

Fig. 1. Numbers of hydration for various 1-1 and 1-2 electrolytes and their dependence on the temperature (assuming that the compressibilities of both solute and hydrated water are zero).

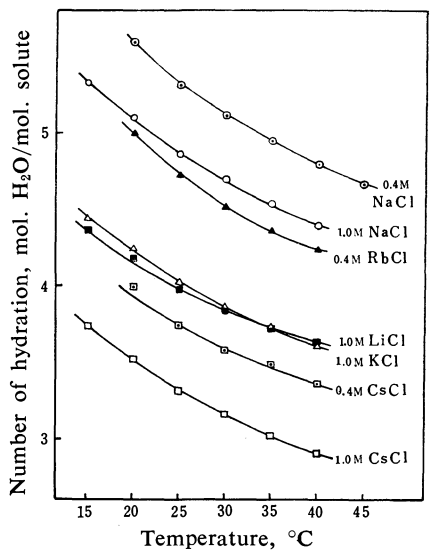

Fig. 2. Numbers of hydration for various 1-1 electrolytes and their dependences on the temperature and concentration.

of hydration are different from each other at the same temperature, but they decrease in parallel with each other with an increase in the temperature. The same is true for solutions of 1-2 electrolytes also. This phenomenon is significant in contrast to the results obtained for the amino acids to be described in a subsequent paper. As may be seen from Fig. 2, the hydration numbers are also dependent on the concentration. Therefore, the number of hydration should be determined at an infinite dilution. However, since many authors[2,6,21-23] have determined these numbers for various concentrations and since the measurement of these numbers is not the main purpose of this paper, their concentration dependence was not studied.

Table I summarizes the numbers of hydration of various electrolytes at 20 and 40°C. As may be seen from this table, for most electrolytes the change in the number of hydration with the temperature for 1-1 electrolytes is about two-thirds of that for 1-2 electrolytes. That is to say, the change with the temperature is proportional to the number of ions in the solution. This can be explained as follows: the states of hydrated water which are built up in a strong electric field are not affected simply by the change in the temperature but also by the exchange reaction velocity between the unhydrated and hydrated water molecules.

The numbers of hydration of various electrolytes at 20°C (when their compressibilities are assumed to be zero) decrease in the following order:

$$Sr^{2+}>Ba^{2+}>Ni^{2+}>Co^{2+}>Mn^{2+}>Mg^{2+}>$$
$$Ca^{2+}>Cd^{2+}>Na^{+}>Rb^{+}>K^{+}>Li^{+}>Cs^{+}$$

This finding contradicts the results obtained from the dielectric constants,[5] entropy,[19] viscosity,[4] and so on. The disagreement may be due to differences between the definitions of hydration.

TABLE I. HYDRATION NUMBERS OF VARIOUS ELECTROLYTES IN AQUEOUS SOLUTIONS AT 20 AND 40°C (ASSUMING THAT THE COMPRESSIBILITIES OF BOTH SOLUTE AND HYDRATED WATER ARE ZERO)

Salt	Concn. mol./l.	Number of hydration mol. H_2O/mol.

TABLE II. COMPARISON OF β_c, THE COMPRESSIBILITY CHANGE OF THE SOLVENT, WITH V^e_c, THE VOLUME OF WATER DECREASED BY ELECTROSTRICTION (GIVEN IN THE PREVIOUS PAPER) AT 20°C

Salt	Concn. mol./l.	β_c	V^e_c	β_c/V^e_c
LiCl	0.989	0.340	0.305	1.11
NaCl	0.992	0.415	0.538	0.77
KCl	0.997	0.347	0.426	0.81
RbCl	0.415	0.171	0.156	1.10
CsCl	1.001	0.289	0.303	0.95

The values for K in Eq. 2 were compared with the V^e_c, the volume of water decreased by the electrostriction, given in the previous paper.[1] The results for 1-1 electrolytes at 20°C are summarized in Table II, where c is the molal concentration of the electrolyte. β_c, the compressibility change of the solvent, is given as

$$\beta_c = K \times c$$

As may be seen from this table, the β_c/V^e_c value for sodium and potassium chloride is about 0.8, but the values for lithium, rubidium and cesium chloride are larger (0.95~1.1) than for sodium and potassium chloride. This suggests that the compressibility of hydration water varies with the states of the hydration water, as for instance, in the primary and secondary hydration shells. In the previous paper of this series, we suggested that there are hydration water molecules around such ions as lithium, rubidium and cesium, as clathrates with nearly the same density as pure water. Though this hydration water probably does not affect the volume change, it may affect the compressibility of the solvent to some extent (causing a change from zero, for example, to that of ice.) In consequence, the compressibility of an electrolyte solution is not in proportion to the electrostriction effect.

Summary

The numbers of hydration of various 1-1 and 1-2 electrolytes in aqueous solutions and their

Studies of the Hydration and the Structure of Water and Their Roles in Protein Structure. III. Proton Magnetic Resonance Shifts of Water in Aqueous Solutions of Electrolytes and Their Relation to the Structure of Water

By Sachio GOTO* and Toshizo ISEMURA

(Received May 29, 1964)

In the preceding papers[1,2] of this series we reported on the states of water in aqueous electrolyte solutions and proposed that there are clathrates around various ions, perhaps forming an secondary hydration shell. In the present paper the effect of electrolytes and organic compounds on the structure of water, as estimated by measuring the chemical shift of the nuclear magnetic resonance frequency of water protons, will be described. It has been assumed that the number of hydrogen bond between water molecules decreases with an increase in the temperature and also that the structure of water is affected by such variables as the pressure and composition of the solution. A proton magnetic resonance spectrometer is one of the most useful instruments for studying weak molecular interactions, particularly those of hydrogen bonds.[3]

Experimental

A JNM-3 high-resolution nuclear magnetic resonance spectrometer operating at 40 Mc./sec. in conjunction with an 12-in. magnet (Japan Electron Optics Laboratory Co.) was used. Proton magnetic resonance shifts relative to pure water were measured for the various salt solutions using the side-band method. The shifts observed for aqueous salt solutions were corrected for bulk diamagnetic susceptibilities. Acetone was found to be a suitable internal reference substance when corrections were made for the diamagnetic susceptibilities of salts, since the methyl protons of acetone are chemically unreactive and their resonance shifts are independent of the temperature. The procedure used was as follows: The same amount of acetone was added to the test salt solution and to the solvent used as an external reference. The relative shift of the methyl protons of acetone thus measured depends on the difference between the bulk diamagnetic susceptibility of the solution and that of the solvent. Therefore, it can be used to correct the observed proton magnetic resonance shifts of water protons.

All the solutions studied were prepared in a 0.01 M sodium ethylenediaminetetraacetate (EDTA) buffer and were adjusted to pH 7.0.

Measurements were made at 20°C.

Results

The relative shifts of the proton resonances of aqueous solutions containing various electrolytes or organic compounds are presented in Figs. 1, 2 and 3, where the shift, δ, is expressed in c. p. s. (at 40 Mc./sec.). A positive value indicates a shift to a higher resonance field than that of the external reference. Figure 1 shows the observed relative shifts of water protons (uncorrected for bulk diamagnetic susceptibilities) at various concentrations of salts. Figure 2 shows the corrected relative shifts for the bulk diamagnetic susceptibilities obtained by the measurement of the relative shift of the methyl protons of acetone. This correction is very important since the bulk diamagnetic susceptibilities of salt solutions are of the same order of magnitude or often even larger than the proton resonance shifts.

These relative shifts were additive in all the salt solutions studied. Thus, as assumed by Hertz and Spalthoff,[4] if the relative shifts caused by potassium and by chloride ions in an aqueous potassium chloride solution are arbitrarily assumed to be equal, the relative shifts for each ion can be estimated. Figure 3 shows the dependence of the relative shifts for various ions on the concentration of the solution.

Discussion

The present paper will report on the effect of 1-1 electrolytes and organic compounds on the structures of water. Measurements were made of the shift of the nuclear magnetic resonance frequency of the protons of water molecules. At present a few reports[4-6] are available on the shift of water protons in aqueous solutions of various diamagnetic salts. However, in these reports the corrections of

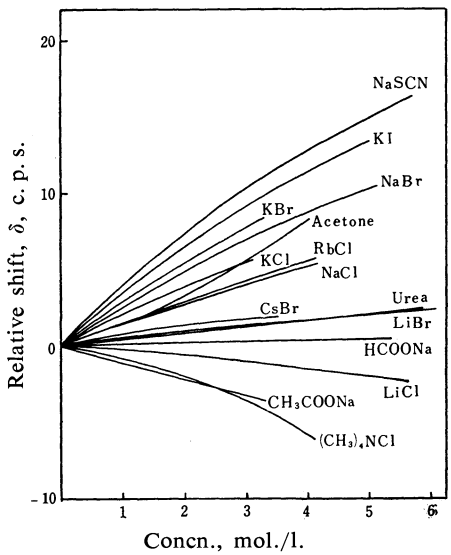

Fig. 1. Relative shifts of water protons (uncorrected) in aqueous solutions of electrolytes and organic compounds as a function of the concentration.

the diamagnetic susceptibilities of salts do not seem to be satisfactory. Shoolery and Alder,[5] for instance, did not make this correction.

From Figs. 1 and 2 it can be seen that the relative shifts are in some cases as great as several cycles per second, which may be comparable with the correction values for ionic diamagnetic susceptibilities. Therefore, the shifts of water protons without correction for

diamagnetic susceptibilities of crystals for this correction, because the relationship between the relative shifts, thus corrected, and the ionic crystal radius are linear. However, such a linear relation does not always hold true, since the behavior of water molecules in the presence of electrolytes is very complex, as has been described in the preceding papers.[1,2]

As has been mentioned above, acetone is a suitable homogeneous internal reference for studying the proton magnetic resonance of water. If corrections for the observed relative shifts of water protons are made using this method, no linear relation, such as that of Fabricand and Goldberg, holds any longer. This is shown in Fig. 4, which illustrates the relation between the ionic crystal radius and the relative shift of 1 M salts obtained from Fig. 3 and from calculations using Pauling's theoretical ionic diamagnetic susceptibilities for corrections. The straight lines are drawn in accordance with the values of Fabricand and Goldberg. The deviation from this linear relation is striking in the case of lithium and cesium ions. This will be discussed below.

Shoolery and Alder[5] interpreted the relative shifts of water protons in terms of the following two factors; (1) the ionic electric field distorts the polarization effect; and (2) the ion disrupts the structure of water and breaks the hydrogen bonds between water molecules. In the former case, the water molecule is polarized so that fewer electrons are found on the proton, which is therefore less shielded from the external magnetic field. On the other hand, in the latter case, the hydrogen bonds are generally broken by the ions. When a solute particle is pushed into a space between water molecules, the hydrogen bonds between water molecules are broken. Therefore, the proton is more shielded from the external magnetic field. This effect eventually counteracts the polarization effect on the proton.

As is shown in Figs. 2 and 3, in general, the resonance frequency of water protons in an inorganic salt solution is higher than that in pure water, and there is a tendency for a shift to a higher field to occur with an increase in the ionic radius. The direction of this shift agrees with that of the breakage of the hydrogen bonds. The results obtained in this experiment clearly demonstrate that the relative shift is more sensitive to the hydrogen bonds of water than the polarization effect.

Figure 3 shows the results obtained using the shift of the methyl protons of acetone for the correction of the diamagnetic susceptibility. It can be seen that the cesium ion is not so effective as the potassium ion in producing a water proton shift, although it has a larger ionic radius. This result agrees with those obtained by Hertz and Spalthoff[4] and Sato.*

It is generally believed that the number of the water hydrogen bonds decreases with an increase in the ionic radius.[7] In addition, the water molecules are thought to be less polarized when the ionic size is great. As a result of these effects, the proton is more shielded, and thus the relative shift to a high field becomes larger. In this respect, the behavior of the cesium ion is unusual. However, in the preceding papers of this series we proposed that around such ions as the cesium ion there is a clathrate which consists of water molecules mutually bound with hydrogen bonds. This conclusion is strongly supported by the present results, obtained by the method of nuclear magnetic resonance. This method is very sensitive to the state of hydrogen bonding, as will be described below.

In aqueous electrolyte solutions, the degree of hydration increases with a decrease in the ionic radius, as has been shown previously by studies of the ionic mobilities,[7] diffusion coefficients,[8] viscosity,[9] etc. However, the previous results were all based on various assumptions. Around ions there are not only water molecules of primary hydration but also

of secondary hydration, the structures of which are different from that of pure water. The ions with strong electric fields, such as lithium, beryllium and magnesium, cause not only the contact of water molecules with the ions but also exert an orienting influence on more remote water molecules, resulting in a secondary hydration shell.[10,11]

Furthermore, in most electrolytes the water molecules in the first hydration shell probably exert an ordering effect upon the outer molecules by means of hydrogen bonding. This may also be inferred from a comparison of the behavior of anions and cations. As is shown in Fig. 4, the relative shifts of anions in relation to the ionic radius varies linearly. On the basis of viscosity studies,[9,10] anions such as chloride, bromide and iodide are thought to have little hydration, but to break the water structure. On the other hand, in the case of cations the relative shifts do not vary linearly with the ionic radius. The viscosity of an electrolyte solution referred to a cation is also complicated. These findings perhaps result from differences in the orientation of the water molecules to the ions.

Frank and Evans[12] suggested that an iceberg is formed around non-polar groups. Icebergs have also been demonstrated in gas hydrates,[13] proteins,[14-16] and molecular ions.[11,17,18] From studies of the partial molal heat capacities[11] and X-ray diffraction,[18] it has been suggested that the clathrates are formed around the tetraalkylammonium ions. Similarly, as is shown in Fig. 2, the resonance frequency of water protons affected by the tetramethylammonium ion shifts to a lower field than that in pure water. Compared with other ions, the number of hydrogen bondings of water molecules around the tetramethylammonium ion is probably large. That is to say, the shift is in agreement with the direction of the formation of hydrogen bonding, in spite of its larger size, which has a small polarization effect on water molecules. This result also supports the consideration that the shifts of water protons as a result of the presence of ions are mainly due to a change in the number of hydrogen bonds.

From these facts, it is likely that clathrates are formed around the cesium as well as the tetramethylammonium ion. This may be the reason why the increase in the relative shifts to higher fields is reduced in an aqueous cesium salt solution. In the case of the cesium ion, however, the increase in the number of hydrogen bonds is not greater than the decrease in the number of hydrogen bonds broken, since the relative shift is still positive.

On the other hand, another mechanism must be considered for the lithium ion, which has a smaller ionic radius and exerts a negative shift on the proton resonance. The lithium ion has a larger polarization intensity and exerts an orientating influence not only on the neighboring water molecules but also on remote water molecules. It is known that the lithium ion has a larger effective radius in viscosity.[9] The fact that the relative shift of the lithium ion is found at a lower resonance frequency than that deduced from the linear relation with the ionic crystal radius may be explained as follows: the many water molecules orientated to the ion change the relative shift to a lower field, and water molecules outside the orientated water molecule may induce the formation of hydrogen bondings between water molecules.

Thus, each of these ions, as has been mentioned above, would contribute to the denaturation of proteins and nucleic acids. For example, as there are two kinds of hydration, one of which is orientated to the polar groups of proteins and the other orientated as an iceberg or a clathrate around the non-polar groups of the protein, both these hydrations may be important in maintaining the secondary and tertiary structures of protein. Thus we must consider the actions of ions as protein-denaturing agents in connection with breakers and inducers of the water structure. Details of this will be discussed in the following paper.

Similarly, as may be seen from Fig. 3, formate and acetate ions also form a water structure with increased hydrogen bonds. The acetate ion has more ability to form hydrogen bondings than the formate ion. The methyl group of acetate may cause the formation of clathrates.

Furthermore, as is shown in Fig. 2, urea caused a slight breakage of the water structure. However, as urea has hydrophilic groups, water molecules are attracted to the urea molecule. There may be two kinds of water molecules around the urea molecule: water molecules with broken hydrogen bonds, and those with more than normal hydrogen bonding. This mechanism may resemble that of the large ions, such as cesium or formate. The number of these broken and formed hydrogen bonds may

be nearly the same. Therefore, it appears from these properties of urea that the phenomenon of the urea denaturation of proteins is complicated by such variables as the concentration of urea, the temperature and the kinds of substance.[19-21]

Summary

The effects of various electrolytes and organic compounds on the structure of water, and particularly on hydrogen bonding, have been investigated by measuring the chemical shift of water protons in the nuclear magnetic resonance frequency. The chemical shift observed for salt solutions has been corrected for the bulk diamagnetic susceptibility, using methyl protons of acetone as a reference. The chemical shifts of water protons in aqueous solutions of various solutes have been considered.

Studies of the Hydration and the Structure of Water and Their Roles in Protein Structure. IV. The Hydration of Amino Acids and Oligopeptides[1]

By Sachio GOTO* and Toshizo ISEMURA

(Received May 29, 1964)

To what degree is hydration formed around the molecules of proteins and nucleic acids? How does the hydration contribute to the maintenance of their native structure? What structure may be considered for the hydration?

It seems that solutions to these problems are essential for an understanding of the behavior of biological macromolecules in aqueous solutions. Nevertheless, we have as yet little information about such problems. However, since the molecules of proteins or nucleic acids are hydrated, it is natural to consider that the structure of the solvent water affects the state of the hydration around the macromolecules and, correspondingly, affects the configurations to a great extent. The possibility that the structure of the solvent water and the structure and degree of hydration around protein molecules play important roles in maintaining the native structure can be inferred from a study of the denaturation processes. Facts which suggest the dependence of the configuration of proteins or nucleic acids on the structure of the solvent water have been accumulated recently.[2-4]

In the preceding papers of this series[6-7] we reported on the states of water in aqueous electrolyte solutions and proposed that there are clathrates around various ions. The present paper will report on the numbers of hydration for various amino acids, oligopeptides and saccharides, as measured by the method of ultrasonic interferometry.

Experimental

The methods used in this study have been described in a previous paper.[6] The amino acids and oligopeptides used were supplied by the Peptide Center of the Institute for Protein Research, Osaka University.

Results and Discussion

The following equation, described in a preceding paper[6] as Eq. 2, was used for the determination of the number of hydration:

$$\frac{\beta_0-\beta}{c}-\bar{v}\beta_0=-\bar{v}\beta_1+\frac{v_2}{c}(\beta_0-\beta_2)\equiv K$$

where β, β_1, β_0 and β_2 are the compressibilities of the solution, solute, solvent and hydrated water respectively; v, the partial specific volume of the solute; c, the weight concentration of the solute, and v_2, the volume fraction of the hydrated water. From the results reported by Shiio,[8,9] it can be assumed that the compressibilities of the solutes, amino acids and saccharides are zero. Therefore, as in the previous study, for the purpose of comparing various amino acids, oligopeptides and saccharides we temporarily assumed that the compressibilities of both solute and hydrated water were zero and determined the numbers of hydration on the basis of this assumption.

As has been described in the preceding paper, in aqueous 1-1 electrolyte solutions the numbers of hydration of the electrolytes differ from each other at any given temperature, but decrease in parallel with an increase in the temperature. As may be seen from Fig. 1, the number of hydration of glycine decreases in parallel with those of 1-1 electrolytes with an increase in the temperature. This suggests that both the cation and the anion of the amino acid resemble those of strong electrolytes in the mechanism of hydration and that the hydration of the ions is strong and depends only slightly on the temperature.

From Fig. 2 it is clear, from a comparison of the numbers of hydration of aspartic acid and asparagine or glutamic acid and glutamine, that the dependence on the temperature of the acid type is greater than that of the amide

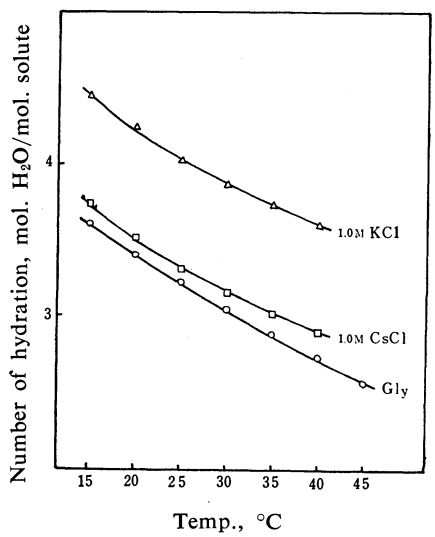

Fig. 1. Numbers of hydration and their temperature dependence.

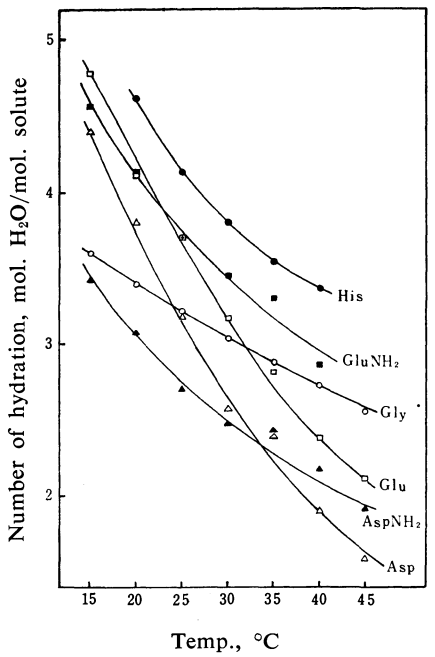

Fig. 2. Numbers of hydration and their temperature dependence.

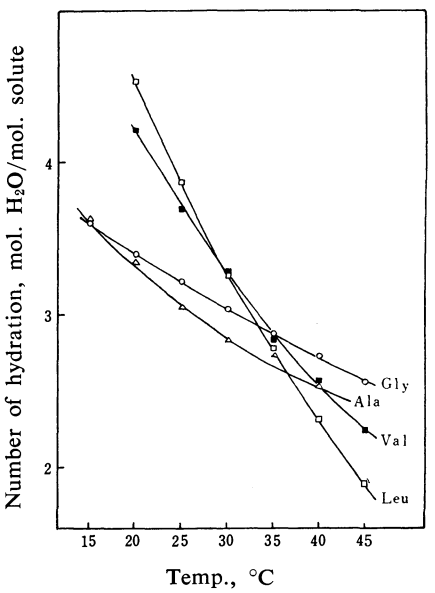

Fig. 3. Numbers of hydration and their temperature dependence.

type. This finding is similar to that seen in the comparison of 1-1 and 1-2 electrolytes described in a preceding paper. This also suggests that the state of hydration of the amide group is different from that of ionic groups. On the other hand, histidine, a basic amino acid, in an aqueous solution has a number of hydration which is larger, but its dependence

8) H. Shiio, *J. Am. Chem. Soc.*, **80**, 70 (1958).
9) K. Ito and H. Shiio, This Bulletin, **30**, 745 (1957).

on the temperature is less than those of acidic amino acids.

Figure 3 shows the numbers of hydration of some aliphatic amino acids and their temperature dependence. At lower temperatures the numbers of hydration increase with an increase in the hydrophobic side chains, as may be seen by a comparison of the numbers of hydration for alanine, valine and leucine. This apparently indicates that there is hydration around the non-polar side chain. Frank and Evans[10] suggested the existence of icebergs around non-polar substances judging from the thermodynamic properties of their solutions. Also, from the results of X-ray studies, Jeffrey et al.[11-13] proposed that the structure of water around tetraalkylammonium salts consists of molecules of water mutually bound by hydrogen bonds and forming clathrates. From the data given in Table I, it will be seen that at 20°C the difference in the numbers of the hydration water of alanine and valine is about 1 mol. H_2O/mol. solute. Their numbers were determined assuming that the compressibility of the hydrated water was zero. However, as was mentioned in the preceding paper, compressibility of the water of this hydration clathrate may not be negligible. Therefore, it may be that the number of molecules of the water of hydration around non-polar side chains is quite large.

Another point of interest is that the hydration of the hydrophobic side chains of amino acids depends greatly on the temperature, although the hydration of strong electrolytes and the ionic sites of amino acids depends only slightly on the temperature, as has been mentioned above. As may be seen from Table I, the difference in the number of hydration water at 20°C and at 40°C increases in the following order: glycine, alanine, valine and leucine. This phenomenon is to be regarded as additional evidence for the hypotheses that the icebergs melt with an increase in the temperature or that the structure of the clathrates is broken down at higher temperatures.[10,14,15]

Similarly, as may be seen from Fig. 4, the hydration of the side chain of methionine, containing a sulfur atom, is similar to that of the aliphatic hydrocarbon chain in such an amino acid as valine.

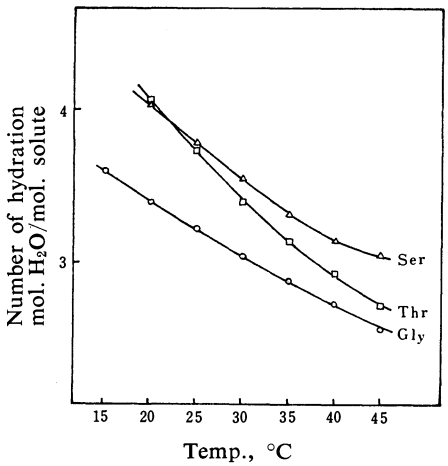

Fig. 5. Numbers of hydration and their temperature dependence.

On the other hand, as may be seen from Fig. 5 and Table I, the side chains of serine and threonine, in which there is a hydroxyl group, cause a slight increase in the numbers of hydration, but the numbers for serine and threonine decrease in parallel with that of glycine with an increase in the temperature. This suggests that the hydration of hydrophilic groups, such as the hydroxyl group, is comparatively small and acts competitively with that of hydrophobic groups, and that the former is stronger. The evidence for these conclusions is given in Fig. 6. The hydration of the hydroxyl group is suggested more strongly from the results for sucrose and mannite.

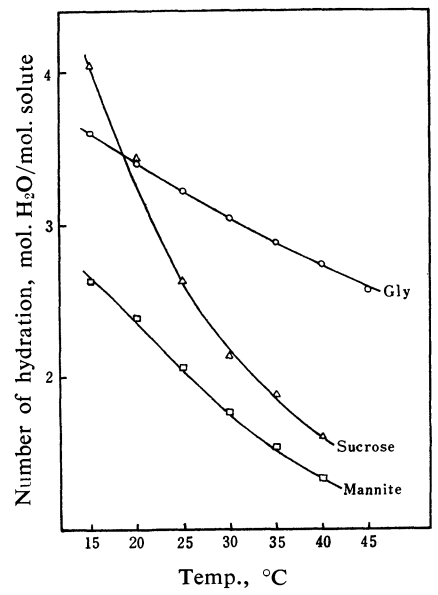

Fig. 6. Numbers of hydration and their temperature dependence.

These saccharides have several hydroxyl radicals, but their numbers of hydration are comparatively small. Also, Table I indicates that the number of hydration of sucrose decreases greatly with an increase in the temperature.

The numbers of the hydration of proline, a cyclic imino acid, and phenylalanine, containing a benzene ring, are shown in Fig. 7. As may be seen from this figure, the hydration of phenylalanine is very similar to that of leucine. This indicates that the phenyl radical is also hydrated. On the other hand, the hydration of proline is nearly the same as that of glycine, but at a higher temperature it is nearly the same as that of leucine and phenylalanine. From the results for proline and sucrose, it seems that the hydration of cyclic compounds is very dependent on the temperature.

As may be seen from Fig. 7, the numbers of the hydration of leucine and phenylalanine at higher temperatures are much smaller than that of glycine. It can be supposed that the hydration of hydrophobic regions is not only broken at higher temperatures, but that it also affects the hydration of ionic sites, giving mutual compensation.

The hydration of peptide bonds was also investigated. Pauling[16] reported that there is no adsorption of water on the peptide bond.

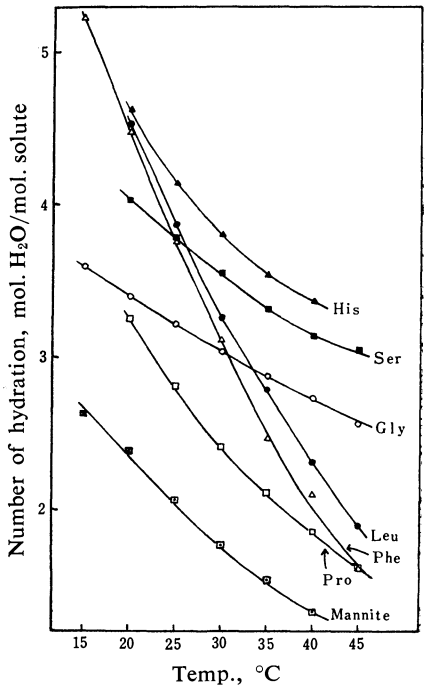

Fig. 7. Numbers of hydration and their temperature dependence.

16) L. Pauling, *J. Am. Chem. Soc.*, **67**, 555 (1945).

On the other hand, Mellon et al.[17] reported the hydration of peptide bonds. As may be seen from Fig. 8, the results for glycine, diglycine, triglycine and tetraglycine indicate that the peptide bond is hydrated. The stoichiometry of their numbers of hydration and their temperature dependence are good. Therefore the hydration of the peptide bond is probably like that of hydrophilic groups.

In conclusion, the hydration of various amino acids and the effect of various conditions on these hydrations differ. However, the hydration of amino acids can be classified roughly into the following three types: the hydration of (1) ionic sites, (2) hydrophilic sites, and (3) hydrophobic sites. Further, the hydrations of the hydrophobic sites of various amino acids differ in number and in temperature dependence. These properties may effect various physicochemical properties of proteins, such as their secondary and tertiary structures, the stability of their hydrophobic bonds, and the processes of their denaturation. Further studies of these problems will be reported in a following paper.

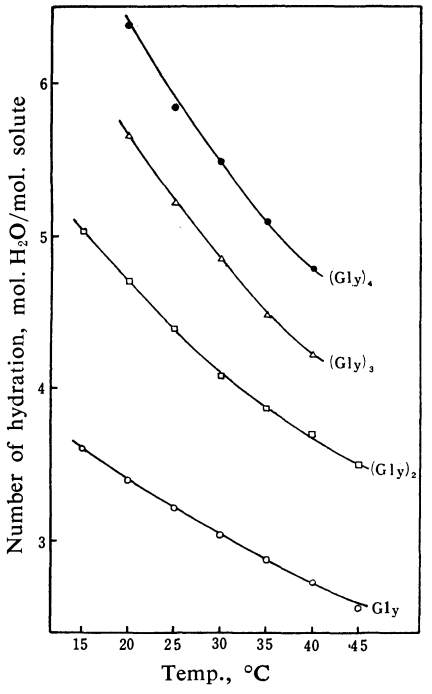

Fig. 8. Numbers of hydration and their temperature dependence.

It is very interesting that the results obtained by Whitney and Tanford[18] on the solubilities of amino acids in aqueous urea solutions agree with our results on the temperature dependence of the hydrations of amino acids. Therefore, the solubility of various compound must depend on their states and numbers of hydration.

Summary

The numbers of hydration of various amino acids, oligopeptides and saccharides in aqueous solutions and their dependence on the temperature have been determined by the method of ultrasonic interferometry. The hydration on ionic, hydrophilic and hydrophobic sites has been discussed. Particularly, evidence for the hydration around hydrophobic groups has been obtained. Also, we have established the hydration of the peptide bond.

The authors wish to express their hearty thanks to Dr. Kozo Hamaguchi for his valuable advice and discussion. Thanks are also due to Mrs. Reiko Kiyoi for preparing peptides for this work.

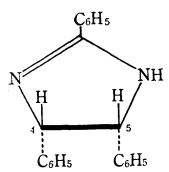
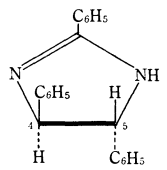
On the Mechanism of Dehydrogenation of the 2, 4, 5-Triphenyl-4, 5-dihydroimidazole over Solid Catalysts



By Taro HAYASHI, Mineko KUYAMA, Emiko TAKIZAWA and Masako HATA

(Received June 1, 1964)



There have been a number of stereochemical studies of the hydrogenation of olefinic double bonds and aromatic rings over metal catalysts.[1,2] The results suggest that, at least in the cases of platinum catalysts used at room temperature, cis-addition predominates both in the hydrogenation of olefinic double bonds[1] and in the hydrogenation of aromatic rings.[2,3]

In contrast with the case of hydrogenation, however, little is known about the mechanism of dehydrogenation over metal catalysts. In order to obtain some information about the mechanism of the dehydrogenation of ring compounds over metal catalysts, the catalytic dehydrogenations of a dihydroimidazole ring over a Raney nickel catalyst and other metal catalysts have been studied. The present paper will report on the results of an investigation with stereoisomers of 2, 4, 5-triphenyl-4, 5-dihydroimidazole.

2, 4, 5 - Triphenyl - 4, 5 - dihydroimidazole is known to give three stereoisomers because of the differences in the conformations of the 4- and 5-hydrogen atoms; the cis isomer, amarine, which is not resolvable into optical antipodes, and the trans isomer, isoamarine, which is resolvable into optical antipodes, *d*- and *l*-isoamarine.

isoamarine

amarine

The dehydrogenations of amarine and *dl*-isoamarine in solutions over such solid catalysts as Raney nickel, platinum black, palladium black and active carbon have been investigated to ascertain the steric course of the dehydrogenation at the adjacent carbon atoms of a planar ring.

Experimental

Amarine and *dl*-isoamarine were prepared by the method of Japp and Moir;[4] amarine, m. p. 130~131°C, and *dl*-isoamarine, m. p. 200~201°C.

Raney nickel, platinum black and palladium black were prepared by the ordinary methods. The active carbon used was Norite-A. The reagents and solvents used were special-grade chemicals of Wako Pure Chemical Industries, Ltd.

The investigations of dehydrogenation with solid catalysts were carried out by the following procedure. A solution of 0.1~0.6 g. of amarine or isoamarine in 5~25 ml. of a solvent was refluxed with 0.1~0.5 g. of a catalyst for 3 hr. Then the catalyst was filtered off and washed. The filtrate was evaporated under reduced pressure, and the residue was warmed with 2 N hydrochloric acid. The amarine and isoamarine were dissolved, whereas the 2, 4, 5-triphenylimidazole (lophine) formed by the dehydrogenation was scarcely dissolved at all. The lophine was filtered off, and the weight of the lophine was determined to ascertain the extent of dehydrogenation carried out in the solution with a catalyst.

Results and Discussion

When amarine was heated in a hard glass tube at about 140°C[5] in a boiling xylene bath for 3 hr., amarine[6] was completely dehydrogenated in a molten state, giving lophine (m. p. 271~272°C), which was identified by no depression of its melting point on mixture with an authentic sample. However, when amarine was heated at 110°C in a boiling toluene bath in which amarine did not melt, dehydrogenation did not take place. The dehydrogenation of isoamarine did not occur at all when it was heated in a hard glass tube at 140°C in a boiling xylene bath in which isoamrine was not in a molten state. The dehydrogenation of isoamarine occurred

4) F. R. Japp and J. Moir, *J. Chem. Soc.*, **77**, 781 (1900).

5) A catalytic action of hard glass in the dehydrogenation of molten amarine was recognized, since the dehydrogenation of amarine did not occur in a quartz tube at 140°C.

6) H. L. Snape and A. Brook, *J. Chem. Soc.*, **75**, 211 (1881).

in a molten state at 240°C. These facts showed that amarine, the cis isomer, tended to be subjected to dehydrogenation in itself much more easily than *dl*-isoamarine, the trans isomer.[7] When amarine was heated in a solution in xylene, toluene or benzene under reflux for 3 hr., lophine, the product of the dehydrogenaton, was not isolated. As expected, the dehydrogenation of isoamarine did not take place in solutions under the same experimental conditions. Hence, it was confirmed that neither amarine nor isoamarine was subjected to dehydrogenation by refluxing solutions without the addition of a catalyst, at least below 140°C.

Raney nickel was found to exhibit a catalytic action in dehydrogenation of the *cis*-4, 5-dihydroimidazole ring, since the hydrogenation of amarine with Raney nickel in ethanol at room temperature yielded 2, 4, 5-tricyclohexylimidazole, from which the 4- and 5-hydrogen atoms of amarine had been removed, along with *cis*-2, 4, 5-tricyclohexyl-4, 5-dihydroimidazole.[8] The dehydrogenation of amarine and isoamarine over Raney nickel in solutions was first investigated.

A solution of 0.5 g. of amarine in 20 ml. of xylene was refluxed at 140°C in an oil bath for 3 hr. with Raney nickel, prepared from 0.7 g. of Raney nickel alloy powder. The xylene was then evaporated in vacuo, the residue being extracted with ethanol. The ethanolic solution was poured into water to yield a precipitate. The filtered precipitate was treated with 2 N hydrochloric acid to separate lophine. An almost theoretical amount of lophine was obtained. This result showed that amarine was completely dehydrogenated at 140°C in xylene with Raney nickel. Under the same conditions, no dehydrogenation of isoamarine occurred. Without the presence of oxygen, amarine was dehydrogenated with Raney nickel by refluxing a solution in xylene in an atmosphere of hydrogen or nitrogen. Hence, the dehydrogenation of amarine with Raney nickel in xylene was not due to oxidation, but was directly concerned with the catalyst. The dehydrogenation of amarine with Raney nickel was also completely effected by refluxing solutions in toluene, benzene, ethyl methyl ketone or acetone and partly occurred in cyclohexane, carbon tetrachloride or ethanol[9]. No dehydrogenation of amarine was effected by refluxing solutions in ethyl acetate, hexane, chloroform, acetic acid or pyridine with Raney nickel. In each of these solvents, no dehydrogenation of isoamarine took place either. These results indicate that, in the presence of solid catalysts, amarine in solutions is dehydrogenated in the absence of oxygen, even at rather low temperatures, such as the boiling points of benzene and acetone, and that the nature of solvents, as well as the temperature of reflux, is a strongly effective factor in dehydrogenation, although the polar nature of the solvents appears to play no part in the dehydrogenation, its mechanism being consequently considered to be non-ionic.

As in the experiments with Raney nickel, platinum black and palladium black, the dehydrogenation of amarine was carried out by refluxing solutions in xylene, toluene or benzene respectively. No dehydrogenation of isoamarine took place with these catalysts either.

With active carbon, which usually shows no catalytic action in hydrogenation, amarine was dehydrogenated by refluxing solutions in xylene, toluene, benzene or acetone without the presence of oxygen, whereas no dehydrogenation of isoamarine was effected under the same conditions.

Since the dehydrogenation of amarine over active carbon suggested that adsorption on solid catalysts might be strongly effective in the dehydrogenation of amarine, adsorptions of amarine and isoamarine on active carbon from solution in benzene were measured at room temperature. Amarine 0.14 g. was adsorbed on 0.58 g. of active carbon from a solution of 0.30 g. of amarine in 35.0 ml. of benzene at 22.5°C, whereas hardly any isoamarine was adsorbed on active carbon under the same conditions. As was expected from the conformational structures of these stereoisomers, the difference in the adsorptions was very marked of these isomers.

From the experimental results mentioned above, the steric course of the dehydrogenation of amarine was considered to be as follows; an amarine molecule is adsorbed on a solid catalyst with the side of plane of the imidazole ring, from which two cis hydrogen atoms at the 4- and 5-carbon atoms project. These two hydrogen atoms lie very close to the surface of the solid catalyst in such an adsorbed state. (Isoamarine is not adsorbed, since there exists no molecular side such as

7) When amarine and isoamarine were each heated at 300°C in a hard glass tube, both compounds, which were in molten states at this temperature, were dehydrogenated to yield lophine with a small amount of *trans*-stilbene.

8) T. Hayashi and M. Kuyama, *Natural Science Reports of Ochanomizu University*, 6, 99 (1955).

9) Although no dehydrogenation of amarine occurred when solutions were refluxed in ethanol or methanol without solid catalysts, the dehydrogenation of amarine did take place in butanol or pentanol without solid catalysts. In the latter cases oxygen was found to be necessary. This fact shows that the mechanism of dehydrogenation by reflusing solutions in alcohols is different from that in the other solvents mentioned above.

that of amarine mentioned above.) Both hydrogen atoms, which originally tend to move from the imidazole ring, as has been mentioned above, are eliminated from the 4- and 5-carbon atoms under the effect of the solid catalyst. Isoamarine is not dehydrogenated with a solid catalyst, since isoamarine is not be adsorbed on a solid catalyst.

This mechanism was supported by the following experiment with sulfur. When a solution of amarine in xylene was refluxed with fine powders of sulfur, amarine was dehydrogenated and hydrogen sulfide was evolve. The dehydrogenation of amarine is likely to follow the reverse couse to the *cis*-hydrogenation of aromatic rings over a platinum catalyst.[5]

Summary

1) Amarine has been completely dehydrogenated, without the presence of oxygen, by refluxing solutions in xylene, toluene, benzene or acetone with Raney nickel, whereas no dehydrogenation of isoamarine occurred at all under the same conditions. Amarine was also dehydrogenated without the presence of oxygen by refluxing solutions with platinum black, palladium black or active carbon. The dehydrogenation of amarine, carried out by refluxing a solution in benzene with sulfur powder, was accompanied by the evolution of hydrogen sulfide.

2) Amarine was adsorbed with active carbon from a solution in benzene at room temperature, whereas hardly any isoamarine was adsorbed under the same conditions, the difference in the dehydrogenation behavior of these cis- and trans-isomers being very marked.

3) Considering the results obtained, the dehydrogenation of amarine by refluxing solutions with solid catalysts may reasonably be considered *cis*-dehydrogenation, the mechanism being as follows; an amarine molecule is adsorbed on solid catalysts with the side of the plane of an imidazole ring, to which cis 4- and 5-hydrogen atoms are attached, and these hydrogen atoms, which tend to move from the imidazole ring, are eliminated under the effect of solid catalysts. Isoamarine, which has a trans-conformation unfavorable to adsorption, is not subjected to dehydrogenation with solid catalysts.

The authors wish to express their hearty thanks to Dr. Hiroshi Midorikawa of the Institute of Physical and Chemical Research for his kind help, and to the Ministry of Education for its grant-in-aid for scientific research.

The Reaction of Carbon Monoxide with Organometallic Compounds. IX. The Syntheses of Cyclic Ketones and Polyketones by the Reaction of Carbon Monoxide with Polymethylene Dilithiums*[1]

By Membo RYANG, Yoshihiko SAWA, Terukuni HASIMOTO and Shigeru TSUTSUMI

(Received June 10, 1964)

In the preceding paper[2] of this series, it was reported that carbon monoxide reacted with organolithium compounds in an ether solution at $-70°C$, producing corresponding symmetrical ketones in good yields. In these reactions, it was assumed that carbon monoxide attacked organolithium compounds nucleophilically and abstracted the lithium as lithium carbonyl, producing symmetrical ketones (Eq. 1):

$$2\,\text{R-Li} + 3\,\text{CO} \rightarrow \text{R-}\underset{\underset{\text{O}}{\|}}{\text{C}}\text{-R} + 2\,\text{LiCO} \qquad (1)$$

As this new method is simple and can be extended to similar reactions in good yields, the present authors carried out the reaction of carbon monoxide with polymethylenedilithiums by applying this reaction to a

* Part VIII: This Bulletin, 37, 341 (1964).

synthetic method of cyclic ketones (by intramolecular ketonization) and poly-ketones (by intermolecular ketonization).

The polymethylenedilithiums (tetramethylenedilithium, pentamethylenedilithium and hexamethylenedilithium) were prepared by the reaction of the corresponding polymethylenedibromide with methallic lithium in an ether solution at $-10\sim-5°C$.[3] Then pure, dry carbon monoxide was bubbled into the solution at $-70°C$. Thus cyclic ketones (Eq. 2) (cyclopentanone, cyclohexanone and cycloheptanone) and several poly-ketones (Eq.3) were synthesized :

$$Li(CH_2)_nLi + 3CO \longrightarrow (CH_2)_n\overset{\frown}{C}{=}O + 2LiCO \qquad (2)$$

$$m\,Li(CH_2)_nLi + 3m\,CO \longrightarrow H\text{-}\left[\text{-}\underset{\underset{O}{\|}}{C}\text{-}(CH_2)_n\text{-}\right]_m\text{-}\underset{\underset{O}{\|}}{CH} + 2m\,LiCO \qquad (3)$$

n=4, 5 and 6.

The synthesis of poly-ketones by the reaction of ethylene and carbon monoxide under high carbon monoxide pressure was exclusively studied by Hanford, Brubaker and Coffman.[4] Brubaker, Coffman and Hoehn[5] have reported detailed studies of the formation condition and structure of the poly-ketone. These reactions were carried out under high carbon monoxide pressure and the carbonyl groups were irregularly inserted, while the authors' method can be used at low temperatures under atmospheric pressure and the carbonyl groups in poly-ketones are regularly inserted.

Also, we have undertaken a study of the effect of dilution with a solvent (diethyl ether) on the yields of cyclic ketones; it has been found that the yields of cyclic ketones are considerably increased by the high dilution of polymethylenedilithium with a solvent.

Results and Discussion

The results of the reactions of carbon monoxide with polymethylenedilithiums are summarized in Table I.

Poly-ketones. — The poly-ketones (products a) were obtained as an ether-insoluble precipitate after the hydrolysis of the reaction mixtures with dilute hydrochloric acid and purification by the ordinary method.[5]

(3)	b. p.	～180°C/ 3 mmHg		～160°C/ 3 mmHg

The infrared spectra of the poly-ketones showed the presence of methylene and a carbonyl group (1690～1700 cm^{-1}); the elementary analysis of these poly-ketones are correct for $C_{n+1}H_{2n}O$ (n=4, 5, 6,), which indicates that these poly-ketones have a $-[-(CH_2)_n-\overset{\overset{O}{\|}}{C}-]-$ unit as a monomer unit. Typical infrared spectra of poly-ketone are reproduced in Fig. 1.

Cyclic Ketones. — Cyclic ketones (products b) were obtained by the distillation of the neutral part under reduced pressure, and their structures were determined by ordinary methods, such as elementary analysis, mixed-melting-point measurements of their 2, 4-dinitrophenylhydrazones, and infrared spectra measurements. It was found that dilutions of polymethylenedilithiums with diethyl ether lead to increasing yields of cyclic ketones and decreasing yields of poly-ketones. (Cf., for example, Table II.) This method of synthesizing cyclic ketones under high dilution with a solvent seemed to be the simplest way to prepare cyclic ketones from aliphatic compounds. (Earlier methods may be seen in the literature cited in Ref. 6.)

Other Products. — Various by-products were produced by these reactions. Among these by-products, the following compuuds (I—III) were isolated; their structures were assumed on the basis of the results of elementary analyses, infrared spectra measurements and molecular weight measurements.

$$Br(CH_2)_n-\overset{\overset{O}{\|}}{C}H, \qquad HC-\overset{\overset{O}{\|}}{C}-(CH_2)_n-\overset{\overset{O}{\|}}{C}H,$$

I II

$$HC(CH_2)_4\overset{\overset{O}{\|}}{C}(CH_2)_4\overset{\overset{O}{\|}}{C}(CH_2)_4\overset{\overset{O}{\|}}{C}H$$

III

These products are thought to be the precursors to the poly-ketones.

Experimental

Materials.—Commercial polymethylenedibromides were purified by fractional distillation: tetramethylenedibromide (b. p. 113～115°C/60 mmHg), pentamethylenedibromide (b. p. 118～119°C/34 mmHg, n_D^{15} 1.5146), and hexamethylenedibromide (b. p. 138～139°C/34 mmHg, n_D^{15} 1.5111).

The Preparation of Polymethylenedilithiums.— Into a 500 ml. four-necked flask equipped with a mechanical stirrer, a low temperature thermemoter, a reflux condenser protected from moisture, a gas bubbler and a dropping funnel, 50 ml. of anhydrous diethyl ether (dried over sodium) were placed; after the apparatus had been swept with dry oxygen-free nitrogen, 3.5 g. (0.5 g. atom.) of lithium in the form of small pieces of thin coil was added. A solution of polymethylenedibromide (0.1 mol.) in 100 ml. of anhydrous diethyl ether was stirred in via the dropping funnel over a period of 1 hr., while the internal temperature was maintained at −10～−5°C.

The Reaction of Carbon Monoxide with Polymethylenedilithium.—After the addition had been completed, the stirring was continued for another hour, after which the reaction mixture was cooled to −70°C with a dry ice-methanol bath kept at −78°C. Dry pure carbon monoxide was then introduced from the gas bubbler at a rate of 0.5 l./min. for 1 hr. The reaction mixture was then decomposed with 50 ml. of 95% ethanol and, further, with 100 ml. of 6 N hydrochloric acid. Then poly-ketone was precipitated as an ether-insoluble solid and was filtered off under reduced pressure. The organic layer separated from the filtrate was treated with three succesive 50-ml. portions of saturated aqueous potassium carbonate and divided into (1) the organic layer and (2) the potassium carbonate solution.

Poly-ketones. — The precipitate was dissolved in hot benzene, and then this solution was added to methanol by means of a vigorous agitation. The polymer, separated as a powder, was filtered; this procedure was repeated three times, and then the polymer was dried to a constant weight. The elementary analysis of these poly-ketones are:

$-[-(CH_2)_4-\overset{\overset{O}{\|}}{C}-]-$ polymer. Found: C, 70.99; H, 8.93. Calcd. for C_5H_8O: C, 71.39; H. 9.53%

$-[-(CH_2)_5-\overset{\overset{O}{\|}}{C}-]-$ polymer. Found; C, 74.40; H, 10.80. Calcd. for $C_6H_{10}O$: C, 73.43; H, 10.27%.

$-[-(CH_2)_6-\overset{\overset{O}{\|}}{C}-]-$ polymer. Found: C, 76.59; H, 10.83. Calcd. for $C_7H_{12}O$: C, 75.00; H, 10.78%.

The organic layers containing neutral compounds were washed with water and dried over anhydrous sodium sulfate. The brownish residual oils obtained after the removal of the solvent were distilled under reduced pressure to give the following fractions (Table III).

6) L. Ruzicka et al., *Helv. Chim. Acta*, **9**, 249, 499 (1926); J. C. Sauer, *J. Am. Chem. Soc.*, **69**, 2448 (1947); J. Heer and K. Miescher, *Helv. Chim. Acta*, **31**, 1289 (1948); Monsanto Chemical Co., *Chem. & Eng. News*, **1957**, 85; K. Ziegler et al., *Ann.*, **504**, 94 (1933).

Cyclic Ketones.—Fraction 1 was assumed to be mainly cyclic ketones, which were identified by mixed-melting-point measurements of their 2, 4-dinitrophenylhydrazones and by elementary analysis. The yields of cyclic ketones were calculated from the results of gas chromatographic analysis (Column-SiDC 550, 2 m.; or P. E. G. 6000, 2 m.; carrier gas, H_2).

Cyclopentanone. — 2, 4 - Dinitrophenylhydrazone (m. p. 144°C, recrystallized from ethanol).

Found: C, 49.62; H, 4.25. Calcd. for $C_{11}H_{12}O_4N_4$: C, 49.80; H, 4.53%.

Cyclohexanone. — 2, 4 - Dinitrophenylhydrazone (m. p. 157.5~158°C, recrystallized from ethanol).

Found: C, 52.16; H, 5.09. Calcd. for $C_{12}H_{14}O_4N_4$: C, 51.80; H, 5.07%.

Cycloheptanone. — 2, 4 - Dinitrophenylhydrazone (m. p. 146.5~147°C, recystallized from ethanol).

Found: C, 53.13; H, 5.32. Calcd. for $C_{13}H_{16}O_4N_4$: C, 53. 42; H, 5.52%.

From fraction 1 (from hexamethylenedilithium), 6-bromohexamethylenealdehyde was also isolated. 2, 4-Dinitrophenylhydrazone (m. p. 227~228°C, recrystallized from ethylacetate).

Found: C, 42.20; H, 4.83. Calcd. for $C_{13}H_{17}O_4N_4Br$: C, 41.83; H, 4.60%.

Dialdehyde. — Fraction 2 was assumed to be dialdehyde, $HCO(CH_2)_nCHO$; n=4, 5, 6. Pimeloaldehyde (II) was identified from the results of the mixed-melting-point measurement of its 2, 4-dinitrophenylhydrazone (m. p. 183~184°C, recrystallized from ethanol-ethylacetate).

Found: C, 46.32; H, 3.98, Calcd. for $C_{19}H_{20}O_8N_8$: C, 46.74; H, 4.09%.

Ketoaldehyde (trimer).—Fraction 3 was assumed to be ketoaldehyde (trimer) from the results of its infrared spectra and molecular weight measurements. For example, tetradeca-5, 10-dione-1, 14-dialdehyde (III);

Found: C, 70.21; H, 9.74. Mol. wt. (in benzene). 285. Calcd. for $C_{16}H_{24}O_4$: C, 68.05; H; 9.28%. Mol. wt. 282.

IR Spectrum.—1680 cm^{-1} and 1700 cm^{-1}.

Other Products.—The sublimable brownish crystals obtained from fraction 3 (in tetramethylenedilithium) were recrystallized from benzene to give yellowish crystals, m. p. 202°C; mol. wt. 145; elementary analysis: C, 72.98; H, 7.56%; IR spectrum 1670 cm^{-1}). However, the structure of these crystals has not yet been determined. The acidic parts were not examined.

Summary

The reactions of carbon monoxide with tetramethylenedilithium, hexamethylenedilithium and pentamethylenedilithium at −70°C have yielded the corresponding poly-ketones (monomer unit: $-CO(CH_2)_n-$, n=4, 5 and 6) and cyclic ketones (cyclopentanone, cyclohexanone and cycloheptanone). In these reactions, high dilutions of polymethylenedilithiums with a solvent (diethyl ether) lead to the formation of cyclic ketones in good yields. For example, cyclopentanone has been obtained in a 40% theoretical yield.

TABLE I. BENZYL ESTER HYDROCHLORIDES OF α-AMINO ACIDS

Amino acid	Benzyl ester hydrochlorides of α-amino acids				
	M. p., °C.	Yield, %	Formula	Nitrogen, %	
				Calcd.	Found
Glycine	129	28	$C_9H_{12}O_2NCl$	6.97	6.99
L-Valine	138	78	$C_{12}H_{18}O_2NCl$	5.85	5.91
DL-Valine	91	95	$C_{12}H_{18}O_2NCl$	5.75	5.91
L-Leucine	145	62	$C_{13}H_{20}O_2NCl$	5.45	5.72
L-Phenylalanine	202	96	$C_{16}H_{18}O_2NCl$	4.80	4.82

acid or the benzenesulfonic acid salt of α-amino acid with benzyl alcohol,[3,10-13] and the reaction of α-amino acid and benzyl alcohol in polyphosphoric acid.[14]

Erlanger and Brand have synthesized benzyl ester hydrochlorides of glycine, D- and L-alanines by causing the corresponding *N*-carboanhydrides (NCAs) to react with benzyl alcohol in the presence of dry hydrogen chloride in ether.[1] In this preparation, the NCAs have been made by the reaction of *N*-carbobenzoxy α-amino acid with phosphorus pentachloride.

During the course of our investigation of poly-α-amino acid synthesis, we have found that the preparation from NCAs makes a convenient method for benzyl ester hydrochlorides of α-amino acids when it is combined with the phosgenation process of α-amino acids, which is now recognized as the most useful route to NCAs. The synthesis of L-alanine benzyl ester hydrochloride by this process has been briefly reported by Rudinger and Pravda.[15]

The phosgenation was carried out in an inert solvent, such as tetrahydrofuran, dioxane, benzene and toluene, at a temperature between 40 and 80°C. When the solvent was removed after the phosgenation was completed, a curde NCA was obtained; this was further treated with a solution of benzyl alcohol in dry ether containing dry hydrogen chloride. The reaction proceeded smoothly at room temperature; carbon dioxide was evolved, and the benzyl ester hydrochloride was precipitated out of the solution. The ether-soluble benzyl ester hydrochloride of L-leucine was isolated by removing the solvent and then recrystallizing it from chloroform/cyclohexane.

In the phosgenation, a prolonged reaction time and a large excess of phosgene decreased the yield of product, mainly because of the formation of *N*-carbonyl α-amino acid chloride.[16] In order to shorten the reaction time, it was necessary to use a finely powdered α-amino acid and to create an efficient agitation through the introduction of phosgene. The preparation is summarized in Table I.

Experimental

L-Phenylalanine Benzyl Ester Hydrochloride. — Into a mixture of 20.0 g (0.12 mol.) of finely powdered L-phenylalanine suspended in 200 ml. of dry tetrahydrofuran, phosgene was stirred efficiently in a thin stream at a temperature between 50 and 60°C. The mixture gave a clear solution after about forty minutes. The solution was then evaporated under reduced pressure, and the residue (crude NCA of L-phenylalanine) was dissolved in 200 ml. of ether containing 7 g. (0.19 mol.) of dry hydrogen chloride. To the solution 20 g. (0.19 mol.) of benzyl alcohol was immediately added. The evolution of carbon dioxide began approximately ten to fifteen minutes after the mixing. The mixture was then allowed to stand at room temperature overnight protected from moisture. The whole mixture became a solid mass because of the precipitation of L-phenylalanine benzyl ester hydrochloride, which was collected on a sintered glass filter and washed repeatedly with dry ether. The product weighed 33.2 g. (96%) and melted at 200~201°C. It was recrystallized from benzene. M. p. 202°C.

L-Valine Benzyl Ester Hydrochloride.—Thirty-five grams (0.30 mol.) of L-valine was phosgenated in 400 ml. of tetrahydrofuran at 50°C. The crude NCA of L-valine was treated with 65 g. (0.6 mol.) of benzyl alcohol in 500 ml. of ether containing 22 g. (0.6 mol.) of dry hydrogen chloride. The product, L-valine benzyl ester hydrochloride, weighed 57 g. (78%). It was recrystallized from ethyl acetate. M. p. 137~138°C.

L-Leucine Benzyl Ester Hydrochloride.—Twenty grams (0.153 mol.) of L-leucine was phosgenated in 200 ml. of tetrahydrofuran at 50°C. A clear solution was obtained within one hour. The crude NCA of L-leucine was treated with 25 g. (0.23 mol.) of benzyl alcohol in 200 ml. of ether containing

The Melting of Glassy Carbon

By Tokiti NODA and Michio INAGAKI

(Received May 22, 1964)

It has previously been reported[1] that carbon was melted at 4000°K under a pressure of 110 atm. and that the molten carbon had the same lattice constants as natural graphite, i. e., $c_0=6.707_8$ Å and $a_0=2.461_4$ Å. However, Bundy[2] has reported that the carbon which was melted under very high pressure and using the flash heating technique had a large lattice constant, 6.748 Å for c_0. In the present work, glassy carbon, which has been found to be a typical non-graphitizing carbon,[3,4] was melted in the same pressure vessel as has been reported on previously.[1]

Glassy carbon rods 4 mm. in diameter, which had previously been heat-treated at 2000°C, were melted by the passage of electrical current directly through them in argon under a pressure above 110 atm. The melting of carbon usually occurred in the middle part of the rod. With a coke-based carbon, the molten carbon formed a ball attached to a crater-type cavity.[1] With glassy carbon, the melting started in the inner part of the rod and made a molten mass of a thin spindle form along the central axis of the rod. Frequently, the molten carbon spouted out from the break of the cavity wall, and a narrow but long cavity of a spindle form was formed inside the rod. The spouted molten carbon was scattered in balls smaller than 0.5 mm. in diameter. When a glassy carbon rod 5 mm. in diameter was used, the spouted molten carbon had a cochleate appearance. Minute fragments of the molten carbon were also found on the inside wall of the cavity.

The molten carbon was soft and of a metallic luster. Its lattice constant, c_0, was 6.708 Å. The X-ray powder pattern for a rod specimen cut out from the molten carbon had only diffraction lines of the hexagonal modification of graphite, and none of the rhombohedral modification. By grinding the same carbon in a mortar, however, traces of the rhombohedral modification were detected from the X-ray pattern.

In one case, where no change in the appearance of the rod specimen was observed after the passage through of an electrical current, a cavity about 10 mm. long and about 1.5 mm. in diameter at the maximum was found in the central part of the rod. The wall of the cavity was composed of three layers, which

were clearly distinguished from each other in hardness and appearance. The innermost layer was the molten carbon, judging from its properties and its lattice constant, c_0. The outermost layer, which was about 0.05 mm. thick, was so soft that it could be whittled by a razor blade, but it had no metallic luster. Its lattice constant, c_0, was measured as 6.748 Å. It seemed that the graphitization of this part was promoted by the presence of a minute amount of oxygen mixed in the ambient gas phase of argon.[5] The carbon of the middle layer was very hard and showed a conchoidal fracture, which was one of the characteristics of glassy carbon. As is shown in Fig. 1, the profile of (002) diffraction for the middle layer was unsymmetrical, while the profiles for the other layers were symmetrical. This unsymmetrical profile shows that the non-graphitized part remained in the glassy carbon at the middle layer, even after heating at temperatures very near to the melting point of carbon. This phenomenon is somewhat similar to the finding that the crater part of the rod of a coke-based carbon had the lattice constant, c_0, of 6.714 Å.[1] It must be noticed that glassy carbon did not lose its characteristics, even at temperatures very near to its melting point.

The Electronic Structures of NO_2, NO_2^+ and NO_2^-

By Hiroshi KATO, Teijiro YONEZAWA, Keiji MOROKUMA and Kenichi FUKUI

(Received may 25, 1964)

Several quantum-mechanical investigations have been carried out on the electronic structures of NO_2,[1,2,3] NO_2^+,[1,4,5] and NO_2^-.[1] That is, Walsh[1] discussed the electronic structure of these molecules by qualitative considerations. Tanaka[2] and McEwen[3] treated the π electronic structure of NO_2 by the LCAO SCF method, and, further, McEwen investigated the σ non-bonding electrons by the semi-emprical method.

On the other hand, the present authors and others have developed the Hückel molecular orbital treatment of saturated compounds and also the σ electronic structure of unsaturated compounds.[6] Hoffmann has recently proposed an extended Hückel molecular orbital method in which σ and π electronic structures of saturated and unsaturated hydrocarbons are treated simultaneously.[7]

In the present paper, the electronic structures of NO_2, NO_2^+ and NO_2^- will be calculated by Hoffmann's method, and some physico-chemical properties of these compounds will be discussed.

Method of Calculation

By Hoffmann's method the molecular orbitals (MO) of these compounds are represented by the linear combination of valency atomic orbitals (AO), that is, the 2s, $2p_x$, $2p_y$ and $2p_z$ orbitals of the nitrogen and oxygen atoms. Therefore, the secular determinant is given by

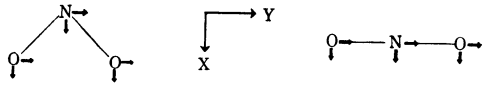
$$\det |H_{ij}-ES_{ij}| = 0$$

whers H_{ij} is the off-diagonal element and S_{ij} is the overlap integral between the ith and jth atomic orbitals. The values of the diagonal elements, H_{ii}, are given with reference to those given by Skinner and Pritchard[8]:

$H(2s, N) = -27.5$ eV. $H(2p, N) = -14.5$ eV.

$H(2s, O) = -35.3$ eV. $H(2p, O) = -17.8$ eV.

and the off-diagonal element, H_{ij}, is expressed as:



$$H_{ij} = 0.5K(H_{ij}+H_{ji})S_{ij}$$

where the value of K is taken as 1.75, as in Hoffmann's paper,[7] and the values of S_{ij} are

obtained by Mulliken's Table.[9]

The shapes of these molecules are given as follows:[10] The N–O distance is 1.15 Å for NO_2^+, 1.20 Å for NO_2, and 1.235 Å for NO_2^-, and the angle of ONO is 180° for NO_2^+, 132° for NO_2, and 115° for NO_2^-. Thus, NO_2 and NO_2^- belong to the point group C_{2v}, and NO_2^+ belong to the group $D_{\infty h}$. The coordinate is taken as shown in Fig. 1, where the p_z orbitals are perpendicular to the XY plane.

Results and Discussion

Electronic Levels and Distributions.—The calculated MO energies (in eV.) and the values of the coefficients of AO's in some MOs are listed in Table I (a), (b) and (c), together with the irreducible representations of each MO. From the results listed in Table I, the following facts can be deduced: In NO_2^+, the highest occupied orbital (HO) consists of the π orbitals of the oxygen atoms, the odd electron in NO_2 is mainly localized on the lone-pair orbital of the nitrogen atom, and a

* Forbidden transitions

similar tendency is observed in the HO of NO_2^-. The lowest orbitals (LV) of these compounds are all π anti-bonding orbitals, largely localized on the nitrogen atom. The order of our calculated orbitals of NO_2 and NO_2^- are consistent with the results estimated by Walsh[1],* and that of NO_2^+, with the results of Clementi and McLean.[5]

The energy of LV of NO_2^+ was estimated as -11 eV. by Nagakura and Tanaka[4]; the present result is -10.88 eV. The energy of the HO of NO_2 is calculated as -13.19 eV., while the value obtained by McEwen was -13.21 eV. The observed ionization energy is 13.98[11] or 11.7 eV[12],**. The π orbital energies of NO_2 obtained by the present calculations are -19.11, -17.69 and -11.58 eV., while by the LCAO SCF method, Tanaka[2] computed -18.86, -15.63 and $+0.40$ eV. and McEwen obtained -19.18, -15.85 and -2.23 eV..

The electronic distributions of the above-mentioned results, however, are considerably different. That is, the magnitudes of the π electron densities obtained by Tanaka are 1.018 on the nitrogen atom and 1.491 on the oxygen atom, whereas the values obtained by McEwen are 0.728 on the nitrogen atom and 1.637 on the oxygen atom in NO_2. In our calculations, the values of the atomic populations[13] of π electrons are 0.516 on the nitrogen atom and 1.742 on the oxygen atom in this molecule. For the odd electron distributions, the values by McEwen are 0.364 on the nitrogen atom and 0.318 on the oxygen atom, while our calculated atomic populations are 0.630 on the nitrogen atom and 0.158 on the oxygen atom. The net charges by our calculations are $+1.68$ on the nitrogen atom and -0.84 on the oxyen atom (considering all valence electrons), whereas Tanaka estimated the net charges to be $+0.88$ on the nitrogen atom and -0.44 on the oxygen atom (including σ and π electrons). Our calculated negative charge of the oxygen atom, however, seems to be too large. Although this might partly arise from the oozing of nitrogen lone-pairs, the difference in electronegativity between nitrogen and oxygen atoms might be overestimated to a certain extent in the present treatment.

Reactivity.—As has been described in the section on electronic levels, the highest occupied orbitals of NO_2 and NO_2^- are the lone-pair orbitals, in which the bonding electrons are largely localized on the nitrogen atom.*** Accordingly, by our frontier electron theory, the radical reaction of NO_2 will more likely take place at the nitrogen atom than at the oxygen atom. This theory may be supported by the following experimental facts: The hydrogen atom abstraction reaction by NO_2 produces $H:NO_2$,[1] and the structure of N_2O_4, produced by the association of NO_2, is regarded as $O_2N:NO_2$ rather than $ONO:NO_2$.[14] The structure of N_2O_3 produced from NO and NO_2 is represented by $ON:NO_2$.[14] Also, the NO_2^- ion mostly reacts with alkyl ions to form a nitro-compounds.[1] Considering the values of the coefficients of the AO's of the HO orbital in NO_2 and NO_2^-, the reaction described above may occur partly at the oxygen atoms, corresponding to the experience in the reaction of alkyl compounds with NO_2 producing the nitrous esters as by-products.[15]

Similarly, for the NO_2^+ cation, the "nucleophilic" reaction will take place on the nitrogen atom (for instance, as in the "electrophilic" nitration of aromatic hydrocarbons), and it may be predicted that the electrophilic reaction

* McEwen assumed a different order in NO_2, that is, $-(b_1)^2(a_2)^2(a_1)^2(b_2)^2(a_1)$. (cf. Table II.)

** The calculated energy of the HO of NO_2^- seems to be too low. This discrepancy might be partly attributed to the disregard of the change in Coulomb integrals in the ionized state.

*** The Lone-pair orbital of the nitrogen atom is directed towards $(-X)$. This may have some relation with its orientation as a nitrating reagent.

will occur on the oxygen atoms.

Transition Energy. — Walsh discussed in detail the ultraviolet spectroscopic data of NO_2 in connection with the type of transition.[1] The types of transition estimated by Walsh and the calculated energy differences are summarized in Table II, together with the observed absorptions. Except for the transition to the highest vacant a_1 orbital,* the calculated values agree well with the observed values. On the other hand, the π-π transition energies computed by Tanaka[2] are 8.30 and 7.53 eV, while our calculated values are 7.36 and 6.11 eV.

As has been mentioned above, the calculated results have a good correlation with the experimental values and other calculations, though there are a few discrepancies. The discrepancy of the electron distribution can be modified by the ω-technique[16] or by using larger values of the parameter K (in particular for π-π bonding). This point will be published in the near future.

A part of the calculations have been carried out on the digital computer, KDC-I, of Kyoto University.

SHORT COMMUNICATIONS

The Effect of Magnetic Field on the Radiation-induced Polymerization of Formaldehyde in the Solid State at a Low Temperature

By Yoneho TABATA, Harutaka KIMURA, Hiroshi SOBUE and Keichi OSHIMA

(Received April 11, 1964)

The radiation-induced solid state polymerization of formaldehyde has been reported by several workers.[1,2] In this paper, the effect of magnetic field on this radiation-induced polymerization of formaldehyde in the solid state will be reported.

The experimental apparatus is shown in Fig. 1. The apparatus consists of a pair of electromagnets, a ^{137}Cs γ-irradiation source, and shieldings, as is shown in the figure. The irradiation space is covered by a thick lead wall on the top, while a pair of electromagnets serve as side walls, the maximum magnetic field of which is 6×10^3 gauss. A Dewar vessel is inserted from the upper side into a hole in this lead shield, as is shown in Fig. 1-a. The radiation source is ^{137}Cs of 40 curies, and the structure of the capsule of the source is as shown in Fig. 1-c. The source is located inside the lead container which is installed at the bottom of the electromagnet. The source can be moved from the safe position (inside the container) up to the irradiation space by remote control.

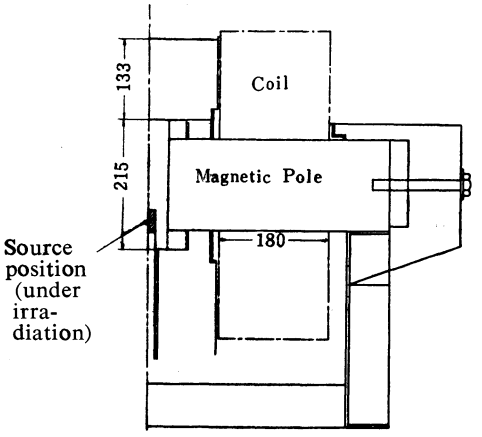

Fig. 1-b. A side view of the electromagnet and shielidings.

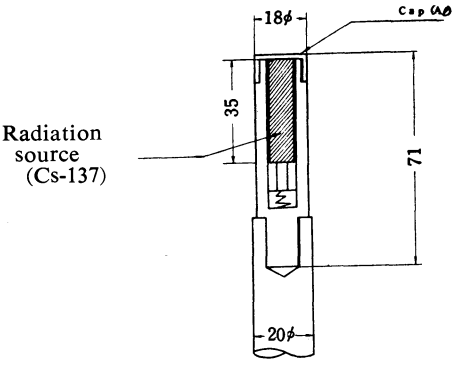

Fig. 1-c. Datails of the ^{137}Cs source.

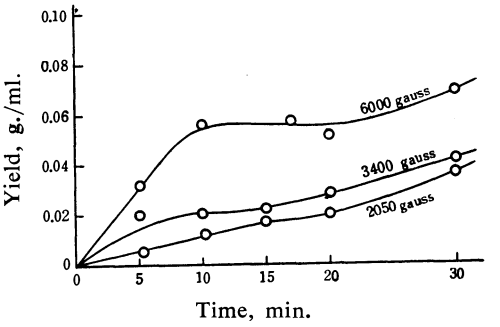

Fig. 2. The relation between the polymerization yield and the irradiation time in various magnitudes of magnetic field. Dose rate was 4.3×10^2 r./hr.

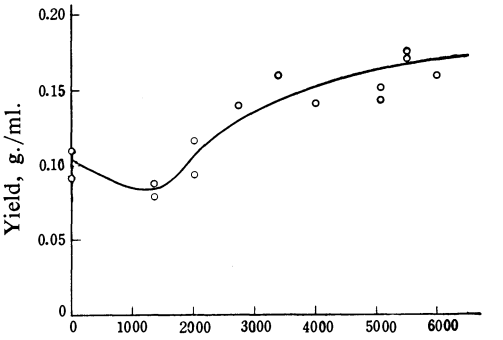

Fig. 3. The relation between the polymerization yield and the magnitudes of magnetic field at −196°C. Dose rate was 1.6×10^3 r./hr.

Formaldehyde was prepared by the heat-decomposition of para-formaldehyde at 160～170°C; it was then refined by distillation in vacuo at −78°C. The monomer was prepared and purified, just prior to use. The monomer in a glass tube was sufficiently degassed and sealed in vacuo. Irradiation was carried out by γ-rays in the solid state of the monomer at −130°C and −196°C, under the influence of the magnetic field. The yield of the polymerization was determined gravimetrically.

The relation between the polymerization yield and the irradiation time for various magnitudes of the magnetic fields at −196°C is shown in Fig. 2. It is obvious from the figure that the rate of polymerization increases with the magnitude of the magnetic field and that the saturation value of the yield also increases.

The relation between the polymerization yield and the magnitude of the magnetic field in the solid state polymerization at −196°C is shown in Fig. 3. The dose rate was 1600 r./hr. and the irradiation time was 10 min.; hence, the total dose was 270 r. To prevent an explosive polymerization, the dosage was appreciably lower than the 400 r. above which Chachaty and Magat[1] have observed that an explosive polymerization takes place.

From the experimental results, it is evident that the polymerization yield increases with the magnitude of the magnetic field in the region of 1500～6000 gauss.

The polymerization was also carried out at −130°C under the same irradiation conditions. It was found from the experiments that the polymerization yield was not affected by the magnetic field at −130°C; on the contrary, however, the polymerization was affected profoundly by the magnetic field at −196°C.

It is difficult to explain this interesting phenomena at the present stage of investigation. However, there are three possible explanation; the first is the interaction of the δ-ray (electrons ejected by an incident γ-ray) with the magnetic field, the second is the effect of the magnetic field on the termination reaction, and the third is the effect of the magnetic field on

a collective excited state of the monomer crystal.

The details of the results will be reported in the near future.

The Electron Spin Resonance of Sodium Polyphosphate Labeled with ^{32}P

By Masaji MIURA and Akinori HASEGAWA

(Received August 13, 1964)

Many substances, such as alkali halides, glasses and so on, become colored upon irradiation with X-, γ- or β-rays. In the literature no reports have been found, however, on the coloration of a substance by the internal irradiation from its radioactive constituent. We have recently found that sodium polyphosphate labeled with ^{32}P (SPP*) becomes red on standing but that the color fades away when it is heated to 200°C. We also studied this substance by means of a ESR technique and found that the absorption bands of ESR are closely related with the red color of SPP.*

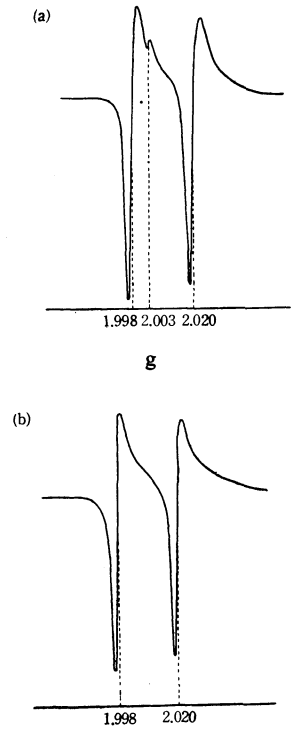

Fig. 1. ESR spectra at 77°K:
(a) SPP*, (b) SPP irradiated with X-rays.

Sodium polyphosphate (SPP), the so-called Graham salt, was prepared by heating sodium dihydrogen phosphate at 800°C for 6 hr. and then cooling rapidly on dry ice.

SPP irradiated with X-rays from a copper target gave two absorption bands of ESR, at $g=1.998$ and 2.020 (Fig. 1b), while SPP itself showed no absorption bands. On the other hand, SPP* exhibited one weak shoulder, at $g=2.003$ (Fig. 1a), in addition to two strong absorption bands, as in the case of SPP irradiated with X-rays. When SPP* was heated at 150°C for 20 min., its color became faint and the shoulder in ESR sbsorption band disappeared; the remaining two bands are of the same shapes as those of irradiated SPP. The intensity of each of two bands was similarly reduced by the heat treatment. It seems, therefore, that these two bands have the same origin. On the other hand only one absorption band was obtained from SPP* which had been prepared by using ^{32}P, a large part of which had already decayed to ^{32}S. This band corresponds to the shoulder in Fig. 1. a.

This conclusion follows from these results: SPP* as well as irradiatd SPP has two absorption bands, at $g=1.998$ and 2.020, which may be the hyperfine structure arising from the interaction of a trapped electron with a phosphorus nucleus (^{31}P, $I=1/2$), as has already been pointed out.[1] Further, SPP* has a shoulder, at $g=2.003$, which may result from a free electron near the sulfur atom (^{32}S, $I=0$) which is the decay product of ^{32}P. This is supported by the fact that the radical of sulfur is easily produced by the irradiation.

Full details will be published later.

The Stereochemistry of Illudin S (Lampterol)[1,2a]

By Takeshi MATSUMOTO, Yohei FUKUOKA, Akitami ICHIHARA, Yoshihiro MORI, Haruhisa SHIRAHAMA, Yutaro TAKAHASHI and Masahiko WATANABE

(Received August 14, 1964)

Recently the structure of illudin S,[3] an antitumor substance obtained from a culture liquid of *Clitocybe illudens*, has been proposed. We now wish to propose stereochemical formula I for illudin S on the basis of the following evidence.

I

II : $R_1, R_2, R_3 = H$

III : $R_1, R_2 =$  , $R_3 = H$

IV : $R_1, R_2 =$  , $R_3 = COCH_3$

V : $R_1, R_2 = H$, $R_3 = COCH_3$

The infrared spectrum[4] of illudin S in carbon tetrachloride (7.84×10^{-4} mol.) showed absorption bands at 3631 cm^{-1} (ε, 58.4, free primary OH), 3601 cm^{-1} (ε, 68.4 free secondary allylic OH) and 3485 cm^{-1} (ε, 67.1 bonded tertiary OH), while illudin M,[3] in which the hydroxymethyl group is replaced by a methyl group, showed bands with almost identical intensities at 3601 cm^{-1} (ε, 61.6, free secondary OH) and 3485 cm^{-1} (ε, 71.7, bonded tertiary OH) in carbon tetrachloride (7.72×10^{-4} mol.).

These observations clearly indicate the trans orientation of the hydroxymethyl group and the secondary hydroxyl group.

Isoilludin S[2a,b] (II), formed by the acyloin rearrangement of illudin S with alumina, has infrared absorption bands at 3632 cm^{-1} (ε, 41.4, free primary OH), 3601 cm^{-1} (ε, 56.5, free secondary OH) and 3503 cm^{-1} (ε, 65.2, bonded tertiary OH) in carbon tetrachloride (1.03×10^{-3} mol.). These data show that the tertiary hydroxyl group has a pseudoequatorial conformation in illudin S (the stronger hydrogen bond) and a pseudoaxial conformation in isoilludin S.

The treatment of isoilludin S (II) with dihydropyran and the subsequent acetylation of the dipyranyl compound III, gave IV, which was then hydrolyzed with methanolic hydrogen chloride to monoacetylisoilludin S (V) : τ, 8.90, 8.42, 8.31 (methyl groups), 7.89 ($2\times CH_3CO_2-$), 6.58 ($-CH_2OH$), 5.31 (proton α to hydroxyl group), 4.62 (olefinic proton), and 7.95~9.15 (two methylene groups of cyclopropane), whose infrared spectrum in carbon tetrachloride (1.00×10^{-3} mol.) showed, in addition to an absorption band at 3603 cm^{-1} resulting from a secondary hydroxyl group, an absorption band at 2632 cm^{-1} (free primary OH) with a rather decreased intensity and a newly-appeared band at 3532 cm^{-1} (bonded primary OH).

These results provide evidence of the cis orientaion of the hydroxymethyl group and of the tertiary hydroxyl groups in isoilludin S (II).

The stereochemistry of illudin S should, therefore, be represented by formula I in view of the known steric course of acyloin migration.[6]

The absolute configuration of illudin S was determined by applying Horeau's procedure.[7]

When I (0.2×10^{-3} mol.) was treated with ($\pm$) α-phenylbutyric anhydride (0.1×10^{-2} mol.),

1) Presented at the IUPAC Symposium on the Chemistry of Natural products, Kyoto, Japan, April, 1964.

2) a) Lampterol, which was isolated from *Lampteromyces Japonicus*, has been proven identical with illudin S on the basis of direct comparison of their nuclear magnetic resonance and infrared spectra as well as mixing melting point.

the resultant α-phenylbutyric acid showed a rotation of $\alpha_D^{20}+8.75°$ (optical yield, 9.01%). Since the steric requirement of substituents around C_1 can be regarded to be as indicated in formula I, it may be concluded that illudin S should have the absolute configuration of I.

A Kinetic Study of the Photochromism of 2,2',4,4',5,5'-Hexaphenyl-1,1'-biimidazolyl with Electron Spin Resonance

By Taro HAYASHI, Koko MAEDA and Makoto TAKEUCHI

(Received August 19, 1964)

The mechanism the of photochromism[1] of 2, 2', 4, 4', 5, 5'- hexaphenyl - 1, 1' - biimidazolyl, m. p. 199~201°C, in a solution has been studied with electron spin resonance. In a benzene solution ($C=1.48\times10^{-4}$ mol./l.) which turned from pale yellow to reddish purple when irradiated with a mercury vapor lamp for 3 min., the ESR was measured.[2] The line width (peak to peak) of the ESR signal (w in Fig. 1) was 9.1 gauss, and its g value was measured as 2.003. The intensity of the ESR signal, h in Fig. 1, gradually decreased with time in the dark, while its line width scarcely changed in 20 min. When the recording of the first signal had been almost finished, the sweep direction of the magnetic field was reversed and an ESR signal was immediately recorded. When this was followed by a similar procedure, the chart shown in Fig. 1 was obtained. The signal intensity, h, and the time, t, at which a signal curve intersected the base line was measured for every ESR signal on the chart. A graph of the reciprocal of h versus the time, t, gave a straight line, as is shown in Fig. 2.

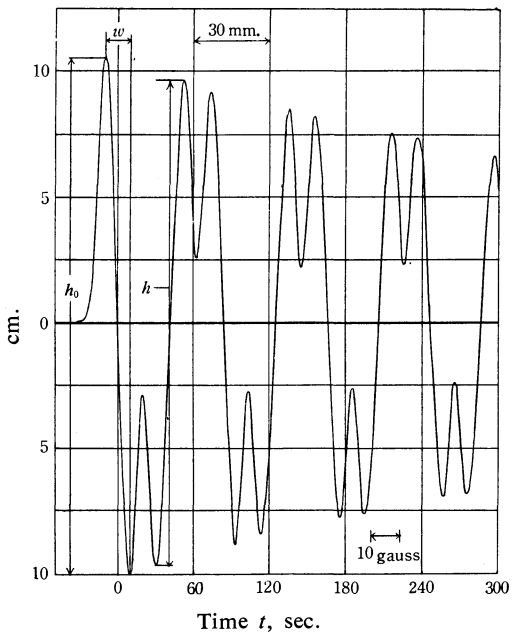

Fig. 1. Intensity change of an ESR signal of a benzene solution of hexaphenyl-biimidazolyl ($C=1.48\times10^{-4}$ mol./l.) with time in the dark at 23°C.
Gain, −34 db; modulation width, 3 gauss

2) An electron spin resonance instrument of the Japan Electron Optics Laboratory Co., type JES-3BX (standard frequency 9400 Mc; modulation frequency 100 kc).

The linearity shows that the reaction which diminishes an ESR signal is a second-order radical reaction, since the signal intensity, h, is assumed to be approximately proportional to the concentration of free radicals, provided that the line width does not change, as in the present case. The radical reaction is considered to be a recombination of triphenylimidazolyl radicals. This conclusion agrees with the mechanism of photochromism, which has been confirmed[1] to be the homolytic dissociation of an N–N bond of hexaphenyl-biimidazolyl to triphenyl-imidazolyl.

A similar kinetic study of the photochromism of 2, 2', 4, 4', 5, 5'-hexa-*p*-tolyl-1, 1'-biimidazolyl, m. p. 194~195°C, with an ESR signal gave a similar conclusion, showing that the substitution of methyl groups diminished the rate of the recombination of free radicals.

A New Colorimetric Determination of Nitrate Ions by Solvent Extraction with Crystal Violet

By Yuroku YAMAMOTO, Sumio UCHIKAWA and Kozo AKABORI

(Received September 2, 1964)

In the course of our study[1] of the solvent extraction of anions, it was found that nitrate ions can be extracted into chlorobenzene when the aqueous solution contains an excess of crystal violet and that there is a linear relationship between the color intensity of the organic phase and the concentration of the nitrate ions.

Figure 1 shows the absorption spectra of crystal violet; curve 1 is a spectrum of the extract when nitrate ions are absent, while curve 2 is that of the extract with nitrate ions. The crystal violet was extracted with chlorobenzene from the aqueous solution at pH 6.0 buffered with phosphate. It was thus shown that, when a small amount of nitrate ions is present, the cation of crystal violet is quite extractable into the organic layer. The maximum of absorbance is found at 595 mμ in the organic phase, but in the aqueous phase the maximum is slightly shifted to 591 mμ (curve 3). A maximum extraction is obtained in the range of pH 5.0~7.0, when the molar concentration of the dyestuff is held at the concentration of 10^{-4} M. The recommended procedure for the calibration curve is as follows.

Mix 5 ml. of the crystal violet chloride solution (1×10^{-3} M), 2 ml. of a phosphate buffer solution (1 M, pH 6.0) and various volumes of the standard nitrate solution (5×10^{-5} M). Dilute to 25 ml. with distilled water. Take the aliquot (10.0 ml.) into a separatory funnel. Shake the solution with 10.0 ml. of chlorobenzene for 5 min. Transfer the organic layer

Curve 2: Spectrum of organic phase extracted from the aqueous solution (10 ml.), containing the same component as that of curve 1 and nitrate ions (2×10^{-5} M). pH 6.0
Curve 3: Spectrum of the aqueous solution of crystal violet (4×10^{-6} M). pH 6.0 (KH_2PO_4: 0.08 M)

1) Y. Yamamoto et al., This Bulletin, 37, 434, 594, 785 (1964).

