the intermediary oxidation product will re-oxidize the reduced dye back to the original form. The transient spectra appearing in these solvents are shown in Figs. 2a—2e. Except in acetic acid, the region of strong absorption is in the 400 mμ~430 mμ range. There is also a second peak around 515 mμ; a near-infrared absorption is also observed. As may be seen in the above figures, the absorption persists longer than that observed in plain water.

In the cases of 1- and 2-propanol, two absorptions seem to be superposed. The one which has a peak at a shorter wavelength appears later and persists longer. In these solvents and in glycerol there is a period during the reaction when the absorption in the visible range of the spectrum almost disappears. In time the methylene blue absorption is restored. This phenomenon is quite analogous to that observed in an aqueous medium when ferrous sulfate or hydroquinone is used as the reductant, and it must be attributed to the transitory formation of leuco methylene blue. All these observations suggest that the absorption around 400 mμ at a later stage of the reaction is mainly due to the semiquinone of the dye, although its peak is red-shifted compared with that in an aqueous medium. The spectrum in 1- or 2-propanol at early stages of photolysis may be nearly that of the triplet state. The spectrum observed in acetic acid shows reasonable shifts due to the acidity of the solvent (cf. Part I). Another difference between the transient absorption in an organic solvent and in an aqueous solvent is that, in the latter, a peculiar increase around 520 mμ at a later stage of photolysis is observed, while it is lacking in the former.

Summary

The flash photolysis of methylene blue in an aqueous medium with added *N*-phenylglycines or photolysis in organic solvents results in a more or less apparent bleaching of the dye. In the former case, the general features of the transient spectra are similar to those in the reversible photolysis treated in Part I. An absorption peak at 400 mμ in a solvent with a pH of 8.0 shifts to 430 mμ in a solvent with a pH of 8.8; it is to be attributed to the semiquinone of methylene blue. The absorption around 255 mμ increases at a later stage of the reaction, indicating the formation of leuco methylene blue. The photolysis seems to proceed in a way similar to that of the reversible cases. The results of flash photolysis with several derivatives of *N*-phenylglycine support the general idea of their reactivity obtained in a study with continuous illumination. There is a difference between the ways in which *N*-*p*-bromophenylglycine and *N*-*p*-methoxyphenylglycine retard the photoreduction, although this may be superficial. In the former case, some early intermediate (probably the triplet state of the dye) is deactivated almost catalyticaly, while in the latter case the deactivation takes place at the stage of a long-lived semiquinone-like intermediate. Peculiar features of photolysis with α-methyl-*N*-phenylalanine and *N*-phenyl-β-alanine have also been noted.

The degree of irreversible bleaching in an organic solvent has no regular relation to the ease with which the solvent molecule is dehydrogenated by an ordinary oxidant. The main part of the transient absorption in organic solvents is attributed to the semiquinone of the dye. The peak has somewhat red-shifted compared with that in water. Triplet absorption seems also to appear at an early stage of photolysis. The photolysis in 1- or 2-propanol reveals the reversible feature observed when ferrous ions were used as reductants.

The author is indebted to Professor Noboru Ando and Professor Ikuzo Tanaka of the Tokyo Institute of Technology, who kindly permitted him to use their laboratory facilities and gave him much helpful advice. He also wishes to express his thanks to Professor Masao Koizumi of Tohoku University and to Dr. Yuji Mori of the Tokyo Institute of Technology for their valuable discussions.

The Spectrophotometric Determination of Cadmium with Xylenol Orange[1]

By Makoto Otomo

(Received September 26, 1963)

The most sensitive spectrophotometric method for the determination of traces of cadmium has been found to be the extraction procedure employing dithizone.[2-4] In this method, however, different amounts of dithizone must be used, depending on the amount of cadmium to be determined, indicating that the method is unfavorable for the determination of cadmium over a wide concentration range. A rapid, sensitive and accurate method which is applicable over a wide concentration range of cadmium is, therefore, desirable. A spectrophotometric method with xylenol orange was formulated for this purpose by the present author, and a suitable method was developed. This method is based on the formation of the cadmium-xylenol orange complex in a solution buffered with hexamethylenetetramine and nitric acid. The complex has an absorption maximum at 575 mμ and a molar extinction coefficient of 18000. By this method, 20 to 120 μg. of cadmium can be determined rapidly within the range of experimental error. In a study of the complex formation, it has been found that xylenol orange forms a 1 to 1 complex with cadmium and that the complex has an apparent formation constant of 6.1×10^3 at a pH value of 5.5.

Experimental

Reagents.—*Standard Cadmium Solution.*—A stock solution of cadmium (about 0.01 M) was prepared by dissolving a reagent-grade cadmium chloride in distilled water. This solution was standardized against a standard EDTA solution, using xylenol orange as the indicator.[5] A working standard solution was prepared by diluting the stock solution with water.

Buffer Solution.—Except where otherwise indicated, solutions of hexamethylenetetramine in conjunction with potassium nitrate and nitric acid were used for pH adjustments.

Xylenol Orange Solution.—A 1×10^{-3} M solution of xylenol orange was prepared by dissolving a Dotite XO reagent (Dôjindô & Co., Kumamoto) in distilled water.

All the other solutions were prepared from reagent-grade chemicals.

Apparatus.—A Hitachi spectrophotometer, Model EPV-2, was used for all absorbance measurements, using 1-cm. glass cells. A Hitachi glass-electrode pH meter, Model EHP-1, was used for all pH determinations.

All experiments were carried out at 25±0.5°C.

Results and Discussion

Absorption Spectra.—The absorption spectra of xylenol orange and its cadmium complex are shown in Fig. 1. When the absorbance measurements were made against a reagent blank, an absorption maximum was found at

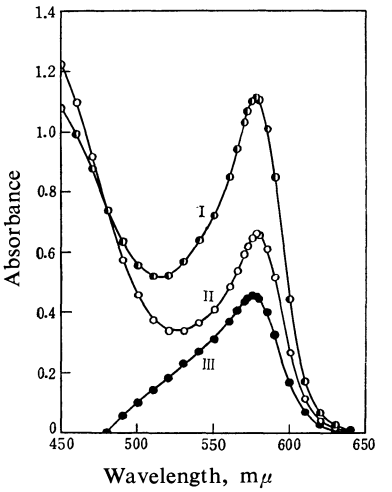

Fig. 1. Absorption spectra of xylenol orange and its cadmium complex at pH 6.3.

III : Cd-XO vs. a reagent blank

575 mμ. As the considerable absorbance by the blank is evident around the absorption maximum of the complex, all absorbance measurements were made using a reagent blank. The order of the addition of the reagents has no effect on the absorbance values.

Choice of Buffer and the Effect of pH.—A preliminary test showed that xylenol orange

1) A part of this work was presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

reacts with cadmium only in a slightly acidic or a neutral solution, giving a red color. Therefore, two buffers are found to be useful: sodium acetate - acetic acid and hexamethylenetetramine - mineral acid. The former has a great buffering capacity in the pH range from 3.5 to 5.6 and has widely been used for many purposes. However, acetate ions form certain acetato-complexes with cadmium[6-8] to inhibit the color formation between cadmium and xylenol orange. The latter, with a great buffering capacity in the pH range from 4.5 to 6.5, has occasionally been used in complexometric titrations. It has no complexing action for cadmium ions. At the same pH values, the cadmium - xylenol orange complex always gave higher absorbances in solutions buffered with the latter than with the former. A hexamethylenetetramine - nitric acid - potassium nitrate buffer was, therefore, adopted throughout the investigation. Potassium nitrate was always used to reduce the error caused by the indicator salt effect.

The variation in the absorbances of the reagent blank and of the cadmium complex with a change in pH value was then studied; the results are shown in Fig. 2. The optimum pH range is fairly narrow, the maximum color development for the complex being found to occur in the pH range from 6.2 to 6.4.

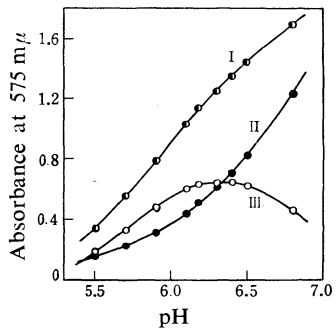

Fig. 2. Effect of pH on color development.

II: XO vs. water
III: Cd-XO vs. a reagent blank

The Effect of the Amount of Buffer.—In order to investigate the effect of the amount of the buffer on the absorbances of the reagent and complex, experiments were made with solutions containing 90 μg. of cadmium, 2.8 ml. of a 1 $\times10^{-3}$ M solution of xylenol orange, and varying amounts of a 20% hexamethylenetetramine solution which had been titrated with nitric acid to give a pH value of 6.3. The results showed that, both for the solution containing no potassium nitrate and for the solution containing potassium nitrate (0.35 M at a final concentration), the intensity of the absorbances of xylenol orange and of the complex is greatly affected by the amount of the buffer; larger amounts of the buffer must be added to obtain higher absorbances. However, 10 ml. of a 20% hexamethylenetetramine - nitric acid solution was used for further investigation. The addition of 10 ml. of the buffer to the system gave a reproducible absorbance.

The Effect of the Potassium Nitrate Concentration.—The absorbance of a solution containing a fixed amount of cadmium was found to be dependent also upon the concentration of potassium nitrate. This effect was studied by varying the concentration of potassium nitrate. The pH value of the solution was held constant at 6.3 by the addition of the buffer. The results are shown in Fig. 3. Both xylenol orange and the complex give the maximum absorbance at the potassium nitrate concentration of 0.30 to 0.35 M in a final volume. In further experiments, therefore, 5 ml. of a 1.5 M solution of potassium nitrate was used. This gives 0.30 M at a final concentration.

The Effect of the Amount of Xylenol Orange.—In measuring the effect of the amount of xylenol orange on color development, the amount of a 1×10^{-3} M solution of xylenol orange was varied from 0.7 to 4.5 ml., keeping

8) N. Tanaka, M. Kamada, H. Osawa and G. Sato, This Bulletin, 33, 1412 (1960).

other variables constant. As can be seen from Fig. 4, the maximum color formation is obtained when 2.2 to 3.8 ml. of the reagent solution is used. Therefore, 2.8 ml. was chosen as the working volume of the reagent.

The Stability of the Color.—The absorbances of a solution, prepared under the optimum condition, were measured as a function of time following the preparation of the solution. There was no change of absorbance over a period of 3 hr.

Adherence to Beer's Law.—To ascertain the adherence of the system to Beer's law, a calibration curve was prepared in the following manner: To a series of 25 ml. volumetric flasks were added varying quantities of cadmium, 10 ml. of the buffer and 2.8 ml. of a 1×10^{-3} M solution of xylenol orange; the solutions were then diluted to the mark with water. After about 15 min., the absorbance of each solution was measured at 575 mμ against a reagent blank which had been treated in a similar manner. The data showed a linear relationship between concentration and absorbance over the 20 to 120 μg. range of cadmium.

Sensitivity.—According to the notation of Sandell,[9] the sensitivity of the reaction is 0.006 μg. of cadmium per cm^2. The molar extinction coefficient was calculated from the calibration curve to be 18000 at 575 mμ.

Effect of Diverse Ions.—The data concerning the effect of diverse ions were obtained on solutions containing 67.4 μg. of cadmium and the diverse ions added individually. Alkali metal salts of the anions were used. Diverse cations were added as the chloride, nitrate or sulfate salts.

Of the anions tested, the following did not interfere under the described conditions: chloride and sulfate up to 500 μmol., thiocyanate up to 100 μmol., and fluoride and phosphate up to 50μmol. NTA and EDTA, especially the latter, bleach the color of the complex, even when only trace amounts are present.

Because all of the metal cations tested, with the exception of alkaline earth metals, interfere seriously, attempts were made to eliminate the interfering cations with some masking agents; the addition of 60 μmol. of fluoride was effective for rare earths up to 0.5 μmol. and for thorium and zirconium up to 0.05 μmol., while the addition of 50 μmol. of thiocyanate was effective for mercury(II) up to 0.5 μmol.

A Comparison with Other Methods.—Except for dithizone, of the previously-proposed reagents for the spectrophotometric determination of cadmium, di-β-naphthylthiocarbazone[10] and 1-(2-pyridylazo)-2-naphthol (PAN)[11] are perhaps the most sensitive. These reagents can be used even for the determination of a few micrograms of cadmium. Diethyldithiocarbamate[12] has also been reported to be sensitive for cadmium and has been widely utilized for the determination of 50 to 300 μg. of cadmium. All the above reagents, however, form water-insoluble complexes with cadmium. Therefore, these cadmium complexes must be extracted into a suitable organic solvent; this complicates the process of the determination.

Other reagents which have been utilized successfully for the determination of cadmium are 4-hydroxy-3-nitrophenylarsonic acid,[13] chrome dark blue[14] and cadion IREA.[15] These reagents can form water-soluble complexes with cadmium but are far less sensitive than xylenol orange. The colloidal cadmium sulfide formed with cadmium and thiosinamine is unstable,[16] indicating that the absorbance measurements must be made in the presence of a stabilizing agent. An indirect method, based on the interaction of cadmium and the zinc-complex of α-β-γ-δ-tetraphenylporphine,[17] has been proposed for the determination of cadmium, but it is not capable of determining traces of cadmium.

Therefore, it may be concluded that, of the reagents which can form water-soluble cadmium complexes, xylenol orange is the most preeminent colorimetric reagent for cadmium. The proposed method, which is rapid, sensitive and accurate, seems to be applicable for the determination of traces of cadmium in many samples, when cadmium is preliminarily separated from the interfering ions by an ion-exchange or a precipitation method.

Complex Formation.—*Continuous Variations.*—A very rapid and excellent method for determining the composition of the main complex formed in a given concentration range of the reactants is Job's method[18] of continuous variations as extended by Vosburgh and Cooper.[19]

Figure 5 shows, for three wavelengths, the absorbances, Y, that exceed the absorbances expected for no reaction in various mixtures of equimolar solutions of cadmium and xylenol orange. The pH value was held constant at 6.3 and the potassium nitrate concentration, at 0.3 M. The total concentration of cadmium and xylenol orange was 3.2×10^{-5} M throughout. The curves in Fig. 5 clearly indicate that only one complex, 1 to 1, is formed in solutions containing cadmium and xylenol orange.

Reference : water

orange, 2.4×10^{-5} M, and potassium nitrate, 0.30 M, but with various concentrations of cadmium, were studied. The location of the absorption maximum was constant at 578±2 mμ for the range of cadmium concentration investigated. The results are shown in Fig. 6, indicating the existence of only one form of the complex.

The Apparent Formation Constant.—Using as a guide the results of the experiments reported on the previous sections, the calculation of the apparent formation constant of the cadmium - xylenol orange complex was attempted. A method described by Newman and Hume[20] was employed.

Since only a 1 to 1 complex is formed, the equilibrium constant, K, can be expressed as:

$$K=[\mathrm{Cd(XO)}]\,[\mathrm{H^+}]^x/[\mathrm{Cd^{2+}}]\,[\mathrm{XO}] \quad (1)$$

where XO and Cd(XO) represent the total unbound xylenol orange and the total cadmium-xylenol orange complex respectively, and x is the number of hydrogen ion liberated from one molecule of xylenol orange by the chelation. Assuming that two species, the complex and xylenol orange, absorb at the wavelengths under investigation, the apparent formation constant, $K'=K/[\mathrm{H^+}]^x$, may be given by:

$$\log\,(D-D_{\mathrm{XO}})/(D_{\mathrm{C}}-D)=\log K'+\log\{[\mathrm{Cd^{2+}}]_t-(D-D_{\mathrm{XO}})/(\varepsilon_{\mathrm{C}}-\varepsilon_{\mathrm{XO}})\} \quad (2)$$

where ε_{C} and $\varepsilon_{\mathrm{XO}}$ are the molar extinction coefficients of the complex and xylenol orange respectively; D is the absorbance of the solution containing a mixture of cadmium and xylenol orange, and D_{XO} and D_{C} are the absorbances of a solution containing only xylenol orange or a large excess of cadmium ions added to a known amount of xylenol

20) L. Newman and D. N. Hume, ibid., 79, 4571 (1957).

orange respectively. When $\log(D-D_{XO})/(D_C-D)$ is plotted against $\log\{[Cd^{2+}]_t-(D-D_{XO})/(\varepsilon_C-\varepsilon_{XO})\}$, a straight line with a unit slope and intercept $\log K'$ is obtained.

In the work performed in this section, each solution was 2.0×10^{-5} M in xylenol orange, the concentration of cadmium was varied from 1.0×10^{-4} to 4.58×10^{-3} M, the pH value of each solution was adjusted to 5.5 with hexamethylenetetramine-nitric acid, and the concentration of potassium nitrate was maintained constant at 0.3 M. Table I shows the results of the Newman-Hume plots, all of which give good straight lines with a unit slope.

TABLE I. DETERMINATION OF THE APPARENT FORMATION CONSTANT

Wavelength, mμ	Slope	K'
570	1.05	5.1×10^3
575	1.04	5.4×10^3
578	1.06	5.9×10^3
580	1.09	7.1×10^3
585	1.09	7.1×10^3

Av.: Slope=1.07; $K'=6.1\times10^3$

Summary

The red cadmium-xylenol orange complex has been studied spectrophotometrically to establish the optimum conditions for determining traces of cadmium. The absorption spectrum of the colored complex showed a maximum absorption at 575 mμ when measured against a reagent blank. The reaction was carried out in a buffered solution at a pH value of 6.3. Beer's law is obeyed over the 20 to 120 μg. range of cadmium. The sensitivity of the reaction was 0.006 μg. cadmium per cm^2. Job's method of continuous variations and the method of Newman and Hume have been applied to determine the composition of the complex. Both methods showed the existence of only one form of the complex, 1 to 1. The apparent formation constant was calculated to be 6.1×10^3 at a pH value of 5.5.

The author wishes to express his gratitude to Professor Kôichi Tonosaki for his kind guidance and encouragement throughout the course of this study. The author is also indebted to Professor Toshiyasu Kiba of Kanazawa University for his interest and valuable advice concerning this work.

II(Red)

(2)

The colored species I is more stable than II.[8] On the other hand, it has never been found that *p*-nitroanisole gives the colored intermediate III.

III (3)

The formation of Meisenheimer's intermediates I and II has been confirmed by Nagakura and Oosawa[5,8] and by Dyall[7] on the basis of the infrared spectra of these colored complexes. They indicate that the carbon atom at the seat of substitution has sp^3-hybridization. Recently the constitution of Meisenheimer's type has been widely accepted for many colored complexes of polynitrobenzene derivatives with alkalies.*

In order to interpret the formation of the above intermediates, Bunnett et al.,[9] Nagakura et al.[5,6] and Parker et al.[10,11] presented the two-stage mechanism shown in Fig. 1, for the color reactions.

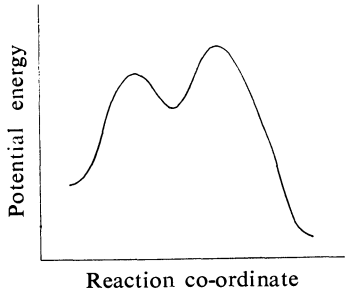

Fig. 1. The energy profile for two-stage mechanism.

From the energy level diagrams for reagents and aromatic molecules,[12] and from the above findings regarding the infrared spectra, Nagakura[13] proposed the following mechanism for the formation of an intermediate in the process of aromatic substitution:

1) A charge transfer occurs between a reagent and an aromatic compound.

2) A π-electron is localized on the carbon atom at the seat of substitution, and the atom is consequently removed from conjugation.

3) The carbon atom undergoes a change in hybridization from sp^2 to sp^3.

Recently, from the concept of Meisenheimer's intermediate complex, Miller[14] made energy calculations for the aromatic nucleophilic substitutions, utililizing bond energies, electron affinities and solvation energies.

In the present work, by means of the simple LCAO MO method, qualitative attempts will be made to account for the visible absorption spectra of Meisenheimer's intermediates I and II and for the fact that the intermediate I is more stable than II, while the intermediate III can not be observed, and to examine the possibility of the appearance of potential-energy minima on the potential energy curves for the substitutions (1)—(3).

Experimental

The Red Complex of 2, 4, 6-Trinitroanisole with Methoxide.—When a methanolic solution of sodium methoxide is added to a methanolic solution of trinitroanisole, a red solution is produced. When the resulting solution is allowed to stand at room temperature, reddish orange crystals precipitate. The spectrum of the orange methanolic solution of the crystals collected was measured as that of Meisenheimer's intermediate I. The orange solution was decolorized soon after, giving an absorption curve similar to that for 2, 4, 6-trinitroanisole.

The Red Complex of 2, 4-Dinitroanisole with Methoxide.—When dinitroanisole in methanol is treated with sodium methoxide, a red solution is formed. The spectrum of the colored solution was measured as that of Meisenheimer's intermediate II, since red-colored crystals did not precipitate from the solution. It is known that the red complex is rapidly converted, mainly into 2, 4-dinitroanisole, in methanol.[8]

The Complex of *p*-Nitroanisole with Methoxide.—When nitroanisole in methanol was treated with sodium methoxide, no colored solution was formed.

Spectra.—The spectra of the solutions were measured using a Hitachi EPU-2 spectrophotometer at room temperature.

Results of the Measurements

The spectra measured are indicated in Fig. 2. From the above reports,[1-8] Absorption curves 1 and 2 in Fig. 2 can be considered to be due to the Meisenheimer intermediates I and II respectively. The intermediate I has two absorption maxima, at ca. 485 and 415 mμ, while the intermediate II has a maximum at ca. 495 mμ.

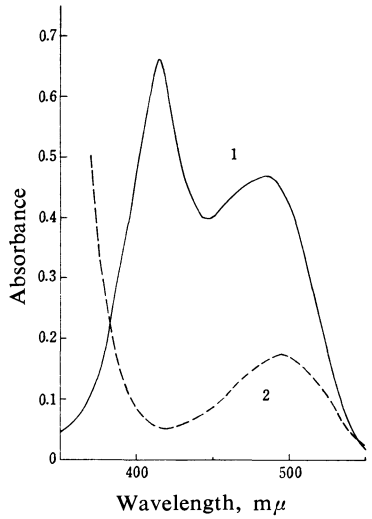

Fig. 2. Absorption spectra of Meisenheimer's intermediates in methanol (at room temperature).
1 [Trinitroanisole·CH_3O]$^-$
2 [Dinitroanisole·CH_3O]$^-$

Method of Calculation

In order to indicate the degree of proceeding of the substitution, the author has introduced the reaction parameter t, which takes continuous values from 1 through zero to -1. Let t change the values of the resonance integrals in the process of the substitution in order to represent the initial and final states at $t=1$ and -1 respectively, and in order to form Meisenheimer's intermediate at $t=0$. As Fukui et al.[15] found, the change in the electronic structure of each activated complex is assumed to be divided into two parts, a σ- and a π-part.

The resonance integrals β' and β for the σ- and π-parts respectively are assumed to be expressed as follows:

In the case of $t=1\rightarrow 0$:

σ-part, $\beta'_{C'O2}=(1-t)b'_{C'O2}\beta'_{CC}$

π-part, $\beta_{C'O1}=tb_{C'O1}\beta_{CC}$

$\beta_{C'C}=t\beta_{CC}$

In the case of $t=0\rightarrow -1$:

σ-part, $\beta'_{C'O1}=(1+t)b'_{C'O1}\beta'_{CC}$

π-part, $\beta_{C'O2}=-tb_{C'O2}\beta_{CC}$

$\beta_{C'C}=-t\beta_{CC}$

Here the suffix C′ denotes the carbon atom at the seat of substitution, while the symbols O1 and O2 indicate the oxygen atoms of the outgoing and ingoing CH_3O-groups respectively.

Coulomb and Resonance Parameters.—The Coulomb integrals are represented by α' and α for the σ- and π-parts respectively.

σ-Part,

for CH_3O (for which the parameters for OH[16] are used directly):

$$\alpha'_O=\alpha'_C+0.5\beta'_{CC}$$
$$b'_{C'O1}=b'_{C'O2}=0.5$$

π-Part,

for CH_3O:[17-19]

$$\alpha_O=\alpha_C+2\beta_{CC}$$
$$b_{C'O1}=b_{C'O2}=0.6$$

for NO_2:[20]

$$\alpha_N=\alpha_O=\alpha_C+\beta_{CC}$$
$$\beta_{CN}=\beta_{NO}=\beta_{CC}$$

In the present calculation the following approximations have been made for convenience:

1) The change in energy due to the change in hybridization from sp^2 to sp^3 has not been considered. This energy will be small. For instance, Coulson[21] estimated the bond energies of the CH bonds of sp^2 and sp^3 as 106 and 103 kcal./mol. respectively.

2) Hyperconjugation has been ignored.

3) The symmetry of C_{2v} has been assumed to hold for the reaction processes of *p*-nitroanisole and 2, 4, 6-trinitroanisole.

On the basis of the above assumptions, the energy levels of the molecular orbitals of the σ- and π-parts in the three activated complexes at $t=1\rightarrow 0\rightarrow -1$ were calculated by means of the simple LCAO MO approximation. In each complex, the molecular orbital of the σ-part was represented as a linear combination of a pseudo-π-atomic orbital of the methoxy group and one of π-atomic orbitals of the polynitroanisole, and the orbital of the π-part was

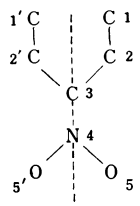
represented as a combination of all the π-orbitals. A bonding molecular orbital of each σ-part is occupied by two electrons. The bonding molecular orbitals of the π-parts for *p*-nitroanisole, 2, 4-dinitroanisole and 2, 4, 6-trinitroanisole are occupied by 12, 16 and 20 electrons respectively.

For example, in the case of *p*-nitroanisole at $t=1\rightarrow0$, the x'_{ti} energy levels (in units of $(\varepsilon'_{ti}-\alpha'_C)/\beta'_{CC}$) of the molecular orbitals of the σ-part and the x_{ti} levels (in units of $(\varepsilon_{ti}-\alpha_C)/\beta_{CC}$) of the A_1-molecular orbitals of the π-part are obtained from the following secular equations, 4 and 5, respectively:

For the σ-part:



$$0=\begin{vmatrix} -x'_{ti} & 0.5(1-t) \\ 0.5(1-t) & -x'_{ti}+0.5 \end{vmatrix} \qquad (4)$$

and for A_1-orbitals of the π-part:

$$0=\begin{vmatrix} -x_{ti}+2 & 0.6t & 0 & 0 & 0 & 0 & 0 \\ 0.6t & -x_{ti} & 2t & 0 & 0 & 0 & 0 \\ 0 & t & -x_{ti} & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & -x_{ti} & 1 & 0 & 0 \\ 0 & 0 & 0 & 2 & -x_{ti} & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & -x_{ti}+1 & 2 \\ 0 & 0 & 0 & 0 & 0 & 1 & -x_{ti}+1 \end{vmatrix}$$

$$=x_{ti}(x_{ti}-2)D_0(x_{ti})-0.6^2t^2D_0(x_{ti})+t(x_{ti}-2)D_{11}(x_{ti}) \qquad (5)$$

Here $D_0(x_{ti})$ and $D_{11}(x_{ti})$ are the secular determinants of the conjugated system IV and the minor of its 11th element respectively.

IV

The energy levels for $t=0\rightarrow-1$ are symmetric to those for $t=1\rightarrow0$ with respect to $t=0$, because the reagent and the group to be substituted are the same.

Results of Calculation

The Energy Levels of Meisenheimer's Intermediates.—The energy levels of the molecular orbitals in Meisenheimer's intermediates are obtained, as indicated in Fig. 3, by calculating the energy levels for the π-parts at $t=0$. Figure 3 shows that the excitation energies are greater in the order of 2, 4-dinitroanisole, 2, 4, 6-trinitroanisole and *p*-nitroanisole. The excitation energy for the intermediate III is considerably greater in comparison with the others. Accordingly, even if the intermediate III should be formed, its longer absorption would not appear in the visible region. It can be expected that the two absorption bands of the intermediate I will appear at the longer wave lengths, because the second lowest vacant orbital lies close to the lowest one. The above predictions qualitatively agree with the experimental results.

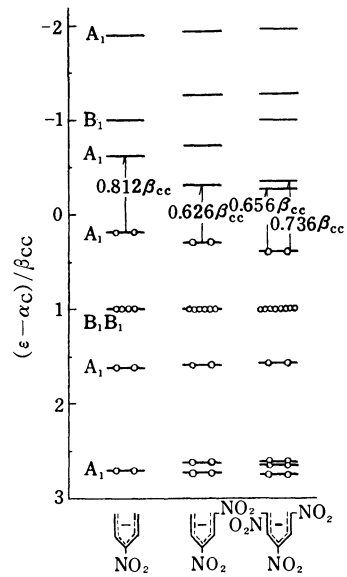


Fig. 3. The energy levels and transitions of π-electrons in Meisenheimer's intermediates.

The Change in the Occupied Orbital Energy of the σ-Part.—The occupied orbital energy ε'_t of the σ-part is obtained from the secular Eq. 4. If the value of ε'_t at $t=1$ is represented as ε'_1, the change in the energy of the σ-part at t can be obtained from:

$$(\varepsilon'_t-\varepsilon'_1)=(x'_t-x'_1)\beta'_{CC} \qquad (6)$$

Figure 4 is drawn by calculating according to

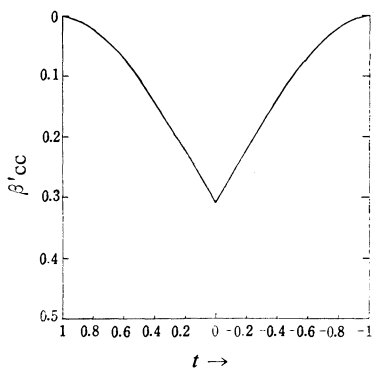

Fig. 4. The change in the occupied orbital energy of each σ-part.

Eq. 6. Of course, the energy of the σ-part is the lowest at $t=0$, because the reagent CH_3O^- is covelently bound to the nucleus of each polynitroanisole.

The Changes in the Occupied Orbital Energies of the π-Parts.—The ε_{ti} energies of the occupied molecular orbitals in the activated complex of each polynitroanisole are indicated in Figs. 5—7. As may easily be seen in these figures, the change in the orbital energy with t is the greatest in the highest occupied orbital. The second greatest change is found for the orbital with the energy value of 2 at $t=0$. These orbitals are to be ascribed to the methoxy groups to be substituted.

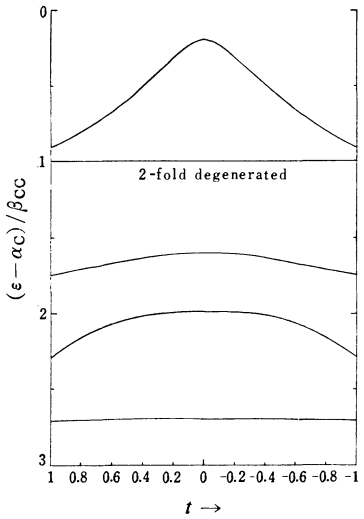

Fig. 5. The change in the occupied orbital energy levels of the π-part for nitroanisole.

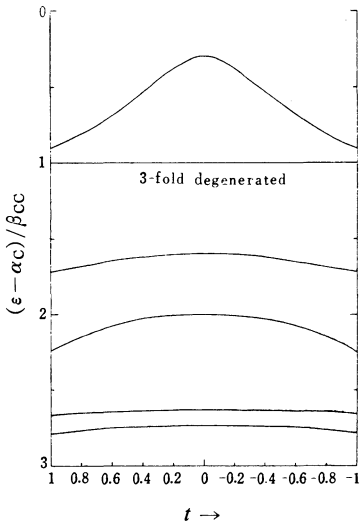

Fig. 6. The change in the occupied orbital energy levels of the π-part for dinitroanisole.

If ε_{1i} denotes the value of ε_{ti} at $t=1$, the change in the electronic energy of the π-part of each polynitroanisole can be given as:

$$\sum_{i}^{occu}(\varepsilon_{ti}-\varepsilon_{1i})=\sum_{i}^{occu}(x_{ti}-x_{1i})\beta_{CC} \qquad (7)$$

The results calculated are shown in Fig. 8. It is reasonable that the change in the electronic energy of each π-part is at its maximum at $t=0$, because the conjugated system is at its minimum at $t=0$. It follows from Fig. 8 that the changes in the energies of the π-parts are

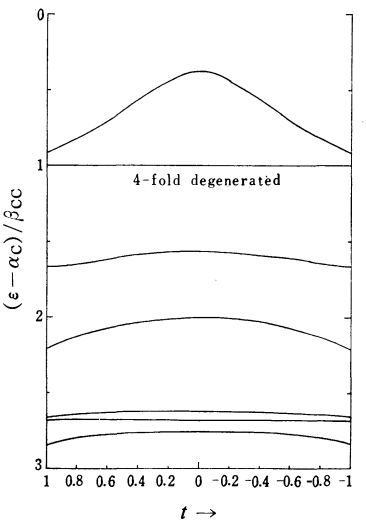

Fig. 7. The change in the occupied orbital energy levels of the π-part for trinitroanisole.

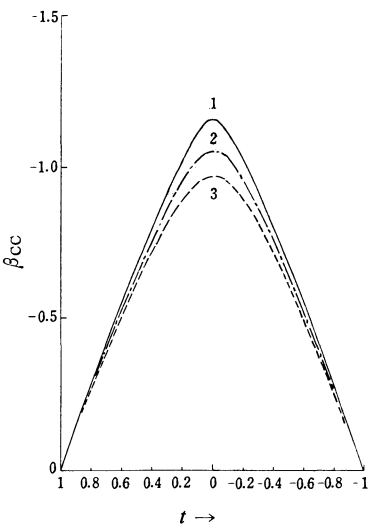

Fig. 8. The changes in electronic energies of the π-parts.
1 Nitroanisole
2 Dinitroanisole
3 Trinitroanisole

smaller with the increasing numbers of nitro groups.

The Total Changes in Electronic Energies.— By adding Eq. 6 to Eq. 7, the total change in the electronic energy of the activated complex of each polynitroanisole at t is given as

$$(\varepsilon'_t-\varepsilon'_1)+\sum_i^{occu}(\varepsilon_{ti}-\varepsilon_{1i})=(x'_t-x'_1)\beta'_{CC}+\sum_i^{occu}(x_{ti}-x_{1i})\beta_{CC} \quad (8)$$

By using $\beta'_{CC}=-6.364$ eV.[22] and $\beta_{CC}=-3$ eV.,* one can find the total changes in electronic energies according to Eq. 8, as is indicated in Fig. 9. It can be seen from Fig. 9 that the activation energies for the formation of the intermediates become smaller as the numbers of nitro groups increase, and that the stabilization energies at $t=0$ are similarly greater. These lead to the expectation that, in the color reactions of the polynitroanisoles with the methoxide ion, the colored intermediates are more easily formed and more stable as the numbers of nitro groups increase. In fact, it has been observed that the intermediates are stable in the order of the increasing numbers of nitro groups. It may also be expected from Fig. 9 that Meisenheimer's intermediate III of *p*-nitroanisole with the methoxide ion is the hardest to form because the energy of activation is the greatest and the stabilization energy at $t=0$ is the smallest in the case of *p*-nitroanisole.

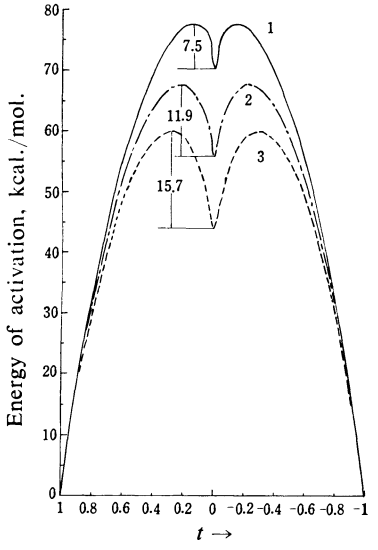

Fig. 9. The total changes in electronic energies.
1 Nitroanisole 2 Dinitroanisole
3 Trinitroanisole

Discussion

As has been mentioned above, the results of the calculation show that the energies of activation for the formation of Meisenheimer's intermediates becomes smaller with the increasing numbers of nitro groups. This is in accordance with the experimental results[23-26] for the similar reactions of polynitrobenzene derivatives.

The fact that the intermediate II is more labile than I can be ascribed to the low stabilization energy of II. Because of the low energy, the intermediate II is more easily converted into 2, 4-dinitroanisole than is I, although the energy of activation for the formation of II is higher than that for I.

Nagakura, Oosawa and Tsubomura[5] reported that the energy of activation for the decomposition of Meisenheimer's complex of 2, 4-dinitroanisole with hydroxyl ions to 2, 4-dinitroanisole is 15.0 kcal./mol. The corresponding energy for 2, 4-dinitroanisole is calculated as 11.9 kcal./mol. in the present work.

The changes in π-electronic energies in the polynitroanisoles at $t=0$, calculated according to Eq. 7, are equal to the localization energies presented by Wheland.[27] Accordingly, the energies of activation for the formation of the three activated complexes are governed by the localization energies, since the changes in energy for the three 6-parts are the same in the calculation. These energies of activation are mainly dependent on the greatest changes of the highest-occupied orbital energies for the π-parts, as is indicated in Figs. 5—7.

The present calculation is too rough to predict the observed values. The following points must be considered in order to calculate them more precisely:

1) It is better to represent the molecular orbital of each activated complex as a combination of all the $2p\pi$-orbitals of each polynitroanisole and the atomic orbital of the reagent.

2) The change in hybridization, $sp^2 \rightarrow sp^3 \rightarrow sp^2$, in the carbon atom at the seat of substitution must be considered.[13]

3) A calculation including hyperconjugation might possibly afford a somewhat smaller

22) K. Fukui, H. Kato and T. Yonezawa, This Bulletin, 33, 1197 (1960).

* This value has often been used in the simple LCAO MO approach.

change in the energy of each π-part.

4) It is necessary to examine the parameters of the coulomb and resonance integrals used.

According to the energy level diagrams of Nagakura and Tanaka,[12] the highest-occupied orbital energy in the methoxy ion CH_3O^- is higher than the lowest vacant one for each polynitroanisole. The parameter of the coulomb integral for the methoxy group used in the present calculation is one for the methoxy radical $CH_3O\cdot$. Miller[14] estimated the loss of the electron affinity of $-O^-$ as -61 kcal. It is necessary to change the coulomb parameter for the methoxy group from CH_3O^- to $CH_3O\cdot$ with t.

5) If configuration interaction is included, the difference between the two excitation energies for the intermediate I will be calculated as somewhat greater.

6) The solvent effect can not be neglected, because the effect on the spectra and life-times of Meisenheimer's intermediates are considerable.[28] According to Miller's calculation, the solvation energy for these intermediates was estimated as 54 kcal. He calculated the activation energies as 14, 19.5 and 25.5 kcal. for reactions 1—3 respectively. In comparison with these values, the corresponding values in the present calculation are much greater. This is possibly due to the neglect of the solvent effect in the calculation.

7) Steric hindrance must be considered.

Summary

By the simple LCAO MO treatment, introducing the reaction parameter, the following expectations have been obtained for the color reactions of polynitroanisoles with the methoxide ion: 1) Meisenheimer's intermediates are more easily formed and are more stable as the numbers of nitro groups increase. 2) The energies of activation for the formation of the intermediates become smaller as the numbers of nitro groups increase. These expectations are in agreement with the experimental results.

The Kinetics of the Reaction of Formaldehyde with Ammonia

By Yoshiro OGATA and Atsushi KAWASAKI

(Received November 6, 1963)

It is well known that formaldehyde reacts with ammonia to form hexamethylenetetramine or hexamine (VI) in a good yield.[1] Although kinetic studies have been reported,[2-4] no decisive evidence has been presented about the dependency of the rate on the concentration of each reactant. Richmond, Myers and Wright[5] suggested a mechanism not on the basis of the kinetics but on that of the isolated derivatives of intermediates.

The present report summarizes the results of our kinetic study of the reaction of formaldehyde with ammonia, especially the relation between the pH of the solution and the rate, which implies a probable mechanism of the reaction.

Results and Discussion

Rate Equation.—The stoichiometric equation for the formation of hexamine from formaldehyde and ammonia has been expressed as

$$4NH_3 + 6CH_2O \rightarrow N_4(CH_2)_6 + 6H_2O \quad (1)$$

Although the analysis of ammonia and formaldehyde in the reaction mixture indicated that the molar ratio of consumed ammonia vs. formaldehyde was 2 : 3 throughout the reaction, the consumption of formaldehyde estimated by analysis is due not

1) P. Duden and M. Scharf, *Ann.*, **288**, 218 (1895).
2) M. L. Boyd and C. A. Winkler, *Can. J. Research*, **25B**, 387 (1947); J. R. Polley, C. A. Winkler and R. V. V. Nicholls, ibid., **25B**, 525 (1947).
3) E. Baur and W. Rüetschi, *Helv. Chim. Acta*, **24**, 754 (1941).
4) S. Bose, *J. Ind. Chem. Soc.*, **34**, 663 (1957).
5) H. H. Richmond, G. S. Myers and G. F. Wright, *J. Am. Chem. Soc.*, **70**, 3659 (1949).

only to the formed hexamine but also to some intermediates, because the consumed formaldehyde may exist as some intermediates besides hexamine. If the reaction mixture was acidified with dilute acetic acid before analysis, the analytical value of formaldehyde became higher. Since hexamine did not decompose under these conditions, the higher value may be due to the decomposition of the intermediates to formaldehyde and ammonia. In alkaline solutions held at 0～5°C for the analysis of formaldehyde, however, the decomposition of the intermediates was slow and negligible. The presence of methanol did not affect this analysis.

The rate of the consumption of formaldehyde, v, may be expressed as the third-order equation:

$$v=\frac{dx}{dt}=k\left(a-\frac{2}{3}x\right)(f-x)^2 \qquad (2)$$

where a and f are the initial concentrations (mol. l^{-1}) of ammonia and formaldehyde respectively, x is the concentration of consumed formaldehyde after t seconds, and k, the third-order rate constant. If $a=2/3\ f$, Eq. 2 gives:

$$k=\frac{3}{2}\frac{1}{2t}\left\{\frac{1}{(f-x)^2}-\frac{1}{f^2}\right\}$$

If $a\neq 2/3\ f$,

$$k=\frac{3}{2}\frac{1}{t}\left\{\frac{2.303}{((3/2)a-f)^2}\log\frac{(3/2)a(f-x)}{f((3/2)a-x)}+\frac{1}{(3/2)a-f}\cdot\frac{x}{f(f-x)}\right\} \qquad (3)$$

The values of k, as calculated by Eq. 3 from the data in an unbuffered solution up to 70% conversion, are shown in Table I. Although the change in the pH of the solution was small, even in these unbuffered solutions, and although the effect of the pH on the rate was very small within the 10.2～10.5 pH range, most of our experiments were made on buffered solutions. The kinetics except at pH 9～10 follow the above rate equation with a precision similar to that of the example in Table I. The rate constant at pH 9～10 tended to decrease slightly as the reaction proceeded. The rapid titration of ammonia with hydrochloric acid, using rosolic acid as an indicator to estimate the unreacted ammonia alone, also gave the same third-order constants. While these k values show a good constancy, those values obtained by means of the other third-order or the second-order equations do not. Consequently, it may be concluded that the reaction is first-order with ammonia and second-order with formaldehyde.

Table I. Typical rate data for the reaction of formaldehyde with ammonia in unbuffered solution at 20°C

Initial concn.: ammonia, 0.0264 M; formaldehyde; 0.0532 M
Change of pH: 10.5～10.2

been reported for the reaction of amine or phenol with carbonyl compounds.[6] No appreciable acid catalysis was detected, at least in these alkaline solutions. The maximum is not due to general acid catalysis, but to preliminary equilibria of ammonia and formaldehyde (Eqs. 4 and 6). No appreciable salt effect was observed with the run at pH 7.9. These results suggest the following mechanism, involving an attack of ammonia[2] on free formaldehyde, at least under these conditions:

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \quad \text{(fast)} \quad (4)$$

$$CH_2O + H_2O \rightleftharpoons CH_2(OH)_2 \quad \text{(fast)} \quad (5)$$

$$CH_2(OH)_2 + OH^- \rightleftharpoons CH_2(OH)O^- + H_2O \quad \text{(fast)} \quad (6)$$

$$NH_3 + CH_2O \rightleftharpoons \underset{\text{(I)}}{NH_2CH_2OH} \quad \text{(fast)} \quad (7)$$

$$NH_2CH_2OH + CH_2O \rightleftharpoons \underset{\text{(II)}}{NH(CH_2OH)_2} \quad \text{(slow)} \quad (8)$$

The mechanism requires that the rate of the consumption of formaldehyde should be expressed as;

$$v = k_8 [NH_2CH_2OH] [CH_2O] = k_8 K_7 [NH_3] [CH_2O]^2$$

Here, k and K are the rate and equilibrium constants of the subscripted steps respectively. The estimation of formaldehyde by Nessler reagent iodometry[7,8] gives only the concentration of the unreacted formaldehyde, but not those from methylolamine and other formaldehyde derivatives. The experiments were carried out in a dilute aqueous solution; hence,

$$a-(2/3)x = [NH_3] + [NH_4^+] = [NH_3]\left\{1+\frac{K_4[H_2O][H^+]}{K_w}\right\}$$

$$f-x = [CH_2O] + [CH_2(OH)_2] + [CH_2(OH)O^-] = [CH_2O]\left(1+K_5[H_2O]+\frac{K_5K_6K_w}{[H^+]}\right)$$

Hence,

$$v = k_8K_7\frac{1}{1+(K_4[H_2O][H^+]/K_w)}\times\left[\frac{1}{1+K_5[H_2O]+(K_5K_6K_w/[H^+])}\right]^2 \times\left(a-\frac{2}{3}x\right)(f-x)^2 \quad (9)$$

Here, K_w is the ionic product of water. At 20°C, $K_4[H_2O] = K_b$[9] $= 1.75\times10^{-5}$, $K_5[H_2O] = K_f$[10] $= 10^4$, $K_6K_w/[H_2O] = K_s$[11] $= 1.62\times10^{-13}$, and $K_w = 0.681\times10^{-14}$.

Therefore, comparing Eq. 9 with Eq. 2,

$$k = \frac{k_8K_7}{K_f^2}\frac{1}{1+[H^+](K_b/K_w)}\left[\frac{1}{1+(K_s/[H^+])}\right]^2 \quad (10)$$

or

$$\log k = \log\frac{k_8K_7}{K_f^2} + \log\frac{1}{1+[H^+](K_b/K_w)} \times\left[\frac{1}{1+(K_s/[H^+])}\right]^2 \quad (11)$$

The differentiation of Eq. 10 with respect to $[H^+]$ gives the pH value of the maximum rate, where the values of K_b, K_w and K_s were corrected for the ionic strength of 0.35 by means of the Debye-Hückel limiting law.

$$[H^+] = \sqrt{\frac{2K_wK_s}{K_b}} = 2.27\times10^{-11} \text{ or } pH = 10.64$$

The plots of the calculated values of $\log[1/\{1+[H^+](K_b/K_w)\}][1/(1+K_s/[H^+])]^2$ and the observed value of $\log k$ against pH are shown in Fig. 1. The observed values show a little deviation from the calculated ones in acidic solutions. In alkaline solutions (pH>10), the observed rate deviates more from the calculated ones.[12]

The difference in height of 0.80 $M^{-2}\,sec^{-1}$ in both linear parts with the slope of ca. 1.0 gives the value of $\log(k_8K_7/K_f^2)$, which leads to 6.3×10^8 for the value of k_8K_7. However, most of formaldehyde is hydrated—i. e., the concentration of free formaldehyde is very small; hence, the concentration of I is negligible except at the initial stages of reaction. Although step 8 is also reversible, the rate of the reverse reaction may be almost negligible at a higher pH.

The reaction product, hexamine, did not appreciably decompose in dilute aqueous acetic acid, at least in an hour's time, but there were intermediates which decomposed completely to ammonia and formaldehyde in

11) M. Wadano, C. Trogus and K. Hess, *Ber.*, **67**, 174, 191 (1934).

12) This fact may be due to the change of the rate-determining step to the following step:

$$NH(CH_2OH)_2 + H^+ \underset{\text{(slow)}}{\rightleftharpoons} HOCH_2NHCH_2^+ + H_2O$$

The dependence of the rate constant on the acidity at pH 9~10 seems to support this assumption, but there is little further evidence.

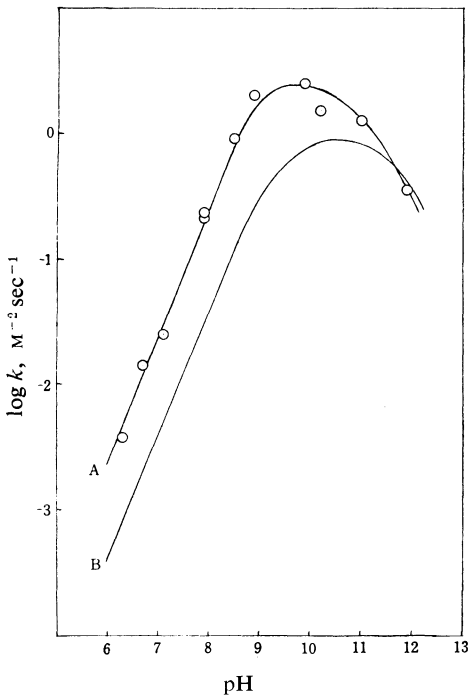

Fig. 1. Plots of logarithm of the observed rate constants (A) and calculated values of $[1/\{1+(K_b/K_w)[H^+]\}][1/\{1+(K_s/[H^+])\}]$ (B) against pH for the reaction of formaldehyde with ammonia.

30 min. under similar conditions. The concentrations of ammonia and formaldehyde produced from the intermediates were observed to be 0.0030 M and 0.0060 M at 15.5 min., 0.0044 and 0.0088 (30 min.), 0.0045 and 0.0094 (60 min.) respectively. Therefore, the molar composition ratio of formaldehyde and ammonia in intermediates should be 2.0, although Bose[4] suggested the value of 1.0 for this ratio. The unstable intermediates may include mono-, di-, and trimethylolamine and other cyclic compounds. Dimethylolamine II rather than *N*-methylolmethylenimine CH_2=N-CH_2OH may be present, since the reaction mixture had no absorption maximum in the range of 210~240 mμ corresponding to a C=N bond,[13] only a maximum at 191~210 mμ (by nitrogen purging), which suggests the presence of amines. Di- and triethanolamine also had absorption maxima in this region. Another probable intermediate, methylenediamine III, the existence of which has been suggested by Richmond et al.,[5] should be more stable than dimethylolamine II and would not decompose, because N-C-N bonds in hexamine VI and 1, 3-diaza-adamantane VIII are stable in aqueous acetic and mineral acids,[14] respectively, and methylenediamine sulfate is isolable in a strongly acidic solution.[5] Nitroso or benzoyl derivatives of cyclotrimethylenetriamine IV and 1, 5-endomethylene-1, 3, 5, 7-tetrazacycloöctane V have been obtained from the reaction mixture.[1,5] When formaldehyde was added to an excess of ammonia and then to benzoyl chloride, methylenedibenzamide (8.4%) was obtained exclusively. On the other hand, both tribenzoylcyclotrimethylenetriamine (7.1%) and methylenedibenzamide (2.6%) were obtained when ammonia was added to an excess of formaldehyde. These facts seem to suggest that the formation of III is faster than that of IV, and that a large ratio of CH_2O vs. NH_3 is favorable for the formation of IV. The following scheme may explain the facts described above.

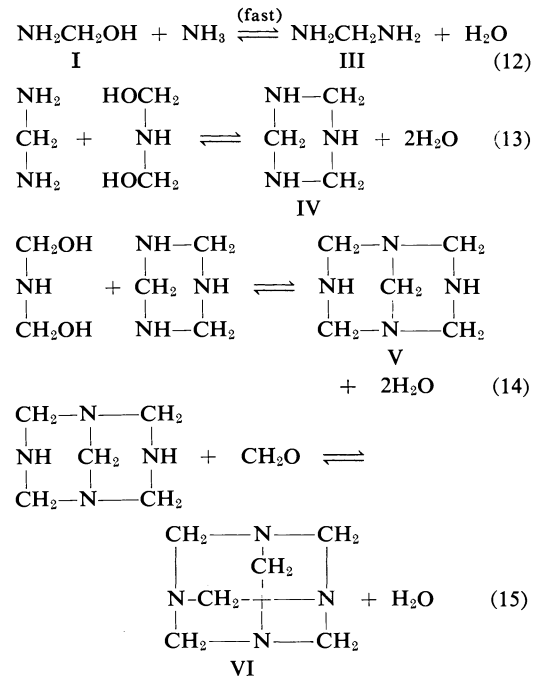

Table III. The molar ratio of formaldehyde vs. ammonia produced from unstable intermediate using 0.0265 M formaldehyde at 23°C after 1 hr.

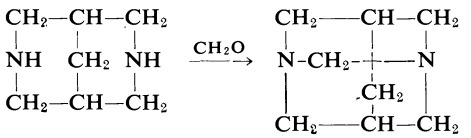

Run	Increase in concn., M		Molar ratio

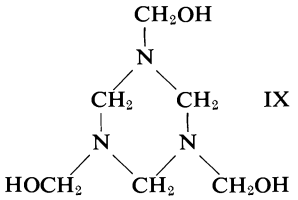
1[a]	0.0044	0.0090	2.0
2	0.0019	0.0044	2.3
3	0.0029	0.0054	1.9
4	0.0014	0.0023	1.7
5	0.0018	0.0041	2.3
			Av. 2.0

a) 0.0530 M formaldehyde was used.

13) R. P. Linstead and M. Whalley, *J. Chem. Soc.*, **1955**, 3530; G. E. Ficken and R. P. Linstead, ibid., **1955**, 3525; A. Maccoll, *Quart. Revs.*, **1**, 28 (1947).
14) H. Stetter, *Angew. Chem.*, **74**, 361 (1962).



We followed the reaction by estimating the remaining formaldehyde alone; thus, steps 13, 14 and 15 may not be very fast. Therefore, it is not surprising that the derivatives of IV and V were isolated as stable intermediates.

Analogous reactions to steps 13 and 14 have been observed in the reaction between dimethylolnitramide and methylenediamine sulfate to form 1, 5-endomethylene-3, 7-dinitro-1, 3, 5, 7-tetrazacycloöctane.[5] In support of step 15, it has been known that bispidines VII with a structure similar to V react readily with formaldehyde to form 1, 3-diaza-adamantane VIII;[14] for example,

VII VIII

Another mechanism,[3,5] by which hexamine is formed through trimethylolcyclotrimethylenetriamine IX, requires that all three methylol groups should be in cis-configuration.[15] Moreover, the reaction of the trimethylols with

IX

ammonia would be more difficult, since 1-aza-adamantane has been prepared, not directly by the reaction of *cis*-1, 3, 5-tris-methylolcyclohexane with ammonia, but by that of its bromoderivative or methanesulfonate and ammonia in a low yield.[14,16]

Experimental

Materials.—The ammonia and formaldehyde used were of G. R. grade. Small amounts of formic acid and methanol in the formaldehyde had no effect on the rate.

Buffer solutions were prepared from 0.4 M monopotassium phosphate and 0.2 M borax solutions for pH 6~9 and from 0.2 M borax and 0.1 N sodium hydroxide solutions for pH 9.8~12. No Cannizzaro reaction of formaldehyde using this buffer solution with a pH of 11 was observed.

Rate Measurements.—A solution of 0.1 M aqueous fomaldehyde (50 ml.) and a solution of 0.05 M aqueous ammonia (50 ml.), maintained previously at 20°C were mixed in a flask and thermostated at 20±0.1°C. At known intervals of time, an aliquot (5 ml.) was pipetted out into an ice-cooled Nessler solution[7,8] (6.5 ml.) containing mercuric chloride (3 g.) and potassium iodide (40 g.) in distilled water (100 ml.). An aqueous solution of 0.1 N iodine (10 ml.) and then 2 N aqueous sodium hydroxide (5 ml.) were added to the solution, and it was kept standing for 30 min. at 0~5°C. The solution was then acidified with 2 N hydrochloric acid (10 ml.), the excess iodine being titrated with 0.1 N sodium thiosulfate. The amount of unreacted formaldehyde was determined by a blank test. A crystalline precipitate of hexamine (84%), (m. p. 295°C (decomp.)) was obtained at the end of these rate measurements.

Intermediates.—*Methylolamines and Related Intermediates.*—0.1 M aqueous formaldehyde (50 ml.) and 0.05 M aqueous ammonia (50 ml.) were mixed in a flask and thermostated at 20°C. After 15~20 min. the reaction mixture was added to 0.1 M aqueous acetic acid (100 ml.) which had been previously cooled with ice-water. Two aliquots (10 ml. or 20 ml. each) were immediately pipetted out; one was employed to determine the concentration of formaldehyde by Nessler reagent iodometry, and the other, to determine that of ammonia by titrating excess acetic acid with 0.1 N sodium hydroxide using phenolphthalein. The solution was kept standing at 20°C for one hour to complete the decomposition, as above. Then the concentrations of ammonia and formaldehyde was again determined; they indicated the composition of the unstable intermediates—i. e., it was found to be composed of $NH_3 : CH_2O = 1 : 2$.

Methylenedibenzamide and Tribenzoylcyclotrimethylenetriamine. — Aqueous formaldehyde (0.1 mol.) was added to aqueous ammonia (0.2 mol.) cooled by ice for over a 10 min. period. The solution was treated with benzoyl chloride (0.13 mol.) as described by Richmond.[5] Methylenedibenzamide (2.14 g., 8.4%) (m. p. 223°C) was obtained. The freezing point method, using dimethylsulfoxide as a solvent, gave a molecular weight of 227; calcd. for $C_{15}H_{14}O_2N_2$: 254. IR spectrum: ν cm^{-1} 3370 (-NH-); 1640, 1535, 1290 (*s*-amide). A trace of tribenzoylcyclotrimethylenetriamine was obtained.

On the other hand, aqueous ammonia (0.1 mol.) was added to a cold solution of formaldehyde (0.2 mol.), and then the solution was treated with benzoyl chloride. The chloroform extract gave tribenzoylcyclotrimethylenetriamine (1.88 g., 7.1%) (m. p. 219~220°C). IR spectum: ν cm^{-1} 1655 (*t*-amide) (Found: C, 72.3; H, 5.26; N, 10.9. Calcd. for $C_{24}H_{21}O_3N_3$: C, 72.2; H, 5.26; N, 10.5%.). Futhermore, methylenedibenzamide (0.324 g., 2.6%) was obtained from the ethanolic extract.

The change in pH measured by a Hitachi M4 pH meter during the reaction is shown in Table IV. The ultraviolet absorption spectra were measured by a Shimadzu SV50A spectrophotometer in the ranges of 210~300 mμ and 190~210 mμ by nitrogen purging.

TABLE IV. THE VARIATION OF pH IN UNBUFFERED SOLUTION AT 23°C
Initial concn.: Ammonia, 0.0265 M (with pH of 10.94)
Formaldehyde, 0.0530 M

Reaction time, min.	0	3	7	10	15	25	35	55	80	285
pH	10.57	10.47	10.40	10.36	10.32	10.26	10.17	10.03	9.88	9.64

has been investigated in dilute aqueous solutions at 20°C in the pH range between 6.3 and 11.9. The reaction was first-order with respect to ammonia and second-order with respect to formaldehyde. The rate increased sharply with the increasing pH to a maximum between 9 and 10, and then it decreased gradually. These results may be explained by a mechanism involving a rate-determining attack of methylolamine on free formaldehyde to form dimethylolamine, followed by the formation of hexamine through cyclotrimethylenetriamine and 1, 5-endomethylene-1, 3, 5, 7-tetrazacycloöctane.

*Electronic Spectra of Substituted Aromatic Hydrocarbons. IV. Anthramines**

By Satoshi SUZUKI and Hiroaki BABA

(Received November 6, 1963)

In this series of papers,[1-3] the effect of substitution on the electronic transitions of aromatic hydrocarbons, benzene, naphthalene and anthracene has been discussed in terms of the perturbation by the substituent group concerned. Along the same lines, the absorption and fluorescence spectra of α- and β-anthramines have been examined in the present study.

Theoretical calculations[4-6] predicted that the $^1A_g \rightarrow {}^1B_{3u}^-$ ($^1A \rightarrow {}^1L_b$ in Platt's notation[6]) transition of anthracene is hidden under the stronger $^1A_g \rightarrow {}^1B_{2u}$ ($^1A \rightarrow {}^1L_a$) transition. The present authors reported in a preceding paper[3] that the ^1L_b band emerged in the absorption spectrum of β-anthrol on the lower frequency side of the ^1L_a band. This shows that the ^1L_b band increases in intensity and undergoes a characteristic frequency shift as a result of the introduction of an electron-donating group at the β-position. As is well known, an amino group is of a more electron-donating nature than a hydroxyl group, so that one may naturally expect that the separation of the ^1L_b band from the ^1L_a band should be pronounced in the spectrum of β-anthramine. In this paper, special attention will be paid to this point. Furthermore, it will be shown that in the low-frequency region α-anthramine has two absorption bands which seem to correspond to the ^1L_a and ^1L_b transitions.

Experimental

Materials.—α-Anthramine was prepared from α-aminoanthraquinone by refluxing it with zinc dust in an aqueous solution of sodium hydroxide.[7] The product was purified by column chromatography, and finally it was subjected to vacuum sublimation; m. p. 117~119°C in a sealed tube (lit.,[7] 121.5~122.5°C). β-Anthramine was prepared from β-aminoanthraquinone by the same procedure.[8] The product was sublimed in vacuo after crystallization from benzene; m. p. 237~238.5°C (lit.,[8] 238°C). Dioxane was purified by the method described in a previous paper.[9] Triethylamine was fractionally distilled, dried with alumina, and then distilled in vacuo.

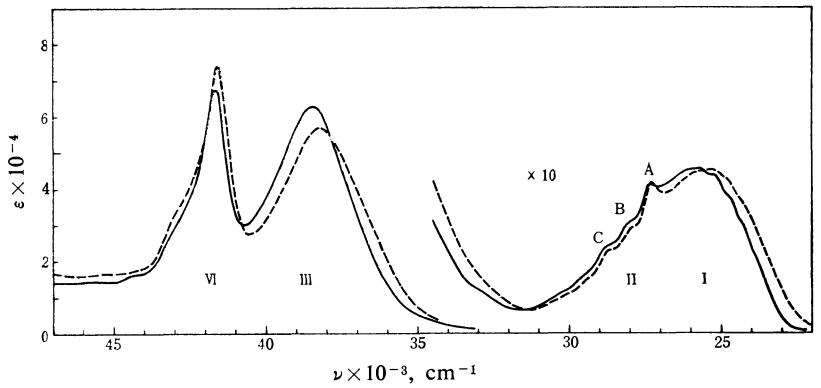

Fig. 1. Absorption spectrum of α-anthramine in isooctane at 20°C and the effect of hydrogen bonding. Solid curve, free molecule; dashed curve, spectrum in the presence of dioxane the concentration of which is 1.0 mol./l.

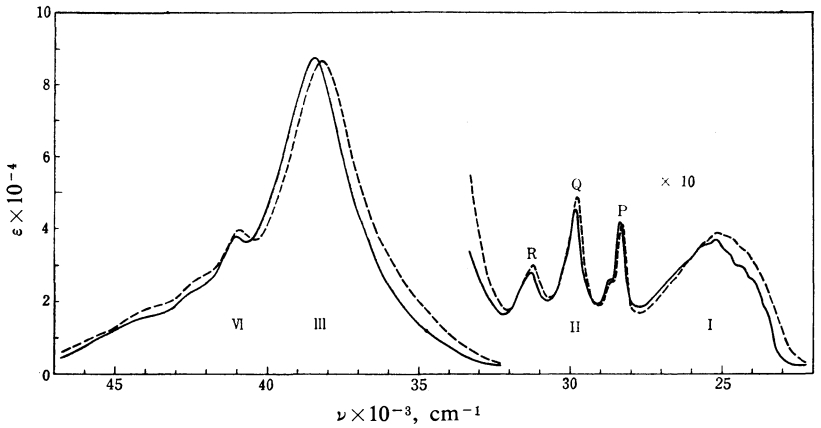

Fig. 2. Absorption spectrum of β-anthramine in isooctane at 20°C and the effect of hydrogen bonding. Solid curve, free molecule; dashed curve, spectrum in the presence of dioxane the concentration of which is 1.0 mol./l.

Apparatus and Procedures.—Absorption spectra at an ordinary temperature were measured with a Hitachi model EPU-2A photoelectric spectrophotometer at the controlled temperature of 20°C. Fluorescence spectra were observed at room temperature by attaching a fluorescence accessory of the L-3 type to the spectrophotometer. Samples were excited with the 365 mμ line of mercury. The slit was kept 0.2 mm. wide for all the fluorescence measurements. The observed spectra were corrected to quantum fluorescence spectra by the procedure described in a preceding paper.[3] All the absorption and fluorescence spectra at ordinary temperature were observed in an isooctane solution.

Absorption spectra at the liquid-nitrogen temperature were obtained using as a solvent the 6 : 1 isopentane—methylcyclohexane mixture which was recommended by Potts[10] as a glass-forming solvent. Measurements of the low-temperature spectra were performed by combining a Hitachi model EPS-2 recording spectrophotometer with a specially-designed low-temperature absorption apparatus. The latter is an all-glass Dewar vessel which has four parallel-plane glass windows transparent down to 250 mμ. Datails about the absorption apparatus and the procedures have been published elsewhere.[11]

Results

Figures 1 and 2 illustrate the absorption spectra of α- and β-anthramines in isooctane at 20°C and the changes in them caused by the addition of dioxane as a proton acceptor. The solid curves depict the spectra of anthramines free from hydrogen bonding. The dashed curves represent the spectra of solutions containing dioxane at a concentration of 1.0 mol./l.

The fluorescence spectra of α- and β-anthramines in isooctane at room temperature are shown in Figs. 3 and 4. In the figures, absorption spectra are given with dashed curves for easy reference.

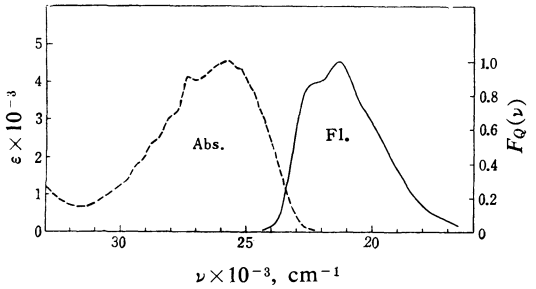

Fig. 3. Fluorescence and absorption spectra of α-anthramine in isooctane. Solute concentration for fluorescence: 8.90×10^{-5} mol./l.

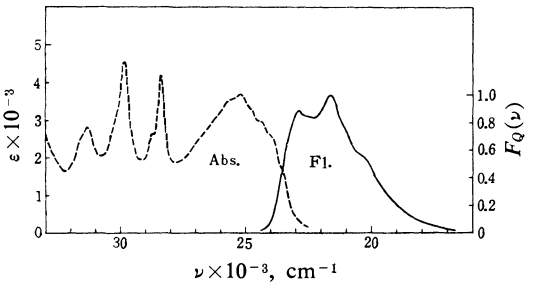

Fig. 4. Fluorescence and absorption spectra of β-anthramine in isooctane. Solute concentration for fluorescence: 3.20×10^{-5} mol./l.

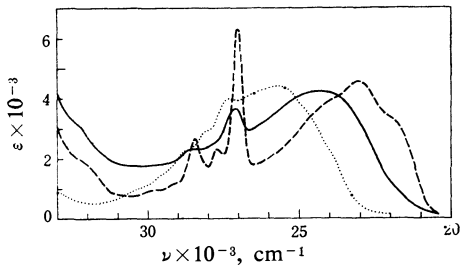

Fig. 5. Absorption spectra of α-anthramine at liquid-nitrogen temperature in 6 : 1 isopentane —methylcyclohexane mixture. Solid curve, free molecule; dashed curve, spectrum in the presence of triethylamine the concentration of which is 0.2 mol./l.; dotted curve, free molecule at room temperature.

The absorption spectra of α-anthramine at the liquid-nitrogen temperature may be seen in Fig. 5. The solid curve is the spectrum of α-anthramine, while the dashed curve is the spectrum in the presence of triethylamine at a concentration of 0.2 mol./l. In the same figure, the absorption spectrum of α-anthramine at room temperature in the same solvent is cited with a dotted line for the purpose of comparison. The absorption spectra at the liquid-nitrogen temperature have been corrected for the solvent contraction.

Discussion

Jones[12] discussed the effect of substitution on the electronic absorption spectrum of anthracene in terms of the resonance theory. From a consideration along his lines, one may predict whether or not the ^1L_b band will appear in some anthracene derivatives. A substituent group introduced at the β-position lies nearly along the long axis of the molecule. The ^1L_b transition of anthracene has a transition moment along the long axis of the molecule, whereas the ^1L_a has a moment along the short axis. Therefore, the ^1L_b transition is subjected to a greater influence than is the ^1L_a transition by the introduction of the substituent group at the β-position. In fact, the authors have reported that in β-anthrol the ^1L_b band emerged on the lower frequency side of the ^1L_a band.[3,13] In the case of β-anthramine, which has a more electron-donating substituent than does β-anthrol, it is expected that the separation of these two bands will become more distinct. On the other hand, upon substitution in the α-position, the ^1L_a transition is expected to show a large frequency shift as compared with the ^1L_b transition, since the α-substitution seems mainly to perturb transitions along the short axis of the molecule. Consequently, when an amino group is introduced in the α-position of anthracene, the ^1L_a band may probably be displaced to the red, leaving the ^1L_b band in its original position. If this is the case, the ^1L_b band will appear on the higher frequency side of the ^1L_a band. Indeed, the ^1L_b band can be detected in the spectrum of α-anthramine.

When a molecule forms a hydrogen bond, characteristic changes are effected in the positions and intensities of its absorption bands. Thus the authors suggested that the observation of this spectral behavior in hydrogen bonding would be useful for distinguishing and assigning the electronic transitions of a given molecule. The hydrogen-bonding effects on the absorption spectra of the anthramines support the band assignments presented here.

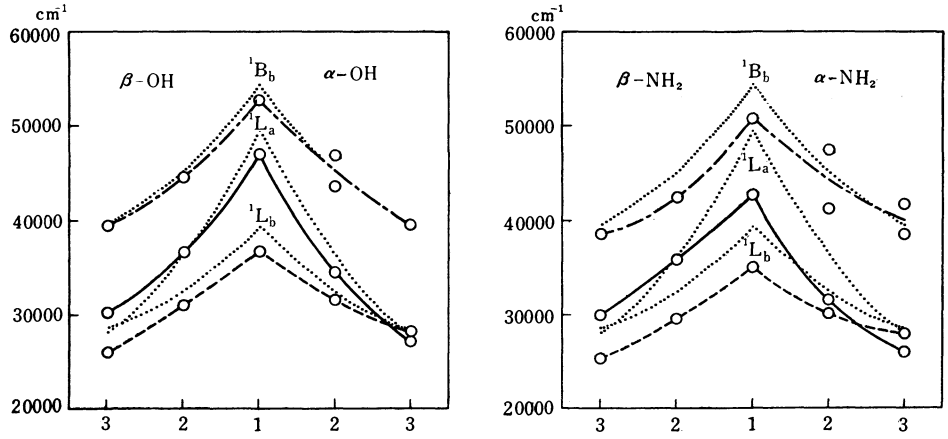
Bands in the Low-Frequency Region. — The absorption spectrum of β-anthramine in the low-frequency region (below 35000 cm^{-1}) consists of an absorption band, II, which has three sharp vibrational components, P, Q and R, with almost equal spacings (ν_{max} : 28370, 29830, 31300 cm^{-1}), and a broad band, I (see Fig. 2). (I, II, etc. refer to the absorption bands in the order of increasing frequency.) Such a spectral constitution suggests that there are two kinds

12) R. N. Jones, *Chem. Revs.*, **41**, 353 (1947).
13) S. Suzuki and H. Baba, *J. Chem. Phys.*, **38**, 349 (1963).

of electronic transitions in this region. This is supported by the following two facts. First, due to the formation of a hydrogen bond, the two absorption bands behave differently in their frequency shift; the shifts of the components, P, Q and R, are quite small compared with the shift of the I band. Second, the mirror image relation between fluorescence and absorption spectra favors the view that there are two transitions in the low-frequency region; the fluorescence spectrum of β-anthramine can be interpreted as corresponding to the I absorption band alone. It has therefore been concluded that in this region β-anthramine has two different electronic absorption bands, namely, the I and II bands.

By reference to the band assignment for the related compound, β-anthrol,[3,13] the I band at the longer wavelengths can safely be assigned to the $^1A \rightarrow {}^1L_b$ transition and the II band, to the $^1A \rightarrow {}^1L_a$. Döller et al.[14] and Förster and Renner[15] have made the same assignment without any comments. In agreement with the expectation from the foregoing qualitative argument, the separation of these two bands is considerably larger in β-anthramine than in β-anthrol. It may be noted that there is a close resemblance in the spectral shapes of β-anthramine and β-anthrol anion.[3]

The low-frequency spectrum of α-anthramine appears to involve only a single electronic transition, but on closer inspection it is found that there are also weak vibrational components, A, B and C, at the shorter wavelength side. As may be seen in Fig, 1, the components, A, B and C, are little shifted by the formation of a hydrogen bond; on the other hand, the band with a maximum at 25910 cm^{-1}, I, is considerably shifted toward the red. From these facts one may assume that there are two different electronic transitions in this frequency region. One is the I transition, and the other is the transition to which the vibrational components, A, B and C, belong, the latter being referred to hereafter as the II transition. Although the observed fluorescence spectrum gives no reliable evidence in support of the above statement, it does not conflict with the assumption of two transitions.



In order to confirm the existence of two different transitions in the frequency region concerned, absorption spectra at the lipuid-nitrogen temperature have been observed (Fig. 5). In general, a lowering of the temperature will be accompanied by a contraction of the solvent and, hence, by an increase in its refractive index. Accordingly, the solvent effect on absorption spectra will be enhanced by the change from room temperature to the liquid-nitrogen temperature. In Fig. 5 it may be seen that the spectrum of α-anthramine, free from hydrogen bonding, is as a whole displaced to the red by lowering the temperature, but the shift of the I band is much larger than that of the vibrational peaks, A, B and C. This indicates that the solvent has different effects on the I and II transitions. When α-anthramine forms a hydrogen bond with triethylamine at room temperature, the I band exhibits a large red shift, whereas the A, B and C peaks show almost no shift in their frequencies. This tendency becomes more pronounced at a low temperature. Thus, as may be seen in Fig. 5, upon the formation of the hydrogen bond with triethylamine at the liquid-nitrogen temperature, the I band is markedly shifted to the red, and, consequently, a clear minimum appears between the I and II bands. The occurrence of such a large separation of the two transitions, I and II, can be interpreted as due to the co-operative effects of hydrogen bonding and the solvent. The absorption spectra of aryl alkali amides have been observed by Döller et al.[14] and Förster and Renner.[15] By referring to their experimental results, one will find that at the liquid-nitrogen temperature α-anthramine does not seem to dissociate a proton, even in the presence of triethylamine.

All of the results of the low-temperature experiments mentioned above show that in the α-anthramine spectrum the vibrational components, A, B and C, belong to an electronic transition which is entirely different in origin from the I transition. As was stated at the beginning of this section, the I band of α-anthramine can reasonably be assigned to the $^1A \rightarrow {}^1L_a$ transition and the II band, to the $^1A \rightarrow {}^1L_b$.

Bands in the High-Frequency Region.—α-Anthramine has two absorption maxima with comparable intensity in this region (above 35000 cm^{-1}). It is evident from their behavior in the hydrogen bond formation that these two bands originate in different kinds of transitions. The one at the lower frequencies shifts toward the red and decreases in intensity, but the other at the higher frequencies shows only a little shift with a slight increase in intensity.

As may be seen in Fig. 2, β-anthramine possesses one intense band, with a weak one on the higher frequency side. The spectral changes caused by hydrogen bonding indicate that the latter belongs to a transition distinct from the former.

(a) Hydroxyl derivatives (b) Amino derivatives

Fig. 6. Energy correlation diagrams of substituted aromatic hydrocarbons. Circles represent the experimental electronic energies. (Dotted curve refers to parent hydrocarbons.) --○--: ^1B_b, —○—: ^1L_a, --○--: ^1L_b.

In this region anthracene gives an intense absorption band which is assigned to the $^1A_g \rightarrow {}^1B_{3u}^+$ ($^1A \rightarrow {}^1B_b$) transition.[4-6] The intense band of β-anthramine is considered to correspond to the ^1B_b transition of anthracene. The appearance of two intense bands in α-anthramine is interpreted as follows: In anthracene there are symmetry-forbidden or low-intensity transitions in the vicinity of the ^1B_b transition. The introduction of a substituent into the anthracene molecule leads to the destruction of the symmetry of the molecule; therefore, in α-anthramine the ^1B_b transition may happen to be mixed with a neighboring transition to give two mixed transitions of a high intensity. The situation is similar to the case of high-frequency transition in some α-derivatives of naphthalene.[2]

The Correlation of Energy Levels for Derivatives of Aromatic Hydrocarbons from Benzene to Anthracene.—The papers of this series have revealed the origins of the electronic bands of hydroxyl- or amino-substituted aromatic hydrocarbons. The results are summarized in Fig. 6. In the figure, observed electronic energies are plotted against the number of rings separately for α- and for β-derivatives. A diagram of this kind was previously presented by Klevens and Platt for the polyacene series.[4] Adopting the assignment or classification of the electronic bands proposed by the present authors for the derivatives, one will see that the plots give smooth curves, as in the case of the parent hydrocarbons. Regarding the ^1B_b states of α-derivatives, the average energies of two transitions with comparable intensities fall on smooth curves. (In order to facilitate comparison, curves for the parent hydrocarbons are depicted with dotted lines in the same figure.) An inspection of these curves will show that the substitution effect can be interpreted in terms of the perturbation by the substituent.

From the figure one may find several similarities in behavior of the transitions which belong to the same class. In α-derivatives, the curve for the ^1L_b state declines more gently than in the parent hydrocarbons with an increasing number of rings, while the curve for the ^1L_a state of the same derivatives runs almost parallel with that of the hydrocarbons. Consequently, the curves for the ^1L_a and ^1L_b states cross at a smaller number of rings in both hydroxyl and amino derivatives than in the unsubstituted hydrocarbons. On the other hand, the ^1L_a state of β-derivatives moves downward more slowly than does the ^1L_a state of the parent hydrocarbons with an increasing number of rings, but the curve for the ^1L_b state is nearly parallel with the curve for the same state of the parent hydrocarbons, the former curve being located at lower energies. Thus the interval between the ^1L_a and ^1L_b state increases so that, in the β-derivatives of anthracene, the ^1L_b band is clearly separated from the ^1L_a band, as has already been stated. The behavior of the ^1B_b state of β-derivatives resembles that of the same state of the parent hydrocarbons. In α-derivatives the correlation of the high-frequency bands is somewhat complicated, but their average energies lie on smooth lines. This, in turn, suggests that the ^1B_b state is split into two states by substitution because of mixing with one of the neighboring

states. It should be noted here that the state of aniline at 42700 cm^{-1} falls on the intersecting point of the two curves extrapolated from α- and β-amino-derivatives of naphthalene and anthracene. In view of this fact, there is no reason to believe that the corresponding absorption band of aniline should be assigned to a band characteristic of the substitution product, e. g., to a charge-transfer band.

The ^1L_a bands of β-derivatives have a sharp, fine structure, with equally-spaced vibrational peaks.

There are some resemblances in the band shifts produced by the hydrogen bond formation. Thus, in α-derivatives the magnitudes of the frequency shifts of the ^1L_b bands are smaller than those of the ^1L_a bands. On the contrary, the ^1L_a bands of β-derivatives are little shifted, but the ^1L_b bands are noticeably shifted to the red by the formation of hydrogen bonds.[9,13]

Summary

Absorption and fluorescence spectra of α- and β-anthramines have been observed. The $^1A \rightarrow {}^1L_b$ transition, which is masked by the $^1A \rightarrow {}^1L_a$ in anthracene, emerges in both α- and β-anthramines because of the perturbation by the substituent. In β-anthramine, the ^1L_b band is clearly separated from the ^1L_a band. In α-derivatives, the ^1L_b band exists on the higher frequency side of the ^1L_a band. These results may be confirmed by observing the effects of hydrogen bonding on the spectra. At the liquid-nitrogen temperature remarkable changes in the absorption spectrum of α-anthramine occur in the presence of triethylamine; these changes have been interpreted as due to the co-operative effects of hydrogen bonding and the solvent. By using the band assignments proposed in this series of papers, reasonable correlation diagrams of the electronic energy levels have been presented for substituted aromatic hydrocarbons, from benzene to anthracene.

The Anisotropy of the ESR Spectrum of Irradiated Poly(β-propiolactone)

By Shun-ichi OHNISHI,* Shun-ichi SUGIMOTO, Koichiro HAYASHI and Isamu NITTA

(Received November 6, 1963)

Many works have reported on the electron spin resonance (ESR) of irradiated polymes. Most of these studies, however, have been made with unoriented specimens. They have usually been amorphous polymers, or, even when they have been highly-crystalline, the crystallites are oriented randomly in the specimens. Recently, however, a few studies[1-6] have appeared using some oriented polymers as the samples. Analysis of the anisotropy in the ESR spectra obtained from such oriented specimens would inform us of the structure as well as of orientation of the free radicals in the specimens, as is evident from studies of single crystals of low-molecular-weight compounds. Using stretched polyethylene, Kiselev et al.[1] and Libby and Ormerod[2] have made definite the previous identification of the alkyl-type radical while Ohnishi et al.[3] have given a conclusive choice on the identification of the allyl-type radical. Kashiwagi[4] has discussed molecular orientation in polyethylene on the basis of the doublet splitting in the double-quintet spectrum of the alkyl-type radical.

In the present paper we have measured the angular variation of the ESR spectrum of irradiated poly(β-propiolactone). The polymer was obtained by radiation-induced solid-state polymerization of a single crystal of the

monomer at low temperatures. The sample thus obtained was known to be a highly-oriented crystalline polymer.[7] From an analysis of the anisotropy of the spectra, we have made a definite identification of the radical produced, and we have also discussed molecular orientation in the specimen through the α-proton hyperfine-coupling tensor.

Experimental

Material. — The monomer (Celanese Co. Ltd.) was distilled twice in a nitrogen stream. The single crystal was obtained as a thin plate (~2.5×1.5×0.2 mm^3) by keeping the monomer at −35°C. The polymer was obtained by irradiating the single crystal of the monomer with γ-rays from a cobalt-60 source at −78°C to a dose of 2 Mrad. After

polymerization, the unreacted monomer was removed by washing it several times with methanol, and then the polymer was dried in a vacuum at 50°C. The polymer sample thus obtained had a shape quite similar to the thin plate of the monomer crystal, although the polymerization yield never exceeded 15%. A sketch of the sample and the orthogonal coordinate system xyz used in the present investigation are shown in Fig. 1. X-Ray photographs taken perpendicular to the xy and yz planes showed a fiber structure, while the photograph perpendicular to the xz plane gave only a halo. Okamura et al.[7] suggested that the molecular conformation is a planar zigzag chain pointed in the z direction.

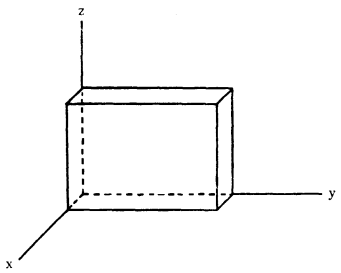

Fig. 1. A sketch of the polymer sample and the xyz coordinate system.

ESR Measurement. — The polymer was irradiated in a vacuum at −196°C with an electron beam from a Van de Graaff accelerator to a dose of 30 Mrad. The ESR spectra of the radical produced were measured at −196°C with a Varian Model V4500 spectrometer (operating frequency: 9160 Mc.). The angular variation of the spectra was measured at 15° intervals in the three planes. Hyperfine splitting values were estimated on the derivative tracing, based on the splitting value of Mn^{2+} resonance.

Results and Discussion

Angular Dependence of the Spectrum. — The spectrum showed anisotropy in the yz and zx planes, while in the xy plane it was nearly the same at all angular positions. The change of the spectrum in the zx plane is shown in Fig. 2. The main four-line spectrum at an angle $\phi=0°$ changes to a six-line one at $\phi=90°$. Here ϕ is the rotation angle measured from the z axis. The feature of the spectral change suggests that this is a double-triplet spectrum and that the doublet splitting changes with the angle, while the triplet remains almost unchanged. The free radical showing this spectrum, therefore, should have an α proton and two β protons. The angular variation of the spectrum in the yz plane is similar to that in the zx plane. At a magnetic field parallel to the z axis, the spectrum is the same one as that observed at $\phi=0°$ in Fig. 2, and, as the field direction changes, it is gradually converted to the six-line spectrum. The spectrum in the xy plane does not change appreciably with the angle, and it is a six-line spectrum similar to the one shown in Fig. 2(4) at all field orientations.

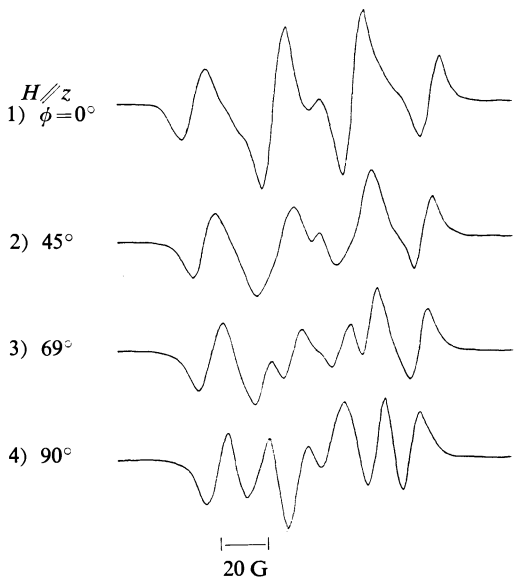

Fig. 2. Angular variation in the zx plane of the ESR spectrum of the irradiated polymer.

The doublet splitting of the α proton, A_α, was read from the separation between the first and the second peaks of the derivative curve; it is plotted against the rotation angle in Fig. 3. The curves in the yz and zx planes approximately obey the $(3\cos^2\phi-1)$ rule, as expected for the dipolar interaction. The triplet splitting value of the β proton, A_β,

was estimated by using the relation:

$$A_\beta = (\Delta H_{overall} - A_\alpha)/2 \quad (1)$$

Here $\Delta H_{overall}$ means the distance between the outermost peaks.

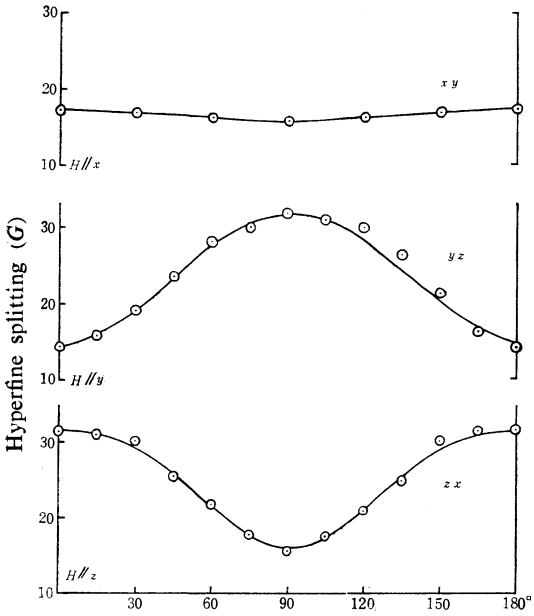

Fig. 3. Angular dependence of the hyperfine splitting of the α proton in the three basic planes.

The triplet splitting was almost isotropic, changing, for example in the yz plane, from 31.2 to 32.5 gauss.

These results indicate that the radical showing the spectrum can be attributed to $-CH_2-\dot{C}H-CO-O-$ or $-CH_2-\dot{C}H-O-CO-$, and also that the orientation of the radical is almost at random in the xy plane, although in the other planes the radicals are highly oriented. Of the two radical species proposed, the former one seems to be more probable because of the resonance stabilization.

Hyperfine-Coupling Tensor.—From the above data, the hyperfine-coupling tensor can be obtained. The spin Hamiltonian for the hf interaction with one proton may be written as[8]

$$\mathscr{H} = \beta\vec{S}\tilde{g}\vec{H} + \vec{S}\tilde{T}\vec{I} - g_N\beta_N\vec{I}\vec{H} \quad (2)$$

where β is the Bohr magneton, β_N the nuclear magneton, g_N the nuclear g-factor, $\tilde{g}$ the g-tensor, $\tilde{T}$ the hf-coupling tensor, $\vec{H}$ the external field, and $\vec{S}$ and $\vec{I}$ the electron spin and nuclear spin operators respectively. Since the electron g-factor showed only a slight anisotropy and since its value was nearly the free-spin value, the g-tensor is taken to be isotropic for the present radical. Moreover, the strong-field approximation is assumed to be as usual; i. e., $\vec{S}$ is replaced by $M_S\vec{Z}$, where $\vec{Z} = \vec{H}/|H|$. Then the spin Hamiltonian becomes:

$$\mathscr{H} = \beta g M_S H + M_S\vec{Z}\tilde{T}\vec{I} - g_N\beta_N\vec{I}\vec{H} \quad (3)$$

From the eigen value of the Hamiltonian, the doublet splitting of the α proton is given as:

$$\begin{aligned} A_\alpha = {} & [l^2(1/2A - \nu_H)^2 + m^2(1/2B - \nu_H)^2 \\ & + n^2(1/2C - \nu_H)^2]^{1/2} \\ & + [l^2(1/2A + \nu_H)^2 + m^2(1/2B + \nu_H)^2 \\ & + n^2(1/2C + \nu_H)^2]^{1/2} \end{aligned} \quad (4)$$

Here ν_H is the nuclear resonance frequency, A, B and C are the principal values of the hf coupling tensor, and l, m, and n are the direction cosines of the field direction with respect to the three principal axes, a, b and c. When evaluating the tensor component from the experimental data, the further assumption was made that the nucleus is also aligned along the field direction.[9] In this case the doublet splitting can be given by a simple formula:

$$\begin{aligned} A_\alpha = \vec{Z}\tilde{T}\vec{Z} = {} & l^2T_{xx} + m^2T_{yy} + n^2T_{zz} \\ & + 2(lmT_{xy} + lnT_{xz} + mnT_{yz}) \end{aligned} \quad (5)$$

Making use of Eq. 5, the tensor components were evaluated and the principal values, as well as the principal directions were calculated (cf. Table I).

As for the hf coupling tensor of the β-proton, only the isotropic component was evaluated as the average of the diagonal components. Its value was found to be 31.9 gauss.

The Orientation of the Free Radical. — The anisotropic hf couping of the α proton in organic radicals has been extensively studied, and the principal axes as well as the principal values of the tensor have been determined for many radicals.[10] For the HOOCCHCOOH radical in malonic acid, for example, the principal values, A, B and C, are reported to be -61, -29 and -91 Mc./sec, with the principal axes parallel to the unpaired π-axis,

TABLE I. HYPERFINE COUPLING TENSOR OF THE α PROTON

Tensor			Principal value	Principal axis		
				l	*m*	*n*
−16.3 (−45.6)	− 0.18 (− 0.52)	− 2.52 (− 7.06)	−15.9 (−44.5)	0.983,	0.092,	−0.160
− 0.18 (− 0.52)	−15.1 (−42.2)	− 0.65 (− 1.83)	−15.0 (−42.1)	−0.097,	0.995,	−0.026
− 2.52 (− 7.06)	− 0.65 (− 1.83)	−31.7 (−88.8)	−32.1 (−90.0)	0.160,	0.039,	0.986

Isotropic component: −21.0 (−58.9)

Values are shown in gauss. Those given in parentheses are in Mc./sec.

to the C–H_α bond, and to the direction perpendicular to both a and b axes respectively.[11] Comparing the values with those obtained for the present radical, the value *C*, −91 Mc., agrees fairly well with one of the observed values, −90.0 Mc. whose axis is almost parallel to the z axis (l=0.160, m=0.039, n=0.986). This suggests that the carbon zigzag chain of the polymer points in the z direction. On the other hand, the other principal values, −44.5 and −42.1 Mc., deviate from the reported values, −61 and −29 Mc., for malonic acid and take some averaged. values. This is a consequence of the almost axially-random orientation of the radical- or zigzag-plane. We may formally evaluate the degree of orientation of the radical in the xy plane from the observed principal values. Suppose that the magnetic field is set along the a axis and that θ measures the angle of the deviation of the π-axis of a radical from the field direction. Making use of Eq. 4 and putting A_α=−44.5 Mc., n=0 and ν_H=13.9 Mc. into the equation, $\langle l^2=\cos^2\theta\rangle$=0.337 was obtained. If we use the following relationship[12] to define the degree of orientation, f becomes 0.02 for the present case.

$$f = (3\langle\cos^2\theta\rangle - 1)/2 \qquad (6)$$

Conclusion

Some conclusions can be drawn from the present ESR study. The produced radical in irradiated poly(β-propiolactone) can be assigned to -CH_2-$\dot{C}$H-CO-O-. The zigzag chain of the radical almost points in the z direction of the sample. In the x and y directions, however, the orientation of the C–H_α and the unpaired π-axis (i.e., the zigzag plane) is almost at random. These resuts are consistent with the reported X-ray result.[7] However, some slight orientation of the zigzag plane is evident from the present study; the principal values, *A* and *B*, are not the same but are slightly different. The average orientation of the π-axis, although almost random, is nearly parallel to the x axis (l=0.983, m=0.092, n=−0.160).

The authors would like to express their thanks to Professor Seizo Okamura of Kyoto University for his helpful discussions and also to Mr. Masanobu Nishii of this Association for his kindness in the sample preparation.

*Infrared Spectra of Metal Chelate Compounds. X. A Normal Coordinate Analysis of Dithiooxalato Complexes**

By Junnosuke FUJITA and Kazuo NAKAMOTO

(Received November 16, 1963)

In general, the infrared spectra of metal chelate compounds are markedly different from those of the pure ligands in the low frequency region. This is mainly due to the difference in vibrational coupling, which in turn is a result of differences in steric configuration and electronic structure.

In order to assign the low frequency bands of metal chelate compounds, it is essential to carry out normal coordinate analysis on the metal chelate ring, including the coordinate bonds. Such attempts have already been carried out on acetylacetonato,[1] oxalato,[2] and carbonato[3] complexes, and the results have proved to be highly important in estimating the strength of the metal-oxygen bonds[4] and in elucidating the electronic structure of the chelate ring.[5] It is, therefore, desirable to extend this work to metal chelate compounds containing other coordinate bonds.

Infrared studies on metal chelate compounds containing metal sulfur bonds are very few. Chatt et al.[6] have, however, reported the infrared spectra of *N*-alkyl, *N*, *N*-dialkyl dithiocarbamato, and xanthato complexes in the NaCl region, and we have carried out a normal coordinate analysis of dithiocarbamato complexes.[7] In view of the scarcity of work on metal chelate compounds containing metal-sulfur bonds, we decided to undertake a similar study on dithiooxalato complexes. Accordingly, we prepared the dithiooxalato complexes of four metals, and obtained their infrared spectra over the wide range of frequency between 4000 and 280 cm^{-1}. We also carried out a normal coordinate analysis of the platinum(II) dithiooxalato complex in order to estimate the force constants as well as to make complete theoretical band assignments.

Experimental

Preparation of Compounds.—Bis(dithiooxalato)-nickel(II), palladium, and platinum(II),[8] and tris-(dithiooxalato)-cobalt(III)[9] were prepared according to the methods described in the literature and were recrystallized several times from an aqueous solution.

Spectral Measurements.—Infrared spectra were obtained on a Perkin-Elmer Model 21 infrared spectrophotometer equipped with NaCl and CsBr optics. The KBr disk method was used for the spectra in the NaCl region, whereas the Nujol mull technique was employed for the spectra in the CsBr region. Frequency calibrations were made with polystyrene film (NaCl region), with 1,2,4-trichlorobenzene (CsBr region), and with water vapor (both regions).

Procedure and Calculations

Figure 1 shows the 1 : 1 (metal/ligand) model of the dithiooxalato complex used for normal

	H_5(S-Pt-S) =0.05	F_5(S·····S) =0.35

coordinate analysis. Since the symmetry of this model is C_{2v}, the fifteen normal vibrations are grouped into four species. The in-plane vibrations ($6A_1+5B_2$) can be separated from the out-of-plane vibrations ($2A_2+2B_1$) because they do not interact with each other. Thus, only the eleven in-plane vibrations are calculated in this paper. Most of the out-of-plane vibrations are expected to appear beyond our observable region, since the dithiooxalato complex consists of relatively heavy atoms. The symmetry coordinates used for the calculation are shown in Table I. The $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices are similar to those previously reported for the oxalato complex.[2] In evaluating the $\boldsymbol{G}$ matrix elements of the platinum(II) complex, the following molecular parameters were used: $r=r'=1.28$ Å, $R=1.47$ Å, $d=d'=1.80'$ Å, $D=D'=2.32$ Å, $\alpha=\alpha'=\beta=\beta'=\gamma=\gamma'=120°$, $\delta=\delta'=105°$, and $\varepsilon=90°$. Both the A_1 and B_2 species involve one redundant condition which is a complicated function of the bond distances and angles. It is not necessary, however, to eliminate these redundancies from the calculation since they give "zero frequencies" in the final result. Thus, one seventh-order (A_1) and one sixth-order (B_2) secular equation of the form, $|\boldsymbol{GF}-E\lambda|=0$, were solved using an IBM 709 computer.

The Urey-Bradley force field[10] was used to express the potential energy. Except for those relating to the Pt-S bonds, force constants were transferred from molecules with similar structures[11] and were adjusted so as to obtain the best fit with the observed spectrum. Table II lists the best set of force constants thus obtained. Table III compares the observed frequencies with those calculated with this set of force constants. In order to make theoretical band assignments, the potential energy distribution[12] in each normal vibration was

calculated with respect to each symmetry coordinate. The results are shown in Table IV, along with numbers indicating the relative contribution from each symmetry coordinate.

Results and Discussion

Figure 2 shows the infrared spectra of 1 : 2 and 1 : 3 dithiooxalato complexes with various metals. It is noted immediately that the spectra of the various divalent metal complexes are very similar to one another. Thus, the band assignments obtained for the platinum(II) complex are in the main applicable to the other divalent metal complexes. Although the calculation was carried out using the 1 : 1 complex model, it has already been demonstrated that errors due to this approximation are fairly small.[2]

According to the results shown in Tables III and IV, the strong bands observed near 1600 cm^{-1} (λ_1, λ_7) are assigned to the C=O stretching modes. In the platinum(II) complex, this band appears at 1594 cm^{-1}, and the corresponding force constant is calculated to be 8.85×10^5 dyn./cm. In the $[Pt(ox)_2]^{2-}$ ion, however, the stretching bands due to the uncoordinated C=O bonds were observed at 1674 cm^{-1}, and the corresponding force constant was estimated to be 9.30×10^5 dyn./cm. This comparison seems to suggest that the C=O bonds in dithiooxalato complexes are weaker than those in oxalato complexes.

As is seen in Fig. 2, all the compounds exhibit two bands at about 1080 (λ_2) and 940 cm^{-1} (λ_8). Table IV indicates that the former is a coupled vibration between C–C and C–S stretching modes, whereas the latter is a coupled vibration between C–S stretching and CO bending modes. A similar pattern of vibrational coupling occurs in the oxalato complex,[2] where the bands near 1400 and 900 cm^{-1} are assigned to the coupled vibrations between C–C and C–O stretching, and between C–O stretching and CO bending modes, respectively.

The bands near 570 cm^{-1} (λ_3) are due to an almost pure C–S stretching mode, and the corresponding force constant is calculated to be 3.30×10^5 dyn./cm. This value is similar to that obtained for thiourea (3.20×10^5 dyn./cm.),[13] but it is larger than that of diethylthioether (2.50×10^5 dyn./cm.),[11] which has pure C–S single bonds. The strengthening of the C–S bonds can be accounted for if it is assumed that electron migration occcurs from C=O to C–S bonds in dithiooxalato complexes. It is also interesting to compare the C–S stretching bands in the dithiooxalato and dithiocarbamato platinum(II) complexes.[6] The C–S stretching

13) A. Yamaguchi, S. Mizushima, T. J. Lane, C. Curran and J. V. Quagliano, *J. Am. Chem. Soc.*, **80**, 527 (1958).

force constant of the former is larger than that of the latter (3.00×10^5 dyn./cm.), whereas the C–S stretching frequency of the former is lower than that of the latter (622 cm^{-1}). This result clearly demonstrates the structural dependence of the vibrational frequency.

According to the results shown in Table IV, the weak bands at ca. 515 cm^{-1} (λ_9) are due to a coupling mode between the CO bending, ring deformation and Pt–S stretching vibrations. The bands at 398 (λ_{10}) and 322 (λ_5) cm^{-1} are the ring deformation coupled with the C–S stretching mode and with the CO bending mode respectively.

The Pt–S stretching vibrations are assigned to the bands observed at 436 and 422 (λ_4) and 322 (λ_{11}) cm^{-1}. These frequencies are higher than those observed for the dithiocarbamato platinum(II) complex (375 and 288 cm^{-1}), mainly because the Pt–S stretching force constant of the dithiooxalato platinum(II) complex (2.30×10^5 dyn./cm.) is greater than that of the dithiocarbamato platinum(II) complex (2.10×10^5 dyn./cm.) This seems to suggest that the Pt–S bond of the dithiooxalato complex is slightly stronger than that of the dithiocarbamato complex. These values for the Pt–S stretching force constant would be reduced slightly if the calculation were made on the actual 1 : 2 model instead of the present 1 : 1 approximate model. In the case of the oxalato platinum(II) complex, however, the Pt–O stretching force constant obtained from the 1 : 2 model was only about 6% smaller than that calculated on the 1 : 1 approximate model.[2]

It has been recognized that such sulfur-containing ligands as thioethers and thiols form strong coordinate bonds with platinum(II).[14] The Pt–S bonds may be strengthened in the dithiocarbamato and dithiooxalato complexes, since they presumably involve pertial $d\pi$-$p\pi$ or $d\pi$-$d\pi$ bonding. Therefore, the relatively large Pt–S force constants obtained here are not surprising. This is also in good accord with the chemical observation that the $[Pt\cdot(C_2O_2S_2)_2]^{2-}$ ion is formed immediately after a solution of $K_2(C_2O_2S_2)$ is added to that of $K_2[PtCl_4]$ (The Pt–Cl stretching force constant is estimated to be 1.50×10^5 dyn./cm.[15])

Figure 2 indicates that, except for the lowest frequency band (λ_{11}), the spectra of the dithiooxalato complexes are little sensitive to the nature of the metal. This result is rather unusual, since all the metal chelate compounds studied so far exhibit several metal-sensitive bands in the low-frequency region. The origin of this anomaly can only be understood through normal coordinate analyses of individual complexes; this remains a problem to be solved in the future.

Summary

The infrared spectra of dithiooxalato complexes of platinum(II), palladium(II), nickel(II) and cobalt(III) have been obtained in the range between 4000 and 280 cm^{-1}. A normal coordinate analysis has been carried out for the 1 : 1 (metal/ligand) model of the dithiooxalato platinum(II) complex. The results indicate that the Pt–S stretching bands are at ca. 430 and 320 cm^{-1} and that the corresponding force constant is 2.30×10^5 dyn./cm.

Photolyses of Isobornyl and Bornyl Nitrites

By Masao NAKAZAKI and Koichiro NAEMURA

(Received November 18, 1963)

Barton et al.[1] scrutinized the photolysis of alkyl nitrite[2] and demonstrated its usefulness to synthetic organic chemistry, especially in introducing functional groups into an otherwise inert, angular methyl group of steroids by means of a dramatic three-step synthesis of aldosterone acetate from corticosterone acetate.[1a]

They also pointed out that the NO group migrates to the methyl group located at the 1, 3-diaxial position. An inspection of the molecular model of isobornyl nitrite (Ia)[3] reveals that one of the gem-methyl groups and the NO group are in a quasi 1, 3-diaxial relation, fulfiling the conformational requirement of this photochemical migration; therefore, the photochemical product of Ia can be expected to be *cis*-π-oxoisoborneol oxime (IIa). In contrast to the readily-available trans-π-substituted camphor derivatives,[4] *cis*-isoketopinic acid (IIIa) and *cis*-π-hydroxycamphor (IIIb) are the only known examples of cis-π-substituted camphor derivatives. Since we have been interested in the studies of the reactivity of *cis*-π-oxocamphor (IIIc), we hoped that this expected photochemical synthesis would turn out to be the most convenient process to IIIc, as well as a general synthetic route to a cis-π-substituted camphor series of compounds which has been obtained through multistep routes.[4]

When a solution of isobornyl nitrite (Ia) in benzene was irradiated with an ultraviolet lamp for 1 hr., needles (m. p. 214~215°C, $[\alpha]_D$ −71.1° (in ethanol) were obtained. Although this compound's molecular formula was $C_{10}H_{17}O_2N$, isomeric with the starting material, and although its color reaction with ferric chloride was purple, indicating the oxime structure IIa, it soon became evident that this compound has no oxime group. The heating of the compound with acetic anhydride and sodium acetate gave only the monoacetate (m.p. 80~82°C), instead of the expected nitrile. Barton et al. observed the photochemical cleavage of the 5-membered D ring of the nitrite of a 17-ol steroid[1d] (e. g. 5α-androstane-3α, 17β-diol 3α-acetate 17β-nitrite), affording a 6-membered hydroxamic acid derivative. We suspected that the photolysis of Ia did not follow the expected schema (Fig. 1) and that the strained 5-membered ring of Ia was cleaved to the hydroxamic acid derivative, VIIIa. This was confirmed by the reduction of VIIIa with zinc powder in acetic acid to give the lactam IXa (m. p. 156~160°C, $[\alpha]_D$ −51.3° (in ethanol)), which was further converted into the imine IXb with lithium aluminum hydride. Although two alternative direction of the photochemical cleavage reaction seem possible, the one between the carbon atom carrying the nitrite group and the neighboring methylene is inconceivable by analogy with the results established by Barton et al, (*vide supra*) on the nitrite of a 17-ol steroid. This is further supported by the fact that the lactam IXa and the imine IXb were found to be not identical with α-camphidone[5] and camphidine[5] respectively. The oily reaction product freed from the hydroxamic acid VIIIa was chromatographed on an alumina column to give isoborneol (IVb) and an oil which distilled to yield a yellow liquid (b. p. 65~70°C/4 mmHg), the infrared spectrum and NMR spectrum of which showed the presence of an aldehyde group. Although the aldehyde could be converted to α-campholenic acid amide (XIIb) (m. p. 127~128°C) via α-campholenic acid (XIIa) and although its 2, 4-dinitrophenylhydrazone and semicarbazone melted rather sharply (124~126°C and 142~143°C respectively), its vapor phase chromatogram exhibited two peaks with almost equal intensities, indicating that the aldehyde is unhomogeneous. The infrared spectrum of this mixture had

peaks at 880 and 800 cm^{-1}, suggesting the presence of $>C=CH_2$ and $-CH=C<$; this was further supported by the NMR spectrum (4.80 and 5.24 τ*). These results imply that the aldehyde fraction consists of α-campholenic aldehyde (X) and iso-α-campholenic aldehyde (XI); the latter was first detected in the reaction mixture of the lead tetraacetate oxidation of isoborneol (Ib),[6] not in the photolysis of camphor (see the Experimental section). The relative molar amounts of these products together with their retention times in the vapor phase chromatograph, are summarized in Table I.[7] It is noteworthy that, in the photolysis of isobornyl nitrite (Ia) at a much higher concentration, camphor (IIId) was detected in the reaction mixture, which also contained the unsaturated aldehydes X and XI, isoborneol (Ib) and the hydroxamic acid VIIIa; however, the ratio of VIIIa to Ib, in this case, was found to be just the reverse of that observed in the low concentration experiment. The photolyses of bornyl nitrite (IVa) at low and high concentrations were carried out to give analogous results (Table II)[7] in spite of the different stereochemistry of the starting materials.

These facts suggested that these photolyses would be nonstereospecific, and that an intermediate such as VI might be common in both cases. The disproportionation of the intermediate radicals Va and Vb would be enhanced at a higher concentration, thus accounting for the relatively high yields of borneol, isoborneol and camphor in the photolyses performed in higher concentrations, but it does not seem possible to advance, without further study, a plausible mechanism to explain the rather interesting predominant formation of the hydroxamic acid (VIIIa) in the low concentration experiments.

Since Professor Barton[8] has announced that Dr. Kabasakalian of his laboratory has carried out extensive studies of the photolyses of aliphatic nitrites, including bornyl and isobornyl nitrite, we will refrain from further investigation of this problem.

Experimental*

Isobornyl Nitrite (Ia).—Into a chilled solution of 63.0 g. of isoborneol (Ib) (m. p. 211~213°C, $[\alpha]_D^{22}$ −23.5° (*c* 0.845 in ethanol)) in 450 cc. of pyridine, 38.0 g. of nitrosyl chloride[9] gas was passed in a period of 3 hr. After being stirred for 1.5 hr. at room temperature, the reaction mixture was poured into ice water and extracted with ether. The extract was washed with 2% hydrochloric acid and dried over anhydrous sodium sulfate. Removal of the solvent yielded an oil which distilled to afford 66.2 g. of yellow liquid (89% yield) (b. p. 175~176°C/9 mmHg). An infrared spectrum exhibited peaks at 1645 and 1605 cm^{-1} (-NO).

The Photolysis of Isobornyl Nitrite (Ia). — A solution of 6.0 g. of Ia in 600 cc. of benzene was cooled with running water and irradiated with a Toshiba SHL-100UV mercury lamp for 1 hr. in an atmosphere of nitrogen. The crystals which precipitated were collected and recrystallized from benzene-petroleum ether to afford 1.6 g. of the hydroxamic acid VIIIa (m. p. 214~215°C, $[\alpha]_D^{22}$ −71.1° (*c* 0.562 in ethanol)), which gave a red color with a ferric chloride solution. Infrared spectrum in Nujol mull: peaks at 3100, 1640, 1400, 1370 cm^{-1}.

Found: C, 65.70; H, 9.27; N, 7.32. Calcd. for $C_{10}H_{17}O_2N$: C, 65.54; H, 9.35; N, 7.64%.

The reaction mixture freed from the hydroxamic acid VIIIa was concentrated and chromatographed through a column of alumina to give isoborneol (Ib) (m. p. 209~210°C), identified by an infrared spectrum. The second fraction of the chromatographic separation was distilled to afford a liquid (b. p. 65~70°C/4 mmHg); an infrared spectrum in Nujol mull showed peaks at 2740, 1725, 1655, 880 and 800 cm^{-1}, and a NMR spectrum exhibited peaks at 0.26, 4.80, 5.24, 7.62 and 8.40 τ which correspond to $\underline{CHO}$, $>C=\underline{CH}-$, $>C=\underline{CH_2}$, $\underline{CH_2}CHO$, and $-HC=CH\cdot\underline{CH_3}$ respectively.

The 2, 4-dinitrophenylhydrazone was recrystallized from ethanol; m. p. 124~126°C.

Found: C, 57.91; H, 6.11; N, 16.63. Calcd. for $C_{16}H_{20}O_4N_4$: C, 57.82; H, 6.07; N, 16.86%.

The semicarbazone was recrystallized from ethanol; m. p. 142~143°C (lit.[6,10] m. p. 141~142.5°C).

Found: C, 63.12; H, 9.15; H, 20.08. Calcd. for $C_{11}H_{19}ON_3$: C, 63.07; H, 9.00; N, 19.86%.

The quantitative analyses of these products, except that of the hydroxamic acid VIIIa, were performed by means of vapor phase chromatography; they are summarized in Table I.

The Acetate VIIIb of the Hydroxamic Acid VIIIa.—A mixture of 0.5 g. of the hydroxamic acid VIIIa, 27.5 cc. of acetic anhydride and 5.5 cc. of pyridine was heated at 90~100°C for 1/2 hr. After the mixture had been concentrated at reduced pressure, the residue was recrystallized from petroleum ether to yield 0.55 g. of the acetate VIIIb.

Found: C, 64.27; H, 8.42; N, 6.51. Calcd. for $C_{12}H_{19}O_3N$: C, 63.97; H, 8.50; N, 6.22%.

The Lactam IXa.—A mixture of 0.95 g. of the hydroxamic acid VIIIa, 8.0 g. of zinc powder and 60 cc. of acetic acid was refluxed for 6 hr. After

* NMR spectra were measured at 60 Mc. in carbon tetrachloride, using tetramethylsilane as an internal reference.

7) Use was made a 5 m. column of 30% dioctyl phthalate on Cellite 545 (80~100 mesh) at 150°C, and a helium flow rate 80 cc./min. on Yanagimoto Gas Chromatograph GCG-3D type.

* The analyses were performed in the Microanalytical Laboratory of the Institute of Polytechnics, Osaka City University.

9) J. R. Morton and H. W. Wilcok, "Inorganic Syntheses," Vol. 4, 48 (1953).

10) R. Srinivasan, *J. Am. Chem. Soc.*, **81**, 2604 (1959).

being freed from the excess zinc powder, the solution was concentrated at reduced pressure. The residue was made basic with aqueous sodium hydroxide and extracted with ether. After being washed with water and dried over anhydrous sodium sulfate, the solution was concentrated to give needles which were recrystallized from petroleum ether to afford 0.50 g. of needles (m. p. 156~160°C, $[\alpha]_D^{22}$ −51.2° (*c* 0.516 in ethanol)).

Found: C, 72.01; H, 10.39; N, 8.07. Calcd. for $C_{10}H_{17}ON$: C, 71.81; H, 10.25; N, 8.38%.

The Imine IXb.—To a stirred mixture of 0.4 g. of lithium aluminum hydride and 50 cc. of dioxane, a solution of 0.30 g. of the lactam IXa in 70 cc. of dioxane was added in a period of 15 min. The mixture was refluxed for 28 hr. and decomposed with water. After the alumina deposited had been filtered, the filtrate was concentrated and made basic with aqueous ammonia. The aqueous mixture was extracted with ether, and removal of the solvent left a residue which resisted crystallization. This was then converted directly into the picrate, yellow needles (decomp. p. 250°C).

Found: C, 49.84; H, 5.78; N, 14.73. Calcd. for $C_{16}H_{22}O_7N_4$: C, 50.26; H, 5.80; N, 14.65%.

α-Campholenic Acid Amide (XIIb).—The aldehyde fraction (1.0 g.) obtained from the photolysis of isobornyl nitrite (Ia) was added to a solution of 2.4 g. of silver nitrate in 10 cc. of water. To the stirred mixture, 1.2 g. of sodium hydroxide were added, and the stirring was continued for 30 min. After being freed from the deposit, the mixture was washed with ether. The aqueous solution was made acidic with hydrochloric acid and extracted with ether. After washing with water, the solvent was removed, yielding 0.75 g. of a viscous liquid; 0.3 g. of this was converted into the acid chloride with thionyl chloride (1.5 cc.). The acide chloride was added to concentrated aqueous ammonia, and the acid amide XIIb deposited was recrystallized from aqueous ethanol (m. p. 127~128°C (lit.[11] 130.5°C)), which was identified as α-campholenic acid amide by comparing it with an authentic specimen prepared from α-campholenic nitrile[11] (XIIc) by alkaline hydrolysis.

Found: C, 71.65; H, 10.28; N, 8.35. Calcd. for $C_{10}H_{17}ON$: C, 71.81; H, 10.25; N, 8.38%

Bornyl Nitrite (IVa).—A chilled solution of 22.3 g. of borneol (IVb) in 200 cc. of pyridine was saturated with nitrosyl chloride gas, and the solution was allowed to stand at room temperature for 30 min. After the usual work up (*vide supra*), 17.9 g. of yellow liquid (b. p. 72~74°C/6 mmHg) was obtained.

The Photolysis of Camphor (IIId).—A solution of 2.0 g. of camphor (IIId) in 200 cc. of benzene was irradiated as was isobornyl nitrite for 1 hr. The product was analyzed by vapor phase chromatography,[7] which indicated the presence of 0.31 g. of α-campholenic aldehyde (X) and 1.26 g. of camphor, but no trace of iso-α-campholenic aldehyde (XI).

*The Isotopic Hydrogen Exchange between Propene and Deuterium Oxide Catalyzed by Nickel Powder**

By Kozo HIROTA and Yoshie HIRONAKA

(Received November 19, 1963)

The catalyzed, isotopic hydrogen exchange of olefins and related compounds with hydrogen gas has been investigated by many workers for thirty years[1] in connection with the mechanism for the catalytic hydrogenation of double bonds.[2] Similar exchange reactions with water have not been reported so much, though it is simpler to clarify their mechanisms because of the lack of simultaneous hydrogenation. One of us (K. H.) studied the exchange reaction of paraxylene with deuterium oxide and found that only the exchange of methyl hydrogen could be recognized at 100°C in the presence of nickel powder.[3] Similar characteristic catalytic activity was recently reported by Crawford and Kemball[4] on nickel films in the exchange of alkylbenzenes; however, they used deuterium gas instead of deuterium oxide.

On the other hand, rhodium, palladium and

platinum—the metals also with a face-centered cubic lattice—were found to exchange ring hydrogen to the same order of magnitude under the same experimental conditions.[3c]

Such difference in reaction would seem of interest in order to understand the nature of selectivity on catalytic hydrogenation, so the study has been extended to other olefinic compounds with methyl groups. The exchange reaction of propene with deuterium oxide by the use of nickel catalysts, supported and unsupported, will be described in the present report.

Experimental

Materials. — Commercial pure isopropanol was dehydrated with activated alumina. The propene thus obtained was purified by distillation in vacuo. The deuterium oxide (99.7%) obtained from Showa Denko K. K. was used without any further purification. The other materials were commercial grade pure reagents.

The nickel catalyst was prepared by decomposing commercial nickel formate (Mitsuwa Yakuhin Kogyo K. K.) at 270°C and then degassing it at the same temperature for about 20 hr. A nickel catalyst supported on alumina in the ratio 1 : 1 was prepared by the thermal decomposition of nickel formate supported on activated gamma-alumina (Wako Junyaku K. K.). The nickel formate was prepared as follows:—Nickel carbonate was obtained by the addition of ammonium carbonate into a nickel nitrate solution; the precipitate was washed until the filtrate did not show any alkaline reaction. The dried nickel carbonate and activated alumina (Al_2O_3: Ni=1 : 1 in weight) were mixed well, and then water was added to the mixture until it became a a jelly substance. This jellified mixture was turned into nickel formate by treating it with formic acid. In order to precipitate the formate on alumina completely, acetone was added finally; then the precipitate was dried for 24 hr. at 80°C.

Procedure.—The reaction was always carried out in a glass ampoule into which propene and deuterium oxide had been charged in vacuo. The detailed procedure was nearly the same as that already reported by one of the present authors.[3]

For the quantitative analysis of the deuterated products, both mass-spectrometry (Hitachi RMU-5 installed at the Osaka Laboratory, Japanese Association for Radiation Research on Polymers) and NMR spectrometry (Varian A-60) were adopted.

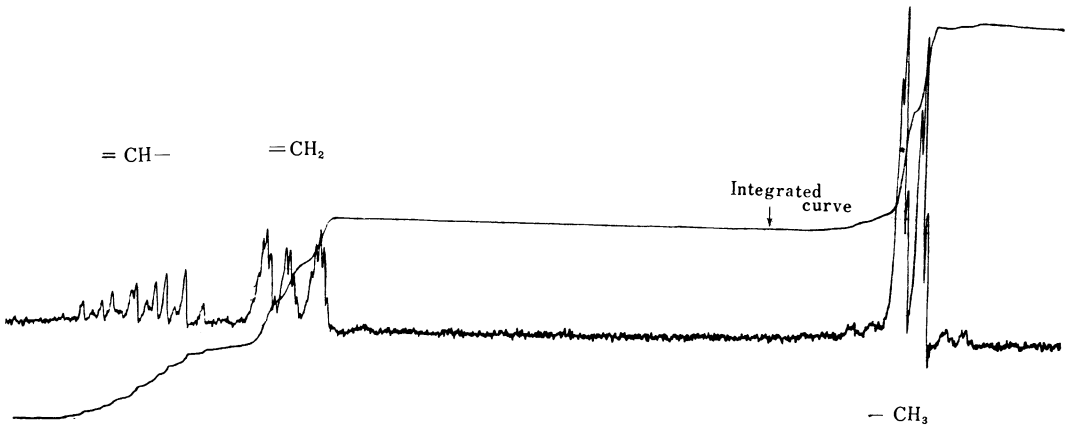

Fig. 2a. NMR spectrum of propene.

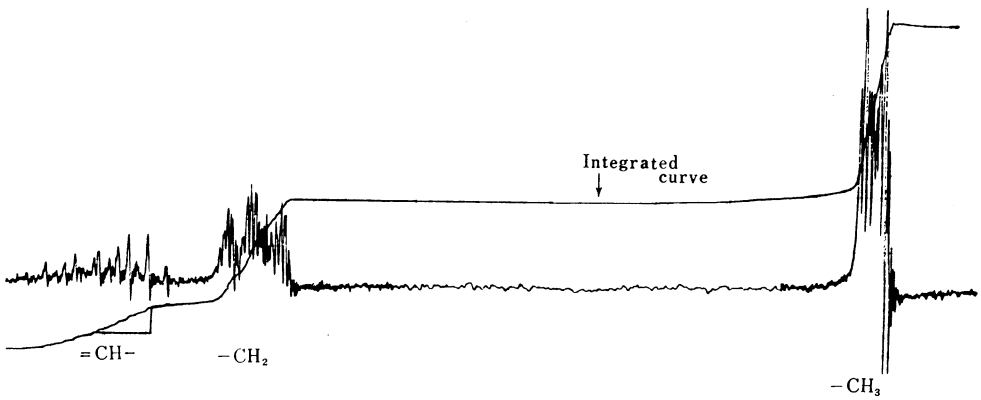

Fig. 2b. NMR spectrum of No. A-4.

For the qualitative analysis, however, infrared-spectrometry (Hitachi EPI-2 and DS 402G of Japan Spectroscopy Co.) was adopted.

Results

Deuterium Distribution.—Table I shows the deuterium distribution in the products which were produced under the experimental conditions described, with $C_3H_{6-i}D_i$ denoted by d_i. Generally speaking, propene exchanged more easily than *p*-xylene with D_2O, because the reaction is measurable even at room temperature.* Secondly, the data on nickel seem to show that the exchange proceeded as a successive reaction, judging from the deuterium distribution in the products. The Datum of No. K1-*i* is a part of those of No. K1 shown in Table II, which gives another indication of the successive production of d_2 via d_1, because the d_1% vs. time curve reaches a maximum value at 5 hr.

* However, so far as the exchange of methyl hydrogen is concerned, the rates may not be so different, as will be found.

The Identification of the Deuterated Groups.—Before entering into a detailed discussion, let us investigate the deuterated groups in the products on No. A4, which was obtained without any carrier, by comparing the infrared spectra (dotted line in Fig. 1a) with that of propene (solid line in Fig. 1a). The infrared data of deuteropropenes obtained by various researchers[5-8] seem to show that the deuterium exchange occurs more easily at the vinyl group rather than at the methyl group in the 2100~2300 cm^{-1} region; because the C–D stretching bands of the vinyl group appearing at 2248 and 2265 cm^{-1} in Fig. 1a show stronger intensities than the bands of $-CH_2D$. appearing at 2161, 2170 and 2183 cm^{-1} [8]

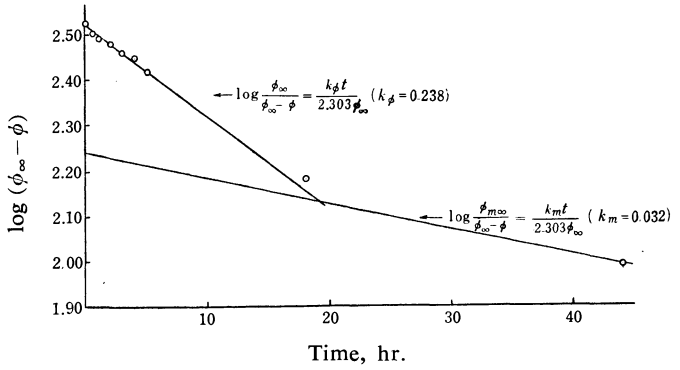
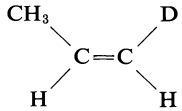
* The intensity decreased.
** Shapes of the bands changed and their intensities decreased.

in the products. This finding is interesting if compared with the fact that the exchange occurred overwhelmingly at the methyl hydrogen in the case of *p*-xylene.*

* The exchange degree at the ring hydrogen was estimated to be less than 5%, if it occurred at all.[3a]

In order to confirm such an unexpected result, the NMR spectrum of the products of No. A4 was measured in the liquid state. As Fig. 2 shows, the above tendency was also observed. The signal of the methyl protons was complicated by the pertial deuteration of both





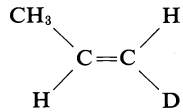


Fig. 3. Plots of log $(\phi_\infty - \phi)$ vs. time.

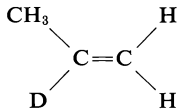
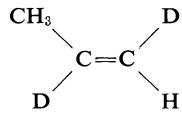
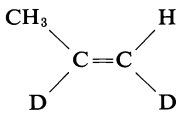
hydrogens of the methin and methen groups.



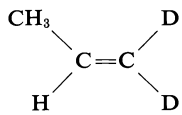
To summarize the above conclusion, all the bands of No. A4 can be assigned as shown in Table III, where the nomenclature used for deutero-propenes deuterated at the vinyl groups is as follows:



cis-propene-1-d_1 (*c*-1-d_1)



trans-propene-1-d_1 (*t*-1-d_1)



propene-2-d_1 (2-d_1)

trans-propene-1,2-d_2 (*t*-1,2-d_2)

cis-propene-1,2-d_2 (*c*-1,2-d_2)

propene-1,1-d_2 (1,1-d_2)

Table III shows further that the bands of medium intensity at 1613, 1628, 1643 and 1645 cm^{-1}, as well as other bands at shorter wavelengths, support the above conclusion. However, even if the exchange at both hydrogens of the methin and methen groups is found, the exchange degree is hard to determine quantitatively on the basis of the infrared data alone. According to the NMR measurement which is now in progress, the exchange at the methin hydrogen appears to be easier.

Kinetics of the Reactions. — In order to investigate the progress of the exchange reaction, the kinetic data of No. K1 (Table II) were analyzed by plotting log $(\phi_\infty - \phi)$ against t. As curve a in Fig. 3 indicates, a straight line was obtained at the initial stage, suggesting that the reaction is of the first order, when only d_1, d_2 and d_3 were the products. This result is concordant with the fact that the exchange proceeds mostly at the hydrogen atoms of the reactive vinyl hydrogen. The failure of linearity at the later stage, when propene-d_4 was produced, may, however, be ascribed to the fact that the less reactive methyl hydrogen began to play the main role in the exchange as the exchange equilibrium of the vinyl hydrogen was gradually attained. Therefore, by the method given by Kemball and Crawford,[4] the ratio of the rate constant of methyl hydrogen, k_m, to that of vinyl hydrogen, k_v, was calculated, assuming the initial rate constant to be 0.23$_8$. The solid line in Fig. 3 was drawn by using the $k_v/k_m = 6.4$ thus obtained.

The explanation assuming the reactivity of different hydrogens can be justified by the deuterated products of Nos. B19-a, -b and -c (Table I), in which the long reaction times of 25, 50 and 100 hr. respectively at 25°C were adopted. In this series, the curve plotting log d_0 vs. time is not linear, as in the case of No. K-1 (cf. Fig. 2), suggesting the presence of at least two kinds of hydrogen atoms with different reactivities. Besides, as Fig. 4 shows, the infrared spectra of Nos. 19 indicate the successive production of propenes deuterated at both the vinyl (2265 and 2248 cm^{-1}) and methyl (2183 cm^{-1}) groups with time, and shows parallel with the increase of propene-d_2 (cf. the bands at 2223 cm^{-1} as well as at 712 cm^{-1} which are not shown). The ratio of d(methyl)/d(vinyl) was preliminarily estimated on the basis of the infrared bands in Fig. 4 to be 3, if the amount of propene-d_1 is proportional to the absorbance of the bands at 2248 cm^{-1} and 2265 cm^{-1} for vinyl and at 2183 cm^{-1} for methyl C–D stretching respectively, and if their absorption coefficients are equal. The numerical value 3 above mentioned coincides with that of 3.4 determined by the

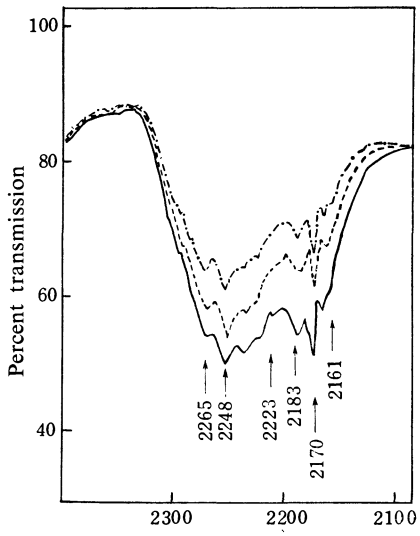


Fig. 4. IR spectra of Nos. B19-a, B19-b and B19-c.

—·— B19-a ---- B19-b —— B19-c

NMR data,* within the range of experimental error.

Effect of Carriers. — As has already been reported,[3] both methyl and ring hydrogen of *p*-xylene were exchangeable if nickel was supported on alumina.[3] Some change in selectivity was also found in the present reaction by the comparison of infrared data of Nos. A5, 6, 7, 8 and 9 with each other, although the change occurred in the direction opposite to that of paraxylene. For example, in the spectrum of No. A-9 shown in Fig. 1b, the band at 2183 cm^{-1} is stronger than those at 2248 and 2265 cm^{-1}. Thus the exchange rate of methyl hydrogen became comparable with or larger than that of vinyl hydrogen as a result of the use of this carrier.

Another point to be mentioned is the absolute decrease in the catalytic activity of carried catalysts. As Table I shows, the exchange degree of Nos. A6, A7, A8 and A9 became similar to that of No. A5 when the reaction time or the amount of the catalyst was increased, while in the case of paraxylene, the activity was always increased by the use of carriers.

Discussion

Propene was found to exchange its three kinds of hydrogen with deuterium oxide. Such a simultaneous exchange of different kinds of hydrogen has already been reported by Twigg[9] on the system when propene and deuterium gas came in contact with the nickel catalyst. Since his results were obtained indirectly by the determination of the total isotopic concentration, it may be said that his conclusion was first confirmed without ambiguity by the present report. It has been found, moreover, that the exchange of methyl hydrogen is more difficult than that of vinyl hydrogen. This finding is to be explained as follows.

As has already been mentioned, the scission of the methyl hydrogen of paraxylene is easier than that of ring hydrogen from the thermochemical viewpoint, because $D(C_6H_5CH_2\text{–}H)$ is 77.5 kcal./mol. and $D(C_6H_5\text{–}H)$ is 104 kcal./mol., according to Szwarc's data.[10] These numerals are favorable for use in the explanation of the experimental results of the exchange reaction carried out on a nickel catalyst. However, the same argument cannot be applied in the present case. Since $D(CH_2 : CH\cdot CH_2\text{–}H)$ is 76.5 kcal./mol. and $D(CH_2CH\text{–}H)$ is 104 kcal./mol., the scission of vinyl hydrogen would be more difficult than that of methyl hydrogen, unlike the present exchange data. The above contradiction may not be very serious, however, because no attention was paid in the argument to the existence of a catalyst on which olefins may be adsorbed at their double bond. Moreover, it must be remembered that the two absolute rates of the exchange of methyl hydrogen are not so different as those which occur in the double bonds.

On the exchange reaction of ethene and heavy water, ethene is often regarded, since Horiuti-Polanyi's work,[1] as forming bonds with metals opening its double bond as follows:

$$C_2H_4 \rightarrow \underset{*\ *}{H_2C\text{–}CH_2} \rightarrow \underset{*}{H_2C\text{–}CH_3}$$

where the star * denotes the bonding thereby produced. From such an adsorbed state of the associated type, a half-hydrogenated state, $CH_2\text{–}CH_3$, is produced if a sufficient amount of $\overset{*}{H}$ exists on the surface. These presumed $\overset{*}{}$ species were recently concluded to be present in ethene and higher olefins by the application of the infrared method[11] so far as silica-supported nickel was concerned. It is natural to adopt the same line of argument in the present exchange reaction, assuming the following scheme:

$$\underset{(I)}{CH_3\text{–}C_2H_3} \rightarrow \underset{(II)}{CH_3\text{–}\underset{*}{CH}\text{–}\underset{*}{CH_2}} + \underset{*}{D}$$

* Details will be published in the future.

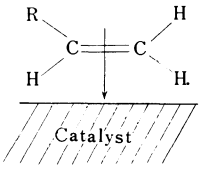
$$\begin{cases} \xrightarrow{\alpha} CH_3CHCH_2D \xrightarrow{-H} CH_3\overset{*}{C}HCHD \\ \xrightarrow[\beta]{} CH_3CHDCH_2 \xrightarrow{-H} CH_3\overset{*}{C}DCH_2 \end{cases}$$

(III)

However, propanes would not be produced due to the low surface concentration of $\overset{*}{D}$ in equilibrium with D_2O. The degree of deuterium substitution at the methin or methen group in propene-d_1 may be determined by the relative rate of steps α and β.

The assumption of the adsorbed state II, according to which the most stable valency angle, θ, of carbons would be near to the tetrahedral valency angle of 109°28', may be allowed for geometrical reasons, as has been shown by Twigg and Rideal.[12] Using recent data,* the angle θ is estimated to be 105° if the distance of closest packing is assumed to be 2.47Å, instead of the lattice constant of nickel. This angle is an allowable magnitude for propene to be chemisorbed. On the other hand, the intermediate II, if produced, may not be so stable in the case of paraxylene because of the break in the resonating benzenoid structure. This is the reason why the exchange rate of the ring hydrogen was so small as not to be measured at 100°C in the presence of nickel, while it could be measured in the presence of platinum the angle θ of which was calculated to be 108°17'.



Besides the above adsorbed state, some other state must be assumed to explain the exchangeability of methyl hydrogen. Considering the magnitude of bond-energy mentioned above, an intermediate with the structure of $\overset{*}{C}H_2$–$CH{=}CH_2$ may be produced easily on nickel. The deuterium exchange would proceed by the interconversion of species IV and V:

$$\underset{*}{CH_2CH{=}CH_2} + \overset{*}{D} \rightleftharpoons DCH_2CH{=}CH_2$$

(IV) (V)

where $\underset{*}{CH_2CH{=}CH_2}$ may be expressed by $\dot{C}H_2$–$CH{=}CH_2$, considering the stability of this allyl radical. However, there remains a possibility that the adsorbed species IV may be formed by the isomerization of II. By this process the exchange may occur.*

It must be added that a π-complex intermediate may be formed as an adsorbed state, VI, of ethane and its derivatives, as has been proposed by Crawford and Kemball in the exchange of xylenes with deuterium[4] as well as in some heterogeneous catalyses generally. However, in order to make the exchange proceed, an assumption that the state III is in equilibrium with the state VI is necessary. For sake of simplicity, the traditional state II, allowable from the energetic viewpoint, was adopted in the above discussion.

(VI)

There remains one point to be discussed, i. e., whether the intermediates II—IV mentioned above are charged or not, through they have been treated as if uncharged. This problem will be discussed in a future report.

Summary

Deuterium exchange between propene and deuterium oxide has been found to occur at room temperature successively on a nickel catalyst, but about six times more easily at the vinyl hydrogen than at the methyl hydrogen at room temperature, although this finding is not concordant with the expectation derived from the scission energy of the bonds concerned and although it is also different from the easier exchangeability of the methyl hydrogen in the similar exchange reaction of paraxylene.

The discrepancy has been explained by assuming the classical chemisorbed species of propene as an intermediate, i. e., a state of propene which forms bonds between nickel atoms and the C=C group, besides the formation of adsorbed allyl type species on nickel.

The authors wish to express their thanks to Mr. Motoyoshi Hatada of the Osaka Laboratories of the Japanese Association for Radiation Research on Polymers for his help in the mass-spectrometric measurement, and also to Drs. B. S. Rabinovitch and G. Zerbi for their information on infrared spectra.

The Mercury-photosensitized Decomposition of Neopentane at High Temperatures

By Shin SATO and Shigeru TSUNASHIMA

(Received November 22, 1963)

The investigation of mercury-photosensitized reactions has been restricted mainly to simple hydrocarbons. Recent developments in gas chromatographic techniques have, however, made the study of the reactions of complex hydrocarbons feasible.

Darwent and Steacie[1] have studied the mercury photosensitization of neopentane and have found that the main products at room temperature were hydrogen and dineopentyl. Methane was a minor product, and its formation was assumed to be due to atomic cracking. One of the characteristic features observed in their study of neopentane was that the quantum yield of hydrogen was extremely low and fairly temperature-dependent, the apparent activation energy being 4.3 kcal. The mercury photosensitization of methane also gives low quantum yields of hydrogen.[2] It is possible that there is some correlation between the low quantum yield of hydrogen and the symmetry of the methane and neopentane molecules. Recently Back and van der Auwera[3] have discussed the various possibilities in an attempt to explain this abnormality.

The mercury-photosensitized decomposition of most alkane molecules proceeds initially by the scission of the C–H bond. The radicals thus produced may combine together or may disproportionate at room temperature, while at high temperatures they decompose to smaller radicals and olefin molecules.[4-6] Neopentyl radicals may be expected to behave similarly, with a rather low activation energy.

Experimental

Neopentane (supplied by Takachiho-Shoji Co.) was purified by bulb-to-bulb distillation, and the middle third was used for the photochemical studies. No impurities were detected by gas chromatographic analysis, indicating that the impurity content is at most below 0.1 %.

The quartz reaction cell (5 cm. wide internally, 8 cm. long) was placed in a furnace, the temperature of which was controlled by a thermister within ± 1°C below 200°C and ± 5°C above 250°C. A spiral mercury resonance lamp (filled with 4 mm. neon) illuminated the reaction cell through a quartz window of the furnace. The reaction cell was connected to the rest of the apparatus through a mercury cut-off.

After each run, the products were transferred to a trap at the liquid nitrogen temperature. The non-condensable gases (hydrogen and methane) were collected by a Toepler pump and the amount measured by a gas buret. The gas was passed over cuprous oxide at 250°C to remove hydrogen, and the amount of gas remaining was measured as methane. The condensable fraction was analyzed by gas chromatography. The column for the analysis of C_3 hydrocarbons and greater was packed with a Celite-dimethylsulpholane mixture (17 m. long) supplied by Shimadzu Co., and the column for the separation of ethane and ethylene was packed with a silica-squalane mixture (1 m. long).

Results and Discussion

The Temperature Dependence of the Photosensitized Reaction.—In Fig. 1 the amounts of analyzed products from the mercury-photosensitized decomposition of neopentane are plotted as a function of the temperature. The initial neopentane pressure is 30 mmHg and the irradiation time is 5 min. in all cases. Below 250°C, the main products were hydrogen, isobutane, neohexane and methane, while propane was a minor product in all runs. The apparent activation energies for the rate of the formation of hydrogen (25°C to 150°C) and of isobutane and neohexane (25°C to 250°C) were calculated as 4.2 kcal. This value agrees with the activation energy of hydrogen formation obtained by Darwent and Steacie.[1]

Above 250°C, the amounts of methane, isobutene, ethane and propylene markedly increase with the increasing temperature. These products may arise from the decomposition of the neopentyl radicals produced initially. The apparent activation energies for the rates of the formation of methane, isobutene and propylene were 9 kcal. The amounts of isobutane and neohexane decreased with the increasing temperature above 250°C, possibly corresponding to the decomposition of neopentyl radicals. The curve for hydrogen is obviously abnormal. This will be discussed later.

Initial Process.—Table I shows the amounts of the main products from the mercury-photosensitized decomposition of neopentane at various initial pressures and at the temperatures of 50, 100 and 150°C. The ratios of the amounts of methane to those of hydrogen are plotted against the initial pressures in Fig. 2.

To explain these results, the following

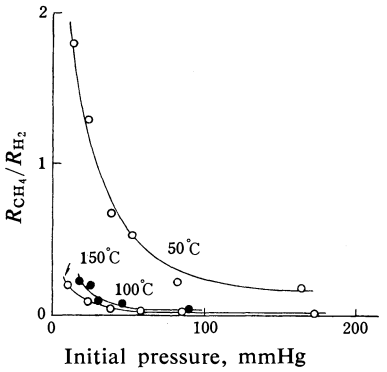

Fig. 2. Pressure dependence of the formations of hydrogen and methane.

mechanism is proposed for the formation of hydrogen and methane:

$$Hg + h\nu \rightarrow Hg^* \ (^3P_1)$$

$$Hg^* \rightarrow Hg + h\nu \quad (1)$$

$$Hg^* + neo\text{-}C_5H_{12} \rightarrow Hg + neo\text{-}C_5H_{12} \quad (2)$$

$$Hg^* + neo\text{-}C_5H_{12} \rightarrow Hg + neo\text{-}C_5H_{11} + H \quad (3)$$

$$H + neo\text{-}C_5H_{12} \rightarrow H_2 + neo\text{-}C_5H_{11} \quad (4)$$

$$H + neo\text{-}C_5H_{11} \rightarrow CH_3 + t\text{-}C_4H_9 \quad (5)$$

$$CH_3 + neo\text{-}C_5H_{12} \rightarrow CH_4 + neo\text{-}C_5H_{11} \quad (6)$$

Here, reaction 2 refers to the physical quenching of the excited mercury atom by the neopentane molecule. This reaction is considered to take part in the mechanism because the quantum yield of hydrogen is known to be extremely low in the mercury-photosensitized reaction of neopentane.[1] Reaction 5 is atomic cracking of neopentyl radicals by hydrogen atoms.[7] The steady-state treatment of

7) E. W. R. Steacie, "Atomic and Free Radical Reaction," Reinhold Publishing Co., New York (1946).

the above mechanism gives the following relation:

$$\frac{I}{R_{non}}=\frac{k_2+k_3}{k_3}\left\{1+\frac{k_1}{(k_2+k_3)\,[C_5H_{12}]}\right\} \qquad (I)$$

where I is the intensity of light, R_{non} is the rate of the formation of non-condensables, and k_1 is the reciprocal of the life-time of the excited mercury atom ($\tau=1.08\times10^{-7}$ sec.). Using the data from Table I, a linear correlation between the reciprocal of the rate of the

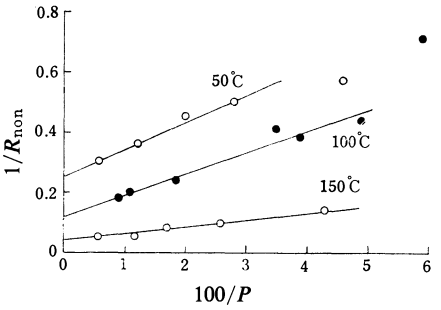

Fig. 3. Reciprocal of the rate of formation of non-condensables as a function of reciprocal of the initial pressure.

formation of non-condensables and the reciprocal of the initial neopentane pressure is obtained (see Fig. 3). The values of k_2+k_3 calculated from the slope and intercept are given in Table II. In Fig. 3, data obtained at low

TABLE II. QUENCHING CROSS SECTIONS OF THE NEOPENTANE MOLECULE

	50°C	100°C	150°C
k_2+k_3 (l. mol^{-1} sec^{-1})	4.3×10^9	4.4×10^9	5.3×10^9
$\sigma_{C_5H_{12}}$ (Å^2)	0.63	0.60	0.68

pressures are scattered, probably due to the importance of the recombination of methyl radicals and wall effects. Therefore, the scattered data have not been used for the calculations of k_2+k_3 in Table II.

The calculated values of k_2+k_3 are almost temperature independent. From these values, the mean quenching cross section of neopentane for excited mercury atoms is calculated as 0.64Å^2, which is smaller than one-half of the value obtained photometrically by Darwent.[8] In the previous section, 4.2 kcal. was obtained for the apparent activation energy of hydrogen formation. This can be explained from Eq. I if $k_2 \gg k_3$ and $E_3 \simeq 4$ kcal. However, the reason for the high activation energy of reaction 3 cannot be explained from the findings of the present work. The same problem has been encountered by Back and van der Auwera for methane.[3]

Atomic Cracking. — Most of the neopentyl radicals produced may combine with each other to give dineopentyl at low temperatures, i. e.,

$$2\ C_5H_{11} \rightarrow C_{10}H_{22} \qquad (7)$$

When neopentane pressure is high, R_4 would be much greater than R_5 and, thus, the steady state treatment would give the following equation:

$$R_{CH_4}{}^2/R_{H_2}{}^3=k_5{}^2/k_4{}^2k_7\,[C_5H_{12}]^2 \qquad (II)$$

where R_{CH_4} and R_{H_2} are the rates of the formation of methane and hydrogen respectively. If it is assumed that reactions 5 and 7 have no or very little activation energy and that reaction 4 has an activation energy of several killocalories,[4] the values of R_{CH_4}/R_{H_2} at high pressures are consistent with Eq. II (see Fig. 2).

Below 150°C, small amounts of propane have always been found by gas chromatography and may arise from the atomic cracking of the tert-butyl radicals produced by reaction 5:

$$H + t\text{-}C_4H_9 \rightarrow CH_3 + C_3H_7 \qquad (8)$$

$$C_3H_7 + C_5H_{12} \rightarrow C_3H_8 + C_5H_{11} \qquad (9)$$

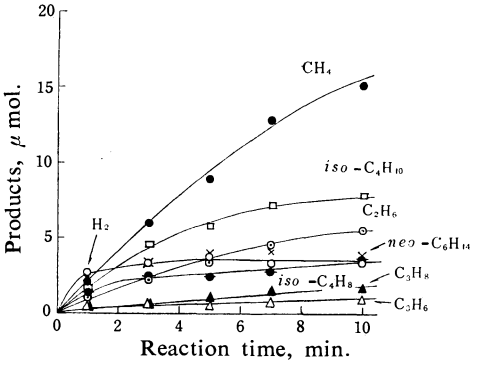

Fig. 4. Time dependence of the photosensitized reaction at 350°C.

The Decomposition of Free Radicals. — As Fig. 1 shows, above 200°C the rates of the formation of methane and isobutene increase with the increasing temperature because of the following reaction occurring at high temperatures:

$$neo\text{-}C_5H_{11} \rightarrow CH_3 + i\text{-}C_4H_8 \qquad (10)$$

The methyl radicals produced in reaction 10 may abstract hydrogen atoms from neopentane molecules and give neopentyl radicals, which may again undergo reaction 10, so that metane and isobutene are produced by a chain mechanism.

Table III and Fig. 4 show the time dependence on the reaction products. The amounts of hydrogen and isobutene are not linear with the irradiation time up to one minute below

* C_2H_6 1.33 μ mol., C_2H_4 0.14 μ mol.
** C_2H_6 2.11 μ mol., C_2H_4 0.21 μ mol.