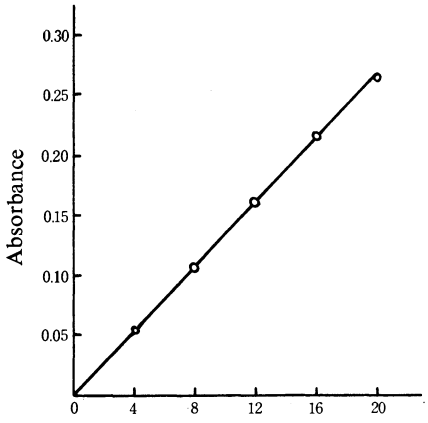

Fig. 2. Calibration curve at 595 mμ.
Reference: Reagent blank
Water phase { Crystal violet 2×10^{-4} M; KH_2PO_4 0.08 M; NO_3^- $x\times10^{-6}$ M; pH 6.0

into the cell, and measure the absorbance at 595 mμ using a reagent blank as a reference. Beer's law is followed in the range of 4×10^{-6} $\sim2\times10^{-5}$ M. The presence of diverse ions, such as phosphate and sulfate, does not interfere with the determination, even when they are present in amounts 1000 times that of the nitrate. Chloride give rise to a slight positive error when it exists in an amount more than ten times that of the nitrate.

Although various colorimetric methods for nitrate are known,[2] the method presently proposed is based on a different mechanism of color development and has a higher sensitivity.

The Direct Formation of Biferrocenyl and Polyferrocenyls from Ferrocenyllithium

By Kazuo HATA, Izumi MOTOYAMA and Hamao WATANABE

(Received September 10, 1964)

Although many synthetic methods of biferrocenyl have been proposed, all of these routes are circuitous and troublesome. Moreover, the formation of polyferrocenyls other than biferrocenyl has never been reported. The present authors wish to report on the direct formation of biferrocenyl and polyferrocenyls from ferrocenyllithium.

In a previous paper[1] the synthesis of glycidylferrocenes was reported. In the course of this synthesis, when chlorohydrin derivatives of ferrocene were derived from the products of the reaction between ferrocenyllithium and epichlorohydrin, a small amount of biferrocenyl was obtained as orange crystals. The yield was ca. 0.3% based on ferrocene. In order to determine the step of the formation of biferrocenyl, a mixture containing lithiated ferrocene was hydrolyzed by pouring it into ice water immediately after the reaction of ferrocene and *n*-butyllithium in ether. An organic solid mixture, obtained from the ethereal layer, was submitted to vacuum sublimation in order to collect the recovered ferrocene. Even in this reaction biferrocenyl was isolated from the sublimation residue in a 0.4% yield. On the other hand, the reaction between *n*-butyl bromide and ferrocene in an ethereal solution did not occur, and the formation of biferrocenyl could not be observed. From these facts, it is obvious that biferrocenyl was directly derived from ferrocenyllithium, and that the formation of biferrocenyl is attributable to the Wurtz-type reaction as follows:[2]

$$\mathrm{FcLi} \xrightarrow{n\text{-BuBr}^*} \mathrm{FcBr} \xrightarrow{\mathrm{FcLi}} \mathrm{Fc\text{-}Fc}$$

$$\mathrm{FcLi} \xrightarrow{\mathrm{FcBr}} 2\mathrm{Fc}\cdot \longrightarrow \mathrm{Fc\text{-}Fc}$$

$$\mathrm{FcLi} \longrightarrow \mathrm{Fc}\cdot \longrightarrow 1/2\ \mathrm{Fc\text{-}Fc}$$

(Fc = ferrocenyl)

Among these reactions, the radical species are considered on the basis of the results mentioned below to be mainly participated in the formation of biferrocenyl. The radical

mechanism is also suitable for the explanation of the experimental results which Goldberg et al. have observed previously.[3]

With a view to finding a possibility of the formation of any polyferrocenyls and one of the increase in the yield of biferrocenyl, a reaction of ferrocenyllithium and cobaltous chloride was carried out according to the method reported by Kharasch and his co-workers,[4] and Wittig and Lehmann.[5] A small amount of anhydrous cobaltous chloride was added to an anhydrous ethereal solution of lithiated ferrocene, in the presence of an equimolar amount of *n*-butyl bromide to the ferrocence used as the starting material. A considerably vigorous reaction occurred, with an evolution of gas as had been expected. After the reaction was over, the mixture was poured into ice water in order to hydrolyze the remained lithium compounds, and many solid products were separated from the organic mixture by means of an appropriate procedure. The products were found to be biferrocenyl, butylated biferrocenyl, terferrocenyl, many polyferrocenyls and butylated polyferrocenyls, some of which were not yet identified. The analytical results of the identified products are shown in Table I. The identification was also supported by their infrared spectra. Other polyferrocenyls and butylated polyferrocenyls were found to have a larger molecular weight than 600, and they are scarcely soluble in common organic solvents. As a whole, about 36% of the ferrocene used was converted into these reaction products. A detailed investigation of all these products is in progress and will be reported on later.

Iron(III) Chloride-Triphenyl Phosphite as a New Catalyst for the Polymerization of Tetrahydrofuran

By Iwo YAMASHITA and Minoru SERIZAWA

(Received September 15, 1964)

The polymerization of tetrahydrofuran by the use of Friedel-Crafts catalysts with co-catalysts, such as alkylene oxides, active halogen compounds and so on, was first examined by Meerwein.[1] Subsequently Muetterties[2] reported the use of phosphorus pentafluoride to give a polymer. Recently Saegusa et al.,[3] Weissermel and Nölken[4] and the present authors[5] have reported that triethyl aluminum is a effective catalyst when used with co-catalysts. In this communication, it will be reported that iron(III) chloride-triphenyl phosphite is an interesting new catalyst system for the polymerization of tetrahydrofuran.

Bulk polymerization was carried out in a nitrogen atmosphere in a sealed glass ampoule. The polymerization mixture was allowed to stand at a desired temperature. The polymeric product was isolated by pouring the reaction mixture into a large amount of diluted hydro chloric acid (0.001~0.005 N). The crude polymer was washed with methanol and then dissolved in tetrahydrofuran. The purified polymer was recovered by again pouring the solution into a large excess of water and then dried in vacuo at room temperature.

The effects of the amount of iron(III) chloride and the polymerization temperature on the yield and the reduced viscosity of the polymer are shown in Figs. 1, 2A and 2B.

When the other Lewis-acid (aluminum

chloride, boron fluoride etherate, titanium chloride and zinc chloride) was used in place of iron(III) chloride, together with triphenyl phosphite, these catalyst systems gave no polymer under the polymerization conditions examined. Moreover, none of the polymerizations occurred when triphenyl phosphite was used alone or when iron(III) chloride itself was used as a catalyst.

The infrared spectra, the solubilities and the thermal properties of the polymer were very similar to those of the polytetrahydrofuran prepared by the use of the other catalysts (phosphorous pentafluoride[2] and triethyl aluminum-epichlorohydrin[3]).

Further details on such polymerization results and on the role of triphenyl phosphite in such a catalyst system will soon be published.

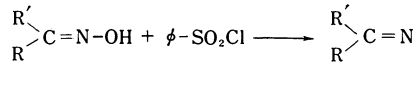
The Solvent Effects of Esterification: The Reaction of l-Menthol with Acetyl Chloride in Liquid Sulfur Dioxide[*1]

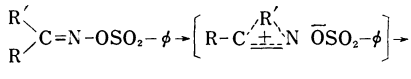
By Niichiro TOKURA[*2] and Fuminori AKIYAMA[*2]

(Received January 6, 1964)



It has been reported in a previous paper[1] that, in the rearrangement of cyclohexanone oxime *p*-toluenesulfonate in various solvents, there are no clearcut correlations between the log. of the rate constants versus the dielectric constants, the dipole moments or the *Z*-values of the solvents. Among the solvents used, liquid sulfur dioxide gave the largest rate constant for the rearrangement. It has been suggested that liquid sulfur dioxide, as an electrophilic solvent, favors the formation of a *bare* cation, without interfering with the formation of the aza-cyclopropenyl cation which is a requisite intermediate to carrying out the Beckmann rearrangement.

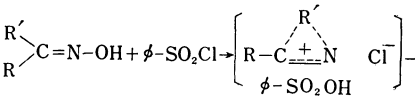
It has also been indicated in previous paper[2-4] that the rate of the cationic polymerization of styrene in liquid sulfur dioxide is the fastest among the solvents used for the polymerization, giving a polymer of the highest degree of polymerization with a narrow molecular weight distribution.



On the other hand, it has already been shown that the reaction rate of the Wagner-Meerwein rearrangement[5] is very fast in liquid sulfur dioxide and that the decomposition of an allylsulfinate is the fastest in liquid sulfur dioxide.[6]

On the contrary, the rate of the Menschutkin reaction[7] in liquid sulfur dioxide is the slowest among the solvents used. All of these results naturally lead to the conclusion that in liquid sulfur dioxide those reactions are advantageous in which cations or carbonium ions play the principal role, while the reactions of anions or carbanions are retarded or inhibited by strong interaction with liquid sulfur dioxide. In general, the reaction of $\rho<0$, (ρ is a constant in Hammett's relation, $\log k/k_0=\rho\sigma$[8]), is very much favored in liquid sulfur dioxide, as is seen in the Beckmann rearrangement and in cationic polymerization.[2,3,9]

The purpose of the present article on the esterification of *l*-menthol is to study the solvent effects on the esterification in connection with the elucidation of the solvent effects of the Beckmann rearrangement,[10] since the latter rearrangement consists of two, consecutive steps, viz., the esterification of the oxime and the rearrangement of the oxime ester, as may be illustrated as follows:



(1)

(2)

Alternately, a concerted one-step mechanism may also be considered:

(3)

When the rearrangement follows the consecutive processes 1 and 2, the solvent effects of the esterification may have an important bearing and influence if the rate-determining step is the esterification of the oxime. The solvent effects of the rearrangement step have already been discussed.[1] It has been believed that, in liquid sulfur dioxide, an acyl halide such as acetyl chloride is partly ionized, such as:

$$CH_3COCl = CH_3CO^+ + Cl^- \quad (4)$$

as has been evidenced by the cationic polymerization of styrene with acetyl chloride as an initiator in liquid sulfur dioxide. Thus the esterification of an alcohol in liquid sulfur dioxide by acyl halide is expected to proceed with an unusual rapidity.

l-Menthol was chosen as the alcohol because of the convenience of its kinetic rate measurement by polarimetry. Acetyl chloride was used as the acylating agent. As was expected, the esterification rate in liquid sulfur dioxide was the largest among the solvents used.

Experimental

Materials. — The commercial *l*-menthol was used without further purification, m. p. 41.5~43°C, $[\alpha]_D^{25}$ in benzene=47.6°. Acetyl chloride was distilled, and a fraction with a b. p. of 52.0~53.0°C was used. Liquid sulfur dioxide was dried with phosphorus pentoxide and distilled. The other solvents were purified by the authorized methods as indicated in a previous paper.[1]

Polarimetry.—A Shimadzu Lippich II-type polarimeter with a sodium lamp (D-line, 589.2 mμ) in a thermostat was used. A pressure cell about 2.2 dm. long and 10 mm. in diameter and equipped with a needle valve on its center was used for the measurement of the rate in liquid sulfur dioxide (Fig. 1). An ordinary polarimetry cell was used for the measurement in other solvents. As the initial concentration, 0.45 mole per liter each of *l*-menthol and acetyl chloride was used.

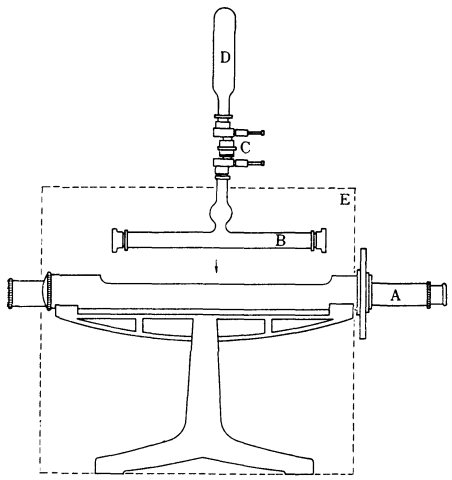

Fig. 1. A polarimeter equipped with a pressure cell.

A: Polarimeter
B: Measuring pressure cell
C: A joint-coupling with two kneedle valves
D: A pressure cell
E: A thermostat

Kinetic Procedure.—The rate of the esterification was followed conveniently by polarimetry. However, the specific rotations of *l*-menthol slightly differed from solvent to solvent.

The esterification is a reversible reaction and generally might be acid-catalyzed, so the reaction rate should be expressed as:

Rate = (Rate of the forward reaction)
− (Rate of the reverse reaction)
+ (Acid catalysis by HCl formed by the reaction)

However, since the over-all yield of the ester after the reaction was over 80~90 per cent and since the catalytic effect of HCl in such non-aqueous solvents was found to be negligibly small (Fig. 2), the rate expression may be simplified to the following equation, especially when the rate is estimated in the initial stage of the reaction. Then the rate is:

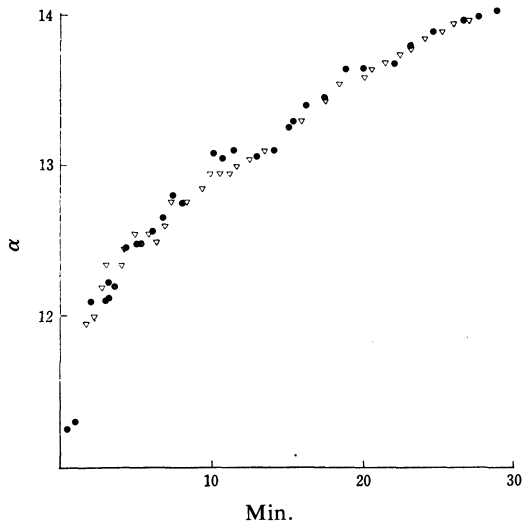

Fig. 2. Effect of HCl concentrations on the reaction rate.
● HCl 0.926 mol./l. ▽ HCl 0.501 mol./l.
liq. SO_2 38.38 mol. % SO_2-CCl_4 system

$$\text{Rate} = dx/dt = k(a-x)^2 \quad (5)$$

where equimolar initial concentrations, a, of *l*-menthol and acetyl chloride were used, k is the second order rate constant, and x is the concentration of the ester at time t. Equation 5 is integrated to Eq. 6:

$$1/(a-x) - 1/a = k \cdot t \quad (6)$$

We can assume, at $t=0$, $\alpha_0 = a \cdot [R]_A^\circ \cdot l$, and $t=t$, that $\alpha_t = (a-x) \cdot [R]_A^\circ \cdot l + x \cdot [R]_E^\circ \cdot l$, where l is the length of the cell of the polarimeter in dm., α_0 and α_t are rotations at the times 0 and t, $[R]_A^\circ$ is the molar rotation of *l*-menthol (degree·dm^{-1}·mol^{-1}·l.), and $[R]_E^\circ$ is that of the ester formed. After the completion of the reaction, α_t at the end or α_∞ may be written approximately as:

$$\alpha_\infty = a \cdot [R]_E^\circ \cdot l \quad (7)$$

$$\alpha_\infty - \alpha_t = (a-x) \cdot l \cdot ([R]_E^\circ - [R]_A^\circ)$$

Then:

$$\alpha - x = (\alpha_\infty - \alpha_t)/l \cdot ([R]^\circ_E - [R]^\circ_A) \quad (8)$$

$$a = (\alpha_\infty - \alpha_0)/l \cdot ([R]^\circ_E - [R]^\circ_A) \quad (9)$$

Substituting 8 and 9 in 6, we get:

$$1/(\alpha_\infty - \alpha_t) - 1/(\alpha_\infty - \alpha_0) = k \cdot t/l \cdot ([R]^\circ_E - [R]^\circ_A) \quad (10)$$

The second-order rate constant, k, may be obtained from the slope of a linear plot, $1/(\alpha_\infty - \alpha_t)$ vs. t. An example is shown in Fig. 3. The specific rotations of the alcohol and the ester, $[\alpha_A]^{25}_D$ and $[\alpha_E]^{25}_D$, are listed in Table I.

Table I. Specific rotations in various solvents at 25°C

Solvent	$[\alpha_A]^{25}_D$	$[\alpha_E]^{25}_D$
Dimethylformamide	46.1	72.3
Nitromethane	42.0	76.4
Chloroform	45.1	80.2
Ethylenedichloride	45.5	72.7
Benzene	47.6	73.7

liq. SO_2 100 mol. % $k = 6.95 \times 10^{-2}$ l./mol. sec.

the rate constant by this procedure, the rate constant in liquid sulfur dioxide was obtained by the following extraporation. A variety of mixtures of liquid sulfur dioxide in carbon tetrachloride were prepared, and the rates in these mixtures were estimated. The log·k's vs. the molar per cents of sulfur dioxide concentrations-plots were strictly linear, and the line was extrapolated to the 100 per cent sulfur dioxide to obtain the rate constant, k, in liquid sulfur dioxide. The rates of the esterification in other solvents were directly measured by the above procedure; the results are listed in Table II, together with the values of liquid sulfur dioxide.

Table II. The second-order rate constants of the esterification at 25°C *l*-Menthol and acetyl chloride

Solvent	k, l. mol^{-1} sec^{-1}
Dimethylformamide	2.66×10^{-3}
Nitromethane	2.17×10^{-3}
Chloroform	1.26×10^{-3}
Ethylenedichloride	8.61×10^{-4}
Benzene	3.56×10^{-4}
Toluene	3.47×10^{-4}
Acetonitrile	2.85×10^{-4}
Ethyl methyl ketone	6.27×10^{-5}
Tetrahydrofuran	5.05×10^{-5}
Liq. SO_2	6.95×10^{-2}
Carbon tetrachloride	0

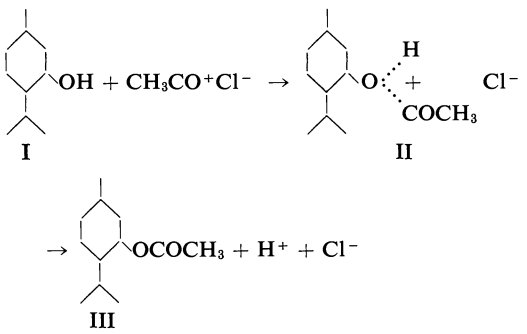
Results and Discussion

The solvent effects of the esterification of *l*-menthol with acetyl chloride have been shown in Table II. The rate was the largest in liquid sulfur dioxide. Moreover, the order of the specific rates in the respective solvents

is similar to that in the case of the Beckmann rearrangement. The orders are:
Esterification:

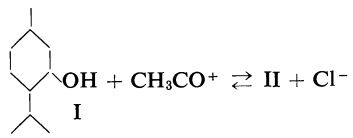
Liq. SO_2 > Dimethylformamide> Nitromethane> $CHCl_3$> Ethylenedichloride> Benzene> Toluene> Ethyl methyl ketone> Tetrahydrofuran> CCl_4

Rearrangement:[9]



Liq. SO_2 > CH_3OH > CH_3COOH> Nitromethane> Ethanol> CH_3CN> Pyridine> $CHCl_3$> Acetone> Ethylenedichloride> Ethyl methyl ketone> CCl_4

As a control experiment, the optical stabilities of *l*-menthol and *l*-menthyl acetate in each solvent have also been examined. These materials were both optically stable in any solvent used for the experiment at 25°C.



No catalytic effect of hydrochloric acid on the reaction rate was observed (Fig. 2). The lack of acid catalysis may be accounted for by the observation that the dissociation of hydrochloric acid in liquid sulfur dioxide and in a non-aqueous solvent is very small as compared to that in water and may be presumed to result in triplet- or multiplet-ion formation.[10] Although the esterifications obey a strictly second-order rate law within the experimental limitations, the mechanism of the reaction may differ somewhat according to the nature of the solvent.

In a solvent such as liquid sulfur dioxide, acetyl chloride may ionize to acetylium cation and chloride anion as in Eq. 4, though the degree of the dissociation may not be very large. A *bare* (unsolvated) acetylium ion is to be expected in this case, while chloride anion may be strongly solvated by liquid sulfur dioxide. Thus, the rate-determining attack of the acylium ion on the oxygen atom of the alcohol is facile and effective. In Scheme 1, if the rate-determining step is the formation of intermediate II, the step of expelling a proton from II being very fast, the reaction rate must be determined by the effective concentration of the acylium cations. In liquid sulfur dioxide, the reaction rate is very large since a *bare* cation, viz., a free cation not solvated by the solvent, is thought to be available and the effective concentration of the cations is assumed to be the largest.

On the other hand, ethyl methyl ketone and tetrahydrofuran are solvents in which the cations or the carbonium ions are strongly solvated by the solvents; thus the effective concentration of the cations is rather depressed. Nitromethane, chloroform, ethylenedichloride, benzene and toluene rank midway between these two kinds of solvents. It is interesting that, in dimethylformamide, the reaction is also rapid in spite of the nucleophilicity of this solvent. A different reaction mechanism may be considered, though a second-order rate law still holds. One possibility is that a rate-determining proton abstraction, preceded by an equilibrium of the formation of II (Scheme 2), is very easy in dimethylformamide.

Scheme 1

Scheme 2

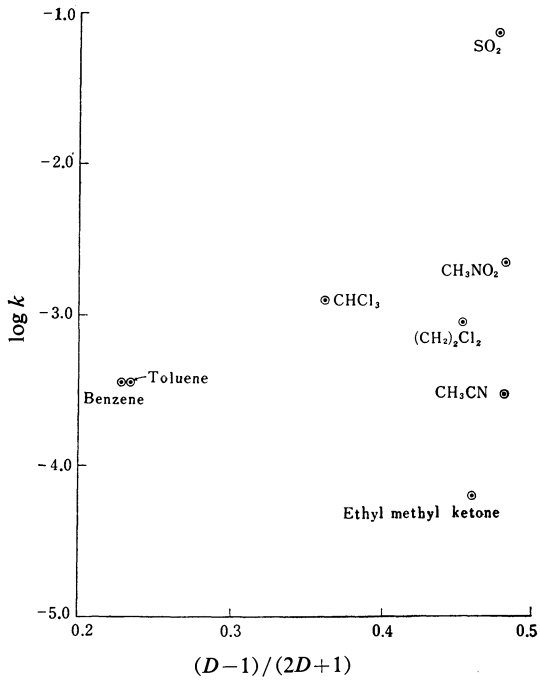


Fig. 5. Log k vs. $(D-1)/(2D+1)$ plots.

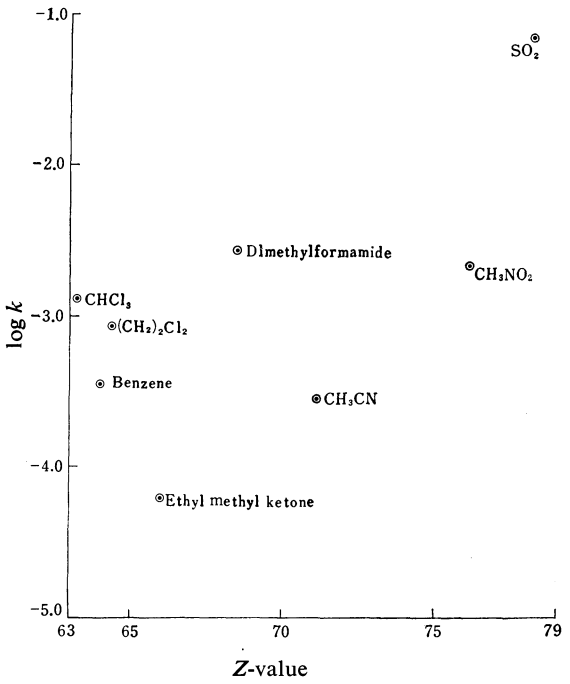

Fig. 6. Relationship between log k and Z-value.

The rate constants in various solvents vs. the ionizing powers (such as the dielectric constants and Z-values) of the solvents-relations, were further examined, as is illustrated in Figs. 5 and 6. The plots of log·k vs. $(D-1)/(2D+1)$ or Z-value[11] resulted in complete randomness, without any linear correlation.

Summary

The solvent effects of the esterification of *l*-menthol with acetyl chloride in various solvents have been examined polarimetrically. In liquid sulfur dioxide, the rate of the esterification was the fastest among the solvents used. A *bare* carbonium ion formation in liquid sulfur dioxide may be the reason for this. The comparably large rate in dimethylformamide has also been discussed, along with the solvent effects in various other solvents.

The authors are indebted to the Seitetsu Kagaku K. K. for the gift of liquid sulfur dioxide.

The Stability Constants of the Palladium, Copper, Nickel, Zinc and Manganese Chelates of 3-Hydroxy-3-phenyl-1-o-tolyltriazene and -1-p-tolyltriazene

By D. N. PUROHIT and N. C. SOGANI

(Received February 14, 1964)

In a previous communication,[1] the stabilities of the palladium, copper, nickel, zinc and manganese chelates of 3-hydroxy-3-phenyl-1-*p*-chlorophenyltriazene have been reported. The present investigation will deal with the influence of methyl groups at ortho and para positions of the parent compounds upon the stabilities of the metal chelates formed by them.

Experimental

Solutions of the Chelating Agents.—3-Hydroxy-3-phenyl-1-*o*-tolyltriazene and 3-hydroxy-3-phenyl-1-*p*-tolyltriazene were prepared by employing the method of Sogani et al.[2,3] Weighed amounts of these compounds were dissolved in a 70% v/v dioxane-water mixture, and the solution was diluted to give a 0.04 M solution. Solutions of 0.002 M palladium, copper, nickel, zinc and manganese ions and 0.02 M sodium hydroxide were prepared by usual, classical methods.

Potentiometric Titration. — Ten milliliters of a 0.04 M chelating agent solution in a 70% v/v dioxane-water mixture were pipetted in a titration vessel. A sufficient amount of 0.02 M nitric acid was added to it to lower the pH to about 2. The final ionic concentration was maintained at 0.1 M

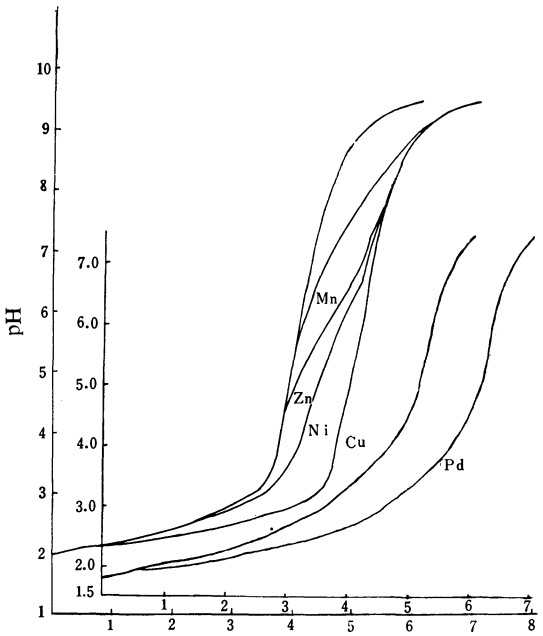

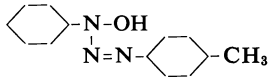

Fig. 1. Titration curves for

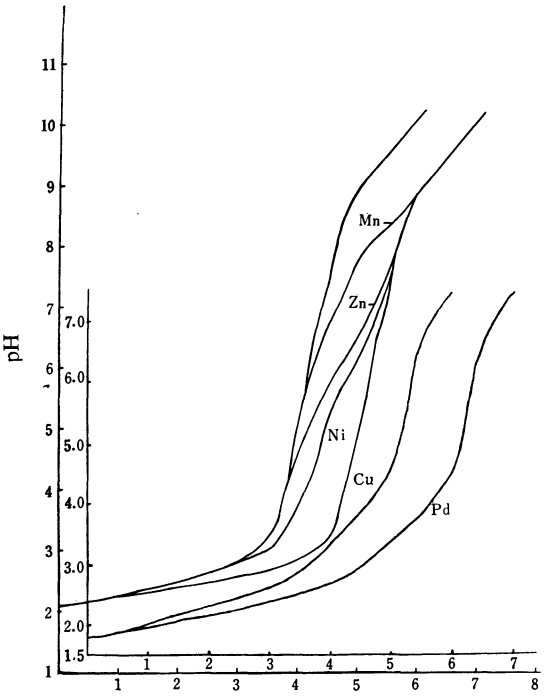

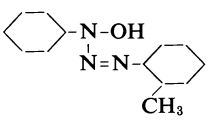

Fig. 2. Titration curves for

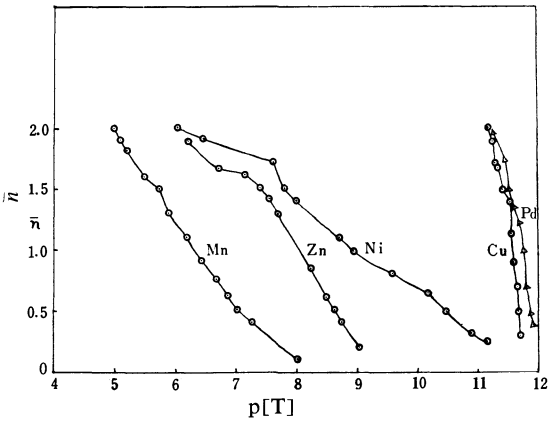
by adding 2.5 ml. of 2 M potassium chloride. When titrating in the presence of metal ions, 5 ml. of a 0.002 M metal solution were added at this stage. The total volume of the contents was increased to 50 ml. by adding varying amounts of dioxane and distilled water in such proportions that it finally became a 70% v/v dioxane-water mixture. It was then titrated against 0.02 M sodium hydroxide. The temperature of the solution throughout the titration was maintained at 25±0.5°C. The titration curves are given in Figs. 1 and 2.

Calculations. — The pK_a values of 3-hydroxy-3-phenyl-1-*o*-tolyltriazene and 3-hydroxy-3-phenyl-1-*p*-tolyltriazene have been determined spectrophotometrically as 11.55 and 11.78 respectively. These values were used for calculating free chelating ion concentrations at different pH values. The values of $\bar{n}$ were calculated as has been described earlier.[1] The formation curves for metal chelates are given in Figs. 3 and 4. The values of log k_1 and log k_2



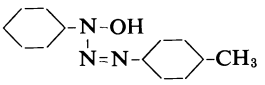


Fig. 3. Formation curves for metal chelates of

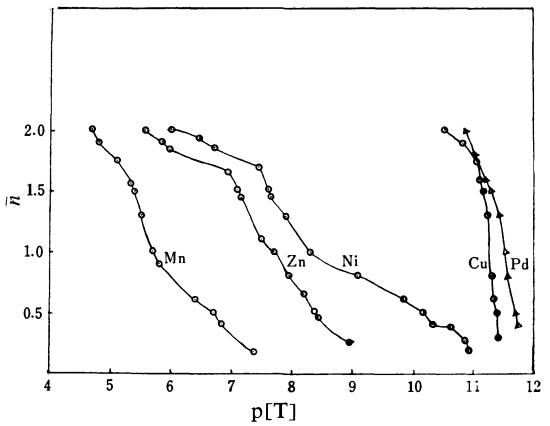

Fig. 4. Formation curves for metal chelates of

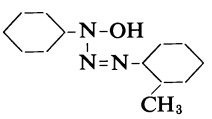

TABLE I. THE STABILITY CONSTANTS OF THE METAL CHELATES OF 3-HYDROXY-3-PHENYL-1-*o*-TOLYLTRIAZENE AND 3-HYDROXY-3-PHENYL-1-*p*-TOLYLTRIAZENE

Metal	3-Hydroxy-3-phenyl-1-*o*-tolyltriazene		3-Hydroxy-3-phenyl-1-*p*-tolyltriazene	
	$\log\beta_1$ ($\log k_1$) (first stability const.)	$\log\beta_2$ ($\log k_1k_2$) (over all stability const.)	$\log\beta_1$	$\log\beta_2$
Palladium	11.70	22.97	11.89	23.35
Copper	11.35	22.47	11.69	23.09
Nickel	10.17	17.76	10.46	81.23
Zinc	8.38	15.46	8.62	15.99
Manganese	6.68	12.07	7.02	12.74

for different metal chelates were read directly from the formation curves; they are given in Table I.

Discussion

An examination of the titration curves will show that curves for hydroxytriazenes in the presence of metal ions lie considerably below the simple chelating agent curves. This is due to the liberation of hydroxytriazene protons during complex formation. The chelate formation of palladium starts at pH 1.9; that of copper, at pH 2.0; that of nickel, at pH 2.6; that of zinc, at pH 4.5, and that of manganese, at pH 5.7. This corresponds to the order of stabilities of the hydroxytriazene chelates of these metals.

For the sake of simplicity, only the stabilities of palladium chelates with different hydroxytriazenes are discussed. A comparison of the values of the overall stability constants of the palladium chelates of para-chloro-substituted (reported earlier, $\log\beta_2=20.95$), ortho- and para-methyl-substituted ($\log\beta_2=22.97$ and 23.35 respectively) with the parent hydroxytriazene[3] ($\log\beta_2=22.66$) reveals that, while the chloro substitution lowers the stability of the resulting chelate, the methyl substitution increases it. The $-$I effect of the halogen lowers the pK_a value of the chloro-substituted hydroxytriazene (pK_a of parent compound $=11.41$, and chloro-substituted, $=10.72$) and hence the stability of its metal chelates.

The stabilities of the chelates given by methyl-substituted compounds are higher than those of the parent hydroxytriazene. This is due to the +I effect (electron pushing) of the methyl group. A hyperconjugation effect for the methyl group would have a similar effect. The hydroxytriazene with a methyl group at the ortho position should have been a weaker acid and formed more stable complexes than its para isomer because of the nearness of the +I effect of the group on –OH-bearing nitrogen atoms. However, the contrary is true. The greater acidity and lesser stability of the chelates of the ortho isomer compared to the para isomer are due to the ortho effect of the methyl group.

Summary

The stabilities of the palladium, copper, nickel, zinc and manganese chelates of 3-hydroxy-3-phenyl-1-*o*-tolyltriazene and 3-hydroxy-3-phenyl-1-*p*-tolyltriazene have been determined in a 70% v/v dioxane-water mixture and at an ionic strength of 0.1 M potassium chloride, by employing the Bjerrum-Calvin pH titration technique.

*The Preparation of Phosphorus-32 in a High Specific Activity Using the Szilard-Chalmers Effect**

By Kichizo TANAKA

(Received February 17, 1964)

It is desirable that reference sources of radioactive isotope be of a high purity and also of a high specific activity, particularly in the case of β-ray emitters. In the case of phosphorus-32, the carrier-free source has usually been prepared by the (n, p) reaction on a sulfur target. However, this source is often contaminated with a considerable amount of phosphorus-33, which is produced by the (n, p) reaction on the sulfur-33 in the target. It is possible to prepare phosphorus-32 free from phosphorus-33 by the use of the (n, γ) reaction of phosphorus-31; however, its specific activity is considerably less than the product of the (n, p) reaction.

The Szilard-Chalmers process is considered to be an effective method for preparing phosphorus-32 of a high specific activity, which then furnishes a stock solution for the preparation of the reference sources. In this paper the process for the preparation of phosphorus-32 in a high specific activity using the Szilard-Chalmers effect will be studied with several inorganic phosphorus compounds.

Experimental

Target Materials. — The sodium dihydrogen phosphate, disodium hydrogen phosphite and sodium hypophosphite used were guaranteed reagents from the Wako Chemicals Co. The disodium hydrogen phosphate, potassium dihydrogen phosphate, dipotassium hydrogen phosphate and tripotassium phosphate were guaranteed reagents from the Kanto Chemicals Co. Each of these hydrated salts was dehydrated, dried, and analyzed as has been previously reported.[1]

Neutron Irradiation.—The salts were irradiated in the JRR-1 reactor (a water-boiler type, operated at 40 kW.). The salts, sealed in a polyethylene tube in the presence of air, were irradiated at an ambient reactor temperature. After irradiation, the samples were stored in a Dewar vessel cooled with dry ice for about one week.

The Preparation of the Ion Exchange Resin Column. — Strongly basic anion exchange resin (Diaion SA 100, 100~200 meshes) was washed with a large excess of concentrated hydrochloric acid and redistilled water and was then made into a column 0.8 cm. in diameter and 10 cm. long. The column was washed with 50 ml. of a chloride solution (eluting agent I in Fig. 1) before use.

Separation Procedure. — The irradiated sample was dissolved in an equimolar mixture of a 0.025 M potassium chloride solution and 0.025 M hydrochloric acid, and the concentration of the sample was made 0.1 M. In order to find the best conditions for separating orthophosphate and pyrophosphate ions, the following items were studied: the concentrations andmixing the ratio of the chlorides, the concentration of the irradiated salt in the sample solution, and the composition of the eluting agent. The separation of complex phosphate mixtures by the ion exchange method has been studied by several other workers,[2-7] and several different procedures have been proposed. However, in the present experiment, some improvement of the separation process was necessary because trace amounts of complex polyphosphate ion had to be separated from a large amount of orthophosphate, orthophosphite or hypophosphite ions. From the orthophosphate containing a trace amount of pyrophosphate ions, e. g., 1 μM of pyrophosphate in 0.1 M of orthophosphate, the pyrophosphate was

TABLE I. VOLUME OF THE ELUTING AGENT I REQUIRED FOR COMPLETE ELUTION OF ORTHOPHOSPHATE IONS

cleanly separated by eluting it with 0.025 M of an equimolar chloride mixture solution. To avoid the incomplete separation between orthophosphate and pyrophosphate ions caused by the tailing of the former, the total aliquot of the sample solution was made 10 ml. per column for each run. The tailing of orthophosphate ions was influenced by the concentration of irradiated salt in the sample solution and the volume of the sample solution, as is shown in Table I. The overall separation procedure is shown in Fig. 1. It was

found that when orthophosphate, orthophosphite or hypophosphite containing trace amounts of pyrophosphate and higher polyphosphate ions in a chloride solution was passed through the column, the pyrophosphate and higher polyphosphates were adsorbed on the resin column, while the orthophosphate, orthophosphite and hypophosphite ions were completely eluted with 60 ml. of the chloride solution. The adsorded polyphosphate ions were eluted with an 8 M hydrochloric acid solution.

The Chemical Analysis of Phosphorus.—For the analysis of phosphorus, the sample solution was evaporated to fuming with sulfuric acid after the addition of 5 ml. of concentrated nitric acid, 1 ml. of 40% perchloric acid, and 0.5 ml. of concentrated sulfuric acid. The residual sulfuric acid solution was then diluted to a 1 N acid solution. The trace amounts of phosphorus were analyzed by the colorimetry reported by Gaitanis.[8] The ammonium phosphomolybdate, formed by the addition of ammonium molybdate to the pretreated sample solution in 1 N sulfuric acid, was extracted with benzene. The solvent phase extracted was shaken with a stannous chloride solution, and the absorbancy of the solvent phase was measured at 735 mμ. The macroamounts of phosphorus, on the other hand, were analyzed by gravimetry with an ammonium phosphomolybdate precipitate.

8) M. J. Gaitanis, "Master Analytical Manual," Section 1-12, TID-7015 (1957).

Radioactivity Measurements.—The sample solution was evaporated in a glass planchet 2.5 cm. in diameter and was counted with a thin-end window-type G. M. gas flow counter. The decay rate was measured by the G. M. counter in its constant geometry. The 2π-β counter, whose efficiency was corrected by a 4π-β counter for phosphorus-32 activity, was used for the absolute measurement of phosphorus-32 activity. In this absolute measurement, small portions of the sample solution were dropped on a stainless steel disk covered with a thin Ducocement film, weighed, evaporated to dryness, and counted.

Results and Discussion

The distribution of the chemical species containing phosphorus-32 in neutron-irradiated phosphorus compounds has been studied by many workers,[9-23] and also the fragmentation of chemical species induced by the thermal neutron capture of phosphorus-31 in phosphates has been discussed. However, many questions still remain. In the present experiment, it was found that phosphorus-32 could be recovered in the polyphosphate fraction with specific activities considerably higher than those of the original irradiated salts, such as orthophosphates, orthophosphite, or hypophosphite.

The recoveries and enrichment factors obtained by the ion exchange method for several irrradiated samples are shown in Table II. All the samples were irradiated for 2 hr. in the same capsule in the pneumatic tube (the nominal neutron flux, 0.64×10^{12} n./cm^2·sec.) of the JRR-1. Each value shown in the table is the average of three separate experiments. It may be seen in the table that the recovery is higher for the orthophosphates, except tripotassium phosphate, than those for sodium orthophosphite and sodium hypophosphite. The residual activity in the resin

in unirradiated samples was also separated by the ion exchange method, and the phosphorus amounts in the polyphosphate fraction were determined by colorimetry. The amount of phosphorus per gram of sample adsorbed on the resin column, which was detected as the polyphosphate fraction, is shown in Table IV for the unirradiated samples. There was not much difference between the amounts adsorbed on the resin column for the unirradiated and irradiated samples. However, the amount of the polyphosphate formed by neutron irradiation in a reactor seemed to be of the order of the values to be expected from the results

24) K. Tanaka, This Bulletin, 37, 1032 (1964).

recovery was not much affected by the irradiation time for several orthophosphates in the time range of 30 min. to 15 hr.

The product obtained by treating the potassium dihydrogen phosphate was evaporated to dryness, and an analysis of the radiochemical purity was made. The gross decay curve was measured for the time more than ten times the half life of phosphorus-32. The decay rate for the curve was constant and was exactly the same as for phosphorus-32 (14.3 day). The absorption curves of radiation with an aluminum disk were also obtained for this product. The curves obtained 150 days after irradiation were compared with those 20 days after irradiation. The two curves were the same. No weak β-ray emitters could be detected for the product.

The products thus prepared were radiochemically pure, no gamma ray peaks were observed by scintillation spectrometry with a NaI crystal, and the total solids which were detected after the evaporation of the product solution were less than 0.1 mg./ml. The specific activity higher than 1 mc./mg. could be prepared, even in irradiations of total neutrons of approximately 2×10^{15}.

Summary

A process has been developed for obtaining phosphorus-32 free from phosphorus-33 and with a high specific activity. Phosphorus-32 has been prepared by an anion exchange method, in which a chloride solution containing 0.025 M of potassium chloride and 0.025 M of hydrochloric acid of neutron irradiated phosphate was passed through the column of a strongly basic anion exchanger, and the adsorbed phosphorus-32 has been eluted with 8 M hydrochloric acid. The anhydrous orthophosphate shows a good recovery compared with several orthophosphates, sodium orthophosphite and sodium hypophosphite. The recovery is not much affected by the irradiation time. Enrichment factors higher than 10^3 have been obtained.

The Polarographic Determination of Divalent Tin in Sodium Formate

By G. S. DESHMUKH and S. V. S. S. MURTY*

(Received April 8, 1964)

Heyrovsky,[1] Kalousek[2] and Lingane[3] have recommended 1 molar sodium hydroxide as a supporting electrolyte for the polarographic determination of stannous tin. In this medium, Sn^{2+} gives both anodic and cathodic waves. Well-defined cathodic and anodic polarograms of stannous tin in an acetic acid - ammonium acetate buffer have been adopted for the determination of the element by Pribil[4] and Desesa[5]. The use of sodium citrate, sodium hydroxide and alkali tartrate solutions as supporting electrolytes has been indicated by Kalousek,[2] Shakhov[6] and Lingane[7]. In the latter case the half-wave potential of the anodic polarogram was found to be dependent on the pH of the solution, on the concentration of sodium tartrate, and on that of stannous tin. The symmetry of the wave was also affected by the above parameters. However, the half-wave potential of the cathodic polarogram was constant under these conditions.

A similar type of polarographic behaviour of stannous tin in sodium formate has now been observed. It has already been mentioned that

stannous tin yields well-defined anodic and cathodic polarograms in sodium formate.[8] The behaviour of the anodic polarogram of tin is of considerable importance for its determination in the presence of other metallic elements with which it is commonly associated. The present investigation was, therefore, undertaken to obtain detailed information about the polarographic characteristics of stannous and stannic complexes in sodium formate media.

Experimental

The polarograms were recorded at 25±0.1°C with a Leeds and Northrup Electrochemograph, type E; the capillary characteristics with the open circuit were $m=3.09$ mg./sec. and $t=3$ sec. The pH of the solution was measured with a line-operated Beckmann Zeromatic pH meter.

Sodium formate of a pure-reagent-grade quality was used to prepare solutions of the desired strength. Stannous chloride solution was prepared by dissolving pure metallic tin in the requisite quantity of concentrated hydrochloric acid and storing the solution in an inert atmosphere. Nitrogen was bubbled through the solutions in order to deaerate them and the inert atmosphere was maintained to prevent the oxidation of stannous tin while the polarograms were being recorded. Freshly-prepared gelatin was used as the maximum suppressor. The pH of the solution was adjusted by means of pure formic acid.

Results and Discussion

Effect of pH.—Table I shows that the pH exerts profound effect on the half-wave potentials of the anodic polarogram. The anodic half-wave potential became more positive as the pH was decreased from 3.7 to 3.1. As the pH increased from 3.1, however, the anodic polarogram was characterized by a drawn-out wave which finally merged with the initial plateau of the cathodic polarogram at pH 5.2. The half-wave potential of the cathodic polarogram was not altered with the change in pH.

TABLE I. EFFECT OF pH ON DIVALENT TIN POLAROGRAMS

Formate concn., 1 M Gelatin, 0.005%
Concn. of Sn^{2+}, 1.584 mg.

Sample No.	pH	$E_{1/2}$, V. vs. SCE	
		Anodic	Cathodic
1	3.1	−0.17	−0.56
2	3.3	−0.185	−0.56
3	3.5	−0.195	−0.56
4	3.7	−0.23	−0.56
5	5.2	Anodic wave merged with cathodic wave	

Effect of Formate Concentration.—Variation in the formate concentration has an appreciable effect on the half-wave potential of the anodic and cathodic polarograms of stannous tin. The half-wave potential of the anodic polarogram shifted to negative potentials with the increase in the formate concentration, thus showing the formation of a more stabilized complex. The $E_{1/2}$ of the cathodic polarogram was, however, shifted to negative potentials, this shift being comparatively much less pronounced than that observed with the anodic polarogram. The diffusion current of both the polarograms was suppressed with the increase in formate concentration, especially above 1.5 M; this might be due to the increased viscosity of the medium. The results are reported in Table II.

TABLE II. EFFECT OF FORMATE CONCENTRATION ON Sn^{2+} POLAROGRAMS

pH ~3.5 Gelatin, 0.005%
Concn. of Sn^{2+}, 1.584 mg.

Sample No.	Concn. of formate M	$E_{1/2}$, V. vs. SCE	
		Anodic	Cathodic
1	0.3	−0.13	−0.525
2	0.5	−0.155	−0.54
3	1.0	−0.185	−0.555
4	1.5	−0.19	−0.575
5	2.0	−0.215	−0.59
6	2.5	−0.23	−0.605

Effect of Stannous Tin Concentration.—The anodic half-wave potential shifted to positive potentials with the increase in stannous tin concentration. For example, with 1 molar sodium formate and at pH 3.0 with 0.005% gelatin, the anodic half-wave potentials of 0.514, 1.028, 2.056, 3.084 and 4.112 mM were, respectively, −0.185, −0.175, −0.15, −0.09 and −0.035 V. vs. SCE. On the other hand, the cathodic half-wave potential in the above experiments remained constant at −0.57 V. (cf. Fig. 1).

These results indicate that the oxidation of the stannous formate complex was thermodynamically irreversible at the dropping electrode. The irreversibility was confirmed by investigating polarograms of stannic tin in formate media. In formate solutions stannic tin does not show a reduction wave, whereas, if the stannic-stannous system is reversible, a reduction wave would be observed with stannic formate solutions at the same potential at which the anodic wave occurs with the stannous formate solutions. The irreversibility of the

8) G. S. Deshmukh and Y. D. Kane, *J. Sci. Ind. Research*, **21B**, 135 (1962).

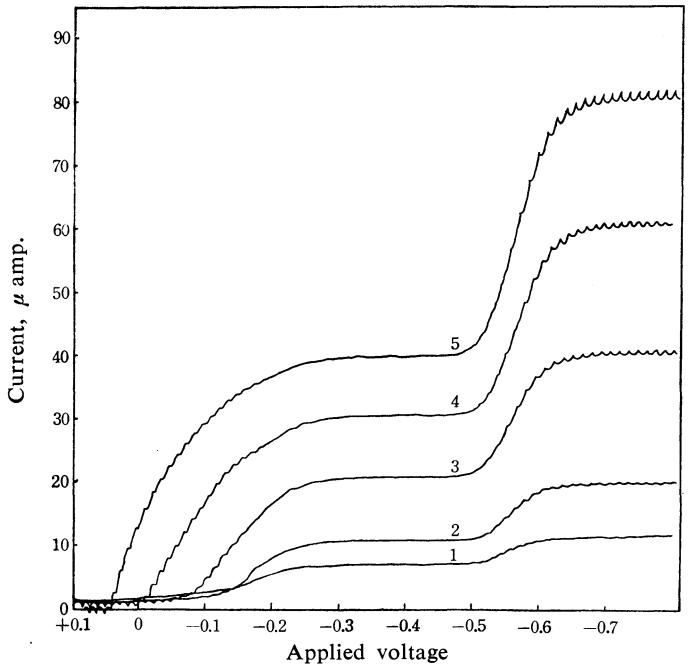

Fig. 1. The polarograms of (1) 0.514 (2) 1.028 (3) 2.056 (4) 3.084 and (5) 4.112 mM Sn^{2+} in 1 M sodium formate. pH=3.0 Gelatin=0.005%

anodic polarogram was also increased with the concentration of Sn^{2+}, as is evidenced by the increase in the difference between $E_{3/4}$ and $E_{1/4}$. Thus, with 1 molar formate at pH 3.0 with 0.005% gelatin, the difference between $E_{3/4}$ and $E_{1/4}$ of the anodic polarogram of 1.028, 2.056, 3.084 and 4.112 mM was 60, 80, 100 and 120 mV. vs. SCE respectively, but for the cathodic polarogram it was constant, the values always being 50 mV. For a thermodynamically-reversible wave, the expected value should be 28 mV. This shows that the cathodic wave was also irreversible.

Calibration curves were drawn with 1 molar sodium formate at pH 3.0±0.1. It was observed that the diffusion current was directly proportional to the concentration of tin for both the anodic and cathodic polarograms between 10^{-5} to 10^{-4} M.

Summary

Well-defined cathodic and anodic polarograms of stannous tin in sodium formate have been reported. The diffusion current is directly proportional to the concentration of stannous tin between 10^{-5} to 10^{-4} M. The anodic half-wave potential of tin is shifted to positive values with the increase in the concentration of Sn^{2+}, whereas the cathodic half-wave potential is constant. The anodic polarogram is highly irreversible. The cathodic polarogram is also irreversible. The irreversibility of the anodic polarogram is increased with the concentration of stannous formate. This is evidenced by a corresponding increase in the difference between $E_{3/4}$ and $E_{1/4}$. Above pH 5.0 the anodic polarogram merges with the cathodic polarogram, thereby limiting the polarographic determination of Sn^{2+} to the pH value 3～5. The $E_{1/2}$ of the anodic polarogram shifts to negative potentials when the pH was increased, whereas that of the cathodic wave is constant. The polarogram with equal wave heights obtained in 1 molar sodium formate at pH 3.0 with 0.005% gelatin has been taken for the determination of tin.

Sincere thanks of the authors are due to Professor G. B. Singh for providing the necessary facilities.

Studies of Ammonium Dioxovanadium(V) Bisoxalate Dihydrate

By D. N. SATHYANARAYANA and C. C. PATEL

(Received April 7, 1964)

Complexes of vanadium containing VO_2^+ are rare. Ammonium dioxovanadium(V) bis-(oxalate) tetrahydrate was prepared by Rosenheim[1] by treating an ammonium oxalate solution with vanadium pentoxide; his compound was said to be remarkably stable. Although this oxalato complex has been known since 1893, its physico-chemical properties, except the conductivity of its aqueous solution,[2] have not been investigated. During the course of our investigations of oxovanadium(IV) complexes, it was thought desirable to study some properties of the ammonium dioxovanadium-(V) bis(oxalate) complex and to assign it a structure.

Experimental

Materials Employed.—The oxalic acid dihydrate, ammonium oxalate monohydrate and ammonium meta-vanadate were of reagent grade. Vanadium pentoxide was prepared by heating ammonium meta-vanadate (A. R.) at 450°C for about 2 hr.

Preparation.—When a solution of ammonium oxalate is boiled with vanadium pentoxide,[1] ammonium dioxovanadium(V) bis(oxalate) is not easily obtained. Hence, an easy method was developed to prepare the complex from ammonium meta-vanadate on the basis of the following possible reaction:

$$NH_4VO_3 + H_2C_2O_4 + (NH_4)_2C_2O_4 \rightarrow (NH_4)_3[VO_2(C_2O_4)_2] + H_2O$$

When calculated amounts of oxalic acid and ammonium oxalate were added to an aqueous solution of the metavanadate so that the molar ratio of $NH_4VO_3 : H_2C_2O_4 : (NH_4)_2C_2O_4$ was 1 : 1 : 1, a quick reaction occurred, giving a deep yellow solution. An excess of oxalic acid has to be avoided to prevent the reduction of pentavalent vanadium. A drop or two of dilute hydrogen peroxide was added to prevent any reduction of vanadium(V). The solution was warmed on a water bath to decompose the hydrogen peroxide and filtered through a sintered glass funnel. The filtrate was concentrated by passing a current of dry air at room temperature; when yellow crystals were obtained in about two days. The crystals were separated from the mother liquor and recrystallized from water. The crystals were then air-dried and analysed.[3]

Vanadium was estimated by igniting a known amount of the complex (about 200 mg.) to vanadium pentoxide, the oxalate by oxidation with potassium permanganate and ammonia by its liberation with aqueous alkali. The water was determined by the weight loss of the complex over anhydrous phosphorus pentoxide in a vacuum The V_2O_5, $C_2O_4^{2-}$, NH_4^+ and H_2O found were 26.1, 50.0, 15.1 and 10.2% respectively, while the corresponding calculated values for $(NH_4)_3[VO_2 \cdot (C_2O_4)_2] \cdot 2H_2O$ are 26.07, 50.42, 15.51 and 10.32% respectively. Thus, the complex obtained is a dihydrate and not the tetrahydrate.[1]

The complex is highly soluble in water, but insoluble in most of the organic solvents. When the complex was kept over fused calcium chloride, it lost both the molecules of water, giving a pale yellow powder. The complex is highly susceptible to reduction by oxalic acid and acid vapours. Ion-migration experiments in an aqueous solution indicated that vanadium was present wholly in the anion. The molecular weight determination in aqueous solutions by Beckmann's cryoscopic method showed that the complex dissociated into four ions.

Apparatus.—*Magnetic Susceptibility.*—The magnetic susceptibilities of the powdered samples were determined by the Gouy method[4] at room temperature, using $Hg[Co(NCS)_4]$ as the calibrant.

Thermal Studies.—The thermal behaviour of the complex was studied by both the differential thermal (DTA) and thermogravimetric (TGA) analyses. The DTA studies were carried out by a standard manual apparatus[5] using chromel-alumel thermocouples. The powdered samples (200 mg.) were pyrolysed at a heating rate of 8±1°C per minute in atmospheric air. The TGA studies were carried out with a quartz spring balance using 150~160 mg. of the substance, the rate of heating being maintained at 3°C per minute.

Absorption Spectral Studies.—The electronic spectrum of an aqueous solution of the complex was studied with a Hilger-Uvispek spectrophotometer, model H 700, using a pair of 1 cm. matched quartz cells. The infrared spectrum of the complex in Nujol mull was taken with a double-beam Perkin-Elmer Infracord spectrophotometer, model 137, employing sodium chloride optics.

Results and Discussion

The magnetic susceptibility measurements indicated the compound to be diamagnetic, showing the pentavalent oxidation state of vanadium. The diamagnetic susceptibility found was $\chi = -0.51 \times 10^{-6}$ c. g. s. units.

The Thermal Behaviour of the Complex.—The differential thermogram of the complex is given in Fig 1. The small endothermic peak at 75°C is due to the loss of absorbed moisture. The medium endothermic peak at 125°C in the range from 85 to 145°C is due to the complete loss of two water molecules. The big endothermic peak at 225°C in the 170~270°C range was identified by heating the complex at 200°C for about 15 min. and by then analysing[3] the solid product, which corresponded to ammonium di-oxovanadium-(IV) trisoxalate, $(NH_4)_2[(VO)_2(C_2O_4)_3]$. (Analysis found in %: V_2O_5, 41.3 and $C_2O_4^{2-}$, 61.4, while the calculated % were V_2O_5, 41.94 and $C_2O_4^{2-}$, 60.83). The reaction taking place at 200°C can be represented as follows:

$$2(NH_4)_3[VO_2(C_2O_4)_2] \rightarrow (NH_4)_2[(VO)_2(C_2O_4)_3] + 2CO_2 + 4NH_3 + 2H_2O \quad (1)$$

The complex formed at 200°C is bluish-grey in colour and is paramagnetic, indicating the quadrivalency of vanadium. The complex is soluble in water, giving a bluish-green solution. Recently, it has been shown that europic(III) oxalate gives rise to europous(II) oxalate during the thermal decomposition of the former.[6] A number of other metal oxalato complexes, for example, those of nickel,[7] ferric[8] and plutonium[9], are also known to behave in a similar fashion.

The exothermic peak at 300°C is due to the decomposition of the dioxovanadium(IV) oxalato complex formed, giving rise to vanadium dioxide. This peak is followed by a big exothermic peak, with a maximum at 350°C. This peak was identified as due to the oxidation of vanadium dioxide to vanadium pentoxide.

The percentage-weight-loss vs. temperature curve is given in Fig. 2. The break in the curve corresponding to 170°C shows the completion of the loss of two water molecules from the complex, giving rise to the anhydrous oxalato complex. The anhydrous complex is found to be stable below 200°C. The formation of the intermediate compound $(NH_4)_2 \cdot [(VO)_2(C_2O_4)_3]$ starts from 200°C and is complete near 260°C (loss: 38%). The intermediate compound then starts decomposing, yielding vanadium(IV) oxide. The oxidation of vanadium(IV) oxide to vandium(V) oxide is not clearly shown by the TGA curve, probably because of the small gain in weight and the small contraction of the quartz spring with the increase in temperature.[10]

The Electronic Spectrum of the Complex.—In the ultraviolet region, there is a band below 220 mμ ($\log \varepsilon > 4.5$) and a shoulder at 265 mμ ($\log \varepsilon = 3.9$). These strong absorption

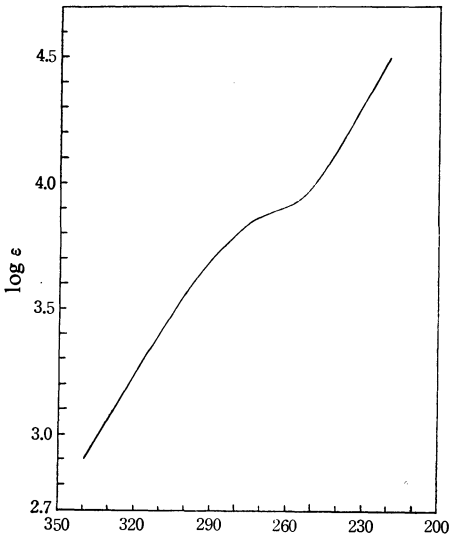

Fig. 3. Electronic absorption spectrum of $(NH_4)_3[VO_2(C_2O_4)_2]\cdot 2H_2O$ in water. Concn., 1×10^{-4} M.

bands can be assigned to the charge transfer arising from the promotion of an electron from the π-orbital of oxygen to the vacant 3d orbitals of the vanadium of the VO_2^+ group. In the oxovanadium complex containing the VO^{2+} ion, there is a band below 220 mμ ($\log\varepsilon=4.0$) and a shoulder at 245 mμ ($\log\varepsilon=3.2$); these are assigned as electron-transfer bands arising from the promotion of an electron from the oxygen π-orbital to the 3d levels of the vanadium of the VO^{2+} ion.[11] In the present complex containing the VO_2^+ ion, the absorption bands have shifted to higher wavelengths with an increase in the intensity. This effect may be due to the presence of another oxygen atom, with a certain amount of π-bonding to vanadium, along the V-O axis and a higher valence state of vanadium in the VO_2^+ ion.

The ultraviolet absorption spectra of a large number of oxalato complexes resemble those of dimethyl oxalate and molecular oxalic acid, with a low intensity band in the 250~270 mμ[12] region. This carboxylate band in the present compound has obviously merged with the intense electron-transfer band occurring in the ultraviolet region. No absorption peak was observed in the visible region, but the ultraviolet absorption band extends up to nearly 400 mμ. The light yellow colour of the compound, therefore, appears to be due to the charge transfer.

The infrared band assignments of the complex are given in Table I. The presence of a strong band around 3550 cm^{-1} indicates crystal lattice water. The strong band at 3080 cm^{-1} is due to the NH stretching of NH_4 groups.[13] The band at 1629 cm^{-1} may be due to the bending of water. The bands arising due to the oxalate group are assigned after Fujita, Martell and Nakamoto.[14] The spectrum shows a very strong absorption at 1720 cm^{-1}, indicating a highly covalent character of the bonds between the metal and the oxalate group.[15]

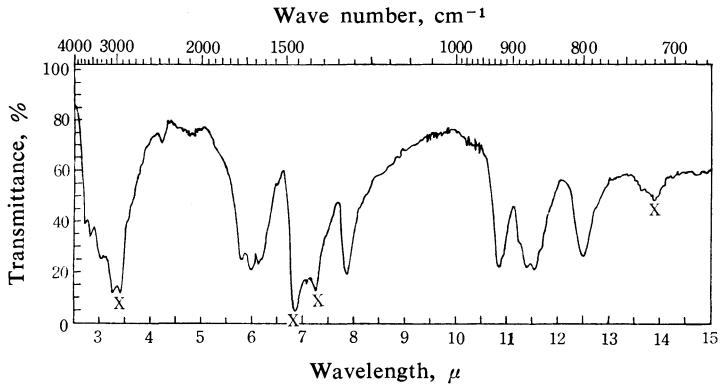

Fig. 4. Infrared spectrum of $(NH_4)_3[VO_2(C_2O_4)_2]\cdot 2H_2O$.

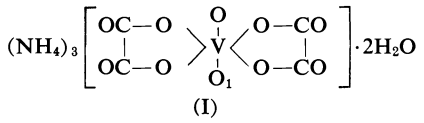

The infrared spectrum of the complex is given in Fig. 4

The band at 924 cm^{-1} is assigned to O–V–O asymmetrical stretching frequency, although it is predominantly a V–O mutiple-bond stretching frequency. Selbin et al.[16] assigned the strong band around 980 cm^{-1} to the V–O stretching in the oxovanadium compounds. It is interesting to note that the V–O stretching in the present complex occurs at a frequency much lower than that of the V–O stretching in hydrated oxovanadium(IV) oxalates (985 cm^{-1}) and in ammonium oxovanadium(IV) bisoxalates (978 cm^{-1}).[16] The lowering of the V–O frequency in the present case is due to the oxygen atom in the sixth position (of an octahedral structure) along the V–O axis, which is vacant in the above oxalates.[16] Such a position of oxygen will have the effect of slightly weakening the V–O bond, with also some reduction in its π-bond character. Nakamoto et al.[17] reported the lowering of the V–O stretching from 995 to 964 cm^{-1} in the solid complexes the addition of one pyridine molecule to oxovanadium(IV) bisacetylacetonate, $VO(acac)_2$.

Another band at 866 cm^{-1}, occurring as a doublet, may be due to the symmetrical stretching of O–V–O. The appearance of this second band may be due to the absence of the centre of symmetry of the O–V–O linear group, as has been suggested in the literature.[18,19]

The Structure of the Complex

Since the two water molecules in the complex are easily lost and since the infrared spectrum does not give any evidence of their being coordinated to the metal atom, they are considered to be lattice-held. Further, the infrared spectrum shows that the oxalate groups are covalently bonded. Hence, a six-coordinated octahedral structure with d^2sp^3 bonding can be assigned to the complex anion (I):

(I)

As there are no d electrons in vanadium(V), no distortion from the linear arrangement of the oxygen atom is expected in the VO_2^+ group of the complex.[18,19] Since the complex easily undergoes reduction to the oxovanadium-(IV) state at about 200°C, as given by Eq. 1, it is likely that one of the oxygen atoms (say, O_1) in the VO_2 group of the complex is more weakly bonded than the other. This is supported by the similar instances of V_2O_5[20](V), $KVO_3\cdot H_2O$[21](V) and VO_2[22](IV), in which it has been found by X-ray diffraction studies that one of the V–O bonds is much shorter than the rest. A sulphate oxygen along the V–O axis, completing the octahedral structure in $VOSO_4\cdot 5H_2O$,[23] is held at a much longer distance than the four water molecules in the tetragonal plane, and the V–O bond of VO^{2+} complexes is much shorter than the other bonds.[23,24] This characteristic feature of the oxovanadium compounds can be attributed to the strong V–O bond with a predominantly high π character. The appearance of the two

vibrational stretching frequencies of the O–V–O may thus be due to the differently bonded oxygen atoms.

Summary

A simple method for the preparation of the yellow diamagnetic complex, $(NH_4)_3[VO_2 \cdot (C_2O_4)_2] \cdot 2H_2O$, is described. Around 200°C, the complex suffers decomposition, giving a bluish-grey paramagnetic compound $(NH_4)_2 \cdot [(VO)_2(C_2O_4)_3]$. The infrared spectrum of the yellow complex shows a covalent bonding between vanadium and the oxalate groups. The absorption in the ultraviolet region is due to the electron transfer within the VO_2 group. An octahedral structure, with the two linearly-arranged oxide oxygens at unequal lengths from vanadium(V), is suggested for the complex anion.

The authors wish to thank Professor M. R. A. Rao for his keen interest in this work.

The Reaction of Acetylenecarboxylic Acid with Amines. XII.[1] *On the Hydrolysis of the Products Obtained by the Reactions of Diethyl Acetylenedicarboxylate with Amines*[*1]

By Yasuo IWANAMI, Yoshihisa KENJO,[*2] Koji NISHIBE,[*3] Makoto KAJIURA[*3] and Seiko ISOYAMA

(Received April 11, 1964)

In the preceding papers of this series, the products of the reactions of diethyl acetylenedicarboxylate (I) with amines, diethyl *N*-substituted-aminofumarates (type A),[2-4] 2-oxo-3-ethoxycarbonylmethylene-3,4,5,6-tetrahydro-2*H*-1, 4-oxazines (type B),[4,5] 2-oxo-3-ethoxycarbonylmethylene-3, 4-dihydro-2*H*-1, 4-benzoxazines (type C),[4,5] and 2-oxo-3-ethoxycarbonylmethylene-1, 2, 3, 4-tetrahydroquinoxalines (type E)[6-9] have been reported. It has been shown[3-9] that the compounds of types A, B and C are hydrolyzed into pyruvic acid (VII), carbon dioxide, and amines by the cleavage of the heterocyclic rings of types B and C, while the quinoxaline rings of the copomunds of type E remain unchanged, with only a decarboxylation of the side chain.

The present paper deals with the synthesis 2-oxo-3-ethoxycarbonylmethylenepiperazines (type D), and with the different behaviors of types D and E in hydrolysis. When ethylenediamine (II) and propylenediamine (III) were added to I, exothermic reactions occurred, and 2-oxo-3-ethoxycarbonylmethylenepiperazine (IV) and its 6-methyl derivative V were obtained respectively. While the 5-methyl derivative also seemed to have been produced in the reaction of I with III, only the 6-methyl derivative V could be isolated from the reaction mixture. The structural assignment of V was

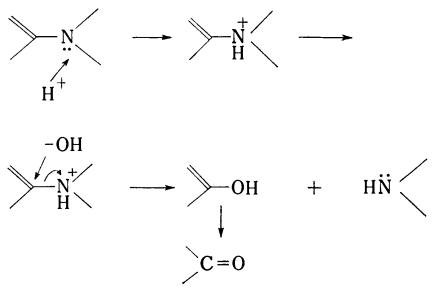
supported by a successful conversion of the reaction product from I and 1-amino-2-chloropropane (VI) into a substance which was identical with V.

The chelate structure[4] of IV and V is suggested by their infrared spectra, the main absorption maxima of which are shown in Table I.

TABLE I. MAIN INFRARED ABSORPTION BANDS (KBr disk) (cm^{-1})

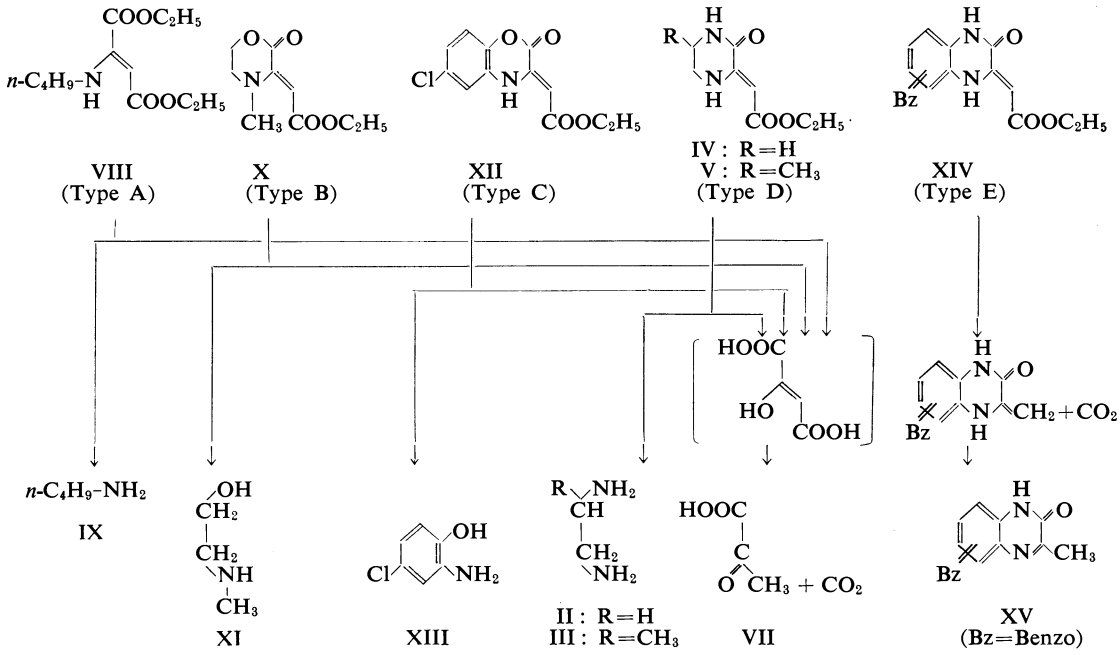


Product	Amine ν_{NH}	Chelated ester $\nu_{C=O}$	Amide $\nu_{C=O}$	Double bond $\nu_{C=C}$
IV	3350	1692	1660	1615
V	3365	1694	1650	1623

IV: R=H
V: R=CH_3

By hydrolysis with hydrochloric acid, both IV and V gave puruvic acid (VII), carbon dioxide, and the amines (II and III), as is shown in Chart 1. The formation of VII and carbon dioxide can be explained by assuming the intermediate formation of oxalacetic acid. Thus, the hydrolysis, followed by the decarboxylation, of the newly-synthesized compounds of type D is quite similar to that of the compounds of types A, B and C reported on in the preceding papers. Diethyl *N*-(*n*-butyl)-aminofumarate (VIII), 4-methyl-2-oxo-3-ethoxycarbonylmethylene-3, 4, 5, 6-tetrahydro-2*H*-1, 4-oxazine (X), 6-chloro-2-oxo-3-ethoxycarbonylmethylene-3, 4-dihydro-2*H*-1, 4-benzoxazine (XII) and 2-oxo-3-ethoxycarbonylmethylene-1,2,3,4-tetrahydroquinoxaline (XIV) were newly hydrolyzed. Their decarboxylation caused by hydrolysis is also similar to that in the above cases, except for that of XIV.

On the other hand, the decarboxylation of XIV through its hydrolysis gave 2-oxo-3-methyl-1, 2-dihydrobenzoquinoxaline (XV), although its structure resembles that of the compounds of type D. In any discussion of the above discrepancy, the breaking of the carbon-nitrogen bond which occurs by hydrolysis in all these compounds except in the compounds of type E seems to be important. The splitting mechanism in the compounds of types A, B, C and D, which have an enamine structure, is probably as follows:



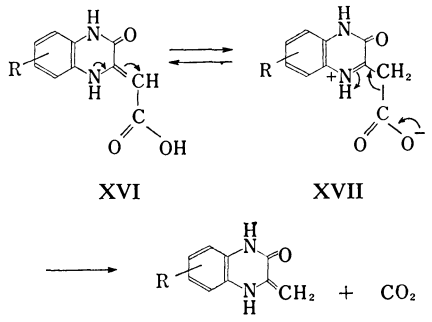


Chart 1

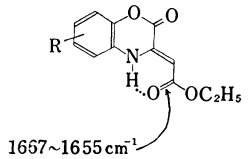
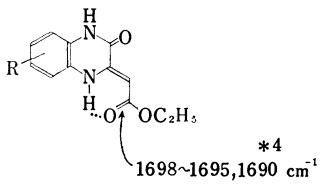
Hünig, Lücke and Benzing[10] have shown that ordinary simple enamine was easily hydrolyzed into a carbonyl compound and an amine even when such an enamine was titrated with dilute hydrochloric acid.[11]

An independent type of hydrolysis observed in the compounds of type E can be analogously explained by Doering and Pasternak's hypothesis[12] regarding the decarboxylation hydrolysis of ethyl α-pyridylacetates. That is to say, the tautomerization of enamine (XVI) to ketimine (XVII) appears to take place when the compounds of type E are hydrolyzed to the corresponding acid (XVI). Then the spontaneous decarboxylation may be supposed to proceed as follows:



XVI XVII

At least in the case of the compounds of type E, assuming the formation of the intermediate acid (XVI) is fairly satisfactory as a means of interpreting the decarboxylation mechanism, although it is not known whether the corresponding acids of A—E are intermediately formed or not. Probably an insufficient tautomerization of the compounds of types A, B, C and D to their ketimine forms causes them to be hydrolyzed as enamines.



The carbon-carbon double bond of the enamine form conjugates with two carbonyl groups. Furthermore, the chelate ring[4] needs the double bond of the enamine form. The two carbonyl groups and the chelate ring will, therefore, facilitate the adoption of the enamine form shown in Chart 1. In the case of the compounds of type E, however, it is tempting to tautomerize them into the ketimine form, because they have a condensed aromatic ring and the ketimine double bond is stabilized by taking a quinoxaline structure. Thus, the different decarboxylation mechanisms of the compounds of type D and E appears to depend on whether or not they have an aromatic ring.

However, the compounds of type C, which have a condensed aromatic ring, are hydrolyzed to result in the cleavage of a oxazine ring, as in the case of the compounds of type B. This discrepancy may be explained on grounds that the quinoxaline ring of the compounds of type E is more stabilized by an easier mesomerism through its whole ring than through the benzoxazine ring of the compounds of type C. The chelate bond in the compounds of type E is, therefore, weakened for the reason already described. Evidence of such a tendency is given by the shift of the infrared absorption[4,13] of chelated ester-carbonyl groups.

1667~1655 cm^{-1}

Type C
R=H, 6-NO_2 and 6-Cl

*4
1698~1695,1690 cm^{-1}

Type E
R=H, 6-CH_3, 7-CH_3, 7-Cl, 6-NO_2 and 6, 7-Benzo

The larger shift towads a lower frequency in the compounds of type C than that in type E is observed. The presence of the more stabilized chelate ring in the compounds of type C appears to support the above hypothetical interpretation.

Experimental

2-Oxo-3-ethoxycarbonylmethylenepiperazine (IV). —Into a solution of I (1.7 g., 0.01 mol.) in ethanol (25 ml.), a solution of II (0.6 g., 0.01 mol.) in ethanol (25 ml.) was dropped with stirring. The mixture became brown, and its temperature rose

*4 In most of the compounds of type E, carbonyl groups give rise to absorption bands in regions which do not overlap with those of type D (1694~1692 cm^{-1}), A (1673~1665 cm^{-1}), B (1672 cm^{-1}) and C (1667~1655 cm^{-1}). In the case of R=H, however, the region (1690 cm^{-1}) overlaps with that of type D; this result is not satisfactory for the above interpretation. Nevertheless, there is experimental evidence of a dissimilarity in decomposition between the compounds of types E and D, which may thus come to show clearly different absorption bands in their excited state. At least it should be noted that the absorption band of type E is in the region nearest to that of the normal ester-carbonyl group.
13) Y. Iwanami, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **83**, 597 (1962).

to 35°C from the room temperature (28°C). After the mixture had been stirred for a further 35 min., the solvent was removed in vacuo, and the residue was allowed to stand overnight in an ice box. The crystals formed (1.0 g., 56%) were then filtered off and recrystallized from ethanol to afford IV as colorless flakes; m. p. 164~165°C (corr.).

Found: C, 51.87; H, 6.68; N, 15.01. Calcd. for $C_8H_{12}O_3N_2$: C, 52.16; H, 6.57; N, 15.21%.

6-Methyl-2-oxo-3-ethoxycarbonylmethylenepiperazine (V).—Into a solution of I (1.7 g., 0.01 mol.) in ethanol (100 ml.), a solution of III (0.7 g., 0.01 mol.) in ethanol (100 ml.) was added dropwise with stirring. The mixture gradually became yellow, and its temperature reached 23°C from the room temperature (17°C). The crystals deposited (1.8 g., 89%) were recrystallized from ethanol to give V as colorless prisms; m. p. 166~167°C (corr.).

Found: C, 54.52; H, 6.99; N, 13.86. Calcd. for $C_9H_{14}O_3N_2$: C, 54.53; H, 7.12; N, 14.13%.

The Formation of V by the Amination of the Reaction Product from I and 1-Amino-2-chloropropane (VI).—VI hydrochloride was prepared according to Schaefer's[14] and Ulrich's[15] methods; colorless crystals melting at 179~181°C (lit.[15] m. p. 180~181°C) were obtained. The free amine VI was obtained by treating the hydrochloride with aqueous sodium hydroxide and by distilling the resulting oil under diminished pressure; colorless liquid boiling at 59~61°C/378 mmHg (lit.[14] b. p. about 70°C under slightly reduced pressure) was obtained.

Into a solution of I (5.0 g., 0.03 mol.) in ethanol (100 ml.), a solution of VI (2.5 g., 0.03 mol.) in ethanol (100 ml.) was dropped with stirring. A yellow color developed in the mixture, and the temperature of the mixture rose to 24°C from the room temperature (19°C). After the mixture had been stirred for a further 30 min., the solvent was removed in vacuo. To a solution of residual oil in ethanol (20 ml.), a saturated solution of ammonia in ethanol (30 ml.) was added, and the mixture was heated at 100°C for 4 hr. in a sealed tube. The mixture was then evaporated to dryness, and water was added to the remaining dark red oil. The suspension was extracted with benzene, and the solvent was removed in vacuo. The residue was allowed to stand for two weeks in an ice box, and then a vacuum desiccator. The crystals thereby formed were collected by filtration and repeatedly washed with ether. The recrystallization of the crystals (20 mg., 0.3%) from ethanol gave colorless prisms; m. p. 166~167°C (corr.) (Found: N, 13.82%). No depression of the melting point was observed on admixture with V.

6-Chloro-2-oxo-3-ethoxycarbonylmethylene-3, 4-dihydro-2*H*-1, 4-benzoxazine (XII).—To a solution of I (1.7 g., 0.01 mol.) in ethanol (20 ml.), a solution of 4-chloro-2-aminophenol (XIII) (1.5 g., 0.01 mol.) in ethanol (30 ml.) was added. The temperature of the mixture reached 24°C from the room temperature (21°C). After the mixture had stood overnight, the precipitated crystals (2.5 g., 94%) were collected by filtration and recrystallized from ethanol to afford XII as pale yellow needles; m. p. 122~123°C (corr.).

Found: C, 53.73; H, 4.08; N, 5.49. Calcd. for $C_{12}H_{10}O_4NCl$: C, 53.85; H, 3.77; N, 5.23%.

IR (KBr disk): 3260, 1765, 1655, 1625 cm^{-1}.

2-Oxo-3-ethoxycarbonylmethylene-1, 2, 3, 4-tetrahydro-5, 6(or 7, 8)-benzoquinoxaline (XIV).[*5]—Into a solution of I (1.7 g., 0.01 mol.) in ethanol (50 ml.), a solution of 1, 2-diaminonaphthalene (1.6 g., 0.01 mol.) in ethanol (500 ml.) was added with stirring. After the mixture had been stirred for 1 hr., the precipitated crystals (1.7 g., 60%) were collected by filtration and recrystallized from a large amount of ethanol to give XIV as orange needles; m. p. 227~228°C (corr.).

Found: C, 67.85; H, 5.36; N, 10.06. Calcd. for $C_{16}H_{14}O_3N_2$: C, 68.07; H, 5.00; N, 9.92%.

The Hydrolysis of IV.—One neck of a two necked flask was equipped with a reflux condenser. Into the other neck an inlet tube for bubbling the reaction mixture with a stream of air was fitted. The end of the inlet tube was connected to the outlet of two, in-series-connected scrubbing bottles containing aqueous sodium hydroxide for eliminating carbon dioxide from the air stream. A glass tube joined the top of the condenser to a wash bottle containing water. This was in turn connected to an empty bottle, which served as a trap, and to an absorption bottle containing an aqueous barium hydroxide solution. IV (0.80 g.) was placed in the flask, and 6 N hydrochloric acid (60 ml.) was added. By applying gentle suction (about 750 mmHg) to the outlet of the absorption bottle, a slow stream of air was continuously introduced into the mixture. The mixture bubbled with air was refluxed for 3 hr. During the reflux, IV was gradually dissolved and carbon dioxide was evolved. The precipitated barium carbonate in the absorption bottle was collected by filtration and dried after it had been washed with water (0.65 g., 76%).

A half of the solution containing the hydrolysates was partially concentrated in vacuo, and the crystals thereby formed were recrystallized from water to give the hydrochloride of II as colorless prisms; m. p. 240°C (subl.) (microscopically observed) (the description on its melting point in the literature: sublimes;[16] does not melt at 270°C[17]) (Found: C, 18.30; H, 7.75. Calcd. for $C_2H_{10}N_2Cl_2$: C, 18.05; H, 7.58%).

The remaining half of the solution was diluted with water until the concentration of hydrochloric acid became 2 N, and to the resulting solution the saturated solution of 2, 4-dinitrophenylhydrazine in 2 N hydrochloric acid was added. The precipitated crystals (0.36 g., 62%) were collected and recrystallized from ethanol to give 2, 4-dinitrophenylhydrazone of VII as yellow plates; m. p. 222°C (lit. m. p. 221~222°C) (Found: C, 40.46; H, 3.08. Calcd. for $C_9H_9O_6N_4$: C, 40.30; H, 3.01%).

The Hydrolysis of V.—6 N Hydrochloric acid (80 ml.) was added to V (1.0 g.). In a manner similar

14) F. C. Schaefer, *J. Am. Chem. Soc.*, 77, 5929 (1955).
15) H. Ulrich, U. S. Pat. 2163181 (1939).

*5 The infrared absorption of this compound will be reported on in a following paper, together with the structural assignment and the location of its benzo group.
16) A. W. Ipatow, *J. Russ. Phys. Chem. Soc.*, 49, 302 (1917).
17) T. Curtius and H. Hechtenberg, *J. prakt. Chem.*, 105, 215 (1920)

to that described above, the mixture was refluxed for 1 hr., and the evolved carbon dioxide was collected as barium carbonate (0.73 g., 73%). Although a half of the hydrolyzed solution was evaporated to dryness, the resulting hygroscopic hydrochloride of III failed to crystallize. The residue was dissolved in alkali, and the presence of III was confirmed by paper chromatography (ascending); solvent: 1-butanol saturated with a 25% aqueous solution of acetic acid; paper: Tōyō Roshi No. 50; location reagent: 0.2% bromophenol blue in ethanol. The same R_f value (0.36) with an authentic specimen was observed. The alkaline solution was then evaporated under diminished pressure, and the vapor was introduced into a solution of picric acid in ethanol. The deposited crystals (0.22 g., 21%) were collected and recrystallized from water to afford the picrate of III as yellow prisms; m. p. 273°C (lit.[18] m. p. 273°C) (Found: N, 21.30. Calcd. for $C_{15}H_{16}O_{14}N_8$: N, 21.05%).

From the other half of the solution, VII was isolated as its 2, 4-dinitrophenylhydrazone, which was recrystallized from ethanol to give yellow plates; m. p. 221~222°C (Found: N, 20.95. Calcd. for $C_9H_8O_6N_4$: N, 20.89%).

The Hydrolysis of VIII, X and XII.—The syntheses of VIII and X have been reported in the preceding paper.[4]

6 N Hydrochloric acid (100, 100 and 50 ml.) was added to VIII (2.4 g.), X (2.0 g.) and XII (0.50 g.) respectively in the flask of an apparatus similar to that described above, but nitrogen instead of carbon dioxide-free air was bubbled into the mixture under a slightly elevated pressure. In every case, VIII, X and XII, barium carbonate (1.2, 1.7 and 0.32 g. respectively; 61, 72 and 89% respectively) was precipitated in an absorption bottle. From a very small portion of the reaction mixtures, IX, XI and XIII were detected by paper chromatography, and the same R_f values (0.60, 0.26 and 0.18 respectively) with authentic specimens were observed. The separately-formed VII was isolated from the remaining mixtures as its 2, 4-dinitrophenylhydrazone (1.9, 1.5 and 0.46 g.; 75, 56 and 94%), which was recrystallized from ethanol to give yellow plates; m. p. 221~222°C (Found: C, 40.30; H, 3.28, C, 40.61; H, 3.13, and C, 40.17; H, 3.32%).

The Hydrolysis of XIV.—XIV (1.0 g.) was placed in the flask of the above-described apparatus, to which 6 N hydrochloric acid (100 ml.) was then added. The mixture was refluxed 3 hr., and the evolved gas was led into an absorption bottle with a stream of nitrogen. The precipitated barium carbonate (0.54 g., 79%) was separated. After the mixture had stood overnight, dark brown crystals were deposited; they became brown after being washed with water. The dried crystals (0.53 g., 71%) were recrystallized from ethanol with decolorizing carbon to give XV as colorless needles; m. p. 295~296°C (corr.).

Found: C, 74.45; H, 4.99; N, 13.33. Calcd. for $C_{13}H_{10}ON_2$: C, 74.27; H, 5.33; N, 13.54%.

Summary

2-Oxo-3-ethoxycarbonylmethylenepiperazine (IV) and its 6-methyl derivative (V) have been synthesized by the reactions of diethyl acetylenedicarboxylate with ethylenediamine and propylenediamine. These compounds (IV and V), the previously-reported diethyl *N*-(*n*-butyl)aminofumarate (VIII), 4-methyl-2-oxo-3-ethoxycarbonylmethylene-3, 4, 5, 6-tetrahydro-2*H*-1, 4-oxazine (X), the newly-synthesized 6-chloro-2-oxo-3-ethoxycarbonylmethylene-3, 4-dihydro-2*H*-1, 4-benzoxazine (XII), and 2-oxo-3-ethoxycarbonylmethylene-1, 2, 3, 4-tetrahydrobenzoquinoxaline (XIV) have been hydrolyzed with 6 N hydrochloric acid. The compound XIV has been hydrolyzed, with decarboxylation, to give 2-oxo-3-methyl-1, 2-dihydrobenzoquinoxaline, while all the other compounds have been hydrolyzed into pyruvic acid, carbon dioxide, and the amines by the splitting of the carbon-nitrogen bond.

These two types of hydrolyses shown by the compounds have been discussed in connection with their tautomerism between enamine and ketimine forms.

The authors wish to express their deep gratitude to The late Professor Shin-ichiro Fujise for his valuable instruction and advice.

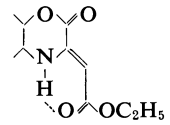
Die Reaktion von Acetylencarbonsäure mit Aminen. XIII.[1] *Substituierte 2-Oxo-3-äthoxycarbonylmethylen-3, 4-dihydro-2H-1, 4-benzoxazine*

Von Yasuo IWANAMI, Seiko ISOYAMA und Yoshihisa KENJO

(Eingegangen am 30. Mai, 1964)

Durch Einwirkung von Acetylen-dicarbonsäure-diäthylester (I) auf Aminophenole (II) in analoger Weise wie früher bereits kurz beschrieben[2] konnten substituierte 2-Oxo-3-äthoxycarbonylmethylen-3, 4-dihydro-2*H*-1, 4-benzoxazine (III) dargestellt werden.

Wenn man Rücksicht auf diese Reaktion nimmt, kann man leicht verstehen, dass sich die spontane Cyclisation des als Zwischenprodukt entstehenden substituierten *N*-(2-Hydroxy-phenyl)-amino-fumarsäure-diäthyl-esters ohne Erhitzen vollzieht.



IIa—f und IIIa—f

a: $R_1=R_2=R_4=H$, $R_3=CH_3$
b: $R_1=R_2=R_4=H$, $R_3=NH_2$
c: $R_2=R_4=H$, $R_1=CH_3$, $R_3=NO_2$
d: $R_1=R_2=H$, R_3, R_4 = Benzo
e: $R_1=H$, $R_2=SO_3H$, R_3, R_4 = Benzo
f*: $R_1=R_2=R_4=H$, $R_3=Cl$

Alle diese Produkte (IIIa—f) fluoreszieren wie die Übersicht in Tabelle I.

Die Infrarot-Spektren von IIIa—f zeigen im Bereich zwischen 1670 und 1644 cm^{-1} deutlich erkennbare Estercarbonylbanden, die nach niedrigeren Frequenzen auss erordentlich verschoben sind. Im Vergleich mit den entsprechenden Banden der analogen Substanzen[2,3] wird die Existenz von einer ähnlichen Chelatbindung[3] zwischen einer Estercarbonyl- und einer Aminogruppe gezeigt.

Durch saure Hydrolyse wurden IIIa—f zu Brenztraubensäure (IV) und Kohlendioxyd unter Wiederbildung der entsprechenden Amine (IIa—f) abgespalten.

Beschreibung der Versuche

6-Methyl-2-oxo-3-äthoxycarbonylmethylen-3, 4-dihydro-2*H*-1, 4-benzoxazin (IIIa).—Eine Lösung von 1.3 g (0.01 Mol) 4-Methyl-2-aminophenol (IIa) in 30 ccm Äthanol liess man unter Rühren zu einer Lösung von 1.7 g (0.01 Mol) I in 20 ccm Äthanol tropfen. Bald begann sich die Temperatur der Mischung zu erhöhen, die von Raumtemperatur (21°C) bis 25°C anstieg, und ein gelbbrauner kristalliner Niederschlag begann auszufallen. Nach der Zugabe wurde die Mischung noch 1.5 Stunden weiter gerührt, und über Nacht bei Raumtemperatur

* Die Synthese von IIIf ist schon in der vorstehenden Arbeit[1] beschrieben worden.
3) Y. Iwanami, ebenda., **83**, 593 (1962).
*2 Die Fluoreszenz-Spektren wurden mit einem Spektrophotometer Hitachi Typ UPI-2 und seinem Nebenstückapparat für Fluoreszenz aufgenommen.
*3 Wegen der Ungleichheit von jedem Fluoreszenz-Maximum kann der Wert nicht so genau sein, der für dem von IIId=100% berechnet wird.

stehen gelassen. Am anderen Tage wurde der ausgeschiedene Niederschlag abfiltriert. Das Filtrat wurde unter vermindertem Druck eingedampft, wobei noch ein wenig Niederschlag zurückblieb. Ausb. 2.4 g (97% d. Th.). Diese gesamten Niederschläge wurden dreimal aus Äthanol umkristallisiert: faserartige glänzendgelbe Nadeln vom Schmp. 98~99°C.

Gef.: C, 63.00; H, 5.45; N, 5.98. Ber. für $C_{13}H_{13}O_4N$: C, 63.15; H, 5.30: N, 5.67%.

UV-Spektrum: λ_{max}^{EtOH} mμ (log ε) 255 (4.10), 370 (4.20). IR-Spektrum (KBr): 3295, 1772, 1669, 1620 cm^{-1}.

6-Amino-2-oxo-3-äthoxycarbonylmethylen-3, 4-dihydro-2*H*-1, 4-benzoxazine (IIIb).—Zu einer Lösung von 3.4 g (0.02 Mol) I in 30 ccm Äthanol/Wasser (1 : 1) wurden eine Lösung von 3.95 g (0.02 Mol) 2,4-Diaminophenol (IIb)-Hydrochloride (Amidol) in 80 ccm Äthanol/Wasser (1 : 1) und dann eine Lösung von 1.6 g (0.04 Mol) Natriumhydroxyd im 20 ccm des gleichen Lösungsmittels unter Rühren getropft. Bald begannen rotbraune Kristalle langsam sich auszuscheiden, die nach 2 stdg. Stehenlassen bei Raumtemperatur abfiltriert wurden. Ausb. 2.9 g (59% d. Th.) Dreimalige Umkristallisation aus Äthanol ergab rotbraune Nadeln vom Schmp. 180~181°C (korr.).

Gef.: C, 57.71; H, 4.95; N, 11.48. Ber. für $C_{12}H_{12}O_4N_2$: C, 58.06; H, 4.87; N, 11.29%.

UV-Spektrum: λ_{max}^{EtOH} mμ (log ε) 255 (3.99), 370 (4.03). IR-Spektrum (KBr): 3272, 1754, 1644, 1619 cm^{-1}.

6-Nitro-8-methyl-2-oxo-3-äthoxycarbonylmethylen-3, 4-dihydro-2*H*-1, 4-benzoxazin (IIIc).—Das Hydrochlorid von 4-Nitro-6-methyl-2-aminophenol (IIc) wurde nach Cazeneuve[4] dargestellt.

Zu einer Lösung von 1.7 g (0.01 Mol) I in 70 ccm Äthanol/Wasser (25 : 1) wurden eine Lösung von 2.3 g (0.01 Mol) IIc-Hydrochlorid in 35 ccm Äthanol/Wasser (25 : 1) und dann eine Lösung von 0.4 g Natriumhydroxyd im 5 ccm gleichen Lösungsmittel unter Rühren getropft. Während der Zugabe färbte sich die Lösung orange. Nach ungefähr 10 Minuten bildete sich ein gelber kristalliner Niederschlag, der abfiltriert und aus Äthanol umkristallisiert wurde: faserartige gelbe Nadeln vom Schmp. 148.5~149°C (korr.). Ausb. 0.4 g (14% d. Th.).

Gef.: C, 53.28; H, 4.18; N, 9.77. Ber. für $C_{13}H_{12}O_6N_2$: C, 53.43; H, 4.14; N, 9.59%.

UV-Spektrum: λ_{max}^{EtOH} mμ (log ε) 260 (4.15), 340 (4.03). IR-Spektrum (KBr): 3250, 1771, 1670, 1625 cm^{-1}.

3-Oxo-2-äthoxycarbonylmethylen-1, 2-dihydro-3*H*-naphth[2, 1-b]-1, 4-oxazin (IIId).—Zu einer Lösung von 3.4 g (0.02 Mol) I in 80 ccm Äthanol/Wasser (3 : 1) wurde eine Lösung von 1-Amino-2-naphthol (IId), dargestellt aus 3.5 g (0.02 Mol) 1-Nitroso-2-naphthol (in 135 ccm Äthanol und 135 ccm Wasser) und 11 g Natriumhydrosulfit, zugegeben. Während der Zugabe färbte sich die Lösung rotbraun. Nach wenigen Minuten schieden sich gelbe Kristalle aus, die mit Äther gewaschen wurden. Ausb. 1.9 g (34% d. Th.). Nach Umkristallisieren aus Äthanol/Benzol gelbe Nadeln vom Schmp. 155.5~156.5°C (korr.).

Gef.: C, 67.51; H, 4.81; N, 4.92. Ber. für $C_{16}H_{13}O_4N$: C, 67.84; H, 4.63; N, 4.95%.

UV-Spektrum: λ_{max}^{EtOH} mμ (log ε) 245 (4.39), 320 (3.91) 390 (4.02). IR-Spektrum (KBr): 3224, 1770, 1653 1622 cm^{-1}.

3-Oxo-2-äthoxycarbonylmethylen-1, 2-dihydro-3*H*-naphth[2, 1-b]-1, 4-oxazin-6-sulfonsäure (IIIe).—4.8 g (0.02 Mol) 1-Amino-2-naphthol-4-sulfonsäure (IIe) wurde in einer Lösung von 0.8 g Natriumhydroxyd in 30 ccm Wasser gelöst und unter Rühren 90 ccm Äthanol hinzugefügt. Diese Lösung wurde zu einer Lösung von 3.4 g (0.02 Mol) I in 120 ccm Äthanol/Wasser (3 : 1) unter kräftigem Rühren tropfenweise gegeben. Die Reaktion war etwas exotherm und die Temperatur der Mischung erhöhte sich von Raumtemperatur (ca. 20°C) bis 23°C. Während der Zugabe bildete sin brauner kristalliner Niederschlag, der abfiltriert und mit Wasser gewaschen wurde. Das zurückbleibende gelbbraune Rohprodukt des IIIe-Natriumsalzes wurde über konz. Schwefelsäure getrocknet, Schmp. 248~250°C. Ausb. 6.5 g (84.5% d. Th.).

Man versetzte 3.85 g (0.01 Mol) Natriumsalz unter Rühren mit 1.7 ccm 6 N Salzsäure und 10 ccm Wasser. Die Mischung wurde 30 Minuten bei Raumtemperatur gerührt. Die freie Sulfonsäure (IIIe) (mit 2 Mol Kristallwasser) wurde abfiltriert und fünfmal mit Wasser gewaschen. Durch verlustreiches Umkristallisieren aus viel Äthanol erhielt man IIIe rein in zitronengelben Nadeln vom Schmp. 284.5°C (korr.) (Zers.).

Gef.: C, 48.02; H, 4.40; N, 3.72; H_2O, 9.06. Ber. für $C_{16}H_{13}O_7NS \cdot 2H_2O$: C, 48.12; H, 4.29; N, 3.51; H_2O, 9.02%.

UV-Spektrum: λ_{max}^{EtOH} mμ (log ε) 248 (4.41), 380 (4.10). IR-Spektrum (KBr): 3541, 1753, 1647, 1623 cm^{-1}.

Hydrolyse von IIIa—f.—Eine Suspension von 0.5 g IIIe (kristallwasserhaltige) in 50 ccm 6 N Salzsäure wurde 2.5 Stunden unter Rückfluss gekocht, wobei die suspendierten Kristalle sich allmählich lösten und die Lösung sich rotbraun färbte. Während des Erhitzens bildete sich langsam ein grauweisser mikrokristalliner Niederschlag, der abfiltriert und mit Wasser gewaschen wurde. Ausb. 0.3 g (97% d. Th. als $^1/_2H_2O$-haltige Kristalle von IIe).

Gef.: C, 48.67; H, 4.48; N, 5.69. Ber. für $C_{10}H_9O_4NS \cdot {}^1/_2H_2O$: C, 48.78; H, 4.06; N, 5.64%.

Das Filtrat versetzte man mit der doppelten Menge Wasser und zu dieser verdünnten Lösung wurde eine überschüssige gesättigte Lösung von 2,4-Dinitro-phenylhydrazin in 2 N Salzsäure zugegeben. Nach dem Stehenlassen über Nacht wurde der gelbe Niederschlag abfiltriert. Ausb. 0.3 g (79% d. Th.). Durch Umkristallisieren aus Äthanol erhielt man Brenztraubensäure (IV) rein als deren 2,4-Dinitrophenylhydrazon vom Schmp. 221~222°C (Lit.[5]: 221~222°C). Die Substanz war identish mit einem authentischen Präparat durch Vergleich auf papierchromatographischem Wege. R_f-Wert: 0.86 nach aufsteigender Methode auf Tōyō Roshi Nr. 50 mit

dem Gemisch von *n*-Butanol/25% wässriger Essigsäure-Lösung (1 : 1).

Die anderen Oxazine IIIa—d und IIIf konnten unter gleicher Bedingung wie bei IIIe hydrolysiert werden. Die entstehenden Aminophenole (IIa—d und IIf) und IV wurden als deren Hydrochloride und deren 2,4-Dinitro-phenylhydrazon chromatographiert und respektive mit den authentischen Präparaten identifiziert. Das Hydrazon wurden in der oben beschriebenen Weise und die Hydrochloride nach aufsteigender Methode auf ein gleiches Papier mit Methanol/Isoamylalkohol/Benzol/Wasser (40 : 20 : 20 : 20) isoliert. Die Aminophenole auf Chromatogramm wurden durch Besprühen mit 0.2% Natriumnitrit-Lösung in 0.1 N Salzsäure bzw. 0.2% *N*-Äthyl-α-naphthylamin-hydrochlorid-Lösung in Äthanol angefärbt.[6]

R_f-Werte: IIa, 0.72; IIb, 0.59; IIc, 0.84; IId, 0.76 und IIf, 0.82.

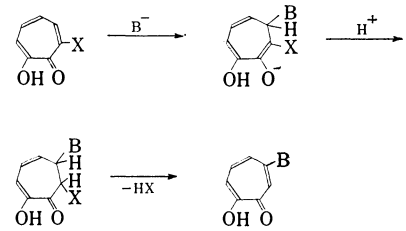
Heptafulvenes. I. The Synthesis of 8,8-Dicyano-2,3-dihydroxyheptafulvene[1]

By Yoshio KITAHARA, Kozo DOI and Tadahiro KATO

(Received April 21, 1964)

A number of studies of the substitution reactions accompanying rearrangement, which are explainable by an elimination-addition mechanism involving benzyne or its related intermediates, have been made, and a detailed review of this problem has been published.[2] In the field of tropolone chemistry, several reactions deduced to involve analogous intermediate tropolonyne[2] or dehydrotropolone (I, exactly its anion) have also been found: the formations of 3-hydroxy- (III) and 4-hydroxytropolones (IV) from 3-bromotropolone (II) by high-temperature alkaline hydrolysis,[3,4] of 4-cyanotropolone (V) from II reaction with potassium cyanide,[5] and of 4-aminotropolone (VII) from 3-iodotropolone (VI) by treatment with potassium amide in liquid ammonia.[6]

I

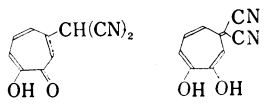


II: X=Br
III: X=OH
VI: X=I

IV: X=OH
V: X=CN
VII: X=NH_2

Very recently, novel examples of synthesizing bicyclic tropolones by intramolecular cyclization involving dehydrobromination have also been reported.[7]

In these reactions of halotropolones, however, the following process is also a possible mechanism to explain the above abnormal substitutions:[8]



The Michael-type addition of an anion (B^-) to halotropolone, which is an unsaturated conjugated carbonyl compound, would occur, and then hydrogen halide would be eliminated, giving an abnormal substitution product.

No experimental proofs of these possible mechanisms have yet been obtained, so further detailed investigations of these abnormal substitution reactions are desirable. Some compounds containing an active methylene were found to be phenylated in a reaction with benzyne in liquid ammonia.[9] Accordingly,

the authors expected to obtain 4-dicyanomethyltropolone (VIII) from the reaction of 3-iodotropolone (VI) with malononitrile under similar conditions. The product actually obtaind, however, was confirmed to be a heptafulvene derivative (IX), and an enolic isomer of VIII, the details of which will be described in this paper.

3-Iodotropolone (VI) reacted with sodiomalononitrile in liquid ammonia to give a yellow product with the composition of $C_{10}H_6O_2N_2$ in about a 30 per cent yield. Its ultraviolet absorption maxima (Fig. 1) are at a longer wavelength region than those anticipated for the structure VIII, and its infrared spectrum indicates the presence of the conjugated nitrile grouping (Table I). Therefore,

VIII IX

X: X=OCH_3 XII: X=CO_2H
XI: X=OAc XIII: X=H
XVI: X=H

this product is deduced not to be the expected tropolone derivative (VIII) but its enolic isomer, 8, 8-dicyano-2, 3-dihydroxyheptafulvene (IX). This deduction is strongly supported by the fact that IX reacted with diazomethane and acetic anhydride to yield the dimethoxy (X) and diacetoxy (XI) derivatives respectively. On being heated in concentrated sulfuric acid, IX was hydrolyzed and partially decarboxylated to give 4-carboxymethyltropolone (XII), which led to 4-methyltropolone (XIII). From the above facts, the position of the dicyanomethylene grouping of IX can also be elucidated. In the course of the formation of the carboxymethyl derivative (XII) from IX, the corresponding dicarboxymethyltropolone or its isomeric heptafulvene derivative was assumed as an intermediate, but it has not yet been actually isolated.

On being treated with dilute alkali under mild conditions, both X and XI were readily hydrolyzed to give IX, maintaining the dicyanoheptafulvene skeleton. It is possible that the reactivities of the methoxyl and acetoxyl groups of the above heptafulvenes, X and XI, depend on their positions, but in alkaline hydrolyses of X and XI no partially hydrolyzed products other than IX have been isolated.

The methylation of IX with dimethyl sulfate give a yellow monomethylated product (XIV), which led to the dimethoxy derivative (X) upon reaction with diazomethane and to the acetoxy derivative (XV) upon heating with acetic anhydride. These facts indicate that the reactivities of the two hydroxyl groups of IX depend on their positions in the heptafulvene nucleus. A study attempting to determine the position of methoxyl group of the partially-methylated product, XIV, will be reported elsewhere.

XIVa: X=OH XIVb: X=OH
XVa: X=OAc XVb: X=OAc

Figure 1 indicates the ultraviolet absorption spectra of three heptafulvene derivatives, the features of which resemble those of 8, 8-dicyanoheptafulvene[10] (XVI).

Table I indicates some principal absorption maxima of the infrared spectra of the heptafulvenes compared with those[10] of XVI. The details of these spectroscopic analyses will be described in the near future.

As has been described hitherto, it has been clarified that 3-iodotropolone (VI) reacts with sodiomalononitrile in liquid ammonia to yield an abnormally-substituted product, 8, 8-dicyano-2, 3-dihydroxyheptafulvene (IX), which is an enol form of 4-dicyanomethyltropolone (VIII). For the following reasons, this reaction presumably proceeds by way of an intermediate dehydrotropolone or tropolonyne (I), as has been stated by other authors.[2,6] First, this

Table I. The infrared absorption maxima of 8,8-dicyanoheptafulvenes (cm^{-1})

XVI	2205	1633	1585	1520	1490	1406	1269	885
IX	2190 2215	1626	1570	1550	1485	1410	1260	874
X	2205	1630	1564	1550	1487	1412	1284	862
XI	2220	1645	1597	1560	1490	1405	1265	870

reaction proceeds under as mild conditions as in the amination of halobenzenes.[2] Second, the addition of a carbanion to the intermediate (I) would be expected to occur at the 4-position rather than the 3-position because of the polar effect of the carbonyl group. Third, under forced conditions, 3-halotropolones were found to react with carbanions to give normal substitution products: for example, when 3-bromotropolone (II) was heated with a sodium compound of acetoacetate or malonate in dioxane, a normally-substituted product (XVII: X=$COCH_3$ or $CO_2C_2H_5$) was obtained, although ring closure was followed.[11]

XVII

XVIII

Under conditions similar to those in the case of VI, however, 5-iodotropolone (XVIII) has been found not to react with sodio- or potassiomalononitrile. Taking this fact into account, we can say that the above abnormal substitution reaction, which led to an enolic form (IX) of VIII from a reaction of 3-iodotropolone (VI) and malononitrile, presumably proceeds by way of the above-mentioned addition-elimination mechanism, involving the Michael-type reaction rather than elimiation-addition-involving tropolonyne (I). Some efforts to resolve this problem are now being made.

Heptafulvene itself was first synthesized in 1954 and found to be an extremely unstable liquid,[12] in spite of having 13.2 kcal./mol. of stabilization energy based on the heat of hydrogenation.[13] Nozoe and his collaborators indicated, however, that some heptafulvenes having two electronegative groups at the 8-position are fairly stable, and that especially 8,8-dicyanoheptafulvene (XVI) resists bromination, Diels-Alder addition, and catalytic hydrogenation over palladium carbon.[10] The present authors have been able to synthesize many heptafulvenes by the new synthetic method described above and have studied their properties as a new system of non-benzenoid aromatic compounds. Details will be reported in the following papers.

Experimental

The ultraviolet absorption spectra were measured in a methanol solution with a Hitachi model EPU-2A spectrophotometer. The infrared absorption spectra were measured on potassium bromide disks with a Hitachi model EPI-2 infrared spectrometer, using rock salt prisms. All melting points are uncorrected.

8,8-Dicyano-2,3-dihydroxyheptafulvene (IX). — The addition of malononitrile (4 g.) to a sodium amide solution prepared from liquid ammonia (300 ml.), sodium (5.6 g.) and a catalytic amount of ferric nitrate gave sodiomalononitrile as silver-white crystals. Into this mixture 3-iodotropolone (VI, 15 g.) was stirred at −50°C over a period of a few minutes, and then the mixture was gently refluxed at −33°C for 2 hr. After ammonium chloride (4.8 g.) had been added, the ammonia was allowed to evaporate. The solid residue was washed out with water (300 ml.) and some insoluble solid (6 g.), which consisted mainly of ammonium salt of VI, was removed by filtration. When this filtrate was acidified with dilute hydrochloric acid, yellow solids separated out; these solids, after filtration and recrystallization from acetone, gave IX (3.6 g.) as yellow prisms; m. p. 222°C (decomp.)

Found: C, 64.58; H, 3.56; N, 15.22. Calcd. for $C_{10}H_6O_2N_2$: C, 64.51; H, 3.25; N, 15.05%.

λ_{max} mμ (log ε): 300 (4.19), 390 (4.25), 405 (4.26).

8,8-Dicyano-2,3-dimethoxyheptafulvene (X). — To a stirred suspension of IX (1.2 g.) in ethanol (50 ml.) an excess of diazomethane in ether was added with ice cooling. The evaporated residue in vacuo was dissolved in ethyl acetate, the solution was chromatographed over alumina using ethyl acetate, and the reddish effluents were collected; these effluents, after evaporation in vacuo and recrystallization from the same solvent, yielded X (0.6 g.) as orange needles; m. p. 227~228°C.

Found: C, 67.44; H, 4.42; N, 13.32. Calcd. for $C_{12}H_{10}O_2N_2$: C, 67.28; H, 4.71; N, 13.08%.

λ_{max} mμ (log ε): 238 (4.09), 273 (4.11), 405 (4.38).

2,3-Diacetoxy-8,8-dicyanoheptafulvene (XI). — IX (0.1 g.) and acetic anhydride (4 ml.) were heated under reflux for 1 hr. The excess acetic anhydride was then removed under reduced pressure, and the residue was crystallized from ethyl acetate to give XI as red needles; m. p. 166~167°C.

Found: C, 62.36; H, 3.76; N, 10.36. Calcd. for $C_{14}H_{10}O_4N_2$: C, 62.22; H, 3.73; N, 10.37%.

λ_{max} mμ (log ε): 230 (4.03), 260 (3.96), 315 (3.67), 390 (4.28).

The Acid Hydrolysis of 8,8-Dicyano-2,3-dihydroxyheptafulvene (IX).—A mixture of IX (0.56 g.) and 75% sulfuric acid (4 ml.) was heated at 100°C for 1 hr., diluted with water (10 ml.), and then cooled. 4-Carboxymethyltropolone (XII, 0.25 g.)

precipitated out as colorless needles; m. p. 154~155°C (decomp.). When heated at its decomposition point, XII gave 4-methyltropolone (XIII), m. p. 76~77°C. The melting points of XII and XIII did not show any depression on admixture with respective authentic samples.[14]

The Alkaline Hydrolysis of 8, 8-Dicyano-2, 3-dimethoxyheptafulvene (X).—A mixture of X (0.1 g.) and 2 N methanolic sodium hydroxide (10 ml.) was heated under reflux for 5 min., and then the solvent was removed under reduced pressure. The acidification of the residue with dilute sulfuric acid afforded IX (0.08 g.) m. p., alone and mixed, 222°C (decomp.).

The Alkaline Hydrolysis of 2, 3-Diacetoxy-8, 8-dicyanoheptafulvene (XI).—A mixture of XI (0.1 g.) and 2 N sodium hydroxide (5 ml.) was heated on a water bath for 1 hr.; neutralization with dilute sulfuric acid then yielded IX, m. p., alone and mixed, 222°C (decomp.).

The Methylation of 8, 8-Dicyano-2, 3-dihydroxyheptafulvene (IX) with Dimethyl Sulfate.—Dimethyl sulfate (1 g.) was added to the solution of IX (0.2 g.) in 2 N sodium hydroxide (2 ml.) under ice cooling, and then the mixture was stirred for 4 hr. The precipitated solid, after collection by filtration and subsequent recrystallization from acetone, gave a monomethylated product (XIV, 0.2 g.) as yellow prisms; m. p. 164~165°C.

Found: C, 65.73; H, 4.23; N, 13.86. Calcd. for $C_{11}H_8O_2N_2$: C, 65.99; H, 4.03; N, 13.99%.

14) T. Nozoe, Y. Kitahara, K. Doi, M. Funamizu and T. Terasawa, *Bull. Chem. Res. Inst. Non-Aqueous Solutions, Tohoku Univ.*, 10, 199 (1961).

XIV reacted with an excess of diazomethane in ether to give the dimethoxyl derivative (X), m. p., alone and mixed, 227~228°C.

3 (2)-Acetoxy-8, 8-dicyano-2 (3)-methoxyheptafulvene (XV).—A mixture of XIV (0.08 g.) and acetic anhydride (1 ml.) was heated under reflux for 1 hr.; the residue obtained after the removal of acetic anhydride under reduced pressure was crystallized from ethyl acetate, giving XV as red needles; m. p. 141~142°C.

Found: N, 11.57. Calcd. for $C_{13}H_{10}O_3N_2$: N, 11.33%.

The Reaction of 5-Iodotropolone (XVIII) and Sodiomalononitrile.—To a mixture of sodium amide or potassium amide and malononitrile in liquid ammonia, XVIII was added; the following procedure was essentially that used in the case of VI. No reaction product other than the starting material was isolated.

The authors wish to take this opportunity to express their gratitude to the Ministry of Education and to the Sankyo Co., Ltd., for their financial support. The authors wish also to thank the Misses Yoko Endo and Yukiko Endo of this Institute for carrying out the microanalyses.

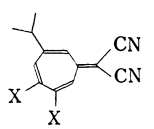
Heptafulvenes. II. The Synthesis of 8, 8-Dicyano-2, 3-dihydroxy-isopropylheptafulvenes[1]

By Yoshio KITAHARA, Kozo DOI and Tadahiro KATO



(Received April 21, 1964)

Our recently reported[2] method of synthesizing heptafulvenes has now been applied to two isopropyl derivatives of 3-iodotropolone; the experimental results will be described in this paper.

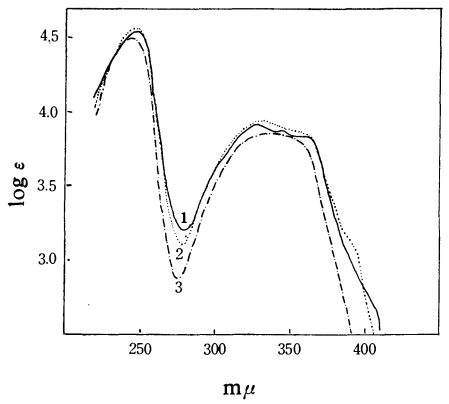
From the reaction of 3-iodo-6-isopropyltropolone (I) with sodiomalononitrile in liquid ammonia, a yellow product with a poor solubility in common organic solvents was obtained in a 48 per cent yield. Its ultraviolet absorption spectrum (Table I) is similar to that of 8, 8-dicyano-2, 3-dihydroxyheptafulvene,[2] while its infrared spectrum (Table II) indicates the presence of conjugated nitrile groups. This product II gave dimethyl III and diacetyl IV derivatives when treated with diazomethane and acetic anhydride respectively; when treated with dimethylsulfate, II afforded the monomethyl ether X.

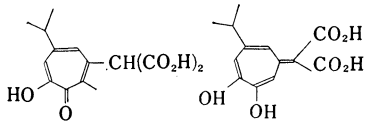
I

II: X=OH
III: X=OCH_3
IV: X=OAc

1) This work was presented in part at Tohoku Local Meetings of the Chemical Society of Japan held in June, 1959, and October, 1961.

2) Y. Kitahara, K. Doi and T. Kato, This Bulletin, 37, 1747 (1964).





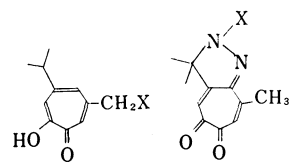


Fig. 1. Ultraviolet absorption spectra of
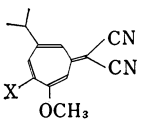
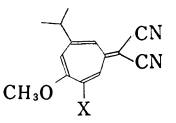
1: 4-dicarboxymethyl-(V),
2: 4-carboxymethyl-(VII), and
3: 4-methyl-(VIII)-6-isopropyltropolone.

In the preceding paper,[2] it was shown that when 8, 8-dicyano-2, 3-dihydroxyheptafulvene was heated with sulfuric acid, 4-carboxylmethyltropolone was formed as a hydrolysis product. When the heptafulvene (II) was carefully heated with sulfuric acid following the directions previously described,[2] the 4-dicarboxymethyltropolone derivative V was obtained as a hydrolysis product. From the fact that its ultraviolet spectrum (Fig. 1) resembles the spectrum of an alkyltropolone more closely than that of the heptafulvene (II), this hydrolysis product appears to be a tropolone (V) rather than a heptafulvene (VI) derivative. When V was heated to its decomposition point, it gave the 4-carboxymethyltropolone derivative VII, which showed a depression of its melting point on admixture with authentic 3-carboxymethyl-6-isopropyltropolone.[3] The further decarboxylation of VII yielded the 4-methyltropolone derivative VIII, which was not identical with authentic 6-isopropyl-3-methyltropolone.[3]

V VI



VII: X=CO_2H IX: X=*p*-Tolyl
VIII: X=H

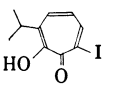


3) K. Takase, This Bulletin, to be published.

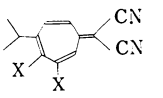
The methyltropolone VIII reacted with diazotized *p*-toluidine to yield 4', 6-dimethylhinopurpurin (IX) rather than the expected *p*-tolyazotropolone. On the basis of a comparison of its ultraviolet spectrum with that of hinopurpurin itself,[4] structure IX was assigned to the compound.

In the preceding paper[2] it was also reported that mild hydrolyses of 2, 3-dimethoxy- and 2, 3-diacetoxy-8, 8-dicyanoheptafulvenes gave 8, 8-dicyano-2,3-dihydroxyheptafulvene. On the other hand, the isopropyl-dimethoxy derivative (III) was found to be partially demethylated to X under the same conditions. III was regenerated when X was treated with diazomethane;

Xa: X=OH
XIa: X=OAc

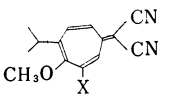


Xb: X=OH
XIb: X=OAc

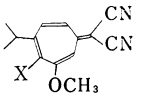


X afforded a monoacetate XI. The further heating of the monomethoxyheptafulvene (X) in dilute alkali gave the dihydroxy derivative II. The careful hydrolysis of the diacetoxy compound IV yielded only II.

The fact that the dimethoxyheptafulvene (III) is easily hydrolyzed to II and then to V suggests that the replacement of the methoxyl groups of the heptafulvene may be possible with other nucleophilic reagents, but no experiments have been undertaken to verify this.



Analogous results were obtained from another isopropyltropolone derivative XII. Dihydroxyheptafulvene (XIII) easily formed a dimethoxy XIV derivative with diazomethane and diacetate XV when reacted with acetic anhydride. It also gave a monomethoxy compound XVI by reaction with dimethyl sulfate; this could be acetylated to XVII.



XII

XIII: X=OH
XIV: X=OCH_3
XV: X=OAc

XVIa: X=OH
XVIIa: X=OAc

XVIb: X=OH
XVIIb: X=OAc

The ultraviolet and infrared absorption maxima for these heptafulvenes are summarized

in Tables I and II; these data will be discussed elsewhere.

Experimental

The ultraviolet absorption spectra were measured for methanol solutions on a Hitachi model EPU-2 recording spectrophotometer. The infrared absorption spectra were measured on a Hitachi model EPU-510 infrared spectrometer (rock salt prism, potassium bromide pellet). All melting points are uncorrected.

8, 8-Dicyano-2, 3-dihydroxy-5-isopropylheptafulvene (II).—The addition of malononitrile (3.3 g.) to a sodium amide solution prepared from sodium (3.4 g.) and liquid ammonia (300 ml.) gave sodiomalononitrile as silver white crystals. I (14.5 g.) was stirred into this mixture at −50°C over a period of 10 min., and the resulting deep red solution was refluxed for 2 hr. under atmospheric pressure. After the addition of ammonium chloride (8 g.), the ammonia was allowed to evaporate. The residue was then washed with water (300 ml.), and the insoluble substance was filtered off. The acidification of the filtrate precipitated a yellow solid which, after recrystallization from methanol, gave II as yellow needles, m. p. 227°C (decomp.), 5.5 g. (48%).

Found: C, 68.85; H, 5.26: N, 12.34. Calcd. for $C_{13}H_{12}O_2N_2$: C, 68.41; H, 5.30; N, 12.27%.

8, 8-Dicyano-2, 3-dimethoxy-5-isopropylheptafulvene (III).—To a cooled, stirred solution of II (0.23 g.) in methanol (10 ml.) an ether solution of diazomethane was added until no more gas was evolved. After 1 hr., the solvent was removed, and a solution of the residue in ethyl acetate was chromatographed over alumina (1.5×10 cm.). The yellowish orange eluate was collected and evaporated under reduced pressure. The recrystallization of the residue from ethyl acetate afforded II as yellowish orange prisms, m. p. 176~177°C, 0.2 g.

Found: C, 70.19; H, 6.32; N, 10.90; mol. wt. (Rast), 263. Calcd. for $C_{15}H_{16}O_2N_2$: C, 70.29; H, 6.29; N, 10.93%; mol. wt. 256.

2, 3-Diacetoxy-8, 8-dicyano-5-isopropylheptafulvene (IV).—II (0.2 g.) in acetic anhydride (5 ml.) was heated under reflux for 2 hr. The removal of the solvent under reduced pressure and the recrystallization of the residue from benzene gave reddish needles, m. p. 138~140°C, 0.1 g.

Found: C, 65.36; H, 4.77; N, 9.03. Calcd. for $C_{17}H_{16}O_4N_2$: C, 65.37; H, 5.16; N, 8.97%.

4-Dicarboxymethyl-6-isopropyltropolone (V).—A mixture of II (0.46 g.) and 75% sulfuric acid (3 ml.) was heated at 80~90°C for 1 hr., and then diluted with water to 10 ml. and cooled. The colorless crystals which separated were filtered and recrystallized from methanol to afford V as colorless prisms, m. p. 135~136°C (decomp.), 0.36 g. A methanol solution of V showed a red coloration with ferric chloride.

Found: C, 51.86; H, 6.29. Calcd. for $C_{13}H_{14}O_6 \cdot H_2O$: C, 51.65; H, 6.00%.

4-Carboxymethyl-6-isopropyltropolone (VII).—V (0.13 g.) was heated at its decomposition point until no more carbon dioxide was evolved. The product formed colorless crystals when allowed to cool under reduced pressure. Recrystallization from a mixture of benzene and methanol gave VII as colorless prisms, m. p. 153~154°C (decomp.), 0.07 g.

Found: C, 64.59; H, 6.49. Calcd. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35%.

VII decomposes sodium hydrogencarbonate, and its alcoholic solution showed a red coloration with ferric chloride. A mixture of VII and 3-carboxymethyl-6-isopropyltropolone (m. p. 153~154°C (decomp.))[3] had an m. p. of 120~125°C.

6-Isopropyl-4-methyltropolone (VIII).—VII (0.11 g.) was heated at its decomposition point in a sublimation apparatus until the evolution of carbon dioxide ceased; then it was submitted to sublimation in vacuo. The recrystallization of the sublimate from petroleum ether (b. p. 40~60°C) gave VIII as white prisms, m. p. 52~53°C, 0.05 g.

Found: C, 74.16; H, 7.80; mol. wt. (Rast), 192. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%; mol. wt., 188.

VIII did not afford a picrate or an *o*-phenylenediamine compound, thus differing from 6-isopropyl-3-methyltropolone (liquid).[3]

The Azo-coupling of 6-Isopropyl-4-methyltropolone (VIII).—A diazonium chloride solution prepared from *p*-toluidine (30 mg.) was stirred into a cooled solution of VIII (45 mg.) in pyridine (2 ml.) over a period of 10 min. After 30 min., the reddish solution was acidified with dilute hydrochloric acid, and the resulting reddish violet solution was extracted with ethyl acetate (30 ml.). The extract was chromatographed over alumina (1×5 cm.), and the reddish violet eluate was collected. After the removal of the solvent under reduced pressure, the residue was recrystallized from cyclohexane, giving the dimethylhinopurpurin compound IX as reddish violet needles, m. p. 130~132°C.

λ_{max}^{MeOH} mμ (log ε): 257 (4.49), 320 (4.09), 360 (3.98), 500 (4.09).

Found: C, 37.67; H, 5.73; N, 9.42. Calcd. for $C_{18}H_{18}O_2N_2$: C, 73.45; H, 6.16; N, 9.52%.

The Alkaline Hydrolysis of 8, 8-Dicyano-2, 3-dimethoxy-5-isopropylheptafulvene (III).—III (0.1 g.) in 2 N methanolic sodium hydroxide (5 ml.) was heated under reflux for 5 min. The neutralization with dilute hydrochloric acid caused the separation of crystals which, after recrystallization from acetic acid, gave 8,8-dicyano-3(or 2)-hydroxy-5-isopropyl-2(or 3)-methoxyheptafulvene (X) as yellow leaflets, m. p. 278°C (decomp.).

Found: C, 69.55; H, 5.74; N, 11.60. Calcd. for $C_{14}H_{14}O_2N_2$: C, 69.40; H, 5.83; N, 11.56%.

Upon treatment with diazomethane in ether, X gave a product which showed no depression of its melting point on admixture with an authentic sample of III. X was soluble in aqueous caustic alkali, and its alcoholic solution did not show any coloration with ferric chloride. When it is heated under reflux in 2 N methanolic sodium hydroxide for 2 hr., III and II are afforded.

3(or 2)-Acetoxy-8, 8-dicyano-5-isopropyl-2(or 3)-methoxyheptafulvene (XI).—A solution of X (0.1 g.) in acetic anhydride (2 ml.) was heated under reflux for 1 hr. The solvent was then evaporated under reduced pressure; the residue after recrytallization from benzene afforded XI as reddish orange needles, m. p. 185~186°C.

Found: C, 67.83; H, 5.18; N, 9.99. Calcd. for $C_{16}H_{16}O_3N_2$: C, 67.59; H, 5.67; N, 9.85%.

The Alkaline Hydrolysis of 2, 3-Diacetoxy-8, 8-dicyano-5-isopropylheptafulvene (IV).—A solution of IV (0.1 g.) in 2 N methanolic sodium hydroxide (5 ml.) was heated under reflux for 10 min. Neutralization with dilute hydrochloric acid afforded II, m. p. and mixed m. p. 227°C (decomp.) with an authentic sample.

The Methylation of 8, 8-Dicyano-2, 3-dihydroxy-5-isopropylheptafulvene (II) with Dimethyl Sulfate.—A mixture of II (0.46 g.), sodium hydroxide (0.2 g.), water (5 ml.), and dimethyl sulfate (0.63 g.) was stirred at room temperature for 2 hr. The crystals which separated out were filtered off and recrystallized from acetic acid to give X (0.42 g.), m. p. and mixed m. p. with an authentic sample, 278°C (decomp.).

3-Iodo-7-isopropyltropolone (XII).—To a refluxing mixture of 3-isopropyltropolone (41 g.), anhydrous potassium carbonate (72 g.) and methanol (300 ml.), a solution of iodine (64 g.) and potassium iodide (42 g.) in methanol (300 ml.) was added drop by drop; refluxing was then continued for an additional 4 hr. After most of the methanol had been removed under reduced pressure, the residue was diluted with dilute sulfuric acid and then extracted with chloroform. The extract was washed with sodium hydrogen sulfite and then dried. The removal of the solvent gave crude XII as a dark red oil, 58 g.

Into a cooled solution of the oil (0.2 g.) in pyridine (3 ml.) a solution of *p*-toluenediazonium chloride prepared from *p*-toluidine (0.11 g.) was stirred. After 1 hr. the mixture was diluted with dilute hydrochloric acid, and the crystals which separated out were recrystallized from acetone to give 3-iodo-7-isopropyl-5-*p*-tolylazotropolone as orange needles, m. p. 167~168°C; 90% yield.

Found: C, 50.35; H, 4.29; N, 6.88. Calcd. for $C_{17}H_{17}O_2N_2I$: C, 50.01; H, 4.19; N, 6.86%.

8, 8-Dicyano-2, 3-dihydroxy-4-isopropylheptafulvene (XIII).—XII (41 g.) was added to a mixture of malononitrile (14 g.), liquid ammonia (500 ml.) and sodium amide prepared from sodium (16 g.). The subsequent procedure is the same as that used in the case of I. After recrystallization from a mixture of methanol and acetone, XIII was obtained as yellowish orange needles, m. p. 242°C (decomp.), 13 g.

Found: C, 68.75; H, 5.19; N, 12.28. Calcd. for $C_{13}H_{12}O_2N_2$: C, 68.41; H, 5.30; N, 12.27%.

8, 8-Dicyano-2, 3-dimethoxy-4-isopropylheptafulvene (XIV).—A solution of diazomethane in ether was added to a mixture of XIII (0.7 g.) and ethanol (3 ml.) with stirring and cooling. After the removal of the solvent under reduced pressure, the product was dissolved in ethyl acetate and chromatographed over alumina. The reddish orange eluates were evaporated to afford XIV as reddish prisms, m. p. 124~125°C, 0.25 g.

Found: C, 70.08; H, 5.89; N, 10.59. Calcd. for $C_{15}H_{16}O_2N_2$: C, 70.29; H, 6.29; N, 10.93%.

2, 3-Diacetoxy-8, 8-dicyano-4-isopropylheptafulvene (XV).—A mixture of XIII (0.2 g.) and acetic anhydride (5 ml.) was heated under reflux for 3 hr., and then the solvent was removed under reduced pressure. The residue was recrystallized from ethyl acetate to give XV (0.1 g.) as reddish prisms, m. p.

183～184°C, 0.1 g.

Found: C, 65.46; H, 5.06; N, 8.93. Calcd. for $C_{17}H_{16}O_4N_2$: C, 65.37; H, 5.16; N, 8.97%.

The Methylation of 8, 8-Dicyano-2, 3-dihydroxy-4-isopropylheptafulvene (XIII) with Dimethyl Sulfate.—To a solution of XIII (0.45 g.) in 2 N sodium hydroxide (6 ml.) dimethyl sulfate (1.6 g.) was added, and then the mixture was stirred at room temperature for 6 hr. The crystals which separated out were filtered and recrystallized from methanol to give XVI as yellow prisms, m. p. 254～255°C (decomp.), 0.4 g.

Found: C, 69.34; H, 5.86; N, 11.79. Calcd. for $C_{14}H_{14}O_2N_2$: C, 69.40; H, 5.83; N, 11.56%.

The treatment of XVI with diazomethane in ether afforded XIV. When XVI was heated in acetic anhydride, the acetyl derivative XVII was yielded as reddish orange needles, m. p. 176～178°C.

Found: C, 67.75; H, 5.47; N, 9.55. Calcd. for $C_{16}H_{16}O_3N_2$: C, 67.59; H, 5.67; N, 9.85%.

The authors wish to take this opportunity to express their sincere gratitude to the Ministry of Education and to the Sankyo Co., Ltd., for their financial support. They also wish to thank the Misses Yoko Endo and Yukiko Endo of this Institute for carrying out the microanalyses.

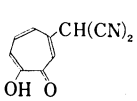
Heptafulvenes. III.[1] *The Synthesis of 8-Cyanoheptafulvenes*[2]

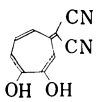
By Yoshio KITAHARA, Kozo DOI and Yoshio SATO

(Received April 24, 1964)

Heptafulvene (I), which is a theoretically-interesting non-benzenoid aromatic hydrocarbon, was synthesized and found to be an extremely unstable liquid.[3] It was discovered,[1,4] however, that its derivatives substituted by two electronegative groups at the 8-position, i. e., 8, 8-dicyano- (II: X=CN) and 8-cyano-8-ethoxycarbonylheptafulvene (II: X=CO_2Et), are fairly stable.

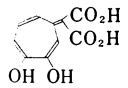


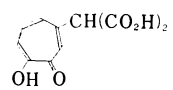
In a previous paper,[5] we have reported that the reaction product of 3-iodotropolone (III) with sodiomalononitrile in liquid ammonia is not a tropolone (IV) but its enolic isomer, 8, 8-dicyano-2, 3-dihydroxyheptafulvene (V). Similar results were also found in the case of two isopropyl derivatives of III.[1]



I

II





III: X=H IV V
IX: X=CH_3
X: X=i-C_3H_7

On the other hand, an acid hydrolysis product of V was also found not to be a heptafulvene (VI) but a tropolone derivative (VII).[1] Therefore, it seemed interesting to study keto-enol tautomerisms between tropolone derivatives possessing a side-chain with active hydrogen at the α-position and the corresponding heptafulvenes. We have found that cyanomethyltropolones gave diacetyl derivatives of the heptafulvene-type on acetylation:

VI VII

Details will be described in this paper.

When 3-iodotropolone (III) reacted with sodioacetonitrile in liquid ammonia, 4-cyanomethyltropolone (VIII) was obtained in a 26 per cent yield. Its structure was confirmed by direct comparison with the dehydration product of 4-carbamoylmethyltropolone.[6] It has been reported that a similar reaction of

XV

chlorobenzene and acetonitrile afforded diphenylacetonitrile other than phenylacetonitrile,[7] but in this case no by-products other than VIII were isolated. In a similar manner, alkyl derivatives (IX and X) of 3-iodotropolone also gave corresponding cyanomethyltropolones (XI and XII).

Figure 1 indicates the ultraviolet absorption curves which are characteristic of other alkyltropolones, while Table I shows several principal maxima of the infrared absorption spectra of the cyanomethyltropolones.

This spectral evidence suggests that the above reaction products of iodotropolones and sodioacetonitrile are tropolone derivatives and that they cannot be their enolic forms (XIII). 4-Cyanomethyltropolone (VIII) afforded only

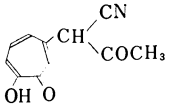
(1) 4-cyanomethyl-(VIII),
(2) 4-cyanomethyl-6-methyl-(XI), and
(3) 4-cyanomethyl-6-isopropyl-(XII) tropolone.

TABLE I. INFRARED ABSORPTION MAXIMA OF 4-CYANOMETHYLTROPOLONES (cm^{-1})

	ν_{OH}	$\nu_{C\equiv N}$	$\nu_{C=O}$	$\nu_{C=C}$	δ_{CH_2}
VIII	3200	2255	1613	1553	1410
IX	3200	2260	1613	1546	1413
XII	3150	2255	1608	1535	1420

two kinds of crystalline monomethoxytropone derivatives on treatment with diazomethane. The structures of these products, 6-cyanomethyl-2-methoxy- (XIV) and 4-cyanomethyl-2-methoxytropone (XV), were determined by a comparison of their absorption peaks based on the CH out-of-plane vibration of the infrared spectra with those of other known substituted tropones[8]: the peaks at 778 (XIV) and 828 (XV) correspond to those at 776 of 2-methoxy-6-methyltropone and 822 cm^{-1} of 2-methoxytropone respectively.



On the other hand, we have found that cyanomethyltropolones yielded products of the heptafulvene-type on acetylation. When 4-cyanomethyltropolone (VIII) was treated in pyridine with acetic anhydride at room temperature, 8-cyano-2, 3-diacetoxyheptafulvene (XVI) and 8-acetyl-8-cyano-2, 3-diacetoxyheptafulvene (XVII) were obtained. The structures of these products were easily drawn out from their analytical values, ultraviolet (Figs. 2 and 3) and infrared spectra (Table II), and hydrolyzed to the starting material VIII under mild conditions.

XVI: X=H
XIX: X=CH_3
XXI: X=*i*-C_3H_7

XVII: X=H
XX: X=CH_3

XVIII

An attempted further acetylation of the diacetyl compound XVI to the triacetyl derivative (XVII) was found to result in only the recovery of the starting material. In the course of the formation of XVII from VIII, there may exist an intermediate, such as XVIII or its enol isomer, which has not yet been isolated.

The similar acetylation of two other alkyl-4-cyanomethyltropolones afforded also similar results: XI yielded both diacetyl (XIX) and triacetyl (XX) derivatives, but XII only a diacetyl compound (XXI). The ultraviolet absorption spectra of these heptafulvenes are shown in Figs. 2 and 3.

Table II indicates some principal maxima of

XX	2195	1770	1650	1640	1200

the infrared absorption spectra of these heptafulvenes. The bands based on the stretching vibration of nitrile groups correspond to the conjugated cyano groups and satisfy their presumed structures. The maxima in the second and fifth columns have strong intensities and can be assigned to acetate groups. The bands at 1650 cm^{-1} of XVII and XX, which are sharp and moderately strong, probably indicate the conjugated ketones. The maxima in the fourth column, based on carbon-carbon double bonds, are medium or weak and are distinguishable from those at 1650 cm^{-1}. Bands corresponding to these have also been discussed in 8, 8-dicyanoheptafulvenes,[1,5] fulvene[9] and 6, 6-dialkylfulvenes.[10] The band of heptafulvene itself has been reported to appear at 1585 cm^{-1} (strong).[3]

Experimental

The ultraviolet absorption spectra in methanol were measured with a Hitachi model EPU-2 recording spectrometer. The infrared spectra were measured with a Perkin-Elmer model 21 infrared spectrometer (rock salt prism and potassium bromide pellets). All melting points are uncorrected.

4-Cyanomethyltropolone (VIII).—Into a sodium amide solution prepared from liquid ammonia (400 ml.) and sodium (9.2 g.) acetonitrile (7 g.) at −50°C was stirred. After 10 min., iodotropolone (III, 25 g.) was added to the above mixture, and then it was stirred while the ammonia was refluxed at atmospheric pressure for 2 hr. After ammonium chloride was added, ammonia was evaporated. The residue was dissolved in water (500 ml.), and the insoluble matter was filtered off. The filtrate was acidified and extracted with ethyl acetate (500 ml.). After the solvent had been removed, the residue was recrystallized from a mixture of benzene and methanol, giving VIII as colorless scales; m. p. and mixed m. p.[6] 134~135°C; 4.2 g. (26% yield).

4-Cyanomethyl-6-methyltropolone (XI). — This was prepared from IX (26.2 g.) under the same conditions as those used for III. Recrystallization from ethyl acetate gave XI (2.6 g., 15%) as colorless prisms; m. p. 154~155°C.

Found: C, 68.72; H, 5.07; N, 8.01. Calcd. for $C_{10}H_9O_2N$: C, 68.56; H, 5.18; N, 8.00%.

4-Cyanomethyl-6-isopropyltropolone (XII).—This was prepared from X (29 g.) under the conditions used for III. Recrystallization from benzene gave XII as colorless needles; m. p. 83~84°C; 8.2 g. (40%).

Found: C, 70.67; H, 5.78; N, 6.66. Calcd. for $C_{12}H_{13}O_2N$: C, 70.91; H, 6.45; N, 6.89%.

XII (0.19 g.) in 75% sulfuric acid (2 ml.) was heated at 150°C for 1 hr., diluted with water, and extracted with ethyl acetate. After the solvent had been removed, the residue was recrystallized from petroleum ether, giving 6-isopropyl-4-methyltropolone; m. p. and mixed[1] m. p. 42~43°C.

The Methylation of 4-Cyanomethyltropolone (VIII). — The addition of an ethereal solution of diazomethane to a cooled suspension of VIII (2 g.) in methanol (5 ml.) caused a violent evolution of gas, and the mixture became a clear solution. When the colorless crystals which separated out soon were filtered, a crude mixture of methoxytropones, m. p. 105~115°C, was obtained (1.9 g.). Fractional crystallization from ethyl acetate gave 6-cyanomethyl-2-methoxytropone (XIV) as colorless prisms from the less soluble portion, m. p. 130~131°C; 0.7 g.; Found: C, 68.66; H, 4.85; N, 8.07. Calcd. for $C_{10}H_9O_2N$: C, 68.56; H, 5.18;

10) J. H. Day and R. Jennkins, *J. Org. Chem.*, **23**, 2039 (1958).

N, 8.00%. λ_{max} mμ (log ε) : 237 (4.42), 320 (3.93). ν_{max} cm^{-1} : 2250, 1630, 1410, 778 ; and 4-cyanomethyl-2-methoxytropone (XV) as colorless needles from the more soluble portion, m. p. 139~140°C ; 0.9 g.; Found : C, 68.64 ; H, 4.83 ; N, 7.98%. λ_{max} mμ (log ε) : 240 (4.43), 320 (3.89). ν_{max} cm^{-1} : 2258, 1630, 1425, 828.

The Acetylation of 4-Cyanomethyltropolone (VIII).—To a solution of VIII (0.2 g.) in pyridine (3 ml.), acetic anhydride (0.5 g.) was added. The mixture was stirred at room temperature for 3 hr., and then acidified with cold dilute hydrochloric acid and extracted with ethyl acetate. The addition of benzene to the residue of the evaporation of the solvent separated out a yellowish solid. Filtration and recrystallization from acetone gave 2,3-diacetoxy-8-cyanoheptafulvene (XVI) as yellow needles ; m. p. 172°C ; 0.05 g.

Found : C, 63.95 ; H, 4.20 ; N, 5.64. Calcd. for $C_{13}H_{11}O_4N$: C, 63.67 ; H, 4.52 ; N, 5.71%.

The benzene filtrate, from which XVI had been removed, was chromatographed on alumina using benzene, and red effluents were collected. The benzene was removed from the effluent, and the residue was recrystallized from a mixture of benzene and cyclohexane to give 8-acetyl-8-cyano-2,3-diacetoxyheptafulvene (XVII) as reddish orange needles ; m. p. 154°C ; 0.1 g.

Found : C, 62.41 ; H, 4.40 ; N, 4.99. Calcd. for $C_{15}H_{13}O_5N$: C, 62.71 ; H, 4.56 ; N, 4.88%.

Further reaction of XVI with acetic anhydride in pyridine resulted in the recovery of only the starting material.

The Alkaline Hydrolysis of XVI and XVII.—XVI (0.12 g.) in 2 N sodium hydroxide (5 ml.) was heated at 50°C for 20 min., and then the solution was acidified with dilute hydrochloric acid, giving 4-cyanomethyltropolone (VIII). The hydrolysis of XVII under the same conditions resulted in the formation of VIII.

The Acetylation of 4-Cyanomethyl-6-methyltropolone (XI).—A solution of XI (0.35 g.), pyridine (4 ml.) and acetic anhydride (0.6 g.) was stirred at room temperature for 3 hr., neutralized by dilute hydrochloric acid, and then extracted with ethyl acetate. The evaporation of the solvent and fractional recrystallization from ethyl acetate gave the following products, which are arranged in the order of increasing solubility to the solvent :

i) 8-Acetyl-8-cyano-2,3-diacetoxy-5-methylheptafulvene (XX) ; m. p. 151~152°C ; reddish orange needles ; 0.2 g.

Found : C, 63.80 ; H, 4.56 ; N, 4.93. Calcd. for $C_{16}H_{15}O_5N$: C, 63.78 ; H, 5.02 ; N, 4.65%.

ii) 8-Cyano-2,3-diacetoxy-5-methylheptafulvene (XIX) ; m. p. 150~151°C ; yellow prisms ; 0.08 g.

Found : C, 65.17 ; H, 5.03 ; N, 5.54. Calcd. for $C_{14}H_{13}O_4N$: C, 64.86 ; H, 5.05 ; N, 5.40%.

iii) 4-Cyanomethyl-6-methyltropolone acetate ; m. p. 118~119°C ; colorless needles ; 0.03 g.

Found : C, 66.20 ; H, 5.09 ; N, 6.69. Calcd. for $C_{12}H_{11}O_3N$: C, 66.35 ; H, 5.10 ; N, 6.45%. λ_{max} mμ (log ε) : 235 (4.43), 318 (3.90). ν_{max} cm^{-1} : 2255, 1755, 1615, 1406.

The Acetylation of 4-Cyanomethyl-6-isopropyltropolone (XII).—A solution of XII (0.38 g.), pyridine (4 ml.) and acetic anhydride (0.6 g.) was stirred at room temperature for 3 hr. and then treated in the same manner as was used in the case of VIII. After recrystallization from ethyl acetate, 8-cyano-2,3-diacetoxy-5-isopropylheptafulvene (XXI) was obtained as yellow needles ; m. p. 154~155°C ; 0.16 g.

Found : C, 67.10 ; H, 5.74 ; N, 5.05. Calcd. for $C_{16}H_{17}O_4N$: C, 66.88 ; H, 5.96 ; N, 4.88%.

*Studies of the Configuration and Conformation of Vinyl-type Polymers. III. The Temperature Dependence of the Infrared Spectra of 2,4-Dichloropentane as a Model Compound of Polyvinyl Chloride**

By Kazuyoshi IIMURA, Takatsugu HAMA, Teruo SHIBUYA and Masatami TAKEDA

(Received April 27, 1964)

In a previous study[1] of the temperature dependence of the infrared spectra of polyvinyl chloride (PVC) in cyclohexanone solution, we found that the intensity ratio of the 696 cm^{-1} band to the 616 cm^{-1} band depends on the temperature, and that this temperature dependence increases with an increase in the syndiotactic configuration of the PVC chain. The temperature dependence has been interpreted as being due to the energy differences among the conformational isomers in the syndiotactic sequences of the PVC chain. Recently, Germar et al. have made a similar study of PVC using the CH_2 bending bands[2] at 1428 and 1432 cm^{-1} and the C–Cl stretching bands[3] near 600~700 cm^{-1}, and have determined its syndiotacticity.

Shimanouchi and Tasumi,[4] however, have studied the infrared spectra of *meso*- and *dl*-2, 4-dichloropentanes as a model compound of PVC and have suggested that the *dl*-compound, which has the same configuration as the syndiotactic PVC, exists only in one stable conformation in which the C–C chain takes the extended T-T form. This suggests that the syndiotactic sequence in PVC might have the only stable conformation in solution; if so, our previons explanation would be invalid, as well as the explanation by Germar et al.

In order to obtain further information on this problem, we have studied the infrared spectra of the *moso*- and *dl*-compounds in various physical states.

Experimental

2, 4-Dichloropentane was prepared from acetylacetone; 2, 4-pentanediol was prepared[5] by the catalytic hydrogenation of acetylacetone with Raney nickel in an autoclave (H_2 pressure: 125 atm.; reaction temperature: 115~125°C; reaction time: 150 min.), and it was converted to 2, 4-dichloropentane by reaction with thionylcloride.[6] The boiling point range of the product was 142~144°C. For the separation of the *meso*- and *dl*-compounds, a Beckman Megachrom preparative gas chromatograph has been used. The purity of the separated compound was certified by infrared inspection.

A Hitachi EPI-2-type double-beam spectrophotometer equipped with a KBr prism was used for the measurement of the infrared spectra. The observation of the solution spectra and their temperature dependence was carried out by using a closed-type cell mounted in a heating device. In order to aid the compensation of absorptions caused by the solvent, a variable-thickness-type cell was inserted in the path of the reference beam. The absorption spectra in a gaseous state were observed with a gas cell 7 cm. in optical path length and with a heating device.

The absorption spectrum in the region of the C–Cl stretching vibrations, which is sensitive to the conformational changes, was also examined.

Results and Discussion

The infrared spectra of the *meso*- and *dl*-compounds in the cyclohexanone solutions at room temperatures are shown in Fig. 1. The results are very similar to the infrared spectra of the pure liquids observed by Shimanouchi and Tasumi;[4] the *meso*-compound has two absorption bands at 683 and 616 cm^{-1}, and the *dl*-compound also has two absorption bands at 629 and 607 cm^{-1}. On the basis of the empirical rules concerning the relation between the frequencies of the C–Cl stretching bands of some chlorohydrocarbons and their geometrical conformations, Shimanouchi and Tasumi[4] have concluded that the *dl*-compound has only one stable conformation in which the C–C chain takes the T-T conformation, and that the *meso*-compound is stable in the conformation of the T-G or G'-T with respect to the C–C

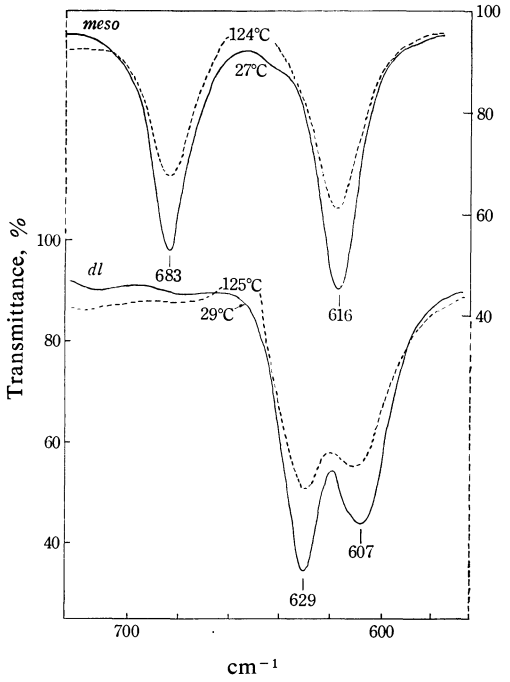

Fig. 1. The infrared spectra of the *meso*- and the *dl*-compounds in a cyclohexanone solution at the various temperatures.

main chain, as Fig. 2 shows. Since the T-G conformation is a mirror-image of the G'-T conformation, both conformations should give the same spectra. The observed infrared spectra of the *dl*- and the *meso*-compounds in the cyclohexanone solutions are caused by the structures of the T-T and the T-G or G'-T conformations respectively.

The purpose of this investigation is to investigate the possible existence of the other species of the rotational isomer of both compounds in a cyclohexanone solution at higher temperatures. Especially, the G'-G' conformation for the *dl*-compound may be expected to appear in the solution at higher temperatures, because the potential energy of the G'-G' conformation would be the next lowest after that of the T-T conformation.[3,8]

However, the infrared spectra of both the *dl*- and the *meso*-compounds in solution at a temperature near 120°C are identical with the respective spectra at room temperature, as is shown in Fig. 1. In the gaseous state, none of the new bands which could be expected from the new conformational isomers other than the T-T conformation in the *dl*-compound can be observed, even in the higher temperatures near 170°C. For the *meso*-compound, in the

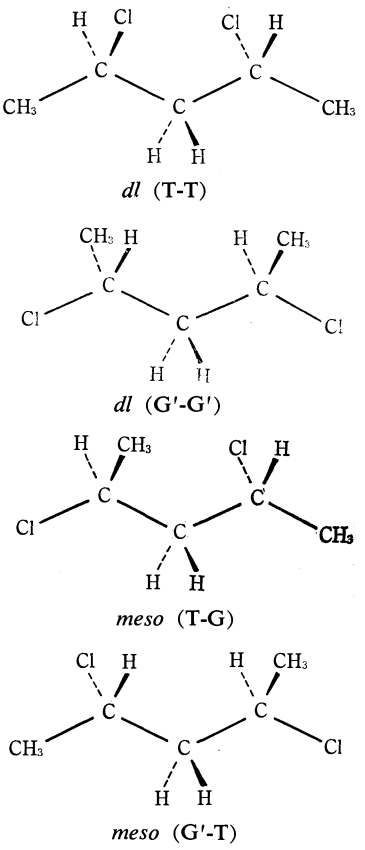

Fig. 2. The probable conformations in the *meso*- and the *dl*-compounds.

gaseous state the infrared spectrum at 164°C does not differ from that at room temperature. These results are shown in Fig. 3.

These facts show that the G'-G' conformation in the *dl*-compound may be rejected because the band centered near 690 cm^{-1}, which is expected from the stretching vibration of the C–Cl bond trans to the adjacent C–C bond in the G'-G' conformation, does not appear in the spectra of the *dl*-compound. Thus, it may be concluded that the sole structure which is stable in the *dl*-compound in the cyclohexanone solution is the structure of the T-T extended conformation in the temperature range of this investigation, as in the previous examination of the solution spectra of PVC. For the *meso*-compound, no stable structures other than the T-G or G'-T conformation could be found in the same temperature range. Consequently, it is impossible to explain the temperature dependence of the intensities of the C–Cl stretching bands of the solution spectra of PVC as being due to the rotational isomerism of the polymer chain so long as 2,4-dichloropentanes are applied as model compounds of PVC.

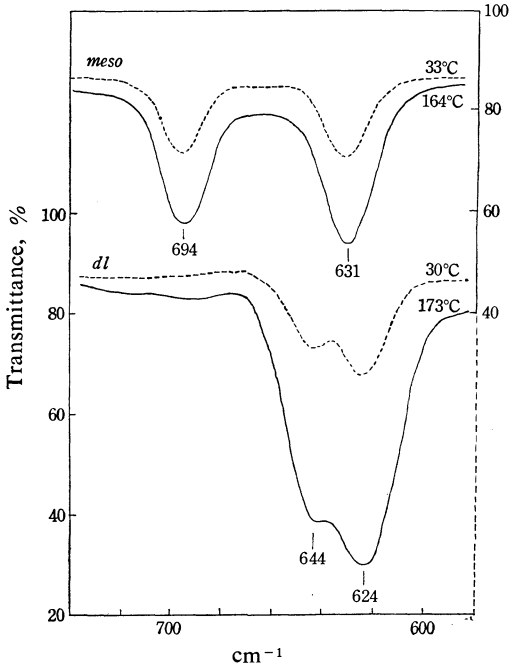

Fig. 3. The infrared spectra of the *meso*- and the *dl*-compounds in the gaseous state at the various temperatures.

In order to obtain further information on the temperature dependence of the intensities of the C–Cl stretching bands of PVC, the infrared spectra of a mixture of 1 cc. of the *meso*-compound and 2.4 cc. of the *dl*-compound (a model of 70% syndiotactic PVC) was investigated in the cyclohexanone solution. In the spectrum of the mixture, the highest frequency and the second highest frequency are caused by the *meso*- and *dl*-compounds respectively. The band at 616 cm^{-1} of the *meso*-compound and the band at 607 cm^{-1} of the *dl*-compound are superposed on the band centered to 612 cm^{-1}. As is shown in Fig. 4, the intensity ratio, D_{612}/D_{683}, of the mixture depends only slightly on the temperature, while the corresponding intensity ratio, D_{616}/D_{696}, of PVC depends strongly on the temperature. In the case of the isolated compound, the relative intensity of the two C–Cl stretching bands of the *meso*-compound only slighty depends on the temperature. However, that of the *dl*-compound shows a remarkable dependence on temperature, as Fig. 5 shows. The change in the intensity ratio D_{612}/D_{683} in the solution spectra of the mixture with heating is dut to the contribution from the temperature effect on the intensities of the absorption bands of the *dl*-component. However, the reason why the greater temperature effect can be found in the *dl*-compound can not be determined.

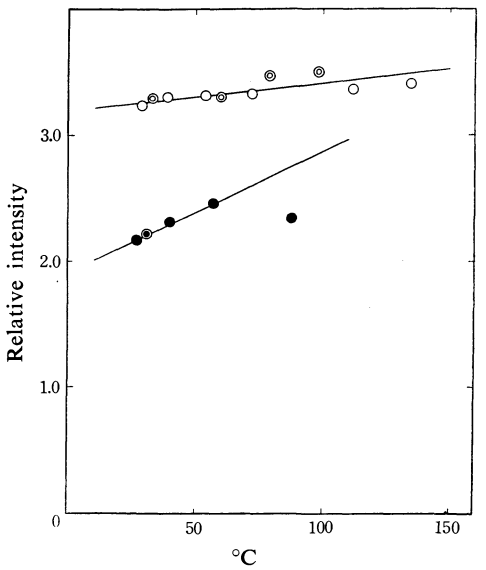

Fig. 4. The temperature dependence of the relative intensities of the C–Cl stretching bands of the *dl-meso* mixture and of the syndiotactic PVC (polymerized at −60°C) in cyclohexanone solutions. The double circles denote the observed points obtained on cooling.

-○- *dl*, D_{629}/D_{607}
-●- *meso*, D_{683}/D_{616}

The remarkable temperature dependence of the solution spectra of PVC may probably be ascribed to the effect of the interchain interaction among the polymers. This speculation is consistent with the result reported by Asahina and Enomoto;[9] in a cyclohexanone solution, the intensity of the 648 cm^{-1} band of PVC has a tendency to decrease with the concentration decrease of the syndiotacticity. In a rather concentrated solution, it seems likely that the longer syndiotactic sequences of the polymer chain lie in a quasi-crystalline state, in which the conformation of the polymer chain may be in the extended T-T form. As Fig. 6 shows, this is confirmed by the fact that, in the solution spectra, the intensity of the 648 cm^{-1} band to which the crystalline syndiotactic parts contribute[10] becomes stronger as the polymerization temperature of the polymer is lowered. Figure 7 gives the intensity change with the heating of the C–Cl stretching bands of the syndiotactic PVC (polymerized at −60°C) in the cyclohexanone solution. With an increase in the temperature, the desolvation of the quasi-crystalline parts in the solution occurs and leads to a decrease in the relative intensity ratio, D_{648}/D_{696}, accompanied by an increase in the relative intensity ratio, D_{616}/D_{696}. In the later intensity ratio, the 616 cm^{-1} band has been assigned to the amorphous syndiotactic part.[10]

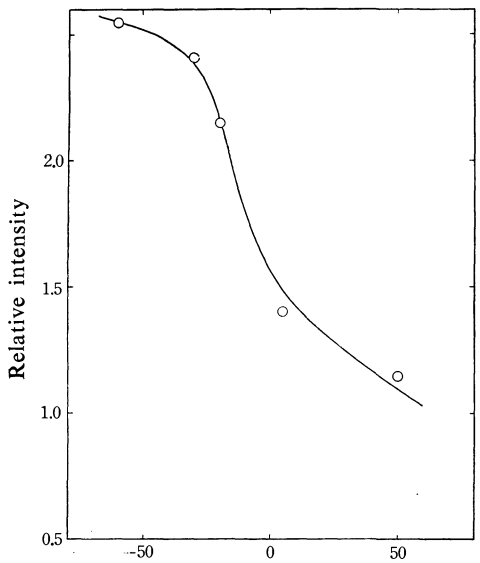

Fig. 6. The relation between the relative intensities of the C-Cl stretching bands of PVCs in cyclohexanone solutions at 30~35°C, against the polymerization temperature of the polymers. -○- D_{648}/D_{696}

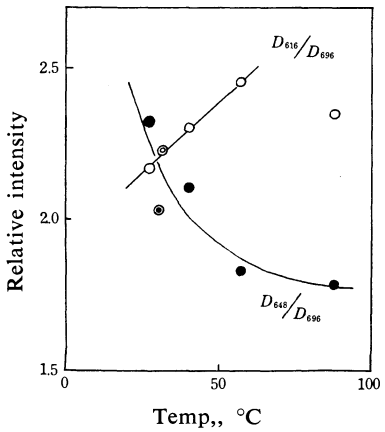

Fig. 7. The temperature dependence of the relative intensities of the C-Cl stretching bands of the syndiotactic PVC (polymerized at −60°C) in a cyclohexanone solution. The double circles; as for Fig. 4.

In the light of the above experimental results, we have come to the following conclusions. Firstly, if the C–Cl stretching bands fall in different frequency regions depending on the two substituents which are trans to the Cl atom across the two adjacent C–C bonds, as has been pointed out by Krimm,[11] a compound which at least consists of the three monomeric units of PVC must be employed as a model compound of PVC. Secondly, the temperature dependence of the absorption intensity in the spectra of PVC cannot be directly related to the rotational isomerism of the polymer chain. Moreover, the intensity of the C–Cl stretching bands of the syndiotactic and the isotactic sequences of PVC may be differently affected by the temperature.

In addition to the results given by us[1] and Germar[3], such a temperature effect on the intensity of the C–Cl stretching band and the effect of the interchain interactions among the polymers must be taken into account in the interpretation of the temperature dependence on the infrared spectra of PVC.

We are indebted to Dr. Yōichirō Mashiko and Mr. Hiroshi Tomita of the Government Industrial Research Institute of Tokyo for letting us use the Beckman Megachrom of that Institute.

*Nuclear Magnetic Resonance Spectra of Polymethyl Methacrylate in Solution. II. The Calibration of the Infrared Absorption Method and Some Applications to the Study of the Polymerization Mechanism**

By Yoshinori KATO, Haruaki WATANABE and Atsuo NISHIOKA

(Received May 12, 1964)

In the preceding paper,[1] it was shown that the degree of the stereoregularity of polymethyl methacrylate could be determined from the NMR spectrum by analyzing three peaks due to α-methyl protons. The proportions of their areas were represented in the ternary diagram with a single point. For free radical polymers, the plots were found to be in good accordance with a relationship that was represented by a unique curve in the diagram. It was also found that the manner of the growth of the molecular chains in free radical polymerization could be described by a single parameter, p, which depends only upon the polymerization temperature. On the other hand, polymers prepared in anionic polymerization exhibited quite different stereochemical configurations from those obtained in free radical polymerization, depending on the initiators employed.

It is the purpose of this paper to extend our method further and to apply it, as far as possible, to the investigation of the anionic polymerization mechanisms. As a matter of convenience, the infrared method[2] calibrated by our NMR method has been frequently employed for the measurement of the stereoregularity. The same notations as have been discussed in the previous paper will be used here.

Experimental

The preparation of samples and the NMR spectra have already been described in the preceding paper.[1] The infrared spectra were observed with a Hitachi EPI-2 infrared spectrometer. In order to improve the reproducibility of the results, the sample films were made on glass plates from a benzene solution by evaporating the solvent. So far as we know, benzene is the best solvent to use to obtain sample films uniform in thickness. Two pairs of bands of the infrared spectra, i. e., the 1063 cm^{-1} and 1393 cm^{-1} and the 749 cm^{-1} and 757 cm^{-1} bands, were used to estimate the fractions of the *S*- and *I*-parts of the sample respectively.[2,3] The rest was taken to be the *D*-part. The estimations were based on a quantitative curve which had been obtained through the analysis of mixtures of two samples. The infrared spectrum of a "stereoblock polymer" is exactly the same as that of a mixture of isotactic and syndiotactic polymers if the proportions of their quantities are appropriately chosen. Therefore, two standard samples were employed to fix the quantitative curve; one was a polymethyl methacrylate prepared with benzoyl peroxide at −35°C, and the other was a sample obtained with phenylmagnesium bromide at 20°C. The stereochemical configurations of these samples were determined by the NMR method. For the former, $s=0.85$ and $h=0.13$, while for the latter almost all of the monomer placements in the molecular chains were recognized as isotactic. Taking account of these findings, the samples were mixed in various proportions to

obtain the infrared spectra. Once the quantitative curve is fixed, the estimation of the degree of stereoregularity for any polymethyl methacrylate becomes possible. Part of the results, together with those obtained by the NMR method, are given for ready comparison in Table I. There is practical agreement between these two sets of results. Therefore, they will be used without distinction throughout the rest of this paper.

The extraction of the sample with acetone was carried out at room temperature in order to measure the stereoregularities of both the extract and the residue. If any difference is found between them, the process of polymerization will consist of more than one mechanism.

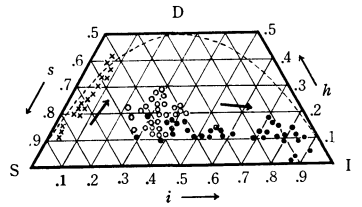

Fig. 1. Ternary diagram representing the stereoregularities of polymethyl methacrylates prepared with free radical initiators (×), and anionic initiators: R_2Mg (○), and RMgBr (●). Two bold arrows indicate how the stereoregularities vary as the polymerization temperature increases.

Results

To examine the habit of distribution in the ternary diagram, many samples, prepared with different catalysts at various polymerization temperatures, were used. The results are shown in Fig. 1. Most of them were obtained by the infrared method described above. The types of catalyst for our anionic polymerization of methyl methacrylate may be represented as RMgBr and R_2Mg, where R indicates an alkyl group, and so on. For our experiments, ethyl, *n*-butyl, *n*-propyl, *n*-amyl, *n*-heptyl and phenyl groups have been taken as R in RMgBr, and, again, ethyl, *n*-butyl, isobutyl, phenyl and cyclohexyl groups as R in R_2Mg.

From Fig. 1 it may be seen that the polymer prepared with an R_2Mg-type catalyst, especially at 0°C and below, seems to have a rather constant stereochemical configuration regardless of the polymerization temperature and the species of R. As compared with the above polymer, the stereochemical configuration of the polymer with RMgBr as a catalyst is more isotactic and varies to a considerable degree with the polymerization temperature. The bold horizontal arrow in Fig. 1 indicates how the configuration changes as the polymerization temperature increases from −78°C to 20°C.

It is not correct to base discussions of the mechanism of polymerization upon the apparent stereochemical configuration of the polymer chains if the apparent configuration is not homogeneous. In fact, the extraction of the samples with acetone frequently resulted in two components with different stereoregularities. For polymers made with R_2Mg as the catalyst, the extracted components include more *D*-units than the residues. On the other hand, samples with RMgBr as the catalyst seem to contain both isotactic (the extracts) and stereoblock (the residues) components. In Fig. 2 are collected the results of the extraction with acetone. As has been mentioned previously, a mixture of two components of different stereoregularities exhibits an average stereochemical configuration. This configuration can be represented, in terms of our ternary diagram, by the point which divides the distance between the two plots corresponding to the two components in the inverse ratio of each weight. Therefore, in order to discuss the mechanism of the polymerization, it is necessary to weigh both the extract and the residue separately. Otherwise we can not say which mechanism is more important in the course of polymerization. These average configurations are also shown in Fig. 2.

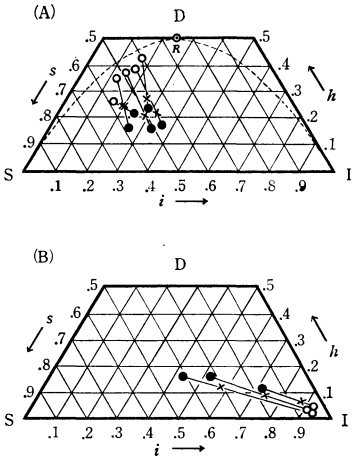

Fig. 2. Ternary representation of the stereoregularities of the acetone-extract (○) and the residue (●) of the samples: (A) with R_2Mg, at −50°C; (B) with ethylmagnesium-bromide; at −40, −20 and −10°C. The average configurations of unseparated samples are represented by the crosses, ×.

Statistical Treatment. — In the preceding paper, a simple statistical method was applied to some cases.

Here we will initially consider the concept of the Ising model, which has been used in formulating the statistical mechanics of the

linear chain.[4] In has also been applied in an extended way to a problem of the polymer chain by Chûjô and Miyake.[5] Since the proportions of *I*-, *D*- and *S*-units in the polymer chains are given through the analysis of the NMR spectrum, the statistical method can be applied to interpret any locus in the ternary diagram which corresponds to the change in stereoregularity of polymers with the polymerization temperature under the conditions of a definite type of catalyst. For free radical polymers, however, the situation is so simple that, on the basis of the statistics, we can discuss the mechanism of the polymerization itself.[1]

In order to cover all the distributions of the plots in the ternary diagram, two parameters must be introduced, because the degree of freedom of our data obtained from NMR measurements is two by nature; that is the proportions of stereoregularity of the three components, *i*, *h* and *s*, always satisfy the relationship;

$$i+h+s=1 \tag{1}$$

and, therefore, only two of them are independent.

We define a transition matrix as:

$$\boldsymbol{A}=\begin{array}{c} \\ 0 \\ 1 \end{array}\begin{array}{c} \begin{array}{cc} 0 & 1 \end{array} \\ \begin{pmatrix} BC & B^{1/2} \\ B^{1/2} & 1 \end{pmatrix} \end{array} \tag{2}$$

where B and C are the parameters whose physical meanings are to be clarified in connection with the polymerization reaction. The notations of rows and columns are the same as those defined with the sequence $\oplus\{A\}$, which represents the states of bonds. Let us denote the product of the matrix as:

$$\boldsymbol{A}^n=\overbrace{\boldsymbol{A}\times\boldsymbol{A}\times\cdots\cdots\times\boldsymbol{A}}^{n} \tag{3}$$

Then it can easily be shown that the element of $\boldsymbol{A}^n$, for example, in the upper row and the right column represents the possible transitions which begin with the state "0" and end in the state "1". The number of ways of transition equals 2^{n-1}, the same as the number of terms contained in the matrix element. The correspondence between the element expressed by B and C and the binary sequence of 0's and 1's, that is, the sequence $\oplus\{A\}$, is illustrated (for $n=10$) in the following example:

$$\begin{array}{cccccccc} 0 & 0 & 1 & 0 & 0 & 1 & 0 & \\ BC\times & B^{1/2}\times & B^{1/2}\times & BC\times & B^{1/2}\times & B^{1/2}\times & B^{1/2}\times & \\ 1 & 0 & 1 & 1 & : \oplus\{A\} & & & \\ \times B^{1/2}\times & B^{1/2}\times 1 & = & B^{11/2}C^2 & & & & \end{array}$$

From this, we may say that the matrix element increases by the factor of B when any 0 occurs in the sequence $\oplus\{A\}$, and by the factor of C only when a 0-0 pair is formed in it. The square root of B in Eq. 2 was taken so as to prevent the double counting of 0's. Since the above-mentioned 0-0 pair represents two isotactic placements among three consecutive monomer units, we may say that C in Eq. 2 has been introduced to denote a kind of longer-range effect which will occur within the three consecutive monomer units. As is always the case with very long chains,[6] we can close the sequence $\oplus\{A\}$ on the assumption that the first digit is equal to the last one. On this assumption, the off-diagonal elements of the matrix $\boldsymbol{A}^n$ vanish for the large integer, N. Our next problem is to calculate only the sum of the diagonal elements which will contain, on our assumption, all the possible sequences of $\oplus\{A\}$. In practice, however, the sequences are represented by two parameters, B and C, in the sum instead of by 0 and 1. We designate the sum by Z. Then, for instance, the number of 0's in a possible sequence of $\oplus\{A\}$ equals the weighted mean of all the terms in Z, each weighted by the power of B. Therefore, it can be obtained as the partial derivative of $\ln Z$ with respect to $\ln B$.

It is clear that:

$$Z=\text{Trace}\,(\boldsymbol{A}^n) \tag{4}$$

If we transform $\boldsymbol{A}$ into a diagonal matrix:

$$\boldsymbol{S}^{-1}\boldsymbol{A}\boldsymbol{S}=\begin{pmatrix}\lambda_1 & 0\\ 0 & \lambda_2\end{pmatrix} \tag{5}$$

then from Eq. 4 we get:

$$\begin{aligned} Z&=\text{Trace}\,((\boldsymbol{S}^{-1}\boldsymbol{A}\boldsymbol{S})^n)\\ &=\text{Trace}\begin{pmatrix}\lambda_1{}^n & 0\\ 0 & \lambda_2{}^n\end{pmatrix}=\lambda_1{}^n+\lambda_2{}^n \end{aligned} \tag{6}$$

Without the loss of generality, we may assume here that $\lambda_1 > \lambda_2$.

Finally, if the length, n, of the sequence $\oplus\{A\}$ tends to infinity, the smaller root, λ_2, may be neglected. That is:

$$Z\cong\lambda_1{}^n \tag{7}$$

The larger eigenvalue, λ_1, can be given from the secular equation:

$$\begin{vmatrix} BC-\lambda & B^{1/2} \\ B^{1/2} & 1-\lambda \end{vmatrix}=0 \tag{8}$$

4) H. A. Kramers and G. H. Wannier, *Phys. Rev.*, **60**, 252 (1941).

5) R. Chûjô and A. Miyake, *Busseiron-Kenkyu*, [2], **3**, 754 (1958), (in Japanese); A. Miyake, ibid., [2], **4**, 671 (1958); A. Miyake and R. Chûjô, *J. Polymer Sci.*, **46**, 163 (1960).