300°C, while methane increases linearly even at 400°C. This may be explained by the combination of two effects; hydrogen has a much larger quenching cross section for the excited mercury atom than does methane ($\delta_{H_2}=8.60$ Å^2, $\sigma_{CH_4}=0.085$ Å^2)[9], and isobutene is reactive to radicals; for example:

$$H + i\text{-}C_4H_8 \rightarrow t\text{-}C_4H_9 \qquad (11)$$

On the basis of these discussions, the abnormality of the curve for hydrogen in Fig. 1 may be understood. In fact, the initial rates of the formation of hydrogen do not show any abnormality (see Table III). At 500°C, however, the amount of hydrogen increases markedly. A possible explanation is that the scission of the C–H of radicals is occurring at higher temperatures,[4] for example,

$$t\text{-}C_4H_9 \rightarrow i\text{-}C_4H_8 + H \qquad (12)$$

Figure 5 shows the relationship between the logarithm of the initial rates of the formation

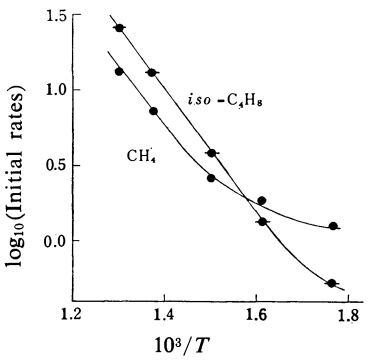

Fig. 5. Logarithm of initial rate of formation as a function of reciprocal of temperature.

9) K. J. Laidler, "The Chemical Kinetics of Excited States," Clarendon Press., London (1955), p. 107.

of methane and isobutene and the reciprocal of the temperature. Values for the logarithm of the initial rate of methane formation are not linear at low temperatures, since small amounts of methane produced by atomic cracking. At high temperatures, the amout of methane is a little less than that of isobutene, probably because methane is not an only product from the methyl radical.

These results may reasonably be explained by the following mechanism:

$$H + C_5H_{12} \rightarrow H_2 + C_5H_{11} \qquad (4)$$

$$C_5H_{11} \rightarrow CH_3 + i\text{-}C_4H_8 \qquad (10)$$

$$CH_3 + C_5H_{12} \rightarrow CH_4 + C_5H_{11} \qquad (6)$$

$$C_5H_{11} + C_5H_{11} \rightarrow C_{10}H_{22} \qquad (7)$$

$$CH_3 + C_5H_{11} \rightarrow C_6H_{14} \qquad (13)$$

$$CH_3 + CH_3 \rightarrow C_2H_6 \qquad (14)$$

When the temperature is not too high, it may be assumed that $R_7 \gg R_{13}$, because the concetration of the methyl radical is much lower than that of the neopentyl radical. Therefore the steady-state treatment gives the following relation:

$$R_{CH_4}/\sqrt{R_{H_2}} \simeq R_{C_4H_8}/\sqrt{R_{H_2}} = k_{10}/\sqrt{k_7} \qquad (III)$$

$R_{C_4H_8}$ and R_{H_2} are calculated from Table III using the data at short irradiation times. Figure 6 shows the straight relationship between the logarithm of $R_{C_4H_8}/\sqrt{R_{H_2}}$ and the reciprocal of the temperature. From the slope of this line,

$$E_{10} - 1/2E_7 = 15.0 \text{ kcal.}$$

Since the activation energy of reaction 7 can be assumed to be about zero to 4 kcal., 17 $\pm$2 kcal. is obtained for the activation energy of reaction 10. This value is reasonable when compared to the activation energy of hydrocarbon radical decomposition.[4]

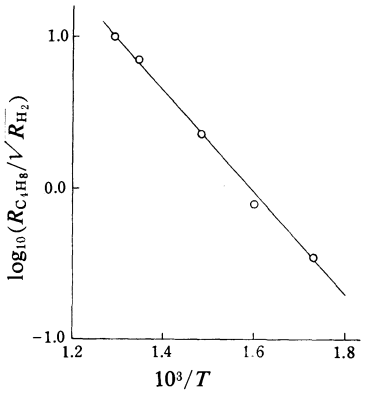

Fig. 6. Activation energy of decomposition of neopentyl radical.

The propylene observed at higher temperatures may be due to the decomposition of the butyl radical, as follows:

$$t\text{-}C_4H_9 \rightarrow i\text{-}C_4H_9 \rightarrow CH_3 + C_3H_6 \qquad (15)$$

However, no quantitative treatment has been attempted, because the amount of propylene produced is small and many speculations have to be made for the isomerization of radicals, although much information has recently been accumulated.[10]

10) J. R. McNesby and W. M. Jackson, *J. Chem. Phys.*, **38**, 692 (1963).

Summary

The mercury-photosensitized decomposition of neopentane has been investigated over the temperature range 25°C to 500°C. If the quenching of excited mercury atoms by neopentane molecules is assumed to occur both physically and chemically, as follows:

$$Hg^{*+}(^3P_1) + neo\text{-}C_5H_{12} \begin{cases} \rightarrow Hg + neo\text{-}C_5H_{12} & (2) \\ \rightarrow Hg + C_5H_{11} + H & (3) \end{cases}$$

it has been shown that $k_2 \gg k_3$ and that the quenching cross section of reaction is about 0.6 Å^2, which is almost temperature independent, and $E_3 \simeq 4$ kcal. Above 250°C, neopentyl radicals decompose to methyl radicals and isobutene molecules with an activation energy of 17 ± 2 kcal.

The authors wish to express their deep thanks to Professor Shoji Shida for his continued encouragement of this work. They are also indebted to Dr. John M. S. Jarvie, Gulf Research & Development Co., Pittsburgh, U.S.A., for his kind advice regarding this manuscript.

A Convenient Method for the Monobromination of Active Methylene Compounds

By Tsujiaki HATA

(Received November 26, 1963)

A general procedure for the conversion of active methylene compounds to the corresponding monobromoderivatives consists in treating the active methylene compounds with bromine. Numerous examples, however, show that a mixture of dibromo- and monobromo-derivatives is yielded even by the equimolar reaction of the active methylene compounds and bromine.

Although dibromocyanoacetamide was prepared by Hesse[1] as early as 1896, the monobromoderivative was not prepared until 1922 by Gupta and Thorpe.[2] They prepared monobromocyanoacetamide in a 55% yield by the partial debromination of dibromocyanoacetamide with dimethylaniline. Later, Wideqvist[3] reported that monobromocyanoacetamide was obtained in a high yield when an equimolar amount of cyanoacetamide and dibromocyanoacetamide was heated in an aqueous solution. In a previous paper,[4] it was shown that

1) B. C. Hesse, *Am. Chem. J.*, **18**, 723 (1896).

2) B. M. Gupta and J. F. Thorpe, *J. Chem. Soc.*, **121**, 1896 (1922).

3) S. Wideqvist, *Acta. Chem. Scand.*, **7**, 696 (1953).

4) T. Hata and T. Mukaiyama, This Bulletin, **35**, 1108 (1962).

monobromocyanoacetamide was also obtained in a high yield by the reaction of cyanoacetamide and dibromocyanoacetamide in 95% ethanol.

In the present experiment, the proportionation procedure was extended to the preparation of *N*-ethyl monobromocyanoacetamide and *N*-cyclohexyl monobromocyanoacetamide, which were obtained in 84% and 90% yields respectively, according to the following equation:

$$NCCH_2CONHR + NCCBr_2CONHR \rightarrow 2\ NCCHBrCONHR$$

R: C_2H_5 or C_6H_{11}

Similarly, monobromomalonitrile was obtained in a 60% yield by the proportionation reaction of malonitrile and dibromomalonitrile in the presence of a catalytic amount of boron trifluoride.

$$CH_2(CN)_2 + CBr_2(CN)_2 \xrightarrow{BF_3} 2\ CHBr(CN)_2$$

Next, the monobromination of various active methylene compounds by the use of dibromomalonitrile was tried, since it was found that the bromine atoms of dibromomalonitrile are much more active than those of the other dibromoamides.

When two moles of malonamide were treated with one mole of dibromomalonitrile, monobromomalonamide was obtained in a 75% yield, along with malonitrile, as is shown in the following equation:

$$2\ CH_2(CONH_2)_2 + CBr_2(CN)_2 \rightarrow 2\ CHBr(CONH_2)_2 + CH_2(CN)_2$$

Similarly, monobromocyanoacetamide, *N*-cyclohexyl monobromocyanoacetamide, ethyl bromocyanoacetate and ethyl bromomalonate were obtained in high yields by the reaction of dibromomalonitrile with two moles of the corresponding active methylene compounds (see Table I).

On the other hand, it has been reported[5] that the bromination of malonanilide with bromine gives a mixture of several brominated products because the anilide has six replaceable hydrogen atoms in the para- and ortho-positions in each phenyl group, and two hydrogen atoms in the malonyl group.

It was established by the present experiment that the bromination of malonanilide by means of dibromomalonitrile resulted in the exclusive formation of α-monobromomalonanilide in a 85% yield.

$$2\ CH_2(CONHC_6H_5)_2 + CBr_2(CN)_2 \rightarrow 2\ CHBr(CONHC_6H_5)_2 + CH_2(CN)_2$$

5) J. V. Backes, R. W. West and M. A. Whiteley, *J. Chem. Soc.*, **119**, 362 (1921).

Certain mono-bromoderivatives of anilides and *N*-benzylamides were prepared by this method from the corresponding amides (see Table II).

It can be said that the method of monobromination by means of dibromomalonitrile proved remarkably effective for the synthesis of α-monobromo-derivatives of active methylene compounds containing a phenyl group.

Experimental

Reagents.—Cyanoacetamide,[6] dibromocyanoacetamide,[7] malonitrile,[8] dibromomalonitrile,[9] malonamide,[10] malonanilide,[11] cyanoacetanilide,[12] *N*-benzyl cyanoacetamide,[12] acetacetanilide[13] and *N*-benzyl acetacetamide[14] were prepared by the literature procedures.

Ethyl malonate and ethyl cyanoacetate were obtained from a commercial source and were purified by distillation.

***N*-Ethyl Monobromocyanoacetamide and *N*-Cyclohexyl Monobromocyanoacetamide.**—A solution of *N*-ethyl cyanoacetamide (1.12 g., 0.01 mol.) and *N*-ethyl dibromocyanoacetamide (2.70 g., 0.01 mol.) in 100 ml. of 95% ethanol was refluxed for 2 hr. After the ethanol had been removed, a large amount of a white solid was separated, washed with benzene, and recrystallized from 50% ethanol. *N*-Ethyl monobromocyanoacetamide (3.21 g., 84%, m. p. 79~81°C) was obtained.

In a similar fashion, *N*-cyclohexyl monobromocyanoacetamide (90%, m. p. 138~141°C) was obtained.

Monobromomalonitrile.—A solution of 0.01 mol. of malonitrile and 0.01 mol. of dibromomalonitrile in 70 ml. of 95% ethanol was refluxed for 15 min. in the presence of a catalytic amount of boron trifluoride. After the ethanol had been removed under reduced pressure, the brownish-yellow residue was distilled in vacuo to give 1.74 g. (a 60% yield) of the yellow liquid (b. p. 90°C/16 mmHg), which solidified at room temperature and melted at 63~64°C.

General Procedure of the Monobromination by Means of Dibromomalonitrile.—A solution of 0.02 mol. of an active methylene compound and 0.01 mol. of dibromomalonitrile in 70 ml. of 95% ethanol was refluxed for 15 min. in the presence of a catalytic amount of boron trifluoride. After the ethanol had been removed under reduced pressure, the precipitates were filtered and washed with ether and recrystallized from 95% ethanol. The yields and the physical constants are listed in Table I.

In a similar fashion, mono-bromoderivatives of anilides and *N*-benzyl amides were prepared. The yields and the physical constants are listed in Table II.

Summary

The monobromination of the active methylene compounds by means of the proportionation procedure between the active methylene compound and its dibromo-derivative has been investigated.

Next, the monobromination of various active methylene compounds by the use of dibromomalonitrile has been tried. The method proved remarkably effective for the synthesis of α-mono-bromoderivatives of active methylene compounds containing a phenyl group.

The author wishes to express his hearty thanks to Professor Dr. Teruaki Mukaiyama for his encouragement and for his kind advice, to Mr. Koa Tasaka for his help during the course of this experiment, and to Miss Toshiko Aoyagi for the microanalysis.

The Absorption Spectra of Chromium(II) Acetate and Copper(II) Acetate

By Sigeo KIDA, Yoshiaki NAKASHIMA, Yukiyoshi MORIMOTO, Kiyoshi NIIMI and Shoichiro YAMADA

(Received December 3, 1963)

Copper(II) acetate and chromium(II) acetate have the same binuclear structure, as Fig. 1 shows.[1,2] The two compounds show a magnetic susceptibilities much lower than those of usual monomeric copper(II) and chromium-(II) complexes (1.39 B. M.[3] for copper(II) acetate and nearly zero for chromium(II) acetate[4] at room temperature). Some direct interaction, therefore, has been assumed between two metal ions at a distance of 2.64 Å.

Yamada et al.[5] have reported the electronic spectra of copper(II) acetate and other cupric alkanoates[6] in solution and in the crystalline state; they have pointed out that the band observed at 27.3 kK. is characteristic of the binuclear structure.

◎ H_2O

The spectrum of chromium(II) acetate in the visible region has been measured by Furlani,[7] but he has not reported the spectrum of the shorter wavelength region, where one may expect a band corresponding to the band observed at 27.3 kK. in copper(II) acetate.

In this investigation the absorption measurements have been carried out on chromium(II) acetate in solution and in Nujol mull from the visible to the near-ultraviolet region, and the dichroism of the single crystal has been determined.

Experimental

Chromium(II) acetate hydrate, $Cr_2(C_2H_3O_2)_4 \cdot 2H_2O$, was prepared by the method described in "Inorganic Syntheses."[8] The material was dissolved in 99% ethanol or water which had been distilled in a nitrogen atmosphere, and it was used for absorption measurements. The absorption measurements were carried out with a Shimadzu spectrophotometer model QR-50 using 1 cm. quartz cells. All these procedures were carried out in a nitrogen atmosphere using the apparatus devised for this purpose; the apparatus is shown in Fig. 2. The concentrations of the solutions used for the measurements were determined by the spectrophotometric analysis of chromium[9] after converting it into chromate ions.

Chromium(II) acetate anhydrate, $Cr_2(C_2H_3O_2)_4$, was prepared from the hydrate, $Cr_2(C_2H_3O_2)_4 \cdot 2H_2O$, by keeping it at 78°C in vaccuo for 8 hr. in an Abderhalden desiccator. The chromium(II) acetate anhydrate thus obtained showed dark orange color in the powder state. The Nujol mulls of these compounds were prepared in a box filled with nitrogen gas; they were used for the absorption measurements.

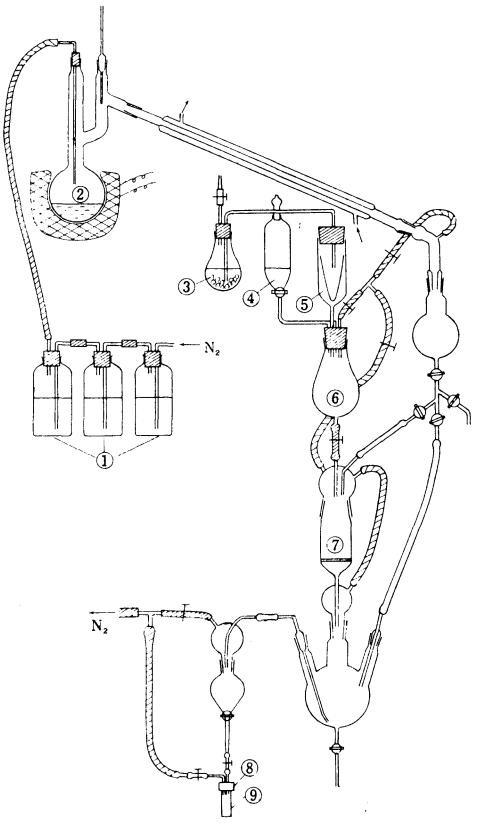

Fig. 2

Quantitative dichroism measurement was made at room temperature by the microscopic method.[10] The measurement was carried out on the (110) face, using the light polarized along the c-axis and the light polarized perpendicular to it. On the basis of crystal structure analysis, the ratio of K_z to K_{xy} is calculated to be about 1/4.5 for the first band and 4 for the second band, where K represents the molar absorption coefficient, and z refers to the Cr-Cr direction in the molecule.

Results and Discussion

The results of the absorption measurements are shown in Figs. 3 and 4 and in Table I. The alcoholic solution shows the same red color as the crystal and obeys Beer's law. On the other hand, the aqueous solution does not obey Beer's law, and the absorption intensity is much lower than that of the alcoholic solution relative to its chromium concentration. This fact implies that the compound considerably hydrolyzes in an aqueous solution.

7) C. Furlani, *Gazz. Chim. Ital.*, **87**, 876 (1957).

However, since the peaks in the two absorption curves are nearly identical, it is obvious that the binuclear molecules still exist in considerable concentration in an aqueous solution. This fact contrasts with the fact that the concentration of the binuclear molecule was observed to be much less in an aqueous solution of copper(II) acetate. The absorption in the visible region agrees with Furlani's result.[7] In addition to this absorption ($\nu_{max}=20.58$ kK., $\log\varepsilon=1.80$), another absorption ($\nu_{max}=30.77$ kK., $\log\varepsilon=2.22$ with a shoulder at 29 kK.) was newly observed in this experiment. This absorption, which is tentatively named the "second band," seems to correspond with the "second band" observed at 27.3 kK. in copper(II) acetate. The dichroism of chromium(II) acetate is similar to that of copper(II) acetate,[5] as may be seen in Fig. 4. Thus, the first absorption is more intense in x and y than in z polarization, and vice versa in the case of the second absorption.

From the frequency and the intensity, the first band of chromium(II) acetate and copper(II) acetate in the visible region can undoubtedly be attributed to the d-d transitions. For the second band of copper(II) acetate, Ross[11] has suggested the possibility of a triplet-triplet transition. However, there is no such possibility in the case of chromium(II) acetate, since it is diamagnetic at room temperature. Forster and Ballhausen[12] attributed both the first and the second band to the d-d transitions on the basis of a molecular orbital scheme. However, the molecular orbital method may not give a good approximation in this case, as will be discussed below, and their conclusions were only tentative. Therefor, the origin of the two bands of both compounds will be the subject of the following discussion.

For this type of compounds, the d-d transitions may be devided into two origins; 1) interatomic transitions such as transitions from a bonding to an anti-bonding orbital, or charge transfers from one ion to another, and 2) transitions in a single ion, which correspond to the origin of a usual ligand field band.

Interatomic d-d Transitions.—Since the interatomic distance between two metal ions is relatively large, the interaction should be weak; Forster and Ballhausen[12] estimated the overlap integrals of Cu–Cu interaction to be $S(d_{z^2}, d_{z^2})=0.019$, $S(d_{x^2-y^2}, d_{x^2-y^2})=0.002$ and $S(d_{xz}, d_{yz})=0.012$, which are of the magnitude of about $10^{-1}\sim10^{-2}$ of the usual C–C bond. Therefore, the bonding system between two metal ions is best approximated by the valence bond method rather than by the molecular orbital method.*,[13]

According to the valence bond theory, the wave functions of the valence orbitals in a diatomic unit are expressed as;

$$\Psi=(1-\lambda^2)^{-1/2}[2^{-1/2}\{a(1)b(2)+b(1)a(2)\}+2^{-1/2}\lambda\{a(1)a(2)+b(1)b(2)\}] \quad (1)$$

11) I. G. Ross, *Trans. Faraday Soc.*, **55**, 1057 (1959).
12) L. S. Forster and C. J. Ballhausen, *Acta. Chem. Scand.*, **16**, 1385 (1962).
13) C. A. Coulson, "Valence," Oxford Univ. Press., London (1953), pp. 147—148.
* Discussion was also made of copper(II) acetate on the basis of a similar concept. Cf. M. L. Tonnet, S. Yamada and I. G. Ross, to be published shortly.

for the ground state, where a and b denote atomic wave functions of the different atoms respectively, and λ is a constant which determines the contribution of the ionic term.

In the case of a large interatomic distance, we may neglect the ionic term.

$$\Psi = 2^{-1/2}\{a(1)b(2)+b(1)a(2)\} \quad (2)$$

Similarly, the next higher singlet state may be expressed as:

$$\Psi' = 2^{-1/2}\{a(1)b(2)-b(1)b(2)\}$$

or

$$2^{-1/2}\{a(1)a(2)+b(1)b(2)\} \quad (3)$$

The electronic repulsion energies of the two states are calculated from (2) and (3):

$$E(\Psi) = J(ab)+K(ab)$$

$$E(\Psi') = J(aa)-K(ab) \quad \text{or} \quad J(aa)+K(ab)$$

Since we are dealing with the system of large interatomic distance, $J(ab)$ and $K(ab)$ should be much smaller than $J(aa)$.

$$E(\Psi')-E(\Psi) \fallingdotseq J(aa)$$

This result indicates that the energy of the first spin-allowed transition from the ground state is of the magnitude of $J(aa)$,* which must be larger than 100 kK., as may be roughly estimated from the ionization potentials of the chromium ion.[14]

For the other type of transitions, such as charge transfer from one ion to another, we also have to assign a very high energy to this system, since any charge transfer transition in this system will give rise to a great increase in inter-electronic repulsions, in addition to the energy of the charge separation.

Therefore, the present observed bands are not due to the interatomic d-d transitions.

d-d Transitions in a Single Ion.—To judge from the absorption intensities, the bands under discussion are undoubtedly due to spin-allowed transitions. Therefore, we consider spin-allowed transitions only in this discussion, and, accordingly, the d^4 and the d^9 system can be treated like a d^1 system. In an octahedral field five degenerate d-orbitals are split into triply-degenerate $d\varepsilon$ and doubly-degenerate $d\gamma$ orbitals. In this case only one transition is possible for a d^1-system. As the symmetry goes down from O_h to D_{4h} or C_{4v}, the $d\varepsilon$ and the $d\gamma$ orbital are split, as is shown in Fig. 5: if the tetragonal distortion is considerably large, one can observe two or more separate

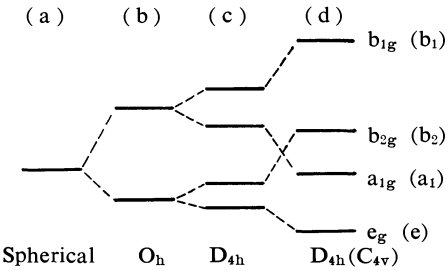

Fig. 5. Energy levels of the d-orbitals.
(c) Weak tetragonal distortion
(d) Strong tetragonal distortion

peaks. However, only one broad band was observed in this region in usual copper(II) and chromium(II) (high spin type) complexes, though these complexes are more or less tetragonally distorted by the Jahn-Teller effect.[15] This fact implies that the tetragonal distortions of these complexes are not large enough to separate the absorption into two distinct peaks. Even if one would assume the larger tetragonal distortion in chromium(II) acetate and copper(II) acetate, the observed value, 8~10 kK., seems to be too large for the splitting due to the tetragonal distortion.

As Table I shows, the first band of chromium(II) acetate anhydrate shows a remarkable blue shift relative to that of the hydrate. On the other hand, very little blue shift was observed in the second band. This implies that the second band is not as sensitive to the change in the tetragonality of the ligand field as the first band is. Therefore, the second band is not likely to be one of the ligand field bands, since if the band were split and shifted by the effect of the tetragonal distortion, it would show a considerable shift upon the change in the tetragonality.

The result of the dichroism measurements also support the above conclusion. If both the observed bands in the visible and near-ultraviolet region were due to the d-d transitions, the most probable assignment should be b_1-a_1 and b_1-e transitions for the first and the second band respectively, as may be seen in Fig. 5. Since the electric vectors transform like E(x, y) and $A_1(z)$ in the symmetry of C_{4v}, the second band, which has been attributed to the b_1-e transition, would be more intense in x and y than in z polarization. However, the experiments show that the second absorption is z-polarized in both compounds, as is shown in Fig. 4 and Ref. 5. Therefore, it is reasonable to assign the b_1-e transition to

* In this system the differences in the nuclear attractions and kinetic energies of the two states are negligibly small relative to $J(aa)$. The Coulomb integral, $J(aa)$, corresponds to the difference between the first and the second ionization energy of the ion.

14) "Atomic Energy Levels," Natl. Bur. Standards, Circ. 467, Vol. 2 (1952), p. 14.

15) T. M. Dunn, "The Visible and Ultra-violet Spectra of Complex Compounds," in J. Lewis and R. G. Wilkins, ed., "Modern Coordination Chemistry," Interscience Pub. Inc., New York (1960), pp. 253—261 and references therein.

the first absorption (x, y-polarized) rather than to the second. On this assumption, one can elucidate the fact that the first absorption band of chromium(II) acetate and copper(II) acetate are considerably more intense than the ligand field bands of usual monomeric chromium(II) (high spin type) and copper(II) complexes. Since the b_1-e transition is allowed in the x, y-plane in C_{4v} symmetry, whereas all the d-d transitions in D_{4h} symmetry are forbidden, one can expect a higher absorption in the former case than in the latter. The above discussion may be regarded as essentially correct, even though in these compounds the deviation from D_{4h} is not very large and the vibronic origin is not negligible.

For the origin of the second band, no definite conclusion can be drawn at present. However, since the second band is characteristic of this type of binuclear configuration, some orbitals, which are characteristic of this configuration, must be responsible for the origin of this band. For instance, the ligand and the metal atoms constitute planar 8-membered rings in this molecule, and some electronic transitions among the molecular orbitals of π-orbital systems on these rings may possibly be one of the origin of the second band. In this connection, however, it seems worth mentioning that cupric formate tetrahydrate and cupric benzoate trihydrate, which contain infinite chains, each consisting of alternate cupric ions and formate[6] or benzoate ions[16], show no absorption band corresponding to band II.

Summary

The electronic absorption spectra of chromium(II) acetate have been determined in ethanol and Nujol mull in the region between 10 and 40 kK. Dichroism in that region has also been determined with a single crystal of the compound. A new absorption band, which has not previously been observed, has been found at about 30.77 kK. ($\log \varepsilon$ 2.22), in addition to a band at about 20.58 kK.

The origins of these bands have been discussed in relation to the absorption bands of copper(II) acetate.

Studies of the Metal Ketyls of Phenanthraquinone and Its Derivatives

By Kazuhiro MARUYAMA*1

(Received October 7, 1963)

The electron-spin resonance (ESR) spectra of the potassium ketyl of phenanthraquinone and of the zinc ketyl of phenanthraquinone have been studied by Kazakoba et al.[1] and Adams et al.[2] respectively. They obtained rather broad ESR signals. Recently a more precise study of the ketyl, produced electrolytically in an *N*, *N*-dimethylformamide solution with tetra-*n*-butylammonium perchlorate as a supporting electrolyte, has been reported by Dehl and Fraenkel.[3] The present author has been interested in how the free spin distribution varies with the introduction of a substituent into the aromatic nucleus. It is well known that the introduction of a substituent such as a chlorine atom and a nitro group into the aromatic nucleus of triphenylmethyl does not change its free spin distribution essentially.[4] However, the electron-spin resonance spectra of monosubstituted benzene mononegative anions are very sensitive to the nature of the substituent; small changes in the substituent can lead to drastic changes in the appearance of the spectrum.[5] Therefore,

lithium-, sodium-, potassium-, cesium-, magnesium-, calcium and barium-ketyl of phenanthraquinone and the potassium-ketyls of 2-nitro-, 2, 7-dinitro-, 2, 7-dibromo- and 2, 7-diamino-phenanthraquinone are examined in the present study. Furthermore, the influence of metal species as a reducing agent upon the splitting constant and dimerization reaction of these ketyls is examined for the metal ketyls of phenanthraquinone in tetrahydrofuran.

Results and Discussion

2-Nitrophenanthraquinone. — Commercial phenanthraquinone was treated with nitric acid (sp. gr. 1.4). The crude crystals were recrystallized from acetic acid; m. p. 257°C.

2,7-Dinitrophenanthraquinone. — Commercial phenanthraquinone was treated with a mixture of nitric acid (sp. gr. 1.5) and conc. sulfuric acid. The crude crystal was recrystallized from acetic acid; m. p. 302~303°C.

2,7-Dibromophenanthraquinone. — Commercial phenanthraquinone was treated with bromine in a sealed tube at 160°C. The crude crystal mass was recrystallized from acetic acid several times; m. p. 323°C.

2,7-Diaminophenanthraquinone. — 2,7-Dinitrophenanthraquinone was reduced by tin and hydrochloric acid. Recrystallization was performed from alcohol. The crystals were deep violet needles and did not melt even above 300°C.

Measurement. — *Metal Ketyl of Phenanthraquinone.*—The electron-spin resonance measurement was performed by using a spectrometer with an X-band, and 100 kc. modulation. The low temperature runs were made by allowing cool nitrogen gas evaporated from liquid nitrogen to flow through.

The electron-spin resonance spectra of metal ketyls of phenanthraquinone produced by reduction with different metals are shown in Fig. 1. It is well known that mononegative anions produced by reduction with an alkali or an alkali earth metal form ion pairs.[6,7] Therefore, the observed additional hyperfine structure from the metal cation attached to the radical may be taken to indicate the ion pair formation. The term "ion pair" is used to represent the associated counter ions which weakly perturb each other. As the metal ketyls form ion pairs in a usual solvent, such as tetrahydrofuran and dimethoxyethane, the details of each spectra are different because of the different nuclear-spin quantum numbers of the metals used as reducing agents. However, the largest splitting consists of the five lines (intensity ratio; 1 : 4 : 6 : 4 : 1) due to four equivalent hydrogen atoms on the phenanthraquinone ring. On the other hand, it has been reported that benzophenone and other ketyls do not show any metal splittings in liquid ammonia;[8] these ketyls do not form ion pairs in liquid ammonia but exist as completely dissociated mononegative anions. A mononegative anion in this state is designated by the term "free ion radical" in this article. From the examination of the spectrum of the free ion radical produced by the reduction of phenanthraquinone by potassium metal in liquid ammonia, it was found that the spectrum can be analysed into the following splitting pattern (Fig. 1-1, Table I).

Although the ESR spectra of metal ketyls of phenanthraquinone are more complicated than that of a free ion radical as the result of ion pair formation, their ESR spectra can be analyzed by means of a comparison of the spectrum with that of a free ion radical. Thus, the splitting constants of the first splitting due to the four equivalent hydrogen atoms of metal ketyls, which were in the ion-pair state in tetrahydrofuran, could be determined. These results are shown in Table II. It is interesting that the value of the splitting constant of the first splitting due to the four equivalent hydrogen atoms is affected by the species of metal. The cause of these changes in the splitting constants with the difference of metal is not clear. The same phenomena are found also in the case of the anion radical of nitrobenzophenone and others.[10]

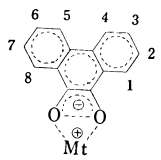
TABLE II. VARIATION OF SPLITTING CONSTANT BY CHANGING THE METAL IN THF

Metal	Overall width of spectrum (gauss)	Color of soln.	Splitting const. of the four equiv. hydrogen atoms (gauss)
Li	10.8	green*2	2.2
Na	9.4	green-red*2	1.7
K	8.0	red	1.5
Cs	9.8	red	—
Mg	9.6	green	1.7
Ca	9.6	green	1.7
Sr	9.1	green	1.6
Ba	9.5	green	1.6



THF: tetrahydrofuran

The ESR spectra of metal ketyls of phenanthraquinone have a narrower overall width (the largest splitting constant due to the four equivalent hydrogen atoms is 1.56 gauss) than the metal ketyl of benzophenone (the largest splitting constant due to para hydrogen atoms is 3.4 gauss.[8]) This means that most of the free spin is accummulated around two carbonyl groups.

The structure of ketyl of phenanthraquinone may be represented by the next resonance formula (structure I), or it may be expressed more conveniently by structure II. The results shown in Table I can be satisfactorily explained by considering the structure proposed and the results of calculations.[3,9] That

Structure I Mt: metal

Structure II Mt: metal

is, H_1, H_3, H_6 and H_8 are responsible for the first splitting, and H_4 and H_5 are responsible for the second splitting for a reason which will be described later; therefore, H_2 and H_7 are responsible for the third splitting.

The Metal Ketyl of Phenanthraquinone Derivatives. — The spectra obtained are shown in Fig. 2. From a comparision of the spectra of 2,7-dibromophenanthraquinone potassium ketyl (Fig. 2-3) and of the free ion radical phenanthraquinone (Fig. 1-1), it can be concluded that the second splitting is caused by the two equivalent hydrogen atoms H_4 and H_5, because

*2 The red substance is paramagnetic. The green substance is diamagnetic and this becomes a red substance in an extremely dilute state. The red substance becomes yellow if it is in contact with a metallic surface; furthermore, this yellow substance is diamagnetic, This yellow substance becomes a red paramagnetic solution when it is mixed with a solution in which unreduced phenanthraquinone remains. Therefore, the yellow substance is a dinegative anion.

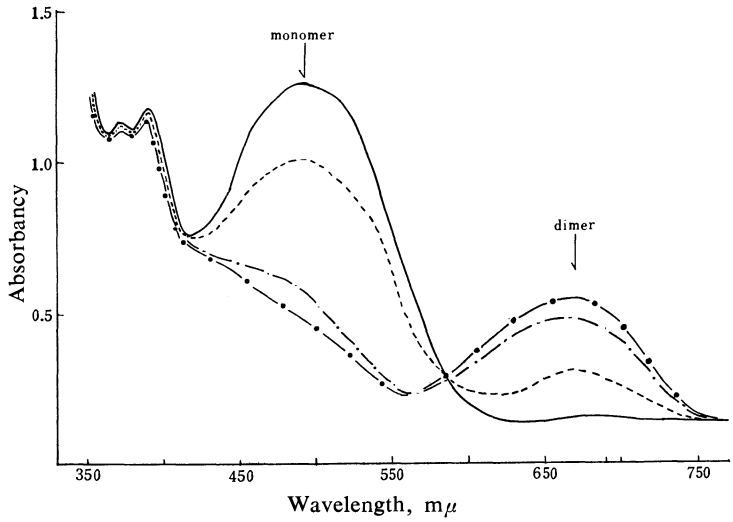

Fig. 3. Absorption spectra of Na-ketyl of phenanthraquinone at different temperatures.
——— 23°C ------ −30°C —·—· −70°C —•—• −85°C

the bromine atom, in general, does not show ESR splitting. This experimental result coincides with calculations based on the molecular orbital theory.[3,9],*3 With regard to the effect of the introduction of substituents into the aromatic nucleus upon free spin distribution, it seems reasonable to deduce that the introduction of bromine and amino groups does not change the intensity ratio (1 : 4 : 6 : 4 : 1) of the five line groups due to the four equivalent hydrogen atoms, but that the introduction of a nitro group does change the appearance of the spectrum. That is, i) in the K-ketyl of 2-nitrophenanthraquinone, the number of apparent line groups in the spectrum is seven and the intensity ratio is nearly 1 : 3 : 3 : 6 : 3 : 3 : 1, and ii) in the K-ketyl of 2, 7-dinitrophenanthraquinone, the number of the apparent line groups is seven and the intensity ratio is nearly 1 : 2.5 : 3.5 : 6 : 3.5 : 2.5 : 1. However, the obtained spectra were too broad to obtain a quantitative estimation of the effect.

Equilibrium between Paramagnetic Monomers and Diamagnetic Dimers. — The existence of an equilibrium between the metal ketyl monomer and the dimer was examined by means of a study of absorption spectra in the visible region and by an absolute free spin determination by an overmodulated ESR technique.[11] The results of the examination of the absorption of metal ketyls of phenanthraquinone in the visible region at different temperatures and with different reducing alkali metals are shown in Table III and Fig. 3.

Table III. Absorption spectra of metal ketyls of phenanthraquinone at different temperatures

Metal	Temp. °C	Paramagnetic monomer mμ	Diamagnetic dimer mμ
Li	23	484 v.s.	646 w.
	−50	484 w.	646 s.
	−70	—	646 v.s.
Na	23	494 v.s.	670 v.w.

	−85	507 v.w.	641 v.s.
Mg	23	508 w.	646 w.
	−80	—	646 s.
Ca	23	—	670 v.s.
	−80	—	670 v.s.
Sr	23	—	670 v.s.
Ba	23	—	687 v.s.

Solvent : THF

v.w. : very weak
v.s. : very strong
w. : weak
s. : strong

It is interresting to note that the diamagnetic dimer shows an absorption band at longer wavelength region than does the paramagnetic monomer.

*3 The splitting constant changes with the solvent and with the metal species used as a reducing agent. This coincidence with the results of molecular orbital calculations is, therefore, only a rough estimate.

11) a) K. Halbach, *Phys. Rev.*, **119**, 1230 (1960); b) J. E. Hyde and H. W. Brown, *J. Chem. Phys.*, **37**, 368 (1962).

On the other hand, the decrease of paramagnetic species with a decrease in temperature, was examined with the aid of an overmodulated ESR technique. This results are shown in Fig. 4. This process was found to be completely reversible by a temperature change. The tendency to dimerization is especially strong when a divalent metal such as magnesium, calcium, strontium or barium was used as the reducing agent. Almost all the metal ketyls produced from these reducing agents (in tetrahydrofuran and dimethoxyethane) dimerize in an equilibrium state at room temperature (color: green) except when they were extremely dilute (color: red). Even if the metal ketyl solutions were made by the reduction of phenanthraquinone with lithium, sodium and potassium, they became green when at a high concentration. Only the metal ketyl solution produced by reduction with cesium was strongly red even if it was at a high concentration at room temperature. These results accord with absorption spectrum examinations and with ESR measurements.

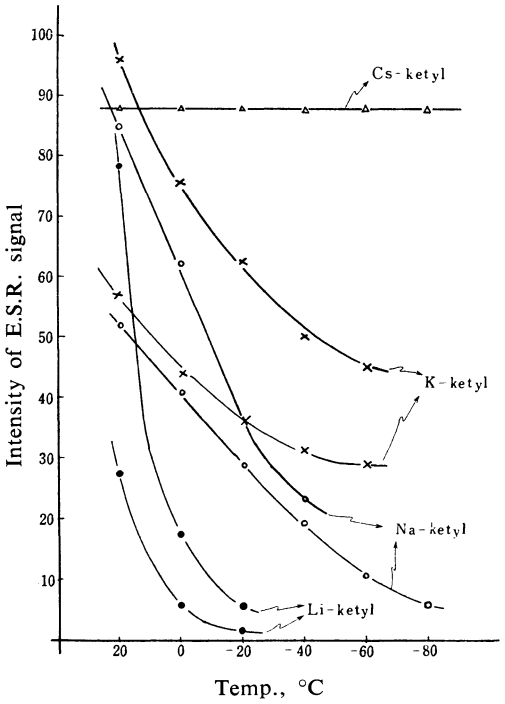

Fig. 4. Change of paramagnetic species with temperature.

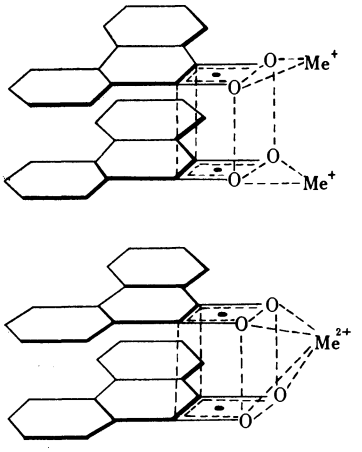
To summarize the facts mentioned above:



i) The dimer shows absorption at a longer wavelength region (~650 mμ) than the paramagnetic monomer (~500 mμ);

ii) The dimerization reaction is completely reversible with temperature and with concentration, and the dimer is diamagnetic;

iii) The tendency to form dimers is more remarkable in the metal ketyls produced by reduction with metals of smaller atomic size than in the metal ketyls produced by reduction with monovalent metals of larger atomic size. The metal ketyl produced by reduction with cesium metal does not appreciably dimerize even at −80°C.

iv) Metal ketyls produced by reduction with divalent metals show a strong tendency to dimerize.

Considering these results, the following structure, III, seems to be the most favorable for the diamagnetic dimer:

Structure III

*The Ultrasonic Velocity and Absorption of Aqueous Solutions of Polyvinyl Alcohol**

By Kiyoshi ARAKAWA, Nobuo TAKENAKA, Mineo WATASE and Kazunari KUBOTA**

(Received December 4, 1963)

A number of rheological studies of polymer solutions have been made by various authors. However, for the aqueous solution of polyvinyl alcohol we do not have much information concerning the rheological properties of the solution except for those obtained by the method of stationary flow viscosity. At audio frequencies an extensive study of the dynamic mechanical properties of the solution has been made recently by Onogi and his co-workers.[1] At ultrasonic frequencies several studies by means of ultrasonic interferometers have been made,[2] but with limited success.

Recently, an ultrasonic pulse technique has been developed as the most convenient and standard means for the study of the rheological properties of liquids and solutions at ultrasonic frequencies.[3] In the present experiment we measure the velocity and absorption of the longitudinal sound wave which propagate through an aqueous solution of polyvinyl alcohol.

The oscillational displacement, ξ, at a distance, x, from a source of a sound wave is:

$$\xi=\xi_0 \exp(-\alpha x) \exp\{i\omega(t-x/c)\} \qquad (1)$$

where c is the sound velocity, ω the angular frequency, ξ_0 the amplitude of oscillation, α the absorption coefficient, and t time.

The complex longitudinal wave modulus, M^*, in an infinitely spread medium is:

$$M^*=M_1+iM_2=K^*+(4/3)G^* \qquad (2)$$

where K^* is the complex bulk modulus and G^* is the complex shear modulus.

The real part, M_1, and the imaginary part, M_2, of the complex modulus, M^*, are respectively, expressed as follows;

$$M_1=K_1+\frac{4}{3}G_1=\rho c_l^2 \frac{1-\left(\frac{\alpha_l c_l}{\omega}\right)^2}{\left\{1+\left(\frac{\alpha_l c_l}{\omega}\right)^2\right\}^2} \qquad (3)$$

$$M_2=K_2+\frac{4}{3}G_2=\rho c_l^2 \frac{2\left(\frac{\alpha_l c_l}{\omega}\right)}{\left\{1+\left(\frac{\alpha_l c_l}{\omega}\right)^2\right\}^2} \qquad (4)$$

where ρ is the density and where the suffix l refers to a longitudinal wave.

According to Eqs. 3 and 4 described above, we can obtain the dynamic elastic modulus, M_1, and the loss modulus, M_2, from the values of c_l and α_l.

Experimental

Apparatus and Procedure.—The apparatus used in this experiment for the measurement of the velocity and absorption of a longitudinal ultrasonic wave, is basically similar to that reported previously by Pinkerton and others.[3] A block diagram of it is shown in Fig. 1.

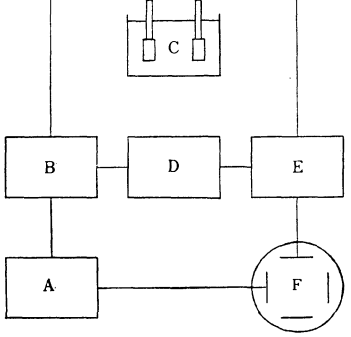

Fig. 1. Block diagram of the apparatus.
A: Pulse generator B: Oscillator
C: Cell D: Attenuator
E: Amplifier F: Synchroscope

A pulse generator supplies an electric pulse of about 10 μ sec. duration and with a repetition rate of 2~5 kc./sec. into a high-frequency oscillator, which operates as an oscillator only during the loading period of the pulse. The pulse-modulated high frequency voltage from the oscillator is led

to a transmitter quartz crystal in a cell which contains a sample solution and is there transduced into an ultrasonic pulse. At the same time, the electric pulse is led also to an attenuator. An ultrasonic pulse which has propagated through the solution is again transduced into a pulse-modulated high frequency voltage by a receiver quartz crystal. The two pulses from the receiver quartz and the attenuator are amplified and, thereafter, supplied into the vertical axis of a synchroscope.

The velocity of the sound wave in a solution is obtained from the amount of the shift of the pulse which has propagated through the solution on the synchroscope screen when the separation of two quartz crystals is varied by the rotation of a micrometer screw.

The absorption coefficient α is obtained by comparing the pulse which has passed through the solution with that which has passed through the attenuator on the synchroscope screen. That is, α is obtained from the tangent of the linear plot of the attenuator reading against the distance between two quartz transducers, when the ultrasonic path is varied and when the height of the two pulses is kept equal by adjusting the attenuator. The separation of two quartz transducers is designed to be always within the Fresnel region.[3]

Samples.—Two commercial samples of polyvinyl alcohol were used. The specification of each sample is given in Table I.

TABLE I. SAMPLES

Sample	Intrisic viscosity $[\eta]_{30°C}$ (100 cc./g.)	Residual acetate groups (mol. %)
A	0.91	<0.7
B	1.00	12.2

The intrinsic viscosity of each aqueous solution at 30°C, $[\eta]_{30}$ was obtained by mean of an Ostwald-type viscometer. The amounts of residual acetate groups were determined by the titration method. The viscosity average molecular weight of sample A, $\overline{M}_V$, was found to be 8×10^4 from the value of $[\eta]_{30°C}$ according to the following formula reported by Nakajima and Furutate:[4]

$$[\eta]_{30°C}=6.66\times10^{-4}\,\overline{M}_V^{0.64} \qquad (5)$$

The integral molecular weight distribution function of sample A was determined by using Spencer's method according to the procedure reported by M. Matsumoto.[5] The integral distribution curve thus obtained is given in Fig. 2.

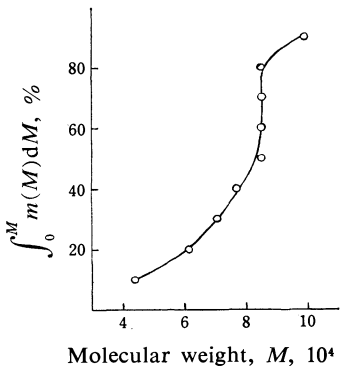

Fig. 2. Integral molecular weight distribution function for sample A obtained from the solution component by Spencer's method.

From the curve it may be seen that the distribution function, $m(M)$, has a sharp peak at 8.5×10^4.

Aqueous solutions of polyvinyl alcohol were prepared as follows. The aqueous solutions were prepared by heating a mixture of a powder sample and a calculated quantity of water, (where the quantity of adsorbed water in a powder sample as determined by the dessication method was taken into account) on a boiling water bath for more than two hours. The solution was poured into a cell which was held in a temperature bath directly after the sample had been completely dissolved, and then the measurement was begun as soon as the thermal equilibrium in the cell was reached.

Measurement. — In this experiment the sound velocity and the absorption were measured for solutions of sample A in which the range of concentration was over 5~15% by weight and also for solutions of sample B in which the range of concentration was 5 and 10% by weight. The temperature was varied within the range of 3~70°C at 10°C intervals. The temperature in the cell was controlled to an accuracy of ±0.1°C for lower temperatures and ±0.2°C for higher temperatures. The frequency of the ultrasound was 1.42 Mc./sec. for all measurements throughout this experiment.

Results and Discussions

Data of Sound Velocity and Absorption.—In

5) M. Matsumoto, ibid., **9**, 137 (1952).

Fig. 3 the sound velocity obtained for solutions of sample A is plotted against the temperature, while the velocity for solutions of sample B is similarly treated in Fig. 4. The velocity versus temperature curve for pure water reported by Greenspan and Tschiegg[6] is also shown in Figs. 3 and 4 for the sake of comparison. Figures 5 and 6 give, respectively, data of sound absorption for solutions of samples A and B.

The values of M_1 and M_2 were calculated according to Eqs. 3 and 4 for all the solutions used in this experiment. Two examples of M_1 and M_2 versus T curves are given in Figs. 7 and 8, where values of M_2/ω are plotted in place of those of M_2 for the convenience of further discussions.

It is well known that the sound velocity versus temperature curve for pure water at ultrasonic frequencies has a peak at 74°C, and that the maximum value of velocity is 1555.5

6) M. Greenspan and C. E. Tschiegg, *J. Res. Nat. Bur. Standards*, **59**, 249 (1957); *J. Acoust. Soc. Am.*, **31**, 75 (1959).

m./sec.[6-7] Concerning the temperature dependence of the sound velocity, the curves given in Fig. 3 for solutions of sample A, which is completely saponified polyvinyl alcohol, are found to have, on the whole, characteristics similar to the curve for pure water, though the peaks of the curves of sample A seem to shift to a little lower temperature side than in those of the latter. For solutions of sample B which contain acetate groups and hydroxyl groups in a mole ratio of about one to eight, the situation appears quite different, as may be seen in Fig. 4.

The peak of velocity versus temperature curve becomes broader and shifts towards a lower temperature region than do the curves for solutions of sample A and for pure water.

Concerning the concentration dependence of the sound velocity, each curve shown in Fig. 3 may be clearly seen to ascend upon an increase in the concentration. In this respect also, the circumstances for solutions of sample B appear to differ considerably from those for sample A, as may be seen in Fig. 4. In the lower temperature region the concentration dependence of the sound velocity for solutions of sample B does not seem to differ much from that for solutions of sample A, but when temperature is raised above about 50°C, the concentration dependence is found to have a reverse tendency; that is to say, the sound velocity becomes smaller with an increase in the concentration for solutions of sample B. This fact suggests that the configuration of high polymers in aqueous solutions of sample B differs considerably from that in solutions of sample A, and that this different behavior may safely be attributed to the presence of acetate groups in the proportion of about one to eight by mole ratio.

The absorption of ultrasound is found to increase with the concentration for both groups of solutions, as may clearly be seen in Table II from the values of the absorption coefficient α_m averaged over the temperature range used in the present experiment. In Table II the values of $(M_2/\omega)_m$ which are averaged over the temperature range are also given, together with the values of the temperature, T_{max}, where the M_2/ω versus T curve has a peak.

TABLE II. DATA OF SOUND ABSORPTION

Sample	Concn., c wt.%	α_m db/cm.	$(M_2/\omega)_m$ poise	T_{max} °C
A	5.0	0.17	1.8	60
	7.5	0.18	1.9	50
	10.0	0.21	2.3	50
	15.0	0.24	2.8	35
B	5.0	0.21	2.1	50
	10.0	0.26	2.6	40

The values of $(M_2/\omega)_m$ are nearly all within the range of 2~3 poises. According to the results reported by Onogi and his co-workers,[1] the values of (G_2/ω) are found to approach the value of about 10 poises or so for 15% solutions at audio frequencies, for example, as may be seen in Fig. 15 of their paper. Our values at the ultrasonic frequency may tentatively be said to be compatible with those of Onogi et al. at audio frequencyies, although our data with respect to M_2/ω, of course, include the contribution from the imaginary part of the bulk modulus, K^*.

The Compressibility of Polymer Molecules in Solutions.—Concerning the compressibility of polymer molecules in solutions, Miyahara, Shiio and others have made several studies by means of ultrasonic interferometers.[8]

We calculate the compressibility of polymer molecules in solutions as follows.

The volume of an aqueous solution V is

$$V = V_1 + V_2 + V_3 \tag{6}$$

where V_1 is the volume of free water, V_2 the volume of bound water, and V_3 the volume of polymer molecules in the solution.

Therefore, the adiabatic compressibility, κ, of the solution may be represented as follows:

$$\kappa = (V_1/V)\kappa_1 + (V_2/V)\kappa_2 + (V_3/V)\kappa_3 \tag{7}$$

where κ_1 is the adiabatic compressibility of free water, κ_2 the adiabatic compressibility of bound water, and κ_3 the adiabatic compressibility of polymer molecules in solutions.

We can obtain values of κ from the data of the sound velocity described above, ignoring the contribution from the shear elasticity, which is supposed to be much smaller than that from the bulk elasticity.[8-9] The values of κ_1 are calculated from the data for pure water reported by Greespan et al.[6] For the values of the compressibility of bound water, κ_2, the value 18×10^{-12} (c.g.s.) is substituted, following Hall and others;[8,10] this is assumed to be the value for the ice structure in water. As has previously been pointed out by Shiio;[11] bound water, which is attracted to solute molecules by a hydrogen bond, is supposed to be in a different state from ordinary water,

10) L. Hall, *Phys. Rev.*, **73**, 775 (1948).

assumed, that is to say, to be already in a kind of "solid state" at ordinary temperatures. Therefore, it may be reasonable to assign the same value as that of the compressibility of ice to the value of the compressibility of bound water, κ_2. The value of V_2 is estimated from the amount of bound water, for which the value of 0.45 cc. per gram solute is assigned, as reported by Shiio et al.*,[2] The value of V_3 is calculated from the value of concentration by weight in solutions without much error, where the density of solute molecules is assumed to be 1.3 g./cc., which is the value of the density of polyvinyl alcohol in the solid state. The value of V_1 is calculated from the values of V_2 and V_3 according to Eq. 6. The values of κ_3 for solutions of sample A may now calculated from Eq. 7 as in Table III.

Table III. Values of κ_3 at 25°C

Concn., wt.%	5.0	7.5	10.0	15.0	Mean value
κ_3, 10^{-12} c.g.s.	29.5	28.7	23.7	24.0	26.5

In Table III the values of κ_3 may be seen to decrease gradually with the increase in concentration. On the other hand the tendency to decrease is small, and we will not discuss it here. Rather, the fact that the values of κ_3 are nearly equal in spite of a fairly large difference in concentration has been noted; this finding may be said to support the adequacy of employing the concept, "compressibility of solute molecules in a polymer solution," as proposed by Masuda, Hasegawa and Miyahara.[8] In the present case where polymer molecules are supposed to be spread throughout a solution, a polymer solution is regarded as a hypothetical mixture of segments of polymer molecules and solvent molecules, and the compressibility, κ_3, which we discuss here may be regarded as that of the segments in the solution. It may be said that the term "segment" employed here is not always identical with "segment" in the ordinary sense. The values of κ_3 we obtained here are larger than that reported by Shiio et al.[2] However, the discrepancy does not matter at present considering the difference in the procedure for the determination of κ_3.

* Yasunaga et al. have recently reported that the amount of bound water is 0.46 cc./g.[2]

Summary and Conclusions

An ultrasonic pulse technique has been applied to measure the velocity and absorption of the longitudinal sound wave in aqueous solutions of polyvinyl alcohol at ultrasonic frequencies. Two samples of polyvinyl alcohol have been used: sample A, completely saponified polyvinyl alcohol, and, sample B, partially saponified Polyvinyl alcohol (including residual acetate groups by 12.2 mol.%). The following results have been obtained.

1) Ultrasonic velocity and absorption have been measured over the temperature range of 3~70°C in the concentration range of 5~15% by weight.

2) For sample A the temperature dependence of velocity is similar to that for pure water, but for sample B the velocity vs. temperature curves have been found to have a broader peak.

3) Concerning the concentration dependence of the velocity, in sample A the sound velocity increases with the increase in the concentration, but in sample B a reverse dependence of velocity on concentration has been found at higher temperatures.

4) The value of M_2/ω amounts to about 2~3 poises on the average for both samples.

5) The compressibility of polymer molecules in solutions has been calculated to be 26.5×10^{-12} c.g.s.u. on the average for completely saponified polyvinyl alcohol.

The authors wish to thank Mr. Yoshihisa Nagashima and Mr. Keiichi Kasuga for their cooperation in performing this experiment.

The Photochemical Transformation of Some p-Quinol Ethers[1]

By Teruo MATSUURA[2]

(Received December 5, 1963)

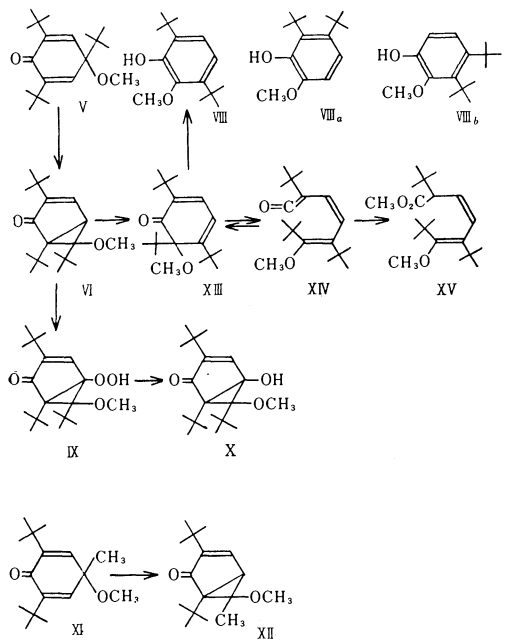
In our previous reports on the biosynthetic mechanism of thyroxine formation, several quinol ethers III were synthesized by the tri-*t*-butylphenoxy radical I with analogs II of diiodotyrosine.[3,4] Some of these quinol ethers were also converted into analogs IV of thyroxine by reaction with acid or by pyrolsis. This sequenece of reactions represents a complete model for the mechanism by which, according to Johnson and Tewkesbury,[5] thyroxine is synthesized from two molecules of diiodotyrosine *in vivo*. On the basis of the assumption that quinol ethers of type III may be converted into analogs of thyroxine by ultraviolet irradiation, we initiated the photochemical reactions of these quinol ethers. A preliminary investigation of the photoreaction of the quinol ether (III: $R_1=H$, $R_2=(CH_2)_2$-COOEt) gave quite complex results.

R_1=H ; Br ; I
R_2=$(CH_2)_2COOC_2H_5$; $CH_2CH(NH_2)COOH$, etc.

Therefore, the quinol ether V[6] was chosen as the first compound to be studied in the systematic investigation of the photochemical behavior of such quinol ethers.

The irradiation of the quinol ether V[6] in methanol under bubbling nitrogen gave a photoketone $C_{19}H_{32}O_2$ (VI), isomeric to V, in an 11% yield and tri-*t*-butylphenol (VII) in a 3% yield. The photoketone VI was characterized as a conjugated enone from its ultraviolet spectrum (λ_{max} 248 and 282 mμ) and its infrared spectrum (1650 and 1630 cm^{-1}). The structure of VI was indicated by its NMR spectrum (Table I), which consists of four groups of peaks, and by considering the analogous transformation of 2, 5-cyclohexadienones into "photoketones" with bicyclo[3, 1, 0]hex-2-ene-1-one structures.[7,8] Three peaks, at τ=9.07, 8.81 and 8.75, and a singlet at τ=6.40 are readily assigned to the three *t*-butyl groups and a methoxyl group respectively. Two other doublets, at τ=7.03 and 3.67, are attributed to an allylic proton on a cyclopropane ring conjugated with a double bond[9] and to a proton of a double bond. The spin-spin coupling constant (J= 6 c.p.s.) of these doublets suggests that these two protons may be adjacent to each other.

On the other hand, the irradiation of V in ether gave a crytalline photophenol $C_{15}H_{24}O_2$ (VIII) in a 10% yield, in addition to a small amount of VI. The dealkylation of this phenol with aluminum chloride in hot benzene yielded pyrocatechol. The NMR spectrum of VIII shows the presence of two adjacent protons on a benzene ring (AB type quartet, centering at τ=3.27; J=8.5 c.p.s.). The infrared spectrum (815 cm^{-1}) also indicates two adjacent hydrogen atoms on a benzene ring. Therefore, it follows that the structure of the photophenol is represented by the formula VIII, VIIIa, or VIIIb. Among these three formulae, the structure VIII is assigned to the photophenol by considering that the minimum rearrangement has occurred, and by reasoning on the basis of a pre-considered mechanism.



In the presence of oxygen, the irradiation of V in ether gave the photophenol VIII and a crystalline product (IX) $C_{19}H_{32}O_4$ in an 11% yield. The hydroperoxyl nature of IX was

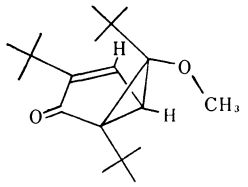
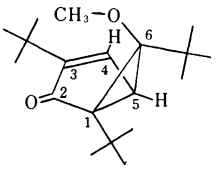
TABLE I. CHEMICAL SHIFTS AND SPIN-SPIN COULING CONRTANTS*

Compound	Chemical shifts[a] of protons				
	t-Butyl	Methoxyl	Vinyl	Cyclopropyl	Others
V[b]	9.08 s (9) 8.77 s (18)	6.88 s (3)	3.55 s (3)	—	—
VI[b]	9.07 s (9) 8.81 s (9) 8.75 s (9)	6.40 s (3)	3.67 d (1) (J=6 c.p.s.)	7.03 d (1) (J=6 c.p.s.)	—
VIII[b]	8.62 s (18)	6.21 s (3)	3.27 q (2)[d] (J=8.5 c.p.s.)	—	4.45 s (1)[e]
IX[c]	9.01 s (9) 8.75 s (9) 8.67 s (9)	6.00 s (3)	3.58 s (1)	—	2.03 s (1)[f]
X[c]	9.03 s (9) 8.77 s (9) 8.67 s (9)	6.15 s (3)	3.70 s (1)	—	7.93 s (1)[e]
XII[b]	8.92 s (9) 8.88 s (9)	6.96 s (3)	3.17 d (1) (J=3.5 c.p.s.)	8.02 d (1) (J=3.5 c.p.s.)	8.45 s (3)[g]
XI[b]	8.78 s (18)	6.97 s (3)	3.70 s (1)	—	8.70 s (3)[g]

* The NMR spectra were taken in a Varian A-60. a) τ-values: internal TMS reference. s, singlet; d, doublet; q, quartet. Proton numbers in parentheses. b) Taken in carbon tetrachloride (ca. 5% solution). c) Taken in deuteriochloroform (ca. 5% solution). d) Aromatic protons. e) Hydroxyl proton. f) Hydroperoxyl proton. g) Methyl protons.



confirmed by the reaction with potassium iodide to yied two equivalents of iodine and a hydroxyl compound (X), $C_{19}H_{32}O_3$. The ultraviolet spectra of IX (λ_{max} 237 and 285 mμ) and of X (λ_{max} 237 and 256.5 mμ; λ_{infl} 290 mμ) and the infrared spectra of IX (1665 and 1625 cm^{-1}) and of X (1660 and 1630 cm^{-1}) indicate the presence of a conjugated enone. The NMR spectrum of IX shows no peak corresponding to a cyclopropane proton conjugated with the double bond, but it does show a singlet at τ=2.03, which is assigned to a hydroperoxyl proton. In this case, the peak attributed to the double bond proton (τ=3.58) is not split. We can thus formulate the hydroperoxide and the hydroxy compound as IX and X respectively. The formation of the hydroperoxide can be explained the photo-induced allylic oxidation[10] of the photoketone VI.



The irradiation of the quinol ether XI[11] in ether gave a crystalline photoketone XII in an 11% yield, whereas irradiation in methanol did not give crystalline products. The structure is assigned to the formula XII by the interpretation of its NMR spectrum, which is similar to that of VI (Table I). The photoketone is unstable, and, on standing for several weeks, it liquefied to form a unidentified product.

Recently Zimmerman and Schuster proposed a mechanism for the photochemical rearrangement of 4, 4-diphenylcyclohexa-2, 5-dienone.[8] This mechanism involves the $n\rightarrow\pi^*$ excitation of the cyclohexadienone system as the initiating step, and it can also account for the formation of VI, VIII and XII. The fact that the phenol VIII is not formed on the irradiation of V in methanol may be due to the conversion of XIII, under these conditions, into the ester XV via the ketene XIV.[12]

VIa

VIb

XIIa

We wish also to discuss the stereochemistry of the photoketone VI. Of two possible stereochemical structures, VIa and VIb,[13] VIa with an *exo*-methoxyl group was tentatively assigned to the photoproduct for the following reasons: i) A stereomodel for VIb demonstrates that the two *cis*-*t*-butyl groups of the cyclopropane ring strongly hinder each other, whereas the trans arrangement of the *t*-butyl groups in VIa is sterically more favored. ii) The NMR peak of the methoxyl protons of the starting dienone V ($\tau=6.88$) and also of XI ($\tau=6.97$) is located at a higher magnetic field than is usual for methoxyl protons. This shows that these protons must be shielded by the dienone system. It seems, therefore, very likely that this shielding is cancelled in the *exo*-configuration of the methoxyl group ($\tau=6.40$) of VIa. iii) The unusual downward shift ($\tau=6.15$) of the methoxyl peak of the hydroxy compound X suggest that the methoxyl group is sterically close to the hydroxyl group,[14] that, namely, both groups are cis. This argument is also applicable to the hydroperoxide IX (methoxyl protons, $\tau=6.00$), whose precursor is considered to be VI.

On the other hand, the methoxyl protons ($\tau=6.96$) of XII are apparently much shielded by the enone system. This shows that XII may have the stereochemical structure XIIa,[13] with an *endo*-methoxyl group.

The irradiation of the peroxide XVI[15] in petroleum ether gave two crystalline products; one was identified as tri-*t*-butylphenol (VII) (13% yield), and the other as 2,6-di-*t*-butyl-*p*-benzoquinone (XVII) (48% yield). The formation of these products can be formulated as follows:

13) Each one enantiomeric structure was given for VIa, VIb and XIIa.

Experimental[16]

Photolysis was carried out in a cylindrical vessel, into which a 60 W. low-pressure mercury lamp (spiral type) had been inserted; during irradiation, a nitrogen stream was bubbled through a sintered glass disk jointed at the bottom of the vessel.

The Photolysis of 2, 4, 6-Tri-*t*-butyl-4-methoxycyclohexa-2, 5-dienone (V).—*In Methanol.*—A solution of 4.0 g. of the quinol ether V[6,17] in 160 ml. of absolute methanol was irradiated at 35~40°C under bubbling nitrogen for 7 hr. The progress of the reaction was followed by the decrease of an ultraviolet absorption maximum at 248 mμ and by the appearance of a new maximum at about 280 mμ. The mixture was evaporated under reduced pressure. The residual liquid was dissolved in petroleum ether and chromatographed on a containing 100 g. of neutralized alumina (activity 1). Elution with 100 ml. of petroleum ether yielded 1.43 g. of a pale yellow liquid (A) which deposited 0.44 g. (11%) of crystals. Recrystallization from methanol gave 0.31 g. (7.8%) of the photoketone VI as colorless plates (m. p. 87~87.5°C). IR spectrum (Nujol): 1650, 1630, 1595 cm^{-1}. λ_{max}^{EtOH} 248 mμ (ε, 7780) and 282 mμ (ε, 3070).

Found: C, 78.00; H, 11.01. Calcd. for $C_{19}H_{32}O$: C, 78.03 H, 11.03%.

The fractional recrystallization of the residue from the mother liquor yielded 0.09 g. (3%) of colorless prisms (m. p. 129~130°C), which were identified as 2, 4, 6-tri-*t*-butylphenol (VII) (mixture melting point and infrared spectrum). The other products were not obtained in a pure form.

In Ether.—A solution of 4.0 g. of the quinol ether V in 100 ml. of absolute ether was irradiated at 36°C under bubbling nitrogen for 29 hr. The solvent was removed under reduced pressure, and the residual liquid was dissolved in petroleum ether and chromatographed through a column containing 80 g. of neutralized alumina. Elution with 150 ml.

16) Melting points were determined in capillary tubes and are uncorrected. The infrared spectra were measured with a Nippon Bunko recording spectrophotometer, Model IR-S. The ultraviolet spectra were measured with a Hitachi recording spectrophotometer, Model EPS-2. The microanalyses were made by Mr. J. Goda and his associates of this Faculty.

17) The starting materials, 2, 4, 6-tri-*t*-butylphenol and 2, 6-di-*t*-butyl-*p*-cresol, for the preparation of V, XI and XVI, were kindly supplied by the Koppers Co., Inc.

of petroleum ether yielded 3 g. of a yellow liquid (A). Elution with petroleum ether and then with benzene yielded 0.98 g. of a liquid which crystallized on standing. Recrystallization from petroleum ether at −70°C gave 0.33 g. of the photophenol VII as needles (m. p. 86.5~87.5°C). These crystals were further purified by sublimation at 75~80°C/5 mmHg to give colorless plates (m. p. 87~88°C). IR spectrum (Nujol): 3350, 1610, 815 cm^{-1}. λ_{max}^{EtOH} 209 mμ (ε, 16900) and 278 mμ (ε, 2360).

Found: C, 76.42; H, 10.33. Calcd. for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24%.

This substance gave a positive phenol reaction with a ferric chloride-ferricyanide reagent.[18] The yellow liquid (A) was distilled at 115~118°C/1 mmHg to give a yellow liquid (n_D^{21} 1.4925). The chromatography of the liquid on an alumina column yielded a few milligrams of plates (m. p. 87~87.5°C), which were identified as the bicyclic enone VI by a comparison of the infrared spectra.

In Ether in the Presence of Air.—A solution of 1.50 g. of the quinol ether V in 100 ml. of absolute ether was irradiated at 36°C under bubbling air for 4 hr. The reaction mixture was evaporated under reduced pressure. The residue was dissolved in petroleum ether and chromatographed on a column containing 40 g. of neutralized alumina. Elution with 80 ml. of petroleum ether yielded 0.78 g. of a liquid containing crystals. The hydroperoxide IX, insoluble to petroleum ether, was collected by filtration. It had a m. p. of 145 °C decomp.; yield, 0.175 g. (10.5%). Recrytallization from ether and petroleum ether gave colorless prisms (m. p. 146°C, decomp.). IR spectrum (Nujol): 3350, 1665, 1625, 1595 cm^{-1}. λ_{max}^{EtOH} 237 mμ (ε, 6680), and λ_{infl}^{EtOH} 285 mμ (ε, 2630).

Found: C, 70.52; H. 10.03. Calcd. for $C_{19}H_{32}O_4$: C, 70.33; H, 9.94%.

This substance turned yellow under diffused light.

Elution with benzene and then with methanol yielded 0.40 g. of a liquid which crystallized on standing. Recrystallization from petroleum ether gave 20 mg. (2%) of colorless needles (m. p. 87~88°C), which were identical with an authentic sample of the photophenol VIII (mixture melting point).

In another run, the hydroperoxide IX and the phenol VIII were isolated in 7.5% and 13% yields respectively.

The Dealkylation of the Photophenol VIII.—A solution of 60 mg. of the photophenol VIII in 10 ml. of dry benzene was heated under reflux with 1 g. of powdered anhydrous aluminum chloride. The mixture was then treated with ice-water and extracted with ether. The ethereal layer was washed with water, dried over anhydrous sodium sulfate, and evaporated. Recrystallization of the residue from benzene gave 10 mg. (36%) of plates (m. p. 103~105°C), which were identical with catechol (mixture meeting point and infrared spectrum).

The Reduction of the Hydroperoxide IX to X.—A solution of 64 mg. of the hydroperoxide in 4 ml. of acetic acid was mixed with a solution of 300 mg. of sodium iodide in 3 ml. of acetic acid. The mixture was then warmed at 50°C for 5 min. After dilution with water, the iodine which had been liberated was titrated with 3.50 ml. (corresponding to 0.89 atom oxygen) of a 0.101 N sodium thiosulfate solution. The separated solid was collected by filtration, dried (52 mg.), and recrystallized from ether and petroleum ether to give 38 mg. of the hydroxy compound X as colorless plates (m. p. 147~148.5°C). IR spectrum (Nujol): 3510 (with 3600 infl.), 1660, 1630, 1585 cm^{-1}. λ_{max}^{EtOH} 237 mμ (ε, 5480) and 256.5 mμ (ε, 4780), $\lambda_{infl.}^{EtOH}$ 290 mμ (ε, 2290).

The Photolysis of 2, 6-Di-*t*-butyl-4-methoxy-4-methylcyclohexa-2, 5-dienone (XI).[10,17] — *A) In Ether.*—A solution of 4.0 g. of the quinol ether XI in 160 ml. of absolute ether was irradiated at 36°C under bubbling nitrogen for 6 hr. The solvent was then removed under reduced pressure. The residue was dissolved in petroleum ether and chromatographed on a column containing 100 g. of neutralized alumina. Elution with 300 ml. of petroleum ether yielded 2.0 g. of a yellow liquid which did not crystallize. Elution with petroleum ether, benzene, and then ether yielded 1.13 g. of a yellow liquid which partly crystallized on standing.

After digestion with a small amount of petroleum ether, crystals (0.43 g.; 11%) were collected by filtration and recrystallized from petroleum ether at −70°C to give XII as colorless prisms, m. p. 69~70°C. IR spectrum (Nujol): 1695, 1612 cm^{-1}. λ_{max}^{EtOH} 278 mμ (ε, 2860) and λ_{infl}^{EtOH} 235 mμ (ε, 2550).

Found: C, 76.55; H, 10.27. Calcd. for $C_{16}H_{26}O_2$: C, 76.75; H, 10.47%.

This substance, on standing for several weeks, decomposed to give a yellow liquid whose infrared spectrum showed a broad band centering 1700 cm^{-1} and a broad hydroxyl band near 3200 cm^{-1}.

B) In Methanol.—A solution of 4 g. of the quinol ether XI in 160 ml. of absolute methanol was irradiated under bubbling nitrogen and cooling with tap water for 9 hr. The mixture was treated as described in A). Elution of the chromatogram with 200 ml. of petroleum ether yielded 0.89 g. of an orange liquid which crystallized on standing. Recrystallization from methanol gave 0.28 g. of colorless prisms (m. p. 68~70°C) which were identical with an authentic sample of 2, 6-di-*t*-butyl-*p*-cresol (infrared spectrum). Further elution yielded an orange liquid which did not crystallize.

The Photolysis of Bis(1, 3, 5-tri-*t*-butyl-2, 5-cyclohexadien-4-one) Peroxide (XVI).[15,17]—A solution of 4.0 g. of the peroxide XVI in 160 ml. of petroleum ether was irradiated under bubbling nitrogen and cooling with tap water for 12 hr. The solution showed a greenish yellow color during irradiation. The solvent was removed under reduced pressure. The residue, on treatment with 10 ml. of methanol, deposited some crystals which were collected by filtration. Yield, 0.64 g. (16% recovered); m. p. 139~142°C. The melting point was not depressed on admixture with the starting peroxide XVI. The filtrate was evaporated under reduced pressure, and the residue was dissolved in petroleum ether and chromatographed on a column

18) G. M. Barton, R. S. Evans and J. A. F. Gardner, *Nature*, **170**, 249 (1952).

containing 40 g. of neutral alumina. Elution with 450 ml. of petroleum ether yielded 0.40 g. (13%) of colorless crystals (m. p. 129~131°C), which were identified as 2, 4, 6-tri-*t*-butylphenol (VII) (infrared spetrum).

Elution with 50 ml. of a mixture of petroleum ether and benzene (1 : 1) yielded 0.9 g. of a yellow liquid which did not crystallize. Further elution with the same solvent mixture and then with benzene yielded 1.22 g. (48%) of orange crystals (m. p. 67~68°C), the infrared spectrum of which was identitcal with that of 2, 6-di-*t*-butylbenzoquinone (XVII).[19]

Summary

The ultraviolet irradiation of 2, 4, 6-tri-*t*-butyl-4-methoxycyclohexa-2, 5-dienone (V) in methanol and in ether has yielded a photoketone VI and 3, 6-di-*t*-butylguaiacol (VIII) respectively. The irradiation of V in the presence of oxygen in ether has yielded VIII and the hydroperoxide of VI. Other related *p*-quinol ethers have also been subjected to photolysis.

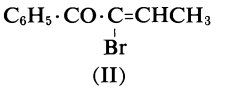
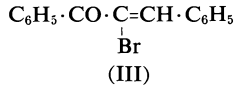
The Reaction Mechanism of α-Bromo-α,β-unsaturated Ketones with Amines

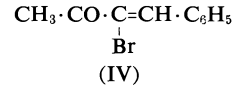


By Hiromi INOKAWA

(Received October 19, 1963)

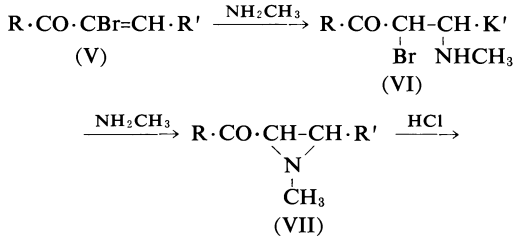


In previous papers,[1] the reaction products of α-bromo-α, β-unsaturated ketones, such as 2-bromo-1-phenyl-2-propen-1-one (I), 2-bromo-1-phenyl-2-buten-1-one (II), 2-bromo-1, 3-diphenyl-2-propen-1-one (III), and 3-bromo-4-phenyl-3-buten-2-one (IV), with methylamine and dimethylamine, were described.

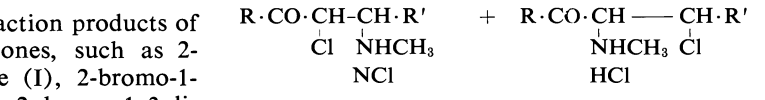


(I)

(II)



(III)

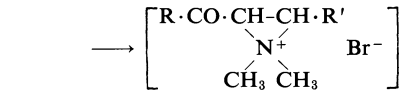


(IV)

The general course of the reactions of α-bromo-α, β-unsaturated ketones with methylamine has been schematized as follows:

(V) (VI) (VII)

(VIII) (IX)



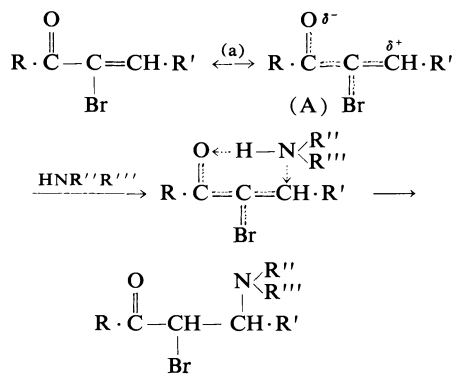
The first step consists of the addition of methylamine to the β-carbon atom of the unsaturated ketones V, followed by the formation of α, β-ethylenimine ketones VII with the excess methylamine. The α, β-ethylenimine ketones VII are converted into α-chloro-β-methylamino ketone hydrochlorides (VIII) and β-chloro-α-methylamino ketone hydrochlorides (IX) by the action of hydrogen choride. However, when R′ is H, only α-chloro-β-methylamino ketone hydrochloride (VIII) is obtained.

The reaction steps of α-bromo-α, β-unsaturated ketones with dimethylamine may be represented as follows:

(V) (X)

1) H. Inokawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 84, 932, 988 (1963).

(R'=H or CH_3)



(XI)

The first step is the addition of dimethylamine to the β-carbon atom of the unsaturated ketones. When R' is H or CH_3, the resulting α-bromo-β-dimethylamino ketones (X) give 1, 1-dimethylaziridinium bromides (XI). When R' is C_6H_5, however, the α-bromo-β-dimethylamino ketones (X) remain unchanged.

The products and their yields in these reactions are summarized in Table I.

The facts summarized in Table I led the author to conclude (1) that the addition reactions of amines to the β-carbon atom of α-bromo-α, β-unsaturated ketones become difficult in the order of I<II<III<IV, and (2) that the values of the VIII/IX ratio, in which VIII and IX are produced by the ring-opening reactions of α, β-ethylenimine ketones with hydrogen chloride, decrease in the order of I > II > III > IV.

The former conclusion will be discussed first in relation to the reaction mechanism. The first step of the reactions of α-bromo-α, β-unsaturated ketones with amines may be formulated as the following scheme 1:

Scheme 1

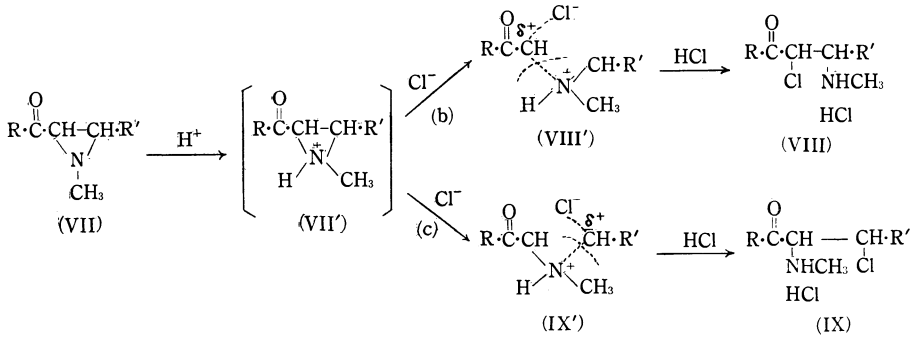
When R is C_6H_5 and R' is turned into H, CH_3, or C_6H_5, the fractional positive charge of the β-carbon atom should decrease as a result of the delocalization caused by the hyperconjugation with a methyl group or by the resonance with a phenyl group. The effect of a phenyl group on the delocalization is larger than that of a methyl group.[2] Consequently, the positive charge of the β-carbon atom should decrease in the order of I > II > III. Comparing III with IV, the formula A in the resonance (a) should contribute more when R is C_6H_5 than CH_3, and thus the addition of amines to the β-carbon atom of III takes place more easily than that of IV. Therefore, the addition of amines becomes difficult in the order of I<II<III<IV.

This conclusion seems to be in agreement with the experimental results obtained by Kohler,[3] who showed that the yields of 1, 4-addition products of phenyl magnesium bromide to 1-phenyl-2-propen-1-one, 1-phenyl-2-buten-1-one, 1, 3-diphenyl-2-propen-1-one, and 4-phenyl-3-buten-2-one are 100, 100, 94, and 12% respectively.

The second conclusion as to the ring-opening reactions of ethylenimine ketones will be discussed in terms of the reaction mechanism. In the reactions of ethylenimine ketones with hydrogen chloride, the intermediate VII' must be produced first* by the addition of a proton, the resulting positive charge facilitates the fission of an ethylenimine ring. Therefore, the reaction proceeds according to two paths, b and c, in Scheme 2.

In the path b, the fractional positive charge on the α-carbon atom is important. The fractional positive charge is caused by the strong electron-attracting force of –CO– and facilitates the attack of Cl^- on the α-carbon atom. The electron-attracting force of a benzoyl group is larger than that of an acethyl group. Accordingly, the path b proceeds more easily when R is C_6H_5 (in VII') than when it is CH_3. In the path c, on the other hand, the stability of

Table I. Yields of Reaction Products



No.	V: R	V: R'	With methylamine: VII %	With methylamine: VIII X	With methylamine: IX %	VIII/IX	With dimethylamine: X %	With dimethylamine: XI %

3) E. P. Kohler, *Am. Chem. J.*, 38, 511 (1907).

* The ionization constants (k_b) of the ethylenimines much are greater than 3.8×10^{-10}. H. C. Brown and M. Gerstein, *J. Am. Chem. Soc.*, 72, 2926 (1950).

Scheme 2

the transition state IX′ seems to be of importance. As has been mentioned in the discussion of the addition reaction, the delocalization of the fractional positive charge on the β-carbon atom is caused by the resonance with a methyl or phenyl group, and the stability of IX′ increases by the delocalization energy in the order of I<II<III, the reactions through the path c becoming easier in the order of I<II<III. Consequently, the values of VIII/IX become smaller in the order of I>II>III>IV.

Summary

It has been considered that, in the reaction of α-bromo-α, β-unsaturated ketones with amines, α-bromo-β-amino ketones are produced first by the 1, 4-addition of amines and converted to ethylenimine ketones in the presence of excess amines. The ethylenimine ketones react with hydrogen chloride to give α-chloro-β-amino and β-chloro-α-amino ketones, the yields of these ketones depending on the variation of the fractional positive charge at the α-carbon atom and on the delocalization energy on the β-carbon atom by R′.

The Peroxide-induced Polymerization of Epoxides

By Akira OKU, Masaya OKANO and Ryohei ODA

(Received December 5, 1963)

Free radical reactions of epoxides have been studied by some workers and classified into two types, one involving the abstraction of a hydrogen atom at the ring carbon and the other involving ring-opening by a radical attack. The observation by Gritter and

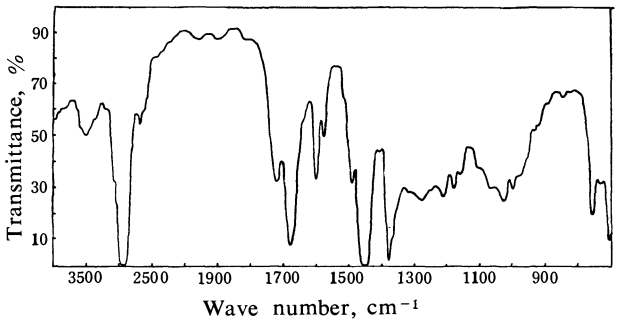

Fig. 1. Infrared spectrum of the SO polymer (Nujol).

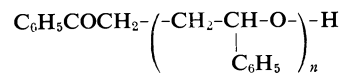
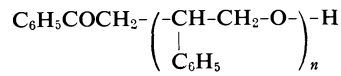
Wallace[1] that 5-oxy-2-hexanone and 2-undecanone were formed by two competing reactions, Eqs. 2 and 3, in the di-*t*-butyl peroxide-induced addition of propylene oxide to 1-octene, has been of great interest to us.



If reaction 3 occurs successively to any appreciable extent, the formation of a polyether having acyl and hydroxyl end groups is to be expected. Indeed, Gritter and Wallace recently pointed out a slight formation of telomers when propylene oxide was treated with peroxides,[2] but no additional information on the polymer was given. Conant and Peterson[3] also observed that, in the presence of a benzoyl peroxide catalyst, cyclohexene oxide was polymerized to a viscous liquid with difficulty, even under severe conditions. On the contrary, Hopff and Zahner[4] reported that styrene oxide could not be polymerized using peroxides and an aliphatic azo compound as initiators.

In order to check the radical polymerization of epoxides and to characterize the resulting polymers, we have now examined the reaction of styrene oxide (SO) and phenyl glycidyl ether (PGE) with some radical initiators. To facilitate the isolation of the polymer, high boiling aromatic or aliphatic epoxides which might be expected to yield a solid polymer have been selected.

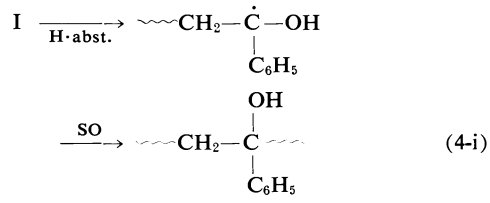


Results and Discussion

The Polymerization of SO with Di-*t*-butyl Peroxide (DTBP).—Some of the results are shown in Table I. Acetophenone was the only low molecular-weight product isolated. This clearly indicates the formation of phenacyl radical which corresponds to acetonyl radical in Eq. 1. By fractional precipitation, a polymeric residue was separated into two fractions, i. e., ethanol-insoluble and ligroin-insoluble fractions. Since their infrared spectra were almost identical, the former was investigated in detail. In addition, control experiments in which SO was heated alone, with *t*-butanol or acetone, gave no polymer.

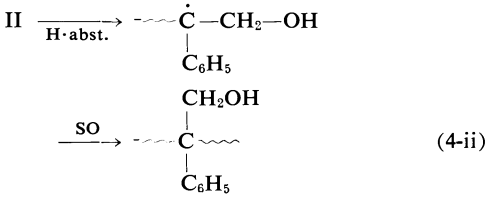
The polymer was insoluble in aliphatic alcohols and parafinic hydrocarbons, but it was soluble in other solvents. It was tensile when molten, but it was too brittle to be of practical use. Analytical data showed fairly good agreement with the calculated value of $(SO)_n$. The average molecular weight was found to be ca. 1500~2000. An estimation of the epoxy value by the hydrochloric acid-dioxane method showed no evidence for the existence of an epoxide ring. The infrared spectrum exhibited a characteristic absorption at 3500 (hydroxyl), at 1720 and 1680 (carbonyl), and at 1030~1100 cm^{-1} (ether) (see Fig. 1). It seems that these data do not conflict with the tentative structures, I and/or II, for the polymer which are deduced from Eq. 3.

(I)



(II)

However, the following additional data indicate that the polymer structure should be represented in somewhat modiffed forms.



First, the hydroxyl number, as estimated by both acetic anhydride and phenyl isocyanate methods, was 1.8~2.0 per molecule. This result seems to imply that a terminated polymer (initially formed)[5] is revived by hydrogen atom abstraction with any radical at the α-carbon of the phenyl or hydroxyl groups and that then a branching involving a repeated

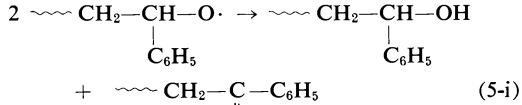
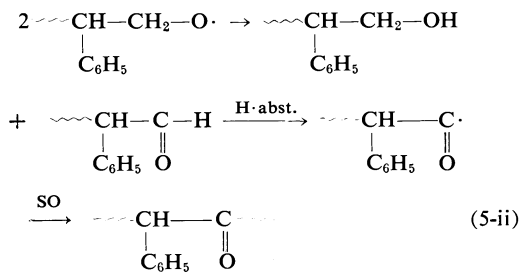
4) H. Hopff and H. Zahner, *Angew. Chem.*, **72**, 117 (1960).
5) The average degree of polymerization of this polymer is estimated to be nearly 6~7 on the basis of both hydroxyl number and carbonyl number (see below).

attack on the epoxide occurs (see Eqs. 4-i, ii). Here, the facile abstraction of an α-hydrogen atom of alcohols and benzyl compounds is a well-known type of reaction.

(4-i)



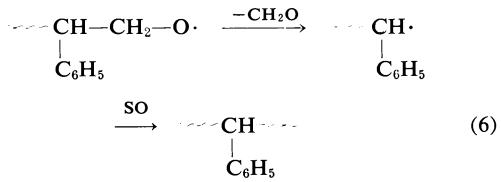
(4-ii)



A clear demonstration of a hydroxyl group in the product indicates that, in the propagation step, a preferential attack occurs on the ring carbon atom rather than on the oxygen atom of epoxide. On the other hand, an attack on the ring oxygen would not lead to the appearance of a hydroxyl end group. It is noteworthy that propagation proceeds in a form different from that in the cationic polymerization of epoxides. In connection with the above radical polymerization, the formation of an alternating polymer[6] from ethylene oxide and perfluoropropene under photo- or radical-initiation is of interest; it seems to involve a somewhat similar propagation step ($C\cdot \rightarrow O\cdot \rightarrow C\cdot \rightarrow O\cdot \rightarrow \cdots$). It has also been reported that the copolymerization of trifluoronitrosomethane and perfluoroolefins[7] yielded alternating polymers by a similar mechanism.

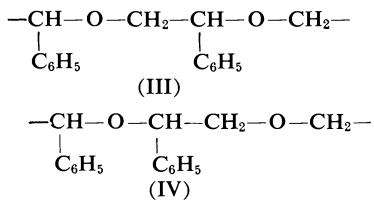
There remains the problem of which α-carbon the attack of radicals occurs in. As has been described above, Gritter and Wallace[1] observed a predominant formation of a secondary ketoalcohol in a similar reaction; however, a minor attack on the secondary ring carbon, which seems to be energetically favorable,[8] although sterically unfavorable, may also be considered (see below).

Second, the content of the carbonyl group as determined by the 2, 4-dinitrophenylhydrazine method was, unexpectedly, 1.5~1.6 units per molecule. By this treatment, two carbonyl bands (1720 and 1680 cm^{-1}) which were found in the original polymer completely disappeared. One carbonyl group is clearly due to the phenacyl end group; and the other one would be produced by disproportionation between two alkoxy radicals (see Eqs. 5-i, ii). In the latter case, a revival of the initially-terminated polymer with an aldehyde end group by means of hydrogen transfer may also be considered.



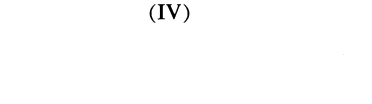
(5-i)

(5-ii)



The 1680 cm^{-1} band may be assigned to the carbonyl absorption of phenacyl end groups (cf. Eq. 5-i), and the 1720 cm^{-1} band, to that of the aldehyde and/or the ketone in Eq. 5-ii. The possibility of the radical attack on the secondary ring carbon of the epoxide cannot be excluded because of the appearance of the latter (1720 cm^{-1}) band.

The elimination of formaldehyde, which is a well-known reaction of primary alkoxy radicals,[8] may also be considered (see Eq. 6). However, this was not confirmed experimentally.



(6)

In addition, the absorption in the 1030~1100 cm^{-1} region, corresponding to ether, exhibited a medium but broad band with two peaks, although ether absorption is known to be considerably strong. Perhaps this is to be ascribed to the separate contributions of two different ether units, III and IV, in which the latter is produced by a competitive attack on another ring carbon of the epoxide during the propagation.

The Polymerization of PGE with DTBP.— The results are presented in Table II. In this reaction, no appreciable amount of the ketone derived from phenoxyacetonyl radical, $C_6H_5OCH_2COCH_2\cdot$, could be isolated. The polymer obtained from PGE was soluble in ethanol, but it could be fractionally precipitated with isobutanol. Its elementary analysis was in good agreement with the expected value, and the average molecular weight was 1200. The polymer had strong absorption bands at 3500 (hydroxyl), 1720 (carbonyl) and 1030~1100 cm^{-1} (ether). Besides, the hydroxyl and carbonyl groups in the polymer were both

estimated to be 1.8 units per molecule.[9] These data seem to predict the contribution of abnormal structures as in the case of the SO polymer.

A comparison of the polymerizing ability of SO and PGE seems to reflect the difference in their reactivities in radical ring-opening. As to the concentration of initiator radicals (acylmethyl radicals), the phenacyl radical would be superior to the phenoxyacetonyl radical. In fact, Wallace and Gritter[2] have recently found that SO was much more reactive than propylene oxide in a hydrogen atom abstraction by *t*-butoxyl radical, and that in the addition of the resulting keto radical to 1-octene, the yield of adduct from SO was higher than that from propylene oxide. If the ring-opening of SO and of PGE is equally facile, it may then be expected that SO will yield a polymer with a lower degree of polymerization but in a higher yield than in the case of PGE. However, the observed degree of polymerization of SO was about twice as large as that of PGE (see Footnotes 5 and 9), and the yield of SO polymer and PGE polymer in similar conditions were 9.6% and 7.7% respectively. Therefore, it may safely be deduced that the polymerizing ability of epoxides is largely dependent upon the ease of their ring-opening.

The Polymerization of SO with Benzoyl Peroxide (BPO).—Initially, a control experiment was conducted with SO and benzoic acid in order to ascertain the possibility of cationic polymerization with the acid (probably present in the reaction mixture). There was, however, no formation of a polyether, and considerable amounts of 1 : 1 and 2 : 1 adducts were isolated (see Experimental). Hence, it is obvious that the polymer from SO using a BPO catalyst would be formed by a radical mechanism. The results are presented in Table III. The ethanol-insoluble fraction of the polymer showed good analytical data. Its average molecular weight was found to be ca. 1300. This value nearly corresponds with that from the hydroxyl number in the DTBP-induced polymer. Its infrared spectrum showed a characteristic absorptin at 3500 (hydroxyl), 1720 and 1680 (carbonyl), and 1030～1100 cm^{-1} (ether). In this polymerization, the ring-opening of SO by an attack of benzoyloxy radical (formed by the decomposition of BPO) as well as by that of phenacyl radical may be expected. In fact, when the polymer was treated with aqueous sodium hydroxide in dioxane, a marked disappearance of the 1720 cm^{-1} band and an increase in the intensity of the hydroxyl band were observed. The determination of hydroxyl and carbonyl groups in the original polymer gave values of 1.0 and 0.75 units per molecule respectively. These results clearly indicate that both benzoyloxy and phenacyl radicals are used to initiate the polymerization and that the polymer has the normal polyether structure, in contrast with the DTBP-induced polymer. The low molecular weight and straight-chain structure of this polymer may result from the low reaction temperature.

The Reaction of SO with α, α'-Azo-bis-isobutyronitrile (AIBN).—An attempt to polymerize SO using an AIBN catalyst was unsuccessful. The reaction resulted in a complete recovery of SO and the quantitative isolation of tetramethylsuccinonitrile derived from AIBN, without any formation of acetophenone or any polymeric product. This would seem to arise from the poor ability of AIBN in hydrogen atom abstraction.

Conclusion

From these results, it can be concluded that the preparation of high molecular weight polyethers from epoxides by peroxide-induced polymerization is practically impossible. The reasons for this may be summed up as follows. The chain propagation reaction involving the ring-opening seems to be energetically somewhat unfavorable, as compared to the initiation reaction containing an α-hydrogen abstraction from epoxide and successive rearrangement to acylmethyl radical. In addition, the facile hydrogen abstraction and disproportionation reactions of the growing alkoxy radical, especially at high temperatures, promote the short-chain termination and cause the branching.

Experimental

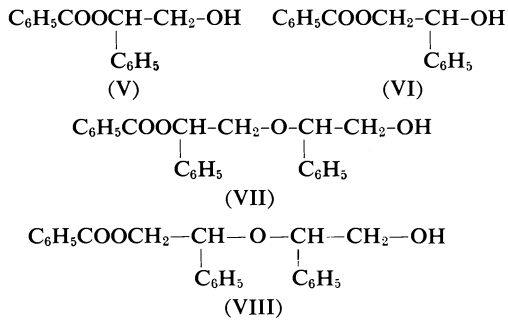
The DTBP-induced Polymerization of SO.—In a four-neck flask flushed with purified nitrogen, 240 g. (2.0 mol.) of SO and 29 g. (0.20 mol.) of DTBP were mixed. Under a nitrogen stream, the mixture was gradually heated and refluxed while being stirred at 135～143°C for 5 hr. All volatile fractions (up to 230°C/2 mmHg), such as acetone, *t*-butanol, acetophenone and unreacted SO etc., were removed, and 23 g. of a resinous polymeric residue was obtained. This was fractionated by precipitation from benzene with ethanol or ligroin into two fractions. Anal. of the ethanol-insoluble fraction. Found: C, 81.65; H, 6.71. Calcd. for $(C_8H_8O)_n$: C, 79.97; H, 6.56%.

The Determination of Hydroxyl and Carbonyl Groups.—The determination of hydroxyl and carbonyl contents in the polymer was carried out according to the following well-known methods.

9) On the basis of these data, the average degree of polymerization (i.e., that of propagation) is estimated to be about 3.

To obtain reliable data in these estimations, both original and reacted polymers were submitted to treatment in pulverized form.

Acetic Anhydride Method.[10]—The polymer (1.0 g.) was acetylated with a mixture of acetic anhydride (1.0 ml.) and pyridine (3.0 ml.) at 75°C for 2 hr. In the estimation of unreacted anhydride, it was necessary to wash thoroughly with water the polymer which separated from the reaction mixture upon the addition of water.



Phenyl Isocyanate Method.—The polymer (0.5 g.) was treated with phenyl isocyanate (0.3 g.) in the presence of pyridine (0.2 g.) in benzene (7 ml.) at 80°C for 2 hr. After the evaporation of low-boiling fractions, the residue was extracted with benzene several times to remove benzene-insoluble by-products (diphenylurea and isocyanate dimer). The dissolved polymer was precipitated with ethanol, and the hydroxyl number was calculated from its nitrogen content.

2, 4-Dinitrophenylhydrazine (2, 4-D) Method.[11]—The polymer (0.5 g.) was added to a dioxane solution (15 ml.) of 2, 4-D (0.4 g.) containing concd. hydrochloric acid (1.0 g.) ; the mixture was refluxed for 1 hr. (when tetrahydrofuran was used as a solvent, the heating was continued for 2 hr.). After evaporation to dryness, the benzene-soluble portion in the residue was collected and repeatedly washed with a mixture of ethanol and hydrochloric acid. Then the polymer was redissolved in benzene and reprecipitated with aqueous ethanol containing hydrochloric acid.

The DTBP-induced Polymerization of PGE.—The procedure was similar to that used in the case of SO. The polymer obtained was a colored viscous oil, and it was fractionated by precipitation from benzene with isobutanol. Anal. of the isobutanol-insoluble fraction. Found: C, 72.72; H, 5.89. Calcd. for $(C_9H_{10}O_2)_n$: C, 71.98; H, 6.71%.

The BPO-induced Polymerization of SO.—To SO in a flask flushed with nitrogen, BPO was added in small portions, and the mixture was stirred at 80~82°C. After dilution of the cooled reaction mixture with ether, the solution was washed four times each with aqueous sodium carbonate, with aqueous sodium thiosulfate and with water, and dried over anhydrous calcium chloride. By the removal of ether and of all volatile fractions (up to 230°C/2 mmHg), a resinous polymeric product was obtained; this was reprecipitated from ether with ethanol. Anal. of the ethanol-insoluble fraction. Found: C, 81.34; H, 6.14. Calcd. for $(C_8H_8O)_n$: C, 79.97; H, 6.71%.

The Reaction of SO with Benzoic Acid (BA).—As a control experiment for the BPO-induced polymerization, a mixture of SO and BA was heated under the same conditions. The distillation of the reaction mixture afforded considerable amounts of 1 : 1 and 2 : 1 (SO : BA) adducts (b. p. 167~172°C/2.5 mmHg and 220~225°C/3 mmHg respectively) and a trace of an ethanol-soluble residue, as Table IV shows. On referring to an authentic material of VI (m. p. 62°C) obtained by an independent method, it was ascertained that the former adduct was a mixture of two structural isomers, V and VI. In view of the facile rearrangement of V to VI, as in the case of the corresponding acetate,[12] the determination of its composition was not carried out. A rough gas-chromatographic analysis of the latter adduct indicated that it was a 2 : 1 mixture of two isomers. Judging from the orientation of the ring-opening of the epoxide, these isomers would correspond to VII and VIII among the four possible isomers:

The Reaction of SO with AIBN.—To 120 g. (1.0 mol.) of SO in a flask flushed with nitrogen, 16.5 g. (0.1 mol.) of AIBN was added over a 1 hr. period at 79~80°C and then stirred for 2 hr. each at 80 and at 90°C. In addition to the complete recovery of SO, a nearly quantitative amount of tetramethylsuccinonitrile and a trace of poly(α-methyl acrylonitrile) were isolated.

Spectrochemical Study of Microscopic Crystals. XXIV.[1] *The Structure and Light Absorption of Copper(II) Complexes of Benzoic and Substituted Benzoic Acids*

By Shoichiro YAMADA, Hiroaki NISHIKAWA and Seiko MIKI

(Received December 10, 1963)

In previous reports about the molecular structure of copper(II) complexes of fatty acids[2] and halogenoacetic acids[3] in the crystalline state and in solution, it was found that the acid dissociation constant of the carboxylic acid seemed to be related in one way or another to the tendency of their copper(II) complexes to form binuclear complexes. It seemed that it would be interesting to examine, in more detail, the conditions for the formation of the binuclear cupric carboxylates of this type, in relation to the dissociation constant of the ligand carboxylic acids and to the copper-to-oxygen bond in their cupric complexes. In the present paper, copper(II) complexes of benzoic and substituted benzoic acids were examined, mostly on the basis of their electronic absorption spectra.

Experimental

Materials. — Cupric benzoate was prepared by conventional methods,[4] either from cupric carbonate or hydroxide and benzoic acid, or from cupric sulfate and sodium benzoate. Recrystallization of the product from hot water yielded pale-blue needle-like crystals of $Cu(benz)_2 \cdot 3H_2O$, where "benz" denotes a benzoate ion. Recrystallization of the same product from ethanol yielded blue-green prismatic crystals of $Cu(benz)_2 \cdot C_2H_5OH$, as reported by Inoue, Kishita and Kubo.[5] Recrystallization from methanol containing benzoic acid yielded blue-green crystals of $Cu(benz)_2(benzH) \cdot 0.5H_2O$.

Other cupric complexes of substituted benzoic acids were prepared in a way similar to that used for cupric benzoate and were purified by repeated recrystallization. The recrystallization was carried out using dioxan, dioxan-water, dioxan-methanol or dioxan-ethanol. The isolation of the crystals of all the possible forms with a substituted benzoic acid was not attempted in the present work, but one typical form of the cupric complex for each substituted benzoic acid was isolated as crystals by some of the normal procedures and was used for the spectral examination. The different forms of cupric benzoates and substituted benzoate were found to show identical electronic absorption spectra in dioxan. Some of them were also examined in the crystalline state.

The compounds in Table I were prepared according to the methods already reported, and their elemental analyses agreed with the formulae previously given. The main characteristics and elemental analyses of the other compounds are shown in Table II.

Measurements. — Dichroism was determined in the visible and near-ultraviolet regions by Tsuchida and Kobayashi's microscopic method[6] with crystals of cupric benzoate, *o*-methylbenzoate, *o*-chlorobenzoate, *o*-nitrobenzoate, *m*-hydroxybenzoate and *p*-hydroxybenzoate.

The electronic absorption spectra of the compounds in non-donor organic solvents, such as methanol, ethanol and dioxan, were determined with a Beckman DU spectrophotometer, insofar as the solubility allowed. Beer's law was generally obeyed in the concentration range between 10^{-2} and 10^{-5} F, but deviation from the law was sometimes observed in more dilute solutions.

The reflection spectra in the same frequency region were determined with a Hitachi EPU-2A spectrophotometer.

The notations are the same as those in the former papers of this series. Extinction coefficients are based on the monomeric formulae.

Results and Discussion

Cupric Benzoate in Solution and in the Crystalline State.—The electronic absorption spectra of cupric benzoate and substituted benzoates were determined in non-donor organic solvents. The solubility of these compounds in common solvents was generally low, except for dioxan. The results with dioxan as a solvent will be described extensively in the present paper.

* Analyzed after dehydration.

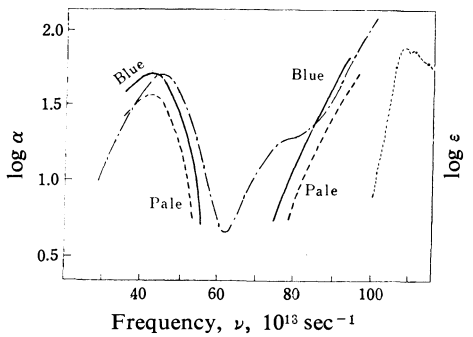

Fig. 1. Absorption spectra of $Cu(benz)_2 \cdot 3H_2O$ in dioxan containing benzoic acid in 1/50 F (—·—) and in the crystalline state (——). The notation "blue" and "pale" represent the absorption spectra along the blue polarization direction and along the pale-blue polarization direction, respectively. The absorption spectrum of benzoic acid in ether (----) is taken from H. Dannenberg, *Z. Naturforsch.*, **4b**, 327 (1949).

Cupric benzoate in dioxan shows an absorption band at about 80×10^{13} sec^{-1} (Band II) in addition to a band at about 44×10^{13} sec^{-1} (Band I), as may be seen in Fig. 1. It is found that Band I of cupric benzoate in dioxan is about ten times more intense than the intensity of the ligand field band of typical cupric complexes with no specific metal-to-metal bond, and that the intensity of Band II of cupric benzoate is considerably lower than the intensity of Band I of the same compound. These relations, which are quite similar to those of cupric alkanoates with the binuclear configuration,[2] seem to show that cupric benzoate in dioxan consists of binuclear molecules similar to those of cupric alkanoates with the copper-to-copper bond.

At least two types of crystals of cupric benzoate were obtained, one being green-blue crystals of $Cu(benz)_2 \cdot C_2H_5OH$ or $Cu(benz)_2 \cdot (benzH) \cdot 0 \cdot 5H_2O$ (Form A) and the other, pale-blue crystals of $Cu \cdot (benz)_2 \cdot 3H_2O$ (Form B). The absorption spectrum of the pale-blue crystal (Fig. 1) was determined on the (010) face with light polarized along the two extinction directions of the crystal. Cupric benzoate trihydrate in the crystalline state exhibits one ligand field band in the low frequency region (about 42×10^{13} sec^{-1}), but no absorption band at 80×10^{13} sec^{-1} until an intense absorption

band, due mainly to the ligands, appears in the region of about 90×10^{13} sec^{-1} to a higher frequency. The band at 42×10^{13} sec^{-1} may be assigned to spin-allowed *d-d* transition. According to the crystal structure analysis,[7] the crystal consists of octahedra of [CuO_6], which share two water molecules in such a way that a column extending along the c-axis is formed. The crystal structure analysis also indicates that the z-axis of one component of [CuO_6] is inclined to the c-axis of the crystal at an angle of about 37° and to the a-axis at an angle of 53°. The estimate using the data of the crystal analysis shows that the ratio of K_{xy} to K_z is approximately 9 for the ligand field band at about 42×10^{13} sec^{-1}. The ratio derived above shows clearly that the xy-absorption is much more intense than the z-absorption, in agreement with the results of the former studies of cupric complexes of an ordinary kind with no specific copper-to-copper bond.[1,8] Thus the crystal spectrum of cupric benzoate trihydrate at room temperature is quite different from that expected for the binuclear complex with the copper-to-copper bond. It is concluded that, in the crystal of cupric benzoate trihydrate at room temperature, there is no copper-to-copper bond similar to the case of cupric acetate monohydrate, although the nearest copper-copper distance is comparatively short (3.15Å). This result is in agreement with the magnetic measurement.[5] This, however, does not completely exclude the possibility that the copper-to-copper bond formation may occur at a lower temperature.

On the contrary, the green-blue crystal of $Cu(benz)_2\cdot C_2H_5OH$ (Form A), which usually grows in the form of hexagonal prisms, exhibits absorption bands at about 79 and 44×10^{13} sec^{-1}, the polarization of the former band being the reverse of that latter. The absorption at about 79×10^{13} sec^{-1} is far more intense along the needle-axis of the crystal than along the direction perpendicular to the needle-axis. The absorption at about 44×10^{13} sec^{-1} is slightly (1/1.5 times) weaker along the needle-axis. This type of dichroism is quite similar to the dichroism reported for a number of cupric carboxylates with the copper-to-copper bond.[2,3] Although the crystal structure analysis of this form is not available, it may safely be concluded from the dichroism that the blue-green form of $Cu(benz)_2\cdot C_2H_5OH$ consists of binuclear molecules of the cupric-acetate type, with the copper-to-copper bond within the molecule. This result agrees with that of magnetic study.[5] An essentially similar relation was obtained for $Cu(benz)_2\cdot(benzH)\cdot 0.5H_2O$ through the dichroism measurement.

The assignment of the absorption bands of the binuclear cupric complex with the metal-to-metal bond has not been finally settled, but it certainly is similar to cupric acetate and alkanoates.[9] A detailed discussion will be presented elsewhere.[10]

Forms A and B were found to give quite identical absorption curves in dioxan; it is therefore concluded that both of them consist of binuclear molecules of the acetate type in dioxan. It is also found, for substituted benzoates of copper(II), that different forms exhibit identical electronic absorption spectra in solution.

Cupric Complexes of Substituted Benzoic Acids.—As Fig. 2 shows, cupric complexes of *o*-, *m*- and *p*-methylbenzoic acids in dioxan all show an absorption band at about 43~45 $\times10^{13}$ sec^{-1} (Band I). In addition, the compounds show a band at about 80×10^{13} sec^{-1} (Band II) the intensity of which is considerably lower than the intensity of band I. Another intense absorption band, which rises sharply from about 90×10^{13} sec^{-1} towards a higher frequency, may be due to the charge-transfer-absorption system of the binuclear cupric complex, superposed over the absorption band due mainly to the methylbenzoate ion, since the methylbenzoate ions alone are found to show absorption bands in this frequency region. The intensity of Band I is several times higher than the ligand field band of cupric complexes of an ordinary type. On the same grounds as in the case of cupric

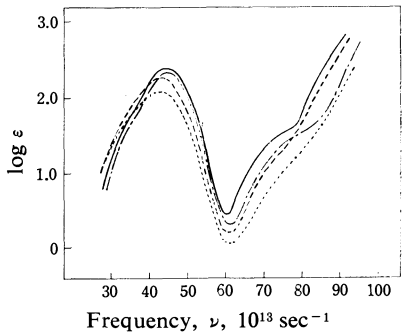

Fig. 2. Absorption spectra of cupric *o*-methylbenzoate in dioxan (——), and in methanol (----), and of cupric *m*-methylbenzoate in dioxan (—·—) and in methanol (·····). Each solution contains *o*- or *m*-methylbenzoic acid in 1/50 F.

alkanoates, it has been concluded that *o*-, *m*- and *p*-methylbenzoates of copper(II) in dioxan consist of the binuclear molecules of the acetate type.

The *o*-, *m*- and *p*-chlorobenzoates of copper-(II) in dioxan also show absorption spectra which are similar, in both the band maxima and the intensity relation, to one another and to the spectra of the methylbenzoates (Fig. 3).

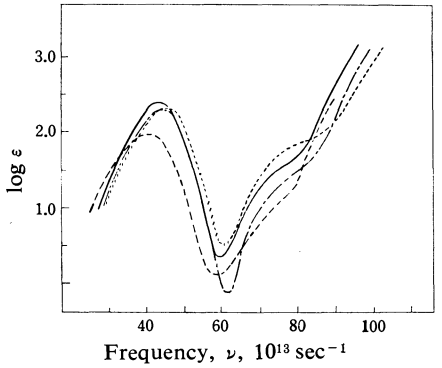

Fig. 3. Absorption spectra of cupric *o*-chlorobenzoate in dioxan (——) and in methanol (----), cupric *p*-chlorobenzoate (—·—), and cupric *p*-hydroxybenzoate (·····) in dioxan. The solutions all contain the corresponding substituted benzoic acid in 1/50 F.

It has been similarly concluded that *o*-, *m*- and *p*-chlorobenzoates of copper(II) in dioxan consist of binuclear molecules of the acetate type with a direct type of linkage between the two copper ions.

The electronic absorption spectra of *o*- and *p*-methoxybenzoates of copper(II) have been determined in dioxan. Since the two complexes show quite similar spectra, only one of them is shown in Fig. 4. For the same reason, only cupric *o*-nitrobenzoate is shown in the figure. It has been concluded, in the same way as has been described above, that cupric complexes of *o*- and *p*-methoxybenzoates in dioxan consist of binuclear molecules of the acetate-type.

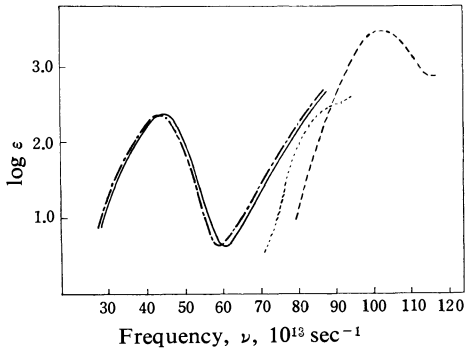

Fig. 4. Absorption spectra of *o*-nitrobenzoic acid (·····), cupric *o*-nitrobenzoate (—·—) and *o*-methoxybenzoate (——) in dioxan. The latter two solutions contain the corresponding substituted benzoic acid in 1/50 F. The absorption curve of *o*-methoxybenzoic in dioxan (----) is taken from E. D. Bergmann, Y. Hirshberg and S. Pinchas, *J. Chem. Soc.*, **1950**, 2351.

The *m*- and *p*-hydroxybenzoate ions in the cupric complexes reported in this paper are considered to be co-ordinated with the cupric ion through their carboxylate group. The *o*-hydroxybenzoate is different from the *m*- and *p*-homologues in their way of co-ordination to the metallic ion, since it can be co-ordinated to the cupric ion through the oxygen atoms of both the phenolate and the carboxylate groups. The *o*-hydroxybenzoate of copper (II) is, therefore, omitted in the present paper.

Cupric *m*- and *p*-hydroxybenzoates show absorption bands at about 45×10^{13} sec^{-1}, but the band at about 80×10^{13} sec^{-1} is obscured to some extent by a much stronger specific absorption bands due mainly to the ligand ion (Fig. 3). A more precise inspection of the curves, however, clearly reveals the presence of the band at about 80×10^{13} sec^{-1}, which corresponds to Band II. It is concluded, therefore, that cupric *m*- and *p*-hydroxybenzoates consist of binuclear molecules similar to those of cupric alkanoates with copper-to-copper linkage within the molecules.

As may be seen in Fig. 4, cupric *o*-, *m*- and *p*-nitrobenzoates in dioxan all show their ligand field band at about 43 to 44×10^{13} sec^{-1}, in the frequency region slightly lower than that of cupric benzoate, but still in the region expected for the binuclear copper(II) carboxylates. Moreover, the intensity of Band I is several times higher than that of ligand field bands of ordinary cupric complexes. The quite high intensity of Band I and the frequency of the band maximum are in agreement with the assumption that the nitrobenzoates of copper-(II) in dioxan consist of binuclear molecules similar to the molecules of cupric alkanoates. The band at about 80×10^{13} sec^{-1}, which is observed with the chloro- and methylbenzoates of copper(II), is not observed with cupric nitrobenzoates. This failure to be observed is, however, regarded as due to the much stronger absorption of the ligand, which is superposed over Band II. An analysis of the absorption curve, which involves the subtraction of the absorption expected for the ligand, reveals the presence of the band at about 80×10^{13} sec^{-1}, the intensity of the band being much lower than that of Band I. This agrees with the binuclear model for the cupric nitrobenzoates in dioxan.

The electronic absorption spectra of cupric chlorobenzoates and methylbenzoates were determined in methanol containing the corresponding substituted benzoic acids in 1/50 F (Figs. 2 and 3). The intensity of the absorption band at about 80×10^{13} sec^{-1} is greatly lowered, and Band I is displaced toward a lower frequency compared with the dioxan solution. This shows that the cupric carboxylates are more liable to form the binuclear complex of the acetate type in dioxan than in methanol, the dissociation of the binuclear complex most probably taking place to an appreciable extent in the latter solvent. This conclusion agrees with the findings about many other cupric carboxylates.[3]

Crystal absorption spectra were examined with some of these cupric complexes (Table III). Since, however, the crystal structure of none of these complexes has been determined, a detailed analysis of the crystal spectra is not possible at the moment. The following points, however, have been definitely confirmed for the cupric *o*-methyl-, *o*-chloro-, *o*-nitro- and *m*-hydroxybenzoates. (1) The blue-green crystals of these complexes show absorption bands at about 43~45 and 80×10^{13} sec^{-1}, the former being several times more intense than the latter. (2) The polarization of the former band is the reverse of the latter. It has been safely concluded that these cupric carboxylates consist of binuclear molecules with the copper-to-copper bond.

Table III. Absorption maxima of cupric benzoate and substituted benzoates in the solid state*

Cmpound	ν(Band I)	ν(Band II)
$Cu(benz)_2\cdot3H_2O$	41.5	None
$Cu(benz)_2\cdot C_2H_5OH$	44.5	79.5

ν: 10^{13} sec^{-1}
* Unless otherwise indicated, the value is based upon the crystal spectrum.
** Reflection spectrum of the powder.

On the contrary, $Cu(p\text{-}OH\text{-}benz)_2\cdot6H_2O$ in the crystalline state shows an absorption band at about 41.5×10^{13} sec^{-1}, but no band at about 80×10^{13} sec^{-1}, so the crystal contains no binuclear complex of the acetate type.

General Discussion. — Regarding the same substituent, an inspection of Table IV reveals that the absorption maximum of Band I of cupric complexes is parallel with the acid dissociation constant of the substituted benzoic acids. Since the frequency of Band I is regarded as representing approximately the magnitude of the crystal field splitting of the copper(II) ion, the above relation may readily be understood if it is assumed that copper-to-ligand bond becomes stronger as the acid dissociation constant of the parent acid of the ligand decreases. This agrees qualitatively with the previous results about cupric complexes.[11,12] It was also pointed out formerly[3] that the larger acid dissociation constant of the ligand carboxylic acid does not favor the formation of the binuclear molecule with the copper-to-copper bond.

Table IV. Absorption maxima of band I of cupric substituted benzoates and dissociation constants K of the substituted benzoic acids*

R		*o*-	*m*-	*p*-

* The values of K are taken from A. E. Remick, "Electronic Interpretations of Organic Chemistry," John Wiley & Sons, Inc., New York (1950), p. 65.

On closer examination of the data, however, deviation from the parallelism may be recognized in connection with the compounds of the *o*-series. Thus, it may be seen in Fig. 5 that, among *m*- and *p*-substituted benzoates of copper(II) with various substituents, there is a linear proportionality between the pK values of the carboxylic acids and the maxima

11) B. R. James, M. Parris and R. J. P. Williams, *J. Chem. Soc.*, **1961**, 4630.
12) R. May and M. M. Jones, *J. Inorg. Nucl. Chem.*, **24**, 511 (1962).

of the ligand field bands (Band I) of their cupric compounds. The *o*-derivatives, however, show an appreciable deviation from the straight line of the *m*- and *p*-derivatives, although there seems to be a linear relation among the derivatives of the *o*-series alone. This behavior of the *o*-substituted benzoates seems to be related with the so-called "ortho-effect" which is often observed, for example, in the reactions of aromatic compounds, including the substituted benzoic acids.[13] The apparent anomaly of the cupric complexes of *o*-substituted

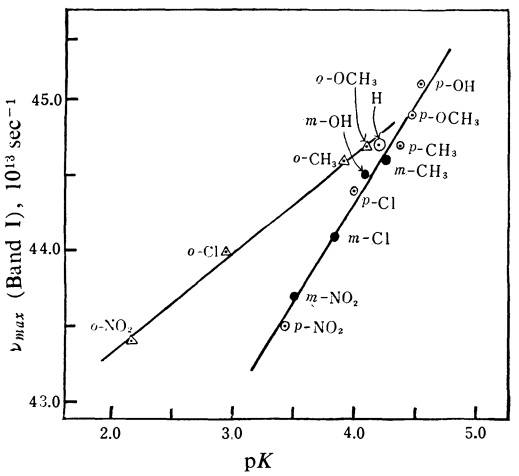

Fig. 5. Plots of absorption maxima (ν) of Band I of cupric substituted benzoates vs. pK of the substituted benzoic acids.

benzoates, as observed in the present work, seems to show that the ortho-effect may be operative in the case of cupric complexes, but in a different way from that of the substituted benzoic acids themselves. The ortho-effect in the dissociation constant of the substituted benzoic acids may be interpreted as mostly due to a twisting of the carboxyl-group from the benzene plane.[13] If this mechanism is assumed to be correct, the observed deviation of the *o*-substituted complexes seems to indicate that the twisting of the carboxyl-group from the benzene plane may be different in the cupric complexes from the twisting in the nucomplexed ion of the substituted benzoates.

On the other hand, Band II is obscured more or less significantly by much stronger absorption bands of other origins, so that it is difficult to determine the exact maximum for most complexes. No discussion similar to that above was, therefore, attempted on the basis of Band II.

Summary

Cupric complexes of benzoic and substituted benzoic acids have been prepared, and their configurations in the solid state and in dioxan examined. The substituents have included methyl, chloro, methoxy, nitro and hydroxy groups.

These cupric complexes in dioxan all consist of binuclear cupric complexes with the copper-to-copper bond. Crystal absorption spectra show that $Cu(benz)_2 \cdot C_2H_5OH$ and $Cu(benz)_2 \cdot (benzH) \cdot 0.5H_2O$ in the crystalline state consist of the binuclear complexes, whereas $Cu \cdot (benz)_2 \cdot 3H_2O$ has no such complexes with the copper-to-copper bond. The absorption spectra of several substituted benzoates of copper(II) in the solid state have also been determined, and the structure of the complexes discussed.

It has been found that the maxima of Band I of substituted benzoates of copper(II) in dioxan are linearly dependent upon the pK values of the substituted benzoic acids themselves.

The authors wish to record their gratitude to the late Professor Ryutaro Tsuchida for his interest in the present work, to Dr. Kenji Osaki of the Physics Department for information about the crystal structure of cupric benzoate trihydrate, and to the Ministry of Education for financial support.

NOTES

*The Radiation-induced Reaction of Sulfur in Various Solvents**

By Wataru ANDO, Ken'ichi SUGIMOTO and Shigeru OAE

(Received September 9, 1963)

Previous papers have described studies of the radiolysis of both benzene and toluene solutions of sulfur.[1-2] The reaction products reported have included such substances as mercaptan, disulfide, sulfide, hydrogen sulfide, hydrogen and other hydrocarbons. Among these products, quantitative determination is possible for mercaptan, hydrogen and hydrogen sulfide.

The radiolysis of solvent hydrocarbon produces free radicals which attack sulfur at room temperature; mercaptan is then formed in this manner:

$$RH \xrightarrow{I} R + H \quad (1)$$

$$R + S_8 \rightarrow RS_8 \rightarrow RS \quad (2)$$

The formation of mercaptan depends mainly on the bond dissociation energy of C–H in the solvent, because the formation of mercaptan through Eq. 3

$$RS + H \rightarrow RSH \quad (3)$$

$$RS + RH \rightarrow RSH + R \quad (4)$$

is rare, even though the reaction in benzene shows very little tendency to undergo radical displacement (reaction 4).

In the reaction with toluene, the benzyl mercapto radical would abstract hydrogen from the methyl group of toluene since its C–H bond is known to be quite weak.

In this investigation, *G*-values for the formation of various mercaptans and hydrogen in the radiolysis of various hydrocarbon solutions of sulfur will be determined, and the *G*-value of hydrogen formation will be compared with these of the corresponding hydrocarbons with the hope of obtaining some direct infomation on the effect of hydrocarbons as solvents on the radiolysis of hydrocarbon solutions of sulfur.

Experimental

The experimental details are similar to those outlined in an earlier paper.[1] The sulfur used in this work was a portion of an exceptionally pure sample previously employed. The solvents were purified by conventional fractional distillations. A solution of sulfur in a solvent was made by weighing and then degassing it by freezing, pumping and thrawing in vacuo. After irradiation, each ampoule was attached to a vacuum line in order to analyze the hydrogen formation. The amount of mercaptan was determined by a potentiometric titration with silver nitrate.[3]

Results and Discussion

The data in Table I on the radiolysis of sulfur in various hydrocarbons indicates that the *G*-values of the formations of mercaptans were of similar magnitudes, with only a little difference caused by the differences in the stabilities of the mercaptans formed.

TABLE I. THE FORMATION OF MERCAPTANS IN THE RADIOLYSIS OF SULFUR WITH HYDROCARBONS AS SOLVENTS (THE CONCENTRATION OF SULFUR IS 0.2 g. PER 50 ml. OF SOLVENT)

Solvent	*G*-value for the mercaptan formation
Hexane	0.06
Cyclohexane	0.07
Mesitylene	0.06
Ethylbenzene	0.06
p-Xylene	0.05
Toluene	0.09
Diphenylmethane	0.013

The interesting feature of Table I is that the radicals formed in the radiolysis of these hydrocarbons as solvents showed similar reactivities toward sulfur. The formation mercaptan is considered to depend on the concentration of sulfur and on the stability of the

radical formed.

In a diphenylmethane solution of sulfur, the *G*-value for the mercaptan formation is about one-fifth that of the other solvents. Probably the radical, formed in the radiolysis of diphenyl methane, is substantially resonance-stabilized and is, therefore, not reactive enough to open the sulfur ring as do the other solvents.

The Effects of Sulfur on the Formation of Hydrogen from Solvents. — The *G*-value of hydrogen formation observed for various solvent solutions of sulfur are given in Table II, together with those from hydrocarbons without sulfur.

The *G*-values of hydrogen formation in both hexane and cyclohexane solutions of sulfur are appreciably decreased by the presence of sulfur. A similar decrease in hydrogen formation has been reported in other cyclohexane solutions with other solutes dissolved in them.[7] Therefore, these decreases do not seem to be due to any specific chemical nature of the added solute but merely to the introduction of some new physical impurities into the system. The *G*-values of hydrogen formation for mesitylene, ethylbenzene, *p*-xylene and toluene do not change regardless of the presence or absence of sulfur in the hydrocarbons. Here the formation of hydrogen is mainly due to the following reaction:

$$H + RH \rightarrow H_2 + R$$

It is, therefore, not affected by the presence of sulfur. A similar observation on the lack of the effect of the hydrogen atom in the formation of hydrogen sulfide has been reported previously in the system of toluene and sulfur.

TABLE II. THE *G*-VALUE OF HYDROGEN FORMATION IN THE RADIOLYSIS OF HYDROCARBONS

Solvent	In the presence of sulfur	Without sulfur
Hexane	1.6	5.0

Synthesis of Fluoro-aryloxy Fatty Acids and Their Mono-mercurated Derivatives

By K. C. SRIVASTAVA

(Received September 17, 1963)

A considerable amount of work has been done in recent years on pest control chemicals, but comparatively very little work has been done on aromatic fluorine compounds which may act as potential pest control chemicals. The synthesis of several fluoro-aryloxy fatty acids and their mercury derivatives has been reported earlier.[1] Some of these compounds have been investigated for their toxicity against "Alternaria solani" with encouraging results.[2] The present investigation deals with the synthesis of some flourine substituted aryloxy fatty acids and their mercury derivatives as possible antifungal agents.

The condensation of 2-chloro-4-fluorophenol and 2-bromo-4-fluorophenol with halogenated fatty acids in sodium hydroxide solution[3] provides a good method for preparation of fluorine substituted aryloxy fatty acids. The fluoroaryloxy fatty acids have been mercurated

by the mtehod of Joshi.[1]

Further work on these compounds, viz. their suitability as fungicides against a wide range of fungi, is in progress.

Experimental

2-Chloro-4-fluorophenol was conveniently prepared by passing chlorine gas (40 g.) into *p*-fluorophenol (135 g.) in presence of iron fillings at room temperature for 7~8 hr., b. p. 60.5~61.5°C/0.1~1 mmHg. Finger et al.[4] reported b. p. 88°C/40 mmHg (Mol. wt., Found : 148.8. Calcd. : 146.55). 2-Bromo-4-fluorophenol was prepared by treating *p*-fluorophenol (50 g.) with bromine (72 g.) in carbon disulphide, b. p. 58~60°C/0.5 mmHg. Finger etal.[4] reported b. p. 89°C/1 mmHg. (Mol. wt., Found : 192.5. Calcd. : 191.01).

α-Fluoro-aryloxy fatty acids were prepared by the method of Joshi et al.[1] The compounds were characterized by the determination of their neutralization equivalents and are listed in Table I.

Preparation of Mercury Derivatives.—The α-fluoro-aryloxy fatty acids were mercurated by the method of Joshi.[1] A mixture of equimolecular quantities of fluoro-aryloxy fatty acids in ethyl alcohol and yellow mercuric oxide in acetic acid was treated for 4 to 6 hr., till a sandy powder separated. The powder was washed with hot water, hot dilute acetic acid and hot ethyl alcohol. The results of elementary analyses are recorded in Table II. It is evident that mono-mercurated derivatives are formed.

Hydrogenation and Hydrogenolysis. VIII.[1] *The Ruthenium-catalyzed Hydrogenation of Aromatic Compounds Containing C–O Linkage to be Easily Hydrogenolyzed*

By Yuzuru TAKAGI, Takatoshi NAITO and Shigeo NISHIMURA

(Received October 23, 1963)

In a series of papers[1,2] it has been shown that (3 : 1) or (7 : 3) rhodium-platinum oxide of Adams' type is a very effective catalyst for selective hydrogenation where one desires to avoid the hydrogenolysis of the C–O linkage. Similar results have also been reported in hydrogenation with 5% rhodium-on-alumina as the catalyst.[3-6]

Only a few examples of the use of ruthenium catalysts in the selective hydrogenation of this kind seem to have been described in the literature. Fairly good yields have been obtained in the hydrogenation of some phenyl-substituted α, ω-glycols,[7] *p*-aminoacetophenone[8] and benzaldehyde[9] to the corresponding saturated glycols or alcohols.

This paper will describe the general applicability of ruthenium dioxide catalyst to the selective hydrogenation of aromatic compounds containing C–O linkage to be easily hydrogenolyzed. This catalyst was also compared with rhodium or (7 : 3) rhodium-platinum oxide in some hydrogenations.

The ruthenium-catalyzed hydrogenation of the aromatic compounds listed in Table I was carried out at 95 to 100°C and under 80 to 100 kg./cm^2 of hydrogen pressure. Usually the use of a solvent was unnecessary, although a small amount of acetic acid was added to neutralize a trace of alkaline substances remaining in the catalyst. Under these conditions most hydrogenations proceed rather rapidly, and good yields of the corresponding saturated alcohols or ethers are obtained. For the successful hydrogenation of benzyl alcohol and benzaldehyde, it was necessary to use ethanol or water as the solvent; otherwise the rate decreased markedly during the hydrogenation. It should be noted that the hydrogenation of these compounds with rhodium or (7 : 3) rhodium-platinum oxide was unsuccessful, even in the presence of alcohol or water.[10] Platinum oxide gives a good yield of cyclohexylcarbinol in the hydrogenation of benzyl alcohol in ethanol containing a small amount of acetic acid,[11] but the rate of the hydrogenation is slow, even under high pressure.

The proportion of hydrogenolysis was somewhat greater with ruthenium dioxide than with rhodium or (7 : 3) rhodium-platinum oxide in the hydrogenation of phenyl ether, hydroquinone dimethyl ether and ethyl *p*-hydroxybenzoate. The probable cause of the higher selectivity of rhodium and (7 : 3) rhodium-platinum oxides over ruthenium dioxide is their use at lower temperature, the former catalysts being sufficiently active at that temperature. It may be explained on the basis of the same reasons that a somewhat larger quantity of *trans*-1, 4-dimethoxycyclohexane and ethyl *trans*-4-hydroxycyclohexane-1-carboxylate was obtained with ruthenium dioxide than with rhodium or (7 : 3) rhodium-platinum oxide.

Benzyl acetate, where the most extensive hydrogenolysis occurred among the compounds investigated, gave a 30% yield of hexahydrobenzyl acetate with ruthenium dioxide. This yield was better than those obtained with rhodium or (7 : 3) rhodium-platinum oxide, though the reaction temperature was higher for the ruthenium catalyst.

Experimental

Catalysts—Ruthenium dioxide was prepared according to the method of Pichler and Buffleb.[12]

Rhodium oxide and (7 : 3) rhodium-platinum

Aminocyclitols. II. Stereochemical Studies of 2-Amino-1,3-cyclohexanediol

By Tetsuo SUAMI and Seiichiro OGAWA

(Received November 1, 1963)

In connection with the previous studies of 2-amino-1, 3-cyclohexanediols,[1] an inversion reaction of *trans-O*-acetyl-*O*-mesyl-2-acetamido-1, 3-cyclohexanediol (II) has been studied. II is prepared by the mesylation of *trans-O*-acetyl-2-acetamido-1, 3-cyclohexanediol (I)[1] with mesyl chloride and pyridine. The displacement of the mesyloxy group of II gives DL-*O*-acetyl-2-acetamido-1, 3-cyclohexanediol (III) when the reaction is carried out with sodium acetate in aqueous 2-methoxyethanol. III is identical with an authentic sample[2] which is prepared from *trans-O*-dimesyl-2-acetamido-1, 3-cyclohexanediol. The demesylation of II takes place in boiling water without sodium acetate, and the product is identified as DL-isomer by converting it to the triacetyl derivative (V).[1,2] Moreover, V is obtained by the acetylation of III with acetic anhydride and pyridine.[2] Since there is only one mesyloxy group in II, the product III should have suffered from Walden inversion only at the place where the mesyloxy group had been linked. Thus, the previously-reported DL-configuration of III[1,2] is further confirmed by the present experiments.

Experimental*

***trans*-*O*-Acetyl-*O*-mesyl-2-acetamido-1, 3-cyclohexanediol (II).**—To a stirred solution of 1.1 g. of I in 15 ml. of pyridine, 0.8 ml. of methanesulfonyl chloride was added under ice cooling. After it had been stirred for 4 hr. at room temperature, the mixture was poured into ice and water. The solution was evaporated untile the precipitate appeared. The precipitate was collected by filtation. The second crop of the product was obtained by the further evaporation of the filtrate; the total yield was 1.05 g. (70%); m. p. 125~128°C. The product was recrystallized twice from acetone to give colorless needles; m. p. 137~139°C.

Found: C, 45.12; H, 6.61; N, 4.84; S, 10.83. Calcd. for $C_{11}H_{19}NO_6S$: C, 45.04; H, 6.53; N, 4.78; S, 10.93%.

DL-*O*-Acetyl-2-acetamido-1, 3-cyclohexanediol (III).—A mixture of 1.0 g. of II, 1.0 g. of anhydrous sodium acetate and 20 ml. of 95% 2-methoxyethanol was refluxed for 10 hr. The mixture was evaporated in vacuo to dryness, and the residue was extracted with boiling acetone. The acetone extract was evaporated, and the residue was recrystallized from ethanol-ether to give 0.28 g. (38%) of crystals (m. p. 151~152°C). The product was found identical with an authentic sample[2] on the basis of its mixed melting point and infrared spectra.

DL-Triacetyl-2-amino-1, 3-cyclohexanediol (V).—A mixture of 0.3 g. of II and 5 ml. of water was refluxed for 5 hr. The mixture was evaporated to

The Synthesis of 7-Methoxyisoflavan-4α-ol[1]

By Naoto INOUE, Shozo YAMAGUCHI and Shizuko FUJIWARA

(Received November 11, 1963)

In a previous paper[2] it was reported that the reduction of 7-methoxyisoflavanone[3] (I) with sodium borohydride gave 7-methoxyisoflavan-4α-ol (II) as a minor product and 7-methoxyisoflavan-4β-ol (III) as the main product. Trans configuration was tentatively assigned to the alcohol II and cis configuration to the alcohol III, mainly on the basis of the reduction mechanism:

I

II

III

The following experiments were undertaken to find a synthetic method which affords only II in a good yield. A solution of 7-methoxyisoflavan[2] (0.25 g.) and lead tetraacetate (0.76 g.) in dry benzene (16.8 g.) was refluxed for 6 hr.; The reaction was run until an iodine-starch test for unreacted lead tetraacetate became negative. From this reaction there was obtained II-acetate (45 mg.), but no III-acetate. Acetic acid was not used as a solvent in this reaction, since the acetate of III had been found to be converted into the acetate of II by mild treatment with acetic acid.[2] 7-Methoxy-4-aminoisoflavan acetate (IV), m. p. 145°C (Found: C, 68.73; H, 6.63; N, 4.27. Calcd. for $C_{18}H_{21}O_4N$: C, 68.55; H, 6.71; N, 4.44%) was prepared from the oxime of I[3] by catalytic hydrogenation over a palladium charcoal catalyst in acetic acid. Hydrochloride (V), m. p. 220°C (Found: C, 65.98; H, 6.12; N, 4.47. Calcd. for $C_{16}H_{18}O_2NCl$: C, 65.86; H, 6.22; N, 4.83%). 7-Methoxy-4-aminoisoflavan, m. p. 111°C (Found: C, 75.38; H, 6.63; N, 5.25. Calcd. for $C_{16}H_{17}O_2N$: C, 75.27; H, 6.71; N, 5.49%). A solution of sodium nitrite (0.24 g. in 10 ml. water) was added, over a 30 min. period, to a stirred solution of V (0.49 g.) in 50% acetic acid (30 ml.) at 0°C. The mixture was then stirred for a further 30 min. at room temperature. After the usual treatment, II (70 mg.) was obtained and III was not.[5] With a view of obtaining II as the result of equilibration, III (300 mg.) was treated with aluminum isopropoxide (300 mg., molar ratio to III : 1.3) in a mixture of isopropyl alcohol (10 ml.) and acetone (0.1 ml.) at 95~100°C for 96 hr. The reaction mixture was poured into ice-water (300 ml.) containing concentrated hydrochloric acid (1 ml.). The precipitates were collected, dried and recrystallized from ethyl alcohol. Needles with an m. p. of 111°C were obtained, and II was not found. The product with an m. p. of 111°C did not show a depression of melting point on admixture with the 4-isopropoxy-7-methoxyisoflavan which had been

The Rate of Vaporization from the Surface of Molten Germanium Dioxide

By Taneki TOKUDA and W. D. KINGERY

(Received November 30, 1963)

Following the measurement of the oxygen diffusion rate in the solid germanium dioxide,[1] the same experiment was tried on the melt. As it was noticed that the vaporization from the melt was much faster than that from the crystal, and as the movement of the boundary surface could not be ignored, the rate of the vaporization, or the movement of the boundary between the melt and the vapor, was measured. In order that the results could be employed for diffusion measurements, the measurements were made under an oxygen pressure of about 150 mmHg, which corresponds to the partial pressure of oxygen in air. The results obtained seem reasonable compared to those for relative substances.

As a starting material, electronic grade germanium dioxide powder made by the Baker & Adamson Co. was employed. The melting points of the substance are 1116°C for the hexagonal, and 1086°C for the tetragonal crystal respectively.[2] The former form is the high temperature stable phase, and the latter, the low temperature stable phase. When the powder is melted down in the air by an electric furnace, it forms a white translucent glass including a lot of air. To expel the bubbles from the glass, it was heated for one hour each at 1150, 1350, 1400, 1480, 1496 and 1560 °C. The best condition was found experimentally to be 1500±10°C. At higher temperatures than this, much of the substance is lost by evaporation. The transparent bubble-free glass thus obtained was used as a sample.

The rate of boundary movement was calculated from the weight decrease of the sample kept in a platinum dish (Fig. 1) during heating by a high frequency furnace working at 10,000 cycles per second. The temperature of the sample was measured by a potentiometer-type optical pyrometer* made by the Leeds & Northrop Co. (Catalog No. 8622c). Absorption by the window made by a pyrex glass plate was corrected employing the experimental curve (Fig. 2). To avoid the condensation of germania and platinum on the surface of the observation glass window, it was protected by a sheet of iron plate held by a magnet outside, and the iron plate was slid aside only during the temperature observation. When this step was taken, no change in the correction curve was observed before or after the run. The other parts of glass, which had not been protected, changed their absorptivity after the run.

The results of the experiment are shown in Table I. The weight loss of the platinum dish was smaller than the experimental error. The relations between the reciprocal of the absolute temperature ($1/T$°K) and the logarithm of

the rate of vaporization are shown in Fig. 3. The rate constant for the vaporization can be expressed by the following formula;

$$k_v = 4.07\times10^6 \exp(-96{,}000/\boldsymbol{R}T)$$

According to Condon,[3] the activation energies of vaporization for the one oxygen atom in both silicon oxide and boron oxide are 22 kcal. The one in germanium(IV) oxide which we obtained is 96/4=24 kcal. The value we obtained here seems quite reasonable. Assuming that Eyring's equation

$$k_v = (1/6)e\lambda^2(\boldsymbol{k}T/\boldsymbol{h}) \exp(\Delta S^{\neq}/\boldsymbol{R})$$

is applicable in this case, where $\boldsymbol{k}$ is the Boltzmann constant, $\boldsymbol{h}$ is the Planck constant, and $\boldsymbol{R}$ is the gas constant, and where the jump distance, λ, is about 2.7Å, the entropy of vaporization, $\Delta S^{\neq}$, can be calculated. Around the melting point (1116°C), it is calculated as follows; $\Delta S^{\neq} = 39.6$ cal. mol^{-1} deg^{-1}.

Sorboses. III. The Acetonization of L-Sorbose by Ketal Interchange[1]

By Kanji TOKUYAMA and Etsuko HONDA

(Received December 5, 1963)

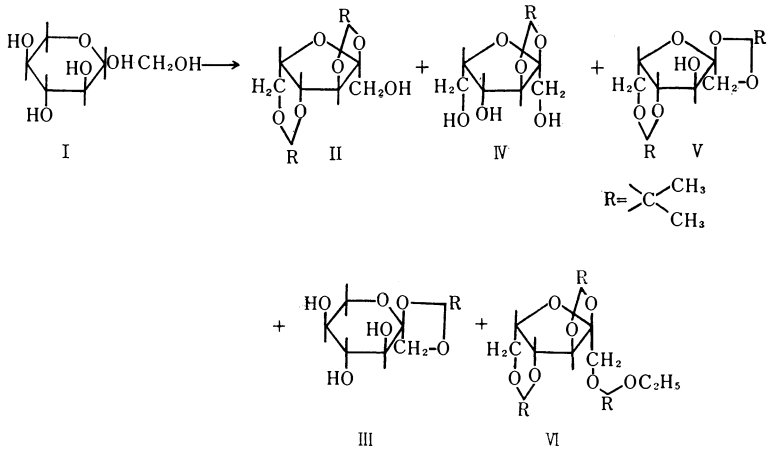
In a previous paper,[1] the reaction mechanism of the acid-catalyzed acetonization of L-sorbose (I) with acetone was reported. The acetonized derivatives proved to be useful materials for the production of L-ascorbic acid. However, when the most important derivative, 2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (II),[2] is formed from I with acetone, it is desirable to remove the water formed during the reaction in order to move the equilibrium toward the favorable side. As azeotropic procedures and the use of various dehydrating agents brought no improvement, we turned to a ketal interchange reaction,[3] that is, to a reaction with a ketal of acetone in the presence of an acid, because no water was formed.

The reaction of I with 2, 2-diethoxypropane[4] (acetone diethyl ketal) in the presence of *p*-toluenesulfonic acid gave a crystalline sirup, whose gas chromatogram exhibited three major components (A, B, and C). L-Sorbose (I), 1, 2-*O*-isopropylidene-α-L-sorbopyranose (III)[1] and 2, 3-*O*-isopropylidene-α-L-sorbofuranose (IV)[1] were detected only as minor spots on thin layer chromatography. The major products, A, B, and C, were separated in pure states by fractional gas chromatography. The infrared absorption spectra showed that all the products had a furanose ring[5] and that the product B was identical wih the desired II.

The product A had a hydroxyl group, which was not considered to be primary because it did not react with trityl chloride. On the basis of these facts and the optical rotation, the structure of the product A was determined to be 1, 2 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (V). The product C had one ethoxy and no hydroxyl group, and it was converted into II by partial hydrolysis. Therefore, the structure of the product C was determined to be 1-*O*-1'-ethoxyisopropyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (VI).

No change in ultraviolet absorption spectra was observed throughout the course of the reaction.[1] The interchange was also achieved from IV,[6] but not from III, which is a key intermediate in the acetonization with acetone in which only II was obtained as a major product. Consequently, we would like to suggest that the acetonization of I with ketal proceeds on the path, I → IV — II → VI, which is quite different from the process of the acetonization with acetone, I → III → II ⇄ IV.

Experimental[7]



The Ketal Interchange of L-Sorbose (I) with 2, 2-Diethoxy-propane. — Dry, powdered L-sorbose (I) (19.5 g.) was added to a solution of *p*-toluenesulfonic acid (0.5 g.) in 2, 2-diethoxypropane (100 ml.). The dissolution of I was completed after stirring it for 4 hr. at room temperature.[8] The solution was neutralized with ethanolic sodium ethylate, the solvent was removed in vacuo, and the residue was distilled to give a pale yellow sirup (12.7 g.) (b. p. 120~160°C/2 mmHg), which crystallized on cooling. The sirup was fractionated by gas chromatography under the following conditions :[9] Column — silicone 550 (HCl-treated). Flow rate—hydrogen, 200 ml./min. Temperature — 200°C. Sample used : 30~33 mg. (5 times). Yields : V, 18 mg., II, 69 mg., and VI, 43 mg. Retention times : V, 14 min., II, 18 min. and VI, 22.5 min. Ratio of area : V, 19 : II, 67 : VI, 44.

V :[10] colorless rods, m. p. 72~73°C (recrystallized from *n*-hexane), $[\alpha]_D^{23}$ −23.9 (*c* 1.059, acetone). Found : C, 55.32 ; H, 7.63. Calcd. for $C_{12}H_{20}O_6$ (260) : C, 55.39 ; H, 7.79%.

VI :[11] colorless needles, m. p. 99~100°C (recrystallized from *n*-hexane), $[\alpha]_D^{25}$ +1.3 (*c* 1.109, acetone). Found : C, 58.25 ; H, 8.73 ; OC_2H_5, 12.97. Calcd. for $C_{17}H_{30}O_7$ (346) : C, 58.94 ; H, 8.73 ; OC_2H_5, 13.00%.