6) E. W. Montroll, *J. Chem. Phys.*, **9**, 26 (1941).

and the results is:

$$\lambda_1=\frac{BC+1+\sqrt{(BC-1)^2+4B}}{2} \tag{9}$$

From this equation, the probability of the occurrence of 0's in a possible sequences of $\oplus\{A\}$ is given by:

$$P_0=\frac{1}{n}\cdot\frac{\partial \ln Z}{\partial \ln B}=\frac{\partial \ln \lambda_1}{\partial \ln B}$$

$$=\frac{BC\sqrt{(BC-1)^2+4B}+BC(BC-1)+2B}{(BC+1)\sqrt{(BC-1)^2+4B}+(BC-1)^2+4B} \tag{10}$$

and that of 1's is found to be:

$$P_1=1-P_0$$

$$=\frac{\sqrt{(BC-1)^2+4B}-(BC-1)+2B}{(BC+1)\sqrt{(BC-1)^2+4B}+(BC-1)^2+4B} \tag{11}$$

In the sequence $\ominus\oplus\{A\}$, the relationships:

$$P_0=i+h/2 \tag{12}$$

and

$$P_1=s+h/2 \tag{13}$$

must hold, where i, h and s represent the probabilities of the occurrence of I-, D- and S-units respectively in the sequence $\ominus\oplus\{A\}$. Since

$$i=\frac{\partial \ln \lambda_1}{\partial \ln C}$$

$$=\frac{BC\sqrt{(BC-1)^2+4B}+BC(BC-1)}{(BC+1)\sqrt{(BC-1)^2+4B}+(BC-1)^2+4B} \tag{14}$$

therefore, from Eq. 10 to Eq. 13, it is found that:

$$s=\frac{\sqrt{(BC-1)^2+4B}-(BC-1)}{(BC+1)\sqrt{(BC-1)^2+4B}+(BC-1)^2+4B} \tag{15}$$

$$h=\frac{4B}{(BC+1)\sqrt{(BC-1)^2+4B}+(BC-1)^2+4B} \tag{16}$$

Here we notice that when the parameter C tends to unity, these results must become as follows:[7]

$$i=B^2/(B+1)^2 \tag{14'}$$

$$s=1/(B+1)^2 \tag{15'}$$

$$h=2B/(B+1)^2 \tag{16'}$$

Equations 14' to 16' correspond to Eqs. 16 to 18 in the previous paper,[1] where only the single parameter p was introduced into our discussion. The equivalent to Eq. 19 in the paper may be obtained from Eqs. 14 to 16 as:

$$4i\cdot s/h^2=C \tag{17}$$

This means that the parameter C is a measure of the deviation from the single parameter case. When C is given, the locus in the ternary diagram will be fixed by using Eqs. 1 and 17.

Using h and s, BC and B may be represented as:

$$BC=1+\left(\frac{h}{s}\right)\left(\frac{1-2s-h}{2-2s-h}\right) \tag{18}$$

$$B=\frac{1}{4}\left(\frac{h}{s}\right)^2\left\{\frac{1}{2-2s-h}\right\} \tag{19}$$

Further, we define the following matrix to calculate the average sequence lengths in the sequence $\ominus\oplus\{A\}$:

$$\boldsymbol{G}=\begin{array}{c} \\ 0\,0 \\ 0\,1 \\ 1\,0 \\ 1\,1 \end{array}\begin{array}{c} \begin{array}{cccc} 0\,0 & 0\,1 & 1\,0 & 1\,1 \end{array} \\ \begin{pmatrix} BC & B^{2/3}C^{1/2}E & 0 & 0 \\ 0 & 0 & B^{2/3} & B^{1/3}F \\ B^{2/3}C^{1/2}E & B^{1/3} & 0 & 0 \\ 0 & 0 & B^{1/3}F & 1 \end{pmatrix} \end{array} \tag{20}$$

The derivation of the matrix element in the 00th row and the 01th column, which corresponds to an ID pair, is illustrated in the following sequence of $\oplus\{A\}$:

$$\cdots\cdots\ 1\quad 0\quad 0\quad 0\quad 1\ \cdots\cdots$$

$$1\quad B^{1/3}\quad \underbrace{B^{1/3}\ B^{1/3}}\quad 1$$

$$1\quad C\quad \underbrace{C\quad 1}$$

$$E\quad 1\quad E$$

Two temporary parameters, E and F, have been introduced into Eq. 20 to specify the pairs, ID (or DI) and SD (or DS) respectively. The secular equation of this problem is:

$$\begin{vmatrix} BC-\lambda & B^{2/3}C^{1/2}E & 0 & 0 \\ 0 & -\lambda & B^{2/3} & B^{1/3}F \\ B^{2/3}C^{1/2}E & B^{1/3} & -\lambda & 0 \\ 0 & 0 & B^{1/3}F & 1-\lambda \end{vmatrix}=0 \tag{21}$$

which is equivalent to the equation:

$$\lambda^4-(1+BC)\lambda^3+B(C-1)\lambda^2$$
$$+B(1+BC-F-BCE^2)\lambda$$
$$+B^2C(E^2+F^2-1-E^2F^2)=0 \tag{22}$$

Let us denote the largest eigenvalue by λ_2. If we replace both E and F by unity, λ_2 becomes equal to λ_1. Therefore, in our previous notation[1] we obtain:

$$[\{I\}]=\frac{n}{2}\lim_{E,F\to 1}\frac{\partial \ln \lambda_2}{\partial \ln E}$$

$$=\frac{nB^2C}{4\lambda_1^3-3(1+BC)\lambda_1^2+2B(C-1)\lambda_1} \tag{23}$$

7) A. Miyake, Private communication.

Finally, from Eqs. 9 and 23 we get:

$$\langle I\rangle = [I]/[\{I\}] = \lambda_1(\lambda_1-1)/B$$
$$= \frac{BC^2-C+2+C\sqrt{(BC-1)^2+4B}}{2} \quad (24)$$

Similarly,

$$\langle S\rangle = \frac{\lambda_1-B(C-1)}{B}$$
$$= \frac{1-BC+2B+\sqrt{(BC-1)^2+4B}}{2B} \quad (25)$$

and

$$\langle D\rangle = \frac{2\lambda_1}{BC+1} = \frac{BC+1+\sqrt{(BC-1)^2+4B}}{BC+1} \quad (26)$$

are obtained by noticing that

$$[\{I\}] + [\{S\}] = [\{D\}] \quad (27)$$

Using measurable values, these average lengths may be written in this form;

$$\langle I\rangle = 1+2i/h \quad (28)$$
$$\langle S\rangle = 1+2s/h \quad (29)$$
$$\langle D\rangle = 1+h/\{1-h-(i-s)^2\} \quad (30)$$

The same procedure has been independently developed by Miyake and Sakakibara.[8] In spite of our different interpretation of the parameters, the two sets of obtained results are easily interchangeable by replacing our BC and B parameters with their B and C^2 parameters respectively.

Discussion

Table II lists the observed results of the samples prepared in anionic polymerization. They are also shown in Fig. 2.

Since the product of the parameters B and C corresponds to the probability of forming a 0-0 pair in the sequence $\oplus\{A\}$, the polymer characterized by $BC=1$ has the same values of i and s. It is easily shown that when $BC>1$, the value of i is larger than that of s, while when $BC<1$, that of i is smaller. The average sequence lengths can be calculated from Eqs. 28 to 30; they are given in Table III.

The extraction with acetone has been made in expectation of separating the contributions from several different mechanisms which coexist in our anionic polymerization.

As for the sample prepared with an R_2Mg-type catalyst, the stereochemical configuration depends little upon the polymerization temperature, especially between $-30°C$ and $-60°C$. Therefore, the extraction was carried out only with the samples obtained at $-50°C$. It must be noticed that, in the ternary diagram, the plots for the soluble parts are located comparatively near the point, R, which corresponds to the random polymer. This implies that the configuration of these parts resembles that of the polymer made in free radical polymerization. Unfortunately, because of the narrow range of the polymerization temperature, we can not conclude at present whether or not the mechanism yielding these soluble parts may be interpreted by the single parameter p.

Assuming, however, the uniformity of stereochemical configuration in each polymer chain, it is certain that two mechanisms of polymerization take place with an R_2Mg-type catalyst. They may be ascribed to two states of the catalyst, such as the monomer state and the associated state.[9] If this is the case probably the catalyst in the former state would produce polymer chains with a configuration similar to those obtained in free radical polymerization. On the other hand, the catalyst in the latter state would have a strong influence on the addition of the monomer and yield more stereoregular polymer chains. In

26	0.94	0.18	30.8	5.53	7.82	1.18

fact, the results shown in Fig. 2 demonstrate that the insoluble part of the sample made with an R_2Mg catalyst has nearly the same stereochemical configuration as that of the polymer prepared with RMgBr as a catalyst. These facts may be also found from the values of the parameters $B^{1/2}$ and C collected in Table II. For each sample prepared with various R_2Mg-type catalysts, a comparison of the parameters of the insoluble part with those of the soluble one clearly shows that the value of B decreases, while that of C conspicuously increases. For the sake of simplicity, let us assume here that no essential change will occur in the S-blocks of both parts. Then, following the notations defined with the sequence $\ominus \oplus\{A\}$, the above-mentioned change of parameters indicates the possibility of forming subsequences which contain even D's between I-blocks, such as:

$$\cdots\cdots SIIIDDIIDDDDIS\cdots\cdots$$

Of course, we have no evidence to support the assumption concerning the S-blocks, so it is impossible to discuss the formation of such polymer chains. However, as has been mentioned already, from the unique locus of the plots in the ternary diagram, it seems quite reasonable to conclude that two mechanisms take place in the course of the polymerization using an R_2Mg catalyst and that they yield both atactic and stereoblock polymer chains separately.

Next, let us consider the polymers made with an RMgBr catalyst. In this case, the results of the viscosity measurement strongly suggest that the apparent difference in the configuration parameters between the soluble and the insoluble parts can not be attributed to the polymerization mechanisms alone. This point has been examined in detail using the polymer prepared at $-78°C$. The typical value of η_{sp}/C ($C=0.20$ g./100 cc.) for the soluble part in acetone is about 0.2, while that for the insoluble part is about 0.6. In spite of these broad molecular weight distributions, the average stereochemical configurations did not change with the values of conversion. On this basis, we may conclude that a single mechanism takes place in the polymerization catalyzed by RMgBr.

It has been shown that the statistical treatment of the polymer chain is a convenient method for the analysis of the polymerization mechanism. However, there is a limitation in this treatment. Since the NMR spectra of polymethyl methacrylate can only give the proportions of I-, D- and S-units in the polymer chains, any longer-range effect needs another parameter whose interpretation is not always unique. Recently several workers[8,10-12] have dealt with the data obtained from the NMR spectra, and very recently the applicability of the statistics based on these data has been discussed in detail from the viewpoint of statistical stationarity.[13]

Summary

In the preceding paper[1] it was reported that the degree of the stereoregularity of polymethyl methacrylate could be determined from the NMR spectrum through the analysis of three peaks due to the α-methyl groups. It has been found that the infrared spectrum can also give an equivalent result if it is once calibrated by the NMR method.

We have considered a statistical method to interpret any locus in the ternary diagram which corresponds to the change in the stereoregularity of polymers with the polymerization temperature and with the type of catalyst. By

introducing two parameters, the average sequence lengths of *I*-, *D*- and *S*-blocks have been calculated.

On the other hand, the acetone-extraction of the samples prepared in anionic polymerization has been carried out in order to determine the degree of stereoregularity of both the extract and the residue. From the plots in the ternary diagram, we have discussed some mechanisms of the anionic polymerization. We may conclude that two different mechanisms take place in the course of the polymerization using an R_2Mg catalyst in contrast with the polymerization catalyzed by RMgBr.

We wish to thank Professor Akira Miyake of the Department of Physics, International Christian University, for his valuable advice and criticism.

A Possibility for Determining the Entropies of Electrolytes from the Initial Thermoelectric Powers of Thermocells

By Toshio IKEDA

(Received May 13, 1964)

The partial molar entropy of a uni-univalent electrolyte (MX) in an aqueous m molal solution, can usually be calculated by the formal formula:

$$\left.\begin{aligned} S_{MX} &= S_+ + S_- = S^\circ_{MX} - 2\boldsymbol{R} \ln m\gamma_\pm \\ &\quad - 2\boldsymbol{R}\boldsymbol{T} \mathrm{d} \ln \gamma_\pm / \mathrm{d}\boldsymbol{T} \\ S^\circ_{MX} &= S^\circ_+ + S^\circ_- \end{aligned}\right\} \quad (1)$$

where S_+ and S_- are the partial molar entropies of cations and anions respectively, and S°_+ and S°_- refer to those at the standard state; $\gamma_\pm$ denotes the mean ion activity coefficient; $\boldsymbol{R}$ is the gas constant and $\boldsymbol{T}$ is the absolute temperature. The conventional values of the standard partial molar entropies of ions are available in Latimer's work[1] and also in NBS services.[2] Slight differences can be seen between them, however, and they are always worked up to yield the third-law molecular entropies (S°_{MX}) so as to be independent of the choice of the convention for the ion entropies. At any rate, it must be noted that most of these values have been determined from thermodynamic data on isothermal systems. The present writer will report a rather different basis for determining the partial molar entropies of electrolytes in aqueous solutions at the third-law convention from the thermoelectric data on non-isothermal systems without making any conventional assumptions.

Thermodynamic Relations. — In the case of thermocells with a single uni-univalent electrolyte, MX, which yields M^+ and X^- on dissociation, the initial thermoelectric power, ε_0, can be written as follows:[3]

$$\boldsymbol{F}\varepsilon_0^{\mathrm{C}} = -t_+ S^*_+ + t_- S^*_- + \Delta S^{\circ\mathrm{C}} - (S^{\mathrm{C}}_{\mathrm{el}} + S^{*\mathrm{C}}_{\mathrm{el}}) - S_+ \quad (2)$$

for thermocells with cation-reversible electrodes, whose characteristics are indicated by the superscript C, and

$$\boldsymbol{F}\varepsilon_0^{\mathrm{A}} = -t_+ S^*_+ + t_- S^*_- + \Delta S^{\circ\mathrm{A}} - (S^{\mathrm{A}}_{\mathrm{el}} + S^{*\mathrm{A}}_{\mathrm{el}}) + S_- \quad (3)$$

for thermocells with anion-reversible electrodes, whose characteristics are indicated by the superscript A. Here, $\boldsymbol{F}$ is the Faraday constant; t_+ and t_- are the transport numbers of cations and anions respectively, related in $t_+ + t_- = 1$ by difinition; S^*_+ and S^*_- are the partial molar Eastman entropies of the transfer of cations and anions respectively, the quantities defined by the ionic heats of transfer divided by the absolute temperature; S_{el} and S^*_{el} are the partial molar entropy and the entropy of the transfer of electrons in the metallic leads of the thermocell respectively; S_+ and S_- are the partial molar entropies of cations and anions respectively; ΔS°'s refer to the contributions from the changes in the standard molar entropies of the electrode materials of the thermocells for the electrode reactions per Faraday, differing according to the electrode

* If an alternative value of $\varepsilon_0^A=296$ μV./deg., which is given by interpolation of Sasaki's recent data on thermocell [Ag/AgCl, HCl (0.01 M)] at 25°C, is used, we get $S_{HCl}=31.7_6$ e. u. or $S^\circ_{HCl}=12.9_6$ e. u. (K. Sasaki, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **82**, 654 (1961); Haase and his co-worker gave 290 μV./deg. for [Ag/AgCl, HCl (0.01 M)] and 437.7 μV./deg. for [Ag/AgBr, HBr (0.01 M)] at 25°C (R. Haase and H. Schönert, *Z. physik. Chem. N. F.*, **25**, 193 (1960)).

systems (their practical forms are, for example, $\Delta S^{\circ C}=(1/2)S^\circ_{H_2}$ for a hydrogen electrode; $\Delta S^{\circ A}=S^\circ_{Ag}-S^\circ_{AgX}$ for silver/silver halide electrodes, $S^\circ_{Hg}-S^\circ_{HgCl}$ for mercury/mercurous chloride electrodes, and so on). From Eqs. 2 and 3, the partial molar entropy of a uni-univalent electrolyte, MX, is derived as follows:

$$S_{MX}=S_+ +S_- =\boldsymbol{F}(\varepsilon_0^A-\varepsilon_0^C)+\Delta S^{\circ C}-\Delta S^{\circ A} -(S_{el}^C+S_{el}^{*C}-S_{el}^A-S_{el}^{*A}) \quad (4)$$

Since the quantities on the right-hand-side of 4 are all measurable experimentally, the left-hand-side quantity can be determined.

Calculations. — In the literature, however, there are unexpectedly few examples to which the present method is applicable.[4,5] The only examples now available are the following combinations of thermocell systems;* (a) [Pt, H_2/HCl] with [Hg/HgCl, HCl]; (b) [Pt, H_2/HCl] with [Ag/AgCl, HCl]; (c) [Pt, H_2/HBr] with [Ag/AgBr, HBr], and (d) [Pt, H_2/HI] with [Ag/AgI, HI], all at 25°C and 0.01 M. The values of the initial thermoelectric powers which were used in our calculations are accurate to within 1.8 μV./deg. at worst, judging from the accuracy of other experiments we have performed along similar lines. Finally, the entropy terms regarding electrons in the metallic leads of two thermocells can be estimated from the thermoelectric power of a thermocouple composed of two metals of the same kinds as those used as the leads in these thermocells. The thermoelectric power, ε(C/A), of a metal C with respect to A can be defined as follows:[3]

$$\boldsymbol{F}\varepsilon(C/A)=-(S_{el}^C+S_{el}^{*C}-S_{el}^A-S_{el}^{*A}) \quad (5)$$

Here the sign of ε(C/A) was taken, in accordance with the convention adopted by most authors, to be positive if the current so produced in the thermocouple flows at the cold junction from C to A. According to Temkin and Khoroshin,[6] we have ε(Pt/Cu) = -6.39 μV./deg. at 25°C, while ε(Ag/Cu) = $+0.08\pm0.01$ μV./deg. was observed by the present writer. Therefore, we have ε(Pt/Ag) = -6.47 μV./deg., or equivalent to -0.15 e.u.; it is ready to use in the cases of b, c and d. In the case of a, on the other hand, such an electronic contribution vanishes, because the electrode leads of these two thermocells are both made of the same platinum. By using the authorized values of the standard partial molar entropies ($S^\circ_{H_2}$ = 31.211 ($\pm$0.01) e. u.,[2] $S^\circ_{Hg(liq.)}=18.187$ ($\pm$0.02) e. u.,[7] $S^\circ_{HgCl}=23.4$ e. u.[2], $S^\circ_{Ag}=10.206$ ($\pm$0.01)

4) Ref. 3, p. 285.
5) T. Ikeda, *Rep. Liberal Arts Sci. Fac., Shizuoka Univ., Nat. Sci.*, 2, 159 (1959).
* For example, [Ag/AgCl, HCl] represents a thermocell system, Ag/AgCl (T), HCl, AgCl/Ag ($T+\Delta T$).

e. u.,[2,8] $S^{\circ}_{AgCl}=22.97\pm0.10$ e. u.[2,9] $S^{\circ}_{AgBr}=25.62\pm0.10$ e. u.[9] and $S^{\circ}_{AgI}=27.59$ (±0.4) e. u.[10]), all at the third-law convention, the errors indicated in the brackets being estimated by us, taking into consideration the accuracy of the data given in the original papers), we can get from 4 the third-law partial molar entropies of three halide acids at 25°C and 0.01 M, as well as their standard values by the aid of 1. The results are listed in Table I. Here the calculated values of entropies are found to be lower than the accepted values[1,2] except for the case of a. Consequently, if the thermoelectric data on thermocells and the entropy data on the electrode materials are correct in our calculations, the current standard partial molar entropies of halide acids, particularly those of hydrobromic acid and hydroiodic acid, might have to be corrected considerably; our values may be accurate to within 0.2 e. u. in the cases of b and c, and may be within 0.5 e. u. in the case of d (the accuracy of the case of a can not be estimated because we do not know the probable error of S°_{HgCl}). The disagreement between the calculated values of S_{HCl} in the cases of a and b might be due to the use of an incorrect value of S°_{HgCl} in the calculations.

Summary

An alternative method for determining the third-law partial molar entropies of electrolytes in aqueous solutions from the data on non-isothermal systems has been presented. They can be obtained from the difference between the initial thermoelectric powers of two different thermocells, the one being formed by cation-reversible electrodes and the other being formed by anion-reversible electrodes, both with common electrolytes of the same concentration. The partial molar entropies have been calculated to be 31.59, 37.53 and 42.87 e. u. for hydrochloric acid, hydrobromic acid, and hydroiodic acid respectively at 25°C and 0.01 M.

*Infrared Spectra and Rotational Isomerism of Some Long-chain n-Alkoxy Ethanols**

By T. K. K. SRINIVASAN, C. I. JOSE and A. B. BISWAS

(Received May 14, 1964)

In connection with a program on water evaporation control, the infrared spectra of a series of alkoxy ethanols, $CH_3(CH_2)_nO-CH_2-CH_2-OH$, where $n=13$, 15, 17, 19 and 21, have been investigated in various physical states. These studies show that the ethanols exhibit rotational isomerism and that the changes in the spectra can be related to definite geometrical arrangements of the molecule.

The alkoxy ethanols have a long chain of CH_2 groups as well as an OCH_2CH_2OH group. As a liquid or in solution, molecules containing long CH_2 chains give a large number of absorption bands because of the various conformations possible by rotation around the single bonds.[1] These sometimes show up as broad bands on account of overlapping. In the crystalline state, on the other hand, only a single rotational species is usually accommodated, and the absorption pattern is considerably simplified.[2] In polyethylene[3] and certain other long-chain compounds[4,5] additional bands appear as a result of the specific molecular arrangement of the CH_2 chain (orthorhombic) in the crystal favorable for intermolecular coupling. The ($O-CH_2-CH_2-O$) group can be considered to take up independently a gauche or trans configuration by rotation around the single bonds. However, the presence of a hydroxyl group suitably

located for intramolecular hydrogen bonding[6] with ether oxygen can be expected to influence the type of configuration taken by the molecule.

It is known that the compounds of the type $X-CH_2-CH_2-X$ give four rocking modes, two each corresponding to the gauche (A and B) and trans (A_u and B_g) configurations with C_2 and C_{2h} symmetries respectively, in the 1000 cm^{-1}~700 cm^{-1} region. While both the gauche modes are active, only the A_u trans mode is active in the infrared region. Though these modes are sensitive to changes in the remaining part of the molecule, they have been found useful in identifying rotational isomers of a large number of compounds.[7,8] Indirect evidence can also be obtained regarding the configuration of the $(O-CH_2-CH_2-O)$ group by studies of the hydroxyl group attached to one of its CH_2 groups.

In the present study, the infrared spectra of alkoxy ethanols have been discussed and the configurations of the $(O-CH_2-CH_2-O)$ group investigated in solution as well as in the liquid and solid states by analysis of the CH_2 rocking modes in the 1000 cm^{-1}~700 cm^{-1} region and of the hydroxyl stretching bands.

Experimental

The spectra were obtained either with a Perkin-Elmer model 221 instrument, equipped with an NaCl prism, or a Grubb Parsons model S3, with an LiF prism.

The preparation and purity of the alkoxy ethanols have been reported elsewhere.[9] A heating cell was constructed to obtain the spectra of solid and liquid films (Fig. 1) between sodium chloride plates at a few relevant temperatures. The reproducibility of the spectra upon repeated heatings or coolings of the substances was checked in situ; little variation in position and intensity was observed. The temperature during a run, as measured with a calibrated copper-constantan thermocouple, was maintained within $\pm 1°C$.

The spectra of solutions of octa-decoxy-ethanol (ODE) in carbon tetrachloride and carbon disulfide are also given (Fig. 1) to show their similarity with that of the liquid. The spectra of these compounds in carbon tetrachloride were studied particularly, using a variable path cell, in the hydroxyl-stretching region in order to elucidate the nature of the internal hydrogen bonding and of the rotational isomerism of these molecules.

Results and Discussion

Since the absorption characteristics of the different alkoxy ethanols are alike, the discussion will center upon ODE.

In the CH stretching region strong bands at 2925 cm^{-1} and 2850 cm^{-1} are observed in both the solid and liquid states; they are ascribed to the CH stretching modes of the CH_2 and CH_3 groups.[10] The additional band at 2958 cm^{-1} observed in the solid state is grouped with a similar sharpening and doubling of the bands near 1110 cm^{-1} and 1060 cm^{-1} observed on liquid-solid transformation.

The absorption bands at 1466 (S) and 1376~1379 (W) observed in the solid and liquid states are assigned to the CH deformation of the CH_2 and CH_3 groups.[10] The band at 1471 cm^{-1}, which appears as a shoulder in the solid state and which is observed as a separate band in the compound $CH_3(CH_2)_{17}(O-CH_2-CH_2)_2OH$ is assigned to the CH deformation mode of the CH_2 groups adjacent to oxygen. The absorption bands in the 1416~1403 cm^{-1} region are similar to those observed for normal higher alcohols at 1412 cm^{-1}; they are ascribed to the C–O stretching or O–H deformation modes.[10]

The 1360 cm^{-1}~1150 cm^{-1} region in the spectra of the solid alkoxy ethanols features a band progression of irregular intensity, varying from medium to weak. In the liquid state, they broaden out completely, as is observed in other long-chain compounds; they are ascribed to the CH_2 wagging modes. Below 1150 cm^{-1} strong broad bands at 1117 cm^{-1} and 1056 cm^{-1} are observed in the liquid state. The band near 1050 cm^{-1} is characteristic of a primary alcohol[10] and is considered to arise either from an OH deformation or C–O stretching mode. However, normal vibration calculations and the analysis of *n*-paraffin spectra indicate skeletal modes of hydrocarbon chains (C-C stretching) in the 1050 cm^{-1}~950 cm^{-1} region.[11] The observed enhanced intensity of the band at 1058 cm^{-1} is, therefore, due to the overlapping of both the C–O stretching or O–H deformation and the skeletal modes. The band progression from 1050 cm^{-1} to 950 cm^{-1} would correspond to the various C–C skeletal modes.[12]

In a large number of ethers, a band at about 1120 cm^{-1} is noticed; in dimethyl ether this has been ascribed to an antisymmetric C–O–C stretching vibration. Hence, the band at 1117 cm^{-1} may be assigned to a C–O–C stretching mode. In the solid state, the two

$CH_3(CH_2)_{17}$-O-CH_2-CH_2-OH : C_{18} (solution)
$CH_3(CH_2)_{19}$-O-CH_2-CH_2-OH : C_{20} (solid) ; C_{20} (liquid)
$CH_3(CH_2)_{21}$-O-CH_2-CH_2-OH : C_{22} (solid) ; C_{22} (liquid)

bands in the liquid are found doubled and sharpend at 1117 cm^{-1} and 1137 cm^{-1} and at 1058 cm^{-1} and 1071 cm^{-1} respectively. The sharpening and doubling of bands on liquid-solid transformation observed in this region and also in the CH stretching region (see above) appears to be due to an imposed symmetry in the crystalline state or to changes due to hydrogen bonding rather than to rotational isomerism. The splitting of bands due to intermolecular effects[5] has so far been established only for CH_2 chains among long-chain compounds. However, a similar doubling and sharpening of bands observed in the case of $CH_3(CH_2)_{17}(O\text{-}CH_2\text{-}CH_2)_2OH$, in which the splitting of the CH_2 rocking at 720 cm^{-1} is absent (see below), indicates that they are not connected with the intermolecular interaction of the long sequence of CH_2 groups.

The 950 cm^{-1}~800 cm^{-1} Region. — In this region considerable changes are observed in the spectra of alkoxy ethanols. In the liquid state or in solution, only a band of medium intensity is observed at 889 cm^{-1}. This is in good agreement with that observed by Chalkowsky[13] for the lower liquid homologues at 892 cm^{-1}. In the solid state, on the other hand, two sharp bands of almost equal intensity (medium) at 864 cm^{-1} and 892 cm^{-1} are observed, in addition to a weak band at 962 cm^{-1}. From the measurement of the areas under the bands during the liquid-solid transformation, it was found that the band at 864 cm^{-1} developed at the expense of that at 889 cm^{-1}. The development of the band at 864 cm^{-1} at the expense of that at 889 cm^{-1} during crystallization may be explained as the conversion of one of the rotational isomer into another. The assignment of the bands to the two rotational isomers was made by comparison with disubstituted ethanes, particularly ethylene glycol, its derivatives and polymers. It has been shown by theoretical calculations[14] that in disubstituted ethanes the CH_2 rocking frequencies increase in the order A_u(trans)< B(gauche)<A(gauche)<B_g(trans), so that the gauche mode frequencies lie between those of the trans modes. This has been well established in the case of the simple disubstituted ethanes $X\text{-}CH_2\text{-}CH_2\text{-}Y$, where X and Y are CH_3, Cl, Br, SCN, etc. Miyake[7] recently assigned CH_2 rocking modes of the $(O\text{-}CH_2\text{-}CH_2\text{-}O)$ group in ethylene glycol, its derivatives and polymers on the above basis. He found that the A_u type mode of the $(O\text{-}CH_2\text{-}CH_2\text{-}O)$ group occurs near 850 cm^{-1}, which is about 100 cm^{-1} higher than in compounds where the two oxygens are replaced by other atoms, and that the spacing between the two A and B gauche forms is approximately 20 cm^{-1}. In the present case, therefore, the bands 864 cm^{-1} and 964 cm^{-1} are assigned to the CH_2 trans modes A_u and B_g of the $(O\text{-}CH_2\text{-}CH_2\text{-}O)$ group respectively and the band at 889 cm^{-1}, to the two gauche modes coalesced into one. A single band for a gauche mode has also been observed at 895 cm^{-1} for polyethylene terephthalate.[15] The formation of the cis species with a higher symmetry, C_{2v}, may be a possible explanation for a single CH_2 rocking mode for the gauche form.[16]

The above assignment indicates that the $(O\text{-}CH_2\text{-}CH_2\text{-}O)$ group in alkoxy ethanols has a predominantly gauche configuration in a liquid or in solution, while in the crystalline state both the gauche and trans forms are present in approximately equal numbers. The presence of the gauche configuration in solution is supported by observations in the hydroxyl-stretching region. In the case of polyethylene glycol, it has been concluded by Miyake[7] that a gauche configuration is predominant in the melt, while both the gauche and trans forms exist in the solid state. In contrast, Davison,[17] and Kuroda and Kubo,[18] on the basis of a different assignment of the CH_2 rocking modes, have arrived at a complete gauche configuration in the solid state. Recently Miyazawa[19] has made calculations for the infrared frequencies and molecular conformations of various polymers by a normal coordinate treatment and compared the results with the observed results. In the case of polyethylene glycol these studies have shown that the most likely structural model consists of trans-gauche-trans (TGT) conformations of the $(O\text{-}CH_2\text{-}CH_2\text{-}O)$ group. Further recent X-Ray diffraction studies[20] of the long-chain alcohols with an odd number of carbon atoms have shown that both trans and gauche configurations of the OH group are present in the crystalline state.

The 730 cm^{-1}~720 cm^{-1} Region.—The bands in this region are attributed to the methylene rocking modes of the long hydrocarbon chain. The band at 719 cm^{-1} in the liquid state splits into two bands, at 729 cm^{-1} and 719 cm^{-1}, of almost equal intensity in the solid state, as observed in the case of polyethylene[3] and certain long-chain compounds. Chapman[4] has shown that the presence of two bands of the

20) A. Watanabe, This Bulletin, **36**, 336 (1963).

same intensity indicates an orthorhombic packing of the CH_2 chains, while both the hexagonal and triclinic packing give rise to a single band in this region. Using this criterion, the long CH_2 chain in alkoxy ethanols would be expected to have an orthorhombic packing (orthorhombic sub-cell). It is interesting to note that the compound $CH_3(CH_2)_{17}(O-CH_2-CH_2)_2OH$ shows only a single band[21] at 729 cm^{-1} in the solid state, while the absorption pattern in the 950~800 cm^{-1} regions remains similar to that of the alkoxy ethanols.

Solution Spectra.—ODE (Fig. 2) in a dilute

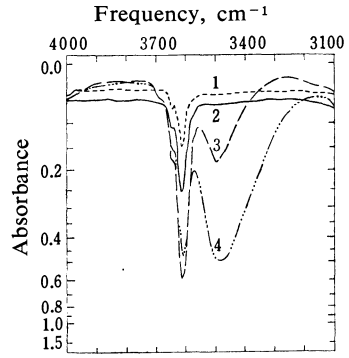

Fig. 2. Octadecoxy ethanol (ODE) in carbon tetrachloride.

1 ------ 0.005 M (3 mm. path length)
2 —— 0.01 M (3 mm. path length)
3 - - - 0.1 M (1 mm. path length)
4 ·····- 0.5 M (0.2 mm. path length)

carbon tetrachloride solution (0.005 M~0.01 M) shows a strong band at 3600 cm^{-1} and a weak band at 3636 cm^{-1}. These, as in the methoxy ethanol reported on by Flett[22] and by Kuhn[23], would correspond to monomer units of the intramolecularly bonded gauche, and trans or nonbonded gauche, forms respectively. At higher concentrations until the solubility limit at about 0.5 M is reached, a dimer band at 3480±10 cm^{-1} is observed which increases in intensity with the concentration at the expense of the band at 3600 cm^{-1}.* at 0.1 M, in addition to the dimer and monomer bands at 3484 cm^{-1} and 3636 cm^{-1} respectively. In the liquid state ODE shows only the broad dimer band at 3465 cm^{-1}. The ODA (octadecanol) shows, on the other hand, a broad polymer band at 3350 cm^{-1} in the liquid and bands at 3270 cm^{-1} and 3230 cm^{-1} in the solid state.[24]

During solidification the band at 3465 cm^{-1} in ODE is slowly shifted to lower frequencies; in the crystalline solid, it is located as a strong broad band at 3260 cm^{-1}. The dimer formation of alkoxy ethanols in the liquid state, in contrast to higher polymers by normal long chain alcohols in the liquid state and even in solution, supports the earlier conclusion that, in the liquid state, the alkoxy ethanols exist predominantly in gauche configuration.

Summary

The infrared spectra of *n*-alkoxy ethanols $CH_3(CH_2)_nO-CH_2-CH_2-OH$ with $n=13$, 15, 17, 19 and 21 have been obtained in the solid and liquid states as well as in solution. From a study of the CH_2 rocking modes of the ($O-CH_2-CH_2-O$) group at 893 cm^{-1} and 864 cm^{-1} during liquid-solid transformation and from the solution spectra in the hydroxyl-stretching region, it has been shown that this group exists predominantly in a gauche configuration in liquids or in solution, while both gauche and trans configurations are present in the solid state.

The authors are grateful to Professor Sanichiro Mizushima and Drs. Ichiro Nakagawa and Mitsuo Tasumi of the University of Tokyo, Japan, for their valuable comments and for communicating results on the infrared spectra of normal higher alcohols prior to publication.

We are also grateful to Dr. (Miss) S. B. Kulkarni for supplying the purified compounds used in the present studies.

Heats of Mixing for Binary Mixtures. The Energy of Hydrogen Bonding between Alcohol and Ketone Molecules

By Sachio MURAKAMI, Kazuo AMAYA* and Ryoichi FUJISHIRO

(Received May 29, 1964)

It is well known that the measurement of the heats of mixing of associated solutions is significant in investigating the interaction energy in a single component and between the different components. In a particular case such as the alcohol-nonpolar solvent system, such thermochemical treatments have already been extensively carried out and have revealed the energy of the intermolecular hydrogen bonding between alcohol molecules.[1] In cases where the associated solutions consist of alcohol and acceptor components, such as ketone, thermochemical data are not ample and detailed enough to allow us to estimate the energy of the intermolecular hydrogen bonding between these pair molecules.

In this paper we shall report the heats of mixing for such alcohol - ketone systems as isopropanol - acetone and *s*-butanol - ethyl methyl ketone systems, as well as those for alcohol - hexane and ketone - hexane systems, and shall estimate the energy of the hydrogen bonding of the O–H···O= type by means of the thermochemical cycle.

Experimental

Materials.—All the samples were purified from commercial products according to the usual method described in the literature,[2] and then they were finally distilled with a Stedman-type column. Considerable attention was devoted to removing the small amount of remaining water; as a result, these fractionated samples did not show a peak for water on a gas chromatogram. Therefore, the water content in these samples was estimated to be 1/100 weight percent or less.

Apparatus and Procedure.—A block diagram of the entire apparatus for measuring heats of mixing is shown in Fig. 1. The calorimeter is of the twin type, shown in Fig. 2, consisting of a mixing vessel and a reference vessel, each held with a vessel holder and fixed in a submarine vessel, installed in a water thermostat at 25°C kept constant to 1/1000°C. The mixing vessel is similar to that described in a previous paper[3] but was modified in some points, as is shown in Fig. 3. For the measurement of dilute solutions, another mixing vessel was used, one which was larger than that one used in the moderate concentration range and which could accomodate about 4 ml. of the liquid sample.

Before mixing, two components are separated by mercury in the mixing vessel; during mixing, the holder is turned upside down by rotating it around the pivot through the manipulation of the handle from the outside of the submarine vessel.

The temperature change on mixing is detected as the difference in the thermal electromotive force of the thermocouple between the mixing vessel and the reference vessel, which acts as a reference bath for the thermocouple and which contains only mercury. Even a small difference in the electric

potential is amplified by the d.c.—a.c. converted narrow band amplifier, the output signal of which is fed to an automatic pen recorder (YEW type E-30). With this amplifier a $\pm 1\times10^{-8}$ V. change can be detected; the temperature coefficient of one junction of a copper-constantan thermocouple is about 40 μV./°C, so that the sensitivity of our thermometer made of 7 junctions corresponds to about $\pm 3\times10^{-5}$ deg.

The main construction of the electrical circuit for the automatic thermal compensation is almost the same as that described previously, except that the meter relay is replaced with a microswitch connected to the recorder. The period during which the electric current from the constant current supply passes through the calorimeter heater is automatically registered on the binary decade counter operated with a standard 100 kc. oscillator.

Results and Discussion

The results obtained are given in Tables I, II, III, IV, V and VI and in Figs. 4 and 5, where x_1 is the mole fraction of component 1, and where ΔH^M and $\Delta H^M_{x_1}$ are the heats of mixing expressed as cal./mol. of the mixture and those expressed as kcal./mol. of component 1 at mole fraction x_1 respectively.

Plotting $\Delta H^M_{x_1}$ against x_1 and then extrapolating the curve to the infinite dilution ($x_1 \rightarrow 0$) for each system, as is shown in Figs. 4 and 5, we can obtain the heat of mixing per mole of component 1 at the infinite dilution as: 1.76 kcal. for the isopropanol (1) - acetone (2) system, 2.15 kcal. for the acetone (1) - *n*-hexane (2) system, 1.82 kcal. for the *s*-butanol (1) - ethyl methyl ketone (2) system and 1.90 kcal. for the ethyl methyl ketone (1) - *n*-hexane (2) system.

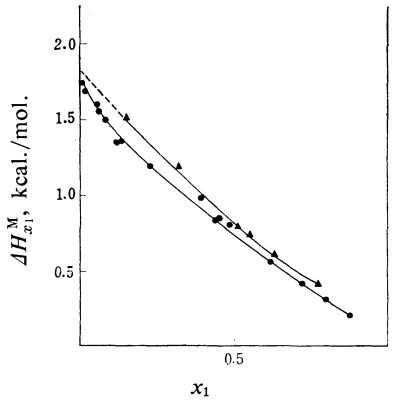

Fig. 4. Heats of mixing, alcohol - ketone systems.

● Isopropanol + Acetone
▲ *s*-Butanol + Ethyl methyl ketone

We also measured the heats of mixing $\Delta H^M_{x_1}$ for the isopropanol - *n*-hexane (2) and the *s*-butanol (1) - *n*-hexane (2) systems; the results obtained are plotted in Fig. 6 against x_1, together with the dotted curves for other kinds of alcohol - *n*-hexane systems taken from the literature.[4] As this figure shows, the curves are very steep at small x_1 values, and the extrapolation to $x_1=0$ is apt to produce some errors. The value of $\lim_{x_1\to 0} \Delta H^M_{x_1}$ obtained by Pahlk[4] for the isopropanol-hexane system is 5.90 kcal., and his $\Delta H^M_{x_1}$-x_1 curve coincides with ours in the concentrated range, as is

$\lim_{x\to 0} \Delta H^M_{x_1}$=5.8 kcal. for the dotted curve
$\lim_{x\to 0} \Delta H^M_{x_1}$=5.9 kcal. for the broken curve

shown in Fig. 6. Therefore, we have adopted 5.90 kcal. for the $\lim_{x_1\to 0} \Delta H^M_{x_1}$ of this system. For the *s*-butanol - hexane system, however, we could not find a $\lim_{x_1\to 0} \Delta H^M_{x_1}$ in the literature. In order to estimate the value for this system, we compared $\Delta H^M_{x_1}$ for the normal alcohol - hexane systems with those for the secondary alcohol - hexane systems. In the former cases, the $\lim_{x_1\to 0} \Delta H^M_{x_1}$ values were reported to be 5.8 kcal.,[4] and for the isopropanol system this value is 5.9 kcal., as has been mentioned above. On the basis of the comparison of these three curves

in Fig. 6, we may estimate $\lim_{x_1 \to 0} \Delta H_{x_1}^M$ to be 6.0 kcal. or a little less for the *s*-butanol - hexane system.

In pure alcohol, all the molecules form hydrogen bondings with each other, while each alcohol molecule in the infinite dilution of alcohol in hexane is surrounded by hexane molecules and the hydrogen bonds are broken. Therefore, the values of about 6 kcal. represent energy sufficient to break the hydrogen bonds of pure alcohol. Similarly, the $\lim_{x_1 \to 0} \Delta H_{x_1}^M$ value for each alcohol - ketone system corresponds to the energy of transfer from the pure alcohol state to one in which each alcohol molecule makes a hydrogen bond with a ketone molecule and in which such complexes are surrounded with a large amount of the ketone medium. Roughly speaking, the difference between the $\lim_{x_1 \to 0} \Delta H_{x_1}^M$ value for the alcohol - ketone system and that for the same alcohol - hexane system, that is about 4 kcal., may correspond to the energy of alcohol - ketone hydrogen bonding.

In order to estimate these hydrogen bond energies in some detail, we have considered the thermochemical cycle shown in Fig. 7, where A, K, H and A-K represent molecules of alcohol, ketone, hexane and alcohol - ketone complexes respectively, and where the hypothetical state IV is assumed. Further, we assume that the whole system contains one mole of A, x mol. of K, and y mol. of H, and that $1 \ll x \ll y$.

Judging from this figure, it is reasonable to consider that the true hydrogen bond energy of the A-K complex is equal to the energy change, ΔH_5, for process 5 from state III to state IV. This energy change is easily given by the thermochemical cycle as:

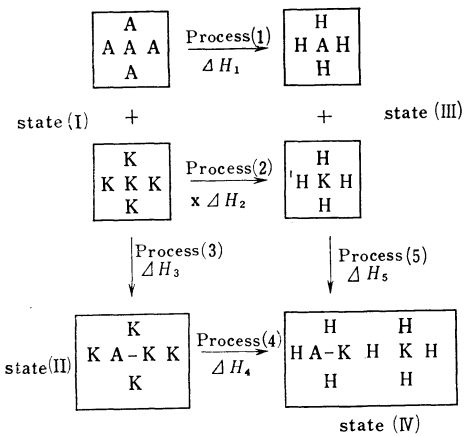

Fig. 7. Thermochemical cycle.

State (I) : One mole of alcohol and x mol. of ketone, both being separated.
State (II) : One mole of A-K complex in the ketone medium, each complex being separated each other.
State (III) : One mole of alcohol, x mol. of ketone in the hexane medium.
State (IV) : One mole of A-K complex and $x-1$ mol. of ketone in the hexane medium.
Process (1) : One mole of alcohol is diluted by a large amount of hexane.
Process (2) : x mol. of ketone are diluted by a large quantities of hexane.
Process (3) : Mixing of alcohol and ketone.
Process (4) : The state (II) is diluted by a large quantities of hexane without breaking A-K complex.

$$\Delta H_5 = -\Delta H_1 - x\Delta H_2 + \Delta H_3 + \Delta H_4 \qquad (1)$$

Since ΔH_1, ΔH_2 and ΔH_3 were measured, it is necessary to estimate the ΔH_4 in process 4 in order to determine ΔH_5.

Two energy changes will contribute to ΔH_4.

The first one, ΔH_4^{KH}, is the heat of the dilution of $(x-1)$ mol. of ketone by large quantities of hexane, which is equal to $(x-1)\ \Delta H_2$. The second one, ΔH_4^d, is due to the difference in the dipolar stabilization enegy of an A-K complex dipole arising from the reaction field by different media, though the van der Waals energy contributes in the latter case to some extent, though this extent is very difficult to estimate and so is disregarded here.

To estimate the energy change for the latter case, we have followed the usual treatment of polar liquids by Onsager,[5] according to which the dipolar stabilization free energy, ΔG_i, is expressed as:

$$\Delta G_i = -(1/2)\mu^2 R/(1-R\alpha)$$
$$R = 2(\varepsilon_i - 1)/(2\varepsilon_i + 1)a^3 \qquad (2)$$

where μ, a and α are the dipole moment, the molecular radius, and the polarizability of the A-K complex, respectively, and where ε_i is the dielectric constant of the medium, i, that is, K or H. Further, the dipolar stabilization energy, ΔH_4^d (i=H or K), is obtained from ΔG_i as:

$$\Delta H_i^d = \frac{\partial(\Delta G_i/T)}{\partial(1/T)}$$

Therefore, the dipolar part of the energy change in process 4 may be given as:

$$\Delta H_4^d = \Delta H_H^d - \Delta H_K^d$$

The data necessary for this calculation and the results obtained are summarized in Table VII. The values of the dipole moment of A-K complexes were determined by the vector addition of those of two component molecules, and the α and a of a complex molecule were assumed to be the sum of those of the two component molecules.

The ΔH_4^d values thus obtained are 2.50 kcal. for the isopropanol - acetone and 1.93 kcal. for the *s*-butanol - ethyl methyl ketone systems. To check the magnitude of these energies, we obtained the difference between the dipolar energy of one mole of ketone in the hexane medium and that of one mole of pure ketone by calculations similar to those described above. The results are as follows: 2.48 kcal. for acetone - hexane and 1.88 kcal. for ethyl methyl ketone - hexane. These values should correspond to the dipolar part of the heats of the dilution of ketone in hexane. Since the measured heats of dilution are 2.15 kcal. and 1.90 kcal. for acetone and ethyl methyl ketone respectively, the calculated dipolar energies are more than or nearly equal to the heats of dilution, indicating that the dipolar energies have been overestimated, particularly in the system containing such small molecules as acetone. Therefore, the ΔH_4^d value of 2.50 kcal. for isopropanol - acetone seems to be overestimated and some correction (at least 0.4 kcal.) may be necessary.

Using ΔH_4^d and other measured values, ΔH_5 is calculated by Eq. 1 as:

for isopropanol - acetone:

$$\Delta H_5 = -5.90 - 2.15\,x + 1.76 + 2.50 + 2.15(x-1)$$
$$= -3.79 \text{ kcal.}$$

for *s*-butanol - ethyl methyl ketone:

$$\Delta H_5 = -6.0 - 1.90\,x + 1.82 + 1.93 + 1.90(x-1)$$
$$= -4.15 \text{ kcal.}$$

Taking account of the overestimation of dipolar energy, the hydrogen bond energy of alcohol - ketone complexes may be estimated to be about 4 kcal. or a little more for the two systems.

Summary

A microcalorimeter of the twin type has been constructed, one which is operated semi-automatically. Using this apparatus, the heats of mixing for alcohol - ketone, alcohol - hexane, and ketone - hexane solutions have been measured. From these heats of mixing, the hydrogen bond energy of the O–H···O= type has been estimated to be about 4 kcal. by means of the thermochemical cycle.

The authors wish to thank Dr. Ko Kimura for his kind advice. The expenses of this work have been partly defrayed by a Grant from the Ministry of Education.

Studies of Methionine Sulfoxide. I. The Acidic Degradation of Methionine Sulfoxide

By Kensaku MORIHARA

(Received June 4, 1964)

Although biochemical attention[1-3] has recently been focussed on methionine sulfoxide (MSO), the chemical properties of this amino acid have not been sufficiently investigated. It is well-known that MSO is converted to methionine by the action of hydrochloric acid under the usual conditions for the acidic hydrolysis of proteins with hydrochloric acid, and it is also known that on storage of a hydrochloric acid solution of methionine (Met), the formation of MSO by oxidation occurs in air.

This action of hydrochloric acid upon sulfoxide is unusual and has been reported in only a few cases. In the case of MSO, the reaction does not seem to be a simple reduction, as Reiner et al. observed in the course of their studies of the agene factor of wheat flour. They observed that MSO yielded two additional ninhydrin positive spots besides Met on a paper chromatogram after acidic hydrolysis.[4]

In the present work, in order to investigate the mechanism of the degradation and chemical properties of this amino acid through the action of hydrochloric acid upon it, the degradation products will be isolated.

On treating MSO with 12 N hydrochloric acid at 105°C in a sealed tube for 20 hr., seven ninhydrin positive spots were observed on two-dimensional chromatograms. The hydrolyzate was submitted to column chromatography, and four of the seven products were isolated and identified as methionine, homoserine, homocystine and homolanthionine.

Results and Discussion

Two-Dimensional Paper Chromatography.— The reaction mixture obtained by the hydrolysis of 31.7 mg. of DL-MSO with 2 ml. of 12 N hydrochloric acid in a sealed tube was treated with the cation exchange resin, Amberlite IR-120 (H^+) in the usual manner in order to remove hydrogen chloride. The resulting mixture of reaction products was submitted to two dimensional paper chromatography. As may be seen in Figs. 1 and 2, seven ninhydrin-positive spots were observed on the chromatograms and the main product, spot A, appeared to be Met judging from its R_f values. Spot B seemed rather unstable, and its location and size varied according to the reaction condition. The size of this spot B decreased with the reaction period, whereas the sizes of spots C, D and E increased with the reaction time. This must indicate that the compound giving spot B was a precursor of the substances in spots C, D and E. Spot B seemed to be too unstable and spots F and G were too small to attempt their identification. Therefore, the isolation of only the substances corresponding to spots C, D and E was carried out.

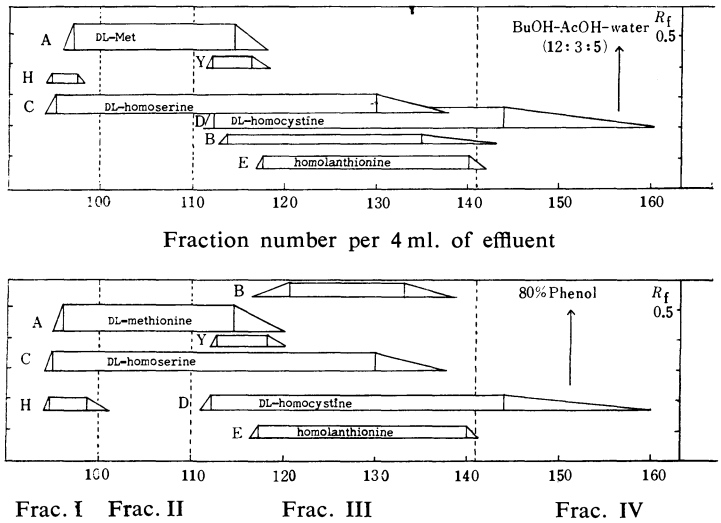

Fig. 3. Displacement chromatography of the hydrolyzate.

Elution Chromatographic Separation. — To isolate the reaction products from the hydrolyzate of 5 g. of DL-MSO, fractionation was carried out by displacement chromatography on a column of the Amberlite CG-120 type II with 0.5 N ammonia and then by gradient chromatography with 4 N hydrochloric acid, following the procedure of Hirs et al.[5] with some modifications. Aliquots of each fraction were analyzed by one dimensional paper chlomatography. The results are summarized in Figs. 3, 4 and 5. The five spots of Fig. 1, spots A, B, C, D and E, correspond to five zones of Fig. 3, zones A, B, C, D and E respectively. However, the zones corresponding to spots F and G were not obtained, and, on the other hand, a new zone H appeared which did not correspond to any spot in Fig. 1. These products were too small in quantity to be identified. Moreover, unknown ninhydrin-negative yellow zone was observed, as is shown in Fig. 3.

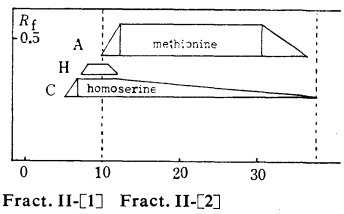

Fig. 4. Rechromatography of fraction II.

Products Isolated and Identified. — DL-Met, corresponding to spot A, was isolated as crystals from fractions II-[2] and III-[4]; DL-homoserine, corresponding to spot C, from fraction III-[2]; DL-homocystine, corresponding to spot D, from fraction IV, and homolanthionine, corresponding to spot E, from fraction III-[6].

From the other fractions, though they contained ninhydrin-positive materials, no pure product was isolated.

The Mechanism of Degradation.—From the results obtained, the route of the degradation of MSO seems to be complex; the most plausible one is drawn in Fig. 6. Route A is the ordinary route of the reduction of MSO to Met.

The initial products in route B may be supposed to be methane sulfinic and α-amino-β,γ-dehydro butyric acid if an elimination reaction takes place, or methane sulfinic acid and homoserine, if hydrolytic splitting occurs.

However, according to Ostemayer et al.[6], *S*-methylcysteine sulfoxide is split into methane sulfinic acid and dehydroalanine, the latter being further decomposed to ammonia and pyruvic acid in hot dilute sulfuric acid. Therefore, we suggest that an analogous reaction series occurs in the case of MSO and that it is reasonable to assume that α-amino-β,γ-dehydro butyric acid is an intermediate. Route C is the rearrangement of the sulfoxide to yield homocysteine and formaldehyde, and the resulting homocysteine can be easily converted to homocystine by air oxidation.

The formation of homolanthionine is explained by the addition of homocysteine to α-amino-β,γ-dehydro butyric acid.

When MSO was treated with 6 N hydrochloric acid for 12 hr., only one ninhydrin-positive

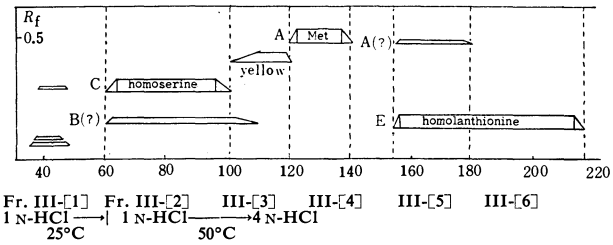

Fig. 5. Gradient chromatography of fraction III.

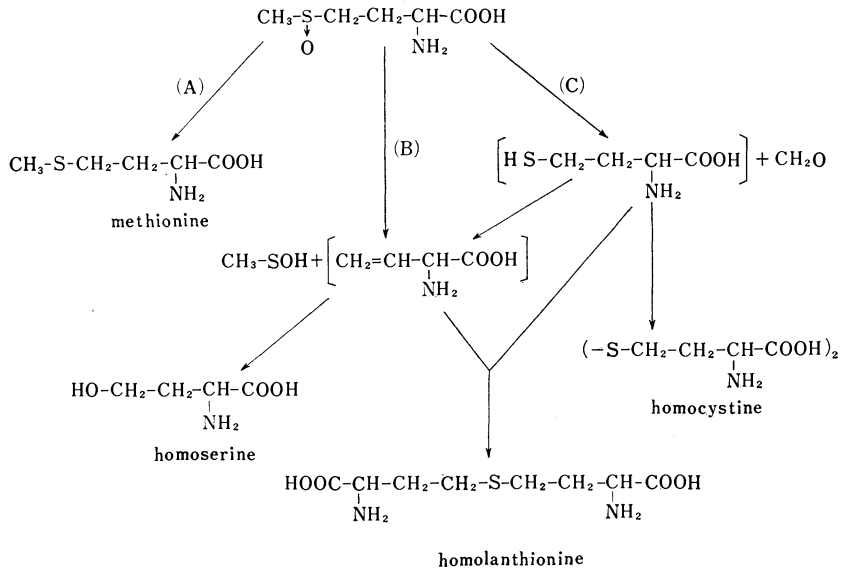

Fig. 6

spot of Met was detected on the paper chromatogram, showing that only the reduction of route A took place, and that only when it is treated with 12 N hydrochloric acid the complex reactions of routes B and C take place, thus giving rise to the above-mentioned products. Therefore, the fact that these products have not been detected in the usual hydrolyzate of protein with 6 N hydrochloric acid does not completely exclude the possibility of the presence of a MSO residue in protein molecules.

Experimental

Materials.—DL-Methionine sulfoxide was prepared by the method of Toenis et al.[7] with the slight modification of using more methanol and less water. M. p. 186°C (decomp.).

Found: C, 36.35; H, 6.89; N, 8.56. Calcd. for $C_5H_{11}O_3NS$: C, 36.35; H, 6.71; N, 8.48%.

Concentrated hydrochloric acid prepared by the saturation of distilled water with hydrogen chloride gas was used first, but later concentrated hydrochloric acid, special grade, purchased from Wakō Pure Chemical Industries, Ltd., was used, as it was proved to give the same result.

Hydrolysis and Chromatographic Separation.—Five grams of DL-methionine sulfoxide were dissolved in 30 ml. of concentrated hydrochloric acid, and the mixture was heated in a sealed tube at 105°C for 20 hr. The hydrolyzate was then brought to dryness and transferred to a column of the Amberlite CG-120 type II (H^+ form), 1.5 cm.×25 cm. Distilled water was passed through the column until the effluent became neutral. Then the absorbed hydrolytic products were eluted with 0.15 N ammonium hydroxide at 60°C, and the effluent was collected in 4 ml. fractions. An aliquot of each fraction was submitted to one dimensional chromatography (BuOH : AcOH : Water—12 : 3 : 5) in order to analyze the components. Fraction II was rechromatographed in the same way.

For the further fractionation of fraction III, the chromatographic system described by Hirs et al.[5] was employed with some modifications. A shorter column than that described by Hirs et al. (40 cm. ×2 cm.) was used, and Amberlite CG-120 type II was employed instead of Dowex 50×4. The column was pretreated with 10 volumes of 1 N hydrochloric acid.

7) G. Toenis and J. J. Kolb, *J. Biol. Chem.*, **128**, 399 (1939).

Fraction III was brought to dryness and dissolved in a few milliliters of 1 N hydrochloric acid, and the solution was transferred to the column. The chromatography was carried out by elution with 1 N hydrochloric acid at a room temperature of 25°C, and the effluent was collected in 4 ml. fractions. When 324 ml. of effluent had been eluted, the concentration of hydrochloric acid was gradually increased from 1 to 4 N using a mixing chamber of 200 ml., and the temperature of the column was raised and kept at 50°C. Each fraction was dried, and the components were analyzed by one-dimensional paper chromatography. As may be seen in Fig. 5, homocystine was not eluted under these conditions.

DL-Methionine.—Fraction II-[2] was decolorized with active charcoal and concentrated under reduced pressure until it was almost dry. The ethanol was added, and the resulted solution was allowed to stand. The precipitate formed was collected by filtration and recrystallized from water and ethanol. The recrystallization was repeated until the contaminating homoserine and another ninhydrin-positive material had been removed. The crystals formed were identical in their infrared spectrum with authentic methionine. From fraction III-[4], pure methionine was also isolated without decolorization after the fraction had been treated with ion exchange resin to remove the hydrogen chloride.

DL-Homoserine. — Fraction III-[2] was concentrated under reduced pressure and treated with cation exchange resin to remove the hydrogen chloride in the usual manner. The ammoniacal effluent was concentrated, ethanol was added to this solution until the cloudy point was obtained, and then the solution was allowed to stand. The resulting precipitate was collected and recrystallized from water and ethanol.

Found: C, 39.68; H, 7.53; N, 11.04. Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76%.

The infrared spectrum of this material and its R_f values in two solvent systems, *n*-butanol - acetic acid - water (12 : 3 : 5) and 80% aqueous phenol, were identical with those of authentic L-homoserine obtained from the Kyowa Hakko Kogyo Co., Ltd.

DL-Homocystine. — Fraction IV was treated in virtually the same way as methionine, and an amino acid was isolated. M. p. 258°C.

Found: C, 35.43; H, 6.60; N, 9.50. Calcd. for $C_8H_{16}O_4N_2S_2$: C, 35.82; H, 6.01; N, 10.45%.

Though the value of the nitrogen content was less for homocystine, the chromatographic behavior and infrared spectrum of this material were identical with those of authentic DL-homocystine perchased from Wakō Pure Chemical Industries Co., Ltd.

Homolanthionine. — An amino acid was isolated from fraction III-[6] in virtually the same way as homoserine. In this case, decolorization was necessary as the ammoniacal effluent was acompanied with an unknown red violet material. M. p. 270°C (decomp.).

Found: C, 40.25; H, 6.97; N, 11.92. Calcd. for $C_8H_{16}O_6N_2S$: C, 40.67; H, 6.83; N, 11.86%.

The authentic homolanthionine prepared from DL-menthionine and DL-homoserine according to the procedure described by Stekol[8] was found to contain three components on paper chromatograms, DL-homolanthionine, meso-homolanthionine and a trace of unchanged DL-methionine. However, the infrared spectrum of the isolated amino acid was identical with that of a mixture of DL and meso-homolanthionine, and its R_f values in two solvent systems, *n*-butanol - acetic acid - water (12 : 3 : 5) and 80% aqueous phenol, were identical with those of one component of the mixture. Therefore, the amino acid isolated must be an isomer of homolanthionine.

The author is indebted to Professor Shiro Akabori and Dr. Yoshiharu Izumi for their constant interest and encouragement in this work, and to the Misses Kiku Koike and Masako Kawakita of this Institute for their elemental analysis.

Studies of Methionine Sulfoxide. II. The Transformation of Methionine Hydantoin Sulfoxide

By Kensaku MORIHARA

(Received June 4, 1964)

During our study[1] of the acidic degradation of methionine sulfoxide (MSO), the products homocystine, homolanthionine, homoserine and methionine (Met) were isolated. The formation of homocystine and homolanthionine indicated that the demethylation of MSO occurs much more easily than that of Met, for Met does not give the above-mentioned products under these conditions. Moreover, it may be assumed that this demethylation is due to the conversion of the sulfoxide group to give *S*-hydroxymethyl-homocysteine.

Smythe studied the action of some kinds of hydrogen chloride on dibenzyl sulfoxide in detail and suggested that there was a dynamic tautomerism between the sulfoxide and the corresponding α-oxy-sulfide during the reaction.[2] Later, Horner et al. demonstrated that several sulfoxides were converted to the corresponding α-acyloxy-sulfoxides in a good yield by the action of acid anhydride.[3] Therefore, it is reasonable to assume that such a rearrangement occurs to yield *S*-hydroxymethyl-homocysteine derivatives from MSO prior to demethylation, as has already been reported in the previous paper.[1] This transformation of sulfoxide to α-hydroxy-sulfide radicals is very interesting with regard to the biochemical role of sulfoxides, especially that of MSO.[4]

In this paper, it will be demonstrated that the quantitative transformation of methionine hydantoin sulfoxide (MHSO) occurs through the action of acetic anhydride, yielding the corresponding α-acetoxy-sulfide, the structure of which will be determined mainly from the fact that formaldehyde is quantitatively released from the product when it is hydrolyzed with acid or alkali.

Results and Discussion

The Transformation of MHSO. — The substrate of this reaction, MHSO, was prepared as white crystals by the oxidation of DL-methionine hydantoin (MH) with hydrogen peroxide. MHSO is a strongly polar substance, as it is freely soluble in water, slightly soluble in alcohol, and insoluble in other non-polar solvents, while MH is freely soluble in non-polar solvents but insoluble in water. MHSO was used instead of MSO in this study because when MSO was treated just as MHSO with acetic anhydride, the color of the reaction mixture turned red-brown, showing that an undesirable side reaction, mainly due to the formation of azlactone, took place. On the other hand, when a suspension of MHSO (1.74 g.) in acetic anhydride (3 ml.) was heated under reflux on an oil-bath, it was resolved in a few minutes, and the color of the reaction mixture turned only slightly yellow, showing that no side reaction occurred. The reaction was allowed to proceed for about an hour, and then excess water was added to decompose the unchanged acetic anhydride. The resulting mixture was concentrated under reduced pressure to remove the acetic acid and water. The residue was then extracted with ethyl acetate, an the extract washed with water and dried on sodium sulfate. When the ethyl acetate was removed under reduced pressure, a yellow syrup was obtained (about 2.0 g.). This material was quite different from MHSO; it was insoluble in water and easily soluble in ethyl acetate, showing, as expected, that the strong polarity of MHSO had been lost by the action of acetic anhydride to give the corresponding α-acetoxy-sulfides, as is shown in Fig. 1. Only when the reaction was stopped within a few minutes was the starting MHSO recovered from the aqueous layer.

The Structure of the Product.—Attempts to purify and crystallize the product in order to determine its structure were unsuccessful. However, from the results of Horner et al. it seems that the structure is either II or III.

Desulfurization with Raney nickel[5] was carried out to see whether the structure was II or III. If it was II, homoserine derivatives should be formed, while if it is III, α-amino-butyric acid derivatives may be expected by this treatment. A small portion of the syrup was treated with Raney nickel for about 3 hr. The catalyst was then filtered off, and the filtrate was hydrolyzed with 6 N hydrochloric acid. The hydrolyzate was evaporated to dryness and submitted to paper chromatography.

Only one ninhydrin-positive spot was detected, and this had the same R_f value as an authentic sample of α-amino-butyric acid, showing that only III was formed when MHSO was treated with acetic anhydride. Furthermore, it was expected that formaldehyde should be formed from III or methyl mercaptan from II when the syrup was hydrolyzed with acid or alkali. Small portions of the syrup was transferred to Kjehldahl distilling tubes, together with 6 N sulfuric acid, or to 3 N sodium hydroxide, and the samples were submitted to steam-distillation for 15 min. The distillate was neutralized with sodium bicarbonate when it had been treated with sulfuric acid. To the distillates was added a 0.4% aqueous solution of dimedone, and the mixtures were allowed to stand overnight. White needle-shaped crystals were obtained; they melted at 189°C and were identified as formaldimedone[6] by infrared spectroscopy. This also showed that III was the product, and, though a slight mercaptan-like odor was detected in the distillate, no aldehyde was detected with Schiff's reagent in the residual mixture. In the same way, when the reaction mixture of MHSO, treated with acetic anhydride and then by hydrolysis with sulfuric acid or sodium hydroxide, was submitted to steam distillation, formaldehyde was also caught directly as the dimedone derivative.

The Recovery of Formaldehyde.—To confirm the above results, the formaldehyde released from MHSO was determined quantitatively. Five samples of MHSO, each about 100 mg., were boiled with 2 ml. of acetic anhydride for 3, 10, 30, 60 and 180 min. respectively, while another sample of about 100 mg. of methionine hydantoin (MH), was treated in the same way, for 180 min., as a control. The reaction was stopped by then addition of 1 ml. of water to each reaction mixture. Then to each was added 5 ml. of 6 N sulfuric acid, and the solutions were distilled for 15 min. with steam as has been described above. The distillates were received in ice-cooled Erlenmeyer flasks containing sodium bicarbonate roughly equivalent to 2 ml. of acetic anhydride suspended in 10 ml. of water. The distillate was neutralized with sodium bicarbonate or acetic acid, and then the distilled formaldehyde was determined by iodometry by the direct bisulfite method.[7] The results are shown in Table I. The quantitative liberation of formaldehyde from MHSO was observed during the first 30 min. of the reaction period. This confirms that the product of the rearrangement is not II but III, and it also suggests that this rearrangement is essentially useful for the determination of MSO and its derivatives. When MSO was treated by the same procedure as MHSO, the reaction mixture turned red-brown; formaldehyde was also distilled off and trapped as the dimedone derivative, but its recovery was low and not quantitative, and, furthermore, this results was so reproducible as that with MHSO.

Table I. Quantitative liberation of formaldehyde from MHSO

Substrate mg. (μ mol.)	Reaction period	Formaldehyde found μ mol.	Recovery %
MHSO 99.5 (523)	3	112	21.2
100.2 (527)	10	417	92.2
101.7 (534)	30	533	100
101.2 (532)	60	525	99
100.8 (531)	180	539	101
MH 99.6 (573)	180	0	0

In conclusion, although this procedure is not suitable for the determination of MSO for the above-mentioned reason, it may be practically useful for the determination of MHSO itself, even if the iodometric titration by the direct bisulfite method is somewhat troublesome and time-consuming.

Experimental

The Preparation of DL-Methionine Hydantoin (MH) and Its Sulfoxide (MHSO).—DL-Methionine hydantoin (MH) was prepared by boiling DL-methionine with an aqueous urea solution in the usual manner.[8] M. p. 94°C.

Found: C, 41.43; H, 5.63; N, 16.25. Calcd. for $C_6H_{10}O_2N_2S$: C, 41.38; H, 5.79; N, 16.09%.

Seventeen and a half grams (0.1 mol.) of DL-methionine-hydantoin was dissolved in 200 ml. of methanol while being gently warmed. This solution was then cooled, and 15 ml. of a (30%) hydrogen

peroxide solution was added drop by drop over about a 30 min. period. The reaction temperature was kept below 20°C by cooling, and the solution was allowed to stand for a further 3 hr. Then the mixture was concentrated to 20~30 ml. under reduced pressure at below 40°C. One hundred milliliters of benzene was added, and the resulting azeotropic mixture was distilled off to remove any traces of water. This procedure was repeated twice, and on concentration the mixture became cloudy and the crystalline product precipitated. About 40 ml. of acetone was added in small portions to precipitate the crystalline product completely. White crystals were collected by filtration and washed first with acetone and then with a small amount of ether. The yield of the crude product was 19 g. Nineteen grams of the product was suspended in 19 ml of water, resolved by warming, and filtered. Then 250 ml. of acetone was added in small portions while the solution was being cooled, and the mixture was stored in a refrigerator overnight. The fine white crystals obtained were washed with a small amount of acetone and then with ether. The yield was 15.75 g.; M. p. 156~157°C (corr.)

Found: C, 37.46; H, 5.27; N, 14.42. Calcd. for $C_6H_{10}O_3N_2S$: C, 37.90; H, 5.30; N, 14.73%.

This substance is soluble in water and hot methanol. It is slightly soluble in hot ethanol but insoluble in methanol, ethanol, acetone, ethyl acetate and ether.

Studies of Methionine Sulfoxide. III. A New Colorimetric Method for the Determination of Methionine Sulfoxide and Its Derivatives

By Kensaku MORIHARA

(Received June 9, 1964)

In a previous paper of this series,[1] the author reported that a rearrangement reaction occurred when methionine hydantoin sulfoxide (MHSO) was treated with acetic anhydride giving the corresponding α-acetoxy-thio-ether quantitatively. In the present work, a new photometrical method for the determination of methionine sulfoxide (MSO) and its derivatives based on this rearrangement reaction will be established. The method is based on the facts that formaldehyde is easily released from the products of the rearrangement reaction by hydrolysis and that it can be determined photochemically by using chromotropic acid.[2]

Though one is needed for biochemical studies, no direct method for the determination of MSO in the presence of methionine (Met) has yet been reported except that of polarography.[3] Recently, Neumann et al. developed an indirect procedure for the chromatographic determination of MSO residues in ribonuclease,[4] but their method cannot be applied to the routine analysis of MSO as it is very complicated. On the other hand, the present method is very simple and suitable for routine determinations of MSO, although it is impossible to use it to analyze the MSO residues in proteins accurately.

Results and Discussion

The Colorimetric Determination of the Formaldehyde Released from MSO and MHSO.— The formaldehyde released from the products of the above-mentioned rearrangement reaction can be effectively determined by the photometrical method of MacFadyen using chromotropic acid.[2] As the chromotropic acid reagent is strongly acidic, its use could eliminate the necessity of treating the reaction mixture with acid or alkali to release the formaldehyde. The procedure for the determination is given below (see "Recommended Procedure"). The experiments reported in this paper were carried out essentially by means of this procedure.

Reaction Conditions. — As is summarized in Table I, various conditions for the rearrangement were investigated. Thirty minutes boiling with acetic anhydride was found to be the most practical condition.

The Reaction Period of the Rearrangement. —To find the time taken for the rearrangement reaction, the formaldehydes released from

TABLE I. REACTION CONDITIONS

Condition	O. D. (observed)

Reflux for 30 min. (bath temp. 170~180°C)	0.382
97°C for 30 min.	0.057
97°C for 120 min.	0.357
97°C for 150 min. and then room temp. for 17 hr.	0.344
97°C for 20 hr.	0.332

MHSO and from MSO were successively analyzed by the colorimetric method. The results obtained are shown in Fig. 1; they confirm the results previously reported. The liberation of formaldehyde from MHSO began more rapidly than that from MSO without any lag in time, and the optical density became constant after the first 10 min. On the other hand, the liberation of formaldehyde from MSO was rather slow for the first 5 min. In this period, an azlactone ring may be formed prior to the rearrangement. The optical density became a little less after about 20 min., as the reaction period became longer, indicating that some unkown decomposition reaction took place. Twenty to 30 min. was a suitable reaction period for either reaction. In all the experiments described below, therefore, the reaction period was 30 min.

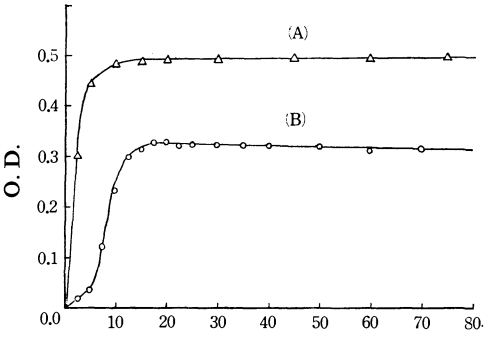

Fig. 1. Reaction period.
(A) MHSO 31.2 μ mol. in 1 ml. of acetic acid
(B) MSO 29.3 μ mol. in 1 ml. of acetic acid

The Optimal Ratio of Acetic Anhydride to Acetic Acid.—It was observed experimentally that the recovery of formaldehyde was affected by the amount of acetic anhydride relative to that of the sample solution, though the acetic anhydride used was stoichiometrically sufficient for the reaction. The results are shown in Fig. 2.

Thus, in standard determinations 2 ml. of acetic anhydride and 1 ml. of an acetic acid solution of the sample were used.

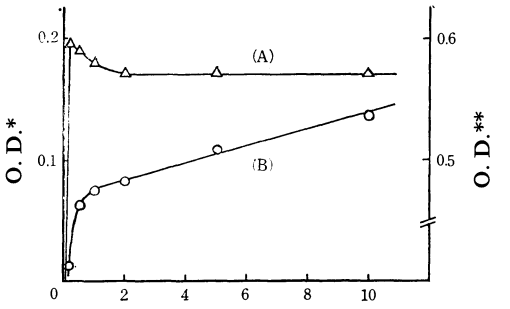

Fig. 2. Ratio (volume of acetic anhydride/volume of acetic acid solution of substrate).
(A) MSO (B) MHSO
* For curve A ** For curve B

The Period of Heating with a Chromotropic Acid Reagent.—In the usual procedure for the determination of formaldehyde with a chromotropic acid reagent, full color development was obtained by heating the solution at 100°C for 30 min. In this case, however, the chromotropic acid reagent acted in two ways: as a hydrolytic reagent to liberate formaldehyde on the one hand, and as a color reagent for the resulting formaldehyde on the other. Thus the optimal heating period had to be tested experimentally. As is shown in Table II, the optical density of the color increased with the heating period, but that of an authentic formaldehyde solution also increased at almost the same rate. Therefore, heating at 100°C for 30 min. was adopted as the standard procedure. However, in the presence of a large amount of an interfering substance, heating for 30 min. was not always sufficient, as will be mentioned below. In such cases, the period had to be prolonged until the optical density became the maximum value.

TABLE II. PERIOD OF HEATING WITH CHROMOTROPIC ACID REAGENT

1 ml. of sample solution was mixed with 10 ml. of chromotropic reagent.
* 6.06×10^{-1} μ mol. per ml.
** 6.55×10^{-1} μ mol. per ml.

Standard Curves of MHSO and MSO.—As is shown in Fig. 3, good linear standard curves of MHSO and MSO were obtained in the range between 1.0×10^{-1} μ mol. per ml. and at least 8.0×10^{-1} μ mol. per ml. It was found that, as the standard curve of MHSO was more constant and was reproducible in different determinations than that of MSO, the standard curve in Fig. 3 (C) could be used with a good accuracy. However, the standard curve of MSO shown in Fig. 3 (B) was more variable in different determinations, though it was always linear, so a parallel solution of MSO of a known concentration must be treated under the same conditions in order to determine the exact amount of MSO in a given sample. However, the variation in the standard curve of MSO was so slight that in practice MSO could be determined with a maximal error of only 5 per cent even when curve B in Fig. 3 was used. Moreover, when a ratio of 1 ml. of acetic anhydride to 1 ml. of MSO acetic acid solution was used, almost the same linear standard curve was obtained (curve A in Fig. 3.) However, this standard curve was more variable in different determinations than that obtained with 2 ml. of acetic anhydride (curve B in Fig. 3).

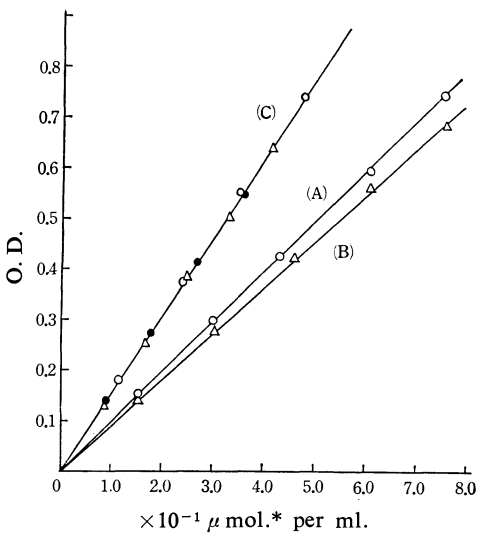

Fig. 3. Standard curves of MSO and MHSO.

(B) MHSO 2 ml. of acetic anhydride and 1 ml. of the sample solution were used.
(C) MHSO -○- and -●- 1 ml. of acetic anhydride and 1 ml. of the sample solution were used. The determinations were independently carried out.
-△- 2 ml. of acetic anhydride and 1 ml. of the sample solution were used.
* Final concentration of substrate when the reaction mixture was diluted to 100 ml.
The procedure used is described in "Recommended Procedure."

The Recovery of the Formaldehyde Released from MHSO and MSO. — It has previously been reported that the quantitative liberation of formaldehyde may be confirmed by iodometric titration.[5] This result was confirmed by the photometrical method. An exact, known weight of hexamethylene tetramine which had been twice purified by sublimation was dissolved in 100 ml. of 3 N sulfuric acid. To hydrolyze the hexamethylenetetramine to formaldehyde, this solution was incubated at 80°C until the aliquots gave a constant value for optical density when treated with a chromotropic reagent. Using this hydrolyzate as the standard formaldehyde solution, an optical density of 0.498 was obtained for 31.2 μ mol. of formaldehyde and an optical density of 0.648, for 41.1 μ mol. of MHSO. Thus the optical density per 1 μ mol. of the two was identical; the recovery was quantitative. The recovery of formaldehyde from MSO was determind indirectly by a comparison with that from MHSO, which was reacted in parallel; it was always found to be about 60 per cent of that of MHSO.

The Recovery of Formaldehyde from Other Derivatives of MSO and Their Standard Curves. —To ascertain why the recovery of formaldehyde from MSO was considerably lower than that from MHSO, the relationship between the structure of the sulfoxide and the recovery of formaldehyde was investigated by studying the

Table III. Recoveries of MSO derivatives

Substrate*	Recovery** %

standard curves of their recoveries. The results are shown in Table III and Fig. 4, but no clear conclusion can be deduced from them. The recovery from AcMSO* was almost identical with that from MSO, indicating that azlactone formation occurred prior to the rearrangement reaction. This conclusion was also supported by the curve in Fig. 1 mentioned above. Thus, it seems unlikely that steric hinderance due to the hydantoin ring decides the direction of the rearrangement to give a quantitative liberation of formaldehyde, because the steric effect due to the azlactone ring seems similar to that due to the hydantoin ring. This is also supported by the fact that the recovery of formaldehyde from Cbz-MSO,* Cbz-MSO-OEt* and Cbz-MSO-MSO-OEt* was not quantitative, though there is more steric hinderance in these compounds. Moreover, it is impossible to ascribe the lower recovery of formaldehyde from MSO than from MHSO to the consumption of sulfoxide by the oxidation of the amino group, because the recovery of formaldehyde from AcMSO, which had no amino group to be oxidized, was identical with that from MSO. Another possibility is that the azlactone formed from MSO strongly inhibited the color reaction of chromotropic acid. Although this possibility was indirectly disproved by the fact that an equivalent molarity of Met scarcely interfered at all with the determination of MSO and MHSO, this possibility was examined directly. If interference occurred, the addition of acyl amino acids, which easily form azlactones, to the substrate solution, or the addition of the acyl

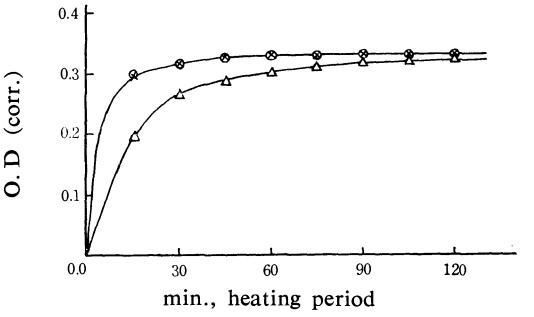

Fig. 5. Development of the color under copresence of interfering substances.

amino acid to the reaction mixture of MHSO after they have been treated with acetic anhydride should markedly inhibit the color developed with a chromotropic acid reagent.

As is shown in Table IV, this did not hold true. Furthermore, when large amounts of Met were present, the inhibition observed could be overcome by prolonging the heating period with a chromotropic acid reagent, as may be seen in Fig. 5. Thus, the cause of the relatively lower recovery of formaldehyde from MSO than from MHSO is uncertain. Perhaps the hydantoin stabilizes the sulfoxide group in the molecule, since it acts on hydrogen peroxide as a stabilizer.

Interference by Other Substances. — For the practical application of the method it is necessary to know what kinds of substances interfere with the present determination. As may be seen in Table V, MSO and MHSO were each determined in the presence of various substances. In the case of the inhibition of methionine, which is required in biochemical studies, the presence of 10 times the molarity of MSO scarcely affected the results at all, but more than 20 times the molarity reduced the value to some extent. However, even this does not decrease the usefulness of the present method much.

Substances that interfere markedly can mainly be divided into four groups. The first group are reducing substances, e.g., cysteine hydrochloride and ascorbic acid. These substances are thought to reduce the sulfoxide prior to the rearrangement. The second group (e.g., trimethylamine oxide and dimethyl sulfoxide) are substances that release formaldehyde when treated with acetic anhydride and subsequent hydrolysis. Here, it should be noted that trimethylamine oxide also released formaldehyde under these conditions. It seems possible that methyl-*N*-oxide might be determined by this method.

The third group (e.g., tryptophan) are substances that are decomposed so as to cause complications when treated with a strong acid.

The forth group (e.g., tyrosine) are substances that compete with chromotropic acid in combination with formaldehyde.

The last case was studied as follows. The substance to be tested, tyrosine in the present case, was added to a reaction mixture containing MHSO treated with acetic anhydride; the mixture was then boiled with a chromotropic

TABLE VI. INHIBITION OF CHROMOTROPIC ACID DEVELOPMENT WITH TYROSINE

reagent in the standard way. As may be seen in Table VI, tyrosine inhibited the color developed with the chromotropic acid reagent.

Determinations were made on a mixture of MHSO and MSO. No mutual interference was observed, and the recoveries were additive in the range of concentrations studied, as may be seen in Table VII. As is shown in Table VIII, the protein ovoalbumine does not seem to interfere with the determination of MSO or MHSO.

The Determination of MSO and MHSO in an Aqueous Solution. — As the method was to be applied to biochemical measurements of samples of MSO or its derivatives, the present method had to be used on aqueous mixtures of the substrates. When acetic anhydride was present in more than five times the molarity of water, the water in the aqueous solution was completely converted to acetic acid. Subsequent boiling resulted in the rearrangement, and satisfactory results were obtained, as is shown in Fig. 6. In these experiments, the ratio of 7.5 ml. of acetic anhydride was used to 0.5 ml. of MSO and MHSO aqueous solutions.

Recommended Procedure.—When the sample to be analyzed is in the solid state, dilute it exactly with purified acetic acid (see "Experimental" section) in a measuring flask to about 10 to 60 μ mol. of the substrate per ml. Pipette 1 ml. of this sample solution into a test tube attached to a suitable reflux condenser, and then add 2 ml. of purified acetic anhydride (see "Experimental" section). After stirring, heat the mixture under reflux for 30 min. on an oil bath.

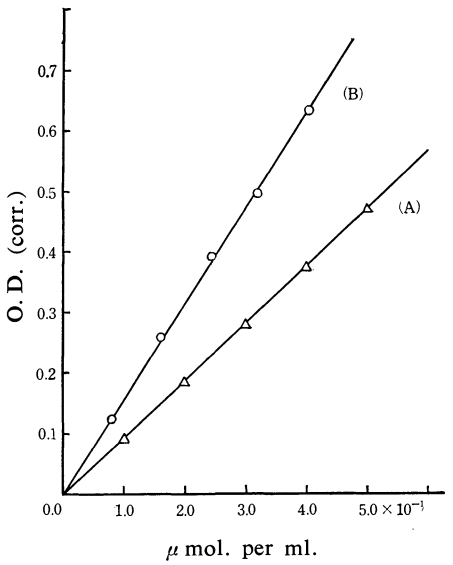

Fig. 6. Standard curves of MSO and MHSO in aqueous solution.
(A) MSO (B) MHSO

A standard solution of the sulfoxide which contains a known amount of the substrate (10 to 60 μ mol. per ml.), as a control, and 1 ml. of the purified acetic acid, as a blank, should be treated in the same way. When the sample to be analyzed is in an aqueous solution, dilute it with purified acetic acid to about 10 to 60 μ mol. per ml. Add 7.5 ml. of purified acetic anhydride to 0.5 ml. of the sample solution, and heat the mixture as described above. The standard aqueous solution of the sulfoxide and 0.5 ml. of water, as a blank, should be treated in parallel. Cool the reaction mixtures with water, and dilute them to 100 ml. with distilled water. Transfer 1 ml. of the resulting solution to a test tube, and then add 10 ml. of a chromotropic acid reagent; after stirring, heat the mixture in a boiling water bath for 30 min. When many other substances are present, it is desirable to prolong the heating period until a constant optical density is observed, since a heating period of 30 min. is

not always sufficient, as has been described above. After the mixture has been cooled to room temperature, measure the color developed with a photometer at 580 mμ. The optical density of the blank should then be subtracted from that of the sample. The optical density obtained here is O. D. (corrected).

As Beer's law holds exactly in the present concentration range, the sulfoxide can be determined by comparison with the optical density of the standard solution. For methionine sulfoxide the accuracy is within a range of error of 3 per cent.

Experimental

The Preparation of Acetyl Methionine Sulfoxide (AcMSO). — This material was obtained by the oxidation of acetyl-L-methionine, m. p. 101~103°C, prepared by the Schotten-Baumann reaction in the standard way. To 1.9 g. of acetyl-L-methionine dissolved in a mixture of 2 ml. of methanol and 2 ml. of water, 2 ml. of a 30% hydrogen peroxide solution was added while the mixture was cooled on ice; the solution was then allowed to stand for 1.5 hr. at room temperature. The reaction mixture was concentrated to a syrup under reduced pressure at below 40°C, and the syrup was dehydrated three times with benzene by the azeotropic procedure. The residual syrup was dissolved in a small amount of acetone and stored in a refrigerator for a long time, with occasional scratching until crystallization occurred. Crystals were collected, washed thoroughly with cold ethanol, and recrystallized from hot acetone. Yield, 500 mg.; m. p. 181~183°C.