Partial Hydrolysis of VI. — The mixture of VI (170 mg.) and 60% acetic acid (2 ml.) was warmed at 80°C for 40 min. After cooling, the solution was made alkaline with sodium carbonate, the

SHORT COMMUNICATIONS

*Stable Radicals of a High Molecular Weight Produced by Oxidizing Diphenylamine with Vanadium Pentoxide**

By Kozo HIROTA and Yoichi KAGEYAMA

(Received November 19, 1963)

In a previous report[1] we reported obtaining an absorbed radical very stable, even in air, by oxidizing diphenylamine at 150°C with vanadium pentoxide; we considered this radical to be $(C_6H_5)_2NO\cdot$, because the ESR signal measured at $g=2.0$ showed a hyperfine structure consisting of a triplet.

The absorbates extracted with carbon disulfide and/or benzene were brown and also showed an ESR signal at $g=2.0$, which had a hyperfine structure consisting of a quintet and splitting equally (5 gauss). However, as Fig. 1 shows, this spectrum is different from that of DPPH in solution, although is very similar to the spectra of DPPH in semifluid Duco cement[2]; moreover, the coupling constant of the nitrogen atom is smaller than that of DPPH and diphenyl nitric oxide. These findings suggest the production of a large radical, whose anisotropic hyperfine interaction with two nitrogen nuclei is involved. Therefore, some reaction seems to have occurred in or after the process of dissolution between the radicals adsorbed on the surface.

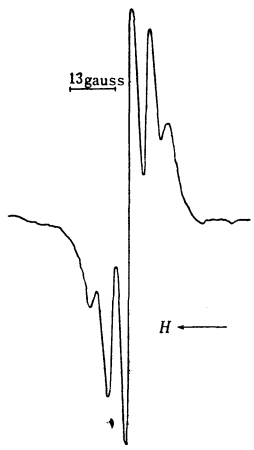

Fig. 1. The ESR spectrum of the products in carbon disulfide solution.

After purification, the solvent was evaporated. A dark brown powder then precipitated which also showed a sharp signal of the Lorentzian type ($\Delta H_{msl}=8$ gauss) at $g=2.0$; its intensity ($10^{19\sim20}$ spins/g.) did not change, even after heat treatment in air at 100°C for more than 300 hr. The cryoscopy in benzene showed the molecular weight to be between 600 and 3000. If the powder was left alone in the solution at 100°C, its molecular weight increased and it became insoluble in solvents. The elemental analysis of a sample (molecular weight: 600~700) showed the composition to be: C, 85.04; H, 5.66; N, 8.36% (total, 99.06%); calculated for $C_{48}H_{38}N_4$: C, 85.92; H, 5.71; N, 8.35%. Therefore, this substance has a composition which corresponds approximately to a condensed product of four diphenylamine molecules. Moreover, the ESR measurements show that one-tenth~one-hundredth of its total molecules are free radicals. The insoluble substance did not melt at 150°C, but slightly sintered at 200°C. It was semiconductive, because its specific resistance was 2.5×10^9 and 8×10^7 ohm·cm. at 20°C and 100°C respectively. The product showed infrared bands at 1270,** 820 and 3420 cm^{-1}, corresponding to ν_{C-N} of a tertiary nitrogen, δ_{C-H} of the hydrogen of a paradisubstituted benzene ring, and ν_{N-H} of the terminal hydrogen respectively.

* A part of this paper was presented at the ESR Meeting, Kyoto, November, 1963.

1) K. Hirota, Y. Kageyama and K. Kuwata, This Bulletin, **36**, 875 (1963).

2) N. W. Lord and S. M. Blinder, *J. Chem. Phys.*, **34**, 1963 (1961).

** In our measurements, triphenylamine showed a strong band at 1270 cm^{-1} which did not appear in the spectrum of diphenylamine.

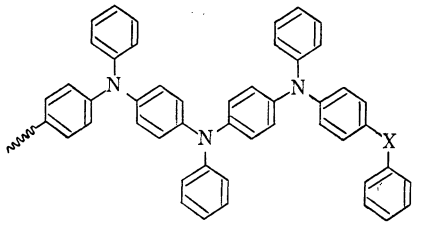

Fig. 2.

In short, the product includes stable radicals of a high molecular weight. Judging from the above discussion, the non-radical and radical structures of the product may be considered to be as shown in Fig. 2, N–H and N· respectively. However, as the radical species, another structure (X=NO·) is possible, for this structure is considered to be more stable.

A Spectrophotometric Determination of Mercury(II) or Cadmium(II) by Solvent Extraction with 2, 2'-Dipyridyl Iron(II) Chelate

By Yuroku YAMAMOTO and Keiya KOTSUJI

(Received December 23, 1963)

The present paper will report on a continuation of our study concerning the solvent extraction of an anion with a metal chelate cation and its application to a spectrophotometric determination of the anion. Diamond et al.[1] and Kuznetsov[2] have described in their reviews that a large anion can be extracted into a polar solvent such as nitrobenzene with a large cation of onium or metal chelate. However, there seems to have been no mention of the solvent extraction of the anionic complex of a metal with a metal chelate cation. In our study, it is found that mercury (or cadmium) can be extracted into 1, 2-dichloroethane with 2, 2'-dipyridyl iron(II) chelate if the aqueous solution contains a large excess of iodide ions. Figure 1 shows the absorption spectra in the organic phase. Curve 1 (or 2) is a spectrum of the extract when mercury(II) (or cadminm) is absent in the aqueous solution. Curve 3 (or 4) is that of the extract when a small amount of mercury (or cadmium) is present. It may be observed that the presence of mercury(II) or cadmium ions leads to a considerable increase in the extraction. The absorbance maximum of the chelate cation in the organic phase is at 526 mμ. The maximum of the chelate cation in the aqueous solution was at

2) B. I. Kuznetsov, "The Chemical Basis for the Photometric Method by Solvent Extraction in Analytical Chemistry," State Printing Office of USSR, Moscow (1963), p. 11.

522 mμ, which coincides with the reported value.[3] This red shift of the spectrum may be attributed to the effect of the association of the cation and the anion in the organic layer. Feigl[4] has shown that 2,2'-dipyridyl iron(II) chelate can be precipitated as a red crystal with a divalent complex anion, such as tetra-iodo-mercury(II) or cadmium. From these facts, it is quite likely that a chemical form of the extracted species is $Fe(dip)_3 \cdot HgI_4$ or $Fe(dip)_3 \cdot CdI_4$. To obtain optimum conditions for the determination of mercury(II) or cadmium, various factors were studied: the effect of the concentration of iron(II) ions and dipyridyl, the pH of the solution, the stability of the color, the shaking time, and the presence of diverse ions. The recommended procedure for the calibration curve is as follows:

1) For Cd: 2.0 ml. of the 2,2'-dipyridyl solution (8×10^{-3} M), 2.0 ml. of the ferrous ammonium sulfate solution (2×10^{-3} M), 2.0 ml. of the sodium acetate solution (3 M), 7.0 ml. of the potassium iodide solution (0.3 M), and varying amounts (1~7 ml.) of the standard cadmium solution (10 p. p. m.), were mixed, and the pH of the solution was adjusted to 6.5. After it had been diluted to 25 ml. with distilled water, the solution was shaken for 4 min. with 10.0 ml. of dichloroethane. The organic layer was then transferred to a flask containing 1 g. of anhydrous sodium sulfate, and the absorbance of the solution was measured at 526 mμ using the reagent blank as a reference. Beer's law is followed in the range of 0.4~2.8 p. p. m. (Fig, 2).

2) For Hg: 3.0 ml. of the 2,2'-dipyridyl solution (8×10^{-3} M), 3.0 ml. of the ferrous ammonium sulfate solution (2×10^{-3} M), 2.0 ml. of the sodium acetate solution (3 M), 7.0 ml. of the potassium iodide solution (0.3 M) and varying amounts of the standard mercury(II) solution (10 p. p. m.) were mixed, and the pH of the solution was adjusted to 6.5. After it had been diluted to 25 ml. with distilled water, the solution was shaken for 6 min. with 10.0 ml. of the organic solvent. Then it was treated as in the procedure for cadmium. Beer's law is followed in the range from 0.4 to 2.4 p. p. m. Although several methods for the determination of mercury or cadmium are presented in the literature,[5] the proposed method is based on a new principle.

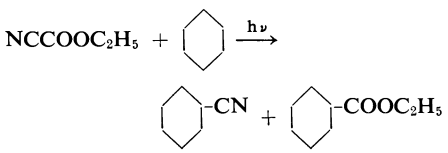
The Direct Introduction of Cyano and Ethoxycarbonyl Radicals into Cyclohexane by a Photochemical Reaction

By Tamotsu TOMINAGA, Yoshinobu ODAIRA and Shigeru TSUTSUMI

(Received February 28, 1964)



Since the cyanation of cyclohexane by a cyano radical generated photochemically from cyanogen chloride was first attempted by Müller,[1] increasing interest has, from the standpoint of organic synthesis, been shown in the study of the new direct method of introducing the important functional groups (such as cyano and alkoxycarbonyl) by radical reaction.

The present investigation was undertaken to examine the possibility of the direct and concurrent introduction of cyano and ethoxycarbonyl radicals into hydrocarbon by means of photochemical reaction.

For this purpose, ethyl cyanoformate was selected as a source of the above radicals. It has been shown by previous investigations[2,3] that the primary steps occurring in the photolyses of various alkyl esters are as follows:

$$\begin{aligned} RCOOR' + h\nu &\rightarrow RCO\cdot + \cdot OR' \\ &\rightarrow R\cdot + \cdot COOR' \\ &\rightarrow RCOOH + \cdot R'' \end{aligned}$$

Since the above steps may be applicable in the decomposition of ethyl cyanoformate in the presence of cyclohexane, both cyano and ethoxycarbonyl derivatives may be expected to be produced by recombinations between the cyano or ethoxycarbonyl radicals that were generated by the above processes and the cyclohexyl radical formed by hydrogen abstraction from cyclohexane.

The irradiation of a solution of ethyl cyanoformate (99 g.) in cyclohexane (252 g.) with a 600 W. high pressure mercury arc lamp was carried out under nitrogen for 48 hr. at room temperature. During the irradiation, the continuous evolution of gas was observed, and at the end of the reaction, 4000 ml. of gas, consisting of carbon dioxide, carbon monoxide and methane, in the ratio of 30 : 8 : 1 was collected and analyzed, by gas chromatography.

Moreover, the 0.56 g. of hydrogen cyanide produced was determined quantitatively as a cyanide ion by volumetric analysis using silver nitrate. The conversion percentage of the reaction was 38.4% and, as the liquid products a cyanide (1.8 g.) and an ester (3.5 g.) were obtained, accompanied by propionitrile (4.2 g.), ethanol (3.4 g.), ethylcyclohexane (2.5 g.) and bicyclohexyl (0.5 g.). The above cyanide and ester were identified as cyclohexyl cyanide and ethyl cyclohexanecarboxylate respectively by gas chromatographic and infrared analyses and by the mixed melting point tests using an authentic cyclohexanecarboxamide (m. p. 184~186°C) with the amides derived separately from the above compounds.

Although no quantitative interpretation of the results has been given because of the complexity due to the many different radicals generated in the primary steps, the direct introduction of cyano and ethoxycarbonyl radicals has been successful.

In this connection, it would be interesting to study the direct-introducing reaction of the α-keto ester radical, which should be more stable than the ester radical.

The Sensitivity of Radioactivation Analysis by a Low Level Neutron Source

By Yuzuru KUSAKA, Haruo TSUJI and Takayoshi ADACHI

(Received February 5, 1963)

General discussions of the sensitivities attainable with the thermal neutron activation analysis of various elements have been undertaken in several reports.[1-7] Most of their sensitivity estimations have, however, been made for reactor irradiation, based on theoretical computation and expressed with the radioactivities at the end of the irradiation. Although these data are very useful for rough estimations of the sensitivities of each element, even in a low-level neutron flux, they often do not coincide exactly with the experimental values because of the decay effect in the short-lived nuclides to be measured, because of the differences in the kind of detector used, and so on. Moreover, in some reports long-time irradiations such as those for one week or even one month have been adopted. These durations are too long for routine analysis.

The use of a low level neutron source is suited to a " non-destructive " assay of a macro amount of elements possessing high-neutron cross section. In such cases, gamma ray measurement, for example, the use of a well-type sodium iodide scintillator, is a useful counting method. Moreover, the induced radioactivity, in general, is so weak that the counting period must be longer than in the case of a high neutron flux.

In such practical work using a low-level neutron source, therefore, the sensitivity values previously reported must be re-evaluated experimentally. This paper will describe some experimental findings on the sensitivities obtained by irradiation and measurement procedures which are designed to be suitable for a routine analysis of all the elements under consideration. The results of thermal neutron flux determination are also included.

Experimental

Neutron Source. — The source consisted of a mixture of 84.2 mg. radium bromide (49.3 mg. as a radium element) with beryllium, which was sealed in a platinum tube (length ; 40 mm.; diameter, 5 mm.; thickness, 0.5 mm.) with a polyethylene outer tube (length, 85 mm.; diameter, 16 mm.).

Neutron Irradiation.—The geometry of the paraffin moderator block used in this work was the same as that in Ref. 8. The irradiation periods for all the samples under consideration were 10.0 min., 1.0 hr. and 17.0 hr.

Radioactivity Measurement. — The radioactivity induced in the sample was measured by a well-type sodium iodide scintillation detector (Harshaw, 4.45 cm.ϕ×5.08 cm. h ; hole, 1.91 cm.ϕ, 3.81 cm. deep) with a No. 6097F E.M.I. photomultiplier tube. After a 20.0 sec. interval after the end of irradiation, the measurement was started and the gross gamma ray counting was done for 3.0 min., 10.0 min. and 30.0 min.

The measurement of the absolute disintegration rates for the determination of thermal neutron flux was made with a 4π gas flow counter (Kobe Kogyo GM-917) using Q gas.

Irradiation Sample.—A definite amount of the sample was put in a polyethylene capsule (inner diameter, 16 mm.; length, 86 mm.; thickness, 1 mm.) and irradiated. The chemical forms of the samples were as follows: silver, aluminum, gold, bismuth, calcium, cadmium, cerium, cobalt, chromium, copper, iron, germanium, hafnium, iodine, indium, iridium, lithium, magnesium, manganese, molybdenum, nickel, phosphorus, platinum, rhodium, ruthenium, sulfur, antimony, selenium, silicon, tin, tantalum, tellurium, thallium, tungsten, zinc and zirconium as the elements; arsenic, dysprosium, europium, gallium, mercury, lanthanum, niobium, lead, praseodymium, samarium, titanium, vanadium and yttrium as the oxides, cesium, potassium, sodium and rubidium as the carbonates; barium and strontium as the acetates; bromine as the dibromobenzene; chlorine as the hydrogen chloride; fluorine as the calcium fluoride; nitrogen as the ammonium nitrate, and oxygen as the water. All the samples were chemically pure.

of various thicknesses as the neutron monitors, the thermal neutron flux in the inside bottom of the polyethylene sample capsule in the paraffin block was determined.

For the determination of the absolute disintegration rates, a conventional 4π counting method[9] was applied. In the observed counting rates, some decreasing effects based on a self-absorption effect for soft beta rays and a self-shielding effect for thermal neutrons were recognized in the relatively thick foils. To correct them, an extrapolation to zero thickness was applied, and the extrapolated value was used in the calculation of the neutron flux. The extrapolations in the case of the indium and gold foils are shown in Figs. 1 and 2.

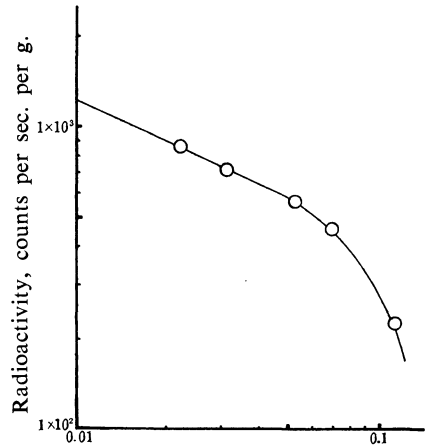

Fig. 1. 4π counting of gold foil.
(Saturation factor in irradiation is 1.0.)

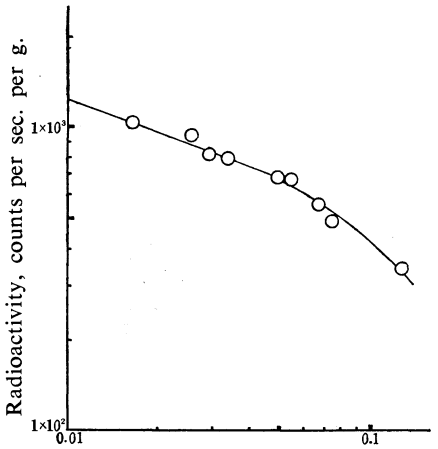

Fig. 2. 4π counting of indium foil.
(Saturation factor in irradiation is 0.5.)

9) G. Friedlander and J. W. Kennedy, "Nuclear and Radiochemistry," John Wiley & Sons, Inc., New York (1955), p. 293.

In obtaining the results, the thermal neutron fluxes were calculated as 4.1×10^3 neutrons per cm^2 per sec. in the indium foil experiment and 4.8×10^3 in the gold foil one. On the basis of these data, 4.5×10^3 was adopted as the probable neutron flux.

The Radioactivation Degree of the Elements. — All the experimental results are shown in Figs. 3, 4 and 5, in the lump. In these figures, the counting rates obtained by 3.0 min., 10.0 min. and 30.0 min. measurments for each element are plotted against the half-life of the induced radioactivity. However, when plural radioactive nuclides are produced in an element, the half-life is represented with that of the radioactivity, which is strongest at the end of the irradiation. No ambiguous radioactivities of less than 100 counts in the measurments are plotted in the figures.

If the detection limit in the radioactivation analysis is assumed to be the number of grams of an element required to give about 100 counts in 10 min., the detection limits summarized in Tables I, II and III can be obtained. In the tables, the elements listed in each group of detection limits are arranged in the order of decreasing sensitivity, except for "more than 1 g."

Discussion

Because of the sodium iodide scintillation-counting method, such pure beta emitters as Tl-206 and such soft gamma emitters with a high internal conversion efficiency as Co-60m and Ir-192m were measured with a low counting efficiency. For such elements a beta-ray counting method using a Geiger counter would be more suitable.

The self-shielding effect for thermal neutrons, although important in certain cases, was not considered in the treatment of the sensitivity data.

Furthermore, in a practical application, one must remember that an appropriate cooling time after the irradiation allows one to discriminate the nuclides with different half-lives; gamma ray spectrometry is also useful for the discrimination of each species.

It is possible to improve the sensitivities by using more sensitive gamma ray detectors or higher neutron fluxes. However, even then the relative sensitivity value should not change from the data reported here. Therefore, this data should be useful in general radioactivation analysis using a low-level neutron source.

The cost of this research was partly defrayed by the Scientific Research Expenditure Fund of the Ministry of Education, to which the authors' thanks are due.

Studies of Synthetic Isoflavanones. V. The Reduction of Isoflavanones[1]

By Naoto INOUE

(Received June 5, 1963)

In the preceding papers of this series, synthetic methods,[2,3] alkaline degradation,[4] and dehydrogenation with *N*-bromosuccimide[5] of isoflavanones have been reported. The present study was undertaken to examine the reduction of isoflavanones. Of the isoflavonoid group, isoflavan-4-ol is one level lower in oxidation state than isoflavanone, and pterocarpin (IV) and homopterocarpin[6,7] (V) are regarded as the derivatives of isoflavan-4-ol. The substance with the lowest oxidation level in this group is isoflavan, and its 7, 4'-dihydroxy derivative (VI) was found in the urine of a mare by Anderson and Marrian.[8] Therefore, the reduction of isoflavanones is of interest not only for organic chemists but also for biochemists.

White and Bradbury[9] carried out the hydrogenation of 7, 4'dimethoxyisoflavanone (III) over platinum oxide in acetic acid and obtained 7, 4'-dimethoxyisoflav-3-en (VII), but they did not isolate 7, 4'-dimethoxyisoflavan-4-ol (III'). In their work, 2-methyl-7-acetoxy-4'-methoxyisoflavone and 2-methyl-7, 4'-diacetoxyisoflavone were hydrogenated to the corresponding isoflavan-4-ols by the same method, and 2-methyl-7, 4'-dimethoxyisoflavone, to the corresponding isoflav-3-en, which was also formed by the reduction of the same isoflavone with lithium aluminum hydride. Prillinger and Wessly[10] obtained 7-hydroxy-4'-methoxyisoflavan, 7, 4'-dihydroxyisoflavan, and 7, 4'-dimethoxyisoflavan (III'') by the catalytic hydrogenation of the corresponding isoflavones over a palladium-charcoal catalyst in acetic acid. The Clemmensen reduction of isoflavanones was carried out by Marrian and Anderson[8] and by King et al.[11] They obtained 7, 4'-dimethoxyisoflavan and 5, 6, 7, 4'-tetramethoxyisoflavan respectively. Adkins and Mozingo[12] hydrogenated 2-methyl-7-hydroxyisoflavone to 2-methyl-7-hydroxyisoflavan at high pressure with a copper chromite catalyst. Suginome and Iwadare[13] reduced 2'-hydroxyisoflavone with lithium aluminum hydride or sodium borohydride and obtained a substance with the skeletal structure of pterocarpin. Since carbon atoms at the 3- and 4- positions of isoflavan-4-ol are asymmetric carbons, there must be cis and trans isomers with reference to the phenyl group at C_3 and the hydroxyl group at C_4. In the reduction of flavanone, either one or the other of the stereoisomers of flavan-4-ol is obtained by changing the method of reduction; it has, therefore, been assumed that different kinds of stereoisomeric isoflavan-4-ols might be obtained by changing the reduction method, as in the case of flavanone. Therefore, isoflavanone (I), 7-methoxyisoflavanone (II), and 7, 4'dimethoxyisoflavanone (III) were reduced by various methods.

The catalytic hydrogenation of isoflavanone (I) over Raney nickel gave a compound with a m. p. of 75°C. Catalytic hydrogenation with platinum oxide in acetic acid, Meerwein-Ponndorf reduction, or reduction with sodium borohydride gave the same product, and the other stereoisomeric isoflavan-4-ol was not obtained. This reduction product was characterized as isoflavan-4-ol (I') on the basis of its infrared spectrum and the analytical results. The catalytic hydrogenation of I over palladized charcoal in ethanol gave a substance with a m. p. of 54°C, which indicated no stretching vibration band of the hydroxyl group in its infrared spectrum and which was found to be isoflavan (I''), which was also obtained by the Clemmensen reduction of I.

7-Methoxyisoflavanone (II) was hydrogenated over Raney nickel, at ordinary temperature and pressure, to 7-methoxyisoflavan-4-ol (II') with a m. p. of 144°C, which was characterized on the basis of its infrared spectrum and from the analytical results. Meerwein-Ponndorf reduction gave the same product. However, when a larger quantity of II was used and when the reaction time was prolonged, needles with a m. p. of 111°C, besides the main product of II', separated from the mother liquor of the recrystallization of the reduction product. The infrared spectrum of this substance indicated the absence of the hydroxyl group, and its analytical results were consistent with 4-isopropoxy-7-methoxyisoflavan (VIII). The formation of isopropyl ether was reported in the Meerwein-Ponndorf reduction of dibenzalacetone (X) and 9, 9-dimethylanthrone-10 (XI).[14]

X

XI

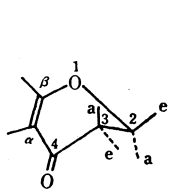
The reduction of II with sodium borohydride in ethanol gave an alcohol (II') with a m. p. of 144°C along with a minor product of needles with a m. p. of 131°C. The infrared spectrum of this reduction product with a lower melting point demonstrated the presence of a hydroxyl group and the absence of a carbonyl group, and its analytical results agreed with those of II'. The mixed melting point of the two reduction products was depressed more than 10 degrees. Stretching vibrations of the hydroxyl group in these two reduction products exist at different frequencies in KBr and at the same frequencies in chloroform or carbon tetrachloride, as is shown in Table I.

TABLE I. OH STRETCHING VIBRATION OF 7-METHOXYISOFLAVAN-4-OLS

	m. p. 144°C	m. p. 131°C
νOH (KBr)	3570, 3450 cm^{-1}	3310, 3240 cm^{-1}
νOH (CCl_4)	3550, 3450 cm^{-1}	3550, 3450 cm^{-1}

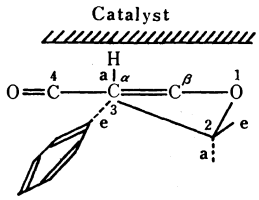
These two reduction products gave different infrared absorption curves in a finger-print region in KBr and in carbon tetrachloride but similar ultraviolet spectra with an absorption maximum at 280 mμ. On the basis of this evidence, the compounds with melting points of 144°C and 131°C were considered to be stereoisomers of 7-methoxyisoflavan-4-ol, and the product with a m. p. of 144°C was designated as the β-compound and that with a m. p. of 131°C, as the α-compound. The acetylation of the β- and α-compounds with acetic anhydride in the presence of pyridine gave acetates with melting points of 121°C and 111°C respectively. The mixed melting point of the two acetates depressed more than 10 degrees. The catalytic hydrogenation of II over a palladium-charcoal catalyst in ethanol afforded 7-methoxyisoflavan (II'') with a m. p. of 111°C, which was also obtained by the Clemmensen reduction of II.

The catalytic hydrogenation of 7, 4'-dimethoxyisoflavanone (III) over Raney nickel yielded a compound with a m. p. of 143°C, which was identified from its infrared spectrum and analytical results as 7, 4'-dimethoxyisoflavan-4-ol (III'). III' was also obtained by the reduction of III with sodium borohydride in ethanol, but the other stereoisomer of III' has not been obtained to date. The Meerwein-Ponndorf reduction of III afforded III'. When a larger quantity of III was used for this reduction and when more time was required for the disappearance of a positive acetone test, a product with a m. p. of 75.5°C was obtained which was identified as 4-isopropoxy-7, 4'-dimethoxyisoflavan (IX) on the basis of its infrared spectrum and analytical results.



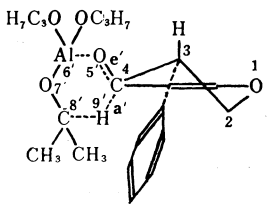
Further, a very small quantity of 7, 4'-dimethoxyisoflav-3-en (VII) separated from the mother liquor of recrystallization. Both II and III afforded a large quantity of unchanged starting material when hydrogenated over platinum oxide in acetic acid even after the absorption of one mole of hydrogen. This phenomenon may perhaps be ascribed to the hydrogenation of the benzene ring at an early stage of the reduction. In the case of the

14) A. L. Wild in "The Organic Reactions," Ed. by R. Adams, Vol. II, John Wiley & Sons, New York (1944), p. 190.

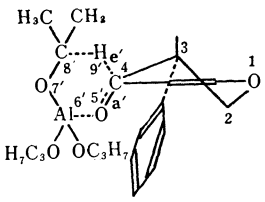


hydrogenation of I over platinum oxide in acetic acid, the starting material was not recovered and isoflavan-4-ol was obtained in about a 70% yield.

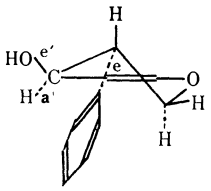
Isoflavanone is considered to have the conformation shown in XIIa and XIIb, a conformation which is in accordance with that of flavanone proposed by Phillibin and Wheeler[15] and by Mitsui and Kasahara.[16] The two hydrogen atoms at C_2 are equatorial and axial, and five atoms, O_1, C_3, C_4, C_α and C_β, are coplanar; only C_2 is out of the plane. The conformation of the phenyl group in the 3-position of isoflavanone is assumed to be equatorial, as usual.



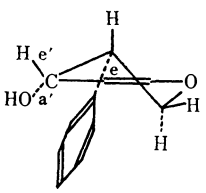
According to Mitsui and Kasahara[16], the Meerwein-Ponndorf reduction of flavanone gave flavan-4α-ol exclusively, contrary to the results of catalytic hydrogenation or of reduction with complex metal hydrides. However, in the case of isoflavanone, the Meerwein-Ponndorf reduction yielded the same isoflavan-4-ol as the product of catalytic hydrogenation with Raney nickel or that of reduction with complex metal hydride. This difference in the results of reduction between flavanone and isoflavanone may be caused by the difference in the positions of the phenyl group in these compounds. In the case of isoflavanone, the steric effect of the phenyl group at C_3 on C_4 carbonyl carbon must be considered. For example, 2, 4-dinitrophenylhydrazine reacts with isoflavanones much slower than with flavanones[2], and the Girard P reagent does not react with isoflavanone,* although it does react with flavanone.



XIIa



XIIb



XIIc

XIId

trans
XIIe

cis
XIIf

The transition state of the Meerwein-Ponndorf reduction is regarded as a six-membered ring consisting of a carbonyl group, aluminum, and one of the three isopropoxy groups shown in XIIc and XIId.[17] The isopropyl group which transfers its hydrogen ($H_{9'}$) to carbonyl carbon (C_4) is half fixed and exists nearer to the pyran ring than the other two isopropyl groups, which can move relatively freely. As XIIc shows, when the C_4–$O_{5'}$ bond in the cyclic transition state is quasi-equatorial (e'), two methyl groups on carbon atom 8' are close to the phenyl group in the 3-position and steric interference occurs between these groups. Because of this steric hindrance, the transition state shown in XIIc would have a higher potential energy and may be less stable. On the other hand, in the transition state shown by XIId, which would form a product with a quasi-axial hydroxyl group (XIIf), the two methyl groups on the carbon atom 8' are distant from the phenyl group in the 3-position and there is no steric interference between these groups; the compound XIId is, therefore, more stable than XIIc. For this reason the isoflavan-4-ols which are formed by the Meerwein-Ponndorf reduction of isoflavanones are likely to be cis compounds with a quasi-axial C_4 hydroxyl group, and 7-methoxyisoflavan-4α-ol, which cannot be obtained by the Meerwein-Ponndorf method, would be a trans isomer with a quasi-equatorial hydroxyl group (XIIe).

As has been indicated in Table I, the stretching vibrations of 7-methoxyisoflavan-4α-ol exist at lower frequencies than that of 4β-ol in the KBr disk, but they are in equal posi-

tions in carbon tetrachloride. This phenomenon indicates that 7-methoxyisoflavan-4α-ol is associated intermolecularly by hydrogen bonding in the KBr disk, but that the β-alcohol is not associated. Since 7-methoxyisoflavan-4β-ol has a cis C_3 phenyl group, the intermolecular association of the C_4 hydroxyl group by hydrogen bonding would be difficult. However, it would not be difficult for the hydroxyl group of *trans*-isoflavan-4-ol to associate intermolecularly by hydrogen bonding, since the phenyl group in the 3-position would not interfere with the trans C_4 hydroxyl group.

The results of the catalytic hydrogenation of isoflavanone can be explained well by the theory proposed by Mitsui and his co-workers.[16,18] As XIIb shows, isoflavanone is adsorbed by a catalyst on the side opposite that where the axial hydrogen in the 2-position projects. According to Mitsui and Imaizumi[18] the first step in the catalytic hydrogenation is the addition of one proton and two electrons, released from the catalyst surface, to the carbonyl carbon atom. In the case of isoflavanone, the conformation of the thereby-formed C–H bond at C_4 would be quasi-equatorial, and the subsequently-formed C–O bond at C_4 would project in the quasi-axial orientation (XIIb, XIIf), away from the catalyst surface. The phenyl group in the 3-position is equatorial and would be cis to the quasi-axial hydroxyl group in the 4-position. Consequently, the isoflavan-4-ol formed by the catalytic hydrogenation of isoflavanone would be the cis isomer. The experimental determination of the cis and trans configurations of 7-methoxyisoflavan-4α-ol and -4β-ol is in progress.

Experimental*

Isoflavan-4-ol.—*1) The Catalytic Hydrogenation of Isoflavanone*[2] *over Raney Nickel.*—When a solution of isoflavanone (0.5 g.) in ethanol (100 ml.) was shaken with hydrogen at atmospheric pressure and at 28°C in the presence of Raney nickel (0.5 g.) for 80 min., 55 ml. (1 equiv.) of hydrogen was absorbed. After the separation of the catalyst, the solution was concentrated to a small volume and diluted with water. The precipitate was collected by filtration, dried, and recrystallized from petroleum ether to prisms (m. p. 75°C). Yield, 0.38 g.

Found: C, 79.81; H, 6.30. Calcd. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%.

A mixture of this alcohol (0.2 g.), acetic anhydride (2 ml.), and dry pyridine (1 ml.) was set aside for 20 hr. at room temperature. The solution was then diluted with water (100 ml.), and the precipitate was recrystallized from petroleum benzine. 4-Acetoxyisoflavan of m. p. 93°C was obtained almost quantitatively.

Found: C, 75.83; H, 5.92. Calcd. for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

2) Over Platinum Oxide.—Isoflavanone (1.0 g.) in acetic acid (40 ml.) over platinum oxide (0.2 g.) absorbed 230 ml. of hydrogen in 28 min. at 28°C. The evaporation of acetic acid from the filtered solution under reduced pressure gave a residue which was crystallized from petroleum benzine as needles with a m. p. of 75°C. Yield. 0.7 g.

3) Meerwein-Ponndorf Reduction.—A mixture of isoflavanone (1.0 g.), aluminum isopropoxide (3.7 g.), and dry isopropanol (30 ml.) was heated in a boiling water bath under a Hahn partial condenser. After one hour, another 10 ml. of isopropanol was added and heating was continued for a further 30 min. After the removal of isopropanol in vacuum and the addition of a small amount of water, the syrup was acidified with dilute sulfuric acid and extracted with ether. From the ether solution, isoflavan-4-ol with a m. p. of 75°C (0.8 g.) was obtained after the usual treatment.

Isoflavan. — *1) The Catalytic Hydrogenation of Isoflavanone over a Palladium-charcoal Catalyst.* — Isoflavanone (1.0 g.), palladium-charcoal (10%, 0.3 g.), and ethanol (100 ml.) were shaken with hydrogen at atmospheric pressure until 50 ml. had absorbed. After the removal of the catalyst and ethanol, isoflavan (0.75 g.) was obtained as needles (m. p. 55°C).

Found: C, 85.79; H, 6.78. Calcd. for $C_{15}H_{14}O$: C, 85.68; H, 6.71%.

2) Clemmensen Reduction.—Concentrated hydrochloric acid (5 ml.) was added to a cooled mixture of isoflavanone (0.3 g.), amalgamated zinc dust (0.5 g.), and acetic acid (20 ml.) over a 5 min. period. The mixture was left for 24 hr. at room temperature and poured into water (100 ml.). Isoflavan with a m. p. of 54°C was crystallized from ethanol. Yield, 0.22 g.

7-Methoxyisoflavan-4-ol.—*1) The Catalytic Hydrogenation of 7-Methoxyisoflavanone*[2,3] *over Raney Nickel.* — When 7-Methoxyisoflavanone (1.0 g.), Raney nickel (1.2 g.) and ethanol (60 ml.) were shaken with hydrogen at 28°C in atmospheric pressure for 4 hr., 139 ml. (1.43 mol.) of hydrogen was absorbed. When this was worked up in the usual way and crystallized from ethanol, 7-methoxyisoflavan-4β-ol of m. p. 144°C (0.4 g.) separated.

Found: C, 75.14; H, 6.44. Calcd. for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29%.

The acetylation of this alcohol with acetic anhydride in the presence of pyridine at room temperature gave 7-methoxy-4-acetoxyisoflavan (m. p. 121°C) (from ethanol).

Found: C, 72.75; H, 6.12. Calcd. for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%.

2) Meerwein-Ponndorf Reduction.—A solution of 7-methoxyisoflavanone (1.0 g.) and aluminum isopropoxide (2.5 g.) in anhydrous isopropanol (30 ml.) was heated under a Hahn partial condenser in a boiling water bath. About 20 ml. of isopropanol distilled out in one hour, and an acetone test with 2, 4-dinitrophenylhydrazine was negative. Most of

18) S. Mitsui and S. Imaizumi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon kagaku Zassi*), **77**, 1516 (1956).

* All melting points are uncorrected.

the excess isopropanol was removed under reduced pressure. The cooled residue was hydrolyzed with dilute sulfuric acid. The separated crystals were collected, dried, and recrystallized from ethanol. 7-Methoxyisoflavan-4β-ol (m.p. 144°C) was obtained. Yield, 0.65 g.

3) Novel Meerwein-Ponndorf Reduction.—A solution of 7-methoxyisoflavanone (1.5 g.) and aluminum isopropoxide (3.0 g.) in anhydrous isopropanol (50 ml.) was heated under a Hahn condenser as described above. In 3.5 hr., 38 ml. of isopropanol distilled out and an acetone test was negative. After the addition of another 15 ml. of isopropanol, 7 ml. of liquid distilled out in one hour. The usual treatment gave crystals with a m. p. of 143.5°C (0.9 g.); those were undepressed by admixture with the 7-methoxyisoflavan-4β-ol obtained in 1) and 2). From the mother liquid, needles (m. p. 111°C, 0.2 g.) were obtained which were characterized as 4-isopropyl ether of 7-methoxyisoflavan-4-ol.

UV $\lambda_{max}^{C_2H_5OH}$ 280 mμ (log ε 3.45).

Found: C, 76.44; H, 7.56. Calcd. for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%.

4) Reduction with Sodium Borohydride.—A solution of 7-methoxyisoflavanone (10.0 g.) and sodium borohydride (1.2 g.) in ethanol (600 ml.) was stirred for 2 days at 36°C. The ethanol was then distilled off under reduced pressure, and the residue was decomposed with acetic acid. The precipitate was fractionally recrystallized from ethanol to give prisms (m. p. 144°C, 4.5 g.) which were undepressed on admixture with the 7-methoxyisoflavan-4β-ol obtained in the experiments described above.

The residual liquor furnished more soluble needles (m. p. 131°C, 2.2 g.), which were identified as 7-methoxyisoflavan-4α-ol.

Found: C, 75.14; H, 6.10. Calcd. for $C_{16}H_{16}O_3$: C, 74.98; 6.29%.

The mixed melting point of 7-methoxyisoflavan-4α- and -4β-ol was 114~116°C.

7-Methoxyisoflavan-4α-ol was acetylated with acetic anhydride and pyridine at room temperature. Recrystallization from ethanol gave plates with a m. p. of 111°C.

Found: C, 72.67; H, 5.98. Calcd. for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%.

The mixed melting point of the acetyl derivatives of 7-methoxyisoflavan-4α- and -4β-ol was 95~100°C.

7-Methoxyisoflavan. — *1) The Catalytic Hydrogenation of 7-Methoxyisoflavanone.*—When a mixture of 7-methoxyisoflavanone (0.5 g.) and palladized charcoal (10%, 0.3 g.) in acetic acid (40 ml.) was shaken with hydrogen at 24°C, 72.4 ml. (0.93 mol.) of hydrogen was absorbed in 37 min. After the usual treatment, crystals with a m. p. of 95~97°C were obtained. The recrystallization of this product gave needles (m. p. 105~106.5°C). Yield, 0.25 g.

Found: C, 80.17; H, 6.87. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

2) Clemmensen Reduction.—To a mixture of 7-methoxyisoflavan (0.5 g.), acetic acid (30 ml.), and amalgamated zinc (10 g.), concentrated hydrochloric acid (10 ml.) was added over a 20 min. period. After standing at room temperature for 24 hr., the mixture was poured into water (200 ml.) and the precipitate formed was recrystallized from ethanol to crystals with a m. p. of 106°C (0.3 g.). This was identified by mixed melting point with the compound prepared in 1).

7, 4'-Dimethoxyisoflavan-4-ol.—*1) The Catalytic Hydrogenation of 7, 4'-Dimethoxyisoflavanone over Raney Nickel.*—7, 4'-Dimethoxyisoflavanone (0.5 g.) over Raney nickel (from 2.0 g. alloy) in ethanol (200 ml.) absorbed 59 ml. of hydrogen (1.41 mol.) at 19°C in one hour. The removal of ethanol from the filtered solution under reduced pressure gave a solid which was crystallized from ethanol as prisms with a m. p. of 143°C. Yield, 0.31 g.

Found: C, 71.04; H, 6.20. Calcd. for $C_{17}H_{18}O_4$: C, 71.31; H, 6.34%.

2) Reduction with Sodium Borohydride.—A solution of 7, 4'-dimethoxyisoflavanone (1.0 g.) and sodium borohydride (0.1 g.) in ethanol (450 ml.) was kept at 15°C for 2 days. After the usual treatment crystals with a m. p. of 143°C (0.5 g.) were obtained and identified as identical with the compound prepared in 1).

3) Meerwein-Ponndorf Reduction.—A solution of 7, 4'-dimethoxyisoflavanone (1.0 g.) and aluminum isopropoxide (0.7 g.) in anhydrous isopropanol (40 ml.) was heated under a Hahn partial condenser in a boiling water bath. About 32 ml. of isopropanol distilled out in one hour, and an acetone test with 2, 4-dinitrophenylhydrazine was negative. The residual isopropanol was removed under reduced pressure, and dilute hydrochloric acid was added. The recrystallization of the separated solid gave prisms with a m. p. of 142.5°C which were identified as identical with the compound in 1). Yield. 0.6 g.

4) Novel Meerwein-Ponndorf Reduction.—A solution of 7, 4'-dimethoxyisoflavanone (2.0 g.) and aluminum isopropoxide (2.0 g.) in anhydrous isopropanol (120 ml.) was treated as above. A total of 120 ml. of isopropanol was added in 5 portions, and the solution was heated for 10 hr. After the usual treatment, crystals (m. p. 75.5°C, 1.2 g. from ethanol) were obtained. The product, which could not be acetylated with acetic anhydride in the presence of pyridine, was characterized as 7, 4'-dimethoxy-4-isopropoxyisoflavan.

Found: C, 73.12; H, 7.14. Calcd. for $C_{20}H_{24}O_4$: C, 73.14; H, 7.37%.

The recrystallization of the solid which separated from the ethanolic mother liquid with petroleum benzine gave plates with a m. p. of 161°C (50 mg.) which were identified as 7, 4'-dimethoxyisoflav-3-en.

UV $\lambda_{max}^{C_2H_5OH}$ mμ (log ε): 250 (4.22), 335 (4.38).

Found: C, 75.87; H, 6.09. Calcd. for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

The author is grateful to Professor Sekio Mitsui of Tohoku University for his valuable suggestions on the catalytic hydrogenation of isoflavanones. A part of the experiments were carried out by Mannosuke Arai, to whom the author's thanks are also due.

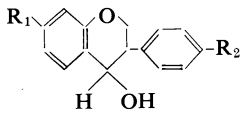
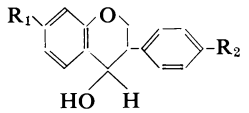
Studies of Synthetic Isoflavanones. VI. The Reaction of Isoflavan-4-ols with Acetic Acid[1]



By Naoto INOUE

(Received June 11, 1963)



Bradbury and White[2] carried out the hydrogenation reaction of 7, 4'-dimethoxyisoflavanone (II) with platinum oxide in acetic acid to the corresponding isoflav-3-en (XI), but they did not isolate 7, 4'-dimethoxyisoflavan-4-ol (IX) and it is not clear whether or not 7, 4'-dimethoxyisoflavan was produced in their experiment. They hydrogenated 2-methyl-7, 4'-dimethoxyisoflavone by the method similar to the one used for the corresponding isoflavanone and obtained 2-methyl-7, 4'-dimethoxyisoflav-3-en, which was also obtained by the reduction of the same isoflavone with lithium aluminum hydride.

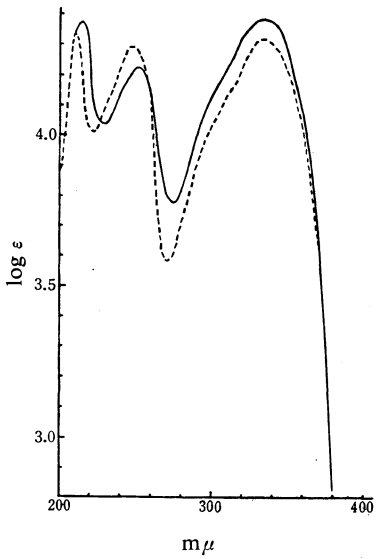
It has been assumed that the isoflav-3-ens obtained in White's experiments were derived from the reduction products, isoflavan-4-ols, by dehydration with acetic acid. With a view to confirming this assumption, several experiments on isoflavan-4-ols were carried out. In the preceding paper of this series,[1] the author reported that 7-methoxyisoflavanone (I) was converted into 7-methoxyisoflavan-4β-ol (III, m.p. 144°C) by catalytic hydrogenation over Raney nickel or by the Meerwein-Ponndorf reduction and that 7-methoxyisoflavan-4α-ol (IV, m. p. 131°C) was obtained as a minor product, along with III, by the reduction of I with sodium borohydride. In order to obtain 7-methoxyisoflav-3-en (VII), III was heated on a water bath with dilute sulfuric acid, phosphoric acid, phosphoric anhydride in benzene, or formic acid. Treatment with all these reagents yielded an amorphous substance which was insoluble in ethanol. The treatment of III with concentrated sulfuric acid at room temperature gave the same result. However, when boiled with acetic acid III was converted into plate crystals (m. p. 108°C) whose ultraviolet absorption spectrum was similar to that of stilbene with absorption maxima at 335 mμ ($\log \varepsilon = 4.31$) and 245 mμ ($\log \varepsilon = 4.28$), as is shown in Fig. 1. The analytical values of this compound conformed with those of the anhydride of III. The product was hydrogenated over palladized charcoal to 7-methoxyisoflavan (VIII), which was also obtained by the Clemmensen reduction of I.[1] These results indicate that the compound with a m. p. of 108°C



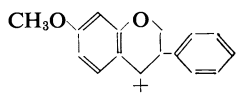


Fig. 1. Ultraviolet spectra of VII (——) and XI (·····) in ethanol.

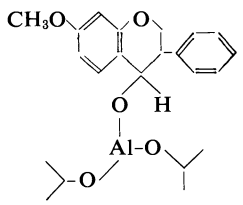
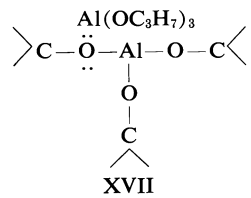
1) Presented at the 13th and 14th Annual Meetings of the Chemical Society of Japan, Tokyo, April, 1960 and 1961. Part V of this series: N. Inoue, This Bulletin, 37, 601 (1964).



2) R. B. Bradbury and D. E. White, *J. Chem. Soc.*, **1953**, 871.

has the stilbene-type structure VII and that heating it with acetic acid did not cause any migration of the C_3 phenyl group.



Considering the result of White's experiments, it was presumed that the dehydration of III might occur under milder conditions; therefore, III was treated with acetic acid at 50°C for one hour, by which method a compound with a m.p. of 111°C was obtained. The infrared spectrum of this substance indicated the absence of hydroxyl group and the presence of a carbonyl group ($\nu_{C=O}$ 1732 cm^{-1} in KBr), and its analytical results conformed with that of the acetate of 7-methoxyisoflavan-4-ol. Mixed melting point determination showed the product to be 4α-acetoxy-7-methoxyisoflavan (VI, m.p. 111°C). It is interesting that α-acetate was obtained by the treatment of the β-alcohol (III) with acetic acid. When III was allowed to stand overnight in acetic acid at room temperature, the starting material was recovered unchanged. 7-Methxyisoflavan-4α-ol (IV) was converted into VII on treatment with boiling acetic acid, and into VI on that with acetic acid at 50°C. In the preceding paper[1] it was reported that III and IV were acetylated with acetic anhydride and pyridine to 4β-acetoxy-7-methoxyisoflavan (V, m.p. 121°C) and 4α-acetoxy-7-methoxyisoflavan (VI, m.p. 111°C) respectively. Treatment with sodium methoxide in methanol gave III from V and IV from VI. Both V and VI were converted into VII by being boiled with acetic acid. These experimental results suggest that VI might be an intermediate product in the dehydration of III, IV, and V with boiling acetic acid.

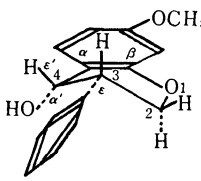
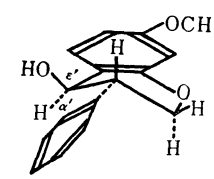
XVI

XVII



XVIII



XIX

In the conversion of III to the epimeric acetate VI by treatment with the acetic acid, a proton from acetic acid is thought to be added to the C_4 hydroxyl group, followed by the elimination of water from the oxonium ion to give the carbonium ion (XV), which then reacts with acetic acid to yield the epimeric acetate VI. This is a solvolysis reaction of the S_N1 type in acetic acid. In a previous paper, the author assigned trans configuration to 7-methoxyisoflavan-4α-ol (IV) and a cis to 4β-ol (III) on the basis of the stereochemistry of the transition state of the Meerwein-Ponndorf reduction[3] and Mitsui's theory for catalytic hydrogenation.[4,5] As III' and IV' show, the perferred conformation of the C_3 phenyl group of 7-methoxyisoflavan-4-ol is equatorial and that of C_3 hydrogen atom, axial. The C_4 hydroxyl group could be either quasi-axial (a') or quasi-equatorial (e'), and the C–H bond and C–O bond projected from C_4 are inclined at the same angle to the plane in which C_α, C_β, O_1, and C_4 exist. The catalytic hydrogenation and Meerwein-Ponndorf reduction of I gave III with a quasi-axial C_4 hydroxyl group which is cis to the C_3 equatorial phenyl group (III'). On the other hand, the IV formed as a minor product by the reduction of I with sodium borohydride is a trans compound with a quasi-equatorial C_4 hydroxyl group (IV').

cis
III'

trans
IV'

Because of its quasi-equatorial conformation and trans configuration, the α-compound IV is considered to be more stable than the β-compound III. Therefore, the reactions which proceed through the planar sp^2 form of the C_4 of isoflavan would give the trans or α-type compound. As has been described above, the reaction between III and acetic acid thus proceeds via the C_4 carbonium ion, with sp^2 hybridization, to give a more stable α-acetate. This conclusion suggests that when the carbonium ion XV reacts with water instead of acetic acid, the stereoisomeric alcohol IV will be produced. Therefore, III was dissolved in a dioxane-water mixture with one drop of concentrated sulfuric acid or hydrochloric acid

3) L. M. Jackman, A. K. Macbeth and J. A. Mills, ibid., **1953**, 871.
4) S. Mitsui and K. Kasahara, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **79**, 1382 (1958); **81**, 1583 (1960).

and the solution was set aside overnight. The desired alcohol IV was obtained as expected. When pure dioxane was used as the solvent instead of a dioxane-water mixture, an amorphous compound was obtained.

7, 4'-Dimethoxyisoflavan-4-ol (IX), which had been obtained by the hydrogenation of 7, 4'-dimethoxyisoflavanone (II) over Raney nickel or by its reduction with aluminum isopropoxide or with sodium borohydride, was treated with acetic acid at 50°C and was converted into 7, 4'-dimethoxyisoflav-3-en (XI) in one experiment and into 4-acetoxy-7,4'-dimethoxyisoflavan with a m. p. of 123°C in another. As has been reported in the preceding paper, the acetylation of IX with acetic anhydride and pyridine gave the acetate (X) with a m. p. of 128°C, which was different from the acetate (m. p. 123°C) obtained above (mixed melting point determination).

Bradbury and White[2] hydrogenated II with platinum oxide in acetic acid to 7, 4'-dimethoxyisoflav-3-en (XI). It was assumed that XI would be derived from the primary reduction product, IX, through reaction with acetic acid. The experimental results mentioned above support this assumption. The reaction of IX with boiling acetic acid gave isoflav-3-en XI, which was then converted into 7, 4'-dimethoxyisoflavan (XII) by catalytic hydrogenation over palladized charcoal. XII was prepared from II by the Clemmensen reduction.

Unlike III and IX, the isoflavan-4-ol (XIV) obtained by the reduction of isoflavanone (XIII) was not converted into 4-acetoxyisoflavan with acetic acid at 50°C, but was recovered unchanged. As has been mentioned above, the conversion of isoflavan-4-ols to 4-acetoxyisoflavans could go through the transition state in which C_4 is a carbonium ion. The resonance stabilization of the carbonium ion might affect the rate of this reaction. A methoxyl group in the 7-position will facilitate the formation of this transition state, and, consequently, the acetylation of the 4-hydroxyl with acetic acid will proceed smoothly. The lack of a electron-releasing substituent in this position makes the transformation of the starting substance into this transition state difficult; in the case of unsubstituted isoflavan-4-ol, acetylation with acetic acid does not occur.

As reported in the previous paper,[1] the Meerwein-Ponndorf reduction of I and II gave isopropyl ethers of the corresponding isoflavan-4-ols. This fact can be explained by the carbonium ion-intermediate theory as follows. The aluminum atom of excess aluminum isopropoxide would combine with the oxygen atom of the intermediate aluminum compound of I or II (XVI) as Lewis acid (XVII), and the oxygen atom in C_4 is likely to be eliminated from C_4, thus forming the carbonium ion XV. Then the carbonium ion would react with isopropanol to give the isopropyl ether of the isoflavan-4-ol. The carbonyl carbons of all the compounds which have been reported to give isopropyl ethers by the Meerwein-Ponndorf reduction[6] have a stable structure when they form carbonium ions (XVIII, XIX). As has been shown above, I and II have the structure which can produce a stable carbonium ion and give isopropyl ether in the Meerwein-Ponndorf reduction.

Experimental*

The Reaction of 7-Methoxyisoflavan-4β-ol (III) with Acetic Acid. — *1) In the Boiling State.* — A solution of III (500 mg.) in acetic acid (10 ml.) was refluxed for one hour. After the acetic acid had been removed under reduced pressure, water (30 ml.) was added to the residue and the mixture was allowed to stand for several hours. The precipitate formed was collected and recrystallized from ethanol in the form of plates (VII) (m. p. 108°C). Yield, 300 mg.

UV: λ_{max}^{EtOH} mμ (log ε): 335 (4.31), 245 (4.28).
Found: C, 80.55; H, 6.09. Calcd. for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92%.

2) At 50°C. — A solution of III (100 mg.) in acetic acid (10 ml.) was heated at 50°C for one hour. After the acetic acid had been removed below 50°C under reduced pressure, water (30 ml.) was added to the residue and the mixture was set aside for several hours. The product formed was collected and recrysallized from ethanol, giving plates with a m. p. of 111°C (70 mg.) which showed no depression of melting point when admixed with 4α-acetoxy-7-methoxyisoflavan (VI).

The Reactions of 7-Methoxyisoflavan-4α-ol (IV) with Acetic Acid.—*1) In the Boiling State.*—A solution of IV (50 mg.) in acetic acid (5 ml.) was refluxed for one hour. The reaction mixture, when worked up as described for III, gave VII (55 mg., m. p. and mixed m. p. 108°C).

2) At 50°C. — A solution of IV (100 mg.) in acetic acid was heated at 50°C for one hour. After the acetic acid had been removed under reduced pressure, the residue was recrystallized from ethanol in the form of plates with a m. p. of 111°C, either alone or mixed with 4α-acetoxy-7-methoxyisoflavan (VI).

The Reactions of 4β-Acetoxy-7-methoxyisoflavan (V) with Acetic Acid.—*1) In the Boiling State.*—A solution of V (100 mg.) in acetic acid (10 ml.) was refluxed for one hour. The reaction mixture, when worked up as described for III, gave VII (m. p. and mixed m. p. 106°C).

2) At 50°C.—A solution of V (100 mg.) in acetic acid (10 ml.) was heated at 50°C for one hour.

6) A. L. Wild in "The Organic Reactions," Ed. by R. Adams, Vol. II, John Wiley & Sons, New York (1944), p. 190.

* All melting points are uncorrected.

The reaction mixture, when worked up as described for III, gave VI (55 mg., m. p. and mixed m. p. 108°C).

The Reaction of 4α-Acetoxy-7-methoxyisoflavan (IV) with Boiling Acetic Acid.—A solution of VI (100 mg.) in acetic acid (10 ml.) was refluxed for one hour. When the reaction mixture was worked up as described for III, it gave VII (70 mg., m. p. and mixed m. p. 108°C).

The Hydrolysis of 4β-Acetoxy-7-methoxyisoflavan (V).—A mixture of V (100 mg.), N/2 methanolic sodium methoxide (1.0 ml.), and methanol (20 ml.) allowed to stand for 24 hr. at room temperature. After dilution with water (100 ml.), the precipitate formed was separated, dried, and recrystallized from ethanol to III (60 mg., m. p. and mixed m. p. 143°C).

The Hydrolysis of 4α-Acetoxy-7-methoxyisoflavan (VI).—A mixture of VI (50 mg.), N/2 methanolic sodium methoxide (0.5 ml.), and methanol (20 ml.) was allowed to stand for 12 hr. at room temperature. On treatment as described above, IV (28 mg.) was obtained (m. p. and mixed m. p. 130°C).

The Reactions of 7-Methoxyisoflavan-4β-ol (III) with Mineral Acid.—Two drops of concentrated sulfuric acid or hydrochloric acid were added to a solution of III (50 mg.) in hydrous dioxane (1 : 1, 40 ml.). The solution was then allowed to stand for 48 hr. at room temperature. After dilution with water (200 ml.), the precipitate formed was recrystallized from ethanol to IV (20 mg., m. p. and mixed m. p. 129°C).

The Reaction of Isoflavan-4-ol (XIV) with Acetic Acid.—A solution of XIV (50 mg.) in acetic acid (10 ml.) was heated at 50°C for one hour. The usual after-treatment of the mixture gave XIV unchanged.

The Reactions of 7, 4'-Dimethoxyisoflavan-4-ol (IX) with Acetic Acid.—*1) At 50°C.*—A solution of IX (50 mg.) in acetic acid (10 ml.) was heated at 50°C for one hour. The reaction mixture, when worked up as described for III, gave 7, 4'-dimethoxyisoflav-3-en (XI) (m. p. 161°C). Yield, 20 mg.

UV: λ_{max}^{EtOH} mμ (log ε): 335 (4.38), 250 (4.22). (Found: C, 75.87; H, 6.09%.)

2) At 50°C.—A solution of IX (100 m.) in acetic acid (10 ml.) was heated at 50°C for one hour. The usual after-treatment gave crystals with a m. p. of 123°C. Yield, 30 mg.

Found: C, 69.63; H, 6.15. Calcd. for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14%.

IR (KBr): 1728 cm^{-1}.

3) In the Boiling State.—A solution of IX (100 mg.) in acetic acid (20 ml.) was refluxed for one hour. The usual treatment of the reaction mixture gave XI (60 mg., m. p. and mixed m. p. 161°C).

7-Methoxyisoflavan.—*The Catalytic Hydrogenation of the VII Obtained by the Reaction of III with Boiling Acetic Acid.*—A mixture of VII (500 mg.) in acetic acid (140 ml.) and palladized charcoal (20%, 500 mg.) was shaken with hydrogen at 30°C until the absorption of hydrogen stopped. One mole of hydrogen had been absorbed. The catalyst was then filtered off, and the filtrate was concentrated under reduced pressure. The residue was recrystallized from ethanol in the form of plates with a m. p. of 106°C (300 mg.). The product was identified, by mixed melting point determination, to be the same compound prepared by the Clemmensen reduction of I[1].

7, 4'-Dimethoxyisoflavan (XII).—*1) The Catalytic Haydrogenation of the XI Obtained by the Reaction of IX with Acetic Acid.*—A mixture of XI (500 mg.) in acetic acid (150 ml.) and palladized charcoal (5%, 1.0 g.) was shaken with hydrogen at 20°C until the absorption of hydrogen stopped. One mole of hydrogen (46 ml.) had been absorbed. Upon working up the product in the usual manner, XII (200 mg., m. p. 113°C (from ethanol)) was obtaind. (Found: C, 75.69; H, 6.78%.)

2) The Clemmensen Reduction of II.—A mixture of II (250 mg.), amalgamated zinc dust (3.6 g.), concentrated hydrochloric acid (5 ml.), and acetic acid (30 ml.) was allowed to stand for 24 hr. at room temperature. The mixture was then poured into water (200 ml.). The recrystallization of the precipitate from ethanol gave a product with a m. p. 114°C (150 mg.) which showed no depression of the melting point when admixed with XII prepaped as above.

Aromatization of Some 4-Substituted 2, 6-Dimethyl-3, 5-diethoxycarbonyl-1, 4-dihydropyridines to Pyridines

By Ahmad KAMAL, Mansoor AHMAD, Nazar MOHD and Abdul Majid HAMID

(Received June 19, 1963)

Following the preparation of a series of dihydropyridine compounds[1] it was considered interesting to investigate the possibility of preparing the corresponding piperidines through "hydrogen-transfer." When 2,6-dimethyl-3,5-diethoxycarbonyl-4-phenyl-1,4-dihydropyridine was refluxed in cyclohexene in the presence of 5% palladium/charcoal catalyst with a catalytic amount of glacial acetic acid added to it, the product that was obtained was not the corresponding piperidine, instead 2,6-dimethyl-3,5-diethoxycarbonyl-4-phenylpyridine was obtained in 90% yield. The identity of this product was confirmed by comparison with the authentic sample prepared through oxidation of the corresponding dihydropyridine with nitrous oxide.[2]

Accordingly, all the dihydropyridine compounds reported earlier[1] were subjected to this reaction. Since cyclohexene did not play any part, this reaction was carried out by boiling the dihydropyridines in toluene or benzene, containing a catalytic amount of glacial acetic acid and 5% palladium-charcoal catalyst. In the absence of acetic acid, however, no aromatization could be achieved. It was also interesting to observe that in this reaction aromatization did not proceed at all, if the substituent in the fourth position happened to be a phenol. As for instance 2,6-dimethyl-3,5-diethoxycarbonyl-4-(3-hydroxyphenyl)-1,4-dihydropyridine, 2,6-dimethyl-3,5-diethoxycarbonyl-4-(3-methoxy-4-hydroxyphenyl)-1,4-dihydropyridine and 2,6-dimethyl-3,5-diethoxycarbonyl-4-(4-hydroxyphenyl)-1,4-dihydropyridine failed to give the corresponding pyridine derivatives. However, on methylation of phenolic OH the aromatization with palladium/charcoal proceeded as usual.

Reference to literature reveals that Knoevenagel and Fuchs prepared 2,6-dimethyl-3,5-diethoxycarbonylpyridine by heating 2,6-dimethyl-3,5-diethoxycarbonyl-1,4-dihydropyridine with palladium-black at 200~265°C,[3] and also by heating with concentrated hydrochloric acid when the corresponding pyridine derivative was obtained in 5% yield only.

Since oxidation with nitrous oxide gave invariably poor yields of the corresponding pyridine derivatives, oxidation with potassium permanganate in glacial acetic acid was also tried when the pyridine derivatives were obtained in comparatively high yields. Oxidation in acetone however, failed, the dihydropyridines being recovered unchanged.

Experimental

All melting points are corrected. Ultraviolet absorption spectra were determined with a Beckman spectrophotometer model DB in 95% ethanol.

General Method.—*A) Aromatization of the Dihydropyridine Ring with 5% Palladium/Charcoal-Acetic Acid.*—A dihydropyridine (0.002 mol.) dissolved in toluene (25 ml.) containing palladium-on-charcoal catalyst (5%; 50 mg.) and glacial acetic acid (5 ml.) was refluxed (42 hr.) on a sand bath, filtered and filtrate washed thrice with water and then with aqueous sodium hydrogen carbonate (10%; 2 ml.) followed by water. Drying and removal of the solvent gave the corresponding pyridine.

B) Aromatization of Dihydropyridine Ring through Oxidation with Potassium Permanganate.—A dihydropyridine (0.01 mol.) was dissolved in glacial acetic acid (50 ml.) and powdered potassium permanganate (1 g., 0.006 mol.) added. The mixture was heated on a water bath (about 5 hr.) till almost whole of the permanganate was consumed. The very slight excess of the permanganate was destroyed by heating with a little ethyl alcohol and the solvent was removed in vacuo. Water (25 ml.) was added to the residue and the product was isolated with ethyl acetate and worked up.

The pyridine compounds are generally soluble in acetone, benzene, chloroform, dioxane, ethyl acetate, ethyl and methyl alcohols, sparingly soluble in ether, carbon tetrachloride, light-petroleum (60~80°C) and insoluble in water.

Confirmation of 5-Pyrophosphomevalonate as an Intermediate in the Enzymatic Synthesis of Bacterial Phytoene from Mevalonate

By Ginzaburo SUZUE

(Received June 25, 1963)

It is well known that MVA is a precursor of isoprenoid compounds, such as carotenoids and steroids, which are found universally in the biological world. In the course of their biosynthesis, MVA is believed to react with ATP by specific kinases to form phosphorylated compounds.[1] Though several phosphorylated intermediates have been confirmed in the case of the biosynthesis of steroids,[2-4] 5-P-MVA is the only intermediate which has been reported in carotenogenesis.[5]

The present paper is concerned with the confirmation of 5-PP-MVA as an intermediary product formed during the biosynthesis of phytoene from MVA or 5-P-MVA, and with its enzymatic conversion into phytoene.

As 5-P-MVA and 5-PP-MVA are formed from MVA by means of reactions with ATP catalyzed by enzymes extracted from a phytoene-accumulating mutant of *Staphylococcus*,[6] the pathway of the phytoene biosynthesis by means of this microorganism may be written as follows:

MVA→5-P-MVA→5-PP-MVA

→(Isopentenylpyrophosphate)→Phytoene

Experimental and Results

Chemicals and Instruments.[5,8] — The ATP used was equally labeled with ^{32}P at β and γ positions.[7] The prostatic phosphomonoesterase used was the generous gift of Professor Tomoji Suzuki of Kyoto University.

Radioactivity was measured by the instruments and techniques previously described.[5]

Preparation of Enzymes.—For the extraction of the cell-free enzymes from a phytoene-accumulating mutant of *Staphylococcus*, the method described previously was applied.[8] After the adjustment of the protein concentration of the crude extract to 10 mg./ml., a 2% solution of protamine was stirred into the diluted enzyme extract to give a final concentration of 0.1% protamine. The resulting supernatant solution was fractionated with ammonium sulfate. Mevalonic kinase was precipitated at 45~60%, phosphomevalonic kinase at 40~55%, and pyrophosphomevalonic decarboxylase, at 60~75% saturation. For the synthesis of 5-PP-MVA from MVA, the precipitate of the 40~60% ammonium sulfate-saturated fraction (tentatively named enzyme I) was employed, while with that of 5-PP-MVA from 5-P-MVA the 40~55% fraction (tentatively named enzyme II) was employed as the method of enzyme preparation.

A 0.1 M Tris buffer (pH 8.0) solution of the proteins precipitated from the crude extract at 0~90% saturation with ammonium sulfate was used for the synthesis of phytoene from MVA or 5-PP-MVA, as has been reported previously.[8]

Isolation and Identification of 5-Pyrophosphomevalonic Acid. — In the previous paper,[5] it was reported that an undetermined substance Y was found in an earlier stage of the enzymatic conversion of MVA to phytoene but that it disappeared in a later stage. Hence, it is quite reasonable to postulate that compound Y is one of the intermediates in the biosynthesis of phytoene from MVA. The enzymatic formation of compound Y from MVA or 5-P-MVA was established in the following experiment.

A reaction system which contained MVA and enzyme I, or 5-P-MVA and enzyme II, and ATP was incubated as shown in Table I. The incubation was carried out at 30°C for 30 min., and then the enzyme action was stopped by heating the reaction vessel at 100°C for 30 sec. After the denatured proteins had been removed by centrifugation, the

TABLE II. R_f VALUES OF COMPOUND Y (5-PP-MVA)

Solvent system	R_f
A	0.03～0.08
B	0.23～0.33
C	0.29～0.36
D	0.06～0.11

Pure compound Y (5-PP-MVA) enzymatically synthesized from 2-^{14}C-MVA was paper chromatographed (ascending) by the following four solvent systems. The component of each system: A, *n*-butanol - formic acid - water (77 : 10 : 13, by volume); B, isobutyric acid - concd. ammonia - water (66 : 3 : 30); C, *t*-butanol - formic acid - water (40 : 10 : 16); D, *t*-amyl alcohol - acetic acid - water (4 : 1 : 2).

supernatants were analyzed by column chromatography or paper chromatography.

By paper chromatographic techniques, using four solvent systems, it was found that the compound Y formed from 2-^{14}C-MVA gave the R_f values shown in Table II. These R_f values are identical with those of 5-PP-MVA previously reported.[3,4,9,10]

When the supernatant (1.1～0.9 ml., incubation scale: Table I) of the enzymatically-synthesized sample is paper chromatographed (paper Toyo-roshi No. 50, size 20 cm.×40 cm.) without prior purification, the observed R_f value of Y is 0.42～0.51 in the methanol - concentrated ammonia - water system. When, however, after the isolation of the material with R_f 0.42～0.51, it was rechromatographed with the same solvent, an R_f value of Y of 0.03～0.08 was observed, corresponding to that of purified 5-PP-MVA. This behavior during the initial chromatography may be attributed to the presence of a large amount of nucleotides.

After purification by paper chromatography using two solvent systems (methanol - concentrated ammonia - water 'R_f 0.42～0.51' and isobutyric acid - concentrated ammonia - water 'R_f 0.23～0.33'), compound Y was further identified using column chromatography on a Dowex 1 - formate column (0.7 cm.×10 cm.). By this technique, too (Fig. 1), compound Y was identified with 5-PP-MVA.[11]

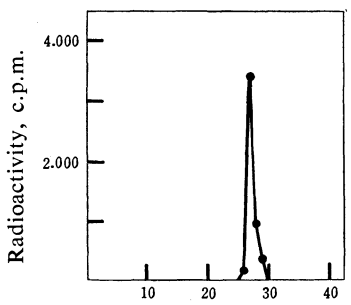

Fig. 1. Chromatographic analysis of compound Y on Dowex 1-formate column (1.7 cm.× 10 cm.).
Sample applied: 5000 c. p. m. (4.5 mμmol.).
Solution used for elution: Fractions 1—16, water; 17—26, 4 N formic acid; 27—31, 0.4 M ammonium formate in 4 N formic acid; 32—35, 0.8 M ammonium formate in 4 N formic acid.

High-voltage paper electrophoresis was performed under the following conditions: buffer solution, pyridine - acetate (pH 6.2); 41 V./cm., 65 mamp.; 120 min.; paper: Toyo-roshi, No. 2. Here compound Y, 5-P-MVA and MVA migrated 21.8 cm., 21.6 cm. and 16.8 cm. respectively. The results also indicate that compound Y is 5-PP-MVA.[3]

Further confirmation was undertaken as follows. The ^{14}C, ^{32}P double-labeled compound Y was enzymatically synthesized from DL-2-^{14}C-MVA, AT^{32}P (β,γ position labeled) and the enzyme preparation described in Table I. The compound Y thus formed was purified at least three times by paper chromatography using the methanol - concentrated ammonia - water or isobutyric acid - concentrated ammonia - water solvent systems. The results are shown in Table III. From the ratio of ^{32}P to ^{14}C in the purified compound Y, it consists of MVA and phosphate in the molar ratio of 1 : 2.

The results of the analysis of the incubation products are summarized in Table IV, where it is shown that these incubation systems are suitable for the preparation of 5-PP-MVA.

TABLE III. RATIO OF ^{32}P TO ^{14}C OF DOUBLY LABELED Y

MVA	98	99	18	22

Radioactive 5-P-MVA and compound Y (4000 c. p. m., 3.6 mμmol., respectively) were hydrolyzed by prostatic phosphomonoesterase (0.01 ml.; protein concentration: 0.45 mg./ml.) with acetate buffer (pH 5.3, 2 μmol.) and $MgSO_4$ (1 μmol.) in a volume of 0.1 ml. Products were separated and analyzed by actigraphic method after paper chromatography with isobutyric aicd - concentrated ammonia - water and *t*-butanol - formic acid - water systems.

Enzymatic Synthesis of Bacterial Phytoene from 2-^{14}C-5-PP-MVA. — 2-^{14}C-5-PP-MVA (4000 c. p. m., 3.6 mμmol.) or DL-2-^{14}C-MVA (13000 c. p. m., 12 mμmol.) was incubated at 37°C for 3 hr. while being gently shaken with NADP (0.5 mg.), 6-phosphogluconate (2 μmol.), nicotinamide (50 μmol.), ATP (10 μmol.), FAD (0.05 mg.), a Tris buffer (pH 8.0, 40 μmol.), manganese sulfate (10 μmol.), magnesium sulfate (5 μmol.), Tween 20 (final concentration: 0.17%), KF (10 μmol.) and a 0.1 M Tris buffer (pH 8.0) solution of enzyme preparation precipitated at 90% saturation with ammonium sulfate (0.3 ml.; protein concentration: 42 mg./ml.) in a volume of 0.6 ml. The enzymatic reactions were stopped by the addition of 2 ml. of a 10% ethanolic sodium hydroxide solution to the mixture. *p*-Hydroquinone (10 mg.) and a petroleum benzine solution (1.00 ml.) of pure bacterial phytoene (absorbancy: 8.42 at 286 mμ) were added to the mixture simultaneously. After saponification, the unsaponifiable fraction was washed with water three times, and the aliquots were dried on aluminum planchets and their radioactivity counted as infinitely thin samples. The separation of the phytoene in the unsaponifiable fraction was carried out by chromatography on an activated-alumina column. The fractions containing purified phytoene were dried on aluminum planchets, and their radioactivities were measured. The results obtained are summarized in Table VI. The conversion of 5-PP-MVA or MVA to phytoene is evident.

TABLE VI. BIOSYNTHESIS OF PHYTOENE FROM MVA AND 5-PP-MVA

Substrate	Unsaponifiable fraction c. p. m.	Phytoene c. p. m.
DL-MVA (13000 c.p.m.; 12 mμmol.)	2550	1109
5-PP-MVA (4000 c.p.m.; 3.6 mμmol.)	3320	2625

Each system was consisted of NADP (0.5 mg.), 6-phosphogluconate (2 μmol.), nicotinamide (50 μmol.), ATP (10 μmol.), FAD (0.05 mg.), Tris buffer (pH 8.0, 40 μmol.), $MnSO_4$ (10 μmol.), $MgSO_4$ (5 μmol.), Tween 20 (final concentration: 0.17%), KF (10 μmol.), enzyme (0.3 ml., protein concentration: 42 mg./ml.) and the substrates indicated, in a volume of 0.6 ml. Incubation, in nitrogen (99.9%) for 3 hr. at 37°C.

Discussion

Compound Y is detected in an early stage of the biosynthesis of phytoene from MVA and 5-P-MVA. The behavior of this compound has now been shown to be identical with that of 5-PP-MVA, judging from paper chromatographic, column chromatographic, and paper electrophoretic criteria. It contains two atoms of phosphorus per molecule of mevalonic acid. One phosphorus atom has been shown to be located at the 5-position of MVA, as 5-P-MVA is regenerated by the hydrolytic action of prostatic phosphomonoesterase. The liberation of the first phosphorus moiety from compound Y is slow with this enzyme, as has been previously shown using 5-PP-MVA and other phosphomonoesterases.[9] The rapid regeneration of MVA is readily explicable, as the liberation of the second phosphorus is quite rapid, as in Table V shows. Thus, it seems reasonable to conclude that compound Y has one pyrophosphate linkage and that, after one phosphorus atom is liberated, the 5-P-MVA thus formed is readily susceptible to phosphomonoesterase action with the generation of MVA. On the basis of those facts compound Y has been concluded to be 5-PP-MVA, a substance which has been previously found in the pathway of squalene and cholesterol biosynthesis.[1-4]

5-PP-MVA was incorporated into phytoene with more than twice the efficiency of the DL-MVA, thus showing that 5-PP-MVA is also in the biosynthetic pathway of phytoene from MVA or 5-P-MVA.

Summary

In phytoene biosynthesis from mevalonic acid and 5-phosphomevalonic acid by the

enzyme preparation from the mutant of *Staphylococcus aureus*, a phosphorus-containing substance has been isolated as an intermediate compound. After purification by paper chromatography, column chromatography and paper electrophoresis, this substance has been shown to contain phosphorus and mevalonic acid in the molar ratio of 2 : 1. From its behavior with regard to prostatic phosphomonoesterase, together with the above-mentioned results, this substance has been concluded to be 5-pyrophosphomevalonic acid.

*The Polarography of Terephthalaldehydic Acid**

By Masataka NISHIYAMA, Masao MARUYAMA and Hiroshi HAMAGUCHI

(Received June 29, 1963)

Holleck and Marsen[1] were the first to study the d. c. polarography of terephthalaldehydic acid. Their purpose was to investigate the effect of a substituted group on the polarographic behavior of benzaldehyde for eleven substituted benzaldehydes. Terephthalaldehydic acid has been investigated only qualitatively as one of these substituents.

In a previous paper[2] the present authors investigated the polarographic behavior of terephthalaldehydic acid in a sodium hydroxide solution; they reported a polarographic method for the rapid determination of a small amount of this acid in terephthalic acid, because terephthalic acid was well dissolved only in an alkaline solution.

In this paper, the authors will study in detail the d. c. and a. c. polarography of terephthalaldehydic acid in buffered solutions not containing ethanol over the pH region from 1 to 13.

The experimental results give some new information with respect to the polarographic reduction of terephthalaldehydic acid. The acid recombination and dissociation rate constants for this compound will be calculated, and a reduction scheme will be proposed.

Experimental

Apparatus.—A Yanagimoto AC/DC polarograph, model PA 102, was used for recording d. c. and a. c. polarograms. For the pH measurements, a Toa Dempa pH meter, model HM-5, was adopted. The dropping mercury electrode used had the following characteristics; $m=2.01$ mg./sec., $h=65$ cm., and $t=4.65$ sec. at an open circuit. The polarographic cells were of a modified H-type; the electrolytic compartment contained a mercury pool. When the a. c. polarograms were recorded, a "pool-condenser" of a 100 μF capacity was connected between the saturated calomel electrode and the mercury pool anode.[3]

All polarographic measurements were made at 25±0.5°C in a thermostat. Purified nitrogen gas was bubbled through the test solution for 10 min. to remove any dissolved oxygen.

Reagents. — The terephthalaldehydic acid* and other reagents used were of a guaranteed reagent grade.

Buffers and Test Solutions.—The Britton-Robinson buffers were mainly used to cover the pH range from 1 to 13. The other buffer systems used were as follows; 0.2 N potassium chloride - 0.2 N hydrochloric acid (pH 1.0~2.2), 0.2 N potassium biphthalate - 0.2 N hydrochloric acid (pH 2.2~3.8), 0.2 N potassium phosphate - 0.2 N sodium hydroxide (pH 4.0~6.2), 0.2 M potassium phosphate (monobasic) - 0.2 N sodium hydroxide (pH 6~8), 0.2 M boric acid - 0.1 N sodium hydroxide (pH 8~10), 0.1 M sodium citrate - 0.1 N hydrochloric acid (pH 1.1~5.8) and 0.2 N borax - 0.1 N sodium hydroxide (pH 9.5~12.0).

The test solution was prepared by taking 20 ml. of the buffer of the desired pH value and a given volume of a terephthalaldehydic acid standard solution[2] in a 25 ml. volumetric flask, adjusting the ionic strength to $\mu=0.13$ with 1.0 M potassium chloride, and then filling the flask up to the mark with water. No surface active substances were used. The pH value of the solution was again measured after the preparation of the test solution.

* Terephthalaldehydic acid was obtained from the Tokyo Kasei Co.; the analysis data gave a purity of 100±2% from the determination of the carboxyl group of this compound. The melting point was 257°C.

Results and Discussion

D. C. Polarography.—Figure 1 shows some typical d. c. and a. c. polarograms of 0.4 mM terephthalaldehydic acid in Britton-Robinson buffers over the pH range studied.

The Effect of pH.—The variations in the wave height and the half-wave potential with variation in the pH are illustrated in Figs. 2 and 3 respectively. The reduction wave of terephthalaldehydic acid at a pH below 4.4 was accompanied by a pre-wave (Fig. 1-a). This pre-wave was not reported in the earlier investigation.[1] The behavior of terephthalaldehydic acid waves above pH 4.4 accorded approximately with the results of Holleck and Marsen; in the pH range from 4.4 to 5.5, a single wave (designated as wave I) was observed (Fig. 1-b); in the pH range from 5.5 to 7.5, two waves appeared—the height of the first wave, a positive one corresponding to wave I, decreased, and that of the second one, designated as wave II, increased with the increasing pH (Fig. 1-c). In the vicinity of pH 8, wave II alone was observed (Fig. 1-d), and as the pH increased from 8.2 to 11.5 the

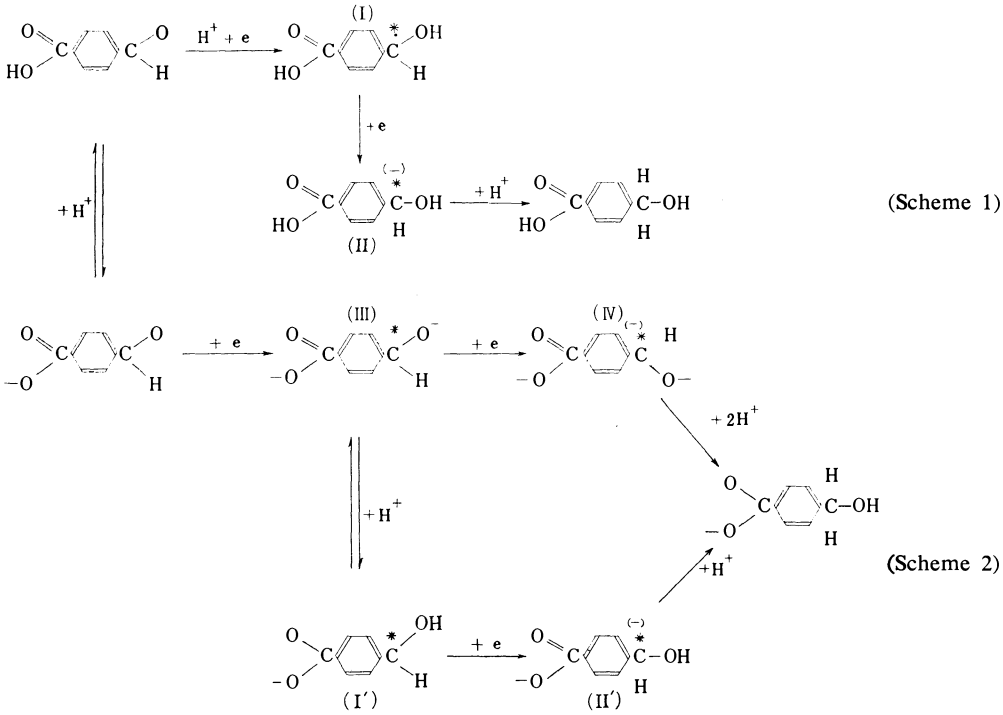
height of wave II decreased while a third wave (wave III) appeared at a more negative potential, increasing with the ascending pH, both approaching about half of the sum of the wave heights (Fig. 1-e). The sum of the wave heights was kept approximately constant over the pH range from 4.4 to 13.2, but it increased slightly in the acidic pH region below 4.4 because of the occurrence of the pre-wave. The half-wave potential of wave I depended on the pH. In the pH range from 4.4 to 7.5 where the pre-wave disappeared, the plots of $E_{1/2}$ against pH gave a straight line with a slope of 64 mV./pH, and $E^0_{1/2}$, the half-wave potential extrapolated to pH 0, was −0.69 V. vs. SCE. The $E_{1/2}$-pH plot of wave I in the acidic pH range below 4.4 deviated from the $E_{1/2}$-pH relation line in the pH range from 4.4 to 7.5 and gave a slope of 54 mV./pH. It is an interesting fact, however, that in the biphthalate buffer the height of the pre-wave increased slightly and the $E_{1/2}$-pH plot of wave I, even in the pH range below 4.4, fitted on that straight line with a slope of 64 mV./pH (Figs. 2 and 3). The half-wave potentials for waves II and III under the conditions studied were about −1.30 and −1.60 V. vs. SCE respectively, and neither showed any pH-dependence.



The occurrence of the two waves* in the pH range from 5.5 to 7.5 and their pH-dependence can be explained reasonably by the acid dissociation-recombination mechanism; wave I is due to the reduction of the carbonyl group of the undissociated terephthalaldehydic acid, and wave II, to that of its anion. The pK_a of terephthalaldehydic acid, determined by the acid-base titration method, was 4.47±0.03 at 25°C**. On the other hand, pK'_a, which was obtained from the limiting current against the pH curve of wave I, was 6.60 at 25°C (Fig. 2). This result suggests the existence of an acid recombination kinetic current, as was pointed out by Holleck and Marsen[1]. Furthermore, the second occurrence of two-step waves, weves II and III, above pH 8.2 may be understood by applying the carbinolate-free radical dissociation theory.[4,5] The "pK" for this dissociation equilibrium was about 9.5, which is the pH value corresponding to the increase in the height of wave III to one-fourth of the sum of the wave heights.

The Effect of the Ionic Strength on the Half-wave Potentials.—An investigation of the effect of the ionic strength on the half-wave potentials for waves I, II and III indicated the results given in Fig. 4. Figure 4 reveals that the half-wave potential of wave III is markedly affected by the ionic strength of the test solution. At pH 13.2 wave III was shifted to more positive potentials with the increasing ionic strength. Since wave II scarcely changed, the two waves were inclined to make a single wave. Similar phenomena were observed in

* The methyl ester of terephthalaldehydic acid gave a single wave over the pH range from 1 to 12.[6]

** The dissociation constant of *o*-phthalaldehydic acid has been reported to be 3.6×10^{-5}.[1]

the case of the increasing concentration of such a supporting electrolyte as sodium hydroxide.[2] The positive shift of the half-wave potential of wave III is considered to be a key for elucidating the reduction mechanism for wave III.

The Dependence of the Limiting Current on the Mercury Pressure and the Temperature.—With respect to the mercury pressure-dependence, the plots of i_l against $h^{1/2}$ gave a straight line of a general expression, $i_l = ah^{1/2}+b$. If i_l is controlled exclusively by the diffusion, b should be equal to zero; if it is controlled completely by the reaction rate, a may be expected to be zero. On the other hand, the adsorption current is proportional to the mercury pressure. Table I shows the experimental data of the parameters a and b, and of the temperature coefficients at a proper pH value in five representative pH ranges. Table I reveals that wave I at pH 6.8 and the wave III at pH 13.2 are obviously of a kinetic nature, although both showed temperature coefficients of less than 1%. It is noticable that the temperature coefficient for wave I at pH 6.8 was practically zero.

The pre-wave appears to be the adsorption current, i_a, submitting to a general equation, $i_a = a'h$, where a' is a proportional constant (Table I). The single waves at pH 5.1 and 7.9, waves I and II respectively, seem to be controlled by the diffusion.

The Concentration-dependence and the Diffusion Current Constant.—Linear relationships between the sum of the wave heights and the concentration of terephthalaldehydic acid in the range from 1 to 0.04 mM were obtained over the pH range studied. The diffusion current constants for the single waves were calculated

by Ilković equation as 3.48±0.04 for wave I at pH 5.2 and 3.36±0.07 for wave II at pH 7.9. For wave II and the sum of the two waves at pH 13.2, 1.82±0.03 and 3.38±0.03 were obtained respectively.

The number of electrons, n, involved in the electrode process can be calculated by the equation, $I_D = 607\, n\, D^{1/2}$, where I_D is the diffusion current constant and D is the diffusion coefficient. If the diffusion coefficient for terephthalaldehydic acid is assumed to be 7.35×10^{-6} cm^2 sec^{-1}, that is, the value of the diffusion coefficient for phthalic acid as calculated by the Stokes-Einstein equation, $n = 2.12$, 2.04 and 2.05 are obtained for wave I at pH 5.2, for wave II at pH 7.9, and for the sum of the waves at pH 13.2 respectively. These values indicate that the sum of the wave heights for terephthalaldehydic acid, over the pH range studied, corresponds to a two-electron reduction of the carbonyl group.

Relationships between the heights of the pre-wave and of wave I at pH 2.1 and the concentration over the range from 0 to 0.4 mM of terephthalaldehydic acid are shown in Fig. 5. The height of the pre-wave reached a limiting value with the increasing concentration, substantiating the conclusion that the pre-wave is due to the adsorption of an organic substance, possibly the reduced form of undissociated terephthalaldehydic acid, at the dropping mercury electrode. Wave I at pH 2.1 could be distinguished, down to 0.08 mM of terephthalaldehydic acid, from the pre-wave (Fig. 5). Using the pK value of terephthalaldehydic acid, the bulk concentration of undissociated molecules at pH 2.1 is calculated as approximately equal to that of terephthalaldehydic acid, and at pH 5.16 the bulk concentration of undissociated molecules is calculated as 0.08 mM, when the analytical

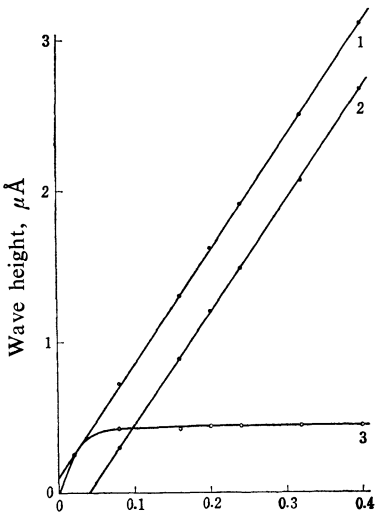

Fig. 5. Relationship between the terephthalaldehydic acid concentration and the d. c. wave heights at pH 2.1.
1) sum of wave heights, 2) wave I, 3) pre-wave

concentration of terephthalaldehydic acid is 0.4 mM. The pre-wave is still expected, therefore, to appear at pH 5.16, but experimentally it was observed at a pH lower than 4.4. To elucidate this fact, the effect of concentration of terephthalaldehydic acid on the half-wave potentials of the pre-wave and wave I at pH 4.0 was investigated (Table II). It was found that the pre-wave was shifted to a more negative potential with the decreasing concentration; on the other hand, the main wave I shifted to more positive potentials. At 0.2 mM terephthalaldehydic acid, the pre-wave marged into wave I, and the half-wave potential for the coalesced wave remained unchanged with

the decreasing concentration. It may be concluded that, since the equilibrium concentration of undissociated molecules in the bulk solution decreases visibly when the pH increases from 3 to 6, the difference in half-wave potentials between the pre-wave and wave I decreases, and the two waves coalesce.

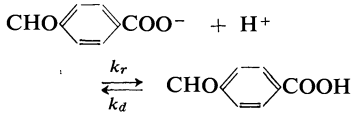

Table II. The effect of terephthalaldehydic acid concentration on the half-wave potentials at pH 4.0

0.2		0.89	—
0.08		0.90	—
0.04		0.90	—

Log Plot.—For the study of the slopes and shapes of the terephthalaldehydic acid waves, the term $\log i/(i_d-i)$ was plotted against E, at 0.4 mM terephthalaldehydic acid. Wave I at pH 2.0 and 5.6 gave a linear log plot with a slope of about 43 mV., considerably greater than the theoretical value for the reversible two-electron reduction. In other media, the slopes of the log plot for wave I were in the range from 48 to 52 mV. Because wave II in the vicinity of pH 8 tended to show a maximum if a maximum suppresser such as gelatine was not added to the electrolytic solution, the log plot for wave II was slightly curved, even in 0.4 mM terephthalaldehydic acid, and the slopes were in the range from 62 to 78 mV. However, waves II and III at pH 13.2, the heights of which corresponded to a one-electron reduction, gave linear log plots with slopes of 43 and 98 mV. respectively. It seems that the abnormally large value of the slope for wave III indicates the irreversible nature of the electrode process involved.

Recombination and Dissociation Rate Constants.—The reduction current of terephthalaldehydic acid in the pH range from 5.5 to 7.5 well fits the theory of the kinetic recombination currents.[7]

The mechanism of the electrode process is given by;

$$\xrightarrow{2e+2H^+} \quad CH_2OH\text{-}C_6H_4\text{-}COOH \qquad (1)$$

where k_r and k_d are the recombination and dissociation rate constants respectively. The recombination rate constant can be calculated by the following equation;[8]

$$\log K_r = 2pK'_a - pk_a - 2\log 0.886 - \log t \qquad (2)$$

where t is the drop time. t was 4.48 sec. at -1.0 V. vs. SCE in the electrolytic solution studied. The k_r and k_d were calculated as follows; $k_r = 1.5\times10^8$ 1. (mol. sec.)$^{-1}$, and $k_d = 5.2\times10^3$ sec^{-1}.

A. C. Polarography.—*The Behavior of A. C. Waves.*—A. C. polarograms in buffered solutions of various pH values are shown in Fig. 1. As compared with the d. c. wave heights, a. c. wave heights were greatly influenced by the change in the pH (Fig. 2). The peak potential for each a. c. wave agreed approximately with the half-wave potential for the corresponding d. c. waves (Fig. 3). In the acidic pH range below 4, a small "kink" was observed on the positive side of the a. c. first wave (a. c. wave I), where the pre-wave appeared on the d. c. polarogram. This "kink" is considered to be caused by the adsorption of the reduced form of undissociated molecules at the dropping mercury electrode. However, this "kink" differs from the adsorption peak of dyes;[9] riboflavin,[10] methylene blue,[11] flavinmononucleotide[12] and others[9] are known to give a d. c. pre-wave and a sharp, well-defined corresponding a. c. peak as a result of the adsorption of the reduced form in acidic solutions.

The height of a. c. wave I was strongly depressed in the pH range from 1 to 3. In the case of terephthalaldehydic acid, it seems that a strong adsorption of undissociated molecules was present in the potential region where the pre-wave and wave I were observed, resulting in the depression of the a. c. wave heights. (See the discussion of base current effects.) Although the concentration of undissociated terephthalaldehydic acid in equilibrium is considered to decrease rapidly when the pH is increased from 3 to 6, the height of a. c. wave I increased up to a maximum at pH 5.2, where the d. c. pre-wave merges into a

coalesced wave. It seems that the decreasing concentration of adsorbable species in the bulk solution weakens the depression of the a. c. wave height. However, the abnormal rise of the height of a. c. wave I in the pH range from 5.1 to 5.5 implies that the a. c. wave formation process in that pH range involves both the reduction of undissociated molecules and the adsorption of the reduced form. Furthermore, the deviation of the wave height against the pH curve of a. c. wave I from the theoretical dissociation curve reveals that it is necessary to take into account the a. c. kinetic current for the formation of a. c. waves. The pH values of the disappearance of a. c. wave I and of the appearance of a. c. wave II were shifted to a pH range more acidic by 0.5 pH unit than in the d. c. polarography (Fig. 2). It is considered that in this case the a. c. current is less affected by the kinetic reaction than are the d. c. kinetic currents.

The a. c. wave height-pH curve for a. c. wave II was found to have a shape analogous to that for d. c. wave II. On the other hand, a. c. wave III was ill-defined, and at pH 13.2 its height was as small as a tenth of the height of a. c. wave II (in the d. c. polarography, the ratio of the height of wave II to III was about unity). The reduction process for wave III is irreversible.

Base Current Effects.—In the pH region below 3, the base current was depressed on both the positive and the negative sides of a. c. wave I, indicating that the undissociated terephthalaldehydic acid and the reduced form were strongly adsorbed at the surface of the dropping mercury electrode (Fig. 1-a). As has been described above, this strong adsorption affects the a. c. pre-wave and wave I so as to depress the heights of these waves. As the pH increased from 3 to 5, the lowering of the base current was decreased, and the depression of a. c. wave I was weakened.

In the pH range from 5.1 to 5.5, where the abnormal rise of the height of a. c. wave I occurred, the base current between a. c. waves I and II was lowered.

Simultaneously, a new and small peak was observed on the negative side a. c. wave II, although there was no corresponding d. c. wave at this potential. This peak was shifted to more positive potentials with the increasing pH, and then it was merged into a. c. wave II. This fact suggests that the new peak is a kind of tensammetric one, because of the desorption of the reduced form of undissociated terephthalaldehydic acid. Further, above pH 5, a "hump" was observed at about —0.5 V. vs. SCE, probably due to the weak adsorption-desorption process for the dissociated terephthalaldehydic acid.

The Relation between A. C. Wave Height and the Concentration of Terephthalaldehydic Acid.—The plot of the a. c. wave heights at pH 2.1, 5.1 and 13.2 against the concentration of terephthalaldehydic acid are shown in Fig. 6. The plot for a. c. wave I at pH 2.1 and 5.1 were non-linear and fit the equation of the Langmiur adsorption isotherm, $i_p = abC/(1+bC)$, where i_p is the a. c. wave height, C is the molar concentration of terephthalaldehydic acid in the bulk solution, and a and b are the parameters with the following values; a= 669.1 l./mol., b=254.0 μU at pH 2.1 and a= 2364.0, b=163.0 at pH 5.1. In strongly alkaline solutions, a. c. waves II and III each gave a straight line. These results may also substantiate the conclusion that the reduction of undissociated terephthalaldehydic acid includes the adsorption process, at least in the pH range below 5.1.

The Dependence of A. C. Wave Heights on the Mercury Pressure and the Temperature.—The a. c. wave heights of terephthalaldehydic acid change with the mercury pressure, as Table III shows, indicating that the d. c. polarographic electrode process in the reduction of terephthalaldehydic acid is irreversible.[13] The

13) M. Senda, *Kagaku no Ryoiki*, Suppl., No. 50, "Polarography I," p. 28 (1962).

temperature coefficients for a. c. waves gave considerably greater values than those usually observed for a. c. waves.

Reduction Mechanism.—From the d. c. and a. c. polarographic results and the discussion above, and from the similarity between the reduction of the carbonyl group of terephthalaldehydic acid and that of benzaldehyde,[14,15] the following mechanism is proposed; wave I is ascribed to the two-electron reduction of the carbonyl group of undissociated molecules following the adsorption at the electrode surface, and *p*-carboxyl benzyl alcohol is formed. Applying the reduction mechanism for benzaldehyde proposed first by Holleck and Marsen,[4] the process is written as Scheme 1. In this case, the electrode reaction via the intermediate carbinolate-free radical (I) and its radical ion (II) proceeds successively. The electrode reaction product, *p*-carboxyl benzyl alcohol, is adsorbed at the electrode surface, at least in the pH range below 4.4. Wave II is due to the reduction of anions; in the pH range below 8 the anion is reduced first to its radical ion (III), which combines rapidly with a proton, and then the electrode reaction proceeds successively to the formation of dissociated *p*-carboxyl benzyl alcohol. The whole reaction is a two-electron reduction (Scheme 2).

In the pH range from 5.5 to 7.5, the two waves, I and II, form a system of kinetic recombination currents in which the electrode process is given by Eq. 1. In view of the a. c. polarographic behavior in this pH range, it may be concluded the molecules of the undissociated terephthalaldehydic acid formed by the recombination in the reaction layer are first adsorbed at the electrode surface and then reduced. In the treatment of the acid-recombination kinetics of terephthalaldehydic acid, however, the adsorption was not taken into consideration.

The fact that the temperature coefficient of d. c. wave I at pH 6.8 was zero indicates that the dissociation equilibrium is shifted in favor of the anions with an increase in the temperature.

On the basis of their analysis of current-time curves in a drop life of the dropping mercury electrode, Kasening and Holleck[15] recently rejected the carbinolate-free radical dissociation theory for the reduction of benzaldehyde; instead, they proposed a new reduction scheme, in which a dissociation equilibrium of benzaldehyde was antecedent to the competitive reduction processes of the free molecule and the cation.

In the case of terephthalaldehydic acid, however, the polarographic behavior above pH 8.2 cannot be explained by the new theory, but only by the carbinolate-free radical dissociation theory. A dissociation equilibrium between radical ion III and radical I′ is established in the electrode reaction. Radical I′ is reduced at the same potential as the dissociated molecule, while radical ion III is reduced at more negative potentials than wave II, resulting in the appearance of wave III. In a strongly alkaline solution, wave II is due to the reduction to radical ion III, and wave III, to that from radical ion III to *p*-carboxyl benzyl alcohol, both corresponding to a one-electron reduction. The positive shift of the half-wave potential of wave III with the ionic strength or concentration of a supporting electrolyte is attributed to the unstability of radical ion III.

Summary

The d. c. and a. c. polarography of terephthalaldehydic acid has been investigated in buffered solutions containing no ethanol over the pH range from 1 to 13.

D.C. Polarography.—Terephthalaldehydic acid gives a pre-wave and three reduction waves. The pre-wave, which is due to the adsorption of the reduced form of undissociated molecules, is followed by wave I below pH 4.4. Our results above pH 4.4 accord approximately with Holleck and Marsen's. The half-wave potential for the wave I is pH-dependent, and the $E^0_{1/2}$ is -0.69 V. vs. SCE. The half-wave potentials of waves II and III, both pH-independent, are -1.30 and -1.60 V. vs. SCE under the conditions studied. The sum of the wave heights has been kept constant in

14) For review, Y. Nagata, *Rev. Polarography*, **7**, 12 (1959).
15) B. Kasening and L. Holleck, *Z. Elektrochem.*, **63**, 166 (1959).

the pH range from 4.4 to 13.2, and it corresponds to the two-electron reduction of the carbonyl group. The two-step waves, in which wave I is due to the reduction of the undissociated molecule and wave II, to that of its anion, in the pH range from 5.5 to 7.5 form a system of kinetic recombination currents. The recombination and dissociation rate constants have been calculated as $k_r = 1.5 \times 10^8$ l. (mol. sec.)$^{-1}$ and $k_d = 5.2 \times 10^3$ sec^{-1}. The double waves above pH 8.2 have been explained by the carbinolate-free radical dissociation theory.

A. C. Polarography.—A. c. waves have been obtained to corresponding to the d. c. waves. The heights of the a. c. pre-wave and wave I are depressed below pH 5. This depression has been attributed to the strong adsorption of undissociated molecules at the dropping mercury electrode. The relationship between the a. c. wave height and concentration below pH 5 is non-linear. It has been noted that the a. c. kinetic current should be taken into account for the a. c. wave formation.

The electrode process for wave III is irreversible, and a. c. wave III is ill-defined.

A reduction mechanism over the pH range studied has been proposed.

*A New Rearrangement Reaction of β-Hydroxy-α-amino Acid N-Carboxy Anhydrides to 2-Oxazolidone Derivatives**

By Tomoo SAITO

(Received August 15, 1963)

An α-amino acid *N*-carboxy anhydride polymerizes into poly-α-amino acid, which is a model substance of protein. The synthesis of β-hydroxyl-containing poly-α-amino acids is of interest, because the polymers provide models of water-soluble proteins.

Polymers containing protected β-hydroxyl groups, viz., poly-*O*-acetyl-DL-serine,[1] poly-*O*-acetyl-L-serine,[2,3] and poly-*O*-acetyl-L-threonine,[3] have been prepared by the polymerization of the corresponding *N*-carboxy anhydrides by using a trace amount of a suitable amine, e. g., triethylamine. The subsequent complete deacetylation of the resultant protected polymers was, however, accompanied by many difficulties. An attempt to polymerize DL- and L-serine *N*-carboxy anhydrides with a free β-hydroxyl group was unsuccessful in obtaining poly-DL- and L-serine, as has been reported by Fasman and Blout.[2]

The present paper will describe a rearrangement of the *N*-carboxy anhydrides of several α-amino acids with free β-hydroxyl groups to 2-oxazolidone derivatives.

Two cyclic compounds, *N*-carboxy anhydride (III) and 2-oxazolidone derivative (VII), are supposed to be produced by the reaction of β-hydroxyl-α-amino acid (I) with phosgene, in which reaction *N*-chlorocarbonyl-β-hydroxy-α-amino acid (II) is a possible intermediate (Scheme A).

The reaction of L-serine, DL-threonine, L-threonine, and DL-β-phenylserine with phosgene

in anhydrous dioxane at 50°C afforded exclusively products corresponding to III. The structure III of these substances was inferred from the following data. The equivalent weights determined for the substances III, by anhydrous sodium methylate titration using thymol blue as an indicator,[4] agreed with those of the corresponding *N*-carboxy anhydrides (III) (Table I), and the ready elimination of carbon dioxide by the action of dilute hydrochloric acid under mild conditions was observed for the substance III, while the use of this reaction in the qualitative identification for *N*-carboxy anhydrides is well known. The infrared absorption spectra showed two typical carbonyl-stretching absorption bands[5] for the cyclic acid anhydride, at 1860~1850 cm^{-1} and at 1780 cm^{-1}, and a hydroxyl-stretching absorption band at 3540 cm^{-1} (Figs. 1—4).

III did not polymerize into polyamino acids under the conditions suitable for the polymerization of *N*-carboxy anhydrides of general amino acids; rather, it was rearranged into a 2-oxazolidone derivative (VII). The evidence is as follows. Some physical constants (Table II) for the products derived from III attracted our special attention and led us to suggest a rearranged product, VII. Confirmatory support was given to the suggested structure VII by the infrared absorption spectra (Figs. 1—4), which indicated two carbonyl-stretching vibration bands at 1770~1650 cm^{-1} assignable to vibrations of cyclic lactone[5] and the free carboxyl group[5] and to the lack of the hydroxyl vibration at 3540 cm^{-1}.

4) A. Berger, M. Sela and E. Katchalski, *Anal. Chem.*, **25**, 1554 (1953). They reported that *N*-carboxy anhydride could be titrated with sodium methylate in non-aqueous solvent, and the reaction proceeds according to the following equation:

TABLE I

β-Hydroxy-α-amino acid *N*-carboxy anhydrides

III	R		Yield %	M. p. °C		Equiv. wt. ($NaOCH_3$ tit.) Found	Calcd.
a	-H	(L)	72	115 [115	(decomp.) (decomp.)][2]	127	131.1
b	$-CH_3$	(DL)	41	117	(decomp.)	141	145.1
c	$-CH_3$	(L)	82	111~112	(decomp.)	147	145.1
d	$-C_6H_5$	(DL)	98	195	(decomp.)	200	207.2

TABLE II

2-Oxazolidone-4-carboxylic acid 5-derivatives

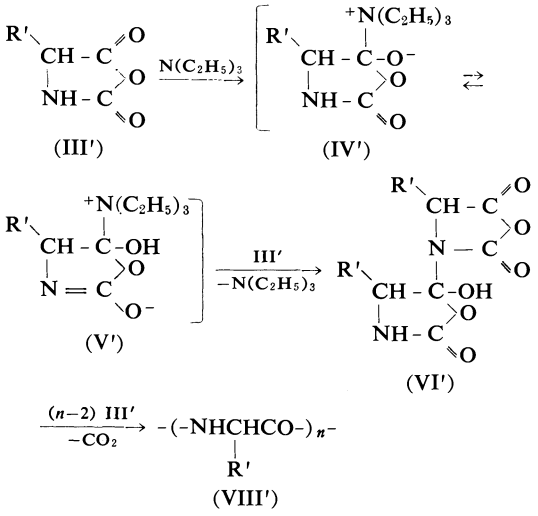
VII	R		Yield %	M. p. °C	Equiv. wt. ($NaOCH_3$ tit.) Found	Calcd.	$[\alpha]_D$	Hydrolysis by 6 N HCl
a	-H	(L)	36	118	134	131.1	−10.95°	L-Serine
b	$-CH_3$	(DL)	78	128~129 (127~128)[6,10]	143	145.1		DL-Threonine
c	$-CH_3$	(L)	90	139 (139)[7]	146	145.1	+41.0° (+41.7°)[7]	L-Threonine
d	$-C_6H_5$	(DL)	96	204 (decomp.) [206~207 (decomp.)][6]	208	207.2		DL-β-Phenyl-serine

Thus, rearranged products VII, viz., L-2-oxazolidone-4-carboxylic acid (VIIa), DL- and L-*trans*-5-methyl-2-oxazolidone-4-carboxylic acid (VIIb and VIIc), and DL-trans-5-phenyl-2-oxazolidone-4-carboxylic acid (VIId), were derived from the corresponding *N*-carboxy anhydrides (III) under the influence of the basic reagent.

Incidentally, Kaneko and Inui[6] have reported the preparation of DL-*trans*-5-methyl-2-oxazolidone-4-carboxylic acid (m. p. 127~128°C) in the different way, from DL-threonine, and they have also obtained its optically active form (m. p. 138.5~139.5°C) by resolution of the DL-compound.[7] VIIb and VIIc, respectively, were also identified with these two oxazolidones by melting point and infrared absorption spectra.

All of the compounds VII are all easily soluble in water, with the exception of the 5-phenyl derivative (VIId), which is slightly soluble, without decomposition, and their aqueous solutions indicate a strong acidity.

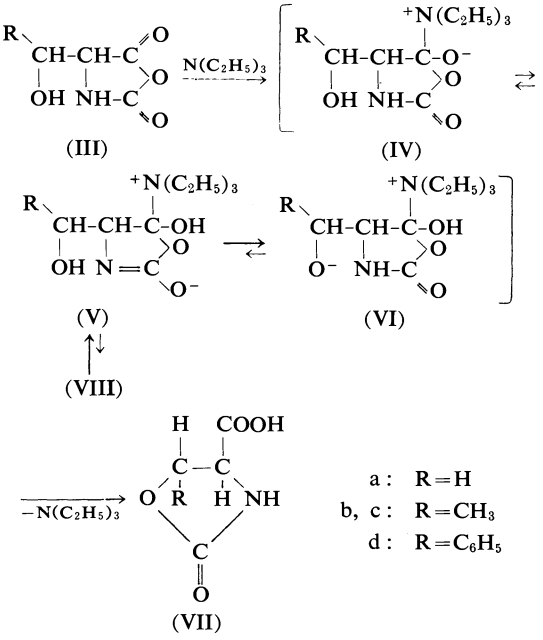
Hydrolysis by heating with 6 N hydrochloric acid converted VII into the starting β-hydroxy-α-amino acid (I). Optically-active VIIa and VIIc[7] gave optically-pure L-serine[8] and L-threonine[8] respectively.



Therefore, during the rearrangement, the configurations at both asymmetric centers remain unchanged. This rearrangement resulted in the formation of VIIb, VIIc, and VIId from the corresponding structures, IIIb, IIIc, and IIId, the rearrangement was especially smooth in the last two cases. However, L-serine *N*-carboxy anhydride (IIIa) gave a considerable amount of amorphous polymeric material, which showed a positive Biuret reaction. This material was characterized as *O*-acyl-polyamino acid by its infrared absorption spectra, but this polymer was not investigated further.

The rearrangement never proceeds exclusively without a side reaction affording a polymer, and the facility of the latter reaction depends on the β-substituted group within the anhydride molecule III. The order of such an effect of decreasing the yield of 2-oxazolidones was as follows:

$$C_6H_5\text{-(DL-)} < CH_3\text{-(L-)} < CH_3\text{-(DL-)} \ll H\text{-(L-)}$$



The mechanism of the rearrangement from III to VII is not certain, but the following hypothesis may be proposed. In the initial stages of the polymerization of general α-amino acid *N*-carboxy anhydrides by using a trace amount of amine (cf. Scheme B), the first step is the reversible formation of a complex IV' by the addition of the base to carbonyl-5; this complex may coexist with its tautomeric form V'. The reaction of the latter with an *N*-carboxy anhydride molecule is supposed to lead to the dimer VI' with a scission of the tertiary base molecule. The subsequent addition of

8) L-Serine: $[\alpha]_D^{25} = +14.5°$ (in 1N hydrochloric acid), L-Threonine: $[\alpha]_D^{26} = -28.3°$ (in water). S. Akabori and S. Mizushima (Eds.), "Protein Chemistry" (Tanpakushitu Kagaku), Vol. 1, Kyoritsu Shuppan K. K., Tokyo (1952), p. 112.

Scheme B

N-carboxy anhydrides to the dimer VI' leads to a polyamino acid VIII'.[9] However, in the case of an N-carboxy anhydride which possesses a free β-hydroxy group (cf. Scheme C), the tautomer of a complex V corresponding to V' in Scheme B transfers rapidly with the proton migration to another tautomeric form, VI.

Scheme C

This migration rate is supposed to be greater than that which affords polyamino acid (VIII) and which is caused by the addition of N-carboxy anhydride to V. Then the rearrangement may proceed smoothly with the elimination of a tertiary base molecule from VI to VII as a stable form. In the case of IIIa it seems probable that the same intermediate Va in Scheme C affords VIIa through VIa, and VIII by two competing paths.

Experimental

All melting points are uncorrected.

Infrared Measurements. — All infrared spectra were recorded in Nujol mulls with a Koken DS 301-type double-beam spectrometer using a sodium chloride prism.

L-Serine N-Carboxy Anhydride (IIIa).[2]—Phosgene was bubbled into a suspension of L-serine (Ia) (10 g.) in dry dioxane (200 ml.) for three hours, while the temperature was maintained at 50°C. Then carbon dioxide was passed through the solution until it was phosgene-free. After filtration, the solvent was evaporated under reduced pressure, with the temperature kept below 40°C. The resultant oil solidified on rapeated trituration with petroleum ether. The solid was collected, dried, and recrystallized from ethyl acetate and petroleum ether; yield, 4.5 g. (72%); m. p. 115°C (decomp.). Found: N, 10.53; equiv. wt. 127 (determined by anhydrous sodium methylate titration). Calcd. for $C_4H_5O_4N$: N, 10.69%; equiv. wt. 131.1.

DL-Threonine N-Carboxy Anhydride (IIIb), L-Threonine N-Carboxy Anhydride (IIIc), and DL-β-Phenylserine N-Carboxy Anhydride (IIId). — IIIb, IIIc, and IIId were produced, by minor alterations of the method used in the preparation of IIIa, from DL- and L-threonine, and DL-β-phenylserine (m. p. 190°C (decomp.))[11,12] respectively. IIIb: yield, 41%; m. p. 117°C (decomp.). Found: N, 9.70; equiv. wt. 141. Calcd. for $C_5H_7O_4N$: N, 9.65%; equiv. wt. 145.1. IIIc: yield, 82%; m. p. 111~112°C (decomp.). Found: N, 9.61; equiv. wt. 147. Calcd. for $C_5H_7O_4N$: N, 9.65%; equiv. wt. 145.1. IIId: yield, 98%; m. p. 195°C (decomp.). Found: N, 6.68; equiv. wt. 200. Calcd. for $C_{10}H_9O_4N$: N, 6.76%; equiv. wt. 207.2.

L-2-Oxazolidone-4-carboxylic Acid (VIIa).—To a solution of IIIa (2.0 g.) in anhydrous dioxane (20 ml.), triethylamine (0.015 ml.) was added, and the mixture was stirred at room temperature for three days. Some polymeric precipitate was filtered off; this substance gave a positive Biuret reaction and showed not only amide I and II absorption spectra at 1625 cm^{-1} and 1545 cm^{-1} respectively, but also a carbonyl band at 1750 cm^{-1} which may be assignable to the ester. The solvent was evaporated under reduced pressure below 35°C. The resultant crystals were recrystallized from ethyl acetate and petroleum ether; yield, 0.72 g. (36%); m. p. 118°C, $[\alpha]_D^{15} = -10.95°$ (c 4.20, water). Found: C, 36.60; H, 3.91; N, 10.59; equiv. wt. 134 (determined by

anhydrous sodium methylate titration). Calcd. for $C_4H_5O_4N$: C, 36.65; H, 3.85; N, 10.69%; equiv. wt. 131.1.

DL-*trans*-5-Methyl-2-oxazolidone-4-carboxylic Acid (VIIb), L-*trans*-5-Methyl-2-oxazolidone-4-carboxylic Acid (VIIc), and DL-*trans*-5-Phenyl-2-oxazolidone-4-carboxylic Acid (VIId).—VIIb, VIIc, and VIId were obtained from IIIb, IIIc, and IIId respectively in the same way as VIIa, but in the case of the preparation of VIIc and VIId, no polymeric materials were produced. VIIb: yield, 78%; m. p. 128~129°C.[6,10] Found: C, 41.40; H, 4.92; N, 9.69; equiv. wt. 143. Calcd. for $C_5H_7O_4N$: C, 41.38; H, 4.86; N, 9.65%; equiv. wt. 145.1. VIIc: yield, 90%; m. p. 139°C, $[\alpha]_D^{15}=+41.0°$ (*c* 3.97, water).[7] Found: C, 41.42; H, 4.92; N, 9.68; equiv. wt. 146. Calcd. for $C_5H_7O_4N$: C, 41.38; H, 4.86; N, 9.65%; equiv. wt. 145.1. VIId: yield, 96%; m. p. 204°C (decomp.).[6] Found: C, 58.01; H, 4.41; N, 6.73%; equiv. wt. 208. Calcd. for $C_{10}H_9O_4N$: C, 57.97; H, 4.38; N, 6.76%; equiv. wt. 207.2.

The Hydrolysis of 2-Oxazolidone Derivatives (VII) by Hydrochloric Acid. — VII (1.0 g.) was dissolved in 6 N hydrochloric acid (20 ml.), and the solution was heated on a boiling water bath. After three hours, the solution was decolorized with active charcoal and concentrated to dryness. The residue was dissolved in absolute alcohol, and the addition of a suitable amount of pyridine to this solution gave crystalline products in an almost theoretical yield. The recrystallization of them was carried out from water and alcohol. The products were identified by comparison with respective authentic samples in all their characteristics. Ia from VIIa: m. p. 220°C (decomp.), $[\alpha]_D^{18}=+14.4°$ (*c* 2.3, 1 N hydrochloric acid);[8] Ib from VIIb: m. p. 233°C (decomp.); Ic from VIIc: m. p. 254°C (decomp.), $[\alpha]_D^{18}=-28.0°$ (*c* 2.6, water);[8] Id from VIId: m. p. 202°C (decomp.).

The author wishes to thank Professor Hiroshi Kotake for his helpful discussions in the course of this study. He also wishes to express his sincere thanks to the Ajinomoto Co., Ltd., for its kind donation of L-serine, DL-threonine, and L-threonine.

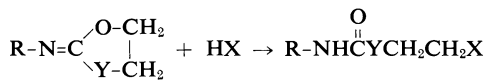
The Ring-opening Addition Reactions of Exo-imino Cyclic Compounds with Carboxylic Acids

By Teruaki MUKAIYAMA, Yorikazu TAMURA and Tamotsu FUJISAWA



(Received October 10, 1963)

Preceding papers[1-5] have reported that the 1, 4-addition type ring-opening polymerization of exo-imino cyclic compounds, such as ethylene iminocarbonates, 2-iminooxazolidines and 2-iminotetrahydrofurans, in the presence of cationic catalysts, such as Lewis acids or protonic acids, affords polyurethanes, polyureas and polyamides respectively, as is shown in the following equation:

where Y is an oxygen atom, a substituted imino or a methylene group.

Further, it has been shown there that the exo-imino cyclic compounds react with acidic substances, such as carboxylic acids or phenols, to give the corresponding addition compounds by a ring-opening 1, 4-addition reaction:

In the present investigation, the rate constants, the activation energies and the entropies of the activation of the reactions of the exo-imino cyclic compounds with carboxylic acids in various solvents were determined in order to study the mechanism of the reactions.

The results lead to the conclusion that the ring-opening addition reactions involve two stages, namely, the initial formation of the salt from the exo-imino cyclic compound and the acid, followed by the reaction of the salt with another molecule of the acid to yield the addition compounds.

Experimental

Materials. — Ethylene *N*-phenyliminocarbonate was prepared from phenylimidophosgene and sodium ethylene glycolate.[1]

2-Phenylimino-3-methyloxazolidine was prepared by the treatment of 1-(2-chloroethyl)-1-methyl-3-phenylurea with hot water.[5]

The *N*-substituted 2-iminotetrahydrofurans were prepared from 2,2-diethoxytetrahydrofuran and the corresponding amines.[8]

The carboxylic acids were obtained from a commercial source and were purified by recrystallization. The melting points and the pK_a values for these carboxylic acids are listed in Table I.

Table I. The melting points and pK_a values of carboxylic acids used

Acid	M. p., °C	$pK_a^{25°C}$
C_6H_5-	121.7	4.17
o-CH_3O-C_6H_4-	101.5	4.09
p-CH_3O-C_6H_4-	184.0	4.49
o-Cl-C_6H_4-	141.0	2.89
m-Cl-C_6H_4-	154.5	3.82
p-Cl-C_6H_4-	234.0	3.98

p-CN-C_6H_4-	219.0	3.51
o-NO_2-C_6H_4-	148.0	2.21
p-NO_2-C_6H_4-	240.0	3.40
o-Br-C_6H_4-	149.0	2.82
3,5-$(NO_2)_2C_6H_3$-	205.0	2.80
$ClCH_2$-	63.0	2.81

Solvent.—Dioxane (b. p. 101.0°C), toluene (b. p. 111°C), xylene (b. p. 138~140°C) and benzene (b. p. 78°C) were distilled and dried over metallic sodium wire, and chlorobenzene (b. p. 132°C) was purified by distillation.

General Kinetic Method. — An equimolar solution of ethylene *N*-phenyliminocarbonate and carboxylic acid in various solvents in a 50 ml. reaction tube was maintained at a desired, constant temperature by immersion into a thermostat. The temperature control of the thermostat was accurate to ±0.03~0.07°C within the temperature ranges between 20~90°C. Five milliliter aliquots of this solution were withdrawn from time to time by means of a pipet and were put into 15 ml. of dioxane in a 50 ml. Erlenmeyer flask in order to make the titration mixture homogeneous. The unreacted carboxylic acid was titrated with a standard 0.5 N sodium hydroxide solution, using phenolphthalein as an indicator. In the case of the reaction with *m*-cyano-, *p*-cyano- and 3,5-dinitro-benzoic acids, thymolcresolgreen was used as an indicator.

Similarly, the percentage reaction of 2-phenylimino-3-methyloxazolidine or *N*-substituted 2-iminotetrahydrofurans with carboxylic acids was measured by this method.

Results and Discussion

The Reaction of Ethylene *N*-Phenyliminocarbonate with Carboxylic Acids. — Figure 1

shows plots of the percentage reaction against time (min.) for the reaction of ethylene *N*-phenyliminocarbonate (0.33 mol./l.) and benzoic acid (0.33 mol./l.) in xylene at various temperatures. As Fig. 2 shows, the third-order plots show sufficiently straight lines, from which the overall reaction order of ethylene *N*-phenyliminocarbonate with benzoic acid is shown to be third from a 20% to 90% completion of the reaction, without any noticeable side reaction.

On the basis of the experimental results mentioned above, the mechanism of the reaction can be considered to proceed via two stages, namely, the initial formation of the salt from the iminocarbonate and the acid, followed by the reaction of the salt with the other acid to yield β-benzoyloxyethyl *N*-phenylcarbamate.

For the first stage, the rate of the formation of the salt may be expressed as:

$$d[\text{salt}]/dt = k_1\left[C_6H_5\text{-}N{=}C\begin{matrix}O\text{-}CH_2\\ |\\ O\text{-}CH_2\end{matrix}\right][C_6H_5COOH] - k_{-1}[\text{salt}] - k_2[\text{salt}][C_6H_5COOH]$$

For the second stage, the rate of formation of the product may be given by:

$$d[\text{product}]/dt = k_2[\text{salt}][C_6H_5COOH]$$

where k_1, k_{-1} and k_2 are the rate constants of these stages.

When the rate of the formation of the salt is zero at the steady state, the overall kinetic equation is expressed as:

$$d[\text{product}]/dt = k_1 \cdot k_2\left[C_6H_5\text{-}N{=}C\begin{matrix}O\text{-}CH_2\\ |\\ O\text{-}CH_2\end{matrix}\right] \times [C_6H_5\text{-}COOH]^2/(k_{-1}+k_2[C_6H_5COOH])$$

If k_{-1} is much larger than $k_2[C_6H_5COOH]$, when, namely, the second stage is the rate-determining step, the rate of the reaction can be expressed as follows:

$$d[\text{product}]/dt = K\left[C_6H_5\text{-}N{=}C\begin{matrix}O\text{-}CH_2\\ |\\ O\text{-}CH_2\end{matrix}\right][C_6H_5COOH]^2$$

The plots of the logarithm of the rate constants vs. the reciprocal absolute temperatures gave a satisfactorily straight line (Fig. 3); the activation energy of the reaction was thus found to be 20.4 kcal./mol.

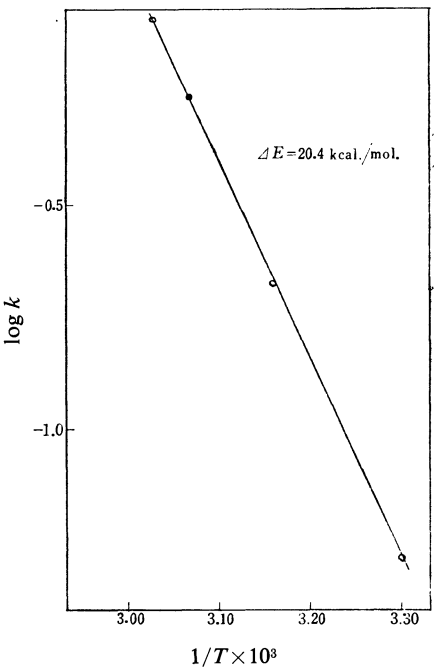

Fig. 3. The reactions of ethylene *N*-phenyliminocarbonate with benzoic acid in xylene. The plots of the rogarithm of the rate constants against the reciprocal absolute temperature.

Moreover, the reaction order changes to the second from the third, when the equimolar reaction of ethylene *N*-phenyliminocarbonate with benzoic acid (pK_a=4.17) was carried out in the presence of a stronger acid, e. g., diphenyl phosphate (pK_a=ca. 1.9), in xylene, as is shown in Fig. 4. The rates of the second-order reaction increase as the concentration of diphenyl phosphate increases. These results show that the reaction is a general acid-catalyzed reaction.

Furthermore, the reactions of ethylene *N*-phenyliminocarbonate with various substituted benzoic acids or chloroacetic acid in dioxane show that the rate increases as the acidity of carboxylic acid increases, as Table II shows. The effect of substituents in meta- and para-substituted benzoic acids follows the Hammett equation. As is shown in Fig. 5, $\log(k/k_0)$ is a linear function of the substituent constant σ given by Hammett,[6] and the gradient of the plots gave a value for the reaction constant ρ of +1.74 for the reaction. In ortho-substituted benzoic acids, the reactions are

not so fast as might be expected from their acidities; this may be attributed to the steric hindrance of the ortho substituents.

In addition, the rates of this reaction are slightly influenced by the polarity of the solvents used. The results listed in Table III show that the reactions in xylene are about 8~9 faster times than those in dioxane. The slower rate in dioxane than in xylene may result from the possible formation of a complex from a carboxylic acid and dioxane, a complex which prevents the formation of the above-mentioned salt of ethylene *N*-phenyliminocarbonate by the carboxylic acid. It

was also observed that the addition of dioxane to a toluene solution retards the reaction considerably.

The Reaction of 2-Phenylimino-3-methyloxazolidine with Carboxylic Acids. — Figure 6 shows that the reaction of 2-phenylimino-3-methyloxazolidine with benzoic acid in xylene satisfied the requirement for the third-order reaction kinetics. Analogous to the case of ethylene *N*-phenyliminocarbonate, the reaction can also be considered to proceed via two stages to give 1-(2-benzoyloxyethyl)-1-methyl-3-phenylurea.

The activation energy of this reaction was determined to be 19.6 kcal./mol. (see Fig. 7).

It was also confirmed that the rates of the reactions of 2-phenylimino-3-methyloxazolidine

with various substituted benzoic acids in dioxane increase as the acidities of the acids increase (see Table IV). The gradient of the plot $\log(k/k_0)$ against the substituent constant σ shown in Fig. 8 gave a value for the reaction constant ρ of +1.64, which was nearly equal to the case of ethylene *N*-phenyliminocarbonate mentioned above.

The Reaction of *N*-Substituted 2-Iminotetrahydrofurans with Chloroacetic Acid.—2-Phenyliminotetrahydrofuran reacts so very slowly

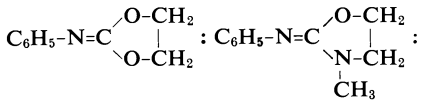
with benzoic acid in xylene that the rate of the reaction cannot be measured. Since it was found by the above experiment that the rate increases as the acidity of carboxylic acid increases, the rates of the reaction of 2-phenyliminotetrahydrofuran were determined by using chloroacetic acid. As Fig. 9 shows, the third-order plots have sufficiently straight lines, suggesting that the reaction also proceeds via two stages to give γ-chloroacetoxybutyranilide, as in the case of ethylene *N*-phenyliminocarbonate.



On the other hand, the effect of *N*-substituents on the reactions of *N*-substituted 2-iminotetrahydrofurans with chloroacetic acid indicated that the *N*-aliphatic derivatives react faster than *N*-aromatic ones and that the rates

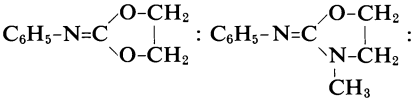
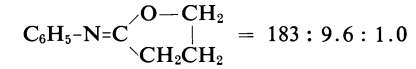
of the reactions of *N*-substituted phenyliminotetrahydrofurans decrease when the electron-attractive groups, such as *o*-chloro, *p*-chloro- or *m*-chlorophenyl groups, are introduced, as is shown in Table V. The gradient of the Hammett plots in Fig. 8 gave a value for the reaction constant ρ of -0.763. This evidence shows that the rate of the reaction increases as the electron density of the imino group increases.

Finally, the relative rate of the reactions of the three exo-imino cyclic compounds, e.g., ethylene *N*-phenyliminocarbonate, 2-phenylimino-3-methyloxazolidine and 2-phenyliminotetrahydrofuran, with carboxylic acids has been determined as:



In conclusion, it can be said that the rates of the reactions of the exo-imino cyclic compounds with carboxylic acids depend both on the basicity of the cyclic compounds, which affects the initial formation of the neccessary intermediate salt, and on the number of the oxygen-carbon bond to be cleaved in the ring opening.



Summary

The rate constants, the activation energies and the entropies of the activation of the ring-opening addition reactions of exo-imino cyclic compounds, such as ethylene *N*-phenyliminocarbonate, 2-phenylimino-3-methyloxazolidine and *N*-substituted 2-iminotetrahydrofurans, with carboxylic acids in various solvents have been determined in order to study the mechanism of these reactions.

The rate of the reactions increases as the acidity of carboxylic acids increases, and the linear Hammett relation is observed in the reactions of ethylene *N*-phenyliminocarbonate or 2-phenylimino-3-methyloxazolidine with meta- and para-substituted benzoic acids.

The relative rate of the reactions of the three exo-imino cyclic compounds, ethylene *N*-phenyliminocarbonate, 2-phenylimino-3-methyloxazolidine and 2-phenyliminotetrahydrofuran, with carboxylic acids is as follows:

These results show that the ring-opening addition reaction involves two stages, namely, the initial formation of the intermediate salt from the exo-imino cyclic compound with carboxylic acid, followed by the reaction of the salt with the other acid to give the ring-opening addition compound.

Studies of Isocyanide. II. The Reaction of Isocyanide with Some Radical Sources

By Tatsuya SHONO, Masatoshi KIMURA, Yoshihiko ITO, Kiyoto NISHIDA and Ryohei ODA

(Received March 24, 1964)

The first paper[1] of this series reported that the reactions of some electrophiles, such as *t*-butyl hypochlorite, *N*-bromosuccinimide and hydroxylamine, with isocyanide produce urethanes and ureas. On the other hand, the reactions of compounds with a lone pair on the nitrogen[2] or phosphorus[3] atom with some radical sources, for example, the reaction of dimethylaniline with benzoyl peroxide, are well known. Since the isocyanide also has a lone electron-pair on its terminal carbon atom, the reactions of isocyanide with radical sources seem interesting.

When cyclohexyl isocyanide was treated with perbenzoic acid, cyclohexyl isocyanate was obtained in a 61% yield, along with *N*-cyclohexyl benzamide. A reasonable path for this reaction would be the electrophilic attack of perbenzoic acid on the lone electron-pair of the isocyanide to form an adduct, which in turn decomposes to give cyclohexyl-isocyanate and benzoic acid:

$$C_6H_{11}N{\rightleftharpoons}C + C_6H_5CO_3H \rightarrow \left[C_6H_{11}N{=}\overset{+}{C}\text{-}OH \quad {}^{-}OOC\text{-}C_6H_5\right]$$
$$\rightarrow C_6H_{11}NCO + C_6H_5CO_2H$$

The reaction of the isocyanide with benzoyl peroxide gave three major products, I, II and III, and one minor product, IV:

$C_6H_{11}NHCOC_6H_5$ (I) $\quad C_6H_{11}N{=}CHOOCC_6H_5$ (II)

$C_6H_{11}N{=}C(C_6H_5)OOCC_6H_5$ (III) $\quad C_6H_{11}NHCONHC_6H_{11}$ (IV)

A preliminary test indicated that the isocyanide did not contribute kinetically to the decomposition of benzoyl peroxide. Thus, the decomposition of benzoyl peroxide must be spontaneous thermal decomposition according to the free radical mechanism. The formation of II and III is rationalized by the following reaction scheme:

$$C_6H_{11}N{\rightleftharpoons}C + C_6H_5COO\cdot \rightarrow C_6H_{11}N{=}\dot{C}OOCC_6H_5$$
$$\xrightarrow{H\cdot} C_6H_{11}N{=}CHOOCC_6H_5 \quad \text{II}$$
$$\xrightarrow{C_6H_5\cdot} C_6H_{11}N{=}C(C_6H_5)OOCC_6H_5 \quad \text{III}$$

An analogous reaction of isocyanide with *t*-butyl perbenzoate yielded similar products, such as I, II and IV, and also unexpected new minor products, V and VI:

$C_6H_{11}NH_3OOCC_6H_5$ (V) $\quad C_6H_{11}NHCHO$ (VI)

In the reaction of isocyanide with *N*-nitroso-acetanilide, two major products, VII and VIII, attributed to the reaction of isocyanide with acetoxy radical, were obtained as expected, along with two minor products, IV and VI:

$C_6H_{11}N{=}CHOOCCH_3$ (VII) $\quad C_6H_{11}NHCOCH_3$ (VIII)

The formation of VII is analogous to the formation of II, but the formation of VIII and other minor products still remains to be explained.

It seems that the isocyanide reacts predominantly with acyloxy radicals: therefore in the reactions with benzoyl peroxide, *t*-butyl perbenzoate or *N*-nitroso-acetanilide, no other products in which the acyloxy radicals are not involved can be obtained.

In order to obtain the product involved with the phenyl radical, the reaction of isocyanide with potassium phenylazoformate was tried, it was verified to yield one major product, IX, and one minor product, IV:

$C_6H_{11}N{=}CHC_6H_5$ (IX)

The formation of IX is rationalized by the following free radical reaction scheme:

$$C_6H_{11}N{\rightleftharpoons}C + C_6H_5\cdot \rightarrow C_6H_{11}N{=}\dot{C}\cdot C_6H_5$$
$$\rightarrow C_6H_{11}N{=}CHC_6H_5$$

Finally, the reaction of isocyanide with di-*t*-butyl peroxide was carried out in order to obtain the product involved with the methyl radical: however, only a resinous product and two minor products, X and IV, were obtained.

1) M. Okano, Y. Ito, T. Shono and R. Oda, This Bulletin, **36**, 1314 (1963).
2) L. Horner and K. Scherf, *Ann.*, **573**, 35 (1951).
3) M. A. Greenbaum, D. E. Denney and A. K. Hoffmann, *J. Am. Chem. Soc.*, **78**, 2563 (1956).

This resinous product may result from the polymerization of the azomethine compound which is formed by the reaction of the isocyanide with the methyl radical:

$$C_6H_{11}NHCOCONHC_6H_{11}$$
X

Experimental

The Reaction of Cyclohexyl Isocyanide with Perbenzoic Acid. — Into a solution of 12.75 g. (0.117 mol.) of cyclohexyl isocyanide in dry chloroform, a solution of 16.21 g. (0.117 mol.) of freshly-prepared perbenzoic acid in 300 ml. of dry chloroform was added drop by drop with stirring at such a rate that the reaction temperature was below 0°C.

After the reaction mixture had been allowed to stand overnight at 0°C, the solvent was removed and the residue was distilled in vacuo to yield 8.9 g. (61%) of cyclohexyl isocyanate (b.p. 39°C/2 mmHg). The distillation residue consisted of 4.6 g. of *N*-cyclohexylbenzamide and 16 g. of benzoic acid.

The Reaction of Cyclohexyl Isocyanide with Benzoyl Peroxide.—Under a nitrogen atmosphere, a solution of 8 g. (0.033 mol.) of benzoyl peroxide in 73 g. of cyclohexyl isocyanide was heated while being stirred at 80~90°C for 5 hr. The reaction mixture was washed with aqueous sodium carbonate and then dried and distilled in vacuo to yield 5.5 g. of an oily product (b. p. 120~135°C/3 mmHg) and 2 g. of a resinous product. The oily product was crystallized on standing and separated into four parts. The part which was easily soluble in ligroin was II (2 g., m. p. 65~67°C), and the hardly soluble part was IV (0.1 g., m. p. 217~220°C). The moderately ligroin-soluble part consisted of two parts; one was III (1 g. recrystallized from acetone, m. p. 129~130.5°C), while the other was I (1 g., recrystallized from ligroin, m. p. 148~150°C). The resinous product afforded 0.6 g. of I after recrystallization from ligroin. The products I and IV were identified by a mixed melting point determinations with the respective authentic samples. The structures of the products II and III were inferred on the basis of their infrared spectra and results of analysis and of hydrolysis. When the II or III was hydrolyzed, benzoic acid and cyclohexylamine were obtained.

The two spectra resembled closely each other. They showed the existence of an ester group (1715 cm^{-1}, 1270 cm^{-1}, 1120 cm^{-1} in III; 1750 cm^{-1}, 1270 cm^{-1}, 1120 cm^{-1} in II), a double bond between nitrogen and carbon (1675 cm^{-1} in II; 1660 cm^{-1} in III), and a monosubstituted phenyl group (735 cm^{-1}, 700 cm^{-1} in II; 725 cm^{-1}, 700 cm^{-1} in III), but exhibited neither a secondary amide group nor a hydroxy group. The results of the analysis of these products were as follows:

Found (for I): C, 76.86; H, 8.41; N, 6.79.
Calcd. for $C_{13}H_{17}NO$: C, 76.81; H, 8.43; N, 6.89%.
Found (for II): C, 73.00; H, 7.49; N, 6.07.
Calcd. for $C_{14}H_{17}NO_2$: C, 72.72; H, 7.36; N, 6.06%.
Found (for III): C, 78.55; H, 7.10; N, 4.60.
Calcd. for $C_{20}H_{21}NO_2$: C, 78.14; H, 6.88; N, 4.55%.
Found (for IV): C, 69.92; H, 10.73; N, 12.23.
Calcd. for $C_{13}H_{24}N_2O$: C, 69.59; H, 10.78; N, 12.48%.

The Reaction of Cyclohexyl Isocyanide with *t*-Butyl Perbenzoate. — The procedure and conditions employed were similar to that used for the above reaction, except that the radical source was divided into ten parts and added at intervals of one hour. 54.5 g. (0.5 mol.) of the isocyanide and 9.7 g. (0.05 mol.) of the perbenzoate were allowed to react. Working-up of the reaction mixture, as described above, gave I (2.1 g.), II (1.6 g.) and IV (0.1 g.) and two new minor products, V (0.2 g.) (recrystallized from acetone, m. p. 179~181°C) and oil (1.4 g.) presumed to be VI on the basis of its infrared spectrum (b. p. 107°C/2 mmHg).

The product V showed no depression in melting point when mixed with an authentic material.

Found (for V): C, 70.72; H, 8.61; N, 6.14.
Calcd. for $C_{13}H_{19}NO_2$: C, 70.55; H, 8.65; N, 6.32%.

The Reaction of Cyclohexyl Isocyanide with *N*-Nitroso Acetanilide.—By the method and conditions described above, the reaction of 136 g. (1.245 mol.) of cyclohexyl isocyanide with 22.8 g. (0.143 mol.) of *N*-nitrosoacetanilide was carried out. The reaction mixture was distilled in vacuo to yield 11.5 g. of an oily product (b. p. 98~125°C/3 mmHg). This was dissolved in ether and washed successively with 5% cold aqueous hydrochloric acid, aqueous sodium carbonate, and finally water. After the oil had been dried, the ether was evaporated off and the residual oil was distilled in vacuo to give 4 g. of VII (b. p. 98~99°C/3 mmHg). The 5% aqueous hydrochloric acid layer was alkalified with sodium carbonate, and the oil which separated was extracted with ether. The ethereal solution was evaporated and distilled in vacuo to yield 2.8 g. of an oily product (b. p. 103~105°C/3 mmHg), which consisted of two parts; one was VIII (1 g., melting at 100~101°C after recrystallization from ligroin), and other was an oil (1.7 g.), presumed on the basis of its infrared spectrum to be VI. The structure of product VII was also presumed on the basis of its infrared spectrum and analytical data.

The spectrum had the absorption resulting from the ester group (1740 cm^{-1}, 1220 cm^{-1}) and double bond between carbon and nitrogen (1675 cm^{-1}) but showed no absorption originating in hydroxy group and secondary amide group. The melting point of the product VIII was undepressed on admixture with an authentic sample.

Found (for VII): C, 64.61; H, 9.23; N, 7.98.
Calcd. for $C_9H_{15}NO_2$: C, 63.88; H, 8.94; N, 8.28%.

The Reaction of Cyclohexyl Isocyanide with Potassium Phenylazoformate.[4]—In a similar way 43.7 g. (0.4 mol.) of cyclohexyl isocyanide and 7.5 g. (0.04 mol.) of potassium phenylazoformate were allowed to react. After the removal of the unreacted isocyanide, the residue was distilled under reduced pressure to afford an oily product (1.4 g., b. p. 92°C/2 mmHg) and IV (0.1 g.).

The oily product had the same infrared spectrum as the authentic sample of IX, and it reacted

4) A Nagasaka and R. Oda, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zassi*), **58**, 48 (1955).

with 2,4-dinitrophenylhydrazine to give benzaldehyde 2,4-dinitrophenylhydrazone in the theoretical yield. These facts clearly indicate that the oily product is IX.

The Reaction of Cyclohexyl Isocyanide with Di-*t*-butyl Peroxide. — The reaction of 35.5 g. (0.325 mol.) of cyclohexyl isocyanide with 14.6 g. (0.1 mol.) of di-*t*-butyl peroxide was performed in a similar manner described above.

The reaction mixture was distilled to remove the unchanged isocyanide and peroxide. The resulting resinous product (4.8 g.) was dissolved in ethanol, and IV (0.1 g.) and X (0.15 g., m. p. 270~271.5°C, recrystallized from dioxane) were separated from the ethanol solution. The product X showed no depression in melting point when mixed with an authentic sample prepared from cyclohexylamine and oxalyl chloride.

Found (for X): C, 66.05; H, 9.46; N, 11.29. Calcd. for $C_{14}H_{24}N_2O_2$: C, 66.63; H, 9.59; N, 11.10%.

Summary

The reactions of cyclohexyl isocyanide with some radical sources, such as perbenzoic acid, benzoyl peroxide, *t*-butyl perbenzoate, *N*-nitrosoacetanilide, potassium phenylazoformate and di-*t*-butyl peroxide, have been studied. The isocyanide does not contribute kinetically to the mechanism of the decomposition of benzoyl peroxide, but the lone pair electrons existing on the carbon atom of isocyanide react very easily with free radicals, especially with acyloxy radicals.

In the reaction with benzoyl peroxide, *t*-butyl perbenzoate or the *N*-nitrosoacetanilide acyloxy radical chiefly contributes to the reaction. With potassium phenylazoformate, the phenyl radical is the main reacting species. However, in the case of perbenzoic acid, the reaction is heterolytic, and the main product is cyclohexyl isocyanate.

*Dihydropyridine Derivatives. I. The Reaction of 1,4-Diphenyl-3,5-diacetylpyridinium Salts with Inorganic Bases**

By Noboru SUGIYAMA, Kimie KUBOTA, Goro INOUYE** and Takasi KUBOTA***

(Received December 6, 1963)

During the structural studies of 1, 4-dihydro-1, 4-diphenyl-3, 5-diacetylpyridine (I), a chromium-containing compound was isolated by Inouye[1] from a reaction mixture of I with chromium trioxide in acetic acid, although its structure has not yet been determined. In the present investigation, this compound was found to be 1, 4-diphenyl-3, 5-diacetylpyridinium bichromate (II) on the basis of its analysis, its infrared spectrum and its reaction with inorganic bases. In addition, some new pyridinium salts have been prepared and their reactions with inorganic bases studied.

Mumm[2] and Borsche[3] reported that 1, 4-dihydropyridine derivatives were oxidized to pyridine derivatives with chromium trioxide. However, the isolation of bichromates of pyridine or its derivatives has not been reported. In the present investigation, I was oxidized to II with chromium trioxide in acetic acid. It was found that II is stable even when heated in water, but in organic solvents such as acetic acid, alcohols or acetone, it was decomposed by long heating. A characteristic blue fluorescence was observed with I, but not with II, either in the solid state or in solution. The infrared spectrum of I has an absorption band at 1645 cm^{-1} ($\nu_{C=O}$) which is attributed to a vinylogous amide gruop,[4] while that of II has a band at 1700 cm^{-1} ($\nu_{C=O}$). These facts indicate that the dihydropyridine ring of I was oxidized to a pyridinium ring. The elementary analysis of II also supports the pyridinium salt structure.

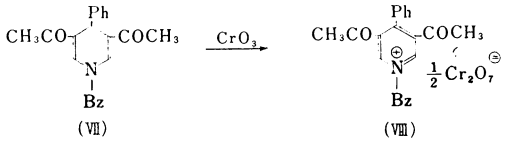
By treatment with barium chloride, II was converted to 1, 4-diphenyl-3, 5-diacetylpyridinium chloride (III). By oxidation with nitric acid, I gave 1, 4-diphenyl-3, 5-diacetylpyridinium nitrate (IV). Infrared spectra of III and IV, like those of II, show their carbonyl band at 1700 cm^{-1}. Also, they did not show fluorescence, as was expected from the pyridinium structure.



The reaction of II, III and IV with sodium dithionite gave a yellow crystalline compound (m. p. 181°C), which was identified with I by a study of their infrared spectra and by a mixed melting point determination. It has been known that the reduction of a pyridinium derivative with sodium dithionite affords a 1, 4-dihydropyridine derivative.[5]

Mumm[2] reported the formation of an addition compound of the cyano group by the treatment of pyridinium derivatives with potassium cyanide. II, III and IV were converted to 2-cyano-1, 2-dihydro-1, 4-diphenyl-3, 5-diacetylpyridine (V) by reaction with potassium cyanide. The infrared spectrum of V exhibits split carbonyl bands at 1672 cm^{-1} and 1646 cm^{-1} instead of a single band at 1645 cm^{-1} this can be attributed to two acetyl groups at the 3 and 5 positions. The shift to the higher frequency (1672 cm^{-1}) seems to be due to the decrease in the conjugation of the acetyl group with the dihydropyridine ring. It is reasonable that this decrease may be caused by the interaction of the bulky phenyl group and the cyano group.[6] The reaction of II, III and IV with such bases as sodium hydroxide, potassium carbonate or sodium acetate afforded 2-hydroxy-1,2-dihydro-1,4-diphenyl-3,5-diacetylpyridine (VI). No compound analogous to VI has yet been isolated by the reaction of pyridinium salt, similar to the cases of II, III or IV with hydroxide ions. VI is unstable and can be recrystallized only from ethylene dichloride. The infrared spectrum of VI shows bands at 1660 and 1608 cm^{-1} ($\nu_{C=O}$); the latter band is attributed to the 3-acetyl group hydrogen-bonded with the 2-hydroxy group. V and VI show a bluish-green fluorescence in the solid state as well as in solution. They were decomposed by being heated in organic solvents for a long time. After acidifying an ethanolic solution of V and VI with hydrochloric acid, the solvent was removed under reduced pressure to give colorless crystals. These were identified with III by mixed melting point determination and by a study of the infrared spectrum.