Found: C, 40.60; H, 6.28; N, 6.72. Calcd. for $C_7H_{13}O_4NS$: C, 40.50; H, 6.36; N, 6.82%.

The Preparation of Benzoyl-L-methionine Sulfoxide (BzMSO). — Benzoyl-L-methionine (0.6 g.) (m. p. 85~90°C), prepared by the stndard Schotten-Baumann reaction was dissolved in 5 ml. of acetone, and 0.3 ml. of 30% hydrogen peroxide was added to the solution while the mixture was cooled with water. Then the mixture was allowed to stand for an hour at room temperature. When the solution was concentrated under reduced pressure at 40°C, a powder was obtained. The crystalline powder was collected by filtration and recrystallized with acetic acid containing 30 per cent water. The yield was 0.1 g.; m. p. 184~185°C.

Found: C, 53.72; H, 5.58; N, 5.21; S, 11.90. Calcd. for $C_{12}H_{15}O_4NS$: C, 54.09; H, 5.31; N, 5.60; S, 11.98%.

The Preparation of Carbobenzoxy-L-methionine Sulfoxide (Cbz-MSO).—To 5.67 g. (0.02 mol. of Cbz-Met in 50 ml. of methanol was added 2.2 ml. of a (30%) hydrogen peroxide solution with mechanically stirring in for 20 min. at 0~5°C. The solution was then allowed to stand for a further 2 hr. at room temperature. Fifteen milliliters of water was added to the mixture, which was then concentrated to about 20 ml. under reduced pressure at 35°C to remove the methanol. The resulting aqueous mixture was extracted four times with 25 ml. of ethyl acetate. The ethyl acetate extracts were combined and washed with a small amount of a saturated aqueous sodium chloride solution, and then dried over sodium sulfate overniglt. The dried ethyl acetate solution was concentrated under reduced pressure at below 40°C until the residue became slightly viscous. When seeded with Cbz-MSO (see below), the solution became cloudy, and on storage in a refrigerator crystallization occurred. The crystalline product was collected, washed with a mixture of ether and petroleum benzine, and dried in vacuo. The yield was 4.8 g., or 80%. The material was then recrystallized from methanol-water. M. p. 134°C.

Found: C, 52.44; H, 5.64; N, 4.61. Calcd. for $C_{13}H_{17}O_5NS$: C, 52.16; H, 5.72; N, 4.68%.

The Cbz-MSO used for seeding was obtained as follows: The ethyl acetate extract mentioned above was concentrated to a syrup and dissolved in a minimum amount of 1 N sodium hydroxide. The alkaline solution was titrated drop by drop with 6 N sulfuric acid until it became cloudy. One drop of 1 N sodium hydroxide was added to make the solution clear, and then the mixture was stored in a refrigerator for a few days. Fine needle-like crystals were obtained. Yield, 38%.

The Preparation of the Carbobenzoxy Methionine Sulfoxide Ethyl Ester (Cbz-MSO-OEt).— This compound was obtained by the esterification of Cbz-MSO in ethanol containing thionylchloride. To 10 ml. of ethanol at below −10°C was added, drop by drop, 0.65 ml. (9 mmol.) of thionylchloride. After 15 min. 2.14 g. of Cbz-MSO (7.15 mmol.) was added with strring and then the mixture was allowed to stand for about 24 hr. at room temperature. The ethanol was distilled off under reduced pressure, and the residual syrup was washed thoroughly with ether by decantation. The syrup, covered with ether, was kept in deep-freeze for about two weeks. Aggregated white crystals were deposited. The crystals were filtered off, washed thoroughly with ether, and dried in vacuo. The yield was 1.37 g. (58%). On the addition of petroleum benzine to the combined ether extracts, a second crop of crystals was obtained. These were recrystallized from ethyl acetate-petroleum benzine. M. p. 53.5°C.

Found: C, 55.21; H, 6.46; N, 4.96. Calcd. for $C_{15}H_{21}O_5NS$: C, 55.04; H, 6.47; N, 4.28%.

The Preparation of the Carbobenzoxy-*S*-oxomethionyl Methionine Sulfoxide Ethyl Ester (Cbz-MSO-MSO-OEt). — Cbz-Met-Met-OEt, prepared by the mixed anhydride method, was easily oxidized to Cbz-MSO-MSO-OEt with a hydrogen peroxide solution. To Cbz-Met-Met-OEt (2.21 g.; 5 mmol.) in a mixture of 30 ml. of water and 300 ml. of methanol, 1.2 ml. of (30%) hydrogen peroxide solution was added; the mixture was then allowed to stand overnight. The mixture was concentrated under reduced pressure to obtain a solid white product. The yield was 0.6 g., and the crystals melted at 185~186°C.

From the mother liquor 0.7 g. of the product was obtained. The second crop of crystals melted at 165~171°C, and from the mother liquor of the second crop, 0.8 g. of the product was obtained (m. p. 110~112°C). 0.6 g. of the first crop was

recrystallized from a methanol-ether mixture. Yield, 0.45 g.; m. p. 189~190°C.

Found: C, 50.52; H, 6.40; N, 5.75. Calcd. for $C_{20}H_{30}O_7N_2S_2$: C, 50.61; H, 6.37; N, 5.90%.

The Preparation of 2, 4-Dinitrophenyl-L-methionine Sulfoxide (DNP-MSO).—This compound was prepared according to the directions of Levy et al.; [6] m. p. 195°C (Ref. 184.5°C).

Found: C, 39.91; H, 4.15; N, 12.47. Calcd. for $C_{11}H_{13}O_7N_3S$: C, 39.88; H, 3.96; N, 12.68%.

The Purification of Acetic Acid and Acetic Anhydride.—The usual methods for the purification of acetic acid, and acetic anhydride, were not satisfactory for the present photometrical method. Acetic acid was, however, purified effectively as follows. A solution of 5 per cent phenylhydrazine (by weight) in 10 per cent (by volume) of acetic anhydride and 800 ml. of acetic acid was boiled under reflux for several hours. The acid was then distilled, and the fraction boiling at 115~117°C was collected. Distillation was repeated two or three times. The purified acid was kept in a brown bottle. When it was diluted 10 times (by volume) with distilled water, 1 ml. of the resulting solution showed an optical density of 0.005~0.008 when treated with 10 ml. of a chromotropic acid reagent.

Acetic anhydride was purified as follows: 800 ml. of acetic anhydride was mixed with a few drops of concentrated sulfuric acid, and the mixture was boiled under reflux for several hours. The mixture, which turned dark, was distilled, and the fraction boiling at 137~139°C was collected. One milliliter of the anhydride had an optical density of about 0.025 when treated with 10 ml. of a chromotropic reagent.

6) A. L. Levy and D. Chung, *J. Am. Chem. Soc.*, **77**, 2899 (1955).

Chromotropic Acid Reagent. — A chromotropic acid, disodium 1,8-dihydroxynaphthalene-3,6-disulfonate, commercially available, was recrystallized from a mixture of water and ethanol. One gram of the purified salt was dissolved in 100 ml. of distilled water, and 400 ml. of 24 N sulfuric acid was added to this solution.

Summary

1) A new colorimetric method for the determination of methionine sulfoxide and its derivatives on the basis of the rearrangement of sulfoxide by the action of acetic anhydride has been established.

2) From about 10 μ to 80 μ mol. of methionine sulfoxide can be determined with an experimental error of 3 per cent.

3) The interference with the reaction by various amino acids and related substances has been investigated.

4) Several compounds related to methionine sulfoxide have been prepared and analyzed by the present method.

The author is indebted to Professor Shiro Akabori and Dr. Yoshiharu Izumi for their constant interest and encouragement in this work, and to the Misses Kiku Koike and Masako Kawakita of this Institute for their elemental analyses.

The Anodic Oxidation of Esters

By Toshihiko OKUBO and Shigeru TSUTSUMI

(Received June 4, 1964)

A previous work[1] in this series dealt with the electrochemical coupling reaction of diethyl malonate and ethyl acetoacetate in absolute alcohol. Although the desired products were obtained in a small yield, they were contaminated with many by-products which were formed by the electrolysis of the alcohol itself. It has also been concluded that the solvent might play an important role in this reaction.

Therefore, as a new attempt, the present work was carried out for the purposes of obtaining a better yield of the dimer of esters in the electrolysis and of controlling the side reaction by using acetonitrile as a solvent, with no active hydrogen, and, as a supporting electrolyte, a potassium iodide which gave a better conductivity than the sodium salt of esters in the same solvent.[2]

The dimerization of esters is a novel method not only because of the electrolysis but also because of the chemical synthetic method.

In order to make a comparison with the case of an absolute alcohol, a malonic ester,

1) T. Okubo and S. Tsutsumi, *Tec. Rep. Osaka Univ.* **13**, 495 (1963).

2) E. White, *J. Chem. Soc.*, **1928**, 1414. (Although the data are for conductivities in an alcohol solution, this statement is also true for an acetonitrile solution in our blank test.)

an acetoacetic ester and a phenylacetic ester were used in this experiment.

Results and Discussion

The yield of a coupling product was calculated on the basis of the amount of product per unit qantity of electricity.

The experimental results are summarized in Table I.

As is shown in the table, the modified method in which acetonitrile was used as a solvent afforded more satisfactory results in all cases.

The Electrochemical Coupling of Esters in an Alcoholic Solution.—According to the explanation proposed by Allen,[3] the electrolytic coupling of these esters in an alcoholic solution proceeds in a manner similar to that of the Kolbe reaction, with the exception that no carbon dioxide is eliminated, as is shown below.

Step 1) The metallation of the ester (The formation of the anion of the ester)

$$Na + H\text{-}\underset{\diagup}{\overset{\diagdown}{C}}COOR \longrightarrow Na\text{-}\underset{\diagup}{\overset{\diagdown}{C}}\,COOR$$

Step 2) The dissociation of the alkali salt of the ester

$$Na\text{-}\underset{\diagup}{\overset{\diagdown}{C}}COOR \rightleftarrows Na^+ + -\underset{\diagup}{\overset{\ominus}{C}}COOR$$

Step 3) The anodic oxidation of the anion

$$\ominus\!\!\diagdown\!CCOOHR \xrightarrow{-e} \cdot\!\diagdown\!CCOOR \longrightarrow$$

$$ROOCC\text{-}\underset{\diagup\ \diagdown}{\overset{\diagup\ \diagdown}{C}}COOR$$

For the electrolysis in an alcoholic solution, it was observed that the reactivity of the ester toward the electrolytic coupling was dependent on the electron-attracting force of the substituents on the methyl group (CH_3) of ethyl acetate ($CH_3COOC_2H_5$). The decrease in the reactivity of the ester caused by the substituent was in the order; carbethoxy $COOC_2H_5$, acetyl CH_3CO and phenyl C_6H_5. The order was just the same as Taft's substituent constants[4] for CH_2X–, as is shown below.

$$C_6H_5, +0.215 < CH_3CO, +0.60 < COOC_2H_5, +0.7$$

On the reaction of ethyl acetoacetate and ethyl phenylacetate in alcohol, because their releasing force of hydrogen is lower than that of ethyl malonate, the yield of coupling products was very poor (ethyl acetoacetate, 0.2 g./amp. hr.; ethyl phenylacetate, a trace, and by the following reaction, acetoaldehyde and its polymeric material were the main products;

$$C_2H_5O\overset{\ominus}{:} \longrightarrow C_2H_5O\cdot + e$$

$$C_2H_5O\cdot \longrightarrow CH_3CHO + 1/2\ H_2$$

The Electrochemical Coupling of Esters in an Acetonitrile Solution.—When these esters were submitted to electrolysis in a potassium iodide-acetonitrile medium, the dimer of esters was yielded, especially in the cases of both ethyl acetoacetate and ethyl phenylacetate. The dimer which could not hitherto be isolated as a crystal in the case of an alcoholic solution was obtained as a fine crystal and in a good yield.

The reasons for this may be as follows:

1) An acetonitrile was scarcely oxidized in

Table I. Summary of the results

Ester	Product: In absolute alcohol	Product: In acetonitrile
Diethyl malonate	$HC(COOC_2H_5)_2$ | $HC(COOC_2H_5)_2$ (1.4 g./amp. hr.)	$HC(COOC_2H_5)_2$ | $HC(COOC_2H_5)_2$ (2.1 g./amp. hr.) (0.013 mol./amp. hr.)
Ethyl acetoacetate	(1) $CH_3COCH(COOC_2H_5)$ | $CH_3COCH(COOC_2H_5)$ (identified as acetonylacetone) (0.2 g./amp. hr.) (2) CH_3CHO and polymeric materials	$CH_3COCH(COOC_2H_5)$ | $CH_3COCH(COOC_2H_5)$ (1.5 g./amp. hr.) (0.0115 mol./amp. hr.)
Ethyl phenylacetate	(1) $C_6H_5CH(COOC_2H_5)$ | $C_6H_5CH(COOC_2H_5)$ (trace) (2) CH_3CHO and polymeric meterials	(1) $C_6H_5CH(COOC_2H_5)$ | $C_6H_5CH(COOC_2H_5)$ (2.3 g./amp. hr.) (0.014 mol./amp. hr.) (2) a small amount of a tarry product

3) M. J. Allen, "Organic Electrode Processes," Reinhold Pub. Corp., New York (1958), p. 111.

4) M. S. Newman, "Steric Effects in Organic Chemistry," John Wiley and Sons, New York (1956), p. 595.

the anodic oxidation as compared with an alcohol, and the amounts of by-products are small.

2) The dissociation of the potassium salt of the ester is easier than that of sodium salt.

3) The velocity of the reaction was accelerated by the action of the iodide formed, as is shown in the reaction path.

The yield of coupling products indicated in (mol./amp. hr.) was nearly constant in each case. It is noticeable that the difference in the acidity between esters is not very important in the reactions in acetonitrile because the acidities of the esters used are much stronger than that of acetonitrile.[5]

The following reaction path may be inferred.

$$KI \longrightarrow K^+ + I^- \quad (1)$$

$$K^+ \xrightarrow{+e} K\cdot \quad (2)$$

$$I^- \xrightarrow{-e} I\cdot \quad (3)$$

$$K\cdot + RCH_2COOC_2H_5 \longrightarrow RC(K)HCOOC_2H_5 + 1/2\ H_2 \quad (4)$$

$$RCH(K)COOC_2H_5 \longrightarrow R\bar{C}HCOOC_2H_5 + K^+ \quad (5)$$

$$R\bar{C}HCOOC_2H_5 \xrightarrow{-e} R\dot{C}HCOOC_2H_5 \quad (6)$$

$$2R\dot{C}HCOOC_2H_5 \longrightarrow \begin{matrix} RCHCOOC_2H_5 \\ | \\ R\dot{C}HCOOC_2H_5 \end{matrix} \quad (7)$$

$$I\cdot + RC(K)HCOOC_2H_5 \longrightarrow KI + R\dot{C}HCOOC_2H_5 \quad (8)$$

$R = C_6H_5,\ COOC_2H_5,\ CH_3CO$

Experimental*

Materials.—*Acetonitrile.*—Commercial grade acetonitrile was carefully purified in the usual manner. (B. p. 81.0°C, n_D^{20} 1.3440).

Ethyl Malonate and Ethyl Acetoacetate (commercial grade) were fractionated. (Ethyl malonate: b. p. 197~198°C, n_D^{18} 1.4120; Ethyl acetoacetate: b. p. 89~90°C/30 mmHg, n_D^{20} 1.4190) Ethyl phenylacetate was prepared by the method given in the literature[6] (115~117°C/20 mmHg, n_D^{23} 1.4959).

Apparatus.—Electrolyses were carried out in a cylindrical glass vessel fitted with a reflux condenser and two platinum foil electrodes with an area of 20×30 mm^2 and spaced 5 mm. apart. During the coures of the electrolysis, the contents were stirred magnetically and the temperature was controlled by a water bath.

The Electrolysis of Ethyl Malonate in Acetonitril Containing Potassium Iodide.—A solution of 30 g. of ethyl malonate and 0.5 g. of potassium iodide in 100 ml. of acetonitrile was electrolyzed at 10°C for 36 hr. A current was maintained at 0.2 amp. After the removal of the acetonitrile, the electrolyte solution was poured into cold water and extracted with ether. The ethereal layer was then washed with water and dried over anhydrous magnesium sulfate, and the ether was removed. The remaining oil was distilled under reduced pressure. The fraction with a b. p. of 180~187°C/12 mmHg was 15 g. After recrystallization from alcohol, they afforded tetraethyl ethanetetracarboxylate (m. p. 74~75°C), and the melting point was undepressed on admixture with an authentic sample.[7] Moreover the infrared spectrum of this compound was identical with that of an authentic sample.

The Electrolysis of Ethyl Acetoacetate in Acetonitrile Containing Potassium Iodide.—A mixture of 30 g. of ethyl acetoacetate, 0.5 g. of potassium iodide, and 100 ml. of acetonitrile was electrolyzed at 10°C for 27 hr. During the electrolysis, a current was maintained at 0.3 amp. After the removal of the acetonitrile, the residue was vigorously shaken with cold water and a solid was separated by filtration. When the solid was then washed with water and dried in vacuo, the yield was 12 g. It was then recrystallized from alcohol (m. p. 81~83°C). The recrystallization of this crystal from aqueous alcohol gave the β-form of diethyl diacetosuccinate* (m. p. 86.5~88°C). The melting point of this compound was not depressed on admixture with an authentic sample prepared according to the directions of Knorr and Haber.[8] The infrared spectra of the compound were identical with those of an authentic sample.

Found: C, 55.72; H, 6.83. Calcd. for $C_{12}H_{18}O_6$: C, 55.81; H, 6.97%.

The Electrolysis of Ethyl Phenylacetate in Acetonitrile Containing Potassium Iodide.—The experiment was conducted in a manner essentially similar to that of the experiment described above. The solid (m. p. 128~135°C) (3.5 g.) was suspended between aqueous and ethereal layers, and the residue (14 g.) was obtained from an ethereal layer. The solids were combined and submitted to sublimation. The sublimated crystals were extracted with hot petroleum ether (b. p. 40~55°C) to remove low melting parts. The remaining crystals were recrystallized from alcohol, melted at 138.5~140°C and identified as ethyl β-diphenyl-succinate[9] by mixed melting point measurement.

Found: C, 73.27; H, 6.62. Calcd. for $C_{20}H_{22}O_4$: C, 73.61; H, 6.74%.

A trace of unidentified crystals (m. p. 77~81°C) was obtained from the hot petroleum ether-soluble part.

The Electrolysis of the Sodium Salt of Ethyl Phenylacetate in Absolute Alcohol.—To a solution of 25 g. of ethyl phenylacetate in 100 ml. of absolute alcohol, 0.5 g. of sodium was added, and then the

* Melting points and boiling points are uncorrected.

6) "Organic Syntheses," Coll. Vol. I (1948), p. 270.

7) C. A. Bischoff, *Ber.*, **17**, 2781 (1884).

* Diethyl diacetosuccinate has many tautomers. Among them are the β-form (diketo form) and the γ-form (diketo form). Their melting points are 89~90°C (plate form) and 74°C (needle form) respectively. In the presence of water, the γ-form is transformed into the β-form.

8) L. Knorr and F. Haber, ibid., **27**, 1155 (1894).

9) H. Wren and C. J. Still, *J. Chem. Soc.*, **1915**, 444.

solution was subjected to electrolysis. The electrolysis was carried out at an average current of 0.2 amp. at 20°C for 30 hr. The precipitate (2 g.) was separated by filtration. This precipitate was dissolved in water, acidified with dilute hydrochloric acid, and then extracted with ether. After the removal of the ether, a trace of crude crystals was obtained; when sublimated, it yielded ethyl β-diphenylsuccinate (m. p. 120~135°C). An attempt to purify this compound was unsuccessful. After the evaporation of the alcohol, the filtrate was distilled under reduced pressure to give the following fractions.:

Fraction 1: 100~118°C/20 mmHg 17.8 g. (unchanged ester)
Fraction 2: 40~80°C/3 mmHg
Fraction 3: 80~85°C/3 mmHg 1 g. n_D^{24} 1.496
Fraction 4: 100~110°C/3 mmHg 0.9 g. n_D^{24} 1.500
Fraction 5: 115~130°C/3 mmHg 0.9 g. n_D^{24} 1.558

Fraction 2 was converted into its 2,4-dinitrophenylhydrazone (m. p. 230~233°C (recrystallized from a mixture of alcohol and nitrobenzene)). As the I. R. of this hydrazone showed no C=O band, the fraction seems not to be an ester and aldehyde polymer resulting from the electolysis of alcohol. Fractions 3, 4, and 5 were soluble in both ether and alcohol, and the I. R. of these fractions showed the characteristic absorption bands of the ester.

We wish to express our thanks to Mr. Yoshinobu Odaira and Mr. Kikuhiko Koyama for their advice during the course of this work, and also to Miss Junko Maenaka for her elemental analysis.

*Characterization of the Alumina-Boria Catalyst**

By Yūsuke Izumi and Tadao Shiba

(Received June 5, 1964)

Alumina-boria is a well-known type of acidic cracking catalyst.[1,2] However, the details of its characterization still remain unsettled, in contrast to the case of silica-alumina, which has been the subject of numerous investigations. It has been previously suggested[3-6] that active alumina may react with boric acid to form strongly acidic centers, but more experimental evidence is necessary for an understanding of the reaction and of a probable mechanism of the development of activity. Although Ikebe[4] showed the remarkable effect of the chemical composition of alumina-boria upon its cracking activity, little is known so far about the best method of preparing the catalyst. This study was undertaken in order to obtain such information.

The present investigation started from the observation that the activity of alumina-boria was considerably affected by the chemical and the physical nature of the alumina used as the catalyst-base, the effect of the conditions of catalyst preparation upon the activity of the toluene disproportionation was examined. In the second step, the chemical interaction of active alumina with boric acid was studied by thermographic analysis, and the mechanism of developement of activity was discussed on the basis of the results, together with those of X-ray diffraction, infrared absorption and the colorination of adsorbed indicators. Kinetic studies of some specific reactions over alumina-boria were made in order to establish the applicability of the catalyst.[7-11]

Experimental

Alumina as a Catalyst Base.—A hydrous alumina gel was prepared at a given pH by adding an aqueous solution of ammonia (4 N) to a solution of aluminum nitrate (10%). The precipitate was washed to remove nitrate ion and dried in an electric oven for several hours at 130°C to form an alumina hydrate. The greater part of the alumina

hydrate, which was obtained at pH 10 with or without the aging of the precipitate, was found to consist of bayerite, while the alumina hydrate prepared at pH 7 to 8.2 showed a clear diffraction pattern assigned to gibbsite. It was suggested that the particle sizes of these two kinds of aluminum trihydroxide might be supposed to be very fine,[12,13] since only one endothermic peak was observed, at about 330 to 370°C, in the course of the thermal transformation.[7] Gibbsite and bayerite were dehydrated by calcination at 300 to 600°C in a muffle furnace for several hours, and transformed into χ-alumina and η-alumina respectively, as is shown in Table I.

Table I. X-Ray analysis of alumina for a catalyst base

Condition of precipitation pH, aging	Calcination temp. °C	Structure of alumina	Relative intensity of maximum diffraction peak*

7.0, 30 days	400	χ-Alumina	7

* Angular position of the maximum diffraction peak (2θ); gibbsite 18.3°, bayerite 18.8°, η-alumina 66.8°, χ-alumina 67.2°.

The Preparation of Alumina-Boria. — Both hydrous and anhydrous alumina were used as catalyst bases. Powdered alumina was impregnated with the required amount of an aqueous solution of boric acid, and the mixture was heated in a kneader by an infrared lamp in order to evaporate the excess water. The resulting wet composite was pelleted into cylindrical form (4 mm.ϕ×4 mm.); then the pellets were calcined at 400 to 500°C for 4 hr. in a muffle furnace.

The Determination of Boria Content.—Boron in silicate ores is generally determined by a fusion method, but in the present case it was found that boric acid was so easily extracted from the catalyst with hot water that an almost complete determination was possible by means of titration with a sodium hydroxide solution in the presence of mannitol. The boria content thus determined agreed well with that determined by the fusion method,[14] as well as with that calculated from the amount of boric acid which was impregnated into the alumina. Such easy extraction of boric acid suggests that the structure of alumina-boria may be very different from that of aluminum borate. All the boria contents shown in the experimental results were calculated from the amount of boric acid used in the catalyst preparation (B_2O_3/cat., wt.%).

Reaction Apparatus and Product Analysis.—Some specific reactions over an alumina-boria catalyst were carried out with a fixed-bed flow reactor under atmospheric pressure. The reactor consisted of a Pyrex double tube (24 mm.ϕ×600 mm.—10 mm.ϕ× 600 mm.) and a feeder which was a syringe driven by a clock sinker. The reactor was placed vertically in a fluidized bed of powdered alumina with automatic temperature regulation.

The reaction products were analyzed by gas chromatography at 80°C using a column packed with 30% D. O. P. on celite. For the separation of xylene isomers, a 5 m. column of 30% 7,8-benzoquinoline[15] was used.

Acidity and Acid Strength Measurements.—The acidity of alumina-boria was determined following Benesi's[16] and Leftin-Hall's[17] methods as modified by Shiba and his co-workers.[18] The total acidity was determined by *n*-butylamine titration, using benzeneazodiphenylamine as an indicator, and the Lewis acidity, by the chemisorption of triphenylmethyl chloride on alumina-boria. The difference between the total and the Lewis acidity was attributed to the Brönsted acidity.

Color tests were made[16] by transferring roughly 0.1 g. of a dried, powdered sample into a test tube which contained 5 ml. of dry cyclohexane, adding a few drops of a solution of indicator in cyclohexane, and, after leaving it overnight, observing the color of the adsorbed indicator. The indicators used were benzeneazodiphenylamine, dicinnamalacetone and benzalacetophenone. Their acidic colors are purple, red and yellow, and the values of pK_a are +1.5, −3.0 and −5.6 respectively.

Other Measurements. — The differential thermal analysis for the examination of chemical interaction between alumina and boric acid was carried out under atmospheric pressure. The sample holder was a quartz vessel 5 mm. in diameter and 20 mm. deep.

X-Ray diffractions were recorded by a Phillips X-ray diffractometer with Ni-filtered Cu-K_α radiation.

Infrared absorption measurement was made on samples in potassium bromide discs in the region between 2 and 16 microns, using a Shimadzu AR-275 spectrophotometer.

The Structural Effect of Alumina Used for a Catalyst Base

The relationship of the structure of alumina used for a catalyst base with both the activity and the acidity of alumina-boria is shown in Figs. 1 and 2. The conversion of toluene* is taken for the activity since the selectivity of the disproportionation of toluene is almost identical with the different catalyst compositions (the mole ratio of produced xylene to benzene was 0.9±0.05). Both the η-alumina and χ-alumina used for catalyst bases were calcined at 400°C so as to give maximum activities of the catalysts.

○ Total acidity ◑ Lewis acidity
● Brönsted acidity ⊙ Surface area

* The conversion represents the value which was obtained with an "equilibrated" catalyst. The decrease in activity with the length of run will be discussed later.

The catalyst prepared from η-alumina gave a higher activity than that from χ-alumina, while α-alumina was an ineffective base. The maximum activity was obtained at 15 wt.% of boria** in both of the active catalysts. It is suggested that the excessive boria might have been deposited on active sites, so lowering the activity, since boria by itself showed little activity. The aging treatment of the alumina used for a catalyst base was found to have little effect on the activity.[7]

The greater part of the acidic centers of alumina-boria are of the Brönsted type, as is shown in Fig. 2. By comparing Fig. 1 with Fig. 2, it may also be seen that the catalytic activity has a correlation with the Brönsted acidity. This information fits in well with the reliable conception that the reaction may proceed via a carbonium ion mechanism. The surface area of the catalyst did not have any definite relationship with the activity. The activity per unit of Brönsted acidity of the catalyst derived from η-alumina was much higher than of that derived from χ-alumina.[7] This may be due to the difference in acid strength or in the distribution of acid sites among the effective catalyst surfaces, because the structural deviation of η-alumina from χ-alumina is generally recognized as the difference in the distribution of aluminum ions among oxygen ions.[12]

As for the synthetic silica-alumina, the catalyst of 50 wt. % of silica showed a best activity of toluene conversion (1.6 mol. %/g. cat. at the

** Ikebe[4] has shown that the maximum cracking activity of alumina-boria is obtained at about 12~15 wt.% boria, and that the alumina used for his catalyst base contains hydrous alumina.

same condition as shown in Fig. 1) and the maximum Brönsted acidity (0.164 meq./g. cat.); the total acidity was 0.300 meq./g. cat. The result indicates that the activity per unit mass of the silica-alumina is much lower than that of the alumina-boria prepared from η-alumina. This is probably due to the lower concentration of acid sites in the former in spite of its higher activity per unit of Brönsted acidity.

The effect of the calcination temperature of the alumina used for the catalyst base upon the activity is shown in Fig. 3. The maximum activity was given by the catalyst which was derived from η-alumina calcined at 400°C. In view of the higher crystallinity of the alumina with the higher calcination temperature, it may be concluded that an alumina calcined at a higher temperature may be less reactive upon boric acid, resulting in a less effective base for the catalyst.

The Development of Active Centers

The Chemical Interaction of Alumina with Boric Acid. — Ikebe and his co-workers[6] have shown that the thermogram of a hydrous alumina alone and that of an alumina impregnated with boric acid were almost identical. This result may be explained as an overlapping of the endothermic transformation of the hydrous alumina with the thermographic behavior of chemical interaction between alumina and boric acid. They concluded from an X-ray study that boric acid reacts with alumina at about 300 to 400°C on the basis of their observation of the disappearance of some sharp diffraction peaks of a mixture of hydrous alumina and boric acid at that temperature. However, a careful examination of their data shows that the interaction might have occurred at a lower temperature, since some angular locations of the diffraction peaks of the hydrous alumina* are almost identical with those of boric acid or of boron oxide.**

In the procedure of the differential thermal analysis in the present study, the probable thermal effects of alumina and the remaining water were eliminated, in order to obtain clear information about the interaction, by the use of a powdered anhydrous η-alumina as the reference and a dry mixture of the same weight of the alumina and various amounts of powdered boric acid as the sample. It is not unsuitable to test the chemical interaction by the use of the dry mixture because the activity of alumina-boria prepared from the dry mixture was almost identical with that of the catalyst derived by impregnation in an aqueous solution so long as the boria content was the same. The results of the differential thermal analysis are shown in Fig. 4. In the case of the η-alumina-boric acid system, the *a* or *b* composite (corresponding to 15 or 20% boria) gives only one broad endothermic peak, at about 130°C. On the other hand, the thermogram of the *c* or *d* composite (corresponding to 25 or 30% boria respectively) shows two sharp peaks, at approximately 170 and 185°C, besides a broad shoulder at 130°C. These peaks apparently accord with the two sharp peaks given in the transformation of boric acid alone (curve *h*) or of the α-alumina-boric acid system (curve *g*). Since two peaks of the *g* or *h* curve give no shoulder at 130°C, they clearly and even quantitatively correspond to

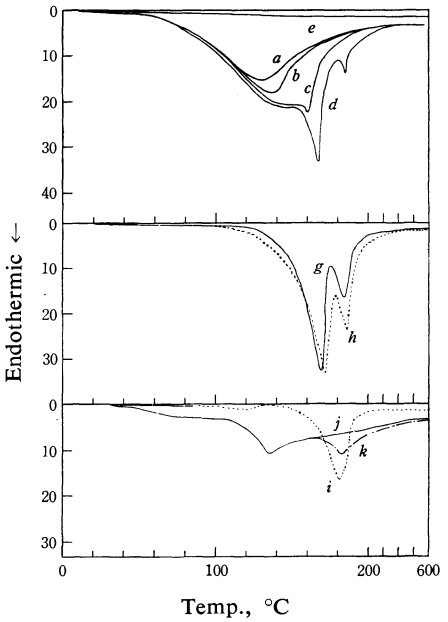

Fig. 4. Differential thermal analysis of the systems of alumina-boric acid (*a*, *b*, *c*, *d*, *g*) and alumina-metaboric acid (*i*, *j*, *k*).

* $2\theta = 28.1°$ and 14.4° for boehmite with a strong intensity.
** $2\theta = 27.9°$ (for H_3BO_3 and B_2O_3), and 14.6° for B_2O_3 with a medium intensity.

the transformations of boric acid into metaboric acid, and of metaboric acid into boria, respectively.[19] As for the η-alumina-metaboric acid system, a peak at 183°C in the thermogram of the *k* composite (corresponding to 30% boria), as well as a peak at 181°C of the *i* curve (metaboric acid), indicates the formation of isolated boria from metaboric acid, while the *j* composite (corresponding to 15% boria) gives only one endothermic peak, at 135°C. Judging from the results, it is probable that boric acid is dehydrated to form metaboric acid as an intermediate and that it reacts with an active anhydrous alumina at about 130°C to yield active centers, while boric acid does not react with α-alumina. It is also shown that excessive boric acid is transformed into isolated boria which might be deposited on the active centers and so lower the activity. The reactivity of χ-alumina with boric acid was found to be almost identical to that of η-alumina.[7]

The X-Ray Study of Alumina-Boria.—Table II gives the results of the X-ray diffraction of some catalysts with different compositions prepared from various forms of alumina. The relative diffraction intensity of the η-alumina which remains in the catalyst derived from anhydrous alumina is not very much reduced with the increase in boria content, whereas the intensity of the alumina in the catalyst made from hydrous alumina were remarkably reduced. This fact indicates that the reaction between anhydrous alumina and boric acid is probably localized on the surface of the alumina and that the crystal structure of alumina is not very much disturbed, whereas boric acid reacts more uniformly with hydrous alumina. In comparison with Fig. 3, it is supposed that excessive boria reduces the activity of alumina-boria because of the deposition of isolated boria. It is also shown that the reactivity of α-alumina with boric acid is very poor, since the diffraction of isolated boria appeared even in the composite of 5% boria. Attention must also be paid to the fact that alumina-boria did not give any definite diffraction pattern characteristic of aluminum borates such as $9Al_2O_3 \cdot B_2O_3$, $2Al_2O_3 \cdot B_2O_3$ and $Al_2O_3 \cdot B_2O_3$.

TABLE II. X-RAY ANALYSIS OF THE ALUMINA-BORIA CATALYST CALCINED AT 500°C

assigned to the B–O vibration.[21-23] A slight shift in the position of the B–O vibration-band center towards longer wavelengths, as well as a considerable change in the band shape, was observed in the spectrum of the alumina-boria catalyst with 10% boria. In view of the mass effect[20] of the aluminum atom upon the B–O vibration, it is suggested that alumina may react with boric acid and that a B–O–Al bond is formed in the catalyst. On the other hand, the band position of the B–O vibration of the catalyst prepared from α-alumina (10% boria) accorded with that of boria. This shows that α-alumina is inactive for the interaction with boric acid. The disappearance of the B–O–H bending band in the case of the catalyst (10% boria) which appears at 8.3 μ with strong intensity in the spectrum of boric acid may suggest that such a bond as Al–O–B–O–Al is formed in the course of the fore-treatment of the catalyst.

The Effect of the Calcination Temperature of the Catalyst upon the Activity.—The activities and acid strengths of some alumina-boria catalysts calcined at different temperatures are shown in Fig. 6 and Table III. It was observed that the heating of the mixture of active alumina and boric acid at a temperature as low as 100°C brought about an acid color with benzeneazodiphenylamine (pK_a +1.5), while the alumina alone and evacuated boria did not give the acid color by calcination, even at 400°C. This is consistent with the conclusion of the thermographic analysis. The data in Fig. 6, however, indicate that an effective catalyst for toluene disproportionation or for xylene isomerization could be obtained by calcination above 400°C. Since the catalyst gave an acid color with benzalacetophenone

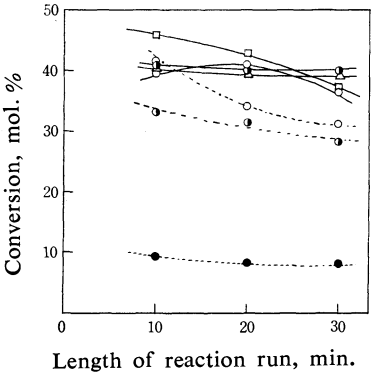

Fig. 6. Effect of the calcination temperature of catalysts upon activity.
Catalyst: η-Alumina-boria (10 wt. % boria) calcined at 300°C ●, 400°C ◑, 500°C ○, 600°C △, 700°C □.
——: Toluene disproportionation at 480°C, catalyst 20.1 g., feed rate 0.0285 mol./hr.

(pK_a −5.6) only when it was heated above 300°C, it may be concluded that the catalyst should be activated at a higher temperature than 400°C in order to develop the activity for these reactions. This is analogous to the finding of Topchiev's study of the alumina-chromia catalyst.[23] It is suggested, consequently, that the large amount of water which is produced in the course of chemical interaction between alumina and boric acid, and which still remains adsorbed on the resulting catalyst, hinders the development of activity.

Kinetic Studies of Some Specific Reactions over an Alumina-Boria Catalyst

The Disproportionation of Toluene.—A number of kinetic studies of the transalkylation

of aromatic compounds with solid acidic catalysts have been made by several workers.[24-28] However, few studies of these reactions with an alumina-boria catalyst have been kinetically forwarded. In the present paper, the role of the catalyst and the reaction kinetics are discussed. The results of the disproportionation of toluene at 450 to 510°C, with or without the dilution of the reactants with nitrogen, are shown in Fig. 7. Among the products, the quantity of benzene was larger than that of xylene in every run, and some cracking reactions (the demethylation of toluene and xylene) were found to occur simultaneously. A small amount of a gaseous substance was produced; it consisted of hydrogen and methane (in a 9 : 1 mol. ratio). These side reactions caused a decrease in the activity of the catalyst as a result of the coke formation. For this reason, the samples were taken when the activity became constant about an hour after the start of the run. The reaction scheme is expressed as follows:

Disproportionation:

$$2C_6H_5CH_3 = C_6H_6 + C_6H_4(CH_3)_2$$

Cracking:

$$\begin{cases} C_6H_5CH_3 \rightarrow C_6H_6 + CH_2\cdot \\ C_6H_4(CH_3)_2 \rightarrow C_6H_5CH_3 + CH_2\cdot \end{cases}$$

Johnson and Watson[24] studied the formation of toluene from benzene and xylene over a silica-alumina catalyst and showed that the rate was controlled by the surface reaction between the adjacent centers occupied by adsorbed reactants. In the present study, the disproportionation of toluene was likewise well interpreted kinetically by assuming that the rate was controlled by the surface reaction. The rate is described by an expression following the Langmuir-Hinshelwood mechanism;

Rate of disproportionation:

$$r_d = \frac{C_d(p^2_t - p_b p_x/K_d)}{(1+K_b p_b + K_t p_t + K_x p_x)^2} \qquad (1)$$

where C_d is the rate constant; K_d, the equilibrium constant of the disproportionation and p_b, p_t and p_x and K_b, K_t and K_x, partial pressures (atm.) and adsorption equilibrium constants for benzene, toluene and xylene respectively. Other expressions for the rate derived from the Rideal mechanism and the adsorption or desorption-controlling mechanisms were found to be unsuccessful in explaining the results of an examination of the relationship between the initial rate of the formation of xylene and the partial pressure of the feed. The overall rate of the reaction is given by the following expression, by assuming that the retardation term of the denominator of Eq. 1 is constant so long as the partial pressure of the feed is fixed;

$$\left.\begin{aligned} &\text{The rate of the formation of xylene:} \\ &\quad r_x = dx/d(W/F) = k_d(p^2_t - p_b p_x/K_d)/2 - k_x p_x \\ &\text{The rate of the formation of benzene:} \\ &\quad r_b = db/d(W/F) = k_d(p^2_t - p_b p_x/K_d)/2 + k_t p_t \\ &\text{The rate of subsequent cracking:} \\ &\quad r_c = r_b - r_x \end{aligned}\right\} \qquad (2)$$

where k_d, k_x and k_t denote rate constants of toluene disproportionation, xylene cracking and toluene cracking at a constant partial pressure of the feed; W the mass of the catalyst (g.); F the feed rate (mol./hr.) and x and b, mole fractions of xylene and benzene in the product. The above assumption is found to hold true because there is a good linear relationship between r_x/p_x and $(p^2_t - p_b p_x/K_d)/p_x$, as is shown in Fig. 8. The k_d values at 1 atm. of partial pressure of the feed are listed in

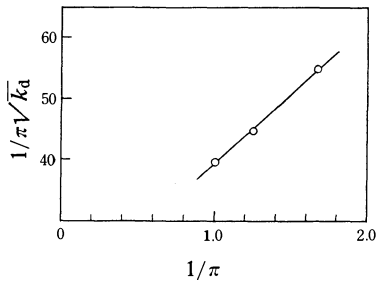

Fig. 9. Consistence of the rate expression derived from the Langmuir-Hinshelwood mechanism.

Table IV. From an examination of Eq. 1 for the reaction in the presence of benzene in the feed,[8] the following relation is found:

$$2K_t \fallingdotseq K_b + K_x$$
$$(K_t=0.48,\ K_b=0.42,\ K_x=0.63)$$

Accordingly, the rate constant, k_d, is expressed by the equation:

$$k_d = C_d/(1+\sum K_i p_i)^2 = C_d/(1+K_t\pi)^2$$
or $$1/\pi = (\sqrt{C_d}/\pi\sqrt{k_d}) - K_t \quad (3)$$

where π represents the partial pressure of the feed. The consistence of the above mechanism was verified by a linear relationship between $1/\pi$ and $1/\pi\sqrt{k_d}$ for the reaction at 480°C, as is illustrated in Fig. 9, and the mean value of K_t was obtained. The numerical expression of the disproportionation of toluene is as follows:

$$r_d = \frac{34.9\exp(-7400/T)}{\{1+4.12\times10^{-6}\pi\exp(9060/T)\}^2} \times (p^2_t - p_b p_x/K_d)$$

(mol./hr. g. cat.), $T=723$ up to 783°K.

The mean value of the heat of the adsorption of reactants, 18 kcal./mol.

The apparent activation energy, 14.7 kcal./mol.

The relation between the time factor (W/F) and the mole fraction of xylene in the product (x) is described approximately by an integrated expression:

$$W/F = -\{\ln(1-mx)\}/n \quad (4)$$

when m and n denote constants when the

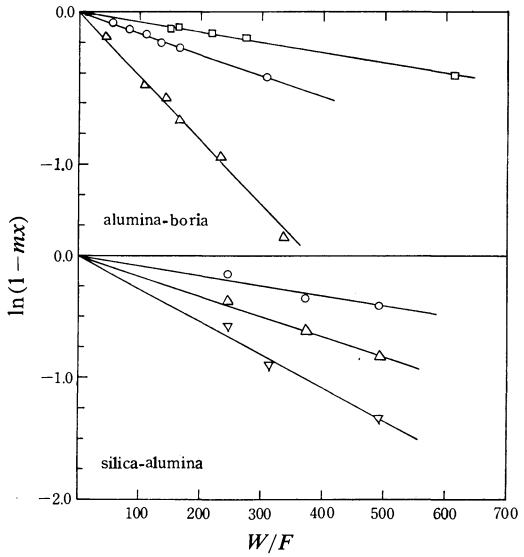

Fig. 10. Consistence of the integrated expression of Eq. 4 with experimental results at 1 atm. of partial pressure of the feed.

-○-	480	4.2	1.41	-△-	510	5.0	1.54
-△-	510	6.0	4.16	-▽-	540	5.0	2.72

reaction temperature is fixed. The consistency of Eq. 4 with the results of the reactions over alumina-boria and a commercial silica-alumina is shown in Fig. 10, where the optimum values of the constant, m, are also given. Equations 2 and 4 give the following relation:

$$\{dx/d(W/F)\}_{WF\to0}=n/m=k_d/2 \qquad (5)$$

Table IV demonstrates the good accordance of k_d values calculated from Eq. 5 with those calculated from Eq. 2.

In the next place, the selectivity of the disproportionation is to be discussed. The following expression is derived from Eq. 2:

$$\{(1-dx/db)/2\}(p^2_t-p_bp_x/k_d)/p_x = (1/S_x)+(1/S_t)(dx/db)(p_t/p_x) \qquad (6)$$

where $S_t(=k_d/k_t)$ and $S_x(=k_d/k_x)$ are defined as the selectivities of the disproportionation to toluene cracking and to xylene cracking respectively. Since dx/db can be calculated graphically, the numercal values of S_t and S_x are obtained by plotting the left term of Eq. 6 against $(dx/db)(p_t/p_x)$. The linear relationship of Eq. 6 is shown in Fig. 11. The values of S_t and S_x are calculated and listed in Table IV. It may be concluded that both the selectivity and the activity of alumina-boria are much higher than those of the commercial silica-alumina. The lower activity of the latter may be due principally to a higher tendency

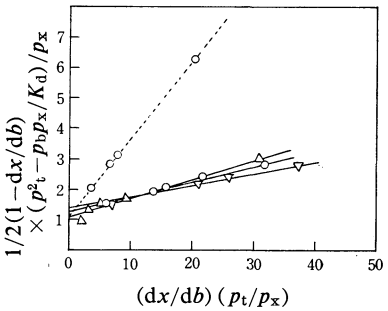

Fig. 11. Linear relationship between the left term of Eq. 6 with $(dx/db)(p_t/p_x)$.

----: Silica-alumina

of coke fomation as well as to a lower concentration of active centers. The difference between the apparent activation energy of toluene cracking and that of xylene cracking, which are given in Table IV, suggests that the cracking reactivity is affected by the basicity of the aromatic nucleus.

The Decrease in Activity upon Coke Formation.—The toluene conversion of the disproportionation decreased with the length of the run and approached a constant value asymptotically, as is shown in Fig. 12. A carbon deposit on alumina-boria caused by the subsequent cracking reactions was observed, but regeneration could be easily accomplished by burning off the coke with air, giving the original activity. It may probably be concluded that a carbonaceous material covers the active

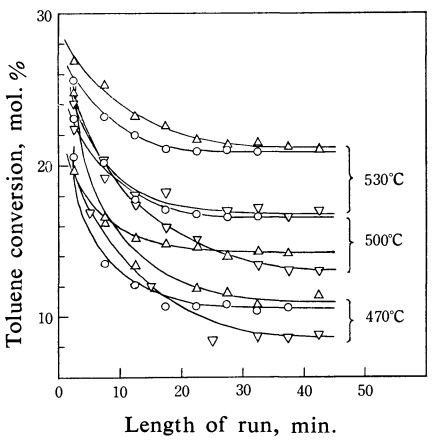

Fig. 12. Decrease in the activity of toluene disproportionation over the alumina-boria catalyst (15 wt. % boria).

Feed rate: ○, △ 0.0568 mol./hr., ▽ 0.0660 mol./hr.

centers of the catalyst and lowers the activity.[29-31] Assuming that the concentration of active sites decreases in proportion to the amount of coke produced by the cracking of toluene and xylene, the following expression is given, taking into account the facts that the cracking of benzene is negligible and that the concentration of active centers is approximately proportional to the toluene conversion:

$$q=q_0\left\{1-\phi F\int_0^{\theta}(b-x)\,\mathrm{d}\theta\right\} \qquad (7)$$

where q_0 is the initial toluene conversion; q, the toluene conversion at a given time of run (θ); ϕ, the deactivation coefficient; b and x, the mole fractions of benzene and xylene of the product at θ, and F, the feed rate of toluene. The term of the integration denotes the cumulative quantity of cracking up to θ. When it is replaced by the average mole fraction of benzene ($\bar{b}$) and xylene ($\bar{x}$) instead of b and x during each successive fraction of time ($\Delta\theta$), the integration in Eq. 7 is expressed as a summation of the fractional terms. Assuming further that a stationary-state conversion, q_s, is reached at a certain length of run when the covering effect of the coke on the active sites approaches equilibrium, a relative activity, q/q_s, is given by the following equation:

$$\left.\begin{aligned} q/q_s&=R\{1-\phi F\textstyle\sum(\bar{b}-\bar{x})\,\Delta\theta\}\\ R&=q_0/q_s\end{aligned}\right\} \qquad (8)$$

The linear relationship between q/q_s and $F\sum(\bar{b}-\bar{x})\Delta\theta$ is shown in Fig. 13. Since the deactivation coefficient and the relative activity, R, were approximately constant at a given reaction temperature, irrespective of either the regeneration of the catalyst or the change in the feed rate, the above interpretation of the decrease in activity seems to be analytically proved. If the ϕ coefficient is proportional to the adsorption equilibrium constant of the contaminant, a 4.2 kcal./mol. value is obtained for the apparent heat of its adsorption. The change in the ϕ values with the reaction temperature may be caused by the difference in the mechanism of the coke formation.[31] From a similar analysis of decrease in the activity of alumina-boria catalysts of different compositions, the relationship between the acidity and the initial activity, which is given as the product of q_s and R, is confirmed to be almost analogous to the correlation between the activity of the "equilibrated" catalyst and its acidity.[11]

The Isomerization of Xylene.—In the course of the isomerization of xylene, toluene and trimethylbenzene were produced simultaneously. Since the amount of benzene produced was negligible under the conditions of this study, only the disproportionation of xylene was taken into consideration as a side reaction.

Table V. Rate constants of xylene isomerization over the alumina-boria catalyst (15% boria, η-alumina for base) at 420 to 480°C

Rate constant of xylene isomerization, $k_{1j}=k'_{1j}/(1+\pi K_x)$, (mol./hr. cat. g. atm.)

29) W. G. Appleby, J. W. Gibson and G. M. Good, Div. Petrol. Chem., Am. Chem. Soc., New York (Sept. 1960), 5, No. 4, B.
30) E. M. Gladrow and C. N. Kimberlin, Jr., ibid., B-79.
31) D. J. Wynnermen, ibid.

Assuming that both the rate of the isomerization and that of the disproportionation are controlled by surface reactions between adsorbed xylene molecules, the overall rate of the isomerization for the xylene isomers may be described by following expressions:

$$\left.\begin{aligned}
&\text{The rate of conversion of } o\text{-xylene:}\\
&r_o=-\mathrm{d}o/\mathrm{d}(W/F)=\pi\{(k_{om}+k_{op})o-k_{mo}m-k_{po}p\}+\pi^2k_d ox\\
&\text{The rate of conversion of } m\text{-xylene:}\\
&r_m=-\mathrm{d}m/\mathrm{d}(W/F)=\pi\{(k_{mo}+k_{mp})m-k_{om}o-k_{pm}p\}+\pi^2k_d mx\\
&\text{The rate of conversion of } p\text{-xylene:}\\
&r_p=-\mathrm{d}p/\mathrm{d}(W/F)=\pi\{(k_{po}+p_{pm})p-k_{op}o-k_{mp}m\}+\pi^2k_d px\\
&\text{The rate of disproportionation of xylene:}\\
&r_d=-\mathrm{d}x/\mathrm{d}(W/F)=\pi^2k_d x^2\\
&\text{or}\qquad (1/x)-1=\pi^2k_d(W/F)\\
&k_{ij}=k'_{ij}/(1+\pi K_x)\\
&k_d=k'_d/(1+\pi K_x)^2\\
&x=o+m+p
\end{aligned}\right\}\quad(9)$$

where o, m, p denote mole fractions of o-, m-, p-xylene in the product; k'_{ij}, the rate constant of the isomerization of the i-isomer to the j-isomer; k'_d, the average rate constant of the disproportionation of xylene isomers; π, the partial pressure of the total reactants, which is almost identical to that of the feed; K_x, the average adsorption equilibrium constant of the reactants; W, the mass of the catalyst, and F, the feed rate. The sum of k_{om} and k_{op} was obtained numerically from the initial rate of o-xylene conversion. The linear relationship between $1/\pi$ and $1/\pi(k_{om}+k_{op})$ gave the numerical values of $(k'_{om}+k'_{op})$ and K_x. All the constants in Eq. 9 were determined by a similar analysis searching for the initial rates of conversion of other isomers and by using the integrated formula of the disproportionation.[9] Table V represents the numerical expressions of the rates of isomerization and disproportionation. A comparison between the equilibrium constants of isomerization calculated from thermodynamic data[32] and those

Table VI. Equilibrium constants of xylene isomerization calculated from thermodynamic data

obtained by the experiment is shown in Table VI.

Amemiya and his co-workes[27,28] reported that the rate of xylene isomerization over a silica-alumina catalyst may be described by expressions similar to those in Eq. 9 except for the terms of the subsequent disproportionation. The integrated formula derived by them, however, was applicable only to such isomeric compositions as were not far from equilibrium. In the present study, the following integrated expressions are proposed for a wide range of the isomeric composition, (they include the subsequent disproportionation) :

$$\left.\begin{aligned} \ln\{(o_0-o_e x)/(o-o_e x)\} &= \alpha(W/F) \\ \ln\{(m_0-m_e x)/(m-m_e x)\} &= \beta(W/F) \\ \ln\{(p_0-p_e x)/(p-p_e x)\} &= \gamma(W/F) \end{aligned}\right\} \quad (10)$$

where o_0, m_0, p_0 are initial mole fractions of xylene isomers in the feed; o_e, m_e, p_e, equilibrium mole fractions of the isomers, and α, β, γ, the constants which are determined by a comparison of Eq. 9 with the differentiated forms of Eq. 10. The experimental data are very consistent with the expression of Eq. 10, as is shown in Figs. 14, 15 and 16.

Transethylation between Benzene and Diethylbenzene. — The reaction was carried out at 450°C, and ethylbenzene was produced with a negligible amount of toluene and gaseous products. The results are kinetically described by the following numerical rate expression, which is derived from the Langmuir-Hinshelwood mechanism:[10] the rate of formation of ethylbenzene at 450°C (mol./hr. cat. g.):

$$r = dx/d(W/F) = \frac{0.281(p_b p_d - p^2_e/K)}{(1+2.76p_b+11.85p_e+1.58p_d)^2} \quad (11)$$

where x denotes the mole fraction of ethylbenzene in the product; p_b, p_e, p_d, the partial pressures (atm.) of benzene, ethylbenzene and diethylbenzene; W, the mass of the catalyst (g.), and F, the feed rate (mol./hr.). Since any side reactions can be neglected, Eq. 11 is easily integrated. The results are very consistent with the observed data, as is shown in Fig. 17, where the experimental finding of the reaction over a synthetic silica-alumina is also given for the sake of comparison. The acitivity of the silica-alumina was less than that of the alumina-boria. This is probably due to the lower concentration of active sites in the former.

Summary

This study has aimed to secure an optimum means for the preparation of an alumina-boria catalyst by a systematic examination of the relationship between the physical characteristics of the catalyst and its activity, and to clarify

the mechanism of the development of activity on the basis of the experimental evidence about the chemical interaction of alumina with boric acid and about the chemical structure of the catalyst. The applicability of the catalyst has been studied kinetically for some specific reactions relating to the transalkylation of aromatic compounds. It has been found that alumina-boria shows a higher activity for these reactions than does silica-alumina.

The results and conclusion may be summarized as follows:

I) Boric acid is dehydrated to produce metaboric acid as a probable intermediate and reacts with an active alumina at about 130°C with little disturbance of the crystal structure of alumina, and effective acidic centers are produced. Most of the acid centers are of the Brönsted type. Alumina-boria does not show any definite chemical structure characteristic of aluminum borates, such as $9Al_2O_3 \cdot B_2O_3$, $2Al_2O_3 \cdot B_2O_3$ or $Al_2O_3 \cdot B_2O_3$. It is suggested that such a bond as Al–O–B–O–Al may be formed between surfaces of the crystal structure of alumina and may result in acidic centers.

II) The catalytic activity of toluene disproportionation shows a good correlation with the Brönsted acidity. This is well compatible with the likely theory that the reaction proceeds via a carbonium ion mechanism.

III) The activity of the disproportionation is considerably affected by the structure of the alumina used as the catalyst base as well as by the boria content of the catalyst. The catalyst prepared from η-alumina shows a higher activity than that from χ-alumina, while α-alumina does not give an active catalyst because of its poor reactivity with boric acid. A rise in the crystallinity of alumina lowers the reactivity. Excessive boria reduces the catalytic activity. An effective catalyst for the transalkylation of aromatic compounds can be obtained when alumina-boria is calcined above 400°C.

IV) The results of such reactions as the disproportionation of toluene, the isomerization of xylene and the transethylation between benzene and diethylbenzene can be well interpreted kinetically by assuming that the rates of these reactions are controlled by surface reactions between adsorbed molecules of the reactants.

V) In the disproportionation of toluene, a decrease in the activity of the catalyst with the length of the run was observed. This phenomenon can be explained analytically by taking into account the fact that some contaminant such as the carbonaceous material, which is produced by side reactions (cracking of toluene and xylene), covers effective sites of the catalyst.

VI) It seems to be due essentially to the higher concentration of active sites in alumina-boria that its activity of the transalkylation of aromatic compounds is higher than that of silica-alumina.

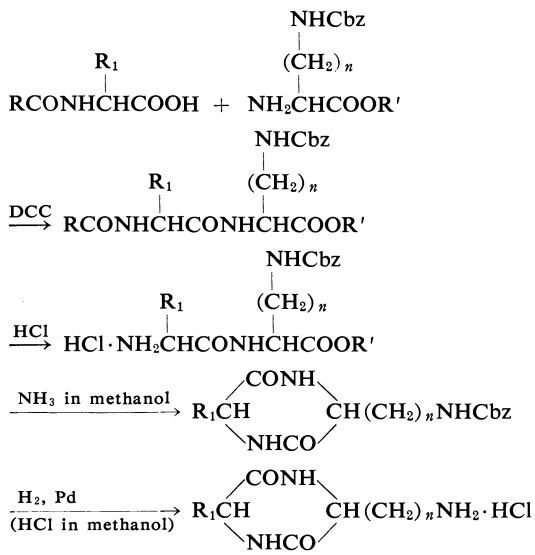
Studies of Peptide Antibiotics. I. Dipeptide Anhydrides as Models of Cyclic Peptide Antibiotics

By Nobuo IZUMIYA, Tetsuo KATO, Yoshimasa FUJITA, Motonori OHNO and Michio KONDO

(Received June 9, 1964)

Some peptide antibiotics,[1] such as gramicidin S, tyrocidin A and polymixin B, possess several structural features in common. These include a cyclic structure, a basic character due to the presence of one or more diamino acid residues, and the possession of at least one D-amino acid residue. The effectiveness of a cyclic structure for an antibiotic activity is indicated by the finding that a synthetic open-chain decapeptide, with the same sequence of amino acid residues as is found in gramicidin S, shows a weaker antibacterial activity than that of gramicidin S.[2]



Since dipeptide anhydrides, wherein one (or

1) R. O. Studer and K. Vogler, *Helv. Chim. Acta*, **45**, 819 (1962).

2) B. F. Erlanger and L. Goode, *Nature*, **174**, 840 (1954); *Science*, **131**, 669 (1960).

both) of the component amino acid residues possesses a D-configuration and a basic character, reveal the characteristics mentioned above, it became of interest to ascertain whether these relatively simple compounds would exhibit the antibacterial properties. For that purpose, the L-L, D-D, D-L and L-D stereomers of both valyllysine anhydride and phenylalanyllysine anhydride, and the L-L and D-L stereomers of both valylornithine anhydride and phenylalanylornithine anhydride were selected as model compounds. Lysine was used as one of the diamino acids because Schwyzer and Sieber[3] had reported that no loss in activity occured upon the replacement of an ornithine residue in gramicidin S with a lysine residue. Ornithine, valine and phenylalanine were chosen because of their relatively high frequency of occurrence in cyclic peptide antibiotics of natural origin.[1]

The sequence of reaction employed for the synthesis of the anhydrides is indicated in the following equations. All final dipeptide anhydride hydrochlorides were crystalline materials which showed satisfactory elemental analyses. The L-L and D-D antipodes of the final products exhibited specific rotation values that were equal in absolute value within the limits of experimental error, as did the D-L and L-D antipodes. The products revealed no contamination with other ninhydrin-positive materials when subjected to paper chromatography.

R-: H- or $C(CH_3)_3O$-, R_1: $(CH_3)_2CH$- or $C_6H_5CH_2$-, n: 3 or 4, R'-: $-CH_3$ or $-C_2H_5$, Cbz-: $C_6H_5CH_2OCO$-, DCC: dicyclohexylcarbodiimide.

3) R. Schwyzer and P. Sieber, *Helv. Chim. Acta*, **41**, 1582 (1958).

Since in this laboratory it has been reported that L-valyl-L-lysine amide and L-phenylalanyl-L-lysine amide are susceptible to the hydrolytic action of trypsin at the lysine carbonyl linkage,[4] it became relevant to determine whether this same enzyme would similarly cleave L-valyl-L-lysine anhydride and L-phenylalanyl-L-lysine anhydride at the same linkage with the formation of valyllysine and phenylalanyllysine respectively as the hydrolytic products. In addition, the known susceptibility of phenylalanine-containing peptides to the hydrolytic action of chymotrypsin[5] indicated that the possible conversion of L-phenylalanyl-L-lysine anhydride to lysylphenylalanine by this enzyme should also be studied. For the purpose of chromatographic comparison, valyllysines, phenylalanyllysines and lysylphenylalanine were synthesized via the mixed anhydride method, and their R_f values ascertained. Finally, paper chromatography of the enzymic digests showed only a single ninhydrin-positive spot, which possessed the same R_f values as the unhydrolyzed dipeptide anhydride substrate.

In order to ascertain whether or not the dipeptide anhydrides described herein possessed antibacterial activity, the effect of various levels of the anhydrides on the growth response of *B. subtilis*, *St. aureus*, *E. coli* and *Pr. vulgaris* was examined. No retardation of growth was noted with any one of these microorganisms, at levels for each compound at 100 μg. per ml. of the assay medium. In this connection, it should be noted that Fruton has shown no influence by D-leucyl-L-tryptophan anhydride[6] on the growth of several microorganisms. From these findings, it appears that other structural characteristics in addition to those described previously are necessary, such as a certain minimum ring size, before a peptide molecule can exhibit antibacterial properties. Further experiments on the preparation and properties of larger cyclic peptides are thus in progress in this laboratory.

Experimental

Melting points are uncorrected. Samples are prepared for analysis by drying them at 100°C in vacuo for 2 hr.

Formyl-D-valine (I) and Formyl-D-phenylalanine (II).—Each of these compounds was prepared, according to the procedure of Sheehan and Yang,[7] by the treatment of D-valine or D-phenylalanine

with 98% formic acid and acetic anhydride; yield, 84% and 80%, m. p. 152~153°C and 167°C, $[\alpha]_D^{20}$ −13.1° and −75.2° (*c* 2, ethanol), for I and II respectively. Each of these compounds had been obtained previously by the resolution of formyl-DL-valine or -phenylalanine with brucine;[8-10] m. p. 153°C[8] and 148~149°C[9], $[\alpha]_D^{20}$ −12.8°[8] and −13°[9] for I, and m. p. 167°C,[10] $[\alpha]_D$ −75.2°[10] for II.

ε-Carbobenzoxy-D-lysine Methyl Ester Hydrochloride.—This compound was prepared as was the L-antipode;[11] m. p. 114~116°C; $[\alpha]_D^{25}$ −16.9° (*c* 2, water). The reported values for the L-antipode[11] are m. p. 117°C and $[\alpha]_D^{25}$ +17.2°.

δ-Carbobenzoxy-L-ornithine Ethyl Ester *p*-Toluene-sulfonate (III).—This compound was prepared according to the general procedure of Kato et al.[12] Thus, a suspension of δ-carbobenzoxy-L-ornithine[13] (53.3 g.) and *p*-toluenesulfonic acid monohydrate (42 g.) in a mixture of ethanol (80 ml.) and carbon tetrachloride (400 ml.) was refluxed, and the water liberated was removed as an azeotropic mixture. The reaction mixture was then concentrated in vacuo, and the residual material treated with ether. The precipitate filtered off was recrystallized from hot acetone (170 ml.)-ether (650 ml.); 87 g. (95%); m. p. 111~112°C; $[\alpha]_D^{20}$ +8.9° (*c* 2, dimethylformamide).

Found: C, 56.19; H, 6.56; N, 6.17. Calcd. for $C_{22}H_{30}O_7N_2S$: C, 56.63; H, 6.48; N, 6.01%.

***t*-Butyloxycarbonyl-D-phenylalanine (IV).**—This compound was prepared as an oily product in the same manner as was the L-antipode;[14] yield, 88%. As a minor modification, sodium bicarbonate was used instead of magnesium oxide.[14] The reported yield of the oily L-antipode is 79%.[14]

Formylvalyl-ε-carbobenzoxylysine Methyl Esters (V—VIII).—The coupling reaction was achieved according to the general procedure of Sheehan et al.[15] To a stirred solution of formyl-L-valine[7] or I (7.26 g., 0.05 mol.), ε-carbobenzoxy-L(or D)-lysine methyl ester hydrochloride (16.55 g., 0.05 mol.), and triethyl amine (7.0 ml.) in a mixture of tetrahydrofuran (150 ml.) and chloroform (150 ml.), at 0°C, was added DCC (10.3 g.) The mixture was stored in the cold overnight, after which time the L-L and D-D stereomers were recovered as described under a), and the D-L and L-D stereomers, as described under b). a) The precipitated dicyclohexylurea was removed, and the filtrate was concentrated in vacuo to an oil. After the latter had been dissolved in chloroform (300 ml.), the solution was washed successively with 4% sodium bicarbonate, 2% hydrochloric acid, and water. The organic layer was dried over sodium sulfate and concentrated in vacuo, and the residual material was treated with ether and petroleum ether. The precipitate filtered off was recrystallized from ethyl acetate (30 ml.) - ether (60 ml.) - petroleum ether (60 ml.). b) The dicyclohexylurea, admixed with a small amount of the desired product, precipitated. After the crystals of the latter had been taken into a solution by warming them at 50°C, the reaction mixture was cooled to room temperature under tap water and the urea filtered off. The remainder of the procedure was identical with that described under a) above. Recrystallization was effected from ethyl acetate (90 ml.) - ether (50 ml.) - petroleum ether (50 ml.). The elemental analyses, yields, and physical constants of the compounds so procured are given in Table I.

Formylphenylalanyl-ε-carbobenzoxylysine Methyl Esters (IX—XII).—These compounds were prepared on a 0.05 mol. scale following the procedure described above. The recrystallization of the crude products was achieved from ethyl acetate - petroleum ether (70 ml.: 50 ml. for IX and X, and 110 ml.: 30 ml. for XI and XII).

Formyl-L-phenylalanyl-ε-carbobenzoxy-L-lysine Ethyl Ester (XIII).—This compound was prepared from formyl-L-phenylalanine and ε-carbobenzoxy-L-lysine ethyl ester *p*-toluenesulfonate[12] in the same manner as that used for V and was recrystallized from ethyl acetate - ether - petroleum ether.

Formylvalyl-δ-carbobenzoxyornithine Ethyl Esters (XIV—XV).—These compounds were prepared following the procedure described for the preparation of V. The L-L stereomer (XIV) was more soluble in ethyl acetate than the D-L stereomer (XV), as was observed in the cases of V and VII.

***t*-Butyloxycarbonyl-L-valyl-δ-carbobenzoxy-L-ornithine Ethyl Ester (XVI).**—This compound was prepared by the treatment of a solution of *t*-butyloxycarbonyl-L-valine[14] (2.18 g.), III (4.66 g.) and triethyl amine (1.4 ml.) in tetrahydrofuran-chloroform with DCC (2.06 g.), following essentially the same procedure as that employed for the preparation of V. As a minor alteration, however, 0.5 M citric acid was used instead of 2% hydrochloric acid to wash the reaction mixture.

Formylphenylalanyl-δ-carbobenzoxyornithine Ethyl Esters.—The L-L stereomer (XVII) was prepared following the procedure described for the preparation of V. The D-L stereomer was obtained as crystals with a m. p. of 145~149°C in a yield of 63%; however, the elemental analyses were not satisfactory.

***t*-Butyloxycarbonyl-D-phenylalanyl-δ-carbobenzoxy-L-ornithine Ethyl Ester (XVIII).**—This compound was obtained from IV and III by the procedure described in the case of XVI. The recrystallization of the crude product was achieved from ethyl acetate - ether - petroleum ether.

Valyl-ε-carbobenzoxylysine Methyl Ester Hydrochlorides (XIX—XXII).—A suspension of 8.43 g. each of V—VIII in 0.5 N methanolic hydrogen chloride (60 ml.) was stored at room temperature for 2 days. The resulting clear solution was then concentrated in vacuo. The treatment of the residual material with acetone and ether led to a

a) Abbreviations are as follows; For: formyl, BOC: *t*-butyloxycarbonyl, LysCbz: ε-carbobenzoxylysine residue, OrnCbz: δ-carbobenzoxyornithine residue, Val◇Lys·HCl L-L: L-valyl-L-lysine anhydride monohydrochloride.

b) Optical rotations were determined using a 20 cm. tube. All concentrations were 1% except the compounds, XLIX and L. Concentrations of XLIX and L were 0.3%.

c) Yield was based on the parent formyl or *t*-butyloxycarbonyl carbobenzoxy-substituted dipeptide ester.

d) This was hydroscopic crystal; optical rotation was approximate.

crystalline product which was recrystallized from acetone-ether. Although the crystallization of the L-D and D-L stereomers occurred more readily than that of the L-L and D-D stereomers, the latter nevertheless crystallized within an hour by the procedure described above.

Phenylalanyl-ε-carbobenzoxylysine Methyl Ester Hydrochlorides (XXIII—XXVI). — These compounds were prepared following the procedure described above. Although the L-L and D-D stereomers (XXIII, XXIV) could be recrystallized from methanol-acetone-ether, attempts to solidify the D-L and L-D forms (XXV, XXVI) were unsuccessful.

Valyl-δ-carbobenzoxyornithine Ethyl Ester Hydrochlorides (XXVII,XXVIII).—The L-L stereomer (XXVII) was prepared as follows: To a solution of XVI (4.94 g.) in ethyl acetate (15 ml.), 4 N hydrogen chloride in ethyl acetate (50 ml.) was added. The reaction mixture was stored at room temperature for 3 hr. and then evaporated in vacuo. The residual crystals were filtered off with the aid of ether and recrystallized from methanol-ether. The melting point was 175~177°C, as is shown in Table I. The crystalline product was also obtained from the formyl dipeptide ester (XIV) with methanolic hydrogen chloride. This compound, however, showed the low melting point of 108~115°C and did not give the analytically-pure valyl-δ-carbobenzoxyornithine anhydride.

The oily D-L stereomer (XXVIII) was obtained from the formyl dipeptide ester (XV). Attempts to solidify the oil were unsuccessful, although this oily product gave the analytically-pure dipeptide anhydride (XL).

Phenylalanyl-δ-carbobenzoxyornithine Ethyl Ester Hydrochlorides (XXIX, XXX).—The crystalline L-L stereomer (XXIX) was obtained from the formyl dipeptide ester (XVII) by the procedure described in the case of XIX, while the oily D-L stereomer (XXX) was obtained from the *t*-butyloxycarbonyl dipeptide ester (XVIII) as in the case of XXVII.

Valyl-ε-carbobenzoxylysine Anhydrides (XXXI—XXXIV).—A solution of 4.3 g. each of XIX—XXII in 100 ml. of methanol, which had been previously saturated with dry ammonia at 0°C, was stored in a glass-stoppered bottle at room temperature for 2 days.[16] In the case of the L-D and D-L stereomers (XXXIII and XXXIV), a mass of crystals appeared within about 1 hr. whereas a complete solution was maintained with the L-L and D-D stereomers (XXXI and XXXII) over the entire reaction period. The reaction mixture was then concentrated to dryness with a rotary evaporator, and the crystalline residue was filtered off with the aid of a little water. The recrystallization of XXXI and XXXII was achieved from 30% methanol (85 ml.), whereas 50% ethanol (100 ml.) was used with XXXIII and XXXIV.

Phenylalanyl-ε-carbobenzoxylysine Anhydrides (XXXV—XXXVIII). — The conversion of XXIII—XXVI to XXXV—XXXVIII followed the same procedure as was employed in the preparation of XXXI—XXXIII. Recrystallization was effected from 70% ethanol.

Valyl-δ-carbobenzoxyornithine Anhydrides (XXXIX, XL) and Phenylalanyl-δ-carbobenzoxyornithine Anhydrides (XLI, XLII).—These compounds were obtained from the dipeptide ester hydrochlorides, XXVII, XXVIII, XXIX and XXX, as described in the cases of XXXI and XXXIII. Recrystallization was effected from 40% ethanol for XXXIX and XL, and from 70% ethanol for XLI and XLII.

Valyllysine Anhydride Hydrochlorides (XLIII—XLVI).—A suspension of 3.61 g. (0.01 mol.) each of XXXI—XXXIV in 0.1 N methanolic hydrogen chloride (105 ml.) was subjected to hydrogenolysis with dry hydrogen in the presence of palladium black which had previously been washed with methanol. Upon the completion of the reaction, the catalyst was removed by filtration, with prior warming if necessary to dissolve any product which may have precipitated, and the filtrate was concentrated to dryness in vacuo. The crystalline product was then filtered off, with the aid of a mixture of acetone and ether, and recrystallized from methanol-acetone.

Phenylalanyllysine Anhydride Hydrochlorides (XLVII—L). — A suspension of 2.05 g. each of XXXV—XXXVIII in acetic acid (50 ml.) was subjected to hydrogenolysis as has been described above. The filtrate was then concentrated to dryness, the residual material was dissolved in water, and the solution was treated with 1 N hydrochloric acid (5.3 ml.). After the concentration of the solution, the residual product was recovered by filtration with the aid of acetone. Recrystallization was effected from methanol-acetone.

Valylornithine Anhydride Hydrochlorides (LI, LII).—These compounds were obtained from XXXIX and XL as has been described in the case of XLIII. The D-L stereomer (LII) was less soluble in methanol than the L-L stereomer (LI).

Phenylalanylornithine Anhydride Hydrochlorides (LIII, LIV). — These compounds were obtained from XLI and XLII as has been described in the case of XLIII. The air-dried crystals contained half moles of crystal waters; they lost 3.0% (LIII) and 3.2% (LIV) of their weight upon being dried for 3 hr. in vacuo at 100°C. Calcd. for $C_{14}H_{20}O_3N_3Cl \cdot 1/2H_2O$: H_2O, 2.94%.

Carbobenzoxyvalyl-ε-carbobenzoxylysine Methyl Esters (LV—LVIII).—To a stirred solution of carbobenzoxy-L(or D)-valine[17] (5.03 g.) and triethyl amine (2.8 ml.) in toluene (40 ml.) at 0°C, isobutylchlorocarbonate (2.7 ml.) was added.[18] After 15 min., a mixture of ε-carbobenzoxy-L(or D)-lysine methyl ester hydrochloride (6.61 g.) and triethyl amine (2.8 ml.) in chloroform (40 ml.) was also added. The reaction mixture was then left at room temperature overnight, after which time LV and LVI were recovered as has been described under a), and LVII and LVIII, as has been described under b). a) After being washed successively with 4% sodium bicarbonate, 2% hydrochloric acid, and water, the organic layer was dried over sodium

sulfate and concentrated to dryness. The crystalline residue was recrystallized from ethyl acetate-petroleum ether. b) The mass of crystals which precipitated was filtered off after the addition of 80 ml. of petroleum ether and some water. Recrystallization was achieved from acetone-ether-petroleum ether.

Carbobenzoxyphenylalanyl-ε-carbobenzoxylysine Ethyl Esters (LIX, LX).—These compounds were prepared from carbobenzoxy-L-phenylalanine[19] and ε-carbobenzoxy-L-lysine ethyl ester *p*-toluenesulfonate[12] in the manner described above.

Carbobenzoxyvalyl-ε-carbobenzoxylysines (LXI—LXIV).—To a solution of 5.28 g. each of LV—LVIII in dioxane (100 ml.), 1 N sodium hydroxide (11 ml.) was added. The reaction mixture was then stored at room temperature for 6 hr., after which time it was neutralized with 1 N hydrochloric acid (12 ml.) and concentrated to dryness in vacuo. The residual material was filtered off with the aid of water, dried well, and recrystallized from ethyl acetate-petroleum ether.

Carbobenzoxyphenylalanyl-ε-carbobenzoxylysines (LXV, LXVI).—These compounds were prepared from LIX and LX following the procedure described above.

Valyllysine Hydrochlorides (LXVII—LXX).—A solution of 2.57 g. (0.005 mol.) each of LXI—LXIV in a mixture of methanol (60 ml.) and 0.5 N hydrochloric acid (10.3 g.) was subjected to hydrogenolysis in the presence of palladium black. The filtrate was then evaporated to dryness in vacuo, and the residual product was filtered off with the aid of ethanol or a mixture of ethanol and acetone. The L-L and D-D stereomers (LXVII, LXVIII) were recrystallized from water (5 ml.)-ethanol (30 ml.). The L-D and D-L stereomers (LXIX, LXX) were obtained as hygroscopic crystalline products. However, their paper chromatographic behavior in a number of solvent systems indicated that they gave only a single ninhydrin-positive spot and, hence, were suitable as chromatographic reference compounds for the present purposes.

Phenylalanyllysine Hydrochlorides (LXXI, LXXII).—The hydrogenolysis of LXV and LXVI was carried out in the manner described above. The free dipeptide hydrochlorides were obtained as hygroscopic crystals. However, each of them yielded only a single ninhydrin-positive spot when subjected to paper chromatographic criteria.

α,ε-Dicarbobenzoxy-L-lysyl-L-phenylalanine Benzyl Ester (LXXIII).—This compound was prepared from α, ε-dicarbobenzoxy-L-lysine[11] and, L-phenylalanine benzyl ester[20] in the same manner as was used for LV.

L-Lysyl-L-phenylalanine Hydrochloride (LXXIV). This compound was obtained from LXXIII by hydrogenolysis, and was recrystallized from water-ethanol.

***Rf* Values.**—The R_f values of the compounds on ascending paper chromatography, employing *n*-butanol-acetic acid-pyridine-water (15 : 3 : 10 : 12, v/v) and No. 50 paper of the Toyo Roshi Co., are given in Table II. The R_f values of the L-L and D-D antipodes were the same within the limits of experimental error, as were those of the D-L and L-D antipodes. The R_f value for a L-L stereomer, however, differed appreciably from that of the diastereomeric L-D stereomer. In this connection, it should be noted that, recently, some results on the paper chromatographic separation of diastereomeric dipeptides have been published.[21]

Table II. R_f values of dipeptide anhydrides and dipeptides

Compound	Configuration	R_f volue
Val◇Lys·HCl	L-L or D-D	0.50
	D-L or L-D	0.52
Phe◇Lys·HCl	L-L or D-D	0.54
	D-L or L-D	0.60
Val◇Orn·HCl	L-L	0.47
	D-L	0.51
Phe◇Orn·HCl	L-L	0.53
	D-L	0.58
H-Val-Lys-OH·HCl	L-L or D-D	0.25
	D-L or L-D	0.20
H-Phe-Lys-OH·HCl	L-L	0.32
	D-L	0.27
H-Lys-Phe-OH·HCl	L-L	0.34

The Action of Enzymes on Dipeptide Anhydrides.—To a 1 ml. flask were added 0.01 mmol. each of XLIII—XLVI and XLVII—L, crystalline trypsin (3.0 mg.) and a 0.2 M phosphate buffer (0.5 ml.) at pH 7.5 The solution was made up to 1 ml. by water and incubated at 37°C for 24 hr. Similar experiments with each of XLVII—L and crystalline α-chymotrypsin (3.0 mg.) were also carried out. Paper chromatographic analysis of an aliquot sample of the enzymic digests yielded only a single ninhydrin-positive spot, which, in each instance, possessed the same R_f values as the unhydrolyzed dipeptide anhydride substrates.

Biological Assays.* — The microorganisms employed were *B. subtilis* (*Bacillus subtilis* PCI 219), *St. aureus* (*Staphylococcus aureus* FDA 2099), *E. coli* (*Escherichia coli* IFO 3044), and *Pr. vulgaris* (*Proteus vulgaris* IFO 3045). The minimum amounts of the compounds necessary for the complete inhibition of growth were determined by a dilution method with a bouillon agar medium at pH 7.0. As is shown in Table III, no antibacterial activity by the dipeptide anhydrides was observed against any of the microorganisms used even at a high concentration of each compound. In contrast with the lack of activity of each dipeptide anhydride, gramicidin S, a cyclic decapeptide, exhibited considerable activity against some of the microorganisms.

Erlanger and Goode have reported that, in a synthetic medium, the minimum amount of gramicidin S for the complete inhibition of the growth of *E. coli* was 5 μg. per ml.[2] As is indicated in

TABLE III. INHIBITORY ACTIVITY OF PEPTIDE ANHYDRIDES ON MICROORGANISMS

Compound	Amount of compound necessary for complete inhibition of growth, μg./ml.			
	B. subtilis	*St. aureus*	*E. coli*	*Pr. vulgaris*
Gramicidin S·H_2SO_4[a)]	12.5	12.5	>100	50
Val◇Lys·HCl (XLIII—XLVI)	>100	>100	>100	>100
Phe◇Lys·HCl (XLVII—L)	>100	>100	>100	>100
Val◇Orn·HCl (LI, LII)	>100	>100	>100	>100
Phe◇Orn·HCl (LIII, LIV)	>100	>100	>100	>100

a) A product of Astra Co., U.S.A.

Table III, in a bouillon medium, gramicidin S exhibited no activity at the 100 μg. per ml. level. In this connection, experiments concerning the growth inhibition of *E. coli* in a synthetic medium by the dipeptide anhydrides, XLIII—LIV, are in progress in this laboratory.

Summary

The D-D, L-L, D-L and L-D stereomers of both valyllysine anhydride and phenylalanyllysine anhydride, and the D-L and L-L stereomers of both valylornithine anhydride and phenylalanylornithine anhydride, have been synthesized in order to compare them with the cyclic peptide antibiotics, with which they possess several structural features in common.

Synthesis has been achiveved by the dicyclohexylcarbodiimide-induced condensation of formyl, (or *t*-butyloxycarbonyl) valine (or phenylalanine) with the ω-carbobenzoxylysine (or ornithine) ester, followed by the treatment of the resulting acyl dipeptide ester with hydrogen chloride in methanol or ethyl acetate to remove the formyl- or *t*-butyloxycarbonyl-blocking group. The dipeptide ester hydrochlorides so derived have been converted by the action of ammonia to the corresponding carbobenzoxy-substituted dipeptide anhydrides and these, in turn, transformed to the desired unacylated dipeptide anhydride hydrochlorides by palladium-catalyzed hydrogenolysis.

Enzymic experiments have been carried out to determine whether the dipeptide anhydride hydrochlorides are attacked by trypsin or chymotrypsin. The results indicate that no hydrolysis of any of the anhydrides occurs. In this connection, valyllysines, phenylalanyllysines and lysylphenylalanine have been synthesized for the purposes of chromatographic comparison.

The effects of the dipeptide anhydride hydrochlorides on bacterial growth have been examined. The results indicate that no antibacterial activities are observed against microorganisms in a bouillon agar medium.

The authors are grateful to Dr. Milton Winitz, of the National Institutes of Health, U.S.A., for his valuable suggestions and generous assistance in the preparation of this manuscript.

Kinetics and Isotope Effect in Methanol Synthesis at Low Pressures

By Toyoyasu SAIDA and Atsumu OZAKI

(Received June 11, 1964)

The methanol synthesis has been the object of many investigations, among which a few works have been devoted to the kinetics of the reaction. The kinetic equations thus obtained are different from each other in form:

by Temkin et al. at low pressures:[1]

$$r=kC_{H_2}C_{CO}^{0.6}/C_{CH_3OH} \quad (1)$$

by Natta et al. at high pressures:[2]

$$r=kP_{H_2}^{2}\cdot P_{CO}/(A+BP_{CO}+CP_{H_2}+DP_{CH_3OH})^3 \quad (2)$$

by Ogino et al. at high pressures[3]:

$$r=k(P_{H_2}^{2}\cdot P_{CO})^{0.7} \quad (3)$$

although they may all be approximated to (3) or (1) in nature. In consequence, different fundamental postulates of the rate-determining step in the synthesis of methanol have been suggested, that is, the adsorption of carbon monoxide or hydrogen for (1), the surface reaction for (2), and the desorption of the product methanol for (3).

Such disagreement in interpreting the kinetics of the same reaction is suspicious, since the equations are all similar in nature. In this connection, the isotope effect on the reaction rate has been useful in identifying the rate-determining step of many reactions. The effect in methanol synthesis, however, has not been reported. Corval and Viallard[4] studied the synthesis of heavy methanol CD_3OD, but they didn't compare the rate with that of light methanol. It was, therefore, decided to undertake an investigation of the isotope effect in methanol synthesis. The work was done in the vicinity of atmospheric pressure with a reactant mixture of varying compositions.

Experimental

Reagents.—Cylinder hydrogen was passed over a platinum catalyst to remove any oxygen and then dried with liquid nitrogen. Deuterium gas was prepared by the reaction of heavy water of 99.7% D, which had been supplied by the Showa Denko Co., with a magnesium ribbon at 400 to 450°C. Carbon monoxide was prepared by the decomposition of sodium formate with concentrated sulfuric acid and was passed over sodalime and dried with liquid nitrogen. The catalyst was supplied in a partially-reduced state by the Government Chemical Industrial Research Institute, Tokyo, and contained zinc, chromium, and copper in the atomic ratio of 1 : 0.49 : 0.16.[5] The catalyst was used as particles of 1 to 2 mm. The reduction of the catalyst was carried out with the reactant gas of excess hydrogen in situ at 250°C for 12 hr.

Experimental Procedures. — The experiments were carried out at a constant pressure in a closed flowing system, which is shown schematically in Fig. 1. The synthesis mixtures were circulated on the catalyst at various velocities by means of an all-glass electromagnetic pump. In order to preheat the gas mixture, the reaction tube was packed 5 cm. thick with glass beads over the catalyst bed (10 mm. thick), through which the gas stream flowed downwards. The catalyst was placed on a fritted glass plate of a coarse grade. A thermocouple well was inserted through the glass beads bed and the catalyst bed. The reaction tube was

placed in an aluminum block furnace, and the temperature was controlled within ±0.5°C by means of a thermoelectric temperature controller. The temperature difference between the two ends of the catalyst bed was within 0.2°C during the measurement. The two traps, which were placed before and after the reaction tube, were put into the same liquid-nitrogen bath, and the liquid level of the bath was adjusted to a certain position during the measurement. According to Temkin et al., the satisfactory trapping of methanol vapor with liquid nitrogen is difficult because the vapor tends to form aerosol. In order to avoid this difficulty, the trap next to the reaction tube shown in Fig. 1 was designed so as to give a low linear gas velocity; that is, the trap was made from a tube 18 mm. in inner diameter at the bottom corresponding to the liner velocity of 0.1 cm./sec. at the liquid nitrogen temperature for the gas velocity of 3 l. N. T. P/hr. It was confirmed by the absence of deposition in the other trap that the trap was satisfactory for condensing the methanol vapor.