In the same way, 1-benzyl-4-phenyl-1, 4-dihydro-3, 5-diacetylpyridine (VII) was also oxidized to 1-benzyl-4-phenyl-3, 5-diacetylpyridinium bichromate with chromium trioxide.

Experimental

1, 4-Diphenyl-3, 5-diacetylpyridinium Bichromate (II).—A solution of 1 g. of chromium trioxide in 1 ml. of water and 2 ml. of acetic acid was added gradually to a solution of 0.5 g. of 1, 4-dihydro-1, 4-diphenyl-3, 5-diacetylpyridine (I) in 10 ml. of acetic acid. The resulting solution immediately became yellowish brown and cloudy, and then an oily product separated. The mixture was heated at 50°C for ten minutes, and 10 ml. of water was added. After standing at room temperature, 0.42 g. of orange crystals were obtained. Recrystallization from water gave 1, 4-diphenyl-3, 5-diacetylpyridinium bichromate (II) as orange-yellow plates; these did not show a definite decomposition point, but gradually turned black above 150°C.

Found: C, 59.44; H, 4.33; N, 3.27. Calcd. for $C_{21}H_{18}O_{21}N \cdot 1/2(Cr_2O_7)$: C, 59.43; H, 4.24; N, 3.30%.

1, 4-Diphenyl-3, 5-diacetylpyridinium Chloride (III).—To a solution of 0.5 g. of II in 100 ml. of hot water, 0.1 g. of barium chloride in 10 ml. of

5) D. Mauzerall and F. H. Westheimer, ibid., 77, 2261 (1958); R. F. Hutton and F. H. Westheimer, *Tetrahedron*, 3, 73 (1958).

6) Curiously the infrared spectrum of V has not a band due to C≡N bond stretching. Reasonable explanation can not be given at present.

water was added in one portion. The solution immediately became yellowish and cloudy. The mixture was heated in a water bath for 1 hr. After the solution had cooled, the precipitate was filtered off and the filtrate was concentrated to dryness under reduced pressure. Ethanol (10 ml.) was added to the residue, the insoluble substance was filtered off, and the filtrate was concentrated to dryness under reduced pressure. The same procedures were repeated several times. The final residue was recrystallized from ethanol-ethyl acetate to give 1, 4-diphenyl-3, 5-diacetylpyridinium chloride (III) (0.35 g.) as colorless needles (m. p. 245~247°C (decomp.)).

Found: N, 3.99. Calcd. for $C_{21}H_{18}O_2NCl$: N, 3.96%.

1, 4-Diphenyl-3,5-diacetylpyridinium Nitrate (IV). I (0.5 g.) was dissolved in 30 ml. of methanol, and 0.5 ml. of concentrated nitric acid was added. The mixture was allowed to stand at room temperature overnight. The solvent was distilled off under reduced pressure, and the residue was recrystallized from ethanol-ethyl acetate. 1, 4-Diphenyl-3, 5-diacetylpyridinium nitrate (IV) (0.32 g.) was obtained as pale brownish needles (m. p. 177~178°C (decomp.)).

Found: N, 7.17. Calcd. for $C_{21}H_{18}O_5N_2$: N, 7.40%.

The Reduction of III with Sodium Dithionite.—To a solution of 0.1 g. of III in 10 ml. of water, 0.5 g. of sodium dithionite was added. The solution became yellowish and exhibited a blue fluorescence. After standing at room temperature for 3 hr., the separated precipitate was collected by filtration. Recrystallization from ethanol gave greenish yellow prisms (0.07 g., m. p. 181°C). No depression of melting point was observed on admixture with an authentic sample of I.

The Reduction of II and IV with Sodium Dithionite.—When the reduction of II and IV with sodium dithionite was carried out as described above for III, I was obtained in both cases.

2-Cyano-1, 2-dihydro-1, 4-diphenyl-3, 5-diacetylpyridine (V).—(i) To a solution of 0.4 g. of II in 100 ml. of water, 1.5 g. of potassium cyanide in 5 ml. of water was added. The solution became yellowish and cloudy. After the solution had stood overnight in an ice box, the yellowish crystals were collected by filtration. Recrystallization from ethanol-water gave 2-cyano-1, 2-dihydro-1, 4-diphenyl-3, 5-diacetylpyridine (V) (0.28 g.) as yellowish green needles (m. p. 154~155°C).

Found: C, 77.35; H, 5.10; N, 7.87. Calcd. for $C_{22}H_{18}O_2N_2$: C, 77.19; H, 5.26; N, 8.18%.

(ii) The similar reaction of III or IV with potassium cyanide afforded the same compound V.

The Reaction of V with Hydrochloric Acid.—To a solution of 0.2 g. of V in 5 ml. of ethanol, 0.1 ml. of concentrated hydrochloric acid was added. The solution turned from yellowish to colorless. After ten minutes, the solvent was distilled off under reduced pressure and the residue was recrystallized from ethanol-ethyl acetate to give colorless needles (0.12 g.) (m. p. 245~247°C). No depression of melting point was observed on admixture with an authentic sample of III.

2-Hydroxy-1, 2-dihydro-1, 4-diphenyl-3, 5-diacetylpyridine (VI).—To a solution of 0.3 g. of III in 5 ml. of water, 0.2 g. of potassium carbonate in 4 ml. of water was added. The solution immediately became yellowish and cloudy. After a few minutes, the yellow precipitates which had separated out were collected by filtration and the crude product was dissolved in ethylene dichloride at 20~30°C. The solution was cooled in an ice box, and 2-hydroxy-1, 2-dihydro-1, 4-diphenyl-3, 5-diacetylpyridine (VI) (0.2 g.) was obtained as yellowish prisms (m. p. 145~147°C (decomp.)).

Found: N, 4.14. Calcd. for $C_{21}H_{19}O_3N$: N, 4.20%.

II and IV also afforded VI by similar procedures. VI was also obtained by the treatment of II, III or IV with sodium hydroxide or sodium acetate instead of potassium carbonate.

1-Benzyl-4-phenyl-3, 5-diacetylpyridinium Bichromate (VIII).—A solution of 0.2 g. of chromium trioxide in 1 ml. of water and 3 ml. of acetic acid was added to a solution of 0.06 g. of 1, 4-dihydro-1-benzyl-4-phenyl-3, 5-diacetylpyridine (VII) in 3 ml. of acetic acid. The mixture was heated at 40°C for ten minutes, and 10 ml. of water was added. After cooling, 0.04 g. of orange crystals were obtained by filtration. Recrystallization from water gave orange yellow plates which decomposed at 350°C.

Found: C, 60.10; H, 4.57; N, 3.25. Calcd. for $C_{22}H_{20}O_2N \cdot 1/2Cr_2O_7$: C, 60.27; H, 4.60; N, 3.19%.

Infrared Spectroscopic Studies of Acido-pentammine Cobalt(III) Complexes. Sulfato, Nitrito, Nitrato and Carbonato Complexes

By Nobuyuki TANAKA, Haruko SUGI and Junnosuke FUJITA

(Received December 6, 1963)

Several infrared spectroscopic studies of cobalt(III) complexes co-ordinated with oxyanions, such as sulfate, nitrate, carbonate and nitrite, have been reported.[1-4] The spectra of these co-ordinated oxyanions have been found to differ from those of the free anions, because the co-ordination usually causes a change in the symmetry and structure of the ligands. For the nitrato, carbonato and nitrito complexes, empirical assignments of the observed absorption bands have been carried out, but not for the sulfato complexes.

In this investigation, the assignment of the observed frequencies of sulfato and other acido pentammine complexes has been made on the basis of a normal co-ordinate treatment. The effect of co-ordination on the structure of these oxyanions and the applicability of the Urey-Bradley type potential field have been discussed.

Experimental

Preparation.—The $[Co(SO_4)(NH_3)_5]^+$, $[Co(NO_3)(NH_3)_5]^{2+}$ and $[(NH_3)_4Co\langle^{NH_2}_{SO_4}\rangle Co(NH_3)_4]^{3+}$ complexes were prepared according to the methods of Jörgensen,[5] Benrath[6] and Werner[7] respectively, and they were recrystallized more than three times. Since all the compounds studied were typical metallic complexes, their purity was checked by comparing the visible and ultraviolet spectra with the published data.[8,9]

Measurements.—The infrared spectra in the NaCl and the KBr prism region (5000~400 cm^{-1}) were obtained by using a Hitachi EPI-2G infrared spectrophotometer, while those in the CsBr prism region (400~250 cm^{-1}) were obtained by using a Nihonbunko 402-G infrared spectrophotometer. The wavelength calibration was made with the polystyrene, water vapor and carbon dioxide in the air. Spectra were measured by the KBr disk and the Nujol mull methods.

Calculation and Discussion

The vibrations of metal complexes can be divided into two types, one the vibration of ligands, and the other, that of metal-ligand bonding. The former generally appears in the rock salt region, while the latter appears in the longer wavelength region. The infrared absorption spectra of sulfato and nitrato complexes and their deuterated complexes show only two bands, near 330 and 270 cm^{-1}, in the range from 400 to 250 cm^{-1}.

In the calculation, the ligand vibrations were treated separately, without considering the coupling between the ligand vibrations and the metal-ligand vibrations, which has been found to be fairly small in carbonato-pentamminecobalt(III) complexes.[10] The secular equations were set up according to Wilson's procedure,[11] and the Urey-Bradley potential field[12] was used. Internal co-ordinates and symmetry co-ordinates for the

$S_5=\Delta/\sqrt{2}$ $(\beta_1-\beta_2)$

oxyanions investigated are given in Fig. 1 and in Tables I and II respectively.

(1) Sulfato Complexes.—The symmetry of a free SO_4^{2-} ion belongs to the point group T_d, and only two triply-degenerate vibrations of the four fundamentals are infrared active. When this ion is co-ordinated to a metal as a unidentate ligand, its symmetry is lowered to the point group C_{3v} and the triply-degenerate vibration splits into a doubly-degenerate vibratoin (E) and a totally symmetric vibration

(A_1), and all vibrations become infrared-active. On the other hand, in the case of the binuclear complex, in which the SO_4^{2-} ion is co-ordinated as a bidentate, its symmetry becomes C_{2v} and all degeneracies split.[1] This correlation is apparent from the observed spectra shown in Fig. 2 and from the results of the normal co-ordinate calculation.

The vibrational frequencies were calculated with the force constant values listed in Tables III and IV ((a) in Table III) using the Urey-Bradley potential field. Those force constants were determined on the basis of the values of the free ions.[13] The bond angles were regarded as tetrahedral, while the bond lengths, r_{SO^*}=1.53 and r_{SO}=1.47 Å, were assumed from the value of the free SO_4^{2-} ion (r_{SO}=1.50 Å[14]). The asterisk indicates the co-ordinated oxygen atom. The values of F', the linear terms of the interaction between non-bonded atoms, were determined from the relation, $F'=-1/10\,F$.[15] The results are given in Tables III and IV ((a) in Table III).

Since the calculated frequencies were not in satisfactory agreement with the observed ones, especially for the stretching vibrations, the calculation was also made, in the case of the sulfatopentamminecobalt(III) complex, using a modified Urey-Bradley potential function[16] expressed as:

where ρ represents the bond-bond interaction constant. The calculated frequencies which were obtained with Eq. 1 using the force constants of (b) in Table III are given in Table III(b).

The potential energy distribution was calculated, and the band assignments were made. These are given in Table V and Fig. 2 respectively.

The use of the Urey-Bradley potential field failed to give a satisfactory agreement between the calculated and the observed frequencies in the C_{2v} calculation (Table II) also. This, however, seems partly due to the neglect of the effect of the ring vibration, which should have been taken into account for the metal chelate complexes.[10]

Nevertheless, it may be concluded, from the force constants obtained, that a SO_4^{2-} ion combines with cobalt(III) more strongly as a unidentate than as a bidentate.

(2) Nitrito Complex.—In the nitrito complex, ONO* belongs to the point group C_s, and the three A_1 vibrations are all infrared-active. Table VI shows the calculated and the observed frequencies of the nitritopentammine-cobalt(III) complex. The molecular dimensions given in Table VI were assumed from the structures of $NaNO_2$[17] and CH_3ONO.[18] Table VI shows that the effect of the bond angle on the calculated values is not significant. The force constants in Table VI indicate a marked difference in bond orders between the NO and NO* bonds. This suggests that the co-ordination effect is fairly large.

1 R(N-O)=1.30 Å r(N-O)=1.20 Å,
*2 (a) ∠ONO=120°, (b) ∠ONO=115°

(3) Nitrato and Carbonato Complexes.—Both NO_3^- and CO_3^{2-} in the state of free ions belong to the point group D_{3h}, and two degenerate and one out-of-plane vibrations of the four fundamentals are infrared-active. When these anions are co-ordinated as unidentate ligands, the symmetry lowers to C_{2v} and the irreducible representation, E, splits into A_1 and B_2. Tables VII and VIII present the observed and the calculated frequencies. The latter was obtained with the force constants given in these tables. The bond angles of the nitrato and the carbonato complexes are assumed to be 120° ((a) and (b) in Tables VII and VIII), but in the case of the nitrato complex the calculation was made also with the bond angles, $\alpha=130°$ and $\beta=115°$ ((c) in Table VII). The bond lengths of these complexes are considered to be $r_{XO^*}=1.30$ and $r_{XO}=1.25$ Å. The potential energy distributions of the co-ordinated nitrate and carbonate as unidentate ligands are given in Table IX.

The results of the calculation show that the usual Urey-Bradley force field does not apply well in these molecules. The following four points, therefore, will be discussed:

(i) The effects of the coupling with oxygen-cobalt bond vibrations;

(ii) The effect of hydrogen-bond formation;

(iii) The effect of the molecular dimension and

(iv) The applicability of the Urey-Bradley type force field to the molecules that have unlocalized π-electrons.

In order to investigate the effects of the coupling with oxygen-cobalt bond vibrations, the spectra in the CsBr prism region were obtained. The observed frequencies are given in Table X. The bands of some 330 cm^{-1} shift to lower frequencies by 30 cm^{-1} upon deuteration, while those of some 27 cm^{-1} do not. Although the assignments of these bands are not clear at present, the calculation was made with the value, $K_{Co-O^*}=2$ mdyn./Å[10] and the C_{2v} point symmetry. The results suggested that the effect of the coupling with oxygen-cobalt bond vibrations is insignificant.

As to the molecular dimensions, the effects of the bond length and the bond angle were taken into consideration. It was found that the former is negligibly small, as Table XI shows, whereas the latter is considerably large, as may be seen from the calculated frequencies given in Table VII.

According to the electron diffraction studies of nitric acid in the solid state,[19] the bond angle of ONO is 134° and that of HO–NO, 113°, indicating that the HO–N bond is a

NO_3^-	2.11	1.59	1.41
CO_3^{2-}	2.27	1.74	0.53
SO_4^{2-}	2.47	0.76	0.15

single bond and that, as a result of the resonance of structures I and II, the N–O bonds come to have a more double-bond character.

(I) (II)

From this fact and from the results of the calculation shown in Table VII, it may be concluded that the complex formation distorts the bond angles of a NO_3^- ion in a way similar to that it does nitric acid. The magnitude of this deformation, however, could not be estimated from these calculations.

The effect of hydrogen bond formation has not been considered in the present investigation, although there must be some influence, because in the case of these pentammine complexes, hydrogen atoms are located close around oxygen atoms.

Recently, several papers have reported on the potential field that can be applied to the compounds with unlocalized π-electrons. These compounds give larger repulsive force constants than the values that would be expected from the interatomic repulsive forces between the iso-electronic inert gas atoms. For example, the *F* constants for NO_3^-, CO_3^{2-} and SO_4^{2-} are much larger than those calculated from the Lennard-Jones equation[20] (Eq. 2), as Table XII shows.

$$F=(12\varepsilon^*/q^2)\ [13(r^*/q)^{12}-7(r^*/q)^6] \qquad (2)$$

were $\varepsilon^*=4.89\times10^{15}$ erg, $r^*=3.08$ Å

In the treatment of such compounds, the interaction terms are generally introduced as additional terms. In this study the bond-bond interaction terms were added to the usual Urey-Bradley function. The calculation of the potential energy distribution, however, requires no change in the assignment.

The negative sign of all the ρ_{XOXO} interaction terms could be interpreted by considering the localization of π-electrons in the X–O bonds.

It may be concluded from the normal coordinate treatment that the co-ordination effects in the sulfato-, nitrito-, nitrato- and carbonato-pentamminecobalt(III) complexes

20) T. Shimanouchi, "Force Constants of Small Molecules," Tokyo University, Tokyo (1962).

are fairly large. Upon co-ordination, the bond orders of X–O and X–O* become considerably different. Consequently, the bond length of X–O decreases and that of X–O* increases. At the same time, the bond angle of O–X–O increases and that of O–X–O* decreases. It may also be concluded from this investigation that the bond character between cobalt and oxygen is considerably covalent; if it is ionic, such a large difference would not appear among the X–O bonds of the co-ordinated oxyanions.

Summary

The infrared spectra of twelve acido-pentammine cobalt(III) complexes have been obtained in the range between 5000 and 250 cm^{-1}, and the vibrational frequencies of the co-ordinated oxyanions have been assigned from the normal co-ordinate treatment based on Wilson's method and on the Urey-Bradley potential field. The results of the calculation show that the co-ordination effects on these oxyanions are fairly large and that the bonds between cobalt and oxygen atoms have a considerably covalent character.

The authors wish to thank the Ministry of Education and the Japan Society for the Promotion of Science for the financial support granted to this research. They are also grateful to Dr. Tsutomu Takamura, Tokyo Shibaura Electric Company, for the measurement of the infrared spectra in the cesium bromide prism region.

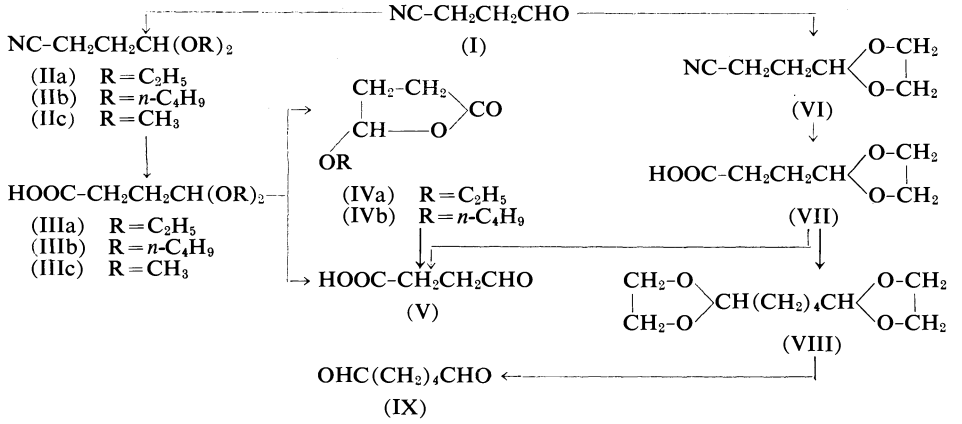
Synthetic Studies Starting from β-Cyanopropionaldehyde. I. The Synthesis of Adipic Dialdehyde

By Shinichi MOTOKI, Sadayoshi SATSUMABAYASHI and Isao TAJIMA

(Received December 9, 1963)

β-Cyanopropionaldehyde (I) is an interesting compound which has two reactive functional groups. Although several procedures for the synthesis of this compound have hitherto been available, all of them are rather cumbersome as methods of preparation. In recent years, however, an improved technique for the oxo reaction of acrylonitrile to form I in a high yield has been developed by the members of the Ajinomoto Co., Ltd.,[1,2] and this cyanoaldehyde is now being used as an intermediate in the manufacturing of glutamic acid.

The purpose of our work is to extend synthetic studies, starting with β-cyanopropionaldehyde. In this paper the synthesis of adipic dialdehyde by Kolbe's electrolytic reaction is presented.



It is expected that the hydrolysis of the nitrile group will lead to β-formylpropionic acid (V), to which Kolbe's reaction is applicable. Although the procedure proposed has already been investigated with diethyl acetal of I (IIa) by Wohl,[3] little attention has been paid to the yield of each step of the reaction and to the isolation of the intermediate, β-formylpropionic acid diethyl acetal (IIIa). Therefore, our experiments will be described in detail in the present communication.

First the authors reinvestigated Wohl's procedure and purified the crude oily product (IIIa) by distillation under reduced pressure. A colorless liquid was obtained in a fairly good yield, but its analytical values were different from those of IIIa. It was a neutral substance, which was insoluble in water and which was hydrolyzed with dilute acid to V. Analytical values were very close to those of 5-ethoxy-γ-butyrolactone (IVa), and the infrared spectrum exhibited characteristic strong peaks at 1790 cm^{-1}, corresponding to that of the γ-lacton linkage. On the basis of these data, it has been concluded that the product is IVa formed by the loss of one molecule of ethanol from IIIa. In addition, it was also found that β-formylpropionic acid dibutyl acetal

2) J. Kato, H. Wakamatsu, R. Iwanaga and T. Yoshida, ibid., **64**, 2142 (1961).

3) A. Wohl and H. Schweizer, *Ber.*, **39**, 890 (1906).

(IIIb) was decomposed in a fashion similar to 5-butoxy-γ-butyrolactone (IVb) by distillation, whereas methyl acetal (IIIc) was readily hydrolyzed to V during the course of the isolation.

As an attempt to isolate the acetal acid III of monohydric alcohol was unsuccessful, hydrolysis with the more stable cyclic ethylene acetal VI was examined. In this case, the reaction product was an acidic viscous liquid which was hydrolyzed with dilute acid to V. The analytical values and neutralization equivalent were in harmony with those of the expected acetal acid VII. Therefore, it was identified as β-formylpropionic acid ethylene acetal (VII).

The electrolysis of VII proceeded as usual, and the diethylene acetal of adipic dialdehyde (VIII) was obtained in about a 40%, yield with a small amount of by-product.

Experimental

Material. — β-Cyanopropionaldehyde (β-C.P.A.) (I) was obtained by the hydrolysis of its methyl acetal, supplied by the Ajinomoto Co., Ltd. It was used at once after distillation; b. p. 85°C/3 mmHg.

β-C.P.A.diethyl (IIa) and Dibutyl Acetals (IIb). —These acetals are prepared directly by the oxo reaction of acrylonitrile in the corresponding alcohols.[2] In our experiment, these were obtained by the acetalization of β-C.P.A. with the corresponding alcohols in the presence of hydrochloric acid as a catalyst; diethyl acetal, b. p. 84°C/5 mmHg; dibutyl acetal, b. p. 122°C/3 mmHg.

5-Ethoxy-γ-butyrolactone (IVa). — According to Wohl's method,[3] a crude potassium salt of β-formylpropionic acid diethyl acetal (IIIa) was obtained by the alkaline hydrolysis of β-C.P.A. diethyl acetal (IIa). This potassium salt was dissolved in as little water as possible, and the solution was acidified with dilute hydrochloric acid. Then the acetal acid was separated as a brown oil, which was extracted with ether and dried with anhydrous sodium sulfate. Distillation gave 14.1 g. of 5-ethoxy-γ-butyrolactone (b. p. 85°C/6 mmHg) from 31.4 g. of β-C.P.A. diethyl acetal. It was a neutral substance, insoluble in water, and its infrared spectra exhibited a strong absorption peak at 1790 cm^{-1} (characteristic of γ-lactone). Analysis gave the following results:

Found: C, 55.06; H, 8.01. Calcd. for $C_6H_{10}O_3$: C, 55.36; H, 7.75%.

To 5 g. of 5-ethoxy-γ-butyrolactone, 5 g. of 3% hydrochloric acid were added, and the mixture was refluxed for one hour. After cooling to room temperature, the resulting product was extracted with ether and dried with anhydrous sodium sulfate. Distillation gave 2.1 g. of β-formylpropionic acid (V) (b. p. 130~135°C/14 mmHg) forming a 2,4-dinitrophenylhydrazone, (m. p. 199°C), which showed no depression on admixture with an authentic specimen.

5-Butoxy-γ-butyrolactone (IVb).—Similarly, the hydrolysis of β-C.P.A. dibutyl acetal (IIb) gave 5-butoxy-γ-butyrolactone (b. p. 107°C/6 mmHg).

Found: C, 60.48; H, 9.08. Calcd. for $C_8H_{14}O_3$: C, 60.74; H, 8.92%.

β-Formylpropionic Acid (V). — A Similar treatment of β-C.P.A. dimethyl acetal (IIc) gave β-formylpropionic acid (V), identified as its 2,4-dinitrophenylhydrazone. In this case, no oil was separated after the acidification of the aqueous solution of the potassium salt of IIIc.

β-C.P.A.ethylene Acetal (VI). — A mixture of 1 mol. of β-C.P.A.dimethyl acetal, 1.5 mol. of ethylene glycol and 0.5 g. of *p*-toluenesulfonic acid was heated at 100~130°C in a distillation flask. The methanol formed in the reaction was immediately distilled off. The residue was poured into water, and the oil was extracted with ether. The fractional distillation of the extract gave 92.4 g. of β-C.P.A.ethylene acetal; b. p. 82°C/3 mmHg, yield 72.7%.

Found: N, 11.18. Calcd. for $C_6H_9O_2N$: N, 11.02%.

β-Formylpropionic Acid Ethylene Acetal (VII). —β-C.P.A. ethylene acetal (VI) was hydrolyzed by a method similar to Wohl's procedure. The aqueous solution of the potassium salt of VII was acidified to pH 3 with dilute hydrochloric acid. Since no oil was separated, the solution was extracted with ether repeatedly. The extract was then distilled, and the fraction boiling at 124~126°C/3 mmHg was collected. When this fraction was distilled two more times, 39.1 g. of pure β-formylpropionic acid ethylene acetal was given from 127 g.

of β-C.P.A.ethylene acetal (b. p. 114°C/1 mmHg). The yield was 26.8% of the theoretical amount. The acetal acid was a hygroscopic colorless liquid which solidified on standing at room temperature; m. p. 36°C.

Found: C, 49.07; H, 7.16. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 6.90%.

Neutralization equivalent. Found: 143.62. Calcd.: 146.14.

Adipic Dialdehyde Diethylene Acetal (VIII).—Forty-five grams (0.31 mol.) of β-formylpropionic acid ethylene acetal (VII) was electrolyzed in 130 ml. of methanol to which 1.7 g. (0.031 mol.) of potassium hydroxide had been added to neutralize about 10% of the total amount of acid used. The solution was placed in a cell consisting of a tall, flat-bottomed cylindrical, glass vessel fitted with a spiral-tube condenser, thermometer, and two parallel electrodes (platinum plate) (4×2.5 cm.), placed about 1~2 mm. apart. The cell was cooled by immersion in an ice-bath (internal temperature of cell, about 25~30°C), and a current of 5 amp. was passed through until the electrolyte became slightly alkaline. This usually required about 20% longer than the calculated time. At the end of the electrolysis, the solvent was removed and the residue diluted with 50 g. of water; the product was separated as an oil, which was extracted with ether and dried with anhydrous sodium sulfate. Distillation gave 12.1 g. of adipic dialdehyde diethylene acetal (b. p. 101~103°C/3 mmHg, yield 38.4%), which solidified upon being cooled in an refrigerator. Plates, m. p. 25~25.5°C.

Found: C, 59.11; H, 9.17. Calcd. for $C_{10}H_{18}O_4$: C, 59.39; H, 8.97%.

Besides, 4.1 g. of a colorless liquid was obtained as an unidentified by-product; b. p. 58~67°C/3 mmHg. VIII was mixed with the same amount of 3% hydrochloric acid and refluxed for one hour. After hydrolysis, the organic layer was extracted with ether and dried with anhydrous sodium sulfate. By distillation, adipic dialdehyde (IX) was obtained at a b. p. of 92~94°C/9 mmHg; yield ca. 95%. Bis-2,4-dinitrophenylhydrazone: m. p. 172~172.5°C (lit. m. p. 170°C).

Summary

A detailed study has been made of the synthesis of adipic dialdehyde starting from β-cyanopropionaldehyde. The hydrolysis of the acetal of this cyanoaldehyde gave β-formylpropionic acid acetal, to which Kolbe's electrolytic reaction was applied. The intermediate acetal acid has been successfully isolated in the case of ethylene acetal, whereas ethyl or butyl acetal decomposed by distillation into ethoxy- or butoxy-γ-butyrolactone, the structure of which has been established by analysis, infrared spectra and conversion to β-formylpropionic acid. Methyl acetal was also readily hydrolyzed to free aldehydic acid during the course of the isolation. Electrolysis of the ethylene acetal of β-formylpropionic acid in methanol gave adipic dialdehyde as its diethylene acetal.

The authors wish the thank Professor Yojiro Tsuzuki for his helpful advice and encouragement. Acknowledgment is also made to the Ajinomoto Co., Ltd., for a grant and for a supply of raw materials.

The Thermal Decomposition of Ammonium Polymolybdates. II

By Eikoh MA

(Received December 11, 1963)

It was reported in a foregoing paper[1] that the weight-decrease curves and the ammonia evolution curves of ammonium dimolybdate, ammonium heptamolybdate, ammonium octamolybdate and ammonium trimolybdate are step-like. A certain crystal structure should correspond to each stage of these curves. The present paper, therefore, deals with the structural change in the process of thermal decomposition.

1) E. Ma, This Bulletin, 37, 171 (1964).

Experimental

Chemical Analysis.—The starting materials and their decomposition products were chemically analyzed; the quantity of molybdenum was determined by gravimetric analysis, using lead acetate, and that of ammonia, by the Kjeldhal method. The starting materials were found to be in agreement with these empirical formulae: $(NH_4)_2O \cdot 2MoO_3$ for dimolybdate, $3(NH_4)_2O \cdot 7MoO_3 \cdot 4H_2O$ for heptamolybdate, $2(NH_4)_2O \cdot 8MoO_3 \cdot 2H_2O$ for octamolybdate, and $(NH_4)_2O \cdot 3MoO_3 \cdot xH_2O$ for trimolybdate,

where x depends upon the condition of preparation.

Differential Thermal Analysis.—The differential thermal analysis was performed in air at a heating rate of 7~10°C/min. The reference junction of the differential couple was embedded in inert fused quartz. Fifty milligrams of the sample was sandwiched between two layers of about 300 mg. of the fused quartz in a platinum cell. The thermo-couple employed was alumel-chromel.

X-Ray Analysis.—The X-ray diffraction powder patterns were taken by a Guinier focussing camera using Cu$K\alpha$ radiation. The powder patterns of the starting materials were reported on in the foregoing paper.

Results and Discussion

As is usual with differential thermal analysis, the peaks indicate the temperature at which reaction actually ends. The beginning of the reaction corresponds to a cross-point of the straight-line parts of the base line and the relevant peak. Thermograms of ammonium hepta-, di-, octa- and trimolybdates are given in Fig. 1 for purposes of comparison. They give characteristic thermograms and exhibit good reproducibility. Three endothermic peaks are observed for ammonium heptamolybdate tetrahydrate, at 130, 245, and 355°C. Also, three endothermic peaks are observed for ammonium dimolybdate, at 225, 255 and 355°C. Two endothermic peaks are observed for ammonium octamolybdate dihydrate, at 287 and 377°C. Five endothermic peaks are observed for ammonium trimolybdate, at 98, 145, 200, 358, and 375°C. Two exothermic peaks are observed for the trimolybdate, at 255 and 425°C.

Ammonium Heptamolybdate Tetrahydrate.—The X-ray diffraction pattern of ammonium heptamolybdate tetrahydrate, Fig. 2a, does not change until 130°C, the first endothermic peak. At 130°C the crystal lattice of the heptamolybdate collapses, and a new, previously unknown structure appears (Fig. 2b). This structure, which will be called pattern A hereafter, is obtained in the temperature range from 130 to 245°C. The decomposition product corresponding to pattern A was identified as $2(NH_4)_2 \cdot O \cdot 5MoO_3$ through chemical analysis. At 245°C, the second endothermic peak, pattern A changes into another pattern which is identical with the pattern of octamolybdate (Fig. 2c). The octamolybdate is obtained in the temperature range from 245 to 355°C, and it is followed by the pattern of molybdenum trioxide above 355°C (Fig. 2d), which corresponds to the last endothermic peak.

A correlation of the differential thermal analysis curve, the weight decrease curve, and the deammoniation curve in the case of ammonium heptamolybdate tetrahydrate is shown in Fig. 3. The three endothermic peaks in the differential thermal analysis curve correspond to the stages in the weight decrease curve

d) Molybdenum trioxde

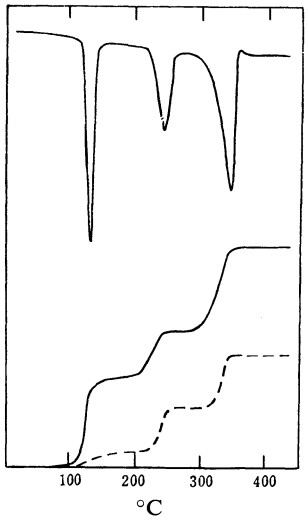

Fig. 3. Ammonium heptamolybdate tetrahydrate.

and in the deammoniation curve, and they are in good agreement. The endotherm at 130°C is referred principally to dehydration, which results in the structural change from ammonium heptamolybdate tetrahydrate to pattern A. Since dehydration does not proceed step-by-step in this case, and since most of the water is lost without resulting in any structural change, they may be regarded as of the zeolitic type. When, however, dehydration proceeds to completion, structural change does occur. The rest of the water, in consequence, must have an important role in constructing the crystal structure. The endotherm at 255°C corresponds to the deammoniation which results in the structural change from pattern A to octamolybdate. The endotherm at 355°C corresponds to the change from octamolybdate to molybdenum trioxide through further deammoniation.

Thus, ammonium heptamolybdate tetrahydrate changes upon heating in the following manner;

$$3(NH_4)_2O\cdot 7MoO_3\cdot 4H_2O \xrightarrow[115\sim130°C]{} 2(NH_4)_2O\cdot 5MoO_3 \xrightarrow[225\sim245°C]{} 2(NH_4)_2O\cdot 8MoO_3 \xrightarrow[320\sim355°C]{} MoO_3$$

The results obtained by previous authors are given below for the purpose of comparison:

Funaki:[2] $3(NH_4)_2O\cdot 7MoO_3\cdot 4H_2O \xrightarrow[110°C]{} 3(NH_4)_2O\cdot 7MoO_3 \xrightarrow[200°C]{} (NH_4)_2O\cdot 4MoO_3 \xrightarrow[280°C]{} MoO_3$

Duval:[3] $3(NH_4)_2O\cdot 7MoO_3\cdot 4H_2O \xrightarrow[50\sim90°C]{} 2(NH_4)_2O\cdot 5MoO_3 \xrightarrow[140\sim200°C]{} (NH_4)_2O\cdot 4MoO_3 \xrightarrow[270\sim340°C]{} MoO_3$

Hegedüs:[4] $3(NH_4)_2O\cdot 7MoO_3\cdot 4H_2O \xrightarrow[110\sim150°C]{} 2(NH_4)_2O\cdot 5MoO_3 \xrightarrow[210\sim255°C]{} (NH_4)_2O\cdot 4MoO_3 \xrightarrow[350\sim400°C]{} MoO_3$

Ammonium Dimolybdate. — In the case of ammonium dimolybdate, the room temperature pattern, Fig. 4a, is preserved until 225°C, the first endothermic peak, and is transformed into a previously unknown structure which has a narrow stability range of 225~255°C. The powder pattern of the structure will be called pattern B. At 225°C, the second endothermic peak, another structure begins to appear; this structure is crystallographically identical with the octamolybdate, Fig. 4c. The pattern of

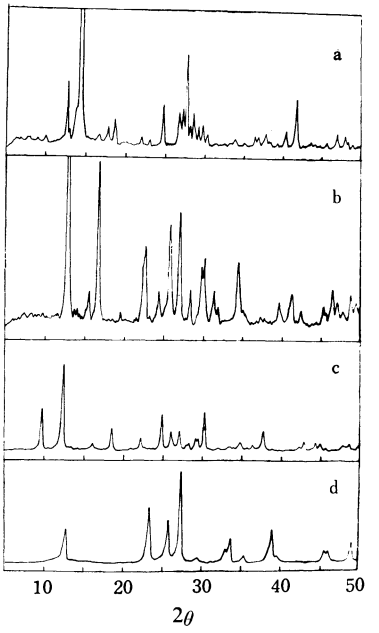

Fig. 4. X-Ray powder patterns.
a) Ammonium dimolybdate

the octamolybdate is observed in the temperature range from 255 to 335°C and is followed by the pattern of molybdenum trioxide above 355°C, the last endothermic peak (Fig. 4d).

A correlation of the differential thermal analysis curve, the weight decrease curve and the deammoniation curve is shown in Fig. 5. The inflection around 225°C in the weight decrease curve is indicative of a decomposition product with a narrow stability range. Deammoniation until the inflection gives rise to the first endothermic peak at 225°C. The second endothermic peak is, therefore, due to deammoniation from the inflection to the plateau. The plateau in the weight decrease curve between 250 and 320°C corresponds to the octamolybdate. The endotherm at 355°C corresponds to further deammoniation, which results in the change from the octamolybdate to molybdenum trioxide.

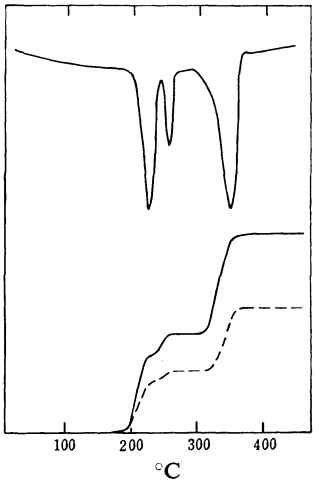

Fig. 5. Ammonium dimolybdate.

Ammonium Octamolybdate. — Figure 6 shows thermograms of three sorts of ammonium octamolybdates of different origins. Figure 6a is octamolybdate dihydrate from an aqueous solution, Fig. 6b is anhydrous ammonium octamolybdate prepared through the calcination of ammonium heptamolybdate tetrahydrate, and Fig. 6c is one prepared through the calcination of ammonium trimolybdate. These three octamolybdates, notwithstanding their non-coincidence in thermogram, give the same X-ray powder pattern as well as the same mole ratio of $(NH_4)_2O : MoO_3 = 1 : 4$ upon chemical analysis. All the octamolybdates change into molybdenum trioxide around 370°C, at the strong endothermic peak. A correlation of the differential thermal analysis curve, the weight decrease curve and the deammoniation

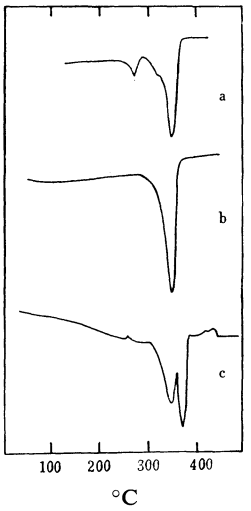

Fig. 6. Differential thermal analysis curves of ammonium octamolybdates.

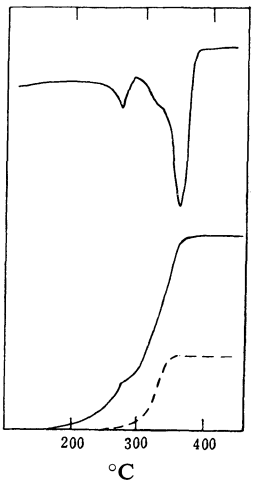

Fig. 7. Ammonium octamolybdate dihydrate.

curve of ammonium octamolybdate dihydrate is shown in Fig. 7. The endotherm at 287°C is referred mainly to dehydration, which results in no structural change. It is an outstanding feature of the octamolybdate that no endotherm which can be referred to dehydration appears around 100°C. Accordingly, the water of crystallization in this case must be of a different character from that in the case of heptamolybdate. As one of five water molecules of copper sulfate pentahydrate is held up to 250°C, so the water molecules in the case of the octamolybdate must be tenaciously held through the hydrogen bond.

Ammonium Trimolybdate.—The existence of the trimolybdate as a chemical species has not yet been confirmed. Lindqvist has suggested

the possibility that the trimolybdate is actually double-salts of hepta- and octamolybdates.[6] The X-ray examination of a sample with the chemical composition of trimolybdate illustrates that octamolybdate is predominant and that a previously unidentified pattern exists as an auxiliary part instead of the heptamolybdate. The trimolybdate has been found to change into an intermediate molybdate, $(NH_4)_2O \cdot 3.5MoO_3$, after two months of standing still and into the octamolybdate after another half-year. The auxiliary part in the powder pattern also definitely diminished in strength after two months, finally disappearing in half a year. Therefore, the starting material might have included some volatile ammonium molybdate, the normal ammonium molybdate, for instance. The first and second endothermic peaks, at 99°C and 146°C are due to dehydration. The powder pattern of the trimolybdate does not change until 200°C, the third endothermic peak, above which the pattern becomes exclusively that of the octamolybdate. The exothermic peak at 255°C is due to the crystallization of the octamolybdate. The last endothermic peak is resolved into two maxima. Above 358°C, the first maximum, molybdenum trioxide is produced, while the octamolybdate is still predominant. Above 375°C, the second maximum, the molybdenum trioxide becomes predominant and the octamolybdate, auxiliary. Above 425°C, the exothermic peak which corresponds to the crystallization of the molybdenum trioxide, the formation of the molybdenum trioxide is complete. A correlation of the differential thermal analysis curve, the weight decrease curve and the deammoniation curve of the ammonium trimolybdate is shown in Fig. 8.

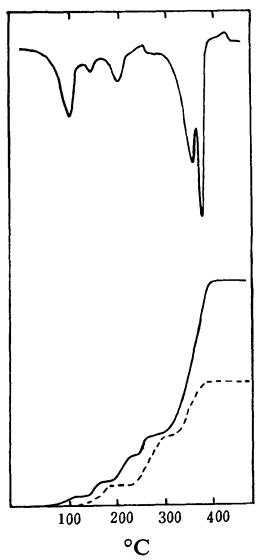

Fig. 8. Ammonium trimolybdate.

Change of Color.—The color of the final decomposition product obtained in air is yellow above 350°C and pale grey-green when cooled to room temperature, while that of the final product in vacuo is purple-black, and this does not change when the product is cooled to room temperature. In respect to the color change during the thermal decomposition, there is little difference among various kinds of polymolybdates. The X-ray investigation revealed that the purple-black oxide is a mixture of MoO_3, Mo_8O_{23}, Mo_9O_{26}, and Mo_4O_{11}, as has been reported in the foregoing paper.[7] The purple-black color may be referred to an oxygen deficiency. When the purple-black oxide, the decomposition product in vacuo, was heated again in air, it became yellow above 350°C, and a slight increase in weight was observed. The change of color in air and in vacuo is given in Tables I and II.

Table I. Change of color in air

100°C	200°C	300°C	400°C	500°C
White	Light grey-green	Yellow green	Yellow	Golden yellow

Table II. Change of color in vacuo

20°C	70°C	100°C	200°C	250°
White	Light green	Yellow green	Dark yellow-green	Purple-black

Summary

The thermal decomposition of ammonium di-, hepta-, tri- and octamolybdates has been investigated by means of differential thermal analysis, chemical analysis, and X-ray diffraction techniques. The steps of the decomposition may be described as follows:

Heptamolybdate

$$3(NH_4)_2O \cdot 7MoO_3 \cdot 4H_2O \xrightarrow[130°C]{} 2(NH_4)_2O \cdot 5MoO_3 \xrightarrow[245°C]{} 2(NH_4)_2O \cdot 8MoO_3 \xrightarrow[360°C]{} MoO_3$$

Dimolybdate

$$(NH_4)_2O \cdot 2MoO_3 \xrightarrow[226°C]{} (NH_4)_2O \cdot 3MoO_3 \xrightarrow[225°C]{} 2(NH_4)_2O \cdot 8MoO_3 \xrightarrow[360°C]{} MoO_3$$

Octamolybdate

$$2(NH_4)_2O \cdot 8MoO_3 \cdot 2H_2O \xrightarrow[287°C]{} 2(NH_4)_2O \cdot 8MoO_3 \xrightarrow[370°C]{} MoO_3$$

6) I. Lindqvist, *Nova Acta Reg. Soc. Sci. Upsal., Ser. IV*, 15, 7 (1950).

7) Cf. Ref. 1.

Trimolybdate

$$(NH_4)_2O \cdot 3MoO_3 \cdot xH_2O \xrightarrow{200°C} 2(NH_4)_2O \cdot 8MoO_3 \xrightarrow{370°C} MoO_3$$

The author wishes to express his deep gratitude to Professor Kumasaburo Kodera and to Professor Sukeji Kachi of Kyoto University for their continued interest in this investigation and for their valuable suggestions. He is also greatly indebted to Dr. Minoru Ozasa of the Matsushita Electronics Corporation for courtesies extended to him and for fruitful discussions.

Synthetic Ammonia Iron Catalysts Containing Magnesia as Its Principal Promoter. I. The Catalysts' Performances[1]

By Hiroshi UCHIDA, Iwao TERAO[2] and Kiyoshi OGAWA

(Received December 12, 1963)

Although the literature contains a few descriptions[3-6] of the synthetic ammonia iron catalysts of the magnesia-promoted type, nothing decisive has ever been reported about the catalysts' performances in relation to the promoter compositions. The present investigation has been undertaken in an attempt to ascertain the kinds and amounts of promoters which are most effective in producing a practicable catalyst of this type. The experimental results here obtained will be able to shed some light on the roles played by the individual promoters.

Experimental

The synthesis gas of $3H_2$-$1N_2$ was compressed into a gas storage vessel (40 l.) and then introduced into another, smaller one (2.5 l.) in which the pressure was automatically controlled at about 110 kg./cm^2 gauge. It was then led, through a needle valve and a high pressure gas flowmeter, into a gas purification train at the fixed pressure of 100 kg./cm^2 gauge. The purification train consisted of a hot nickel-on-kieselguhr plus palladium asbestos deoxidizer, a water cooler, a condenser, and an activated-alumina tower. The gas feed from the train was conducted into a reactor for the ammonia synthesis.

Figure 1 is a simplified diagram of the reactor and its internal parts. The reactor was somewhat different in design from the one which had been used in our previous works (e.g.[7]). An amount (3 cc. in volume, 7.46~7.54 g. depending upon the kinds of catalyst samples) of a granular catalyst was packed into the annular space between the

inner wall of a copper tube and the outer wall of a thermocouple protection tube to form a bed (14.4 mm. O. D. and 4 mm. I. D. by 20 mm. high) which was supported on a perforated stainless steel plate. Caution was paid to decrease the axial temperature gradient along the bed. An electric heating wire was wound more closely near the top and the bottom of copper tube, and the whole space above the bed in the tube was filled with copper chips to preheat the synthesis gas to a temperature as close to the bed temperature as possible. The axial temperature profile was measured by means of moving a thermocouple in the protection tube (4 mm. O. D. and 2 mm. I. D.). Throughout all the synthesis runs, the axial temperature difference remained within 2°C. The arrows in the figure indicate the movements of the gas flow in the reactor. The synthesis runs were conducted at several temperatures in the range between 300 and 500°C at a fixed pressure of 100 kg./cm^2 gauge and at a fixed gas flow rate of 5000 ± 50 hr^{-1} in terms of space velocity measured on the basis of the exit gas from the reactor. The exit gas was analyzed for ammonia in the same way as has been stated previously[7] and was metered. Plots of the ammonia concentration in the exit gas vs. the reaction temperature for individual catalysts give their relative activities for the ammonia synthesis.

The catalysts were prepared by a fusion process in a manner which has been reported elsewhere,[8] starting with a mixture of powders of electrolytic iron supplied by the Showa Denko Co. and promoter materials of the E. P. grade. Lumps of the finished catalysts were crushed, and granules 1.0~1.5 mm. in size were used. The bed of granular catalysts was reduced at 440°C in a current of the synthesis gas at 100 kg./cm^2 gauge at gas flow rates ranging from 1×10^4 to 2×10^4 hr^{-1}. The reduction was continued until no more increase in the ammonia concentration was observed at the temperature of 425°C and at the gas flow rate of 5000 hr^{-1} after successive six-hour periods of reduction.

After the afore-mentioned synthesis runs had been finished, the catalysts were heated at 650°C for five hours in a current of the synthesis gas at atmospheric pressure, and then the synthesis runs were repeated in the same way as before. The change in the ammonia concentration before and after the heat treatment gives a measure of the thermal stabilities of the catalysts.

With a view to calculating the specific activity constant, which corresponds to the specific activity per unit of the catalyst surface area, from the results of the activity measurement, the bed density and the specific surface area of the catalyst sample after the run were determined. The bed density was determined by weighing the catalyst sample, for the bed volume is not changed by the synthesis run. The specific surface area was determined by applying the BET equation to the nitrogen adsorption isotherm at −196°C. It should be noticed that, in general, the surface area determination was made on the catalyst samples after runs at temperatures below 500°C, but that in some special cases where the activity was increased by the heat treatment of the reduced catalyst at 650°C, the determination was made on the catalyst samples after the thermal stability test.

The catalysts in the present investigation seemed more likely to be reduced easily than the catalysts of the alumina-promoted type. In this connection, the increase in the ammonia concentration with the time of reduction was examined in catalysts of particular interest. The catalyst was heated up to 440°C in four hours according to a predetermined schedule at the pressure and at the gas flow rate of the synthesis conditions; it was then kept at this condition until the ammonia concentration in the exit gas became constant.

Results

Catalytic Activity and Thermal Stability.— The activity measurements made on the individual catalysts of different promoter compositions are illustrated in Figs. 2, 3 and 4 as plots of the ammonia concentration in the exit gas vs. the reaction temperature. The promoter compositions, which are summarized in Table I, are expressed in the weight percentages of promoters in the oxide catalysts, on the basis of the exact oxidation of iron to Fe_3O_4. The expression is a conventional one, for the oxidation does not always proceed to, or stop at, the Fe_3O_4 stage, and the ratios between ferrous and ferric irons of the oxide preparations usually show deviations from the 0.5 that corresponds to Fe_3O_4, as the table shows. On the other hand, the expression is rather convenient for defining the promoter composition from the point of view of practical catalyst-manufacturing. To express the promoter composition in the strict sense of the word, the numerals in the table can be corrected by taking the respective ratios into

account. The figures include the thermal stability measurements for the individual catalysts also.

Figure 2 indicates the results on the catalysts, including an unpromoted one (cat. M-0), a couple of magnesia-promoted ones (cats. M-1 and -2), and three doubly-promoted ones, containing potash, lime, and silica (cats. M-3, -4 and -5 respectively) as the second promoter. After reduction, the magnesia-promoted catalysts give essentially the same activity as an alumina-promoted catalyst.[9] A remarkable difference between the above two catalysts, however, appears in their activities after heat treatment at 650°C; the activities of the magnesia-promoted catalyst becomes greater after the heat treatment, whereas that of the alumina-promoted catalyst decreases somewhat (cf.[10]). The increased activity after the heat treatment of the former catalyst stays at the same level, even after prolonged heat treatment for the succeeding five hours, thus demonstrating its excellent thermal stability. Both potash and lime act not as promoters but as moderately effective inactivators (cf. the results on cats. M-3 and -4) insofar as the activities

9) H. Uchida and N. Todo, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zassi*), **60**, 1235 (1957).

10) H. Uchida, *Rpt. Gov't. Chem. Ind. Research Inst. Tokyo*, **46**, 1 (1951).

after reduction are concerned. Of the above two catalysts, only the one containing lime as the second promoter shows an increase in the activity after the heat treatment at 650°C to such a high level as to be comparable with that after the reduction of a catalyst doubly-promoted by alumina and potash.[9] No such phenomenon was observed in the case of the corresponding catalyst of the alumina-promoted type. Silica added as the second promoter has an unfavorable effect on the thermal stability but has little effect on the activity after reduction.

Figure 3 shows the results on a series of triply-promoted catalysts containing varying amounts of silica and potash with a fixed amount of magnesia (4%). The activities of the triply-promoted catalysts can be much higher than those of the doubly-promoted ones, provided that the added amounts of silica and potash are appropriate. Among the three catalysts (cats. M-8, -10, and -11) with the same magnesia (4%) and potash (1%) content, the catalyst with 1% silica (cat. M-8) exhibits a higher activity than any of the catalysts with 0.5% (cat. M-11) and 2% silica (cat. M-10). Moreover, the activity of the catalyst M-10 with a greater silica content, or with a higher ratio of potash to silica, is apt to descend more rapidly with the lowering of the reaction temperature than do the activities of the catalysts with smaller contents, or with lower ratios. This is also the case for the two catalysts with the same magnesia and silica content but with different amounts of potash (cf. cats. M-9 and -12). Of all the triply-promoted catalysts under investigation, a catalyst (cat. M-7) with a minor magnesia content (2%) and with the same content of silica and potash as that of cat. M-8 gives the highest activity, as is shown in a separate figure of Fig. 4. Unfortunately, the highly active catalysts here obtained have poor thermal stability, the catalyst of the highest activity being the poorest.

Triply-promoted catalysts containing alumina, potash, and lime are in current use in industrial ammonia synthesis. One such catalyst (cat. A-102) is compared with one of the present triply-promoted catalysts (e.g. cat. M-7) for activity and for thermal stability in Fig. 4. The former catalyst exhibits a little more activity than does the latter one, with nearly the same thermal stability. The poor thermal stability of cat. M-7 can be improved by the further addition of a small amount of alumina, accompanying a small decrease in the activity (cf. the plot of cat. M-14).

Bed Density and Specific Surface Area.—The results are summarized in Table I. The bed densities are in a narrow range from 1.84 to 1.96 (g./cc.). As regards the present catalysts, the bed densities may be considered to be of a constant value without bringing about any serious errors in the discussion of the promoters' effects on the catalyst performances. A brief outline of the promoters' effects on the change in the specific surface area of the iron catalysts can be obtained from the data in the table. A detailed description will, however, be made in the next chapter in connection with their contributions to the activities of the individual catalysts.

Reduction of the Catalysts.—The results concerning the five kinds of catalysts, an unpromoted catalyst (cat. M-0), a magnesia-promoted catalyst (cat. M-1), two triply-promoted catalysts of different principal promoters (cats. M-7 and A-102), and a quadruply-promoted catalyst containing magnesia, alumina, potash, and silica (cat. M-14), are illustrated in Fig. 5 as the

plots of the ammonia concentration in the exit gas vs. the reduction time. It is almost certain that the increase in the ammonia concentration runs parallel to the extent of reduction except for the final stage, where the removal of the last traces of oxygen causes a considerable increase in the activity.

The results disclose that the addition of magnesia serves to retard the reduction rate of a magnetite only to a very small extent (compare curve I with curve II), whereas the reduction rate is greatly reduced in the presence of alumina (compare curves IV and V with curve II). Potash and silica, when simultaneously added in addition to magnesia,

seemingly have no effect on the rduction rate at the earlier stage, but they have the effect of enabling the resulting catalyst to be reduced more easily toward the end of the reduction (compare curve II with curve III[11]).

Discussion

Rate Constant and Specific Activity Constant. —A quantitative comparison of the catalyst activities at a fixed temperature can be made in terms of the rate constant, k, of the ammonia synthesis reaction. In this paper, k is calculated by the aid of the expression derived from the Temkin-Pyzhev rate equation:

$$k=\left(\frac{\nu_{H_2}{}^{3/2}}{\nu_{NH_3}}\right)P^{1/2}\cdot SV_0\int_0^z \frac{z(1-z)^{3/2}\,dz}{(1+z)^2\{L^2(1-z)^4-z^2\}} \quad (1)$$

where

$$k=273(3/4)^{-3/2}k_2 \quad (2)$$

and

$$L^2=z_{eq}/(1-z_{eq}) \quad (3)$$

In the above equations, ν is the fugacity coefficient, P (atm. abs.) is the total pressure, SV_0 (hr^{-1}) is the space velocity based on the inlet gas,[12] R (atm. m^3/mol. °K) is the gas constant, and k_2 is the rate constant of the reverse reaction. It should be noticed that k ($atm^{0.5}\,hr^{-1}$) is based on the unit bed volume. Table II lists the values of k at 400°C with the various individual catalysts. Unless otherwise stated, k in this paper will hereafter denote the rate constant at this temperature. On the assumption that the entire catalyst surface is available to the catalytic reaction, the specific rate constant, k', ($atm^{0.5}$ cc./hr. m^2) at 400°C is then calculable from the relation of

$$k=k'\rho S \quad (4)$$

where ρ (g./cc.) is the bed density[13] and where S(m^2/g.) is the specific surface area of the catalyst after use in the synthesis run. In view of the findings of Bokhoven et al.,[14] who calculated the effectiveness factor, i. e., the ratio of the experimental rate constant in the absence of retardation due to diffusion effects in pores of the catalyst, and in view of previous activity measurements by other investigators, the assumption seems to be reasonably applicable to the present results at 400°C. The values of k' thus calculated are summarized in Table II. On the basis of the data available on the k' as well as on the S values of the individual catalysts, a better insight into the promoter effects on the activity or k can be obtained.

Magnesia as a promoter contributes to the increase in k' as well as to the establishment and stabilization of a large S. The smaller amount of 2 wt. % in the oxide catalyst is preferred because the greater amount of 5 wt. % accompanies such a considerable decrease in k' as to result in the smaller k, even though S becomes larger to a small extent. Potash, as the second promoter, increases k' to a certain degree, but it reduces S to so extremely small a value that its effect on k is rather unfavorable. As it is, the effect of potash addition on k appears to be of the opposite kind to that with the catalyst of the alumina-promoted type. Lime as the second promoter has little effect on S, but it contributes to the increase in k', and, as a result, the higher k is established. Silica as the second promoter behaves in a peculiar way; while it is remarkably effective in producing a large S, it reduces k' to such a low level as to be below that of a pure iron catalyst.

In view of the information just obtained on the promoting action of potash and silica, an attempt will be made to interpret the high activity that appears with a few of the present triply-promoted catalysts. Figure 6 gives plots of k, S and k' as a function of the ratio of K_2O/SiO_2, with respect to the series of catalysts containing different amounts of potash

11) The final activity was a little low as compared with the activity in the synthesis run. This catalyst of particularly poor thermal stability may have exhibited lower activity because of the lower gas flow rate during the reduction process.
12) SV_0 is given by $SV_0=SV_z(1+z)$, where SV_z is the space velocity based on the exit gas.
13) In the present discussion, ρ requires little consideration, since it remains almost constant for all the catalysts.

and silica, besides a fixed amount of magnesia. In the figure, k' rises rapidly with the ratio at first but much more slowly beyond a ratio of ca. 1, whereas S descends almost linearly as the ratio rises. Accordingly, the high activity, or the high value of k, in the intermediate range of the ratio may be ascribed to a sufficiently high k' and a moderately large S.

Activation Energy and Frequency Factor. — The substitution of Arrhenius equation with reference to k' into Eq. 4 results in the following expression of k:

$$k=k'\rho S=A'\exp(-E/RT)\rho S \qquad (5)$$

where E (kcal./mol.) as defined by Eq. 2 stands for the activation energy of ammonia decomposition, and A' ($atm^{0.5}$ cc./hr. m^2) is the frequency factor per unit of the catalyst surface area, namely, $A'=A/\rho S$. Accordingly, the catalyst activity at a reaction temperature of T (°K) is expressed as a function of A', E, ρ, and S, which are parameters independent of the reaction temperature, T. and E and A' were determined from the Arrhenius plot of k' between 300 and 425°C. The results are summarized in Table II. A rough examination of the table shows that both E and A' change in the same direction as the promoter compositions are changed, both of them being highest with the unpromoted catalyst and lowest with one of the triply-promoted catalysts (cat. M-11).

Since the activity measurements were made mainly on the catalysts promoted doubly and triply, the effects of individual promoters on the change of E and A' can not be clarified separately. However, within certain limits, it is possible to say that magnesia, potash, and lime act similarly to reduce E and A', whereas the situation is the reverse with silica. The differences in effects on E and A' between potash and silica can be seen in a more concrete way from the findings available on the series of triply-promoted catalysts containing varying amounts of potash and silica besides a fixed amount of magnesia. In this connection, Fig. 7 shows the plots of E and A' as a

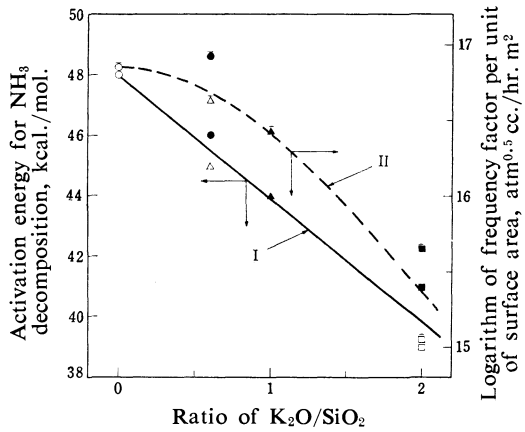

Fig. 7. Activation energy (I) and logarithm of frequency factor per unit of surface area (II) as function of ratio between contents of potash and silica in weight percentage.

△ Cat. M-10 □ Cat. M-11 ■ Cat. M-12

function of the ratio of K_2O/SiO_2. Both E and A' tend to diminish almost linearly with the ratio. Further, the highest value of k' is found at the highest ratio, at which E and A' are lowest (cf. the plot III in the figure). This, however, does not necessarily mean that silica is useless as a promoter, for the large S that contributes to the establishment of a high k does not develop until the catalyst contains

some silica.

Reduction Rate and Catalyst Activity. — Kobosev[15] stated that magnesia added as a promoter to a ferrous oxide had rather an accelerating effect on the reduction rate and that it was not at all effective in increasing the catalyst activity. The above statement differs from the present results; the addition to a magnetite does retard the reduction rate, even though to a very small extent, and between the two series that of catalysts containing magnesia as the principal promoter and that of catalysts containing alumina as the principal promoter, no essential differences appear in their activities notwithstanding the fact that their reduction rates differ greatly. A triply-promoted catalyst belonging to either one of the two series can, similarly, be highly active provided appropriate kinds and amounts of promoters are added. Moreover, nothing remarkably different between the two series is recognizable with respect to the factors of S, k', E and A'. Accordingly, the generally accepted opinion (cf.[5]) that oxides which greatly retard the reduction rate are good promoters can not always be true.

Summary

A catalyst promoted singly by magnesia can be as active as one promoted singly by alumina. The activity of the former catalyst is increased by a succeeding reduction at 650°C to a higher level; the increased level is preserved even after the prolonged heating at this temperature. Potash, lime, and silica added as second promoters behave in their respective peculiar manners. Among the catalysts under investigation, a triply-promoted catalyst performs in nearly the same way as one of the catalysts of the alumina-promoted type in current use in industrial ammonia synthesis, provided the amounts of such kinds of promoters as magnesia, potash, and silica are appropriate.

The activity or the rate constant is expressed as a function of the temperature-independent parameters, which are the bed density, the specific surface area, activation energy, the frequency factor per unit of the catalyst surface area, and the reaction temperature. The effects of individual promoters have been discussed in view of the changes in magnitude of each parameter which result from their additions.

The catalysts of the magnesia-promoted type can be reduced much more easily than the catalysts of the alumina-promoted, type, but the reduction rate is only a little below that of the unpromoted catalyst.

A Note on the Solid Chemisty of the NiO-Li_2O Solid Solution

By Yoshio IIDA and Naoyoshi HAYASHI

(Received December 19, 1963)

Verwey[1] found that an oxide contains a higher or lower valency in its crystal when foreign atoms with, respectively, a lower or a higher valence than the cation of oxide are dissolved in the oxide. From a consideration of the formation of a higher or lower valency of the cations, he successfully explained the electrical conductivity of oxides incorporating foreign atoms with a different valence in terms of the cation of the oxide. This finding is known as the valency control principle. According to the principle, nickel oxide should have x atoms of Ni^{3+} ions to satisfy the electrical neutrality of the crystal when x atoms of Li^+ are dissolved in nickel oxide. The high electrical conductivity of the NiO-Li_2O solution is attributed to the formation of Ni^{3+}. Accordingly, the molecular formula of nickel oxide containing lithium oxide may be expressed by $Ni_{1-2x}{}^{2+}\ Li_x{}^+\ Ni_x{}^{3+}\ O$. However, it seems to be questionable that the number of Ni^{3+} ions is the same as that of Li^+ ions dissolved. Johnston and Heikes[2] did not refer to Mn^{3+} in their report on the

MnO-Li_2O system. There has also been no report dealing with the relation between Li^+ and Ni^{3+} in the NiO-Li_2O solid solution.

The present study has been undertaken to clarify the question and to measure the solubility limit of lithium oxide in nickel oxide. In addition, from these data the ionic radius of Ni^{3+} has been determined.

Experimental

Nickel oxide was prepared by heating high purity nickel sulfate at 800°C. Mixtures of nickel oxide and lithium carbonate were pressed into tablets heated at various temperatures in air. To prevent the loss of lithium oxide by evaporation, the tablets in a platinum boat were covered by a powdered mixture of lithium carbonate and nickel oxide during the heating.

Free lithium oxide and dissolved lithium oxide were determined by a flame photometer in the way described in a previous paper.[3] The chemical analysis of Ni^{3+} was made according to the directions of Verwey.[1] The X-ray powder diffraction patterns were recorded by a diffractometer with a copper target. The lattice parameter of nickel oxide was determined as a function of dissolved lithium oxide by measuring the spacings of the (420) and (422) peaks.

Results and Discussion

It is not yet known how much lithium can be dissolved in nickel oxide when a mixture of lithium carbonate and nickel oxide is heated in air at high temperatures. To determine the temperature dependency of the solubility of lithium oxide in nickel oxide, a mixture of 90 at.% of nickel oxide and 10 at.% of lithium carbonate was heated in air for 3 hr. Figure 1 shows that the amount of lithium oxide dissolved in nickel oxide decreases with an increase in the heating temperature above 800°C. This decrease is attributed to the extensive evaporation of lithium oxide from the NiO-Li_2O solid solution[4] and to the evaporation of the unreacted lithium oxide. Accordingly, it is found that the temperature of 800°C is most suitable for lithium oxide to dissolve in nickel oxide. It has been reported[3] that the amount of lithium oxide dissolved in nickel oxide becomes essentially constant in a heating period of 3 hr. Mixtures of various ratios of lithium carbonate and nickel oxide were heated in air at 800°C for 3 hr. and then air-quenched.

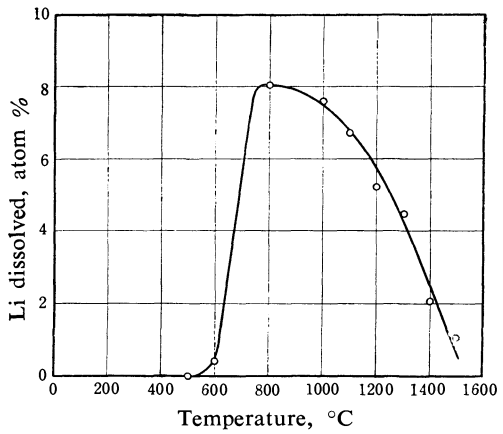

Fig. 1. Relation between the amount of dissolved lithium and heating temperatures.

It may be seen from Fig. 2 that the amount of lithium oxide dissolved in nickel oxide is always lower by a constant ratio than that of additive lithium oxide. Figure 2 shows that the amount of lithium oxide dissolved is constant above 25 at.%. It has, therefore, been concluded that the solubility of lithium oxide in nickel oxide is 25 at.% at 800°C.

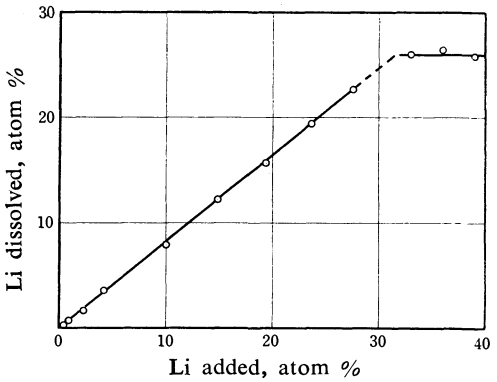

Fig. 2. Relation between the dissolved lithium and added lithium when NiO-Li_2O mixture is heated at 800°C for 3 hr.

The relation between the amount of lithium oxide dissolved and the Ni^{3+} formed in nickel oxide is shown in Fig. 3. The amount of Ni^{3+} ions is essentially the same as that of the dissolved lithium oxide within the solubility of lithium oxide. It is certified that the valency control principle established by Verwey[1] is applicable for the case of the NiO-Li_2O solid solution. Accordingly, the NiO-Li_2O solid solution can reasonably be expressed by the chemical formula of $Ni_{1-2x}^{2+} \cdot Li_x^{+}\ Ni_x^{3+}\ O$. The X-ray pattern of the NiO-Li_2O solid solution exhibits a broad peak as is shown in Fig. 4, as the amount of lithium oxide dissolved increases. The broad peak results from the deformation of the crystal of the NiO-Li_2O solid solution or from

4) Y. Iida, ibid., **43**, 171 (1960).

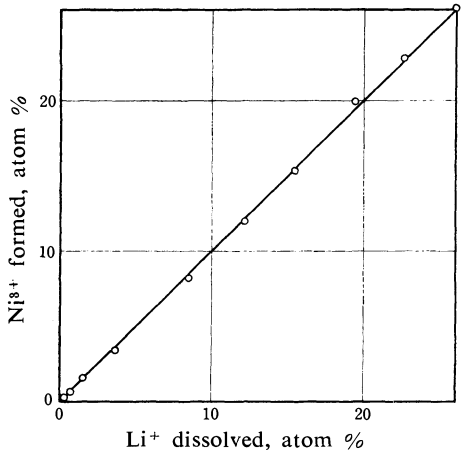

Fig. 3. Relation between the dissolved Li^+ and Ni^{3+} formed in NiO-Li_2O solid solution.

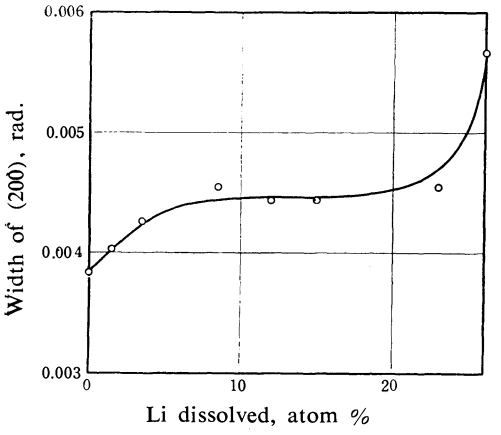

Fig. 4. Width of (200) X-ray peak of NiO-Li_2O solid solution as a function of lithium dissolved.

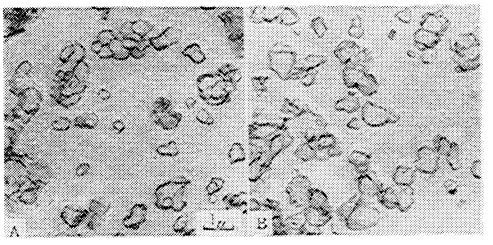

Fig. 5. Electron micrographs of pure NiO (A) and NiO-Li_2O (25 atom %) solid solution (B).

a decrease in its crystal size. The electron microscope photographs shown in Fig. 5 show that the particle size of the NiO-Li_2O solid solution does not vary with an increase in the amount of dissolved Li^+. Therefore, it is reasonable to assume that the crystal lattice of the original NiO is somewhat deformed when the nickel is replaced by lithium in the lattice.

Fensham[5] reported the lattice parameter of the NiO-Li_2O solid solution as a function of the Li^+ ions added. However, the amount of Li^+ ions dissolved is smaller than that of Li^+ ions added, as Fig. 2 shows. It is necessary to plot the Li^{1+} ions dissolved against the lattice parameter of the NiO-Li_2O solid solution. Figure 6 shows that the lattice parameter of nickel(II) oxide decreases linearly with an increase in the amount of lithium oxide dissolved. As the amount of Ni^{3+} ions

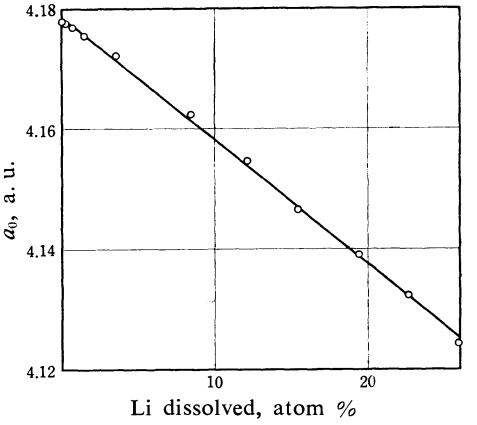

Fig. 6. Lattice parameter of NiO as a function of lithium dissolved.

is the same as that of Li^+ ions dissolved, the variation in lattice parameter can be expressed by Vegard's law as follows:

$$\Delta a_0 = 2(\Delta r_1 + \Delta r_2) \cdot x$$

where Δa_0 is the change in the lattice parameter,
Δr_1 is the difference between the ionic radii of Ni^{2+} and Ni^{3+},
Δr_2 is the difference between the ionic radii of Ni^{2+} and Li^+, and
x is the atomic % of the Li^+ ions dissolved.

There is no literature about the ionic radius of Ni^{3+}. The ionic radius of Ni^{3+} can, however, be calculated by the above equation. According to Ahrens,[6] the ionic radii of Ni^{2+} and Li^+ are 0.69 and 0.68 a. u. respectively. Therefore, the ionic radius of Ni^{3+} is found to be 0.60 a. u., which is quite reasonable in view of the fact that the ionic radius decreases with an increase in its positive valency.

Summary

In the NiO-Li_2O solid solution, it has been certified by a chemical analysis that the

5) P. J. Fensham, *J. Am. Chem. Soc.*, **76**, 969 (1954).

amount of Ni^{3+} formed in the solid solution was the same as that of Li^{+} dissolved. The $NiO\text{-}Li_2O$ solution can be expressed by a molecular formula, $Ni_{1-2x}^{2+}\ Li_x^{+}\ Ni_x^{3+}\ O$. The solubility limit of lithium to nickel oxide is 25 atomic per cent at 800°C, which is an optimum temperature for the formation of the solid solution.

The lattice parameter of nickel oxide decreases with the increase in the amount of lithium dissolved. From Vegard's law, the ionic radius of Ni^{3+} has been calculated to be 0.60 a. u.

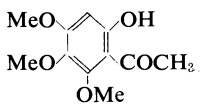
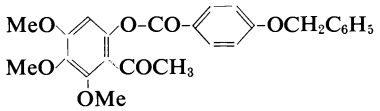
Synthetic Studies of the Flavone Derivatives. IV. The Synthesis of Cirsimaritin*

By Kenji FUKUI, Takashi MATSUMOTO and Takashi KINOSHITA



(Received December 20, 1963)

Cirsimarin, an almost colorless glycoside, has been isolated from *Cirsium martimum* MAKINO (Compositae) by Morita and Shimizu.[1] Their hydrolysis of this glycoside with hydrochloric acid has afforded cirsimaritin, a slightly yellow aglycone. They established the latter constitution as 4', 5-dihydroxy-6, 7-dimethoxyflavone (I) on the basis of analytical, spectroscopic and degradative studies. The substitution pattern belongs to the 5, 6, 7-hydroxy or methoxy type as found in scutellarein[2] and pectolinarigenin.[3] However, the new flavone has a unique structure in that it contains two methoxyl groups in the 6, 7-positions. The present report will describe the synthesis of the flavone I.



The esterification of 6-hydroxy-2, 3, 4-trimethoxyacetophenone (II)[4] with *p*-benzyloxybenzoyl chloride in the presence of dry pyridine gave the benzoate III. III was subjected to the Baker-Venkataraman rearrangement with pyridine-potassium hydroxide. The resulting diketone IV was converted into 4'-benzyloxy-5, 6, 7-trimethoxyflavone (V) by heating it with acetic acid and sodium acetate. The debenzylation of V with hydrogen afforded 4'-hydroxy-5, 6, 7-trimethoxyflavone (VI), which was demethylated with aluminum chloride in the 5-position to the flavone I. The synthetic product was identical with the natural cirsimaritin in melting point, color reactions and spectral characteristics (Figs. 1 and 2). I was partially methylated with diazomethane in the 4'-position to 5-hydroxy-4', 6, 7-trimethoxyflavone (scutellarein 4', 6, 7-trimethyl ether) (VII). The permethylation of VI or VII gave the same 4', 5, 6, 7-tetramethoxyflavone (scutellarein tetramethyl ether) (VIII).

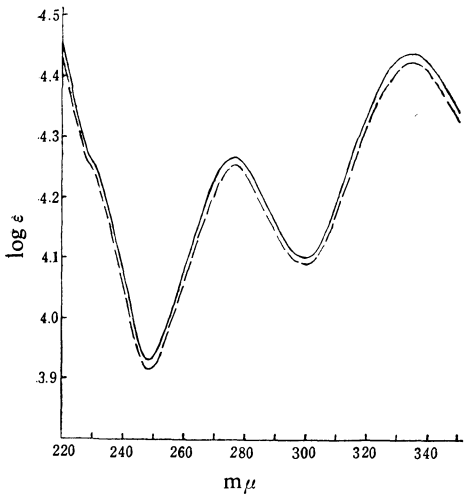

Fig. 2. Ultraviolet absorption spectra of natural (----) and synthetic cirsimaritin (——) in ethanol.

Experimental*

6-(*p*-Benzyloxy)benzoyloxy-2, 3, 4-trimethoxyacetophenone (III).—A mixture of *p*-benzyloxybenzoic acid (1.0 g.) and thionyl chloride (10 ml.) was gently refluxed for 30 min. The acid chloride, obtained by the removal of the excess thionyl chloride under reduced pressure, was added to the solution of 6-hydroxy-2, 3, 4-trimethoxyacetophenone[4] (II, 1.0 g) in dry pyridine (10 ml.). The mixture was refluxed in an oil bath for 30 min. After it had cooled, the reaction mixture was poured into ice-cold dilute hydrochloric acid. The precipitate was collected, washed with water and recrystallized from methanol to give III as colorless needles (m. p. 113~115°C; yield 0.8 g.).

Found: C, 68.67; H, 5.67. Calcd. for $C_{25}H_{24}O_7$: C, 68.80; H, 5.54%.

α-(*p*-Benzyloxy)benzoyl-6-hydroxy-2, 3, 4-trimethoxyacetophenone (IV).—A mixture of the benzoate III (13.2 g.), powdered potassium hydroxide (2.6 g.) and dry pyridine (40 ml.) was heated at 45~50°C for 1 hr. while being stirred; then it was poured into ice-cold dilute hydrochloric acid, and the precipitate was collected, washed with water and crystallized from ethanol to give IV as yellow needles (m. p. 113~114°C), which gave a green ferric reaction in ethanol; yield 8.0 g.

Found: C, 69.07; H, 5.59. Calcd. for $C_{25}H_{24}O_7$: C, 68.80; H, 5.54%.

4'-Benzyloxy-5, 6, 7-trimethoxyflavone (V).—The above diketone IV (0.8 g.) was refluxed with acetic acid (10 ml.) and fused sodium acetate (2.0 g.) for 4 hr., and then the solvent was removed under reduced pressure. The residue was washed with water and recrystallized from methanol to give V as colorless plates (m. p. 156~157°C), which gave a yellow solution with concentrated sulfuric acid; yield 0.6 g. UV λ_{max}^{EtOH} mμ (log ε); 268 (4.27) 322 (4.54).

Found: C, 71.67; H, 5.17. Calcd. for $C_{25}H_{22}O_6$: C, 71.76; H, 5.30%.

4'-Hydroxy-5, 6, 7-trimethoxyflavone (VI).—A solution of the above benzyloxyflavone V (1.0 g.) in ethanol (130 ml.) was shaken with hydrogen in the presence of palladized charcoal (10%; 1.5 g.) until the absorption of hydrogen ceased. The filtered solution was evaporated under reduced pressure, leaving an almost colorless residue. The residue was recrystallized from aqueous methanol to give VI as colorless needles (m. p. 230~231°C (reported m. p. 228°C[1]); yield 0.7 g.). This substance gave a yellow solution with concentrated sulfuric acid. UV λ_{max}^{EtOH} mμ (log ε); 266 (4.17) 325 (4.45).

Found: C, 65.52; H, 4.93. Calcd. for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

It formed an acetate (by the use of acetic anhydride-pyridine), which was crystallized as colorless needles (from aqueous methanol) (m. p. 139~140°C). UV λ_{max}^{EtOH} mμ (log ε); 266.5 (4.38) 309 (4.39).

Found: C, 64.64; H, 4.83. Calcd. for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%.

Cirsimaritin (4', 5-Dihydroxy-6, 7-dimethoxyflavone) (I).—A mixture of the hydroxyflavone VI (1.0 g) and anhydrous aluminum chloride (10.0 g.) in dry ether (150 ml.) was refluxed for 10 hr. After it had cooled, the reaction mixture was poured into ice-water. The yellow precipitate was collected, then refluxed with a mixture of concentrated hydrochloric acid (40 ml.) and acetic acid (60 ml.) for 30 min., and the reaction mixture was diluted with water. The yellow precipitate was collected, washed with water and recrystallized from methanol to give I as yellow needles (m. p. 257~258°C (reported m. p. 257°C[1])), alone or mixed with natural cirsimaritin; yield 385 mg. It shows all the color reactions of the natural cirsimaritin. IR 3273 (OH), 1665 (C=O), 1029 cm^{-1} (=C-O-C) (Nujol). UV λ_{max}^{EtOH} mμ (log ε); 277 (4.27) 336 (4.44).

Found: C, 64.70; H, 4.34. Calcd. for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%.

5-Hydroxy-4', 6, 7-trimethoxyflavone (VII).—The flavone I was partially methylated with diazomethane according to the method of Morita and Shimizu.[1] Recrystallization from ethanol gave VII as yellow needles (m. p. 187~188°C (reported m. p.

* All melting points are uncorrected.

183,[1] 188,[3] 189~190°C[5])). UV λ_{max}^{EtOH} mμ (log ε); 278.5 (4.31) 331 (4.45).

Found: C, 65.83; H, 4.62. Calcd. for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

4', 5, 6, 7-Tetramethoxyflavone (VIII).—*From VI.*—The treatment of VI (200 mg.) in acetone (50 ml.) with an ethereal solution of diazomethane for a day at room temperature gave VIII as colorless plates (from methanol) (m. p. 161~162°C (reported m. p. 158~159,[1] 161°C[6])), which in turn gave a yellow solution with concentrated sulfuric acid; yield 130 mg. UV λ_{max}^{EtOH} mμ (log ε); 267.5 (4.23) 321 (4.49).

Found: C, 66.54; H, 5.08. Calcd. for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

From VII.—To a solution of VII (90 mg.) and dimethyl sulfate (0.1 ml.) in acetone (50 ml.), potassium carbonate (2.0 g) was added; the mixture was then refluxed for 48 hr. The product was recrystallized from methanol to give VIII (m. p. and mixed m. p, 161~162°C); yield, 40 mg.

Further Studies of the Neutron Shielding of Metals in Thermal Neutron Activation

By Yuichiro KAMEMOTO and Shigeru YAMAGISHI

(Received December 24, 1963)

In thermal-neutron activation analysis, it is desirable to use samples which are smaller than those in which self-shielding effects are observed. Therefore, the permissible size in neutron irradiation in nuclear reactors is limited by the self-shielding in the sample. For elements with very large neutron absorption cross sections, this effect of shielding occurs when even small amounts of the sample are present; this may sometimes cause an error in the determination of such elements by neutron activation. In order to eliminate this error, the weight of a sample which has an appreciable self-shielding effect must be determined experimentally.

The authors have studied this problem in an attempt to ascertain the relationship between the neutron absorption cross section and the weight of each element which brings about an appreciable self-shielding effect, hoping thus to simplify the experimental process.

As a part of the results obtained, a rough relationship has been reported[1] for silver, gold, antimony, chromium and mercury metals. If this relationship is applicable to numerous other elements, it will be useful in estimating the most suitable amounts of sample to be used in neutron activation analysis.

Further studies will be reported on in this report in order to determine the applicability of this relationship to several other elements. In this investigation, the authors measured the self-shielding effects of gold, silver, copper, cobalt, indium, gallium, antimony, chromium, selenium and tin metals.

Experimental

Samples.—Samples were prepared from commercially-available G. R. metal particles or blocks as follows.

Selenium and Copper.—The method of preparing these samples consists of fusing particles of the metal, solidifying different amounts of fused metal on a quartz plate, making the product spherical with emery paper, and washing the surface in order to decontaminate it.

Indium, Silver, Cobalt, Tin, Gold, Gallium, Antimony and Chromium.—These samples were prepared by cutting them into smaller blocks from the original block, making them spherical with emery paper, and washing the surface in order to decontaminate them.

Each sample was wrapped with a parchment paper and sealed in a polyethylene pouch. As the

standard sample in which self-shielding does not occur, about 20 μg. of a sample was infiltrated into a filter paper (Toyo Roshi No. 5C) 2 cm. in diameter and sealed in a polyethylene pouch. The pouch containing the same element was packed in a capsule with soft paper and irradiated in the reactor.

Neutron Irradiation.—Samples were irradiated in the experimental hole No. 16 (pneumatic tube) of JRR-1 for 30 min.~2 hr. The thermal neutron flux was about 3×10^{11} n/cm^2/sec., and the cadmium ratio was 3~3.7.[2)]

Counting.—The irradiated sample was dissolved in mineral acid and diluted with water. A part of the resultant solution was pipetted into a polyethylene tube and diluted to 5 ml. with water. This sample for counting was mounted on a 3×3 inch NaI crystal attached to the RCL-256 channel pulse height analyzer, and the γ-ray spectrum was measured. By determining the γ-ray energy and the decay time of photopeaks of the γ-ray spectrum, the radiochemical purity of each sample was verified. Thereafter, the relative specific activity of each sample was calculated from the peak height of the γ-ray spectrum.

In the measurement of the γ-ray spectrum, the amount of sample pipetted is abjusted so that the counting rate is similar in each sample, thus reducing error from the difference in counting efficiency between the samples.

The experimental conditions adapted are shown in Table I.

2) T. Kurusu, Y. Saruta and T. Aburai, private communication.

Results and Discussion

The specific activity calculated from the peak height of photopeaks is plotted against the weight of sample. The curves thus obtained are shown in Figs. 1—10.

In the previous report, the weight of a sample (W g.) which has a specific activity 10 per cent smaller than that of "Zero" weight was determined graphically. This weight, W g., was assumed to represent the sample weight at which the self-shielding effect becomes appreciable. As a result of the above assumption, the following rough relationship between W and the neutron absorption cross section of the element (σ_{abs} barn) was found in the case of silver, gold, antimony, chromium and mercury metals. $W\times\sigma_{abs}$/atomic weight of sample = 0.02~0.04.

For the present report, the authors calculated the values of $\sigma_{abs}\times w$/atomic weight of sample (E), where w is the weight of a sample particle and σ_{abs} is the neutron absorption cross section of the sample (the ratio is hereafter shown as E). The relative specific activities were then plotted against E. When E is small, the specific activity is independent of E. Therefore, it is possible to normalize all the curves by bringing together their constant parts. If the neutron absorption cross section is large and if the independent part is not observed, the curves

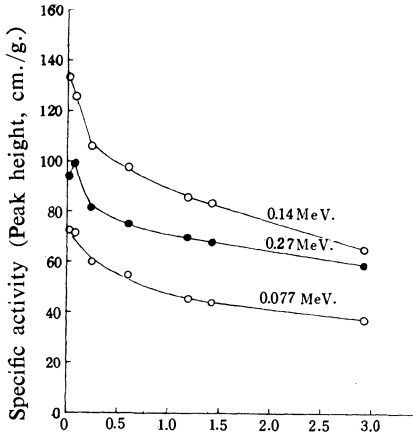

Fig. 1. Neutron shielding of selenium.

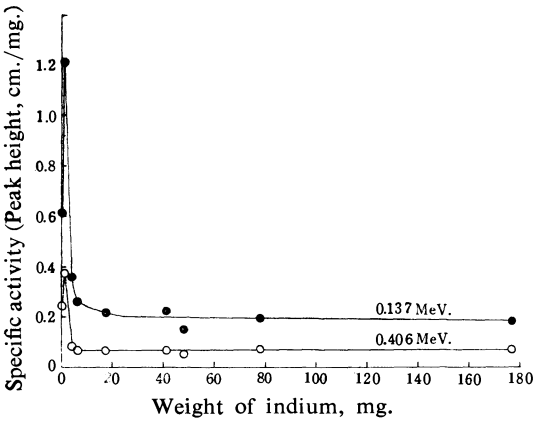

Fig. 2. Neutron shielding of indium.

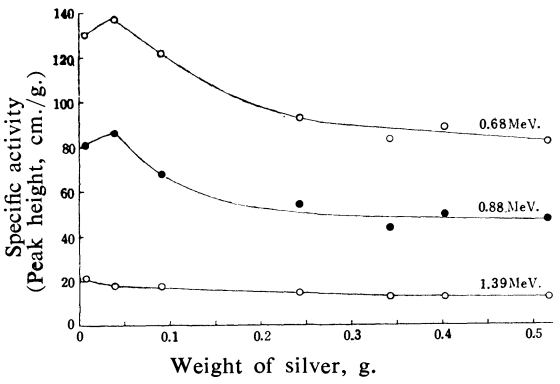

Fig. 3. Neutron shielding of silver.

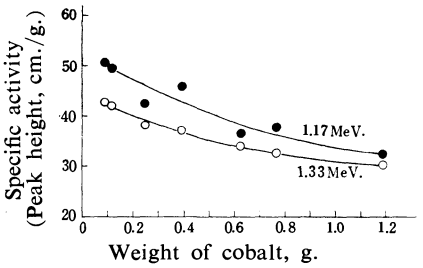

Fig. 5. Neutron shielding of cobalt.

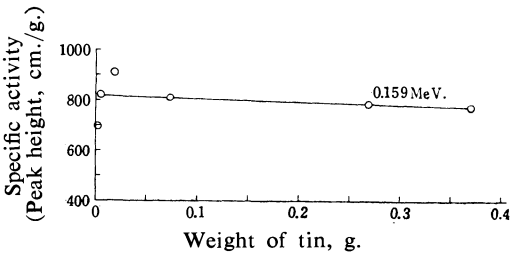

Fig. 6. Neutron shielding of tin.

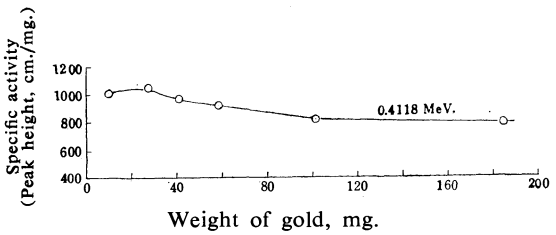

Fig. 7. Neutron shielding of gold.

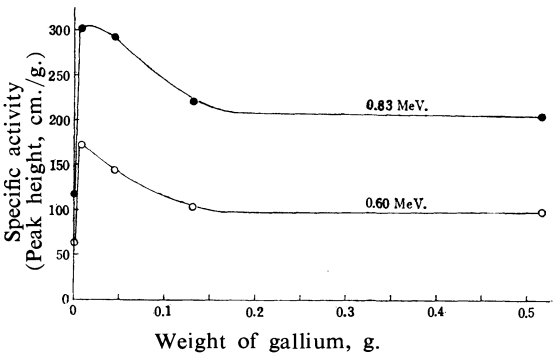

Fig. 8. Neutron shielding of gallium.

are normalized by using the specific activity of the standard samples, which are 20 μg. of the same element, assuming that no self-shieldind effect occurs in the standard. The normalized plots thus obtained are shown in Fig. 11, together with the optimum curve for the combined data.

From Fig. 11 the following relationship is obtained between the neutron absorption cross section in barns, σ_{abs}, and the weight in grams of a element corresponding to a 10 per cent self-shielding effect, W:

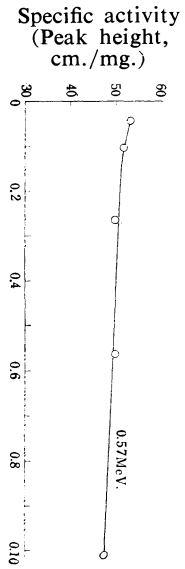

Fig. 9. Neutron shielding of antimony.

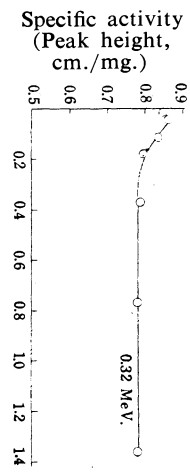

Fig. 10. Neutron shielding of chromium.

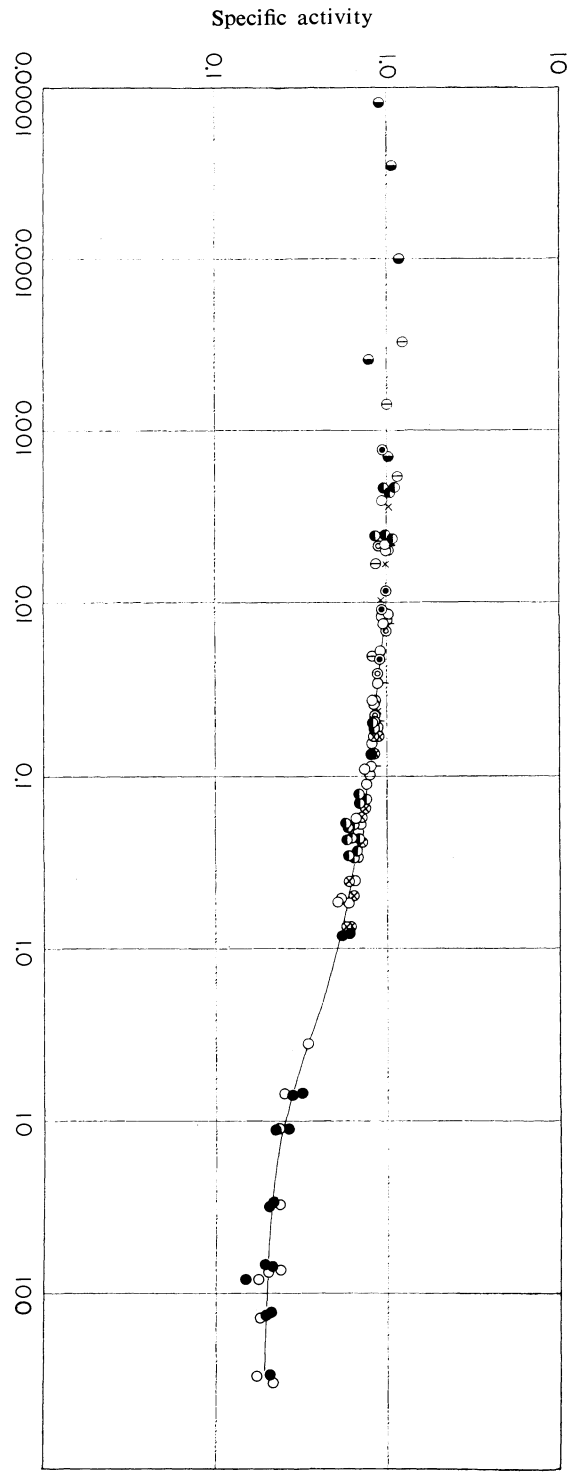

Fig. 11. Normalized plots of specific activity vs. $\sigma_{abs} \times w$/atomic weight.
○ Se ◐ Ag ⊗ Co ⏀ Ga ◎ Sb ● In ⊙ Cu ◑ Sn ◇ Au ×Cr

$$\frac{\sigma_{abs} \times W}{\text{Atomic weight of sample}} \simeq 0.03^{3)} \quad (1)$$

In a similar experiment using indium metal, Okada reported the value of 0.06.[4] However, it was found from our experiments that Eq. 1 was applicable to numerous elements, including indium.

The weight of stainless steel corresponding to a 10 per cent self-shielding effect has been calculated. This value agrees with the value obtained experimentally using an in-pile loop plug in a JRR-3 reactor. The results obtained appear to confirm that this equation is useful in estimating the most suitable amounts of a sample to be used in neutron activation analysis.

On the Electrolytic Rectification Effect in Ion-exchange Membranes

By Manabu SENŌ and Takeo YAMABE

(Received January 25, 1964)

The rectification effect has been observed with many biological membranes.[1] In these systems, a mechanism based on the strength of the contributions of the ionic conduction has been frequently considered. Recently, Lovreček and his co-workers[2] observed the rectification effect in the polyelectrolyte systems. These investigations suggest the possibilty that electric circuits might be constructed with ions as charge carriers. The ions are inferior in their low mobility, but are superior in their various species, to electrons as a charge carrier. This report is our first paper to treat this problem. An experimental and a theoretical treatment of the rectification system of ion-exchange membranes will be given.

Experimental

The ion-exchange membranes used were heterogeneous and were prepared from poly(vinyl chloride) and pulverized ion-exchange resins (commercially-available, Amberlite IR-120 and IRA-400). The membranes were thoroughly washed with hydrogen chloride and sodium hydroxide solutions and then with deionized water. The cation-exchange membrane was made up into the hydrogen form, and the anion-exchange membrane, into the hydroxide form. These membranes were pressed face to face into a double membrane and sandwiched between the two stainless-steel electrodes. Each membrane was 1 cm^2 in area and 0.3 mm. thick. The water content of the membranes, 56% by weight, was maintained through the measurement period by enclosing them in a sealed box.

3. Electrodes (stainless steel)
4. Voltage source
5. Ammeter
6. Resistance (10 kΩ)
7. Oscilloscope
8. Constant-moisture chamber

The measuring apparatus is shown in Fig. 1. A constant voltage was supplied by a battery, and an alternating voltage, by test-oscillators, Toa-Dempa CR-1E (10^{-2}~10^{3} c. p. s.) and National RC-5A (25~10^{5} c. p. s.). The electric current was measured with a micro-ammeter and an oscilloscope.

Results and Discussion

Constant Voltage - Current Characteristics.— The system in which the positive electrode is connected to the cation-selective membrane and the negative electrode to the anion-selective membrane is highly resistant to the

Dotted line, forward → inverse direction

direct current in comparison with the case where the reverse polarity is applied. The current ratio of the forward direction to the reverse one attains 100 or more. A diagram of the current versus the voltage is shown in Fig. 2. The electric current in the forward direction is stable against the passage of time, while in the reverse direction it has a trend to increase with the lapse of time. The values given in Fig. 2 were read at 30 sec. after the application of a voltage. An increase in the applied volage in the reverse direction results in a gradual increase in the current after an initial trend to saturation.

The relationship between the electric current, i, and the applied voltage, V, is represented by Eq. 1;

$$i = i_0 \ (e^{\alpha V} - 1) \qquad (1)$$

where the experimental parameters, i_0 and α, have the following values in the present experiment;

$$i_0 = 5.0 \times 10^{-1} \text{ amp./cm}^2$$

$$\alpha = 0.49$$

This relation will be discussed in the following section.

Alternating Voltage-Current Characteristics.— The rectification effects are very effective when alternating voltages with very low frequencies (lower than 1 c. p. s.) are applied to the system. An example is shown in Fig. 3. However, it must be pointed out that a clear inflection point appears where the polarity changes from the reverse direction to the forward one, while, when the applied voltage in the forward direction is decreased, no current is observed at a finite value of the applied voltage and then the reversed current becomes to be running. A further decrease in the forward voltage and then an increase in the reverse voltage result in an initial increase in the reverse current, followed by an abrupt decrease, and then the reverse current attains a saturation value. There is observed a hysteresis with a negative resistance in the current-voltage diagram. This is found as a spike current in a current wave. This may be caused by a membrane potential and a capacitance of a liquid film adjacent to the membrane.

When an alternating voltage with frequencies higher than 1 c. p. s. is applied, the rectification effect becomes poorer. One of the observed result is shown in Fig. 4. The primary cause would be a contribution by the capacitance current, based on the capacitance of the membrane system. Assuming an R-C parallel circuit as the simplest equivalent circuit of the system, the following values are measured; $R = 5 \times 10^3$ ohm and $C = 7 \times 10^{-6}$ F. It is estimated from this that the contribution of the capacitance current is major at frequencies higher than $f = 1/2\pi CR = 4.54$ c. p. s. A contribution of the relaxation effect of the

ionic atmosphere[3] will appear at very much higher frequencies, probably 10^7 or higher.

Theoretical Considerations.—The charge carriers in this system will be ions; hydrogen ions (protons) and hydroxide ions in this case. Hydrogen ions are rich in the cation-selective membrane, and hydroxide ions are rich in the anion-selective membrane. The distribution of these carriers is ruled by Boltzmann's law in an equilibrium state. The density, n, of protons is given by:

$$n_x = n_0 \exp(-e\varphi_x/kT) \tag{2}$$

where e the elementary charge, k the Boltzmann constant, and T, the absolute temperatures. The potential, φ, of protons is low in the cation-selective membrane phase (I) and high in the anion-selective membrane phase (II); it is schematicaly shown in Fig. 5.

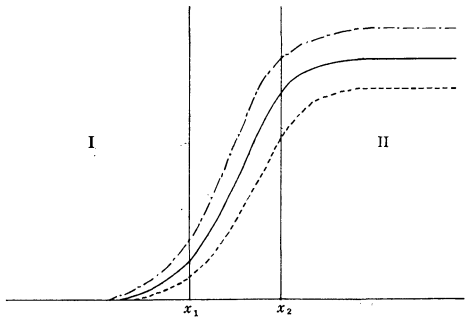

Fig. 5. Potential curve for protons.
I, cation-selective membrane
II, anion-selective membrane
Intermediate, transition region
Steady line, no applied voltage
Dotted line, forward bias voltage
Chain line, inverse bias voltage

The total protonic current is given by adding an driving current to a diffusion current; that is,

$$i_x = eu_n n_x \frac{d\varphi_x}{dx} - eD_n \frac{dn_x}{dx} = en_x \frac{d\varphi_x}{dx}\left(u_n - \frac{e}{kT} D_n\right) \tag{3}$$

In the absence of a bias valtage, Einstein's relation holds true between the mobility, u_n, and the diffusion constant, D_n, of protons; that is,

$$u_n = (e/kT) D_n \tag{4}$$

therefore, the total current does not run.

When a forward voltage is applied, the electric potential difference becomes small in the transient region, as is shown by a dotted line in Fig. 5. As a result, a diffusion current surpasses a driving current and protons flow from the transient region into the region II by diffusion. Then the density of protons in the region II becomes

$$n_x = n_{II} + \Delta n_x \tag{5}$$

according to the principle of electroneutrality, hydroxide ions increase by the same quantity, Δn_x, in this region. At the same time, the excess protons disappear in the formation of water molecules with hydroxide ions. The rate of this recombination reaction, R, is:

$$\begin{aligned} R(x) &= rn_x m_x = r(n_{II} + \Delta n_x)(m_{II} + \Delta n_x) \\ &= rn_{II} m_{II} + rm_{II} \Delta n_x \\ &= g + (1/\tau_n)\Delta n_x \end{aligned} \tag{6}$$

where m is the density of hydroxide ions, $g = rn_{II} m_{II}$ is the rate of the thermal decomposition of water molecules, and $\tau_n = 1/rm_{II}$ is the mean life-time of protons in the region II.

Under such circumstances, the diffusional flow of protons is expressed by:

$$D_n \frac{dn(x+dx)}{dx} - D_n \frac{dn(x)}{dx} = (R(x) - g)dx \tag{7}$$

or

$$D_n \frac{d^2 n}{dx^2} = R(x) - g \tag{8}$$

The boundary condition that, if $x \to \infty$, $n(x)$ equals n_{II}, must be satisfied. The solution of Eq. 8 is at the boundary $x = x_2$:

$$n(x_2) - n_{II} = C \exp\{-(x - x_2)/L_n\} \tag{9}$$

where $L_n = \sqrt{\tau_n D_n}$ is the mean distance which protons proceed in the region II until their disappearance.

Therefore, the current carried by the protonic diffusion is given by:

$$\begin{aligned} i_n(x_2) &= -eD_n\left(\frac{dn(x)}{dx}\right)_{x=x_2} \\ &= \frac{eD_n}{L_n}\{n(x_2) - n_{II}\} \end{aligned} \tag{10}$$

From Boltzmann's law,

$$n(x_2) = n_{II} \exp(eV/kT) \tag{11}$$

These relations lead to the final expression:

$$i_n(x_2) = \frac{eD_n}{L_n} n_{II}(\exp(eV/kT) - 1) \tag{12}$$

Exactly the same relation holds true for hydroxide ions. Therefore, the total current is expressed by:

$$i = e\left(\frac{D_n n_{II}}{L_n} - \frac{D_m m_{II}}{L_m}\right)(\exp(eV/kT) - 1) \tag{13}$$

where the subscript n refers to protons and the subscript m, to hydroxide ions.

TABLE I. PARAMETERS OF CHARGE-CARRIERS

	Hydrogen ion	Hydroxide ion
Density in cation-selective membrane, cm^{-3}	$n_I=4.17\times10^{17}$	$m_I=8.67\times10^{9}$
Density in anion-selective membrane, cm^{-3}	$n_{II}=4.41\times10^{9}$	$m_{II}=8.18\times10^{17}$
Mobility, $cm^2/V.\,sec.$	$u_n=3.0\times10^{-3}$	$u_m=1.7\times10^{-3}$
Diffusion constant, $cm^2/sec.$	$D_n=7.8\times10^{-5}$	$D_m=4.4\times10^{-5}$
Mean life-time, sec.	$\tau_n=6.6\times10^{-12}$	$\tau_m=1.3\times10^{-11}$
Mean invation-distance, cm.	$L_n=2.25\times10^{-8}$	$L_m=2.4\times10^{-8}$
Thermal generation rate, $cm^{-3}/sec.$	$g=6.7\times10^{20}$	

When a reverse bias voltage is applied, the density of protons at $x=x_2$ decreases by a ratio of $\exp(-e|V|/\boldsymbol{kT})$. As a result, protons flow out from the region II by diffusion. However, this current is small and soon attains saturation because of the low density of protons in this region.

These considerations explain the observed results well. Using the values of the parameters in Eq. 1 and those of the specific resistance of each membrane, 5×10^3 ohm·cm. for the cation-selective membrane and 4.5×10^3 ohm·cm. for the anion-selective membrane, and assuming $r_n=r_m$, we can estimate the parameters in the above equations. The results are given in Table I.

Although most of the values estimated above seem to be reasonable, there are many discrepancies. That is, the theoretical value of α in Eq. 1 is 38.6, while the observed value is 0.49. The rate of the dissociation of water into hydrogen and hydroxide ions has been observed to be $2.6\times10^{-5}\,sec^{-1}$,[4] from which the rate of the thermal generation has been calculated as $1.56\times10^{16}\,cm^{-3}\,sec^{-1}$, while the present value is $6.7\times10^{20}\,cm^{-3}\,sec^{-1}$. Moreover, the rate of the recombination of hydrogen and hydroxide ions into water has been observed as $1.3\times10^{11}\,l.\,mol^{-1}\,sec^{-1}$,[3] from which the mean-life time has been calculated to be 5.65×10^{-9} sec. for protons and 1.11×10^{-8} sec. for hydroxide ions, while the estimated values are 6.6×10^{-12} and 1.3×10^{-11} sec. respectively.

However, these disagreements are caused not by wrong treatments, but by the roughness of the model and unexpected errors in the experiments.

The final Eq. 13 is the same as Shockley's equation[5] for the p-n junction diode of semiconductors. This means that the same rectification mechanism holds true for the present system, with ionic charge-carriers, as for the semiconductor diode with electronic charge-carriers. Accordingly, the cation-selective membrane corresponds to the n-type semiconductor and the anion-selective membrane, to the p-type semiconductor. Moreover, it may be very instructive to consider hydrogen and hydroxide ions as protons and proton-defects respectively. By this analogy, most of the properties of the charge-carriers in the present ionic system might be understood by the methods used in the solid state physics, where the electron and its defect play an important role.

Summary

The electrolytic rectification effect has been observed in a double-membrane system. The static and dynamic current-voltage characteristics have been measured, and it has been demonstrated that the mechanism of the rectification similar to that of the p-n semiconductor junction holds true for this system. Reasonable values have been estimated for the characteristic parameters, although there are many discrepancies requiring further examination.

Studies of the Organic Reactions of Metal Carbonyl. II. The Reaction of Olefin Oxide with Cobalt Hydrocarbonyl*

By Yoshinobu TAKEGAMI, Chikao YOKOKAWA, Yoshihisa WATANABE and Hiromitsu MASADA

(Received September 2, 1963)

In connection with the Oxo reaction, the reaction of olefins with cobalt hydrocarbonyl and carbon monoxide has been studied by several workers.[1-5] It has been established[5,6] that alkyl- and acylcobalt carbonyl are formed in this reaction.

Recent papers[7-11] have reported that hydroxy-acids, their derivatives or rearranged carbonyl products are formed in the reaction of olefin oxides with carbon monoxide and water or alcohols using a cobalt salt or cobalt carbonyl as catalyst. With regard to these facts, Heck[13] has established, by isolating β-hydroxyacyl-cobalt tricarbonyl triphenylphosphine, that β-hydroxyacylcobalt tetracarbonyl is formed in the reaction of olefin oxide with cobalt hydrocarbonyl.

In the present paper, this type of reaction has been studied with an emphasis on the following two points: a) the effect of the reaction conditions on the nature of this reaction and the structure of the products, and b) the relation between the reactivity of olefin oxides and their structures.

Experimental

Reaction Procedures.—The reactions were carried out as described in the previous paper,[14] using 50 ml. of 0.09 M cobalt hydrocarbonyl solution in toluene.

Analytical Procedures.—The solution of crude products was treated with iodine and ethyl alcohol as described previously,[14] and the excess of iodine was reduced with crystalline sodium thiosulfate. After concentration, the reaction products were gas-chromatographed on a column, three meters in length and 3 mm. in diameter, filled with dilauryl phthalate or silicon DC 550 on cerite, at 140~160°C, and at the flow rate of carrier gas (hydrogen) of 50 ml./min. The identification of ethyl β-hydroxy-propionate, ethyl β-hydroxy-*n*-butyrate, β-hydroxy-*n*-butyraldehyde, α- and β-phenylethyl alcohol was made by mixing them with authentic samples in gas chromatography. The infrared spectra of the solution of reaction products in toluene were recorded by a Shimadzu model IR-27 infrared spectrophotometer, after removing iodohydrin* by treating the crude solution with potassium hydroxide.

Materials.—Ethylene oxide, propylene oxide, styrene oxide, epichlorohydrin and pentene-1 were commercial products. Cyclohexene oxide was synthesized by the oxidation of cyclohexene with perbenzoic acid.[15] All of these compounds were proved to be sufficiently pure by gas chromatography. The cobalt hydrocarbonyl solution in toluene was prepared by a method described previously.[14]

Results and Discussion

Propylene Oxide.—A recent paper reported[13] that olefin oxide reacts readily with cobalt hydrocarbonyl, but the effects of the reaction conditions on the reaction and on the products are unknown. The authors found that the reactions of some olefins with cobalt hydrocarbonyl are remarkably influenced by the reaction conditions (temperature, atmosphere, etc.).*

In this study, the reaction of propylene oxide with cobalt hydrocarbonyl has been

examined in detail. Two skeletal isomeric products are possible in this case, but the composition of the reaction products has not been studied.[13]

As is shown in Table I, the major product independent of the atmosphere (one atmosphere of carbon monoxide or nitrogen), temperature (25～−45°C) and mole ratio* of propylene oxide (1.4～13.5), was ethyl β-hydroxy-*n*-butyrate,** which was evidently derived from β-hydroxy-*n*-butyrylcobalt carbonyl by cleavage with iodine and ethyl alcohol. Besides this ester, a small amount of β-hydroxy-*n*-butyraldehyde was formed, but there was no indication of the presence of ethyl α-methyl-β-hydroxypropionate under the reaction conditions used. The yields of the ester tended to decrease as the reaction temperature rose; i.e., the total yields of the ester and the aldehyde in the reactions at 25, 0, and −30°C were about 30, 55, and 80% respectively, on the basis of the amount of carbon monoxide absorbed. Under nitrogen, the yields of the ester were much less than those under carbon monoxide; at 0°C, in the case of a 2.7 or 6.2 mol. ratio, only about 0.15 or 0.25 mol. of the ester, independent of the reaction time (15～330 min.), was formed.

The gas absorption curves shown in Fig. 1., in which the amount of carbon monoxide absorbed is plotted against the reaction time, indicate that, at 0°C and under one atmosphere of carbon monoxide, the rate of the gas absorption at the early stage of the reaction is roughly proportional to the square of the mole ratio. The gas absorption at 25, −30

*3 Ethyl β-hydroxypropionate.

(and −45°C) occurred more slowly than at 0°C. The amount of gas absorbed at 25°C was less than that at 0°C.

In connection with the fact that the reactions under nitrogen gave the ester with a low yield, the reaction was carried out in two stages, the first stage under nitrogen for 15 min. and, then the second stage under carbon monoxide. At 0°C, only 0.2 mol. of the gas was absorbed in the second stage (Exp. 15 and curve 15). This value obviously corresponds with that of the yield of the ester in the corresponding reaction under nitrogen (Exp. 11). This fact seems to indicate that, under nitrogen, some side reaction other than the carbonylation reaction occurred rapidly to consume a large part of the cobalt hydrocarbonyl used. At −30°C, however, in the second stage, the gas was absorbed in the usual manner (Exp. 16 and curve 16). The reaction was carried out in two or three stages: at first under carbon monoxide, at the second stage under nitrogen, and then under carbon monoxide. The nitrogen atmosphere had no effect on the reaction when the gas absorption had completely occurred at the first stage (Exp. 17). When, however, the gas absorption was only half-completed at the first stage, the nitrogen atmosphere had the effect on the reaction of decreasing the amount of gas absorbed at the third stage (Exp. 18).

According to Heck and Breslow's suggestion[5] that the formation of acylcobalt carbonyl in this type of reaction of olefin is accelerated under nitrogen, it would be expected that the above-mentioned pretreatment under nitrogen would promote the carbonylation reaction of propylene oxide. In reality, however, the amount of gas absorbed and the yields of the ester and the aldehyde were not good, as is demonstrated by Exp. 15; in other words, the nitrogen atmosphere highly promoted some side reaction and then the formation of carbonylated products (ester and aldehyde) was prevented.

In order to compare the reactivity of olefin oxide with that of olefin, the reaction of pentene-1 with cobalt hydrocarbonyl was carried out. The results, shown in Fig. 2(A), indicate that pentene-1 is obviously less reactive than propylene oxide. In general, olefin oxide seems to be more reactive than olefin in this type of reaction. This fact is supported by the authors' observation[12] that propylene oxide undergoes the hydroformylation reaction at a lower temperature (80~90°C) than the usual Oxo reaction temperature.

Ethylene Oxide.—Ethylene oxide undergoes this type of reaction in the same manner as propylene oxide. The results are shown in Table II. As the major product, ethyl β-hydroxypropionate was given. In a recent study, Heck[13] isolated β-hydroxypropionylcobalt tricarbonyl triphenylphosphine from this reaction.

Cyclohexene Oxide.—Cyclohexene oxide, an internal olefin oxide, reacts readily with cobalt hydrocarbonyl. The results are summarized in Table III. The major product is believed to be ethyl 2-hydroxycyclohexanecarboxylate.* As may be seen from the appearance of the gas absorption, cyclohexene

* The infrared spectrum of the reaction products in toluene had bands at 3600 cm^{-1} and 1735 cm^{-1}. As further evidence, the retention time of the major product in gas chromatography increased as the molecular weight of the alcohol used in the cleavage of the crude products increased, and the retention time of the product (ethyl ester) was longer than that of ethyl cyclohexanecarboxylate, so this compound seemed to have some additional functional group.

* Ethyl γ-chloro-β-hydroxypropionate.

oxide is obviously more reactive than propylene oxide; for instance, in the case of a 2.7 mol. ratio, cyclohexene oxide absorbs 0.8 mol. of carbon monoxide in 150 min., while propylene oxide absorbs only 0.4 mol. of the gas in 240 min.

The rate of the gas absorption at the early stage of the reaction for cyclohexene oxide is about five times that for propylene oxide. This relation between the reactivity and the chemical structure of two kinds of olefin oxide is the reverse of that for olefins; i.e., in general, the order of the reactivity for olefins is terminal>internal>cyclic.[3]

Styrene Oxide.—In the reaction of styrene oxide, a conjugated olefin oxide, with cobalt hydrocarbonyl, exceptional behavior was observed. The mole ratio of styrene oxide had a significant effect on the nature of the reaction. As Table IV shows, when the mole ratio was relatively small (1 and 2) the major products were α- and β-phenylethyl alcohol and the amount of gas absorbed was small. This indicates that the reduction of styrene oxide with cobalt hydrocarbonyl occurred mainly at these mole ratios. As the mole ratio increased (4 and 6), the amount of gas absorbed increased, but it did not exceed 0.6 mol. In these cases, the identification of the products was impossible since a black tarry material was formed in the course of the analysis, but it seemed, mainly because of the relatively large absorption of the gas, that the carbonylation reaction took place. The tarry material may reasonably be attributed to the polymerization of the excess styrene oxide.

Epichlorohydrin.—Epichlorohydrin seems to react with cobalt hydrocarbonyl only with difficulty under the conditions, at 0°C and in a 5 mol. ratio, under which propylene oxide reacts readily; there was, at any rate, no absorption of the gas, as Table V shows. When, however, the mole ratio of epichlorohydrin was increased to 30 and 45, about 0.6 mol. of the gas was absorbed in 5 hr. Therefore, epichlorohydrin is much less reactive than propylene oxide, but it is believed to

give ethyl γ-chloro-β-hydroxy-*n*-butyrate,* the structure of which corresponds with that of the products propylene oxide gives.

As may be seen from the appearance of the gas absorption, epichlorohydrin seems to react with cobalt hydrocarbonyl about many times more slowly than propylene oxide. In contrast with this fact, the relative reactivities of these olefin oxides with ammonia and perchloric acid are represented as follows:[16] with ammonia epichlorohydrin 4>propylene oxide 1; with perchloric acid, epichlorohydrin 1< propylene oxide 70 (with cobalt hydrocarbonyl epichlorohydrin 1<propylen oxide 20~40).

Thus, the order of the reactivity of these olefin oxides with cobalt hydrocarbonyl corresponds to that with perchloric acid. This fact seems to support Heck's suggestion,[13] which has been drawn from other evidence, that cobalt hydrocarbonyl reacts as an acid.

Summary

The reactions of olefin oxides with cobalt hydrocarbonyl have been studied.

The effect of the reaction conditions on the nature of the reaction, especially that of propylene oxide, has been examined in detail. Propylene oxide gave only the products with β-hydroxy-*n*-butyryl structure under these reaction conditions: temperature, 25~−45°C; atmosphere; nitrogen or carbon monoxide; and mole ratio of propylene oxide, 1.4~6.2. The inhibitory effect of a nitrogen atmosphere on the formation of carbonylated products (ester and aldehyde) has been observed; under nitrogen, some side reaction was highly promoted, and the formation of carbonylated products was thereby prevented.

The reactions of ethylene oxide, cyclohexene oxide, styrene oxide and epichlorohydrin have also been studied. In the reactions of styrene oxide, the mole ratio of styrene oxide had a significant effect on the nature of the reaction; at a relatively small mole ratio, the reduction gave, mainly two isomeric alcohols, but as the mole ratio increased, the carboxylation reaction seemed to increase. Epichlorohydrin gave a product with a γ-chloro-β-hydroxy-*n*-butyryl structure, which corresponds to that which propylene oxide gave.

The order of the reactivity of these olefin oxides is as follows: cyclohexene oxide (about 5) and styrene oxide>propylene oxide (1)>ethylene oxide≫epichlorohydrin (1/20~40); (the numbers indicate the relative reactivities).

This fact seems to indicate that, in general, internal (and conjugated) olefin oxides are more reactive than terminal olefin oxides. By analogy with the relative reactivity of propylene oxide and epichlorohydrin with cobalt hydrocarbonyl, perchloric acid and ammonia, it may reasonably be considered that cobalt hydrocarbonyl reacts as an acid.

Pentene-1 appeared to be less reactive than propylene oxide.

* The infrared spectrum of the product solution in toluene had a band at 1740 cm^{-1}. Further evidence: about 0.5 ml. of the sample solution and about 0.2 g. of potassium hydroxide were placed in a test tube. After the test tube had been shaken, the upper layer was gas-chromatographed. The largest peak of the original gas chromatogram, which is supposed to belong to the ester, vanished, and a new peak, with a comparable area, appeared before the position of the original peak. This fact indicates that the ester has a chlorohydrin structure (γ-chloro-β-hydroxy structure).

*Studies of the Organic Reactions of Metal Carbonyl. III. The Hydroformylation of Olefin Oxides**

By Chikao YOKOKAWA, Yoshihisa WATANABE and Yoshinobu TAKEGAMI

(Received September 19, 1963)

Recent papers[1,2] have reported that an olefin oxide reacts with cobalt hydrocarbonyl and carbon monoxide to give acylcobalt carbonyl-type compounds, which are considered to be intermediates of the hydroformylation reactions.[3,4]

The reaction of ethylene oxide with water gas was carried out under the conditions of the ordinary Oxo-type reaction by Hamada, Baba and Hagihara,[5] who concluded that the hydroformylation of ethylene oxide did not take place. Lenel[6] concluded that olefin oxides, except ethylene oxide, undergoes the hydroformylation reaction, but he did not mention about the composition of the products. On the other hand, Seon and Leleu[7] obtained 2-hydroxyethyl hydracrylate from ethylene oxide by reaction with water and carbon monoxide in the presence of dicobalt octacarbonyl. Eisenmann, Yamartino and Howard[8] reported that the reaction product of propylene oxide with carbon monoxide and methanol in the presence of dicobalt octacarbonyl was methyl β-hydroxybutyrate.

Thus, the possibility of the hydroformylation of olefin oxide has been suggested, but no definite characteristics of this reaction are known. In this paper it will clearly be demonstrated that propylene oxide undergoes the hydroformylation reaction at a relatively low temperature (80°C) to give β-hydroxy-*n*-butyraldehyde as the major product.

Experimental

Reaction Procedures.—An autoclave of a 300 ml. capacity, made of 18—8 nickel-chrom-iron steel and equipped with a magnetic stirrer, was used. Ninety milliliters of toluene, 10 ml. of dicobalt octacarbonyl solution in toluene (containing 0.22 to 0.24 g. of cobalt by calculation from the content of the carbonyl), and 10 g. of olefin oxide were put into the autoclave. After replacing the air in the autoclave with hydrogen, hydrogen and carbon monoxide were introduced to 150 to 160 atm. using a compressor. The autoclave was kept at the desired temperature by electrical heating, but the heating was turned off when the gauge pressure ceased to decline.

Preparation and Standardization of the Dicobalt Octacarbonyl Solution in Toluene.—Ten grams of cobalt carbonate and 100 ml. of toluene were placed in the autoclave, and water gas was introduced to 160 atm. The autoclave was heated at about 150°C for 4 hr. The dicobalt octacarbonyl solution in toluene was then transferred into a flask by decantation and stored therein under a carbon monoxide atmosphere. An aliquot portion (10 ml.) of this solution was put into a gasometric apparatus by the use of a syringe, and the excess amount of iodine in toluene was added. The cobalt content of this solution was calculated from the amount of carbon monoxide evolved, with the assumption that all of the cobalt exsisted as dicobalt octacarbonyl or cobalt hydrocarbonyl.

Analysis of the Products.—In almost every case, an oily or resinous material which was insoluble in toluene was formed. After the separation of this material by the decantation of the toluene phase, the products in the toluene solution were identified and determined by gas chromatography. The products with boiling points lower than that of toluene were determined from the crude toluene solution, and other products, from the concentrated solution (the crude solution was concentrated under the reduced pressure of about 30 mmHg). The identification of the products was made by mixed gas chromatography with authentic samples. A column three meters long and 3 mm. in diameter, and filled with dilauryl phthalate on cerite, was used. The column temperature was 50 to 80°C for the analysis of the low-boiling-point products and 130°C for the high-boiling-point products. The rate of flow of the carrier gas (hydrogen) was 60 ml. per min.

The infrared adsorption spectrum was obtained in the toluene solution by the use of a Shimadzu Model IR—27 spectrophotometer.

Materials Used.—Ethylene oxide, propylene oxide and toluene were commercial products which were proved to be sufficiently pure by gas chromatography. As authentic samples, the following commercial chemicals were used: acetaldehyde, acrolein,

Results

The Interpretation of a Typical Gas Chromatogram.—In order to facilitate further considerations, the gas chromatogram for the products obtained from propylene oxide by the reaction at 115 to 120°C (Exp. 1) will be discussed in detail. This chromatogram illustrates 20 peaks, 10 of which were identified by mixed chromatography with authentic samples. These compounds were propylene oxide (9.9), acetone (12.4), isobutyraldehyde (19.1), metacrolein (21.5), *n*-butyraldehyde (25.3), isobutyl alcohol (45.4), crotonaldehyde (53.0), *n*-butyl alcohol (72.6), toluene (100) and β-hydroxy-*n*-butyraldehyde* (194). (The numbers in ( ) denotes the relative retention time.) The peak with the relative retention time of 163 was believed to correspond with that for β-hydroxyisobutyraldehyde, though an authentic sample was not available, because metacrolein** and isobutyraldehyde, which are considered to have been derived from β-hydroxy-isobutyraldehyde, existed in the same sample and because the retention time of this product is a little smaller than that of β-hydroxy-*n*-butyraldehyde. There were 9 peaks of by-products, whose retention times were larger than that of β-hydroxy-*n*-butyraldehyde, in this gas chromatogram. They were not identified, but all of them diminished to negligible amounts when the reactions were carried out at temperatures below 100°C.

The Hydroformylation of Propylene Oxide.—The hydroformylation reaction of propylene oxide seems to take place at temperatures above 80°C; at any rate, the gauge pressure begins to decrease at this temperature.

The composition of the reaction products is listed in Table I, in which the yield of products is given in the number of mol. per 100 mol. of propylene oxide used. These values were obtained by calculations on the basis of the area of each peak in a gas chromatogram after the usual calibration using authentic samples. In the calculation of β-hydroxy-*n*-butyraldehyde, the amount of crotonaldehyde which is considered to be formed from the former in the course of the gas chromatographic analysis was accounted as before.

It is evident that the major product of the reaction at the temperature of the ordinary hydroformylation reaction of olefins, i.e., 110 to 120°C, is acetone, and so it has been concluded that the isomerization reaction predominates in this reaction condition. The hydroformylation reaction also takes place, giving β-hydroxybutyraldehydes, but these products are converted into isobutyraldehyde, metacrolein, *n*-butyraldehyde, isobutyl alcohol, crotonaldehyde and *n*-butyl alcohol by succeeding dehydration and hydrogenation reactions.

* β-Hydroxy-*n*-butyraldehyde is the major product of this reaction. This compound could be isolated by fractional distillation under reduced pressure in a sufficiently pure state. The infrared spectrum of this product showed strong absorptions at 1720 cm^{-1} and 3350 cm^{-1}. 2, 4-Dinitrophenyl hydrazone was formed, but this hydrazone seemed impure because it is known that β-hydroxy-*n*-butyraldehyde is easily dehydrated to form crotonaldehyde under the conditions of hydrazone formation. It was concluded that this product was β-hydroxy-*n*-butyraldehyde on the basis of the facts mentioned above and because this product showed a peak which corresponded to that of crotonaldehyde when gas chromatographed at 130°C.

** Metacrolein was identified in the crude solution. In the concentrated solution it was not observed but after the solution had been refluxed for 1hr. at the boiling point of toluene, it appeared clearly.

Table II. Hydroformylation of ethylene oxide

No.	Reaction temp. °C	H_2/CO	Reaction time hr.	Yield of products (mol. per 100 mol. of ethylene oxide used)		amount of gas absorbed (mol./mol. of ethylene oxide)
				Acetaldehyde	Acrolein	
8	90~100	1.0	0.8	16	2.8	1.3
9	85~ 86	1.0	1.3	28	1.0	1.2
10	80~ 82	1.5	3.0	26	0.9	0.8
11*	80~ 85	1.7	2.0	30	1.8	0.9
12**	85~ 90	4.0	2.0	8	0.9	—

* Two mol. of pyridine were added per mol. of cobalt.
** Four mol. of pyridine were added per mol. of cobalt.

Moreover, various kinds of high-boiling-point products are formed.

By lowering the reaction temperature for about 10°C (Exp. 2), the yields of the hydroformylation products, i. e., β-hydroxy-*n*-butyraldehyde and β-hydroxy-isobutyraldehyde, increased, and those of the by-products decreased, but still more than 20% of the propylene oxide charged were converted into acetone and various kinds of compounds were formed.

At the reaction temperature below 95°C, β-hydroxy-*n*-butyraldehyde is formed as the major product, as Exps. 3, 4 and 5 show, and so it has been concluded that the hydroformylation of propylene oxide proceeds relatively selectively under these controlled conditions.

The addition of pyridine has evident effects on the character of this reaction. As Exps. 6 and 7 show, the addition of this compound seems to prevent not only the isomerization but also the hydroformylation reaction; the amount of acetone decreases, and relatively large amounts of unreacted propylene oxide and resinous material are recovered.

The isomerization of propylene oxide to acetone in the presence of dicobalt octacarbonyl was studied by Eisenmann[9] in several kinds of solvents. He concluded that this isomerization takes place during a reversible exchange between the solvent molecule and propylene oxides serving as a coördinating molecule to cobalt, and that pyridine retards this isomerization reaction because of its strong coördinating effect. It is believed that the present object is to control the two competitive reactions, i. e., hydroformylation and isomerization, but it seems impossible to attain this purpose by the addition of pyridine.

The Hydroformylation of Ethylene Oxide.— The results of the reaction of ethylene oxide are summarized in Table II. Ethylene oxide produces acetaldehyde and a viscous, oily material as the major products, plus a small amount of acrolein. Thus, ethylene oxide seems to undergo isomerization and polymerization under the conditions which are effective for the hydroformylation of propylene oxide. On the other hand, an appreciable amount of gas is absorbed at temperatures above 80°C, as is indicated by the decrease in the gauge pressure, and acrolein is identified as a minor product. This evidence seems to indicate that the hydroformylation has taken to an appreciable extent. It is reasonably considered that the hydroformylation product of ethylene oxide, β-hydroxypropionaldehyde, would be formed, that this compound would be converted into acrolein by succesive dehydration reaction, and that the latter would polymerize to form the oily or resinous product.

9) J. L. Eisenmann, *J. Org. Chem.*, 27, 2706 (1962).

Summary

The hydroformylation reactions of ethylene oxide and propylene oxide have been carried out; the character of this type of reaction may be summarized as follows:

1) Propylene oxide reacts with water gas, in the presence of dicobalt octacarbonyl serving as a catalyst, to give β-hydroxy-*n*-butyraldehyde as the major product, but it is important to keep the reaction temperature between 80 to 100°C in order to hold the high selectivity of this reaction.

2) At temperatures below 80°C, the reaction does not take place; on the other hand, at temperatures above 100°C, the isomerization of propylene oxide to acetone predominates, and the other side-reactions, such as the dehydration of the hydroformylation products, hydrogenation, condensation and polymerization, take place simultaneously.

3) Ethylene oxide seems to undergo hydroformylation under the same conditions as those used for the propylene oxide, but only a small amount of acrolein is obtained as the hydroformylation product. The expected product, i. e., β-hydroxypropionaldehyde, is formed, but this compound is easily converted into acrolein and the latter seems to polymerize to give a large amount of a resinous or oily material.

The Monoterpene Constituents of the Essential Oil of Hinoki (Chamaecyparis Obtusa (Sieb. et Zucc.) Endl.)

By Shûichi HAYASHI, Katsumi YANO and Tamon MATSUURA

(Received October 7, 1963)

There have been some investigations of the monoterpene constituents of the essential oil of Hinoki (*Chamaecyparis Obtusa* (Sieb. et Zucc.) Endl.). A root oil of Hinoki has been investigated by Hirao,[1] who detected *d*-α-pinene, camphene, *d*-limonene, dipentene, camphor, borneol and α-terpinol. A leaf oil has been investigated by Uchida,[2] Kumagai[3] and Moroe;[4] they have reported the presence of α-pinene, *d*-limonene, borneol, bornyl acetate, bornyl pelargonate and α-terpinyl acetate. In the present work an attempt will be made to obtain a satisfactory confirmation for the monoterpene constituents of the essential oil by means of gas chromatography and ultraviolet and infrared absorption spectroscopies.

Results and Discussion

The essential oil obtained from leaves and twigs of Hinoki which grew in Kôchi Prefecture in Japan, after acids and phenols had been taken off, was repeatedly fractionated through a packing distillation column. The physical properties of the fractions are shown in Fig. 1. From these fractions, *d*-α-pinene, β-pinene, myrcene, *d*-limonene, β-phellandrene, *p*-cymene, 1, 8-cineole, camphor, *l*-α-terpineol, α-terpinyl acetate and bornyl acetate were identified in ways described below, while camphene, linalool and borneol were confirmed by gas chromatography. Among these constituents, β-pinene, myrcene, β-phellandrene, 1, 8-cineole, and *p*-cymene were found out for the first time in the essential oil of Hinoki.

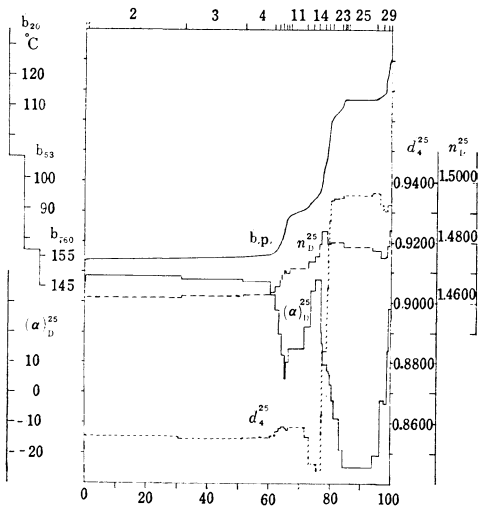

Fig. 1. Fractional distillation of Hinoki oil.

d-α-Pinene.—Each infrared spectrum of fractions 2 to 4 coincides with that of α-pinene,[5] and each gas chromatogram of these fractions shows the main peak corresponding to α-pinene. From fraction 2, *d*-α-pinene hydrochloride[6], (m. p. 131.5~132.0°C) was prepared.

Camphene.—A gas chromatogram of fraction 3 exhibits a small peak corresponding to camphene, besides a main α-pinene peak.

β-Pinene.—A gas chromatogram of fraction 11 shows a strong peak associated with β-pinene, together with other peaks associated with α-pinene, myrcene, limonene, β-phellandrene and

p-cymene, as may be seen in Fig. 2-A. From this fraction a thioglycollic acid adduct of β-pinene was prepared; it was identified by preparing its *S*-benzylthiuronium salt.[7]

Myrcene.—The ultraviolet absorption spectrum of fraction 11 has two absorption maxima: λ_{max}^{EtOH} 224 mμ (ε 4380) corresponding to myrcene,[5] and 230 mμ corresponding to β-phellandrene.[8] When fraction 11 was treated with maleic anhydride in ether[9] at room temperature, both the absorption maximum and the peak of gas chromatogram associated with myrcene disappeared (cf. Fig. 2-B).

Limonene and Dipentene.—The gas chromatogram of fraction 14 shows three peaks associated with limonene, β-phellandrene and *p*-cymene, together with some weak peaks (cf. Fig. 3). On the bromination of this fraction, dipentene tetrabromide[10] (m. p. 123~124°C) and *d*-limonene tetrabromide[10] (m. p. 101~102°C) were obtained.

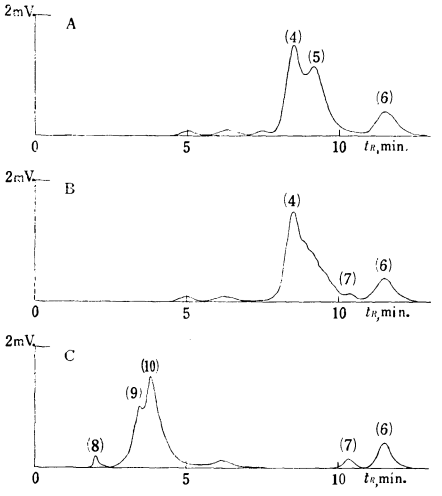

Fig. 3. Gas chromatogram of fraction 14.

C After hydrogenation.
(4) limonene or dipentene
(5) β-phellandrene
(6) *p*-cymene
(7) 1,8-cineole
(8) hexahydromyrcene
(9) *cis*-*p*-menthane
(10) *trans*-*p*-menthane

β-Phellandrene.—The ultraviolet spectrum of fraction 14 shows an absorption band (λ_{max}^{EtOH} 230 mμ, ε 3590) corresponding to β-phellandrene.[8] When maleic anhydride reacted upon fraction 14, the absorption band and the peak of gas chromatogram associated with β-phellandrene disappeared (cf. Fig. 3-B). From fraction 14, β-phellandrene-β-nitrosite[11] (m. p. 96~97°C) was obtained.

***p*-Cymene.**—The ultraviolet spectrum of fraction 14 has another weak absorption band (λ_{max}^{EtOH} 273.5 mμ) characteristic of *p*-cymene,[5] in addition to the band of β-phellandrene. When fraction 14 was hydrogenated with a nickel catalyst, β-phellandrene and limonene vanished, but the peak associated with *p*-cymene in a gas chromatogram of the hydrogenation product remained, as is shown in Fig. 3-C.

1, 8-Cineole.—The peak of 1, 8-cineole was not observed in the gas chromatogram of any fraction. The peak, however, could be observed after the removal of β-phellandrene from fraction 14 by maleic anhydride-treatment or by hydrogenation, as Figs. 3-B and 3-C show.

Camphor, Linalool, Borneol and *l*-α-Terpineol.—The chromatogram of fraction 23 exhibits four peaks associated with linalool, camphor, borneol and α-terpineol (cf. Fig. 4).

The peak associated with camphor disappeared almost completely upon treatment with a 2, 4-dinitrophenyl hydrazine solution, thereby comfirming the existence of camphor.

l-α-Terpineol was identified by preparing *l*-α-terpinyl phenylurethane (m. p. 109~110°C[12]) from fraction 23.

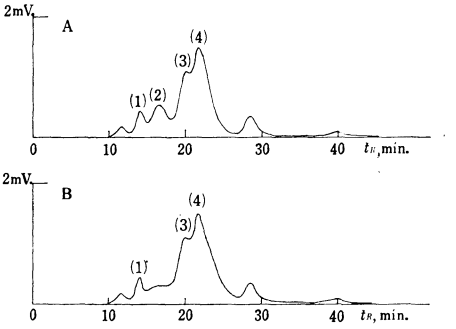

Fig. 4. Gas chromatogram of fraction 23.

acetate and α-terpinyl acetate (cf. Fig. 5). This fraction was then saponified. In a gas chromatogram of the saponification product, the two peaks associated with bornyl acetate and with α-terpinyl acetate both disappeared completely, while a new peak of borneol was found; furthermore, a peak of α-terpineol grew up, as may be seen in Fig. 5-B. On the other hand, from the aqueous layer of the saponification product, acetic acid was detected by paper chromatography as its hydroxamic acid.[13]

The Constitution of the Monoterpene Fractions.—The contents of the above components were calculated in the total monoterpene fractions from the results of fractionation and gas chromatography, as Table I shows. The essential oil of Hinoki was composed of 47.5% monoter penes, 43.2% sesquiterpenes, 7.1% residue and 2.2% acids and phenols.

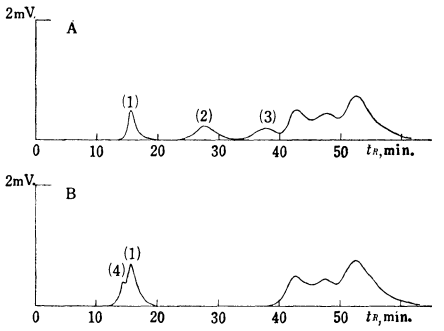

Fig. 5. Gas chromatogram of fraction 29.

13) K. Inoue and M. Noda, *J. Agr. Chem. Soc. Japan (Nôgei Kagaku Kwaishi)*, **23**, 294 (1950); **24**, 291 (1951).

Experimental

The sample was the essential oil* (n_D^{25} 1.4832, d_4^{25} 0.8877, $[\alpha]_D^{25}$ +22.76, ester value 0.5) obtained from leaves and twigs of Hinoki by steam distillation. The oil (13.9 kg.) was shaken with a 3% aqueous solution of sodium carbonate and then a 3% aqueous solution of sodium hydroxide to take off acids and phenols. The neutral oil thus obtained (13.6 kg.) was washed with water, dried over anhydrous sodium sulfate, and repeatedly fractionated through a packing distillation column under reduced pressure.

***d*-α-Pinene.**—Dry hydrogen chloride gas was reacted upon fraction 3 under cooling at −10 to −15°C. The crystals thus obtained, after being recrystallized from methyl alcohol, showed a melting point of 131.5~132.0°C, which agrees with that of *d*-α-pinene hydrochloride.[6]

β-Pinene.—From one milliliter of fraction 11, a thioglycollic acid adduct of β-pinene was prepared and converted into *S*-benzyl thiuronium salt according to the procedure of Sutherland and Wells.[7] The white crystalline solid, after being recrystallized from an acetone-methanol (2 : 1) mixture, showed a melting point of 155~157°C, which did not depress when the solid was admixed with an authentic sample (m. p. 156~157°C).

***d*-Limonene and Dipentene.**—Bromine was added to a portion of fraction 14 under ice-cooling, using ether as a solvent. The crystalline mass obtained was fractionally recrystallized from ethyl acetate to give dipentene tetrabromide (m. p. 123~124°C) and limonene tetrabromide (m. p. 101~102°C). Each tetrabromide was identified by admixing it with an authentic sample.

β-Phellandrene.—Four grams of fraction 14 were treated with acetic acid and a saturated aqueous solution of sodium nitrite. The white crystals obtained, after being recrystallized from ethanol, showed a melting point of 96~97°C, which did not depress on admixture with β-phellandrene-β-nitrosite (m. p. 96~97°C).

1, 8-Cineole.—Eight hundred milligrams of fraction 14 were hydrogenated in an autoclave using nickel catalyst and ethanol (initial pressue of hydrogen, 112 kg./cm²; reaction temperature, 155°C; reaction period, 2 hr.). The gas chromatogram of the hydrogenation product was then examined (Fig. 4).

***l*-α-Terpineol.**—Phenylisocyanate was added to 0.5 g. of fraction 25. The phenylurethane obtained showed a melting point of 109~110°C, which agrees with that of the phenylurethane of *l*-α-terpineol.

Gas Chromatography.—A Shimadzu GC-2 apparatus equipped with a thermal conductivity detector and a copper spiral packing column (inside diameter, 4 mm.; length, 3 m.) was used. For hydrocarbon analysis, Shimalite (24~48 mesh) coated with polyethylene glycol (20%) was used at 80°C as a stationary phase; for an oxygen-containing compound analysis, quartz powder (150~200 mesh) coated with Thermol-1 (5%) was used at 140°C.

* Supplied by the Soda Kôryo Co., Ltd., Tokyo, Japan.

Helium was flowed as a carrier gas at the rate of 60 ml./min.

Summary

d-α-Pinene, β-pinene, myrcene, *d*-limonene, dipentene, β-phellandrene, *p*-cymene, 1, 8-cineole, camphor, *l*-α-terpineol, α-terpinyl acetate and bornyl acetate have been identified, and camphene, linalool and borneol have been gas-chromatographically confirmed. Of these compounds, β-pinene, myrcene, β-phellandrene, 1, 8-cineole and *p*-cymene have been found for the first time in this work. The main constituents of the monoterpene fraction are *d*-α-pinene and *l*-α-terpineol; the former amounts to 66.3%, and the latter to 10.1%, the remaining constituents being within a few %.

Studies of Tritium-labeled Compounds. VII.[1] *The Platinum-catalyzed Exposure Reaction*

By Teruhiko MESHI and Yoshishige SATO

(Received July 4, 1963)

In the gas exposure technique developed by Wilzbach[2] only a small part of the tritium gas used is actually incorporated into organic compounds, and relatively large quantities of tritium gas and prolonged exposure are required to supply sufficient energy to the system. In a previous work,[1] it was found that the platinum catalyst was the most effective in the promotion of labeling, and it was suggested, on the basis of the large increase in the ratio of nonlabile tritium to labile tritium in salicylic acid in the platinum-catalyzed labeling, that this catalytic action probably is due to the catalytic exchange of hydrogen atoms rather than to the increased absorption of the decay energy in the system. It is evident that tritium gas is adsorbed on the surface of the platinum catalyst, but the question remains of whether or not a similar adsorption of solid organic compounds occurs on the catalyst surface. The fact[1] that the aromatic compounds are usually more efficiently labeled than the aliphatic compounds may be accounted for by assuming that the former is more readily chemisorbed on the catalyst surface through such an interaction as the π-complex formation. In order to elucidate the nature of the chemisorption and to obtain some information on possible reaction paths, it seems useful to investigate the effects of the substituents upon the hydrogen-tritium exchange of the aromatic ring and the tritium distributions within aromatic compounds labeled by different methods. Salicylic acid and benzoic acid were chosen as suitable materials for the determination of tritium distribution. The relative amounts of ring tritiation at the *o*-, *m*- and *p*-positions of salicylic acid were determined by the bromination of the recovered salicylic acid, while those of benzoic acid were determined by first converting it into aniline, which was then brominated to give bromination products, whose tritium activities were determined.

Benzoylvaline was used to determine the relative exchange rates of labile, semilabile and nonlabile hydrogen atoms.

Experimental

Samples. — All the chemicals used were of analytical reagent grade and were not subjected to any further purification. Platinum black was prepared by the hydrogenation of Adams platinum oxide. The tritium gas was purchased from the Radiochemical Centre, Amersham.

Exposures. — Exposures were carried out by the same procedure as was described in the previous paper.[1] Since it was found that the highest specific activity was obtainable when the exposure time was less than one hour, all the reactions were performed for one hour at room temperature.

Purifications. — Radiochemical purifications of benzoic acid and salicylic acid have been described in the previous paper. *p*-Aminobenzoic acid and *p*-aminosalicylic acid were purified according to

1) Part VI: T. Meshi and T. Takahashi. This Bulletin, 35, 1510 (1962).
2) K. E. Wilzbach, *J. Am. Chem. Soc.*, **79**, 1013 (1957).

the solvent extraction procedure of Rydberg and Hanngren.[3] Phthalic acid, naphthalene and benzoylvaline were diluted with their respective untritiated compounds and recrystallized from a mixture of ethanol and water until constant specific activities were obtained. Benzene was converted into *m*-dinitrobenzene, which was then purified by repeated recrystallization from ethanol to a constant specific activity. Dimethylaniline was converted into its picrate.

Degradations. — The successive reaction steps used for the determination of tritium distributions of salicylic acid and benzoic acid are as follows:

Salicylic acid $\xrightarrow{Br_2}$ 5-Bromosalicylic acid $\xrightarrow{Br_2}$ 3,5-Dibromosalicylic acid

Benzoic acid $\xrightarrow{SOCl_2}$ Benzoyl chloride $\xrightarrow{NH_4OH}$ Benzamide $\xrightarrow{NaOBr}$

Aniline $\xrightarrow{(CH_3CO)_2O}$ Acetanilide $\xrightarrow{Br_2}$ *p*-Bromoacetanilide

Aniline $\xrightarrow{Br_2}$ Tribromoaniline

The scheme used for benzoic acid was used earlier by Bonner[4] in the determination of the distribution of deuterium.

Benzoylvaline, the labile tritium of which had been removed by treating it with a mixture of water and ethanol, was treated with an alkaline solution to remove the semilabile tritium incorporated at the amide group; then it was hydrolyzed into benzoic acid and L-valine by refluxing it with 6 N-hydrochloric acid.

Tritium Assay. — The tritium activity of each compound was assayed by liquid scintillation counting. An aliquot of a suitable concentration of a compound in ethanol was added to toluene containing 2,5-diphenyloxazole (4 g./l.) and 1,4-bis-2-(5-phenyloxazolyl)-benzene (100 mg./l.), and the solution was counted with a Pachard Tri-Carb liquid scintillation spectrometer cooled to $-10°C$. The efficiency of counting was usually about 13% if the sample was nonquenching. An internal standard consisting of 0.1 ml. of benzene-^3H (2.3×10^5 d. p. m.) was used to correct for the quenching loss and to estimate the efficiency of counting.

Results and Discussion

The data in Table I show the effect of the substituents on the tritium labeling of the aromatic compounds. It may be seen that the amount of nonlabile tritium attached to carbon atoms varies considerably with the nature of the substituents and that the amount of tritium incorporated into the aromatic nucleus is usually small in the substituted compounds, except for salicylic acid. When one compares the amount of tritium incorporation in phthalic acid and phthalic anhydride, one finds that not only the substituents but also the presence of labile hydrogen atoms attached to oxygen or nitrogen substantially lower the amount of tritium incorporation into the aromatic nucleus. If one assumes that the catalytic activity of the platinum catalyst is a consequence of its unfilled d-orbitals and that the chemisorption of the aromatic compounds on a platinum catalyst occurs through the transfer of the π-electrons of the aromatic compounds into the empty d-orbitals of the catalyst, one would expect that the substituents which have higher electron densities than the aromatic rings would monopolize the active centers of the catalyst and that, consequently, the chemisorption of the aromatic ring on the platinum catalyst would be decreased, thus lowering the amount of tritium incorporation into the rings. However, it can not be explained why only the hydroxyl group promotes the isotope exchange of the aromatic ring, as is shown in an experiment carried out with salicylic acid. Garnett et al.[5] studied the catalytic exchange of hydrogen atom using deuterium oxide and concluded that the stronger the chemisorption, the greater the tendency for a compound to poison the catalyst and, consequently, for the exchange to be less efficient.

The competitive incorporation of tritium was performed with a mixture of benzene with another aromatic compounds, using the amount of the tritium incorporation in benzene as the standard. When one compares the specific activities in Table I and Table II, one finds that the tritium incorporation of benzene decreases greatly in the presence of dinitrobenzene, phthalic anhydride, salicylic acid and dimethylaniline, and that of these compounds, except for dimethylaniline, also does in the presence of benzene. These results are in direct contrast to those obtained with the mixture of benzene and cyclohexane, which has only a very small retarding effect on the tritium incorporation of benzene. (Incidentally, the platinum-catalyzed tritium incorporation of cyclohexane is relatively low.)

It is evident from these results that the bond strength of the chemisorption and the π-complex formation are important factors in the determination of the extent of isotope exchange. It may be considered that the amino group and the nitro group are so strongly chemisorbed on the catalyst surface that the specificity of the catalyst is lost, while the hydroxyl group is relatively weakly chemisorbed so as to cause a more facile chemisorption of the aromatic

c) This value was obtained when cyclohexane alone was exposed to the tritium gas in the presence of the catalyst.

nucleus by increasing the electronic density of the aromatic ring. The unexpectedly large decrease in the incorporation of tritium into salicylic acid in the presence of benzene can be explained on the basis of the increased probability of the hydroxyl group of the salicylic acid dissolved in benzene being chemisorbed, which would result in the decreased chemisorption of the nucleus of salicylic acid and the predominant exchange of the labile hydrogen attached to oxygen by the tritium present in the adsorption layer, for the amount of the labile tritium incorporated into salicylic acid is as large as 70.8 μc./μM.

The tritium distribution in benzoic acid in salicylic acid treated with tritium gas was determined by measuring the specific activities of the products derived from their acids; they are shown in Table III and Table IV. It may be seen that, in the gas-exposure experiments, i. e., in the absence of platinum black, the ortho hydrogens exchange at a faster rate than do those of the meta and para positions since salicylic acid has two hydrogens at the meta position but only one at the ortho position.

This is in agreement with the result obtained with benzoic acid,[6] toluene,[7] chlorobenzene[8] and nitrobenzene.[8] It may be of interest that, in the gas-exposure technique, the ortho position is always favored. On the other hand, the tritium distribution in benzoic acid and in salicylic acid labeled by the catalyzed exposure method indicates that the predominant exchange occurs at the meta positions of benzoic acid and at the para position to the

* One hundred milligrams of benzoylvaline was exposed to 100 mc. of the tritium gas for one hour in the presence or in the absence of 100 mg. of platinum black.

hydroxyl group of salicylic acid. From the observed tendency in the tritium distributions, it may well be assumed that, in the catalyzed exposure, the hydrogen-tritium exchange in the aromatic ring may follow the substitution rule for electrophilic aromatic exchange. In the gas exposure method, the reactive tritium species are the energetic tritium ions produced by the radioactive decay of the tritium and by the beta radiation,[9] while in the catalyzed exposure it seems to be a tritium ion or atom formed by the dissociation of the tritium molecule on the catalyst surface. Therefore, it would be natural to expect that the tritium arrangements in benzoic acid and salicylic acid would be different between the gas exposure and the catalyzed exposure, and that, in the catalyzed exposure, just as in the chemical substitution reaction, the reactive tritium ion would be directed in this order: meta>para>ortho in benzoic acid and para>ortho>meta in salicylic acid.

The distribution of tritium in benzoylvaline labeled by both the methods is shown in Table V. It is noticeable that the amount of the semilabile tritium incorporated into the amide group varies remarkably with the different methods. In the catalyzed exposure experiment, the amount of the semilabile tritium becomes much larger than that of the nonlabile tritium, although in the gas exposure experiment the amount of the semilable tritium is less than that of the nonlabile tritium. This also seems to suggest that the chemisorption of the benzoylvaline molecule on the platinum catalyst predominates at the amide group.

As Table V shows, the amount of tritium exchange is the largest for labile hydrogen, intermediate for semilabile hydrogen, and the smallest for nonlabile hydrogen. In other words, the more readily a hydrogen dissociates, the more rapidly it undergoes the exchange with tritium.

9) T. H. Pratt and R. Wolfgang, *J. Am. Chem. Soc.*, 83, 10 (1961).

Summary

In order to elucidate the nature of the chemisorption in the platinum-catalyzed exposure reaction with tritium, the effects of the substituents upon the hydrogen-tritium exchange of the aromatic ring and upon the tritium distribution in benzoic acid, salicylic acid and benzoylvaline have been investigated. All the substituents except the hydroxyl group decrease the hydrogen-tritium exchange of the aromatic ring, and the compounds carrying those substituents poison the catalyst for the tritium incorporation of benzene. This retardation effect of the substituents upon the

hydrogen-tritium exchange of the aromatic nucleus may perhaps be attributed to the preferential adsorption of the substituents on the catalyst surface. The tritium distribution in benzoic acid and salicylic acid suggests that the hydrogen-tritium exchange in the aromatic ring may follow the substitution rule for electrophilic aromatic exchange. The relative hydrogen-tritium exchange rates of benzoylvaline show that the more readily a hydrogen dissociates, the more rapidly it undergoes the exchange.

Reactions of Methylene Radicals with Benzene and Toluene in the Gas Phase[1)]

By Terumi TERAO* and Shoji SHIDA

(Received May 6, 1963)

Many investigations have been made of the reactions of methylene radicals with a variety of organic substances, concerning the electronic state of methylene radicals during the course of the reactions,[2,3)] the reactivity of the radical,[4,5)] and the unimolecular decomposition and isomerization of energetic addition intermediates of the radical and the parent reactants.[6,7)]

A benzene solution of diazomathane was photo-irradiated to give C_7H_8, and its chemistry was formulated equally well as cycloheptatriene or norcaradiene.[8)] Meerwein et al.[9)] reported that cycloheptatriene and norcaradiene were produced under similar conditions. However, they never obtained toluene.

This paper concerns the reactions of methylene radicals resulting from a photolysis of ketene with benzene and with toluene in the gas phase; it is a part of the study of the reactions of methylene radicals.

Experimental

Ketene was prepared by the pyrolysis of acetic anhydride[10)] at 500°C in vacuo; it was distilled from a trap at −120°C to a trap at −196°C three times and then stored in a sample tube kept at −196°C. Its gas chromatograms (columns, benzyl-ether and squalane) showed no impurity.

Benzene and toluene (G. R. grade reagents supplied by the Tokyo Kasei Kogyo Co.) were repeatedly degassed to 10^{-4} mmHg at −196°C and stored in sample tubes kept at −78°C. Nitrogen, Oxygen and nitric oxide (purity, 99.99, 99.98 and 99.5% respectively; supplied by the Takachiho Shoji Co.) were used without further purification. Carbon dioxide was obtained by evaporation from dry ice at −78°C. All of the above chemicals were shown by gas chromatography to have no impurity affecting the results.

The light source was a high-pressure mercury arc lamp (type I-9, supplied by the Wako Denki Co.) operated at 2.5 amp. and 200 V. Cylindrical irradiation cells were made of pyrex glass (transparent down to 2900 Å) or of quartz, their diameters and lengths being 50 mm. and 10∼50 mm. respectively. In some experiments a UV-25 filter (supplied by the Mitsubishi Denki Co.) was used, one which was transparent down to 2300 Å. Although all the spectral region of the light emitted from the lamp was used to irradiate the cell, the most effective radiation in the present study, where rather high pressures were adopted, is considered to be the light around 3130 Å, since the quantum yield of carbon monoxide formation in the photolysis of pure ketene

has been shown by Strachan and Noyes[11] to be 2 and pressure independent at 3130Å or shorter and to be very much smaller and remarkably reduced by raising the pressure at longer wave lengths (around 3660 Å).

Reactants at suitable pressures were introduced successively into the irradiation cell with a breakable seal and then sealed off. After irradiation the cell was attached to the analysis system, and the breakable seal was broken by a steel breaker. The gasses not condensable at −196°C were analyzed by micro-gas analysis. Hydrocarbons which evaporated at −120°C (C_2~C_4) were analyzed by gas chromatography under reduced pressure. The columns used were packed with benzylether and squalane. The ethane and ethylene which emerged from the former column at the same retention time were recovered by a trap kept at −196°C and were subjected to the latter column in order to separate them. Substances which did not evaporate at −120°C were analyzed with a gas chromatograph (type GC-1A, supplied by the Shimadzu Seisakusho Co.). The separation columns used were Silicone DC550 for the reaction products with benzene and 7, 8-benzoquinoline for the products with toluene.

Results

The Reaction of Methylene with Benzene.— The products detected were carbon monoxide, ethylene, cycloheptatriene (designated afterwards as CHT), toluene (T) and small amounts of acetylene, ethane, propylene and propane. All the products, except CHT and T, were produced from the photolysis of ketene.

When the pyrex irradiation cell was used, the percentage yield of CHT (CHT%, CHT×100/(CHT+T)) was found to be 70±7% at any pressure in the cell raised by added nitrogen or carbon dioxide, as Fig. 1 shows.

When the quartz irradiation cell was used, on the other hand, the percentage yield of CHT decreased with an increase in the irradiation period, but it seemed to move to about 70% at no irradiation (see Fig. 2). A small amount of [3.2.0]-bicyclohepta-2, 5-diene (<5% of CHT+T) was also detected. This time dependence of CHT% and the production of the bicycloheptadiene in the quartz cell can be understood in terms of the secondary photochemical isomerization of CHT, which was at first produced by the reaction of methylene with benzene. The photochemical isomerization of CHT in the gas phase has been reported by Srinivasan[12] to yield toluene and a small amount of the bicycloheptadiene.

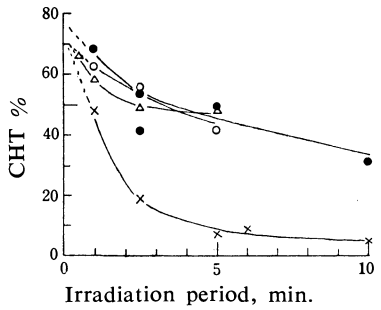

Fig. 2. Percentage yield of CHT plotted against irradiation period.

○: N_2 500 mmHg, filter, ○: filter,
△: CO_2 500 mmHg, filter, ×: none.

The material balance, $\{2(C_2H_4+C_2H_2+C_2H_6)+3(C_3H_6+C_3H_8)+(CHT+T)\}/CO$, was 0.67±0.1, definitely smaller than unity even at the initial stage of the reaction. This poverty in the material balance shows that there existed some products which could not be detected, since the material balance in the photolysis of pure ketene was good at least at the initial stage of the reaction.

The Reaction of Methylene with Toluene.— The results are summarized in Table I. When the pyrex irradiation cell was used, ethylbenzene (EB), *m*- and *p*-xylenes (*m*-Xy, *p*-Xy) and an unidentified compound (X) were the major products other than those resulting from

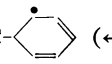
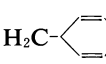
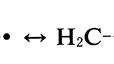
20	60	0	15	1.01	2.14	68

the photolysis of ketene. The amount of *o*-xylene (*o*-Xy) was too small to be measured quantitatively. When the quartz irradiation cell was used, however, there was much more *o*-xylene. About a five-fold increase in the yield of ethane was observed over that from the photolysis of ketene or that in the reaction of methylene with benzene.

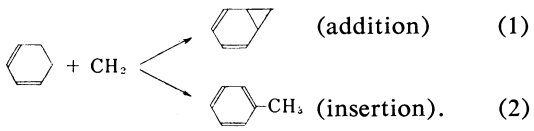






The Effects of Oxygen and Nitric Oxide.— The results are summarized in Tables I and II. The addition of oxygen or nitric oxide did not affect the relative yield among the products which were produced by the reaction of methylene with benzene or toluene.

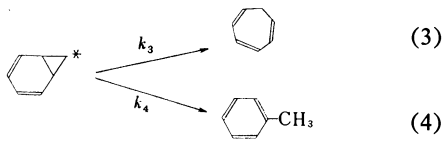
Discussion



The Reaction of Methylene with Benzene.— The most striking difference between our results and those of Doering and Knox[8] and of Meerwein and his co-workers[9] lies in the fact that we have obtained a considerable amount of toluene, while they did not. This difference must have been caused not by the difference in the source of methylene radicals, *i.e.*, of the photolysis of diazomethane employed by them and that of ketene used by us, but by the difference in the phase of the system, the liquid phase in their experiments and the gas phase in ours; there should be no essential difference in the mode of the reactions of methylene radicals whether they are produced by the photolysis of diazomethane or by that of ketene.[6,7,13]

It is almost certain that the methylene produced by the photolysis of diazomethane is at first in a singlet state and that, in the presence of a large amount of inert gas, the singlet-state methylene is collisionally deactivated to a triplet state.[6,14] Although there is no such positive evidence for the methylene produced by the photolysis of ketene, it would also be in a singlet state if the spin conservation rule is applied. Triplet methylene may

13) H. M. Frey, *Trans. Faraday Soc.*, **57**, 951 (1961).
14) G. Herzberg, *Proc. Royal Soc.*, **A262**, 291 (1961).



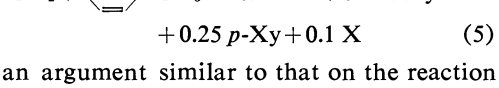
be added to benzene to give a biradical such as H_2C-  ($\leftrightarrow H_2C$-  $\bullet \leftrightarrow H_2C$- ), which may be easily scavenged by oxygen or nitric oxide. The fact that the addition of oxygen or nitric oxide did not alter the CHT%, together with the above discussion, seems to indicate that CHT and T are produced by the singlet methylene and benzene.

As is suggested by the reactions of methylene with olefins, the reaction with benzene may be expected to occur in two parallel ways, namely, the addition to a carbon-carbon double bond and the insertion into a carbon-hydrogen single bond, giving norcaradiene and toluene:

(addition) (1)

(insertion). (2)

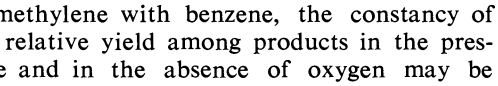
The fact that the photolysis of a benzene solution of diazomethane did not give toluene,[8,9] however, seems to obviate the possibility of inserting methylene into the carbon-hydrogen bond in benzene, and the toluene obtained in the gas phase may be produced not by reaction 2 but by the isomerization of the norcaradiene produced in reaction 1. Unsubstituted norcaradiene has not yet been synthesized,[15] and it must be extremely unstable. The norcaradiene formed in reaction 1 would easily isomerize into CHT and T almost instantaneously.



(3)

(4)

The almost constant value of CHT% (70%) indicates that the rate constant ratio, k_3/k_4, is about 7/3 in the gas phase.



The relative yield of ethane to ethylene did not vary in the photolysis of pure ketene and in the reaction of methylene with benzene. This fact may indicate that the hydrogen atom abstraction from benzene by methylene does not play any important role in the reaction.

The Reaction of Methylene with Toluene.—The overall reaction can be written as follows:

(5)

By an argument similar to that on the reaction of methylene with benzene, the constancy of the relative yield among products in the presence and in the absence of oxygen may be taken as indicating that they are also produced by singlet methylene and toluene. Ethylbenzene can be produced by the insertion of methylene into a carbon-hydrogen single bond of methyl on the benzene ring. The scarcity of *o*-xylene among the products indicates that the steric hindrance caused by the substituted methyl acts strongly in this case.

The approximate five-fold increase in the yield of ethane can be explained by the abstraction of a hydrogen atom by methylene from the substituted methyl in toluene,

(6)

followed by a recombination of the methyl radicals thus formed to give ethane. The complete elimination of ethane by oxygen suggests that ethane is formed by such a radical mechanism.

The formation of *o*-xylene in the quartz cell may be due to the secondary photoisomerization of methylcycloheptatrienes, which might have possibly been produced.

The Reactivity of Methylene Radicals.—The photolysis of pure ketene is accepted as taking place in the following way:

$$CH_2CO + h\nu \rightarrow CH_2 + CO \quad (7)$$

$$CH_2 + CH_2CO \xrightarrow{k_8} C_2H_4 + CO \quad (8)$$

$$\searrow^{k_9} \text{other products.} \quad (9)$$

In the presence of another reactant, R, the methylene produced in reaction 7 reacts with R to give products, P_i's, as follows:

$$CH_2 + R \xrightarrow{k_{10R}} \sum c_i P_i \quad (10)$$

The steady state treatment requires the following relation:

$$\frac{R_{CO}}{R_{C_2H_4}} = 2 + \frac{k_9}{k_8} + \frac{k_{10R}}{k_8}\frac{[R]}{[K]} \quad (I)$$

where [K] refers to the concentration of ketene and k_{10R}, to the rate constant of reaction 10 for a particular reactant, R. The value of k_9/k_8 can be estimated as 0.2 by applying Equation (I) to the photolysis of pure ketene, in which $[R]=0$ and $R_{CO}/R_{C_2H_4}$ is about 2.2.[11] Plotting CO/C_2H_4 against $[R]/[K]$, one can obtain k_{10R}/k_8, the value of which shows the reactivity of methylene with reactant R relative to that with ketene to give ethylene and carbon monoxide.

15) It is highly probable that the product in the liquid-phase reaction of methylene with benzene, which was identified by Meerwein et al.[9] as norcaradiene from the fact that it absorbed two molecules of hydrogen per molecule, was actually [3. 2. 0]-bicyclohepta-2, 5-diene. which is the major product of the photoisomerization of CHT in the liquid phase.[16]

16) W. G. Dauben and R. L. Cargil, *Tetrahedron*, **12**, 186 (1961).

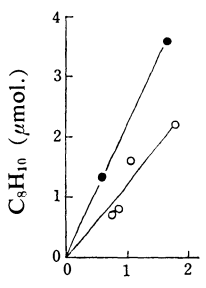

Fig. 5. Amount of C_8H_{10} products plotted against ethylene.
Toluene to ketene ratio,
○: 2, ●: 2.5.

By comparing Reactions (8) and (10), k_{10R}/k_8 can also be obtained from the following equation:

$$\frac{R_{\sum c_i P_i}}{R_{C_2H_4}} = \frac{k_{10R}}{k_8}\frac{[R]}{[K]} \qquad \text{(II)}$$

For benzene, relations I ard II are shown in Figs. 3 and 4, giving 1.4 and 0.7 respectively, for the value of k_{10B}/k_8 where B stands for benzene. The disagreement between the values thus obtained by the two methods implies that, along with CHT and T, some other products which could not be detected are present, possibly a polymer. The poverty of the material balance in the reaction of methylene with benzene supports this idea.

Table III. Rate constant ratios of reactions of methylene with various substances

$$CH_2+CH_2CO \xrightarrow{k_8} C_2H_4+CO$$

$$CH_2+R \xrightarrow{k_{10R}} \sum c_i P_i$$

C_2H_2	1.1	Reference 18.
C_2H_4	~1[c]	Reference 17.
CO	2.7, 1.25	Reference 19.[b]
CO_2	~0.02[c]	Reference 20.

a) The sign > means the minimum value.
b) Two different values have been obtained.
c) The sign ~ means the approximate value.

For toluene, relation II is shown in Fig. 5, the initial slopes of which give 0.75 for the value of k_{10T}/k_8. Since we may not have detected all the products for toluene, this value should be considered as the lower limit of k_{10T}/k_8.

The values of k_{10R}/k_8 for various reactants are summarized in Table III. The value of k_8 was estimated by Kistiakowsky and Rosenberg[17] to be 10^{-16} cc./molec./sec., and reaction 8 is generally accepted to be a very fast one. From the table one can see that the reactivity of methylene radicals is very high with ethylene, acetylene and aromatics also, not only confined with ketene.

Summary

The reactions of methylene radicals produced by the photolysis of ketene with benzene and with toluene in the gas phase have been

17) G. B. Kistiakowsky and N. W. Rosenberg, *J. Am. Chem. Soc.*, **72**, 321 (1950).
18) T. Terao, N. Sakai and S. Shida, ibid., **85**, 3919 (1963).
19) T. B. Wilson and G. B. Kistiakowsky, ibid., **80**, 2934 (1958).
20) G. B. Kistiakowsky and K. Sauer, ibid., **80**, 1066 (1958).

studied. The reaction of methylene with benzene gave cycloheptatriene and toluene in a ratio 7 to 3. The ratio varied neither with the pressure raised by the added nitrogen or carbon dioxide nor with the wave lengths of the incident radiation.

The products obtained in the reaction of methylene with toluene were ethylbenzene, *m*-xylene, *p*-xylene and an unidentified product, their percentages being 25, 40, 25 and 10% respectively. About a five-fold increase in the amount of ethane has been observed over that observed in the reaction with benzene or in the photolysis of pure ketene. This fact indicates that the abstraction of the hydrogen atom by methylene from the methyl in toluene does occur, but that that from the benzene ring does not. Oxygen did not alter the relative yield among the products in the reactions of methylene with either benzene or with toluene. This suggests that the products are formed by the reactions of singlet methylene with benzene and toluene via norcaradiene-type intermediates.

It has quantitatively been shown that the reactivity of methylene redicals is very high with aromatics, ethylene and acetylene, as with ketene.

The Formation Constant of Chromium(III)-Ethylenediamine Complexes

By Mitsuo OHTA, Hiroharu MATSUKAWA and Ryokichi TSUCHIYA

(Received October 10, 1963)

Many reports have been published on the formation constants of complexes since Bjerrem's theory[1] was presented. Most of them, however, have the concerned complexes formed by divalent metal cations. The formation constants of complexes containing ethylenediamine already reported concern the divalent metals, such as cadmium(II),[2] cobalt(II),[1] iron(II),[1] magnese(II),[1] nickel(II),[2] copper(II),[3] zinc(II)[4] and mercury(II).[5]

As for the formation constants of complexes of the tervalent metals, only the data concerning cobalt(III)[1] and the rare earths are known. As for chromium(III), there has been no formation constant data about either the ethylenediamine complex or complexes with any other ligand.

The divalent metals, in general, form labile complexes, and the velocity of the formation or aquation of the complexes is so large that the conventional pH titration method can be employed to find the formation constants, whereas the tervalent metals such as chromium(III) show a tendency to form substitution-inert complexes because of the smallness of the radius and because the reaction velocity is too small for the pH titration method to be employed. Therefore, the determination of the formation constant of chromium(III)-ethylenediamine complexes has been carried out by means of the photometric method.

Theoretical

Tris(ethylenediamine)chromium(III) perchlorate is thought to be aquated in the aqueous solution according to the three steps expressed by the following equations:

$$[Cr\,en_3]^{3+} + 2H_2O \rightleftarrows [Cr(H_2O)_2en_2]^{3+} + en \quad (1)$$

$$[Cr(H_2O)_2en_2]^{3+} + 2H_2O \rightleftarrows [Cr(H_2O)_4en]^{3+} + en \quad (2)$$

$$[Cr(H_2O)_4en]^{3+} + 2H_2O \rightleftarrows [Cr(H_2O)_6]^{3+} + en \quad (3)$$

The measurements of the velocity of these

reactions have already been made by Schläfer et al.[6]

In these reactions, when the total concentration of the metal ions is expressed by C_{Cr} and the concentrations of the complex species, hexaaquochromium(III), tetraaquoethylenediaminechromium(III), diaquobis(ethylenediamine)chromium(III) and tris(ethylenediamine)-chromium(III), in the solution at equilibrium, by $[Cr(H_2O)_6^{3+}]$, $[Cr(H_2O)_4en^{3+}]$, $[Cr(H_2O)_2 \cdot en_2^{3+}]$ and $[Cr\ en_3^{3+}]$ respectively, the total concentration, C_{Cr}, is given as:

$$C_{Cr} = [Cr(H_2O)_6^{3+}] + [Cr(H_2O)_4en^{3+}] + [Cr(H_2O)_2en_2^{3+}] + [Cr\ en_3^{3+}] \quad (4)$$

If the molar extinction coefficients of the above four complex species are expressed by ε_1, ε_2, ε_3 and ε_4, and the absorbancy of the solution at equilibrium, by ε, the following relation exists:

$$[Cr(H_2O)_6^{3+}]\varepsilon_1 + [Cr(H_2O)_4en^{3+}]\varepsilon_2 + [Cr(H_2O)_2en_2^{3+}]\varepsilon_3 + [Cr\ en_3^{3+}]\varepsilon_4 = C_{Cr}\varepsilon \quad (5)$$

The acid hydrolyses of ethylenediamine are presumed to be expressed by;

$$H_2en^{2+} \rightleftarrows H^+ + Hen^+ \quad (6)$$

$$Hen^+ \rightleftarrows H^+ + en \quad (7)$$

If the concentration of H_2en^{2+}, Hen^+ and en are expressed by $[H_2en^{2+}]$, $[Hen^+]$ and [en] respectively, the acid dissociation constants of reactions 6 and 7 are given as:

$$k_1 = [H^+][Hen^+]/[H_2en^{2+}] \quad (8)$$

$$k_2 = [H^+][en]/[Hen^+] \quad (9)$$

respectively, where $[H^+]$ is the hydrogen ion concentration.

The concentration of the total of ligand materials, including those involved in the complex formation, C_{en}, is given as:

$$C_{en} = [H_2en^{2+}] + [Hen^+] + [en] + [Cr(H_2O)_4 \cdot en^{3+}] + 2[Cr(H_2O)_2en_2^{3+}] + 3[Cren_3^{3+}] \quad (10)$$

By eliminating $[H_2en^{2+}]$ and $[Hen^+]$ from Eqs. 8, 9 and 10, the following relationship is obtained:

$$[en] = k_1k_2(C_{en} - [Cr(H_2O)_4en^{3+}] - 2[Cr \cdot (H_2O)_2en_2^{3+}] - 3[Cr\ en_3^{3+}])/(k_1k_2 + k_1[H^+] + [H^+]^2) \quad (11)$$

In order to find the molar extinction coefficients of the tris(ethylenediamine)chromium-(III) and aquoethylenediaminechromium(III) complexes, which are formed by the aquation

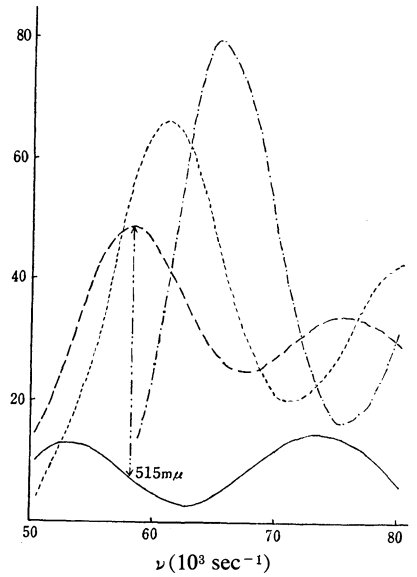

Fig. 1. The absorption spectra of chromium-(III)-ethylenediamine complexes.
Hexaaquochromium(III) complex
Tetraaquoethylenediaminechromium(III) complex
Diaquodiethylenediaminechromium(III) complex
Tris-ethylenediaminechromium(III) complex

of the former, their absorption spectra must be measured; they are shown in Fig. 1. The absorption spectra of the tris(ethylenediamine)-chromium(III) and hexaaquochromium(III) complexes were directly measured, while that of the diaquobis(ethylenediamine)chromium-(III) complex was obtained by tracing the aquation of bromoaquobis(ethylenediamine)-chromium(III) bromide, which is in good agreement with that reported by Schläfer et al.[6] The spectra of the tetraaquoethylenediaminechromium(III) complex was obtained by tracing the aquation of the diaquobis-(ethylenediamine)chromium(III) complex.

From the absorbancy measured at equilibrium in the prepared solution in order to find the formation constant, the following facts could be inferred: The equilibrium state under the conditions selected by the authors is expressed by Eq. 3; that is to say, the equilibrium mixture consists of the tetraaquoethylenediaminechromium(III) and hexaaquochromium(III) complexes. Even though the solution at equilibrium was contaminated with the diaquobis(ethylenediamine)chromium(III) complex, the impurity is no more than 1% of the two main complexes above, the tetraaquoethylenediamine- and hexaaquochromium(III) complexes.

On the assumption that the equilibrium in solution is accurately expressed by Eq. 3, the

6) H. L. Schläfer and O. Kling, *Z. phys. Chem.* **16**, 14 (1958).

formation constant was calculated as is shown below.

In this study, it seems reasonable to consider such condition with regard to the concentration of the complex species as:

$$[Cr(H_2O)_2en_2^{3+}] \text{ and } [Cr\ en_3^{3+}] \ll [Cr(H_2O)_6^{3+}] \text{ and } [Cr(H_2O)_4en^{3+}].$$

Taking into account these conditions, Eqs. 4, 5 and 11 are transformed to the following:

$$C_{Cr} = [Cr(H_2O)_6^{3+}] + [Cr(H_2O)_4en^{3+}] \quad (12)$$

$$[Cr(H_2O)_6^{3+}]\varepsilon_1 + [Cr(H_2O)_4en^{3+}]\varepsilon_2 = C_{Cr}\varepsilon \quad (13)$$

$$[en] = k_1k_2(C_{en} - C_{Cr})/(k_1k_2 + k_1[H^+] + [H^+]^2) \quad (14)$$

By solving Eqs. 12 and 13 with respect to $[Cr(H_2O)_6^{3+}]$ and $[Cr(H_2O)_4en^{3+}]$, the following equations are obtained:

$$[Cr(H_2O)_6^{3+}] = C_{Cr}(\varepsilon_2 - \varepsilon)/(\varepsilon_2 - \varepsilon_1) \quad (15)$$

$$[Cr(H_2O)_4en^{3+}] = C_{Cr}(\varepsilon - \varepsilon_1)/(\varepsilon_2 - \varepsilon_1) \quad (16)$$

By substituting for k_1 and k_2 the values given in the literature[4] and by estimating the range of the hydrogen ion concentration measured, the following orders of magnitude are obtained:

$$k_1k_2 \cong 10^{-8},\ k_1[H^+] = 10^{-12} \sim 10^{-10},\ [H^+] \cong 10^{-6} \sim 10^{-4}$$

Therefore, it is reasonable to express the denominator of Eq. 14 by $[H^+]^2$, neglecting the first and second terms.

By substituting Eq. 16 into Eq. 14 after considering the above approximation, the following equation is obtained as the concentration of the free ligand uncomplexing:

$$[en] = k_1k_2\{C_{en} - C_{Cr}(\varepsilon - \varepsilon_1)/(\varepsilon_2 - \varepsilon_1)\}/[H^+]^2 \quad (17)$$

The equilibrium constant of the reaction

$$[Cr(H_2O)_6]^{3+} + en \rightleftarrows [Cr(H_2O)_4en]^{3+} + 2H_2O, \quad (18)$$

which is the reverse of reaction 3, that is to say, the first formation constant, K_1, of the aquoethylenediaminechromium(III) complexes, is given as:

$$K_1 = [Cr(H_2O)_4en^{3+}]/[Cr(H_2O)_6^{3+}][en] \quad (19)$$

This formation constant may be calculated by substituting Eqs. 15, 16 and 17 into Eq. 19.

The ionic strengths of the solutions at equilibrium, the absorbancies of which were measured, can be calculated by the following equation;

$$\mu = 1/2\{12C_{Cr} + 4[H_2en^{2+}] + [HClO_4] + [H^+]\} \quad (20)$$

where $[HClO_4]$ is the concentration of perchloric acid added in order to control the hydroxo-change of the complex. The concentration of ethylenediamine affecting the ionic strength was thought to be only $[H_2en^{2+}]$, for it was found that the concentrations of $[Hen^+]$ and [en] were negligibly small compared with $[H_2en^{2+}]$ when they were estimated by using the first and second acid dissociation constants and the hydrogen ion concentration.

Experimental

Tris(ethylenediamine)chromium(III) Perchlorate.—When chromium(III) chloride hydrate (green) and ethylenediamine were mixed stoichiometrically, the reaction started with a violent evolution of heat. After the mixture had been kept upon an oil bath for three or four hours in order to complete the reaction and the dehydration, a yellowish-brown residue was obtained. When the product was extracted by water, crystalline tris(ethylendiamine)chromium(III) chloride was obtained and purified by recrystallization.

The perchlorate was obtained by adding perchloric acid to the saturated solution of the chloride and by coolin it with ice. It has no water of crystallization. Analytical values: Cr 9.96% (found), 9.80% (calcd.); C 13.87% (found), 13.58% (calcd.); H 4.53% (found), 4.56% (calcd.)

Procedure.—In order to obtain the equilibrium system, a mixed solution of hexaaquochromium-(III) salt with ethylenediamine was at first used as the starting material, but the reaction did not proceed. Therefore, the equilibrium state was obtained by aquating the tris(ethylenediamine)-chromium(III) salt prepared above.

The procedure by the latter way as follows. The aqueous solutions of various concentrations of tris(ethylenediamine)chromium(III) perchlorate, to which some quantities of free ethylenediamine had been added to prevent complete aquation and to which an excess amount of perchloric acid had been added to protect the chromium(III) aquo-complexes produced in consequence of the reaction from their hydroxo change, were maintained at 25°C in a thermostat for one or two months. The solutions were always kept in brown flasks to avoid photodecomposition.

The absorbancy of the solution was then measured by means of Hitachi EPS-2 type automatic recording and EPU-2 type spectrophotometers after the equilibrium had been attained. Since it was necessary to find the hydrogen ion concentration of the solution at equilibrium in order to calculate the formation constant, the pH was also measured by means of a Horiba HRL model M pH meter. All the measurements were carried out at 25°C.

Results

The measurement of the absorbancy, ε, of the solution at equilibrium was carried out

at the wave length of 515 mμ, where the difference in absorbancy between hexaaquochromium(III) and tetraaquoethylenediaminechromium(III) complex is the greatest, as may be seen in Fig. 1. As the molar extinction coefficients of these two complexes in the solution at this wave length, log $\varepsilon_1=5.97$ and log $\varepsilon_2=48.59$ were used respectively.

As the acid dissociation constants of the first and second steps of ethylenediamine, $pk_1=7.42$ and $pk_2=10.14$[4] were employed respectively.

In order to calculate the value of [en] by inserting into Eq. 17 the measured absorbancy, ε, the acid dissociation constants pk_1 and pk_2 given above, and the total concentrations of chromium(III) salts and ethylenediamine, it is necessary to known the hydrogen ion concentration, $[H^+]$. What is obtained by pH measurement is not $[H^+]$, but the activity. Therefore, [en] was first calculated by inserting the value of the activity instead of the value of hydrogen ion concentration into $[H^+]$ in Eq. 17; then the equilibrium constant, K_1, was obtained by applying the value of [en] to Eqs. 15, 16 and 19. The ionic strength was calculated at the same time by means of Eq. 20.

Subsequently, the activity coefficient of the hydrogen ions at each ionic strength calculated as above was obtained from Kielland's table.[7] After the hydrogen ion concentration, $[H^+]$, had been obtained by dividing the activity by its activity coefficient, the equilibrium constant, K_1, was recalculated by inserting the hydrogen ion concentration into Eq. 17 and by computing the value of Eq. 19.

The values obtained by these measurements and those calculated from them are listed in Table I.

The logarithm of the equilibrium constant, K_1, is plotted against the square root of the ionic strength in Fig. 2.

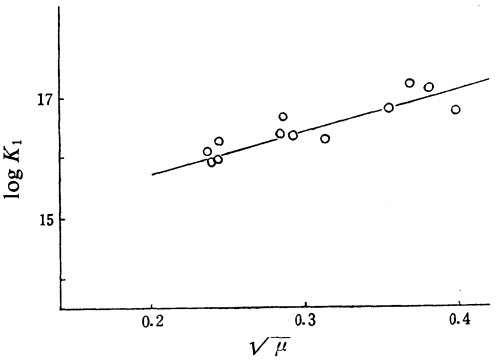

Fig. 2. The relationship between the logarithm of the equilibrium constant and the square root of ionic strength.

The formation constant of the second step of aquoethylenediaminechromium(III) complexes could not be determined spectrophotometrically. The exact formation constants could not be obtained by pH measurements alone, because the error in calculation was too large at low pH values, while decomposition easily occurred at high pH values; consequently, the pH range which gave exact values of formation constants was too restricted. As the rough value of the formation constant of the second step at the ionic strength of $\mu=0.1$, log $K_2<14$ was obtained.

Discussion

It may be seen in Fig. 2 that the formation constants of the first step of aquo-ethylenediaminechromium(III) complexes at the ionic strength of $\mu=0.05$, 0.10 and 0.15 are given by log $K_1=15.9$, 16.5 and 17.0 respectively. As may be seen from these values, the equilibrium constant, K_1, does not depend much on the ionic strength of the solution.

This may be explained by the fact that the hexaaquochromium(III) and tetraaquoethylenediamine chromium(III) complexes, which give

7) J. Kielland, *J. Am. Chem. Soc.*, **59**, 1675 (1937).

TABLE II. FORMATION CONSTANTS OF ETHYLENDIAMINE COMPLEXES OF TERVALENT CHROMIUM OR COBALT AND DIVALENT CHROMIUM AND COBALT

	log K_1	log K_2	log K_3	Condition	
Cr(III)	16.5	<14	—	μ=0.1,	25°C
Co(III)	18.7	16.2	13.8	μ=1.0,	30°C[9]
Cr(II)	5.145	4.035	—	μ=1.4,	25°C[10]
Co(II)	5.93	4.73	3.30	μ=1.0,	25°C[11]

the respective concentrations, $[Cr(H_2O)_6^{3+}]$ and $[Cr(H_2O)_4en^{3+}]$, in the numerator and denominator of Eq. 19 respectively, are both tervalent cations and by the assumption that the ionic radii of these complex cations are approximately equal.

The formation constants of the aquo-ethylenediaminechromium(III) complexes obtained are listed in Table II, together with those of the corresponding cobalt(III) complexes and the ethylenediamine complexes of divalent chromium and cobalt.

Table II shows, in the first place, that the formation constants of the aquo-ethylenediamine complexes of tervalent chromium and cobalt are far larger than those of the corresponding divalent metal complexes. This must be due to the fact that the covalency of the coordinated bond of the ligand with tervalent metal ions is much stronger than that with divalent ions because of the smaller radii of the former ions.

The Table also shows that the formation constants of the aquo-ethylenediaminechromium(III) complexes are a little smaller than those of the corresponding cobalt(III) complexes. On the other hand, it has already been found[8] that the crystal-field stabilization energy of the tris(ethylenediamine)chromium-(III) complex is much smaller than that of the tris(ethylenediamine)cobalt(III) complex. This means that the formation constants of these two complexes can not be determined only by means of the crystal field stabilization energy. In addition, in order to explain the difference in stability between these chromium(III) and cobalt(III) complexes, the following concept is effective: The cobalt complexes are instabilized by the mutual repulsion of the six 3d electrons paired in the bonding orbitals more than the corresponding chromium(III) complexes which have unpaired three electrons; that is to say, the contribution of Racah's electrostatic parameter upon the crystal-field stabilization is greater in the cobalt(III) complex than in the chromium(III) complex.

Summary

1) The formation constants of chromium (III) complexes with ethylenediamine, the simplest bidentate ligand material coordinated by two nitrogen atoms, have been spectrophotometrically determined.

2) It has been shown that the dependence of the formation constant of the first step upon the ionic strength is small.

3) The formation constants of the chromium-(III) complexes with ethylenediamine have been found to be remarkably higher than those of the corresponding chromium(II) complexes and a little lower than those of the corresponding cobalt(III) complexes.

4) The difference between the formation constants of the chromium(III) and cobalt-(III) ethylenediamine complexes has been qualitatively explained with reference to the crystal-field stabilization energy and to Racah's electrostatic repulsive parameter.

Relative Sensitivities of Elements in a Spark-Source Mass Spectrograph[*1]

By Hiroyuki KAWANO[*2]

(Received October 23, 1963)

For the quantitative analysis of solids by spark-source mass spectrography, at least two fundamental problems must be studied. One of them concerns a calibration method to obtain the relative ion intensity from the densities of mass lines recorded on a photographic plate. The other concerns the relative sensitivities of elements in a mass spectrograph with a pulsed radio-frequency spark ion source, which has been generally used as the most suitable ion source for the trace analysis of solids since it was first applied to mass spectroscopy by Dempster.[1,2] The sensitivity is a function of both the darkening rate of a photographic plate and the ion production rate from a solid by a spark discharge between two sample electrodes. Therefore, the sensitivity is not only necessary as an analytical constant in quantitative mass spectrography but also very important for the study of the mechanism of ion production by spark discharges in a vacuum. However, relatively little work has been done on the sensitivity,[3,4] and no study has previously been made of the ion production rate using photographic detection.

Thus, a study of the calibration method has been made in this laboratory, and the findings partly published in a preceding paper.[5] For the present work, five kinds of calibration methods have been investigated by applying them to isotopic analyses of magnesium, copper and zinc. The relative sensitivities have been determined for eleven elements contained in several standard samples using the calibration methods mentioned above, and the constancy of the sensitivity to changes in bulk concentration of the element has been examined. The relative ion production rates have also been determined from the above sensitivities with a correction for the darkening rate. In addition, the reproducibility of the relative ion intensities detected with several plates in many exposure stages has been studied for many pairs of isotopes and pairs of different elements, in order to examine whether the relative ion yields obtained from the spark ion source are always constant for all elements contained in the sample electrodes. Finally, a discussion will be given on the general applicability of the sensitivity as the analytical constant.

Apparatus

The Mattauch-Herzog-type double-focusing mass spectrograph used in this work was constructed in this laboratory in collaboration with the Mitsubishi Elec. Mfg. Co. Since details of the instrument have been reported elsewhere,[6] only an outline and the operating conditions employed will be given here. The ion source used was a Dempster-type vacuum spark ion source; the spark voltage applied between two sample electrodes, each about 1 mm. in diameter and 1 cm. in length, was approximately 30 kV., supplied from a 1 Mc./sec. radio-frequency oscillator with pulses about 200 μsec. long at a repetition rate of 60 c./sec. Ions produced under a vacuum of about 5×10^{-6} Torr were accelerated with 15 kV. through the slit system, inclusive of a 0.21 mm. defining slit. Of the ions passing through the energy selector with a mean radius of 150 mm., about 42 per cent enter the magnetic field, and the rest are collected by the beam-monitor electrode which is situated directly behind a selector slit and which is shielded from the field of the radio-frequency used for the spark source.

Individual ions resolved by the mass analyzer were detected by a 3 cm. $\times$ 15 cm. Ilford Q2 plate, which covers a mass range of 10 : 1 in a single exposure. Moreover, eleven exposures can be recorded on the plate without loss of vacuum. The amount of each exposure was determined by the total ion current arriving at the beam-monitor during the exposure. For this purpose, a vibrating-reed electrometer manufactured by the Electronic Instrument Ltd. was used in combination with a 500 pF polystyrene condenser. The exposed plate was developed by an Ilford ID-19 developer continuously agitated by hand at temperatures 20 ± 1°C for exactly 5 min., then it was fixed by Fujifix for about 3 min., washed, and dried. For the purpose

of determining the optical densities of the mass lines, about 2 mm. long and about 0.2 to 0.8 mm. wide on a photographic plate, each spectrum, magnified about 9 times, was scanned through a 0.20 mm. × 3 mm. slit and was registered by a microphotometer with a recorder manufactured by the Rigaku-Denki Co., Ltd.

Experimental Method

Calibration Curve.—*Expression of Density.*— For quantitative analysis by photometry, it is necessary to make a calibration curve which shows the relation between the density of each mass line and its corresponding exposure. It is desirable that the curve has a linear portion over a wider range of exposure. Thus, various methods have been studied to get useful calibration curves from a series of the mass lines of a certain ion recorded by different exposures on the same plate. Among the methods studied, five have been employed here to express the "density" of each mass line:

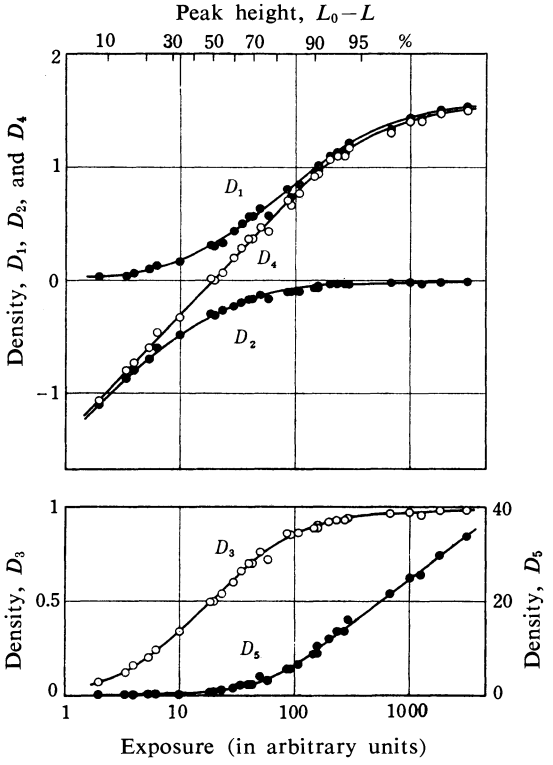

Fig. 1. Examples of the five kinds of calibration curves obtained for zinc isotopes recorded on an Ilford Q2 plate using the different expressions of density. In order to utilize many data points, $r \times Q$ instead of Q was employed as the "exposure", where r and Q are the known relative abundance of each isotope of zinc and the measured value of the integrated monitor current in each exposure stage, respectively.

$$D_1 = \log L_0/L$$
$$D_2 = \log(L_0-L)/L_0$$
$$D_3 = (L_0-L)/L_0$$
$$D_4 = \log(L_0-L)/L$$
$$D_5 = (L_0-L)/L$$

where L_0 and L are the intensities of the incident and the transmitted light in arbitrary units respectively. Examples of the calibration curves using these density expressions are shown in Fig. 1, at the top of which the peak height, L_0-L (i. e., the intensity of the absorbed light) is plotted in per cent of L_0 in order to show the range which corresponds to the linear portion of each calibration curve.

The D_1 expression is the equation of Lambert-Beer's law; it is generally used as an expression of density in mass spectrography. However, in the calibration curve where D_1 is plotted against the logarithm of exposure, more than one-half of the series of mass lines obtained for a certain ion in several exposures are, on the average, unavailable for the calibration only because they are out of the linear portion of the density curve, as may be seen in Fig. 1. For this reason, the usable D_1-curves for all ionic species under investigation can not always be obtained from an exposure range covered by up to eleven exposures. In the other curves, however, using D_2, D_3, D_4, or D_5, it is possible to utilize even those mass lines which are unavailable for the calibration in the D_1-curve because they are too intense or too weak to fall in the linear part. Especially in the D_2- or D_4-curve, any weakline is available so long as it exceeds the noise level around it to a certain degree. Therefore, short exposures less than one-tenth of those necessary in the D_1-curve are sufficient here to get useful curves. Thus, employing the D_2- or D_4-expression is more advantageous when long exposures are undesirable or have produced only weak lines for some of the ions to be studied. Some examples of the D_4-curves obtained from a single Q2 plate, subjected to ten short exposures graded with a factor of about 2 between adjacent stages, is shown in Fig. 2. In the examples no useful curve can be obtained for zinc and manganese if the D_1- or D_5-expression is employed. In the D_5-curve, on the other hand, only intense lines are usable, so this curve is available for the determination of those major elements which from nearly saturated lines. The D_3-curve is appropriate to some of the lines that are unavailable in the D_1- or D_2-curve because they are too weak or too intense respectively. The characteristics of the different expressions of density described above are listed briefly in Table I.

TABLE I. CHARACTERISTICS OF EACH CALIBRATION CURVE, D_n VS. log *Exposure*, OBTAINED FOR AN ILFORD Q2 PLATE (EMULSION NUMBER : S 3399)

The "asymptote" indicates the maximum or the minimum density level to which a calibration curve approaches asymptotically, as the amount of exposure increases or decreases respectively. The "useful range" means (A) the range of peak height in per cent of L_0 or (B) that of the density value which corresponds to the linear part of the curve (cf. Fig. 1). Of the values shown in the second and the third columns, only those with an asterisk are dependent on the characteristics of a photographic plate and on the conditions of development employed.

Density expression	Asymptote	Useful range	Remarks
D_1	$D\approx 1.6$*	(A) 50* ~ 90*%	Useless for low peaks.
	$D=0$	(B) 0.3* ~ 1.0*	Long exposure is necessary.
D_2	$D=0$	(A) 0 ~ 40*%	Applicable to low peaks only.
		(B) $-\infty$ ~ -0.4*	The shortest exposure among the five is sufficient.
D_3	$D=1.0$	(A) 20* ~ 80*%	Applicable to intermediate peaks.
	$D=0$	(B) 0.2* ~ 0.8*	
D_4	$D\approx 1.6$*	(A) 0 ~ 90*%	Applicable from low to high peaks.
		(B) $-\infty$ ~ 1.0*	The linear part is the longest among the five.
D_5	$D=0$	(A) 80* ~ 100%	Applicable to high peaks only.
		(B) 4* ~ ∞	The longest exposure among the five is necessary.

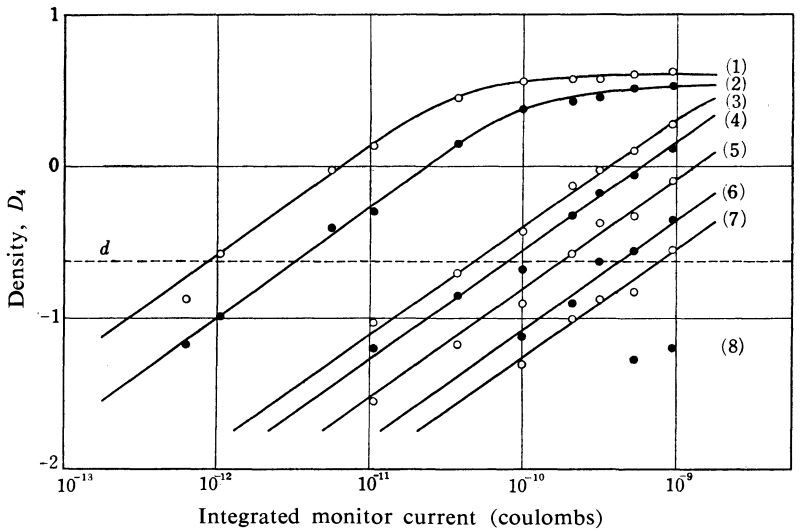

Fig. 2. An example of the calibration graph obtained for the samele S-3 from a Q2 plate using the D_4-expression in ordinate. The integrated monitor current of 10^{-9} coulombs corresponded to an exposure of about 3 min.

Determination of Exposure. — In order to determine the amount of the "exposure" as a measure of the relative ion intensity corresponding to each line density, several methods have been utilized. One of them is Mattauch-Ewald's method, which uses as internal standards the known relative abundances of the isotopes of an element.[7-10] Therefore, its application is generally confined to those samples which contain in a moderate concentration such an element as has several isotopes with a suitable distribution of the relative abundance. As another method, the exposure time is employed.[11,12] However, in many cases the true amount of exposure can not be obtained from the exposure time without making an appropriate correction,[12] because it

is very difficult to keep spark discharges constant throughout all the exposures given to a plate, and much more so from plate to plate or from sample to sample. On the other hand, a monitor-current integration method[4,5,13] is free from the disadvantages mentioned above; i. e., no internal standard is necessary for making a calibration curve, and the error due to fluctuations of the total ion amount produced per sec. by spark discharges is avoidable because the integrated monitor current, Q, can be regarded as always proportional to any individual ion amount focused on a plate in any exposure. Therefore, this monitor method was employed, although the disturbance from the field of the R. F. current for spark discharges had to be shielded.

Isotopic Analysis for Testing the Methods.— For testing the usefulness of each D_n-curve for mass-spectrographic measurements, some isotopic analyses were tried using several samples. Each abundance ratio of the isotopes was calculated from the following equation:

$$r_i/r_j = (q_j/q_i)(m_i/m_j)^{1/2} \quad (1)$$

where r_i and r_i are the abundances of the isotopes i and j respectively, q_i and q_j are the integrated monitor currents required for the line densities of i and j respectively to be at the same value, d, which is chosen so as to be on the linear part of the curves, as is shown in Fig. 2, and m_i and m_j are the masses of the isotopes i and j respectively. $(m_i/m_j)^{1/2}$ is the correction factor for the line widths,[14] needed because they vary in proportion to the square root of the mass in the Mattauch-Herzog arrangement.

The results obtained for copper are listed in Table II, where the ions studied are monatomic positive ions originating from two different samples, A and B, which contain about 90 and 1 weight per cent of copper respectively. As Table II shows, the mean values obtained by means of these calibration methods agree with one another rather well, and they also compare favorably with others referred to there. Therefore, the density expressions, D_2, D_3, D_4 and D_5, can be regarded as reliable as D_1. On the other hand, the standard deviations of the values measured with the five methods are about 10 times as large as those by Ewald[9] and Duckworth and Hogg.[16] This seems mainly due to the difference in calibration method. As the abscissa component of a calibration graph, the known relative abundance of the isotopes of a suitable element (zinc, for instance) has been taken, so that every value in the abscissa is free from erratic fluctuations.

The results obtained for magnesium and zinc are also in fair agreement with the referred values, as is shown in Tables III and IV respectively, where they have been calculated from those individually measured values which

* Cited from Ref. 28.

were obtained by using the most suitable calibration method among the five according to the densities of the isotopic lines to be studied. In the magnesium analysis, the sample used contains more than 90 weight per cent of magnesium, so that the intensities of the C_2^+, C_2H^+ and $C_2H_2^+$ ions, even if they exist, may be negligibly small compared with those of the magnesium ions.

From these results it seems reasonable to conclude that a mean value of the measurements obtained by any of the five calibration methods is as accurate as that by the electrometry, although good reproducibility has not yet been obtained in the present work.

The Determination of Relative Sensitivity.— If the ion intensity, I_X, of an element, X, which forms a line with a density, d, on a plate is expressed in arbitrary units by the following equation:

$$I_X = m_i^{1/2}/q_i \times r_i \qquad (2)$$

where i is one of the isotopes of X and where every isotope is assumed, in a manner similar to that in Eq. 1, to have the same effect on photographic darkening, the relative sensitivity, S_X, of X will be given as:

$$S_X = S_R(\bar{I}_X/C_X)/(\bar{I}_R/C_R) \qquad (3)$$

where S_R is that of the element, R, adopted as a reference, $\bar{I}$ is the arithmetic average of the I's obtained for all or some isotopes of the element, C is the atomic concentration of each element contained in a sample of known chemical composition, and S is assumed to be independent of C. The samples used are listed in Table V, where each relative atomic concentration for S-1 — S-6 was calculated from data by the ASTM,[29] taking C as 100 for the major element. For the purpose of eliminating surface contaminants from the samples, preparative sparking was carried out before a

plate was first exposed. Each value of r_i used in Eq. 2 was taken from data compiled by Moeller.[30]

In this work the monatomic singly-charged positive ion, the yield of which is generally larger than that of any other ion produced by a spark, such as multiply-charged or polyatomic ions, has been studied for the eleven elements shown in Table V. S_R is taken as unity for zinc, because this element is found in moderate concentrations in all the samples except for S-7 and has five isotopes, so that up to five curves can be utilized in a single calibration graph as a reference to measure the ion intensity ratio, I_X/I_R, as may be seen in Fig. 2. Strictly speaking, I_X/I_R is the "apparent" ion intensity ratio of X to R at the line density, d, because ions of different elements can not have the same darkening rate of a plate unless their mass ratio is very close to unity, as will be described later. Therefore, the sensitivity defined by Eq. 3 contains a factor of the darkening rate of a plate in addition to that of the ion production rate by spark discharges.

Results

Relative Sensitivity.—In Eq. 3, S is assumed to be independent of variations in bulk concentration. To certify this assumption, the constancy of S was studied using several samples. The results obtained for magnesium, aluminum and manganese are shown in Table VI and Fig. 3, where the average for each sample has been calculated by the same procedure as that used in the isotopic analyses of magnesium and zinc. The relative sensitivities obtained for the eleven elements contained in some of the samples used are shown in the second column of Table VII. For comparison with results obtained for the "sensitivity/area-factor" by several workers, the relative sensitivities divided by the square root of the corresponding mass ratio, i. e., $S_X/(m_X/m_R)^{1/2}$, are shown for some elements, taking as unity that for iron in Table VIII. Every value in the fourth column of the table was calculated

from the data for the "analysis of copper standards" shown in Ref. 34.

Relative Ion Production Rate.—According to reports by Burlefinger and Ewald,[31] Owens,[32] and Owens and Giardino,[33] the relative darkening rate is approximately proportional to the reciprocal of the square root of the mass. On the basis of their results, it may be deduced that the number of ions necessary for the line density to achieve a certain value, d, is proportional to the square root of the mass.* Thus, applying this correction to Eq. 2, the relative ion production rate, P_X, can be obtained from the following equation:

$$P_X = P_R(S_X/S_R)(m_X/m_R)^{1/2} \quad (4)$$

As is shown in the third column of Table VII, the range of the relative ion production rates obtained is narrower than that of the relative sensitivities. In Table IX the present

* In order to accertain this rule by isotopic analysis using the equation $r_i/r_j=(q_j/q_i)(m_i/m_j)$ instead of Eq. 1, it is necessary to choose those isotopes which are moderate in both mass ratio and abundance ratio. Perhaps ^{6}Li and ^{7}Li are the most suitable isotopes for this purpose. However, the difference in the darkening rate between them is calculated to be no more than 8 per cent. Therefore, the difference in the mass effect among the isotopes of an element of a larger atomic number, such as copper, is negligibly small compared with the erratic fluctuations in the photometry. This is the reason why no correction for the darkening rate is made for any of the isotopes in Eqs. 1 and 2.

data are compared with values determined by the electrometry, taking P_R as unity for iron.

The Constancy of the Relative Ion Yields for Elements.—As may be seen in Fig. 2, the data points for every ion do not exactly fall on a smooth curve. This is presumably due to fluctuations in the relative ion yields for different elements in each exposure, to the non-uniformity of the emulsion of the photographic plate and, to errors in the measurements of both the monitor current and the photometry of the plate. From this point of view, the reproducibility of the relative ion intensities measured for various ions has been studied in every exposure stage using a modified Mattauch-Ewald method. This method employs D_n and $\log r$ as the two components of a calibration graph, while Mattauch-Ewald's method employs $(L_0-L)/L_0$ and r. The former has such advantages over the latter as follows:

(1) A calibration curve with a linear part is always obtainable for the isotopic ions to be used as internal standards only if the most suitable expression of density among the five is employed.

(2) Extrapolation is applicable to the curve according to each "useful range" shown in Table I.

For the purpose of determining the relative intensities of ions detected in the "same" exposure stage, the present method is more suitable than the monitor method, because all the r_i, r_j,..... values in the abscissa are free from erratic fluctuations.

The results are shown in Table X, where the singly-charged ions of the isotopes of zinc contained as one of the impurity elements in S-1 are employed as the internal standards for calibration, and no value in the second column is corrected for the darkening rate.

TABLE X. REPRODUCIBILITY OF RELATIVE ION INTENSITIES MEASURED FOR ISOTOPES AND DIFFERENT ELEMENTS USING THE SAMPLE S-1

Ions	Ion intensity ratio	Number of measurements	Precision %

Sn:	1.377 ± 0.007	(Ref. 18)
Zn:	1.501 or 1.505	(Ref. 15)

Discussion

It will be found in Table X that the results obtained from repeated measurements of many pairs of different elements are less reproducible by several times than those for isotopes. It is the same with those of four pairs of the same element with single and double charges. The results may suggest that the spark source does not always possess a constant ionization efficiency for all the elements contained in the sample electrodes and/or the relative ion transmission rates from the source to a plate are not always constant for all the ion species produced, probably due to the fluctuations of spark conditions during the exposures, rather than the sample used is not mass-spectroscopically homogeneous in chemical composition. It is possible, with a spark ion source, that on spark spots the chemical composition of the sample electrodes, even if they are originally homogeneous, may be varied during spark discharges because of fractional evaporation, selective sputtering, preferential diffusion, etc. The precision for each pair of iron, zinc and tin isotopes shown in Table X can be considered approximately to indicate the errors attributed to the non-uniformity of photographic emulsion and development in the present work.

Although it may be necessary to study further the elements using many samples different in concentration, Fig. 3 is believed to establish that the relative sensitivity of each element is constant, independent of changes in the bulk concentration of the element to within an uncertainty factor of 1.5 on the average; this compares favorably with the results obtained by Hannay and Ahearn using several samples of both silicon and germanium, including

boron and antimony as impurity elements respectively.[11] Table VII indicates that the relative sensitivities are of the same order of magnitude for all the elements studied in spite of large differences in physical and chemical properties among them, and it is also so with the relative ion production rates. This approximate equality is generally accepted for the Dempster-type vacuum-spark ion source.[3, 4, 34, 36-38]

Owens and Giardino discovered that the relative sensitivity of gallium with respect to arsenic increased considerably in value after prolonged sparking.[33] This discrimination effect was also observed with magnesium and zinc by Duckworth et al.[36] using several alloys, and accepted with zinc by Waldron, who has stated (cf. Ref. 36) that the sensitivity ratio of zinc to iron was found to get much lower values than 5.5 (cf. Table VIII) in subsequent measurements. In the present work, ions produced during the early stage of sparking were studied. As Table VIII shows, the values obtained by the four groups of workers have a large discrepancy among them for magnesium, zinc and tin, although they do not differ for the other elements by more than a factor of 2. This is possibly due to either the above discrimination effect in sparking, to matrix effects, or to both; Craig has found that the relative sensitivity of zinc with respect to iron is about 1 for some matrices, e. g., copper and gallium, but about 6 for other matrices, e. g., aluminum and iron.[39] It may be seen from Table IX that the ion production rates for each element agree also to within a factor of 2 among the three works in spite of the essential differences in detection methods.

On the basis of these considerations, it might be concluded that:

(1) The relative ion yields from a spark source are not always constant for all the elements contained in the sample electrodes even if the operating conditions of the instrument are kept constant throughout the exposures.

(2) This can cause variations in the relative sensitivities by up to several tens of per cent.

(3) Under different experimental conditions, the relative sensitivities are apt to change remarkably for some elements, such as magnesium, zinc and tin although they seem to change rather slightly for others, such as chromium, manganese and nickel.

(4) Since they are subject to changes of value according as various conditions, perhaps they can not be generally applicable as the analytical constant without uncertainty factors, such as about 2 for non-volatile elements and more for volatile ones.

However, much more work must be done to obtain precise informations on the sensitivity.

Summary

The relative sensitivities of eleven elements in a spark-source mass spectrograph have been determined for monatomic singly-charged positive ions detected with Ilford Q2 plates. The results show that the elements have approximately the same sensitivities to within a factor of 3 in spite of large differences in both physical and chemical properties among them, and that the sensitivity of each element is constant in value within an uncertainty factor of 1.5, independent of changes in the bulk concentration of the element. Relative ion production rates have also been determined from the above sensitivities; they are in reasonable agreement with published values determined by electrical detection. From repeated measurements of the relative intensities of various ions, it has been suggested that relative ion yields from a spark ion source are not always constant for different elements. On the basis of these investigations, a discussion has been made of the general applicability of the sensitivity as the analytical constant in the quantitative mass spectrography of solids. Five different formulas have been used to express the "density" of mass lines, and exposures have been determined with an integrated monitor current. By trying several isotopic analyses, the calibration methods have been shown to be useful for mass spectrography.

The author would like to express his hearty thanks to Professor Emeritus Nobuji Sasaki of Kyoto University for his valuable suggestions on the calibration methods, to Professor Kumasaburo Kodera of Kyoto University for his guidance throughout the course of the work, and to Assistant Professor Hokotomo Inouye of Tohoku University for his helpful criticism. He would also like to thank Dr. Tsutomu Makita of the Laboratory and Dr. Junjiro Kai of the Mitsubishi Elec. Mfg. Co.

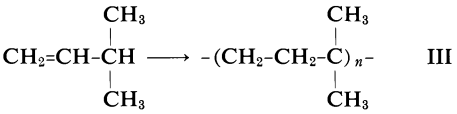
*The Rearrangement Polymerization of Propenylbenzene**

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA,
Kazuhiko TSUBOSHIMA and Yahide KOTAKE

(Received October 21, 1963)



Propenylbenzene belongs to a family of 1, 2-disubstituted ethylenes which are generally reluctant to homopolymerize by means of a radical mechanism.[1] Little information has been reported on the cationic polymerization of the monomer.

In 1935 Staudinger and Dreher observed the cationic polymerization of propenylbenzene when boron trifluoride was used as an initiator.[2] Their close examination of the polymeric product by thermal degradation and viscometric measurements led them to conclude that the chemical structure of the polymer is not the expected one I but structure II.

The occurrance of structure II would, however, involve, in the intermediate stage, an intramolecular hydrogen shift from the primary carbon to the secondary one, a phenomenon which is surprising and contrary to the usual observation on the isomerization of a cation.[3] Although a similar unusual rearrangement during polymerization was reported, without detailed proof, to occur in the polymerization of isobutylene by a Ziegler-type catalyst,[4] it has recently been disproved by Bacskai and Lapporte.[5]

More recently, 3-methylbutene-1 was polymerized by Kennedy and Thomas at a low temperature with a cationic catalyst to give a rearranged polymer III, which involves a normal hydrogen shift from the tertiary to the secondary carbon.[6]

Thus, Staudinger's result presents an example of a rather peculiar type of polymerization reaction, and it seemed worthwhile to reinvestigate it in detail. The present paper will study the chemical structure of polypropenylbenzene by infrared spectroscopy and will also study the effect of reaction conditions on the polymer structure.

Experimental

Monomers. — Propenylbenzene was prepared by the method of Overberger and Tanner[7] through the thermal decomposition of α-ethylbenzyl acetate (b. p. 56.5~63°C 10 mmHg, n_D^{25} 1.5473). The propenylbenzene was found by gas chromatography to consist of 74% trans-isomer and 26% cis-isomer; it was used for polymerization without separation.

Allylbenzene was prepared according to the method of Hershberg from allyl bromide and

phenylmagnesium bromide.[8] B. p. 67.5~69.5°C/35 mmHg.

Catalysts.—Boron trifluoride was prepared when required by the thermal decomposition of phenyldiazonium borofluoride, and it was freed from fluorobenzene by passing it through a dry ice-acetone trap.

Boron trifluoride complexes were prepared by passing a calculated amount of boron trifluoride gas through an appropriate amount of a donor compound, after which it was subjected to vacuum distillation. $BF_3 \cdot 2H_2O$, b. p. 29.0°C/0.33 mmHg; $BF_3 \cdot 2CH_3COOH$, b. p. 138~139°C; $BF_3 \cdot 2CH_3OH$, b. p. 34.0~34.8°C/1.5 mmHg; $BF_3 \cdot (CH_3)_2O$, b. p. 126~127°C.

The other metal halides were commercial products and were used without further purification.

Solvents.—All the solvents used were purified according to the usual method[9] and were stored over a molecular sieve.

The Polymerization of Propenylbenzene.—Polymerization was carried out in a 50 ml. flask under a slight positive pressure of dry nitrogen, with occasional gentle shaking. Solvent and monomer were placed in the flask, which was then flushed with a stream of nitrogen, and the catalyst was injected through a rubber cap using a hypodermic syringe. The fluctuation of temperature of bath was kept at ±1°C. Polymerization was stopped by adding a mixture of concentrated aqueous ammonia and methanol, and the contents of the flask were poured into a large excess of methanol (250 ml.). The precipitated polymer was separated from the mother liquor by filtration through a sintered glass filter of medium porosity, and was weighed after drying as the methanol-insoluble part of the polymer. An aliquot of the filtrate was iodometrically titrated for unreacted monomer using a standard bromate-bromide solution. The remainder of the filtrate was evaporated in vacuo and dissolved in benzene. The benzene solution was washed with dilute aqueous hydrochloric acid and then water, dried with calcium chloride, and evaporated again in vacuo to give the methanol-soluble part of the polymer.

The Polymerization of Allylbenzene.—Allylbenzene (2 g.) was polymerized at 50°C for 48 hr. in a sealed tube using a Ziegler catalyst, which was composed of 6 ml. of heptane, $TiCl_4$ (monomer/Ti=10) and $Al(i\text{-}C_4H_9)_3$ (Al/Ti=1.2).[10] The catalyst was prepared under the refluxing of *n*-heptane.[11] The yield of the polymer was 24%. The polymer was extracted with hot benzene, using a modified Soxhlet apparatus for 15 hr., 32.5% of the total polymer being insoluble (softening pt. 170~210°C).

Molecular Weight. — The molecular weight of the polymers was determined cryoscopically in benzene.

Infrared Spectra.—The infrared spectra of the polymers were obtained in the state of polymer films when possible, in KBr disks, or sometimes in thin liquid films, using a Nihon Bunko DS 402G grating spectrophotometer.

Results and Discussion

The Infrared Spectra of Polypropenylbenzene.—There are two structural possibilities for polypropenylbenzene. One is structure I, resulting from the normal opening of the double bond, and the other is the rearranged structure, II, as has been suggested by Staudinger. In fact, the infrared spectra of polypropenylbenzene obtained show considerable differences in the 2850~2960 cm^{-1} region and in the 1450~1500 cm^{-1} region according to the polymerization conditions.

Figure 1 shows the infrared spectra of the methanol-insoluble part of two polymers obtained by using borontrifluoride as the catalyst at room temperature in toluene and borontrifluoride etherate, at 0°C in toluene. The latter have a very weak absorption of the CH_3 degenerated stretching mode at 2960 cm^{-1} and of the CH_3 symmetric stretching mode at 2870 cm^{-1}, showing a very small methyl-group content. On the other hand, the former BF_3-polymer showed much more intensive absorptions at these two wave numbers, indicating a higher methyl-group content. These differences in spectra correspond to the structural

change from I to II, and it was concluded that the BF_3-polymer is relatively rich in structure I and that the $BF_3 \cdot Et_2O$-polymer is rich in structure II. Thus, the authors hereafter will use the ratio of optical densities at 2960 and 2925 cm^{-1}, $D(CH_3/CH_2)$, as a measure of the methyl to the methylene ratio and, hence, of the ratio of structual units I to II in the polymer.* A definite numerical correlation between the values of $D(CH_3/CH_2)$ and the ratio of the structural units, I/II, has not yet been established. Also, we do not have a standard polymer specimen which has either the pure structural unit I or the pure II. However, there is one example which suggests the correspondence between these two values. Poly-α-methylstyrene of high molecular weight has one methyl group and one methylene group, the ratio of methyl and methylene being unity, and the observed value of $D(CH_3/CH_2)$ was 0.7. In the case of polypropenylbenzene, the value, unity, of the methyl/methylene ratio corresponds to the following structural ratio:

Thus, polypropenylbenzene with the $D(CH_3/CH_2)$ value of 0.7 would correspond to a polymer having a 1/3 rearranged structure II and 2/3 normal structure I, as has been indicated above.

There is one more possible structure of the polymer, the structural unit of which is that of polyallylbenzene. This possibility can not be excluded since the existence of an isomerization equilibrium has been reported between allylbenzene and propenylbenzene under some favorable conditions.[13] A comparison was made between the infrared spectra of the BF_3 etherate polymer and polyallylbenzene, which had been prepared with a Ziegler catalyst (Fig. 2). The spectra showed little difference in the CH stretching region, but there was a remarkable difference in the 1450~1495 cm^{-1} region. The band at 1495 cm^{-1} characteristic of polyallylbenzene is absent in the rearranged polymer. In addition, the residual propenylbenzene after the polymerization was found by gas chromatography to contain no detectable amount of allylbenzene. Therefore, the possibility of the existence of the polyallylbenzene structural unit in the present polymers could be excluded.

It should be noted that, when using $D(CH_3/CH_2)$ as a measure of the polymer structure, we did not take account of the structure of the polymer ends, which would have contributed considerably to the $D(CH_3/CH_2)$ values when the molecular weight was very low. Accordingly, the $D(CH_3/CH_2)$ of the methanol-soluble parts (oligomers) of the polymers is not listed in the present data.

A Comparison of Various Catalysts. — Two groups of catalysts were tested. One group is metal halides, which are considered to need water as a co-catalyst (Table I). The other group is boron trifluoride complexes with definite chemical compositions (Table II). Higher yields of total polymer were obtained with metal halide catalysts, especially with such strong Friedel-Crafts-type catalysts as boron fluoride, aluminum bromide and titanium tetrachloride, than with boronfluoride complexes. Boron fluoride complexes exhibited moderate catalytic action. Some metal halides gave higher yields of polymer at −78°C than at 0°C, while all the boronfluoride complexes showed a better yield at 0°C than at −78°C.

Fractions of the methanol-isoluble part are

* The ratio of optical densities at 2960/2850 cm^{-1} is usually used to estimate the ratio of methyl and methylene groups.[12] In our cases, however, the absorption at 2850 cm^{-1} is invariably very weak and is considered unsuitable for the measurement.

generally smaller in amount with BF_3 complexes than with metal halides. There is a sharp contrast between the two groups of catalysts in the effect of the polymerization temperature on the molecular weights of the resulting polymers. Metal halides yielded a higher fraction of the insoluble polymer at −78°C than at 0°C, while the BF_3-complexes showed reverse results.

Among all the catalysts tested, the milder catalysts generally gave polymers with the smaller value of (CH_3/CH_2) and, hence, the larger proportion of rearrangement during polymerization.

It is interesting to note here that there were observed some unusual absorptions in the infrared spectra of the polymers obtained with the borontrifluoride complexes (Table II, the last column). These absorptions are considered to come from the terminal groups of the polymer, probably being incorporated into the polymers by a termination reaction with

TABLE III. EFFECT OF TEMPERATURE ON THE POLYMERIZATION OF PROPENYLBENZENE WITH BF_3 ETHERATE

"gegen" ions or initiator molecules.* Another unusual infrared band to be noted is the one observed around 800 cm^{-1} (which is not shown here) in polymers obtained with borontrifluoride in *n*-heptane at 0°C as well as at −78°C. This band may possibly be assigned to the occurrence of *p*-disubstituted benzene which originates from the *p*-substitution of the benzene ring by the growing cation in a termination reaction or during the propagation step. This assignment needs further experimental verification, however.

The Effect of the Polymerization Temperature. —The polymerization ofp ropenylbenzene with BF_3 etherate was carried out in toluene at temperatures from −78 to 40°C (Table III and Fig. 3). The total yields polymer increased with a rise in the temperature. However, the methanol-insoluble part showed a maximum at about 0°C and rapidly decreased thereafter while at the same time the yield of the methanol-soluble low polymer fractions

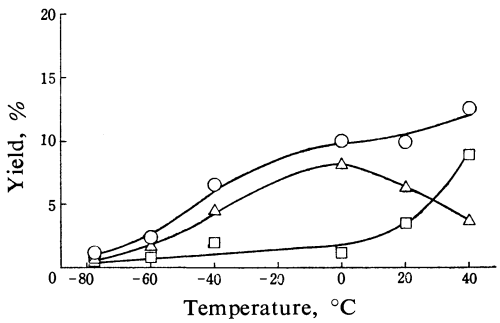

Fig. 3. Effect of temperature on polymerization of propenylbenzene with BF_3 etherate.
○ Total polymer
△ The methanol-insoluble part
□ The methanol-soluble part

* In a preliminary experiment, there was observed less than a first-order dependence of the polymerization rate on the initiator concentration, especially at high initiator concentrations. In addition, the molecular weight was found to decrease with increasing initiator concentrations. These facts appear to suggest qualitatively the existence of a termination or a transfer reaction with initiator molecules.

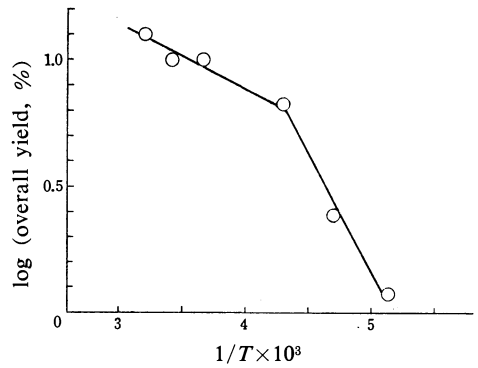

Fig. 4. Effect of polymerization temperature on overall yield of polypropenylbenzene (BF_3Et_2O catalyst).

increased rapidly above 0°C. Correspondingly, the Arrhenius plot of the total yield (Fig. 4) showed a break, giving an activation energy of 1.2 kcal./mol. at the high temperature region and 4.3 kcal./mol. at the low temperature region. The phenomenon seems to indicate that there is some change in the mechanisms of polymerization processes between below and above 0°C.

Although the temperature of the polymerization had a marked effect on the rate of polymerization as well as on the molecular weight, it had no appreciable effect on $D(CH_3/CH_2)$ (Fig. 5). Hence, it is suggested that the activation energy of the normal propagation is nearly equal to that of the rearrangement propagation.

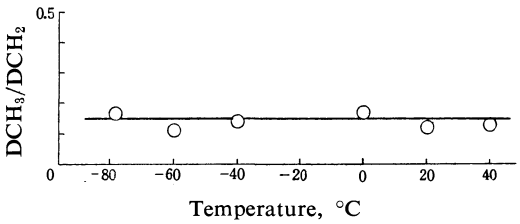

Fig. 5. Effect of polymerization temperature on the chemical structure of polypropenylbenzene (BF_3Et_2O catalyst).

TABLE IV. EFFECT OF DIELECTRIC CONSTANTS OF SOLVENTS ON THE POLYMERIZATION OF PROPENYLBENZENE WITH BF_3 ETHERATE

Monomer (trans 74%) 1 ml.; solvent 4 ml.;
catalyst/monomer mole ratio=1/20; 4 hr. at 0°C

Solvent	Dielectric constant	Yield, %	Methanol-insoluble part			
			Yield, %	$D(CH_3/CH_2)$	Soft. pt., °C	Mol. wt.
CCl_4	2.3	11.5	6.1	0.36	159~167	—
$C_6H_5CH_3$	2.4	9.9	8.1	0.17	155~166	1600
$CHCl_3$	5.2	9.2	5.2	0.33	167~177	2100

$(CH_2Cl)_2$	10.7	13.6	8.4	0.66	153~164	1600

The Effect of the Solvents. — The influence of the dielectric constants of the solvents was studied at 0°C using BF_3-etherate as a catalyst, as is shown in Table IV. The total yields of polymer and those of the methanol-insoluble part were observed to increase slightly with the increasing polarity of the solvents (Fig. 6). The $D(CH_3/CH_2)$ value increased remarkably, showing that the rearrangement in the propagation became unfavorable with the increasing polarity of the solvent (Fig. 7).

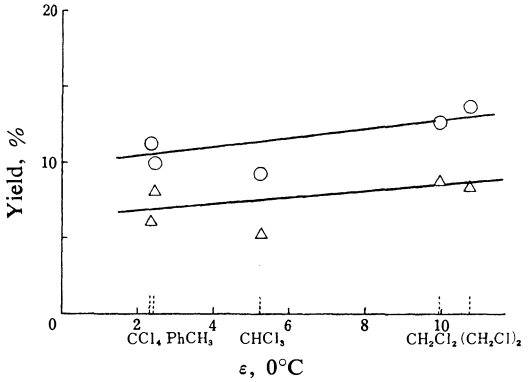

Fig. 6. Effect of dielectric constants of solvents on overall yield of polypropenylbenzene (BF_3Et_2O catalyst).
○ Total polymer
△ The methanol-soluble part

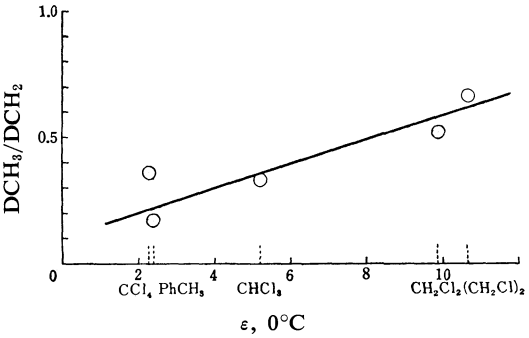

Fig. 7. Effect of dielectric constants of solvents on chemical structure of polypropenylbenzene (BF_3Et_2O catalyst).

The molecular weight of the resulting polymer, on the other hand, appears to decrease with the increasing dielectric constants of the solvents, except for the case of the toluene solvent, where a molecular termination on the aromatic ring may play some role. The decrease of the molecular weight with the increasing polarity of the solvent may be explained as due to a termination reaction which is favored by the polar medium.

Discussion of the Reaction Mechanism.—It has clearly been shown that a variety of "gegen" ions influenced the polymerization of propenylbenzene, i.e., the structure of the resulting polymer as well as the overall rate and the molecular weight. The facts may, as a whole, be interpreted in terms of ion pairs of growing ends. The rearrangement polymerization was found to be favored by mild initiators. Among the catalysts examined, BF_3-etherate showed the better results for the rearrangement polymerization.

Propagation.—The characteristic features of a propagation reaction using BF_3-etherate as a catalyst may be summarized as follows: (i) $D(CH_3/CH_2)$ does not change with a change in the temperature of polymerization, indicating that the activation energy for the usual propagation is nearly equal to that of the rearrangement. (ii) $D(CH_3/CH_2)$ increased markedly with an increase in the dielectric constants of the solvents; in other words, the rearrangement propagation is favored in a less-ionizing medium. This suggests that the growing species may be more intimate ion pairs in the rearrangement propagation than in the usual propagation. Propagation with the usual opening of double bonds (I) will proceed according to Scheme 1, the resonance stabilization of the α-alkylbenzyl cation being the determining factor for the attacking position of the growing cation. This reaction does not seem to need the strong cooperation of "gegen" ions and, hence, will be favored by highly-ionizing solvents. On the other hand, for the rearrangement polymerization two alternative mechanisms, 2 and 3, have to

be considered. Mechanism 2 involves two unfavorable steps, i. e., the prevalent formation of the more unstable secondary carbonium ion instead of the more stable α-alkylbenzyl cation, and the subsequent hydrogen transfer from primary to secondary carbon, which is also energetically unfavorable. Mechanism 3 seems more plausible for the rearrangement propagation. The methyl hydrogen of propenylbenzene would have an acidic nature. The "gegen" ion of the growing ion pair will assist in loosening the proton from the methyl group, and at the same time the growing carbonium ion will make an electrophillic attack on the methyl carbon. The proton will then be transfered to the adjacent

$$P^{\oplus} + C_6H_5\text{-}CH{=}CH\text{-}CH_3 \rightarrow P\text{-}\underset{\displaystyle Ph}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{CH}}}}\text{-}CH^{\oplus}$$

$$\rightarrow \text{Propagation} \qquad (1)$$

$$P^{\oplus} + C_6H_5\text{-}CH{=}CH\text{-}CH_3 \rightarrow P\text{-}\underset{\displaystyle Ph}{\underset{|}{CH}}\text{-}CH^{\oplus}\text{-}CH_3$$

$$\rightarrow P\text{-}\underset{\displaystyle Ph}{\underset{|}{CH}}\text{-}CH_2\text{-}CH_2^{\oplus} \rightarrow \text{Propagation} \qquad (2)$$

$$C_6H_5\text{-}CH{=}CH\text{-}CH_3 + P^{\oplus}G^{\ominus} \rightarrow \begin{array}{c} G^{\ominus} \quad P^{\oplus} \\ \diagdown\ \ \downarrow \quad \diagup \\ H \quad CH_2 \\ \downarrow \quad \diagup \\ C_6H_5\text{-}CH{=}CH \end{array}$$

$$\rightarrow C_6H_5\text{-}\underset{\displaystyle G^{\ominus}}{\overset{\displaystyle \oplus}{CH}}\text{-}CH_2\text{-}CH_2\text{-}P \rightarrow \text{Propagation} \qquad (3)$$

double bond. Thus, the growing ion pair cooperates in the push-pull mechanism, and so highly-ionizing solvents will retard the reaction, making the contribution of the rearrangement propagation relatively smaller than the usual propagation in polar media.

Termination.—In the polymers obtained using boron trifluoride complexes as catalysts, some infrared absorption bands characteristic of the initiator fragments have been observed (Table II). This appears to indicate that the termination reaction with "gegen" ions (4) (self termination) or with an initiator (5) seems to play an important role.

$$P\sim\underset{\displaystyle Ph}{\underset{|}{CH^{\oplus}}}\ BF_3\cdot OEt^{\ominus} \rightarrow P\sim\underset{\displaystyle Ph}{\underset{|}{CH}}\text{-}OEt + BF_3 \qquad (4)$$

$$P\sim\underset{\displaystyle Ph}{\underset{|}{CH^{\oplus}}}\ BF_3\cdot OEt^{\ominus} + BF_3\cdot OEt_2$$

$$\rightarrow \text{dead polymer}-OC_2H_5 \qquad (5)$$

Reaction 5 may actually be considered to be a reaction between the growing ion pair and the ionized initiator molecule $BF_3\cdot OEt^{\ominus}$ $Et^{\oplus}$. The concentrations of the ion pairs are usually fairly small compared to the concentration of total initiators and will increase in polar media. Thus, reaction 5 might be accelerated in a polar solvent, resulting in a decrease in the molecular weight of the polymer (Table IV.) Self-termination reaction 4 is a reaction between opposite-charged ions leading to neutral compounds, and so will be accelerated in non-polar media. The Arrhenius plot, as we have observed, of the polymerization of propenylbenzene by boron-trifluoride etherate (Fig. 4) is composed of two straight lines, with a break at about 0°C. The activation energy above 0°C is lower (1.2 kcal./mol.) than that below 0°C (4.3 kcal./mol.). On the other hand, the activation energies for two kinds of propagation reactions (usual and rearrangement) are shown to be nearly equal over the temperature range examined (Fig. 5). Therefore, if we assume only one kind of initiation reaction, we would have to consider at least two kinds of termination reaction, with different activation energies. The termination reaction with a higher activation energy should be predominant at higher temperatures, thus resulting in a smaller overall activation energy at higher temperatures. The authors do not have any evidence at present to show whether these two kinds of termination reactions correspond to the termination schema 4, 5 and/or to others. At any rate, this termination reaction may be at least partly responsible for the existence of a maximum in the yield of the methanol-insoluble polymer, that is, a rapid decrease in the molecular weight of the total polymer at high temperatures (above 0°C). Chain transfer processes are also to be considered in interpreting the decrease in the molecular weight in polymerizations at high temperatures. Kinetic studies are being undertaken in this respect.

Summary

1) Propenylbenzene has been found to polymerize by a cationic mechanism in two ways. Both the structure $-(CHPh\text{-}CH(CH_3))_n-$ (I) resulting from the usual opening of the double bond and the structure $-(CHPh\text{-}CH_2\text{-}CH_2)-$ (II) resulting from the rearrangement along the backbone chain of the resultant polymer occur.

2) The relative ratio of structures I/II has been pursued using the ratio of infrared absorptions, CH_3/CH_2, as a measure.

3) The rearrangement polymerization is generally preferred by mild catalysts, such as BF_3-etherate, while the polymerization to I has been found to predominate in polymerization with BF_3.

4) On the basis of the observed effect of reaction variables on the rate of polymerization and on the I/II ratio, a propagation mechanism has been proposed which includes the "gegen" ion attack on the methyl hydrogen of propenylbenzene.

5) Termination reaction by a "gegen" ion or an initiator has been shown to be important in polymerization catalyzed by BF_3-complexes.

Added in Proof

During further experiments, the authors have found that the propenylbenzene used in the experiments contains about 5% unknown impurity. They can not at present exclude the possibility that the rearrangement under consideration would have been more or less modified by the existence of this impurity. Experiments for the clarification of this point is in progress.

On the Synthesis of a Hemopeptide

By Sumiko INOUYE, Shumpei SAKAKIBARA and Shiro AKABORI

(Received December 7, 1963)

Cytochrome c is an enzyme which contains one mole of heme as a prosthetic group. The protein part is joined to the heme by two thioether linkages,[1] involving the sulfur of two cysteine residues, as is shown in Fig. 1. The imidazolyl group of the histidine residue is also linked to the iron of heme to form a hemochromogen.[2-4] The heme-containing fragment (hemopeptide) of horse-heart cytochrome c was first isolated by Tsou,[5,6] while

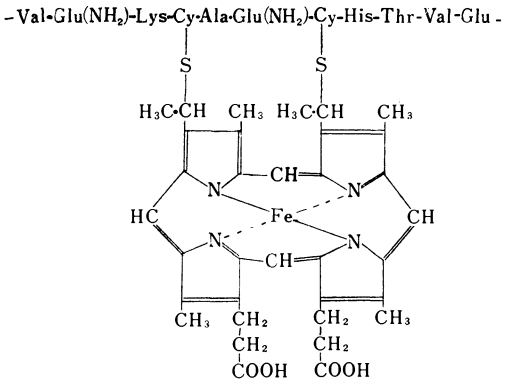

Fig. 1. Hemopeptide obtained from bovine heart cytochrome c by peptic digestion.

the structure shown in Fig. 1 was determined by Tuppy et al.[7-9] After the complete hydrolysis of cytochrome c, there remains a kind of porphyrin which is the so-called "porphyrin c" and which has been considered to be an addition compound of protoporphyrin with two cysteines, as in the case of cytochrome c. More recently, the amino acid sequences of many different hemopeptides which have been isolated from the cytochrome c's of members of various species have been elucidated (Table I). Although the amino acid sequences of those hemopeptides are usually different from one another, they are represented by the general structure -CyS-X-Y-CyS-His-, where X and Y represent two other amino acid residues. It is very interesting that the hemopeptide obtained from beef-heart cytohrome c possesses a much stronger peroxidase-like activity than that of the parent enzyme.[10]

The present work, which adopts a synthetic approach, is on the relationship between the structure and the function of the hemopeptide. Two simplified peptides, cysteinyl-glycyl-glycyl-cysteine and cysteinyl-glycyl-glycyl-cysteinyl-histidine, were selected as the peptide moieties for the synthesis of model hemopeptide.

The Synthesis of Peptide.—Carbobenzoxy-*S*-benzyl-L-cysteinyl-glycyl-glycyl-*S*-benzyl-L-cysteinyl-L-histidine benzylester (V) was synthesized as shown in Fig. 2. First, carbobenzoxy-*S*-benzyl-L-cysteinyl-glycyl-glycine ethylester was prepared according to the procedure of Hooper et al.[11] Although, in their paper, ethyl chloroformate was used for the preparation as a mixed anhydride-reagent, it has been found that the use of isovaleroyl chloride, instead of ethyl chloroformate, afforded a product with a higher melting point and a larger optical rotation than that which they reported. The improved procedure favored the succeeding reaction steps, and it was confirmed that the final melting point and the optical rotation of product III were much higher than those previously reported. The carbobenzoxy-tetrapeptide was successfully coupled with histidine benzyl ester by the azide procedure. Then, the carbobenzoxy-tetra- and penta-peptide benzylesters (III and VI respectively) were converted to free peptides (IV and VII) by treatment with sodium in liquid ammonia; they were then uesd in the preparation of the two hemopeptides.

The Preparation of Hemopeptide. — Theorell first demonstrated[1] that when protoporphyrin IX and cysteine were heated in mineral acid, a porphyrinc like compound was formed. Later, Zeile and Meyer[12] developed a practical way of preparing the same compound using hydrobrominated protoporphyrin as an intermediate. This was fused with excess cysteine hydrochloride without any solvent. Recently, Neilands and Tuppy[13] have published an improved method for the purification

of the product, producing a crystallizable porphyrin c.

No good procedure has as yet been published for the condensation of porphyrin with peptide, which contains two cysteine residues in the molecule. For the present work, the procedures reported for porphyrin c formation could not be used, because they require excess peptide at a high temperature, and this condition may cause a partial decomposition of the peptides. For the addition reaction of free cysteinyl peptide with hydrobrominated protoporphyrin, various alkaline conditions were tested at room temperature. Aqueous solutions of sodium hydroxide, carbonate or bicarbonate caused a partial decomposistion of sulfhydryl groups before the addition reaction was complete. Liquid ammonia, in which the free peptides were generated by sodium hydrogenolysis, was also not suitable for the reaction, because aminolysis by the bromide was faster than the formation of thioether linkages. Finally, the direct addition of protoheme to free cysteinyl peptide in liquid ammonia was tested, whereupon some kind of addition product was obtained. Although the mode of the formation of the complex between peptide and heme is still unknown, only the histidine containing pentapeptide afforded a reasonable amount of product.*

The crude product synthesized from peptide VII was dialyzed against deionized water to remove the unreacted peptide, and then it was subjected to counter-current distribution in a mixture of chloroform, methanol and 0.1 N hydrochloric acid (2 : 2 : 1). This procedure gave two brown fractions, as is shown in Fig. 3. The distribution coefficient of band I, shown in Fig. 3, agreed with that of hemin, and no amino acid was detected by the paper chromatography of a hydrolyzate of this fraction. On the other hand, glycine, histidine and a small amount of cystine were detected in a hydrolyzate of band II.

When the apparent molecular weight of the synthetic hemopeptide was calculated separately from the iron and glycine contents, values of 1030 and 1120 were obtained respectively. Theses values are in good agreement with the theoretical value of 1127.

No sulfhydryl group was detected by the Folin method[14] in the purified hemopeptide. Disulfide bonds were estimated by polarography, using the diffusion current at the half-wave potential in a range proportional to the concentration of cystine (Fig. 4), and it was concluded that the hemopeptide still contained three per cent of the total cysteine residues as disulfide bonds.

The Properties of Hemopeptide.—The synthetic hemopeptide was soluble in a water-methanol or water-acetone mixture (1 : 2 v/v), and in water at alkaline pH values. It was insoluble in chloroform, ether and water at neutrality. Although the infrared spectrum

* The authors wish to thank to Dr. Junzo Noguchi of Hokkaido University for his helpful discussion and advice concerning the coupling method.

resembled that of natural hemopeptide from beef-heart cytochrome c by peptic degradation[15] (abbreviated in this paper as hemopeptide N), the visible absorption spectrum of the synthetic compound was rather more similar to that of hemin than to that of hemopeptide N, as Figs. 5 and 6 show.

The peroxidative activities of hemopeptide N, synthetic hemopeptide, hemin and ferric chloride were compared by Shibata's method, using leuco malachite green as a hydrogen doner. As is shown in Fig. 7, the color of malachite green appeared after the induction period. In the case of ferric ion, no development of color was observed, even after 15 hr. This indicates that the catalytic activity of the synthetic hemopeptide was about 100 times as strong as that of hemin, but it was still inferior to that of natural hemopeptide N (Table II). This could be attributed to differences in the amino acid sequences and/or in the modes of the combination of the peptide and hemin.

After most of this work had been done, Sano[16,17] reported the interesting fact that freshly-prepared protoporphyrinogen combines with various sulfhydryl compounds more readily under mild conditions, and it was demonstrated that a porphyrin c-like compound is readily prepared in this manner by combination with cysteine. This procedure should be quite superior to any previous methods so far published for hemopeptide formation. Studies along these lines are in progress.

TABLE II. REACTION VELOCITIES AND INDUCTION PERIODS OF HEMIN, FERRIC ION AND HEMOPEPTIDES

Material	K*	Induction period, min.
Hemopeptide N	23.9	0.25
Synthetic hemopeptide	1.1	3
Hemin	0.009	23
Ferric ion	—	—

* Moles of malachite grean per mole of sample per min. These values were calculated after the respective induction periods.

Experimental*

Carbobenzoxy-*S*-benzyl-L-cysteinyl-glycyl-glycine Ethyl Ester (I).—Isovaleroyl chloride (6 g.; 0.05 mol.) was slowly stirred into a solution of *S*-benzyl-*N*-carbobenzoxy-L-cysteine (17.3 g.; 0.05 mol.) and triethylamine (6.9 ml.) in chloroform (175 ml.) at −5°C. After 1.5 hr., a mixture of glycyl-glycine ethyl ester hydrochloride (11.8 g.; 0.06 mol) and triethylamine (8.2 ml.) in chloroform (125 ml.) was stirred into the reaction mixture at −5°, and then the mixture was stored overnight in a refrigerator. The solution was washed successively with dilute hydrochloric acid, water, a sodium bicarbonate solution, and water, and then dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure, and the residual oil was redissolved in ethyl acetate (90 ml.). The slow addition of ethyl ether (150 ml.) to this solution resulted in the precipitation of a crystalline product (21 g.). The recrystallization of this material from ethyl acetate gave long needles; m. p. 118°C, yield 74% (18 g.). Hooper et al.[11] reported a m. p. of 114~115°C.

Carbobenzoxy-*S*-benzyl-L-cysteinyl-glycyl-glycine Hydrazide (II).—Hydrazine hydrate (7 ml.; 0.11 mol.) was added to a solution of I (17.5 g.; 0.036 mol.) in ethanol (250 ml.), and the solution was kept overnight at room temperature. The precipitate which formed was collected by filtration. The product was recrystallized from ethanol (200 ml.) and water (50 ml.) as needles; m. p. 173°C, yield 92% (15.7 g.). Hooper et al. reported a m. p. of 164°C.

Carbobenzoxy-*S*-benzyl-L-cysteinyl-glycyl-glycyl-*S*-benzyl-L-cysteine Benzyl Ester (III).—Triethylamine (7 ml.) was added to a suspension of *S*-benzyl-L-cysteine benzyl ester *p*-toluenesulfonate (23.7 g:, 0.05 mol.) in a mixture of ethyl ether (250 ml.) and water (40 ml.). The free benzyl ester which formed was extracted thoroughly with ethyl ether, and the ether extract was dried over anhydrous sodium sulfate. A solution of II (23.7 g.; 0.05 mol.) in a mixture of acetic acid (220 ml.), 2N hydrochloric acid (17 ml.) and water (220 ml.) was treated with sodium nitrite (3.5 g.; 0.05 mol.) at −5°C. The azide formed was extracted three times with cold ethyl ether (total: 600 ml.). The combined ethyl ether layer was washed with cold water 100 ml. and dried over anhydrous sodium sulfate at −5°C. The dry ether solution was added to the solution of *S*-benzyl-cysteine benzyl ester prepared as described above, and the mixture was stored overnight in a refrigerator (0~5°C). The precipitate which formed was collected by filtration and recrystallized from ethanol (500 ml.) as needles; yield 83% (3.17 g.); m. p. 178~179°C; $[\alpha]_D^{15}$ −40.7° (*c* 2.73 in pyridine). Hooper et al.[11] reported a m. p. of 175°C and $[\alpha]_D^{20}$ −29.6° in pyridine.

Found: C, 62.81; H, 5.74; N, 7.57; S, 8.40. Calcd. for $C_{39}H_{42}O_7N_4S_2$ C, 63.05; H, 5.70; N, 7.54; S, 8.63%.

Carbobenzoxy-*S*-benzyl-L-cysteinyl-glycyl-glycyl-*S*-benzyl-L-cysteine Hydrazide (V).—A solution of III (10 g.; 13.5 mol.) in a mixture of dioxan (150 ml.) and ethanol (50 ml.) was treated with hydrazine hydrate (30 ml.; 0.5 mol.). After 24hr. at room temperature, the solvent was removed at 30°C under reduced pressure, and the residue was crystallized by adding ethanol (160 ml.). The product was recrystallized from ethanol (160 ml.) and water (40 ml.) as needles; yield 77% (7.1 g.); m. p. 162°C.

Found: C, 57.28; H, 5.82; N, 12.21. Calcd. for $C_{32}H_{38}O_6N_6S_2$ C, 57.64; H, 5.74; N, 12.60%.

Carbobenzoxy-*S*-benzyl-L-cysteinyl-glycyl-glycyl-*S*-benzyl-L-cysteinyl-L-histidine Benzyl Ester (VI).—Substance V (5 g.; 7.5 mmol.) was dissolved in a mixture of acetic acid (40 ml.) and water (40 ml.), and then 2N hydrochloric acid (7.5 ml.) was added to the solution. The mixture was carefully treated with sodium nitrite (0.52 g.; 7.5 mmol.) at −5°C, and the azide which formed was extracted with cold chloroform total: 300 ml.). The azide solution was washed with ice water, and then dried over sodium sulfate at −5°C. The dry chloroform solution was added to a cold solution of L-histidine benzyl ester di-*p*-toluenesulfonate (6.7 g.; 8.8 mmol.) and triethylamine (3.1 ml.) in chloroform (50 ml.), and the reaction mixture was allowed to stand overnight in a refrigarator. It was then washed with water and a sodium bicarbonate solution. During this procedure, some products appeared as

* The melting points given here are uncorrected.

crystals. Petroleum ether (b. p. 60~80°C) was added to the mixture to complete the precipiation, and the preduct was collected by filtration and recryllized from ethanol (24 ml.) and water (6 ml.); yield 60% (4 g.); m. p. 178°C; $[\alpha]_D^{16}$ −54.3° (*c* 0.98 in dioxan).

Found: C, 61.25; H, 5.59; N, 10.96; S, 7.65. Calcd. for $C_{45}H_{49}O_8N_7S_2$ C, 61.41; H, 5.61; N, 11.14; S, 7.29%.

Hemopeptide.—A solution of substance VI (880 mg.; 1 mmol.) in liquid ammonia (500 ml.) was treated wtih approximately 200 mg. of sodium, in portions, until a permanent blue color appeared in the solution. Then 70 mg. more sodium and protohemin (652 mg.; 1 mmol.) were vigorously stirred into the reaction mixture. After the addition of a small amount of ammonium chloride to neutralize the excess sodium, the reaction mixture was stirred for 4hr. and then stored overnight in a dry ice bath. After the evaporation of the solvent, the product was dried under reduced pressure over sulfuric acid in a desiccaior. The residue was dissolved in water (50 ml.), and the aqueous solution was then dialyzed against running deionized water for 3 days. The lyophilization of the solution gave the sodium salt of the crude product as a brown-red prowder (yield, 930 mg.). The product (400 mg.). was subjected to counter-current distribution in a solvent system of chloroform, methanol and 0.1 N hydrochloric acid (2 : 2 : 1) (Fig. 3.). Band II (tubes 61~70) was concentrated to about 50 ml. at 40°C under reduced pressure. The residual solution was adjusted to pH 9 with a dilute aqueous solution of sodium hydroxide and then dialyzed through cellophane tubing against running deionized water. The final solution was lyophilized to yield the sodium salt of the hemopeptide; yield 163 mg.; m. p. above 260°C. For analysis, the hemopeptide (30 mg.) was dissolved in deionized water, and the solution was acidified with dilute hydrochloric acid to about pH 2. The solution was dialyzed against running deionized water, and the precipitates which formed were collected by centrifugation and dried in vacuo at 80°C.

Found: C, 49.91; H, 4.97; N, 13.66; S+Cl, 9.54; Fe, 5.42. Calcd. for $C_{50}H_{56}O_{10}N_{11}S_2Fe \cdot 2HCl$: C, 51.59; H, 5.02; N, 13.24; S+Cl, 11.60; Fe, 4.80%. Mol. wt. Found: 1030*; 1160**. Calcd.: 1164.

Peroxidative Activity.—The peroxidative activities of the synthetic hemopeptide and other substances were assayed, using leuco malachite green as a hydrogen donor, by the method of Shibata[19] as follows: The reaction system was composed of 2.0 ml. of a 0.2 M phosphate-hydrochloric acid buffer (pH 3.1), 8.82×10^{-2} mol. hydrogen peroxide, 6.77×10^{-3} mol. leuco malachite green and 1.485×10^{-5} mol. synthetic hemopeptide or other substances in a total volume of 3.5 ml. of water. The reaction was started by adding the hydrogenperoxide, and incubation was carried out at 15°C. The activity was estimated spectrophotometrically by measuring the increase in optical density at 620 mμ due to the oxidation of leuco malachite green to malachite green. The activity was expressed as the amount of malachite green formed per minute after the induction period.

Summary

Carbobenzoxy-*S*-benzyl-L-cysteinyl-glycyl-glycyl-*S*-benzyl-L-cysteinyl-L-histidine benzylester has been synthesized, and then it has been hydrogenated to the free peptide by treatment with sodium in liquid ammonia. The free peptide has been coupled with protohemin in the liquid ammonia to form a hemopeptide, which has then been purified by counter-current distribution. The visible and infrared absorption spectra of the product have been compared with those of natural hemopeptide, which was obtained from beef-heart cytochrome c by peptic degradation. The peroxidative activity of the synthetic hemopeptide is about 100 times as strong as that of hemin, but it is inferior to that of natural hemopeptide.

The Electrokinetic Potential of Titanium Dioxide

By Tetsuo MORIMOTO and Masashi SAKAMOTO

(Received December 12, 1963)

Recently attention has been drawn by many investigators to the behavior of hydroxyl groups on the surface of insoluble metal oxides, especially from the viewpoints of the adsorption and the catalytic center of the solid surface.

The existence of hydroxyl groups on the surface of insoluble oxides has been demonstrated by the determination of the water content of powders,[1] by studies of wetting heat[2] and, more directly, by the measurement of infrared absorption spectra.[3-5] It has also been reported that a solid retains a small amount of water even after it has been evacuated at a high temperature.[6]

If an insoluble metal oxide is equilibrated with water, a good many hydroxyl groups will be produced on the solid surface; this formation has a serious effect on the physico-chemical properties of the surface. For this reason, it is of special interest to ascertain the dissociation property of surface hydroxyl groups. In the present work, therefore, the dependences of the electrokinetic potential of titanium dioxide in water on the temperature of the pretreatment and on the concentration of added electrolyte in water have been investigated, in connection with the behavior of surface hydroxyl groups on the solid.

Since the surface properties of a solid, such as the surface charge, are usually affected by the presence of impurities, the effect of sulfate groups contaminating the sample on the electrokinetic potential has also been investigated in detail.

Experimental

Materials.—Titanium dioxide was prepared by the hydrolysis of titanium sulfate*. The raw material thus obtained was contaminated with sulfate groups, the amount of which was 54 mg. SO_4/g. of the sample. X-Ray tests showed the raw material to be anatase in form. The sulfate contained in the raw material was removed by treatment with a definite amount of ammonia water. The conditions of the treatment and the amount of sulfate remaining are shown in Table I. After the raw material had been treated with ammonia water for two hours at 70°C, the sample was thoroughly washed with water. Three kinds of samples thus prepared were dried and calcined in a platinum crucible placed in an electric oven held at a given temperature.

TABLE I. CONDITIONS FOR PREPARING SAMPLES AND THE RESULTS OF THEIR ANALYSIS

	Amouut of ammonia water used	Sulfate remained (mg./g. TiO_2)
TiO_2-0	0	54
TiO_2-1.1	1.1 equivalent of sulfate	12
TiO_2-18	18 equivalent of sulfate	0

Electrokinetic Measurement. — The streaming potential method was used for the determination of the electrokinetic potential (ζ-potential). Both the techniques of the measurement of the streaming potential and the method of calculation used to obtain the ζ-potential were the same as have been reported previously.[7]

Results and Discussion

The Electrokinetic Potential of Titanium Dioxide in Water.—The ζ-potentials of titanium dioxide in water are shown in Fig. 1. The ζ-potential vs. the pretreatment temperature curves of three samples agree almost entirely with one another. In the cases of the samples TiO_2-0 and TiO_2-1.1, especially, when treated at 300°C and 500°C, the streaming potentials showed fairly high values at the beginning of the measurement, but thereafter they decreased continuously for many hours, accompanied with a decrease in the electrical conductance. On the other hand, the potential measured on the TiO_2-18, sample which contains no sulfate, remained constant for many hours. Consequently, the decreases in the streaming potentical and electrical conductance in the case of the samples contaminated with sulfate are possibly due to the decontamination of the samples in the course of the streaming operation.

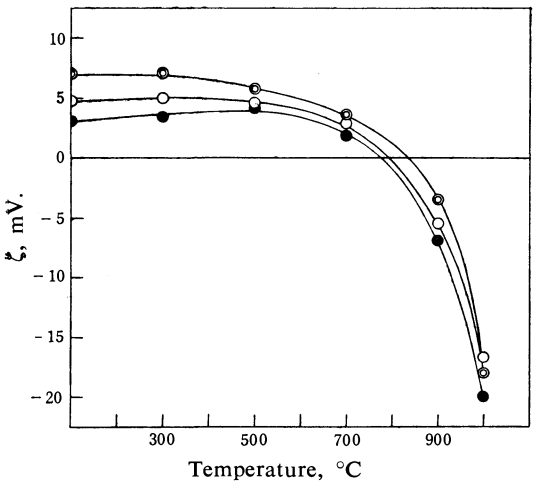

Fig. 1. Dependence of the ζ-potential of TiO_2 on the pretreatment on temperature.
◎ TiO_2-0, ○ TiO_2-1.1, ● TiO_2-18

The results shown in Fig. 1 were obtained after the streaming operation had continued for a long time. It is, therefore, obvious that the values of the streaming potentials on contaminated samples approach those of pure samples when washed with streaming water. Thus, the dependence of the ζ-potential of the TiO_2-18 sample on the pretreatment temperature is considered to be characteristic of titanium dioxide. It may, therefore, be seen from Fig. 1 that titanium dioxide is positively charged in water when it is treated at lower temperatures, whereas it is negatively charged when treated at 1000°C. The inversion of the sign of the surface charge occurs when the sample is treated at about 800°C, a figure which corresponds to the temperature of the transition of anatase to rutile. X-Ray tests on these samples showed that the samples heated at temperatures lower than 700°C are anatase in form, whereas those heated at 1000°C are rutile in form. In order to verify these results, the ζ-potential of rutile powder obtained by the pulverization of the single crystal was measured in water and found to be −36 mV. These results convinced us that the charge of anatase is positive and that of rutile is negative. Although several authors have studied the dependence of the ζ-potential of metal oxides upon their pretreatment temperature,[8-10] no such clearly-established relation has ever been found between the signs of the ζ-potential and the crystal modifications.

When the oxide surface is equilibrated with water, the surface hydroxyl groups will be formed by surface hydration. Further, these hydroxyl groups may be dissociated in two ways:

$$\equiv TiOH \rightarrow \equiv Ti^+ + OH^- \quad (1)$$

$$\equiv TiOH \rightarrow \equiv TiO^- + H^+ \quad (2)$$

If the dissociation of the surface hydroxyl groups occurs according to Eq. 1, it will make the surface positive and basic at the same time. On the contrary, if the dissociation proceeds as in Eq. 2, the surface will become negative and acidic. In our previous study,[11] the surface acidity was observed on the sample of TiO_2-18, which contains no sulfate. Methyl red used as a dyestuff was dissolved in isooctane, a nonpolar solvent. After the dye solution had been shaken with titanium dioxide, the color of the adsorbed dye molecules was observed. When the treatment temperature rises, the color changes from yellow to orange and finally to red, indicating that the surface acidity changes from a basic to an acidic property with an increase in the pretreatment temperature. This proves that the surface hydroxyl groups on titanium dioxide are dissociated following either Eq. 1 or Eq. 2, according to the modifications of the substrate crystal of titanium dioxide.

The crystallographic data of anatase and rutile[12] show that in both crystal forms one titanium atom is surrounded by six oxygen atoms, which are situated on the tops of an octahedron. The bond distances of Ti–O and O–O in anatase and rutile are listed in Table II.[13] It has been reported that the distances

Table II. Bond distances in TiO_2, Å

	Anatase	Rutile
4 Ti–O	1.937	1.946
2 Ti–O	1.964	1.984
O–O	2.802	2.779
O–O	2.446	2.526
O–O	3.040	

of O–O bonds in basic metal hydroxide crystals are longer than about 3.00Å, while in acidic crystals they are less than 2.70 Å.[14] If we assume that the O–O distances remain almost unchanged when the surface of titanium dioxide is hydrated to form surface hydroxyl

groups, it may be expected that the surface of rutile is acidic and that of anatase is basic. From this point of view, the present results lead us to postulate that, among the three kinds of O–O bonds of anatase, the longer ones are exposed on its surface to a larger extent.

Electrokinetic Potential in an Electrolyte Solution.—The effect of elctrolytes on the ζ-potential of titanium dioxide has been investigated on the TiO_2-18 sample, which contains no sulfate. The results obtained are shown in Figs. 2—6. Barium chloride seriously affects the ζ-potential of the samples treated at various temperatures (Fig. 2). In this case, the ζ-potential increases with the increasing concentration of barium chloride, independently of the signs of the surface charge of titanium dioxide in water. This indicates that the effect of barium ions is more pronounced than that of chloride ions. The effect of barium ions is greater on the negatively-charged surface than on the positivery-charged surface, and the inversion of the negative charge occurs at a higher concentration. On the other hand, the effect of potassium chloride is much less than that of barium chloride, indicating that the adsorption forces of potassium ions and chloride ions are comparable (Fig. 3). Although at lower concentrations of potassium chloride, the oppositely-charged ions adsorb on the surface of titanium dioxide, at higher

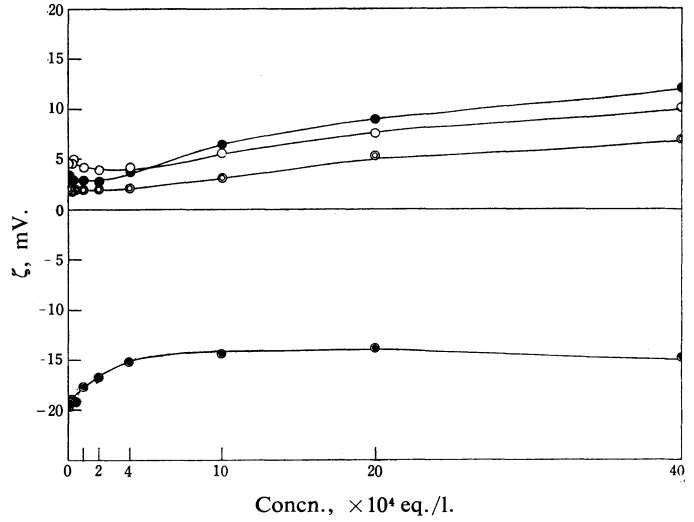

Fig. 4. Effect of hydrochloric acid on the ζ-potential of TiO_2 treated at ● 300°C, ○ 500°C, ◎ 700°C, ◉ 1000°C.

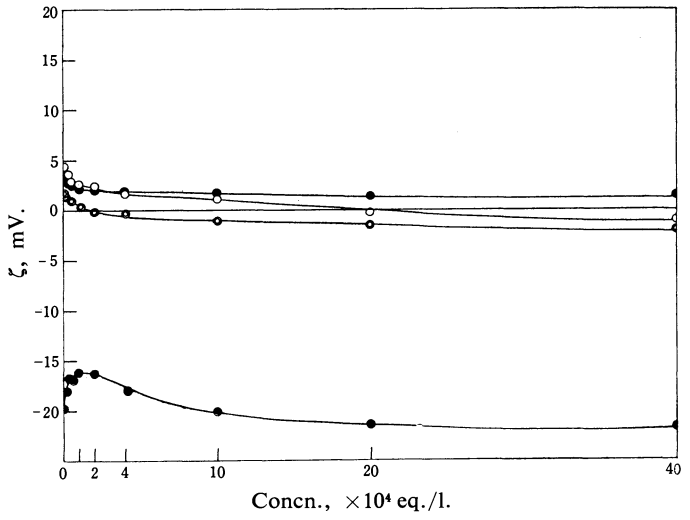

Fig. 5. Effect of potassium hydroxide on the ζ-potential of TiO_2 treated at ● 300°C, ○ 500°C, ◎ 700°C, ◉ 1000°C.

concentrations the counter ions seem to cooperate. The change in ζ-potential in the presence of hydrochloric acid is almost identical with that in the presence of potassium chloride, except that hydrogen ions act more strongly on the solid surface than do potassium ions (Fig. 4). The effect of potassium hydroxide is fairly remarkable, especially in the case of samples treated at moderate temperatures, where the inversion of charge is observed. In the case of a sample treated at 1000°C, the negative potential decreases at first and then increases with the increasing concentration of potassium hydroxide (Fig. 5). In this latter case, the following surface reaction may be considered to take place:

$$\equiv TiOH + KOH \rightarrow \equiv TiOK + H_2O \quad (3)$$

This reaction will promote the dissociation to form the negatively-charged surface, resulting in the increase in the negative potential.

Sodium triphosphate has an extraordinary influence on the ζ-potential of titanium dioxide (Fig. 6) ; the positively-charged surfaces in water are all inverted by the addition of triphosphate, and the negatively-charged rutile surface becomes more negative, even at an extremely low concentration of triphosphate. This is obviously caused by the strong adsorption force of triphosphate, suggesting the formation of a complex compound on the surface of titanium dioxide.

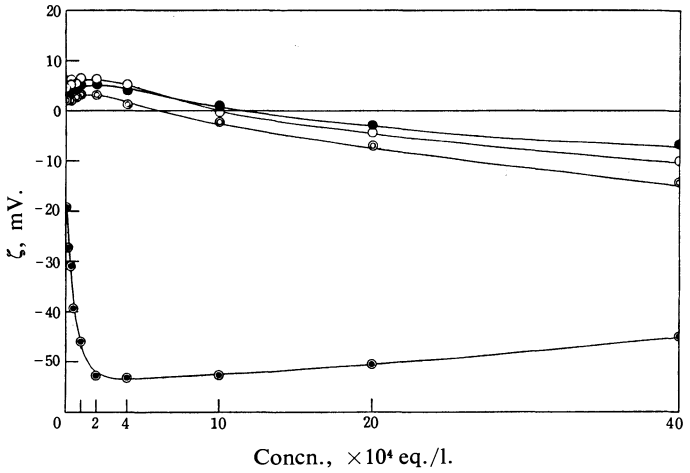

Fig. 6. Effect of sodium triphosphate on the ζ-potential of TiO_2 treated at
● 300°C, ○ 500°C, ◎ 700°C, ◉ 1000°C.

Summary

1) The surface property of titanium dioxide has been investigated by measuring the ζ-potential. The ζ-potential of titanium dioxide in water depends on the temperature of the pretreatment, and its sign changes from positive to negative at about 800°C. This fact has been interpreted in terms of the way of the dissociation of hydroxyl groups on the surface of titanium dioxide, the ways of which depend on its modifications. This phenomenon seems to be supported by crystallographic data.

2) The effects of electrolytes on the ζ-potential of titanium dioxide have been studied. Barium has a chloride greater influence on the ζ-potential of titanium dioxide than does potassium chloride or hydrochloric acid. Hydroxide ions have a fairly great influence on the surface of the solid. The effect of sodium triphosphate is extraordinarily great; by the addition of the electrolyte, the positive potentials of titanium dioxide are inverted to negative potentials and the negatively-charged rutile surface becomes more negative, and this development suggests the formation of a complex compound on the surface of titanium dioxide.

The Electrolytic Preparation of Vanadium(II) Developers

By Kenichi HONDA

(Received December 24, 1963)

Since photographic development is essentially the reduction of silver ions, the ability of a developing agent can be estimated by the degree of its reducing power, by, that is, the redox potential. According to Reinders,[1] when the redox potential of a developer is more negative than +0.120 V. with respect to the standard hydrogen electrode, a silver bromide particle containing a latent image can be reduced.

Vanadium can take the ionic state in the aqueous solution from +5 to +2 valencies, among which range the vanadous ion (V^{2+}) shows a strong reducing power and the redox potential of the system V^{2+}-V^{3+} is:

$$E^\circ = -0.25_5 \text{ V. } (25^\circ\text{C})$$ [2]

1) W. Reinders, *J. Phys. Chem.*, **38**, 783 (1934); *Sci. Ind. Phot.*, **5**, 284 (1934); **6**, 297 (1935).

2) G. Jones and J. Colvin, *J. Am. Chem. Soc.*, **66**, 1573 (1944).

This value seems suitable for photographic development. Further, in order for such a polyvalent ion to be suitable for the development, both the reductant (V^{2+}) and the oxidant (V^{3+}) before and after the development should be soluble in water, and vanadous ion satisfies this requirement also. The developing reaction may be shown in the following equation:

$$Ag^{+} + V^{2+} \rightarrow Ag + V^{3+}$$

Lumiére[3] reported the first use of vanadium salt as a developing agent at the end of the 19th century. After that, no studies were reported on it until 1952 when Roman[4] carried out the fundamental studies for a rapid developing process using V^{2+} salt. Rasch and Crabtree and their co-workers[5-7] also studied this process and especially its application to the development of motion picture positive films, while Fortmiller and James[8] discussed the rate process of this development. In Japan, this process was taken up by the Institute of Industrial Science of the University of Tokyo and by the NHK Technical Research Laboratories. The former constructed a developing machine for reversal and positive films,[9] and the latter gained experience in developing positive films for television use.[10] The processing using the vanadium developer was summarized by Kikuchi.[11]

The characteristics of the vanadium developer are very superior according to the above-mentioned studies, but in actual automatic processing, it is difficult to obtain a good reproducibility due to the different composition of the developer solution, the contamination of the developer, and the unstability of the vanadous ion. It is, therefore, important to prepare a developing solution of a fixed composition. The vanadium developer can also be regenerated electrolytically during development by circulating the solution, so it is necessary to establish the electrolytic conditions. From these standpoints, the preparation of the vanadium developer, including the electrolytic process, will be studied in detail in the present paper.

As the vanadium pentoxide (V_2O_5) is the most easily available commercially-produced vanadium compound, it is adopted as the starting material. A method for obtaining the vanadous ion electrolytically from metallic vanadium has been reported,[12] but it seems to the author not to be practical. Although ammonium metavanadate is also available, it is not used in the present study.

In starting with vanadium pentoxide, it is necessary to reduce V^{5+} to the V^{2+} state. This reduction process consists of the following two steps:

$V^{5+} \rightarrow V^{4+}$, chemical reduction process

$V^{4+} \rightarrow V^{3+} \rightarrow V^{2+}$, electrolytic reduction process

The present paper is, therefore, divided into two parts.

Chemical Reduction Process

As has been mentioned above, this process is the reduction from V^{5+} to V^{4+}, but V^{4+} usually exists in the form of VO^{2+} salt (vanadyl salt) in an aqueous solution. Accordingly, this process is a preparation of vanadyl salt. Three methods are known for preparing vanadyl salt from vanadium pentoxide, (i) the sulfur dioxide process, (ii) the hydrobromic acid process, and (iii) the oxalic acid process.

The preliminary experiences with these three processes have shown that all of them gave a good yield of vanadyl salt, but in process i, excess sulfur dioxide remained in the reaction solution, which was apt to form hydrogen sulfide during the succeeding process of electrolytic reduction and so cause fog. In process ii, the evolution of bromine during the reaction led to considerable difficulty in manipulation. Finally, process iii was adopted as the best one to obtain the pure vanadyl salt. Another advantage of process iii is that the vanadyl ion can be obtained coupled with an optional anion, depending upon the kind of acid used. For example, when sulfuric acid is used, vanadyl sulfate ($VOSO_4$) is obtained, while in case of the hydrochloric acid, vanadyl chloride ($VOCl_2$) is formed. In this study, the syntheses of vanadyl sulfate, vanadyl chloride and vanadyl nitrate are examined.

Experimental

Material. — The vanadium pentoxide used is yellowish-brown, amorphous and of an extra-pure grade. Extra-pure-grade oxalic acid dihydrate and sulfuric acid, hydrochloric acid and nitric acid of various concentrations are used.

Procedure. — A calculated weight of vanadium pentoxide is added to the sulfuric acid. As vanadium pentoxide is not easily soluble in sulfuric acid, most of it is suspended as a brownish color. When vigorously stirred, the oxalic acid dihydrate is added slowly into the solution while it is being heated. The reducing reaction proceeds during a vigorous evolution of carbon dioxide. When the added oxalic acid is completely consumed, the evolution of gas stops and the addition of oxalic acid is again continued. As the reaction proceeds, the solution becomes blue-green, the reaction is considered to be over when the yellowish-brown particles of vanadium pentoxide completely disappear.

Results

The Synthesis of Vanadyl Sulfate. — The vanadyl sulfate solution can be directly used for electrolysis, but in order to use the pure vanadyl sulfate for it and to ascertain the yield of this process, the vanadyl sulfate was isolated. The reaction solution was filtered to remove the unreacted vanadium pentoxide and condensed on a water bath. When the solution was left to cool for about 24 hr., blue crystals of vanadyl sulfate, which were somewhat hygroscopic, were obtained. From the weight of crystals, a crude yield is given.

As this crystal is considered to contain sulfuric acid and water, further purification was carried out. This was achieved by means of repeated washing in ethanol and water, utilizing the good solubility of sulfuric acid in water and the difference in the solubility of vanadyl sulfate between that in water and that in ethanol (it is more easily soluble in water). The crystals were then filtered and dried to obtain pale blue, powdery crystals. From the weight of the crystals thus obtained, the yield of purification is given. The loss caused by purification sometimes reaches a 40% maximum. The purified crystals were considered to have the constitution of $VOSO_4 \cdot xH_2O$, so the VO^{2+} ion content in the crystal was determined in order to decide x by means of oxidation titration with ceric sulfate. The results showed the content of 31%. Hence, x is equal to 3. In other words, it is clear that vanadyl sulfate crystal contains 3 molecules of the water of crystallization. This crystal is not hygroscopic and is sufficiently stable in the open air. The final results are shown in Table I.

The Synthesis of Vanadyl Chloride. — The synthesizing procedure and the reaction process are almost the same as those in the synthesis of vanadyl sulfate, where the sulfuric acid is only replaced by the hydrochloric acid. The reacting solution gradually changes in color from brown to the thick blue characteristic of the vanadyl ion. After the reaction, the solution was filtered and condensed, and the isolation of vanadyl chloride was attempted but in vain. It is, hence, believed that vanadyl chloride itself might be uncrystalline or very easily soluble at an ordinary temperature. Accordingly, the vanadyl ion was determined by the oxidation titration described before and the synthetic yield was calculated from the titration. The results are shown in Table II.

The Synthesis of Vanadyl Nitrate.—Vanadyl nitrate seems not to have been isolated; at any rate, its existence has not yet been recognized according to the literature. Although it is impossible to isolate vanadyl nitrate, if the vanadyl ion is synthesized in a solution in which the NO_3^- ion is the sole anion, it can be simply taken as a state in which vanadyl nitrate is dissolved and electrolytically dissociated. This solution can then be used as a starting solution for the electrolysis. By analogy with the syntheses of vanadyl sulfate and vanadyl chloride, the reaction equation is assumed to be:

$$V_2O_5 + H_2C_2O_4 + 4HNO_3 \rightarrow 2VO(NO_3)_2 + 2CO_2 + 3H_2O$$

At 80~90°C, the reaction was carried out in the same way as the synthesis of vanadyl sulfate or vanadyl chloride. During the reaction, the evolution of a red-brown gas was observed and a considerable quantity of unreacted vanadium pentoxide still remained, even when the theoretical weight of oxalic acid was consumed. The reaction was stopped at this point, and the vanadium pentoxide was

filtered out. The filtrate showed a thick blue color, indicating the formation of VO^{2+}. The concentration of vanadyl ions was determined by oxidation titrations with potassium permanganate or ceric sulfate, resulting in a good coincidence for the two methods. When vanadium pentoxide (20 g.) in nitric acid (ca. 2.9 N, 300 ml.) was reacted with $C_2H_2O_4 \cdot 2H_2O$ (14.3 g.), the yield of vanadyl nitrate calculated from the above results was as follows:

$VO(NO_3)_2$	Found	16 g.
	Calculated	42 g.
	Yield	38%
Unreacted V_2O_5		11 g.

Discussion

Vanadyl Sulfate.—(a) The concentration of sulfuric acid may be diluted down to 20 N as long as the reducing power of oxalic acid is not affected.

(b) It is desirable that the quantity of sulfuric acid be kept at a minimum provided that vanadium pentoxide is kept in the state of suspension.

(c) It is best to add a small excess of oxalic acid (1.2 times of the thoretical weight).

(d) It is desirable that the quantity of water be such that the reaction product is easily crystallized when the solution is condensed and dried (about 95°C) after the reaction.

(e) As for the reaction temperature, it is clear that the threshold temperature for the reduction with oxalic acid is about 70°C. No evolution of carbon dioxide is observed below this temperature, but above 100°C the foaming is very much intensified.

(f) It is naturally desirable to stir the solution as vigorously as possible.

(g) The vanadyl sulfate obtained is stable even at temperatures above 100°C.

Vanadyl Chloride.—(a) The reaction proceeds nearly theoretically.

(b) The reaction does not proceed at temperatures below 60°C. The concentration of hydrochloric acid does not affect the yield if it is in the range of 2 N and above.

(d) As it is difficult to isolate vanadyl chloride, the reaction solution should be directly used for the electrolysis.

Vanadyl Nitrate.—The red-brown gas evolving in the course of the reaction is believed to be nitrogen dioxide or nitrogen sesquioxide resulting from the decomposition of nitric acid. Probably the oxalic acid is partly consumed in decomposing the nitric acid, resulting in the poor yield of vanadyl nitrate.

Electrolytic Reduction Process

As has been described before, in this process the vanadyl salt is cathodically reduced to the V^{2+} state. In this case, VO^{+2} is considered to be reduced first to V^{3+} and then to V^{2+}.

$$VO^{2+} + 2H^+ + e \rightarrow V^{3+} + H_2O\,;\quad V^{3+} + e \rightarrow V^{2+}$$

The theoretical electric quantity necessary for the above reduction is two faradays. The redox potential of the former system is:

$$E^\circ_{VO^{2+}/V^{3+}} = +0.337\ \text{V.}^{13)} \quad (25°C)$$

That of the latter has previously been described.

The solution of vanadous salt can also be prepared by chemical reduction using a reducing agent such as zinc amalgam.[14] In the case of photographic use, the electrolytic method is preferable in order to avoid contamination and in order to carry out the continuous regeneration of the developer. It has been reported[4,5] that vanadyl salts, vanadyl sulfate and vanadyl bromide, were electrolyzed with a lead cathode. Schwarzenbach and Sandera[15] also prepared vanadium dichloride using a mercury cathode, and Jones and Colvin[2] obtained vanadium(II) sulfate with a mercury cathode. However, there has been no systematic study of the electrolytic preparation of vanadous salt from the standpoint of electrolytic conditions. Therefore, in the present paper, the influence of various factors, such as (i) the kinds of electrodes, (ii) the kinds of starting compounds and electrolytes, (iii) the current density, and (iv) the acid concentration of catholyte, upon the yield will be described.

Experimental

Materials.—*Vanadyl Sulfate.*—Blue crystals containing 3 molecules of water ($VOSO_4 \cdot 3H_2O$) prepared as described above were used. Their purity was determined by cerimetry to be more than 98%.

Vanadyl Chloride.—The compound prepared as described before was used. As it was not crystallized, the solution in hydrochloric acid was directly used for the electrolysis. Its concentration was determined by cerimetry.

Vanadyl Nitrate.—A solution of the compound in nitric acid was used for the electrolysis, and its concentration was determined in the same way as before.

Cathode.—Mercury, lead, copper or stainless steel (hereunder abbreviated as S. S.) was used as a cathode. Except for those of mercury, the electrodes were cylindrical plates provided with a number of

13) G. Jones and J. Colvin, *J. Am. Chem. Soc.*, **66**, 1563 (1944).
14) L. Meites, *J. Chem. Educ.*, **27**, 458 (1950).
15) G. Schwarzenbach and J. Sandera, *Helv. Chim. Acta*, **36**, 1089 (1953).

small holes (1 cm.ϕ) to help the flow of the electrolyte solution. The circumference, height and area were 21 cm., 6.8 cm. and 121.8 cm^2 respectively. In the case of mercury, the mercury pool at the bottom of the electrolytic cell served as a cathode.

Anode.—As the anode must be acid-proof, lead peroxide and platinum were tested. The surface layer of lead peroxide peeled in the course of a long run, resulting in the contamination of the anolyte, so the platinum anode was finally adopted. The size of the electrode is not directly related to the results of the cathodic reduction, so it is adequate to choose it according to the dimensions of the anode chamber.

Diaphragm.—A cylindrical porous diaphragm was used. In order to avoid the dissolution of the components of the diaphragm, it was first soaked in acid and alkaline solutions and then the weight change of it and its porosity were measured. The diaphragm was treated in the following order: weighing → washing by water → soaking in hydrochloric acid 5% for 24 hr.→washing by water→ soaking in sodium hydroxide 1% for 24 hr.→washing by water→resoaking in hydrochloric acid 5% for 24 hr.→washing by water→drying→weighing. The hydrochloric acid soaking solution was colored somewhat yellow, clearly showing the dissolution of iron. The ratios of the weight change of two tested diaphragms, a and b, before and after the treatment were as follows;

$$a\ -0.33\%;\ b\ -0.35\%$$

The porosity was measured according to the following formula:

$$\text{Porosity} = \frac{\text{Weight(saturated with water)} - \text{Weight(dry)}}{\text{Total volume}}$$

The results obtained from several samples were 25~35% of porosity.

When these diaphragms were used for electrolysis, the following results were obtained.

(a) There is scarcely any dissolution of diaphragm components.

(b) The separation of the catholyte is perfect, and there is no transference of vanadium ions into the anode chamber.

(c) A part of the anolyte moves into the cathode chamber, and the difference between the levels of the anolyte and of the catholyte becomes 2~3 cm. However, as the same kind of acid is used for both anolyte and catholyte, no unfavorable effect of this movement is observed except for the change in the concentration of the acid.

Electrolytic Cell.—A 500 cc. beaker was used for the electrolytic cell, as Fig. 1 shows. The diaphragm was placed at the center of the cell for the anode chamber, and the outside part of it constituted a cathode chamber. The cathode chamber was closed with a rubber stopper to protect the V^{2+} ion from air oxidation. The stopper was provided with several small holes for measuring the cathode potential, for a thermometer, for the passage of nitrogen, and for removing the evolved hydrogen.

Electrolytic DC Power Supply.—AC power was selenium-rectified to be used as the DC electrolytic power source. The voltage was adjusted by a slidac on the AC side and by a sliding resistance on the DC side.

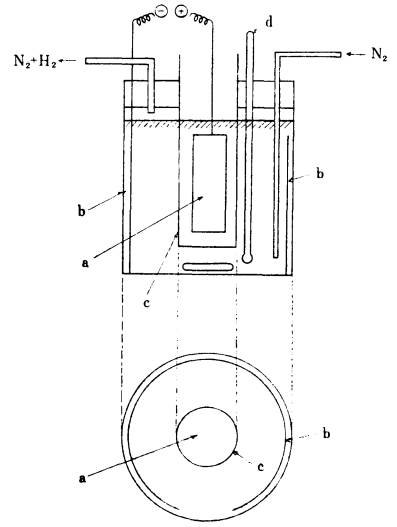

Fig. 1. Electrolytic cell. a, Anode; b, Cathode; c, Diaphragm; d, Thermometer.

Electrolyte.—The three following solutions, (a) a hydrochloric or sulfuric acid solution of vanadyl sulfate, (b) a hydrochloric acid solution of vanadyl chloride, and (c) a nitric acid solution of vanadyl nitrate, served as catholytes, and the same acid was used for the catholyte as for the anolyte.

The acid concentrations of both catholyte and anolyte were kept equal.

When hydrochloric acid or nitric acid was used as an anolyte, stimulative gas evolved; this was removed by an aspirator.

The Possibility of Using V^{3+} Salt as a Starting Material.—If a V^{3+} salt solution exists, there is no need of chemical synthesis and the preparation of developer will be very much simplified. Vanadium trioxide (V_2O_3) is the only V^{3+} compound available on the market. Vanadium trioxide is stable and is almost insoluble in every kind of acid, and the slightly-dissolved components seem to be in a V^{4+} state, judging from the color. On the other hand, V^{3+} precipitates in alkaline solution in the form of vanadium(III) hydroxide. Thus, vanadium trioxide is considered not to be suitable for the starting material in preparing the vanadium developer.

Electrolytic Procedure. — The electrolysis was carried out under strong agitation by a magnetic stirrer. During electrolysis the applied voltage was adjusted so that the current density could be kept constant. The temperature rose with the electrolysis, but it was kept below 30°C by cooling with ice. When vanadyl sulfate or vanadyl chloride was electrolyzed, the catholyte changed its color from blue to green, showing the existence of V^{3+}, and then to the violet of V^{2+}. The hydrogen began to evolve vigorously when the theoretical electric quantity was consumed. When the electric quantity reached twice the theoretical quantity, the electrolysis was stopped and the catholyte was removed

into a stoppered flask. The yield was determined by the simultaneous potentiometric titration of V^{2+} and V^{3+}.[16] During electrolysis, the evolved hydrogen protected V^{2+} from air oxidation, so there was no need for nitrogen passage; otherwise, all the procedures should be carried out in a nitrogen atmosphere.

The electrolysis of vanadyl nitrate will be described later.

Results and Discussion

The Influence of the Kind of Electrodes.—The influence of the kind of electrode upon the electrolytic yield was examined in the case of the catholyte of the vanadyl chloride-hydrochloric acid system. The electrolytic conditions were;

$VOCl_2$ 0.2~0.6 M/1., HCl 1~3 N, cathode current density, D_k=1.64 amp./dm^2. The results are shown in the following table.

Electrode	Yield, %
Pb	82
Cu	62
S. S	25

For the electrolyte of the vanadyl sulfate-sulfuric acid system, the electrolytic conditions were;

$VOSO_4$ 0.1 M/1., H_2SO_4 1 N, and

D_k=1.6~2.0 amp./dm^2

Those results are as follows:

Electrode	Yield, %
Hg	100
Pb	69

The results show that the mercury cathode gives the highest yield, followed by lead and copper, while the stainless steel gives the lowest. In the latter case, a slight corrosion is observed on the surface of the electrode after the electrolysis; the poor yield may be attributed to the fact that a part of the electrolytic current is consumed for the hydrogen evolution due to the corrosion. Furthermore, taking into account the contamination of the electrolyte, the stainless steel electrode is not preferable in the present electrolysis.

The Influence of the Constitution of the Electrolyte.—From the above results, it was clear that the lead electrode was of practical use, so the influence of the constitution of the electrolyte, namely, the relation between the yield and the kind of acids and electrolyzed materials, was studied in the case of the lead electrode. The results are shown in the following table.

Combination of electrolytes	Yield, %
$VOSO_4$ - H_2SO_4	94
$VOSO_4$ - HCl	72
$VOCl_2$ - HCl	82

The other electrolytic conditions were kept constant as follows:

D_k=0.82 amp./dm^2,
acid concentration=1~2 N,
concentration of vanadyl salt=0.1 M/l.

As is clear from the results, the combination of vanadyl sulfate and sulfuric acid gives the highest yield, followed by the combination of vanadyl chloride, hydrochloric acid and vanadyl sulfate - hydrochloric acid. It is concluded that the combination of vanadyl salt and acid gives a higher yield when they possess a common anion.

The Influence of Cathode Current Density (D_k).—The influence of the cathode current density upon the yield, using the lead cathode and the vanadyl sulfate - sulfuric acid electrolyte, the optimum condition so far achieved, was also studied.

The electrolytic conditions were as follows:

Cathode—Pb,		Anode—Pt
Catholyte	$VOSO_4$	0.1 M/l.
	H_2SO_4	1 N
Anolyte	H_2SO_4	1 N

The results are shown in Fig. 2 and in the following table.

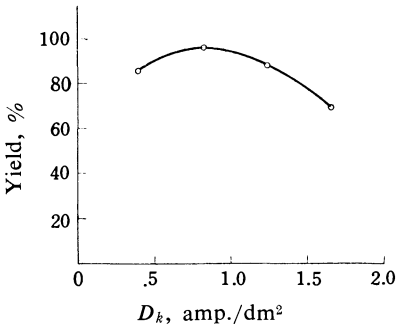

Fig. 2. Relation between the cathode current density (D_k) and the yield.

Current density, amp./dm^2	Yield, %
0.41	85
0.82	94
1.23	87
1.64	69

From the table, it can be seen that the highest yield, 94%, is reached when D_k is about 0.82 amp./dm^2. In general, with the increase of the cathodic current density, the hydrogen over-voltage increases, while the reducing power of the cathode is argumented. However, the results show that, if the current

16) Presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

density rises, the yield decreases. This is supposed to be due to the fact that the evolution of the hydrogen in a very acidic solution like the present electrolyte competes with the reduction of vanadium.

The Influence of the Concentration of Sulfuric Acid as Catholyte.—The influence of the concentration of sulfuric acid upon the yield was then studied under the optimum conditions hitherto mentioned, with the lead cathode, the vanadyl sulfate - sulfuric acid electrolyte, and $D_k = 0.82$ amp./dm^2.

The electrolytic conditions were as follows:

	Cathode—Pb	Anode—Pt
Catholyte	$VOSO_4$	0.1 M/l.
	H_2SO_4	0.1～8 N

Anolyte—H_2SO_4, the concentration being the same as that of the catholyte.

The results are shown in Fig. 3 and in the following table.

Concn. of H_2SO_4, N	Yield, %
0.1	89
1.0	94
8.0	87

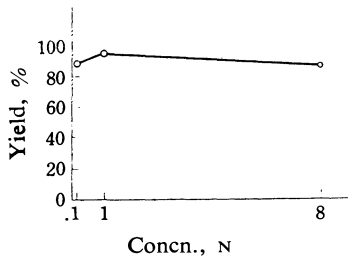

Fig. 3. Relation between the concentration of sulfuric acid as catholyte and the yield.

From the results, it was seen that the concentration of the sulfuric acid in the range of 0.1～8 N does not exert an important influence upon the yield, the variation of the yield being less than 7%.

Therefore, the influence of the concentration of the sulfuric acid may be taken into account in relation with the stability of the V^{2+} ions dissolved and with their reducing power or developing ability.

According to Charlot,[17] the redox potential of the V^{3+}-V^{2+} system becomes more negative with the increase of pH, so its electrochemical reducing power must argument with the decrease in acidity. Furthermore, according to Jones and Colvin,[2] in a strong acid solution, V^{2+} reduces the hydrogen ion, evolving the hydrogen, and V^{2+} itself is oxidized to V^{3+}.

From the above standpoint, it is best if the acid concentration of the catholyte is low as long as the yield of V^{2+} is not affected.

The Electrolysis of Vanadyl Nitrate.—The electrolysis of the solution of vanadyl nitrate mentioned before was attempted under the same conditions as in the case of electrolysis of vanadyl sulfate or vanadyl chloride.

The electrolytic conditions were as follows:

	Cathode—Pb	Anode—Pt
Catholyte	$VO(NO_3)_2$	0.1 M/l.
	HNO_3	ca. 1.3 N
Anolyte	HNO_3	ca. 1.3 N

$D_k = 0.82$ amp./dm^2

The consumption of electricity was three times the theoretical value.

In spite of the excessive consumption of electricity, the color of the electrolyte solution remained blue, a color characteristic of VO^{2+} ions, not showing the violet color of V^{2+}. The potentiometric titration of the electrolyzed solution showed a one-step curve corresponding to the redox potential of VO^{2+}/V^{5+}, undoubtedly indicating that there was no formation of V^{2+} or V^{3+}. Accordingly, it seems impossible to prepare V^{2+} electrolytically from vanadyl nitrate.

The reason why the electrolysis of vanadyl nitrate does not proceed is supposed to be due to the fact that cathodically-formed V^{2+} or V^{3+} reacts with the nitric acid, reduces it, and itself returns to the VO^{2+} state.

Conclusion

The Chemical Reduction Process.—(i) The synthesis of vanadyl sulfate by the oxalic acid method proceeds theoretically, obtaining blue crystals containing 3 molecules of the water of crystallization ($VOSO_4 \cdot 3H_2O$). The crude yield attains 100%, and the purified one, 98%. (ii) The synthesis of vanadyl chloride also proceeds theoretically, and the yield attains 100%. It is, however, impossible to isolate the vanadyl chloride of the crystalline state. (iii) The synthesis of vanadyl nitrate by the oxalic acid method dose not give satisfactory results, showing a yield as poor as 38%. However, the unreacted V_2O_5 can be recovered up to 90%. (iv) None of the synthesizing reactions mentioned above proceed at all at temperatures below 70°C.

The Electrolytic Reduction Process.—(i) The electrolytic preparation of V^{2+} salt from vanadyl sulfate gives the highest yield, 100%. (ii) When the vanadyl chloride is electrolyzed, the maximum yield obtained is 82%. (iii) In both cases, the conditions required for obtaining the maximum yield are:

Cathode—Lead or mercury
Catholyte—All acids contained the same

17) G. Charlot, "L'analyse qualitative et les réactions en solution," Massonet Cie, Paris (1957).

anion as that of vanadyl salt to be electrolyzed.