The reaction rates were measured by following the volume decrease with the gas burette. The volume of the closed system was about 300 ml. besides the burette volume of 70 ml. The reaction products, a mixture of methanol and carbon dioxide collected in the trap during the rate measurements, were subjected to vapor pressure measurements at 0°C and −78°C; cf. the right section of the diagram Fig. 1. The amounts of both products were estimated from these quantities. The respective rates of the formation of both products were calculated as the rates of the volume decrease of the reaction system multiplied by a conversion factor which will be shown later.

Results

In the preliminary experiments on the synthesis at 160 to 230°C, it was shown that the carbon dioxide formation was remarkable at higher temperatures, while the reaction rate was too slow to observe at temperatures lower than 180°C. Accordingly, the measurement of the temperature coefficient of the reaction rate was abandoned and the reaction temperature was fixed at 180°C throughout the experiments.

Since the carbon dioxide formation was not negligible even at 180°C, the reaction path of the formation ought to be assigned in order to give a correction to the reaction rate of methanol synthesis. There can be considered to be three possible ways of carbon dioxide formation:

i) $2CO = CO_2 + C$

ii) $2CO + 2H_2 = CO_2 + CH_4$

iii) The oxidation of CO by the catalyst

In the present analysis, reaction ii was excluded because of the absence of methane in the circulating gas after several hours of reaction. The detection of methane was carried out by gas chromatography. Reaction iii was improbable because the catalyst was, prior to use, thoroughly reduced at a higher temperature, 250°C, than the reaction temperature, 180°C, using the reactant gas, and because no degradation of catalytic activity to form carbon dioxide was observed. Consequently, it was postulated that the carbon dioxide was formed via reaction i. Thus, the rate of the volume decrease due to the formation of methanol and of carbon dioxide, r_M and r_C (N ml./hr.) respectively, was estimated by the equation:

$$r_M = 3N_M r_A/(3N_M + 2N_C) \quad (1)$$

$$r_C = 2N_C r_A/(3N_M + 2N_C) \quad (2)$$

where r_A is the measured rate of volume decrease, N ml./hr., and N_M and N_C are the amounts of methanol and carbon dioxide (mole) formed in each run, each of which was continued for four hours. Since the per-pass conversions were very low and within 5% of the equilibrium conversions, the estimated rate, r_M or r_C, is the initial rate.

The effects of total pressure, P, on r_M and r_C are shown in Fig. 2 for a constant molar

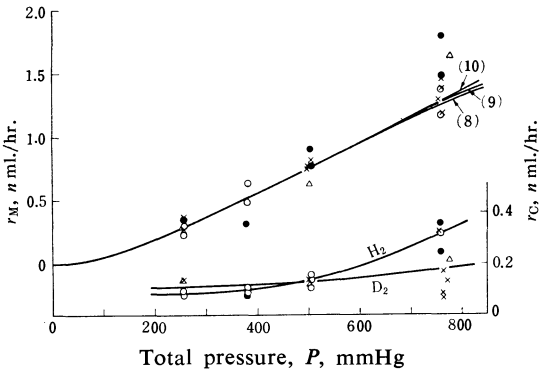

Fig. 2. Total pressure dependence of the rates with stoichiometric mixture.
○ H_2 s. v. 900 ● H_2 s. v. 1800
× D_2 s. v. 900 △ D_2 s. v. 1800

ratio n(=H_2/CO or D_2/CO). Figure 3 shows the variations of r_M and r_C with n at atmospheric pressure. All the experimental data are the time averages, in each run carried out at a fixed condition for four hours. The optimum methanol formation appears at a n value of around 2.

As may be seen in Fig. 2, no marked influence was observed on r_M by changing the space velocity from 900 to 1800. Since the variation in space velocity should give rise to a different value of methanol vapor pressure in the catalyst bed, it seems that methanol has no effect on r_M under the present experimental conditions.

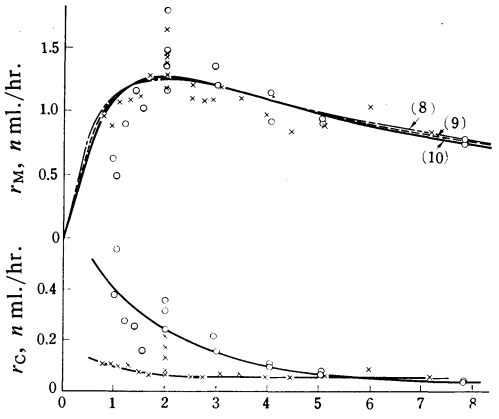

Fig. 3. Variation of the rates with gas composition under 1 atm.
180°C 1 atm s. v.: 900 hr^{-1}

The deuterium isotope effect in methanol synthesis was not observed, as can be seen in Fig. 2, and Fig. 3; that is, both plots for protium and deuterium are distributed along the same line and show no systematical deviation from each other. This result was confirmed by changing the reactant gases in the order; H-D-H-D-D.

On the other hand, the isotope effect was found in the carbon dioxide formation at higher concentrations of carbon monoxide. The amount of carbon dioxide formed was near 20% (mole) of methanol in most runs, the highest value being 30%.

A Kinetic Analysis of the Results

A kinetic equation which incorporates the experimental results shown in Fig. 2 was selected in the following way. A general form, expressed with the total pressure, P,

$$r_M = kP^l/(1+aP^m)^s \quad (3)$$

was considered, and the possible combinations of l, m and s were tested one by one, assigning every half interger from 0.5 to 3 for l and m, and every integer from 1 to 3 for s. Equation 3 was transformed into:

$$1/k^{1/s} + aP^m/k^{1/s} = (P^l/r_M)^{1/s} \quad (4)$$

and the linearity of P^m against $(P^l/r_M)^{1/s}$ was examined.

Table I. Suitable combinations of l, m, and s

No.	1	2	3	4	5	6
l	2	2.5	3	2.5	3	3
m	1	1	1	1.5	1.5	2
s	2	2	2	1	1	1

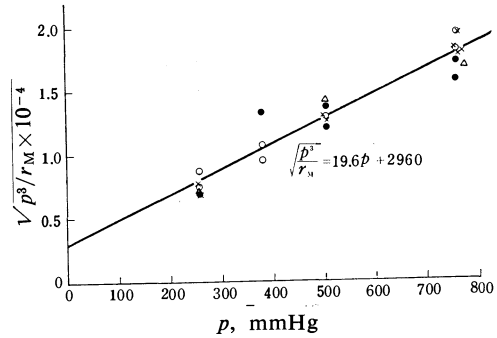

Fig. 4

The suitable combinations thus found were as shown in Table I.
However, the best fit was obtained in Nos. 2 and 3. The plots in No. 3 are exemplified in Fig. 4.

Equation 3 rewritten in terms of the partial pressures, p_{H_2} and p_{CO}, and of n, assuming a first-order dependence on p_{CO}, i.e. the kinetic term of the $k' p_{H_2}{}^{l-1} p_{CO}$ form. For example, with $m=1$, the rewritten equation is:

$$r_M = k' {}_{H_2}{}^{l-1} p_{CO}/(1+a_1 p_{H_2}+a_2 p_{CO})^s \quad (5)$$

$$= \frac{k' n^{l-1} P^l/(n+1)^l}{[1+(na_1+a_2)P/(n+1)]^s} \quad (6)$$

where $k' = k(n+1)^l/n^{l-1}$.

Equation 6 was transformed to:

$$(1+a_2P)+(1+a_1P)n = [k' n^{l-1} P^l (n+1)^{l/s} r_M]^{1/s} \quad (7)$$

The linear relation of the right side of Eq. 7 against n was examined for the l-m-s combinations shown in Table 1, using a k' value obtained by the linear relation of Eq. 4. Any combination which gave a negative value for a_1 or a_2 was discarded. Thus, the suitable combinations in these plots were Nos. 1, 2 and 3 of Table I, in all of which $m=1$ and $s=2$. In other words, these equations are as follows:

$$r_M = k' p_H p_{CO}/(1+a_1 p_{H_2}+a_2 p_{CO})^2 \quad (8)$$

$$r_M = k' p_{H_2}{}^{1.5} p_{CO}/(1+a_1 p_{H_2}+a_1 p_{CO})^2 \quad (9)$$

$$r_M = k' p_{H_2}{}^2 p_{CO}/(1+a_1 p_{H_2}+a_2 p_{CO})^2 \quad (10)$$

The plots in No. 3 are exemplified in Fig. 5, where some systematic deviation is observed in the lower range of n for only the protium series. This deviation was also observed for the other l-m-s combinations.

The k', a_1 and a_2 constants were recalculated by the least squares method with all the data shown in Figs. 2 and 3, excepting those obtained with n values lower than 2 in the case of protium. The best values thus obtained are given in Table II.

TABLE II. BEST VALUES OF k', a_1 AND a_2

Equation	k' $(2H_2+CO)N$ ml.*/ hr. 2.493 g. cat.	k' mol.*/ hr. g. cat.	a_1 $mmHg^{-1}$	a_1 atm^{-1}	a_2 $mmHg^{-1}$	a_2 atm^{-1}

(9)	$(4.35\pm0.64)\times10^{-6}$	$(4.13\pm0.61)\times10^{-4}$	$(2.40\pm0.29)\times10^{-3}$	$1.83\ \pm0.22$	$(3.70\pm0.45)\times10^{-3}$	2.82 ± 0.34
(10)	$(1.36\pm0.50)\times10^{-6}$	$(3.56\pm1.30)\times10^{-3}$	$(0.99\pm0.21)\times10^{-2}$	$7.51\ \pm1.57$	$(0.91\pm0.21)\times10^{-2}$	6.95 ± 1.57

* These dimensions are consistent with those of r_M.

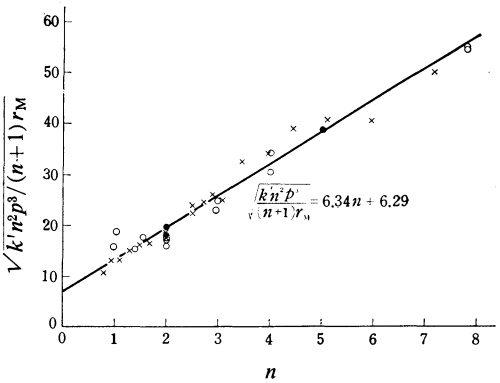

Fig. 5

The rate of methanol formation was calculated using Eqs. 8, 9 and 10 and are shown in Figs. 2 and 3 with lines. These lines overlap each other, and the experimental points are located along them, although some deviations are clearly seen in the lower range of n values.

Discussion

Kinetic Equation.—The range of experimental conditions was not wide enough to discriminate a single rate equation. The three equations finally reached all have the adsorption terms of both hydrogen and carbon monoxide in accordance with the equation of Natta et al., although the exponent to the adsorption term, s, is different. The adsorption term of methanol may disappear because of the low conversion in the present experiment.

The rates of methanol formation under elevated pressures were estimated using the above three equations. The estimated rate with Eq. 8 was independent of the pressure above 20 atm., but not with Eqs. 9 and 10. This independence of the reaction pressure is contradictory with the established fact of pressure dependency in the methanol synthesis. Hence, Eq. 8 may be abandoned.

The kinetic terms $p_{H_2}{}^{1.5}p_{CO}$ and $p_{H_2}{}^2p_{CO}$ of Eqs. 9 and 10 respectively resemble with those of Natta et al. and of Ogino et al.

If the following elementary reactions are assumed to constitute the methanol synthesis:

$$CO + H_2 \rightarrow HCHO \quad (I)$$

$$HCHO + H_2 \rightarrow CH_3OH \quad (II)$$

then Eq. 10 conforms to the postulate that reaction II is rate-determing, because the partial pressure of HCHO, the reactant of reaction II, is expressed as $K_I p_H p_{CO}$, where K_I is the equilibrium constant of reaction II.

For Eq. 9, the reaction scheme may be as follows:

$$H_2 \rightleftarrows 2H(a) \quad (III)$$

$$CO + 2H(a) \rightarrow CH_2O(a) \quad (IV)$$

$$CH_2O(a) + H(a) \rightarrow CH_3O(a) \quad (V)$$

$$CH_3O(a) + H(a) \rightarrow CH_3OH \quad (VI)$$

with reaction V being rate-determining.

The discrimination of the above two schemes must auait further investigation.

Isotope Effect.—The fact that no isotope effect is found in the methanol formation may give rise to the view that the adsorption of carbon monoxide is rate-determining. However, the rate equations obtained here and by other investigators suggest that this view is by no means valid, because the kinetic term of the rate equations clearly depends on the hydrogen pressure. In other words, the rate equations suggest a rate-determining step in which hydrogen or a hydrogen-containing species is involved. A complete interpretation of the above discrepancy can follow only further investigation.

The hydrogen isotope effect was observed in the carbon dioxide formation, particularly in the higher concentrations of carbon monoxide, where the deviation from the rate equation for methanol formation was also observed. These observations may suggest that the carbon dioxide formation takes place on an active site different from that of the methanol formation. Since hydrogen is not involved in the reaction path assumed for the carbon dioxide formation, the observed isotope effect must be ascribed to the higher surface coverage with deuterium, which suppresses the carbon dioxide formation. However, such an interpretation of the results should be subjected to further investigation.

The authors are grateful to Dr. Hiroshi Uchida and Dr. Yoshisada Ogino of the Goverment Chemical Industrial Reseach Institute for providing the catalyst.

Chronopotentiometry of Hexamminechromium(III) Ions in Acetate Buffer Solutions

By Nobuyuki TANAKA, Akifumi YAMADA and Reita TAMAMUSHI*

(Received June 12, 1964)

The reduction of hexamminechromium(III) ions at the dropping mercury electrode has been studied by several investigators under a fairly wide range of conditions.[1-6] Its characteristics in aqueous solutions, both neutral and acid, have been extensively discussed in two recent papers from this Laboratory.[2,6] The first paper demonstrated the role of hydrogen ions on the polarographic reduction of hexamminechromium(III), while the second was concerned with the study of the nature of the one-electron reduction wave of the complex in neutral and acid aqueous solutions.

The present chronopotentiometric investigation was undertaken to support the validity of some of the conclusions reported previously,[6] and to obtain a further insight into the mechanism of the electroreduction of hexamminechromium(III) ions.

Experimental

Hexamminechromium(III) chloride was prepared according to the method of Mori ;[7] the chromium and nitrogen contents were determined by the usual methods.

Found: Cr, 19.79; N, 31.6. Calcd. for $[Cr(NH_3)_6]Cl_3$: Cr, 19.96; N, 32.2%.

As the complex is sensitive to light and not very stable in an aqueous solution,[8] precautions were taken when it was used. All other chemicals were of analytical reagent grade. Redistilled water was used to prepare the solutions of desired concentrations. The contamination of the solutions with surface-active substances was carefully avoided.

A modified apparatus of the constant current supply described in the literature[9] was used for all measurements. A dropping mercury electrode of a long drop time (about 60 sec.) was used for a cathode. A mercury pool electrode with a large surface area served as an anode, which was connected to the cathode compartment of the cell through a salt bridge of low resistance. The characteristics of the dropping mercury electrode used in this study are given in Table I. A potential-time curve was obtained in a small fraction of a drop life, so that the surface area of the mercury drop did not change appreciably during the measurement.[10,11] Potentials of the dropping mercury electrode (working electrode) were measured against a saturated calomel electrode (SCE). The potential difference between the reference and the working electrode was fed through a direct-current preamplifier to a Toshiba oscilloscope, Model ST-1747A. The alternating voltage of audiofrequency from an oscillator, Yokogawa OV-21A, was supplied for the beam modulation. The transition time was

determined by the method of Kuwana.[12] Dissolved oxygen in the electrolytic solution was removed by bubbling purified nitrogen gas through the solution. All measurements were made at 25±0.1°C.

Results

When a hanging mercury drop electrode was used for a working electrode, no reproducible chronopotentiogram was observed. At a dropping mercury electrode, however, reproducible chronopotentiograms were obtained. Figure 1 shows a typical example of a cathodic chronopotentiogram of hexamminechromium-(III) ions obtained in an acetate buffer solution.

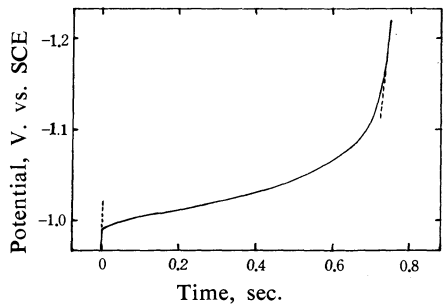

Fig. 1. Chronopotentiogram of 5 mM $[Cr(NH_3)_6]Cl_3$ in 0.1 M acetate buffer + 0.9 M NH_4Cl (pH 4.6) at 25°C. Current density, 1.44_8 mamp. cm^{-2}; surface area of the electrode, 2.93 mm^2. The measurement was started at 55 sec. after the beginning of the growth of a mercury drop.

The effect of the aging of the electrode has been reported by several authors.[9,11,13] Therefore, some preliminary measurements were made with hexamminechromium(III) ions at the slowly dropping mercury electrode. The results given in Table II clearly indicate that no appreciable effect of the aging was observed under the present experimental conditions.

The values of $i\tau^{1/2}$, where i is the current density at the polarizable electrode and τ the transition time, were determined at various current densities for the reduction of hexamminechromium(III) ions at a dropping mercury electrode, with the results given in Table III, which shows that the product $i\tau^{1/2}$ is independent of the current density. This clearly indicates that hexamminechromium(III) ions are directly reduced at the electrode without any preceding chemical reactions prior to the electron-transfer process, being in a satisfactory agreement with the previous conclusion obtained in the polarographic study of the same complex.[6]

Measurements were also made at various concentrations of the complex. The results are presented in Table IV. The average value of $i\sqrt{\tau}/C_O^\circ$ obtained from some hundred runs, where C_O° represents the bulk concentration of the complex, was 0.256 mamp. $sec^{1/2}$ cm^{-2}· mM^{-1}. It may be assumed that a theoretical equation derived for a linear diffusion process is applied to the present system without introducing any significant error. According

to Sand[14] the value of $i\sqrt{\tau}/C_O^\circ$ for a linear diffusion is given by:

$$\frac{i\sqrt{\tau}}{C_O^\circ}=\frac{\sqrt{\pi}}{2}\ nF\sqrt{D_O}=85.51\ n\sqrt{D_O} \qquad (1)$$

where F is the Faraday; C_O°, the bulk concentration expressed in mM; D_O, the diffusion coefficient expressed in $cm^2\ sec^{-1}$ and n the number of electrons involved in the electroreduction. Introducing one for n and $0.85\times10^{-5}\ cm^2\ sec^{-1}$ for D_O, which was determined polarographically, the theoretical value of $i\sqrt{\tau}/C_O^\circ$ is calculated to be 0.250 mamp.$\cdot sec^{1/2}\ cm^{-2}\ mM^{-1}$. This value is in a good agreement with the experimental one.

The potential at $t=\tau/4$ ($E_{\tau/4}$) and the potential at $t=0$ ($E_{t=0}$) were dependent on the current density and the concentration of the complex; these potentials change linearly with log i and log C_O° as are shown in Figs. 2 and 3.

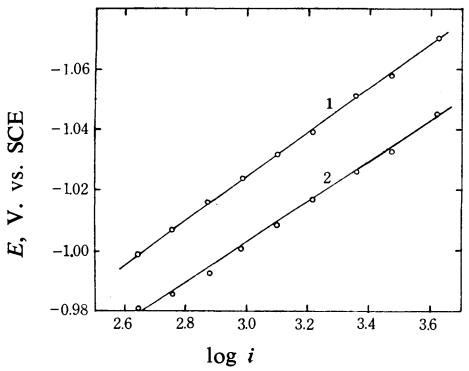

Fig. 2. Relations of (1) $E_{\tau/4}$ with log i and (2) $E_{t=0}$ with log i of 2 mM $[Cr(NH_3)_6]Cl_3$ obtained in 0.1 M acetate buffer + 0.9 M NH_4Cl (pH 4.6). Ohmic drop is corrected.

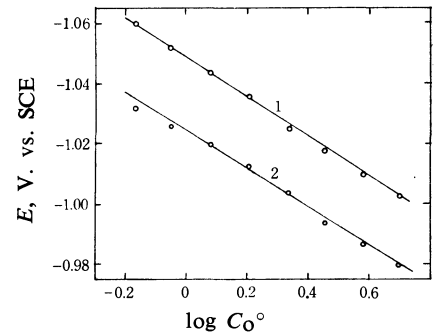

Fig. 3. Relations of (1) $E_{\tau/4}$ with log C_O° and (2) $E_{t=0}$ with log C_O° obtained at various concentrations of $[Cr(NH_3)_6]Cl_3$ in 0.1 M acetate buffer + 0.9 M NH_4Cl (pH4.6) at current density of 1.08_2 mamp. cm^{-2}.

Figure 4 shows the plots of the logarithmic functions of time against the electrode potential.[15] A plot of log $\{(\sqrt{\tau}-\sqrt{t})/\sqrt{t}\}$ versus E yields no straight line, but that of log $(\sqrt{\tau}-\sqrt{t})$ versus E yields a straight line with a reciprocal slope of 76 mV.

the same magnitude with the opposite sign is given in Fig. 5. The cathodic and the anodic potential-time curves are separated by approximately 0.35 V. The ratio τ_c/τ_a determined with 2 mM hexamminechromium(III) ions in an acetate buffer solution is presented in Table V, where τ_c is the transition time for the cathodic process and τ_a, that for the following anodic process. The ratio of τ_c/τ_a fluctuates around 3, the theoretical value that is expected when the reduced species is soluble and the current densities at the forward and the reverse process are equal in magnitude.[16]

Discussion

The mechanism of electroreduction of the heamminechromium(III) ions in acid buffer solutions has been reported as follows;[6]

$$[Cr(NH_3)_6]^{3+} + e \rightleftharpoons [Cr(NH_3)_6]^{2+} \quad (2)$$

$$[Cr(NH_3)_6]^{2+} + n\,H_3O^+ \rightarrow [Cr(H_2O)_n(NH_3)_{6-n}]^{2+} + n\,NH_4^+ \quad (3)$$

It may be concluded from the d. c. polarographic and the chronopotentiometric investigations that hexamminechromium(III) ions are directly reduced at the dropping mercury electrode without any preceding chemical reaction prior to the electron-transfer process. The Kalousek polarograms[6] and the current-reversal chronopotentiograms indicate that the overall process of the reduction of hexamminechromium(III) to chromium(II) proceeds irreversibly at the dropping mercury electrode:

$$[Cr(NH_3)_6]^{3+} + e + n\,H_3O^+ \rightarrow [Cr(H_2O)_n(NH_3)_{6-n}]^{2+} + n\,NH_4^+ \quad (4)$$

Two mechanisms may be considered. One is that, although the electron-transfer process given by Eq. 2 proceeds reversibly, the net electrode process appears to be irreversible on account of the extreme rapidity of the following chemical reactions, while the other is that the electron-transfer process itself proceeds irreversibly.

The characteristics of the chronopotentiogram for the first[17-19] and the second[20,21] mechanism have already been analyzed theoretically, which are given in Table VI.[15]

In the reduction of hexamminechromium(III), the plot of log $(\sqrt{\tau}-\sqrt{t})$ vs. E yields a straight line, whose slope is somewhat greater than 59 mV., a theoretical value expected for a reversible one-electron reduction at 25°C. This suggests the possibility of the electron-transfer process itself being irreversible. According to the results of theoretical analysis given in Table VI, the slope of the plot should be equal to the constant $RT/\alpha nF$ independently of the concentration of the hexamminechromium(III) and the current density i. However, as is seen in Table VII, the slopes of the plots obtained experimentally vary with the transition time, and increase with increasing current density at the same concentration of the complex. This fact can not be explained satisfactorily by the mechanism which assumes the totally irreversible electron-transfer process.

Recently, Gellings[22] studied the characteristics of the current-potential curves for the electrode process of kinetic nature, where he proposed a method by which the potential can be expressed as a function of the current by the application of Lagrange's theorem. This method was applied in this study to a general treatment for the chronopotentiometric potential-time curve for the process represented by the following scheme:

TABLE VI. DIAGNOSTIC CRITERIA FOR KINETIC SCHEMES

No.	Kinetic schem	Linear ln-plot	Slope of ln-plot	$\frac{\partial E_{\tau/4}}{\partial \ln i}$	$\frac{\partial E_{\tau/4}}{\partial \ln C_O^\circ}$	$\frac{\tau_a}{\tau_c}$

2.00	0.44_3	1.36_9	-0.98_0	73

* Corrected for ohmic drop across the electrolytic cell.

$$O+ne \rightleftharpoons R \tag{5}$$

$$R \underset{\sigma_b}{\overset{\sigma_f}{\rightleftharpoons}} Y \quad (\sigma_f/\sigma_b \gg 1) \tag{6}$$

where O is a reducible substance, R its reduction product, Y a substance which is neither reduced nor oxidized at the potentials where the reduction of O occurs and σ_f and σ_b are the rate constants of the following chemical reaction.

When $|i/i_0|$ is less than 2, where i_0 means the exchange current density for the electrochemical reaction given by Eq. 5, i. e., in the case of a reversible electron-transfer, Eq. 7 holds:

$$\psi=\ln\frac{g}{h}+\sum_{n=1}^{\infty}B_n\frac{f^n}{g^{n\beta}h^{n\alpha}} \tag{7}$$

with $\psi=\dfrac{nF}{RT}(E-E_e^\circ)$, $f=i/i_0$, $g=C_O/C_O^\circ$, $h=C_R/C_O^\circ$ and $B_n=\dfrac{(-1)^n\Gamma(n\alpha)}{n!\Gamma(n\alpha-n+1)}$

for which the condition for convergence is:

$$|f\alpha^\alpha\beta^\beta/(g^\beta h^\alpha)|<1$$

In the case of a large current density ($|i/i_0|>2$), i. e., in the case of an irreversible electron-transfer, Eq. 8 is satisfied:

$$-\alpha\psi=\ln\frac{f}{g}+\sum_{n=1}^{\infty}A_n\frac{h^n g^{n\beta/\alpha}}{f^{n(1+\beta/\alpha)}} \tag{8}$$

with $A_n=\dfrac{\Gamma\left(n-\dfrac{n}{\alpha}\right)}{n!\Gamma\left(1-\dfrac{n}{\alpha}\right)}$

for which the condition for convergence is:

$$|h^\alpha g^\beta/(\alpha^\alpha\beta^\beta f)|<1$$

In Eqs. 7 and 8, α and β represent the transfer coefficients for the cathodic and the anodic process respectively ($\alpha+\beta=1$), C_O and C_R the concentrations of O and R at the electrode surface respectively, C_O° represents the concentration of O in the bulk of the solution, E the potential of cathode at time t, E_e the formal standard potential of the electroactive couple, A_n and B_n are the coefficients in power series[22] and Γ is the gamma function. According to Delahay et al.[17] the concentrations of O and R at the electrode surface are given as:

$$C_O(0,t)=C_O^\circ-\frac{2i\sqrt{t}}{nF\sqrt{\pi}\sqrt{D_O}} \tag{9}$$

$$C_R(0,t)=\frac{i}{nF\sqrt{D}}\left(\frac{2\sqrt{t}}{\sqrt{\pi}K}+\frac{\mathrm{erf}\sqrt{\sigma_f t}}{\sqrt{\sigma_f}}\right)$$

where K is the equilibrium constant for the reaction given by Eq. 6 ($K\gg1$), D the common value of D_R and D_Y which are assumed to be the same, and erf means the error function. Introducing Eq. 9 into Eqs. 7 and 8, Eqs. 10 and 11 are obtained for a reversible and an irreversible electron-transfer process respectively. In Eqs. 10 and 11, k_s represents the rate constant for the electron-transfer process at $E=E_e^\circ$.

In Eq. 10 the potential at $t=0$ ($E_{t=0}$) becomes definite only when $\sqrt{\sigma_f t}>2$, otherwise

$$E=E_e^\circ+\frac{RT}{nF}\ln\frac{1-\sqrt{t/\tau}}{\dfrac{i}{nFC_O^\circ\sqrt{D}}\left(\dfrac{2\sqrt{t}}{\sqrt{\pi}K}+\dfrac{\mathrm{erf}\sqrt{\sigma_f t}}{\sqrt{\sigma_f}}\right)}+\frac{RT}{nF}\sum_{n=1}^{\infty}B_n\frac{(i/i_0)^n}{(1-\sqrt{t/\tau})^{n\beta}\left[\sqrt{D_O/D}\left(\dfrac{1}{K}\sqrt{t/\tau}+\dfrac{\sqrt{\pi}}{2}\dfrac{\mathrm{erf}\sqrt{\sigma_f t}}{\sqrt{\sigma_f\tau}}\right)\right]^{n\alpha}} \tag{10}$$

(for a reveversible electron-transfer)

$$E=E_e^\circ+\frac{\alpha nF}{RT}\ln\frac{1-\sqrt{t/\tau}}{\dfrac{i}{nFk_sC_O^\circ}}-\frac{RT}{\alpha nF}\sum_{n=1}^{\infty}A_n\frac{(1-\sqrt{t/\tau})^{n\beta/\alpha}\left[\sqrt{D_O/D}\left(\dfrac{1}{K}\sqrt{t/\tau}+\dfrac{\sqrt{\pi}}{2}\dfrac{\mathrm{erf}\sqrt{\sigma_f t}}{\sqrt{\sigma_f\tau}}\right)\right]^n}{(i/i_0)^{n(1+\beta/\alpha)}} \tag{11}$$

(for an irreversible electron-transfer)

becomes infinite, since the value of the error function virtually is equal to unity for an argument larger than 2. When $\sqrt{\sigma_f t} > 2$, the plot of E vs. log $(\sqrt{\tau} - \sqrt{t})$ should yield a straig lhtine whose slope is equal to $2.3RT/nF$. In Eq. 11, on the other hand, $E_{t=0}$ is independent of σ_f, because the additional term (the third term) of the equation becomes zero when t equals zero. Hence, $E_{t=0}$ vs. log i and $E_{t=0}$ vs. log C_O° should yield straight lines whose slopes equal $-2.3\,RT/\alpha nF$ and $2.3\,RT/\alpha nF$ respectively. Finally, in both Eqs. 10 and 11, it is expected that the logarithmic term, log $(\sqrt{\tau} - \sqrt{t})$, varies with potential linearly or curvilinearly depending on the magnitude of the additional term of the equations. This explains the experimental results that the slope of the apparently linear log-plot varied with the transition time. (See Table VII).

The value of $E_{t=0}$ was found to change linearly with log i and with log C_O°. If Eq. 11 can be applied, the absolute value of the reciprocal slopes of $E_{t=0}$ vs. log i and $E_{t=0}$ vs. log C_O° should be equal to the constant $2.3RT/\alpha nF$, because the additional term of Eq. 11 approaches zero at $t=0$. In the experiments, the reciprocal slopes of $E_{t=0}$ vs. log i and $E_{t=0}$ vs. log C_O° were found to be -66 mV. and 65 mV. respectively at 25°C, as are seen in Figs. 2 and 3. Thus, every slope of log-plot was somewhat greater than 59 mV., a theoretical value expected for a reversible one-electron reduction at 25°C. As for the potential at $t=0$ ($E_{t=0}$), definite values were obtained, which also support the mechanism given by Eq. 11. Consequently, the irreversibility of the electron-transfer process itself is favorably inferred.

In view of the above-mentioned facts a reasonable conclusion that may be drawn from the available data is that hexamminechromium-(III) ions are irreversibly reduced at the dropping mercury electrode without any preceding chemical reactions prior to the more or less irreversible electron-transfer process, followed by the rapid aquation of the reduced species.

Summary

The reduction of hexamminechromium(III) ions at the dropping mercury electrode has been studied chronopotentiometrically in acetate buffer solutions. The electrolysis at constant cathodic current gives a well-defined chronopotentiogram which corresponds to the one-electron reduction of chromium(III) to chromium(II), but the anodic chronopotentiogram which is obtained by the electrolysis at constant anodic current is clearly separated from the cathodic one.

A general treatment for a chronopotentiometric potential-time curve for the electrode process with the following chemical reaction has been developed by the application of Lagrange's theorem. The results indicate that hexamminechromium(III) ions are irreversibly reduced at the dropping mercury electrode without any preceding chemical reactions prior to the more or less irreversible electron-transfer process, followed by the rapid aquation of the reduced species.

The Chlorine Content of Hawaiian Lavas

By Bunji IWASAKI and Takashi KATSURA

(Received June 13, 1964)

Studies of the chlorine content of Hawaiian lavas have been published by Shepherd,[1] Iwasaki et al.,[2] and Yoshida et al.[3] Nevertheless, the rock samples used in their studies were small in number and collected from only a few localities. Recently, 141 new chemical analyses of Hawaiian lavas systematically collected have been reported by Macdonald and Katsura.[4]

In the present paper, the distribution of chlorine in the Hawaiian lavas will be investigated in order to answer the following principal questions: Is there any change in the chlorine content of rocks which were extruded at different times in volcanic history? Is it clear that chlorine tends to be enriched in rock of an alkalic type? Does the frequency distribution of chlorine show a lognormality? Is there any regional change in the chlorine content of the rocks?

Experimental

Rock Specimens.—The rock specimens used for the present study cover all of the rock types found in the Hawaiian Islands, e. g., tholeiitic basalt, tholeiitic olivine basalt, alkalic basalt, alkalic olivine basalt, basanite, basanitoid, ankaramite, hawaiite, mugearite, and trachyte, as defined by Macdonald and Katsura.[4] Most of them were collected by Macdonald during the 1960~1961 period, during which time one of the authors of this paper joined him under a National Science Foundation grant.[5,6]

Method of Analysis. — The total chlorine was determined by the method of Iwasaki et al.[7] with some improvements. About 200 mg. of a fine powdered rock sample was fused with anhydrous sodium carbonate in a platinum crucible. After cooling, the chlorine was completely extracted with hot redistilled water and was determined photometrically by the thiocyanate method.[8]

The water-soluble chlorine in rocks was determined as follows: About 1.00 g. of a fine powdered (100 to 150 mesh) rock sample was put into a centrifugal vessel containing 15 ml. of redistilled water. The vessel was then vigorously shaken about 1 min. After the mixture had stood overnight at room temperature, the solution in the vessel was separated from the rock sample by centrifuge. Almost all of the soluble chlorine was extracted by this procedure. About 0.1 ml. of concentrated perchloric acid was then added to the solution. The total soluble chlorine thus extracted was determined by the method shown above.

The total chlorine in approximately 160 Hawaiian volcanic rocks was duplicatedly determined two or more times, but the water-soluble chlorine was determined only one or two times. It may safely be said that the precision for the present determination of chlorine is within ±5% over the whole range of chlorine contents obtained here.

In addition to the reproducibility of the results of the analyses, a cross-check analysis of one sample was made by Dorothy Powers, with the aid of Dr. H. A. Powers and under the supervision of L. C. Peck, in the laboratory of the Geological Survey in Denver, Colorado, U. S. A. The value of 0.018% chlorine in a rock specimen, G-2907 in Table I-b obtained by the present authors is in good agreement with that obtained by Mrs. Powers, (0.02% chlorine).

According to Shepherd,[1] the chlorine content in the 1926 Mauna Loan volcanic rocks was 0.01% chlorine; as may be seen in Table I-b, the corresponding value for the same rock obtained by the present authors was 0.008% chlorine (C-133). Taking account of the difference in rock specimens, it may be said that these values are in good accordance.

Results

Tables I-a, I-b give both the insoluble and total chlorine contents in the Hawaiian lavas. The insoluble chlorine content was calculated by subtracting the water-soluble chlorine from the total chlorine.

Discussion

Water-soluble Chlorine in Rocks.—It has been found by Kuroda and Sandell[9] and by Iwasaki

et al.[2] that volcanic rocks generally contain a very small amount of water-soluble chlorine compared with amount of total chlorine when the specimens are fresh. Table II shows the amounts of both the total and the water-soluble chlorines of the historic fresh lavas from Mauna Loa and Kilauea. The amount of water-soluble chlorine varies from 0.000 to 0.004% chlorine, as may be seen in Table II,

TABLE II. VARIATION OF CHLORINE CONTENT IN ROCK SAMPLES AT DIFFERENT PERIODS OF AN ERUPTION

	Total Cl %	Insoluble Cl %
The 1955 Kilauea Eruption (Puna)

while the total chlorine content has a slightly wider range, from 0.006 to 0.018% chlorine. The amount of water-soluble chlorine is presumably independent of the total chlorine content, and it seems to be almost constant. On the other hand, a rock sample such as C-33 has a high amount of water-soluble chlorine (0.16% chlorine). The specimen was collected about 2 feet above sea level at the end of a spur; as has been pointed out by Macdonald the specimen has without doubt been washed with sea-water, but it appeared very fresh. Considering this, a rock specimen with a high amount of water-soluble chlorine has possibly been contaminated by sea-water, etc. Indeed, there was only a very small amount of water-soluble chlorine even in a fresh a rock specimen, and we can hardly distinguish the chlorine which was primarily present in a rock sample just after the extrusion from the chlorine due to contamination; however, we may presume that the contaminated chlorine could be completely extracted with water. In the following discussion we will employ the amount of insoluble chlorine, though it is tedious work to determine the soluble chlorine as well as the total chlorine.

The Manner of Occurence of Chlorine in Rocks.—Based on the studies by Shepherd,[1] Behne,[10] and Kuroda and Sandell,[9] Correns[11] summarized the manner of occurence of chlorine in igneous rocks, and pointed out that in all probability the chlorine content of igneous rocks does depend either upon their mineralogical composition or upon their modes of crystallization. Iwasaki et al.[2] determined the chlorine content of about 190 volcanic rocks from Japan, Korea, Manchuria (China), and Hawaii, and of pebbles dredged near Jimmu Seamount,[12] and made it clear that there seems to be no distinct relationship between the chlorine content and the major chemical constituents, especially with respect to the phosphorous and water contents on which Kuroda and Sandell[9] focussed their attention. Iwasaki et al.,[2] therefore, concluded that the chlorine distribution may largely be attributed to the quenching condition at high temperature, at which a magma is equilibrated with the gaseous phase.

The chlorine content of apatite in igneous rocks other than volcanic rocks was determined by Kind,[13] Behne,[10] and Vasilieva,[14] and the average chlorine content of apatite in igneous rocks was estimated by Behne[10] as 0.30% chlorine. Assuming that the Hawaiian volcanic rocks contain apatite in which 0.3% chlorine is contained as an essential constituent on the average, the calculations will lead to the result that the contribution of chlorine due to the appatite present in rocks is limited only to the magnitude of 0.002% chlorine provided the average phosphorus content in Hawaiian tholeiitic basalts is 0.26% P_2O_5.[4] In fact, no close relationship existed between the chlorine content and the phosphorus content. For instance, specimen C-73 in Table I-a is low in chlorine in spite of a high phosphorus content. It is, therefore, clear that apatite in Hawaiian volcanic rocks is of little importance in the distribution of chlorine.

Mica is rarely found in Hawaiian volcanic rocks; as may be seen in Table I-a, the rock specimens, C-73, and C-79, which contain abundant dark mica are low in chlorine (0.006 and 0.007% respectively). Therefore, mica is also of little importance as a chlorine-carrier. The chlorine content of olivine separated from the 1959 lava of Kilauea Iki was very low (0.003% chlorine, as determined by T. Ozawa)

in comparison with that of the original rock (0.012% chlorine).

In contrast to the facts mentioned above, the chlorine content of a ground mass in specimen C-31 (0.008% chlorine), which is a feldspar-phyric basalt and 50% occupied by feldspar phenocryst, is higher than that of the original rocks (0.005% chlorine). It is clear that almost all the chlorine in the bulk is provided by the ground mass, which represents the liquid part of the rock when it was extruded at high temperature. According to Yoshida,[15] the chlorine compounds are evolved at 600°C, and the amount of evolved chlorine compounds increases gradually with an elevation of temperature. It may be considered that the rock samples studied by Yoshida contain an appreciable amount of groundmass, that the glassy parts begin crystallizing at 600°C at a significant speed, and that the chlorine dissolved in the glassy parts is forced to escape to the atmosphere. In addition, it has been found by Iwasaki[16] that the enrichment of chlorine in a rock sample collected from the middle part of one thick basaltic lava flow resulted from the larger amount of glassy parts solidified at the latest stage of the cooling process.

The Variation in the Chlorine Content of the Rock Samples of One Eruption.—Table II shows some examples of the variation in chlorine content of rock samples representing different periods of the time during each dated eruption of Kilauea and Mauna Loa. These samples all belong to aphyric-type basalt, and the amount of phenocrysts is less than 5% (tholeiitic basalt). It may, therefore, be assumed that the chlorine content of a lava flow extruded at a definite period of year will be almost constant when we take rocks with the same texture. In addition, Iwasaki and Ozawa[17] made it clear that the chlorine contents of approximately 120 rock samples of the 1950~1951 lava flow of O-sima Volcano, Japan, were quite homogeneous and ranged from 0.029 to 0.036% chlorine, irrespective of their appearance.

The Variation in the Chlorine Content of Rocks in Stratigraphical Sequences.—From the preceding discussion, we could expect that the chlorine content of a rock will depend mainly on the chlorine dissolved in an original silicate melt which came in contact with a gaseous phase containing a small amount of chlorine compounds. It would be valuable, in studying the descent of magmas, to see whether or not there is any variation in the chlorine content of rocks of each volcano in stratigraphical sequence. In Table I-a, the rock samples are presented in order of stratigraphical sequences; for instance, C-1 represents the lower parts in the stratigraphy of the Waianae Range, and C-52, the uppermost part.

As may be seen in Table I-a, there is a small variation in the insoluble chlorine content of rocks in most of volcanoes with the exception of the West Maui Volcano. Roughly speaking, these variations range from 0.005 to 0.01% chlorine, and there seems no distinct variation scheme with respect to the stratigraphical sequences. In contrast, it may be seen in Table I-b that the rock specimens of Kilauea are higher in chlorine content than those of Mauna Loa. This may be explained, in one way, by the two different magma batches proposed by Powers[18] which are different in chemical composition. Another explanation rests on the difference in volatile-escaping tendency during the movement of a melt from a magma chamber to the surface of the earth; the path in Mauna Loa is longer than in Kilauea.

In the case of West Maui, there seems to be an increase in the chlorine content of rocks toward the end of the period of volcanic eruption.

The Relationship between the Rock Types and the Chlorine Content.—A study by Macdonald[19] has elucidated many detail of the relationships of the tholeiitic rocks of the main shield volcano, which make up about 99 per cent of the volume as an over-all average in Hawaii; only a small percentage of Hawaiian rocks consist of the alkalic rocks which covered the late-stage cap of the volcanic mountains. The numbers of analyzed rock specimens in this study are not proportional to the volumes of each rock type, but the frequency diagrams of insoluble chlorine content in both tholeiitic and non-tholeiitic rocks are given in Figs. 1-a, 1-b. As may be seen in Figs. 1-a, 1b- the chlorine content of both tholeiitic and alkalic basalts range from 0.005 to 0.014%, with a few exceptions in tholeiitic basalt. On the other hand, the chlorine contents of hawaiite are scattered over a wide range from 0.006 to 0.034%. The same distribution will be seen in basanite and basanitoid group, ranging from 0.006 to 0.066%, though there are only four samples. The highest chlorine content was found in trachyte obsidian of Hualalai (0.12%). The other trachytes contain very small amounts of chlorine

(0.001 and 0.003%); thus the range of chlorine content here is larger than in the basanite group.

In general, it is difficult to say that alkali-rich rocks have more chlorine than tholeiitic rocks. We can, however, safely say that the rocks containing much chlorine are without exception of alkali-rich types.

The Frequency Distribution of the Chlorine Contents in Hawaiian Lavas.—Figure 2 gives three cumulative frequency distributions of insoluble chlorine contents of rocks from Waianae, from West Maui, and from all Hawaian volconoes. They show approximately lognormalities, rather than normalities. Strictly speaking, a bi-log-normality is appropriate for Waianae and for all Hawaiian volcanoes. This is in striking contrast to the finding of Iwasaki[16] that the frequency diagram of the chlorine content of the 1950~1951 lava flow of O-sima, Izu, shows a normality. Provided that the frequency diagram of the insoluble chlorine contents in Hawaiian lavas is log-normal, and that the water-soluble chlorine content of a rock is 0.001% chlorine, we obtain the mean chlorine content of Hawaiian lavas as, 0.008% chlorine.

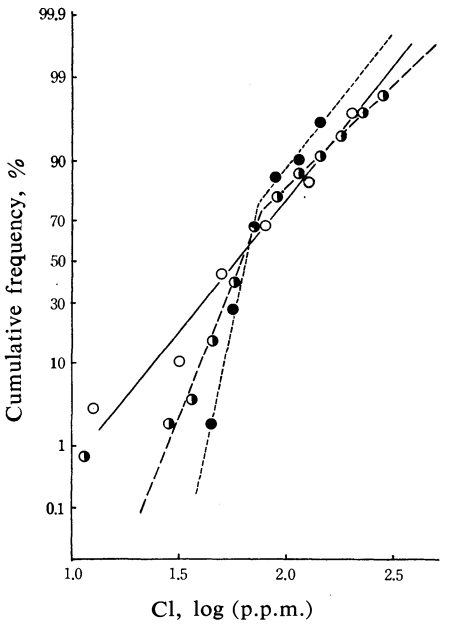

Fig. 2. Cumulative frequency distribution of insoluble chlorine content of rocks.
○ West Maui Volcano
● Waianae Volcano
◑ All Hawaiian lavas

It is valuable to know whether or not the chlorine content of rocks of one region differs from that of others. With respect to this regional variation, Kuroda and Sandell[9] mentioned that Japanese lavas are lower in chlorine content than those of the U. S. A. On the other hand, Iwasaki et al.[2] mentioned that Japanese volcanic rocks do not significantly differ in chlorine content from igneous rocks elsewhere in the world. Here we will compare the chlorine contents of Hawaiian and Japanese basalts. The total chlorine content, that is, 0.001% plus insoluble chlorine, is used in Hawaiian basalts. For the present purpose, we will adopt the available data of the volcanic rocks in Japan studied by Iwasaki et al.[2] Figure 3 shows two cumulative frequency distributions of the chlorine contents of Hawaiian and Japanese basalts. They show approximately lognormal distributions. Japanese basalts are clearly higher in chlorine than are Hawaiian basalts. As may be seen in the slope of straight lines in Fig. 3, the former is greater in the dispersion of chlorine content than is the latter. The mean chlorine contents of two basalts are 0.015% in Japan and 0.008% in Hawaii. The former is, therefore, about twice as high as the latter. Judging from the results obtained, it can be confidently stated that a regional difference in chlorine content exists between Hawaiian and Japanese basalts.

○ Japanese basalt
● Hawaiian basalt

Conclusion

The foregoing evidence: (1) makes it clear that a narrow variation in the insoluble chlorine contents of rocks is common in the history of most Hawaiian volcanoes, especially in the tholeiitic rock series; (2) confirms that the alkali-rich rocks containing much insoluble chlorine are erupted at nearly the end of the volcanic history, although the alkali-rich rocks are not always higher in chlorine content than the tholeiitic rocks; (3) shows, however, that the high chlorine contents are selectively found in the alkali-rich rocks without exception; (4) indicates that the frequency diagram of the insoluble chlorine in Hawaiian lavas is bi-lognormally distributed, while the mean value of chlorine content is 0.008%; (5) shows that a regional difference in chlorine content may be seen in basalts between the islands of Hawaii and Japan, and (6) suggests that the chlorine in rocks is concentrated in the glassy parts, irrespective of their mineral assemblages.

The authors wish to express their hearty thanks to Professor Gordon A. Macdonald, Hawaii Institute of Geophysics of the University of Hawaii, for his valuable advice and criticism in field observations. Their thanks are also due to Professor Iwaji Iwasaki, Tokyo Institute of Technology, who encouraged them throughout the study. Mr. Takejiro Ozawa kindly analyzed the chlorine content of olivine.

Studies on Fluorene Derivatives. XXIII. The Synthesis of 2'-Bromotribiphenylenepropane and Some Related Observations*

By Kazuo SUZUKI and Minoru FUJIMOTO

(Received June 15, 1964)

2'-Bromotribiphenylenepropane (I) was first obtained by the Michael condensation of dibiphenyleneethylene (II) with 2-bromofluorene. The thermal decomposition of such tribiphenylenepropane hydrocarbons is invariably accompanied by the formation of the 9-fluorenyl free radical species. Thus two tribiphenylenepropane isomers (m. p. 291~293°C (decomp.), m. p. 257°C (decomp.)), 2,2'-dibromodibiphenyleneethane, II and dibiphenyleneethane can be obtained by the decomposition of I, as has previously been reported in this series.[1)]

The present investigation will deal with the synthesis of I by the use of 9-fluorenyllithiums, and will reexamine the side reaction in the Michael condensation of II with 2-bromofluorene. The origin of the by-products can be understood on the basis of a sequence of condensation and disproportionation steps.

By refluxing II and 2-bromofluorene in pyridine in the presence of one percent of potassium hydroxide or sodium carbonate, I, a small

amount of tribiphenylenepropane (m. p. 289～291°C),[2] fluorenone, 2-bromofluorenone and 2'-bromodibiphenyleneethylene (IV)[3] were obtained; they were then characterized by a combination of column chromatography, sublimation and recrystallization. I was obtained in a good yield (79%) by the use of one percent sodium carbonate. These results are summarized in Table I.

Moreover, a highly substituted I might lead to II and 2-bromo-9-fluorenyl anions or IV and 9-fluorenyl anions by the elimination of the protons in the 9'- or 9''-positions of I in the pyridine-base solution. On the other hand, a minor portion of III, by means of a proton transfer, could form IV and fluorenyl ions. Then, tribiphenylenepropane (m. p. 289～291°C) could be formed by the addition of fluorenyl ions to II. This compound is identical with that of Suzuki,[2] as is shown by the fact that they have the same infrared absorption spectra and by mixed melting point determination. Figure 1. illustrates these reaction sequences.

I was then refluxed in pyridine with one percent potassium hydroxide under the same conditions for forty hours. Small amounts of fluorene, fluorenone, 2-bromofluorenone and dibiphenyleneethylenes were isolated from the reaction mixture. These results are summarized in Table II. Fluorenone and 2-bromofluorenone might be formed by the oxidation of fluorene and 2-bromofluorene respectively. 2, 7-Dibromofluorenone was obtained when 2-bromofluorene was treated similarly (see Table II), but it seems difficult to explain the formation of this compound.

These compounds were identified by mixed melting points, elementary analyses and infrared absorption spectra.

Aromatic hydrocarbons like fluorene and 9-phenylfluorene[4] have been successfully metalated by organo-lithium compounds. I was

prepared by the following combinations of 9-fluorenyllithiums under similar conditions: 9-bromodibiphenyleneethane and 2-bromo-9-fluorenyllithium, 9-lithiodibiphenyleneethane and 2,9-dibromofluorene, 2',9-dibromodibiphenyleneethane and 9-fluorenyllithium and 2'-bromo-9-lithiodibiphenyleneethane and 9-bromofluorene; the yields were 41.3%, 26.1%, 42.6% and 4.0% respectively. The identity of these compounds was confirmed by a comparison of their infrared absorption spectra with those of authentic compounds.

Dibiphenyleneethanes did not react so satisfactorily with metallic lithium to form 9-lithiodibiphenyleneethanes.

The generalized reaction scheme is shown in Fig. 2.

Experimental*

The Michael Condensation of Dibiphenyleneethylene (II) with 2-Bromofluorene.—A solution of 3.3 g. of II, 2.5 g. of 2-bromofluorene and 2 ml. of a 10% aqueous solution of potassium hydroxide in 20 ml. of pyridine was refluxed for 40 hr., during which time the red color turned dark. After cooling, the reaction mixture was poured into water, and the orange-red precipitate was filtered. The crude product was extracted with hot benzene. The benzene solution was washed with water, dried over anhydrous calcium chloride, and then chromatographed on alumina.

Fluorenone (m. p. 83°C, 0.02 g.) and 2-bromofluorenone (m. p. 143~144°C, 0.2 g.) were isolated from the yellow band in the column and fractionally recrystallized from alcohol. Their identity was confirmed by mixed melting points with authentic samples.

Upon the evaporation of the first two fractions, a red solution, a crystalline material, was deposited. This was separated into yellow crystals and a red benzene solution by filtration. The yellow crystals were digested several times with ethyl acetate; this solution, upon evaporation, gave a small amount of an unknown colorless compound, which melted with bubbling at 120°C, and then gradually solidified and melted again at 255°C (decomp.). The mixed melting point with I was not depressed (254°C (decomp.)). The infrared absorption spectrum was partly different from that of I and did show absorptions at 1730, 1368, 1250 and 1050 cm^{-1} not as did I.

UV: $\lambda_{max}^{CHCl_3}$ $m\mu$ (log ε): 304 (4.22) and 272 (4.73).

The residue was extracted with hot ethyl acetate, and I was obtained from the extracts (m. p. 255°C (decomp.); 1.6 g.).

UV: $\lambda_{max}^{CHCl_3}$ $m\mu$ (log ε): 304 (4.06) and 272 (4.60).

The last insoluble part was recrystallized from benzene and gave tribiphenylenepropane, m. p. 289~291°C (0.2 g.), which did not react to a Beilstein test.

The red benzene mother solution was chromatographed again on alumina. II (0.3 g.) was recovered from the first fraction. The second and third fractions, upon evaporation, left a yellow solid which was recrystallized from ethanol to yield 0.05 g. of 2,7-dibromofluorenone, m. p. 200~202°C;

* All melting points are uncorrected.

(reported[5] m. p. 202~203°C). (Found : Br, 47.33. Calcd. for $C_{13}H_6OBr_2$: Br, 47.28%; IR ; 1714 cm^{-1} (ν C=O) (KBr-disk). This compound was identified by the melting point and the mixed melting point determination and by comparing its infrared absorption spectrum with that of an authentic sample of 2, 7-dibromofluorenone.

The Reaction of 2'-Bromotribiphenylenepropane (I) in a Pyridine-Potassium Hydroxide Solution.—A mixture of 3.0 g. of I and 3 ml. of a 10% aqueous solution of potassium hydroxide in 30 ml. of pyridine was refluxed for 40 hr., giving a dark red solution. The reaction mixture was then poured into water to yield an orange-red precipitate. The work-up of the products by column chromatography (benzene), sublimation and recrystallization gave fluorene (m. p. 114°C, 0.095 g.), fluorenone (m. p. 83°C, 0.04 g.), 2-bromofluorenone (m. p. 143~145°C, 0.2 g.), II (m. p. 187°C, 0.05 g.), IV (m. p. 150~152°C, trace) and the recovered starting material (1.65 g.). All compounds were identified by mixed melting point. These results are presented in Table II.

The Synthesis of 2'-Bromotribiphenylenepropane (I).—1) *n*-Butyl lithium was prepared from 2.0 g. (0.015 mol.) of *n*-butyl bromide in 20 ml. of anhydrous ether and 0.2 g. (0.03 g. atom) of lithium in 20 ml. of anhydrous ether. Then, 2-bromo-9-fluorenyl lithium was prepared by adding 2.9 g. (0.012 mol.) of 2-bromofluorene in 30 ml. of anhydrous xylene to the *n*-butyl lithium solution. Into this mixture there was added slowly with stirring a solution of anhydrous xylene containing 4.9 g. of 9-bromodipiphenyleneethane. After the reaction mixture had stood at room temperature overnight, the precipitate was filtered and then hydrolyzed with dilute ammonium chloride and recrystallized from benzene to give 2.4 g. of I (m. p. 257°C, decomp.; 41.3% (Balance yield); identical by mixed melting point and infrared absorption spectra with the authentic sample).

In addition, 0.6 g. of 9-hydroxydibiphenyleneethane[6] (m. p. 191~193°C) and 0.2 g. of dibiphenyleneethylene (m. p. 187°C) were isolated by chromatography in benzene on alumina.

2) I was obtained by the reaction of 9-fluorenyl lithium with 2', 9-dibromodibiphenyleneethane in a 42.6% yield.

3) A solution of 0.015 mol. of *n*-butyl lithium in 20 ml. of ether was added to a solution of 4.1 g. (0.01 mol.) of 9-bromodibiphenyleneethane in 30 ml. of xylene under the same conditions as in the first method. The wine-red color turned to brown-red, and a yellowish brown precipitate was formed. To this resulting solution there was added 10 ml. of anhydrous xylene containing 3.2 g. (0.01 mol.) of 2, 9-dibromofluorene.

The product was filtered off, hydrolyzed, and then recrystallized from benzene to give I (m. p. 257°C, decomp.; 0.6 g., 26.1%). This propane was identical with the authentic sample of I as shown by mixed melting point determination and infrared absorption spectrum. The xylene mother solution was evaporated to dryness under reduced pressure, and 2, 9-dibromofluorene (1.2 g.) was recovered by chromatography in benzene on alumina.

4) I was also obtained in a 4.0% yield by the reaction between 2'-bromo-9-lithiodibiphenyleneethane and 9-bromofluorene.

The authors wish to express their gratitude to Drs. John and Elizabeth Weisburger of the National Institute of Health, U.S.A., for valuable information, and to Dr. Shôji Kajigaeshi of Kyushu University, Mr. Shigeto Nakagawa and Mr. Masanori Shigehara for their assistance.

Some Properties of Polyoxyethylene Dodecyl Ether over a Wide Range of Polyoxyethylene Chain-lengths

By Fumikatsu TOKIWA

(Received June 16, 1964)

There have been a number of studies of the properties of polyoxyethylated non-ionic surfactants in relation to their polyoxyethylene chain-lengths. Most of these studies have, however, been limited to the non-ionic surfactants with relatively short polyoxyethylene chains; little attention has been paid to the surfactants with considerably long polyoxyethylene chains. Their properties depend to a large extent on the average number of oxyethylene units present. It is, therefore, desirable to have data for non-ionic surfactants over a wide range of the chain-lengths of polyoxyethylene in order better to understand the effect of chain-length on their properties.

The author[1,2] has previously shown the relationship between the properties of polyoxyethylene dodecyl ether, such as its micellar molecular weight, its solubilization and its viscosity, and its polyoxyethylene chain-lengths above the critical micelle concentration.

The present paper will deal with the purification of a non-ionic surfactant, including the determination of its molecular weight, and chromatographic and infrared spectral studies, from short up to quite long polyoxyethylene chains. It is always of importance, when one studies the properties of a polyoxyethylated non-ionic surfactant, to purify the sample, i. e., to remove polyethylene glycol, a by-product of the addition reaction, from the sample. In addition, this paper will deal with the surface tension of aqueous solutions and with the solubilization of oil-soluble dye, on the basis of which the variation in critical micelle concentration with polyoxyethylene chain-length will be discussed.

Experimental

Materials.—Polyoxyethylene dodecyl ethers (abbreviated to PODE), $C_{12}H_{25}O(CH_2CH_2O)_pH$, were prepared from dodecyl alcohol of a high purity. The average degrees of the polymerization of ethylene oxide, p, in these samples are listed in Table I. The purification of the samples and the determination of their molecular weights were carried out as will be described below. Polyethylene glycol (abbreviated to PEG), the molecular weight of which was approximately 4000, was obtained from the Carbide and Carbon Chemicals Co.

The Purification of PODE.—The purification of the samples was carried out by the extraction method by countercurrent partition,[3] using water-saturated *n*-butanol and *n*-butanol-saturated water, in order to remove PEG, a by-product of the reaction.

The purification by liquid chromatography was also attempted for this purpose by using alumina (200 mesh powder for chromatographic analysis) as an adsorbent. Two different solvent systems were used, one a mixture of *n*-butanol and water, the other acetone alone. However, the former was somewhat disadvantageous in the sense that it affords only a small amount of purified sample at one time, and the latter was not satisfactory. Thus, the attempt at purification by liquid chromatography was abandoned.

It was confirmed, by testing through paper chromatography, that the samples purified by the extraction method contained no detectable free PEG. The development was carried out by applying a mixture of *n*-butanol, acetone and water (4 : 1 : 5 by volume[4]). The evaporation of the developer was followed by visualization in the Dragendorff reagent.

The Determination of Molecular Weights.—The molecular weights of PODE were determined by the freezing point depression of their benzene solutions by means of the Beckman method with the usual precautions. The molecular weights were also determined by the anhydrous acetic acid-pyridine method, which is commonly used for measuring hydroxyl values.

Infrared Absorption Spectra.—Infrared measurements were performed on a Shimadzu Type IR-27 spectrometer using a sodium chloride prism. The infrared spectra of PODE were recorded in a liquid or solid state, the PODE with a longer polyoxyethylene chain being solid.

Surface Tension.—Surface tensions were measured by the drop weight method with a tip 5.03 mm. in diameter in a thermostat of 30 ± 0.1°C. The observed values were corrected by using the correction factor of Harkins and Brown. The duration time after the formation of a drop was 0.5～5.0 min., depending on the concentration of the solutions. Under these conditions there was no appreciable change in the surface tension.

Solubilization. — Yellow-OB, an oil-soluble dye used as a solubilizate, was purified by repeated

recrystallization from an ethanol-water mixture. Solubilizations were run in a water bath at a constant temperature of 30±0.1°C for 24 hr. to attain equilibrium, the method described in a previous paper[2] being employed. The amounts of solubilized dyes were determined by optical density measurements using a spectrophotometer, Shimadzu model B-60.

Results and Discussion

Molecular Weights and R_f-Values.—In Table I the molecular weights of the original PODE, obtained from the gain in weight by the addition of ethyhlene oxide, are compared with those of the purified PODE estimated from the freezing-point depressions and the terminal hydroxyl values.* Essentially, the molecular weights obtained from the freezing-point depressions should be equal to those obtained from the hydroxyl values, since both of these molecular weights are number-average molecular weights. The values shown in Table I indicate that they are nearly in agreement with each other and, at the same time, verify that PODE molecules do not form micelles in benzene over a considerably wide range of polyoxyethylene chain-lengths.

The variation in R_f-value with the polyoxyethylene chain-length, i. e., the value of p, is show in Fig. 1-a for the purified PODE and the original PODE containing a small amount of PEG (approximately 5%). Figure 1-b also illustrates the variation in R_f-value with the HLB-value for these samples. The R_f-values decrease with increasing values values of p or HLB. The values of purified PODE are slightly higher than those of the original PODE. On the other hand, the R_f-value of the PEG contained in original PODE seems

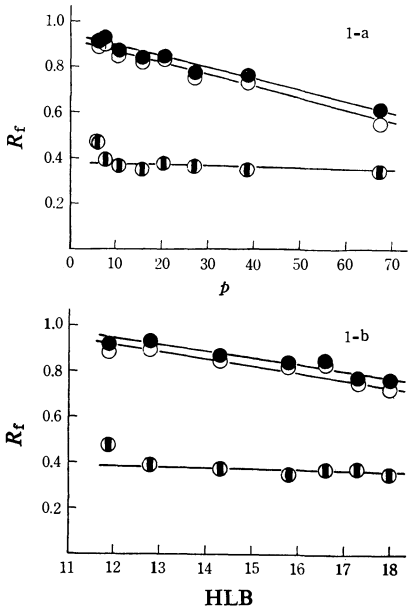

Fig. 1. Relationship between the R_f-value and the p-value (1-a) or the HLB-value (1-b) for purified (●) and original PODE (○), and PEG (◐).

a) The numbers listed after PODE represent the average numbers of oxyethylene units per molecule, which were obtained from the gain in weight by the addition of ethylene oxide.

to be nearly independent of the value of p or HLB.

Infrared Spectra and Surface Tension. — The infrared spectra of purified PODE are compared with those of original PODE. Some of these spectra are shown in Fig. 2, together with the spectrum of PEG. The spectra of the purified samples are identical with those of the original samples except for one absorption band. With purified PODE, a relatively strong absorption appeared at 1725 cm^{-1} up to the PODE value of p=15.8, as may be seen in Fig. 2-a. However, the original PODE and the purified PODE with p-values larger than 20.4 either showed no appreciable absorption at all or had a very weak absorption at 1725 cm^{-1}.

All the absorptions in the region of the frequencies lower than 1500 cm^{-1} have already been assigned by Davison.[5)] The absorption at 1725 cm^{-1} suggests the presence of carbonyl groups in the molecule of purified PODE, since carbonyl absorption is commonly observed around this frequency.[6,7)] The ether bonding in polyoxyalkylene compounds is known to be not very stable in the presence of heating, light, oxidizing agents, and so on.[8-11)] It is possible, therefore, to assume that a certain change occurs through autoxidation[9,10,12,13)] at the ether bonding in the PODE molecule during the course of purification, thus forming carbonyl group in the molecule, whatever the detailed mechanism is. Nemoto[13)] has suggested that the ether bonding of polyoxyethylated non-ionic surfactants is attacked by autoxidation.

Carbonyl absorptions will arise from the -COOH, -COOR, -CHO and >CO groups. If the above assumption is right, there is a possibility of finding one or more of these groups in the purified PODE. In fact, the acid values and the ester values** of all the PODE showing carbonyl absorptions were found to have a range of 10~14 and 11~16 respectively; these values are considered to be rather smaller than those expected from the intensity of the absorption observed. Qualitative tests with 2, 4-dinitrophenyl hydrazine[14)] and benzidine showed the presence of a trace of carbonyl groups, suggesting that the samples contain aldehyde and/or ketone groups. Thus, the reason why such a remarkable absorption appeared at 1725 cm^{-1} with purified PODE could be explained partially by the above data. However, the reason why this absorption was observed exclusively in the case of the PODE with p values smaller than 15.8 is not explainable clearly. Research is continuing to learn more about this problem.

The surface tensions of aqueous solutions of (a) original and (b) purified PODE and (c) the purified PODE to which 5% of PEG had been added to make the sample original were measured for the purpose of learning the effect of the carbonyl group, which was found in purified PODE, on the surface activity. Typical surface tension vs. concentration curves are shown in Fig. 3. The surface tension of PODE solutions is characterized by a sharp initial decrease, followed by a gradual flattening. The inflection of the curve corresponds

to the critical micelle concentration (CMC); it is not so sharp as that of the ionic surfactant because of the distribution of the molecular weights of PODE.

With the PODE with a p value of 7.6, curve c is more similar to curve a than to curve b, as may be seen in Fig. 3. This indicates that PEG has a tendency to make the surface tension higher below the CMC. However, no significant difference in surface tension among the curves of a, b and c could be observed. It could be considered, therefore, that the carbonyl group found in the purified sample by infrared absorption influences the surface activity not very strongly.

The Critical Micelle Concentration.—Figure 4 illustrates the solubilization curves, in which the amounts of solubilized dye are plotted against the concentrations of PODE. The solubilization behavior of PODE is somewhat different from that commonly observed for ionic surfactants. With ionic surfactants, scarcely any solubilization takes place until the concentration of surfactant reaches the CMC,[16] while in the case of PODE the amounts of dye solubilized increase gradually with the increasing concentration, even below the CMC. This may be explained by the following. The sample of PODE has a certain distribution of molecular weights, and some

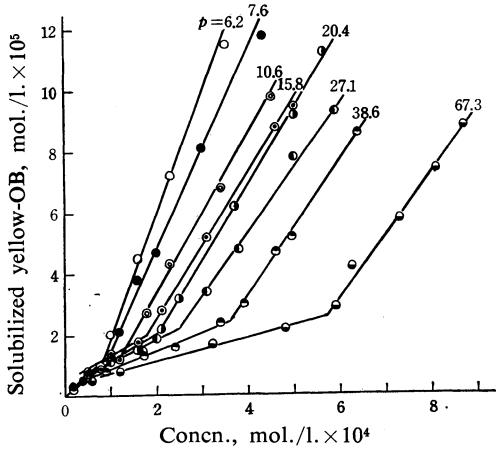

Fig. 4. Solubilization of yellow-OB vs. concentration of PODE curves at 30°C.

solubilization can take place in the region of the surfactant concentration which is lower than the CMC. A much more complicated micellar equilibrium, but which is fundamentally of the same type, appears to occur in non-ionic surfactant solutions.

Solubilization is generally regarded as an effect which begins to be noticeable at the CMC. The break point in the solubilization vs. concentration curve corresponds to the CMC. Table I shows the CMC values of PODE in relation to the chain-length of polyoxyethylene; they increase with the increase in the values of p. The CMC's obtained from the solubilization were relatively sharp as compared with those obtained from the surface tension. The CMC values of PODE are of an order of 10^{-4} mol., in agreement with the results of other investigations of polyoxyethylated surfactants.[17,18]

Concerning the relationship between the CMC value and the polyoxyethylene chain-length, Nakagawa and Kuriyama have already proposed a theory,[19] which is satisfactorily comparable with experimental results over a relatively limited range of chain-lengths, using methoxy polyoxyethylene decyl and dodecyl ethers.[17] Hsiao et al.[18] have also reported that, with aqueous solutions of Igepals (condensate products of alkyl phenol with ethylene oxide), the rate of increase in CMC values is given by the expression:

$$\ln (\mathrm{CMC}) = k + aR$$

where a and k are constants, and where R

represents the mole ratio of oxyethylene to phenol.

According to Hsiao et al., the logarithm of the CMC value given in Table I was plotted as a function of the polyoxyethylene chain-length, as is shown in Fig. 5-a. Such a straight line as he obtained was not obtained in the present experiment. However, if the ordinate is expressed on an ordinary scale, as is illustrated in Fig. 5-b, the relation between the CMC and p value seems to be rather linear; it can be written by:

$$\mathrm{CMC} = (0.30 + 0.083p) \times 10^{-4}$$

This equation indicates that the effect of the oxyethylene unit in the hydrophilic chain on the CMC value is not so marked as that of the methylene unit in the hydrophobic chain. It was reported that the CMC value is approximately doubled by decreasing the number of methylene groups in the hydrophobic chain by one.[15] This is in interesting contrast to the solubility phenomena, where an oxyethylene unit is equivalent to one methylene unit.[20]

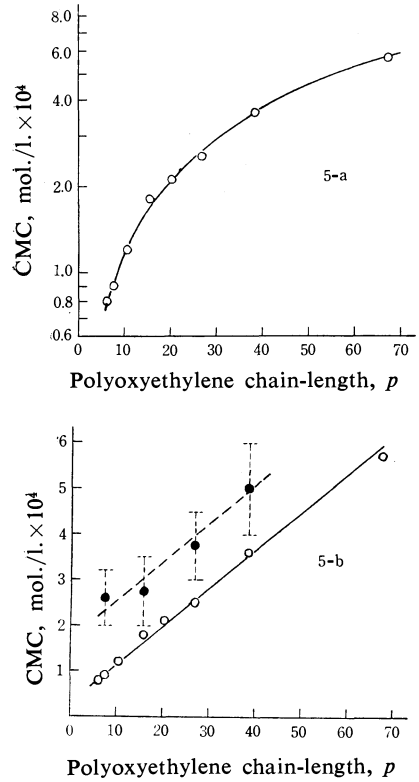

Fig. 5. The relationship between critical micelle concentration and polyoxyethylene chain-length; the ordinate is expressed in a logarithmic scale (5-a) and in decimal scale (5-b) (the dotted line represents the data from surface-tension measurements).

Summary

The fundamental properties of polyoxyethylene dodecyl ether (PODE) with different polyoxyethylene chain-lengths (p) have been studied over a wide range of p values. The molecular weights of the PODE, purified by the extraction method using water-saturated *n*-butanol and *n*-butanol-saturated water, have been determined by both the freezing point depressions of benzene solutions and the hydroxyl values of PODE; the molecular weights as determined by the different methods are in nearly complete agreement with each other. The R_f-values of the original samples containing small amounts of PEG are slightly lower than those of the purified samples, and the PEG contained in original samples show an almost constant R_f-value, irrespective of the p value.

The infrared spectra of purified PODE have been compared with those of the original ones. The spectra of the purified PODE with p-values smaller than about 16 exhibited a carbonyl absorption at 1725 cm^{-1}. However, the reason for this could be established only partially. The effect of the carbonyl group found in the above PODE on the surface tension of aqueous solutions was not observed distinctly.

The solubilization behavior of PODE differs somewhat from the behavior of ordinary ionic surfactants, and some solubilization can take place in the region of the surfactant concentration which is lower than the CMC. There appears to be a simple relationship between the CMC values, obtained from solubilization vs. concentration curves, and the p values of PODE over a wide range of p values.

The author wishes to express his hearty thanks to Professor Toshizo Isemura of Osaka University for his kind advice. He also wishes to express his appreciation to Mr. Zen'ichi Miyagawa, Director of this Laboratory, for the permission to publish this paper, and to Dr. Iwao Maruta for his encouragement.

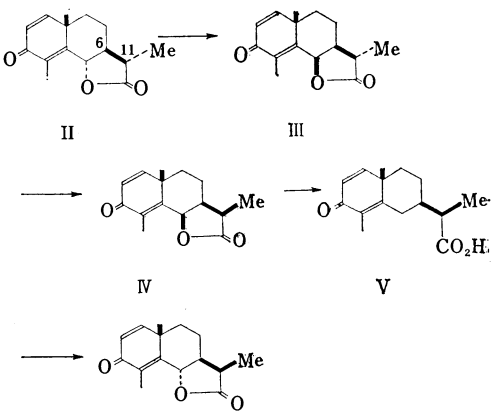
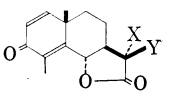
The Conversion of (−)-α-Santonin into (−)-β-Santonin

By Masao NAKAZAKI and Koichiro NAEMURA



(Received June 16, 1964)



(−)-β-Santonin (I), together with (−)-α-santonin (II), was isolated by Clemo from samples of *Artemisia* obtained from the North-West Frontier of India[1] and was shown to be the C_{11} epimer of (−)-α-santonin by various chemical correlations.[2] Recently, Cocker and McMurry[3] converted (−)-β-santonin into (−)-α-santonin by boiling it with potassium carbonate in a xylene solution, but the reverse transformation has not yet been accomplished.

Since we happened to need a quantity of (−)-β-santonin for a stereochemical study of eudesmane-type sesquiterpene, we have tried to convert (−)-α-santonin into difficult-to-obtain (−)-β-santonin. In this communication we will report a successful attempt to effect this transformation.

Thermodynamical stability of the C_{11} methyl group is affected very subtly by the modes of the lactone-ring junctures of the santonin series of compounds. When both the C_{10} angular methyl group and the C_7 side chain have β-configurations,[4,5] the α-configuration is the choice for the stable configuration of the C_{11} methyl group in the *trans*-lactone, as can be seen from the above-mentioned work of Cocker and McMurry.[6] However, in the *cis*-lactone the situation is completely reversed; β-configuration is now favored by the C_{11} methyl group. These stereochemical relations were dramatically demonstrated by the stereospecific decarboxylations[7,8] of the epimeric pair of the lactone-acids, VIa and VIb, with *trans*-lactone junctures and the epimeric pair of the *cis*-lactone acids, VIIa and VIIb, with *cis*-lactone junctures; the former gave racemic α-santonin (II) exclusively, and the latter yielded racemic 6-epi-β-santonin (IV). Barton and his co-workers[9] made use of these experimental facts when they treated (−)-6-epi-α-santonin (III) derived from (−)-α-santonin following Ishikawa's procedure,[10] with potassium *t*-butoxide to obtain (−)-6-epi-β-santonin (IV), which is eventually our starting material.

ring of IV with zinc powder afforded (−)-3-oxo-11-epi-eusantona-1,4-dienic acid (V),[11,12] b. p. 160～180°C/10^{-3} mmHg, $[\alpha]_D$ −107°.

The last of the synthetic sequence was achieved by selenium dioxide oxidation,[13] which has been shown to provide *trans*-lactone stereospecifically and which was successfully applied to the elegant total synthesis of (−)-α-santonin by the Takeda group.[14] This last operation afforded a 10% yield of (−)-β-santonin (I), m. p. 211～212°C, $[\alpha]_D$ −133° (in chloroform), the identity of which was established by mixed melting point determination and by a comparison of the infrared spectrum with an authentic sample of natural (−)-β-santonin,[15] as well as by the conversion into (−)-β-desmotroposantonin.

Experimental

(−)-6-Epi-α-santonin (III).—(−)-α-Santonin (II) was epimerized at C_6 according to the procedure of Ishikawa,[10] affording (−)-6-epi-α-santonin, m. p. 102～105°C, $[\alpha]_D^{10}$ −311° (*c* 1.5, ethanol); yield, 60%.

(−)-6-Epi-β-santonin (IV).—The epimerization of (−)-6-epi-α-santonin (III) at C_{11} was achieved following Barton's procedure.[9] Since the purification of III was accompanied by a considerable loss, the intermediate III was not purified but was directly converted into IV, m. p. 185～186°C, $[\alpha]_D^{10}$ −309° (*c* 0.56, ethanol), yield, 42% from (−)-α-santonin.

The Isomerization to (−)-β-Desmotroposantonin.—A solution of 0.1 g. of (−)-6-epi-β-santonin (IV) in 10 cc. of 55% sulfuric acid was kept at 55°C for 15 hr. Dilution with water precipitated crystals which were recrystallized from methanol to give needles, m. p. 250～252°C, $[\alpha]_D^{18}$ −115° (*c* 0.42, ethanol). A mixture of an equal amount of this (−)-β-desmotroposantonin with (+)-β-desmotroposantonin[2] was recrystallized from ethanol to yield racemic β-desmotroposantonin, m. p. 225～231°C.[2]

(−)-3-Oxo-11-epi-eusantona-1,4-dienic Acid (V).—To a solution of 3.6 g. of (−)-6-epi-β-santonin (IV) in 80 cc. of methanol, 8 g. of zinc powder was added. After 4 cc. of acetic acid had then been added, the reaction mixture was refluxed on a water bath for 8 min., cooled, and filtered. The solution was concentrated in vacuo to half volume and extracted with ether. After being washed with water, the ether solution was extracted with 10% aqueous sodium carbonate. The aqueous layer was made acidic with 2 N hydrochloric acid and extracted with benzene. The benzene extracts were combined, washed with water and a saturated sodium chlorine solution, and then dried over anhydrous magnesium sulfate. When the solvent was removed in vacuo, the residue ($[\alpha]_D^{13}$ −102° (*c* 3.0, ethanol)) was obtained; this was purified by chromatography on 80 g. of silica gel to yield 3.0 g. of a viscous oil. Distillation afforded a pale yellow liquid, b. p. 160～180°C (bath temperature)/10^{-3} mmHg, $[\alpha]_D^{24}$ −107° (*c* 3.8, ethanol). An ultraviolet spectrum in ethanol indicated a peak at 240 mμ (log ε 4.03).

Found: C, 71.25; H, 8.30. Calcd. for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Cyclohexylamine Salt.—The salt was recrystallized from ethyl acetate to yield needles, m. p. 173～174°C, $[\alpha]_D^{24}$ −54.7° (*c* 0.7, ethanol).

Found: C, 72.30; H, 9.44; N, 4.01. Calcd. for $C_{21}H_{33}O_3N$: C, 72.58; H, 9.57; N, 4.03%.

2,4-Dinitrophenylhydrazone.—The 2,4-dinitrophenylhydrazone was prepared by the usual procedure and recrystallized from ethanol to give red needles, m. p. 216～218°C.

Found: N, 13.26. Calcd. for $C_{21}H_{24}O_6N_4$: N, 13.08%.

(−)-β-Santonin (I).—A mixture of 1.1 g. of the acid V, 1.1 g. of selenium dioxide, 22 cc. of acetic acid and 0.4 cc. of water was refluxed for 6 hr. The solution, freed from the selenium which precipitated, was then concentrated in vacuo, and the residue was extracted with benzene. The benzene extract was washed with water, 5% aqueous sodium carbonate, and water successively, and dried over anhydrous sodium sulfate. When the solution was concentrated, a crystalline solid separated. The product was filtered and recrystallized from methanol to give 0.1 g. of crystals, m. p. 211～212°C, $[\alpha]_D^{24}$ −133° (*c* 0.46, chloroform). A mixed melting point determination with an authentic (−)-β-santonin gave no depression. The identity was further confirmed by the infrared spectra of the synthetic and natural product, which were indistinguishable.

Found: C, 73.04; H, 7.44. Calcd. for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%.

The Isomerization to (−)-β-Desmotroposantonin.—A solution of 50 mg. of the synthetic (−)-β-santonin (I) in 2 cc. of 55% sulfuric acid was kept at 55°C for 15 hr. The crystals, which were deposited upon the addition of water were recrystallized from methanol to give needles, m. p. 251～253°C. The mixed melting point with (−)-β-desmotroposantonin obtained from (−)-6-epi-β-santonin (vide supra) was 250～252°C.

Found: C, 72.66; H, 7.52. Calcd. for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%.

We are much indebted to the Nitto Kasei Co. for its financial support and to Dr. Toyohiko Kawatani, The National Hygienic Laboratory, Tokyo, for his generous gift of natural (−)-β-santonin. This work was partially supported by a grant-in-aid for fundamental scientific research from the Ministry of Education, to which the authors' thanks are due.

*Carbonyl Absorption Bands in the Infrared Spectra of Some Cyclic Imides with a Five-membered Ring**

By Taku MATSUO

(Received June 18, 1964)

Organic acid anhydrides always show two characteristic absorption bands in the 1750~1850 cm^{-1} region of their infrared spectra. It was originally suggested that these two bands come from a mechanical coupling of the two carbonyl groups in acid anhydrides.[1] Bellamy and his coworkers observed a parallel correlation between the variations in the frequencies of the two absorption bands of acid anhydrides in many solvents with widely different polarities, and concluded that both bands could be assigned to carbonyl absorptions.[2] Since the relative intensity of the higher frequency absorption band decreases as the acid anhydride forms a closed ring, Dauben and Epstein,[3] as well as Bellamy et al.,[2] considered the higher and the lower frequency absorptions to be due to the in-phase and out-of-phase vibrations respectively of the two carbonyl groups.

Many cyclic imides[4] are also known to have two characteristic absorption bands similar to the split carbonyl absorption bands of acid anhydrides described above. The carbonyl groups of both acid anhydride and cyclic imide are characterized by a structure, O=C–X–C=O where X is an atom carrying lone-pair electrons. Mirone and Chiorboli suggested, in their study of the vibrational spectra of maleic anhydride,[5] that the splitting of the carbonyl absorption is mainly due to the electronic stabilization of the out-of-phase vibration through a contribution of the ionic structures, $O^-–C=O^+–C=O$ and $O=C–O^+=C–O^-$. A quite analogous situation would be expected for derivatives of cyclic imide where two carbonyl groups are connected by a nitrogen atom. The nature of one substituent, R, on the imide group would determine the relative importance of the ionic structures, $O^-–C=\underset{\displaystyle R}{N^+}–C=O$ and $O=C–\underset{\displaystyle R}{N^+}=C–O^-$. Therefore, the extent of the splitting of the carbonyl absorptions is expected to be different when the infrared spectra of a series of *N*-substituted cyclic imides are compared. The infrared spectra of *N*-substituted derivatives of maleimide, phthalimide and succinimide will be examined and their carbonyl absorption bands compared in this paper.

Experimental

Phthalimide was purchased from Wako Pure Chemical Industries, Ltd., and was used after repeated recrystallizations from ethanol. *N*-Methylphthalimide was prepared from potassium phthalimide and methyliodide by a conventional method. Smith and Emerson's method[6] was used to synthesize *N*-*t*-butylphthalimide. *N*-Cyclohexyl-, *N*-benzyl- and *N*-(substituted phenyl)-phthalimides were prepared by the dehydration of the corresponding phthalamic acids by heating them above 200°C. The products were treated with activated charcoal in acetic acid and were purified by repeated recrystallizations from either methanol or benzene.

Maleimide was prepared from furan-maleic-anhydride adducts according to the procedure of Berson and Swidler.[7] *N*-Ethyl- and *N*-arylmaleimides were made from the corresponding maleamic acids through dehydration by the use of sodium acetate and acetic anhydride at 100°C. *N*-Cyclohexyl- and *N*-benzylmaleimides were prepared from (±)-malic acid and cyclohexlamine and benzylamine respectively.[8]

Succinimide was prepared by heating succinic anhydride with aqueous ammonia. All of the *N*-substituted succinimides were prepared by dehydrating the corresponding succinamic acids in a bath maintained between 200°C and 220°C.

The substituents on the nitrogen atom of the imides investigated and their melting points as measured on a Kofler micro-hot stage are listed below:

Phthalimides: hydrogen, 241; methyl, 136; *t*-butyl, 60; cyclohexyl, 174; benzyl, 118; phenyl, 212; *o*-tolyl, 185; *m*-tolyl, 174; *p*-tolyl, 209; *o*-methoxyphenyl, 158; *m*-methoxyphenyl, 126; *p*-methoxyphenyl, 164°C.

Maleimides: hydrogen, 93; ethyl, 44; cyclohexyl, 89; benzyl, 70; phenyl, 90; *p*-tolyl, 155; *p*-methoxyphenyl, 155°C.

Succinimides: hydrogen, 125; benzyl, 104; phenyl, 158; *p*-tolyl, 157; *p*-methoxyphenyl, 166°C.

The infrared spectra were measured with a Nihon Bunko model DS 301 double-beam infrared spectrophotometer with sodium chloride optics. Benzene and acetonitrile were used as solvents. The spectra were obtained with the solution (of the order of $\sim 10^{-2}$ M) in closed cells 0.05, 0.1 or 1 mm. thick.

Experimental Results and Discussion

In general, the two carbonyl absorption bands can be easily identified in the infrared spectra of *N*-substituted phthalimides and succinimides. Typical examples are shown in Fig. 1 and Fig. 2 for *N*-methylphthalimide and *N*-benzylsuccinimide respectively. The higher frequency band with a low intensity is indicated by H, and the counterpart with a low intensity on the lower frequency side is denoted as the L band. *N*-Substituted maleimides, however, do

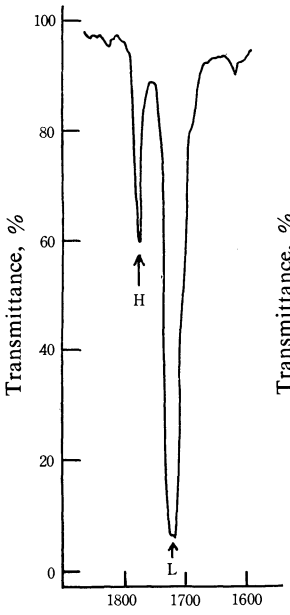

Fig. 1. Carbonyl absorption bands of *N*-methylphthalimide.

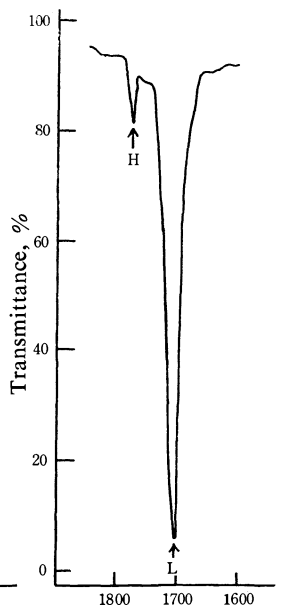

Fig. 2. Carbonyl absorption bands of *N*-benzylsuccinimide.

not show well-defined peaks to be assigned to the H bands in their spectra obtained in the solution. The higher frequency bands appear a little more clearly if the spectra are measured in solid states. Examples can be seen in the spectra of *N*-phenylmaleimide as shown in Fig. 3.

The carbonyl absorption bands, ν_H and ν_L, of the compounds investigated are summarized in Tables I, II and III.

For all types of imides studied, ν_L varies more sensitively than ν_H does upon the substitution on the nitrogen atom. The quotient,

a) A and B stand for acetonitrile and benzene respectively.
b) Frequency of the low-intensity band.
c) Frequency of the high-intensity band. The center of the band was taken as ν_L when the shape was rather broad.
d) $Q=(\nu_H-\nu_L)/(\nu_H+\nu_L)$.
e) Two strong bands were observed at the location of the L band. The intensity ratio of the two bands varies with the solvent. Therefore, the two bands were considered to be a doublet due to the Fermi resonance between the true L band and another band of unknown nature. The central position of the doublet was then used to calculate the value given here.

$(\nu_H-\nu_L)/(\nu_H+\nu_L)$, or Q as given in the tables, was calculated from the data as a measure of the coupling of the carbonyl groups. The Q-values shown in the fifth columns of Tables I, II and III also appear to be dependent on the type of substituent on the nitrogen atom.

The effect of substitution on the nitrogen atom can be seen most clearly in the series of phthalimide derivatives. The substituents here can be classified into three groups depending on the type of atom directly attached to the imide group. Phthalimide, with a hydrogen atom at the nitrogen atom instead of the substituent, makes up the first group by itself. The values of ν_L and Q are the largest and the least respectively among the phthalimide series. The second group consists of compounds where substituents are attached to the imide group through the carbon atom of sp^3 hybridization. *N*-Alkyl- and *N*-benzylphthalimides belong to this group. Considerably lower ν_L-values are observed for the compounds of this group in comparison with that of phthalimide. The Q-values become larger in turn. In the third group, where the substituents are aromatic, ν_L and Q are close to those of the second group. A minor variation is observed when the phenyl group attached to the nitrogen atom has substituents of a different electronic nature.

Three factors are considered to be important in analyzing the effects of a substituent on the splitting of carbonyl absorptions summarized above;

(1) the effect of the mass of a substituent, R, on the vibrational mode of the absorption in question,
(2) the electronic factors which affect the π-electron system of imide the group, and
(3) the steric strain in the five-membered ring of the imide group.

The large difference between phthalimide and its *N*-substituted derivatives might be due to the first factor. Considering the little difference observed between the carbonyl absorption bands of *N*-methyl- and *N*-*t*-butylphthalimides, however, it seems reasonable to conclude that the effect of mass is almost negligible and that the vibrational mode is fairly well localized on carbonyl groups. Hydrogen bonding in phthalimide can not give the answer either, since the effect should be in the reverse direction.[9] The electronic factor, to be considered next, determines the extent of the contribution of the ionic structures, O^-–C=N^+(R)–C=O and O=C–N^+(R)=C–O^-, in the imide system. Other things being equal, an electron-donating substituent is preferred in stabilizing the ionic structures under discussion. The effect of this type could be best measured by the Hammet's sigma-values or other similar parameters representing the electronic character of a substituent. Then the extent of the stabilization of the ionic structures by a substituent, R, is expected to be in the following order;

alkyl group > hydrogen ≅ aromatic group.

The observed values of ν_L and Q indicate an order far from the prediction. Thus it is clear that some factors other than the simple electronic effect are also important. One of the factors is the steric requirement for the lone-pair electrons to be used in conjugation with the carbonyl groups. Lumbroso and

9) C. M. Lee and W. D. Kumler, *J. Am. Chem. Soc.*, 83, 4586 (1961).

Dabard[10] measured the dipole-moments of phthalimide and *N*-methylphthalimide and estimated that the N–R bonds make angles between fifty and sixty degrees in relation to the planes of the imide groups. The angles correspond to the case where the nitrogen atom uses orbitals close to sp^3-hybridization. Lumbroso et al.[11] also suggested that *N*-phenylphthalimide takes an axial and planar conformation, implying sp^2-hybrid orbitals for the nitrogen atom. The change of hybridization from the sp^3 to the sp^2 type facilitates the electron release from the nitrogen atom to carbonyl groups and stabilizes the ionic structures discussed above. The investigation of the longest wavelength absorptions in the electronic spectra of phthalimide series[12] also indicates that the extent of electron donation from the nitrogen atom to the carbonyl groups increases as the substituent is changed in the order of hydrogen, alkyl- and aryl groups. Therefore, it is quite reasonable that the ν_L-values of *N*-arylphthalimides are much less than that of phthalimide itself, contrary to the prediction based on their sigma-values. Reasoning along this line can not account for the fact that the ν_L-values of *N*-alkylphthalimides are close to (or rather less than) those of *N*-arylphthalimides. The only factor left to be considered at this point is the steric strain of the imide ring. The carbonyl absorptions of glutaric anhydride, for example, are observed at considerably lower frequencies (1812 and 1764 cm^{-1}) than those (1863 and 1790 cm^{-1}) of succinic anhydride. The existence of steric strain in the five-membered ring of succinic anhydride is certainly responsible for the shift of its carbonyl absorptions to higher frequencies. A similar strain should be expected for the five-membered rings of phthalimide and its derivatives. The size of the cyclic imide ring, however, may be somewhat different for various types of the hybridization of the nitrogen atom in an imide group. Thus, the ring strain is expected to be dependent on the particular substituent on the nitrogen atom. According to the ν_L-values, the alkyl groups apparently relieve the ring strain to a better extent than do aryl groups. Similar trends were observed also for alkyl- and aryl groups as the *N*-substituents of maleimide and succinimide, as will be discussed later.

The behavior of *N*-arylphthalimide is strongly correlated to the electronic effect of the substituent on the phenyl group. If the steric arrangements are taken as the same among the compounds of this group, the stabilization of the ionic structures of the imide system should be directly affected by the electronic nature of a substituent on the phenyl group. Arranged in the order of decreasing ν_L or increasing *Q*-values, the substituents on the para position give the series;

hydrogen < methyl group < methoxyl group;

and the effects of substituting positions for a given substituent (CH_3 or OCH_3) are;

meta < ortho < para.

These orders agree, qualitatively, with the prediction based on the linear free energy relationships, such as Hammet's sigma-values, of the substituents.

Potassium phthalimide presents a case where the substituent, R, is formed of the paired electrons responsible for the negative charge on the nitrogen atom. Therefore, the extent of the contribution of the ionic structures is expected to be the greatest among the phthalimide series. The carbonyl absorptions in the infrared spectra of potassium phthalimide in the solid state are shown in Fig. 4. The lower frequency absorption is split into a triplet for some unknown reasons, so the center of the triplet is taken tentatively to be ν_L. Both carbonyl absorptions, ν_H and ν_L, are shifted to a considerably lower frequency region, and the *Q*-value is the largest among the phthalimide series, just as expected.

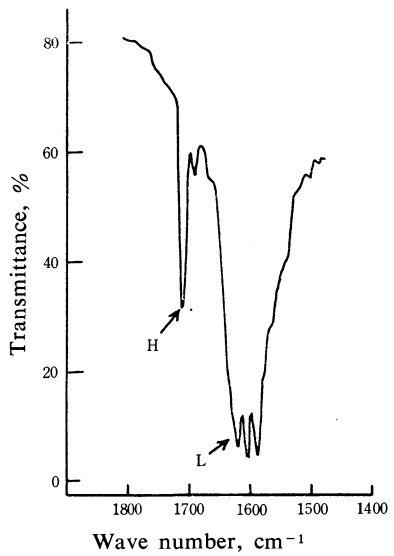

Fig. 4. Carbonyl absorption bands of potassium phthalimide (Nujol).

The carbonyl absorptions of both the succinimide and the maleimide series show a

dependence on their substituents similar to that observed in the phthalimide series. The frequencies of the high intensity absorptions increase in the following order for both series;

N-alkylimides < *N*-arylimides < imide itself.

The minor variation observed in the carbonyl absorptions of *N*-(substituted phenyl)-phthalimides can hardly be noticed in the cases of the corresponding derivatives of succinimide and maleimide. On the other hand, the investigation of the electronic spectra[12] of *N*-substituted maleimides, as shown in Fig. 5,

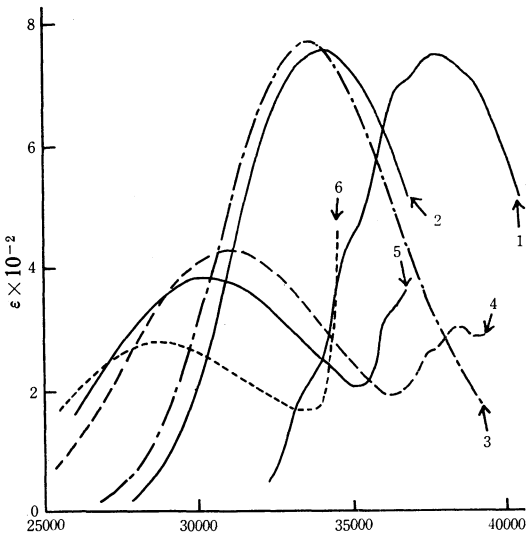

Fig. 5. The absorption spectra of maleimide and its *N*-substituted derivatives in *n*-hexane: 1, maleimide; 2, *N*-ethylmaleimide; 3, *N*-cyclohexylmaleimide; 4, *N*-phenylmaleimide; 5, *N*-(*p*-tolyl)-maleimide; *N*-(*p*-methoxyphenyl)-maleimide.

indicates a trend in the effects of the substituents similar to that mentioned in the phthalimide series. When the substituent is changed in the order of hydrogen, methyl, phenyl, *p*-tolyl and *p*-methoxyphenyl, the longest wavelength absorption band shows a steady red shift as the result of the increase in electron donation from the nitrogen atom to the carbonyl groups. Therefore, the electronic factors apparently have much less effect on the frequencies of carbonyl absorptions in the infrared spectra of maleimide and succinimide derivatives than in the cases of *N*-substituted phthalimides. Because the five-membered ring is fused to the phenyl group in phthalimide derivatives, the framework of the imide system is expected to be fairly tight in this series. On the other hand the corresponding derivaties of succinimide and maleimide have a rather flexible ring system since only hydrogen atoms are attached to the C–C bond joining the carbonyl groups. Thus, the electronic effect of a substituent on the carbonyl frequencies seems to be reduced when the rigidity of the imide ring decreases.

Another problem raised in the infrared spectra of the maleimide series is the extremely low intensity of its higher frequency carbonyl absorption. Judging from the high intensity of the corresponding band in the Raman spectra[13] of maleimide, there seems to be little doubt that the band is due to a symmetrical vibration of the carbonyl groups. The absorption band of the same nature is relatively strong in the infrared spectra of maleic anhydride, the π-electron system of which is isoelectronic to that of maleimide. Thus, the exact answer to this intensity problem is not known at present; the question must be left for future study.

In summary, the lower frequency carbonyl absorption bands of cyclic imides have been found to be strongly affected by the substituent on the nitrogen atom. The effects can be explained in terms of the following factors;

(1) the extent of electron donation from the nitrogen atom, and
(2) the steric strain in the five-membered ring.

The higher frequency carbonyl bands, however, are much less sensitive to these factors. Further study of the problem by means of the normal coordinate treatment, in correlation with the above observations, is expected to reveal the true nature of the two carbonyl absorption bands in the infrared spectra of acid anhydrides and cyclic imides.

The author wishes to thank Miss Yuko Tomita for her help in the measurement of the infrared spectra reported in this paper.

*Physical Properties and Structure of Polyacetonitrile**

By Eizo OIKAWA** and Shu KAMBARA

(Received June 18, 1964)

Although many kinds of polymeric semiconductors have been synthesized, most of them have consisted of carbon-carbon conjugated systems. When nitrogen, which has a free pair of electrons, is involved in a linear conjugated system, it may be expected that polymer will have different properties than when involved in a carbon-carbon conjugated system. Thus, the polymer of a linear alternate carbon-nitrogen conjugated sequence seems to be an interesting object for studies of physical and chemical properties.

As a polymer that has carbon-nitrogen conjugated double bonds, the polymer of cyanic acid is well known. This, however, is not a pure linear polymer of carbon-nitrogen conjugated double bonds; rather, it appears to have a ladder-like structure.[1] The same type of polymer was recently produced from cyanic acid under irradiation.[2] These polymers of cyanic acid have a low degree of polymerization, and their electric conductivity has not been measured. Other examples of polymerization by irradiation are the solid phase polymerization of nitriles at low temperatures[3] and the ring-opening polymerization of cyanuric chloride,[4] but the yield and the molecular weight of both polymers appear to be small.

Thermally-degraded polyacrylonitrile[5,6] and polycopperphthalocyanine[7] are of this type as well. The former has a considerably high electric conductivity when it is heated at a high temperature (e. g., 500°C); the latter also has good electric conductivity.

Recently Kargin et al. synthesized a linear polymer of carbon-nitrogen conjugated double bonds by heating the complex of acetonitrile with zinc chloride; they then examined the electrical properties of the polymer.[8] The same type of polymer has also been synthesized by high voltage discharge, although it has a low molecular weight.[9]

We have studied the polymerization of acetonitrile complexes with several kinds of metal chlorides and have reported the correlations of the infrared shifts of the nitrile-stretching frequency in the Lewis acid complexes with the polymerizability.[10] Moreover, we have obtained some information concerning the properties and structure of the polymer.

Experimental

Materials.—The metal chlorides used are titanium tetrachloride, zirconium tetrachloride, stannic chloride, aluminum chloride, gallium chloride, ferric chloride, and zinc chloride. Commercial reagents were used, including acetonitrile, but gallium chloride was prepared from gallium metal and hydrogen chloride[11] and was purified by sublimation.

Acetonitrile was used after distillation and drying over calcium hydride.

Titanium tetrachloride and stannic chloride were distilled just before the preparation of the complex.

Ferric chloride, zirconium tetrachloride and aluminum chloride were purified by sublimation.

For zinc chloride, a guaranteed reagent was used after drying it at an elevated temperature under reduced pressure.

The Preparation of Complexes.—The distillate or the solid mass of metal chloride was cooled with dry ice-methanol or liquid nitrogen in a flask, into which a little more than the calculated amount (molar ratio $RCN/MX_n=2/1$) of the acetonitrile was added drop by drop in an atmosphere of nitrogen. The excess nitrile was then distilled off under reduced pressure. The complexes were purified by sublimation. Since ferric chloride, zinc chloride and gallium chloride complexes could not be sublimed, these three chlorides were carefully purified before preparation. The complexes were handled afterwards in a dry box because they are easily decomposed, even by moisture in the air.

The properties and analyses of the complexes have been given in a previous publication.[10]

Polymerization.—After having been rinsed with nitrogen, a definite amount of complex was sealed into a thick-wall ampoule under the reduced pressure of 10^{-2} mmHg. The ampoule was then heated in a controlled electric furnace for the required time. The product prepared from the complex was powdered, and water was added. The product was filtered and washed repeatedly with distilled water or diluted hydrochloric acid, since water readily decomposes the complex and dissolves metal chlorides. When the heating time was shorter or the temperature was lower, the filtration was often difficult. Then a centrifuge was used. The infrared spectrum of the filtrate did not show the absorption due to the C=N conjugated double bond at about 1600 cm^{-1}. This suggests that the polymer is scarcely dissolved at all in the filtrate.

Most of the polymers obtained were dark brown to black and were insoluble in common organic solvents, although they were soluble in mineral acids.

The Addition of Silver Nitrate.—About 0.1 g. of a polymer was dispersed in an aqueous 1/10 N silver nitrate solution for 24 hr. at an ordinary temperature. The dispersed liquid was then filtered, and the residue was washed repeatedly with distilled water.

The Measurements of Physical Properties. — 1) The X-ray diffraction measurements were carried out using Cu$K\alpha$ of 30 kV., 20 mamp., and a scanning speed of $2\theta=2°$/min.

2) The infrared absorption spectra were obtained by the usual KBr-pellet method.

3) The intrinsic viscosities of the polymers in sulfuric acid were measured at 40 ± 0.03°C using a modified Ubbelohde viscometer. Since the value of the intrinsic viscosily and the linear gradient of η_{sp}/c versus c did not vary when the same solution was measured again after a week, the polymer in sulfuric acid does not seem to be degraded.

4) The electric conductivity, σ, was measured under the pressure of 90 kg./cm^2. The current was measured with a vibration-reed electrometer. The temperature was raised by 0.5°C/min. from room temperature to about 100°C. The energy gap, ΔE_g, can be determined from the gradient of log σ versus $1/T$:

$$\sigma=\sigma_0\exp(-\Delta E_g/2\boldsymbol{k}T) \quad (1)$$

5) Stable unpaired electrons included in the polymers were observed with an ESR spectrometer at the Nissei Industry Co. Ltd.

Results and Discussion

Electric Conductivity.—The electric conductivity values of 10^{-10} to 10^{-5} $\Omega^{-1}cm^{-1}$ summarized in Table I indicate that the polymer is a semiconductor. The electric conductivity increases and the activation energy decreases when the heat treatment of the complex is increased at a given temperature or at a given

heating time. This suggests that the formation of conjugated double bonds becomes more extensive in the polymer at a higher temperature and a longer heating time, while Eley et al. have shown that ΔE_g decreases to a limiting value as the number of conjugated double bonds increases.[12]

TABLE II. ADDITION OF SILVER NITRATE TO THE POLYMERS

No.	Wt. increase g./g. polymer
T234	0.487
T238	0.516
T254	0.311
T258	0.417
T304	0.419
T308	0.177
T354	0.288
T358	0.590

The number of conjugated π electrons in a polymer chain can be estimated from ΔE_g in Table I if Eley's calculation for a carbon-carbon conjugated system may be applied to a carbon-nitrogen conjugated system. The numbers obtained in this way were 17 for Z254 (ΔE_g= 1.22) to 50 for F354 (ΔE_g=0.40). One-half of this value is the mean number of conjugated double bonds if the polymer is regarded as a completely linear carbon-nitrogen conjugated chain.

The products from the ferric chloride complex show the greatest change in σ at a given change in the heating temperature.

The Addition of Silver Nitrate.—The weight increases in polymers upon the addition of silver nitrate are shown in Table II. They are sizable and seem to be due to chemisorption rather than to mere adsorption. Since the C=N bonds characteristically take up noble metal ions, these considerable weight increases support the idea that the polymer contains C=N bonds.[1] However, the values are not strictly reproducible because they depend on the surface area of the powdered samples.

X-Ray Diffraction. — In X-ray diffraction patterns no sharp peak could be seen, but the 2θ=25° peak (d=3.56 Å) is comparable with that of phthalocyanine (2θ=26°, d=3.38 Å),[13] consisting of a big circular carbon-nitrogen conjugated system. If parts of the resulting polymer are considered to form a band-like structure, the value of 3.56 Å would correspond to the distance between the bands.

It was found that polymers produced in a shorter heating time and at a lower temperature had a higher intensity of diffraction, probably indicating that these polymers have a relatively high regularity.

Electron Spin Resonance.—All the samples showed singlet spectra, as are seen in polyacetylene,[14] under the measuring conditions (Fig. 1). The g-factors were estimated to be from 2.0046 to 2.0003, but most of them have the value of nearly 2.0023, which is the value of a free electron. Hence, the unpaired electrons in polyacetonitrile are believed to be stabilized by resonance energy in a highly conjugated system and to be in a state similar to that of free electrons.

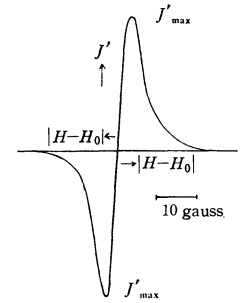

Fig. 1. ESR derivative curve of A352.

The relative spin concentrations in each group of metal chloride decreased with the temperature except for the Z-group and the G-group (products of the gallium chloride complex), in which the concentrations increased with the temperature; this has not yet been explained reasonably.

According to the method of analysis of the line shape proposed by Tikhomirova and Voevodskii,[15] the Gaussian (2) and Lorentzian (3) equations may be described, as respectively:

$$\log(y/J') = a^2y^2/2.3 + \log(0.427/J'_{max}\ a) \quad (2)$$

$$\sqrt{y/J'} = 0.57/\sqrt{bJ'_{max}} + (0.57b\sqrt{b}/\sqrt{J'_{max}})y^2 \quad (3)$$

where $a^2=1/1.45\ \Delta H_G{}^2$, $b^2=1/\Delta H_L{}^2$, $y=H-H_o$, and J' represents the ordinate (arbitrary unit) in a differential spectrum (Fig. 1).

ΔH_G and ΔH_L are obtained from the slope of the linear part in Eqs. 2 and 3 respectively. The value of ΔH corresponding to the transition region between 2 and 3 is ΔH_e. An example is illustrated for A352 in Figs. 1 and 2. Figure 2 suggests that the ESR line investigated is Lorentzian in the center, but Gaussian beyond ΔH=7.6 gauss.

a tendency for ΔH_G and ΔH_e to decrease simultaneously with the increase in the heating temperature. This is more clearly illustrated in Fig. 3. This decrease may not be clear between different complex groups at the same temperature, or at the difference of about fifty degrees, but when the temperature is raised from 230°C to 370°C, distinct decreases in ΔH_G and ΔH_e appear.

The outstanding decreases of ΔH_G and ΔH_e in the pyrolysis of polyvinyl chloride have been explained as resulting from the increase of C=C conjugated double bonds in the process of dehydrochlorination, together with the formation of aromatic rings between polymer chains.[15] The extension of the conjugated system will bring about a delocalization of electrons and an exchange interaction between

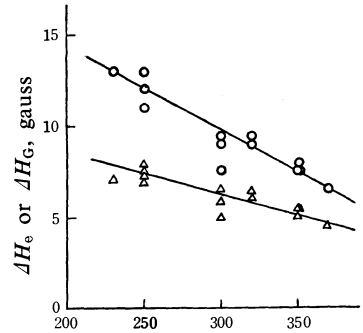

Fig. 3. Correlation of ΔH_e and ΔH_G with heating temperature.
○: ΔH_e, △: ΔH_G

unpaired electrons, resulting in a gradual decrease of ΔH_G and ΔH_e. A similar explanation could be applied to polyacetonitrile. A higher heating temperature will bring about not only the extension of the C=N conjugated system, but also a cross-linking between polymer chains, which may decrease ΔH_G and ΔH_e. The cross-linking is expected from the experimental fact that ammonia was detected after polymerization, and from the results of a noncrystalline pattern of X-ray diffraction, infrared spectra, viscometric measurements (Fig. 5), and elementary analyses (Table IV).

Infrared Absorption. — An infrared spectrum of polyacetonitrile is shown in Fig. 4, where

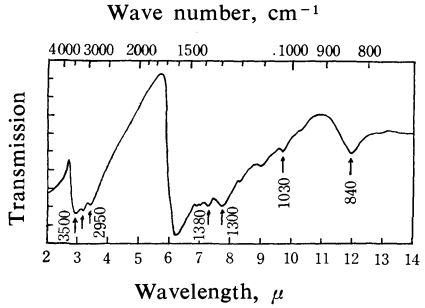

Fig. 4. Infrared spectrum of A304.

the absorption at 2247 cm^{-1} due to the nitrile groups completely disappears and a new strong absorption at 1600 cm^{-1} appears, one which is due to the sequence of C=N bonds, presumably also contributed by C=C double bonds resulting from the separation of ammonia. The existence of C=C double bonds is also supported by the decoloration of a neutral dilute potassium permanganate solution at an ordinary temperature. The oxidation of CH_3 and C=N groups needs more severe conditions. Moreover, a second new absorption, at 840 cm^{-1}, appears; this does not appear in the spectrum of acetonitrile. This absorpition may be due

b) Experimental formula: $C_{15}H_{13}N_4O_2$
c) Calculated value for CH_3CN

to the C–H in $>C=\underset{\underset{H}{|}}{C}-$, and probably >N–H. The absorptions at 2950, 1380, 1300 and 1030 cm^{-1} are weak, but they may be assigned to CH_3 groups. The absorptions at 3200 and 3500 cm^{-1} may be due to imine, amine or hydroxyl groups.

It may be reasonable to consider that the metal halide behaves as a cationic reagent with a trace of water and gives rise to cationic polymerization, nearly as in the case of the heating of polyacrylonitrile,[16] as follows:

$$n\,N\equiv\underset{\underset{R}{|}}{C} + H^+[MX_n(OH)]^- \rightarrow$$

$$HN=\underset{\underset{R}{|}}{C}-(-N=\underset{\underset{R}{|}}{C})_{n-1}{}^+[MX_n(OH)]^- \rightarrow$$

$$HN=\underset{\underset{R}{|}}{C}-(-N=\underset{\underset{R}{|}}{C}-)_{n-1}-OH + MX_n \qquad (4)$$

The experimental fact of separation of ammonia may be brought about by pyrolysis when the complex is heated for a longer time; it gives, for example, the following change in the structure of the polymer:

$$\begin{array}{l} CH_3 \\ NH=C-N=C- \\ \qquad\quad | \\ \qquad CH_3 \\ H_2CH \\ -N=C-N= \end{array} \xrightarrow[-NH_3]{} \begin{array}{l} CH_3 \\ C-N=C- \\ \| \quad\quad | \\ HC \quad CH_3 \\ -N=C-N= \end{array} \qquad (5)$$

This change is supported to some extent by the obscure absorptions due to CH_3 groups, and by the electric conductivities, the oxidation test and ESR analyses. It is also supported by the elementary analyses of the polymers given in Table IV.

It should be noted that the polymers of a highly conjugated system find it difficult to combust completely.

The simultaneous decreases in H and N contents corresponding to increases in the C/H and C/N ratios are attributed to the evolution of ammonia. These changes and the considerable oxygen content indicate that polyacetonitrile may consist of not completely conjugated double bonds of carbon-nitrogen, together with other groups containing oxygen. The followings will be most probable means of the introduction of oxygen into the polymer;

(a) The oxidation of the C=C bond which may be formed in the separation of ammonia. This oxidation is predominant in polyacetylenes.[14]

(b) Hydroxyl groups of polymer end as given in Eq. 4. This contribution to the introduction of oxygen will be small.

It can not be concluded from the infrared spectrum whether or not the polymers have carbonyl groups, because the band due to the carbonyl groups will overlap the band due to the C=N bonds.

Viscometric Measurements. — The intrinsic viscosities $[\eta]$ of the polymers from the titanium terachloride complex versus polymer yields and t^2 (t=heating time, hr.) are shown in Fig. 5. If the polymer consists of a linear chain, then $[\eta]$ versus t^2, as Kargin et at. indicated,[8] should be linear through the origin. However, the linear line greatly deviates from the origin. This fact and an unusual increase in $[\eta]$ with the increase in yields support the structual change illustrated in Eq. 5.

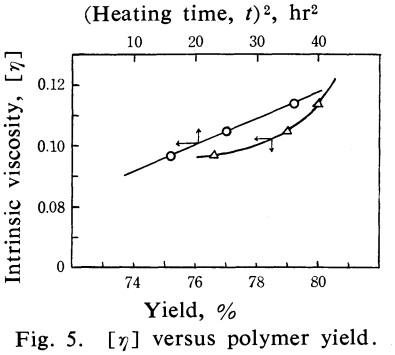

Fig. 5. $[\eta]$ versus polymer yield.

Summary

The fact that a polymer containing C=N double bonds is formed from saturated nitrile

16) W. J. Burlant and J. L. Parsons, *J. Polymer Sci.*, **22**, 249 (1956).

complexes with metal chlorides is supported by the infrared absorption at about 1600 cm^{-1} and the characteristic addition of silver nitrate. The polyacetonitrile has an electric conductivity from 10^{-10} to 10^{-5} $\Omega^{-1}cm^{-1}$ and an energy gap from 0.4 to 1.2 eV., indicating that the polymer is an organic semiconductor.

The electric conductivity increases and the energy gap decreases with increases in the heating time and temperature, suggesting a more extensive formation of a conjugated system, including also C=C double bonds among polymer chains at a higher temperature. This theory is supported by the evolution of ammonia, resulting in simultaneous decreases of the H and N contents of the polymer, the appearance of the absorption at 840 cm^{-1}, by oxidation by potassium permanganate, by analyses of ESR line shapes, and by viscometric measurements. This structual change may bring about a noncrystalline pattern in X-ray diffraction. Therefore, it is indicated that polyacetonitrile does not have a complete C=N conjugated sequence because of some pyrolysis, accompanied by the extension of a conjugated sustem such as cross-linking at a higher temperature and a longer heating.

The authors are very grateful to Professor Kiichiro Kubo and Mr. Seiki Kato for their X-ray data, to Mr. Toyoji Saito for his elementary analyses, to the Nissei Industry Co., Ltd., for its ESR measurements, and to the Dainihon Ink Co., Ltd., for its oxygen analyses. They also wish to express their thanks to Dr. Masahiro Hatano for his helpful suggestions.

The Radiolysis of Liquid cis-2-Butene

By Yoshihiko HATANO, Shoji SHIDA and Shin SATO

(Received June 18, 1964)

Previous investigations of the radiation chemistry of unsaturated hydrocarbons have dealt almost exclusively with radiation-induced polymerization; little attention has been paid to the minor low-molecular-weight products. It therefore appeared of interest to investigate the low-molecular-weight products in the expectation that they might be produced through the non-free radical mechanism. This was of interest because it has been known that olefins (e.g., *cis*-2-butene in this investigation) and other unsaturated compounds behave as effective scavengers for hydrogen and free radicals.[1] Thus, almost all free radicals from the radiolysis of unsaturated compounds may easily react to form dimers and higher polymers, and may not contribute to the formation of the low-molecular-weight products (e.g., hydrogen and $C_1 \sim C_4$ products from C_4 hydrocarbons). Detailed studies of such systems might assist the understanding of the essential features of the molecular mechanism in the radiation chemistry. With these prospects, the radiolysis of liquid *cis*-2-butene at room temperature was undertaken in this investigation. *cis*-2-Butene is simple in chemical structure, although it is readily liquefied.

There has been, to the authors' knowledge, only one paper[2] dealing with the radiolysis of *cis*-2-butene. Kaufman[2] carried out the irradiation of butenes in gas and liquid phases and suggested that the ion-molecule processes are applicable to the dimer formation. On the other hand, Cundall[3,4] carried out radiolysis on particular systems (butenes in hydrocarbon solvents) and explained the cis-trans isomerization of 2-butene by means of the energy transfer mechanism from solvents. In this case the isomerization of 2-butene is not due to the direct effect of radiation.

Experimental

Materials.—Matheson pure-grade *cis*-2-butene was used after the usual degassing and bulb-to-bulb distillations. It was found by gas chromatography to contain less than 0.4% *trans*-2-butene. Commercial reagents of chemically-pure-grade benzene,

4) R. B. Cundall and P. A. Griffiths, *Discussions Faraday Soc.*, **36**, 111 (1963).

naphthalene, anthracene, iodine, and *p*-benzoquinone were used as additives without further purification.

Irradiation.—The radiation employed in the radiolysis of liquid *cis*-2-butene was γ-rays from 16000 c. ^{60}Co. Measured amounts of *cis*-2-butene were sealed in vacuo at −196°C in glass ampoules 10 mm. in diameter and of a 10 ml. capacity fitted with breaker seals. Irradiations were made at room temperature. The total doses were 0.30×10^{21} to 3.59×10^{21} eV./g. for examining the dose dependence of products and 2.90×10^{21} eV./g. throughout the experiments to which additive materials were applied. The dose rate was 2.21×10^{19} eV./g. hr.

Analysis. — After irradiations the sample tubes were attached to the vacuum line and the seals were broken. The gases non-condensable at −196°C (hydrogen and methane) were collected and measured by an analysis device composed of a Toepler pump, a McLeod gauge, and a copper oxide furnace. Products condensable at −196°C were expanded into a reservior of a sufficiently large volume to maintain hydrocarbons up to C_8 in the gas phase. Aliquots of the gaseous mixture were then analyzed by a home-made reduced-pressure-type gas chromatograph. For the separation of $C_1\sim C_4$ hydrocarbons, a benzyl ether column was mainly used at room temperature, but a squalane-alumina column and a dimethylsulfolane column were also used. For the separation of $C_5\sim C_8$ hydrocarbons, a dioctylphthalate column was used at 80°C. After distillation of the volatile products in vacuo at room temperature, a viscous residue was found on the wall of the glass ampoules. This substance was readily soluble in acetone and was determined gravimetrically as a polymer of the butene.

Results and Dicussion

The major products in the radiolysis of liquid *cis*-2-butene at room temperature are hydrogen, *n*-butane, 1-butene, *trans*-2-butene, C_8 hydrocarbons, and higher polymers. Small amounts of $C_1\sim C_3$ and $C_5\sim C_7$ hydrocarbons are also formed. The formation of each product was estimated as a function of the energy absorbed in the liquid *cis*-2-butene (Fig. 1). The data in Fig. 1 show that each product formation is directly proportional to the energy absorbed; that is, the radiation chemical yield, *G*, the number of molecules formed per 100 eV. of energy absorbed in the system, is independent of the total energy absorbed. In view of the fact that *cis*-2-butene itself is an effective radical scavenger,*1 this result can be readily understood.

The *G*-values of products in the radiolysis of liquid *cis*-2-butene at room temperature have been determined from Fig. 1 and are shown in Table I. The sum of *G*-values for hydrogen and $C_1\sim C_4$ hydrocarbons in Table I is 5.20, whereas it is 9.41 in the radiolysis of liquid *n*-butane at room temperature;[7] these results indicate that a smaller amount of gaseous products (55% of the latter) is formed from an unsaturated hydrocarbon than from a saturated one. Further, the ratio $\{G(C_1\sim C_3)+G(C_5\sim C_7)\}/\{G(C_4)+G(C_8)\}$ is 0.098 for *cis*-2-butene and 1.53 for *n*-butane[7] respectively, where $\{G(C_1\sim C_3)+G(C_5\sim C_7)\}$ represents the yield for the C–C bond rupture. These results indicate that in the butene radiolysis the reactive species formed by the C–C bond rupture (e. g., C_1, C_2, and C_3 radicals) do not make an important contribution to the formation of

low-molecular-weight products, but that the greater part of these reactive species may be converted to dimers or higher polymers.

Iodine and *p*-benzoquinone (BQ) were used as radical scavengers more effective than olefins. Table II lists several molecular and radical yields obtained with a *cis*-2-butene/BQ solution. The concentration range of BQ used here is 40 to 180 mM. With a *cis*-2-butene/I_2 solution (although we shall omit detailed information here), the same additive effect on the products formation except for the isomerization were observed as in the *cis*-2-butene/BQ system. The marked increase in the rate of cis-trans isomerization observed with the *cis*-2-butene/I_2 solution ($G=5.5$ at 10 mM) might be due to the catalytic action of iodine atoms and/or the electron-capture effect of iodine molecules. It seems that the effect of added iodine on the reaction mechanism is complicated and presents some difficulty.[8] As is shown in Table II, the free radical mechanism is not important for the formation of any low-molecular-weight products except methane and *n*-butane. Since 95% of *n*-butane is produced through the free radical mechanism, it is proposed that *n*-butane formation occurs by the disproportionation of *s*-butyl radicals: $2C_4H_9 \rightarrow C_4H_8 + C_4H_{10}$. Assuming that *cis*- and *trans*-2-butene are produced simultaneously with *n*-butane in the ratio of 1:1 in the disproportionation reaction, then one obtains the expected radical yield of *trans*-2-butene as 0.32, $\{G_R(n\text{-}C_4H_{10}) - G_R(1\text{-}C_4H_8)\}/2$, which is in good agreement with the observed value, i. e., 0.29.*2 Thus, at least 80% of the *trans*-2-butene is formed through the molecular mechanism.

Since the greater part of the low-molecular-weight products are formed through the molecular mechanism described above, such aromatic hydrocarbons as benzene, naphthalene, and anthracene were used as additives; they were expected to exert remarkable effects on the molecular mechanism. The variation in product yields with the concentration of the additives is given in Fig. 2. The rate of cis-trans isomerization is markedly affected by the sort of additives and their concentrations, whereas the rate of the formation of other products is not so much affected as in the case of isomerization. The increase in G(*trans*-2-butene) at lower concentrations and the decrease at higher concentrations are obvious. On the other hand, the dependence of G(*n*-butane) on additive concentrations is much less than that of G(*trans*-2-butene). Therefore, the decrease in G(*trans*-2-butene) at higher concentrations is not due to the radical-scavenging effect by additives.

The rate of cis-trans isomerization in pure liquid *cis*-2-butene is independent of the total doses, as is shown in Fig. 1. Therefore, the

*2 On the other hand, if an assumption is made that in the disproportionation reaction of *s*-butyl radicals 1-butene, *trans*-2-butene, and *cis*-2-butene are produced with the ratio of 2:1:1, respectively,[9] as found in the corresponding gas-phase reaction, then the radical yield of *trans*-2-butene might be $0.79\times1/4=0.2$ and that of 1-butene $0.79\times1/2=0.4$. The former is again in agreement with the observed value, but not the latter. It is probable that the ratio of 1-butene to *cis*- or *trans*-2-butene is not the same as the ratio in the gas phase.

9) B. S. Radinovitch and R. W. Diesen, *J. Chem. Phys.*, **30**, 735 (1959).

increase in G(*trans*-2-butene) at a lower concentration of additives is not due to the protection by aromatics of the initially-formed *trans*-2-butene from radical attack, a protection which was observed with olefin formation in the radiolysis of a cyclohexane/benzene mixture.[10]

The ionization potentials of benzene, naphthalene, and anthracene have been offered as 9.52, 8.12 and 7.23 eV., and their electron affinities as 2.19, 2.59, and 3.11 eV. respectively.[11] For *cis*-2-butene, the ionization potential is 9.34 eV.,[12] and the electron affinity is less than the values for the aromatics.[13] On the other hand, it may be considered that in the lower concentration of additives the interaction between additives and electrons prevails over the interaction between additives and positive butene ions in a spur, and that with an increasing concentration of additives the latter interaction cannot be set aside. Thus, comparing the results in Fig. 2 with the values listed above one may conclude that the increase in G(*trans*-2-butene) at a lower concentration of additives corresponds to the electron affinities of additives and the decrease at higher concentrations, to the ionization potentials of additives.

In view of the above discussion, the most reasonable conclusion to be drawn from the available data is as follows: The increase in G(*trans*-2-butene) at a lower concentration of additives may be due to the electron-capture effect of additives, which prolongs the lifetime of positive butene ions. As a result, the recombination process of electrons will be altered:

a) $\mathrm{Cis} \rightarrow \mathrm{Cis}^+ + \mathrm{e}$ (Cis; *cis*-2-butene)

b) $\mathrm{e} + \mathrm{M} \rightarrow \mathrm{M}^-$ (M; additives)

c) $\mathrm{Cis}^+ \rightarrow \mathrm{Trans}^+$ (Trans; *trans*-2-butene)

d) $\mathrm{Cis}^+ + \mathrm{e} \rightarrow \mathrm{Cis}^* \rightarrow 1/4$; Cis (singlet)
$\searrow$ 3/4; Cis (triplet) $\rightarrow$ 3/8; Trans
$\searrow$ 3/8; Cis

e) $\mathrm{Trans}^+ + \mathrm{e} \rightarrow \mathrm{Trans}^* \rightarrow 1/4$; Trans (singlet)
$\searrow$ 3/4; Trans (triplet) $\rightarrow$ 3/8; Trans
$\searrow$ 3/8; Cis

where asterisks indicate excited states involving high levels of the different state manifolds, and "singlet" and "triplet" indicate the ground state and the first excited triplet state respectively. The additional processes b, c and e may occur beside the processes a and d if the additives are used. From the processes d and e, the net value, 1/4 of the primary ionization of *cis*-2-butene, additionally contributes to the cis-trans isomerization in the presence of sufficient amounts of the additives, since it might be considered that singlet and triplet states are formed by the recombination of electrons and positive butene ions in the ratio of 1 : 3. When the concentration of additives is increased however, the isomerization due to the process $\mathrm{Cis}^+ + \mathrm{M}^-$ cannot be set aside in comparison with the processes d and e. When the concentration is increased further, $\mathrm{Cis}^+ + \mathrm{M}^-$ prevails over $\mathrm{Trans}^+ + \mathrm{M}^-$, and finally the contribution, the above "1/4," may be ignored. Since butene has a lower ionization potential than benzene, the charge transfer from butene to benzene will be impossible. Although the electronic energy levels of 2-butene are not known with any accuracy, the electronic excitation transfer from butene to benzene may also be impossible. This is supported by theoretical considerations[14-16] and by experimental results from the studies of the benzene-photosensitzed isomerization of 2-butene.[17],*3 When benzene is used as an additive, therefore, no further decrease in G(*trans*-2-butene) is observed with an increase in the concentration. Since butene has a higher triplet energy and a higher ionization potential than naphthalene and anthracene, both electronic excitation transfer and charge transfer are possible as follows:

$$\mathrm{Cis}^* \text{ (triplet)} + \mathrm{M} \text{ (singlet)} \rightarrow \mathrm{Cis} \text{ (singlet)} + \mathrm{M}^* \text{ (triplet)}$$

$$\mathrm{Cis}^+ + \mathrm{M} \rightarrow \mathrm{Cis} + \mathrm{M}^+$$

When naphthalene and anthracene are used as additives, therefore, a steeper decrease in G(*trans*-2-butene) at higher concentrations is observed. From investigations of the sensitized fluorescence,[19] however, an electronic excitation transfer is possible only when two atoms or molecules have energy levels lying near enough together to raise a quantum mechanical resonance effect between them.

Consequently, it may be considered that only the charge transfer process plays a leading role in this case, since the difference between the lowest triplet energy levels of 2-butene and that of naphthalene (2.6 eV.)[20] or that of anthracene (1.9 eV.)[20] is too large compared with that of benzene (3.6 eV).[20,21]

Summary

The radiolysis of *cis*-2-butene has been studied in the liquid phase at room temperature.

(1) The major products (and their *G*-values) were hydrogen (1.02), *n*-butane (0.83), 1-butene (0.40), *trans*-2-butene (2.29), C_8 hydrocarbons (2.30), and higher polymers, the *G*-values being independent of the total dose. Small amounts of $C_1 \sim C_3$ and $C_5 \sim C_7$ hydrocarbons were also formed. The hydrogen and the lower hydrocarbons except for *n*-butane were found, by using *p*-benzoquinone as a radical scavenger, to be produced for the most part through the molecular mechanism.

(2) The addition of benzene, naphthalene, and anthracene to liquid *cis*-butene have remarkable effects on the formation of *trans*-2-butene; thus, the cis-trans isomerization increases at a lower concentration of additives, while it decreases at a higher concentration of additives. The radical scavenging effect cannot explain these results. From a comparison of the experimental results with the ionization potentials and electron affinities of aromatics, it has been concluded that the increase in the isomerization at lower concentrations is due to the electron capture effect of additives, while the decrease at higher concentrations is due to the charge transfer from the butene to the additives.

This research was supported, in part, by the Watanabe Memorial Foundation for Scientific Research Promotion, to which the authors are grateful. This experiment owes much to Dr. Hirofumi Danno, who offered us a ^{60}Co-γ source at the Japan Atomic Energy Research Institute.

The Direct Iodination of Polyalkylbenzenes by the Crossed Jacobsen Reaction[1]

By Hitomi SUZUKI,* Takashi SUGIYAMA and Ryozo GOTO

(Received June 19, 1964)

The direct iodination of aromatic compounds may be effected satisfactorily when these compounds contain such activating groups as hydroxyl or amino groups. If we wish to introduce an iodine atom directly into a nucleus not activated by such powerful activating groups, however, the reaction must be carried out in the presence of an effective oxidizing agent. The reagents commonly employed are iodic acid,[2] common or fuming sulfuric acid,[3] nitric acid,[4] heavy metal oxides,[5] sodium persulfate or perchlorate,[6] silver salts,[7] ferric chloride,[8] and organic peroxides.[9] In the literature, however, few of these reagents have been employed with the

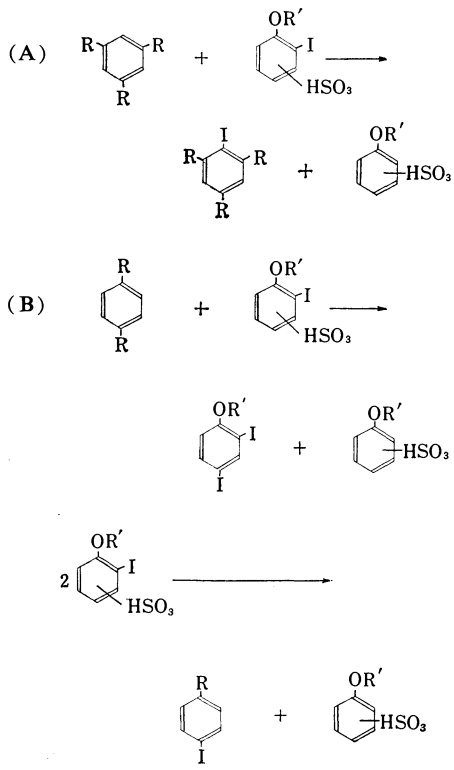
highly alkylated benzenes. As the reaction proceeds through an electrophilic attack of an iodine atom on the nucleus, an increase in the number of alkyl groups attached to the ring enhances the reactivity of the compound. This increase, however, brings about an enhanced susceptibility of the compound to the undesired action of an oxidizing agent, and also to an increased steric repulsion to the entry of a bulky iodine atom into the nucleus. Both these effects reduce the yield of the product so markedly that most of the above reagents cannot be used successfully for the purpose of synthesizing iodo polyalkylbenzenes. Thus, from the synthetic point of view, the direct iodination of highly alkylated compounds is not necessarily a simple matter to effect. For example, if we use sulfuric acid or nitric acid as an oxidizing agent, the sulfonation or the nitration of the compound often proceeds in preference to iodination. Ferric chloride gives a complex mixture in which the desired iodinated product is a minor component, whereas iodic acid or organic peroxides afford the products, in most cases, in unsatisfactorily low yields.



In earlier papers of this series,[10] we have shown that iodophenols and iodoanisoles, in the presence of sulfuric acid, readily undergo the disproportionation at room temperatures and afford polyiodo compounds in fairly high yields. This fact suggested to us that iodophenols or iodoanisoles might be used in conjunction with sulfuric acid as iodinating agents. The present work will present the results of an attempt to use these compounds as iodinating agents for polyalkylbenzenes.

This reaction may be represented by the following general equation:

In the present work, we used *o*-iodoanisole as an iodinating agent. In this reaction (the crossed Jacobsen reaction), the iodination of polyalkylbenzene competes with the disproportionation of *o*-iodoanisole. Since the iodine cation reacts more readily with iodoanisole to form polyiodo anisoles, care must be taken to select conditions which do not favor their formation. This was done by carrying out the reaction in an excess of hydrocarbon, thus avoiding the presence of excess iodoanisole in the system. Under these conditions, iodoanisole cannot successfully compete with the hydrocarbon, and the iodine cation, once formed, goes on to react with the excess hydrocarbon to give the iodinated product. On the other hand, the presence of a large excess of sulfuric acid causes such undesirable side reactions as sulfonation, the migration of the alkyl group, and the further decomposition of the iodinated products (iodo polyalkylbenzenes are generally unstable towards sulfuric acid and are readily decomposed to the resinous materials and free iodine). In order to prevent these side reactions, the hydrocarbon was brought to the simultaneous action of *o*-iodoanisole and sulfuric acid; that is, to the polyalkylbenzene to be iodinated, sulfuric acid and *o*-iodoanisole were simultaneously added drop by drop, while their proportion was maintained slightly in excess of the sulfuric acid.

Nine polyalkylbenzenes were subjected to the crossed Jacobsen reaction: pseudocumene, durene, pentamethylbenzene, *sym*-triethylbenzene, *sym*-tetraethylbenzene, *p*-diisopropylbenzene, *sym*-triisopropylbenzene, *sym*-tetraisopropylbenzene, and *p*-di-*t*-butylbenzene. Only polymethyl- and polyethylbenzenes underwent

this reaction smoothly at room temperature and gave acceptable yields of the products. Polyisopropyl- and poly-*t*-butylbenzenes, as would be expected from our previous works,[10] gave the iodinated products in poor yields. With some compounds, one of the isopropyl or *t*-butyl groups which occupied a position favorable, with respect to the directing effect of other groups present, to the entry of the iodine cation, is in part replaced. Thus, depending upon the structure of the polyalkylbenzenes, the reaction may occur by two different routes, A and B.

With polymethyl- and polyethylbenzenes which are activated by alkyl groups but not so overcrowded with them, the reaction proceeds through the route A. With polyisopropyl and poly-*t*-butylbenzenes, the aversion to the entry of a bulky iodine atom into the nucleus suppresses the formation of normal products so markedly that the reaction proceeds chiefly through the route B and results in either the replacement of an alkyl group or the disproportionation of *o*-iodoanisole.

The direct iodination of polyalkylbenzenes by the crossed Jacobsen reaction is characterized by the absence of a powerful oxidizing reagent, mild reaction conditions, and the easy separation of the products. This reaction, the use of which as a practical means of synthesis seems to be somewhat limited, affords a simple one-step preparation of iodinated polyalkylbenzenes from readily-available starting materials.

Experimental

1) General Procedure.—*a) Liquid Hydrocarbon.*—In a 100 ml. four-necked flask, fitted with a thermometer, a reflux condenser, and two dropping funnels, each a containing sulfuric acid and *o*-iodoanisole, the hydrocarbon was placed and magnetically stirred. The flask was then immersed in a water-bath and heated to the desired temperature. Sulfuric acid and *o*-iodoanisole were added drop by drop at such a rate that a slight excess of sulfuric acid was maintained in the system. Under these conditions, no alkyl migration occured. After completion of dropping, the mixture was stirred for some additional hours and then poured into water. The resulting organic layer was extracted with a small amount of ether, and the extract was washed with a diluted sodium bisulfite solution to remove free iodine and then dried over anhydrous calcium chloride. After this drying, the ether was removed by distillation. The fractionation of the residual oil gave some amounts of unchanged hydrocarbon, followed by the expected iodinated polyalkylbenzene.

b) Solid Hydrocarbon.—Solid hydrocarbon was dissolved in a small amount of cyclohexane and then subjected to iodination in the manner described above. After the completion of the reaction, the mixture was poured into water; the organic layer was separated, washed with a diluted solution of sodium bisulfite, and freed from the solvent. The crystalline residue was chromatographed on an alumina column. The elution of the column with petroleum ether gave unchanged hydrocarbon, followed by the desired iodinated product, which was then recrystallized from an appropriate solvent to yield the pure product. 2, 4-Diiodoanisole, a disproportionation product, was held on a column and readily removed from the iodinated polyalkylbenzene.

2) Dialkylbenzenes. — *p-Diisopropylbenzene.* — *p*-Diisopropylbenzene (24.3 g., 0.15 mol.) was stirred and warmed to 35～40°C. *o*-Iodoanisole (23.4 g., 0.10 mol.) and sulfuric acid (15 g., 0.15 mol.) were added over a 1.5-hr. period. The reddish-violet mixture was, after 4 hours' agitation, poured into water and worked up as described in 1a). The distillation of the oil gave unchanged *p*-diisopropylbenzene (13.8 g., b. p. 91～93°C/19 mmHg), a mixture of *o*-iodoanisole and a lower-boiling iodo compound (7.1 g., b. p. 105～120°C/19 mmHg), a higher-boiling iodo compound (6.4 g., b. p. 140～160°C/19 mmHg), and a residue (ca. 2.0 g.). The mixture fraction, on oxidation, gave a small amount of *p*-iodobenzoic acid, m. p. 262～265°C. Thus, the iodination of *p*-diisopropylbenzene was accompanied by the partial replacement of one of the isopropyl groups. The redistillation of the higher-boiling fraction gave 6.0 g. of monoiodo-*p*-diisopropylbenzene, b. p. 143～146°C/22 mmHg.

Found: C, 49.71; H, 5.81. Calcd. for $C_{12}H_{17}I$: C, 50.00; H, 5.95%.

p-Di-t-butylbenzene.—To the stirred solution of *p*-di-*t*-butylbenzene (3.7 g., 0.02 mol.) in cyclohexane (25 ml.) *o*-iodoanisole (5.9 g., 0.025 mol.) and sulfuric acid (3.0 g., 0.03 mol.) were added at 30～33°C. The reaction mixture turned immediately dark-violet, and a remarkable liberation of free iodine was observed. After 3 hours' agitation, the mixture was worked up as described in 1b). The crystalline residue (6.4 g.), chromatographed on an alumina column, gave unchanged *p*-di-*t*-butylbenzene (3.1 g., m. p. 75～76°C), a pink-colored oil (ca. 0.5 g.), and 2, 4-diiodoanisole (2.5 g., m. p. 65～67°C). After the mixture had stood in the refrigerator, some feather-like crystals were separated out from the oil fraction, which, on recrystallization several times from petroleum ether, gave white soft needles, m. p. 49～50°C. The elemental analysis of this material indicated that it was diiodinated di-*t*-butylbenzene, whose structure, inferred by analogy, might be 2, 5-diiodo-1, 4-di-*t*-butylbenzene.[11]

Found: C, 37.65; H, 4.27. Calcd. for $C_{14}H_{20}I_2$: C, 38.04; H, 4.56%.

The oily part was supposed to be a mixture of *p*-iodo-*t*-butylbenzene, a monoiodinated product, and unchanged *o*-iodoanisole, but none of them could be identified because of its small quantity.

3) Trialkylbenzenes.—*Pseudocumene (1, 2, 4-Trimethylbenzene).*—Pseudocumene (12.0 g., 0.1 mol.)

11) The Jacobsen reaction of halogenobenzenes usually proceeds like the progressive halogenation of the parent compound. Cf. H. Suzuki, This Bulletin, **36**, 1642 (1963).

was iodinated by using *o*-iodoanisole (15.6 g., 0.15 mol.) and sulfuric acid (10 g., 0.1 mol.), and 14.5 g. of a monoiodinated product, b. p. 121~125°C/17~18 mmHg, was obtained. This might be a mixture of several isomers, because it could not be completely solidified on standing in ice bath. The comparatively low yield (69% based on the unrecovered hydrocarbon) is attributed in part to the easy sulfonation of pseudocumene, and in part to the instability of the product towards the action of sulfuric acid. 5-Iodopseudocumene, m. p. 34~36°C.

Found: C, 43.77; H, 4.48. Calcd. for $C_9H_{11}I$: C, 43.92; H, 4.51%.

sym-Triethylbenzene.—To *sym*-triethylbenzene (24.3 g., 0.15 mol.), *o*-iodoanisole (23.4 g., 0.1 mol.) and sulfuric acid (15 g., 0.15 mol.) were added at 30~32°C over a 1.5 hr. period. Little iodine was liberated. After standing overnight, the mixture was worked up as usual. The fractionation of the oil gave unchanged triethylbenzene (12.7 g., b. p. 115~117°C/29 mmHg), *o*-iodoanisole (4.5 g., b. p. 112~115°C/18 mmHg), a monoiodinated fraction (17.9 g., b. p. 150~153°C/16 mmHg), and a residue (ca. 0.5 g.). The redistillation of the monoiodinated fraction gave 17.1 g. of monoiodo-*sym*-triethylbenzene (b. p. 169~170°C/31 mmHg).

Found: C, 49.74; H, 6.00. Calcd. for $C_{12}H_{11}I$: C, 50.01; H, 5.95%.

sym-Triisopropylbenzene.—*sym*-Triisopropylbenzene (20.4 g., 0.1 mol.) was iodinated with *o*-iodoanisole (15.6 g., 0.07 mol.) and sulfuric acid (10 g., 0.1 mol.) at 35~38°C by the same method used above. After 3 hours agitation, the mixture was left to stand overnight. Working up as usual and the distillation of the residual oil gave the starting materials unchanged (20.0 g., b. p. 114~120°C/18 mmHg), iodine containing a higher boiling fraction (6.5 g., b. p. 130~180°C/18 mmHg), and a residue (ca. 2.0 g.). This high boiling fraction was chromatographed on a short column to remove 2,4-diiodoanisole. It yielded 5.9 g. of monoiodo-*sym*-triisopropylbenzene, b. p. 173~175°C/28 mmHg.

Found: C, 54.06; H, 7.02. Calcd. for $C_{15}H_{23}I$: C, 54.56; H, 7.02%.

4) Tetraalkylbenzenes.—*Durene* (*sym-Tetramethylbenzene*).—Durene (4.0 g., 0.03 mol.) was dissolved in cyclohexane (5 ml.) and then iodinated with *o*-iodoanisole (11.7 g., 0.05 mol.) and sulfuric acid (7 g., 0.07 mol.) at 30~35°C. Little iodine was liberated. After 4 hr., the mixture was, diluted with water and extracted with cyclohexane. The evaporation of the solvent, followed by the chromatography of the residual oil on an alumina column, gave unchanged durene (ca. 0.5 g.) and monoiododurene (5.2 g., m. p. 80~81°C). A mixed melting point determination with an authentic specimen showed no depression.

Found: C, 46.29; H, 5.10. Calcd. for $C_{10}H_{13}I$: C, 46.16; H, 5.04%.

sym - Tetraethylbenzene. — *sym* - Tetraethylbenzene (28.5 g., 0.15 mol.) was iodinated by using *o*-iodoanisole (23.4 g., 0.1 mol.) and sulfuric acid (15 g., 0.15 mol.) at 30~33°C. After 4 hr., the mixture was treated as usual. The distillation of the oily product gave the starting materials unchanged (23.5 g., b. p. 105~135°C/19 mmHg), an iodinated products fraction (15.5 g., b. p. 155~175°C/19 mmHg), and a residue (ca. 2.0 g). To remove 2, 4-diiodoanisole, the iodinated products fraction was chromatographed on an alumina column with petroleum ether. The redistillation of the resulting oily material yielded 13.5 g. of modoiodo-*sym*-tetraethylbenzene, b. p. 186~188°C/26 mmHg.

Found: C, 52.60; H, 6.57. Calcd. for $C_{14}H_{21}I$: C, 53.17; H, 6.70%.

sym-Tetraisopropylbenzene.—Attempts to iodinate this compound gave only the starting material unchanged and 2, 4-diiodoanisole. A large amount of free iodine was liberated, and the disproportion of *o*-iodoanisole was the only reaction that proceeded.

5) Pentamethylbenzene.—To the stirred solution of pentamethylbenzene (7.4 g., 0.05 mol.) in cyclohexane (10 ml.), *o*-iodoanisole (15.2 g., 0.07 mol.) and sulfuric acid (10 g., 0.1 mol.) were added at 34~36°C over a 1.5 hr. period. After 4 hr., the mixture was worked up as usual. The chromatography of the crystalline residue on an alumina column gave unchanged pentamethylbenzene (ca. 1.0 g., m. p. 51~53°C), iodopentamethylbenzene (7.9 g., m. p. 141~142°C), and a small amount of 2, 4-diiodoanisole. The melting point of our iodopentamethylbenzene differs from that of Töhl (m. p. 129°C)[5] by 12°C.

Found: C, 48.22; H, 5.59. Calcd. for $C_{11}H_{15}I$: C, 48.18; H, 5.52%.

Summary

A method has been developed for the direct iodination of certain polyalkylbenzenes by the transfer of an iodine atom of iodoanisole. It consists of the simultaneous addition of iodoanisole and sulfuric acid to the polyalkylbenzene to which the transfer is to be made. In this way, iodo compounds have been prepared from eight polyalkylbenzenes.

Acid-base Concept and Catalytic Activity of Oxides

By Ken-ichi TANAKA* and Kenzi TAMARU**

(Received July 1, 1964)

In heterogeneous catalysis by metal oxide, many close correlations between the catalytic activity, including its selectivity, and the acidity of the oxide have been indicated. Most commonly the correlations have been discussed in connection with such typical acidic solid catalysts as silica-alumina. However, a more general treatment has been undertaken in this report to study the general trend of the catalytic activity of metal oxides.

Generally speaking, the strength of an acid is determined by the equilibrium constant between the acid and a base, such as water, for instance, in the following manner:

$$HA + H_2O = H_3O^+ + A^-$$

The more the equilibrium shifts to the right, the stronger the acid HA. It simultaneously depends upon the strength of the conjugate base, A^-; the weaker the conjugate base, thus with less of a tendency to combine with the proton, the stronger, the acid HA. Consequently, the strength of the acid depends upon the relative strength of the acid and its conjugate base.[1]

As is generally accepted, strong acids, such as sulfuric and nitride acids, are neuteralized with water molecules in an aqueous solution to show a "leveling effect," and their acidity practically drops to that of H_3O^+. Consequently, the stronger acids can stay comparatively strong in a medium, the protonated forms of which are stronger acids than the original acids.

Accordingly, it is considered that the proton on an oxide surface can behave as a strong acid if the oxide surface is more acidic, or less basic. The less basic the oxide surface is, and thus with less of a tendency to hold protons, the stronger the "protonated" surface of the oxide behaves as an acid, as the conjugate base is weak. When an acid comes into contact with an oxide surface, it can stay acidic if the protonated surface of the oxide is more acidic, while it is neutralized to form a salt if the oxide is more basic, showing a "leveling effect."

In the case of oxy-acids, it has been shown that the strength of the acid is closely correlated with the partial charge on the oxygen in the acid, or in the conjugate base, as shown in Fig. 1.[2] A high degree of deficiency of electrons on the oxygen is associated with a high acidity of the acid. For instance, as a more electronegative atom is added to an oxy-acid, the electronegativity of the acid increases, with a low partial charge on the oxygen, and the strength of the acid increases. The electronegative atom attracts electrons to itself until the electronegativity of each atom in the acid molecule is equalized. The acidities of hypochlorous, chlorous, chloric and perchloric acids are examples.

The acidity of the oxide surface can be treated in a similar manner, and the partial charge on the oxygen in the oxide can be correlated with the acidity of the oxide surface. The data on the partial charge on the

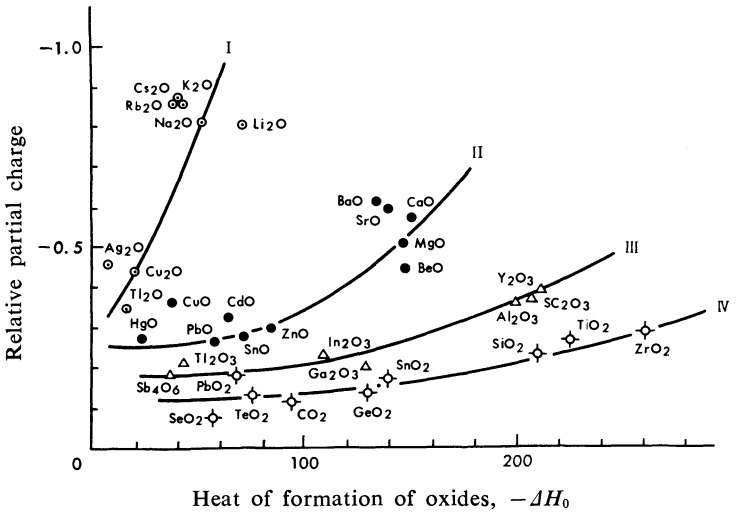

Fig. 2. The relation between the partial charge on oxygen and the heat of formation of oxides (kcal./metal atom).

oxygen in the oxides, which are given by Sanderson,[2] are not available in many oxides. However, as far as all the available data are concerned, a reasonably good correlation can be established between the partial charge and the heat of the formation of the oxides, as is shown in Fig. 2. In the figure, it may be seen that the partial negative charge on oxygen in the oxide becomes lower as the oxidation number of metals increases, and also as the heat of formation of the oxides decreases.

The metals which have lower heats of formation of the oxides have a comparatively higher electronegativities, and the difference between their electronegativities and that of oxygen is small, and they have a more covalent nature in the bond, which results in a low partial charge of oxygen and a high acidity. In these ways, the acid-base concept is applicable to the surface catalysis, especially those by oxide catalysts.

An example where the acidity of the oxide surface seemingly plays a role in the catalysis is the decomposition of alcohol and formic acid.[3-8] In the decomposition of alcohol and formic acid, a common trend has been observed in their selectivity, as is shown in Fig. 3,[3]

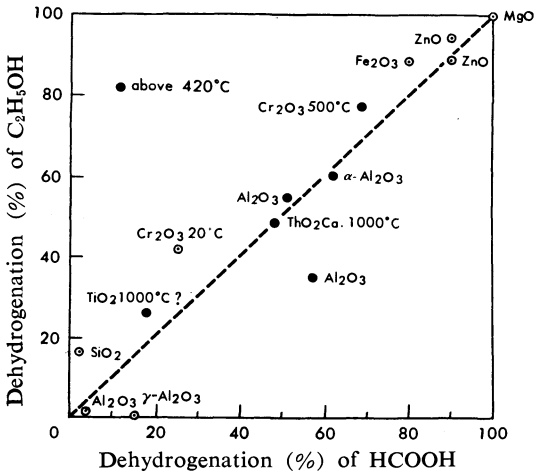

Fig. 3. The selectivity in the decomposition of formic acid and ethyl alcohol on metal oxides. (by Mars[3])

and the dehydration reaction is promoted by the acid, while the dehydrogenation reaction is promoted by the base, phenomena which are analogous to the homogeneous catalytic decomposition of alcohol and formic acid. If we plot the data by Mars[3] against the heat of formation, $(-\Delta H_0)$, Fig. 4 is obtained. Though the number of the oxide in the figure is not large enough, it may be concluded that the selectivity to dehydrogenation increases as the valency of the metal decreases (that is, as the oxide becomes more basic).

As to the effect of the heat treatment of the catalyst on the selectivity, Schwab[4] has revealed that it reduces the dehydration rate, while, in many cases, it increases the dehydrogenation rate. When the catalyst is treated

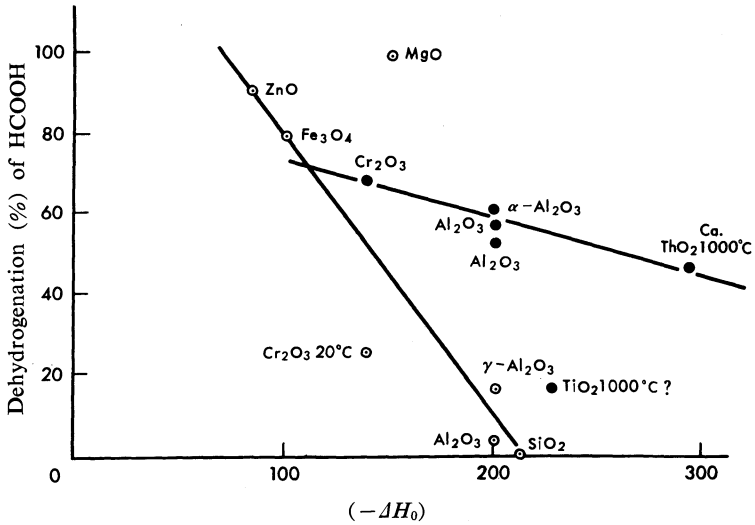

Fig. 4. The selectivity to dehydrogenation of formic acid on metal oxides and their heats of formation (kcal./metal atom).

at higher temperatures, with less oxygen on the surface, the surface behaves in a more basic manner, having a higher partial charge of oxygen, much like such general Brönsted oxy-acids as hypochlorous acid.

The general correlation of the catalytic activity with its acidity is also shown by the retardation of the dehydration reaction by basic substances: The addition of potassium hydroxide or calcium hydroxide reduces the catalytic activity of alumina and silica in the dehydration markedly.[5]

The kinetics of the overall reaction can also be interpreted on the same basis. The dehydration of formic acid is zero-order in formic acid and is not slowed down by the reaction products, while the decomposition of alcohol is retarded by water and is between zero- and first-order in alcohol. The strength of the acidity is in the decreasing order; formic acid>water>alcohol, which is the same order as with the strength of the adsorption on oxide surface. Accordingly, the kinetic behavior of the overall reaction may also reasonably be explained on the common basis.

Eucken attempted to correlate the selectivity of the decomposition with the quantity:

$$\eta=\frac{(\text{cation radius})^3}{(\text{mol. volume per cation})\,(\text{charge of cation})}$$

while Mars[3] worked with;

$$\left(\frac{\text{cation radius}}{\text{anion radius}}\right)^3\frac{1}{(\text{cation charge})^2}$$

The dehydration proceeds when the cation radius is small, that of the anion is large, and the charge of the cation is high. From the electrostatic point of view, a smaller cation radius implies more of a tendency to attract electrons (a stronger acid), while the higher cation charge and the larger anion radius are associated with the acidic property of the oxide. Accordingly, $1/\eta$ is a parameter of the electronegativities or the acidity of metal oxides. Mars suggested the possibility that formic acid donates a proton to the catalyst to result in dehydrogenation, as in the case of a metal catalyst.[3] The basicity of the catalyst surface would be associated with the dehydrogenation selectivity in a similar way.

In the hydration of propylene, the catalytic activities of metal sulfates are as follows, in

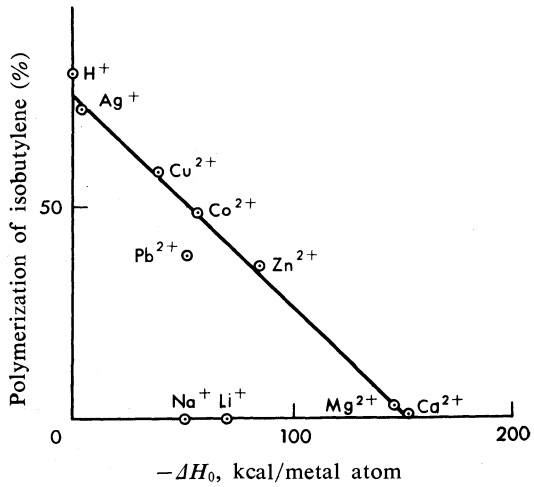

Fig. 5. The catalytic activity of metal phosphates for the polymerization of isobutylene and the heats of formation of the corresponding oxides.

decreasing order:[9] $Fe^{3+} > Al^{3+} > Cr^{3+} > Cu^{2+} > Zn^{2+} > Co^{2+} > Cd^{2+} > Ni^{2+} > Mn^{2+} > Mg^{2+} > K^{+}$, Na^{+}. They obey the general acidity rule—the more acidic ion has a higher activity, much as in the dehydration of alcohol. The sulfates which contain acidic, or less basic, metal ions, have much catalytic activity and, if the charge of metal ions is the same, the activity is high when $-\Delta H_0$ is low. The catalytic activity of phosphates for the polymerization of isobutylene[10] is shown in Fig. 5, where acidic salts are active in the reaction.

The interpretation of the selectivity of the oxide catalyst on the basis of the semi-conductor does not seem likely, for magnesium oxide and silicon dioxide are both insulators and also both the dehydrogenating zinc oxide and the dehydrating titanium(IV) oxide are seemingly *n*-type semi-conductors, as Mars pointed out previously.[3] Thus the acid-base concept of oxide seems to be really useful in interpreting their catalytic behavior.

The chemisorption of gases on the metal surface has been successfully correlated with the heat of the formation of the highest oxide of the metal, and this heat of formation and the electronegativities of gases approximately determine the initial heat of chemisorption of any gases on many metals, according to the available data.[11] The catalytic activity of metals, accordingly, has also been correlated with the heat of the formation of the metal oxide,[12] and, in a similar manner, that for metal oxide has been treated in connection with the heat of the oxide, or with its acidity.

Summary

The catalytic activity of metal oxide has been correlated with the acidity of the oxide surface. The acidity depends upon the partial charge on the oxygen in the oxide and also upon the heat of the formation of the oxide. Consequently, the catalytic behavior may be correlated with the heat of the formation of the oxide, as in the cases of the chemisorption of gases and catalytic activity by metals.

The decomposition of formic acid and alcohol and the polymerization of isobutylene have been treated on the basis of this concept, and the selectivity, or activity, of these reactions, their reaction kinetics, and also the effect of heat treatment have been discussed.

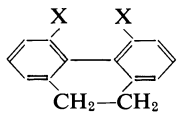
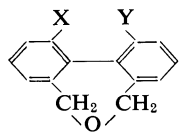
NMR Studies of the Rates of Inversion of o, o'-Bridged Biphenyls[1]

By Michinori Ōki, Hiizu Iwamura and Naohiro Hayakawa



(Received July 9, 1964)

Since the success in the optical resolution of 6, 6'-dinitrodiphenic acid achieved by Christie and Kenner,[2] there have been accumulated many examples of the enantiomers of biphenyls in which the rotation around the pivot bond in the biphenyl skeleton is restricted either by the bulky groups on the ortho-positions or by bridging the two ortho-positions on either ring with a suitable ring number. As early as 1927[3] the kinetic examination of the restricted rotation was performed by measuring the rate of the racemization of the optically labile biphenyls with a polarimeter. The collected data were analyzed by Adams and Yan[4] in order to correlate the optical stability with the steric bulkiness of the ortho-substituents; that study contributed much to modern structural organic chemistry inasmuch as it introduced a measure of steric effects.



Although it is convenient, however, the polarimetric method expects inevitably the prior optical resolution of the samples, and so it can not be applied to those with a short life-time (with a $t_{1/2}$ less than a few minutes at room temperature). Lately the demand for

2) G. H. Christie and J. Kenner, *J. Chem. Soc.*, **1922**, 614.
3) R. Kuhn and O. Albrecht, *Ann*, **455**. 272 (1927).
4) R. Adams and H. C. Yan, *Chem. Revs.*, **12**, 261 (1932).

means of measuring the faster rate of rotation and inversion has been met, by the NMR technique[1,5,6] which, when properly applied,[7,8] should explore the rate processes with the first order rate constant of 1 to 10^3 sec^{-1}. The present paper constitutes a full description of a study of the rates of inversion of 9, 10-dihydrophenanthrenes (I, III, V) and 5, 7-dihydrodibenz [c, e] oxepins (II, IV, VI, VII, VIII).[1]

I: X=H
III: X=CH_3
V: X+X=CH_2CH_2

II: X=Y=H
IV: X=Y=CH_3
VI: X+Y=CH_2OCH_2
VII: X+Y=CH_2CH_2
VIII: X=H, Y=NO_2

When these biphenyls are fixed as non-planar or when the half-lives of their inversion are relatively long, the spectra of the bridging methylene groups will be composed of the A_2B_2 multiplets in I, III and V and AB quartets in II, IV, VI, VII and VIII. On the occasion of the other extreme, e. g., when the rate of the inversion is large relative to the chemical shift, δ_{AB}, in c. p. s. units, the spectra of the bridging methylene groups are expected to be composed of a singlet (A_4 and A_2 respectively). In the intermediate rate of the inversion, the spectra will change with the temperature, and the shape can be related to the life-time of the inversion. Therefore, the measurement of the NMR spectra was performed over a wide range of temperature.

Experimental

Spectral Measurements.—The NMR spectra were preliminarily obtained on a Varian V-4300 spectrometer operating at 56.4 Mc./sec., with a variable temperature probe accessory and a Dewar probe insert attached. The temperature was read from the microvoltage in the copper-constantan thermocouple mounted on the inside wall of the probe insert according to the calibration curve; the temperature can be regarded as accurate to ±1.0°C. Later all the measurements above −60°C were reexamined on a Varian A-60 spectrometer equipped with a variable temperature accessory at 60 Mc./sec.; the spectral data to be reported are based on the latter measurement unless otherwise stated.

The samples for the low- and high-temperature measurement were dissolved in carbon disulfide and in tetrachloroethylene respectively, to make ca. 10% solutions.

Within the measurement of a given sample, the strength of H_1 was held constant at around 0.04 mG. of the dial setting of the r. f. field, and the spectra were established as being far below the saturation condition by observing no lowering in the peak intensity on a slight raising of the r. f. field. The apparent amplitude of the normal signals decreases as the temperature ascends, mainly because of the thermal expansion of the solvent and the consequent apparent dilution. Accordingly, only the recorder level was changed, if necessary, from temperature to temperature, to determine the desired amplitude of the signals. Frequencies were read with respect to tetramethylsilane as an internal standard, and the usual sweep rate was 1 c.p.s./sec.

Since T_2 is practically determined by the inhomogeneity of the magnetic field, T_2 was regarded as independent of the kind of proton and so was measured directly from the width of the signal of tetramethylsilane by the wiggle-decay measurement.[7,9,10]

Materials.—The samples used for the measurement were known compounds, unless otherwise stated, and their physical constants agreed well with those in the literature.

1, 11-Ethano-5, 7-dihydrodibenz[c, e]oxepin (VII).—Ozone was passed from the generator into a solution of 5 g. of 4, 5-dihydropyrene in 100 ml. of chloroform for five hours at the nominal rate of 2 g./hr. at 0°C. Chloroform was distilled under diminished pressure, and the residue was dissolved in 50 ml. of ether. The solution was then added, drop by drop, into a solution of 5 g. of lithium aluminum hydride in 100 ml. of ether. This mixture was heated under reflux for an hour. The excess lithium aluminum hydride was destroyed by the addition of ethyl acetate, and then 100 ml. of 5% sulfuric acid was added to decompose the alkoxides. The organic layer was separated, and the aqueous layer was extracted with three 50 ml. portions of ether. The combined ether solution was washed with a 5% sodium bicarbonate solution and dried over potassium carbonate. The residue, obtained after the removal of the ether, was freed from the unoxidized starting material by chromatography on an alumina column; 4, 5-dihydropyrene was eluted with petroleum ether, and 4, 5-bishydroxymethyl-9, 10-dihydrophenanthrene, with ether.

The bishydroxymethyl compound was, without identification, dissolved in 100 ml. of toluene and heated under reflux with 0.5 g. of *p*-toluenesulfonic acid for eight hours. The solution was washed twice with 5% sodium bicarbonate, and the toluene was distilled off. The residue was recrystallized from petroleum ether to give 2 g. of VII, m. p. 92 ~93°C.

Found: C, 86.51; H, 6.39. Calcd. for $C_{16}H_{14}O$: C, 86.45; H, 6.35%.

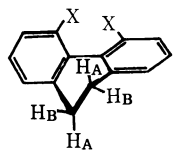
a stirred mixture of 300 ml. of a sodium borohydride solution (1 M in diethylene glycol diethyl ether) and 50 ml. of an anhydrous aluminum chloride solution (2 M in the same solvent),[11] 20 g. of dimethyl 6-nitrodiphenate[12] was added; the resulting solution was warmed on a water bath to 75°C. After five hours' heating, the mixture was cooled to room temperature and poured onto ice-water containing 1 N hydrochloric acid to decompose the remaining reagent; the solution was then evaporated on a water bath, and the higher boiling solvent was distilled under reduced pressure by the application of a water pump. The remaining solid was recrystallized from benzene to afford 13 g. of 2,2'-bishydroxymethyl-6-nitrobiphenyl, m. p. 93°C.

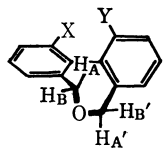
Found: C, 64.95; H, 5.37; N, 5.46. Calcd. for $C_{14}H_{13}O_4N$: C, 64.86; H, 5.05; N, 5.40%.

The bishydroxymethyl compound (7.8 g.) was heated with 200 ml. of 50% sulfuric acid at 100°C for an hour.[13] On cooling, the oily mass solidified and was recrystallized from ethanol to give 5.0 g. of the desired oxepin, m. p. 115°C.



Found: C, 69.84; H, 4.68; N, 5.79. Calcd. for $C_{14}H_{11}O_3N$: C, 69.90; H, 4.59; N, 5.80%.

Results and Discussion



The *o,o'*-bridged biphenyls can be classified into three groups according to the characteristic dependence of their NMR spectra on the change in temperature.

i) Rigid Biphenyls and Biphenyls of a Slow Inversion Rate.—III,[13] IV[14] and VI[15] have been separated into optical antipodes and shown not to racemize easily at room temperature. In these rigid structures, two protons on a methylene group are situated in different magnetic environments and, consequently, are not equivalent (IX and X). As expected, the signals assigned to the methylene protons are of a multiplet structure, although, in the spectrum of III, the separation is not clear and the broadness of the signal relative to those of methyl and TMS is the sole indication at 60 Mc./sec.[16] Table I shows the observed chemical shifts and coupling constants of the methylene protons, together with the half-life of racemization at room temperature.

In order to see the origin of the difference in the chemical shift between the two methylene protons, δ_{AB}, molecular models were

	H_B	2.35	0.19	2.60	2.10	−0.69	

* ρ and z are cylindrical coordinates expressed in units of the radius of the benzene ring (1.39Å) with the z axis normal to the plane of the ring at its center and with the origin at the center. 1 and 2 refer to the contiguous and the remote benzene rings respectively.

set up using conventional structural dimensions,[17] and the difference in the effect of the long-range shielding of the two benzene rings on the two protons in a methylene group was calculated according to the numerical table of Johnson and Bovey.[18] As regards the length of the pivot bond, R, and the interplanar angle, θ, made by the two benzene rings, of III and IV, it is not proper to adopt those of I and II[19] respectively, because the conjugation bands in the ultraviolet spectra of III and IV have been shown[20] to exhibit a hypsochromic shift of 4~5 mμ from those of I and II respectively. Therefore, these parameters were calculated according to the method of Suzuki[19,21] from the absorption maxima of the conjugation band; $R=1.49$Å and $\theta=29°$

20) E. A. Braude and W. F. Forbes, *J. Chem. Soc.*, **1955**, 3776.
21) ν_A's are 38314 cm^{-1} (261.0 mμ) and 41152 cm^{-1} (243 mμ) for III and IV respectively. As the longer-wavelength-side reference, ν_L=37735 cm^{-1} (265 mμ) of 9, 10-dihydrophenanthrene was adopted, for which $\theta=20°$ (G. H. Beavan, D. M. Hall, M. S. Lesslie and E. E. Turner, *J. Chem. Soc.*, **1952**, 854).

for III, and $R=1.51$ Å and $\theta=57°$ for IV.[22]

Table II summarizes the results of the calculation. Agreement in δ_{AB} is fairly good in III, considering the approximation used in the calculation. In IV, however, the calculation leads to a δ_{AB} value higher by 0.4 p. p. m.; this discrepancy should be ascribed to the anisotropy of the neighboring oxygen atom.

The spectra of this class of biphenyls can thus be characterized by the split methylene signals and by no temperature dependence of the spectra in the conventional temperature range of the commercial NMR spectrometer. The rate of inversion can be estimated to be not more than δ_{AB} sec^{-1} at the highest temperature attained by the measurement. Thus, the upper limit of the rate and the lower limit of the energy of activation for racemization can be drawn.

ii) Biphenyls of a Fast Inversion Rate.—I, V and XI show a singlet methylene signal at room temperature and retain the singlet as low as −90°C. Table III shows the chemical

XI

shifts of the methylene protons at room temperature. They are quite independent of the temperature, and only the displacement within 10 c. p. s. towards the higher applied magnetic field is usually observed as the temperature is lowered to −60°C.

TABLE III. THE CHEMICAL SHIFTS OF THE METHYLENE PROTONS
(in carbon disulfide at room temperature)

	I	V	XI
τ-value	7.18	7.15	6.68

There are three possibilities for the temperature-independent singlet methylene signals: 1) The inherent identity of the chemical shifts of the two methylene protons by the genuine or virtual coplanarity of the skeleton. Fluorene, which has a singlet methylene signal at τ, 6.19, is a typical example. 2) The coincidence of the chemical shifts, which in this case are determined by the anisotropy of the neighboring groups, mainly of the two benzene rings, and by the solvent effect, as exemplified by the methylene protons in 1, 11-dimethyl-5, 7-dihydrodibenz [c, e] thiepin in deuteriochloroform.[23,24] 3) rapid inversion and consequent averaging of the magnetic environment.

Case 2 can possibly be explored by the study of the solvent effect.[24] Cases 1 and 3 can be discriminated by the inspection of the ultraviolet spectra, since the ultraviolet spectroscopy conforms to the Franck-Condon principle and, even in case 3, information on the structure at the ground state can be obtained and the non-coplanarity is accompanied by a hypsochromic shift of the conjugation band at ca. 250 mμ.

As far as I, V and XI are concerned, it is likely[20] that they belong to case 3. In these circumstances, the rates of inversion can be estimated to be not less than δ_{AB} sec^{-1} at the lowest temperature measured, and so the higher limit of the energy of activation can be deduced. Since log A of the inversion in o,o'-bridged biphenyls is, on the average, 12,[25] the activation energy of the inversion is obtained as less than 9 kcal./mol. in I, V and XI.

iii) Biphenyls of an Intermediate Inversion Rate. — Although VII shows, at room temperature, two singlet signals at τ 7.20 and τ 5.75 due to the protons on the CH_2CH_2 and CH_2OCH_2 groups respectively, the latter signal begins to decrease and gradually broaden as the temperature goes down to −50°C. At −58°C, the separation into a vague multiplet sets in. At −60°C, a resonance pattern of a characteristic AB-quartet can be clearly recognized, as is shown in Fig. 1. Below −80°C, the signal is rigorously determined as $\delta_{AB}=25.9$ c. p. s. and $J_{AB}=11.4$ c. p. s. at 56.4 Mc./sec. Even at this temperature, the signal at the higher applied magnetic field does not separate into an apparent multiplet, but is only broadened a little. Since the δ_{AB} of the methylene protons on the CH_2CH_2 group is smaller, the averaging of the resonance signals is still occurring in the rate process through which the signal due to CH_2OCH_2 with a larger δ_{AB} does not coalesce. Since the exchange broadening of the two interacting nuclear spin resonance signals has been treated theoretically by Alexander,[26] the analysis of the variation in this behavior of spectra with the temperature can be performed. The height of the coalesced singlet relative to that at zero life-time, $(v/v_0)_{max}$, can be related to the

22) In order to accomodate the molecular models with these structural parameters, a slight distortion of the bond angles in the cyclohexadiene and the dihydrooxepin rings in III and IV respectively is necessary. They are within 2° and do not affect the result materially.

23) "High Resolution NMR spectra Catalog," Vol. II, No. 657, Varian Associates, Palo Alto, California, U. S. A.

24) While this manuscript was being prepared, K. Mislow and his coworkers published a lengthy NMR study of the bridged biphenyls and showed a remarkable solvent effect (*J. Am. Chem. Soc.*, **86**, 1710 (1964)).

25) D. M. Hall and M. M. Harris, *J. Chem. Soc.*, **1960**, 490.

26) S. Alexander, *J. Chem. Phys.*, **37**, 967 (1962).