Concentration of acid—0.1～8 N

Temperature—Room temperature

Cathodic current density—0.82 amp./dm^2

(iv) Vanadyl nitrate is not reduced electrolytically, and it is impossible to obtain V^{2+} salt from it.

Summary

A systematic study of the preparation of a V^{2+} developer for use in the continuous automatic processing machine has been carried out.

At first the vanadyl salts, such as vanadyl sulfate and vanadyl chloride, were chemically synthesized from vanadium pentoxide with a yield of nearly 100%, while vanadyl nitrate was obtained with a yield of only 38%. The synthesizing method using oxalic acid was considered to be the most advantageous from the standpoint of the succeeding electrolytic process.

Concerning the electrolytic reduction process to obtain V^{2+} salt from vanadyl salt, the influence of the kind of electrodes, the combination and concentration of electrolytes, and the cathodic current density upon the yield has been studied. On the basis of these studies, the optimum conditions for the electrolysis have been established except for vanadyl nitrate.

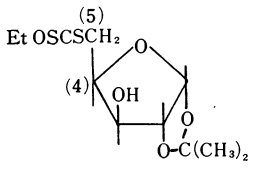
The Rotatory Dispersion and Stereochemistry of Organic Compounds. VI.[1] *Some Observations on the Sign of Partial Rotations in the Derivatives of Xylofuranose and Mannopyranose*

By Yojiro TSUZUKI, Katsumi TANAKA, Koko TANABE, Masuo AKAGI and Setsuzo TEJIMA

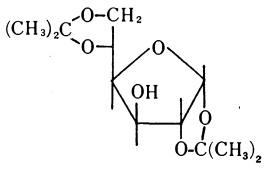
(Received December 24, 1963)

In previous papers[1,2] the rotatory dispersion (RD) of some derivatives of glucose as well as of several anomeric pyranoses has been reported and discussed with relationship to the configuration. In the present paper similar studies will be made on some other monosaccharides, particularly with respect to the sign of the Cotton effect and to the configuration of the functional group, and the results will be compared with the derivatives of glucose. The following compounds will be investigated:



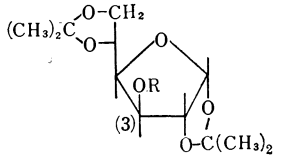
1, 2-*O*-isopropylidene-D-xylofuranose 5-ethylxanthate (compound I),

1, 2-5, 6-*O*-diisopropylidene-D-glucofuranose (compound II),[2]



1, 2-5, 6-*O*-diisopropylidene-D-glucofuranose-3-(*S*-methyl)-xanthate (compound III),[2]

2, 3, 4, 6-tetra-*O*-acetyl-β-D-glucofuranosyl ethylxanthate (compound IV),[1]



2, 3, 4, 6-tetra-*O*-acetyl-β-D-mannopyranosyl-ethylxanthate (compound V).

1) Part V: Y. Tsuzuki, K. Tanabe, M. Akagi and S. Tejima, This Bulletin, 37, 162 (1964).

2) Y. Tsuzuki, K. Tanaka and K. Tanabe, ibid., 35, 1614 (1962).

Results and Discussion

The RD curve of compound I shows a positive Cotton effect in the region from 300 to 380 mμ (Fig. 1-I). It is interesting to compare this anomalous curve with those of diisopropylidene-D-glucofuranose (compound II) and its 3-methylxanthate (compound III) of a similar configuration.

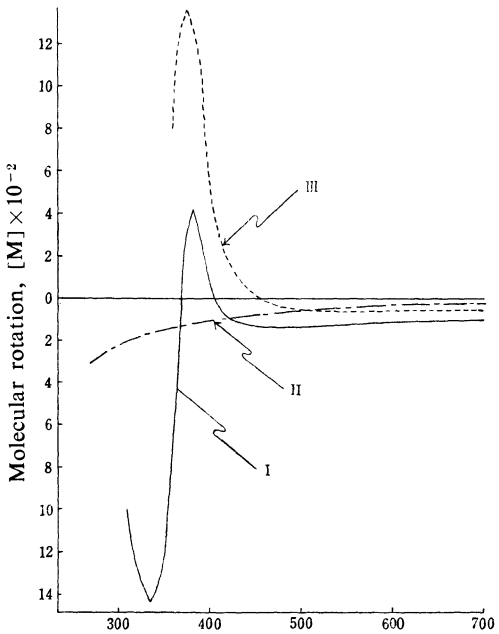

Fig. 1. RD of D-xylofuranose 5-ethylxanthate (I) compared with those of glucofuranose of derivatives (II and III) of similar configuration.

The positive Cotton effect of compound I is due to the $-S-\overset{\overset{S}{\|}}{C}-OC_2H_5$ group attached to the C_4-asymmetric center through the C_5-methylene group. This fact may easily be understood by considering that the compound II, carrying no chromophore, does not show any Cotton effect. In compound III a stronger, positive Cotton effect is observed; this is undoubtedly to be attributed to the $C_3-O-\overset{\overset{S}{\|}}{C}-S-CH_3$ group.[2] In these three compounds the background rotation is always negative, for which the C_3-OH group with an L-configuration may be responsible,[3] although this statement requires further investigation before it can be definitely established.

3) See Y. Tsuzuki, K. Tanaka and K. Tanabe, ibid., 35, 1615 (1962).

The structural difference between compounds IV and V lies in the configuration of the C_2-group, which is reflected in the RD curves seen in Fig. 2. The weaker, positive Cotton effect naturally originates in the $\beta-C_1-S-\overset{\overset{S}{\|}}{C}-OC_2H_5$ group, the amplitude of which is strikingly smaller than that of its epimer (IV).[1]

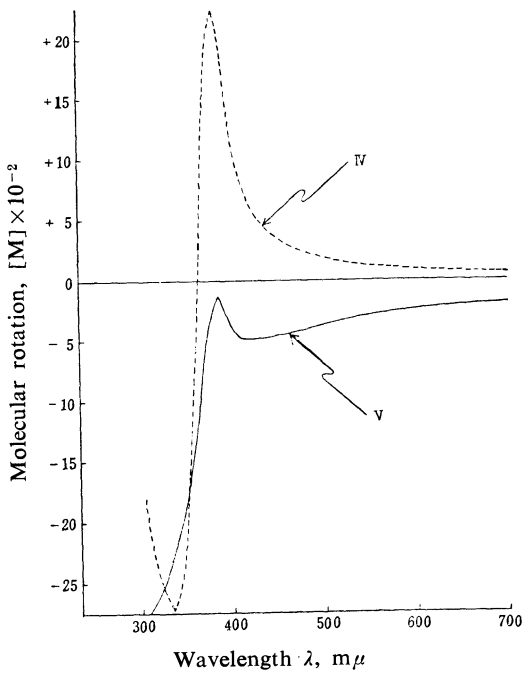

Fig. 2. RD of tetraacetyl β-D-mannopyranosyl 1-ethylxanthate (compound V) compared with its epimer (compound IV).

That the mannofuranose (V) is generally less levo-rotatory than its epimer (IV) is because the C_2-acetoxy group of the former has a configuration of the L-type, suggesting that its partial rotation due to this group is negative in sign. This statement becomes more evident upon analysis of the dispersion data obtained by means of the Drude equation, which will be described later.

The rotatory dispersion constants and the ultraviolet absorption maxima of compounds I and V are tabulated in Table I. The optically-active absorption maximum, λ_0, of compound I lies near 360 mμ, in good agreement with the λ_{max} of its R-band (357 mμ). Although no trough could be observed, the value of λ_0 is presumably not far from the λ_{max} of its R-band (360 mμ), as the amplitude is small.

The data of the RD measurements were calculated according to an abbreviated two-term expression of the Drude equation:

TABLE I. RD CONSTANTS AND UV ABSORPTION MAXIMA

Compound	Rotatory dispersion				Ultraviolet absorption			
	Peak		Trough		R-band		K-band	
	λ, mμ	[M]	λ, mμ	[M]	λ_{max}, mμ	ε	λ_{max}, mμ	ε
I	382	+411°	335	−1420°	357	34.0	280	11800
V	385	−147°	—	—	360	36.7	274	8510

$$[M] = \frac{A}{\lambda^2} + \frac{B}{\lambda^2 - \lambda_c^2}$$

The results are shown in Table II, together with some previous data (III,[2] IV[1]) for the sake of comparison.

TABLE II. DISPERSION CONSTANTS FOR SUGAR DERIVATIVES

Compound	A	B	λ_c^2
I	−61.12	11.79	$(0.361)^2$
III	−37.82	4.54	$(0.380)^2$
IV	−13.68	27.33	$(0.369)^2$
V	−97.29	2.14	$(0.369)^2$

The agreement of the observed and the calculated values of rotation is tolerable over the range from 310 to 700 mμ, the difference between them being mostly only a few percent outside the absorption region.

The values of λ_c are from 361 to 380 mμ, in good accord with the corresponding absorption maxima of the R-band shown in Table I and in previous papers. Among these the λ_c value (0.380 μ) of compound III is particularly high. Here it should be pointed out that the chromophore of III is of the C–O–C(=S)–S–R type, unlike those of the others, which are all of the C–S–C(=S)–OR type.

The rotational strength B due to the chromophore (the xanthyl group) is in all cases positive in sign, but the configuration of the functional group is always of the L-type. This fact is in harmony with the information that the xanthates of L-hydroxylic acids show positive Cotton effects[4] even through the functional group (OH) is expected to contribute to the levo partial rotation, as was pointed out in a previous paper.[2]

The value of B is the largest in β-glucopyranosyl xanthate (IV), but incomparably smaller in the corresponding derivative of mannose (V). Here the chromophore is cis to the adjacent acetoxy group, C_2-OAc (1L-*e*, 2L-*a*), while in the glucose derivative (IV) the conformation (1L-*e*, 2D-*e*) is trans. As there might be some steric disturbance between these two groups, especially in the cis configuration, giving rise to this remarkable difference in B between the epimers (IV and V), the authors have observed the influence of the temperature on RD with V; they expected some change in optical rotation due to thermal agitation, but in reality the RD curve was almost independent of the temperature below 60°C.

The residual rotational strength of A is in all cases negative in sign, and it is greater than that of the main partial rotational strength B except in glucopyranosyl xanthate (IV).

As the RD curve II typically shows, the background rotation of these compounds is negative in sign (Fig. 1). The strong positive rotation near the absorption region of III is, as has already been pointed out, due to the C_3–O–C(=S)–S–CH_3 group.

It is noteworthy that A is negative in compound IV, although the rotation is positive. (Fig. 2-IV) This fact can be interpreted thus: the β-form of the C_1-ligand should contribute potentially to a negative rotation, which is embodied in the negative rotational strength of A, but this negative partial rotation is now canceled by the positive, rotational contribution due to both the C_2 group of D-configuration and the C_1-xanthyl group. That the value of A is unusually large in the mannopyranosyl xanthate (V) may be due to the L-type C_2-acetoxy group, which is evidenced in another expression of RD by the two-term equation of Drude. The RD of compound V is rather better expressed by the following equation, where the calculated values of the molecular rotation are in good agreement with the observed values, with an accuracy of more than 95% over the spectral region from 305 to 700 mμ except in the absorption region:

$$[M] = \frac{-99.35}{\lambda^2 - (0.233)^2} + \frac{13.02}{\lambda^2 - (0.363)^2}$$

In the above equation the first negative term is inferred as expressing mainly the partial rotation due to the C_2-acetoxy group of the L-type; in reality the value of λ_1 (0.233 mμ) nearly coincides with the ultraviolet absorption of the acetoxy group.

4) B. Sjöberg, A. Fredga and C. Djerassi, *J. Am. Chem. Soc.*, **81**, 5002 (1959).

Experimental

The rotatory dispersion was measured in tetrahydrofuran at room temperature over the wavelength region from 300 to 700 mμ with a Rudolph photometric spectropolarimeter. The ultraviolet absorption was measured in the same solvent with a self-recording spectrophotmeter of the Hitachi type. The calculation from the data of RD was made by means of the least-squares method with an electronic computer of the Fuji FACOM 201 type.

The method of preparation and the other properties of the following compounds will be described elsewhere by Akagi and his collaborators.

1, 2-*O*-Isopropylidene-D-xylofuranose 5-Ethylxanthate. (Compound I).—Was prepared from its corresponding iodo compound.[5] Colorless crystals. M. p. 126°C. $[\alpha]_{700}^{16.5} = -33.0°$, $[\alpha]_{589} = -39.9°$, $[\alpha]_{382} = +140°$ (peak), $[\alpha]_{335} = -483°$ (trough), $[\alpha]_{310} = -341°$ (*c* 0.2936, tetrahydrofuran).

2,3,4,6-Tetra-*O*-acetyl-β-D-mannopyranosyl 1-Ethylxanthate (Compound V).—Colorless crystals. M. p. 127~128°C. $[\alpha]_{700}^{17} = -43.4°$, $[\alpha]_{589} = -58.1°$, $[\alpha]_{420} = -110°$ (broad extreme), $[\alpha]_{385} = -32.4°$ (peak), $[\alpha]_{305} = -602°$, (*c*, 0.4362, tetrahydrofuran).

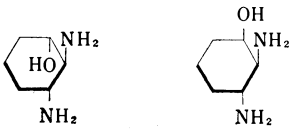
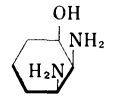
The Synthesis and Configurational Analysis of 2,3-Diaminocyclohexanol



By Tetsuo SUAMI and Seiichiro OGAWA

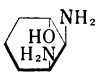
(Received December 28, 1963)

The previous studies on 2-amino-1,3-cyclohexanediol[1] have stimulated our interest in the synthesis of an alicyclic compound with two amino groups and one hydroxyl group. In the present paper, the synthesis of 2,3-diaminocyclohexanol is described, and its structure is established by means of the proton magnetic resonance spectra of the acetyl derivatives. Di-*O*-mesyl-*trans*-2-acetamido-1,3-cyclohexanediol (I)[2] is used as a starting material for this preparation. By treating compound I with sodium azide in boiling aqueous 2-methoxyethanol, DL-2-acetamido-3-azidocyclohexanol (II) is obtained. This compound is hydrogenated by Raney nickel in a hydrogen stream to give DL-2-acetamido-3-aminocyclohexanol (III) in 48.8% yield from compound I. Compound III is treated with acetic anhydride and pyridine, giving the triacetyl derivative (IV), melting at 206.5°C, in 77.0% yield. Compound IV is selectively deacetylated by methanol saturated with dry ammonia to give 2,3-diacetamidocyclohexanol (V). Also compound III or compound IV is hydrolyzed by 6 N hydrochloric acid, giving 2,3-diaminocyclohexanol dihydrochloride (VI). The picrate is prepared from compound VI.



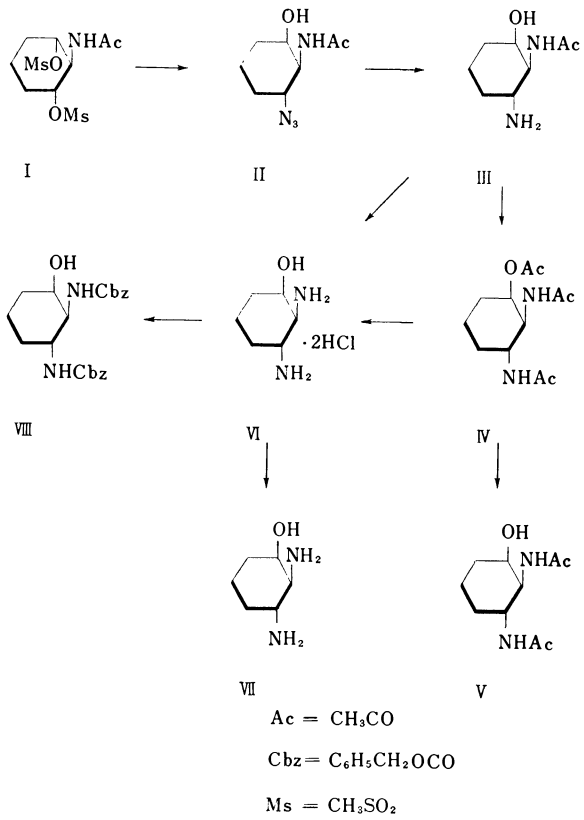
1) T. Suami and S. Ogawa, This Bulletin, **37**, 194 (1964).
2) F. W. Lichtenthaler *Chem. Ber.*, **96**, 845 (1963).

There are four predicted diastereomers of 2,3-diaminocyclohexanol (IX, X, XI and XII), but they are wholly unknown:



IX

X



XI

XII

None of them has a plane of symmetry; hence, they are racemic forms.

In the present experiment, the starting material I has the trans configuration.[1,2] The loss of both the mesyloxy groups takes place when compound I is treated with sodium azide in boiling aqueous 2-methoxyethanol, but azido alcohol II is obtained instead of the diazido derivative. An analogous phenomenon has been described in the solvolysis of compound I with sodium acetate.[2] This fact might be explained as follows: the displacement of

Ac = CH_3CO

Cbz = $C_6H_5CH_2OCO$

Ms = CH_3SO_2

mesyloxy group occurs with formation of oxazolinium ions,[3] which are attacked by water to give the *cis*-acetamido alcohol. Then the displacement of another mesyloxy group would take place via an anchimeric reaction or a direct S_N2 mechanism.

Recently the displacement of a secondary sulphonate group in sugar derivatives with sodium azide has been described by several authors,[4] but that in alicyclic compounds has never been described.

In the present experiment, if an attack by an azide ion occurs at C-3 (or C-1), with a retention of the configuration, the product should have the structure X, but if it occurs with an inversion, the product should have the structure XI.

The NMR spectrum of the triacetyl derivative, IV, gives an equivocal answer on this point. An acetoxy group produces a signal at a different field than does an acetamido group; moreover, an axial acetamido group gives a signal at a lower field than does an equatorial acetamido group in cyclohexane derivatives[1,5]. Therefore, the structure could be assigned on the basis of this point. The NMR spectrum of compound IV, as is shown in Fig. 1-A, reveals two sharp signals of a 1 : 2 relative intensity, as is to be expected from one axial acetoxy group (τ of 7.89)[5] and two equatorial acetamido groups (τ of 8.07). The doublet produced by the proton on a nitrogen atom in the acetamido group with a coupling constant of 10 c. p. s. (τ of 3.76) corresponds to two protons and gives further evidence that the two acetamido groups may be expected to have an identical conformation, since inosadiamine hexaacetate with one axial and one equatorial acetamido groups reveals two doublets.[6] The ring protons show a peak at 4.88 τ, as is to be expected from one equatorial proton at C-1, and a peak at 6.08 τ, as is to be expected from two axial protons at C-2 and C-3.

The NMR spectrum of compound V, shown in Fig. 1-B, shows only one sharp signal at 7.97 τ, as is to be expected from two acetamido

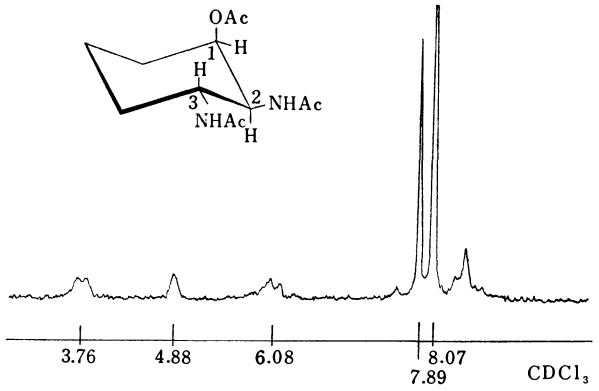

Fig. 1-A

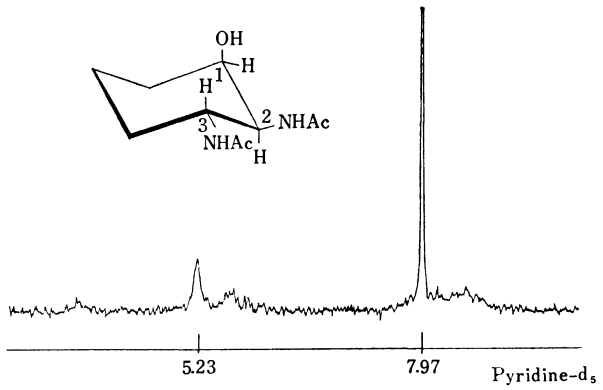

Fig. 1-B

groups; this means that the two acetamido groups are equivalent.

As a result of the consideration of the NMR spectra, it might be concluded that compound IV may be assigned as $2\alpha, 3\beta$-diacetamido-1α-cyclohexyl acetate and that, accordingly, the attack of azide ions occurs anchimerically, with a retention of the configuration.

Experimental

All melting points have been corrected. The NMR spectrum was determined at a frequency of 60 Mc. p. s. with a Varian Associates A-60 spectrometer. Tetramethylsilane was used as an internal reference in the samples. The peak position are given in τ-values.

DL-2α-Acetamido-3β-amino-1α-cyclohexanol (III). — A mixture of 4.0 g. of di-*O*-mesyl-*trans*-2-acetamido-1,3-cyclohexanediol (I), 3.3 g. of sodium azide and 100 ml. of 75% aqueous 2-methoxyethanol was heated under reflux for 2 hr. The mixture was then evaporated to dryness under reduced pressure. The residue was repeatedly extracted with hot acetone. The combined acetone extract was evaporated to give a brownish sirup, which showed infrared absorptions at 3300 (broad) (OH), 2090 (N_3) and 1653, 1544 cm^{-1} (amide).

A solution of the sirup in 40 ml. of ethanol was hydrogenated with Raney nickel T4,[7] obtained from 10 g. of Raney nickel alloy, in a hydrogen stream of an initial pressure of 50 p. s. i. g. for 4 hr. Then the mixture was filtered to remove the catalyst, and the filtrate was evaporated in vacuo. The crystalline residue was recrystallized from ethanol-ether to yield 0.79 g. of compound III, m. p. 174~177°C. The second crop of the product (0.26 g.) was obtained from the mother liquor. The total yield was 48.8% from compound I. The product was recrystallized from the same solvent to give an analytical sample in the form of colorless needles, m. p. 182.5~184°C.

Found: C, 55.63; H, 9.21; N, 16.47. Calcd. for $C_8H_{16}N_2O_2$: C, 55.79; H, 9.36; N, 16.27%.

The infrared spectrum of the product (KBr disk) showed the expected absorptions at 3150 (broad (OH and NH_2), 3290, 1550 (amide) and 1585 cm^{-1} (NH_2.)

DL-2α, 3β-Diacetamido-1α-cyclohexyl Acetate (IV).—A mixture of 1.0 g. of compound III, 50 ml.

7) S. Nishimura, This Bulletin, 32, 61 (1959).

of pyridine and 50 ml. of acetic anhydride was heated at 80°C for 1 hr. and then allowed to stand overnight at room temperature. The mixture was evaporated under reduced pressure. The crystalline residue was recrystallized from ethanol-ether to yield 1.15 g. (77%) of plates, m. p. 203~206.5°C. A sample recrystallized from ethanol-ether (m. p. 205~206.5°C) was subjected to elemental analysis.

Found: C, 56.38; H, 7.78; N, 10.87. Calcd for $C_{12}H_{20}N_2O_4$: C, 56.23; H, 7.87; N, 10.93%.

DL-2α, 3β-Diacetamido-1α-cyclohexanol (V). — A solution of 0.21 g. of compound IV in 20 ml. of methanol previously saturated with ammonia at 5°C was allowed to stand at room temperature overnight. The solution was then evaporated in vacuo. The residue was crystallized from ethanol-ether to yield 0.14 g. (82%) of compound V, m. p. 237~241°C (with decomposition). The sample for analysis obtained from ethanol-ether had an m. p. of 258~259°C (with decomposition).

Found: C, 56.33; H, 8.60; N, 13.09. Calcd. for $C_{10}H_{18}N_2O_3$: C, 56.05; H, 8.47; N, 13.08%.

DL-2α, 3β-Diamino-1α-cyclohexanol Dihydrochloride (VI). — a) A mixture of 0.5 g. of compound IV and 30 ml. of 6 N hydrochloric acid was refluxed for 6 hr. and then evaporated under reduced pressure to dryness, giving 0.31 g. (84.5%) of white crystals, m. p. 289~293°C (with decomposition). The analytical sample was obtained from methanol-ether as colorless plates, which started turning brown at 280°C and which melted at 301~303°C with decomposition.

Found: C, 35.62; H, 7.61; N, 14.26; Cl, 35.45. Calcd. for $C_6H_{14}N_2O \cdot 2HCl$: C, 35.48; H, 7.94; N, 13.79; Cl, 34.91%.

Paper Chromatography. — An upper layer of 1-butanol-acetic acid-water (4 : 1 : 5) gave a single spot of R_f 0.18 in ascending development at 17°C (R_f of glucosamine hydrochloride, 0.15).

b) A mixture of 0.60 g. of compound III and 60 ml. of 6 N hydrochloric acid was treated as described in a) to obtain 0.58 g. (82%) of the product, m. p. 290~293°C (with decomposition.)

DL-2α, 3β-Diamino-1α-cyclohexanol (VII). — A 8 ml. portion of a 0.5 N sodium hydroxide solution was added to a mixture of 406 mg. of compound VI and 20 ml. of methanol. The mixture was evaporated in vacuo, and the residue was extracted with absolute ethanol. The ethanol extract was evaporated to yield 260 mg. of an oily product.

The picrate was obtained by an ordinary method as yellow crystals, m. p. 255°C (with decomposition).

Found: C, 37.06; H, 3.62; N, 19.22. Calcd. for $C_6H_{14}N_2O \cdot 2C_6H_3N_3O_7$: C, 36.74; H, 3.43; N, 19.04%.

Di-*N*-carbobenzoxy-DL-2α, 3β-diamino-1α-cyclohexanol (VIII). — A 0.3 ml. portion of carbobenzoxy chloride in toluene (85% solution) was added to a mixture of 100 mg. of compound VI, 340 mg. of sodium bicarbonate and 3 ml. of water under agitation. After the mixture had been stirred for 6 hr., 157 mg. (79%) of the crude product was obtained as a white powder, m. p. 161.5~164.5°C. The analytical sample was obtained from ethanol as needles, m. p. 163.5~164.5°C.

Found: C, 66.48; H, 6.55: N, 7.07. Calcd. for $C_{22}H_{26}N_2O_5$: C, 66.31; H, 6.58; N, 7.03%.

The authors are indebted to Professor Sumio Umezawa for his helpful advice, to Dr. Frieder W. Lichtenthaler (Technische Hochschule Darmstadt, Germany) for measurements of the NMR spectra and his stimulating discussions on the NMR spectra, and to Mr. Saburo Nakada for his microanalysis. This research has been supported in part by a grant from the Ministry of Education, to which the authors' thanks are due.

*The Solid State Polymerization of Trioxane by the Simultaneous Sublimation of the Monomer and Iodine**

By Hajime MIYAMA and Mikiharu KAMACHI

(Received July 12, 1963)

Recently, Kargin et al.[1] published an interesting method of polymerization by the simultaneous condensation of the vapors of monomers and inorganic substances on a strongly cooled surface. The present authors have now applied Kargin's method to the system of trioxane and iodine, both of which can be easily sublimed, and have thereby obtained polyoxymethylene of a high degree of polymerization in a good yield.

Although many reports[2-10] about the solid state polymerization of trioxane have been published, the method of polymerization catalyzed by iodine in the solid state has not been reported as far as the authors know. Also, the present method of polymerization is very different from other methods. Therefore, it seems worthwhile to report the details of our experimental results.

Experimental

The experimental method is as follows. Commercial trioxane (Eastman Kodak and American Celanese) is purified by several sublimations in a high vacuum and then introduced, at the pressure of $10^{-4}\sim10^{-5}$ mmHg, into an ampoule cooled by liquid nitrogen. At the same time, the desired quantity of iodine, which has also been purified by several vacuum sublimations, is introduced into the ampoule. This ampoule, containing the mixture produced by the simultaneous sublimation of trioxane and iodine, is sealed off and placed into a thermostat of a definite temperature. After being left for the definite time, the ampoule is opened. Then monomer and iodine are removed by benzene, and the undissolved polymer is washed two times with benzene.

The ESR spectra of the polymerization system are measured with a Varian V-4500 spectrometer. Also, the temperature-rise of the system during the polymerization is followed by a thermistor inserted into the reaction ampoule.

The inherent viscosity of the polymer obtained is measured in a *p*-chlorophenol solution (0.1 g./100 ml.) containing 2% of α-pinene by using an Ostwald viscometer at 60°C. The softening temperature is measured by a Kofler's Micro-Hot-Stage. Also, the X-ray diffraction of the polymer is measured by using a Rigaku Denki D-5C diffractometer.

Results

In order to conduct the polymerization, it is necessary to keep the pressure as low as possible. The existence of air, oxygen and other radical scavengers inhibits this reaction. Therefore, all measurements are conducted at the pressure of $10^{-4}\sim10^{-5}$ mmHg. The results obtained are shown in Table I and Figs. 1—4. As Figs. 1 and 2 show, the polymerization yield increases with time, but it reaches a limit only after a few ten minutes. Also, the yield increases with the increase in the temperature and in the iodine concentration. Although the inherent viscosity does not change with the polymerization time regularly, it decreases with the increase in the temperature and in the iodine concentration, as is shown in Figs. 3 and 4, where inherent viscosity is measured for the polymers obtained

by the 30-minute reaction.

The temperature-rise of the reaction system measured by a thermister placed into the ampoule with an internal diameter of 1.8 cm. and a height of 4.0 cm. is shown in Fig. 5. The temperature of the reaction system is not constant during the polymerization, rather, it reaches a constant temperature within 3~4 min. after the ampoule is placed into the thermostat.

By ESR measurements of the reaction system at room temperature, the spectra shown in Fig. 6 are obtained. After opening the ampoule, the intensity of the spectra decreases with time.

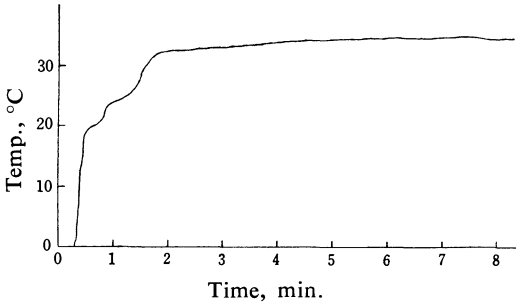

Fig. 5. Temperature change of the reaction system with time.
Reaction temperature; 34.2°C

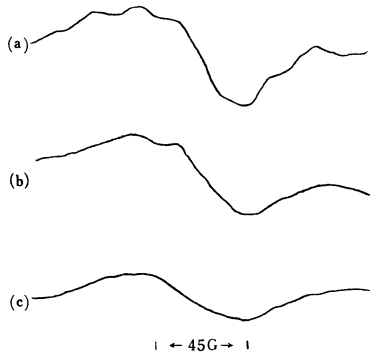

Fig. 6. ESR spectra of reaction mixture.
a) during the polymerization,
b) 10 minutes after the ampoule is opend,
c) 2 days after the ampoule is opend.

Although the ampoule is usually cooled with liquid nitrogen (−196°C) when both trioxane and iodine are sublimed into the ampoule, a higher condensation temperature may be obtained by using other freezing mixtures. As Table II shows, a small quantity of polymer is obtained even at 0°C, but the polymerization yield decreases as the condensation temperature increases. Therefore, all measurements are conducted at the condensation temperature of −196°C.

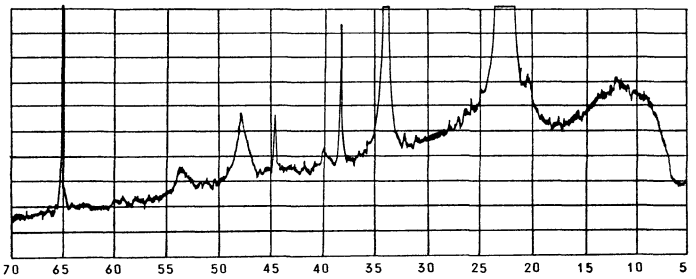

Fig. 7a. X-ray diffraction patterns of polymer obtained by the present method.

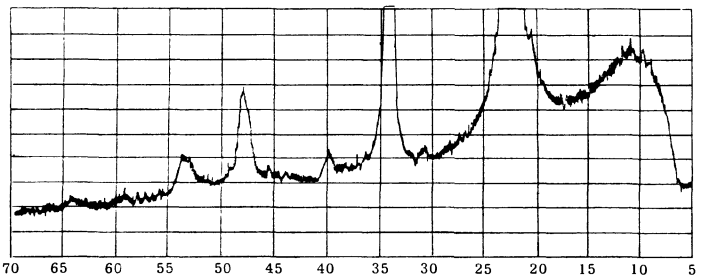

Fig. 7b. X-ray diffraction pattern of polymer made without using iodine.

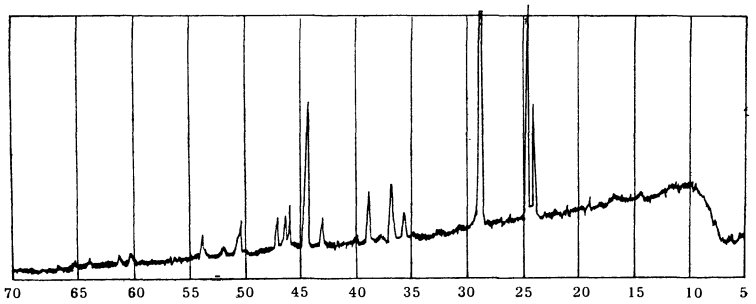

Fig. 7c. X-ray diffraction patterns of iodine.

TABLE II. POLYMERIZATION YIELDS AT VARIOUS CONDENSATION TEMPERATURES

Condensation temp., °C	Yield, %
−196	53.0
− 66	27.7
− 52	25.5
− 31	11.4
− 18	5.0
0	2.5

Here, the iodine concentration is 0.067 weight %, the polymerization time is 30 min., and the polymerization temperature is 42.2°C.

On the other hand, concerning the polymerization temperature (i. e., the temperature of the thermostat), the results shown in Table III are obtained.

TABLE III. POLYMERIZATION YIELDS AT VARIOUS POLYMERIZATION TEMPERATURES

Polymerization temp., °C	Yield
0	none
10	trace
15	26.8
20	32.6
23	42.8
26.7	49.0

Here, the iodine concentration is 0.67 weight %, and the reaction time is 30 minutes. From this result, it is obvious that the polymerization starts in the neighbourhood of 10°C.

No polymerization occurs in the liquid phase when 0.1 g. of iodine and 1.5 g. of trioxane are dissolved into 10 cc. of a solvent such as benzene or ethylene dichloride and heated to 40°C.

In order to confirm that the simultaneous sublimation is absolutely necessary, trioxane is placed into the ampoule first, without sublimation, and then iodine is sublimed into the ampoule. Table IV compares two methods where the iodine concentration is 0.67 weight %, the reaction time is 15 min., and the reaction temperature is 34.2°C.

TABLE IV. A COMPARISON OF TWO METHODS, WITH AND WITHOUT THE SIMULTANEOUS SUBLIMATION OF TRIOXANE

Method	Yield
Simultaneous sublimation	49.2%
Without sublimation of trioxane	trace

Also, in order to confirm whether the initiation of the polymerization occurs in the gas phase or in the solid phase, the alternating sublimations, wherein iodine vapor is removed during the sublimation of trioxane and trioxane vapor is removed during the sublimation of iodine, are compared with simultaneous sublimation in Table V. Here, the iodine concentration is 0.67 weight %, the reaction temperature is 34.2°C, and the reaction time is 30 minutes.

TABLE V. A COMPARISON OF ALTERNATING SUBLIMATION WITH SIMULTANEOUS SUBLIMATION

Method	No. of alterating repetitions	Yield
Alternating sublimation	2	49.4%
	6	52.0
Simultaneous sublimation	—	52.3

From this table, it is obvious that the polymerization does not start in the gas phase.

The inherent viscosity and softening temperature are also shown in Table I. The inherent viscosity is much higher than that (usually 1∼2) of polyoxymethylene obtained by conventional methods. Also, the X-ray diffraction patterns of the polymer obtained by the present method, of the polymer made without using iodine, and of the iodine are shown in Fig. 7. Obviously, a new peak is observed at the diffraction angle of 65°.

Discussion

Since the temperature of the polymerization system reaches the constant temperature after 3∼4 min., as Fig. 5 shows, the polymerization rates have been obtained from the slope of the curves after 4 minutes in Figs. 1 and 2, and the dependence of these rates upon the concentrations of monomer, iodine and polymer has been examined. Thus, it is found that the polymerization rate, V, is proportional to $[C]^{0.25}[M]^2/[P]^2$, as is shown in Fig. 8, where [M], [C] and [P] are weight percentages of the monomer, iodine and the polymer respectively. From the slope of the straight lines

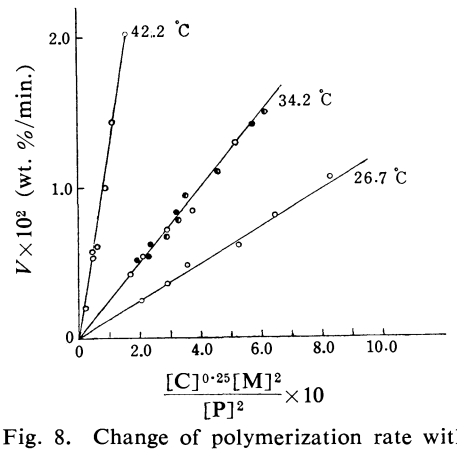

Fig. 8. Change of polymerization rate with $[C]^{0.25}[M]^2/[P]^2$.
○ I_2: 0.67 wt. %
● I_2: 0.33 wt. %
◐ I_2: 0.13 wt. %

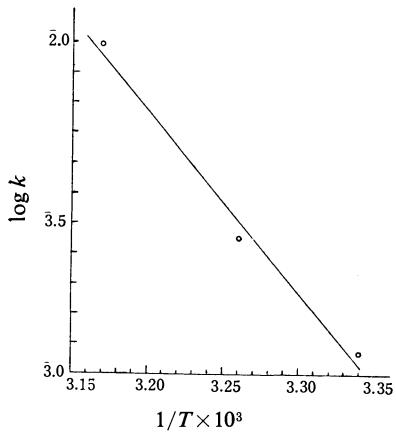

Fig. 9. Arrhenius' plot of $\log k$ via $1/T$.

in Fig. 8, the rate constants at various temperatures are obtained by means of the following equation;

$$V=k[C]^{0.25}[M]^2/[P]^2$$

From the Arrhenius' plot of $\log K$ via $1/T$ shown in Fig, 9, the activation energy is found to be ca. 29 kcal./mol.

According to Kargin et al.,[1] the initiation takes place in the gas phase for the monomer-metal system, but in the solid phase for the monomer-salt and monomer-oxide systems. In our experiment, initiation occurs obviously in the solid phase. This may be due to some crystal defects or dislocations, as has been suggested by Kargin et al.,[1] Bamford et al.[11] and Semenov.[12] As Table II shows, the polymerization yield decreases as the condensation temperature increases. This result may be explained as follows by using their hypothesis. Since the rate of sublimation decreases as the condensation temperature increases, it is expected that number of crystal defects or dislocations produced by simultaneous sublimation will become smaller at a higher condensation temperature and that, therefore, the rate of polymerization will decrease.

The fact that the polymerization system must be heated up to 10°C for the reaction to occur suggests that the favorable orientation of the monomer is necessary for the chain propagation. According to the NMR measurements of Okamura et al.,[13] the movement of the trioxane monomer becomes active about 20°C. Therefore, there is a possibility that this kind of movement causes the orientation favorable to the polymerization. The obtained activation energy of 29 kcal./mol. is large compared with the activation energy of 5 kcal./mol.[14] in the in-source radiation polymerization of trioxane, but it is small compared with the 40 kcal./mol.[15] in the post radiation polymerization. Morawetz[16] obtained the activation energy of 25 kcal./mol. for the post-irradiation polymerization of acrylamide and considered this value to be the activation energy of the propagation step. Taking these results into account, our activation energy might correspond to that of the propagation step.

The ESR spectra shown in Fig. 6 are very close to those obtained by the radiolysis of commercial polyoxymethylene.[17] On the other hand, the results of X-ray diffraction suggest the existence of some interaction between iodine and the polymer. Therefore, it is very difficult to find whether active species of the initiating polymerization are produced from trioxane or from iodine, and no conclusive mechanism can be obtained from the above-described results. The existence of a free radical proved by ESR measurement and the inhibition of polymerization by air, oxygen and other radical scavengers do not support the radical mechanism conclusively. For this purpose, a quantitative agreement between kinetical data and ESR data is necessary. At present, the authors prefer to explain this reaction by assuming that the initiation of the polymerization takes place in association with crystal dislocations or defects caused by the simultaneous sublimation and that the propagation step starts somewhere between 0°C and 15°C.

Summary

It has been found that the polymerization of trioxane occurs in the solid state by subliming the monomers and iodine simultaneously on a cooled surface and raising the temperature over 10°C. This method gives a polymer of a high degree of polymerization in a good yield. As a result of chemical kinetic treatments, the polymerization rate has been found to be proportional to $[C]^{0.25}[M]^2/[P]^2$, where [C], [M] and [P] are the concentrations of iodine, the monomer and the polymer respectively. The reaction mechanism has been discussed in

Monolayer Studies of the Interactions between Histidyl Polypeptides and Metal Ions. I. The Effect of Cupric Ions on the Monolayer Properties of Histidyl Polypeptides

By Takuya YAMASHITA* and Toshizo ISEMURA

(Received September 11, 1963)

The histidyl residue in protein is a very important binding site for metal ions because of the reactivity of its imidazole group.[1] It was found in our laboratory that bacterial-α-amylase interacts strongly with metal ions such as copper, zinc and mercury, and that the interaction of cobalt ions with this enzyme is rather weaker.[2] The combination of metal ions has been studied with imidazole[3,4] and with 4-methylimidazole[5] as model substances of the histidyl residue. Patchornik et al.[6] synthesized poly-L-histidine and found that it forms insoluble complexes with various heavy metals.

Monolayer technique appears to be a useful way to investigate the interaction of protein with metal ions, as has been shown by the monolayer studies of the mineral tanning of proteins.[7,8] Schulman and Dogan[7] have found that copper ions do not react with the carboxyl group but with imidazole in the protein monolayer. We have attempted, by using a monolayer technique, to study the interaction of poly-L-histidine with cupric and other biologically-important metal ions in order to investigate the metal binding property of the histidyl residue in protein. Poly-L-histidine, however, could not be spread as a monolayer, even on a subphase containing 40% ammonium sulfate or on subsolutions containing cupric sulfate at various concentrations, probably because of the strong hydrophility of its side chains. Thus, poly-1-benzyl-L-histidine was chosen as a model substance in the present experiments for studying the interaction of metal ions with the histidyl group, as it could form stable films at the air/water interface. The monolayer of copoly-2:2:2:1-(glycine, *O*-benzyl-DL-serine, β-benzyl-L-aspartate, 1-benzyl-L-histidine) were also studied.

Experimental

Poly-1-benzyl-L-histidine and copoly-2 : 2 : 2 : 1-(glycine, *O*-benzyl-DL-serine, β-benzyl-L-aspartate, 1-benzyl-L-histidine), which were synthesized by the polymerization of the *N*-carboxyanhydrides of their corresponding amino acids, were supplied by Professor Junzo Noguchi of Hokkaido University. The spreading solutions were made by dissolving the former in 0.05 N hydrochloric acid and the latter in a mixture of dichloroacetic acid and benzene (1 : 4, v/v). The concentration of these polymers in solutions was about 0.25 mg./ml.

The Wilhelmy hanging-plate method was found inadequate for the present experiments because the surface of the glass plate became remarkably water-repellent, probably because of the adsorption of poly-1-benzyl-L-histidine onto the plate. Therefore, the surface pressure was measured using a float-type surface balance. In order to avoid the contamination by metal ions in the trough, a trough

made of poly(methyl methacrylate) was used, the rim of which was coated with purified paraffin.

The surface viscosity was measured by the rotatory oscillation of a disk on the surface of the liquid; it was calculated by the following formula;[9]

$$\eta_s = \Delta\lambda_{10} \frac{2.303I}{2\pi P}\left(\frac{1}{a^2}-\frac{1}{b^2}\right)$$

where I is the moment of inertia of the disk; P, the period of oscillation; $\Delta\lambda_{10}$, the difference between the logarithm decrements of the oscillation in the presence of film and in its absence; a, the radius of the disk, and b, the radius of the film surrounding the oscillation disk. In the apparatus used in the present experiments, I was 31.0 g. cm., P was 13.18 sec., a was 1.00 cm., and b was 3.01 cm.

The surface potential was measured by the vibrating-electrode method. The surface moment, μ, was calculated from the surface potential, ΔV, utilizing the Helmholtz formula, $\mu = \Delta V A/4\pi$, where A is the area.

The compression of the film was started 20 min. after the polypeptides had been spread. All the experiments were carried out at room temperature. The fluctuation of the temperature, however, never exceeded one degree during the course of the experiments. The pH of the subsolution was measured by a Horiba M-3 glass electrode pH-meter.

An acetate buffer consisting of 0.1 M sodium acetate and 0.1 M acetic acid in an appropriate ratio was used as the subsolution in some cases.

Results

The effects of potassium chloride, sodium sulfate and sodium acetate (0.1 M acetate buffer, pH 5.6) on the surface pressure-area (Π-A) relationship of the monolayer of poly-1-benzyl-L-histidine are shown in Fig. 1.

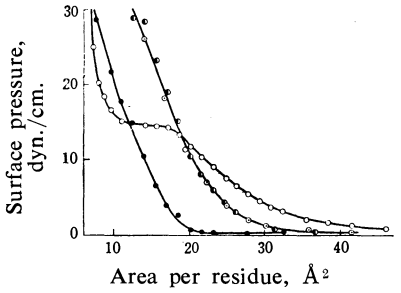

Fig. 1. Surface pressure-area curves of poly-1-benzyl-L-histidine on distilled water (●), 0.1 M potassium chloride (◐), 0.01 M sodium sulfate (⊙) and 0.1 M acetate buffer (pH 5.6, ○): 20°C.

Potassium sulfate (0.01 M, not shown in the figure) gave a Π-A curve identical with that on 0.01 M sodium sulfate. The limiting area per residue, which was determined from the minimum compressibility of the film, was found to be 16.0 Å² for the film on distilled water, a value similar to those for such nonionic polypeptides as poly-DL-phenylalanine (15.6 Å²).[10] The presence of salts in the subsolution resulted in the expansion of the film, which suggests a more horizontal orientation of the side chains. The effect of the acetate ion is very specific. The film expands on the acetate subsolution more than on other salts, such as potassium chloride and sodium sulfate. There appears a plateau region between 12 and 18 Å² per residue in the Π-A curve. The addition of 0.1 M potassium chloride (not shown in Fig. 1) to a 0.1 M acetate buffer had no influence upon the Π-A relationship on the 0.1 M buffer solution.

The effect of cupric sulfate on the poly-1-benzyl-L-histidine monolayer is shown in Fig. 2, together with those of potassium chloride and sodium sulfate. On 0.01 M cupric sulfate, the area per residue is much larger than on 0.1 M potassium chloride, though the film is somewhat more condensed than on 0.01 M cupric sulfate.

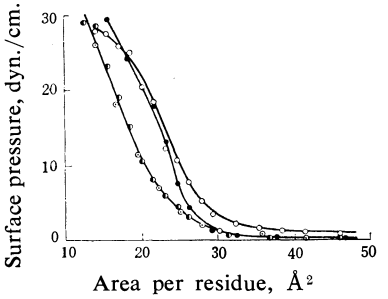

Fig. 2. Effect of cupric sulfate on poly-1-benzyl-L-histidine monolayer at 20°C: ○, 0.01 M cupric sulfate; ●, 0.1 M potassium chloride containing 0.01 M cupric sulfate; ◐, 0.1 M potassium chloride; ⊙, 0.01 M sodium sulfate.

10) T. Yamashita and T. Isemura, This Bulletin, **35**, 929 (1962).

Figure 3 shows the surface viscosity-area (η_s-A) curves of this polypeptide on distilled water, on 0.01 M potassium sulfate and on 0.01 M cupric sulfate containing 0.01 M potassium sulfate. The influence of cupric sulfate is markedly different from that of potassium sulfate. The area where the surface viscosity appears is quite large compared with those on distilled water and potassium sulfate. The results shown in Figs. 2 and 3 suggest that the influence of cupric ions on the monolayer properties of poly-1-benzyl-L-histidine differs from that of alkali salts.

The Π-A curves of poly-1-benzyl-L-histidine on the subsolutions at various concentrations of cupric sulfate, in the absence and in the presence of acetate ions, are shown in Figs. 4 and 5 respectively. In both cases, the Π-A relations are affected markedly by a change in the concentration. The plateau of the Π-A curve found on the acetate buffer disappeared upon the addition of cupric ions. The maximum effect of cupric ions was found to be at the concentration of 0.01 M, whether acetate ions are present or not.

The effect of the concentration of cupric

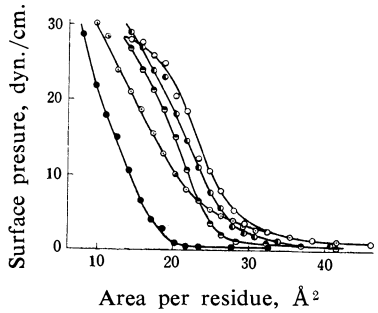

Fig. 4. Effect of the concentration of cupric sulfate on the surfrace pressure-area relation of poly-1-benzyl-L-histidine at 20°C: ●, distilled water; ◓, 0.0001 M; ◐, 0.001 M; ○, 0.01 M; ⊙, 0.05 M.

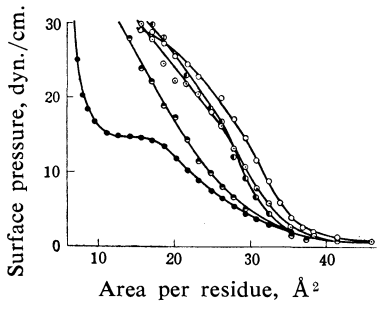

Fig. 5. Effect of the concentration of cupric sulfate dissolved in 0.1 M acetate buffer (pH 5.6) on the surface pressure-area relation of poly-1-benzyl-L-histidine at 20°C: ●, 0 M (control); ◓, 0.0001 M; ◐, 0.001 M; ○, 0.01 M; ⊙, 0.05 M.

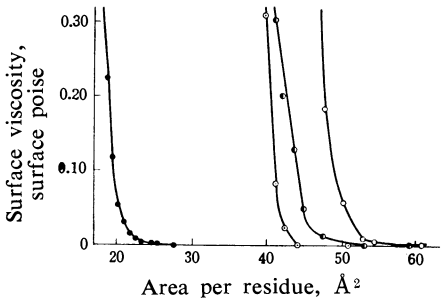

Fig. 6. Effect of the concentration of cupric sulfate dissolved in 0.1 M acetate buffer (pH 5.6) on the surface viscosity-area relation of poly-1-benzyl-L-histidine at 13.5°C: ●, 0 M (control); ◐, 0.001 M; ○, 0.01 M; ⊙, 0.05 M.

sulfate in the subphase of the 0.1 M acetate buffer (pH 5.6) on the η_s-A relation of the poly-1-benzyl-L-histidine monolayer is represented in Fig. 6. The surface viscosity was detected over a much larger area where the surface pressure is considerably lower than in the absence of the cupric ion. The maximum effect of cupric sulfate was found at the concentration of 0.01 M, just as in the case of the Π-A relation.

The surface potential-area (ΔV-A) and the surface moment-area (μ-A) curves of poly-1-benzyl-L-histidine on a 0.1 M acetate buffer (pH 5.6) containing 0.01 M cupric sulfate are compared with those on a copper-free subsolution in Fig. 7.

In the presence of the cupric ion, the surface potential and the surface moment increased more than in its absence in the larger-area region. The surface moment of the film on the subsolution containing the copper ion was higher by about 50 mD in the horizontal portion of the μ-A curve than that on the acetate buffer without the cupric ion.

The effect of the cupric ion on the film properties of this polypeptide is summarized in Table I. It is evident that the interaction

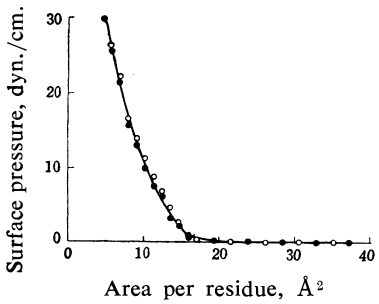

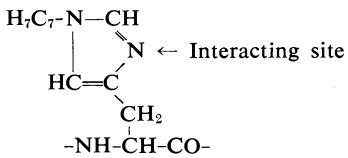

Fig. 8. Surface pressure-area curves of copoly-2 : 2 : 2 : 1-(glycine, *O*-benzyl-DL-serine, β-benzyl-L-aspartate, 1-benzyl-L-histidine) on distilled water (○) and on 0.01 M cupric sulfate (●) at 16°C.

of cupric sulfate with poly-1-benzyl-L-histidine differs from that of alkali salts.

The Π-A curves of copoly-2 : 2 : 2 : 1-(glycine, *O*-benzyl-DL-serine, β-benzyl-L-aspartate, 1-benzyl-L-histidine) on distilled water and on 0.01 M cupric sulfate are shown in Fig. 8. No effects were found with cupric sulfate. 0.05 M potassium chloride and 0.01 N hydrochloric acid also did not affect the Π-A relation of this copolypeptide.

Discussion

As has been described in the preceeding section, cupric sulfate and univalent alkali salts differ significantly in the nature of their interaction with a histidine-containing polypeptide, poly-1-benzyl-L-histidine, although in both cases the interacting site is at the nitrogen atom in the 3-position of the benzylimidazole group,

When cupric sulfate is present in the subsolution, the film expands much more than in the presence of alkali salts. The difference between the effects of alkali salts and cupric sulfate is pronounced in the surface viscosity-area relations. If the cupric ion is present in the subsolution, surface viscosities appear over larger areas and, accordingly, at lower surface pressures than in their absence. Therefore, there might be two types of interaction between poly-1-benzyl-L-histidine and salts: (1) interaction with alkali salts, and (2) interaction with divalent metal salts.

Interaction with Alkali Salts.—On the basis of his study of the properties of long chain amines on aqueous solutions at different pH values, Adam[11] pointed out that the pH's of the subsolution seem to be of little importance in the acid subsolution, and that the films were very much affected by anions in buffer solutions. He concluded that the amines form salts with anions. A similar conclusion was also reached by Hoffman et al.[12]

Patchornik et al.[6] found that a dilute aqueous solution of poly-1-benzyl-L-histidine containing hydrochloric acid gave precipitates of polyvalent salts with various alkali salts. This fact suggests a probable combination of the poly-1-benzyl-L-histidine monolayer with the chloride, sulfate and acetate ions, as in the case of long chain amine monolayers. The salts would be formed between positively-charged benzylimidazolium groups of this polypeptide and anions. Consequently, the film expands on the alkali salt subsolutions more than on distilled water, because the side chains probably take a more horizontal orientation because of the decrease in their hydrophility.

The effect of acetate ions is anomalous.

11) N. K. Adam, *Proc. Roy. Soc.*, **A 126**, 526 (1930).
12) E. J. Hoffman, G. E. Boyd and A. W. Ralston, *J. Am. Chem. Soc.*, **64**, 498 (1942).

Adam[11] found that the monolayer of long chain amine acetate has much less lateral adhesion than that of amine chloride. The monolayer of the salt of poly-1-benzyl-L-histidine with the acetate ion might have much less lateral adhesion than that with chloride or sulfate, which causes a greater expansion and a reorientation of its side chains resulting in the plateau in the Π-A curve.

Interaction with Divalent Metal Salts. — The pronounced effect of the cupric ion on the film properties of poly-1-benzyl-L-histidine can hardly be interpreted in terms of mere interaction between film and anion. A strong interaction exists between the monolayer and the cupric ion. It has been found that the zinc, cobaltous and calcium ions also interact with the poly-1-benzyl-L-histidine monolayer. The results will be reported on in a subsequent paper.

Schulman and Dogan[7] have found a stronger interaction of the copper ion with methemoglobin than with serum albumin in the monolayer, the former having more histidyl groups in its molecule. Patchornik et al.[6] reported that poly-L-histidine forms insoluble complexes with copper, silver, magnesium, mercury, zinc and cobalt. It thus seems reasonable to assume a formation of complexes of poly-1-benzyl-L-histidine with the cupric ions through the nitrogen atoms in the 3-position of benzylimidazole groups. The assumption could possibly be supported by the fact that the surface viscosity of the film appears over a much larger area and at a lower surface pressure in the presence of the cupric ion than in its absence.

It has been found in the mineral or vegetable tanning of protein monolayers that the cross-linkage structure is formed between molecules at the surface, accompanying a remarkable increase in surface viscosity.[13] A similar structure can be considered between poly-1-benzyl-L-histidine molecules as a result of complex formation, which is responsible for the large area over which surface viscosity is first detected. The formation of cross-linkage has been reported also for a protein monolayer reacting with silicic acid.[14][15]

The fact that the surface potential and the surface moment increase more in the presence of the cupric ion than in its absence seems to be another evidence for the formation of complexes. The cationic groups are revealed in the interaction of cupric ions with the poly-1-benzyl-L-histidine monolayer. A similar fact is found to be true in a gelatin monolayer tanned with basic chromium sulfate.[13]

The maximum effect of the cupric ion was found at 0.01 M, above which the area of the monolayer decreased whether acetate ions were present or not, as Figs. 4 and 5 show. It has been found that the coordination ratio of imidazole[3] or 4-methylimidazole[5] to copper decreases from the maximum (4 : 1) with an increasing concentration of the cupric ion. By analogy with this, the number of benzylimidazole groups which associate with a copper ion in subsolution seems to be four at its maximum value and to decrease with an increase in the ion concentration. The decrease may result in the weakening of the cross-linkage structure and may account for the decreases in the areas in Π-A and η_s-A relations.

In contrast with poly-1-benzyl-L-histidine, the monolayer of copoly-2 : 2 : 2 : 1-(glycine, *O*-benzyl-DL-serine, β-benzyl-L-aspartate, 1-benzyl-L-histidine) is not affected by the presence of cupric sulfate in the subsolution. This copolymer contains only 14% of a benzylhistidyl residue, so the polynuclear complexes with copper can be formed only with difficulty.

Summary

The effects of salts on the monolayer properties of poly-1-benzyl-L-histidine and copoly-2 : 2 : 2 : 1-(glycine, *O*-benzyl-DL-serine, β-benzyl-L-aspartate, 1-benzyl-L-histidine) have been investigated.

In the presence of potassium chloride, sodium sulfate, and sodium acetate (pH 5.6), the film expansion has been observed; this has been interpreted in terms of the salt formation between side chains and anions. The addition of cupric sulfate to a subsolution causes the film to expand to increase in surface viscosity and potential, for which cross linkage by complex formation between side chains and metal ions might be responsible.

On the other hand, the monolayer of the copolymer is not affected by the presence of cupric sulfate because of the smaller content of histidyl residue.

The authors wish to express their hearty thanks to Professor Junzo Noguchi of Hokkaido University for supplying them with valuable samples.

*Flammulin, an Antitumor Substance**

By Yumi WATANABE, Koji NAKANISHI, Nobuhiko KOMATSU, Tomohei SAKABE and Hirofumi TERAKAWA

(Received September 16, 1963)

From the aqueous extract of fruit bodies of *Flammulina velutipes*, an edible mushroom, a high molecular weight substance with antitumor qualities against the Ehrlich ascites tumor was isolated by Komatsu et al.[1] and designated "flammulin."

The present paper deals with a procedure for flammulin's purification, some of its physical and chemical properties, and its amino acid composition.

Although the separation of the active component from the material is rendered very difficult by its unstable properties, considerable purification was achieved by the combination of ammonium sulfate fractionation and ethanol fractionation in the cold. Preliminary experiments showed that the precipitates obtained at 66% ammonium sulfate saturation and 75% ethanol were active, while the precipitates, obtained at 50% ethanol were inactive. Further purification was carried out by ion exchange chromatography using DEAE-Sephadex and CM-Sephadex columns. The active component was not bound to DEAE-Sephadex equilibrated with 0.02 M phosphate buffer at pH 7.0. The active fraction, purified on a DEAE-Sephadex column, seemed to be still contaminated with a small amount of colored impurities, and zone electrophoresis on starch showed that it consisted of two or more components, as Fig. 1 shows. Therefore, it was chromatographed on a CM-Sephadex column equilibrated with a 0.005 M acetate buffer at pH 5.6 eluted step by step with 0.01 M, 0.05 M, 0.1 M, and 0.2 M acetate buffers, and separated into two fractions, active and inactive, as is shown in Fig. 2. The active fraction was subjected to rechromatography on a CM-Sephadex column under gradient elution from a 0.005 M to a 0.1 M acetate buffer and then eluted with about a 0.08 M concentration, as Fig. 3 shows. The purified flammulin by chromatography was dialysed against cold tap water and lyophilized. The lyophilization often caused a slight denaturation, but lyophilized flammulin was obtained in an almost colorless state in an average yield of about 120 mg. from 2 kg. of dried fruit bodies. The final fractionation scheme for 2 kg. of the material is given in Scheme 1.

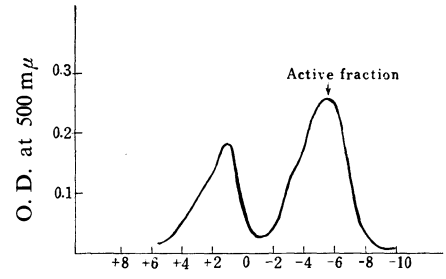

Fig. 1. Zone electrophoresis of partially purified flammulin.
(pH 8.6, μ=0.05, Veronal buffer)

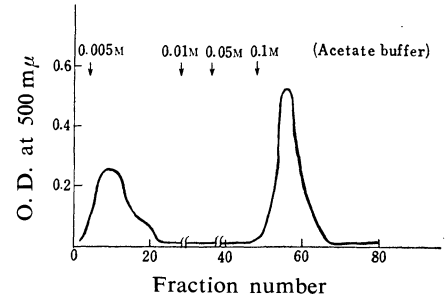

Fig. 2. Chromatogram of partially purified flammulin on CM-Sephadex.

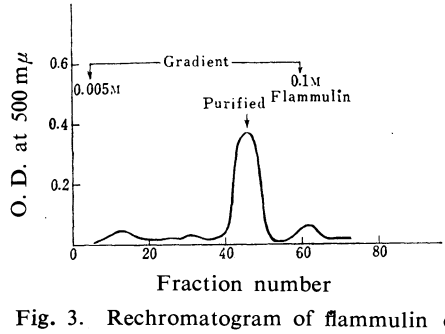

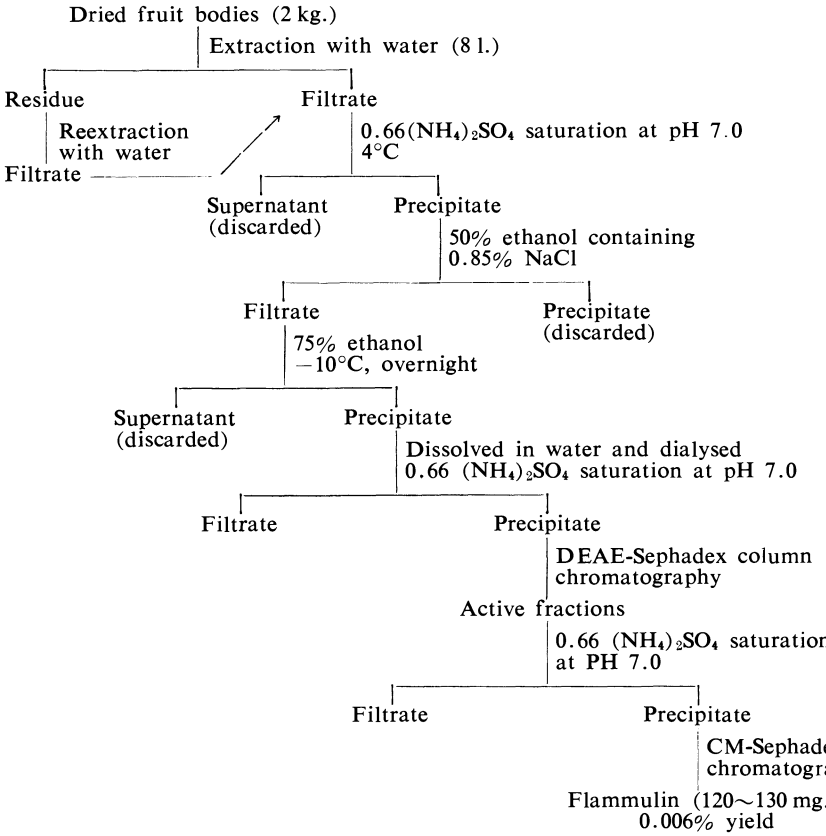

Fig. 3. Rechromatogram of flammulin on CM-Sephadex.

Flammulin purified as above works against the Ehrlichascites tumor when administered at the daily dose of 2.5 γ per mouse.

The purity of lyophilized flammulin was determined by moving boundary electrophoresis, paper electrophoresis, and sedimentation, it was found to be homogeneous in all

* Reported at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

1) N. Komatsu, H. Terakawa, K. Nakanishi and Y. Watanabe, *J. Antibiotics, Ser. A.* **16** (3), 139 (1963).

Scheme 1. Purification procedure of flammulin.

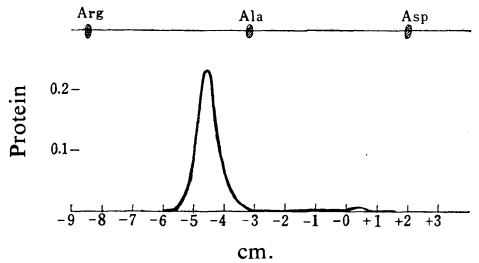

Fig. 4. Paper electrophoresis of flammulin.

these analyses. On the moving boundary electrophoresis, flammulin yielded a single homogeneous peak with a descending mobility of 0.87×10^{-5} cm^2/sec. V. Upon paper electrophoresis at pH 7.0, flammulin moved toward the cathode and showed a single symmetrical peak, as is shown in Fig. 4. The same single bands were obtained on paper electrophoresis over the range from pH 4.6 to 12, and the relative position to the standard amino acids seemed to be unchanged. The sedimentation pattern of flammulin showed only a single symmetrical boundary, indicating that it was homogeneous. The calculated values of the sedimentation and diffusion coefficients were found to be $s_{20w}=2.5$s and $D_{20w}=9.93\times10^{-7}$ cm^2/sec. respectively, figures of which indicate a molecular weight of 24000. The aqueous solution of flammulin shows a typical protein ultraviolet absorption, with the maximum at 277 mμ and the minimum at 251~252 mμ. The nitrogen content of 16.2%, as determined by the micro-Dumas method, is a general value for proteins. Some physical properties are summarized in Table I.

Amino acid analyses of the acid hydrolysates of flammulin were performed on paper chromatography and with an automatic amino acid analyzer; the average results of three separate analyses for the relative stable amino acids are summarized in Table II. The analytical results show that an almost complete liberation of the constituent amino acids was obtained during the first 24-hr. hydrolysis. Since a partial decomposition with an increase in the time of hydrolysis occured with aspartic acid, threonine, serine and proline, the values for these amino acids were corrected for the losses by linear extrapolation to zero time. Similarly, ammonia was found to increase with an increase in the time of hydrolysis, so the value was corrected in the same way as above. As is clear in Table II, flammulin

contained all of the common amino acids except methionine, and no new amino acid composition; this indicates that flammulin is a simple protein composed of only common amino acids. *N*-Terminal amino acid analysis was carried out according to the procedure of Sanger.[2] In chromatography only a single spot of DNP-amino acid was obtained at the position corresponding to DNP-valine. Flammulin is characterized by its high content of aspartic acid and alanine, but the basic properties of flammulin suggest that the carboxyl groups of aspartic acids are masked in the form of amide as well as peptide linkages.

Experimental

The Determination of Antitumor Activity and Protein. — The activity of all the fractions in the purification procedure were assayed by in vivo experiments, using Ehrlich ascites tumor of mice, while the protein contents were determined by the Folin reaction,[3] using the absorption at 500 mμ.

The Extraction of the Active Substance. — Fruit bodies of *Flammulina velutipes* were air-dried and extracted with water (8 l. for 2 kg.) three times in the cold, and aqueous extracts were fractionated.

Fractionation with Ammonium Sulfate and Ethanol. — All fractionations were carried out in the cold to avoid denaturation; ethanol fractionations, especially, were done below −5°C. Ammonium sulfate fractionation was performed by adding solid ammonium sulfate to the aqueous solution while stirring it in the cold.

Chromatographic Purification. — The preparation of DEAE-Sephadex and CM-Sephadex columns and the chromatographic procedure were carried out according to the general method of Sober et al.[4] About one gram of DEAE-Sephadex A-50 was used for the extract from 2 kg. of dried fruit bodies. To the dialysed flammulin solution, a one-tenth volume of 0.2 M phosphate buffer was added at pH 7.0. The effluent was collected in 2 ml. fractions with an automatic fraction collector, and the

3) O. H. Lowry, N. J. Rosenbrough, A. L. Farr and R. J. Randall, *J. Biol. Chem.*, **193**, 265 (1951).

4) H. A. Sober, F. G. Gutter, M. M. Wyckoff and E. A. Perterson, *J. Am. Chem. Soc.*, **78**, 756 (1956).

activity and the protein were measured as has been described above. The active fractions were collected, dialysed, and adsorbed on a CM-Sephadex C-50 column equilibrated with 0.005 M acetate buffer at pH 5.6; the concentration of buffer was changed step by step. The effluent was treated in the same way as above. The crude flammulin preparation obtained in the above chromatography was subjected to rechromatography, using a gradient elution system—one chamber filled with 125 ml. of a 0.005 M, and the other, with 125 ml. of a 0.3 M acetate buffer. The other procedures were the same as have been described above. The purified flammulin was then dialysed and lyophilized.

Electrophoresis. — Moving-boundary electrophoresis was carried out at 8°C for two hours in a phosphate buffer (μ=0.1, pH 7.7) using the Tiselius electrophoresis apparatus. Paper electrophoresis was carried out over the range from pH 4.6 to 12 under the following conditions:

Buffer system: 1/10 M-phosphate or 1/10 M-Veronal-Na-HCl, 1/10 M-Veronal-Na-NaOH.
Filter paper: Toyo-Roshi No. 51, 14.5×35 cm.
Voltage: 300 V./35 cm. (5 mamp.)
Temperature and time: 20°C, 3 hr.

After electrophoresis, the paper was colored with a B. P. B. solution. The excess dye was thoroughly washed out, and the paper was dried and cut off in 0.5 cm. widths. These were then eluted with 3 ml. of a 0.01 N sodium hydroxide aqueous solution, and the protein content was determined from the optical density at 590 mμ. Some amino acids were run under the same conditions, and the positions were detected with ninhydrin.

Sedimentation. — The lyophilized sample of flammulin was dissolved in a phosphate buffer of pH 7.2, μ=0.1, and this solution was subjected to sedimentation. Sedimentation experiments were conducted in a Spinco model E ultracentrifuge at 59780 r.p.m., and the observed sedimentation coefficient was corrected to the value in water at 20°C (s_{20w}) in the conventional manner.

Diffusion. — The diffusion measurements were made with a 0.25% solution in a 1/10 M sodium bicarbonate-carbonate buffer solution (pH 9.75) at 20°C with a Spinco model H diffusion apparatus. The diffusion coefficient was also determined by applying the gel diffusion method of Allison.[5]

Amino Acid Analyses. — The Acid Hydrolysis of Flammulin. — Flammulin (10 mg.) was hydrolysed with 1 ml. of 6 N hydrochloric acid or 0.5 ml. of 12 N hydrochloric acid in a sealed tube at 110°C for 10 to 45 hr. At the end of the hydrolysis period, the hydrolysate was concentrated to dryness on a steam-bath, to remove the excess hydrochloric acid, and finally dried over sodium hydroxide in vacuo.

Amino Acid Composition — The amino acid analyses of the hydrolysated flammulin were performed by two-dimensional paper chromatography (*n*-butanol - acetic acid - water, phenol - water) and with a Beckman-Spinco model 120 automatic amino acid analyser.

Analyses of Tryptophane.[6,7] — To 3 to 5 mg. of flammulin in 1 ml. of water, 30 mg. of dimethylaminobenzaldehyde in 9 ml. of 21.4 N sulfuric acid were added. The solution was allowed to stand at 25°C for 12 hr. in the dark and treated with 0.1 ml. of a freshly-prepared 0.4% sodium nitrite aqueous solution; then, after it had been kept standing for another 30 min. in the dark, the optical density at 580 mμ was measured. The tryptophane content was determined from the standard curve after correction for the blank value.

N-Terminal Amino Acid. — Lyophilized flammulin (10 mg.) was dinitrophenylated in 66% ethanol (3 ml.) containing 8 mg. of 2,4-dinitrofluorobenzene and 10 mg. of sodium bicarbonate at room temperature for 10 hr. The acid hydrolysis of DNP-flammulin was carried out in 1 ml. of 6 N hydrochloric acid at 105°C for 12 hr. The ether-soluble DNP-amino acids were subjected to two-dimensional paper chromatography using *n*-butanol saturated with 2 N ammonium hydroxide as the first solvent and a 1.5 M phosphate buffer as the second solvent. DNP-alanine was used as the standard.

Summary

(1) Flammulin, an antitumor substance of *Flammulina velutipes*, has been demonstrated to be a basic simple protein with a molecular weight of about 24000 and to be homogeneous in electrophoresis and sedimentation.

Analyses of amino acids indicated the following composition:

Lys_5, His_5, Arg_{14}, Asp_{37}, Thr_{20}, Ser_{12}, Glu_{18}, Pro_{19}, Gly_{22}, Ala_{34}, Half-cys_3, Val_5, Met_0, $isoLeu_6$, Leu_9, alloisoLeu$_1$, Tyr_4, phe_8, Try_1, $(CONH_2)_{25}$.

The authors wish to express their thanks to Dr. Nobuhiko Kasai of the Institute for Infectious Dieseases, the University of Tokyo, for the Tiselius electrophoresis analyses, to Dr. Susumu Yamamoto for the sedimentation analyses, and to Takeda Pharmaceutical Industries for the collection of the material. We also wish to acknowledge a grant from the Waksman Foundation.

NOTES

New Routes for the Preparation of 5, 6-Epoxy-6-methylcholestan-3β-ols

By Michio SHIOTA, Misako NOHIRA* and Misako KAWAMOTO**

(Received September 30, 1963)

The reaction of 3β-acetoxy-6-methylcholest-5-ene with monoperphthalic acid has been shown to afford 5α, 6α-epoxide and 5β, 6β-epoxide.[1,2] The present paper will describe new routes to these epoxides.

The acetylation of 3β-acetoxy-6-methyl-5α-cholestan-5, 6β-diol[1] with acetic anhydride and *p*-toluenesulfonic acid at room temperature gave a diacetate (I), which in turn afforded 5, 6α-epoxy-6-methyl-5α-cholestan-3β-ol when refluxed with alcoholic potassium hydroxide. This reaction is analogous to the formation of 5β, 6β-epoxides from 3β, 5, 6β-triacetoxy-5α-steroids,[3] and it has been inferred that the diacetate I is 3β, 6β-diacetoxy-6-methyl-5α-cholestan-5-ol, because the configuration at C_5 is retained in the course of the epoxide formation.

3β-Acetoxy-5-fluoro-5α-cholestan-6-one[4] reacted with methylmagnesium iodide to give 5, 6β-epoxy-6-methyl-5β-cholestan-3β-ol. 3β-Acetoxy-5-chloro-5α-cholestan-6-one[5] also gave 6-methyl-5β, 6β-epoxide, but the reaction of 3β-acetoxy-5-bromo-5α-cholestan-6-one[6] with methylmagnesium iodide afforded 3β-hydroxy-5α-cholestan-6-one[7].

Experimental***

3β, 6β-Diacetoxy-6-methyl-5α-cholestan-5-ol (I).—A solution of 43.1 mg. of *p*-toluenesulfonic acid monohydrate in 6.5 ml. of acetic anhydride was warmed on a water-bath at 90°C for 10 min. and then cooled to room temperature. 3β-Acetoxy-6-methyl-5α-cholestane-5,6β-diol (113.0 mg.) was added to the solution, and the resultant suspension was stirred at room temperature to give a clear reaction mixture in 1 hr. Stirring was continued for another hour, and then the solution was allowed to stand at room temperature overnight. The reaction mixture was treated with water, and the crystalline material which precipitated was collected by filtration. Recrystallization from methanol gave 63.7 mg. of the product (m. p. 137.5~138°C). Additional recrystallization from methanol raised the melting point to 138.5~139°C. $[\alpha]_D$ −26° (*c* 1.03, chloroform). The product gave no yellow color with tetranitromethane and showed hydroxyl absorption in its infrared spectrum. Analysis produced results which agreed with the formula of a diacetate.

Found: C, 73.93; H, 10.60. Calcd. for $C_{32}H_{54}O_5$: C, 74.09; H, 10.49%.

3β-Acetoxy-5, 6α-epoxy-6-methyl-5α-cholestane.—A solution of 41.6 mg. of I and 60 mg. of potassium hydroxide in 2 ml. of absolute ethanol was heated under reflux for 2 hr. The solvent was removed under reduced pressure, and the product was extracted with ether. When the ethereal solution was washed with water a neutral reaction occurred. The removal of the solvent from the dried solution (sodium sulfate) afforded a jelly residue, which was acetylated with acetic anhydride and pyridine at room temperature to give 32.7 mg. of a crystalline, acetylated product (m. p. ca. 142~143°C). Recrystallization from methanol gave 20.7 mg. of 3β-acetoxy-5, 6α-epoxy-6-methyl-5α-cholestane as needles (m. p. 139.5~140°C and 150.5~151°C (double melting points)). The epoxide was identified by the mixed melting point test with an authentic sample. (Found: C, 78.77; H, 11.02%).

3β-Acetoxy-5, 6β-epoxy-6-methyl-5β-cholestane (II).—To a solution of methylmagnesium iodide prepared from 700 mg. of methyl iodide, 116 mg. of magnesium and 11 ml. of absolute ether, 360 mg. of 3β-acetoxy-5-fluoro-5α-cholestan-6-one was added in 9 ml. of absolute ether at 0°C. The reaction mixture was heated under reflux for 2 hr. The solution was treated with an ammonium chloride solution, and the ethereal solution was worked up in the usual way. An oily residue (277 mg.) was

acetylated with acetic anhydride and pyridine at room temperature to afford 280 mg. of a crystalline, acetylated product (m. p. 75~82°C). Filtration through alumina, followed by recrystallization from methanol, gave 196 mg. of 3β-acetoxy-5, 6β-epoxy-6-methyl-5β-cholestane (m. p. 93.5~94.5°C), $[\alpha]_D$ 0° (*c* 1.60, chloroform). (lit.,[2] m. p. 95~95.5°C, $[\alpha]_D$ −2° (*c* 0.94, chloroform)).

Found: C, 78.26; H, 10.72. Calcd. for $C_{30}H_{50}O_3$: C, 78.55; H, 10.99%.

In the attempted reaction carried out at −70°C[8] to obtain 5α-fluoro-6-methyl-6-ol, the starting material was recovered almost quantitatively.

The hydrolysis of II with alkali afforded a free alcohol (m. p. 131~131.5°C) (lit.,[2] m. p. 133~135°C).

Reactions of the Epoxide II.—The reduction of 50 mg. of II with 50 mg. of lithium aluminum hydride in 15 ml. of absolute ether at the boiling point of the reaction mixture afforded 13.4 mg. of 6-methyl-5α-cholestan-3β, 6β-diol[9] (m. p. 191°C).

The hydrolytic cleavage of 49 mg. of II with a 5% solution of phosphomolybdic acid in acetone[10] gave 48 mg. of crude 3β-acetoxy-6-methyl-5α-cholestan-5, 6β-diol (m. p. ca. 185°C). Recrystallization from methanol raised the melting point to 191.5~192.5°C.

These reactions confirm that the epoxide II is 6-methyl-5β, 6β-epoxide.

3β-Acetoxy-5α-cholestan-6-one from 3β- Acetoxy-5-bromo-5α-cholestan-6-one. — 3β-Acetoxy-5-bromo-5α-cholestan-6-one (144 mg.) in 9 ml. of absolute ether was allowed to react with a Grignard reagent prepared from 240 mg. of methyl iodide, 44 mg. of magnesium and 5 ml. of absolute ether for one hour at the boiling point of the reaction mixture. The solution was then worked up in the usual way to give 113 mg. of a semicrystalline residue. The residue was acetylated with acetic anhydride and pyridine at room temperature, and the resultant oily product was crystallized from methanol. The crystalline product (54.8 mg., m. p. ca. 108°C) was recrystallized from methanol to give 25.6 mg. of 3β-acetoxy-5α-cholestan-6-one[11] (m. p. 127.5~128°C). The product was identified by the mixed melting point test and its infrared spectrum.

The authors wish to express their thanks to the Ministry of Education for its grant-in-aid for Fundamental Scientific Research.

A New Alumina Hydrate, "Tohdite" ($5Al_2O_3 \cdot H_2O$)

By Goro YAMAGUCHI, Hiroaki YANAGIDA and Shuitiro ONO

(Received November, 15, 1963)

A new crystal of alumina hydrate has been found by the present authors during an investigation into the hydrothermal reactions of the system aluminum oxide-water.[1] This crystal has been studied by various methods, such as X-ray diffraction, electron diffraction, differential thermal analysis, infrared absorption and polarizing microscopy, and has been proved to be a new alumina hydrate. The formula obtained is $5Al_2O_3 \cdot H_2O$. The species Tohdite is named for the Tokyo Daigaku (The University of Tokyo), where the present investigation was carried out.

Method of Preparation

An appropriate amount of aluminum hydroxide, boehmite AlOOH or gibbsite $Al(OH)_3$, was weighed in a silver capsule of the Morey-type autoclave, and a dilute aqueous solution of aluminum fluoride was added to fill about 80% of the reaction vessel. The autoclave was heated at 450~500°C in an electric furnace for 20~100 hr. The reaction was completed under these experimental conditions. Corundum was found to be useful as the seed crystals, and the new formed hydrate to be useful for the same purpose in the subsequent runs. Aluminum fluoride or titanium (IV) sulfate was effective as the mineralizer.

Properties

Crystallographic Forms and Optical Properties.—The new hydrate, Tohdite, occurs as thin hexagonal plates up to a few microns in thickness when aluminum fluoride is used as the mineralizer (Fig. 1). The crystal form is changed into needles when titanium sulfate is

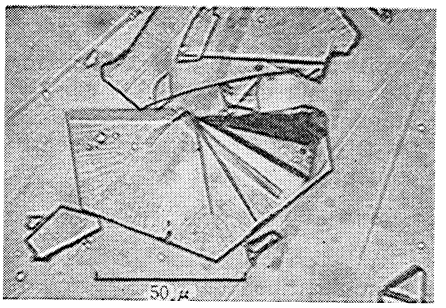

Fig. 1 The new alumina hydrate crystals.

added. Tohdite is uniaxial negative with $\omega=1.738\sim1.748$, $\omega-\varepsilon<0.01$, the c-axis being perpendicular to the plate.

Density.—The density was determined to be 3.72 ± 0.02 g./cm^3.

Thermal Analysis. — Differential thermal analysis was performed up to 1000°C. An endothermic peak was observed between 800 and 900°C, corresponding to the dehydration of Tohdite. The dehydrated form was identified with κ-alumina by X-ray diffraction. The water content, as determined from the weight loss, was about 3.6%. The value calculated for $5Al_2O_3\cdot H_2O$ is 3.42%.

Infrared Absorption Spectra.—The existence of crystalline water was confirmed by the infrared absorption spectra. The absorption band found at 3240 cm^{-1} can be assigned to the stretching frequency for OH groups.

X-Ray Investigations. — The X-ray powder pattern shown in Fig. 2 was recorded on a diffractometer using filtered CuK_α radiation. On the basis of the resemblance of the pattern to that of κ-alumina, this pattern was unmistakably indexed on the hexagonal unit cell with

$$a=5.576\text{Å} \text{ and } c=8.768\text{Å}.$$

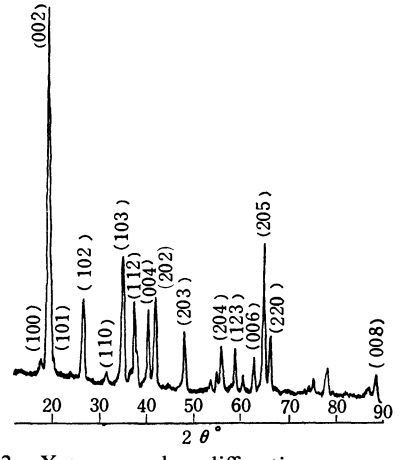

Fig. 2. X-ray powder diffraction pattern of the new hydrate using CuK_α radiation.

TABLE I. X-RAY DIFFRACTION DATA

hkl	d-observed	d-calculated
100	4.85	4.8286
002	4.38	4.3840
101	4.23	4.2296
102	3.246	3.2458
110	2.788	2.7878

403	1.1158	1.1158
207	1.1121	1.1118
008	1.0960	1.0960

The diffraction data are listed in Table I.

Electron Diffraction. — The $\{hk0\}$ spots of the (0001) orientation can be seen in Fig. 3. The incident beam is perpendicular to the hexagonal plate of the crystal. The inner spots gave a d-spacing of 4.8 Å, corresponding to the (100) in Table I. The other diffraction pattern in Fig. 4 represents the periodicity along the c-axis. The beam is perpendicular to the direction of the elongated needle-like crystal, and the observed d-spacing was 4.4 Å, corresponding to the (002) in

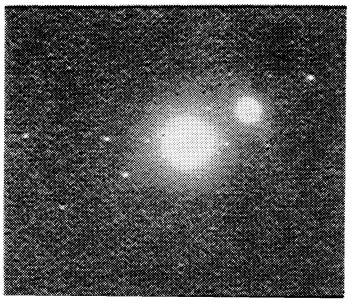

Fig. 3. N-pattern of the new hydrate (electron beam ∥ c-axis).

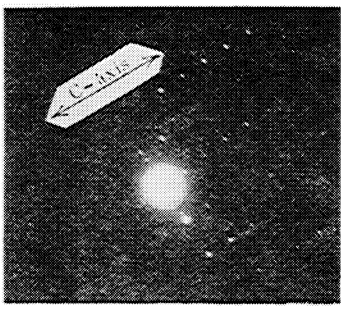

Fig. 4. N-pattern of the new hydrate (electron beam⊥c-axis).

Table I. These results may justify the hexagonal unit cell derived from the powder pattern.

Conclusion

The unit cell dimensions, taken together with the measured values of density and water content, indicate that the unit cell contains $5Al_2O_3 \cdot H_2O$. The calculated density and water content are as follows:

Density	3.71 g./cm^3
Water content	3.42%

The afore-described data seem to establish the existence of a new alumina hydrate, $5Al_2O_3 \cdot H_2O$.

A Note on the Characterization of the Network Structure of the Ion-exchange Resin

By Manabu SENŌ and Takeo YAMABE

(Received December 14, 1963)

The ion-exchange resin is a crosslinked polyelectrolyte,* and the degree of crosslinking is usually designated in terms of the nominal content (weight percent) of divinylbenzene in the monomer mixture. It may be very desirable to describe the degree of crosslinking by a well-defined parameter based on the structural analysis, because it is one of the most important factors in determining the ion-exchange behavior of the resin. It is the purpose of this paper to propose a parameter, M_c, the mean molecular weight per crosslinked unit, for the characterization of the network structure of the ion-exchange resin, and to provide some information on the pore size of the resin.

The degree of crosslinking has a most remarkable effect on the swelling behavior of the resin. Unfortunately, the theory of the swelling of the network of the polyelectrolyte is not established, in spite of great efforts.[1] On the other hand, the theory of the swelling of the neutral crosslinked polymer has been demonstrated by Flory[2] and many experimental investigations have proved its validity. The final expression is:

$$-[\ln(1-v_{2m})+v_{2m}+\chi_1 v_{2m}^2] = (v_1/\bar{v}M_c)(1-2M_c/M)(v_{2m}^{1/3}-v_{2m}/2)$$

where v_{2m}, the volume fraction of the solute at the swelling equilibrium; χ_1, a parameter expressing the first-neighbor-interaction free energy, divided by kT, for the solvent with a polymer; v_1 the molar volume of the solvent; $\bar{v}$, the specific volume of polymer, and M, the molecular weight of a structural unit. The volume ratio of swelling, q_v, is defined by;

$$q_v = 1/v_{2m}$$
$$= (\text{swollen volume})/(\text{unswollen volume})$$
$$= 1+\frac{\rho_2}{\rho_1}q_w-\frac{\rho_2}{\rho_1}$$

where ρ_1 is the density of the pure solvent, ρ_2. is the density of the polymer in a solution**, and q_w is the weight ratio of the swelling.

Therefore, a characteristic parameter, M_c, of the polymer network can be obtained by the

* Most of the ion-exchange resin available commercially is prepared by the sulfonation or by the chloromethylation, followed by the amination, of the base resin of poly(styrene-divinylbenzene).

20.0	1.34	1.38	165	1.57	15.5

measurement of the swelling ratio of the uncharged matrix of the resin. This is a useful parameter for the theoretical consideration of the ion-exchange behavior, if the introduction of the ion-exchange groups into the resin matrix does not have any appreciable effect on the crosslinked structure of the resin.

The experimental procedure is as follows. The copolymer of styrene and divinylbenzene was prepared with benzoyl peroxide as a catalyst, by the block polymerization in the closed tubes. After purification by means of complete drying in vacuo, the polymer was cut into cylindrical rods, about 5 mm. high and 8 mm. in diameter. The weight ratio of the swelling in toluene was measured by weighing of the rods in dry and swelling-equilibrium states.

The results are shown in Table I. This value agrees well with that cited by Kressman and Millar.[3] From this, the volume ratio of the swelling and the mean molecular weight per crosslinked unit are obtained by the use of the above equations. For this, the following figures are used:

$$\rho_1=0.8716, \quad \rho_2=0.978 \ (20°C)$$

$$\bar{v}=0.952, \quad v_1=105.6, \quad \chi_1=0.38^{4)}$$

The results obtained are shown in Table I. In the same table, the mean number of styrene units per crosslinked unit, n, and the mean (maximum) pore diameter in a full-expanded state, $d=\sqrt{2}\,(2.2n+7.5)$, are also given. The latter value is in accord with Grubhofer's estimation[5] by means of a structural model consideration.

The commercial ion-exchange resins of the nominal 8% divinylbenzene are considered to have the mean available pore size of 30 Å.[6] This value is larger than the present value of 24 Å. This disagreement is probable due to the fact that the usually accepted value is based on the observations of large-ion exchange, dye adsorption and so on; therefore, the larger pores are overcounted than the smaller ones.

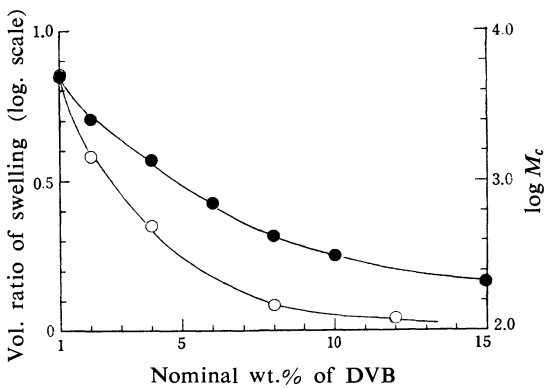

Fig. 1. The volume ratio of the swelling of ion-exchange resins (Dowex 50W, Na-form) in pure water and log M_c–DVB nominal content diagram.
-○- q_v of Dowex 50W, 20°C
-●- log M_c–DVB content

In Fig. 1, the volume ratio of the swelling of the commercially available ion-exchange resin (Dowex 50W, Na-form) in pure water[7] is shown. The ion-exchange resin with a completely dissociated counterion is in a fairly extended state. The details of this will be discussed in a separate paper.

The Formation of Formic Anhydride with N, N'-Dicyclohexylcarbodiimide

By Ichiro MURAMATSU, Michio ITOI, Masaru TSUJI and Akira HAGITANI

(Received December 14, 1964)

It has been reported that various acid anhydrides can be obtained from acids by treatment with *N, N'*-dicyclohexylcarbodiimide (DCC)[1-3] under mild conditions. This suggests the possibility of a successful dehydration of formic acid to yield formic anhydride, when DCC is used as a dehydrating reagent in an inert solvent at low temperature. Formic anhydride is unstable and has not yet been prepared by the usual method. In the present investigation, the dehydration reaction of formic acid with DCC was studied in order to ascertain the formation of formic anhydride.

When formic acid was treated with DCC in ether at room temperature, the evolution of a gas took place rapidly and the precipitate of *N, N'*-dicyclohexylurea was formed in a good yield (Eqs. 1 and 2). When the reaction was carried out below $-5°C$ in the molar ratio according to Eq. 1, no evolution of gas was observed, but the urea was formed in nearly the theoretical yield. Therefore, it was suspected that formic anhydride was formed without decomposition by this reaction.

$$2\ HCOOH + C_6H_{11}\text{-}N{=}C{=}N\text{-}C_6H_{11} \rightarrow HCO\text{-}O\text{-}COH + C_6H_{11}\text{-}NHCONH\text{-}C_6H_{11} \quad (1)$$

$$HCO\text{-}O\text{-}COH \rightarrow HCOOH + CO \quad (2)$$

To confirm the existence of formic anhydride, a part of the solvent was removed from the filtrate under reduced pressure, and the remaining liquid was added into a solution of L-leucine in formic acid or of *p*-nitrophenol in ether; *N*-formyl-L-leucine and *p*-nitrophenyl formate respectively were obtained in good yields. On the other hand, the reactions of formic acid and L-leucine or *p*-nitrophenol in the absence of DCC did not give the formyl compounds. It was concluded from these results that formic anhydride can be obtained from formic acid with DCC at a low temperature, though it has not yet been isolated.

Experimental

***N*-Formyl-L-leucine.**—Into 3.8 ml. (100 mmol.) of formic acid dissolved in 20 ml. of ether, 10.3 g. (50 mmol.) of DCC in 38 ml. of ether was added with stirring in such a way that the temperature did not exceed $-5°C$. After the stirring had been continued for 3 hr., *N, N'*-dicyclohexylurea (10.57 g., 94%) was filtered off. Most of the ether in the filtrate was removed at water-pump pressure. During these procedures the temperature of the mixture was held below $-5°C$. The residual liquid was added into a solution of 1.31 g. (10 mmol.) of L-leucine in 3 ml. of formic acid. After it had been stirred for 2.5 hr. at 0°C, the mixture was concentrated under reduced pressure. The oily residue was recrystallized from ethyl acetate. Yield, 1.27 g. (80%). M. p. 138~139°C. It was identified by comparison with *N*-formyl-L-leucine[4] [m. p. 139~141°C, $[\alpha]_D^{20}$ $-17.7°$ (*c* 4.97, ethanol)], which was obtained with formic acetic anhydride. When 1.31 g. of L-leucine was treated with 8 ml. of formic acid in the same manner without DCC, no formyl compound was yielded.

***p*-Nitrophenyl Formate.**—Nineteen grams (0.41 mol.) of formic acid was treated with 41.2 g. (0.2 mol.) of DCC in 300 ml. of ether as above. *N, N'*-Dicyclohexylurea (43.1 g., 0.192 mol.) was filtered off, and the filtrate was concentrated in an ice-salt bath under reduced pressure to a volume of 170 ml. The resulting solution was added to 9.73 g. (70 mmol.) of *p*-nitrophenol in 20 ml. of ether. Stirring was continued for 2.5 hr. at -10~0°C. After it had stood overnight at room temperature, the mixture was concentrated under reduced pressure to a syrup. Recrystallization of the residue from tetrahydrofuran gave 6.99 g. (41.8 mmol., 60%) of *p*-nitrophenyl formate; m. p. 73~74°C[5]; IR spectrum (in carbon tetrachloride): 1750, 1200, 1090 cm^{-1} (ester). The same run in the absence of DCC did not give the formate, but the *p*-nitrophenol was recovered.

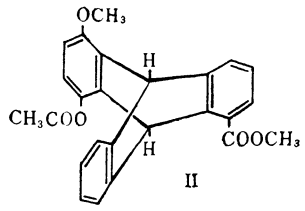
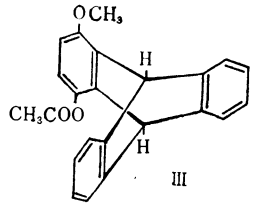
Confirmation of the Structures of 2-Acetoxy-5-methoxy- and 5-Acetoxy-2-methoxy-7-methoxycarbonyl-triptycenes by Means of Electric Dipole Moments



By Fumio OGURA, Yoshio TOSHIYASU,* Ko KIMURA,* Ryoichi FUJISHIRO,* and Masazumi NAKAGAWA

(Received January 24, 1964)



The monomethylation, followed by the acetylation, of 2, 5-dihydroxy-7-methoxycarbonyltriptycene, which was derived from 2, 5-diacetoxy-7-methoxycarbonyltriptycene,[1] afforded two isomers, I (m. p. 269~270°C) and II (m. p. 279~280°C). The deacetylation of I and II yielded the corresponding hydroxymethyl ethers. Only the hydroxy-methyl ether derived from II shows a weak infrared absorption due to an intra-molecular hydrogen bond, indicating the proximate spatial positions of the hydroxyl and methoxycarbonyl groups. On the basis of this evidence, the structures shown below have tentatively been assigned to these compounds.[2]

I

II

III

In order to confirm the structures of I and II, the present authors have measured the electric dipole moments of I and II in *p*-dioxane at 25°C, together with that of 2-acetoxy-5-methoxy-triptycene (III, m. p. 274~275°C) as a reference substance.

The polarization data of these compounds are summarized in Table I. The notations ε, v, n, ω, $p_{2\infty}$, P_2, R_D, and μ represent the dielectric constant, the specific volume, the refractive index, the weight fraction of the solute, the specific polarization, the molecular polarization, the molecular refraction for the sodium D line, and the dipole moment respectively. The dielectric data were analyzed according to the Halverstadt-Kumuler's method, and the dipole moments were obtained on the assumption that distortion polarizations are equal to $1.05\times R_D$.[3]

The estimation of the molecular dipole moments of I, II, and III was carried out on the basis of the following fundamental assumptions: 1) the additivity of the vectors of the group moments,[4] and 2) the D_{3h} symmetry of the triptycene skeleton. The values and directions of the group moments used in the calculation are given in Table II. With regard to the substituents at the 2- and 5-positions, the following three possible configurations (a, b, and c) were taken into consideration: a) both the methoxyl and acetoxyl groups lie in the same plane as that of the aromatic ring A, and the substituent groups take the cis-configuration because of the steric hindrance of the hydrogen atoms at the 1- and 6-positions;[5] b) both the methoxyl and the acetoxyl groups lie on a plane perpendicular to the plane of the aromatic ring A, and the substiuent groups take the cis- or trans-configuration; and c) the methoxyl group takes a coplanar position

n^2	$2.01642+0.436\omega$	$2.01642+0.468\omega$	$2.01642+0.482\omega$
$p_{2\infty}$	0.7034 cc.	0.5402	0.5749
P_2	281.7 cc.	216.3	196.8
R_D	111.8 cc.	111.2	99.0
μ	2.84 ± 0.14D	2.21 ± 0.13	2.13 ± 0.11

Table II. Values and directions of group moments

Group	Moment (D)	Direction
Methoxycarbonyl (CH_3-O-C(=O)-)	1.83	70° with the bond between the carbon of 7-position and the carbonyl carbon.
Methoxyl (CH_3--O-)	1.25	55° with the bond between the carbon of 5- or 2-position and the oxygen atom.
Acetoxyl (CH_3-C(=O)-O-)	1.52	129° with the bond between the carbon of 2- or 5-position and the oxygen atom.

with the aromatic ring A, whereas the acetoxyl group lies on the plane perpendicular to the latter plane. Concerning the methoxycarbonyl group on carbon 7, it was assumed that the group takes a coplanar configuration with the aromatic ring B to attain the maximum mesomeric effect. Since two conformations seem to be possible, i. e., the conformation with the closest distance between the carbonyl oxygen and the hydrogen atom at the 6-position and that with the greatest distance between the above-mentioned two atoms, the notations bearing asterisk (a*, b*, c*) are employed to indicate the latter conformation. The calculated results are given in Table III. The values of the dipole moments based on the configuration b and b* are the root mean square values of the four possible configurations and turn out to be identical. The values based on c and c* are those of the two possible configurations.

Table III. Calculated dipole moments (D)

Configuration	I	II	III
a	2.92	2.09	1.68
a*	2.83	1.95	1.68
b, b*	3.27	2.55	2.29
c	2.98	2.18	2.29
c*	3.53	2.87	2.29

These calculations lead to the conclusion that the dipole moments of I are always greater than those of II for all probable configurations and that discrimination between I and II is, therefore, possible. The most satisfactory agreement with the observed values is obtained in the case of the configuration c which is supported also by the electronic spectral information on I and II.[2)]

The Influence of Heat Treatment on the Solidification Time of the Reversible Sol-Gel Transformation of Gelatin

By Hitoo KAKIYAMA and Tominosuke KATSURAI

(Received January 27, 1964)

In a previous paper it was mentioned that the solidification time of the reversible sol-gel transformation of the sols of silicic acid, of agar-agar and of gelatin is noticeably shortened by heat treatment.[1] The characteristic feature of this phenomenon can be expressed by the formula:

$$T_1 > T_2 \qquad (1)$$

where T_1=the thixotropic solidificatcn time, and
T_2=the solidification time under heat treatment.*

The term "thermopexy," on the model of rheopexy, has been suggested for this phenomenon, indicating that the gelation tendency of thixotropic sol is accelerated by heat treatment.

Lately, however, we have realized that neither the qualification nor the method of preparing the gelatin in the previous experiment was adequate and that the conclusion obtained needed to be corrected. From a comparison of the results of the reinvestigation of gelatin with the data on silicic acid and agar-agar, we came to the following conclusion on the influence of heat treatment: there are two modes in thermopexy, positive and negative, the former being the case with silicic acid and agar-agar, and the latter with gelatin.

Experimental and Discussion

The characteristics of the gelatin used in the experiment are as follows: Water content, 17% wt.; isoionic point, 4.85; viscosity, 5.7 centipoise (measured for 4.2% sol at 35°C by using an Ostwald viscosimeter); rigidity, 4.1×10^5 dyn./cm^2 (measured for the 4.2% gel obtained by keeping the sol 8 hr. at 0~1°C).

The experiments are carried out as follows. Six grams of the gelatin is put into a beaker with 400 ml. of water and is left to stand 2 hr. at room temperature. Swelling takes place. The beaker is then kept at 50°C for 30 min. The swollen gelatin turns out to be a homogeneous sol. The total weight of the sol is then made 500 g. by adding water. Thus we get the gelatin sol of the concentration 1%, i.e., 1 g. gelatin per 100 g. of the sol. Ten milliliters of the sol is put into each of the 20 test tubes, each with a radius 13.5~14 mm. The test tubes are then left to stand at room temperature (10~15°C). The sol changes into a gel which does not flow out, even when the test tube is placed upside down. All of the test tubes are shaken by hand, and the gel in them is brought into sol. The test tubes are then divided into two groups. (a) 10 test tubes are left to stand at room temperature and are used for the study of the thixotropic solidification time, T_1. (b) The other 10 test tubes are used for the study of T_2. They are put into a water bath of 50°C for 2 min. and then left to stand at room temperature; the resulting change is observed. The temperature of 50°C was chosen in order to avoid the denaturation of gelatin. The test tubes (a) and (b) are tilted one after another at certain time intervals, and the resulting decrease in fluidity is observed. The time at which the sol ceases to flow is taken as the solidification time. The average values of T_1 and also of T_2 are taken.

The influence of foreign substances was also studied. Urea and KSCN were chosen as the substances which destroy the hydrogen bond, and $KAl(SO_4)_2$ as the substance which forms bridges between gelatin molecules. The results are summarized in the following table.

Foreign substance	Concn. of the foreign substance mol./1000 g. sol	T_1 min.	T_2 min.	Concn. of sol g./100 g. sol
None	—	25	140	1
$CO(NH_2)_2$	0.1	30	170	1
	0.5	50	225	1
KSCN	0.1	25	140	1
	0	95	220	0.8
$KAl(SO_4)_2$	0.005	80	190	0.8
	0.01	50	180	0.8
	0.02	35	150	0.8

We see that in all cases

$$T_1 < T_2 \qquad (2)$$

1) T. Katsurai and K. Inouye, *Kolloid-Z.*, **142**, 162 (1955).

* For the sake of convenience T_1 is taken as the standard in this article; the change of T_2 is discussed relative to T_1.

This is just the opposite of (1). This means that the influence of heat treatment on the solidification time in the case of gelatin appears in the reverse (or negative) direction as compared with the case of silicic acid and that of agar-agar. Repeated experiments with the same sample gave the same result. Although both T_1 and T_2 increase with the rise in room temperature, relation 2 is still satisfied.

The presence of urea in the sol increases T_1 and T_2. If the concentration of urea exceeds 1 M per 1000 g., the sol does not set into a gel and it becomes impossible to carry out the experiment. In the case of KSCN, the experiment becomes difficult when the concentration exceeds 0.5 M per 1000 g. because of the enormous increase in solidification time. The presence of $KAl(SO_4)_2$ in the sol greatly decreases T_1 and T_2. Thus the experiment was carried out with a sol of a smaller concentration and a small amount of the salt.

The Polarography of 3, 6-Anhydro-galactose

By Teruko FUJIWARA, Kensaku MORIHARA and Choji ARAKI

(Received September 16, 1963)

As 3, 6-anhydro-galactose is so unstable in acid that it decomposes readily to 5-hydroxymethyl furfural and then to levulic acid and formic acid, it is difficult to obtain this sugar by the methods usually used for the hydrolysis of polysaccharides. Using methanolysis, Araki and Hirase[1,2] first isolated the dimethyl acetal of this sugar and thus confirmed the natural occurrence of anhydro-sugars. Later O'Neil and Stewart[3] developed an indirect procedure for the detection of anhydro-sugars in polysaccharides. This procedure was based on the fact that, when polysaccharide is treated with N/50 sulfuric acid, only anhydro-sugar is converted to 5-hydroxymethyl furfural, and the latter can be determined photometrically. Because the pyranose ring of 3, 6-anhydro-sugar tends to open, giving aldehyde much more easily than do any other hexoses, the authors applied a polarographic method in studies of this sugar. In polarographic studies of various monosaccharides, Cantor and Peniston[4] reported that reduction waves could be detected with ketoses, even in 10^{-3} M in a phosphate buffer. On the other hand, under the same conditions as aldoses, these could only be at much higher concentrations, such as 10^{-1} M. Our studies of 3, 6-anhydro-L-galactose (AG)* and agarobiose (AGB)**, 4-D-galactopyranosyl-anhydro-L-galactose, showed that these compounds showed perceptible waves in the neutral and basic range, even in 10^{-3} M. (Fig. 1); this character was different from that of other aldoses. AG showed triplet and AGB, double waves; in each case, only the last wave changed in height with a change in pH value, (Fig. 2). To judge from the results of

A) 3,6-Anhydro-L-galactose, 5.3×10^{-3} M, 3rd wave: $E_{1/2}=-1.42$ V, $i_d=1.77$ μA.
B) Agarobiose, 1.36×10^{-3} M, 2nd wave: $E_{1/2}=-1.38$ V, $i_d=0.66$ μA.
C) A mixture of 3,6-anhydro-L-galactose (4.8×10^{-3} M) and D-fructose (4.1×10^{-3} M), 3rd wave: $E_{1/2}=-1.42$ V, $i_d=1.44$ μA.

The procedures were carried out at 20~25°C using a Shimadzu RP-2 type polarograph. The capillary had an *m*-value of 1.227 mg./sec. and the drop time was 5.6 sec. in 0.2 N potassium chloride at a potential of 0.0 V. vs. S. C. E. with a mercury head of 58 cm.

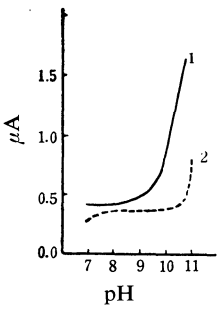

Fig. 2. Relation of wave height and pH for 10^{-3} M. 3,6-anhydro-L-galactose and agarobiose.

1: 3rd wave of 3,6-anhydro-L-galactose
2: 2nd wave of agarobiose

Cantor and Peniston, these waves may be presumed to be reduction waves of the aldehyde of the sugar. The height of the last wave was proportional to the concentration of AG in around 1×10^{-3} M in a Michaelis buffer (0.2 M NH_3-NH_4Cl) at pH 9.0, in which the most typical wave pattern was observed. The half-wave potentials of both sugars were about −1.4 V. vs. S. C. E. respectively (Table I) this value is smaller than those of any other sugars, but larger than that of 5-hydroxymethyl furfural (−1.3 V. vs. S.C.E.), as judged from our preliminary tests. It was also found that 3,6-anhydro-sugars are detectable by polarograpy, even in the presence of fructose (Fig. 1-c). In this case the figure of the wave was partially changed, but the potential of the waves remained unchanged. In conclusion, it may be said that as little 3,6-anhydro-sugar as about 3×10^{-3} M can be determined easily and rapidly by polarography.

The Cation Effect on the Polarographic Reduction of Trioxalatochromate(III) Ions

By Nobuyuki TANAKA, Eiki ITABASHI and Reita TAMAMUSHI

(Received January 13, 1964)

Recently, Pamfilov, Lopushans'ka and Zueva reported that trioxalatochromate(III) ($[Cr(ox)_3]^{3-}$) ions gave two irreversible polarographic waves, with half-wave potentials of -1.315 and -1.450 V. vs. NHE, in a 1.0 N potassium chloride solution.[1] This seemed to contradict our previous statement that $[Cr(ox)_3]^{3-}$ ions gave no reduction wave in a 0.1 M solution of tetramethylammonium bromide.[2] Therefore, the reduction of $[Cr(ox)_3]^{3-}$ ions has been investigated again; a marked cation effect on the half-wave potential and the limiting current of the wave has thus been revealed.

Typical one-step irreversible waves were obtained in various supporting electrolyte solutions. The limitting current was found to be diffusion-controlled and proportional to the concentration of the complex ions. The overall electrode process was considered to be of a three-electron reduction of chromium(III) to chromium(0), (cf. the reduction wave of cis-$[Cr(ox)_2(H_2O)_2]^-$).[3] The half-wave potentials obtained are given in Table I; they clearly indicate that the reduction potentials of $[Cr(ox)_3]^{3-}$ ions depend on the nature and the concentration of the cations present. The half-wave potentials shift to less negative potentials with the increasing ionic charge of the cation and, at the constant ionic charge, with the decreasing radius of the hydrated ion and the increasing concentration of the cations present. The diffusion current constants were also found to be dependent on the nature and the concentration of the cations present.

TABLE I. THE HALF-WAVE POTENTIALS OF THE POLAROGRAPHIC WAVES OF $[Cr(ox)_3]^{3-}$ IONS OBTAINED IN VARIOUS SUPPORTING ELECTROLYTE SOLUTIONS AT 25°C

Electrolyte soln.	$E_{1/2}$ V. vs. SCE
0.1 M $(CH_3)_4NBr$	—
1.0 M LiCl	−1.76
1.0 M NaCl	−1.70
0.1 M KCl	−1.83
0.3 M KCl	−1.76
1.0 M KCl	-1.68_5
3.0 M KCl	−1.64
1.0 M $MgCl_2$	−1.56
1.0 M $SrCl_2$	-1.51_5
1.0 M $BaCl_2$	−1.51

These facts may be explained by taking into account both the double-layer effect and the formation of ion-pairs.[4,5] The $[Cr(ox)_3]^{3-}$ ions are reduced at the negative side of the electrocapillary maximum. If the potential difference across the diffuse double layer decreases with the increasing concentration of electrolytes or by changing the nature of the cation of electrolyte in the solution, the electrostatic hindrance between the electrode and the $[Cr(ox)_3]^{3-}$ ions decreases and, consequently, the surface concentration of the complex anions increases. This and an increase in the effective potential difference in the Helmholtz layer accelerate the reduction of $[Cr(ox)_3]^{3-}$ ions, which therefore takes place at less negative potentials. The formation of ion-pairs, which is to be expected from the change in the diffusion current constant, lessens the total ionic charge of electroactive species and, consequently, facilitates the approach of $[Cr(ox)_3]^{3-}$ anions to the electrode surface.

These results lead to the conclusion that the $[Cr(ox)_3]^{3-}$ ions are reduced to give a one-step polarographic wave provided the electrostatic hindrance between the electrode and the complex ions is decreased by the change in the structure of the double layer and by the formation of the ion-pairs.

The Relative Signs of the ^1H–^1H Coupling Constants of Styrene Oxide

By Hiroshi SHIMIZU and Yoshifumi HAMA

(Received February 4, 1964)

The NMR spectrum of styrene oxide has analyzed by Railly and Swalen[1] at 60 Mc. They reported that, though the position of the lines could be accounted for by two different nonequivalent assignments, J_{AC} and J_{BC}, with the same signs or different signs, the intensities were much more in agreement when J_{AC} and J_{BC} had the same sign, and that equivalent assignments could be obtained by positive or negative J_{AB} with positive (or negative) J_{AC} respectively. They arbitrarily chose both to be positive: $J_{AB}=+5.65$, $J_{AC}=+2.49$, and $J_{BC}=+4.04$ c.p.s.

On the other hand, the relative signs of the geminal and vicinal ^1H–^1H coupling constants are different in many organic compounds,[2] inconsistent with the prediction from the valence bond theory.[3] This suggests that the set of the coupling constants $-J_{AB}$, $+J_{AC}$, and $+J_{BC}$ (or $+$, $-$, $-$) would be correct, whereas the set of $+$, $+$, and $+$ (or $-$, $-$, $-$) would be wrong. In this communication, the result of our analysis, by means of which the correct set can be chosen, will be reported.

Since our calculations showed that the both sets could be practically distinguished from one another at frequencies below 20 Mc., the NMR spectrum of this compound was observed and recorded at 15 Mc. with a Varian 4300C spectrometer. It was found that the observed line-positions could be accounted for by the set of the coupling constants $+J_{AB}$, $+J_{AC}$, $+J_{BC}$ (or $-$, $-$, $-$) as shown in Fig. 1. This rather unexpected result may be ascribed to the specific structure of the three-membered ring of styrene oxide; it suggests that the signs of ^1H–^1H coupling constants are not definite for one type of a coupling of protons, as has been believed generally, but that they change depending on the chemical structure, for example, those in epoxides.

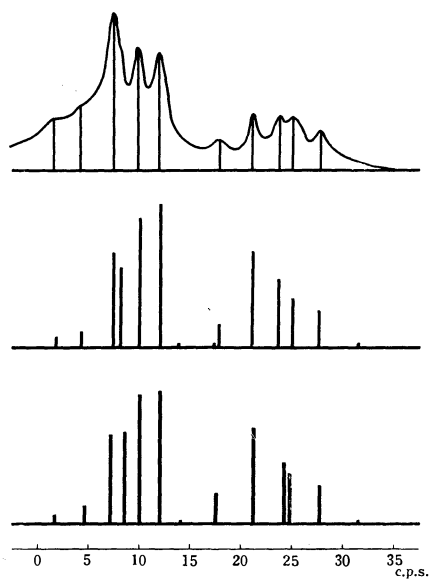

Fig. 1. The observed and calculated spectra of the ABC system of styrene oxide at 15 Mc.: the uppermost one is the observed spectrum and the middle and the lowest ones are the spectra calculated by using the sets $+J_{AB}$, $+J_{AC}$, $+J_{BC}$, and $-J_{AB}$, $+_{AC}$, $+J_{BC}$, respectively. The intensities of the observed lines are inaccurate because the spectrum was not recorded under the optimum conditions.

It is an interesting problem to determine whether the absolute signs of these coupling constants are positive or negative. Our conclusion on this point, as well as more detailed results of our analysis of the NMR spectrum of this compound, will be published elsewhere.

The authors wish to thank Dr. Ichiro Yamaguchi of the Japan Atomic Energy Research Institute for his kindness in measuring the 15 Mc. spectrum.

On the Thermal Analysis of the Phase Transition of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$

By Yôichi IIDA, Minoru KINOSHITA, Asako KAWAMORI and Keisuke SUZUKI

(Received February 22, 1964)

In a previous paper,[1] we presented the temperature dependences of the electrical conductivity and ESR absorption of the TCNQ anion radical salt of triphenylmethylphosphonium, $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$. The magnetic behavior of this salt has been known to show a singlet-triplet nature in the lower temperature range.[2,3] However, the ESR absorption intensity increased abruptly at about 40°C with an increase in the temperature. The discontinuity was also found in the electrical conductivity at 40°C. It was suggested that this discontinuity might be ascribed to a phase transition of the crystal.[1] Our preliminary X-ray study showed that there was a slight but clear difference between the crystal structures above and below 40°C. In this paper we will present other evidence on the phase transition obtained by the method of a differential thermal analysis.

The measurements were performed by means of a Shimadzu DT-10 differential thermal analysis apparatus, using powdered fused silica as a standard substance. One of the thermograms of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ is shown in Fig. 1, in which the rates of raising and lowering the temperature were 3.0°C/min. and 2.8°C/min. respectively. Evidently the endothermic phase transition occurs at 40.4±0.25°C with an increase in the temperature. In order to determine the heat associated with this phase transition, the area of the signal line of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ was compared with that of hexachloroethane. The phase transition of hexachloroethane, C_2Cl_6, occurs at 318.1°K with $\Delta H=0.613$ kcal./mol.[4] By using the molecular weight (686) of $[(C_6H_5)_3PCH_3]^+\cdot(TCNQ)_2^-$, the heat of transition, ΔH, was calculated as 0.558 kcal./mol., and the associated entropy change was estimated as $\Delta S=1.78$ e. u. These small values indicate that the phase transition observed is slight in its nature, which is quite in accordance with our preliminary X-ray study. It is interesting to see that this slight change in the crystal structure results in a fairly large change in its physical properties, such as electrical conductivity and magnetic susceptibility.

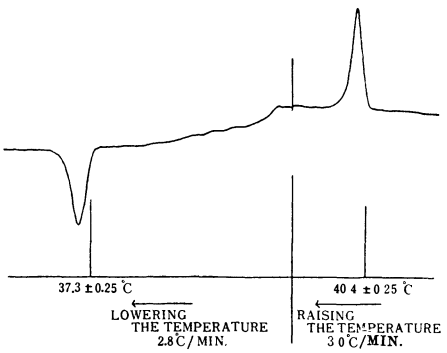

Fig. 1. One of the thermograms of $[(C_6H_5)_3\cdot PCH_3]^+(TCNQ)_2^-$.

On the other hand, a similar result of thermal analysis has been already obtained with Wurster's blue perchlorate crystals by two of the present authors (A. K. and K. S.).[5] McConnell et al.[6] have shown recently that the discontinuity observed in the temperature dependence of the paramagnetic susceptibility of Wurster's blue perchlorate is due to the formation of the dimeric structure below 187°K as a result of the change in the crystal structure. These phenomena appear to be quite analogous to our results.

The Polarography of Ethylenediaminetetraacetato-Cobaltate(III) and Cobaltate(II) Complexes

By Nobufumi MAKI

(Received February 24, 1964)

For analytical purposes the EDTA salts, Na_2H_2 edta·$2H_2O$ and Na_4 edta·1/2 H_2O, have often been used as a masking or a complexing reagent in polarography.[1] However, there have been few reports on the relationship between the structure of EDTA complexes and their polarographic behavior in the absence of an excess $edta^{4-}$ ions.[2]

The present communication dealts mainly with the polarography of EDTA cobalt(III) complexes of the $[Co^{III}$ edta X] type in the absence of an excess $edta^{4-}$ ion, where the unidentate ligand, X, denotes the ion, Cl^-, Br^-, NO_2^-, OH^- or OH_2.

The complex, K $[Co^{III}$ edta] ·$2H_2O$, was found to give rise to only one wave, corresponding to an acceptance of one electron, in a 0.5 F sodium sulfate solution at the dropping mercury electrode (DME). The wave was present in the positive region of the potential. The limiting current of the wave was proportional to the concentration of the complex in the range of 10^{-2}~10^{-4} F and was diffusion-controlled.

The process of the electrode reaction was concluded to be as follows:

$$[Co^{III}\,edta]^- + e^- \rightarrow [Co^{II}\,edta]^{2-}$$

The cobalt(II) complex, $Na_2[Co^{II}$ edta] ·$3/2H_2O$, gave no reduction wave at all in a 0.5 F sodium sulfate solution without an excess $edta^{4-}$ ion.

The hexaquocobalt(II) chloride, $[Co^{II}(OH_2)_6]$·Cl_2, also gave no reduction wave in the presence of 1/4 F sodium ethylenediaminetetraacetate at the DME.

The chloro-, bromo-, nitro- and hydroxo-ethylenediaminetetraacetato-cobaltate(III) complexes, $K_2[Co^{III}$ edta·Cl] ·$3H_2O$, $Na_2[Co^{III}$ edta·Br] ·$4H_2O$, $Na[Co^{III}$ edta$(NO_2)]$ ·$3H_2O$, and $Na_2[Co^{III}$ edta(OH)] ·$3H_2O$,[3] were found to be irreversibly reduced in two steps to the metal through cobalt(II) complexes in a 0.5 F sodium sulfate solution at the DME.

The ratio of the height of the first wave to that of the second was roughly 1 : 2 for all the complexes. All the first waves existed in the positive region of potential except the hydroxo-complex. The limiting current of each wave was proportional to the concentration of the complex in the range between 10^{-4} and 8×10^{-3} F and was diffussion-controlled.

The nitro-EDTA cobalt(III) ion, [Co edta·$(NO_2)]^{2-}$, was found to be reduced up to the cobalt(II) state in a 1 F potassium nitrite solution, not reduced to the metal. Therefore, the second wave obtained in a 0.5 F sodium sulfate solution is due to the reduction of the

TABLE I. HALF-WAVE POTENTIALS OF THE WAVES FOR THE EDTA COBALT(III) AND COBALT(II) COMPLEXES

Compound	$E_{1/2}$ of the 1st wave Co(III) → Co(II)	$E_{1/2}$ of the 2nd wave Co(II) → Co(0)	Supporting electrolyte
$Na_2[Co^{II}$ edta]·$3/2H_2O$	——	No reduction	0.5 F Na_2SO_4 (25°C)
$K[Co^{III}$ edta]·$3H_2O$	+	No reduction	0.5 F Na_2SO_4
K_2[Co edta·Cl]·$3H_2O$	+	ca. −1.6	0.5 F Na_2SO_4
Na_2[Co edta·Br]·$4H_2O$	+	−1.62	0.5 F Na_2SO_4, 0.0058% Triton X 100
Na_2[Co edta $(NO_2)]$·$3H_2O$	+	-1.05_6	0.5 F Na_2SO_4
	+	No reduction	1 F $NaNO_2$
Na_2[Co edta (OH)]·$3H_2O$	-0.10_3	-1.05_5	0.5 F Na_2SO_4 (0°C)*
$[Co^{II}(OH_2)_6]Cl_2$	——	No reduction	1/4 F Na_4 edta (25*C)

Voltage unit: V. vs. SCE. Concentration of the complex: 5×10^{-3} F

* The ion, $[Co\,edta\,(OH)]^{2-}$, is unstable in solution and tends to become the ion, [Co edta·$(OH_2)]^-$ in neutral unbuffered solution.

1) edta = $(OCOCH_3)_2N\cdot CH_2CH_2\cdot N(CH_3COO)_2^{4-}$

2) More exactly, the ions, $edtaH_3^-$, $edtaH_2^{2-}$, etc., are usually present together in solutions.

3) I. A. Shimi and W. C. E. Higginson, *J. Chem. Soc.*, **1958**, 260.

aquated species of this complex.

Table I shows the half-wave potentials of the waves for these complexes. All the waves were irreversible.

The following processes of the electrode reaction are considered to be most plausible:

$$[Co^{III}\,edta\cdot X]^{2-} \xrightarrow{e^-} [Co^{II}\,edta\cdot X]^{3-} \xrightarrow{2e^-} Co\ (metal)\quad X=Cl,\ Br,\ OH$$

$$[Co^{III}\,edta(OH_2)]^{-} \xrightarrow{e^-} [Co^{II}\,edta(OH_2)]^{2-} \xrightarrow{2e^-} \quad \text{in } 0.5\ \text{F } Na_2SO_4$$

$$[Co^{III}\,edta(NO_2)]^{2-} \xrightarrow{e^-} [Co^{II}\,edta(NO_2)]^{3-}$$

in 1 F KNO_2

From these results it can be said that the EDTA-cobalt(II) ion in solution usually contains the $edta^{4-}$ ion as a hexadentate ligand in its coordination sphere.

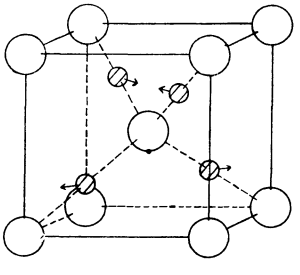
The Infrared Absorption Spectrum of Cuprous Oxide



By Minoru TERADA

(Received February 24, 1964)

Cuprous oxide Cu_2O is a well-known crystal whose bond character is considerably covalent. It has a crystal structure belonging to the space group O_h^4. The unit cell contains four copper atoms and two oxygen atoms. A group theoretical consideration shows that this crystal has two F_{1u} optically-active lattice vibrations. Their vibrational modes are shown in Fig. 1. The a mode in Fig. 1 is considered to cause the relatively higher frequency band, and the b mode, the lower one.

Mode a

Mode b

Fig. 1. Infrared active vibrational modes of Cu_2O.

◍ Copper ○ Oxygen

In order to examine the bond character of cuprous oxide, the present writer made an infrared absorption measurement of cuprous oxide in the KBr pellet and in a polyethylene film.[1] The spectrum obtained is shown in Fig. 2. Absorption measurements in the rock-salt, potassium bromide and cesium bromide regions were made by the use of a Perkin-Elmer model-221 spectrometer, and those in the far infrared region, by the use of a grating spectrometer built by Yoshinaga et al.[2]

In the spectral region examined, two strong absorption bands, were found at 617 cm^{-1} and 147.5 cm^{-1}. These are evidently attributable, respectively, to the optically-active lattice

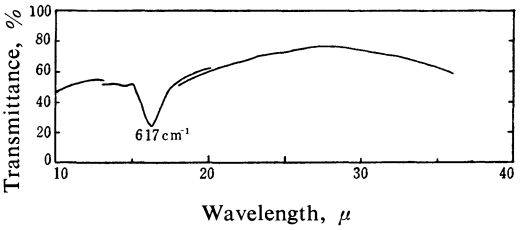


Fig. 2a. Infrared absorption spectrum of Cu_2O in KBr disc.

(------) 100 mg./2 g. polyethylene

vibrations a and b mentioned above. Of these two strong bands, the one at 617 cm^{-1} had already been found by O'Keeffe[3] and had been assigned by him to one (a) of the two expected infrared active vibrations. However, it has been a question where the other band (b) is situated. O'Keeffe assigned a band at 1122 cm^{-1} to one (b) of the two infrared-active lattice vibrations. On the other hand, Huang[4] predicted that it would be at 120 μ (83.3 cm^{-1}) on the basis of his calculation of the lattice frequencies of this crystal.

The problem is now settled by the present experiment. It has been found that the b band is situated at 147.5 cm^{-1}, at much lower frequency than that assigned by O'Keeffe but at a cosiderably higher frequency than that predicted by Huang. Huang assumed in his calculation an ionic character of the Cu-O bond in cuprous oxide. The fact that the actually obserwed frequency (147.5 cm^{-1}) is somewhat higher than that predicted (83.3 cm^{-1}) is considered to indicate that the bond is more covalent than he assumed.

The Isolation of Terephthaldinitrile N-Oxide

By Yoshio IWAKURA, Masayasu AKIYAMA and Kuniharu NAGAKUBO

(Received February 24, 1964)

We wish to report the isolation and characterization of terephthaldinitrile *N*-oxide (I) as a stable compound. Although the chemistry of nitrile *N*-oxides has extensively been studied by several groups of workers in recent years,[1-3] few nitrile *N*-oxides[4-6] have been isolated in a pure state because of the ease of their dimerization to furoxans.[3,6,7]

Terephthaldihydroxamic chloride (II), the starting material in this work, has been used by several previous investigators, but no dinitrile *N*-oxide has been isolated.[7-9]

To a solution of 0.233 g. of II[8] (m. p. 185°C) in 20 ml. of methanol, an equivalent amount of triethylamine in 20 ml. of methanol was added at room temperature. I was soon precipitated out of the mixture as colorless needles. It was filtered and washed thoroughly with methanol (a 70% yield). When the sample was heated gradually, it showed a definite m. p. at 241~243°C (decomp.). On the other hand, when it was put in a bath heated at 150°C, it decomposed instantly.

Found: C, 59.79; H, 2.66; N, 17.77. Calcd.

Long-range Proton Spin-Spin Interactions in Thianaphthenes

By Kensuke TAKAHASHI, Tatsuo KANDA and Yasuo MATSUKI

(Received March 2, 1964)

The long-range coupling between the protons in different aromatic rings has been observed recently by several authors in quinoline,[1] in *N*-benzylthieno [3, 2-b] -pyrrole,[2] in indene,[3,4] in benzofuran[4] and in acridine.[5] In this report we will present the results observed in the long-range coupling between the 3- and 7-hydrogens in some thianaphthenes. In the spectrum of thianaphthene itself, this coupling is difficult to obtain directly from the signals in a carbon tetrachloride, cyclohexane or acetone solution because of the overlapping of the signals, but in the spectra of some methylthianaphthenes it may be observed directly and with certainty. In the spectrum of 2-methylthianaphthene in a carbon tetrachloride solution, the signal of the 3-hydrogen appears at 5.40 p. p. m. with reference to cyclohexane and shows a quintet-like structure. This means that the 3-hydrogen is coupled to the 2-methyl hydrogens and to one of the other hydrogens. In the spectrum of 3-methylthianaphthene, the signal of the 2-hydrogen appears at 5.51 p. p. m. and shows a quartet-like structure, showing the expected coupling with the 3-methyl hydrogens only. In the spectrum of 5- or 6-methylthianaphthene, the signals of the 2- and 3-hydrogens appear as a doublet and as a double doublet respectively. A typical spectrum in the aromatic region of 5-methylthianaphthene is shown in Fig. 1. In the spectrum of 4-methylthianaphthene, the signals of the 2- and the 3-hydrogens look like a singlet in a carbon tetrachloride or cyclehexane solution because of nearly the same chemical shift between the two hydrogens, whereas those in an acetone solution appear as a doublet and as a double doublet, like those observed in 5- or 6-methylthianaphthene.

7-CH_3	1.10	5.85*	5.80*	6.12	5.75	5.57	—	—

* Assignment uncertain

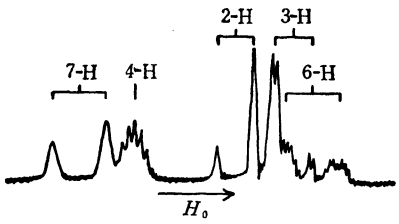

Fig. 1. The ring proton spectrum of 5-methylthianaphthene, in the 5 mole % solution in cyclohexane at 60 Mc./sec.

In the spectrum of 7-methylthianaphthene, the signals of the 2- and 3-hydrogens in a carbon tetrachloride or cyclehexane solution look like a singlet, but those in an acetone solution appear as two doublets, showing no resolved second-order splitting. These facts clearly show that the 3-hydrogen is coupled to the 7-hydrogen in thianaphthenes. The observed second-order splitting gives J_{37}~0.7 c. p. s. in each case.

Another fact of interest has been also observed in the spectrum of 7-methylthianaphthene in an acetone solution. Two doublets originating from the 2- and 3-hydrogens in this compound have different line widths. The one at the lower field is somewhat broader than the other. This suggests the presence of another long-range coupling in this system, for example, one between the 2- and 4-hydrogens, but the assignment is still in question at present.

Table I lists the observed PMR data of our first-order analyses. The chemical shifts were measured in about 0.1 g./cc. solutions in carbon tetrachloride containing 0.5 wt. % cyclohexane as an internal reference.

The Nucleophilic Substitution of a Phenolic Hydroxy Group in Acidic Media

By Shigeru OAE and Reiko KIRITANI

(Received March 19, 1964)

During our study of the acid-catalyzed hydrolysis of phenyl benzenesulfonate with concentrated hydrochloric acid in ^{18}O-enriched water, we have found that the phenol recovered was always incorporated with an excess of ^{18}O and also, that the amount of ^{18}O incorporation increased with prolonged heating.[1] We then suggested that, in a strong acidic medium, phenol readily accepts a proton at either the para- or ortho-position to form a quasi-stable incipient carbonium ion intermediate, A, in which the original hydroxyl function acquires more of a carbonyl character and hence facilitates the oxygen exchange with ^{18}O-enriched water.

A

We have now extended this remarkable oxygen exchange reaction to a number of phenolic compounds. The conditions used for this reaction were: temperature, 180°C; medium, 10 N hydrochloric acid in $H_2{}^{18}O$, enriched with 0.77 atom % ^{18}O; time, 6 hr. and 24 hr. Resorcinol, and both α- and β-naphthols, which are known to have some carbonyl character, were found to exchange their oxygen atoms substantially in 6 hr. and completely in 24 hr.; the oxygen exchange occured substantially with the ease of ^{18}O incorporation, falling in the order of phenol, *p*-nitrophenol, *p*-cresol, *m*-aminophenol, and *p*-bromophenol, while with tri-substituted phenols, such as 2, 4, 6-trimethylphenol and 2, 4, 6-tribromophenol, very little oxygen exchange took place, even under heating for 24 hr. In order for phenol to get a successful oxygen exchange, perhaps the incipient intermediate A should have a substantially long life. The substitution of electronegative groups at either the ortho- or para-position or at both will discourage the electrophilic addition of proton to form a quasi-stable intermediate A, while the substitutions at both ortho- and para-positions, even with electron-releasing alkyl groups such as in 2, 4, 6-trimethylphenol, will give an unstable unsymmetrical intermediate which may not have a life sufficiently long enough to exchange its oxygen.

Other alternative pathways would be aromatic nucleophilic substitution and that involving incipient aromatic carbonium ions. Aromatic nucleophilic substitution is known to be facilitated by substituting electron-withdrawing groups at either ortho- or para-positions or at both. In this case, however, the substitution of an electron-withdrawing group failed to increase the ^{18}O exchange. Meanwhile, the formation of aromatic carbonium ions would be facilitated by electron-donating substituents at ortho- and/or para-positions, but this trend was not observed in this ^{18}O exchange.

As an extension of this ^{18}O exchange experiment, it was expected that the phenolic hydroxyl group would be replaced by more nucleophilic reagents, such as alcohols and mercaptans. Indeed, when about five equivalent moles of ethanol was added in the reaction mixture of phenol and hydrochloric acid used for the ^{18}O exchange experiment and the mixture was heated in an ampoule at 180°C for two days, phenetole was obtained in a yield exceeding 60%. Naphthols and *p*-cresol also gave the corresponding ethyl ethers in good yields in the same procedures. When *n*-butylmercaptan was used instead of ethanol, phenolic oxygen was replaced by an *n*-butylmercapto group under the same reaction conditions. Thus, from phenol, *p*-cresol and both α- and β-naphthols, the corresponding *n*-butylsulfides of phenyl, *p*-tolyl and α- and β-naphthyl were obtained in good yields, recovering some unreacted starting materials.

Although β-naphthol has been known to react with nucleophilic reagents such as sulfurous acid[2] and thioglycolic acid[3] replacing the phenolic hydroxyl group forming β-naphthyl sulfonic acid and thioglycolic acid, our

results are the first general examples in which the phenolic hydroxyl group is replaced by nucleophilic reagents. We believe that this procedure will serve as a general method of substituting the phenolic hydroxyl group with other nucleophilic reagents; further work is in progress here.

Reactivity of Chemisorbed Nitrogen on an Ammonia Synthesis Catalyst

By Kenzi TAMARU*

(Received March 24, 1964)

The ammonia synthesis on an ammonia synthesis catalyst has been treated by means of a new approach, studying the nitrogen chemisorption and the reaction between the chemisorbed nitrogen and hydrogen separately under the reaction conditions. The experimental apparatus and procedures were approximately the same as those previously reported.[1] The catalyst (198 g. with aluminum oxide 5% and potassium oxide 1% before the reduction) was reduced with hydrogen at 500°C for about three thousand hours in a closed circulating system with a liquid nitrogen trap.

The rate of hydrogenation of the chemisorbed nitrogen to form ammonia was proportional to the partial pressure of hydrogen at approximately the same amount of nitrogen chemisorbed, as is shown in Fig. 1, the ammonia produced being always trapped out of the circulating system. The adsorption of hydrogen during the reaction approximately reaches the saturation point at higher pressure, as has been reported previously.[1] Consequently, the rate of the reaction is apparently correlated not with the amount of hydrogen chemisorbed, but with the pressure of hydrogen.

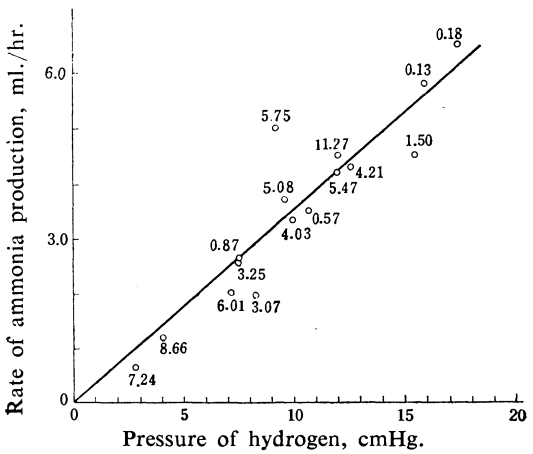

Fig. 1. Dependence of the reaction rate upon hydrogen pressure at 250°C. (N(a)=33~37 ml.(stp)) The numbers designate the pressure of nitrogen in cmHg.

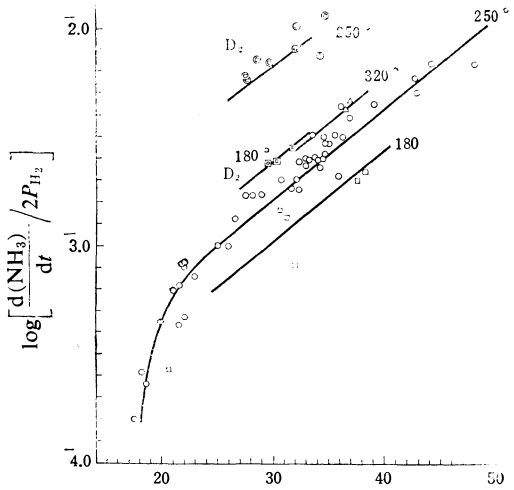

Fig. 2. The rate of hydrogenation of chemisorbed nitrogen to form ammonia as a function of nitrogen adsorption.

* Present Address: Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo.

1) K. Tamaru, Proc. 2nd Intern. Congr. on Catalysis, 1960, p. 325. Technip, Paris, 1961.

The reaction rate was similarly studied in connection with the amount of nitrogen chemisorbed, as Fig. 2 shows. The rate of the reaction was nearly independent of the circulation rate of the reacting gas under the experimental conditions employed.

As Figs. 1 and 2 show, the rate of ammonia formation from the chemisorbed nitrogen and hydrogen, when a negligible amount of ammonia is present, conforms to the following equation except for smaller amounts of nitrogen chemisorbed : $d(NH_3)/dt = CP_{H_2}\exp(\gamma N(a))$ where P_{H_2} is the pressure of hydrogen in the ambient gas, $N(a)$ is the amount of nitrogen chemisorbed, and C and γ are constant. This equation suggests that the Eley-Rideal mechanism is involved.

It is also interesting to note that the reaction of the chemisorbed nitrogen with deuterium proceeds much faster than with hydrogen, as Fig. 2. The author previously found no isotopic effect of hydrogen in the simultaneous adsorption of nitrogen and hydrogen on the catalyst surface.[2] The isotopic effect in the overall reaction, which has been observed by Ozaki, Boudart and Taylor,[3] should, accordingly, be attributed to the effect in the reaction between chemisorbed nitrogen and hydrogen.

Mixed Chelate Compounds of Titanium(III) as Studied by Electron Paramagnetic Resonance and Spectrophotometry

By Shizuo FUJIWARA, Kozo NAGASHIMA and Maurice CODELL*

(Received November 16, 1963)

Titanium(III) possesses low-spin-orbit coupling, and it was recently demonstrated[1] that, when chelated with ethylenediaminetetraacetic acid (EDTA), nitrilotriacetic acid (NTA), and several other chelating reagents, titanium(III) gives strong EPR signals in an aqueous solution at room temperature. This phenomenon suggests that ions of low-spin-orbit coupling produce EPR signals when strongly coordinated. It was, therefore, decided to investigate several aspects of correlation of complex formation with the EPR signal intensities. An increase in the signal intensity of the titanium(III)-EDTA complex was observed upon the addition of certain organic acids. Complex formation was confirmed for the systems titanium(III)-EDTA with oxalate, tartrate, citrate, and lactate. EPR signals are not exhibited by the titanium(III)-EDTA complex at pH values appreciably lower than 5.7. However, in the presence of any of the above acids, signals are exhibited by the complex at pH 2.5. No signals have been obtained for the titanium(III)-organic acid systems for any of the organic acids tested.

It was noted that complexes formed by titanium(III)-EDTA with three of the above acids show optical absorbance maxima at 720 mμ. No absorbance maximum is shown by titanium-(III)-EDTA alone at any pH value.

The aqueous system of metal ion, EDTA, and an organic acid such as tartaric acid has long been utilized in analytical chemistry for chelatometric titrations. The usual understanding of the system has been that the metal-organic acid complex is less stable than the metal-EDTA complex, and that, consequently, when EDTA is added to a solution containing a metal ion and organic acid, the organic acid is displaced to form the more stable EDTA complex. However, the present study gives counter evidence to this interpretation showing that the organic acid is an integral component of the complex.

Experimental

Apparatus and Reagents.—*Electron Paramagnetic Resonance Spectrometer.* — Model JES-118, Japan Electron Optics Company.

Recording Spectrophotometer.—Cary Model 11.

Spectrophotometer.—Hitachi EPU-2 spectrophotometer.

Titanium(III) Chloride Solution.—A pure grade of titanium sponge (courtesy of the Osaka Titanium Corporation, Amagasaki, Japan) was dissolved in hot 6 N hydrochloric acid. An excess of titanium sponge was added to the hydrochloric acid, and additional acid was added as the reaction progressed to prevent the acid concentration from falling to the point where hydrolysis could occur. The solution was decanted from the metal while the vigorous reaction was proceeding in order to prevent the formation of any appreciable quantity of titanium-(IV). The solution was maintained in an atmosphere of nitrogen. The final concentration of titanium(III) ion was determined volumetrically by titration with a ceric sulfate solution.

Electron Paramagnetic Resonance Spectrometric Procedure.—Intensity measurements were carried out using the same capillary tube for all determinations. A tube containing DPPH (diphenylpycrylhydrazyl) was taped to the capillary tube as an external standard of signal intensity, and the capillary tube was placed in the same position in the cavity for all determinations. It was found, however, that a comparison of the signal obtained for the sample with that of the DPPH was not a reliable process for determining absolute signal intensities because a slight change in position caused large deviations between the signals of the sample and of the DPPH. Signal intenstity measurements were, therefore, made comparing the peak heights of the signals obtained, which were found to be reasonably reproducible.

Spectrophotometric Procedure. — Solutions of titanium(III) chloride, EDTA, and organic acids were mixed in volumetic flasks, and the pH was adjusted to various values by the addition of ammonium hydroxide. The absorbances were measured using a Hitachi spectrophotometer, and spectrophotometric curves covering the range from 350 to 800 mμ were made using a recording spectrophotometer.

Results and Discussion

Table I lists the conditions used to obtain the EPR spectra and the signal intensity

measurements of complexes.

The Titanium(III)-EDTA System.—Curves 2, 3, and 4 of Fig. 1 show the absorption spectra obtained for the titanium(III)-EDTA complex at various pH values, where the concentration of titanium(III) chloride was maintained constant at a titanium(III) to EDTA ratio of 1 to 1.2. Curve 1 shows the absorbance of titanium(III) chloride in an acid solution. From pH 2.5 to pH 8, distinct maxima at 550 mμ are observed for the titanium(III)-EDTA complex. At pH 8 the curve is considerably changed, but it still shows a maximum absorbance at 550 mμ, and a distinct shoulder can be seen at 600 mμ. At pH 9.1 a maximum absorbance at 580~600 mμ is observed. These curves suggest that another complex forms at higher pH values and that it absorbs from 580 to 600 mμ. From Fig. 2 it can be seen that the EPR spectra correspond with this assumption, since an increased intensity is seen for the second peak at higher pH values. The EPR spectrum shown for pH 12.2 was obtained for a solution adjusted with sodium hydroxide; a different piece of DPPH was used for this spectrum than for the other spectra shown in Fig. 2. It is seen that, at this pH, only the second peak is obtained. At pH 13, the complex begins to decompose, and the signal intensity is considerably decreased within a short period. At a pH of about 7, a second peak appears which increases in intensity at higher pH values. This phenomenon is observed whether ammonium hydroxide or sodium hydroxide is used to adjust the pH. The g value for the peak obtained at pH 12.2 is 1.956±0.002. The g value for the first peak is 1.960±0.002, which is in agreement with those of other titanium chelate compounds.[1]

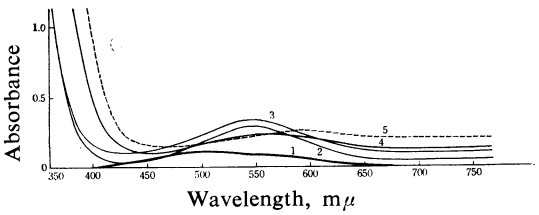

Fig. 1. Absorbance spectra of Ti(III), and Ti-(III)-EDTA at varying pH values.
Curve (1): $TiCl_3$ in 1:10 HCl
Curves (2), (3), (4), and (5): Ti(III)-EDTA (1:1.2 ratio)
Curve (2): pH 2.5, Curve (3): pH 5.0,
Curve (4): pH 8.0, Curve (5): pH 9.1
Ti(III) concentration for all curves: 0.03M

From the above discussion it is apparent that two species of titanium(III)-EDTA complexes exist in neutral and basic solutions, and from the following considerations, we must assume the existence of another titanium(III)-EDTA complex in an acid solution which does not give an EPR signal.

An infrared study[2] has recently shown the presence of five species of EDTA in an aqueous solution, and the existence of acid complexes of metal ions and EDTA has been demonstrated in many instances. From the results of

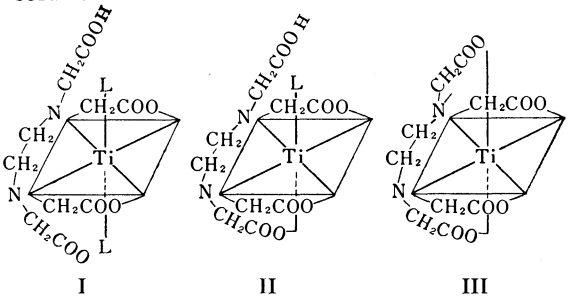
Ti(III) concentration for all spectra: 0.02 M. Arrows designate DPPH.

TABLE II. Ti(III)-EDTA SPECIES IN SOLUTION



Formula	Formation in	Absorbance maxima	Remark
(Ti(III)-EDTAH_2 L_2)	(I) acid solution	550 mμ	No EPR signal
(Ti(III)-EDTAH L)	(II) neutral solution	550 mμ	EPR signal g=1.960
(Ti(III)-EDTA)	(III) basic solution	580 to 600 mμ	EPR signal g=1.956

previous investigations[2-5] and from our own experimental results, the three species listed in Table II are proposed to represent the complexes which exist in the solutions studied.

In Table II, EDTAH_2, EDTAH and EDTA represent ions where two, three, and four hydrogen ions are removed from the EDTA molecule containing four acid groups. L represents ligands other than EDTA, such as H_2O, Cl^-, and NH_3.

From the EPR spectra (Fig. 2), it appears that, at the approximate range pH 5 to 7, equilibrium mixtures of I and II exist, because the first peak becomes smaller with the decreasing pH and disappears at a pH of about 5, but the existence of a chelate is well established by the reasons given below. At pH 7 to 10, equilibrium mixtures of II and III exist. The same mixtures indicated above by the EPR spectra may be deduced from the spectrophotometric curves (Fig. 1), if we assume that the II complex shows a maximum absorbance at 550 mμ and the III complex, at 580 ~600 mμ, and that the shape of the curves for the I and II complexes are similar to that of the I complex in exhibiting lower absorbance. At lower pH values, a complex forms in solution which gives no EPR signal under the experimental conditions used. It was shown spectrophotometrically at pH 2.5 that a high concentration of this complex exists. It was also experimentally demonstrated that a complex of titanium(III)-EDTA forms in an acidic solution. This was accomplished by first forming the complex of titanium(III) with nitrilotriacetic acid (NTA) at pH 3.5. An intense EPR signal is obtained from this complex at this pH. An identical solution was then prepared, to which EDTA of a molar concentration twice that of titanium was added; the solution adjusted to pH 2.5. No signal was exhibited by this solution. The solution of titanium(III)-NTA was green, while that containing EDTA was purple, which is the color of pure titanium(III)-EDTA solutions at this pH. At pH values of 1 or 2, the color of solutions containing titanium(III) and EDTA, or titanium(III), EDTA, and NTA are the same, while the color of solutions containing titanium(III)-NTA are blue. It was also noticed that a solution containing the intensely-colored titanium(III)-acetylacetonate complex is decolorized upon the addition of EDTA. These phenomena appear to offer good evidence that the titanium(III)-EDTA complex is more stable than the titanium(III)-NTA or the titanium(III)-acetylacetonate complexes.

The following structures are proposed to represent the compounds which exist in the solutions studied:

3) G. Schwarzenbach and W. Biedermann, *Helv. Chim. Acta*, **31**, 459 (1948).
4) K. Saito and H. Terrey, *J. Chem. Soc.*, **1956**, 4701.
5) D. C. Olson and D. W. Margerum, *J. Am. Chem. Soc.*, **82**, 5602 (1960).

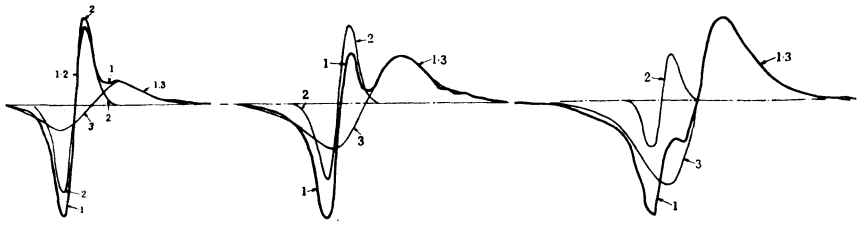


Fig. 3. Procedure for the analysis of signals with two peaks.
Curve 1 is the original spectrum.
Curves 2 and 3 are the reconstructed curve.

Structure I shows the possible complex where EDTA acts a tetradentate. Structure II, in which EDTA acts as a pentadentate, is proposed for the species which exists in neutral solution giving an EPR signal, but the absorbance seen in Fig. 1 is similar to that obtained in acid solutions. The proposed structure III, in which EDTA is a hexadentate, is obtained in a low concentration at pH values above 7, although at pH 10, it appeaes to be the only species in the solution. At pH 7 to 10, a mixture of the two complexes represented by structures II and III appear to be present in the solution.

An analysis was made of the signal of the two peaks obtained for the complex titanium(III)-EDTA at pH 7 to 9, were the concentration of titanium is 0.094 M and the ratio of titanium to EDTA is 1 to 2. The process used in this analysis is shown in Fig. 3; the peaks were first separated into two signals, assuming a normal Maxwell-Boltzmann distribution curve. Each curve was integrated, and the areas under the curves were calculated. The assumption was made that the ratio of the areas represent the ratio of the II and III complexes. Table III lists the results of this analysis. From the information obtained in this analysis, the equilibrium constant can be calculated for the following reaction:

TABLE III. RELATIVE AREAS OF RECONSTRUCTED CURVES AND CALCULATED EQUILIBRIUM CONSTANT FOR THE SYSTEM Ti(III)-EDTA (II AND III IN TABLE II)

pH	Relative areas of separated and integrated curves	*Ke* (mol./l.), calculated
6.9	1 : 1.8	2.07×10^{-7}
7.7	1 : 6.8	1.35×10^{-7}
8.2	1 : 24	1.49×10^{-7}
8.6	1 : 30	0.72×10^{-7}

$$\text{Ti(III)-EDTAH} \rightleftharpoons \text{Ti(III)-EDTA}^- + \text{H}^+$$

$$K_e = \frac{(\text{Ti(III)-EDTA}^-)\ (\text{H}^+)}{(\text{Ti(III)-EDTAH})}$$

The temperature and salt concentrations were not maintained constant for the data obtained for Table III. Although the calculated K_e values shown in Table III are not in excellent agreement, the effect of the temperature and such foreign salts as ammonium chloride and sodium chloride, which usually affect the stability of chelates, must be taken into consideration. The values obtained are of the same order, which strongly indicates that this method of analyzing signals is valid and that the assumed chelate species, II and III, exist in fact.

The Titanium(III)-EDTA-Oxalate System.— The EPR signal intensity and the spectrophotometric absorbance at 720 mμ for the titanium(III)-EDTA system are considerably increased upon the addition of certain organic acids. These effects were studied, and the formation of mixed chelate species was proved.

Spectrum 1 was obtained at three times the sensitivity and spectrum 7 was obtained at four times the sensitivity settings of the other spectra shown in this figure. Ti(III) concentration for spectrum 7 : 0.02 M. The Ti(III) concentration for all other spectra : 0.01M. Arrows designate DPPH.

and oxalic acid. The molar ratio of titanium(III) to oxalic acid is 1 to 3. No EPR signal is given by this complex at any pH value. The optical absorbance of this compound continues to increase with a decrease in the wavelength. Curve 2 is that of an equal molar ratio of titanium(III) and EDTA ; the maximum absorbance is seen at 550 mμ. Curve 3 is that of the amber-colored product of an equal molar ratio of titanium(III), EDTA, and oxalic acid, where the concentration of titanium(III) and EDTA is the same as for curve 2. No absorbance maximum at 550 mμ, such as is characteristic of the titanium(III)-EDTA complex, is observed. These curves undoubtedly prove the formation of a compound of three components; could not be a mixture of two complexes, such as the titanium(III)-EDTA and titanium(III)-oxalate complexes.

In Table I it may be seen that the EPR signal intensity of the titanium(III)-EDTA-oxalate complex increases with an increase in the pH value. The fact that a second peak does not appear at higher pH values (Fig. 5), as occurs with the titanium(III)-EDTA system, the titanium(III)-EDTA-tartrate system and the titanium(III)-EDTA-citrate system, is evidence for the presence of only a single complex. Evidence for the stability of the complex is seen in the fact that quantities of oxalic acid in excess of a 1 to 1 molar ratio have no such apparent effect on the signal intensity as is experienced with tartaric, citric and lactic acids (Table I and Fig. 9).

Figure 6 shows the spectrophotometric establishment of the composition of each component of complexes. A plot of the absorbance versus molar ratio of EDTA to titanium(III) is shown for all points. The pH values of these solutions were adjusted to 5.7 with ammonium hydroxide. A sharp break in the

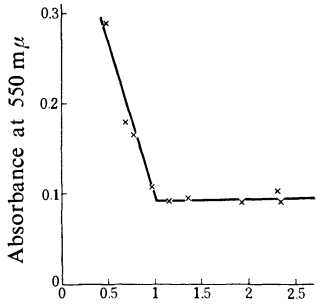

Fig. 6. Molecular ratio method for the determination of the ratio of EDTA in the Ti(III)-EDTA-oxalate complex at pH 5.7. Concentration of Ti(III) : 0.06 M. Concentration of oxalic acid : 0.18 M.

absorbance curve at 550 mμ is seen when the molar ratio of titanium(III) to EDTA reaches unity. The same experimental procedure was carried out at pH 2.5, and the same molar ratio for the complexes was found. The less intense EPR signals obtained at lower pH values probably result from the presence of a higher concentration of a complex of the same composition but possessing a different structure, one which does not give an EPR signal.

The determination of the ratio of oxalate in the titanium(III)-EDTA-oxalate complex is shown in Fig. 7. The ratio of titanium(III) to EDTA was maintained constant, varying amounts of oxalic acid were added, and the pH was adjusted to 4.5. A break in the curve at 550 mμ may be seen when the molar concentration of each component of the complex is approximately equal. At 720 mμ the break in the curve, which is not very pronounced, is seen at approximately the same molar concentration.

$$(Ti^{3+}EDTAH_2^{2-}(COO)_2^{2-})$$
IV

The Titanium(III)-EDTA-Taratrte, -Citrate, and -Lactate Sytems.—As with oxalic acid, tartaric, citric, and lactic acids also affect the titanium(III)-EDTA complex by increasing the EPR signal intensity and permitting the EPR signal to be obtained at lower pH values. The EPR spectra and spectrophotometric curves are shown in Figs. 8 and 9.

It may be seen in Table I and Fig. 9 that the titanium(III)-EDTA-tartrate EPR signal intensity increases up to a molar ratio of tartaric acid to titanium(III) of at least 50 to 1 under the experimental conditions employed. However, no quantitative measurement of this effect could be made because of the insolubility of some tartrate salts at the ratio of tartaric acid to titanium(III) of 3 to 1.

Upon the addition of tartaric acid to the titanium(III)-EDTA complex, the EPR signal intensity continues to increase. It is shown

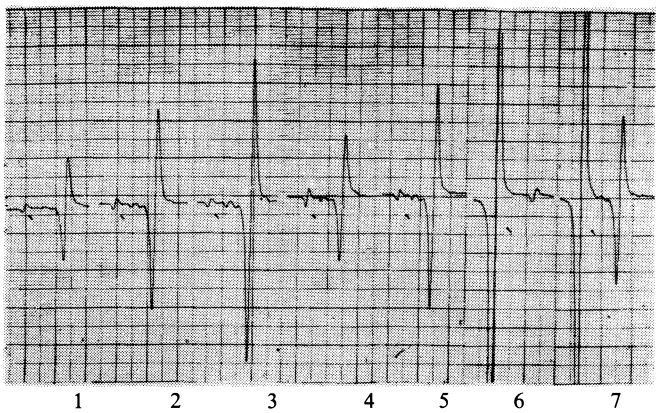

Fig. 9. EPR spectra for the Ti(III)-EDTA-tartrate, -citrate, and -lactate complexes. The sensitivity setting used for spectra 4, 5, 6 and 7 was twice that used for spectra 1, 2 and 3. Arrows designate DPPH.

Spectrum No.	Acid	Ti(III) : EDTA : Acid	Molar Concn. of Ti(III)	pH
1	Tartaric	1 : 1 : 1	0.1	5.7
2	Tartaric	1 : 1 : 2	0.1	5.7
3	Tartaric	1 : 1 : 3	0.1	5.7
4	Citric	1 : 1 : 1	0.2	5.7
5	Citric	1 : 1 : 2.5	0.2	5.7
6	Lactic	1 : 1 : 1	0.2	3.2
7	Lactic	1 : 1 : 3	0.1	5.7

spectrophotometrically in Fig. 8 that, when tartrate ions are present in a 3 to 1 ratio to titanium(III) and EDTA, the concentration of the complex as exhibited by the absorbance at 720 mμ is the same as that shown for the oxalate complex. It may be noted that the EPR signal intensity never reaches half the intensity of the signal obtained for the oxalate complex. The unexpectedly high absorbance which occurs for this complex at 720 mμ may be due to a greater absorbance of the tartrate complex over that of the oxalate complex.

The continuous increase of the EPR signal and in the optical absorbance at 720 mμ with the increase in tartrate ion concentration indicates a lower stability for the three-component complex containing tartrate, but no definite ratio of the complex can be established by these techniques. In this three-component system, the complex obviously exists in pH-dependent and organic acid concentration-dependent equilibria.

With succinic and acetic acids, no maxima are exhibited at 720 mμ, and the absorbance for the entire curve is the same as for the titanium(III)-EDTA complex alone. No EPR signals are obtained for the titanium(III)-EDTA complex in the presence of these acids at low pH values, which appears to show that these acids do not form complexes similar to the titanium(III)-EDTA-oxalate complex.

The spectrophotometric curve for lactic acid falls between curves 1 and 2 in Fig. 8, which indicates that this acid forms a less stable complex than tartaric and citric acids, and we were unable to observe any increase in absorbance at 720 mμ. An EPR signal with lactic acid is obtained at pH 3.2, where the complex with EDTA alone does not give a signal. These spectrophotometric results correspond well with those obtained by EPR.

With the complex formed with citric acid, a spectrophotometric curve is obtained which is very close to curve 1 in Fig. 8. Moreover, the EPR signal obtained for the citrate complex at pH 5.7 is much more intense than that obtained for the titanium(III)-EDTA complex at this pH. These indicate a behavior of citrate similar to that of tartrate with the titanium(III)-EDTA system. At a pH of about 9, a second peak appers for the titanium(III)-EDTA-citrate complex, and at a pH of about 10, a second peak appears for the titanium-(III)-EDTA-tartrate complex. A study of the latter system has been reported on in a previous paper.[1]

Summary

An electron-paramagenetic resonance and spectrophotometric study has been made of the composition of mixed chelate compounds of titanium(III)-ethylenediaminetetraacetic acid (EDTA) and organic acids. The existence of three titanium(III)-EDTA complexes in solution has been established. The complex formation of titanium(III)-EDTA with oxalate, tartrate, citrate and lactate has been confirmed, and the ratio of the oxalate has been established. Structures for the complexes have been proposed, probable equilibrium mixtures of complexes at various pH values have been discussed and new procedures have been proposed for the detection of chelate compounds in solution.

The assistance of Miss Tokuko Seki with the calculations of the equilibrium constans of the complexes is gratefully acknowledged.

*The Volumetric Determination of Manganese in Ores**

By Kozo NAGASHIMA, Maurice CODELL** and Shizuo FUJIWARA

(Received December 20, 1963)

An improved method has been needed for the determination of moderate amounts of manganese in minerals, ores, and metals. Many methods which are applicable to small amounts of manganese cannot be accurately applied to substances containing high concentrations of manganese.

Of the many methods which have been published concerning the determination of manganese, few exist which do not have serious shortcomings. The method where manganese is oxidized to permanganate with sodium bismuthate[1,2] is time-consuming and requires filtration through a substance which does not reduce permangante, and the danger exists that the solution will come into contact with reducing substances. This method is generally applied to low concentrations of manganese. Cerium and cobalt are known to interfere, and chromium requires special attention. The method in which manganese is oxidized to permanganate with peroxysulfate and titrated with arsenite[3] often gives trouble with the end-point detection because of the reoxidation of manganese by the residual peroxysulfate. As with the bismuthate method, this method is generally applied to small amounts of manganese. The direct Volhard titration method with permanganate[1] is attended with great difficulty since manganese(IV) oxide precipitates and imparts a brown color to the solution which partially obscures the end point. The chelatometric titration of manganese with a solution of ethylenediaminetetraacetic acid (EDTA)[4] is non-specific and requires the presence of masking agents and a careful control of the pH values.

Schroder[5] found that manganese is quantitatively converted to manganese(III) from any valence state by heating solutions containing manganese to fumes with a mixture of perchloric and phosphoric acids; he applied this process to the determination of manganese in ferromanganese, steel, and brass by titrating the manganese(III) with a ferrous solution. He also applied the method to the photometric determination of manganese in aluminum alloys,[6] by measuring the intensity of the redish color of the manganese(III) ion. The process was applied by Nagato[7] to the photometric determination of manganese in ferrite. When possible reagents were investigated by Kitakawa and Shibata[8] for the quantitative conversion of manganese to manganese(III), they reported that a mixture of phosphoric acid and sodium bismuthate was also effective for this purpose. Kimura, Tanino, and Kitahara[9] treated various samples containing manganese(IV) oxide with a mixture of phosphoric and sulfuric acids and titrated the resulting manganese(III) with a ferrous solution; however, this process is applicable only to samples containing manganese chiefly as manganese(IV) oxide.

Several methods which appeared to offer the greatest probability of successful application were tested in this laboratory. The method whereby manganese is oxidized to manganese(III) using the phosphoric acid-perchloric acid system seemed attractive because of its simplicity. The applicability of this method to large amounts of manganese is evident since the reduction of manganese(III) to manganese (II) involves a valence change of one, whereas methods in which manganese is oxidized to permanganate and reduced to the manganous ion involves a valence change of five.

It was found that manganese(III) can be kept in the concentrated acid mixture for several days without any noticeable reduction, but if the solution is diluted, titration should follow within a few hours.

The only interference encountered with the method was titanium in excess of 30 mg. It was found that titanium in excess of this amount precipitated as an insoluble phosphate

and co-precipitated some manganese. The separation of 25 mg. of manganese from 200 mg. of titanium was carried out by means of the addition of sodium peroxide to a nearly neutral solution, followed by the filtration of the precipitated manganese dioxide.[10] Quantities of manganese in excess of 25 mg. interfered by causing a rapid decomposition of the peroxide, which resulted in the precipitation of a considerable quantity of titanium.

Manganese ores often contain sulfide minerals such as pyrite (FeS_2). It was found that these minerals dissolve readily in the acid mixture used in the procedure and cause no interference. Up to 5 ml. of sulfuric acid in the acid mixture is without effect, and the presence of up to 3 g. of potassium sulfate causes no interference, but more than 5 g. of potassium sulfate caused bad results because of the precipitation of potassium phosphate upon dilution, which co-precipitated some manganese. The presence of 5 g. of sodium sulfate caused difficulty with some samples because of the insolubility of the mixture, which solidifies upon cooling.

The effects of chromium and vanadium upon the determination were investigated. Chromium imparts a color to the solution which makes the end point difficult to detect. The addition of a ferrous *o*-phenanthroline indicator effectively eliminates any interference from

10) M. Codell, "Analytical Chemistry of Titanium Metals and Compounds," Interscience-Wiley, New York (1959), p. 172.

this source, however. Vanadium is converted to vanadium(V) upon fuming with the acid mixture and consumes the ferrous solution upon titration. In the presence of vanadium, it is, therefore, necessary to add an excess of ferrous solution and back-titrate with a permanganate solution. Vanadium(V) is reduced to vanadium(IV) by the ferrous solution and oxidized to vanadium(V) by the permanganate solution; the net result is the same.

Table I shows the recovery of manganese from various ores to which known amounts of manganese have been added, and from solutions of permanganate to which substances have been added to determine their possible interference with the quantitative recovery of manganese.

Table II gives an analysis, by the proposed method, of ferromanganese and ores which have been previously analyzed for manganese content by other methods.

The following procedure and the two modified procedures should provide a means of analyzing most substances containing moderate amounts of manganese which are likely to be encountered.

Experimental

A Procedure for Samples Other than Silicate Ores and Containing Less than 30 mg. of Titanium.—Transfer a sample to a 300 ml. conical beaker. Add 5 ml. of water to moisten the sample, and, if the presence of organic matter is suspected, add 5 ml. of concentrated nitric acid. Add 10 ml. of phosphoric acid and 10 ml. of perchloric acid. Warm gently on a hot plate. If the sample does not dissolve, add 5 ml. of hydrochloric acid and heat gently. If the sample still remains undissolved, remove from heat and add 5 ml. of 10% hydrogen peroxide. Heat strongly until fumes of perchloric acid issue freely from the top of the beaker. Remove from the hot plate and allow to cool. Add 200 ml. of water and titrate with a 0.1 N ferrous ammonium sulfate solution until the red color disappears.

For samples containing chromium in quantities sufficient to cause a deep color, add 4 drops of a ferrous *o*-phenanthroline indicator to enable the end point to be detected.

For samples containing vanadium, add an excess of a ferrous ammonium sulfate solution and 4 drops of a ferrous *o*-phenanthroline indicator and back-titrate with a 0.1 N potassium permanganate solution.

Procedure for Silicate Ores.—Place the sample in a platinum dish, moisten with water, and 10 ml. of perchloric acid and 10 ml. of concentrated hydrofluoric acid. Evaporate to strong fumes of perchloric acid. Cool, transfer the solution to a conical beaker, and proceed as directed above.

Procedure for Samples Containing up to 200 mg. of Titanium and not more than 25 mg. of Manganese.—Dissolve the sample with hydrochloric acid, with a mixture of hydrochloric and hydrofluoric acids, or by fusion with 3 g. of sodium bisulfate with a few drops of sulfuric acid. If alkali fusion has been used, render the solution slightly acid with hydrochloric acid. To the acidic solution of the sample, add 20% sodium hydroxide until the first permanent precipitate forms; then add 3 g. of sodium peroxide and heat gently until it boils. Allow to cool to about 60°C and, if some titanium appears to have precipitated, add 5 ml. of 10% hydrogen peroxide. Filter through a rapid paper and wash the precipitate with a 1% solution of sodium carbonate containing 1% hydrogen peroxide. Discard the precipitate.

To the filtrate add 10 ml. of phosphoric acid and 10 ml. of perchloric acid and proceed as directed under the first procedure.

The Photometric Determination of Titanium with Acetylacetone

By Shizuo FUJIWARA, Kozo NAGASHIMA and Maurice CODELL*

(Received December 20, 1963)

Many methods have been published concerning the determination of titanium in various substances.[1] The most widely-used method is that based on the yellow complex formed upon the addition of hydrogen peroxide to acidic solutions of titanium. Several factors can affect the results obtained by this procedure; these factors include the quantity of salts present in the solution, the quantity of peroxide used, and the temperature of the solution to which peroxide is added. The method is also subject to much interference, including that of niobium, which forms a red color with peroxide. Niobium frequently accompanies titanium in minerals.

One of the most sensitive and selective methods for the determination of titanium is based upon the measurement of the absorbance of the titanium thiocyanate complex at 432 mμ. after extraction from a hydrochloric or sulfuric acid solution by tri-*n*-octylphosphine oxide dissolved in cyclohexane.[2] The extracted complex follows Beer's law up to at least 1.7 μg. Ti/ml. Niobium and molybdenum are also known to interfere.

Acetylacetone has been of interest in analytical chemistry for many years because of its great ability to form complexes with many metals. Its use in complex formation for the solvent extraction of metals was given an excellent treatment in a monograph on the subject of metal solvent extractions,[3] in which the solvent extraction procedure utilizing acetylacetone was applied to titanium(IV). Acetylacetone forms a complex with titanium-(III) which is intensely red in an acidic solution and blue in neutral and basic solutions. The color and absorbances of titanium(III) acetylacetonate containing 2.0 mg. of titanium in 50 ml. of solution at varying pH values are shown in Table I. The absorbances were measured with a Hirama Filter Photometer using 1 cm. cells. This reagent seemed very desirable for use as an analytical reagent for titanium because of its apparent ease of application, and because of the few ions which may be expected to interfere. Early attempts in this laboratory to utilize this complex for the quantitative determination of titanium were unsuccessful because of the instability of the color, which faded to a considerable extent within a few minutes after the addition of the reagent. This fading was somewhat delayed by the addition of stannous chloride, and a further delay in the fading process was accomplished by adjusting the pH to the range 1.5 to 2.5. Even with these innovations, however, the stability of the color was insufficient for use as an analytical procedure. It was then found that the addition of a few granules of zinc metal to the final solution delayed the fading sufficiently to allow the method to be generally applied.

TABLE I

pH	Lower than 1.5	1.5~2.5	Higher than 2.5
Color	red	red	Becomes more bluish with increasing pH values
Absorbance at 517 mμ	0.20 (at pH 0.5)	0.29	0.28 (at pH 4)

A spectrophotometric curve covering the visible region for titanium(III) acetylacetonate containing 1 mg. of titanium in 50 ml. of solution is shown in Fig. 1. The molar extinction index calculated for the maximum at 500~510 mμ is 350.

Complexing acids were investigated for the purpose of maintaining in solution titanium-(III), tin(II), and other ions likely to be encountered in an analysis. The most desirable reagent for this purpose was found to be citric acid. The pH most suited to color development could be obtained by the addition of citric acid only; there was no necessity of adding any additional reagents to adjust the pH.

It was found that additions of EDTA, ascorbic acid, and thioglycollic acid as a means of eliminating interferences were unsuccessful because the intensity of the color of the titanium(III)-acetylacetonate complex was lower in their presence.

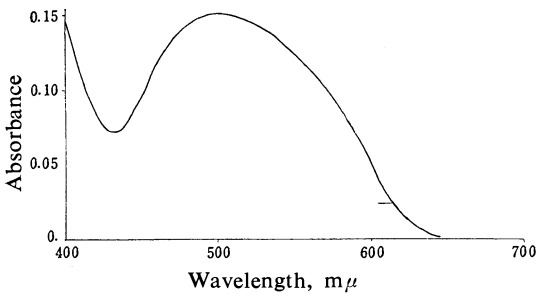

Fig. 1. Absorbance curve of titanium(III)-acetylacetonate.

The Procedure for Silicate Minerals.—Transfer a sample containing 0.2 to 20 mg. of titanium to a platinum dish, and add 10 ml. of sulfuric acid (1 to 1) and 5 ml. of concentrated hydrofluoric acid. Evaporate to fumes of sulfuric acid. Wash the sides of the dish with a small amount of water and again heat to fumes. Repeat the washing and fuming once more to insure the expulsion of all the fluoride. Transfer to a 100 ml. volumetric flask and dilute to 50 ml. Filter, ignite the residue, and fuse with about 2 g. of potassium bisulfate. Dissolve the melt in 10 ml. of sulfuric acid (1 to 10). Transfer the solution to the filtrate. If the titanium content is more than 7 mg. and dilute to a definite volume; then take an aliquot containing 1 to 5 mg. of titanium and add sulfuric acid sufficient to make the total content about 5 ml. of concentrated acid. Adjust the volume to 20 ml. If no aliquot has been taken, evaporate the solution to 20 ml. To the solution in a 100 ml. Ehrlenmeyer flask, add 1 g. of zinc (20 mesh). Let stand for about 10 min. In the presence of more than 20 mg. of iron, allow the solution to stand for 20 min. Add 5 ml. of a stannous chloride solution (5%). Add ammonium hydroxide (1 to 1) until the first faint permanent precipitate forms. Add 10 ml. of a 20% citric acid solution and 5 ml. of a 10% acetylacetone solution, and transfer the solution to a 50 ml. volumetric flask. Add several garnules of zinc metal (approximately 0.1 g.) and dilute to the mark with water. Within 45 min., measure the absorbance of the solution at 510 mμ, and estimate the titanium content by comparison with a calibration curve prepared by the absorbance measurement of a series of standard solutions containing known amounts of titanium, solutions prepared by adding 10 ml. of sulfuric acid (1 to 1) to aliquots of the stock solution contained in a 100 ml. Ehrlenmeyer flask and following the procedure for silicate rocks from the point where 1 g. of zinc is added. A stock standard solution of titanium containing 1 mg./ml. is prepared by heating titanium dioxide with a mixture of sulfuric acid and ammonium sulfate over an open flame and diluting the mixture with 1 : 10 sulfuric acid. A calibration curve prepared in this manner is shown in Fig 2. The results of the titanium analysis of two rock samples are shown in Table II.

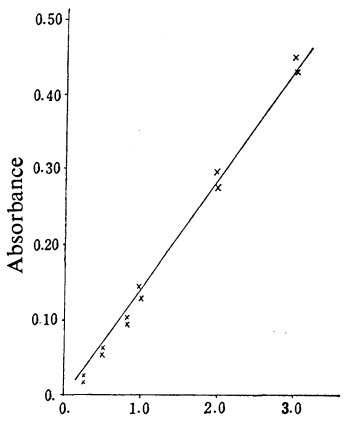

Fig. 2. Calibration curve.

TABLE II. ANALYSIS OF ROCK SAMPLES

Rock	Ti % found	Rock	Ti % found
	0.315		0.465
Granite	0.305	Silica ore	0.443
(2% Fe)	0.300	(0.8% Fe)	0.437
	0.299		0.415
	0.288		
	0.31 (by the H_2O_2 method)		0.45 (by the H_2O_2 method)

The Procedure in the Presence of Niobium Oxide.—Transfer a sample not exceeding 40 mg. of niobium to a platinum crucible. Fuse with 2 g. of potassium bisulfate and dissolve the melt in 10 ml. of sulfuric acid (1 to 1). Transfer the solution to a 100 ml. Ehrlenmeyer flask and dilute to 20 ml. Add 1 g. of zinc and proceed as directed above. The results of the analysis of titanium in titanium-niobium mixtures are shown in Table III.

TABLE III. DETERMINATION OF Ti IN THE PRESENCE OF 30 mg. Nb

Ti added, mg.	Ti recovered, mg.
3.0	3.2, 3.1, 3.0
2.0	2.1, 2.1

The Procedure in the Presence of Chromium, Vanadium and More than 25 mg. of Iron.—Dissolve the sample as directed in either of the above procedures. Transfer to an electrolytic beaker, dilute to 100 ml., adjust the sulfuric acid concentration to 5%, and electrolyze the solution at a mercury cathode for 15 min., using a current of 5 amp. Remove the solution, evaporate to 20 ml., add 1 g. of zinc, and proceed as directed under the

3.00	Cr 30	2.92
3.00	V 30	2.86

first procedure. The results of the analysis of titanium after treatment with a mercury cathode are shown in Table IV.

Summary

A new method has been proposed for the determination of small amounts of titanium in various substances. Acetylacetone forms an intensely-colored red complex in an acid solution with titanium(III), but this complex had not previously been used for the photometric estimation of titanium, probably because of the great instability of its color. A process has now been proposed for stabilizing the color. Up to 30 mg. of niobium and 30 mg. of iron do not interfere. Interference is encountered from chromium and vanadium, and in their presence, or in the presence of more than 30 g. of iron, a mercury cathode separation must be made. The method has been applied to quantities of titanium as small as 0.2 mg. in 50 ml. of solution.

The assistance of Mr. Toshikatu Sugiura in the performance of many of the analyses reported in this paper is gratefully acknowledged.

The Spectrophotometric Determination of Anions by Solvent Extraction with Metal Chelate Cations. I. A New Method for the Determinetion of Perchlorate Ions*

By Yuroku YAMAMOTO and Keiya KOTSUJI

(Received November 22, 1963)

Although there have been no experimental investigations of the extraction for tris-2, 2'-dipyridyl-iron(II)-perchlorate, theoretically the same behavior of the compound as the phenanthroline chelate may be expected.[1,2] In our investigation, it is confirmed that the perchlorate of the dipyridyl-iron(II) chelate can be extracted into nitrobenzene. However, the following differences exist between the dipyridyl and the phenanthroline chelate. If the perchlorate ion is absent in the 0.2 M acetate buffer solution, the dipyridyl chelate can not be extracted into nitrobenzene (this can be confirmed by the colorlessness of the organic layer) ; on the other hand, the phenanthroline chelate can be extracted moderately well. The behavior of iodide ions is more complicated. In the acetate buffer solution (0.2 M), iodide ions can be extracted with the phenenthroline chelate, but not with the dipyridyl chelate. However, the iodide ions are also extracted with the dipyridyl chelate if a small amount of perchlorate is present. Moreover, an anionic complex such as tetra-iodo-cadmium(II) or mercury(II) can be extracted into 1, 2-dichloroethane with the dipyridyl chelate, but not into nitrobenzene. In the case of the phenanthroline chelate, the extraction of the anionic complex is hindered by a large amount of iodide. For other cationic chelates such as cuproine,*1 Kuznetsov[2] has pointed out that chloride ions are extractable into alcohols with cuproine.*1 It is also confirmed by radioactive tracer in this work that a trace amount of chloride ions is extracted into hexylalcohol when bathocuproine*2 is in the organic phase and when copper(I) ions are in the aqueous phase.

These facts suggest that it may be possible to establish a selective and sensitive method for the determination of simple anions or oxygenated anions, and or the anionic complex ions of some metals. The method is thus based upon the estimation of the absorbance belonging to the chelate cations in the organic phase.

The present work is the first of a series of papers on the photometric determination of anions by solvent extraction with a metal chelate. This paper is concerned with the determination of perchlorate with tris-2, 2'-dipyridyl-iron(II) chelate. In that part of the

second paper which has been published as a short communication,[3] a colorimetric determination of iodide is treated in the similar way. The third paper[4] is concerned with mercury(II) and cadmium(II).

Experimental

Apparatus. — The spectrophotometric measurements were made with a Hitachi Model EPU-2 spectrophotometer with 10.0 mm. cells.

The shaking was done with a Iwaki Model KM shaker.

The pH measurements were made with a Horiba M-3 pH meter.

The separation of the organic layer from the aqueous layer was carried out with a separatory funnel of about 120 ml.

Materials.—*Ferrous Ammonium Sulfate Solution.* Guaranteed ferrous ammonium sulfate hexahydrate was dissolved in a small volume of water containing 5 ml. of 1 N sulfuric acid; then the mixture was diluted to 500 ml. with water to make a 3.0×10^{-3} M solution. It was standardized with a standard potassium permanganate solution.

2, 2'-Dipyridyl Solution.—Guaranteed 2, 2'-dipyridyl was dissolved in distilled water containing 1 ml. of 1 M hydrochloric acid, and then the mixture was diluted to 300 ml. with water to make a 1.2×10^{-2} M solution.

Standard Perchlorate Solution.—A standard solution containing 1 mg. of perchlorate ions per millilter was prepared by dissolving guaranteed potassium perchlorate (dried at 100°C) in distilled water. This standard solution was diluted to the concentration required for the experiments.

Nitrobenzene was purified by vacuum distillation at 23~25 mmHg.

Anhydrous sodium sulfate, guaranteed reagent.

All other reagents used were of analytical grade without further purification.

Procedure.—Mix 2, 2'-dipyridyl, ferrous ammonium sulfate, 3 M sodium acetate, and the standard perchlorate solution in the proper concentration. Adjust the pH of the solution to the required value with dilute sulfuric acid or a dilute sodium hydroxide solution and dilute to 25 ml. with distilled water, Add 10.0 ml. of nitrobenzene. Shake for 20 min. After the solution has stood for 30 min., transfer the organic layer into a glass flask containing 1 g. of anhydrous sodium sulfate and shake vigorously to make the solution transparent. Then transfer it through a folded filter paper into a 10.0 mm. cell. Measure the absorbance of the solution at 524 mμ using a reagent blank solution or nitrobenzene as a reference. Measure the pH of the aqueous layer after the separation.

Results and Discussion

Absorption Spectrum.—The spectral absorbance curves are shown in Fig. 1. They were measured for a nitrobenzene solution obtained by extraction from an aqueous solution which contained perchlorate and one which did not. The absorbance maximum is at 524 mμ in the organic layer. The absorbance maximum of the chelate cation in the aqueous solution was at 522 mμ, a value which coincides with that found in literature.[5] This slight red shift in the organic layer may be attributed to the effect of the association between cations and anions in such a polar solvent as nitrobenzene. Therefore, the chemical formula of the extracted species may be $[Fe(II)(dip.)_3]\cdot(ClO_4)_2$.

The Effect of the Reagent.—The extraction of perchlorate ions into nitrobenzene may be governed by the concentration of ferrous ammonium sulfate, 2, 2'-dipyridyl, and sodium acetate. The effect of changing the amounts of their reagents has to be considered.

A) The Effect of the Ferrouso Ammonium Sulfate Concentration.—To a constant amount of perchlorate ions (2.0 p.p.m.), various amounts of ferrous ammonium sulfate and 2, 2'-dipyridyl, in which the mole ratio of dipyridyl to ferrous iron was kept constant, were added. The mole ratio was kept at 4 to 1 because a slight excess of the dipyridyl may be needed for the stoichiometric formation of the chelate cation. The pH of the solutions was kept at 6.5, and the procedure was carried out for the solution. Figure 2 shows the effect of the concentration of ferrous ions on the extraction of perchlorate ions. It is found that the mole ratio of iron(II) to perchlorate ions has to be held at more than 10 to 1. This mole ratio, therefore, was made 12 to 1 in this work.

B) The Effect of the 2, 2'-Dipyridyl Concentration.—The amount of perchlorate ions and the mole ratio of iron(II) to perchlorate ions were kept at the constants of 2.0 p.p.m. and 12 to 1 respectively. A different amount of the dipyridyl was added, and the extraction was carried out according to the procedure described above. Figure 3 shows that the mole ratio of the dipyridyl to iron(II) has to be held at more than 3 to 1. This mole ratio was kept at 4 to 1 in this work.

C) The Effect of the Sodium Acetate Concentration.—If the concentration of sodium acetate is low in the aqueous phase, it is time-consuming to separate the two phases because of the formation of an emulsion. It was found that the formation of an emulsion could be prevented by the presence of sodium acetate in a concentration of 0.2~0.3 M. The salt was also useful as a buffering agent. The concentration of the acetate was kept at 0.24 M in this work.

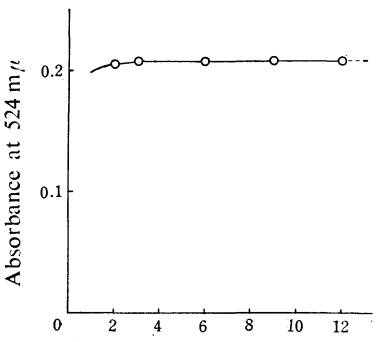

Fig. 3. Effect of mole ratio of dip. to iron(II)
Perchlorate: 2.0×10^{-5} M
Mole ratio of iron(II) to perchlorate: 12
NaAcO: 0.24 M
pH: 6.5
Shaking time: 20 min.

The Effect of the Shaking Time.—The shaking time in the extraction was varied from 5 to 30 min., while the other variables were kept constant. The shaking time had a slight effect on the extraction, and it was enough to shake it for more than 20 min.

The Effect of the pH Value.—It has been stated in the literature,[3] and also confirmed in this work, that the optimum pH for the formation of tris-dipyridyl iron chelate ions is in the range of 3~9 in an aqueous phase. In order to study the effect of pH on the extraction, a series of solutions adjusted to various pH values was preparaed and treated as in the procedure described above. It was found that there is a maximum and constant absorbance in the organic phase over the pH range from 3.5 to 8.5. Therefore, the solution was adjusted at pH 6.5 in this work.

The Stability of the Color.—Color developed immediately at room temperature and was independent of the temperature at 10~20°C. The color of the organic phase was stable, even after 24 hr.

The Choice of an Organic Solvent.—Besides nitrobenzene, various other solvents were tested for the extraction. They are chloroform, 1, 2-dichloroethane, isoamylalcohol, isopropyl ether, butyl acetate, cyclohexanone, chlorobenzene, and benzene. It was found that the perchlorate of the chelate cation was completely non-extractable into these solvents. Moreover, when a mixed solvent, such as nitrobenzene and benzene (1 : 1) or chloroform (1 : 1) was used, the absorbance of the organic layer was remarkably reduced. The reason may be the reducing of the dielectric nature in the mixed solvent. Therefore, benzene-free nitrobenzene has to be used.

The Effect of the Times of Extraction and of the Percentages of Extraction.—The effect of the times of extraction are shown in Fig. 4. The extraction yield using one 10 ml. portion of nitrobenzene is about 90%. The determination of the percentage of extraction was then attempted as follows. By shaking an aliquot of the extract with 1 N sulfuric acid, the perchlorate was transferred again into an aqueous phase. For this aqueous solution, after the reagents had been added and the pH, adjusted the extraction was performed once more. The absorbance value was about 90% of the first extract. It is, therefore, presumed that the percentage of extraction may be about 90%,

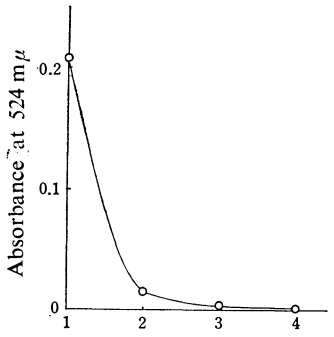

Fig. 4. Effect of times of extraction.
Perchlorate: 2 p.p.m.
(Other valiables were the same as the standard procedure, and the absorbance was measured for the nitrobenzene solution obtained by the extraction)

because Beer's law is followed for the perchlorate, as will be described below.

Calibration Curve.—Four milliliters of the 2, 2'-dipyridyl solution, 4 ml. of the ferrous ammonium sulfate solution, 2 ml. of a 3 M sodium acetate solution, and varying amounts of the standard solution (1~10 ml.) containing 10 μg. per ml. of perchlorate ions were mixed and diluted to 25 ml. with distilled water. Then 10.0 ml. of nitrobenzene was added, and the mixture was treated according to the procedure. The absorbance for each set was measured at 524 mμ against the reagent blank solution. As is shown in Fig. 5, Beer's law is followed in the 0.4~4 p. p. m. range of perchlorate ions.

The Effect of Diverse Ions.—Table I shows the absorbances of a series of extracts which have been treated according to the procedure. Measurement was done at 524 mμ using a reagent blank. Each solution contains 2.0 p. p. m. of perchlorate and various amounts of diverse ions. The absorbance of 2.0 p. p. m. of perchlorate is 0.209. It is shown that the determination of perchlorate is not interferred with, or is given a positive error of a few percentage points, by the presence of a considerable amount of halogen or oxygenated halogen ions other than iodide and periodate. The reason for the positive error of a small amount of iodide is not clear, because the iodide in a considerable concentration could not be extracted when the perchlorate is absent. This behavior of iodide is very interesting in a system of these extractions, as has been described above. A small amount of periodate give a negative error, presumably because of the oxidizing action with regard to ferrous iron. The proposed method may be useful for the determination of a small amount of perchlorate contained in such a salt as chloride, bromide, chlorate, bromate, iodate, and sulfate.

TABLE I. EFFECT OF DIVERSE IONS ADDED TO 2 p.p.m. OF ClO^-_4 (Abs. 0.209)

Analytical Studies Using the Convection Electrode. VIII. A. C. Polarography with the Pushed-out Mercury Drop Convection Electrode

By Junsuke SUZUKI and Tokuro OZAKI

(Received November 25, 1963)

A series of investigations[1] using the rotating-disk convection electrode as an electrode of d. c. polarography has been carried out by the authors. In a previous paper[2] it was reported that the pushed-out mercury drop convection electrode (PMDCE) has a sensitivity about twenty times larger than the dropping mercury electrode (DME) and, also, that it could be used even in a strongly alkaline or an acidic medium and could be reused many times with a good reproducibility.

On the other hand, it is already known that the sensitivity of the a. c. polarographic method is better than that of the d. c. polarographic method for the reversible reaction, and, also, that in a buffer or an acidic medium it is not necessary to remove dissolved oxygen.[3] Therefore, the application of the convection electrode to the a. c. polarographic method can be expected to obtain a much higher sensitivity.

In the present paper, the results of a. c. polarographic studies using cadmium(II) as a depolarizer are reported. The relations between the concentration of the depolarizer and the summit current, and between the stirring rate of the rotating disk and the summit current or the summit potential are discussed in especial detail.

Experimental

Apparatus.—The electrolytic cell, the electrode and the rotating apparatus are the same as have been described in the previous paper,[2] but the position in which the electrode is set is different.

The Shimadzu model RP-2BF polarograph is employed for the measurements of d. c. and a. c. polarograms.

Reagents.—A cadmium solution is prepared from chemicals of reagent grade, extra pure, without further purification. Also, a hydrochloric acid solution is of reagent grade, extra pure.

Procedure.—About 30 ml. of the solution of cadmium in 1 M hydrochloric acid are poured into the electrolytic cell.

While dissolved oxygen remains in the solution, the a. c. polarogram is recorded immediately after the solution is poured into the cell.

As dissolved oxygen is removed from the solution, a hydrogen gas stream is passed constantly through the solution at the rate of about 4 bubbles per second for 1 hr., and then the a. c. polarogram is recorded.

The procedure for each polarographic measurement, i. e., the renewal of the mercury drop as the electrode, is the same as has been described in the previous paper.[2]

The polarograms are recorded with a chart speed of about 2 cm./min., a rate of change of applied potential of about 100 mV./min., and a superposed alternating voltage of 20 mV.

All the measurements are performed at 15± 0.5°C.

Results

The Reproducibility of the Summit Current.—Typical current-voltage curves for cadmium are shown in Fig. 1. The reproducibility of

the summit current for the various concentrations of cadmium was investigated; the results are listed in Table I. As the table shows, the summit current has a good reproducibility. The summit current in the presence of dissolved oxygen in the electrolytic solution is larger than the corresponding current in the absence of dissolved oxygen.

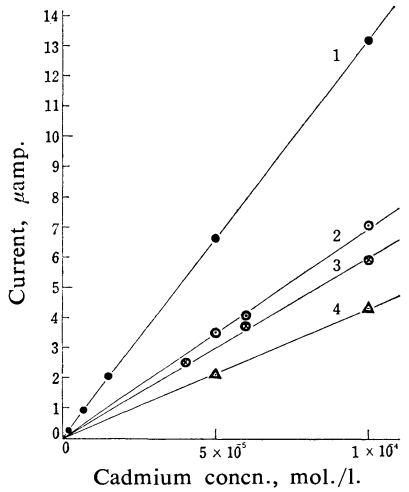

Fig. 2. Relations between the current and Cd^{2+} concentration.
1 At the PMDCE (in the presence of dissolved oxygen, a. c. polarographic method)
2 At the PMDCE (in the absence of dissolved oxygen, a.c. polarographic mothod)
3 At the PMDCE (d. c. polarographic method)
4 At the DME (in the presence of dissolved oxygen, a. c. polarographic method)

The Reproducibility of the Summit Potential.—The summit potential of each concentration was determined by the ordinary method; the results are shown in Table II. As the table shows, the good reproducibility of the summit potential can always be obtained within a mean error of 0.2%. Also, it can be seen that the summit potential in the presence of dissolved oxygen is slightly shifted to a more negative position than the corresponding potential in the absence of dissolved oxygen and that in both cases (in the presence or absence of dissolved oxygen) the potential is not affected by the concentration of cadmium.

The Relation between the Concentration of Cadmium and the Summit Current.—The relation between the concentration and the current is shown in Fig. 2. It can be seen

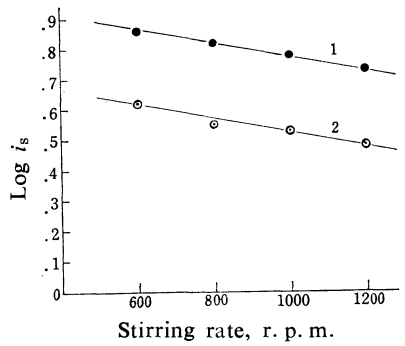

Fig. 3. Relations between the stirring rate and the summit current of 5×10^{-5} M Cd^{2+} in 1 M HCl.

C mol./l. \ P	100		200		Remark
i_s, E_s	E_s	i_s	E_s	i_s	
1.5×10^{-5}	−0.687	2.100	−0.687	2.906	Oxygen dissolved
5×10^{-5}	−0.661	3.514	−0.663	4.285	Oxygen removed

from the figure that a linear relation is obtained between the concentration and the current.

The Effect of the Stirring Rate on the Summit Current.—The effect of the stirring rate of the rotating disk on the summit current was investigated; the results are shown in Fig. 3. From the figure, it can be seen that the current decreases exponentially with the increase in the stirring rate.

The Effect of the Stirring Rate on the Summit Potential.—The dependence of the summit potential on the stirring rate was investigated. The results are listed in Table III. In the oxygen-dissolved solution, the potential is slightly shifted toward a negative position with the increase in the stirring rate (600~1200 r. p. m.), but in the case of the oxygen-free solution, the stirring rate has no effect on the summit potential.

The Relation between the Superposed Alternating Voltage and the Summit Current or the Summit Potential.—The relations between the superposed alternating voltage and the current or potential were investigated. The results are given in Fig. 4 and Table IV respectively. As the figure and the table show, the current is proportional to the superposed alternating voltage, but the potential is not affected.

The Effect of the Rate of Polarization.—The effect of the rate of polarization on the summit current or the summit potential was investigated; the results are listed in Table V.

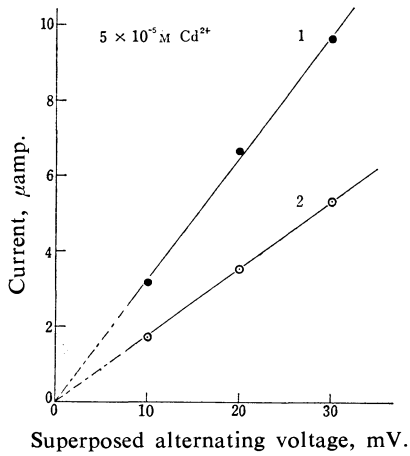

Fig. 4. Relations between the superposed alternating voltage and the summit current.
1 In the presence of dissolved oxygen
2 In the absence of dissolved oxygen

The change of the rate of polarization has no effect on the potential, but the current increases with the increase in the rate of polarization.

A Comparison with the DME.—The summit current obtained with the PMDCE (in the presenceof dissolved oxygen at the stirring rate of 600 r. p. m.) for 1×10^{-4} M cadmium is about thirty times as large as the corresponding diffusion current obtained with the DME using the d. c. polarographic method; moreover, it is about three times as large as the summit current

TABLE VI. COMPARISON OF E_s OR $E_{1/2}$ VALUES WITH THE DME AND THE PMDCE

DME	−0.653	−0.655	−0.656
PMDCE*	−0.662	−0.683	−0.661

* Stirring rate of the rotating disk : 800 r. p. m.

obtained with the DME using the a. c. polarographic method.

The capillary of the DME used has an m value of 0.93 mg./sec. and a drop time of 4.9 sec. in a 1 M hydrochloric acid solution at −0.80 V. vs. SCE.

Discussion

Half-wave Potential and Summit Potential.—In order to compare the half-wave potential and the summit potential with the PMDCE or with the DME, a series of investigations was performed; the results are shown in Table VI. When these values of the half-wave potential and of the summit potential are compared, it can be seen that they agree well each other, except for the summit potential with the PMDCE in the presence of dissolved oxygen. In the absence of dissolved oxygen, both the half-wave potential and the summit potential with the PMDCE are slightly shifted to a more negative position than the corresponding half-wave potential and summit potential with the DME. This effect is considered to be due to the fact that the rate of mass transfer becomes larger than the rate of electron transfer because of the convection. This agrees with the results of Jordan.[4]

The Stirring Rate and the Summit Current.—As is shown in Fig. 3, the summit currents decrease with the increase in the stirring rate in the presence or absence of dissolved oxygen.

As has been pointed out by Jordan,[4] Kolthoff and Jordan,[5] and Delahay,[6] at the convection electrode the rate of mass transfer becomes larger than the rate of electron transfer because of the effect; i. e., the effective thickness of the diffusion layer becomes smaller with the increase in the velocity of convection, which depends on the stirring rate. Therefore, the electrode reaction becomes quasi-reversible.[4] Namely, it is considered that the decrease in the summit current with an increase in the stirring rate is caused by the decrease in the reversibility.

The Influence of Dissolved Oxygen.—It is commonly known in the case of an acidic or a buffer medium that the summit current is not affected by dissolved oxygen. In the present investigation, this phenomenon has been observed with the DME for cadmium in 1 M hydrochloric acid solution. However, the summit current obtained with the PMDCE in the presence of dissolved oxygen is increased more than in the absence of such oxygen. This is considered to be a special feature of this electrode, but it has not yet been explained.

Summary

A. C. polarography with the PMDCE has been investigated, using cadmium in 1 M hydrochloric acid.

A satisfactory proportionality between the summit current and the concentration is obtained in the range from 1×10^{-4} to 2×10^{-6} M, and the summit current obtained with the PMDCE (in the presence of dissolved oxygen at the stirring rate of 600 r. p. m.) for the cadmium depolarizer is about thirty times as large as the corresponding diffusion current obtained with the DME.

The a. c. polarogram obtained with the PMDCE shows a gradual decrease in the summit current as the stirring increases; this decrease is considered to be due to the quasi-irreversibility at the electrode reaction because of the increase in the rate of mass transfer caused by the convection. The relation between the summit current and the stirring rate is exponential in the range from 600 to 1200 r. p. m.

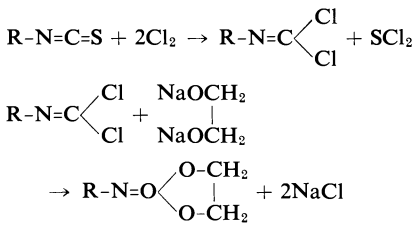
The Synthesis and 1, 4-Addition Type Ring-opening Polymerization of N-Substituted Cyclic Iminocarbonates

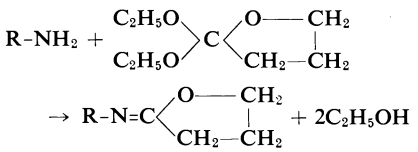
By Tamotsu FUJISAWA, Yorikazu TAMURA and Teruaki MUKAIYAMA

(Received December 11, 1963)

It has been shown in a previous paper that ethylene *N*-phenyl iminocabonate affords poly-(ethylene *N*-phenylcarbamate) by ring-opening polymerization when treated with cationic catalysts.[1]



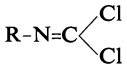
In the initiation step of the polymerization of ethylene *N*-phenyl iminocarbonate, a cationic catalyst adds to the imino group of the iminocarbonate to form a reactive addition compound. The addition compound in turn decomposes, with oxygen-carbon bond fission, to generate a new open-chained carbonium ion by the shift of an electron pair. The chain propagates by the rapid addition of the carbonium ion to a new monomer, a step which may be repeated many times.



As is shown above, the polymerization proceeds by 1, 4-addition; therefore, it can be termed a "1, 4-addition type ring-opening polymerization." This involves the ring-opening polymerizations of such imino compounds as 2-iminotetrahydrofurans[2] and 2-imino-1, 3-oxazolizines,[3] 4-methylene-1, 3-dioxalane,[4] β-pinene,[5,6] diketene[7-9] and 1, 4, 6-trioxaspiro-[4, 4] nonane.[10]

In the present work, the syntheses of various *N*-substituted iminocarbonates and their ring-opening polymerization have been studied.

N-Alkyl and *N*-aryl ethylene iminocarbonates were prepared from the corresponding imidophosgenes and sodium ethylene glycolate according to a procedure similar to that used for ethylene *N*-phenyl iminocarbonate.[11] Alkyl and aryl imidophosgenes were prepared by passing chlorine into a chloroform or carbon tetrachloride solution of the corresponding alkyl and aryl isothiocyanates under cooling. The solvents, yields, physical properties and analysis for these imidophosgenes and iminocarbonates are listed in Tables I and II.



By a procedure similar to that used in the preparation of *N*-substituted iminotetrahydrofurans described in a previous paper,[2] the

preparation of *N*-substituted cyclic iminocarbonates from 2, 2-diethoxy-1, 3-dioxolane[12] and various primary amines was attempted. In contrast to the case of 2-iminotetrahydrofurans, the reaction of 2, 2-diethoxy-1, 3-di-

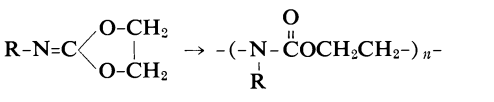
oxolane with primary amines, such as aniline and cyclohexylamine, did not give the corresponding iminocarbonates, even when they were heated at 130°C for 10 hr. in the presence of an acidic catalyst and most of the starting materials were recovered.

Next, *N*-halogeno cyclic iminocarbonates were prepared by the reactions of potassium cyanide, various glycohols and such halogenes, as chlorins and bromine in an alkaline solution. Their yields were comparatively low since they are rapidly hydrolyzed to yield ethylene carbonate when the reaction media become acidic.



It is to be noted that ethylene *N*-bromo iminocarbonate was unstable enough to decompose readily in the air and that it darkened within 8 hr., even when stored in an ethereal solution.

The *N*-halogeno cyclic iminocarbonates thus obtained were less reactive toward acidic substances than ethylene *N*-phenyl iminocarbonate,[11,13] and they did not react with benzoic acid when refluxed in benzene for 2 hr. and the starting materials were recovered quantitatively.

On the other hand, attempts to prepare unsaturated ethylene iminocarbonate by means of ester exchange between diethyl iminocarbonate and glycol, or by means of reductions of *N*-halogeno cyclic iminocarbonates with arsenious trioxide or with fluorene, failed.

When the ring-opening polymerization of *N*-substituted cyclic iminocarbonates was tried in the presence of such cationic catalysts as boron trifluoride etherate or sulfuric acid, the corresponding poly(ethylene *N*-substituted carbamates) were obtained, as Table III shows.

Compared with ethylene *N*-phenyl iminocarbonate, the polymerization of these cyclic iminocarbonates, except for ethylene *N*-*p*-chlorophenyl iminocarbonate, took a long time and their intrinsic viscosities in chloroform were low.

Polyurethane obtained from ethylene *N*-chloro iminocarbonate was comparatively unstable and was gradually decomposed above 60°C, with the evolution of chlorine.

These results show that various poly(ethylene *N*-substituted carbamates) can be produced by the 1, 4-addition-type ring-opening polymerization of cyclic iminocarbonates. On the other hand, the polyurethane can not be successfully produced from oxazolidone, 5-membered cyclic urethane, since it yields exclusively polyethyleneimine, with the evolution of carbon dioxide.

The ease of the 1, 4-addition type ring-opening polymerization of these cyclic iminocarbonates may be interpreted in the following way: since the cyclic iminocarbonates are an enol isomer of cyclic urethane, which seems to be more unstable than the corresponding keto-form structure, it is reasonable to consider that these compounds are readily converted into the polymers with a keto-form structure by the ring-opening polymerization.

Experimental

Alkyl and Aryl Isothiocyanates. — Cyclohexyl isothiocyanate was prepared from cyclohexyl amine, carbon disulfide and mercuric chloride following the procedure of Skita.[14] *n*-Hexyl isothiocyanate was prepared from *n*-hexyl amine, carbon disulfide and ethyl chlorocarbonate by a method analogous to that used for the preparation of methyl isothiocyanate by Moore;[15] yield, 46%, b. p. 80~82°C/3 mmHg. *p*-Chlorophenyl and *p*-nitrophenyl isothiocyanates were prepared from corresponing anilines and thiophosgene according to the methods of Dyson[16] and Dyer.[17]

The Preparation of Cyclohexyl Imidophosgene. —A solution of 40 g. of cyclohexyl isothiocyanate in an equal volume of carbon tetrachloride was saturated with dry chlorine until the reaction mixture became dark red. Since an evolution of heat was noticed during the reaction, the reaction mixture was cooled in ice-water. After the solvent and sulfur dichloride had been removed by distillation, cyclohexyl imidophosgene was fractionated; yield, 48.0 g. (95%); b. p. 100°C/30 mmHg.

In a similar way, *n*-hexyl, *p*-chlorophenyl and *p*-nitrophenyl imidophosgenes were prepared from the corresponding isothiocyanates and chlorine as is shown in Table I.

The Preparation of Ethylene *N*-Cyclohexyl Iminocarbonate.—Into 5.4 g. (0.05 mol.) of sodium ethylene glycolate suspended in 30 ml. of dry benzene was added dropwise a solution of 9.0 g. (0.05 mol.) of cyclohexyl imidophosgene in 20 ml. of dry benzene with vigorous stirring. Then the

16) G. M. Dyson, ibid., Coll. Vol. 1, 165 (1948).

17) E. Dyer and T. B. Johnson, *J. Am. Chem. Soc.*, 54, 777 (1932).

reaction mixture was refluxed on a water bath for 2 hr. while being continuously stirred. It was then poured into water and extracted with benzene. After washing with water, the benzene solution was dried with calcium chloride. The benzene was then removed completely in vacuo and ethylene *N*-cyclohexyl iminocarbonate was distilled; yield, 4.0 g. (48%); b. p. 110~113°C/0.3 mmHg. The infrared absorption bands are 1700(s), 1410(ms), 1370(ms), 1250~1100(ms) broad, 1030(s) and 760(ms) cm^{-1}.

In a similar manner, ethylene *N*-*n*-hexyl, *N*-*p*-chlorophenyl and *N*-*p*-nitrophenyl iminocarbonates were prepared from the corresponding imidophosgenes and sodium ethylene glycolate as listed in Table II.

The Preparation of Ethylene *N*-Chloro Iminocarbonate.[18]—Into a solution of 16.0 g. (0.4 mol.) of sodium hydroxide, 13.0 g. (0.2 mol.) of potassium cyanide and 12.4 g. (0.2 mol.) of ethylene glycol in 80 ml. of water, was passed chlorine with vigorous stirring under cooling by ice-water until red litmus paper no longer changed to blue. When the aqueous solution, became neutral, ethylene *N*-chloro iminocarbonate floated on the surface of the solution. The iminocarbonate was filtered and was recrystallized from ether; yield, 2.9 g. (12%); m. p. 33~35°C. The infrared absorption bands are at 1650(s), 1400(ms), 1230(s), 1060(s) and 700(ms) cm^{-1}.

Similarly, propylene *N*-chloro iminocarbonate was prepared following the above method by using propylene glycol in place of ethylene glycol. Ethylene *N*-bromo iminocarbonate was also prepared by using bromine, of which about 50 g. was required, instead of chlorine as in the above experiment. The yields, physical properties and analysis for these iminocarbonates are also indicated in Table II.

The Polymerization of Ethylene *N*-Cyclohexyl Iminocarbonate.—Into 1.0 g. of ethylene *N*-cyclohexyl iminocarbonate was added a catalytic amount of boron trifluoride etherate; the mixture was then allowed to stand at room temperature for 14 hr. Then poly(ethylene *N*-cyclohexylcarbamate) was reprecipitated from chloroform-acetone. Yield, 0.14 g. (14%); m. p. 178~183°C. Its infrared absorption bands are at 1680(s), 1420(ms), 1230(ms), 1150(ms) and 760(ms) cm^{-1}.

Found: C, 63.23; H, 9.06; N, 7.96. Calcd. for $(C_9H_{15}O_2N)_n$: C, 63.88; H, 8.94; N, 8.28%.

The polymerizations of other *N*-substituted cyclic iminocarbonates were carried out in a similar method under the reaction conditions indicated in Table III in the presence of a small amounts of catalyst (7~10 mg.). The catalysts, yields, physical properties, intrinsic viscosities and solvents of reprecipitation for the polyurethane obtained are also shown in the same table.

18) The preparation of this compound has aleady been published; H. E. Simnous, U. S. Pat. 2972620; *Chem. Abstr.*, 55, 14481 (1961).

Summary

As one of a series of studies of 1, 4-addition type ring-opening polymerizations, the synthesis and ring-opening polymerization of *N*-substituted cyclic iminocarbonates have been studied.

N-Alkyl and *N*-aryl cyclic iminocarbonates have been prepared by the reaction of sodium ethylene glycorate with the corresponding imidophosgenes. *N*-Halogeno cyclic iminocarbonates have been prepared from glycols, potassium cyanide and halogenes.

The ring-opening polymerization of the *N*-substituted cyclic iminocarbonates, which are considered to be cyclic enol derivatives of urethanes, in the presence of cationic catalysts gives the corresponding poly(ethylene *N*-substituted carbamates).

The authors wish to express their hearty thanks to Miss Toshiko Aoyagi for her microanalyses.

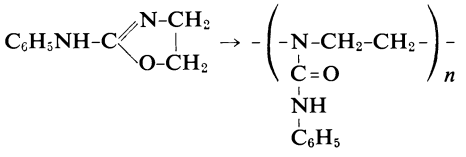
The Preparation of Poly(ethylene N,N'-Disubstituted Ureas) by the 1,4-Addition Type Ring-opening Polymerization of 2-Imino-1,3-oxazolidines

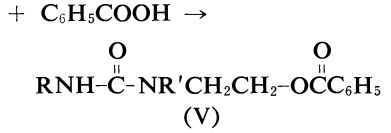


By Hiroyuki NOHIRA, Yoshihiro NISHIKAWA and Teruaki MUKAIYAMA

(Received December 12, 1963)

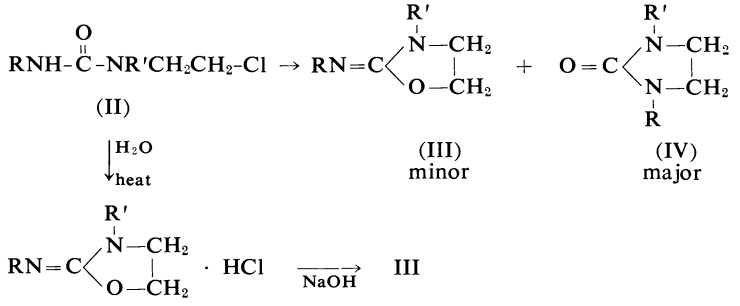
A new type of ring-opening polymerization of ethylene iminocarbonates, cyclic ketene acetals and 2-iminotetrahydrofurans, to give polyurethans, polyesters and polyamides respectively, has been reported in preceding papers.[1,2] It was shown there that the polymerization of 2-phenylimino-1,3-oxazolidine (I) gives a polymer with urea linkage; however, both the melting temperature and the intrinsic viscosity of the resulting polymer are low. Moreover, a troublesome problem remained concerning the structure of the polymer, since there are two possible pathways for the polymerization to yield poly(ethylene *N*-phenyl urea) (Ip) and the polyethylene imine-type polymer (Ip'), which have been attributed to the existence of two tautomeric forms, 2-phenylimino-1,3-oxazolidine (I) and 2-anilino-2-oxazoline (I'), respectively. In this connection, in the present investigation, the polymerizations of 2-imino-3-substituted-1,3-oxazolidines, which have no labile hydrogen atom at the 3-position, have been studied in order to establish the ring-openig polymerization which yields polyureas of the type Ip.

(I) (Ip)



(I') (Ip')

Several methods for the preparation of *N*, *N'*-disubstituted-2-imino-1,3-oxazolidines (III) have been reported: from β-hydroxyethyl thioureas by the action of mercuric oxide,[3] from guanidinoethanols by refluxing in xylene,[4] or from β-chloroethylureas by the action of potassium hydroxide.[5] Although the last route seems to be the most convenient, the yields of the desired compounds are low, and the corresponding cyclic ureas IV have resulted as main products.



It has now been found that II gives the cyclic pseudo ureas III in good yields when treated with hot water and neutralized with sodium hydroxide.

On the other hand, the cyclic pseudo ureas with an unsubstituted imino group (III, R = H) were prepared from ethanolamines and cyanogen bromide through the hydrobromides.[6]

When III was heated with benzoic acid in benzene, ring-opening adducts V were obtained in fairly good yields.

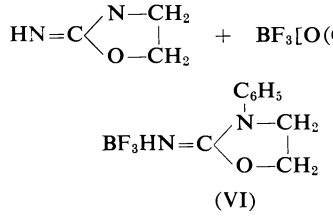
P. M. T., Polymer melting temperature; BF_3[E], Boron trifluoride etherate; BF_3[O], Boron trifluoride 2-imino-3-phenyl-1,3-oxazolidine complex (VI); (a)—(d): reprecipitating media (a), chlroform-acetone; (b), chloroform-petroleum ether; (c), *m*-cresol-acetone; (d), chloroform-ether

This reaction is similar to those of ethylene iminocarbonates or 2-iminotetrahydrofurans with acids reported in the previous papers,[1,2] and it suggests the possibility of a 1, 4-addition type ring-opening polymerization of the imino-oxazolidines.

Successful ring-opening polymerizations of the iminooxazolidines in question were carried out when these oxazolidines were heated in the presence of a cationic catalyst such as boron trifluoride etherate at a temperature between 85 and 160°C. Higher temperatures were necessary for this polymerization than for the polymerization of the ethylene iminocarbonates (25～100°C) and the 2-iminotetrahydrofurans (60～100°C). This result agrees with that of a kinetic study[7] of the 1, 4-addition type ring-opening reaction of three typical cyclic imino-compounds with carboxylic acids, where the order of the reactivities was shown to be as follows:

The structure of the resulting polymers was confirmed to be of the polyethylene-urea-type (IIIp) by means of infrared spectroscopy. That is, the monomers show an absorption in the range 1670～1680 cm^{-1} due to the exo-imino group of the five-membered ring, while all polymers absorb at the region about 1650 cm^{-1}, the same region as that where non-cyclic substituted ureas absorb.



(III) (IIIp)

The polymerization conditions and properties of the resulting polymers are listed in Table I.

2-Phenylimino-3-phenyl-1, 3-oxazolidine (III, R, R' = C_6H_5) gave a hard, tough polymer with a fairly high polymer-melting temperature of 350°C. It was soluble in *m*-cresol, but insoluble in acetone, chloroform, methylene dichloride and dimethylsulfoxide. These properties may be attributable to the high density and to the symmetrical arrangement of phenyl groups along the ethylene urea linkages. The unsubstituted imino oxazolidine (III, R = H, R' = C_6H_5–) gave a polymer with a low polymer melting temperature and a low viscosity in low yields. In addition, the oxazolidine was found to give a stable complex with boron trifluoride when it was mixed with boron trifluoride etherate in a dilute ether solution:

7) T. Mukaiyama, Y. Tamura and T. Fujisawa, This Bulletin, 37, 628 (1964).

(VI)

The difficulty of the polymerization of the oxazolidine may be connected with the stability of the complex VI as this complex can be weighed in small quantities, an attempt was made to use this as a catalyst in the polymerization of the other disubstituted imino oxazolidines. It was found that the complex VI was as effective as boron trifluoride etherate in these polymerizations.

2-Imino-3-methyl-1, 3-oxazolidine (III, R=H, R'=CH_3) did not give any solid polymers, even when it was heated at 120°C for 5 hr.

Experimental

1-(2-Chloroethyl)-3-phenyl-1-methyl Urea (II, R=C_6H_5, R'=CH_3) and 1-(2-Chloroethyl)-3-(3, 4-dichlorophenyl)-1-methyl Urea (II, R=3, 4-$Cl_2C_6H_3$, R'=CH_3).—These compounds were prepared from the corresponding hydroxyethyl ureas and thionyl chloride according to the methods described in the patent literature.[5]

By an analogous method, 1-(2-chloroethyl)-1, 3-diphenyl urea (II, R, R'=C_6H_5) was obtained from 1-(2-hydroxyethyl)-1, 3-diphenyl urea (which had been prepared from phenyl isocyanate and *N*-phenyl ethanolamine in dioxane as a viscous liquid) and thionyl chloride in a 65% yield. It was recrystallized from ligroin (70 parts) and benzene (30 parts). M. p. 71°C.

Found; C, 65.43, H, 5.47; N, 10.43. Calcd. for $C_{15}H_{15}ClN_2O$: C, 65.57, H, 5.50; N, 10.19.

2-Phenylimino 3-Methyl 1, 3-Oxazolidine (III, R=C_6H_5, R=CH_3).—Eleven grams of 1-(2-chloroethyl)-3-phenyl-1-methyl urea was heated with 50 ml. of water with vigorous stirring in a boiling water bath for 30 min. After cooling, the solution was neutralized with aqueous sodium hydroxide. The precipitate was recrystiallized from ligroin. Yield, 7.2 g. (80%); m. p. 74.5~75.5°C (lit.[4] m. p. 82°C). The infrared spectrum (KBr) showed strong absorptions at 1678 cm^{-1} (N=C) and 1039 cm^{-1} (O−C).

Found: C, 68.16, H, 6.86; N, 15.90. Calcd. for $C_{10}H_{12}N_2O$: C, 68.01, H, 7.04; N, 16.10%.

2-(3, 4-Dichlorophenylimino)-3-methyl-1, 3-oxazolidine (III, R=3, 4-$Cl_2C_6H_3$, R'=CH_3) was prepared in the same way. Yield, 80%; m. p. 64~65°C (lit.[5] m. p. 45~47°C). The infrared spectrum (KBr) showed strong absorptions at 1673 cm^{-1} (N=C) and 1035 cm^{-1} (O−C).

Found: N, 11.58. Calcd. for $C_{10}H_{10}Cl_2N_2O$; N, 11.43%.

2-Phenylimino-3-phenyl-1, 3-oxazolidine (III, R, R'=C_6H_5).—This compound was also prepared by a similar method except for the use of a larger amount of water: Ten grams of 1-(2-hydroxyethyl-1, 3-diphenyl urea was heated with 500 ml. of water for one hour. It was then recrystallized from ligroin. Yield, 5.6 g. (65%); m. p. 124°C. A strong absorption due to the imino group appeared at 1679 cm^{-1} (KBr) in the infrared spectrum. This material was identical in all respects with a sample prepared from 1-(2-hydroxyethyl)-1, 3-diphenyl thiourea and mercuric oxide[3].

2-Imino-3-phenyl-1, 3-oxazolidine (III, R=H, R'=C_6H_5) and 2-Imino-3-methyl-1, 3-oxazolidine (III, R=H, R'=CH_3).—These compounds were prepared by the method of Thurston[6] except for the use of cyanogen bromide instead of cyanogen chloride.

2-Imino-3-phenyl-1, 3-oxazolidine: Yield, 46%; m. p. 99~100°C, after recrystallization from ligroin (lit.[6] m. p. 99~100°C).

2-Imino-3-methyl-1, 3-oxazolidine: Yield, 50%; b. p. 56~57°C 3 mmHg. Found: C, 47.80, H, 8.29; N, 26.74. Calcd. for $C_4H_8N_2O$: C, 47.98, H, 8.05; N, 27.98%.

Ring-opening Adducts of the Imino Oxazolidines with Benzoic Acid. (V)—A mixture of 2-phenylimino-3-methyl-1, 3-oxazolididine (1.0 g.) and benzoic acid (0.85 g.) in 5 ml. of dry benzene was refluxed for 2 hr. The solvent was removed under reduced pressure, and the residual 1-(2-benzoyloxyethyl)-3-phenyl-1-methyl urea (V, R=C_6H_5, R'=CH_3) was washed with aqueous sodium carbonate. It was then recrystallized from ligroin and benzene; yield, 1.1 g. (65%); m. p. 116~117°C. The infrared spectrum (KBr) showed strong absortions at 1720 cm^{-1} (C=O of ester linkage) and at 1646 cm^{-1} (C=O of urea linkage).

Found: C, 67.42, H, 6.09; N, 9.67. Calcd. for $C_{17}H_{18}N_2O_3$: C, 68.44, H, 6.08; N, 9.39%.

Similarly, 1-(2-benzoyloxyethyl)-3-(3, 4-dichlorophenylimino)-1-methyl urea (V, R=3, 4-$Cl_2C_6H_3$-, R'=CH_3) was obtained from 2-(3, 4-dichlorophenylimino)-3-methyl-1, 3-oxazoline and benzoic acid in a 60% yield (m. p. 103~104°C) after recrystallization from ligoin and benzene. The infrared spectrum (KBr) showed strong absorptions at 1720 cm^{-1} (C=O of ester linkage) and at 1650 cm^{-1} (C=O of urea linkage).

Found: C, 55.86, H, 4.47; N, 7.80, Calcd. for $C_{17}H_{16}Cl_2N_2O_3$: C, 55.60, H, 4.36; N, 7.83%.

The Boron Trifluoride Complex of 2-Imino-3-phenyl-1, 3-oxazolidine (VI).—To a 2% solution of 2-imino-3-phenyl-1, 3-oxazolidine in dry ether cooled in an ice water bath was added, an equivalent amount of boron triflurorido etherate. The resulting precipitate was filtered and washed with dry ether. The yield was almost quantitative. It is very sensitive to moisture and easily deliquesces. It melts at the range 97~105°C.

Found: N, 11.70. Calcd. for $C_9H_{10}N_2OBF_3$: N, 12.17%.

Polymerizations of the above mentioned imino oxazolidines were carried out in bulk polymerizations. The catalysts, polymerizing temperature and time, reprecipitating media, yields, melting temperature and intrinsic viscosities are shown in Table I. The infrared spectra (KBr) of poly(ethylene *N*-phenyl-*N'*-methylurea), poly[ethylene

N-(3, 4-dichlorophenyl) *N'*-methylurea] and poly-(ethylene *N*, *N'*-diphenylurea) showed strong absorptions at 1648 cm^{-1}, 1647 cm^{-1} and 1659 cm^{-1} respectively. These are attributable to the non-cyclic disubstituted urea linkages.

Summary

Various 2-imino-1, 3-oxazolidines have been prepared from β-chloroethylureas or from ethanolamines and cyanogen bromide.

N, *N'*-Disubstituted 2-imino-1, 3-oxazolidines give poly(ethylene *N*, *N'*-disubstituted ureas) by 1, 4-addition type ring-opening polymerization in the presence of a cationic catalyst such as boron trifluoride etherate. On the other hand, 2-unsubstituted imino-1, 3-oxazolidines polymerize with difficulty and give polymers with low melting temperatures.

The Determination of Water by Gas Chromatography

By Seishi YAJIMA, Koreyuki SHIBA, Muneo HANDA and Yoshihisa TAKAHASHI

(Received December 17, 1963)

In the determination of water, the introduction of a sample directly into a gas chromatograph has been reported by many workers, who have used a wide variety of column packings.[1-5] However, the retention time of water was very long and the peak of water in gas chromatograms was very broad, both of which features interfered with the analysis of the other gases in the sample. In analysing gas samples containing water, Desty et al.[6] decomposed the water to hydrogen, using calcium hydride, before introducing it into gas chromatography they thus obtained satisfactory results for the gases other than water vapor in the sample.

Recently, Arnett[7] ascertaind the amount of heavy water in light water by decomposing the heavy water to DH and by analysing the DH using a charcoal column. Green[8] has reported results obtained by decomposing water to hydrogen, using an iron powder bed heated electrically to heat.

However, detailed experimental conditions have not been examined for the adsorption of water on calcium hydride, for the complete decomposition of water by calcium hydride, for the limitation of detection, for the reaction between calcium hydride and other gases, or for the reproducibility of the experiments.

The present authors used a lithium aluminum hydride, which is widely used in organic chemistry, to reduce water to hydrogen, and developed a method for determining the amount of water by gas chromatography. By this method they could determine water in amounts as small as 0.1 μg. in 10 ml. of a gas sample with a high degree of accuracy. The reaction between lithium aluminum hydride and water follows this chemical equation:[9]

$$LiAlH_4 + 4H_2O = LiOH + Al(OH)_3 + 4H_2$$

To determine such small amounts of water, the following experiments were carried out. By using water of crystallization in hydrated copper sulfate as a standard, it was first confirmed that lithium aluminum hydride could decompose water completely to hydrogen at room temperature. Second, the reactions between lithium aluminum hydride and oxygen, nitrogen, carbon dioxide, carbon monoxide, methane and C_2–C_4 hydrocarbons were studied. Third, the adsorption of water vapor on the lithium hydride surface was studied. Fourth, in order to the limitations of the detection of

water, a molecular sieve-5A column and completely-purified argon carrier gas were used for determining the hydrogen; thereby 10 p.p.m. of hydrogen could be determined in 10 ml. of a gas sample. Last, by applying the above method, the gas content of uranium dioxide was studied; satisfactory results were obtained. One example of the results is reported on in this paper.

Experimental

Apparatus.— A flow diagram of the experimental apparatus is shown in Fig. 1. The apparatus consists of an electric furnace, a U-tube packed with lithium aluminum hydride powder, and an automatic Toepler pump. The sample was heated by the electric furnace, the temperature of which was controlled by an automatic temperature regulator.

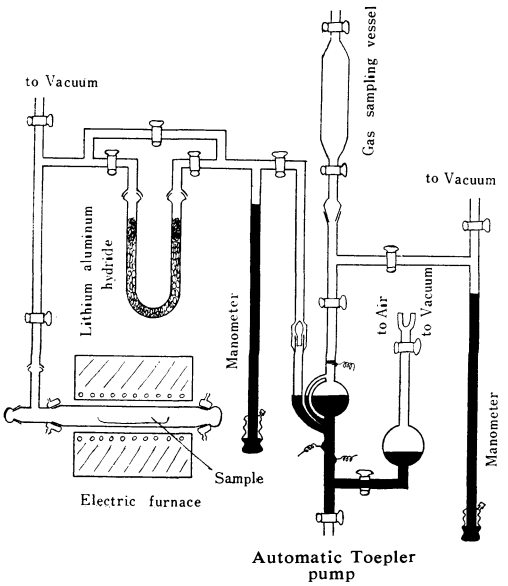

Fig. 1. Apparatus.

The automatic Toepler pump took one minute for one cycle, and its effective volume was about 100 ml., that is, if the pump was operated at S. T. P., it could draw out 100 ml. of gas per minute. The pump could bring the apparatus up to a pressure of 10^{-2} mmHg.

To Pack Lithium Aluminum Hydride into the U-Tube and to Degas the Impurity Gases Adsorbed on It.—The lithium aluminum hydride commercially available is a white powder with particle sizes of less than one micron and with various impurity gases adsorbed on its surfaces.

When lithium aluminum hydride is used as it is sold, these impurity gases are released slowly during the experiment and make the accuracy of the analysis poor. To remove these impurity gases, lithium aluminum hydride was heated for two hours at 100°C in a vacuum. The release rate of the impurity gases was reduced to 0.001 μl. per minute for the degassed lithium aluminum hydride; this release rate was negligible within the range of experimental error. To increase the passage of sample gases through the U-tube, lithium aluminum hydride was mixed with glass wool, which was then packed into the U-tube.

The amount of lithium aluminum hydride packed in the U-tube was about 0.5 g. The U-tube used was 1 cm. in diameter and 20 cm. long.

Procedure.—The sample was placed in the center of an electric furnace, and the whole apparatus was evacuated by a rotary pump to less than 10^{-3} mmHg. Then the automatic Toepler pump was operated, and the temperature in the electric furnace was raised to a given temperature.

The water vapor and the other gases released from the sample were passed through the U-tube packed with lithium aluminum hydride, where the water vapor was decomposed to hydrogen; the hydrogen was collected in the gas-sampling vessel by the automatic Toepler pump, along with other gases. The collected gases were then analysed by means of a gas chromatograph.

Gas Analysis.—A GC-IA type Shimazu gas chromatograph was used in all the experiments. Sample of gas were introduced by an attached apparatus, which is used to make the calibration curve. This apparatus is shown in Fig. 2; it is so designed that the current of the carrier gas is not interrupted during the sampling. The gas-sampling vessel containing the gas sample was attached to this calibration apparatus. Then the gas sample was transferred into a gas pipet by replacing it with mercury in the gas-sampling vessel, and a definite volume of gas was transferred from the pipet to vessel A (cf. Fig. 2).

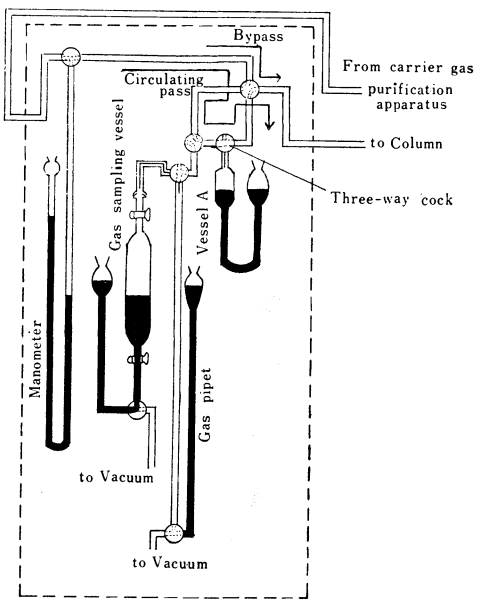

Fig. 2. Apparatus for making calibration curve.

The flow of the carrier gas was changed from the bypass to the circulating path in which the gas sample in vessel A was pushed by mercury; the sample gas was then sent to the gas chromato-

graph, along with the carrier gas. The determination was carried out with a ball-disc-type automatic integrator fixed on the SAP-type recorder. A molecular sieve-5A column was used for the separation of the components (0.6 cm. in diameter and 75 cm. long). The flow rate of the carrier gas was 40 ml. per minute. For the determination of hydrogen, argon gas was used as the carrier, while for oxygen, nitrogen, methane and carbon monoxide, helium gas was used. Both the carrier gases were completely purified by the gas purification apparatus shown in Fig. 3. A constant flow rate of the carrier gas was obtained by maintaining a constant pressure at the inlet of the chromatograph by using the mercury bubbler set in the gas purification apparatus. The sensitivity of the recorder was increased to 30 μV. per full scale by using an electronic galvanometer, model AD-6, made by the Toa Dempa Kogyo Co.

Results and Discussion

The Determination of the Water of Crystallization in Hydrated Copper Sulfate.—To confirm the complete decomposition of water to hydrogen by lithium aluminum hydride at room temperature, hydrated copper sulfate was used as standard material and the water of crystallization in it was determined. The copper sulfate weighed was heated in the furnace at 250°C, and the water vapor released was passed through the U-tube with lithium aluminum hydride powder packing, in which the vapor was decomposed to hydrogen. The hydrogen was then drawn into and collected in the gas sampling vessel by the automatic Toepler pump, and analysed by the gas chromatograph. The results obtained are shown in Table I.

As the table shows, the water completely decomposed to hydrogen by lithium aluminum hydride under the experimental conditions.

The Reaction of Lithium Aluminum Hydride with Gases Other than Water Vapor.—It was confirmed that lithium aluminum hydride quantitatively reduced water to hydrogen at room temperature. Then the reactions between lithium aluminum hydride and other gases were examined. The results of the reaction between lithium aluminum hydride and oxygen are shown in Fig. 4, where the small circles indicate the oxygen calibration points which were obtained by passing it through the U-tube packed with lithium aluminum hydride, and the small triangles show the calibration points which were obtained by not passing it through it. The points obtained for both cases

lie on the same line.

From the results, it is clear that the reaction between lithium aluminum hydride and oxygen does not occur. Following the same procedure, the reactions between lithium aluminum hydride and nitrogen, carbon monoxide, carbon dioxide methane and C_2-C_4 hydrocarbons were examined; no reactions could be detected.

The Adsorption of Water on the Surface of Lithium Aluminum Hydride.—As lithium aluminum hydride is a fine powder, the adsorption of water vapor on its surface must be checked under the experimental conditions.

Standard samples of water with water vapor contents of 0.230 and 0.019% were prepared. The water was decomposed to hydrogen and analysed by the gas chromatograph. The results obtained are shown in Table II. This table shows that the adsorption of water on the surface of lithium aluminum hydride is negligible within the range of experimental error under the present experimental conditions.

The Gas Content of Uranium Dioxide.*—Because of its good heat resistance, good chemical stability, etc., uranium dioxide is widely used as a nuclear fuel. However, uranium dioxide adsorbs various kinds of impurity gases on its surfaces. These gases are released gradually during the reactor operation, which has various harmful effects on the reactor operation, such as reacting with the zirconium used to protect to graphite moderator from the sodium coolant, leading to the deterioration of the physical properties of the zirconium.[10,11]

The analytical method stated above was used to determine the gas content of uranium dioxide, and satisfactory results were obtained. An example of the results is shown in Table III.

The sample of uranium dioxide which was used for the experiments had been stored in a laboratory, sealed in a polyethylene bottle, while the uranium dioxide was purchased from the Yokogawa Kagaku Co., Ltd.

In Table III, the first column shows the

* The gas content of many samples of uranium dioxide was ascertained. The results will be reported in the Journal of the Atomic Energy Society of Japan.

degassing temperature; the second, the degassing time; the third, the volume of gas released equivalent to that at S. T. P., and the fourth and other columns, the results of the analysis of the released gases. About 50 g. of uranium dioxide powder was used for this experiment.

The Limitation of the Determination of Water.—Concentrations of hydrogen as low as about 10 p. p.m. could be determined by the present gas chromatographical method. When 10-ml. gas samples are used, the limitation of the determination of water is as follows. In the decomposition of water by lithium aluminum hydride, one mole of hydrogen is obtained from one mole of water. That is, 10 p. p. m. of water in 10-ml. sample gases (0.1 μl. of water) is the limitation of the determination for water. Converting this value to weight, it follows that about 0.1 μg. is the limitation for water.

An Automatic Recording Analyzer for the Determination of Dissolved Oxygen in Boiler Feed Water[*1]

By Kazuo TANNO

(Received December 28, 1963)

In thermal power plants, the dissolved-oxygen content of feed water for boilers is rigidly controlled in order to prevent the corrosion of the boiler and other equipment. The allowable dissolved-oxygen content is less than a few parts per billion.

The dissolved-oxygen content of the feed water in these plants is usually determined by means of an analyzer with thermal conductivity cells.[1,2),*2] However, when hydrazin is used for reducing the dissolved-oxygen content, the results of oxygen determination by the above type of analyzer are erroneous. This is because nitrogen is formed during the treatment of the feed water with hydrazin, and the thermal conductivity of nitrogen is nearly the same as that of oxygen. Therefore, a new type of oxygen analyzer is required for the determination of dissolved oxygen in hydrazin-treated feed water. The design of such an analyzer was undertaken at this laboratory; it is described in this paper. The underlying principle is to determine the dissolved oxygen automatically by Winkler's method.[3,4)]

Although, while the present work was being conducted, Ridley et al.[5)] published a paper describing the design of an instrument for dissolved-oxygen determination by the same method, their instrument appears to be useful only when the dissolved-oxygen content is of the order of some parts per million. On the other hand, the instrument described in this paper is designed for determination in the range of oxygen concentration up to 50 parts per billion.

Outline of the Method and the Reagents Used

Method.—Briefly, the method involves two main steps: (1) the fixation of dissolved oxygen, and (2) amperometric titration. The dissolved oxygen is fixed by adding the following reagents to the sample water in the order named: an alkaline iodide solution (made alkaline with potassium hydroxide), a manganous sulfate solution, and a sulfuric acid solution. The reactions taking place in this step are the formation of manganous hydroxide (Eq. 1), the oxidation of manganous hydroxide to manganic hydroxide by dissolved oxygen (Eq. 2), and the liberation of iodine (Eq. 3).

$$MnSO_4 + 2KOH = Mn(OH)_2 + K_2SO_4 \quad (1)$$

$$2Mn(OH)_2 + 1/2O_2 + H_2O = 2Mn(OH)_3 \quad (2)$$

$$2Mn(OH)_3 + 2KI + 3H_2SO_4 = 2MnSO_4 + I_2 + K_2SO_4 + 6H_2O \quad (3)$$

*1 Presented at the Autumn Meeting of the Chemical Society of Japan, Tokyo, November, 1962.

3) ASTM Standards, Designation D888-49T (1949).

4) Japanese Industrial Standard, B8224 (1961).

*2 Although a variety of dissolved-oxygen analyzers have been developed in these several years, this type of analyzer has been most widely used.

5) J. E. Ridley, D. B. L. Elliott and A. B. Oaten, *Analyst*, **85**, 508 (1960).

As may be seen from Eq. 3, the iodine liberated is equivalent to the dissolved oxygen. The iodine is, therefore, amperometrically back-titrated with a standard solution of potassium iodate after the addition of an excessive thiosulfate solution.

A blank determination is also carried out in order to make a correction for the effect of the interfering substances both in the sample water and in the reagents. In this case, the reagents for oxygen fixation are added to the sample water in the following order: an alkaline iodide solution, a sulfuric acid solution, and a manganous sulfate solution. The titration is then performed in the same way as has been described above.

The dissolved-oxygen content is calculated from the difference between the quantities of titrant used in the sample and blank titrations by the following equation:

$$X = \frac{8\times10^6}{V}\{m(K'-K)-D\} \qquad (4)$$

Where X = the dissolved-oxygen concentration in parts per billion (p. p. b.)
V = the volume of sample water taken for analysis, ml.
m = the concentration of the potassium iodate solution, N
K = the volume of the potassium iodate solution used in the sample titration, ml.
K' = the volume of the potassium iodate solution used in the blank titration, ml., and
D = the correction for the dissolved oxygen in the reagents.

In the present instrument, 550 ml. of sample water is analyzed by the use of the reagents described below; the quantities of reagents used for oxygen fixation are: 3 ml. of the alkaline iodide solution, 2 ml. of the manganous sulfate solution, and 3 ml. of the sulfuric acid solution. Therefore, Eq. 4 reduces to:

$$X = 72.7\{(K'-K)-0.13\} \qquad (5)^{*3}$$

This is a working formula for use with the present instrument. Although the concentrations and quantities of the reagents employed for oxygen fixation in the present method are different from those specified in the standard method, the present method gives the same results as the standard method.*4

Reagents.—The reagents used in the present instrument are as follows: Alkaline iodide solution (solution A): The concentrations of potassium hydroxide, potassium iodide, and iodine in the solution are: potassium hydroxide 8.3 N, potassium iodide 10%, and iodine 0.003 N.

Manganous sulfate solution (solution B): 32.5% solution.

Sulfuric acid solution (solution C): 18 N solution.

Standard potassium iodate solution: 0.005 N solution.

Thiosulfate solution: Approximately 0.005 N solution.

Automatic Recording Analyzer

A diagram of the automatic recording analyzer is shown in Fig. 1. This instrument was so designed as to perform automatically most of the operations involved in manual analysis, such as sampling, the addition of reagents, titration, recording, and cleansing. In order that such operations might be carried out in a systematic way, a time-cycle-control system was employed. The operations described below are automatically performed in the order of description.

Sequence of Operations.*5—*Cleansing and Sampling.*—The valves,*6 V14, V12, V10, V13, and V11, are opened, and the water to be analyzed is passed through the two fixation vessels, K and L, for a fixed period of time in order to cleanse them. Thereafter, the valves are closed. Thus, the fixation vessels are filled with the sample water.

Fixation.—The fixation of dissolved oxygen in the fixation vessel, K, is carried out first. Solutions A, B, and C in the reservoirs are simultaneously fed to the respective reagent pipets, F, G, and H; then, after the pipets are filled with the reagents, the stirrer*7 in the fixation vessel, K, is started. The reagents in the pipets are then injected into the fixation vessel in the following order: solution A, solution B, and solution C. When these solutions are forced into the fixation vessel, the surplus liquid in the vessel is drained from the top of vessel. After the injection of solution C is completed, the stirrer is stopped.

The blank operation in the fixation vessel, L, is carried out in the same way except that

*3 The value of D has been determined on the following ground. The concentrations of alkaline iodide and sulfuric acid solutions employed in the present method are, respectively, 2/3 the concentrations specified in the standard method; however, the quantities of these solutions used for dissolved-oxygen fixation are 1.5 times as large as the quantities specified in the standard method. The correction term, D, in Eq. 4 was calculated according to the equation of Adams et al.[6] and White et al.[7]

*4 For purposes of comparison, the results of analysis by the two methods are summarized in Appendix Table I.

*5 Wherever necessary, the literal symbols used to designate the parts of instrument in Fig. 1 are used in the description under this head.

*6 All the valves used in this instrument are of the electromagnetic type and systematically operated.

*7 This and two others (in vessels, L and M) are magnetic stirrers.

the reagents in the pipets are injected into the fixation vessel in the order: solution A, solution C, and solution B.

Titration and Recording.—As soon as the fixation in the fixation vessel, K (sample), is completed, all the solution in this vessel is transferred to the titration vessel, M. (Here, the V10 valve, besides V12 and V15, is opened.) At the same time, the reagent pipet, I, is filled with the thiosulfate solution from the reservoir, D. The thiosulfate solution is then delivered to the titration vessel, and the stirrer in this vessel started. Next, the titration motor, N is started in order to deliver the standard potassium iodate solution (in pipet, J) to the titration vessel. (The titration pipet is filled with the titrant as soon as the previous titration is completed.)

In the course of titration, a small residual current flows between the platinum and calomel electrodes in the titration vessel until the end point is reached. After this point is reached, the diffusion current, the magnitude of which is proportional to the quantity of iodine liberated from the excess iodate added, flows between the electrodes. The diffusion current is amplified by the amplifier, U. As soon as the diffusion current attains the predetermined value, the switch in the indicating controller, V, closes, stopping the titration motor. During the titration, on the other hand, the contactor of the potentiometer, R, is driven by the screw connected by gears and a clutch to the titration motor.

After the titration is completed, the titration pipet, J, is refilled with the titrant, and the potentiometer contactor is brought back to the original position. The titrated solution in the vessel is drained, and the vessel washed with the fresh sample water delivered via the V14 and V15 valves. The vessel is then emptied and made ready for the next titration.

After the sample titration, the blank titration is carried out in the same way.

As has been indicated, all the above operations are systematically carried out as a result of the adoption of a time-cycle-control system. This system consists of four controllers, designated as a, b, c, and d. Controller b operates those parts of the instrument which are concerned with the fixation operation. Controller c operates the parts concerned with the titration operation. Controller d operates the indicating lamps. These controllers are, in turn, operated by controller a, which also carries out the operations not performed by the other controllers.

The series of operations described above (the operations in sample analysis together with the operations in blank analysis) is

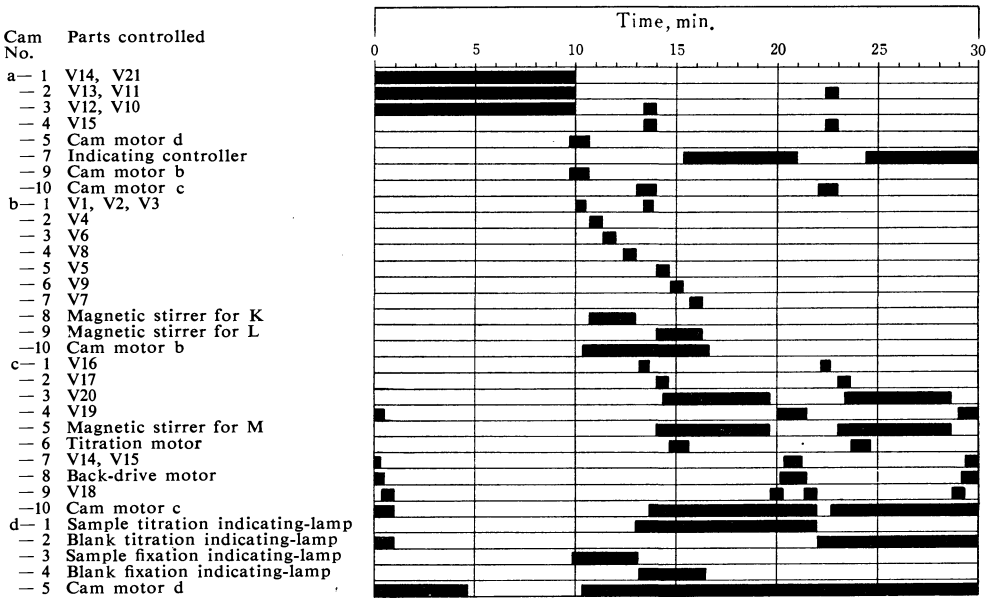

Fig. 2. Time table.

completed in 30 min. The time table for this series of operations is given in Fig. 2.

Apparatus and Some Particular Parts.—*Reagent Pipet.*—As is shown in Fig. 3, the pipet is a modified hypodermic syringe fitted with a branched capillary tube. One of the branches is an entry tube, and the other, an exit tube. When the entry valve is opened, the piston is raised by the hydrostatic head up to the movable stop, which is placed in position by a fine adjustment. When the entry valve is closed and the exit valve opened, the reagent in the pipet is discharged by the hydrostatic head and the weight of the piston. Table I shows that the precision in operation of the pipet is very high and is not affected by the movement of the plugs in the entry and exit valves.

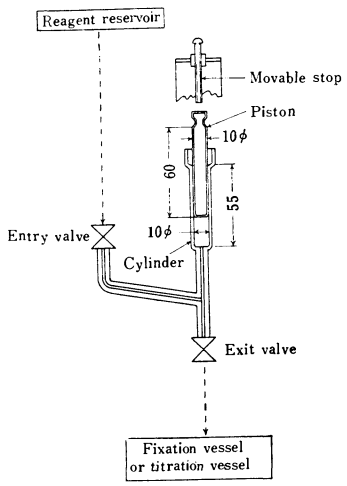

Fig. 3. Reagent pipet.

TABLE I. PRECISION IN OPERATION OF REAGENT PIPET

Pipet	Quantity of reagent transferred, g.*	
	Mean of 10 determinations	Standard deviation
With electromagnetic valves	2.1541	0.0024
With ordinary glass cocks†	1.9857	0.0030

* The reagent is the sodium thiosulfate solution.
† The valves attached to the pipet in the analyzer were replaced by ordinary glass cocks, and the cocks were manually operated.

Fixation Vessel.—In the fixation operation it is necessary that the sample water should not come in contact with air and that the reagents should be mixed thoroughly with the sample in order that complete reactions may be effected. It is also necessary that the quantity of solution remaining in the vessel after the transfer to the titration vessel should be as small as possible. These requirements were met by employing a vessel of the type shown in Fig. 4. The full capacity of the vessel used is 550 ml. The mercury-sealed

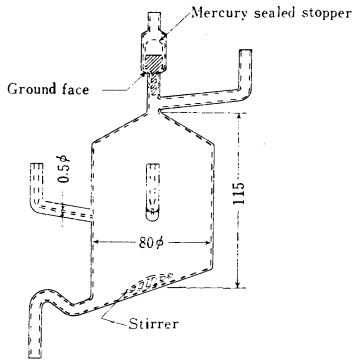

Fig. 4. Fixation vessel.

stopper can readily be raised by the liquid in the vessel when an excess of liquid is introduced. Through the capillary tube (0.5 mm. in inside diameter) attached to the side of vessel, the reagents are introduced into the vessel. The U-bent part of the tube attached to the bottom corner prevents manganese precipitate from entering the valve at the end of the tube.

Electromagnetic Valve.—The construction of the valve and the circuit diagram are shown in Fig. 5. The upper coil is used to open the valve, while the lower coil used to close the valve. The current for the coils is transmitted through a cam-switch-operated relay.

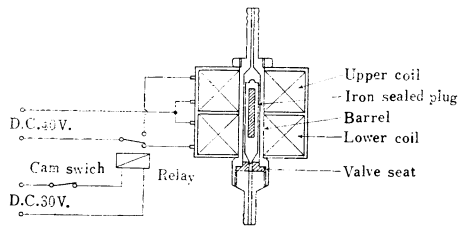

Fig. 5. Electromagnetic valve.

Titration Unit.—The titration pipet is made up of a cylinder and a narrow rod serving as a piston. The piston is 6 mm. in diameter. The pipet delivers the reagent at a rate of 0.42 ml./min., and it can discharge 2 ml. of reagent in the one-stroke operation of piston. The piston is connected by a gear mechanism and clutch either to the titration motor or to the back-drive motor. The clutches (P and Q in Fig. 1) are of the electromagnetic type; when the magnets are energized, the clutches are disengaged. During titration, the back-drive clutch, Q, is disengaged, and the connection between the piston and the back-drive motor (O in Fig. 1) is cut off. In the back drive of piston, the titration clutch, P, is disengaged to cut off the connection between the piston and the titration motor (N in Fig. 1).

The potentiometer has a slide wire 15 cm. long, and the range of movement of the contactor is adjusted by the position of the slide-range-setting switch (X in Fig. 1).

Titration Vessel and Electrodes.—The titration vessel has a capacity of 600 ml.; capillary tubes for delivering sodium thiosulfate and potassium iodate solutions are inserted in the vessel. The platinum electrode is a spiral made by winding a platinum wire 0.5 mm. in diameter and 50 mm. long.*8 The calomel electrode is one commonly used in pH measurement. These electrodes are connected by a 15 kΩ resistor*9 in the amplifier.

Indicating Controller.—The controller is a Hitachi indicating controller. The internal resistance is 100 Ω, and the reading range is 0~1000 μ.

Recorder.—A Hitachi TVK-B recorder is used. The full scale reading is 30 mV.

Performance Tests and Discussion

The instrument was tested by analyzing the water deaerated with or without the addition of hydrazin.

The deaeration was carried out in the following way by employing the apparatus shown diagrammatically in Fig. 6. Pure water was charged to both the boiler and the deaerator, and the boiler was heated. The steam from the boiler was blown into the water in the deaerator, and the water in the deaerator was, in turn, pumped into the boiler. The dissolved air was expelled with steam through

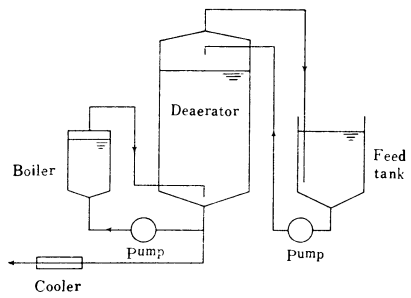

Fig. 6. Deaeration apparatus.

*8 The platinum electrode, after its preparation, is immersed in Mohr's salt solution. If this treatment has been made, the residual current, which flows before the end point is reached, can be not only minimized but also stabilized.

*9 The value of the resistor was determined experimentally. In the experiment, seven resistors (1, 5, 15, 50, 200 and 500 kΩ and 100 MΩ) were tried, and the reproducibility and the slope of titration curve were examined. From the results, a 15 kΩ resistor is considered appropriate for use in the present instrument. The data obtained in the experiment are given in Appendix Table II.

the submerged pipe in the feed tank. This procedure is based on the fact that, above 100°C., the concentration of oxygen in the vapor phase is far greater than the concentration in the liquid phase.[8] In two of the trials made, acidic hydrazin was added to pure water before deaeration by the above procedure.

After the dissolved-oxygen content of water in the deaerator had been reduced, the water was delivered to the analyzer through the cooler, and the analyzer was set in operation. The test was continued for several hours with no interruption in the operation of the deaerator.

A typical chart from the instrument, showing the results of analysis, is presented in Fig. 7. The full scale of the chart corresponds to 0.934 ml. of the titrant used. The oxygen contents calculated from such recorded data are summarized in Tables II and III, together with the results of determination by manual analysis. The data in Table III were obtained in the tests carried out by using the water deaerated with the addition of hydrazin. The hydrazin concentration decreased gradually during the run of test. However, according to Harshman and Woodmard,[9] the reaction between hydrazin and oxygen proceeds very slowly at low pH and low hydrazin concentrations, and it appeared that the conditions prevailing in the deaerator during the test were not such as to favor the reaction. It is, therefore, considered that the oxygen concentration actually remained constant, or nealry so, during the run of test. Hydrazin may have undergone thermal degradation.

The results of oxygen determination by the analyzer agree approximately with the results

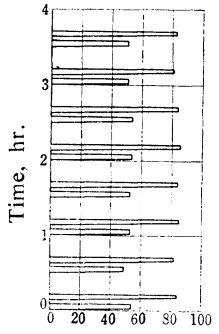

Fig. 7. Typical chart showing the results of analysis.

obtained by manual analysis. The precision of determination by the analyzer is not greater than 2 p. p. b., and the reproducibility is better than that of manual analysis.

Table IV shows the results of the test of the titration unit. In the test, a definite quantity

Table IV. Precision of automatic titration

	Titrant added, ml. Mean of 10 determinations	Standard deviation
Example 1	0.438	0.008
Example 2	0.637	0.006

of a sodium thiosulfate solution was automatically introduced into the titration vessel and titrated with the standard potassium iodate solution, the quantity of titrant added being recorded on the recorder chart. As may be seen from the table, the standard deviation is quite small. Since 0.006 ml. of the potassium iodate solution used corresponds to an oxygen concentration of 0.4 p. p. b., the difference between the error of the integral analytical operation performed by the analyzer and the error of the operation performed by the titration unit appears to be attributable mainly to the fixation operation. The titration unit may also be used for some other types of analysis.

As has been mentioned, the above tests were carried out in the laboratory by empolying a special apparatus for producing the deaerated water. Besides these tests, similar tests were also performed in a thermal power

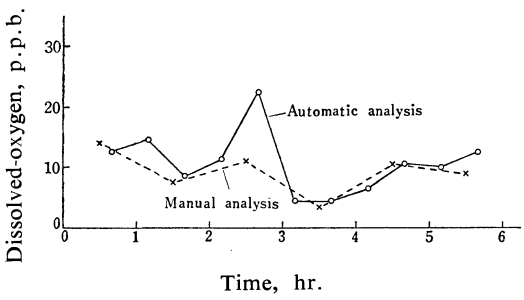

Fig. 9. Results of test in a power plant (During the start-up period)

plant. The analyzer was set in operation at the start-up of the power plant, and in each run, a manual analysis was made at intervals for purposes of comparison. The potassium iodate and thiosulfate solutions used for the analysis in the start-up stage of the boiler operation were 0.01 N solutions, because, during the start-up period, the dissolved-oxygen content was greater than that to be determined by the use of the reagents specified in this paper. The results obtained during the start-up period are shown in Fig. 8, while the results obtained after this period are shown in Fig. 9. In spite of the facts that it was impossible to take the samples simultaneously for both automatic and manual analyses and that the dissolved-oxygen content was apt to fluctuate, a relatively good agreement is again observed between the automatic and manual analyses.

Besides dissolved oxygen and hydrazin, traces of ammonia, iron, copper and silica are contained in feed water. The concentration of ammonia is controlled to around 0.1 part per million[8] as to keep the pH value of feed water within the limits shown in Appendix Table III, and the amounts of other components are usually kept below the limits in the table. Iron and copper exist in ionic state in part, but their possible disturbing influence on the determination of dissolved oxygen is removed by the blank operation as mentioned above.

Summary

An automatic recording analyzer for the determination of dissolved oxygen (in concentrations up to 50 p. p. b.) in boiler feed water by Winkler's method has been described. The instrument is so designed as to perform automatically most of the operations involved in manual analysis, such as sampling, the addition of reagents, titration, recording, and cleansing. The series of required operations (all of the operations in both sample and blank analyses) is completed in 30 min. and is automatically repeated. A more important feature of the instrument is that hydrazin-treated feed water, as well as feed water not treated with hydrazin, can be analyzed with accuracy. The oxygen content, however, cannot be read directly on the recorder chart and must be calculated from the recorded quantities of the titrant used. The precision of oxygen determination is within 2 p. p. b. The reproducibility is better than that of manual analysis.

The author wishes to express his thanks to Professor Mutsuaki Shinagawa of Osaka University, Dr. Isao Makino of Naka Works, Hitachi, Ltd., and Dr. Takeshi Nakatogawa, Dr. Natsuki Kawashima, and Dr. Kaoru Sakai of Hitachi Research Laboratory, Hitachi, Ltd., for their advice and encouragement in this work.

*Semiconducting Properties of Organic Polyiodides**

By Shigekazu KUSABAYASHI, Hiroshi MIKAWA, Shichio KAWAI, Madoka UCHIDA and Ryôiti KIRIYAMA

(Received January 6, 1964)

A new class of organic salts, formed from the radical anion of tetracyanoquinodimethane (abbreviated as TCNQ, or simply as T) and various cations has been reported,[1] and the electrical resistivties of these compounds have also been reported.[2] Quinolinium TCNQ anion radical salt (M^+T^-), for example, has a resistivity of $10^4\Omega$ cm., whereas quinolinium TCNQ anion radical complex salt (M^+T^-T), which contains one molecule of neutral TCNQ in addition to M^+T^-, has such a low resistivity as $10^{-2}\Omega$ cm.

The mechanism of the electrical conduction of M^+T^-T salt is presumed to be essentially the successive electron transfer between T^- and T, resulting in a delocalization of the electrons through the crystal. The M^+ cation seems to be of subordinate importance in the conduction mechanism, acting merely to keep the entity electrically neutral. In other words, the electrical conduction of M^+T^-T salt is primarily the conduction through the charge transfer complex T_2^-, with T^- acting as a donor and T acting as an acceptor. In this sense, M^+T^-T may also be written as $M^+T_2^-$.

Organic polyiodides, $M^+I_x^-$, are a class of compound analogous to TCNQ anion radical complex salts. The only difference between TCNQ complex salt and the polyiodide, except for their different crystal structures, is that the

former is an anion radical salt containing π-electron system and the latter is an ionic salt of a highly-polarized polyatomic ion. The crystal structures of these four organic polyiodides have been analysed: tetraphenylarsonium triiode,[3] tetramethylammonium pentaiodide,[4] tetraethylammonium heptaiodide[5] and tetramethylammonium enneaiodide[6]. The structure of tetramethylammonium pentaiodide, for example, consists of layers of iodine atoms, with V-shaped pentaiodide ions arranged so as to form a nearly square net of iodine. The iodine-iodine distances within an ion are 2.81 and 3.17 Å, whereas the shortest distance between the iodine atoms belonging to the nearest neighboring ions is 3.63 Å; however, the net to net distance is 4.3 Å. The nets are so arranged as to leave large holes for the tetramethylammonium cations.

As for the crystalline polyiodides stated above, it is generally observed that the iodine-iodine distances within each ion are longer than the I–I distance of the I_2 molecule in crystalline iodine (2.68 Å),[7] and that they are considerably smaller than the sum of the normal ionic radius of the I^- ion, 2.16 Å[8], and the covalent radius of iodine, 1.34 Å. These facts show that, as Hach and Rundle have suggested[4], polyiodide ions result from the interaction of a negative iodide ion with a highly-polarizable iodine molecule, the interaction leading to a partial charge transfer through the resonance of the covalent bond. Furthermore, the interpretation of the structure of polyiodide by the molecular orbital method has confirmed the possibility of the delocalization of the outer p-electron.[4,9]

Although quite a large number of organic semiconductors have already been investigated, not so many ionic compounds have been investigated except for some ionic dyes. The present paper will, therefore, deal with the electrical properties of organic polyiodides.

Experimental

Material.—*Monoiodides.*— Tetramethylammonium iodide, trimethylphenylammonium iodide, 1-methyl-2-picolinium iodide and 1-methylquinolinium iodide were prepared by the method of Vogel[10] by the action of methyl iodide on the parent tertiary amines. These were recrystallized three times from water or alcohol. The melting points agreed with those reported in the literature.

Polyiodides.—The following polyiodides were prepared from iodine and monoiodides and were recrystallized twice from alcohol or an iodine-alcohol solution. Single crystals of several polyiodides were grown from a solution over a several-weeks period. *Tetramethylammonium Polyiodides* were prepared by the method of Buckles, Yuk and Popov.[11] The melting points found (and those reported in the literature) are as follows. Triiodide, 116.5~117.5°C (117.0~117.2°C); pentaiodide, 129~130°C (129~130°C). *Trimethylphenylammonium Polyiodides* were prepared by the method of Geuther.[12] Triiodide, 117.0~117.5°C (115°C); pentaiodide, 83.3~83.6°C (82°C); heptaiodide, 63.5~64.0°C (65°C). *1-Methyl-2-picolinium Polyiodides* were prepared by the method of Murrill.[13] Triiodide, 135.5~136.0°C (134°C); pentaiodide, 61.5~62.5°C (60°C); heptaiodide, 57.5~59.0°C (57°C). *1-Methylquinolinium Polyiodides* were prepared by the method of Trowbridge.[14] Triiodide, 109.1~109.3°C (108.6~109.6°C[15]); pentaiodide, 70.5~71.5°C (70°C).

Measurements.—Measurements were mainly carried out on a compressed disk of crystalline powder. Since it is inert to iodine or iodides, graphite was used as the electrode material. The electrode assembly is shown in Fig. 1. Two disk electrodes, 0.4~0.5 mm. thick and 8 mm. in diameter, were prepared first by pressing graphite powder with a 5t/cm² apparatus. Crystalline powder was then

packed between these two graphite electrodes in a mold with a diameter of 13 mm. and pressed at 2.7 t/cm^2 in a vacuum. The thickness of the specimen-between-electrodes thus obtained was about 0.5 mm. Platinum plates with lead wires were attached to the graphite electrodes. In the case of a single crystal, both ends of the crystal rod were wrapped with graphite powder and held with platinum plates. A copper-constantan thermocouple was placed near one of the platinum plates. The whole was closed in a Teflon container of a 3 cc. capacity. The electrode assembly was entirely shielded and placed in a glass vessel.

The resistance was measured by the d. c. method with a Toa Denpa Model PM 18 microvolt-ammeter for the specimens with a high resistivity. A National Model PV 910 A vacuum-tube voltmeter was used for the specimens with a lower resistivity. The applied voltage was less than 70 V./cm. The temperature range of the measurements was from room temperature to about 10~20°C below the melting point.

As graphite had to be used as the electrode material, it was impossible to apply a guard ring electrode. The surface leakage current is, however, negligible, because ε values, the band-gap energy of electrical conduction, do not change, even after the heating and cooling cycles which accompany the slight color change of the material surface, bulk conduction evidently being predominant.

Results and Discussion

In tetramethylammonium pentaiodide, for example, a linear relationship was observed between current and applied voltage as long as the voltage was kept below about 2000 V./cm.

The relationship between the logarithm of resistivity and the reciprocal of temperature is shown for various compounds in Figs. 2 and 3. Generally speaking, the plots obtained for the heating cycle do not agree with those for the cooling cycle. For the reasons to be discussed below, the values of the resistivities and the slopes observed at relatively low temperature for the heating cycle seem to be correct. The specific resistivities at 20°C (ρ_{20}) and the band-gap energy (ε) as calculated from the low temperature slope by the equation $\rho = \rho_0 \exp(\varepsilon/2kT)$ are tabulated in Table I. The values of the specific resistivity and the band-gap energy for several organic polyiodides range between 10^7~10^{10} Ωcm. and 1.3~2.6 eV. respectively.

On the Shape of log ρ versus $1/T$ Curves.— Curve (a, 2) of Fig. 2. shows the log ρ versus $1/T$ curve for tetramethylammonium pentaiodide, where the heating and cooling cycles are repeated successively twice. During the first course of the heating cycle, a distinct break was observed. Moreover, different ρ values were observed in the heating and cooling cycles. However, the plots of the second heating and cooling cycles were found on the same line and coincided with the plots in the first cooling cycle. Besides, no change in ε

** Single crystal: parallel to the cleavage plane along the growth axis.

values was observed throughout all the cycles except just after the break in the first heating cycle.

One possible explanation for the break and the difference in ρ values is the annealing of the strain originally existing in the virgin specimen, i. e. that caused by some unstable grain contact which existed first; the thermal annealing gradually removed such unstable contact in the temperature region higher than a certain temperature. In the case of single crystals, the reproducibility was observed in the $\log\rho$ versus $1/T$ plots, as is shown in Fig. 3, as can be well understood from the assumption that no unstable contact exists in a single crystal.

After the measurement, the surface of the specimen showed some color change, evidently because some iodine was lost from the surface of the material. No color change was observed in the inner part of the specimen, however, and the X-ray powder pattern also remained quite unchanged. As the contact surface between the material and the electrode graphite is deep in the specimen, as Fig. 1 show, it may safely be assumed that the values obtained, especially at relatively low temperatures, are correct.

The general features of the shape of the $\log\rho$ versus $1/T$ plots just explained above using tetramethylammonium pentaiodide as an example are about the same as those observed in other pentaiodides as well as those in the several triiodides investigated, as Figs. 2 and 3 show. The values of ρ and ε calculated at a relatively low temperature seem to be correct for these compounds also.

For heptaiodides the slopes of the plots for the heating and cooling cycles do not agree, as is shown in Figs. 2 and 3. As heptaiodide is the most unstable compound among the polyiodides investigated, the difference in the slopes of the plots for the heating and cooling cycles seems to be due to the slight irreversible decomposition of the compound. Here again the values calculated at low temperatures will be the correct ones.

Although the possible annealing of the strain

which originally existed in the specimen was suggested as the cause of the rather complex feature of the $\log \rho$ versus $1/T$ plots observed with almost every polyiodides, the effects of, say, impurities, lattice defects and a phase transition during the measurements should not be left out of consideration.

Single Crystal.—For the trimethylphenylammonium triiodide single crystal, a considerable anisotropy was observed in ε values between the normal direction and that parallel to the cleavage plane along the growth axis. Although in some organic semiconductors a considerable anisotropy is reported in conductivity, ε values remain isotropic without exception.[2,16] This is natural because the energy gap should remain isotropic in so far as an energy-band scheme is applicable to the conduction in different directions. Hence, it is possible that band-scheme conduction and hopping conduction are taking place in different directions, in the hopping conduction some excess activation energy for hopping being required in addition to the energy of carrier formation.

It is interesting to note that the ε value of a specimen tablet made of powdered trimethylphenylammonium triiodide at a low temperature is about the same as the value of the single crystal measured parallel to the cleavage plane along the growth axis. The absolute value of the specific resistivity can not be estimated at present with a single crystal, because the estimation of the electrode area is not possible. Thereby, it is impossible to ascertain the anisotropy in specific resistivity. To find this, a large single crystal is now being grown.

Electrical Properties and Crystal Structure.—Figures 4 and 5 show how the values of ρ_{20} and ε change with the number of iodine atoms in polyiodide anions. It is indicated clearly that both values decrease with an increase in the number of iodine atoms, the influence of cations being of subordinate importance. That iodine has an important effect upon the conduction of polyiodides is understandable in the light of the crystal structure of the polyiodides. With regard to enneaiodide, the details will be discussed in a forthcoming paper.

As has been stated previously, the crystal structures of tetraphenylarsonium triiodide, tetramethylammonium pentaiodide, tetraethylammonium heptaiodide and tertamethylammonium enneaiodide are known. Although it is sure that the structure of many other polyiodides will deform according to the difference in the nature of the cations, it is certain that the structure will remain essentially similar to the known structures.

The structure of the molecular crystal of iodine itself is also known. In its layer structure, the I–I bond length and the I_2–I_2 intermolecular distance in the layer are 2.68 and 3.56 Å respectively.[7] The values of the electrical resistivity at room temperature are 2×10^{11} and $6\times10^{7}\,\Omega$ cm. for both the normal direction and the direction parallel to the cleavage plane,[17] while the ε value is 1.24~1.30 eV.[18]

As is evident from Table II, the shortest

Heptaiodide	tetraethylammonium	3.47[7] ($I_3^- - I_2$)**
(Iodine)		3.56[7] ($I_2 - I_2$)

* Value reported for CsI_3 (H. A. Tasman and K. H. Boswijk, *Acta Cryst.*, 8, 59 (1955).). $I_3^- - I_3^-$ distances of organic polyiodides investigated for electrical properties in the present report may come, because of the bulkiness of the cation, between 4~5Å.

** I_7^- anion in crystal is better understood as being composed of I_3^- and I_2.

distances between neighboring polyiodide anions in crystsal decrease with an increase in the number of iodine atoms of polyiodide anions. In so far as the electrical conduction is effected through the overlap of molecular orbitals of polyiodide anions, it is quite understandable that the ρ_{20} and ε values of these compounds decrease with an increase in the number of iodine atoms in polyiodide anions.

Although, as has been discussed above, the iodine framework may be of primary importance in the electrical conduction in the crystal, it is possible that the cation has some influence on the conduction, although it should be remembered that the iodine framework itself is being deformed by the differences in the size and shape of the cations. It is possible, for example, that some cation with conjugated double bonds may form a charge transfer complex with the polyiodide anion.

Thermoelectric Power.—To ascertain the sign of the majority carriers, a preliminary examination of the thermoelectric power was made. The flow of the current was clearly observed in pentaiodides, heptaiodides and tetramethylammonium enneaiodide. The direction of the current indicated that the positive hole contributed more to the current than the electron. In other polyiodides the results were not so clear as in the compounds stated above; the positive hole seems, however, to be the main carrier there also. It has been reported that, in the space-charge-limited photocurrent in iodine, the hole conduction was predominant over the electron conduction.[19]

Details of the measurement of thermoelectric power will be reported on in a forthcoming paper.

Optical Properties. — The optical absorption spectra of quaternary ammonium polyiodides in various solvents have been reported.[11,20]

As in connection with the electrical properties of a solid, we are interested in the absorption spectra of solid; they were measured and are shown in Fig. 6. Polyiodides were melted between two glass or quartz plates and then cooled slowly, and the absorption was measured with the usual spectrophotometer. The absorption curves are rather diffuse, and the band-gap energies, as calculated from the temperature dependence of the electrical resistivity, do not agree with the absorption maxima, being grouped rather near the very beginning of the first absorption.

Preliminarily it is observed that all the

polyiodides investigated show a photoconductivity response. Details will be published later.

Summary

1) The electrical conductivities of ten organic polyiodides have been measured: tetramethylammonium triiodide, tetramethylammonium pentaiodide, trimethylphenylammonium triiodide, trimethylphenylammonium pentaiodide, trimethylphenylammonium heptaiodide, 1-methyl-2-picolinium triiodide, 1-methyl-2-picolinium pentaiodide, 1-methyl-2-picolinium heptaiodide, 1-methylquinolinium triiodide and 1-methylquinolinium pentaiodide. At the room temperature specific resistivities are $10^{7}\sim10^{10}\Omega$ cm. and the band-gap energies, as calculated from $\rho=\rho_0 \exp(\varepsilon/2kT)$, are 1.3~2.6 eV.

2) Both ε and ρ_{20} decrease with an increase in the number of iodine atoms in the polyiodide anion, not so much difference in these values being observed with different kinds of cations. The iodine framework in the crystal structure is of primary importance in determining the electrical conductivity.

3) For the trimethylphenylammonium triiodide single crystal, an anisotropy of ε values was observed between the normal direction and the direction parallel to the cleavage plane along the growth axis.

4) Preliminary thermoelectric power measurements show that the majority carrier is the hole.

5) The solid absorption spectra of polyiodides have been measured. The band-gap energy, ε, does not agree with the absorption maximum, being rather near the very beginning of the first absorption.

6) All the polyiodides investigated show a photoconductivity response.

The authors wish to express their thanks to Miss Seiko Oka for her help in the measurement of the absorption spectra.

Colloid Chemical Studies of Starching Materials. VI. Viscometric Studies of the Interaction between Polyvinyl Alcohol and Sodium Dodecyl Sulfate

By Masayuki NAKAGAKI* and Yukiko NINOMIYA

(Received January 6, 1964)

In a previous paper[1] of this series,[2] the intrinsic viscosity of polyvinyl alcohol in a sodium laurate solution was studied, and it was concluded that the effect of sodium laurate may be classified into three types, depending on the detergent concentration. Similar studies made in a sodium dodecyl sulfate (SDS) solution will be reported on here.

Experimental

Materials.—Two samples of polyvinyl alcohol, the same as in a previous paper, were used. They are Gohsenol NM-14 (the degree of polymerization is about 1400; the degree of saponification is 99.3%) and Gohsenol GM-14 (the degree of polymerization is about 1400; the degree of saponification is 87.6%), provided by the Nippon Gosei Kagaku Kogyo K. K. To dissolve the polymer, a weighed sample was added to cold distilled water and heated to 90°C within 15 min.; heating was continued at the same temperature for a further 30 min. As the detergent, sodium dodecyl sulfate, provided by the Nihon Yushi K. K., was recrystallized twice from distilled *n*-butanol and dried in vacuum at room temperature.

Apparatus.—The dilution viscometer used was the same as was described in the a previous paper. All measurements were made in a thermostat at 40°C. A series of viscometric measurements was undertaken in solutions of varying polymer concentrations but of a constant detergent concentration, and the viscosity values were expressed relative to that of the detergent solution, in order to obtain the intrinsic viscosity and related quantities of the polymer at that detergent concentration.

Results and Discussion

The Viscosity of the SDS Solution.—The viscosity of the aqueous SDS solution, used as

2) V of this series: M. Nakagaki and T. Nishii, ibid., 37, 60 (1964).

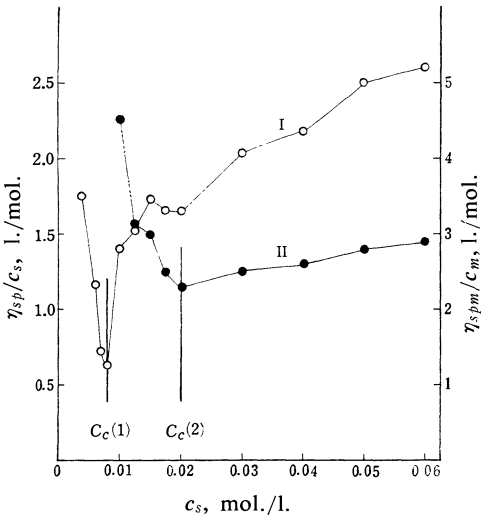

Fig. 1. Reduced viscosity of the SDS solution. Curve I: η_{sp}/c_s, Curve II: η_{spm}/c_m (on the right side ordinate)

the "solvent" in further experiments, was measured; the results are shown in Fig. 1. The relation between the reduced viscosity, η_{sp}/c_s, and the SDS concentration, c_s (mol./l.), as shown by curve I in Fig. 1, reaches a minimum at the SDS concentration of 0.008 mol./l. The minimum point is believed[3] to correspond to the critical micelle concentration, c_c, and agrees well with the values already reported by many authors.[4]

Therefore, the reduced viscosity for the micelle, η_{spm}/c_m, is shown by curve II in Fig. 1, where

$$\eta_{spm}/c_m=(\eta_s/\eta_c-1)/(c_s-c_c) \qquad (1)$$

Here η_s is the relative viscosity of SDS solution (relative to distilled water), and η_c is the relative viscosity at $c_c=0.008$ mol./l. A minimum point is found at 0.02 mol./l. This is believed to correspond to the "second" critical micelle concentration.[3,5] Thus, the following results were obtained:

$$\left.\begin{aligned} c_c(\mathrm{I})&=0.008 \text{ mol./l.} \\ c_c(\mathrm{II})&=0.02 \text{ mol./l.} \end{aligned}\right\} \qquad (2)$$

A Method to Obtain Intrinsic Viscosity.—In order to obtain the intrinsic viscosity, $[\eta]$, the extrapolation to zero of the polymer concentration, c_p (g./100 ml.), was usually made on the basis either of Huggins' equation:

$$f_1=\eta_{sp}/c_p=[\eta]+k_1[\eta]^2c_p \qquad (3)$$

or Staudinger's equation:

$$f_2=\ln \eta_r/c_p=[\eta]-k_2[\eta]^2c_p \qquad (4)$$

It has already been pointed out by Heller[6] that the simultaneous use of f_1 and f_2, together with the mathematical consequence:

$$k_1+k_2=0.5 \qquad (5)$$

can appreciably reduce the arbitrariness in the extrapolation. This method has been used in one of our previous papers.[1]

The new method used in the present paper (in addition to the one described above), is based on the fact that the difference, Δf, between f_1 and f_2 should be proportional to the polymer concentration at a sufficiently low concentration range. The following equation, as readily derived from Eqs. 3, 4 and 5, can be used to estimate the value of $[\eta]$:

$$\Delta f=f_1-f_2=0.5[\eta]^2c_p \qquad (6)$$

An example for NM-14 in a 0.03 mol./l. SDS solution is shown in Fig. 2. As may be seen

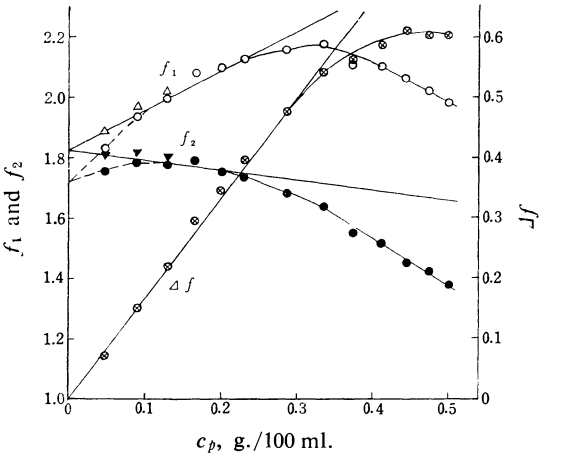

Fig. 2. An example of c_p dependencies of f_1, f_2 and Δf for NM-14 in 0.03 mol./l. SDS solution.
Corrected values for f_1(△) and f_2(▼)

in Fig. 2, a linearity between Δf and c_p holds, and the tangent will give the value of $[\eta]$ according to Eq. 6. Figures similar to Fig. 2 were drawn for all the instances in this paper, and the values of $[\eta]$, k_1 and k_2 were determined to satisfy Eqs. 3, 4, 5 and 6 at the range of small c_p values.

Anomalies at Low Polymer Concentrations.—It is often found in experiments of this kind that the experimentally-obtained values show a kind of anomalous deviation from the linearity to be expected on the basis of Eqs. 3 or 4 at low polymer concentrations. This anomaly is, of course, partly due to the

3) N. Sata and K. Tyuzyo, ibid., 26, 177 (1953).
4) R. Goto and T. Sugano, "Surface Chemistry," (Vol. 7 in the "Zikken Kagaku Koza" series), Maruzen, Tokyo (1963), p. 167. The value of c_c varies between 0.003 and 0.010 mol./l.
5) K. Hess, W. Philippoff and H. Kiessig, *Kolloid-Z.*, 88, 40 (1939).
6) W. Heller, *J. Colloid Sci.*, 9, 547 (1954).

experimental error unavoidable because of the low value of the polymer concentration, but, more often, a systematic deviation from the linearity is observed. One of the expected reasons for this is the effect of the electric charge given to the polymer molecules by the combination of detergent anions, a charge which results in a positive deviation from the linearity; that is, the greater the experimental f-values, the smaller the polymer concentration, as has already been discussed in the previous paper.[1] Another reason should, however, be considered to explain the negative deviation from the linearity shown, for example, in Fig. 2 by broken curves.

The f_1 and f_2 values in the present paper have been calculated by using the viscosity values relative to the viscosity, η_s, of the "solvent," that is, the detergent solution not containing any polymer. If a part of the detergent is combined with the polymer, however, the actual value of the viscosity of the "solvent," η_s^0, should be the value at a concentration a little smaller than the analytical detergent concentration. Then, the values of f_1 and f_2 should be recalculated to f_1^0 and f_2^0. The results will probably show the linearity anticipated by Eqs. 3 and 4. The relations between f_1, f_2, f_1^0 and f_2^0 are given by the following:

$$\left.\begin{aligned} f_1 &= (\eta_s^0/\eta_s)f_1^0 - (1-\eta_s^0/\eta_s)/c_p \\ f_1^0 &= (\eta/\eta_s^0 - 1)/c_p \end{aligned}\right\} \quad (7)$$

and

$$\left.\begin{aligned} f_2 &= f_2^0 - [\ln(\eta_s/\eta_s^0)]/c_p \\ f_2^0 &= [\ln(\eta/\eta_s^0)]/c_p \end{aligned}\right\} \quad (8)$$

where η is the relative viscosity of a solution containing a polymer as well as a detergent. If the amount of detergent combined with the polymer is so small that η_s^0/η_s is very close to unity, $\ln(\eta_s/\eta_s^0)$ can be expanded in a power series of $(1-\eta_s^0/\eta_s)$ and the terms of the second and higher powers can be neglected. Then, Eq. 8 can be appoximated as:

$$f_2 = f_2^0 - (1-\eta_s^0/\eta_s)/c_p \quad (8a)$$

Equations 7 and 8a can explain how a negative deviation is observed when c_p is so small that the value is comparable to $(1-\eta_s^0/\eta_s)$, if $\eta_s^0 < \eta_s$ because of the deficiency of free detergent molecules as a result of the combination with the polymer. Equations 7 and 8a indicate, too, that Δf will not show any serious deviation from the linearity at the low polymer concentration because of the cancellation of the $(1-\eta_s^0/\eta_s)/c_p$ term in both equations (cf. Fig. 2).

$$\Delta f = f_1 - f_2 = (\eta_s^0/\eta_s)f_1^0 - f_2^0 \quad (9)$$

In the example shown in Fig. 2, $\eta_s = 1.060$ was used. If the value $\eta_s^0 = 1.057$ is adopted and if the values of f_1^0 and f_2^0 are calculated, the corrected values (△ and ▼) are on the straight lines, as expected.

The Intrinsic Viscosity of PVA in an SDS Solution.—For the solutions of polyvinyl alcohol NM-14 and GM-14 in an SDS solution, the intrinsic viscosity, $[\eta]$, and the constants, k_1 and k_2, of Eqs. 3 and 4 are as shown in Figs. 3, 4 and 5 respectively, taking the SDS concentration on the abscissa. According to Eqs. 7 and 8a, the corrected intrinsic viscosity, $[\eta_0]$, should be:

$$(\eta_s/\eta_s^0)\,[\eta_1] \geqq [\eta_0] \fallingdotseq [\eta_2] \quad (10)$$

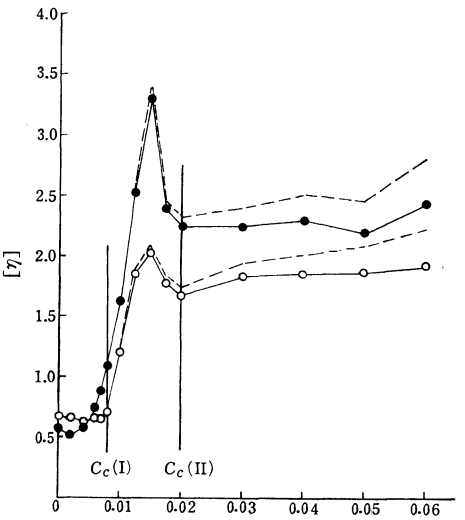

Fig. 3. Intrinsic viscosity of NM-14 (○) and GM-14 (●) in the SDS solution.

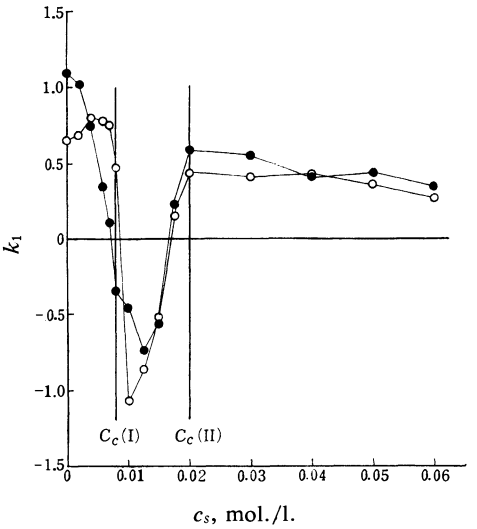

Fig. 4. Huggins' constant k_1 of NM-14 (○) and GM-14 (●) in the SDS solution.

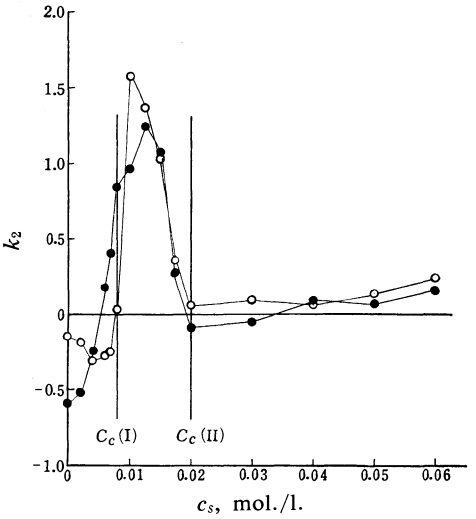

Fig. 5. Staudinger's constant k_2 of MN-14 (○) and GM-14 (●) in the SDS solution.

where $[\eta_1]$ and $[\eta_2]$ are the values of f_1 and f_2 respectively as extrapolated from the concentration range $c_p \gg (1-\eta_s^0/\eta_s)$ to the infinite dilution $c_p \to 0$. Since the correct value of η_s^0 should be larger than that of pure water, or $\eta_s > \eta_s^0 > 1$, the possible upper limit of $[\eta_0]$ is $\eta_s[\eta]$. The unrealizable upper limit, at which all the detergent is assumed to be combined with the polymer and nothing is left free in the solution, is shown in Fig. 3 by broken lines. The actual $[\eta_0]$ is expected to be much closer to $[\eta]$ than to $\eta_s[\eta]$; e. g., in the case of NM-14 in a 0.03 mol./l. SDS solution (cf. Fig. 2), $[\eta]=1.820$ and $\eta_s[\eta]=1.931$, while the value corresponding to the corrected values (△ and ▼) in Fig. 2 is $[\eta_0]=1.825$. Therefore, the errors, which might be caused by the decrease in the viscosity of the medium because of the combination of SDS with the polymer molecules, neither change the essential features of Fig. 3 nor affect the following discussion.

Figures 3, 4 and 5 show that the entire range of detergent concentration, c_s, is divided into three ranges by the first, c_c(I), and the second, c_c(II), critical micelle concentrations of the detergent. These three ranges for SDS exactly correspond to the three ranges described for sodium laurate in a previous paper,[1] although it was not noticed in that paper that the boundary concentration between the second and the third range is equal to the second critical micelle concentration.

The viscometric behavior of the polymer in these three ranges is as follows: (I) In SDS solutions at concentrations lower than c_c(I), $[\eta]$ is small, k_1 is positive and k_2 is negative. In this region, the effect of the detergent seems to be negligible, and the polymer behaves as if it were in water. (2) In SDS solutions of concentrations between c_c(I) and c_c(II), $[\eta]$ becomes large, k_1 becomes negative, and k_2 becomes large. The negative value of k_1, or a rapid increase in η_{sp}/c_p with a decreasing polymer concentration, is usually observed in aqueous solutions of polyelectrolytes. Polyvinyl alcohol molecules are, therefore, presumed to be combined with the SDS anions and to behave like polyelectrolytes. The maximum of $[\eta]$ is explained by the circumstances that the electric repulsion responsible for the expansion of the polymer molecules is partially shielded by the ion atmosphere of the counter ions (sodium ions) with the increase in the detergent concentration. (3) In SDS solutions at concentrations higher than c_c(II), $[\eta]$ is still large, although the value is a little smaller than the value at the maximum point. The value of k_1 is about 0.5, while the value of k_2 is nearly equal to zero. In this range, the viscometric behavior characteristic of the polyelectrolyte was not observed, probably because the electric charges of detergent anions combined with the polymer were almost completely shielded by the counter ions at this high detergent concentration. The high value of the intrinsic viscosity, indicating the high affinity to the medium or the extended configuration of the polymer molecules, may be due, as was already pointed out in the previous paper,[1] to the hydrophilic property of the polymer strengthened by the combination of detergent anions, to the intramolecular repulsion between electric charges resulting from the combination of detergent anions, to the expansion of the polymer molecules in order to secure the space necessary for the combined detergent molecules, or to the decrease in the flexibility of the polymer molecules because of the combination of detergent molecules.

The second critical micelle concentration, c_c(II), is said to be the concentration above which the I-band of X-ray diffraction is observed. It is presumed that this means that the solution is saturated with the usual micelle and that the excess of the detergent forms a large lamellar micelle or a kind of crystallite at concentrations higher than c_c(II). In this range of detergent concentrations, on the other hand, the variations in $[\eta]$, k_1, and k_2 with the concentration, c_s, is not large. This is probably due to the saturation of the solution with the usual micelle.

A Comparison between SDS and SL.—The shape of the curve, $[\eta]$ vs. c_s, for the SDS solution is very similar to that for the sodium laurate (SL) solution reported on in the previous paper,[1] except that the concentration ranges of the detergents used are different.

The difference is obviously due to the difference in the critical micelle concentration, c_c(I), the values being 0.025 N for SL and 0.008 N for SDS. Therefore, it is supposed that all the experimental plots would come onto one curve if the scales of the ordinate and abscissa were changed properly, and that the reduced abscissa would be c_s/c_c. As for the ordinate, it is noticeable that the value of $[\eta]$ shows a tendency to approach a limiting value $[\eta_\infty]$ when c_s becomes large. The values of $[\eta_\infty]$ are assumed to be as cited in Table I, and the reduced curve is drawn as in Fig. 6, in which the data for SL reported in the previous paper are plotted, as well as the data for SDS.

From Table I, it may be seen that the $[\eta_\infty]$ value for GM-14 is about 1.28 times larger than that for NM-14 in either detergent solution, and that $[\eta_\infty]$ in SDS is about 1.08 times larger than in SL for either polymer. In other words, GM, with an imperfectly-saponified polymer, expands more readily when subjected to a combination of detergents than NM, with a completely saponified polymer, and SDS, with a higher lipophilicity can expand the polymers more than SL, with a lower lipophilicity. This would suggest that the polymer-detergent interaction is due to the contact of the hydrophobic parts of the molecules, if it is presupposed that the greater expansion of the polymer is caused by the larger amount of detergent combined.

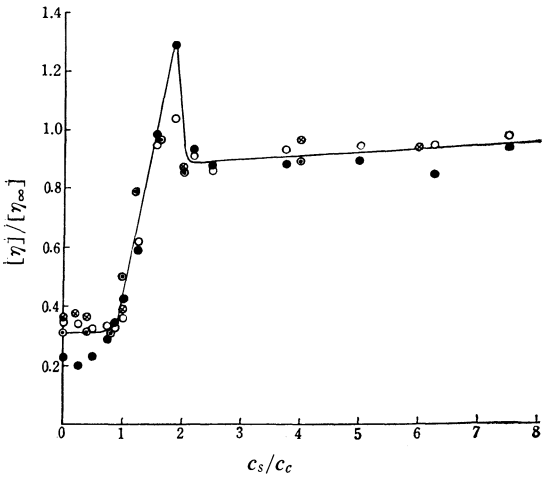

Fig. 6. Reduced curve of intrinsic viscosity vs. detergent concentration.
NM(○) and GM(●) in SDS, and NM(⊗) and GM(⊙) in SL

TABLE I. ASSUMED VALUES OF $[\eta_\infty]$

	NM	GM	GM/NM	Aver.
SDS	1.95	2.56	1.31	1.28±0.03
SL	1.86	2.32	1.25	
SDS/SL	1.05	1.10		1.08±0.03

Summary

The intrinsic viscosity and related constants have been measured for polyvinyl alcohol NM-14 and GM-14 in a sodium dodecyl sulfate solution. At a detergent concentration lower than the first critical micelle concentration (0.008 N), the viscometric property of the polymer is close to that in distilled water. At an intermediate detergent concentration between the first and the second critical micelle concentration (0.02 N), the viscometric property of the polymer is like that of polyelectrolyte, probably because of the electric charges given by detergent anions combined with the polymer. At a detergent concentration higher than the second critical micelle concentration, the intrinsic viscosity of the polymer is high and the polymer combined with the detergent is more extended than in distilled water. The interaction between the polymer and the detergent is very likely due to the contact of hydrophobic parts of the molecules.

The authors wish to thank the Nippon Gosei Kagaku Kogyo K. K. and the Nihon Yushi K. K. for their support of this project.