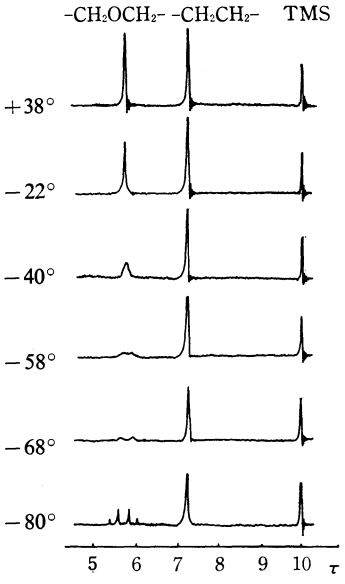

Fig. 1. Temperature dependence of the methylene proton signals of VII (at 56.4 Mc./sec.).

mean life-time, τ, through the observed parameters, δ_{AB}, J_{AB}, and T_2, according to Eq. 1.

$$(v/v_0)_{max} = 1 - \frac{2T_2\delta_{AB}^2\tau + (T_2^2\delta_{AB}^4 + \delta_{AB}^2)\tau^2}{4 + 4\left(\frac{1}{T_2} + T_2\delta_{AB}^2\right)\tau + \left\{\left(\frac{1}{T_2} + T_2\delta_{AB}^2\right)^2 + J_{AB}^2\right\}\tau^2} \quad (1)^{27)}$$

Furthermore, at the very time of coalescence, Eq. 2 is obtained, provided $1/T_2$ is zero:

$$\tau_c = \frac{\sqrt{2}}{\pi(\delta_{AB}^2 + 6J_{AB}^2)^{1/2}} \quad (2)^{28)}$$

Figure 2 corresponds to Eq. 1 applied to VII, and τ at a given temperature can now be obtained graphically from the $(v/v_0)_{max}$ observed in Table IV. $\log(1/\tau)$'s make a straight line against $1/T$, and from the slope, the energy of activation of the inversion can be determined (Table VI).

Since the two methylene groups in VIII are no longer equivalent, VIII exhibits double AB-quartets at room temperature: CH_2 attached to the benzene ring without a nitro-group, τ, 5.77 (center), $\delta_{AB}=28.7$, $J_{AB}=11.80$ c. p. s.; and attached to the benzene ring with a nitro-group, τ, 5.61 (center), $\delta_{AB}=16.05$, $J_{AB}=11.4$ c. p. s.

27) Obtained from the imaginary part of Eq. 57 in reference 26 by putting $\Delta=0$. v_0 can be obtained by extrapolating the peak height, v, vs. the $1/T$ curve to an infinite temperature.

28) Equation 2 is derived by putting the second derivative at $\Delta=0$ of the imaginary part of Eq. 57[26] equal to zero. τ_c stands for the life-time just when the quartet signal coalesces to a singlet signal.

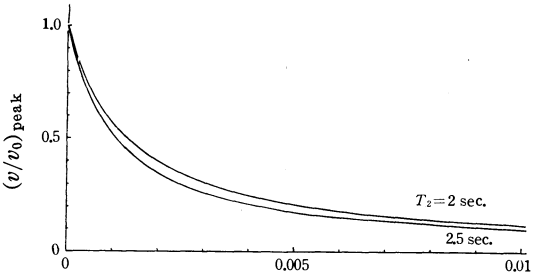

Fig. 2. Relation between the relative peak heights and the mean life-time for VII; $\delta_{AB}=27.5$, $J_{AB}=11.4$ c. p. s., in Eq. 1.[29)]

Table IV. Variation in the peak heights of the methylene signals in VII with the temperature

−58	—	1.94*

* $\log(1/\tau_c)$

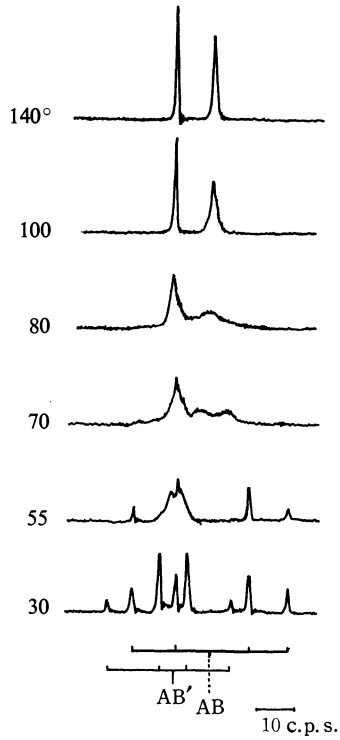
** The v at each temperature is relative to the height of the TMS signal on the same chart.

Contrary to the optically rather stable biphenyls (group i), the quartet signals deform easily as the temperature rises. The quartet at the lower applied magnetic field begins to broaden earlier and coalesces at 56°C, while that at the higher field has the coalescence temperature of 65°C. In the preliminary communication,[1)] the kinetic parameters of the rate process were determined from the two coalescence temperatures of the resonance signals with different chemical shifts. Since it is difficult to determine the temperature of coalescence as accurately as ±2°C, however, there is a danger that the data will contain undesirable errors. Therefore, VIII was subjected to the same analysis as was VII.

Figure 3 shows the dependence of the apparent spectra on the temperature. In Table V are recorded the data on the peak heights.

$\log(1/\tau)$'s from two pairs of CH_2 protons lie on the same line against $1/T$ (Fig. 4);

29) T_2 values ranged between 2.0 and 2.5 sec. in the present measurements. The Arrhenius parameters are rather insensitive to T_2, and the error of ± 0.5 sec. in T_2 corresponds to the 5% inaccuracy of the results.



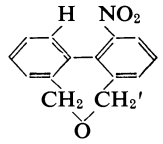


Fig. 3. Temperature dependence of the methylene proton signals of VIII.

from the slope, the energy of activation was determined (Table VI).

Although the authors could not find the broadening of the singlet signal in II in a preliminary study, later measurements revealed a coalescence temperature of as low as ca. −85°C, as has been pointed out by Kurland.[6] II, therefore, belongs to this class of biphenyls and will be dealt with in relation to the effect of the internal interaction of the substituents on the rate of inversion, together

with 5, 7-dihydrodibenz [c, e] thiepin and 1-methyl-3,4 : 5,6-dibenzocyclohepta-3, 5-dien-1-ol.

In conclusion, the NMR technique is unique in determining the rate of inversion of those biphenyl derivatives which can not be submitted to the conventional polarimetric method because of their too great optical lability. The technique will undoubtedly find more applications in related fields.

Crystal Structures of Two Isomers of Bromo-methoxy Tropone

By Kozo FURUKAWA*1 Yoshio SASADA,*2 Akira SHIMADA*3 and Tokunosuké WATANABÉ*4

(Received July 11, 1964)

Hitherto we have reported on the crystal structures of several compounds with a seven-membered carbon ring[1-9] in order to elucidate the structures of molecules, accurate molecular dimensions, and the types of molecular packing as a measure of the forces exerted between molecules. As a part of this series, this paper will deal with the crystal structures of two isomers of bromo-methoxy tropone. Remarkable differences in dipole moment and chemical behavior between these isomers have already been reported and discussed in relation to their conformations.[10,11] It is hoped that this paper's determination of their molecular structures will throw light on these problems.

Experimental

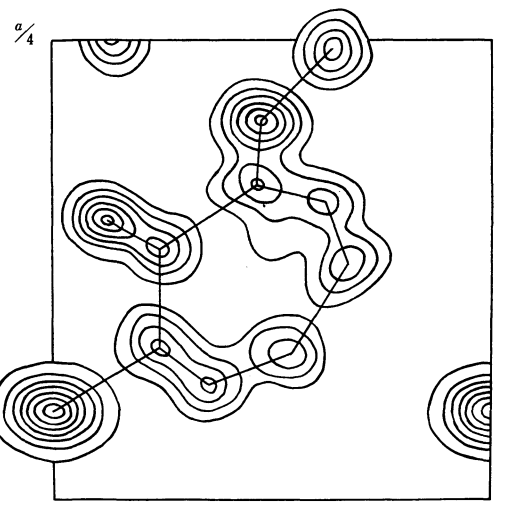
Crystals of two isomers of bromo-methoxy tropone, $C_8H_7O_2Br$, were kindly supplied by Professor Tetsuo Nozoe, Tohoku University. Both of these crystallize out in the form of needle-like prisms; the melting point is 91°C for the 7-bromo isomer (7-bromo-2-methoxy tropone) and 76°C for the 3-bromo isomer (3-bromo-2-methoxy tropone).

Oscillation and Weissenberg photographs were taken around two principal axes for each by means of the Cu$K\alpha$ radiation, and the multiple-film technique was used to correlate the strong and weak reflections. The intensities were estimated by visual comparison with a calibrated scale, and the corrections for polarization, Lorentz and absorption factors were made in the usual way.

The crystal data thus obtained, the dimensions of the crystals used, and the range of intensity observed are given below.

7-Bromo Isomer.—Four molecules in an orthorhombic unit cell with $a=26.56$, $b=6.09$, and $c=4.97$ Å. Absent spectra: ($hk0$) when h is odd, ($0k0$) when k is odd, and ($00l$) when l is odd. Space group: $Pn2_1a$. Volume of the unit cell: 803.7 Å^3. Linear absorption coefficient for Cu$K\alpha$ radiation: $\mu=67.5\,cm^{-1}$. Total number of electrons per unit cell: $F(000)=424$. Rectangular dimensions of a cross section of crystals: 0.02×0.03 cm. for the c and b axis rotations. The relative intensities ranged from 1800 to 1 for ($hk0$) reflections and from 1200 to 1 for ($h0l$) reflections. Reflections from 92 planes were observed out of 108 possible ($hk0$)'s, and those from 129 planes out of 162 possible ($h0l$)'s.

3-Bromo Isomer.—Four molecules in a monoclinic unit cell with $a=7.64$, $b=26.57$, $c=3.99$ Å, and $\beta=101.5°$. Absent spectra: ($h0l$) when h is odd, and ($0k0$) when k is odd. Space group: $P2_1/a$. Volume of the unit cell: 793.7 Å.^{3} Linear absorption coefficient for CuK_α radiation: $\mu=68.2\,cm^{-1}$. Total number of electrons per unit cell: $F(000)=424$. Rectangular dimensions of a cross-section of crystals: 0.02×0.02 cm. and 0.03×0.04 cm. for the c and a axis rotations respectively. The relative intensities ranged from 510 to 1 for ($hk0$) reflections and from 2210 to 1 for ($0kl$) reflections. Reflections from 100 planes were observed out of 167 possible ($hk0$)'s, and those from 100 planes out of 121 possible ($h0l$)'s.



Structure Determination

7-Bromo Isomer.—A modified Patterson projection $P(UV)$ was synthesized, the modification factors being of the form of $(1/f)\cdot \exp B'(\sin\theta/\lambda)^2$, where f is the atomic scattering factor and an appropriate B' value is chosen to get a good resolution. This Patterson map showed not only the position of the bromine atom, but also clearly showed the shape of the molecule projected on the (001) plane, with an ambiguity for the methyl group. Two peaks were observed, both of which could be assigned to the methyl group. Thus, two sets of initial atomic coordinates were obtained, where the y coordinate of the bromine atom is taken arbitrarily to be zero because the b axis is polar in this space group. Atomic coordinates for each model structure

were refined by successive Fourier and partial difference syntheses. The rate of convergence was rather low because of the presence of the heavy atom and the lack of a center of symmetry. The Fourier projection derived from the first model structure contained, in addition to the peaks expected from the initial structure, an unnegligible peak at the position where the methyl group was assumed in the second model structure. Since successive Fourier refinements did not make this ghost peak disappear, the first model structure was abandoned. The second model structure gave a fairly reasonable electron density distribution and a better agreement between observed and calculated structure factors than did the first model. The final electron density projection on the (001) plane is shown in Fig. 1 (a). The discrepancy index, $\Sigma||F_o|-|F_c||/\Sigma|F_o|$, reduced to 0.150 for ($hk0$) reflections if non-observed reflections were omitted. The best over-all temperature factor, B, was 4.4 Å^2.

the c axis downward

Fig. 1 (a)

the b axis upward

Fig. 1 (b)

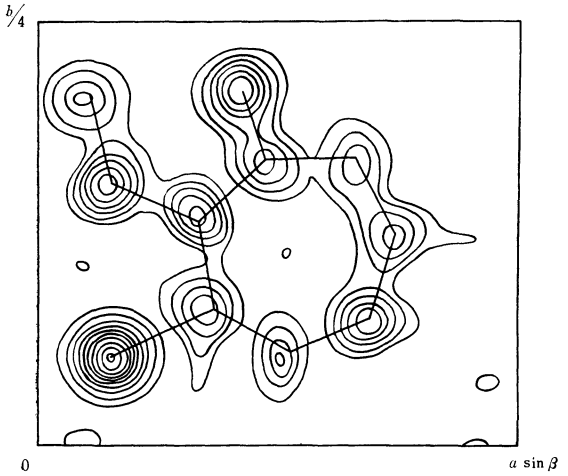

Fig. 1. Electron density of 7-bromo-2-methoxy tropone projected along (a) the c and (b) the b axes. Contours at equi-intervals in an arbitrary scale. One for every five countour lines are drawn around the bromine atom.

The coordinates of the bromine atom in the (010) projection were deduced easily from the Patterson function, $P(UW)$. The first Fourier projection of the electron density in this plane, calculated with $F(h0l)$'s of signs which result from the bromine atom alone, definitely showed the positions of all the atoms in the molecule. The atomic coordinates were refined by the successive Fourier method. The final electron density projection on the (010) plane is shown in Fig. 1(b) ; the discrepancy index was 0.181 for the ($h0l$) zone if non-observed reflections were omitted. The best over-all B factor was 3.0 Å^2.

Although a significant anisotropic thermal motion of the bromine atom was observed from the two projections of the electron density distribution, no correction was made for anisotropic temperature factors. The final atomic coordinates are listed in Table I(a),

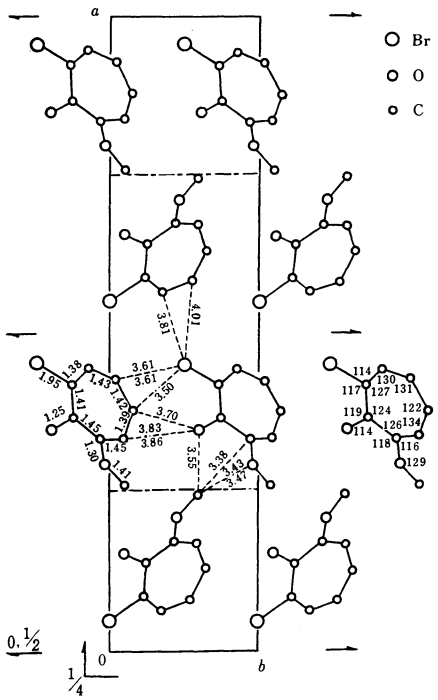
where the x coordinates are the weighted mean of those obtained from the two projections.

3-Bromo Isomer. — The first clue to an approximate structure was obtained, much as in the case of the 7-bromo isomer, by the modified Patterson function, $P(UV)$, along the short c axis. The refinement of each atomic coordinate thus obtained was also done by successive Fourier and partial difference syntheses.

With reference to the x and y coordinates of atoms, the z parameter of each atom was estimated by the trial-and-error method and was refined by the ordinary Fourier method. The final electron density projections along the c and a axes are shown in Figs. 2 (a) and (b) respectively. The final atomic coordinates are listed in Table I(b); the best over-all B factor was found to be 4.0 Å^2. At this stage, the discrepancy indices reduced to 0.152 for ($hk0$) and 0.172 for ($0kl$) if non-observed reflections were omitted.

Discussion

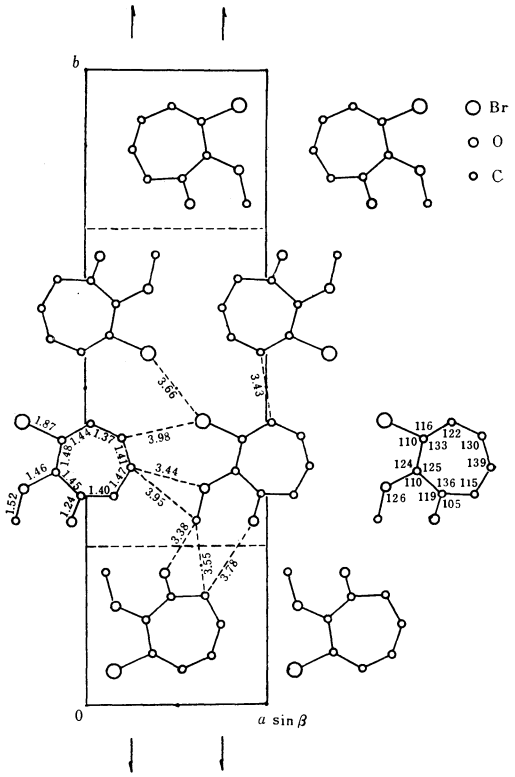
The position of the substituted bromine atom in each isomer was established without any ambiguity from the Fourier projections of the electron density, thus confirming the structural formulae assigned to the two isomers by organo-chemical research.[11]



As a result of the disturbance of the heavy atom, the atomic coordinates are not very accurate, the accuracies of bond lengths being estimated to be about 0.1 Å or more. Within the limits of errors, all the bond lengths and angles shown in Figs. 3 (a) and (b) are considered to be normal. Although the seven-membered carbon ring is found to be approximately planar, the methoxy oxygen, the carbonyl oxygen and the bromine atoms deviate significantly from the ring plane, alternately in opposite directions, so as to keep away from each other.

Another point to be discussed is the conformation of the methoxy group. Let us call three typical conformations the perpendicular, cis and trans forms. In the perpendicular form the methyl group lies on a plane perpendicular to the ring through O_2 and C_2, while in the cis and trans forms the methyl group is located on the ring plane nearest to and furthest from the carbonyl oxygen atom respectively. The methoxy group of the 3-bromo isomer takes a conformation between the cis and perpendicular forms, while that of the 7-bromo isomer has a conformation between the perpendicular and trans forms. These conformations might be caused by a great steric repulsion from the bromine atom and are in agreement with the chemical fact that the 3-bromo isomer is more liable to aromatization than is the 7-bromo isomer.[11]

The dipole moments of these isomers have been measured and compared with the theoretical values for various conformations by Kurita, Seto, Nozoe and Kubo.[10] According to these authors, the observed moments of the 3-bromo and the 7-bromo isomers (3.31 D for the former and 5.51 D for the latter) are closest to the theoretical values for the cis and perpendicular form respectively. Although the



structure of the molecule in crystalline states is not necessarily the same as that in solutions, the molecular structure of the two isomers described in this paper are compatible with the conclusion derived from the dipole moment measurements.

The crystal structure projected along the c axis of the 7-bromo isomer and that projected along the c axis of the 3-bromo isomer are shown in Figs. 3(a) and (b) respectively. It should be noted that the features of molecular arrangement in the crystals of the two isomers are very similar, as can be seen in the lower-half cells shown in Figs. 3(a) and (b), in spite of a considerable difference in the dipole moments of the two isomers. However, while the upper-half cell of the 3-bromo isomer is antiparallel to the lower with respect to the direction of the C–Br bond, so that the crystal is centro-symmetric, the upper-half cell of the 7-bromo isomer is parallel to the lower, so that the crystal is polar. The difference in the melting points of the two compounds is probably connected with this difference in their molecular arrangement.

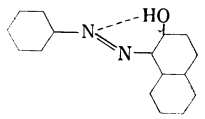
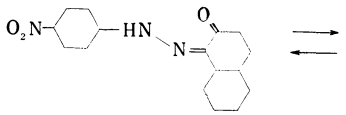
*Studies of Absorption Spectra of Azo Dyes and Their Metal-complexes. VI. The Tautomerism of Phenolazo-β-naphthols and of Phenolazo-α-naphthols**

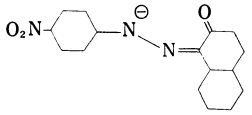


By Yoshiharu YAGI

(Received July 15, 1963)

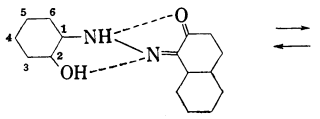


It had long been recognized[1] that phenylazo-β-naphthol (I) and phenylazo-α-naphthol (XI) are in a tautomeric equilibrium between the azo and the quinonehydrazone forms. This study was undertaken in order to obtain more information about this tautomerism.

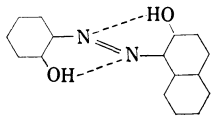


(I)

(II)



(III)



(IV)

In an aqueous methanol containing sodium hydroxide, the hydrazone band[2] of I near 500 mμ markedly decreases in intensity, while the absorption intensity of the azo band increases near 445 mμ. If I turns into a sodium salt by an addition of alkali metal hydroxide, thus forming an anionic species, there should be an appreciable bathochromic displacement of the bands according to the polarity increase of the absorbing system. Compound I, therefore, is not considered to from a salt under such conditions. However, azo compound III, known as pigment Para Red, is an exceptional case. This exists almost exclusively in the phenylhydrazone form (488.6 mμ in 95% methanol) as a result of the strong electron-withdrawing property of a nitro group. The addition of sodium hydroxide to this system, however, causes the appearance of a new band near 550 mμ, and the hydrazone band disappears with an increase in the concentration of alkali metal hydroxide. It is evident that III forms an anion IV in such circumstances, since no band corresponding to the azo form has been observed.

In the equilibrium of phenolazo-β-naphthol (V) in various organic solvents, the hydrazone form is generally more dominant than azo compound I. The phenolic hydroxyl group of V or XII is, in any solvent, in an undissociated state, whereas those of phenolazoacetoacetamides in Part II[3] have been found to be strongly acidic, and thus their dissociation occured in aqueous alcohol.

(V)

(VI)

It had previously[4] been known that such *o,o'*-dihydroxyazo compounds as V undergo marked color changes according to the pH ranges of the media, neutral (weakly acidic), weakly alkaline or strongly alkaline. However, no exact explanation of this has yet been made. Compound V in aqueous 50% methanol shows the hydrazone and the azo bands at 508 mμ

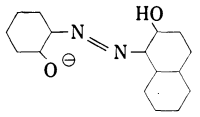
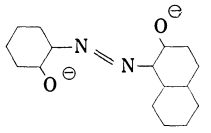
and 422.1 mμ respectively. When measured in the medium roughly the same but containing sodium hydroxide, the hydrazone band undergoes a remarkable shift toward a longer wavelength in the alkali concentration near about 0.01～0.1 N. The molecular structure at this state corresponds to structure VII.



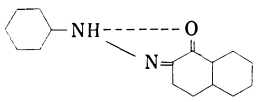
In the neighborhood of the concentration about 0.5～1.0 N, it is noteworthy that the relative intensity of the azo band markedly increases at about 450 mμ. If a two-step dissociation, VII→VIII or IX→X, occurs upon the concentration increase of sodium hydroxide, the increased polarity of the absorbing system



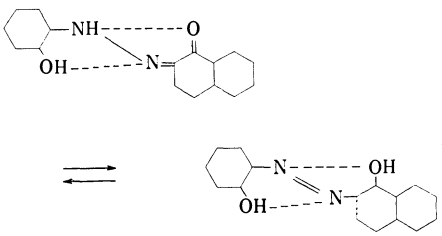
(VII)

(VIII)

(IX)



(X)



would cause a displacement of the spectrum toward a longer wavelength as compared with the absorption maximum of the ionized hydrazone form corresponding to VII. Such spectral change, therefore, may be attributed to the fact that the tautomeric equilibrium is inclined to the azo form, presumably because of (i) an increase in the basic nature of the solvent system, and (ii) an elevation of the electron-donating power of the hydroxyl upon dissociation.

The spectra of the derivatives of V supported the above explanation: the 5-NO_2 derivative in neutral 95% methanol has an absorption corresponding to structure VII as a shoulder (560 mμ) of the main hydrazone band (517 mμ). By the addition of alkali metal hydroxide, the main hydrazone band is turned into this new band. In spite of the concentration increase of alkali metal hydroxide, the location of this band does not change. The azo band, however, undergoes a slight bathochromic and hyperchromic displacement. In the case of the 4-NO_2 derivative, however, the hydrazone structure is exclusively dominant because the electronegative nitro group is para to the hydrazone group. The weak azo band shows no change in location and in intensity in spite of the concentration increase of alkali metal hydroxide. It follows that it is harder for a dissociation VI→IX to proceed than for a dissociation V→VII.

The tautomerism of phenylazo-α-naphthol (XI) is somewhat different from that of I. In *n*-hexane, the weak inflection at 424 mμ proves the slight existence of the azo form of XI, as is shown in Table II. However, the hydrazone band of XI (λ_{max} 507.5 mμ; ε_{max} 1.68×10^4) in 50% aqueous methanol undergoes almost no change in intensity and in location, in spite of the basicity increase of the solvent upon the addition of sodium hydroxide to this system. These facts show that the azo $\rightleftarrows$ quinonehydrazone tautomeric equilibria of the compounds of type XI are biased toward the hydrazone tautomer in any solvent.

(XI)

(XII)

With regard to phenolazo-α-naphthol (XII) the tautomeric eqilibrium is biased to the azo form as a result of the electropositive character of the phenolic hydroxyl group.[5] In the visible absorption region, there is a weak inflection at a longer wavelength side (about 500 mμ) of the main aborption band. This absorption has a relatively high intensity in an acetic acid medium whereas the intensity of the main absorption band at 486.3 mμ is relatively low. In a polar solvent such as methanol, XII also shows a sharply absorbing band at 528.5 mμ, and there is no absorption on a longer wavelength side. Moreover, the visible absorption maximum of XII in *n*-hexane is located at a shorter wavelength position than that of XI, notwithstanding the introduction of the hydroxyl group, with its effectively auxochromic nature.

The azo $\rightleftarrows$ quinonehydrazone tautomerism of XII, therefore, is concluded to be as follows; XII in non-polar solvents exists exclusively as the azo form, resulting in the merely slight appearance of the hydrazone form as the inflection. This equilibrium, however, is susceptible to any increase in the polarity in the solvent system.

The spectral behavior in a mixed solvent system, as is shown in the table, confirms the above view; the addition of methanol to the chloroformic solution of XII converts the visible bands into what appears to be a single absorption band. Such spectra suggest nearly equal contributions of the azo and the hydrazone forms to the tautomeric equilibrium; i. e., the former appears as an inflection at 486.0 mμ, and the latter, at 560.5 mμ.

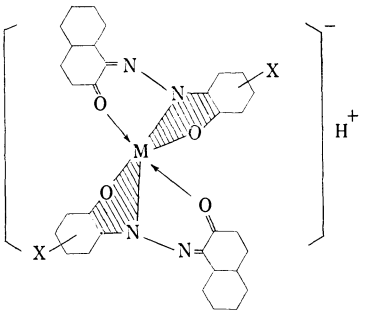
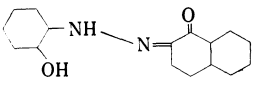
Studies of the Absorption Spectra of Azo Dyes and Their Metal-complexes. VII. The Absorption Spectra of the Metal-complexes Derived from Phenolazo-α- and Phenolazo-β-naphthols[*1]



By Yoshiharu YAGI

(Received July 15, 1963)



The relations between the spectral variation caused by the 2 : 1-metal-complex formation and the nature of the metal-ligand linkages have been investigated with respect to phenolazo-β-naphthols and phenolazo-α-naphthols.

(I)

(II)

(III)

(X : Substituent)

The derivatives of I and III in 95% methanol containing 0.1 g. of acetic acid per liter[*2] exist almost exclusively in the hydrazone form, and their phenolic hydroxyls are fixed in an undissociated state.[1] Most of these derivatives have weak shoulders near 400~420 mμ, shoulders which are due to the small quantity of the azo tautomer in the azo-quinonehydrazone equilibrium.[2]

The 2 : 1-chromium(III)- and cobalt(III)-complexes of the derivatives of I and III, which have an octahedral conformation around the central metal atom,[3] are considered to have the bond type as in II, as was pointed out in Parts III and IV of this study. All the complexes in this study have been purified by column chromatographic separation and by successive reprecipitation.

The main bands in the visible region are shown in the second column.

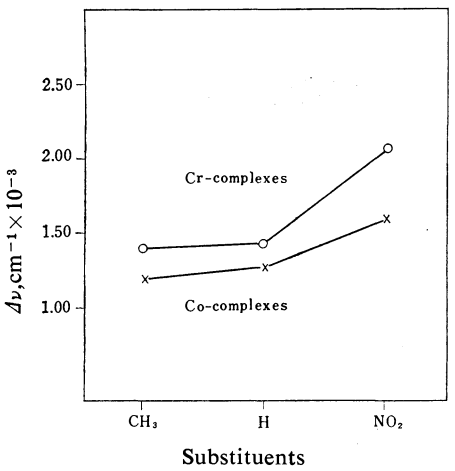

Fig. 2. Relation between the substituents and the shifts of the visible absorption bands with complex-formation; the substituents are on the 5-position of the phenolic nuclei.

As to the chromium(III)- and the cobalt(III)-complexes in the same solvent system as above, the visible absorption bands of the ligands undergo marked bathochromic displacements, resulting in very broad and depressed bands. Generally, the molar extinction coefficients of the complexes alter in the Cr<Co manner, and the half-value widths, in the Co<Cr manner. For instance, the visible absorption band of the chromium(III)-complex (the cobalt(III)-complexes in parenthesis) of (II, X=H) is: λ_{max} =548.9(545.5) mμ, ε=2.52(2.74)$\times10^4$, and the half-value width, l=6.08(4.49)$\times10^3$ cm^{-1}. It is of further interest that there is an inflection at a longer or shorter wavelength side of the main visible band in the spectra of the chromium(III)- or the cobalt(III)-complexes respectively. These are not due to the polarization of the M–O (M, tervalent metal; O, phenolic oxygen) bond by a negative substituent, as was pointed out in Part V, because they show no change in relative

intensity and/or in location as a result of the polarity change of the solvent, and because they also exist in the spectra of the complexes with no nitro group. Their origin is, at present, not known.

The bathochromic shifts of the visible absorption bands of the derivatives of I and III with the complex-formation ($\Delta\nu$, cm^{-1}: differences of absorption maxima between the ligand and the corresponding complex) are shown in Figs. 1 and 2. The substituents at abscissa are conveniently arranged in the generally accepted order[4] of electronegativity at regular intervals.

The bathochromic shifts of the bands with the complex-formation may be ascribed mainly to two factors;[5] (i) the polarity of the M–O (O, phenolic oxygen) bond; i. e., any alteration of the electronic configuration, which polarizes the bond, causes a red-shift[6] of the visible absorption band, and (ii) the perturbation of the π-electron system by the $d\pi$-$p\pi$ interaction between the hydrazone group and the central metal, i. e., the appearance of the resonance stabilized system involving the aromatic nuclei and the chelate ring system.

In the series of complexes II if factor i is markedly dominant, as was shown in the series of complexes in Parts III–V, the 5-OCH_3 derivatives do not have such bathochromic shifts as those of the 5-Cl derivative, as is shown in Fig. 1. It is reasonable to consider that factor ii contributes much to these shifts of bands, since the ligand molecule of II has two powerful aromatic nuclei connected with the hydrazone bridge. Therefore, in the case of the complex the phenolic nucleus of which is substituted by a group of powerful resonance effects, the resonating system involving the d-electrons of the central metal is stabilized, resulting in an increase in the polarizability of the π-electron system and, hence, the bathochromic displacement of the visible absorption band. The visible absorption bands of the complexes, substituted by a nitro group in the 4-position, i. e., in the position para to the hydrazone group, are located at longer wavelength positions than those of the corresponding 5-substituted derivatives. This is presumably because of an intensified effect of factor ii.

With regard to the complexes of III in Fig. 2, however, factors i and ii are considered to be almost equally operative. The relationship between the $\Delta\nu$ and the electronegativities of the substituents if factor i should dominate will be shown in a forthcoming paper.[7]

It has previously been concluded in the series of phenolazoacetoacetamides that the chromium(III)-complex has the ionic M–O (O, phenolic oxygen) bond, whereas the cobalt(III)-complex has the covalent bond. In the II and III series, however, such a peculiarity would be relatively small, since the difference in $\Delta\nu$ between the chromium(III)- and the cobalt(III)-complex is relatively small (that is, the visible absorption positions of both complexes are close together).

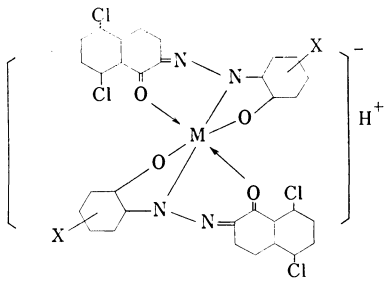
Studies of the Absorption Spectra of Azo Dyes and Their Metal-complexes. VIII. The Absorption Spectra of Azo Compounds Derived from 5,8-Dichloro-1-naphthol and Their Metal-complexes



By Yoshiharu YAGI

(Received August 5, 1963)

In the field of dye chemistry, the 2 : 1-metal complex dyes (II) derived from 2-(2'-hydroxyarylazo) - 5, 8 - dichloro-1-naphthols (I) have been of much interest[1] because of their deeper and relatively clear dyeing shades on the proteinic fibers as compared with the series of complexes studied previously.[2,3] This paper has been undertaken to obtain fundamental information on these azo compounds and their metal complexes.

(I)

(II)
(X: Substituent)

Table I shows the electronic absorption spectra of compound I (X=H) and its methoxy analogue. The characteristic shape of each absorption band exhibits almost no change in spite of the polarity variation of the media. It is noteworthy that both compounds in Table I show splittings of the visible absorption bands and that such absorption maxima are located at markedly longer wavelengths than those of phenolazo-β-naphthols and phenolazo-α-naphthols.[3] If the azo and the quinonehydrazone form coexist[1,3,4] the azo band should appear at about 450 mμ or at a longer wavelength than 450 mμ. No such absorption can, however, be observed at all in a variety of solvents. Compound I and/or its derivatives, therefore, are considered to have the hydrazone structure exclusively.

Table II shows the electronic absorption spectra of the 2 : 1-chromium(III)- and cobalt-(III)- complexes (II) of ligands I, the phenolic nuclei of which are substituted by various kinds of groups in the 4- or 5-position. Marked band-shifts with the complex formation are observed over all the spectra, particularly in the visible region, resulting in appreciably bathochromic displacements and the broad deformation of the bands.

As to the spectra of ligands I, the λ_{max} values of the visible absorptions are in the region of 513~570 mμ and shift towards shorter wavelengths with the introduction of the electronegative substituent at the 5-position of the phenolic ring. There are characteristic inflections close to the main visible bands of the ligands and of their metal-complexes in Table II. In some ligands I (when X=H and

The solvent used is 95% aqueous methanol containing 0.1 g. of acetic acid per liter (the standard solvent).

CH_3), the inflection forms an absorption band, and its intensity is just that, or almost equal to that, of the main band. Regarding the complex bands, the inflection is located on the shorter or the longer wavelength side of the main absorption band of the cobalt(III) or the chromium(III) complex respectively; generally the more electronegative the substituent in the phenolic nucleus, the more intensive the inflection.

The degree of the bathochromic shifts of the visible absorption bands of I and its derivatives with the complex formation, i.e., $\Delta\nu$ (in cm^{-1}) [(ν_{max} of a ligand-band) − (ν_{max} of the corresponding complex-band)] is shown in Fig. 1. Substituents at the abscissa are conveniently arranged in the order of the electronegativity at regular intervals.[5] In this graph, the absorption maxima of the shorter wavelength-side band have been taken as the location of the visible absorptions of the ligands (I, when X=CH_3 and H).

The magnitudes of $\Delta\nu$ in these systems are smaller than those of the phenolazo-β-naphthol series but nearly equal to those of the phenolazo-α-naphthol series discussed in the preceding paper.[6]

As was described in part III of this study, such bathochromic displacements of the bands with the complex formation may be ascribed mainly to two factors; (i) the polarity of the M–O (M, tervalent central metal; O, phenolic oxygen) bond, and (ii) the formation of the resonance-stabilized system involving the aromatic nuclei and the chelate rings. It would be reasonable to apply the above consideration to the system of this study.

If factor ii predominates, the perturbation of the π-electron system by the dπ-pπ interaction between the hydrazone group and the central metal will be emphasized in a system that has a group with a resonance effect as the substituent X. For example, a CH_3 group would cause a larger $\Delta\nu$ value than that in the case of X=H.[6] However, Fig. 1 shows a tendency toward a linear increase in the $\Delta\nu$ value with the increase in the negativity of the substituent. This suggests the dominant character of factor i. Moreover, the actual gradient of the graph becomes markedly steeper, taking into account the fact that the ν_{max} of the ligands (X=H and CH_3) have been taken from the shorter wavelength side bands. Although various factors are conceivable in accounting for such band shifts, the following explanation is considered to be the most reasonable: in the 2:1-metal complexes of formula II, there is a steric repulsion between

the chlorine atom and the quinone oxygen atom, so that the coplanarity of the chelate ring involving the metal atom and the quinone oxygen is much reduced (i. e., factor ii is not effectively operative). Thus, an electron-withdrawing group such as an $-NO_2$ polarizes the M–O bond and increases the polarizability of the absorbing system, resulting in the bathochromic displacements of the visible absorption bands. Such polarization can probably be attributed to both the resonance and the inductive effects, since the $\Delta\nu$ values of the 4-NO_2 derivatives are also appreciably large.

In the metal-complex systems of the previous papers, the wavelength locations of the visible absorption bands have been in the order, Cr> Co. However, this order is reversed in the greater part of Fig. 1. This is presumably because the M–O bond is more ionic in the cobalt(III)-complexes than in the chromium-(III)-complexes.

The author wishes to express hearty thanks to the late Professor Ryutaro Tsuchida of Osaka University for his valuable discussions and encouragement. NOTES

Note on the Association of 3,6-Bis-dimethylaminoacridine in Some Organic Solvents

By Andrzej OLSZOWSKI and Zdzisław RUZIEWICZ

(Received June 12, 1964)

The electronic spectra of 3,6-bis-dimethylaminoacridine (BDAA), i. e., of the acridine orange base, have been subjected to numerous investigations. Mataga[1] has examined the absorption spectra of this compound* in various non-aqueous solvents and reached the conclusion that BDAA dissolved in acetone, buthanol, ethanol and methanol is in a marked degree associated forming the dimers. At concentrations of BDAA of the order of 10^{-6} mol. per liter, this author has obtained only one absorption band, with a maximum at about 500 mμ. With an increasing concentration of BDAA, this band diminished and simultaneously a new band with a maximum at 425~430 mμ, was gradually formed.

In connection with our investigations of the mutual interaction between BDAA and some organic acids in non-aqueous solvents,[3] we have examined anew the dimerization of BDAA in some solvents and have obtained results differing from those cited above.

BDAA was obtained from acridine orange (G. T. Gurr Ltd., London), and was purified chromatographically by a method given by Zanker,[4] the melting point (181~182°C) was in keeping with the literature data.[4] By using proper purification methods[5] the solvents were obtained free from any traces of acids, bases and moisture.

We have found that the absorption spectrum of BDAA in acetone, dioxane, pyridine, benzene and styrene has only one band visible in all the concentrations between 10^{-6} and 10^{-2} mol./1. The maximum of this band lies in range between 23400 and 23600 cm^{-1} (between 427 and 424 mμ) in the dependence of the used

1) N. Mataga, This Bulletin, **30**, 375 (1957).

* In the cited work[1] BDAA was described as 2,8-bis-dimethylaminoacridine probably as a result of the use of another sequence of the numeration of atoms in the rings. However, the description of the preparation method of this compound leaves no doubt that in the work of Mataga[1] an acridine orange base was examined. Cf. also.[2]

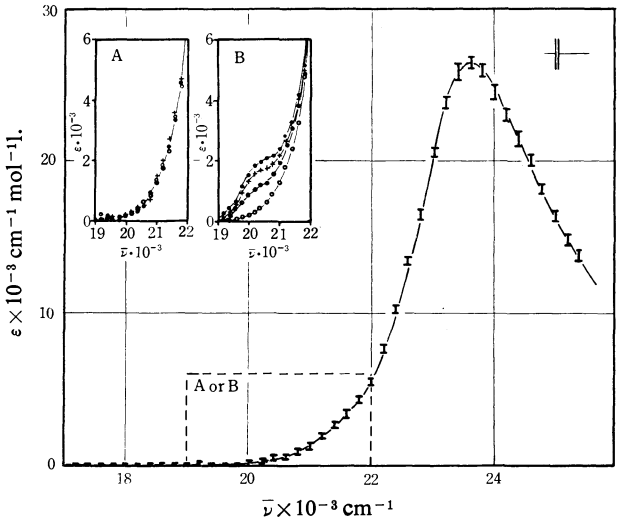

Fig. 1. Absorption spectrum of BDAA solution in acetone.
"A" Part of spectrum in the range of 19000~22000 cm^{-1}; solvent—absolute acetone.
"B" The same part of spectrum, solvent—acetone containing traces of water (<0.1%).
Experimental points correspond to the following BDAA concentrations: ●—● 4.0×10^{-6}, +—+ 4.0×10^{-5}, ◐—◐ 1.6×10^{-4}, ○—○ 6.0×10^{-3} mole per liter.

solvent, and its molar absorptivity at a maximum is equal to 25000~29000 $mol^{-1}\,cm^{-1}\,l$. The corresponding results obtained for the acetone solutions are shown in Figs. 1 and 1A. According to the data of Mataga[1] the above band should appear as a result of the BDAA dimers; however, because of the lack of any relation between the molar absorptivity and the concentration, and because of the presence of this band even at low BDAA concentration, we hold that this band is characteristic of the BDAA monomers. We have not found any changes indicating the association of BDAA molecules in the cases mentioned. It should be emphasized that in pyridine, in which, according to Mataga,[1] no association occurs, we have also observed the same band with a maximum at 23400 cm^{-1}.

The band with a maximum at about 20200 cm^{-1} (495 mμ), which according to Mataga should belong to the BDAA monomer, appears when some compounds of strong proton-donor properties are introduced to the solutions of BDAA in non-aqueous solvents. (Cf. Fig. 2, curves 5 and 6). The mutual interaction of BDAA with week proton donors such as methanol (Fig. 2, curve 3) or phenol[2] through the hydrogen bond brings about only a weak shift of the 23400 cm^{-1} band towards longer wavelengths. However, under the action of carboxylic acids probably some proton transfer from the acid molecule towards nitrogen in the acridine ring of the BDAA molecule takes place, bringing about the formation of an ionic pair. In our opinion this effect seems to be responsible for the appearance of the 20200 cm^{-1} band. This conclusion is to some extent

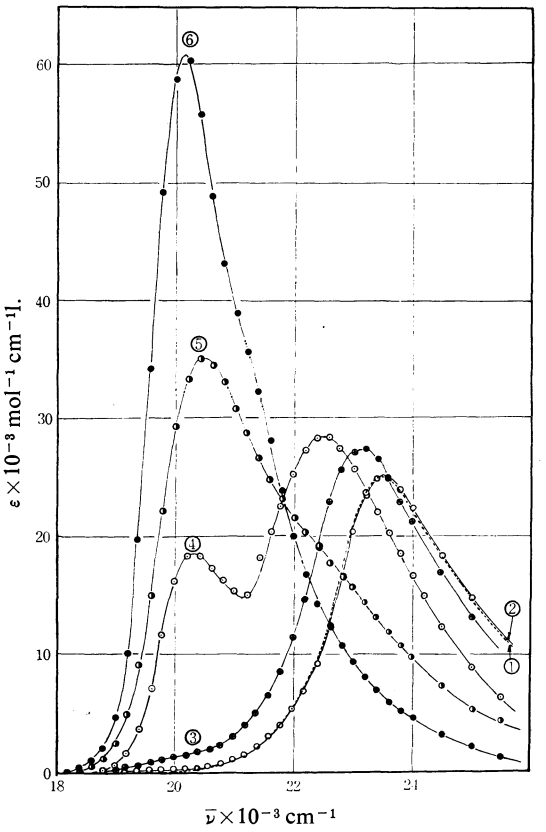

Fig. 2. Absorption spectra of BDAA ($c=4.0\times10^{-5}$) in solutions of benzene.
1: without addition of third component
2: with acetone ($c=2.2\times10^{-1}$)
3: with methanol ($c=2.0\times10^{-1}$)
4: with *p*-hydroxybenzonitrile ($c=1.33\times10^{-3}$)
5: with benzoic acid ($c=1.22\times10^{-3}$)
6: with trichloroacetic acid ($c=1.20\times10^{-4}$)
All concentrations in mole per liter.

confirmed by the fact that an analogous band appears in aqueous and alcohol solutions containing the acridine orange cations, i. e., monocations of BDAA.[4,6] We have also observed an intermediate state by adding *p*-hydroxybenzonitrile to the BDAA solution, thus producing both the shift of the 23400 cm^{-1} band towards red and the appearance of the 20200 cm^{-1} band (Fig. 2, curve 4).

In solvents not sufficiently dried or containing some acidic contaminations besides the 23400 cm^{-1} band, the band at 20200 cm^{-1} appears too. This kind of spectrum was obtained when we used not sufficiently dehydrated acetone (Fig. 1B) or acrylonitrile which we had not succeeded in purifying to a sufficient degree. However, the intensity of the 20200 cm^{-1} band in acrylonitrile does not exceed 15% of the intensity of the 23400 cm^{-1} band, even at very low concentrations of BDAA, and essentially depends on the mode of purifying the solvent. Hence, even in this case we cannot ascertain any association of BDAA.

A more detailed discussion of acidic-basic interaction in BDAA solutions will be published shortly.[3]

The Temperature Dependence of the Limiting Conductances of the Aqueous Solutions of Some Aromatic Sulfonates

By Hatsuho UEDAIRA and Hisashi UEDAIRA

(Received June 23, 1964)

In a previous paper[1], it was reported that hydrophobic bonding plays an important role in the association of the dye ion. It is thought that the transport properties of such organic ions as the dye ion will be influenced by the ice-like structure of water around the non-polar group. These transport properties will also be affected by the interaction between water and the ionized group of organic ions. In this investigation, the limiting equivalent conductances will be obtained for sodium salts of benzenesulfonic (to be abbreviated BSNa), α-naphthalenesulfonic (NSNa), *m*-benzenedisulfonic (BDSNa), and 1,5-naphthalenedisulfonic (NDSNa) acids at 35, 45, and 55°C (and at 25°C for NSNa), and the activation energies of the limiting mobilities for these sulfonate ions, U, will be calculated.

Experimental

Sodium sulfonates were decolorised with active carbon and recrystallized four times for BSNa, NSNa, and NDSNa (G. R. Tokyo Kasei Co.) or six times BDSNa (technical grade) from a water-ethanol solution and dried at 110°C over phosphorus pentoxide.

The experimental method of conductance has been reported elsewhere.[1]

1) H. Uedaira and H. Uedaira, *Kolloid-Z. Z. für Polym.*, **194**, 148 (1964).

Results and Discussion

The limiting equivalent conductances, λ°, of sulfonates were obtained by the Fuoss-Onsager extended equation:

$$\lambda=\lambda^\circ-SC^{1/2}+EC\ \log\ C+JC$$

The symbols are as defined by Fuoss and Accascina.[2] The limiting mobilities, λ_-°, of sulfonate ions were obtained from these limiting conductances.[3] The activation energies, U, of sulfonate ions were calculated from the temperature dependence of their limiting mobilities. The plots of $\log\lambda^\circ$ against $1/T$ are linear for all sulfonate ions in the range of experimental temperatures; thus the activation energies are independent of the temperature. The results are given in Table I. In Table I the radii, r, of the equivalent spheres obtained from models based on Pauling[4] are given also.

As may be seen from Table I, the relation between the activation energy of the limiting mobility and the ionic radius is not linear. Though the ionic radius of BDS^{-2} is nearly

Table I. The limiting mobilities at various temperatures and activation energies of sulfonate ions

Ion	Temp. °C	λ° $cm^2\Omega^{-1}$ $equiv^{-1}$	r Å	U kcal.·mol^{-1}
BS^-	25	34.9[5a]		
	35	41.8	3.50	3.36
	45	50.0		
	55	58.7		
NS^-	25	29.3		
	35	36.6	3.71	3.75
	45	43.6		
	55	52.4		
BDS^{2-}	25	59.9[5b]		
	35	70.0	3.70	3.32
	45	85.9		
	55	99.8		
NDS^{2-}	35	57.8		
	45	70.0	3.89	3.54
	55	82.6		

equal to that of NS^-, the value of U for the former is smaller than that for the latter. Consequently, the activation energy depends not only on the size of the ion, but also on the ion-solvent interaction.

An aromatic sulfonate ion differs from an inorganic ion in having both a hydrophobic part (aromatic ring) and a hydrophilic part (sulfonic group). Each of the two parts has a different interaction with water. The aromatic part increases the ice-like structure of the watar in its neighborhood.[6,7] Therefore, the local viscosity of the water in this region should be higher than that of bulk water. According to Samoilov,[8] the activation energy of the ion transport depends upon the exchange of water molecules in the immediate neighborhood of the ion. As the frequency of the exchange of water molecules around the aromatic ring should be smaller than that of bulk water, the sulfonate ion with the larger aromatic ring has the larger activation energy, and the smaller mobility.

The sulfonic group is considered to be a mono-valent ion with a large radius, and the nearest neighbor water molecules around such ions become more mobile than in pure water because of the destruction of the structure of water by the ionic field.[8]

It is interesting to compare the limiting mobility of the BS^- ion with that of the benzoate ion. The limiting mobility at 25°C and the activation energy of the benzoate ion are 32.5 $cm^2\Omega^{-1}equiv^{-1}$ and 4.21 kcal. mol^{-1} respectively,[9] and its ion radius is 3.35 Å. Though the benzoate ion is smaller than the BS^- ion, the former has the smaller mobility and the larger activation energy. Gurney[10] suggested that the water structure close to the carboxyl group is in order. Consequently, the frequency of the exchange of the water around the carboxyl group is smaller than that of bulk water. The difference between the limiting mobilities of the BS^- ion and the benzoate ion is explained by the structure-breaking effect of the sulfonic group. The sulfonic group will also partially break out the ice-like structure around the aromatic ring.

Thus, it is clear that the activation energy of the NS^- ion is the largest and that of the BDS^{2-} ion is the smallest, and that the mobility of the NS^- ion is the smallest and that of the BDS^{2-} ion is the largest. The interactions between the water and hydrophobic part and the ionized group of organic ions play important roles in the transport properties.

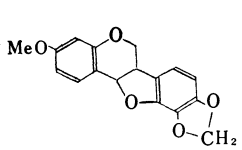
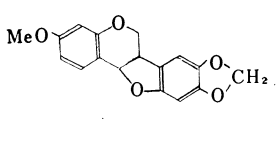
The Synthesis of 7-Methoxy-5′,6′-methylenedioxybenzofurano(3′,2′; 3,4)coumarin

By Kenji FUKUI, Mitsuru NAKAYAMA and Haruo SESITA



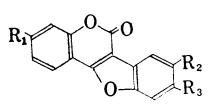
(Received July 10, 1964)

The structure of pterocarpin was proposed by McGookin et al. as 7-methoxy-6′,7′-methylenedioxy-2′,3′-dihydrobenzofurano(3′,2′; 3,4)-chroman (I).[1] Recently, on the basis of nuclear magnetic resonance spectral analysis, Bredenberg and Shoolery proposed the revised structure of 7-methoxy-5′,6′-methylenedioxy-2′,3′-dihydrobenzofurano(3′,2′; 3,4)chroman (II).[2] 7-Methoxy-5′,6′-methylenedioxybenzofurano(3′,2′; 3,4)coumarin (III) has an oxygen pattern similar to that of II in the aromatic rings.



The synthesis of the coumarin (III) by the methylenation reaction of 7,5′,6′-trihydroxy compound (IV)[3] has, however, so far been unsuccessful. On the other hand, 7,5′,6′-trimethoxy compound (V)[3] has already been obtained by the methylation of IV.

In the present paper, we will describe the synthesis of III from 7-methoxy-4-hydroxycoumarin (VI)[4] by the Wanzlick method.[5]



The dehydrogenatic condensation of catechol and VI in the presence of potassium ferricyanide gave a 40% yield of 7-methoxy-5′,6′-dihydroxybenzofurano(3′,2′; 3,4)coumarin (VII) (m. p. > 300°C). VII gave a strong fluorescence in ethanol or acetone and a dark violet color reaction with alcoholic ferric chloride. A dimethyl ether (V) (m. p. 247~248°C) and a diacetate (VIII) (m. p. 225~226°C) of VII were prepared. The former showed no depression of the melting point on admixture with an authentic sample.[3] The methylenation of VII with methylene iodide afforded III (m. p. 269~270°C). III gave a green color reaction with gallic acid, and its infrared spectrum showed the absorption peaks at 1038 and 920 cm^{-1}, indicating the presence of a methylenedioxy group.[6] Moreover, the ultraviolet spectra of III and V are essentially identical (Fig. 1), and III gave a strong fluorescence in ethanol or acetone.

* All melting points are uncorrected; the infrared spectra were measured in Nujol, while the ultraviolet spectra were measured in an ethanol solution.

After 1.5 hr., the resulting mixture was filtered from the precipitates (inorganic salts). The residue was washed with a solution (acetone : water = 3 : 1). The combined filtrate was then treated with 46% formic acid (10 ml.), concentrated to ca. 80 ml. in vacuo, and then left overnight. The precipitates were collected and recrystallized from acetone to given VII in the form of pale yellow needles; m. p. > 300°C; yield 0.65 g. (40%). This gave a blue fluorescence in ethanol or acetone and a dark violet color with an alcoholic ferric chloride solution. IR: 3310 (broad) (OH); 1725 (α-pyrone) cm^{-1}. UV: λ_{max} mμ (log ε); 210 (4.80), 250 (4.34), 288 (3.92), 301_1 (3.94), 310 (3.97), 355 (4.45).

Found: C, 64.69; H, 3.11. Calcd. for $C_{16}H_{10}O_6$: C, 64.43; H, 3.38%.

The diacetate (VIII): acetic anhydride-pyridine method; m. p. 225~226°C (colorless needles from acetone). IR: 1776, 1759, 1730 (acetate, α-pyrone) cm^{-1}. UV: λ_{max} mμ (log ε); 240 (4.34), 266 (3.90), 288.5_1 (3.90), 299 (4.12), 335 (4.54), 342_1 (4.44), 351 (4.45).

Found: C, 62.58; H, 3.54. Calcd. for $C_{20}H_{14}O_8$: C, 62.83; H, 3.69%.

7, 5', 6'-Trimethoxybenzofurano (3', 2'; 3, 4) coumarin (V).—A mixture of VII (0.5 g.) methyl iodide (1.0 g.) and anhydrous potassium carbonate (3.0 g.) in anhydrous acetone (300 ml.) was refluxed for 5 hr. on a steam bath. The reaction mixture was then filtered from the precipitates. The filtrate was distilled and the residue was recrystallized from acetone to give V in the form of colorless needles; m. p. 247~248°C; yield 0.5 g. (88%). This was identical with an authentic sample[3] (m. p. 248~249°C) and gave a blue fluorescence in ethanol or acetone. IR: 1730 (α-pyrone) cm^{-1}. UV: λ_{max} mμ (log ε); 211 (4.77), 246 (4.30), 283.5 (3.98), 297 (3.89), 310 (4.06), 348 (4.52).

Found: C, 66.21, H, 4.42. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

7-Methoxy-5', 6'-methylenedioxybenzofurano (3', 2'; 3, 4) coumarin (III).—A mixture of VII (0.5 g.), methylene iodide (1.0 g.) and anhydrous potassium carbonate (3.0 g.) in acetone (300 ml.) was refluxed for 30 hr. on a steam bath; then the solvent was evaporated. The water was added to the residue. The resulting precipitates were collected and recrystallized from acetone to give III in the form of colorless microcrystals; m. p. 269~270°C; yield 0.25 g. (47%). This gave a green color reaction with gallic acid and a blue fluorescence in ethanol or acetone. IR: 1746 (α-pyrone); 1038, 943 (O-CH_2-O). UV: λ_{max} mμ (log ε); 245 (4.25), 283 (3.87), 297 (3.83), 309 (3.99), 347 (4.40).

Found: C, 65.52; H, 3.14. Calcd. for $C_{17}H_{10}O_6$: C, 65.81; H, 3.25%.

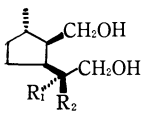
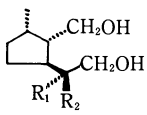
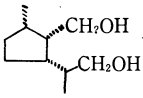
SHORT COMMUNICATIONS

Iridodiols, the Effective Components of Actinidia Polygama for Chrysopidae

By Takeo SAKAN, Sachihiko ISOE, Suong Be HYEON, Teiichi ONO and Ichirō TAKAGI







(Received July 17, 1964; in revised form November 4, 1964)

In previous papers[1] we reported the structures of matatabilactone and actinidine, the effective components of *Actinidia Polygama* Miq. for Felidae animals. It has been privately communicated[2] that the male of a sort of lacewing (*Chrysopa septempunctata* Wesmael)[3] is also attracted by the same plant. Attempts have now been made to isolate the effective component from the gall of *Actinidia Polygama* Miq. The elaborate column chromatography on alumina and silicic acid of the neutral fraction extracted from the ground gall with

methanol yielded an oil which had a potent activity. Although the vapor phase chromatography of this oil revealed three close peaks and the thin layer chromatography of this oil gave two spots, the mass spectrum and the infrared spectrum of this oil were in close agreement with those of α-iridodiol (I),[4] m. p. 80°C, derived from isoiridomyrmecin by lithium aluminum hydride reduction. Therefore, this seemed to be a mixture of α-iridodiol and its stereoisomers. In fact, the α-iridodiol derived from isoiridomyrmecin showed activity of almost the same order for *Chrysopa* as for the oil obtained above.

Fortunately we could assign all peaks in the vapor-phase chromatography of the oil as α or δ-iridodiol (I),[4] β or γ-iridodiol (II)[5] and all *cis*-iridodiol (III)[6] by a comparison of the retention times. The isolation of each effective component is in progress. In addition to iridodiols, the synthetic alcohols IV, V, and VI[6] also showed activity of a much lower order.

The Polymerization of Acetylenes with Dicyclopentadienyl-vanadium

By Ryuichiro TSUMURA and Nobue HAGIHARA

(Received August 18, 1964)

Although a large number of organometallic complexes have been reported in which aromatic rings such as cyclopentadienyl and benzene are coordinated to the transition metals, their possible catalyses have not yet been extensively studied. It has previously been shown in our laboratory that the oxygenated product of dibenzene-chromium has a catalytic activity of the polymerization of ethylene.[1] We will now report that paramagnetic dicyclopentadienyl-vanadium[2] (I) catalytically polymerizes various acetylenes. This seems to be the first example of the polymerization of acetylenes with metallocene only.

As a typical experiment, in a 100 ml. stainless steel autoclave 0.375 g. (2.07 mmol.) of I was dissolved in 50 ml. of benzene under nitrogen. Acetylene was introduced to about 15 kg./cm^2. The reaction system was then continuously shaken and maintained under the pressure of 15~22 kg./cm^2, by means of the occasional addition of acetylene, at 80°C for 6 hr. When the reaction muds were treated with a solution of methanol and hydrochloric acid (1 : 1 by volume) under nitrogen, they gave 2.85 g. of a black solid (Found : C, 87.94 ; H, 7.34 ; Ash, 0.00%). In a similar reaction in toluene, no liquid products such as benzene and linear oligomers were found.

The black solid was thermally stable at 200°C and insoluble in all organic solvents. The infrared spectrum was essentially identical to that of the conjugated *trans*-polyacetylene obtained by Natta et al.[3] and by Hatano[4]. The polymer was gradually oxidized when left standing in air, in a few months changing into an orange solid whose infrared spectrum showed

a) The alkyne and catalyst I were dissolved in 30 ml. of benzene under nitrogen, and the solution was heated at 100°C in an ampule for 5 hr. (1-alkynes) or for 4 hr. (phenylacetylene).
b) The liquid products were separated by distillation, and the solid products were isolated by reprecipitation.
c) The proportion of 1, 3, 5- to 1, 2, 4-trisubstitution was determined by gas chromatographic analyses.
d) By the cryoscopic benzene method.

the presence of carbonyl and hydroxyl groups. A suspension of the black polymer in carbon tetrachloride added chlorine to give a white solid, which was then soluble in dimethyl formamide. These facts indicate that the black solid obtained may be a linear, high-molecular-weight polymer, containing quite long sequences of conjugated double bonds in the trans configuration.

1-Alkynes have been polymerized by catalyst I, too. The experimental results are summarized in Table I. The infrared spectra of the products showed that they are composed of mixtures containing 1, 3, 5- and 1, 2, 4-trialkylbenzene as the major products and a small quantity of higher oligomers. *t*-Butylacetylene was inert in the catalytic reaction; a bulky *t*-butyl radical is presumed to hinder cyclotrimerization by the catalyst.

Phenylacetylene gave an orange-yellow solid, whose infrared spectrum and molecular weight indicate that it may be a linear oligomer in the trans configuration. No cyclization to benzene derivatives was observed in this reaction. Attempts to polymerize propargyl alcohol and disubstituted acetylenes, such as 3-heptyne, 2-butyne-1, 4-diol, and tolane, were unsuccessful.

It is of great interest that the catalysis of dicyclopentadienyl-vanadium is remarkably selective, as has been mentioned above, and different from that[5] of bis(triphenylphosphine)-dicarbonyl-nickel in the catalytic polymerization of acetylenes. In relation to this problem, we have prepared some new, highly air-sensitive acetylene complexes such as π-$C_5H_5(C_2H_2)$-$V(CO)_2$. The investigation of the acetylene complexes of vanadium will be published elesewhere.

The Radioactivation Analysis of Graphite for Nitrogen by the $^{14}N(p, \alpha)^{11}C$ Reaction

By Tadashi NOZAKI and Kazuhiko YAZAWA

(Received August 22, 1964)

A successful method for analyzing graphite for an ultra-trace quantity of nitrogen will be presented. All the methods ever previously reported for determing trace nitrogen (the vacuum-fusion technique, the Kjeldahl method, emission and mass spectroscopy, radioactivation analysis by $^{14}N(n, 2n)^{13}N$ or $^{14}N(\gamma, n)^{13}N$,[1] etc.) are either inapplicable to graphite or are of limited sensitivity. Further, any surface once exposed to air is contaminated with nitrogen. Making use of radioactivation analysis by means of a $^{14}N(p, \alpha)^{11}C$ reaction, we succeeded in determining as small an amount as several tens p. p. b. of nitrogen in pyro-graphite. Recently, pyro-graphite prepared by the thermal decomposition of pyridine was found to have very interesting semiconductor characteristics, which would be due to the presence of a trace of nitrogen.

The excitation function for $^{14}N(p, \alpha)^{11}C$ up to 15 MeV. was measured by the stacked-foil method, each foil being a nylon film about 22 mg./cm^2 thick. The results showed that 1 p. p. m. of nitrogen in carbon gave 5.3×10^3 d. p. s. ^{11}C as the thick-target saturation-activity for 15 MeV.-1 μamp. protons. The mean recoil range of the ^{11}C for the 14.2 MeV. proton was also measured by inserting a recoil-catcher in the stack; it was found to be 0.36 mg./cm^2. With a $^{16}O(\alpha, pn)^{18}F$ reaction, we previously showed that the surface layer, of a thickness about five times the recoil range of ^{18}F, should be removed in order to eliminate the effect of surface oxygen.[3] Therefore, the surface layer about 1.8 mg./cm^2 thick is removed in the present case. Since the irradiated graphite also contained ^{13}N (formed by $^{13}C(p, n)^{13}N$)[4] and longer-lived nuclides (from impurities), chemical treatment was necessary for a reliable measurement of the ^{11}C. Oxidation in strong phosphoric acid developed by Kiba et al.[5] proved useful in decomposing the sample. The graphite itself was the carrier of ^{11}C.

A plate of pyro-graphite ($30 \times 10 \times 2$ mm.) was placed on a water-cooled target-holder and irradiate with protons (15 MeV., 5 μamp., 10 min.). After the surface layer had been uniformly removed by mechanical grinding, the sample was finely pulverized. It was then added into a flask containing strong phosphoric acid (50 ml.), sulfuric acid (30 ml.) and potassium iodate (25 g.) heated to 160~170°C. Gentle heating was continued, and the carbon dioxide formed was introduced into another flask containing sodium hydroxide (2 N, 200 ml.). To make the absorption of carbon dioxide in a closed system smooth and easy, the air in both the flasks had been replaced with nitrogen oxides (from sodium nitrite and sulfuric acid), and the contents of the absorption flask were separated from atmospheric air by a movable layer of carbon tetrachloride. The nitrogen oxides worked also as a hold-back carrier of ^{13}N. When the oxidation became less vigorous, even at 240°C, perchloric acid (65%, a few milliliters) was carefully dripped in to complete the reaction. When all the graphite had been oxidized, nitrogen oxides were passed through to carry all the carbon dioxide into the sodium hydroxide solution. After. the solution had been treated with hydrazine hydrate (1 g.), barium carbonate was precipitated and filtered off. The process after the irradiation required 40 to 50 min. The recovery was almost quantitative, but so large a quantity of barium carbonate was formed that only a part of it was taken for the activity measurement. The annihilation radiation was measured by a scintillation counter of a known efficiency. The decay curve and the γ-ray spectrum were satisfying for a reliable determination of ^{11}C. The nitrogen content was calculated from the disintegration-rate by the absolute method, the only possible source of interference being $^{11}B(p, n)^{11}C$ under our conditions.

Pyro-graphites made from pyridine contained 1 to several p. p. m. of nitrogen, while those made from propane had less than a few hundred p. p. b. This method appears to be

*The Partial Structure of Pederin**

By Takeshi MATSUMOTO, Satoshi TSUTSUI, Mitsutoshi YANAGIYA, Seiichi YASUDA, Sawae MAENO, Junji KAWASHIMA, Akira UETA and Masuo MURAKAMI

(Received September 7, 1964)

In 1949, one of the present authors (A. U.)[1] reported the isolation of a toxic principle, m. p. 114°C, from *Paederus fuscipes*. Reinvestigation of this material has now revealed that it is identical with pederin, $C_{25}H_{45}O_6N$, isolated from the same insect by Pavan and Bo[2] in 1953 and recently studied chemically by Quilico et al. and Cardani.[3,4] The infrared spectrum of pederin exhibits bands at 3480, 3380 (OH, NH), 1665, 1510 (NHCO), 3060 and 900 cm^{-1} ($\rangle C{=}CH_2$). Contrary to the opinion of the Italian workers, however, the latter two bands indicate the presence of at least one double bond in pederin. Since no other band is observable in the olefinic C–H stretching vibration region,[5] the only additional double bond that could possibly be present would be tetrasubstituted. The double bond is not conjugated ($\varepsilon_{200\,m\mu}$ 1400). On being treated with acetic anhydride and pyridine, pederin affords a diacetate, $C_{29}H_{49}O_{11}N$[6], m. p. 106°C, which shows bands at 3500 (broad, OH), 3360 (NHCO), 1740, 1720 (CH_3CO_2), 1700, 1520 (CONH), 3060 and 1650 cm^{-1} ($\rangle C{=}CH_2$). The NMR spectrum of pederin[7] exhibits its main peaks at the following positions (these peaks are assignable to the following groups by comparison with the spectrum of its diacetate): τ 9.11, 9.04 (each s, CH_3–$\overset{|}{C}$–), 8.98, 8.82 (each d, J 7 c. p. s., $\underline{CH_3}$–$\overset{|}{C}$–H), 7.55 (s, –$\overset{|}{C}$–CH_2–CO), 6.67 (s, 2 OCH_3), 6.61 (s, 2 OCH_3 and –O–CH_2–$\overset{|}{C}$–)[8], 6.20 (broad, 2 $\underline{H}$–$\overset{|}{C}$–OCH_3), 5.65 (s, $\underline{H}$–$\overset{|}{C}$–OH), 5.26, 5.18 (each broad s, $\rangle C{=}CH_2$) and 4.66 (m, $\overset{C}{H}\rangle C\langle\overset{OR}{OR}$). Since the peak due to the –$\overset{|}{C}$–CH_2–O– group in pederin does not shift appreciably to a lower field in the spectrum of diacetate, the oxygen atom in this group must be ethereal. Thus, out of the nine oxygen atoms of pederin, four are present as methoxyl groups, one as an amide, one as a C–O–CH_2–$\overset{|}{C}$– group and three as hydroxyl groups, two of which are acylable. A dimethyl acetal group is absent, since the *m/e* 75 peak is negligibly weak in the mass spectrum of both pederin and its diacetate. The spectroscopic evidence described above, coupled with the chemical findings[3] that preudopederin yields oxamic acid upon oxidation and that pederin

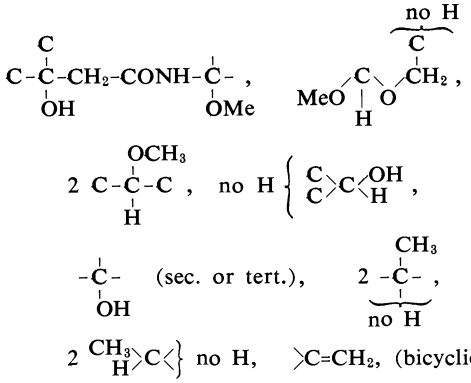
4) The identity of the two substances was confirmed by a direct comparison of m. p.'s and infrared spectra. We wish to express our sincere thanks to Professor Cardani for his generous gift of a sample of pederin.



5) The infrared spectrum was obtained by means of a JASCO 401G grating spectrometer.

6) The molecular formulas of diacetate and pederin itself were confirmed by elemental analysis and mass spectrometry. The mass spectra were measured by Mr. Hiroshi Sato of the Hitachi Naka works, to whom our sincere thanks are due.

7) Measured in a $CDCl_3$ solution containing a small amount of pyridine as a stabilizer for pederin; pederin is very sensitive to acids.

8) In the spectrum of diacetate, the peak due to the -OCH_2-$\overset{|}{C}$- group appears at 6.52 as a broad singlet while the peaks due to methoxyl groups appear at 6.60 (3H), 6.64 (6H) and 6.83 (3H); the singlet line at 5.65 ($\underline{H}$-$\overset{|}{C}$-OH) in the spectrum of pederin is shifted to 4.70. The intensity of the broad absorption centered at 6.20 indicates the presence of two -$\overset{|}{C}$H-OCH_3 groups in acetate.

readily splits off ammonia upon treatment with acid, suggest the presence of the following moieties in pederin:

The molecular formula indicates that pederin is bicyclic if the tetrasubstituted double bond is absent.

The Appearance of Free Radicals during the Photo-decomposition of Nitrosobenzenes

By Kazuhiro MARUYAMA, Rikuhei TANIKAGA and Ryozo GOTO

(Received October 3, 1964)

It has been reported that azoxybenzene, *p*- and *o*-hydroxyazobenzene, nitrobenzene, aniline and other minor amounts of hydroxyazoxybenzenes were formed by the photochemical decomposition of nitrosobenzene.[1] The present authors examined the process of the photochemical decomposition of several nitrosobenzene derivatives by using the ESR technique.

The subject of this investigation is the decomposition of nitrosobenzene, *o*-, *m*-, and *p*-methylnitrosobenzene, and *o*-, *m*-, and *p*-chloronitrosobenzene. Pure nitrosobenzene derivatives were dissolved in dry pure tetrahydrofuran and completely degased and illuminated by a 400-W. high pressure mercury-arc lamp at room temperature. These nitrosobenzene derivatives without exception produce free radicals from the beginning of decomposition. As the decomposition proceeds, the

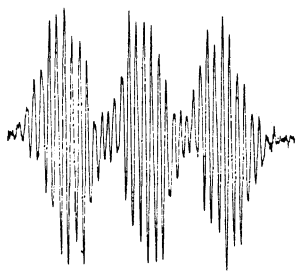

Fig. 1(a) ESR spectrum of free radicals produced by the photo-decomposition of nitrosobenzene.

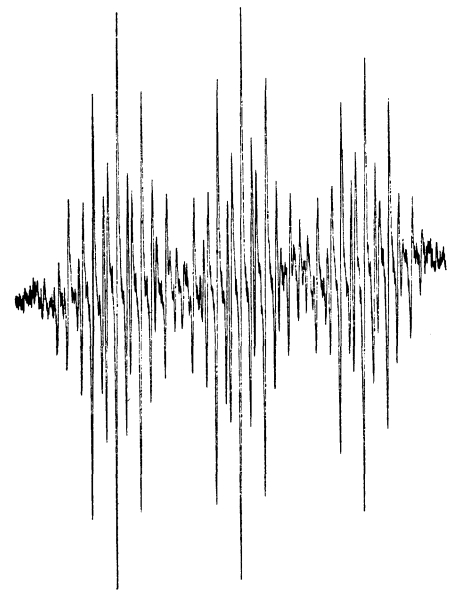

Fig. 1(b) ESR spectrum of free radicals produced by the photo-decomposition of *m*-chloronitrosobenzene.

1) E. Bamberger, *Ber.*, 35, 1606 (1902).

color of the solutions changed from green to brown. The free radicals produced were identified as the derivatives of diphenylnitroxide by the hyperfine structures of their ESR spectra; some of them are reproduced in Fig. 1.

It is noteworthy that the radicals produced from *o*-, *m*-, and *p*-substituted derivatives of nitrosobenzene were highly position-specific; *o*-methylnitrosobenzene decomposed to *o*,*o*'-dimethyldiphenylnitroxide, *m*-nitrosobenzene to *m*,*m*'-dimethyldiphenylnitroxide, *p*-methylnitrosobenzene to *p*,*p*'-dimethyldiphenylnitroxide, *o*-chloronitrosobenzene to *o*,*o*'-dichlorodiphenylnitroxide, *m*-chloronitrosobenzene to *m*,*m*'-dichlorodiphenylnitroxide, *p*-chloronitrosobenzene to *p*,*p*'-dichlorodiphenylnitroxide, and so on. Their ESR spectra show well-resolved hyperfine structures. Diphenylnitroxide, *m*,*m*'-dimethylnitroxide, and *p*,*p*'-dimethyldiphenylnitroxide were identified by a comparison of their ESR spectra with those of known samples. *p*,*p*'-Dichlorodiphenylnitroxide, *m*,*m*'-dichlorodiphenylnitroxide and *o*,*o*'-dichlorodiphenylnitroxide were clearly identified from the analysis of the ESR spectra obtained. Only *o*,*o*'-dimethyldiphenylnitroxide remains to be clarified completely; its spectrum shows a rather broad hyperfine structure.

Experimental.—*Derivatives of Nitrosobenzene.*—All the nitosobenzenes described above were synthesised from the corresponding nitro-derivatives. Nitro-derivatives were reduced to the corresponding hydroxylamine derivatives and oxidized to the nitroso-derivatives by a ferric chloride solution. The nitroso-derivatives obtained were carefully recrystallized from ethanol until their solutions in tetrahydrofuran became free from any ESR signal. Their physical constants were: nitrosobenzene, m. p. 68°C; *o*-methylnitrosobenzene, m. p. 72.5°C; *m*-methylnitrosobenzene, m. p. 53.5°C: *p*-methylnitrosobenzene, m. p. 49.0°C; *o*-chloronitrosobenzene, m. p. 56.5°C; *m*-chloronitrosobenzene, m. p. 72.0°C; *p*-chloronitrosobenzene, m. p. 89.5~90.0°C.

The ESR measurements were carried out by using a JEOL-3X spectrometer manufactured by the Japan Electron Optics Laboratory.

We are now performing the chemical analysis of the photo-decomposition products of nitrosobenzene derivatives, along with an ESR study to find the precise mechanism of the photochemical decomposition of nitrosobenzene derivatives.

The Ultraviolet Spectra of Some Polysilanes[1]

By Hideki SAKURAI and Makoto KUMADA

(Received October 9, 1964)

A recent article[2] prompts us to report some results of our own studies on p_π-d_π bonding in polysilanes. Although the literature contains several references to the participation of 3d orbitals fo silicon to effect enhanced bonding in phenyl[3] or vinyl-substituted silanes,[4] the investigation of this kind of participation has not been extended to the spectral study.

Ultraviolet spectroscopic investigations, however, afford an obvious source of information concerning the electronic levels of these molecules, and will serve to provide an important criterion for the existence of dative p_π-d_π bonding.

During the course of our study of the properties of silicon-silicon bonding, it has been found that polysilanes with a phenyl or vinyl group have a very intense absorption in the ultraviolet region, unlike phenyltrimethylsilane[5] and vinyltrimethylsilane.[6]

The absorption spectra of some phenyl or vinyl substituted disilanes and trisilanes in *n*-hexane were studied in the ultraviolet region, 210~260 mμ; the experimental results are presented in Table I. Hexamethyldisilane, the

parent compound, was found to have no absorption in this region.

Recently, Hague and Prince[7] have reported an intense absorption at 246.5 mμ for hexaphenyldisilane. They described this absorption as an interaction between phenyl groups through the silicon-silicon bond. However, judging from the table, apparently the most striking red shift in the absorption maxima is observed for phenylpentamethyldisilane; namely, the introduction of a pentamethyldisilyl group into benzene causes a red shift to the extent of 28 mμ in the 200 mμ-band.[8]

TABLE I. UV SPECTRA OF SOME POLYSILANES

Polysilane	λ_{max} mμ	ε_{max}
$PhSiMe_2SiMe_3$	231.0	10900
$PhSiMe_2SiMe_2Ph$	238.0	18500
$Ph_2SiMeSiMePh_2$	240.0	25900
$CH_2=CH-SiMe_2SiMe_3$	223.2	5200
$CH_2=CH-SiMe_2SiMe_2-CH=CH_2$	227.0	9790
$PhSiMe_2SiMe_2SiMe_3$	240.0	15400
	221.3	13000
$Me_3SiSiMePhSiMe_3$	243.0	13000

Therefore, the evidence thus obtained suggests that the pentamethyldisilyl group can interact directly with the phenyl group, possibly by p_π-d_π conjugation. A rather small shift in the absorption maxima can be found when a second phenyl group is introduced into phenylpentamethyldisilane at the vicinal position, while the absorption intensity increases. Almost the same trends are observed for vinylpentamethyldisilane and divinyltetramethyldisilane.

Since the trimethylsilyl group has only a small bathochromic effect on benzene[5] or ethylene,[6] it seems reasonable to assume that the silicon-silicon bond is essential as a chromophore to make an enhanced conjugation with benzene or ethylene.

Further details will be published later.

8) Fine structures in the 260 mμ-band are almost masked by the strong absorption near 235 mμ in phenyl-substituted polysilanes.

*Preparation of δ-Cyanovaleric Acid Ester by Cathodic Crossed Coupling**,***

By Kiichiro SUGINO, Kozo SHIRAI and Tsutomu NONAKA

(Received October 12, 1964)

An electrolytic method for preparing adipodinitrile by the cathodic hydrodimerisation of acrylonitrile has recently been described.[1] We have now attempted to extend this to the preparation of the δ-cyanovaleric acid ester by the cathodic crossed coupling of acrylonitrile and the acrylic acid ester.

After many trials, it has now been found that the desired product can be obtained in a good yield when a mixture of a large amount of acrylonitrile (1 mol.) and a small amount of methyl acrylate (1/5 mol.) is reduced at the mercury cathode at as low a potential as possible (about −1.80 V. vs. SCE) in an electrolyte containing quaternary ammonium salt and with a slight excess of the theoretical amount of current. The yield and the current efficiency were both as high as 60% as calculated on the basis of the methyl acrylate used. A small amount of adipodinitrile was produced as a by-product, but neither dimethyl adipate nor propionitrile was produced. The product can be easily separated from the mixture of reaction products and unreacted starting materials by fractional distillation.

** Just before we read this paper at the Symposium on Organic Synthesis using Free Radical Reaction held at Osaka on September 1964[2], M. M. Baiser had also reported the same process in the July issue of the *Journal of Organic Chemistry*.[3] However, his conditions were somewhat different from the ours, and the yield was lower than that in the present paper. Our patent application to the Japanese patent office is dated July 15, 1964.

This may be a new and simple route for preparing this compound from raw materials easily obtainable.

Experimental.—The cell used is an H-type cell; it is shown in Fig. 1. A fine-sintered glass diaphragm separated the cathode chamber from the anode chamber. The cathode chamber was closed with a rubber stopper equipped with a burette, a thermometer, a stirrer through the reflux condenser, two salt bridges connected with reference electrodes, and an antimony electrode connected with the pH meter. A mercury pool at the bottom of the cathode chamber served as the cathode. A platinum disk anode was placed vertically near the diaphragm. A controlled potential electrolyser, constructed by the Yanagimoto Co. in Kyoto, was used for the direct current power supply. The temperature was maintained at 30°C by cooling the cell with water.

A mixture of acrylonitrile (17.3 g., 1/3 mol.) and methyl acrylate (5.7 g., 1/15 mol.) was added to a concentrated aqueous solution of tetraethylammonium *p*-toluenesulfonate (consisting of 25 g. of salt and 25 g. of water), which served as the catholyte. The anolyte was the same electrolyte solution. The electrolysis was carried out by controlling the cathode potential at −1.80 V. A current of 0.70 amp. (cathodic current density: 6 amp./dm^2) flowed at the beggining (cell voltage: 17 V.), but it decreased to 0.50 amp. (cell voltage: 13 V.) at the end. The total amount of current passed was 3.57 amp. hr. (the theoretical amount for methyl acrylate). During the electrolysis, the catholyte was vigorously agitated by a stirrer. The pH of the catholyte was controlled at 5∼8 by adding *p*-toluenesulfonic acid.

After the reduction, the catholyte was thoroughly extracted with benzene. The distillation* of the dried (calcium chloride) benzene solution at temperatures up to 100°C left a light-yellow viscous liquid. After the absence of dimethyl adipate had been confirmed by a distillation test, the liquid was analyzed by vapor phase chromatography.** It consisted of 5.8 g. of methyl δ-cyanovalerate and 1.8 g. of adipodinitrile. Then the liquid was distilled under reduced pressure, to give 5.3 g. of methyl δ-cyanovalerate, b. p. 110°C at 7 mmHg and 1.7 g. of adipodinitrile, b. p. 126∼130°C at 7 mmHg.

For further confirmation, a portion of methyl δ-cyanovalerate fraction was hydrogenated in the presence of a nickel catalyst in an ethereal solution at 100∼120°C and 130 atm. to methyl ε-aminocaproate, which, in turn, was converted to ε-caprolactam by heating it in methanol at 220°C under a 60 atmospheric hydrogen pressure.[4] The methyl ε-aminocaproate and ε-caprolactam thus obtained had b. p. of 88∼89°C at 7 mmHg and 126°C at 8 mmHg respectively, and the latter solidified on standing.

* The distillate was analyzed by vapor phase chromatography. The results showed that propionitrile was not formed and that the unchanged starting materials could be recovered almost quantitatively. As for methyl propionate, it could not be analysed by this method. However, if it existed the amount would be very small.

Some Derivatives of 2, 3-Diphenylcyclopropenone[1]

By Yoshio KITAHARA and Makoto FUNAMIZU

(Received October 19, 1964)

Recently, the aromaticity of the cyclopropenyl system has been investigated theoretically as well as experimentally in several countries.[3] In connection with our studies of the cycloheptatrienyl system, we compared these two systems. This paper will describe the preparation of 2, 3-diphenylcyclopropenethione (I), 3-dicyanomethylene-1, 2-diphenyl-1-cyclopropene (II), 2, 3-diphenylcyclopropenone oxime (III) and 3, 3-dichloro-1, 2-diphenyl-1-cyclopropene (IV) from 2, 3-diphenylcyclopropenone (V).

I: X=S
II: X=C(CN)$_2$
III: X=NOH
IV: X=Cl$_2$
V: X=O

2, 3-Diphenylcyclopropenethione (I). — The reaction of 2, 3-diphenylcyclopropenone[4] (V) with phosphorus pentasulfide in dry benzene at 50~60°C gave 68% of I; m. p. 125~126°C (decomp.), yellow prisms from methanol. Found: C, 81.16; H, 4.70. Calcd. for $C_{15}H_{10}S$: C, 81.06; H, 4.54%. IR (KBr disk):[5] 1780(m), 1597(m), 1438(m), 1350(vs), 1310(s), 1298(s), 1170(m), 1015(m), 760(s), 682(s), 658(m) cm^{-1}; (in CCl_4): 3050(m), 1780(m), 1597(m), 1450(m), 1358(vs), 1311(s), 1298(s), 1172(m), 1020(m) cm^{-1}. The bands at 1780 and 1350~1358 cm^{-1} may be due to the C=C stretching in a three-membered ring and to C=S stretching[6] respectively. UV λ_{max} mμ (log ε) (in cyclohexane): 236(4.32), 245(4.52), 268(4.40), 284(4.28), 298(4.06), 360(3.98); (in methanol): 227(4.17), 234(4.11), 265(4.39), 277(4.36), 336(4.14). The dipole moment of I in benzene at 30°C is 5.8 D. The hydrolysis of I with 75% sulfuric acid regenerated V.

3-Dicyanomethylene-1, 2-diphenyl-1-cyclopropene (II).—The refluxing of V with malononitrile in freshly-distilled acetic anhydride in the presence of a minute amount of boron trifluoride afforded 23% of II; m. p. 299°C (decomp.), pale yellow prisms from tetrahydrofuran. Found: C, 84.64; H, 3.93; N, 10.88. Calcd. for $C_{18}H_{10}N_2$: C, 85.02; H, 3.96; N, 11.02%. IR (KBr disk):[5] 2210(s), 2190(s), 1865(m), 1600(m), 1507(s), 1477(s), 1444(s), 1393(s), 1375(s), 769(s), 687(s) cm^{-1}. UV λ_{max} mμ (log ε) (in dioxane): 244(4.28), 274(4.43), 293(4.45), 306(4.40), 362(4.06). The dipole moment II in dioxane at 30°C is 9.3 D.

2, 3-Diphenylcyclopropenone Oxime (III). — The reaction of V with hydroxylamine hydrochloride in methanol and the neutralization of the resulting mixture with sodium hydrogencarbonate yielded 24% of III, m. p. 99~101°C, colorless prisms. Found: C, 81.35; H, 4.92; N, 6.16. Calcd. for $C_{15}H_{11}ON$: C, 81.43; H, 5.01; N, 6.33%. IR (KBr disk):[5] 3420 (s), 3250(s), 1875(m), 1850(m), 1593(s), 1450(s), 1360(s), 866(s), 764(vs), 690(vs) cm^{-1}.

3, 3-Dichloro-1, 2-Diphenyl-1-cyclopropene (IV).—When V was allowed to react with phosphorus pentachloride in chloroform, it gave IV,[7] m. p. 123~126°C. IR[5] (in CCl_4): 1810(w), 1630(m), 1600(w), 1450(s); (in CS_2): 1342(s), 1145(s), 1120(s), 1013(m), 911(m), 760(s), 725(m), 701(s), 680(s) cm^{-1}. The structure of IV was suggested by a comparison of its infrared spectrum with that of tetrachlorocyclopropene,[8] by the quantitative regeneration of V by hydrolysis with water, and by the neutralization equivalent of the hydrogen chloride yielded in the hydrolysis reaction. Details of this report, a comparison with the corresponding cycloheptatrienyl