Electron Spin Resonance Study of Substituted Nitrobenzene Negative Ions Produced by Electroreduction

By Taitiro FUJINAGA, Yasuo DEGUCHI and Kisaburo UMEMOTO

(Received December 14, 1963)

A number of organic anion radicals, obtained by chemical reduction with metals, have been studied by means of electron spin resonance (ESR). Since the formation of free radicals can be expected in the course of electrochemical reductions, it seemed to us that the radical formation could be conveniently detected by ESR measurements.

Austen et al.[1] electrolyzed certain organic compounds, such as anthracene anthraquinone and benzophenone, and observed the ESR spectra of the free radicals in a frozen state in a dimethylformamide (DMF) solution. This was the first time that the electrolytic formation of organic free radicals was proved directly. However, since the ESR measurements were performed in the frozen solid state, the hyperfine structure (hfs) was lost in the broadened absorption-line width, and no detailed information about the electronic structure could be obtained. A similar method was used by Geske and Maki,[2] who carried out the electrolysis in the cavity and recorded the ESR spectrum of the nitrobenzene anion radical in an acetonitrile solution at room temperature. These authors[3,4] also used this "in situ" method for their study of the ESR of many para-substituted nitrobenzene anion radicals, with interesting results.

Ever since, the electrolytic technique has been employed by many authors[5-8] as a convenient method for the preparation of free radicals for ESR measurements.

Recently some investigators have used ESR measurements for the elucidation of electrode processes by studying the radicals formed during electrolysis;[9,10] Rieger et al.,[11] for instance, elucidated the reduction mechanism of many aliphatic and aromatic nitrile compounds by studying the ESR spectra obtained at different electrode potentials.

The present communication will deal with the investigation of the hfs in the ESR spectra of a series of substituted nitrobenzene anion radicals, obtained by electrochemical reduction. The mechanism of the electrolytic reduction of some halonitrobenzenes will also be studied.

Experimental

Nitrobenzene, a series of ortho-, para- and meta-substituted nitrobenzene derivatives, in the form of their chloro, bromo, iodo, methyl, methoxyl, amino, hydroxyl, cyano and aldehyde compound, as well as anthraquinone and naphthoquinone, were used. Most of the reagents were of an extra pure grade and were supplied by the Maruwaka Chemicals Co., Osaka; an they were used without further purification. Acetonitrile of an extra pure grade was used as a solvent in all ESR measurements unless otherwise mentioned. It was first dried with phosphorous pentoxide and then with anhydrous carbonate.

All solutions were approximately 1 mM and contained 0.1 M tetra-*n*-propylammonium perchlorate as the supporting electrolyte. The electrolytic cell was similar to that used by Geske and Maki.[2] Purified nitrogen gas was used for the de-oxygenation of the solutions; the electrolysis was carried out at a constant potential, the value of which was chosen in accordance with the results of polarographic measurements.

The ESR spectra of chloro, bromo and iodonitrobenzene were observed in both acetonitrile and a DMF solution. The DMF was dried with anhydrous potassium carbonate, and the fraction distilling at 152~153°C was used. The ESR spectrometer was an X-band instrument, manufactured by the Japan Electron Optics Co., Model JES-3B-type; it employs a rectangular reflection cavity, 100 kc./sec. field modulation, and a JES electromagnet with 300 mm.ϕ pole pieces. For all field measurements, the spectrum of the peroxylamine disulfonate anion radical, which shows three lines with a 13.0 gauss separation, due to nitrogen splitting, was referred to as the standard.

Results and Discussion

ESR Spectra.—*Nitrobenzene.*—The spectrum of the nitrobenzene anion is shown in Fig. 1;

	a_N = 9.80	a_{H_1} = 3.36	a_{H_2} = 1.13		a_{H_1} = 3.30	a_{H_2} = 0.60	a_{H_3} = 0.30

it is very similar to that obserbed by Geske and Maki[2] though there is a slight difference in the hyperfine coupling constants. This difference might be due to the presence of traces of water in the solvent used, in accordance with the results we reported previously when dealing with the solvent effect on the width of the line due to nitrogen coupling in the cases of diphenyl nitric oxide[12] and di-*p*-anisyl nitric oxide.[13] It was shown there that the nitrogen-coupling constant obtained in an aqueous solution was larger than that obtained in acetonitrile. Piette et al.[14] also examined the dependence of the nitrogen coupling constant of nitro compounds on the water content of the solvent and showed that the presence of small quantities of water considerably increases the magnitudes of the constant.

Nitrotoluene.—The ESR spectra of electrolytically reduced *o*-, *m*- and *p*-nitrotoluenes are shown in Figs. 2a, 2b and 2c. The coupling constants given in Table I are in good agreement with the observed spectra. The coupling constants were assigned to each proton by referring to the results of Hückel's molecular orbital (MO) method of calculation. It was found that all three methyl protons had the same coupling constant; this shows that there is a hyperconjugative interaction between the methyl group rotating at high speed and the ring π system. In the case of *o*-nitrotoluene, one would expect that the molecule will have an unequal spin distribution in the ring system because of the molecular asymmetry; however, the two protons in the meta position to the nitro group showed the same coupling constant.

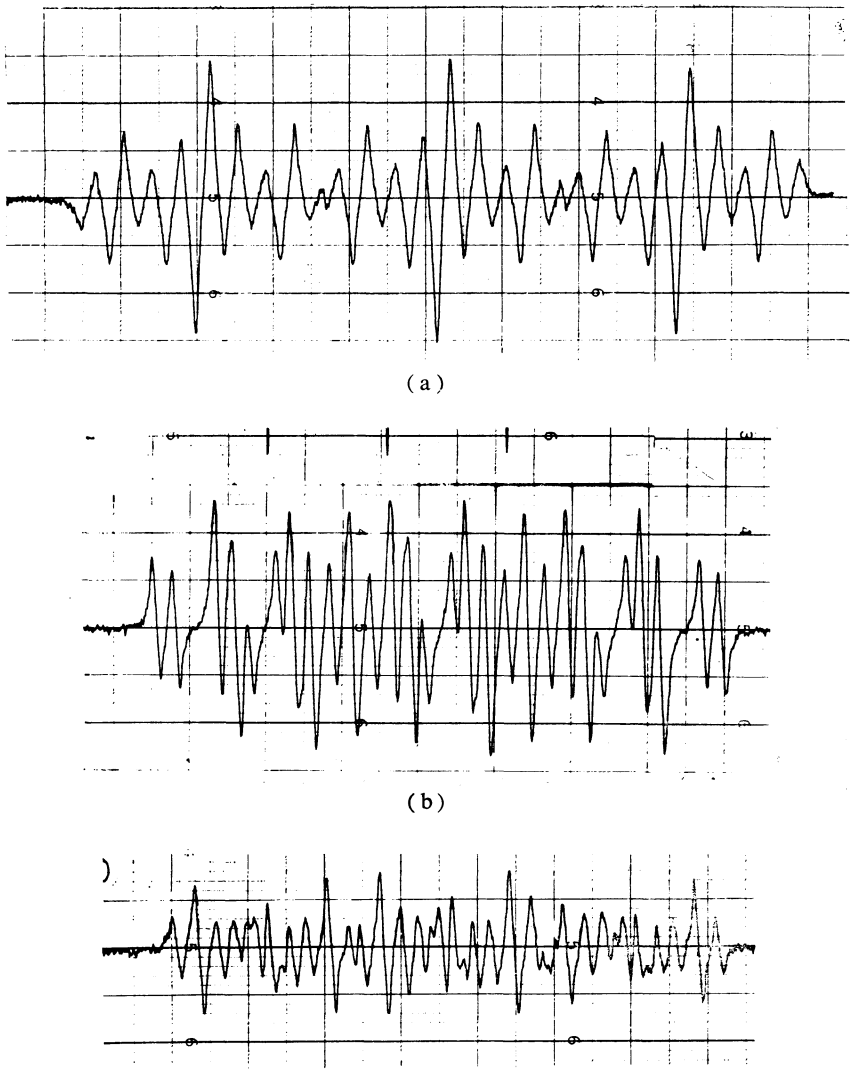

Fig. 3. ESR spectra of (a) *p*- (b) *m*- (c) *o*-nitrochlorobenzene anion radicals.

In the case of *m*-nitrotoluene, the two ortho protons were found to be equivalent. Hence, the spin distribution in the molecule seems to be little affected by the substitution of a ring proton with a methyl group. The nitrogen-coupling constats are a little larger than that of the nitrobenzene anion, showing that the methyl group has an electron-repelling effect. The fact that the ortho and para isomers have a larger nitrogen-splitting constant than the meta compound explains why the electron-repelling effect of the methyl group is directed towards the ortho and para positions.

Chloronitrobenzene.—The ESR spectra of the reduced ortho, meta and para isomers are shown in Figs. 3a, 3b and 3c. Once again the coupling constants shown in Table I agree well with the observed spectra. It was not possible to obtain an hfs spectrum of chlorine. Wertz and Vivo,[15] who studied the ESR spectra of chloro compounds in an aqueous solution, were also unable to observe the hfs of the chlorine because of the small nuclear magnetic moment of this atom. As in the case of nitrotoluene, the two meta protons of the ortho isomer and two ortho protons of the meta isomer have the same coupling constant. Hence, the chloro-substitution seems to affect the spin distribution of the molecule very little. The nitrogen-coupling constants were somewhat smaller than that of the nitrobenzene anion because of the electron-attracting effect of the chlorine

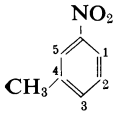
* Data from Ref. 3.

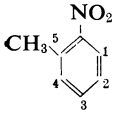
atom. The nitrogen-coupling constants of the ortho isomers of nitrotoluene and nitrochlorobenzene are little larger than those of the corresponding meta and para isomers, indicating a small steric effect. It has been pointed out by Geske and Ragel[16] that the a_N value in an aromatic anion radical approaches that of the aliphatic counterpart when the nitro-group is twisted out of the plane of the benzene ring by steric effects of bulky substituents.

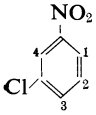
Bromonitrobenzene.—The ESR spectra of the reduced para and meta isomers were very similar to those of the corresponding chloronitrobenzene compounds. However, the ortho isomer showed the same ESR spectrum as the nitrobenzene anion radical, indicating that the elimination of the bromine atom occurs prior to the formation of the free radical.

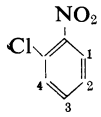
Iodonitrobenzene.—The electrolytic reduction products of ortho, meta and para isomers all showed the same ESR spectrum as the nitrobenzene anion radical. This once again indicates that the iodine is eliminated prior to the reduction of the nitro group.

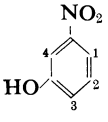
Other Substituted Nitrobenzenes.—The coupling constants of other substituted nitrobenzene anion radicals are also listed in Table I. The different nitrogen-coupling constants are given in Table II; the substituents are arranged according to their increasing electron-attracting effect. Electron-attracting substituents generally reduce the nitrogen-coupling constant, whereas the electron-repelling substituents increase it. In both cases, the electron effect is more pronounced in the case of ortho and para than in the case of meta substitution. *o*-Nitrobenzaldehyde gave an abnormally large nitrogen-splitting constant, and the usual order observed with electron-attracting groups, viz. para<ortho<meta, does not hold; this seems to indicate a strong ortho effect of the aldehyde group.

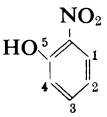






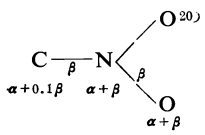






As regards nitrophenol, the authors have discussed the effect of hydrogen bonding in a previous publication.[17]

Hückel's Molecular Orbital Calculations.—Using the coupling constants shown in Table I, the spin density distribution could be calculated from the following relation: $a_i^H = Q_{CH}{}^H \rho_i^\pi$, where $Q_{CH}{}^H = 28$ gauss[18] and, for the methyl group, $a_{CH_3}{}^H = Q_{CCH_3}{}^H \rho^\pi$, where $Q_{CCH_3}{}^H = 30$ gauss.[19] By Hückel's MO method, the spin density in the molecules could also be calculated. The results are listed in Table III, where the parameters employed in this calculation are also listed. The calculated spin density in the ortho and para positions relative to the nitro group is in fairly good agreement with the experimental values; by contrast the calculated meta position is not in agreement with the experimental results. Rieger and Fraenkel[5] calculated the spin density distribution for some nitrile and nitro compounds by both Hückel's MO method and McLachlan's procedure, which employs the concept of approximate configuration interaction; these authors also found that Hückel's MO method generally gave good results for ortho- and para- but not for meta-substitution, while McLachlan's approximation method generally gave very good agreement with the experimental results.



Electrochemical Process.—*Nitrobenzene.*—The nitrobenzene anion radical was generated by electrolysis at −1.3 V. vs. SCE (saturated calomel electrode), that is, at a potential slightly more negative than that of the first wave in the polarogram. The radical was stable for about 30 min. It is known that at the potential of the second wave the mono negative ion is further reduced to the di-negative radical, which is generally rapidly protonated by the reaction with the solvent. Therefore, no ESR spectrum would be expected a priori. However, an ESR spectrum was observed in the potential range of the second wave, although the intensity was reduced to some extent. This shows that the process corresponding to the second wave is slower than the radical formation. When phenol was added as a proton donor to the 1 mM nitrobenzene DMF solution, the radical formation at −1.3 V. vs. SCE was not affected until the concentration of the added phenol reached about 2 mM; at higher potentials, the stability of the radical decreased. Upon the further addition of phenol, the rate of the radical formation at the potential of the first wave

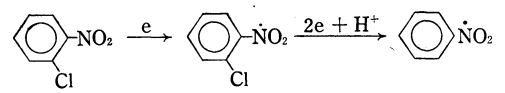
Parameters used in this calculation are as follows.



decreased as well, indicating rapid protonation and, hence, a decreased life time of the free radical.

Chloronitrobenzene.—The reducttion products of the three isomers of chloronitrobenzene, prepared by electrolysis at −1.3 V. vs. SCE in an acetonitrile solution, showed an ESR spectrum. In DMF the para and meta isomers gave their characteristic spectra. When the applied potential was changed from −1.2 V. to −2.0 V. vs. SCE the generated radical species showed little change, although the intensity of the spectrum decreased at potentials lower than −1.8 V. vs. SCE. When the ortho isomer was electrolyzed at −1.3 V. vs. SCE in a 1 mM DMF solution, its ESR spectrum could be observed soon after the electrolysis began, but after about fifteen minutes the spectrum showed the beginning formation of the nitrobenzene radical, which after 45 min. was the major component present. When the applied voltage was changed to −1.5 V. vs. SCE the ESR spectrum became identical with that of the nitrobenzene anion radical, indicating a dehalogenation reaction according to:

The ease of dehalogenation in the case of the ortho isomer might be due to steric reasons. When phenol was added in about an equimolar quantity, the dehalogenation was impeded, and when a quantity about three times greater was added, no dehalogenation was observed at potentials above −1.7 V. vs. SCE; no radical formation could be detected at lower potentials because of enhanced protonation.

Bromonitrobenzene.—The reduction products of the para and meta isomers gave their characteristic ESR spectra when prepared by electrolysis at −1.3 V. vs. SCE in an acetonitrile solution, whereas the ortho derivative, under the same conditions, showed the ESR spectrum of the nitrobenzene anion, indicating dehalogenation in the DMF solution.

In the DMF solution the meta isomer did not show any sign of dehalogenation in the potential range from −1.1 V. to −2.0 V. vs. SCE, whereas the ortho isomer was completely dehalogenated. The reduction product of the para isomer showed its own characteristic spectrum when prepared by electrolysis at −1.0 V. vs. SCE in a 1 mM solution; at −1.3 V. vs. SCE the beginning formation of the

20) J. I. F. Alonso., *Compt. rend.*, **233**, 403 (1951).

22) H. H. Jaffé, *J. Chem. Phys.*, **20**, 279 (1952).

nitrobenzene anion radical could be observed, while as the electrolysis proceeded, the formation of increasing quantities of nitrobenzene anion could be seen. At −1.6 V. vs. SCE a clear spectrum of the nitrobenzene anion alone could be observed. When the concentration of the para isomer was raised to 5 mM, the spectrum of the reduced para isomer alone was observed in the potential region from −1.0 V. to −1.4 V. vs. SCE, whereas at lower potentials dehalogenation became evident. These results suggets the following electrode process:

Indonitrobenzene.—All three isomers showed the formation of the nitrobenzene anion radical, even in a 5 mM solution at −1.2 V. vs. SCE both in acetonitrile and in the DMF solution. Hence, complete dehalogenation occurred in all cases. The reaction can be represented by:

The experiments show that the ease with which the halonitrobenzenes are dehalogenated during the electrolytic reduction follows the order:

$$p, m\text{-Cl}, \quad m\text{-Br} < o\text{-Cl} < p\text{-Br} < o\text{-Br}, \quad p, m, o\text{-I}$$

This series seems to indicate that the ease of dehalogenation depends on steric considerations.

Details of the polarographic studies of the halonitrobenzenes will be reported later.[23]

*Emission and Absorption of the Sodium D-Line behind a Shock Wave in Argon, Nitrogen- and Carbon Monoxide-Argon Mixtures Containing a Trace of Sodium Vapor**

By Soji TSUCHIYA

(Received December 25, 1963)

Large translational energies are given to gaseous atoms or molecules in the duration of several collisions in a shock wave. These thermal energies are transferred by atomic or molecular collisions to other degrees of freedom, such as electronic states, vibration, rotation and chemical conversion or ionization. Therefore, the shock wave technique is a powerful tool for studying the process of energy transfer and high-speed chemical reactions.

This paper will be concerned with the temperature measurement of the shock-heated gas by the simultaneous measurement of the emission and absorption of the sodium D-resonance line ; it aims at the verification of the relation of the excitation and quenching of sodium atoms to the measured temperatures. Gaydon and Hurle have studied the same problems and have concluded that the temperature observed by the sodium D-line reversal method agrees with the vibrational temperature of shock-heated diatomic molecules.[1] Also, they found that the reversal temperature of argon gas behind a shock wave was lower than the calculated value; they explained the observed discrepancy as being due to the existence of a radiative non-equilibrium state. The present report will give a more quantitative elucidation of those problems proposed by Gaydon and Hurle, and will attempt to clarify the physical back-ground of the sodium D-line reversal method.

Sobolev and his collaborators have, using a

spectral line of barium ion, observed the reversal temperature in shock-heated argon and have obtained a value of 4×10^{-17} cm^2 as an effective quenching cross-section of an argon atom.[2] Only a little is known about the quenching or exciting atomic collisions of electronic states. The shock wave technique provides an experimental method which can inform us how the excitation of electronic states of atoms occurs by slow thermal atomic or molecular collisions. Preceding shock wave works on this problem have been undertaken from the viewpoint that the excitation of the electronic states of atoms depends on collisions with electrons rather than on collisions with atoms or molecules in the shock wave.[3,4]

Experimental

The shock tube used here is constructed with steel pipe sections 10 cm. in inner diameter; the inner walls are plated with hard chromium. Some of these sections are connected to form a driver section and a low pressure section; the lengths of these sections are 160 cm. and 480 cm. respectively. The low pressure section is pumped out to pressure below 10^{-4} mmHg by an oil diffusion pump, and the leak rate of the tube is about 3 μHg/hr. Lumirror film (polyethylene terephthalate) is used as bursting diaphragms, which are ruptured spontaneously by the accumulating pressure of the driver gas of hydrogen. There are two windows 410 cm. downstream from the diaphragm position in order to make the spectroscopic measurement. Four platinum-resistance gauges are positioned at intervals 30 cm. upstream from the window. The time interval of the two signal pulses from two platinum-resistance gauges, 60 cm. apart from each other, is measured by a 1 Mc. counter, and the shock velocity is determined. One of the other gauges is used to trigger the synchroscope which records the spectroscopic data.

The real shock velocity is not constant along the entire passage through the shock tube. Simultaneous measurements of shock velocity at two positions along the tube are performed using the four platinum-resistance gauges and the synchroscope. The results show that the uncertainty of shock velocity obtained here is less than 0.5%; this corresponds to the temperature fluctuation of about 30°K in the present experimental conditions.

The sample gases are argon, nitrogen and carbon monoxide, with nominal purities of 99.99, 99.96 and 99.5% respectively. These gases are used without further purification. Gaseous mixtures which contain nitrogen or carbon monoxide of less than 1% are made by successive dilution, and the concentrations are measured by the manometric method. Complete mixing is obtained by allowing at least 2 days for diffusion. A very small amount of sodium vapor is introduced into the test gas as follows: the sample gas is fed into the shock tube through a glass tube in which a piece of sodium metal is heated to 250~350°C. By this method, roughly controlled quantities of sodium vapor, which perhaps forms colloidal dust before the passage of the shock wave, can be mixed with the shock-heated gas. The intensity of the sodium D-line is independent of the time between the shock experiment and the introduction of the sample gas, and the time required for colloidal sodium to vaporize is very short.

The emission and absorption of the sodium D-line is observed by a two-channel monochromator. This monochromator has already been described in detail in another paper.[5] The monochromator is of the Littrow type, with two glass prisms whose apex angle is 60°. The calculated spectral slit width is 8.9 cm^{-1} at 5890 Å when the entrance and exit slit width is 0.1 mm. The doublet lines of the sodium D-line can be resolved by the monochromator, and the experiment is performed using one of the doublet lines corresponding to the $^2P_{3/2}-{}^2S_{1/2}$ transition. The accuracy of the measured temperature has been discussed in the preceding paper; the maximum error is considered to be about $\pm$50°K at 2500°K.

The Temperature Measurement of Shock-heated Gas

The gas temperature is calculated from the measured data of the emission and absorption of a resonance spectral line. In order to discuss the physical limitation of this method, the nature of the radiation from a gaseous distributed emitter should first be considered.

A gaseous atom is here assumed to have only two levels, upper and lower. When the atoms are included within an opaque enclosure, the following equilibrium is attained:

$$N_1[A_{1\to2}+B_{1\to2}\rho(\omega_{12}, T)] - N_2B_{2\to1}\rho(\omega_{12}, T)=0 \quad (1)$$

where N_1, N_2 are populations of atoms on the upper and lower levels respectively, where $A_{1\to2}$, $B_{1\to2}$, $B_{2\to1}$ are Einstein's coefficients for spontaneous emission, induced emission and absorption respectively, and where $\rho(\omega_{12}, T)$ is a radiation density at the wave number of ω_{12}, which corresponds to the energy difference between upper and lower levels. The intensity of radiation in the wave number interval $(\omega, \omega+d\omega)$ can be defined as the amount of radiant energy falling on the unit solid angle in the unit time; it is formulated as:

$$B^\circ(\omega, T)d\omega=\frac{1}{4\pi}c\rho(\omega, T)d\omega$$

2) N. N. Sobolev et al., "Proc. of Fifth International Conference on Ionization Phenomena in Gases," Ed. by H. Maecker, North-Holland Pub. Co., Amsterdam (1962), p. 2122 and cited references.

3) T. Wilkerson, *Univ. Michigan, Technical Note*, AFOSR 1151 (1961).

4) S. H. Bauer, J. H. Kiefer and B. E. Loader, *Can. J. Chem.*, **39**, 1113 (1961).

5) S. Tsuchiya, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **84**, 300 (1963).

where $\boldsymbol{c}$ is the light velocity. $(1/2)B^\circ(\omega, T)\mathrm{d}\omega$ equals the radiant energy emitted from the black body into the unit solid angle in the unit time in the wave number interval $(\omega, \omega+\mathrm{d}\omega)$. The absorption coefficient per unit optical length is formulated by the equation:

$$k(\omega_{12}) = \boldsymbol{h}\omega_{12}(N_2B_{2\to1} - N_1B_{1\to2}) = \frac{\boldsymbol{h}\omega_{12}}{\rho(\omega_{12}, T)}N_1A_{1\to2} \quad (2)$$

Equation 1 does not hold in the case of a gaseous body which is not contained in an opaque enclosure. In this case, the radiation density, $\rho'(\omega_{12}, T)$ is different from $\rho(\omega_{12}, T)$ in Eq. 1, and it is approximated as constant within the gaseous body. The intensity of radiation from the gaseous body concerned can be defined by the use of $\rho'(\omega_{12}, T)$ as follows:

$$B(\omega_{12}, T)\mathrm{d}\omega = \frac{1}{4\pi}\boldsymbol{c}\rho'(\omega_{12}, T)\mathrm{d}\omega$$

The radiation intensity depends on the optical thickness of the gaseous body; this circumstance may be described in the following manner. When the radiation flux passes through the optical length $\mathrm{d}X$, the radiation intensity takes a value of $B(\omega_{12}, T)+\mathrm{d}B(\omega_{12}, T)$. The radiation quanta emitted in the unit time and volume are $\{N_1[A_{1\to2}+B_{1\to2}\rho'(\omega_{12}, T)] - N_2B_{2\to1}\cdot\rho'(\omega_{12}T)\}$. Therefore, the increase in radiation intensity, $\mathrm{d}B(\omega_{12}, T)$, can be formulated as:

$$\mathrm{d}B(\omega_{12},T) = \frac{\boldsymbol{hc}\omega_{12}}{4\pi}\{N_1[A_{1\to2}+B_{1\to2}\rho'(\omega_{12}, T)] - N_2B_{2\to1}\rho'(\omega_{12}, T)\}\mathrm{d}X \quad (3)$$

which is simplified by the introduction of $k(\omega_{12})$ in Eq. 2 as follows:

$$\mathrm{d}B(\omega_{12}, T) = k(\omega_{12})\frac{\boldsymbol{c}}{4\pi}[\rho(\omega_{12}, T) - \rho'(\omega_{12}, T)]\mathrm{d}X = k(\omega_{12})[B^\circ(\omega_{12}, T) - B(\omega_{12}, T)]\mathrm{d}X$$

Therefore, by integrating the above equation, the spectral intensity:

$$B(\omega_{12}, T) = B^\circ(\omega_{12}, T)\{1-\exp[-k(\omega_{12})X]\} \quad (4)$$

is derived.

It is important to notice that the equilibrium condition is admitted into Eq. 4 inexplicitly by introducing the absorption coefficient $k(\omega_{12})$, which is defined in condition 1 of the radiation equilibrium. This means that the Boltzmann distribution between the upper and lower levels is maintained;

$$N_1/N_2 = (g_1/g_2)\exp(-\boldsymbol{hc}\omega_{12}/\boldsymbol{k}T) \quad (5)$$

where g_1 and g_2 are the statistical weights of the upper and lower levels respectively. In Eq. 4, the factor $\{1-\exp[-k(\omega)X]\}$ is a spectral emissivity, and an emission from any body may be represented by such an emissivity and the radiation density of "hohlraum radiation." The emissivity is the function of the concentration of atoms or molecules emitting a spectral line and of the optical length of the gaseous system. The assumption that the emission from the gaseous body is the thermal radiation originates from the acknowledgement of equilibrium relation 5 in the gas.

It is convenient to define the effective emissivity, E_ω, since the emission from the gaseous body is measured by the monochromator, which has a finite spectral resolving power. If $g(\omega', \omega)$ is a spectral slit function when the monochromator is set at a certain wave number, ω, an effective emissivity is:

$$E_\omega = \int g(\omega', \omega)\{1-\exp[-k(\omega')X]\}\mathrm{d}\omega'/\overline{\Delta\omega} \quad (6)$$

and,

$$\overline{\Delta\omega} = \int g(\omega', \omega)\mathrm{d}\omega'$$

where $\overline{\Delta\omega}$ is a spectral slit width expressed in wave numbers.

The observed intensity of the sodium D-line from the high-temperature gas containing sodium atoms is;

$$I_d = \int g(\omega', \omega_d)B^\circ(\omega', T_g) \times\{1-\exp[-k(\omega')X]\}\mathrm{d}\omega'\cdot\Delta\Omega\cdot\Delta s = E_dB^\circ(\omega_d, T_g)\overline{\Delta\omega}\cdot\Delta\Omega\cdot\Delta s \quad (7)$$

where ω_d is the wave number of the sodium D-line, T_g is the temperature of a gas, E_d is the effective emissivity of the sodium D-line, and $\Delta\Omega$ and Δs are the solid angle of a light-flux incident on the monochromator and the area of the slit respectively. Also, the intensity of the light beam from the standard light source, whose spectral radiancy is the same as the black body of the temperature, T_0, is represented as a sum of emission and absorption terms that is,

$$I_l = [E_dB^\circ(\omega_d, T_g) + (1-E_d)B^\circ(\omega_d, T_0)]\overline{\Delta\omega}\cdot\Delta\Omega\cdot\Delta s \quad (8)$$

The light beam from the standard light source without an absorption by the gaseous body has an intensity of

$$I_0 = B^\circ(\omega_d, T_0)\overline{\Delta\omega}\cdot\Delta\Omega\cdot\Delta s \quad (9)$$

The following relation can be derived from Eqs. 7, 8 and 9:

$$\frac{I_l-I_0}{I_d} = 1 - \frac{B^\circ(\omega_d, T_0)}{B^\circ(\omega_d, T_g)} \quad (10)$$

If Wien's radiation formula is applied to Eq. 10, the relation between the temperatures of gas and the light source is shown by the equation:

$$\frac{1}{T_g}=\frac{1}{T_0}+\frac{k}{hc\omega_d}\ln\left(1-\frac{I_l-I_0}{I_d}\right) \qquad (11)$$

Thus, the temperature of the gas can be obtained by the measurement of I_l and I_d; this temperature is the same as the so-called reversal temperature. The physical meaning of the temperature is given by Eq. 5;[6] that is,

$$\frac{[\mathrm{Na}(^2\mathrm{P})]}{[\mathrm{Na}(^2\mathrm{S})]}=\frac{g_{^2\mathrm{P}}}{g_{^2\mathrm{S}}}\exp\left(-\frac{hc\omega_d}{kT_g}\right) \qquad (12)$$

It is necessary to remember that the temperature observed in the simultaneous measurement of emission and absorption is not always the gaseous temperature; it is defined as the population temperature in the upper and lower levels concerned. This population temperature, of course, agrees with the thermodynamic temperature when the whole system is in thermal equilibrium.

In order to clarify the assumption that the sodium D-line in the shock-heated gas containing a trace of sodium vapor is thermal radiation, the relative intensities of the sodium D-line were measured in the cases of various shock velocities.

The effective emissivity of the sodium D-line may be obtained by the relation;

$$E_d=\frac{I_d}{I_0}\left(1-\frac{I_l-I_0}{I_d}\right) \qquad (13)$$

Further, the following relation can be derived from Eqs. 9, 11 and 13;

$$\ln\frac{I_d}{E_d}=-\frac{hc\omega_d}{kT_g}+\text{const.} \qquad (14)$$

If the complete equilibrium between sodium atoms and shock-heated gas is maintained (see below), the temperature, T_2, calculated from the shock velocity equals the temperature, T_g, obtained by the present method. Therefore, the observed emission intensity is expected to be illustrated by the temperature T_2.

The graphic plot of I_d/E_d vs. $1/T_2$ are shown in Fig. 1. The data used are the mean values of the intensities in the steady region behind the shock fronts. (As to the profiles of emission, a more detailed description will be given in the next section). It may be seen in Fig. 1 that the experimental points accord with the theoretical linear slope. It is reasonable that the emission of the sodium D-line in the present experiments arises from a thermal mechanism but not from the other sources, e.g., a chemical luminescence.

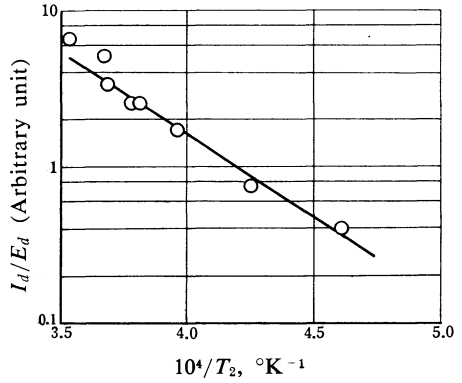

Fig. 1. Relation of sodium D-line emission intensity to reciprocal of the temperature T_2 calculated from shock velocity. The experimental points are the data from shock-heated 1% N_2-99% Ar mixture. The solid line shows the theoretical slope, $-hc\omega_d/k$.

Results

Figure 2 shows the emission and the emission-plus-absorption profiles of the sodium D-line in argon gas behind the shock wave; the temperatures calculated from these two curves are also given. The intensity of the emission rises very fast in less than 10 μsec. (lab. time) after the passage of the shock front, and it is almost constant in the high temperature region between the shock front and the intermixing zone. It is found that the emission becomes more intense near the intermixing zone; this may be attributable to the diffusional mixing of the driver hydrogen and argon gas. These phenomena are also found in the case of argon gas containing less than 0.1% of nitrogen or carbon monoxide. To avoid the confusion

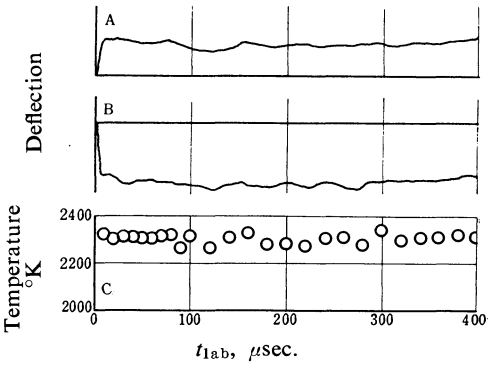

Fig. 2. Emission (A), emission-plus-absorption (B), and temperature (C) profiles behind the shock wave in pure argon gas.
Run No. 012, $v_s=1.724$ mm./μsec., $T_2^{calc}=2921$°K, $p_2^{calc}=1017$ mmHg, $T_0=2583$°K.

6) A. G. Gaydon and H. G. Wolfhard, "Flames," Chapman and Hall, London (1960) p. 234.

which arises from the intermixing of argon and hydrogen, the present observations and discussion are limited to the region of about 300 μsec. after the passage of the shock front.

The observed profile of emission behind the shock front confirms that the vaporization of the colloidal sodium introduced into the argon gas occurs in less than 30 μsec. (gas time), and that the concentration of sodium vapor is almost constant throughout the shock-heated gas. In the later section, the concentration of sodium atoms is calculated to be $10^{12}\sim10^{13}$ atoms/cc. The observed temperature profile is the same as the emission intensity, about 600°K lower than the theoretical temperature calculated from the shock velocity. Gaydon and Hurle have observed that the reversal temperature in the shock-heated argon is 100~200°K lower than the calculated value.[1] Their observed temperature is much higher than the present results; this discrepancy may be attributed to the existence of impurities in their argon gas or to a less efficient vacuum in their shock tube.

An example of the experimental results in the case of nitrogen-argon mixtures is shown in Fig. 3. The emission of the sodium D-line

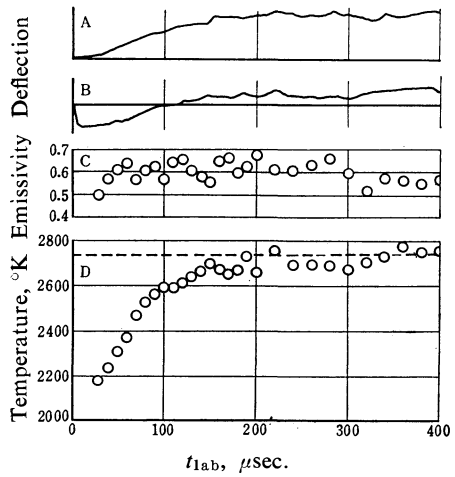

Fig. 3. Profiles of emission (A), emission-plus-absorption, (B), effective emissivity (C), and temperature (D) behind the shock wave in 1% N_2-99% Ar mixture. The dotted line in (D) shows the temperature T_2 calculated from shock velocity. Run No. 1101, v_s=1.662 mm./μsec., T_2^{calc}=2714°K, p_2^{calc}=766mmHg, T_0=2583°K.

rises gradually after the shock front and reaches a steady value of intensity which is much larger than that observed in the case of pure argon gas shocked to the same shock velocity. The rise of the emission intensity just behind the shock front seems to indicate an induction time or a relaxation process. The observed emissivity profile shows that the concentration of sodium vapor is almost constant behind the shock front, even if the emission intensity is low compared with the steady state. In the profile of emission-plus-absorption in Fig. 3, a remarkable intensity decrease is observed just behind the shock front. This decrease is due to low excitation temperature behind the shock front. However, the observed temperature in the steady region agrees well with the theoretical temperature. The difference between these results and those in pure argon can be attributed to the existence of a small amount of nitrogen gas in the mixture.

The time required to reach the steady value of the emission intensity is independent of the concentration of nitrogen in the range of 1~0.1%, and it becomes shorter as the temperature or pressure is raised. On the contrary, the mean temperature in the steady region far from the shock front drops in the shock-heated argon containing less nitrogen. This circumstance is shown in Fig. 4. These findings confirm that, rather than argon atoms, nitrogen molecules in the mixture, even if their concentration is very small, play an important role in the excitation of sodium atoms.

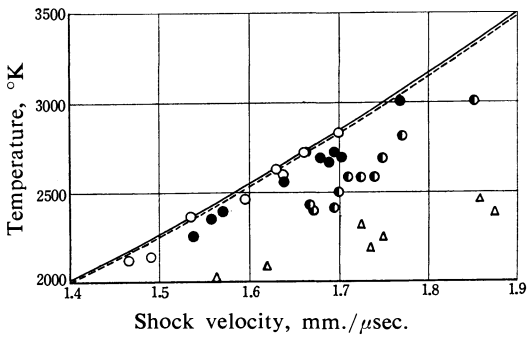

Fig. 4. Temperature obtained from the simultaneous measurement of emission and emission-plus-absorption in the steady regions far from shock front in the case of N_2-Ar mixtures.

The same observations have been made in the carbon monoxide-argon mixture behind the shock wave. The only difference between the experimental results of the carbon monoxide- and nitrogen-argon mixtures is that the emission of the sodium D-line in the carbon monoxide-argon mixture behind the shock front rises a little faster than in the case of the nitrogen-argon mixture. Figure 5 shows

one of the experimental observations in the case of the carbon monoxide-argon mixture.

The dotted line in (D) shows the temperature calculated from shock velocity. Run No. 2203, $v_s=1.675$ mm./μsec., $T_2^{calc}=2774$°K, $p_2^{calc}=1010$ mmHg, $T_0=2583$°K.

The Excitation and Quenching of Sodium Atoms

It has been described that the temperature observed by the present method determines the populations of the ^2P and ^2S states of sodium atom, provided that the populations are distributed by Boltzmann's law. The experimental findings that the measured temperatures are about 600°K lower than the theoretical temperatures calculated from shock velocity in the shock-heated argon and agree with the theoretical temperatures in the nitrogen-argon mixtures, are to be explained by the aforementioned nature of the measured temperature. That is, sodium atoms in the pure argon gas do not attain a thermal equilibrium with argon atoms since the effective cross-section of collisions between sodium and argon atoms is very small. The existence of nitrogen molecules, which have a large cross section in collision with a sodium atom, can excite sodium atoms to ^2P states, thus resulting in the thermal equilibrium of the whole system. These conclusions will be more quantitatively treated in the latter part of this section.

The populations of sodium atoms in the ^2P and ^2S states are supposed to be determined by the following reaction scheme:

$$\begin{aligned} \mathrm{Na}(^2S) + \mathrm{M}^* &\rightarrow \mathrm{Na}(^2P) + \mathrm{M} \\ \mathrm{Na}(^2P) + \mathrm{M} &\rightarrow \mathrm{Na}(^2S) + \mathrm{M}^* \\ \mathrm{Na}(^2P) &\rightarrow \mathrm{Na}(^2S) + \boldsymbol{h}c\omega_d \end{aligned} \qquad (15)$$

where M may be either an atom, a molecule and an electron, and M* is an M which possesses enough energy to excite a sodium atom to the ^2P state. The ionization via the ^2P state of sodium is disregarded in the above scheme. The ionization from the excited electronic state occurs by means of the collisions with electrons, whose content is expected to be too small to make effective collisions with excited atoms (see the latter part of this paper).

As a mean of determining the populations of the ^2P and ^2S states, however, the scheme is not a perfect one. The light quanta emitted spontaneously from ^2P sodium atoms are re-absorbed by the neighboring atoms, re-emitted, and so on. This phenomenon is characteristic of the resonance spectral line, and is called the "radiation imprisonment."

Radiation Imprisonment. — The theoretical treatment of the imprisonment of resonance radiation has been made by Bieberman[7] and Holstein.[8] Their method of analysis may be applied to the present problem. Let $N_1(\boldsymbol{r})$ and $N_2(\boldsymbol{r})$ represent the concentration of sodium atoms in the ^2P and ^2S states respectively at a position, $\boldsymbol{r}$, within the gaseous body. If the reactions 15 represent the mechanism of the excitation or quenching of sodium atoms, $N_1(\boldsymbol{r})$ obeys the following integro-differential equation:

$$\frac{\partial N_1(\boldsymbol{r})}{\partial t} = Z_E N_2(\boldsymbol{r}) - Z_Q N_1(\boldsymbol{r}) - \gamma N_1(\boldsymbol{r}) + \gamma \int N_1(\boldsymbol{r}') G(\boldsymbol{r}', \boldsymbol{r}) \mathrm{d}\boldsymbol{r}' \qquad (16)$$

where Z_E, Z_Q are collision frequencies per unit time of the excitation and quenching respectively, where γ is the reciprocal of the radiative life time, and where the last term expresses the imprisonment of the resonance radiation. $G(\boldsymbol{r}', \boldsymbol{r})$ represents the probability that a light quantum emitted from the $\boldsymbol{r}'$ position in the gaseous body is re-absorbed in the volume element, $\mathrm{d}\boldsymbol{r}$, at the $\boldsymbol{r}$ position, and the integration in Eq. 16 is accomplished over the whole volume of the gaseous body.

Since the present problem concerns the steady state behind the shock wave, $\partial N_1(\boldsymbol{r})/\partial t=0$. Two extreme cases are expected to occur in Eq. 16.

(i) In the case of Z_E, $Z_Q \gg \gamma$, the third and fourth terms in Eq. 16 can be disregarded, and

7) L. M. Bieberman, *J. Exptl. Theoret. Phys.* (*U. S. S. R.*), **17**, 416 (1946).
8) T. Holstein, *Phys. Rev.*, **72**, 1212 (1947); **83**, 1159 (1951).

the following relation is derived;

$$(N_1/N_2)^{equil}=Z_E/Z_Q$$
$$=(g_1/g_2)\exp(-\boldsymbol{hc}\omega_{12}/\boldsymbol{k}T) \quad (17)$$

The exciting or quenching collisions are predominant over the transitions due to the spontaneous emission; therefore, the thermal equilibrium between the atoms emitting the resonance line and the surrounding gaseous particles is maintained.

(ii) In the case of $G(\boldsymbol{r}', \boldsymbol{r})=0$, i.e., when the concentration of atoms is too low to reabsorb the light quanta emitted, Eq. 16 may be arranged to the relation:

$$(N_1/N_2)=Z_E/(Z_Q+\gamma) \quad (18)$$

This formula is an analogous form of the Stern-Volmer equation which is frequently used in the photochemical experiment of the quenching.

For the analysis of the present results, it is convenient to introduce the parameter $y(\boldsymbol{r})$:

$$y(\boldsymbol{r})=\frac{N_1(\boldsymbol{r})}{N_2(\boldsymbol{r})}\Big/\frac{Z_E}{Z_Q} \quad (19)$$

which represents a degree of non-equilibrium between the atoms emitting the resonance line and the gaseous particles; i.e., a value of y is 1 in the complete thermal equilibrium and less than 1 in the radiative non-equilibrium state, where the insufficient energy transfer from the gaseous particles to the atoms results in the lean populations in the upper electronic state.

The mean value of the parameter y, is obtained in the present experiment in the following manner. The physical meaning of the observed temperature, T_g, has already been described by Eq. 12. When the complete equilibrium between sodium atoms and gaseous particles is maintained behind the shock wave, T_g equals T_2 calculated from the shock velocity; i.e.,

$$\left\{\frac{[\mathrm{Na}(^2\mathrm{P})]}{[\mathrm{Na}(^2\mathrm{S})]}\right\}_{equil}=(g^2\mathrm{P}/g^2\mathrm{S})\exp(-\boldsymbol{hc}\omega_d/\boldsymbol{k}T_2)$$
$$=Z_E/Z_Q$$

Therefore, the experimental value of the parameter y is expressed as:

$$y=\frac{[\mathrm{Na}(^2\mathrm{P})]}{[\mathrm{Na}(^2\mathrm{S})]}\Big/\left\{\frac{[\mathrm{Na}(^2\mathrm{P})]}{[\mathrm{Na}(^2\mathrm{S})]}\right\}_{equil}$$
$$=\exp\left[-(\boldsymbol{hc}\omega_d/\boldsymbol{k})\left(\frac{1}{T_g}-\frac{1}{T_2}\right)\right] \quad (20)$$

The introduction of $y(\boldsymbol{r})$ into Eq. 16 gives the equation:

$$1-\left(1+\frac{\gamma}{Z_Q}\right)y(\boldsymbol{r})+\frac{\gamma}{Z_Q}\int y(\boldsymbol{r}')G(\boldsymbol{r}', \boldsymbol{r})\mathrm{d}\boldsymbol{r}'=0 \quad (21)$$

where $N_2(\boldsymbol{r})$ is approximated as equal to N of the total concentration of the emitting atoms. The dependence of $y(\boldsymbol{r})$ upon the position, $\boldsymbol{r}$, in the gaseous body is disregarded in Eq. 21. Therefore, y may be formulated as:

$$y=1\Big/\left[1+\frac{\gamma}{Z_Q}<1-\int G(\boldsymbol{r}, \boldsymbol{r}')\mathrm{d}\boldsymbol{r}'>_{Av}\right] \quad (22)$$

where the symmetric property of the function G, i.e., $G(\boldsymbol{r}', \boldsymbol{r})=G(\boldsymbol{r}, \boldsymbol{r}')$ is used. $\left[1-\int G(\boldsymbol{r}, \boldsymbol{r}')\mathrm{d}\boldsymbol{r}'\right]$ is described as the probability that the light quanta emitted at the $\boldsymbol{r}$ position escape from the enclosure of the gas. Though this probability is dependent on the coordinate $\boldsymbol{r}$, mean probability is adopted here:

$$<1-\int G(\boldsymbol{r}, \boldsymbol{r}')\mathrm{d}\boldsymbol{r}'>_{Av}$$
$$=\int\left[1-\int G(\boldsymbol{r}, \boldsymbol{r}')\mathrm{d}\boldsymbol{r}'\right]\mathrm{d}\boldsymbol{r}\Big/\int\mathrm{d}\boldsymbol{r}$$

By the use of the escaping probability of the resonance light quanta, the effective radiative life time may be defined;

$$\tau_{eff}=\tau/<1-\int G(\boldsymbol{r}, \boldsymbol{r}')\mathrm{d}\boldsymbol{r}'>_{Av} \quad (23)$$

τ_{eff} depends on the absorption coefficient of the gas and the geometrical shape of the gaseous body. y is represented from Eq. 22 as;

$$y=1\Big/\left(1+\frac{\gamma_{eff}}{Z_Q}\right) \quad (24)$$

where

$$\gamma_{eff}=1/\tau_{eff}$$

The assumption that $y(\boldsymbol{r})$ does not depend on the $\boldsymbol{r}$ coordinate contradicts the expectation that the concentration of the emitting atoms in the upper state at the border of the gaseous body is less than in the center part, because the light quanta emitted from the atoms at the border have a great possibility of escaping from the gaseous body. However, in the case of the dense concentration of the atoms, this treatment is satisfactory for the present purpose. The situations may be explained by the following consideration. The light quanta emitted from the atoms can travel only a very short distance because of the great possibility of capture by the neighboring atoms, and at the border of the gaseous body, there is only a thin layer of atoms which have lower value of y than the atoms in the center part have. In addition to this, the experimental value of y obtained from the measured temperature is a mean value, since it is assumed that the radiation density, $\rho'(\omega_{12}, T)$, is constant over the gaseous body in Eq. 3. Walsh confirmed the suitability of the approximation by more

detailed calculations.[9]

The Derivation of the Escaping Probability. —The quantity $G(\boldsymbol{r}', \boldsymbol{r})$ is formulated in terms of the distance, $x=|\boldsymbol{r}'-\boldsymbol{r}|$, and the absorption coefficient of the gas. Holstein shows

$$G(|\boldsymbol{r}'-\boldsymbol{r}|)=\frac{1}{4\pi x^2}\frac{\partial T(x)}{\partial x} \tag{25}$$

where $T(x)$ is the probability that the radiation quantum travels the distance x without absorption; this can be explained by the equation:

$$T(x)=\int_{-\infty}^{+\infty}\varepsilon(\omega)e^{-k(\omega)x}\mathrm{d}\omega \tag{26}$$

The factor $\varepsilon(\omega)$ in Eq. 26 is the distribution function which represents the wave number profile of the emitted line; it is assumed to be proportional to $k(\omega)$. Holstein has given the approximate formula for $T(x)$ as follows:

$$T(x)=1/k_0x(\pi \ln k_0x)^{1/2},$$

for the Doppler line shape (27)

$$T(x)=1/(\pi k_cx)^{1/2},$$ for the

collision-broadened line shape (28)

where k_0 and k_c are the peak absorption coefficients in the Doppler and collision-broadened lines respectively.

In order to calculate the numerical value of the escaping probability, it is necessary to know the geometry of the gaseous body emitting the resonance line. Under present experimental conditions, sodium vapor in the shock-heated gas is enclosed in a cylinder whose diameter and height are the radius of the shock tube and the distance between the shock front and the contact discontinuity respectively. Here, the solution in the enclosure of an infinite slab with the thickness L is applied to the present problem. Though the infinite cylinder is expected to be a better approximation to the real geometry than the infinite slab, Holstein has shown that the escaping probability is nearly equal in these two cases. The above approximation is also based on the the same conditions which are introduced into the definition of the mean escaping probability; in other words, the light quanta emitted from atoms travels only a small distance before absorption.

According to Holstein's calculation, the escaping factor in the case of an infinite slab is as follows:

for a Doppler-broadened spectral line,

$$<1-\int G(\boldsymbol{r}, \boldsymbol{r}')\mathrm{d}\boldsymbol{r}'>_{Av}=\frac{1}{k_0L}\left(\frac{1}{\pi}\ln\frac{k_0L}{2}\right)^{1/2} \tag{29}$$

9) P. J. Walsh, *Phys. Rev.*, **107**, 338 (1957).

for a collision- or dispersion-broadened spectral line,

$$<1-\int G(\boldsymbol{r}, \boldsymbol{r}')\mathrm{d}\boldsymbol{r}'>_{Av}=\frac{4}{3(\pi k_cL)^{1/2}} \tag{30}$$

The Determination of the Absorption Coefficient. — The absorption coefficient may be derived from the effective emissivity obtained from the experiment. The spectral shape of the sodium D-line is considered to be a combined form of the Doppler and the collision broadening in the present shock wave experiment. The absorption coefficient has already been given as a function of parameter a, which is defined as $a=(\ln 2)^{1/2}(\Delta\omega_N+\Delta\omega_c)/\Delta\omega_D$, where $\Delta\omega_N$, $\Delta\omega_c$, $\Delta\omega_D$ are the half-widths of the natural and collision and Doppler-broadened lines respectively.[10] The total absorption of the spectral line is given by the integration:

$$A=\int_{-\infty}^{+\infty}\{1-\exp[-k(|\omega-\omega_0|)L]\}\mathrm{d}\omega \tag{31}$$

where ω_0 is the wave number at the center of the spectral line. The value of A has been calculated numerically in the case of various values of a and is given by the "curves of growth". Since the spectral slit width, $\overline{\Delta\omega}$, is much wider than the half-width of a pure Doppler- or collision-broadened line (e.g., in the present case, $\overline{\Delta\omega}=8.9\,\mathrm{cm}^{-1}$ against $\Delta\omega_D$ or $\Delta\omega_c=0.1\sim0.15\,\mathrm{cm}^{-1}$), the total absorption can be obtained from the observed effective emissivity by the relation:

$$E_d=\int g(\omega,\omega_d)\{1-\exp[-k(\omega)L]\}\mathrm{d}\omega\Big/\int g(\omega,\omega_d)\mathrm{d}\omega\fallingdotseq A_d/\overline{\Delta\omega} \tag{32}$$

For the numerical evaluation of k_0 by the use of the curves of growth*, the collision half-width, $\Delta\omega_c$, is necessary. This is given by the classical collision-damping theory[11]:

$$\Delta\omega_c=\sigma^2\bar{v}N'/c$$

where N' is the concentration of perturbing atoms or molecules, $\bar{v}$, the gas kinetic mean velocity, and σ^2, the optical cross-section of collisions with perturbing particles. Hinnov measured the total absorption of the sodium D_2-line in the acetylene-air flame and obtained

10) S. S. Penner, "Quantitative Molecular Spectroscopy and Gas Emissivities," Addison-Wesley Pub. Co., Mass. (1959), p. 38.

* The relation $k_c=k_0/\sqrt{\pi}\ a$ can be derived, since in any shape of the spectral line, $\int k(|\omega-\omega_0|)\mathrm{d}\omega=(\pi e^2/mc^2)Nf$, where e and m are the electron's charge and mass respectively, and f is the f-number of the concerned spectral line. In the latter part of this paper, the absorption coefficient, k_0, will be used as a measure of optical thickness instead of k_c, because the total absorption is given in terms of k_0L in the curves of growth.

value of σ^2 as 64Å^2 for nitrogen-sodium collisions.[12a] Margenau and Watson observed the absorption profile of the sodium D_1- and D_2-lines in the atmosphere of nitrogen and argon[12b] and found that the half-width of the absorption line in argon at high pressure was larger than that in nitrogen. However, half-widths at less than 1 atm. are almost the same in both cases, as is shown in Fig. 4 of their paper. The difference between half-widths in argon and nitrogen at high pressure may be considered to be due to the fact that the degrees of assymmetrical broadening and the shift of the spectral line are different in argon and in nitrogen. The value of σ^2 obtained by Hinnov is used in the present case, since the present experimental conditions, i. e., high temperature and about 1 atm., resemble Hinnov's case and the sodium D-line is expected to be broadened equally by nitrogen- and argon-sodium collisions.

Effective Collision Cross-section.—The aforementioned procedures make it possible to calculate the numerical value of the quenching collision frequency, Z_Q, by the use of an experimental y value. Table I shows the experimental results of the temperature measurement in the cases of shock-heated nitrogen- and carbon monoxide-argon mixtures, and it also gives the calculated values of k_0L and Z_Q. The value of k_0L is obtained from the curves of growth using the total absorption estimated from the observed emissivity. Z_Q is calculated by Eq. 24, where the value of γ_{eff} is obtained from Eq. 30. Here the value of 1.6×10^{-8} sec. is adopted as the radiative lifetime of the $Na^2P_{3/2}-{}^2S_{1/2}$ transition.[13] In the above calculation, the spectral line, which has a shape combining the Doppler and the collision brandening, is considered to be a pure collision-broadened line, and k_0L is converted to k_cL using the relation $k_cL=k_0L/\sqrt{\pi}a$. This approximation is reasonable taking into account the fact that the spectral shape of the sodium D-line is close to the collision-broadened line in the present experimental conditions.

The calculated Z_Q's have an order of 10^6 sec^{-1} in the cases of both the 0.05% nitrogen and 0.03% carbon monoxide mixtures. This Z_Q should be interpreted from the viewpoint that some particles in the shock-heated heated nitrogen- or carbon monoxide-argon mixture have large efficiencies in exciting or quenching collisions with sodium atoms. The effective collision cross-section, σ^2_{eff}, is defined by the equation;

$$Z_Q=\sigma^2_{eff}\left[8\pi RT\left(\frac{1}{M_{Na}}+\frac{1}{M_q}\right)\right]^{1/2}N_q \quad (33)$$

where M_{Na} and M_q are the atomic or molecular weights of sodium and the quencher respectively, and N_q is the number of quenchers per unit volume.

In order to explain the obtained value of Z_Q in nitrogen- and carbon monoxide-argon mixtures, it is assumed that the collisional excitation and quenching of sodium atoms are performed by nitrogen or carbon monoxide molecules involved in the shock-heated mixtures. The values of σ^2_{eff} for nitrogen or carbon monoxide in collisions with sodium atoms can be calculated on the above assumption; they are shown in Table I. These values agree well with the experimental values given by Norrish and Smith,[14] even though many approximations are made in the process of the

calculation. However, the value of σ^2_{eff} obtained here has only one significant figure, i. e., σ^2_{eff} (for N_2) $=(1.4\pm0.5)\times10^{-15}$ cm^2, because of the uncertainty in the estimation of the absorption coefficient and because of the approximation used in the analysis of the radiation imprisonment. The agreement of σ^2_{eff} with Norrish and Smith's value leads to the conclusion that molecular collisions with sodium atoms are dominant in quenching Na(^{2}P), that is, in exciting Na(^{2}S) in the nitrogen- and carbon monoxide-argon mixtures even if the concentration of nitrogen or carbon monoxide is less than 0.1%. The present values of σ^2_{eff} are obtained in the gas with a high temperature of about 2800°K. On the other hand, the experiment of Norrish and Smith was performed at room temperature. The agreement of the present values with their experimental values shows that the activation energy of the quenching process is zero. Mori has calculated quantum-mechanically the potential surface of the sodium-nitrogen system; the calculated potentials have no activation energy.[15]

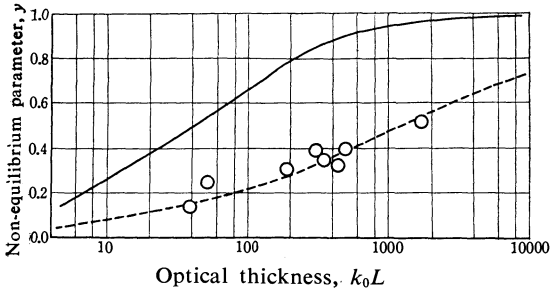

Fig. 6. Relation of non-equilibrium parameter y to optical thickness k_0L. The calculation is carried out in the case of $Z_Q=1.53\times10^6$ sec^{-1} which corresponds to the quenching collision frequency of nitrogen in 0.05%N_2-99.95%Ar mixture at 900 mmHg and 2800°K. In this case, $y=0.0239$ at $k_0L\to0$. Solid and dotted lines shows values of y calculated in the case of Doppler- and collision-broadened spectral lines, respectively. Experimental points are adopted from Table I.

The graphical representation of the theoretical y value vs. the optical thickness, k_0L, is shown in Fig. 6. The theoretical curves are calculated by Eq. 24 in the case of $Z_Q=1.53\times10^6$ sec^{-1}. This value of Z_Q is the collision frequency of quenching by nitrogen molecules in a 0.05% nitrogen - 99.95% argon mixture, which is shocked to the temperature of 2800°K and the pressure of 900 mmHg. Experimental results are also given in Fig. 6, although the experimental shock conditions are not precisely the same as the conditions used in the calculation. The experimental points lie on the curve of y calculated in the case of the collision-broadened line shape.

It is seen in Fig. 6 that the values of y increases as the optical thickness, k_0L, becomes larger. This is due to the radiation imprisonment. If all the light quanta emitted spontaneously from sodium atoms escape from the gaseous enclosure, i. e., if $\tau_{eff}=\tau$ and $k_0L=0$, expected value of y is 0.0239 as calculated from Eq. 25. Gaydon and Wolfhard have explained the radiative non-equilibrium state between sodium atoms and a high temperature medium by the use of τ rather than of τ_{eff}.[16] However, the populations of the ^{2}P state of sodium atoms are much closer to the values of the thermal equilibrium state than those without the imprisonment of resonance radiation.

Vibrational-Electronic Energy Exchange

In this section, the rise of the emission behind the shock wave will be discussed. The results show that a lab. time of 50~100 μsec. after the passage of the shock front is required for the emission intensity to attain a steady value in the nitrogen- or the carbon monoxide-argon mixture. On the contrary, the emission rises in less than 10 μsec. (lab. time) in the shock-heated argon.

Gaydon has described that the excitation of sodium atoms occurs by collision with vibrationally-excited molecules, because the quenching cross-sections of the fluorescence are large when the quenchers are molecules and extremely small when they are inert monoatomic gases.[17] He obtained the vibrational relaxation time on the assumption that the reversal temperature equals the vibrational temperature of diatomic gases.[1] Karl and Polanyi investigated the infrared emission of carbon monoxide, which quenched electronically-excited mercury, and found that the electronic energy of the mercury atom was transferred to the vibrational freedom of carbon monoxide by collisions of second kind.[18] Their findings can be applied to the present problem.

The mechanism of the collisional excitation of the sodium atom may be represented by the following scheme:

$$N_2(v=0) + Ar \rightleftarrows N_2(v=1) + Ar \rightleftarrows N_2(v=2) + Ar \rightleftarrows \quad (34)$$

$$Na(^2S) + N_2(v \geq v^*) \rightleftarrows Na(^2P) + N_2(v < v^*) \quad (35)$$

The successive excitation or de-excitation of vibrational states of carbon monoxide has been recently experimentally ascertained.[19] This has been predicted by Landau-Teller's classical theory of vibrational relaxation, and Eq. 34 reflects this mechanism. Equation 35 represents how the excitation of sodium atoms occurs in collisions with nitrogen of a high vibrational state ($v^* \geq 8$).

First, it will be shown that the process of Eq. 35 is much faster than that of Eq. 34. Equation 16 represents the concentration of $Na(^2P)$ and is formulated by the use of γ_{eff} as follows:

$$dN_1/dt = Z_E N_2 - (Z_Q + \gamma_{eff}) N_1 \quad (16')$$

where the exciting collision frequency, Z_E, is a function of a concentration of vibrationally-excited nitrogen molecules. If Eq. 34 keeps complete equilibrium, that is, if nitrogen molecules are in equilibrium with argon atoms at any moment after the passage of the shock front, Z_E is constant throughout the high temperature region behind the shock front, and the rate of the process of Eq. 35 is represented by Ep. 16'. On the assumption that $N_2 \fallingdotseq N$, Eq. 16' may be integrated to give the relation:

$$N_1 = N_1^{steady}\{1 - \exp[-(Z_Q + \gamma_{eff})t]\} \quad (36)$$
$$N_1^{steady} = NZ_E/(Z_Q + \gamma_{eff})$$

where the integration is carried with the initial condition, $N_1 = 0$ at $t = 0$, and N_1^{steady} is a value of N_1 at the steady region far from the shock front.

Since the emission intensity of the sodium D-line is proportional to the concentration of excited sodium atoms, the profiles of the emission intensity behind the shock front is expressed by Eq. 36. In the case of a 1% nitrogen-99% argon mixture, the time required for N_1 to reach 90% of N_1^{steady} is estimated by Eq. 36; this corresponds to the rise time of the emission intensity behind the shock front. Under the present experimental conditions, $\gamma_{eff} \fallingdotseq 10^6\ sec^{-1}$ and $Z_Q \fallingdotseq 10^7\ sec^{-1}$. The corresponding rise time of the emission intensity is calculated to have an order of 10^{-7} sec., which is much shorter than the rise time observed in the experiment. The discrepancy between this argument and the experimental findings is due to the assumption that Eq. 34 keeps complete equilibrium. Therefore, it can be concluded that the process of Eq. 34 rather than that of Eq. 35 is the rate-determining step of the excitation of sodium atoms; i. e., the distribution of sodium atoms in the ^2S and ^2P states are always in equilibrium with nitrogen molecules in the various vibrational states.

Montroll and Shuler have calculated the relaxational process of harmonic oscillators which are involved in a heat bath with a constant temperature.[20] Their calculations are based on the Landau-Teller-type relaxation, and the solution is applicable to the present problem. Their calculations show that when the temperature of a heat bath is suddenly raised, as in the shock wave, the initial Boltzmann distribution of harmonic oscillators goes to the final distribution, maintaining the Boltzmann distribution at any moment of the relaxation process. Therefore, the vibrational temperature, $T(t)$, of oscillators can be defined as a function of the time, t, after the sudden increase in the temperature of the heat bath. At a large value of t, Montroll and Shuler gave the equation;

$$\Theta - \theta \fallingdotseq e^{-t/\tau}\left[\frac{(1-e^{-\theta})}{(1-e^{-\theta_0})}(1-e^{\theta-\theta_0})\right] - O(e^{-2t/\tau}) \quad (37)$$

In this equation, τ is the vibrational relaxation time of $v=1 \rightarrow v=0$; $O(e^{-2t/\tau})$ is a function of terms higher than $e^{-2t/\tau}$, and $\Theta = \boldsymbol{hc}\omega_{vib}/\boldsymbol{kT}(t)$, $\theta_0 = \boldsymbol{hc}\omega_{vib}/\boldsymbol{kT}(0)$, $\theta = \boldsymbol{hc}\omega_{vib}/\boldsymbol{kT}(\infty)$, where $T(0)$ and $T(\infty)$ are the initial and final temperatures of the system of oscillators, and ω_{vib} is the fundamental vibration frequency of the oscillator. Equation 37 can be arranged to give the relation;

$$\ln\left[\frac{1}{T(t)} - \frac{1}{T(\infty)}\right] \fallingdotseq -\frac{t}{\tau} + \text{const.} \quad (38)$$

As a results of the preceding consideration of the energy transfer between sodium atoms and nitrogen molecules, the observed excitation temperature of the sodium D-line may be concluded to correspond to $T(t)$ of the vibrational temperature of nitrogen. The emission intensity of the sodium D-line is described by Eq. 4, and if the concentration of sodium is constant behind the shock wave, the ratio of the intensities at any time, t, and at the steady state of $t=\infty$ is represented by;

$$\frac{I(t)}{I(\infty)} = \exp\left\{-\frac{\boldsymbol{hc}\omega_d}{\boldsymbol{k}}\left[\frac{1}{T(t)} - \frac{1}{T(\infty)}\right]\right\}$$

therefore,

$$\ln\left[\ln\frac{I(\infty)}{I(t)}\right] \fallingdotseq -\frac{t}{\tau} + \text{const.} \quad (39)$$

Figure 7 shows the experimental determination of τ from the measured temperature and the emission intensity profiles behind the shock wave in the case of the 1% nitrogen-99%

argon mixture. Two methods, i. e., Eqs. 38 and 39, of obtaining the vibrational relaxation time give the same value. In Figs. 8 and 9, the obtained vibrational relaxation times at 1 atm. are given. Since the measurements are made in 1% and 0.1% nitrogen or carbon monoxide in argon, the contribution of nitrogen-nitrogen or carbon monoxide-carbon monoxide collisions to the relaxation time is negligible. The results of the relaxation time measured by the present method in pure nitrogen behind the shock wave agree with the extrapolated value of

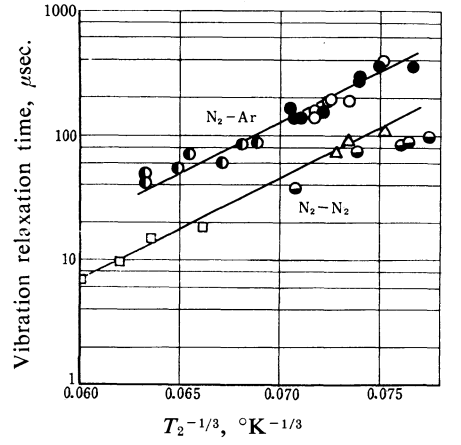

Fig. 8. Obtained vibrational relaxation time at 1 atm. in N_2-Ar and N_2-N_2 collisions.

○: 1.0% N_2 in argon, data obtained from temperature profile
◐: 1.0% N_2, from emission profile
●: 0.09% N_2, from temperature profile
△: data obtained from temperature profile in shocked nitrogen
□: Blackman's data[21]
◒: Gaydon and Hurle's data

Blackman's data,[21] as has already been pointed out by Gaydon.[1] On the other hand, the relaxation times in the 1% nitrogen-99% argon mixture are about three times longer than in the pure nitrogen. This is consistent with Camac and Vaughan's measurement in an oxygen-argon mixture,[22] and Hooker and Millikan's data on a carbon monoxide-argon mixture.[19] The plots of the relaxation time vs. $T^{-1/3}$ give the relation;

$$\log_{10}\tau_{N_2-Ar} = 85T^{-1/3} - 9.8$$

$$\log_{10}\tau_{N_2-N_2} = 81T^{-1/3} - 10$$

where τ is described in sec. The results obtained in carbon monoxide-argon mixtures are the same as Hooker and Millikan's data:

$$\log_{10}\tau_{CO-Ar} = 101T^{-1/3} - 11.45$$

$$\log_{10}\tau_{CO-CO} = 69.3T^{-1/3} - 9.64$$

It is reasonable to expect a longer vibrational relaxation time in nitrogen-argon collisions than in nitrogen-nitrogen collisions, since only a translational-vibrational energy exchange, and novibrational-vibrational one, occurs in nitrogen-argon collisions.

The Excitation of the Sodium Atom in Argon behind the Shock Wave

In order to discuss the mechanism of the excitation of sodium atoms in the shock-heated argon, the method of analysis already described will be applied to the experimental results. Table II shows that the quenching collision frequency, Z_Q, derived from the measured tem-

perature has an order of 10^5 sec^{-1}. By the use of this value, it can be determined what sort of particles in the shock-heated argon performs the excitation and de-excitation by collisions with sodium atoms.

First, the collisions between sodium and argon atoms will be discussed. The effective cross sections can be calculated from the obtained Z_Q's; the values are shown to be about $10^{-19}\sim10^{-20}$ cm^2 in Table II. Laidler has discussed the physical quenching of an excited sodium atom by considering the potential surface between a sodium atom and a quencher;[24] he has concluded that the inert atoms would be poor quenchers, since the potential curves of the $Na^+ + M^-$ (M=inert atom) system do not cross the curves of the Na(^{2}P) + M and Na(^{2}S) + M systems. A very small effective cross-section obtained from the present data reflects these circumstances. Gaydon has proposed the possibility of quenching by an inert atom;[25] though both Na(^{2}S) + Ar and Na(^{2}P) + Ar have potential curves of a repulsive type, the Na(^{2}P) + Ar system is less repulsive than Na(^{2}S) + Ar, and the intersection of the two potential curves occurrs at a high energy point, as Fig. 10 shows. The same discussions were cited by Herzberg.[26] In this mechanism, an activation energy is necessary for quenching.

The present data may be interpreted by the above scheme. It is reasonable that the crossing point of the two potential curves, Na(^{2}P) + Ar and Na(^{2}S) + Ar, lies at an atomic distance of about 10^{-8} cm. Therefore, the collision cross-section is expected to have an order of 10^{-16} cm^2; the $10^{-3}\sim10^{-4}$ factor might come from the necessity of the activation energy for

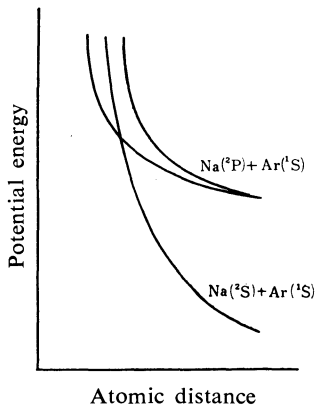

Fig. 10. Potential curves explaining the excitation of sodium atom by collision with argon atom. Two states $^2\Sigma$, $^2\Pi$ are considered in the system Na(^{2}P) + Ar(^{1}S).

quenching, i. e., the energy difference between the crossing point of two potential curves and the energy level of Na(^{2}P) + Ar at a large atomic distance. This activation energy may be expected to be 40~60 kcal. from the results of the present experiment. If the above explanation correctly accounts for the excitation of the sodium atom by collisions with argon atoms, the effective cross-section is strongly dependent on the temperature of the shock wave. The temperature dependency is not certain in the present experiments. Moreover, the constant cross-section is not obtained from the experiments carried out at the various pressures behind the shock wave. These negative facts appear to deny the possibility of the excitation of a sodium atom by collisions with argon atoms.

The collisional excitation of the sodium atom by other particles in argon gas behind the shock wave should also be examined. When the concentration of sodium atoms in the shock-heated argon is calculated from the obtained value of k_0, it is shown to be

24) K. J. Laidler, ibid., 10, 34 (1942).
25) A. G. Gaydon and I. R. Hurle, "The Shock Tube in High Temperature Chemical Physics," Chapman and Hall London (1963), p. 230.
26) G. Herzberg, "Molecular Spectra and Molecular Structure I. Spectra of Diatomic Molecules," D. Van Nostrand Co., N. Y. (1950), p. 463.

$10^{12}\sim10^{13}$ atoms/cc. (cf. Table II). The collisions between sodium atoms cannot take a dominant role in the shock wave unless the effective cross section for a sodium atom is extraordinarily large. There is no possibility of the excitation by Na_2 molecules, which exist in a small concentration because of the low dissociation energy. The other possibility is collision with the nitrogen or oxygen which is involved in argon gas as an impurity. The Z_Q of $10^5\,sec^{-1}$ at 1000 mmHg and 3000°K requires the contamination of about 0.003% nitrogen in argon. The argon gas used in the present experiment contains nitrogen, oxygen, hydrogen and water vapor as follows: $N_2<0.007\%$, $O_2<0.001\%$, $H_2<0.001\%$, $H_2O<0.001\%$. Therefore, the excitation of sodium atoms by these impurities must be taken into consideration; the observed Z_Q can be explained by this scheme. However, there is a phenomenon which contradicts the reality of the excitation by the impurity whose main component is nitrogen; i. e., the rise time of the emission intensity just behind the shock front is very short compared with that in the case of the 1% nitrogen-99% argon mixture. The following explanation of this fact is possible. The proportion of oxygen, hydrogen or other impurities to the amount of nitrogen is much larger than that of the 1% nitrogen - 99% argon mixture. The vibrational relaxation times of oxygen, hydrogen and water vapor are much shorter than that of nitrogen. This is the probable reason why the emission of the sodium D-line rises rapidly behind the shock front. In order to gain a more rigid conclusion, however, it is necessary to perform the experiment using highly pure argon and a highly-evacuated shock tube.

Bauer, Kiefer and Loader have measured the temperature dependency of the emission rise of the chromium line in the 10% nitrogen-90% argon mixture behind the shock wave[4] and have concluded that chromium atoms are excited predominantly by collisions with electrons. Since the large cross-section for the excitation of sodium atoms is expected in collisions with electrons, electrons which are produced by the ionization of sodium atoms can make the quenching collisions of $Z_Q \fallingdotseq 10^5\,sec^{-1}$ if the equilibrium ionization is attained. However, the ionization is known to occur after some delay in the inert gas behind the shock wave. Haught has observed the delayed luminosity in the shock wave of a cesium-argon mixture[27] and has described that the ionization by atom-atom collisions is less effective by a factor of 10^{-3} than electron-atom collisions, and that atom-atom collisions occur only just behind the shock front in argon. In the shocked gas higher than 3500°K, the delayed rise of the emission is observed 100$\sim$300 μsec. (lab. time) later behind the passage of the shock front; this is perhaps attributable to the ionization of sodium atoms. A detailed investigation of this phenomenon will be discussed in another place. Therefore, the emission of the sodium D-line in the shock-heated argon is not due to the ionization of sodium atoms.

The above arguments lead to the conclusions that the excitation of sodium atoms in the shock-heated argon does not occur by sodium-argon collisions in the 2500$\sim$3500°K temperature range, and that molecular impurities such as nitrogen, oxygen and hydrogen, rather than electrons play a dominant role as to the excitation of sodium atoms. This conclusion is compatible with the fact that the translational-electronic energy exchange in nitrogen-sodium collisions cannot occur in the case of a shock-heated nitrogen-argon mixture.

Conclusion

The so-called reversal temperature can be obtained by simultaneous measurements of the emission and of the absorption of the sodium D-line. The physical meaning of the temperature is such that the obtained temperature determines the distribution of populations in the ^2P and ^2S states of the sodium atom according to the Boltzmann distribution. The measured temperatures in argon containing a trace of sodium vapor are about 600°K lower than the values calculated from the shock velocity. However, in the shock-heated 1% nitrogen-99% argon mixture, the measured temperatures agree with the calculated ones, and a complete equilibrium between sodium atoms and the gaseous particles is attained.

These results can be explained by the fact that the effective cross-section for the excitation of the sodium atom in collisions with argon atoms is too small to maintain the thermal equilibrium. The collision frequencies of the second kind can be obtained with the correction of radiation imprisonment, and the calculations show that sodium-nitrogen collisions rather than sodium-argon collisions play a dominant role in the shock wave of a temperature between 2000$\sim$3000°K, even if the concentration of nitrogen is 0.05%. Quite the same conclusions are obtained in the case of a carbon monoxide-argon mixture. The present shock wave experiment may provide a method for obtaining the effective cross-section of collison for quenching an excited atom.

Concerning the feature of the emission rise

27) A. F. Haught, *Phys. Fluid*, 5, 1337 (1962).

in the nitrogen-argon mixture just behind the shock front, the observed temperature follows the vibrational temperature of nitrogen defined by Montroll and Shuler; that is, the electronic excitation occurs in collisions with vibrationally-activated nitrogen molecules. The vibrational relaxation time in nitrogen-argon collisions has a value about three times greater than the value in nitrogen-nitrogen collisions in the temperature range of 2000~3000°K.

The effective quenching cross-section of $Na(^2P)$ for the argon atom has been calculated to be 10^{-19}~10^{-20} cm^2 at 2500~3500°K from the measured temperatures in the shock-heated argon. However, collisions with other impurities, e. g., nitrogen, electrons etc., must be taken into consideration. It has been concluded that molecular impurities, such as nitrogen or oxygen, rather than argon atoms or electrons make exciting collisions with sodium atoms in the shock-heated argon.

The author wishes to express his sincere thanks to Professor Kenji Kuratani for his kind advice and encouragement throughout this work. His thanks are also expressed to Mr. Takuji Sakai for his help in the experimental work.

*Photoconductivity of Polyacenaphthylene and Its Nitrated Derivatives**

By Akira INAMI, Kazuhisa MORIMOTO and Yoshiki HAYASHI

(Received January 10, 1964)

During the last decade a renewed interest in the photoconductive properties of organic compounds has been shown, and many studies of the photoconductivities of polynuclear molecules and of miscellaneous dyes have been reported.

Recently a few photoconductive polymers have been discovered, such as poly-*N*-vinyl carbazole,[1-4] irradiated polyvinylidene chloride,[5] the thermal conversion product of polyacrylonitrile,[6] polyvinylchloride-leuco base complexes[7] and a polymer containing a triphenylpyrazoline group which has been reported on in a previous paper of ours.[8]

The semiconductivity of charge-transfer complexes of polyacenaphthylene with Lewis acids in the dark was studied by Slough.[9] The present authors, in studying the photoconductive behavior of polyacenaphthylene, have detected that the photoconduction of this polymer is small initially but that it increases with adequate nitration of the polymer.

Experimental

Polymerization of Acenaphthylene.[10]—Ten grams of acenaphthylene was dissolved in 10 ml. of ethyl benzene and emulsified with 100 ml. of a sodium stearate solution.** As an initiator, 0.4 g. of potassium persulfate was added to the emulsion, and then the mixture was agitated in a closed container for 10 hr. at 45°C. The resultant polymer was coagulated from the solution by dropping it slowly into dilute hydrochloric acid. The coagulated polymer was then filtered off, dissolved in benzene, and precipitated into methyl alcohol. Yield, 74%. $[\eta]=0.53$ (at 25°C in benzene).

Nitration of Polyacenaphthylene. — The polyacenaphthylene thus obtained was dissolved in a mixture of benzene (or monochlorobenzene) and glacial acetic acid (or acetic anhydride); then the mixture was stirred and concentrated nitric acid (s. g. 1.40) was slowly added. After the addition of nitric acid, the mixture was stirred at a constant temperature and then poured into methyl alcohol. The pale yellow polymer was twice reprecipitated from a monochlorobenzene solution by pouring it into methyl alcohol and then dried at room temperature. The molar per cent of sub-

Table I. Nitration of polyacenaphthylene

No.	Polymer/HNO_3 mole ratio	Solvent ml.		Temp. °C	Time hr.	$-NO_2$ group mol. %
2	1/1	Benzene	60	70	2	7.9
		Acetic acid	10			
3	1/1	Acetic acid	10	75	6	16.4
4	1/1	Benzene	60	70	2	28.7
		Acetic acid	30			
5	1/1.2	Chlorobenzene	60	70	2	40.6
		Acetic anhydride	20			

stituted nitro groups were calculated from the nitrogen contents by the Dumas' microanalysis. Table I shows the reaction conditions and results. The degrees of nitration varied from 7.9 to 40.6 molar per cent, according to the condition of the reaction. The photoconductive properties of these nitrated polyacenaphthylenes were studied.

Photoconductivity of Polymers. — The photoconductivity was investigated by using the same sandwich-type cell as was used in another paper.[8] The preparation of the cell was carried out by the following technique; a 10% polymer solution of monochlorobenzene was placed uniformly flat onto a NESA conductive glass plate used as a transparent electrode, and then the solvent was thoroughly evaporated. After the solvent had been evaporated, the specimen film was 10 μ thick. The second electrode was formed thereafter by the vacuum-evaporation coating of aluminum onto the surface of the specimen film.

The sandwich-type cell thus obtained was then placed in a closed glass chamber, which was kept in a vacuo of 10^{-3} mmHg. The applied field of the specimen was 1600 V./cm., taken from a 1.6 V. drybattery source, and the current measurement was carried out with the aid of a vibration-reed electronic micro-micro ammeter (Takeda Riken, type TR-85) and an electronic X-T recorder (Toa-Dempa, type EPR-2). The light source used for measuring the photocurrent of the cell was a 100 W. tungsten lamp.

From the fact that the V-I plots in the dark passed through the point of origin, it may be seen that the dark currents of specimens obeyed Ohm's law and that the contacts between the specimen films and the aluminum layer, or the NESA conductive surface, were perfect.

Relative Surface Potential.—The resistances in the dark were so high and both rise and decay responses were so slow that the ordinary methods of the mere detection of the photocurrents described above were not enough to determine their photoconductive behaviors. In order to reexamine them, the authors introduced a method of comparing the relative surface potential in the light with that in the dark, a method which had been applied in the determination of the photosensitivity of electrophotographic conductive layers. A typical difference between the sandwich-type cell method and the relative-surface-potential method is that the internal field of the specimen in the latter (ca. 10^6 V./cm.) is much higher than in the former (ca. 10^3 V./cm.).

As has been stated in detail in another paper,[4] a thin specimen film 3 μ thick was formed on an aluminum plate. The top surface of a plate was sensitized in the dark to a potential of 200~300 V. (V_d) by negative corona-charging. Actinic light produces electron-hole pairs, which, under the influence of the electric field, are separated; the hole moves to the surface to neutralize a negative charge, and the negative electron is accelerated to the conductive aluminum base, where it neutralizes the induced positive charge. Therefore, the surface potential decreased with the illuminated time to V_l. The relative-surface-potential was defined as a ratio of potential V_l to V_d, and so the time in which V_l/V_d is reduced to one-half represents the half-decay time $(V_l/V_d)_{1/2}$, which serves as an index of photoconductivity. The experimental results obtained when the surface was illuminated with an incandescent light at 1000 luxes are shown in Table II.

Results

Photocurrents under Illumination with an Incandescent Lamp.—*Polyacenaphthylene.* — When a powerful incandescent light (10^5 luxes) is applied to the negative electrode of the cell, a photocurrent increases slowly, attaining a peak after 200 sec. Then the current tends to decay slowly; when the light is switched off, it decays to the initial value, as Fig. 1 shows.

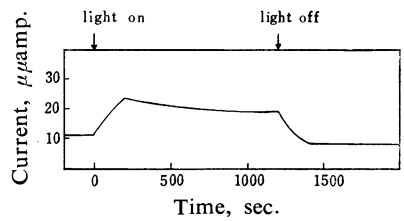

Fig. 1. Rise of the photocurrent under illumination and its decay, polyacenaphthylene.

Nitrated Polyacenaphthylenes. — The time-responses of the photocurrents of the nitrated polyacenaphthylenes are shown in Fig. 2. No photocurrent is observed in the case of Experiment No. 5. The time-responses are very slow; that is, even after 1400 sec. the photocurrents increase gradually. This is the same

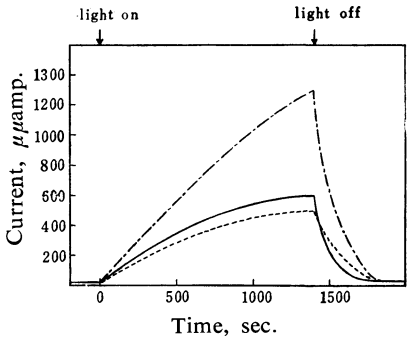

Fig. 2. Rise of the photocurrent under illumination and its decay, nitrated polyacenaphthylenes.
7.9% nitration (dotted line)
16.4% nitration (solid line)
28.7% nitration (broken line)

phenomenon as was observed in crystal violet by Vartanian,[11] and so it can be seen that something in nitrated polymers seems to act as electron-traps.

When a powerful incandescent light (10^4 to 10^5 luxes) is applied to the cell, the photocurrents increase, as is shown in Fig. 3.

The photoconductive natures of these polymers are listed in Table II. In the case of the sandwich-cell method, the sample of 16.4 molar per cent nitration is the most photoconductive, while in the relative-surface-potential method, the sample of 28.7 molar per cent nitration is the most photoconductive. This difference may be due to the different measuring methods. In any case it is clear that the photoconductivity of polyacenaphthylene increases upon the nitration of the polymer.

Discussion

The number of the conjugated double bonds or mobile π electrons of polyacenaphthylene are equal to those of polyvinylnaphthalene, which our experiment establishes as having no photoconductivity. The photoconductivity of polyacenaphthylene, therefore, can not be explained by the mere existence of the mobile π electrons. It may be considered that the conductivity of this polymer depends on the stereoregularity. Between the electron clouds of the acenaphthene groups, which lie one against the other, there are, by virtue of a slight overlapping, interaction forces which cause a slight splitting of the electron orbitals of the groups and, consequently, the formation of narrow energy bands.

The fact that the nitration brings more photoconductivity may be interpreted with a charge-transfer mechanism. The nitrated acenaphthene group may be an electron-donor. When these groups are put in order, as has been discussed above, a charge-transfer complex may be formed between an acenaphthene group and a nitrated acenaphthene group.

Summary

The photoconductive properties of polyacenaphthylene and nitrated polyacenaphthylene have been studied using both the sandwich-cell method and the relative-surface-potential method. The polyacenaphthylene shows little photoconductivity, while the nitrated polymer obtained by the partial nitration of polyacenaphthylene shows considerable photoconductivity. The photocurrent depends on the degree of nitration.

The Condensation of Thujopsene with Formaldehyde

By Shoji WATANABE and Kyoichi SUGA

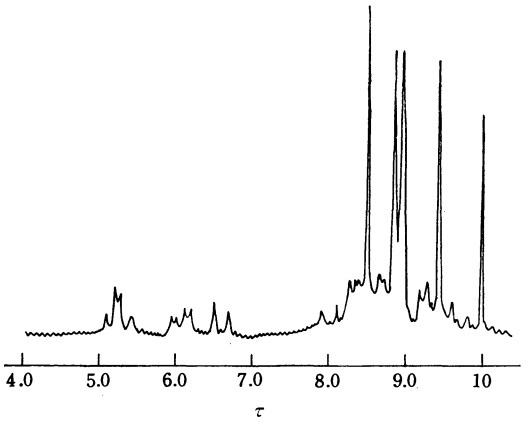
(Received January 11, 1964)

In a previous paper,[1] the thermal condensation of thujopsene with formaldehyde was reported. The reaction of thujopsene with formaldehyde in an acetic acid solution is the subject of this paper.

In this study thujopsene (I) was added to a slurry of paraformaldehyde in glacial acetic acid at 50~60°C. The crude products were isolated by fractional distillation and liquid chromatography. A dioxane II was isolated as the major product. The minor product was an unsaturated alcohol III.

The analytical results ($C_{17}H_{28}O_2$) and the molecular weight of the major product indicated that the product was an adduct of two moles of formaldehyde to I. The infrared absorption spectrum showed characteristic absorption bands of an ethearic group (dioxane type) at 1045 cm^{-1} and 1175 cm^{-1}. It gave no positive reaction with a potassium permanganate solution and bromine water for a double bond; it was not suggested that II had a double bond.

The nuclear magnetic resonance spectrum of II is shown in Fig. 1. The four strong signals, at 8.90, 8.96, 9.45 and 8.52 τ., correspond to the four methyl groups. The quartet signal at 5.30 is presumably due to protons on the ethearic ring (AB type, $-O-CH_2-O-$). The multiplet signal at 6.0~6.7 τ is due to the ABX-type spectrum caused by two non-



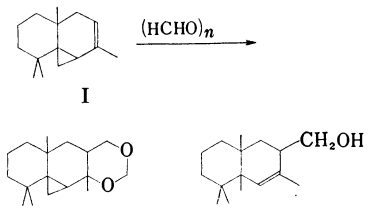


Fig. 1. The nuclear magnetic resonance spectrum of II.

I II III

equivalent protons of $-\overset{|}{C}H-CH_2-O-$.[2] The infrared spectrum exhibits the absorptions at 1000 cm^{-1} and 3050 cm^{-1} which have been reported to be characteristic of the cyclopropane ring.[3,4] The nuclear magnetic resonance spectrum shows the signal of the methylene group of the cyclopropane ring at 9.3 τ. The substance gave a pale yellow color reaction with tetranitromethane, which also indicated the presence of a cyclopropane ring.[5,6] The hydration of II gave an oily product, and the infrared absorption spectrum of this product did not indicate the absorption of the cyclopropane ring at 1000 cm^{-1} and 3050 cm^{-1}. These results indicated that the structure was 1, 3, 5, 6, 7, 8, 9, 9_a-octahydro-4_a, 5, 5, 8_a-tetramethyl-10,10_a-methano-2,4-dioxaanthracene (II).

The structure of the minor product included III. It was demonstrated as follows: the infrared absorption spectrum and gas chromatogram of the substance agreed with those of the authentic III which was prepared from the thermal condensation of I with formaldehyde.

Experimental

The Reaction of Thujopsene with Formaldehyde. —To a mixture of 60 g. of paraformaldehyde, 500 g. of glacial acetic acid and 60 g. of isopropyl ether, 300 g. of thujopsene was added at 60~70°C while the mixture was being vigorously agitated. After the completion of the addition, the mixture

was heated at 60°C while being stirred for an additional 7 hr. The reaction mixture was then dissolved in ether, and the resultant solution was washed with water. The distillation of this solution gave the following fraction: 317 g., b. p. 100~185°C/3 mmHg. The redistillation of this product (250 g.) gave 73 g. of thujopsene (b. p. 102°C/3 mmHg) and the residue (136 g.). The residue was dissolved in acetone, and 44 g. of white polymer was removed to give 92 g. of the clear oil. The liquid chromatography of this oil (15 g.) with silica gel (100 g.) gave 3 g. of viscous II from the elution of benzene; b. p. 154°C/6 mmHg, n_D^{14} 1.5189. It did not give the positive reaction with potassium permanganate and bromine solution for a double bond. It was not hydrogenated over a nickel catalyst under high pressure (40 kg./cm^2) and at a high temperature (120°C). II gave a pale yellow color reaction with tetranitromethane.

Found: C, 77.27; H, 10.43. Calcd. for $C_{17}H_{28}O_2$: C, 77.22; H, 10.67%.

III was given from the elution of methanol. Its nature was confirmed comparing its infrared absorption spectrum and gas chromatogram with those of an authentic sample.

From the elution of benzene and methanol, an ethearic compound was obtained; its structure has not yet, however, been determined.

The Hydration of II.—A mixture of 1 g. of II and 100 cc. of 10% sulfuric acid was agitated at 10~15°C for 10 hr. It was then extracted with ether. When the etheric solution was treated as usual, a small amount of a viscous oil was given. The infrared absorption spectrum did not show the absorptions of the cyclopropane ring at 1000 cm^{-1} and 3050 cm^{-1}.

The authors are indebted to the Takasago Perfumary Co., Ltd., for providing materials, and Dr. Sho Ito of Tohoku University and Dr. Atsuaki Arai of the Kobayashi Institute of Physical Research for the nuclear magnetic resonance spectra.

Asymmetric Hydrogenation with Modified Raney Nickel. III. Studies of the Modified Hydrogenation Catalyst. IV

By Susumu TATSUMI, Masami IMAIDA, Yoshio FUKUDA
Yoshiharu IZUMI and Shiro AKABORI

(Received January 13, 1964)

The asymmetric hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate has been achieved by the use of a R-Ni* catalyst modified with optically active 2-amino or 2-hydroxycarboxylic acids, and it has been found that the asymmetric activity of the catalyst is much influenced by the pH and by the temperature of the modifying solution.[1,2]

In the present investigation, optically-active 2-hydroxycarboxylic acids prepared from L-valine, L-leucine, L-isoleucine and L-phenylalanine were tested as modifying reagents and compared with the parent amino acids.

The modifying effects of diacetyl-D-tartaric acid and monobenzoyl-D-tartaric acid were also tested to study the mode of asymmetric modification.

Materials

Modifying Reagents. — The L-2-hydroxycarboxylic acids used in this report were prepared from L-2-aminocarboxylic acids by the following common reaction:

$$\mathrm{R\text{-}\overset{*}{C}H\text{-}COOH} \xrightarrow{HNO_2} \mathrm{R\text{-}\overset{*}{C}H\text{-}COOH}$$
$$\quad\;\; \mathrm{NH_2} \qquad\qquad\qquad\quad \mathrm{OH}$$

The absolute configurations of amino acids are believed to be maintained during this reaction, and the 2-hydroxycarboxylic acids obtained must have the same configurations as the parent amino acids.

Thus, L-2-hydroxyisovaleric, L-2-hydroxyisocaproic, L-2-hydroxy-3-methylvaleric and L-2-hydroxy-3-phenylpropionic acids were prepared as described by Winitz.[3] *O,O'*-Diacetyl-D-tartaric acid and *O*-monobenzoyl-D-tartaric acid were prepared according to the directions

* Abbreviation: R-Ni, Raney Nickel.

The melting points and the optical rotations $[\alpha]_D^{20}$ of the L-2-hydroxycarboxylic acids, *O*, *O*'-diacetyl-D-tartaric acid and *O*-monobenzoyl-D-tartaric acid, used in the present work are shown in Table I.

Results and Discussion

The Effect of the pH of the Modifying Solution.—Measurements were made of the asymmetric activities of the catalyst modified at 0°C with solutions of L-2-hydroxyisovaleric acid, L-2-hydroxyisocaproic acid, L-2-hydroxy-3-methylvaleric acid and L-2-hydroxy-3-phenylpropionic acid, the pH of which had been adjusted to specified values; the results are shown in Table II.

TABLE II. EFFECT OF pH OF MODIFYING SOLUTION (AT 0°C)

Modifying reagent	pH of modifying solution	$[\alpha]_D^{20}$ of methyl 3-hydroxybutyrate
L-2-Hydroxyisovaleric acid	2.9	+1.05°
	5.0	+1.09
	10.5	−0.08
L-2-Hydroxyisocaproic acid	2.9	+1.26
	4.0	+0.71
	5.0	+0.82
	6.4	+0.76
	10.5	+0.07
L-2-Hydroxy-3-methylvaleric acid	2.9	+1.48
	5.0	+1.14
	7.4	−0.06
	10.5	−0.08

	4.0	+0.62
	5.0	+0.75
	5.8	+0.13
	7.0	+0.19
	10.5	0

The neutralization curve of L-2-hydroxy-3-phenylpropionic acid, and the asymmetric activities of the catalysts modified at 0°C with solutions of L-2-hydroxy-3-phenylpropionic acid, are shown in Fig. 1.

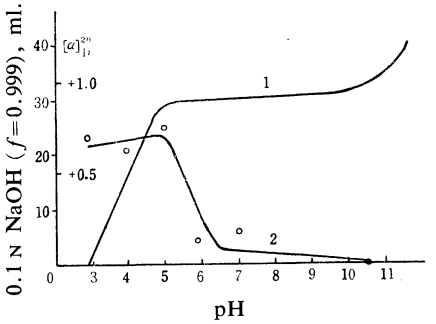

Fig. 1. Effect of pH of L-2-hydroxy-3-phenylpropionic acid solution.
Curve 1, titration curve
Curve 2, asymmetric activity of modified catalyst

With other L-2-hydroxycarboxylic acids, figures similar to those in Fig. 1 are obtained.

Greater asymmetric activities were observed when R-Ni catalysts were treated at pH values below the pH jump of the titration curves of the hydroxycarboxylic acids, as the figure and Table II show. Table II shows that the catalysts modified with L-2-hydroxycarboxylic acids at pH 2.9～10.5, at 0°C, produced dextrorotatory methyl 3-hydroxybutyrate, except for those modified with L-2-hydroxyisovaleric acid at pH 10.5 and with L-2-hydroxy-3-methylvaleric acid above pH 7.4.

The results described above show that L-2-hydroxycarboxylic acids have an asymmetric

8) H. A. Dakin and H. W. Dudley, *J. Biol. Chem.*, **18**, 29 (1914).

effect upon the R-Ni catalyst the reverse of that of the corresponding 2-aminocarboxylic acids. The same relationship has been observed between L-aspartic acid and L-malic acid, as was reported in a previous paper[2].

The difference between 2-amino and 2-hydroxycarboxylic acid can be explained by the difference in the coordination form at the active metallic center of these two series of compounds. Probably the former is tetrahedral and the latter planar, so that stereochemically-different active centers are produced.

The Effect of the Modifying Temperature.—The effect of the temperature of the modifying solution was studied at pH values of 2.9 and 5.0, at 0°C and 70°C. The results are shown in Table III. The catalytic activity of the R-Ni catalyst modified at 100°C was too low to permit any hydrogenation experiments.

Under the conditions shown in Table III, dextrorotatory methyl 3-hydroxybutyrate was formed predominantly on the hydrogenation of methyl acetoacetate.

The catalysts modified at pH 2.9 always showed an increase in their asymmetric activities with an elevation of the modifying temperature. On the other hand, the asymmetric activities of the catalysts modified at pH 5.0 were not always increased by an elevation of the modifying temperature.

TABLE III. EFFECT OF TEMPERATURE OF MODIFYING SOLUTION

Modifying reagent	Modifying conditions pH	Temp., °C	$[\alpha]_D^{20}$ of methyl 3-hydroxybutyrate
L-2-Hydroxyisovaleric acid	2.9	0	+1.05°
	2.9	40	+1.45
	2.9	70	+1.48
	5.0	0	+1.09
	5.0	40	+1.17
	5.0	70	+1.31
L-2-Hydroxyisocaproic acid	2.9	0	+1.26
	2.9	40	+1.27
	2.9	70	+1.54
	5.0	0	+0.82
	5.0	40	+1.12
	5.0	70	+1.01
L-2-Hydroxy-3-methyl-valeric acid	2.9	0	+1.48
	2.9	40	+2.18
	2.9	70	+2.60
	5.0	0	+1.14
	5.0	40	+1.62
	5.0	70	+1.71
L-2-Hydroxy-3-phenyl-propionic acid	2.9	0	+0.70
	2.9	40	+1.03
	2.9	70	+1.08
	5.0	0	+0.75
	5.0	40	+0.86
	5.0	70	+0.47

Modification with *O*-Acylated D-Tatraric Acid.—Catalysts modified with *O*,*O'*-diacetyl-D-tartaric acid and *O*-monobenzoyl-D-tartaric acid were tested for their asymmetric activities in order to study the role of the hydroxy group in the modification of the catalyst.

The effect of the modifying temperature was studied at pH 5.1~5.2, since the catalyst modified at this pH with tartaric acid showed the greatest asymmetric activity, as was reported in a previous paper.[2] The results are shown in Table IV.

TABLE IV. MODIFICATION WITH *O*-ACYLATED D-TARTARIC ACID AND D-TARTARIC ACID SOLUTION

Modifying reagent	Modifying condition pH	Temp. °C	$[\alpha]_D^{20}$ of methyl 3-hydroxybutyrate
Diacetyl-D-tartaric acid	5.1	0	−0.66°
	5.1	50	−0.41
	5.1	100	−0.18
Monobenzoyl-D-tartaric acid	5.2	0	−2.15
	5.1	50	−2.64
	5.2	100	−2.29
D-Tartaric acid[2]	5.1	0	−5.30
	5.2	40	−5.25
	5.2	70	−7.23
	5.2	100	−8.37

The above results show that *O*,*O'*-diacetyl-D-tartaric acid and *O*-monobenzoyl-D-tartaric acid have smaller asymmetric effects upon the R-Ni catalyst than D-tartaric acid.

It is clearly conceivable that the hydroxy group has a certain important role in the asymmetric modification of the R-Ni catalyst, but no reasonable explanation of the effect of acylation on the mode of asymmetric catalytic activity seems possible at present.

Experimental

The Preparation of the R-Ni Catalyst.—The R-Ni catalyst used in the present work was prepared as described in a previous paper.[1]

The Modification of the Catalyst.—The modification of the catalyst was carried out as described in a previous paper.[1] One hundred milliliters of 1% aqueous solutions of each hydroxycarboxylic acid, the pH of which had been adjusted to a specified value with a N sodium hydroxide solution, were added to the newly-prepared R-Ni catalyst; these mixtures were then allowed to stand, with occasional shakings, at a constant temperature for 1.5 hr. After the modifying solution had been removed by decantation, the catalyst was washed with water and then with methanol, and then it was separated by centrifugation.

The Hydrogenation of Methyl Acetoacetate.—Newly-distilled methyl acetoacetate (17.0 g.) was hydrogenated in the presence of the modified R-Ni catalyst prepared from 1.5 g. of alloy. The reaction was run at 60°C under an initial hydrogen pressure of 80~90 kg./cm^2 in a shaking autoclave. The catalyst was filtered off, and the filtrate was distilled under reduced pressure. The main fraction was collected at 61~62°C/12 mmHg.

The Asymmetric Activity of the Catalyst.—The asymmetric activity of the catalyst was measured as described in a previous paper.[1]

Summary

1) The asymmetric activities of R-Ni catalysts modified with L-2-hydroxyisovaleric acid, L-2-hydroxyisocaproic acid, L-2-hydroxy-3-methylvaleric acid and L-2-hydroxy-3-phenylpropionic acid have been compared with those of catalysts modified with the corresponding L-amino acids, which had the same stereochemical configurations.

2) On modification with L-2-hydroxycarboxylic acids, the greatest asymmetric activities are obtained when the catalysts are treated at pH values below the pH jump of the titration curves of the acids.

3) Catalysts modified with L-2-hydroxycarboxylic acids have asymmetric activities the reverse of those modified with L-amino acids with the same configurations.

4) The modifying effects of *O*, *O'*-diacetyl-D-tartaric acid and *O*-monobenzoyl-D-tartaric acid upon the R-Ni catalyst are entirely different from that of D-tartaric acid.

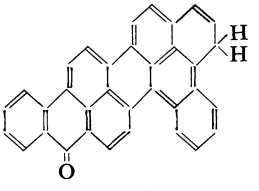
The Paramagnetism of "Violanthrone-B"

By Hideo AKAMATU, Tsuneo MAEKAWA, Yôichi IIDA and Minoru KINOSHITA

(Received January 18, 1964)



Violanthrone (II), a purplish-blue vat dye, is prepared from benzanthrone (I) by alkali fusion in the presence of phenol or sodium acetate. In this process, a dark violet compound is obtained as a by-product. Maki[1] has found that this compound is barely vattable at 65~70°C and slightly soluble in chlorobenzene, while violanthrone is insoluble; he has named this compound "violanthrone-B," as distinguished from the violanthrone which he called "violanthrone-A." He assumed formula III for this compound. However, its formula has not been definitely proven, and an alternative formula (IV) has been suggested by Aoki.[2] According to these proposed formulae, violanthrone-B consists of nine condensed rings with one carbonyl group, and one of its peripheral carbon atoms is attached by two hydrogen atoms, so that it possesses a tetrahedral type of bonding.

In a preliminary experiment, we have found that violanthrone-B is paramagnetic and shows a strong ESR absorption.[3] However, a question remains concerning its spin concentration, which has not been established. The purpose of the present investigation is to verify the paramagnetic nature of this compound. If it is a paramagnetic compound, the semiconductive properties of this compound will be of interest in comparison with those of other condensed polycyclic aromatic compounds.

Material

Violanthrone-B was supplied by Mr. J. Aoki, who prepared it from benzanthrone following the procedure described in Maki's paper[1] with a little modification for the condition of alkali fusion.[2] For the purpose of purification, the sublimation method is not applicable to this compound, for it is not stable enough when heated. It was boiled in glacial acetic acid for 2 hr. and then washed with ethanol. Further purification was made by chromatography. The *o*-dichlorobenzene solution of violanthrone-B was passed through the adsorption column of sodium carbonate anhydride. When the adsorbed layer was washed with the same solvent, it developed into two zones. The zone which traveled faster contained impure components and showed a greenish fluorescence under ultraviolet light. All the procedure was carried out in the dark. The separated solution was concentrated by distillation under reduced pressure, after which violanthrone-B was precipitated by adding ethanol. The absorption spectrum of the violanthrone-B is illustrated in Fig. 1.

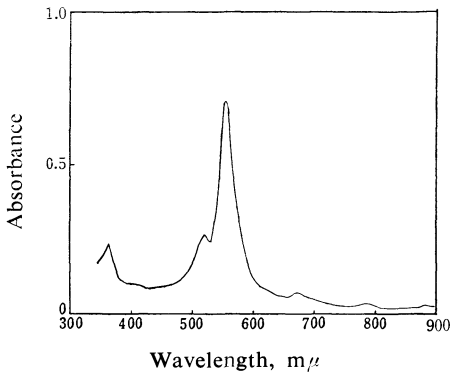

Fig. 1. The absorption spectrum of violanthrone-B in a trichlorobenzene solution.

Magnetic Susceptibility

The magnetic susceptibility of violanthrone-B and its variation with the temperature were measured by the Faraday method. All the measurements were performed under the reduced pressure of 10^{-2}mmHg.

The specific susceptibility was $+0.470\times10^{-6}$ at 259°K and increased with a lowering of the temperature. When the Curie-Weiss law is applied, the susceptibility, χ, can be described by:

$$\chi=\chi_{dia}+\frac{C}{T-\theta} \qquad (1)$$

where the first term, χ_{dia}, is the diamagnetic part of the susceptibility; the second term, the paramagnetic part; T, the absolute temperature, C, the Curie constant, and θ, the Curie point. The diamagnetic susceptibility of violanthrone-B is not known. A large value may be anticipated for a condensed polycyclic aromatic compound because of the contribution of anisotropic diamagnetism. This is ascribed to the non-localized orbitals of π-electrons and depends on the shape and the size of condensed aromatic molecules.[4] It can be said that the skeleton of the violanthrone-B molecule (III or IV) is not much different from that of the violanthrone molecule (II). Violanthrone is diamagnetic, and its molar susceptibility is -247.4×10^{-6}.[5] From this value, corrected by Pascal's rule for the difference in composition, an approximate value for the diamagnetic susceptibility of violanthrone-B was assumed as:

-252.1×10^{-6} for molar susceptibility,

or

-0.572×10^{-6} for specific susceptibility.

Using this value for χ_{dia}, a good linear relationship was obtained when $1/(\chi-\chi_{dia})$ was plotted against T. This is shown in Fig. 2. Hence, the following values were estimated for C and θ:

$$C=0.306\times10^{-3} \text{ emu°K/g.}$$
$$\theta=-45°\text{K}$$

The paramagnetism of violanthrone-B may be associated with the presence of unpaired electrons. As will be discussed in a later section, we assume that some of the violanthrone-B is in the state of a free radical. Therefore, the Curie constant may be given by:

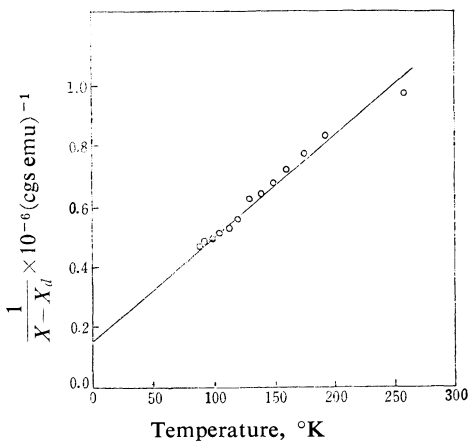

Fig. 2. The temperature dependence for the specific susceptibility of violanthrone-B.

4) H. Akamatu and Y. Matsunaga, This Bulletin, 26, 364 (1953).

5) This value is more plausible than published.[4]

$$C=\frac{Ng^2S(S+1)\beta^2}{3k} \qquad (2)$$

where k is the Boltzmann constant; β, the Bohr magneton; S, the electron spin; $g=2.00$, and N, the number of molecules, each of them possessing an unpaired electron. This gives $N=2.15\times10^{23}$ per mole. This value indicates that about 36 per cent of the molecules possess unpaired electrons.

ESR Absorption

The experiments of ESR absorption were performed at a frequency of 9400 Mc. sec^{-1} in association with a Hitachi MPS-1 spectrometer. The violanthrone-B power showed a strong absorption in a vacuum and in air. Its g-value was 2.0041 ± 0.0005, which was determined in comparison with ultramarine ($g=2.0279$). The line width at the half-intensity maximum, $\Delta H_{1/2}$, was 2.32 gauss in a vacuum. It was broadened to 3.88 gauss in air by the oxygen effect.

The spin concentration at room temperature was determined by a comparison of the integrated ESR absorption with that of a standard sample. A sample of α,α-diphenyl-β-picrylhydrazyl (DPPH) was employed as the standard sample. For this purpose, the spin concentration of the DPPH had to be known. This was determined from the magnetic susceptibility and its variation with the temperature. The Curie point of DPPH has been reported as $\theta=-17°K$.[6] Using this value, when the observed susceptibility was plotted against $1/(T-\theta)$, a good linear relationship was found in the temperature range of 80~260°K. Hence, the Curie constant for the DPPH was estimated as $C=0.857\times10^{-3}$ emu°K/g., and the diamagnetic susceptibility as $\chi_{dia}=-0.533\times10^{-6}$ emu/g. (or -210×10^{-6} emu/mol.). Equation 2 can be applied to its Curie constant. This gives the spin concentration $N=5.42\times10^{23}$ per mole. Thus, our sample of DPPH contained free radicals of 90.3 per cent of all the moles.[7]

In practice, a subsidiary standard sample was used. This was a sample of "crude" violanthrone,[8] the spin concentration of which was determined in comparison with the standard DPPH.

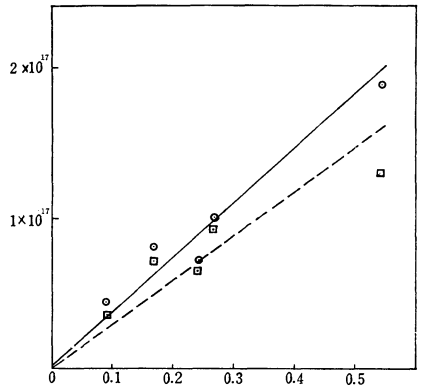

Fig. 3. The number of unpaired electrons in violanthrone-B.
⊙—— in vacuo, ⊡- - - in air

The number of spins of violanthrone-B was measured in air and in a vacuum for the same specimen. The results are shown in Fig. 3. The spin concentration was estimated as 4.9×10^{20} per g. in air and 5.9×10^{20} per g. in vacuum. When we assume that a spin center is a molecule which possesses an unpaired electron, the number of such molecules will be 35.7 per cent of the total molecules in air, and 42.7 per cent of those in a vacuum. A slightly larger value was thus observed in a vacuum than in air. However, the difference is so small as to be within the range of experimental error; thus one can say that the air has essentially no effect on the spin concentration. On the average, the molecules of 39 per cent of the total molecules possess unpaired electrons.

In some cases, the spin population of a solid material increases when the material is ground. In such a case, one can assume a spin center which is ascribed to a trapped electron at a crystal defect. This was not the case with violanthrone-B. For violanthrone-B, when it was ground in an agate-mortar to a fine powder, the line width increased to 5.3 gauss in air, but no appreciable change in the spin concentration has been found.

Furthermore, the ESR-absorption of the violanthrone-B was observed in a dilute solution in trichlorobenzene (0.1 mg. per 1.). Although the hyperfine structure could not be resolved, the absorption line spread into a broad one, the over-all width of which was about 30 gauss.

6) J. Turkevich and P. Selwood, *J. Am. Chem. Soc.*, 63, 1077 (1941); W. Duffy, Jr., *J. Chem. Phys.*, 36, 490 (1962).

7) The purity of the DPPH was determined on the basis of its paramagnetism. Alternatively, spectroscopy can be used for the same purpose. For a chloroform solution of the same sample, the absorbance at absorption maximum (532.5 mμ) gave the extinction coefficient $\varepsilon=30.9\,g^{-1}l.\,cm^{-1}$ for DPPH, after correction had been made for the free radical content as determined from its magnetic susceptibility. The value of $32.3\,g^{-1}l.\,cm^{-1}$ for chemically-pure DPPH has been reported by J. A. Lyons and W. F. Watson [*J. Poly. Sci.*, 18, 141 (1955).].

8) The ESR absorption of violanthrone was reported by Y. Yokozawa and I. Tatsuzaki [*J. Chem. Phys.*, 22, 2087 (1954)]. It has been found, however, that the spin concentration of this substance decreased progressively when it was purified repeatedly. Therefore, a large part of the unpaired spins in "crude" violanthrone seem due to the presence of an impurity. The most probable impurity is violanthrone-B.

After the solution had been kept in a cool, dark place for a month, no appreciable change in the signal intensity was found. This indicates that the absorption is due to a fairly stable free radical.

Physico-Chemical Properties

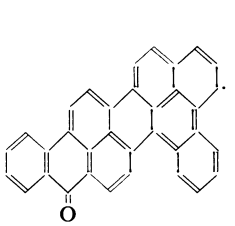
Violanthrone-B is not stable in solution when it is kept in the light. Its *o*-dichlorobenzene solution gradually lost its deep violet color when it was illuminated with ultraviolet light from a mercury lamp. It was also found that the spectroscopic concentration of violanthrone-B decreased rapidly. In this process, a black substance precipitated, and a benzene-soluble product was obtained. Neither part of the products showed any appreciable ESR absorption.

It is well known that, in a polymerization reaction, a stable free radical, for instance DPPH, can terminate the chain propagation. The effect of violanthrone-B on the thermal polymerization of stylene at 80~100°C was examined in comparison with that of DPPH. The rate of polymerization was measured qualitatively by the increase of viscosity. It was remarkably supressed when stylene contained violanthrone-B or DPPH in a concentration of one milligram per 100 cc. The color of both solutions was deep violet at the beginning, but it changed to orange for the violanthrone-B solution and to colorless for the DPPH solution as the polymerization reaction proceeded. It was concluded that violanthrone-B inhibited the thermal polymerization of stylene even more strongly than did DPPH.

Semiconductivity

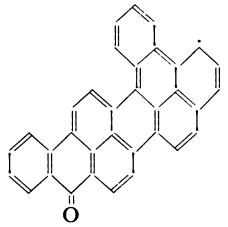
The electrical resistivity of violanthrone-B and its variation when temperature ranges from 10 to 160°C were examined with the DC method. The measurements were performed with the sample powder under a compression of 80 kg. per cm^2 between brass electrodes in a quartz cylinder. A good linear relationship was obtained when the logarithm of the resistivity was plotted against the reciprocal of the absolute temperature. Hence, the resistivity (ρ) was described by:

$$\rho = \rho_0 \exp(E/\boldsymbol{k}T) \qquad (3)$$



where E, the activation energy for conduction, was 0.34 ± 0.01 eV. and ρ_0 was 8.5 ohm. cm; the resistivity at room temperature was $\rho_{15°} = 6.9 \times 10^6$ ohm. cm. These data should be compared with those for violanthrone: $E = 0.39_5$ eV., $\rho_0 = 1.6 \times 10^4$ ohm. cm. and $\rho_{15°} = 1.1 \times 10^{11}$ ohm. cm.

Discussion



Polycyclic aromatics give often a signal of ESR absorption. The origin of spin centers is not known. Usually these signals are weak and are considered to be due to impurities which could be produced incidentally in synthetic processes. In such cases, the signal decreases as the sample is purified repeatedly. However, this was not the case with violanthrone-B. The crude sample of violanthrone-B gave an absorption with a broad line width. When it was purified by chromatography, the line width became narrower and the integrated intensity increased.

There are many reasons to believe that the observed paramagnetism for violanthrone-B is of a free radical. The g-value observed, 2.0041, is similar to those of many organic free radicals. The absorption line width is as narrow as 2.32 gauss, as is characteristic of crystalline-stable free radicals. The same can be said for the relatively high negative Curie point of $-45°K$.[6] The ESR absorption is observable in a dilute solution; this implies that a spin center exists on a molecule. Furthermore, the physico-chemical behavior also suggests the free radical nature of violanthrone-B.

If the observed paramagnetism is a property of violanthrone-B, instead of the structure III or IV, $C_{34}H_{18}O$, the structure V or VI, $C_{34}H_{17}O$, can be assumed as the most plausible one to explain its free radical nature. The tetrahedral bonding in the former structures is replaced by a trigonal bonding in the latter structures, in which the unpaired electron will be delocalized and in which it will be stabilized by some delocalization energy.

(V)

(VI)

Assuming the free radical $C_{34}H_{17}O$, its concentration was estimated from the spin concentration which was observed to be 39 per cent of all the moles. This value coincides with the result of magnetic susceptibility measurements. Hence, although not all the molecules are free radicals, two out of five molecules are. Thus, violanthrone-B might be a mixture of $C_{34}H_{18}O$ and $C_{34}H_{17}O$.

It is uncertain that these two species are in

a chemical equilibrium:

$$C_{34}H_{18}O = C_{34}H_{17}O + \frac{1}{2}H_2$$

However, the free radical may be produced by such a dissociation process. Thus, violanthrone-B behaves as if it were a free radical.

There remain a few points to be discussed. There is no direct proof for the proposed structure, V or VI. Hoping to derive information from the infrared absorption spectrum, we examined it by the KBr-disk technique. The stretching vibration of C=O of violanthrone-B is of particular interest in comparison with that of violanthrone. For violanthrone the absorption peak due to the C=O stretching was observed at 1642 cm^{-1}, while for the violanthrone-B two peaks were observed, at 1619 cm^{-1} and 1643 cm^{-1}, in the same region of frequency. The latter peak coincides with that of violanthrone and may be ascribed to the C=O stretching of $C_{34}H_{18}O$. The peak at 1619 cm^{-1}, which fairly shifts to the low-wave number side, might be due to the C=O stretching of $C_{34}H_{17}O$; this implies somewhat of a reduction of the bond order, which can result from the contribution of the structure of $\geqslant C-\dot{O}$ because of the delocalization of the unpaired electron.

Usually the sharp line width of ESR absorption is ascribed to the narrowing that occurs when electrons are exchanged between the orbitals of different molecules. The line width of violanthrone-B was as narrow as 2.32 gauss, which is comparable with that of DPPH, 2.4 gauss.[9] In this case, however, not all the molecules are free radicals; only two out of five molecules have unpaired spins, and they still showed the effect of exchange interaction.

The semiconductive property of violanthrone-B may be interestingly compared with that of violanthrone, as the molecules of these two compounds have nearly the same shape and size, even though the former has a free radical character. Eley[10] has proposed a potential box model to describe the semiconductive properties of organic solids. This model, assuming the tunnel effect for electron transfer between molecules, indicated that a solid free radical would behave as a semiconductor, with a very small or zero energy gap ($\varepsilon = 2E$). The small value of the activation energy of DPPH (0.13 eV.) was interpreted by means of this model. This theory can not be strictly applied to violanthrone-B, as it contains free radicals only partially. Nevertheless, it is noteworthy that no apprecible difference in the activation energy between violanthrone-B and violanthrone could be found. On the other hand, the electrical conductivity of violanthrone-B is improved more than 10^4 times at room temperature as compared with that of violanthrone. The higher conductivity of violanthrone-B may be ascribed to its free radical character. However, the mechanism for the contribution of unpaired electrons to the conduction still remains in question.

Summary

The paramagnetic nature of "violanthrone-B" has been studied. The spin concentration in this substance has been determined by the ESR absorption, which is consistent with the value estimated from the magnetic susceptibility and its variation with the temperature. It has been concluded that the molecules of violanthrone-B, in the amount of about 40 per cent of all the molecules, are in a free radical state. It has been suggested, according to the proposed structure of violanthrone-B, that the free radical might result from detaching a hydrogen atom from a peripheral carbon of the tetrahedral type of bonding, which changes thereafter to the trigonal type of bonding.

The authors wish to express their thanks to Mr. Junji Aoki, who prepared the sample of violanthrone-B, and to Dr. Chizuko Tanaka, who examined the infrared absorption spectra of violanthrone and violanthrone-B.

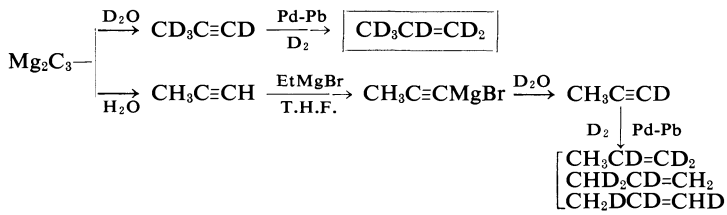
*The Synthesis of Deuterated Polypropylenes**

By Shunsuke MURAHASHI, Shun'ichi NOZAKURA and Katsutoshi YASUFUKU

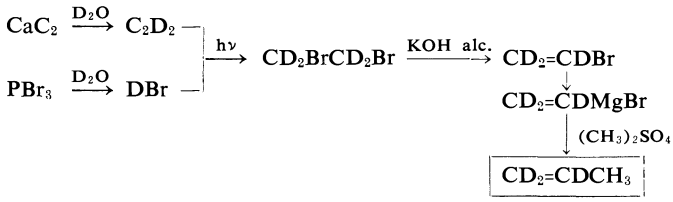
(Received January 18, 1964)

The deuteration of polymers is a useful method for the structural study of high polymers. In previous papers,[1] the authors reported the infrared spectroscopic study of deuterated polystyrenes and were led to the conclusion that some of infrared crystalline sensitive bands observed in isotactic polystyrene originate from the helical structure of the polymer.



The structure of isotactic polypropylene is being investigated extensively by many authors using infrared spectra of deuterated polymers. Propylene-*cis*-1-d_1, -*trans*-1-d_1,[2] -1, 1-d_2, -2-d_1,[3,4] -3, 3, 3-d_3,[4] and -3-d_1,[5] have hitherto been prepared, and the infrared spectra of their polymers have been discussed.

In the present paper, for the purpose of an infrared spectroscopic study of isotactic polypropylene, the authors carried out the preparation and polymerization of propylene-1, 1, 2-d_3 and -d_6. A recent note by Liang and Lytton[6] on polypropylene-d_6 prompted the present authors to report on the syntheses of the two polymers and on interesting information obtained from the copolymerization of the monomers. A more detailed study of infrared spectra of the polymers will be published elsewhere.



Results and Discussion

Propylene-d_6 was prepared by the half-reduction of deuterated propyne, which had been obtained from the hydrolysis of magnesium carbide (method 1) with deuterium oxide. Method 1 was proved unsuitable for the preparation of propylene-1, 1, 2-d_3. It was, however, successfully prepared by the reaction of deuterated vinyl magnesium bromide (method 2). Methods 3 and 4 were also tried. However, method 3 gave a very low overall yield in preliminary runs, while method 4 gave an impure propyl alcohol which was found rather difficult to purify and so was felt unsuitable for the synthesis of the pure end product.

Propylene-d_6.—Magnesium carbide is the only carbide which gives C_3-acetylenic hydrocarbon on hydrolysis.[7] The preparation of propyne-d_4 from magnesium carbide was reported by Leitch.[8] Using the method of Novak,[7] magnesium carbide was prepared by the reaction of

magnesium metal and *n*-pentane at 680±20°C. Hydrolysis of the carbide with deuterium oxide gave crude propyne-d_4, which contained allene (11.2%) and acetylene (0.4%) as by-products. Acetylene was removed from the crude product by repeated distillation. The propyne, which still contained allene, was used in subsequent hydrogenation without further purification. The degree of the deuteration of propyne was estimated by mass spectrographic analysis to be 88.5%. The product was then deuterated over a Lindlar catalyst to propylene-d_6, which was found to contain a considerable amount of propane-d_8 (15.7%) and the unreacted propyne-d_4 (6.0%) the latter being removed as mercuric salt. The propylene, which still contained propane, was used for the polymerization without further purification, since the existence of propane does not impair the succeeding polymerization or the resulting polymer. The degree of the deuteration of propane-d_8 was found to be 78.7% by mass spectrography, and so that of propylene-d_6 could be estimated to be around 82%.

Method 1 was found to be unsuitable for the synthesis of propylene-1, 1, 2-d_3. Propyne-1-d_1, which was obtained by the hydrolysis of propynyl magnesium bromide with deuterium oxide, was found to be highly deuterated, showing no ≡C–H stretching band at 3300 cm^{-1} and a strong ≡C–D stretching absorption at 2550 cm^{-1} in the infrared spectrum (Fig. 1). After the half-reduction with deuterium, however, the product showed a weak absorption at 3060 cm^{-1}, indicating the presence of $=CH_2$ and/or =CHD. Furthermore, a polymer obtained from this product showed a $-CH_2-$ stretching absorption at 2836 cm^{-1}, the inten-

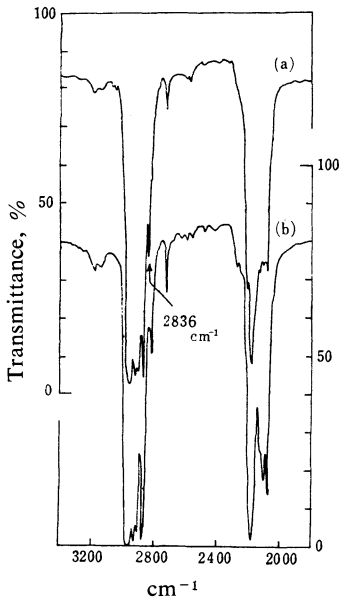

Fig. 2. IR spectra of isotactic polypropylene-1,1,2-d_3, (a) prepared by method 1 and (b) by method 2.

sity of which suggests the existence of more than 15% $-CH_2-$ units in total methylene units (Fig. 2). This unexpectedly high $=CH_2$ group content suggests that there is an equilibrium between propyne and allene on the surface of the Lindlar catalyst. The equilibrium concentration of allene at 100°C is known to be about 14%,[9] and allene is known to be more rapidly hydrogenated than propyne.[10] The observed values of more than 15% $-CH_2-$ in the polymer mentioned above indicates the existence of more than 30% allene in the mixture with propyne. Therefore, allene should have been supplied continuously by the isomerization of propyne during hydrogenation.

Propylene-1, 1, 2-d_3.—Propylene-1, 1, 2-d_3 was successfully prepared by method 2 starting from calcium carbide. The yield of the dedeuterobromination product of deutero-dibromoethane was found to be rather low (30%) compared with the yield of more than 70% in the case of the dehydrobromination of dibromoethane. The yield in the former case could not be improved by various modifications of reaction conditions. This may be explained as follows: The reaction can be considered competitive between an elimination and a substitution reaction. It is known that the substitution reaction is usually accelerated by the deuteration of the substrate ($k_D/k_H = \sim 1.1$),[11] while the elimination reaction is retarded ($k_D/k_H = 1/4 \sim 1/6$).[12] The observed isotope effect in the yield of vinyl bromide, therefore, may be the result of the composite effect of two competing reactions.

The reaction of deuterated vinyl magnesium bromide with dimethyl sulfate gave propylene-1, 1, 2-d_3 in a good yield. The impurity was found by gas chromatography to consist of very small amounts of ethane and butadiene. Since butadiene was expected to be objectionable in the preparation of the pure polymer, it was removed by repeated distillation. The degree of the deuteration of the propylene-1, 1, 2-d_3 thus prepared was estimated to be fairly high from the fact that its infrared absorption spectrum did not show any of the characteristic absorptions which are ascribed to the other partially-deuterated propylenes[13] (Fig. 3). A notable difference of between the infrared spectrum and those of the other deuteropropylenes is found in the position of the stretching mode of the C=C double bond. Propylene-1, 1, 2-d_3 shows the absorption at 1604 cm^{-1}, while propylene, propylene-2-d_1, -1, 1-d_2, and -d_6 show it at 1651, 1613, 1612 and 1587 cm^{-1} respectively.[14]

Polymerization.—The deuterated propylenes obtained above were polymerized to isotactic polymers with a Ziegler-Natta catalyst. The results are shown in Table I, while infrared spectra of the polymers are presented in Fig. 4.

The Infrared Characteristics of Copolymer.—An interesting fact was observed in the infrared spectrum of the copolymer of propylene-

1,1,2-d_3 and propylene. The isotactic copolymer is compared with an artificial mixture of the isotactic homopolymers of these two monomers in Fig. 5. An X-ray examination of the copolymer specimen showed the same order of crystallinity as those of the homopolymers. However, the infrared spectrum of the copolymer is quite dfferent from that of the artificial mixture. The crystalline sensitive bands (shown by arrows in Fig. 5) of polypropylene exist in the spectrum of the artificial mixture, but they do not exist or diminish in that of the copolymer. This suggests that the occurrence of crystalline-sensitive bands in isotactic polypropylene is not due to intermolecular interaction but to intramolecular interaction, as in the case of isotactic polystyrene.[1] If the crystalline-sensitive bands were originated from intermolecular interaction, they would disappear, or at least diminish, in the case of the artificial mixture too. The fact also suggests a random distribution of the deuterated monomer units along a polymer chain, resulting in the complete disturbance of the original intrachain interaction.

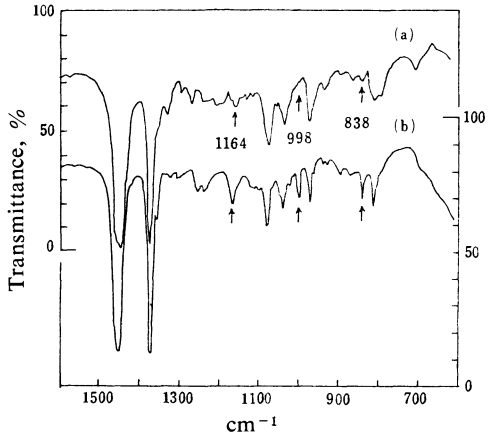

Fig. 5. IR spectra of isotactic propylene-propylene-1,1,2-d_3 copolymer (a), and an artificial mixture of the two homopolymers having the same composition (b). Arrows show the crystalline sensitive bands of the isotactic polypropylene.

Experimental

Mg_2C_3.—Magnesium carbide was prepared by the method of Novak.[7] The vapor of pentane (100 cc.) with a stream of hydrogen was brought into contact with magnesium powder (20 g.) at 680±20°C for 6 hr., yielding 27 g. of the dark gray carbide covered with black carbon powder. On hydrolysis the carbide (20 g.) evolved a gas which was condensed by a dry ice-acetone trap to 14 ml. (−78°C) of liquid products. The gas was found by gas chromatography (1m. silica gel column, 100°C) to be composed of 89.2% propyne, 10.4% allene and 0.4% acetylene.

Propyne-1, 3, 3, 3, d_4.—In a 100 ml. three-necked flask equipped with a stirrer, a condenser and a dropping funnel, magnesium carbide (20 g.) was placed suspended in 50 ml. of dry dioxane. The top of the condenser was connected to a trap kept at about −20°C and then to a collecting trap cooled in dry ice-acetone. Deuterium oxide (26 g., 99.65% purity) was added drop by drop to magnesium carbide at room temperature, yielding 12 ml. (−78°C) of a liquid product. The product was found by gas chromatography to contain 88.4% deuterated propyne, 11.2% deuterated allene and 0.4% deuterated acetylene. In order to remove acetylene, the product was evaporated at about −25°C and condensed at −78°C. Evaporation and

condensation was repeated several times until no acetylene was detected by gas chromatography. The degree of deuteration of the C_3D_4 mixture was found to be 88.5% by mass spectrography.

Propyne-1-d_1.—A mixture of propyne and allene was obtained by the hydrolysis of magnesium carbide with water, and it was freed from acetylene in a manner similar to that mentioned above. The mixture was passed through a solution of ethyl magnesium bromide in tetrahydrofuran, and the unreacted component, allene, was swept by a stream of dry nitrogen while the solution was being refluxed. The tetrahydrofuran solution of propynyl magnesium bromide thus obtained was hydrolyzed by a solution of deuterium oxide (15 g.) in tetrahydrofuran, yielding 14 ml. (−78°C) of propyne-1-d_1. A trace of impurity, ethane-1-d_1, was removed by repeated distillation. The infrared spectrum of the product showed no absorptoin at 3300 cm^{-1}.

Propylene-d_6.—The Lindlar catalyst was prepared as follows. Palladium chloride was dissolved in dilute hydrochloric acid and then absorbed on pumice[10] (Pd/pumice=1/100) by evaporating the solvent. The supported palladium chloride (10 g.) was reduced in a stream of hydrogen at 300°C, and then the cooled catalyst was poisoned by treating it with an aqueous solution of 0.34 g. $Pb(OAc)_4 \cdot 3H_2O$. Propyne-1, 3, 3, 3-d_4 (12 ml. of a liquid at −78°C) was reduced in the stream of deuterium at a flow ratio of $CD_3C{\equiv}CD/D_2=1.2$ at 60～90°C over 8 g. of the Lindlar catalyst. The catalyst had been pretreated by deuterium three times at 70°C in vacuo before use. The product was 6 ml. (at −78°C) of a liquid, which was found to be composed of 15.7% deuterated propane, 78.7% propylene and 6.0% unreacted propyne. The crude product was freed from propyne by treatment with a mixed solution of mercuric iodide (0.4 g.), potassium iodide (0.5 g.), potassium hydroxide (0.3 g.) and water (3 ml.) in a pressure-glass bottle at room temperature. The final product was found to be composed of 14.7% propane-d_8 and 85.3% propylene-d_6. The degree of the deuteration of propane-d_8 was found to be 78.7% by mass spectrography. That of propylene-d_6 could not be measured directly from a mass spectrum, but it may be estimated at 82% if we assume that the same order of impurity was introduced at each step of the reduction.

Dibromoethane-d_4.—Acetylene-d_2, deuterium bromide and dibromoethane-d_4 were prepared by the method of Leitch.[15] The yield of acetylene-d_2 was 75% and that of deuterium bromide was 94% based on deuterium oxide. Dibromoethane-d_4 was obtained by photochemical addition reaction in a vacuum system. The crude product was washed with a dilute aqueous solution of potassium carbonate, dried with sodium sulfate, and distilled; b. p. 128～129°C. The yield was 93% from acetylene.

Vinyl-bromide-d_3.—In a 500 ml. three-necked flask equipped with a stirrer, a Dimroth condenser cooled at 20°C and a dropping funnel, a mixture of 120 ml. of water, 200 ml. of ethanol and 20 g. of potassium hydroxide was placed. Dibromoethane-d_4 (80 g.) was stirred into the mixture at 50°C. Vinyl-bromide-d_3 gas was evolved gradually for 2 hr. and was then condensed in a cold trap. The crude product was dried over calcium chloride overnight and then distilled through a Vigreux column, yielding 14.1 g. of the product (31%) (b.p. 17.3°C).

Propylene-1, 1, 2-d_3.—In a 200 ml. two-necked flask equipped with a magnetic stirrer, a dropping funnel, and a reflux condenser with a gas outlet tube, a dioxane solution of vinyl magnesium bromide-d_3 was prepared under nitrogen from magnesium (2.92 g.) vinyl-bromide-d_3 (12.9 g.), and tetrahydrofuran (50 ml.). The content of the flask was degassed twice and covered with nitrogen. The outlet tube was connected with a trap kept at −20°C and then with a trap cooled at −78°C. Then, 15.2 g. of dimethyl sulfate dissolved in 10 ml. of tetrahydrofuran was vigorously stirred in at room temperature over a one-hour period and heating was continued for an additional two hours. The evolved gaseous product was condensed in the second trap. The yield was 70% (6 ml. at −78°C). The product was found to contain small amounts of ethane and butadiene, which were removed by repeated distillation.

Polymerization.—Polymerizations were carried out in glass pressure tubes. The monomer was charged in vacuo into the tube in which Ziegler-Natta catalyst had previously been prepared, and it was polymerized with occasional shaking at 60°C. The polymerization was quenched by the addition of a methanol-concentrated hydrochloric acid mixture. The precipitated polymer was washed with methanol and dried in vacuo. The atactic part of the polymer was removed by extraction with boiling heptane for 10 hr.

Copolymerization.—Propylene-1, 1, 2-d_3 (0.526 g.) and propylene (0.415 g.) were charged and weighed successively. The mixture of the monomers was transferred by vacuum technique to the polymerization tube containing the catalyst and polymerized for 5.3 hr.

Artificial Mixture.—A mixture of isotactic polypropylene-1, 1, 2-d_3 and isotactic polypropylene was dissolved in toluene at 130°C and precipitated by pouring the hot solution into methanol.

Summary

The synthesis of propylene-d_6 and propylene-1, 1, 2-d_3 has been attempted for the purpose of an infrared spectroscopic study of the isotactic polymers.

Propylene-d_6 has been synthesized by the half-deuteration of the propyne-d_4 which had been obtained by the hydrolysis of magnesium carbide with deuterium oxide, and propylene-1, 1, 2-d_3 has been synthesized by the reaction of deuterovinyl magnesium bromide and dimethyl sulfate. In the half-reduction of propyne-d_1 with a Lindlar catalyst, it was found that an equilibrium between propyne-1-d_1 and allene-1-d_1 exists on the catalyst.

The polymerization of these monomers was carried out with a Ziegler-Natta catalyst, and

15) L. C. Leitch and A. T. Morse, *Can. J. Chem.*, **30**, 924 (1952).

isotactic polymers were obtained. In the copolymerization of propylene and propylene-1,1,2-d_3 with a Ziegler-Natta catalyst, it was observed that some of the infrared crystalline sensitive bands of isotactic polypropylene, 1164, 998 and 838 cm^{-1}, do not exist (or at least diminish) in the copolymer but do exist in artificial mixtures of the homopolymers. This fact evidently suggests that these infrared bands are due to an intrachain interaction in the crystalline part of the polymer.

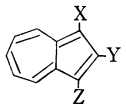
The Synthesis of S-Guaiazulene from Hinokitiol

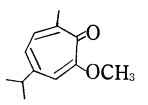


By Yoshio KITAHARA and Tadahiro KATO

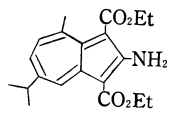
(Received January 30, 1964)

In recent years, a marvelous method of synthesizing azulenes have been developed by Nozoe and his co-workers.[1,2] This method is based on the reaction of tropolone methyl ether (1: X=OCH_3) or 2-halotropones (1: X=Cl, Br) with malononitrile or ethyl cyanoacetate in the presence of sodium methoxide, and it is particularly useful for the synthesis of azulenes (2) having substituents (X, Y and Z) at their 1-, 2- and 3-positions.

(1)



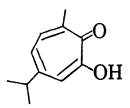
(2)



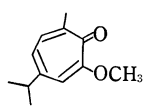
Thus, a number of azulene derivatives of this type were obtained and examined for their properties. Azulene itself (2: X, Y and Z=H) was successfully derived, by the same authors, from 1,3-dicarboethoxy-2-aminoazulene (2: X and Z=CO_2Et, Y=NH_2), which might be recorded as one of the important azulene syntheses.

The syntheses of natural azulenes from tropolones by the above method have, however, so far been unsuccessful.

It was reported,[3] for instance, that in the reaction of 2-methoxy-4-isopropyl-7-methyltropone (3) and cyano ethyl acetate under similar conditions, the formation of an azulene nucleus (4) was impossible because of the steric interference of the methyl group at the 7 position.

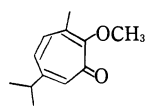


(3)



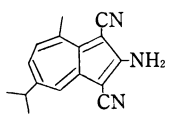
(4)

We tried to synthesize *S*-guaiazulene from hinokitiol although this compound had already been synthesized by Plattner and his coworkers.[4]

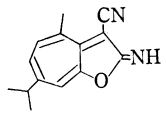


3-Methyl-6-isopropyltropolone (I)[5] gives its methyl ether almost quantitatively by reaction with diazomethane. This methyl ether is assumed to be a mixture of IIa and IIb, which are possible isomers to each other.

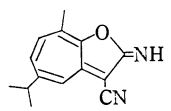
(I)



(IIa)



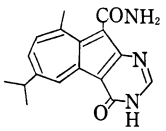
(IIb)



1,3-Dicyano-2-aminoazulene derivative III was obtained in a 48% yield by the addition of malononitrile directly to the mixture of IIa and IIb in the presence of sodium methoxide. In this reaction a small amount of a compound (m. p. 140°C) corresponding to IVa or IVb was isolated.

(III)

(IVa)



(IVb)

It is known that cyano groups at the 1 and

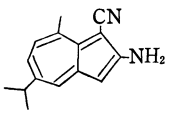
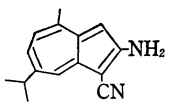
3 positions of the azulene nucleus are generally very stable and resist hydrolysis in acids and alkalis.[6-8] However, when III was heated in a mixture of concentrated sulfuric acid and formic acid, it gave a red crystalline compound, the infrared spectrum of which indicates the absence of a cyano group and which has multiple bands in the 3100~3400 cm^{-1} region which are more complicated than those of III. This suggests the presence of a carbamoyl group.

This compound is deduced to have the structure Va from the results of micro analysis and from its behavior with relation to bases (it does not dissolve in a sodium bicarbonate solution although it does dissolve in a 2 N solution of sodium hydroxide, and the original substance is recovered on acidification).



(Va)



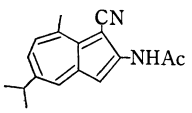
(Vb)

An attribution of the structure Vb to this compound is also possible, but, as will be mentioned later, the cyano group at the 1 position is more apt to be hydrolyzed than the other one. Therefore, Va rather than Vb seems to be more probable for this compound.

When III was heated in concentrated sulfuric acid for a considerable period, it blackened, evolving sulfur dioxide gas, and did not afford any clear product. However, when III was heated in 100% phosphoric acid[9] at 100°C, it gradually generated bubbles to yield a red crystalline compound in a 65% yield. Its infrared spectrum has a band of one cyano group (2150 cm^{-1}); its micro analysis data fits either VIa or VIb.

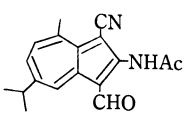
(VIa)

(VIb)



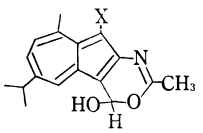
This hydrolysis is considered to proceed through the phosphoric acid ester formed with phosphoric acid and the cyano group. The formation of phosphoric acid ester from the cyano group at the 3-position might be difficult because of the steric interference of the methyl group at the peri position; accordingly, hydrolysis of the cyano group will also become difficult. Therefore, the obtained product is deduced to have the structure VIa. This deduction was finally proved to be true by the synthesis of *S*-guaiazulene from this compound.

We next tried to introduce a formyl group to the 1 position of VIa. It was already known[10] that the 1- and 3-positions of azulenes are easily formylated by the application of the Vilsmeier-Haack reaction.[11]



After the acetylation of the amino group at the 2-position of VIa, the acetylamino compound VII was treated with phosphorous oxychloride-dimethylformamide. Two compounds were produced, m. p. 176°C, and m. p. 232°C (decomp.), in a ratio of almost 3 : 1.

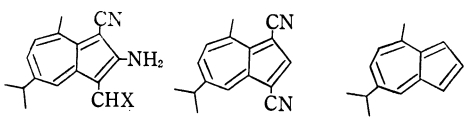
The infrared spectrum of the compound (m. p. 176°C) indicates the presence of a formyl group (2850 and 1626 cm^{-1}), and an acetyl group (1708 cm^{-1}), and the results of its micro analysis are satisfactory for 1-cyano-2-acetylamino-3-formylazulene (VIII). The alkaline hydrolysis of VIII gave X, the formyl group of which reacts easily with hydrazine to give XI.



The red crystalline compound (m. p. 232°C (decomp.)) has the same composition ($C_{18}H_{18}NO_2$) as that of VIII; therefore, it is assumed to be an isomer of VIII. However, its infrared absorption spectrum has the broad band of a hydroxyl group (3450 cm^{-1}) and the band of neither an acetyl group nor of a formyl group. From this infrared spectural date it may be concluded that the compound (m. p. 232°C (decomp.)) would have the structure IX. IX was easily hydrolyzed, when heated with 100% phosphoric acid, producing a red oil (XII):

(VII)

(VIII)



(IX) X=CN
(XII) X=H

In this way, it became clear that the cyano groups at both the 1 and 3 positions, the

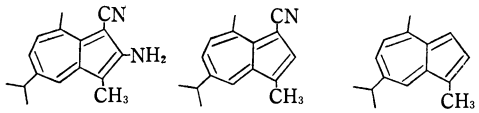
hydrolysis of which has hitherto been regarded as being difficult, could be hydrolyzed using 100% phosphoric acid. Since the yield of IX from VII was so low that it seemed difficult to obtain the last objective *S*-guaiazulene from IX, the preparation of 1, 3-dicyano-4-methyl-7-isopropylazulene (XIII) by the deamination of III, followed by its transformation into 4-methyl-7-isopropylazulene (XIV) was planned.

The diazotization of III is difficult by the usual manner. However, when a concentrated sulfuric acid solution of sodium nitrite was added to a solution of III in concentrated sulfuric acid and formic acid under ice cooling, III was easily diazotized, affording a bright violet solution, which was reductively decomposed, using hypophosphorous acid-copper powder, to give a crystalline compound in a 53% yield. The band of the amino group in the infrared spectrum of this compound disappears, and the ultraviolet absorption spectrum is very similar to that of 1, 3-dicyanoazulene.[12] When heated with phosphoric acid, XIII gave, under an evolution of gas, a small amount of blue oil and a green oil as the main products. The infrared spectrum of the green oil clearly indicates the presence of a hydroxyl group, which suggests that the hydration to the nucleus takes place. XIII can be hydrolyzed neither by sulfuric acid-formic acid nor by alkaline reagents, such as potassium hydroxide and sodium ethoxide, to recover the starting substance XIII. Therefore, the introduction of a methyl group to the 1-position of VIa was tried next.



(X) X=O (XI) X=N·NH$_2$ (XIII) (XIV)

As has been mentioned before, the Vilsmeier reaction of VII produces a mixture of VIII and XI in a low yield; therefore, the above reaction was applied to VIa.

Since it was anticipated[13] that the formyl group at the 1-position of X would be very active in an acidic medium and would form an intermolecular Schiff's base with the amino group at the 2-position, X was directly subjected to Huang-Minlon reduction[14] without isolation and purification. As a result, a red crystalline compound was obtained in a 34% yield calculated from VIa. Its infrared spectrum has a band assigned to the cyano group at 2200 cm^{-1} and several bands at 3220, 3330 and 3450 cm^{-1} assigned to the amino group. The results of its micro analysis also fits the structure XV.

The diazonium salt of XV was reductively decomposed by ethanol, giving, in a 41% yield, a blue compound (m. p. 69~70°C) which is soluble in most organic solvents. The results of its micro analysis are satisfactory for XVI. The melting point, type of crystals, characteristic infrared absorption spectrum, and visible absorption curves of XVI[15] all coincide perfectly with those of 3-cyano-1, 4-dimethyl-7-isopropylazulene, which has already been prepared from *S*-guaiazulene by Stafford et al.[16]

(XV) (XVI) (XVII)

The phosphoric acid hydrolysis of XVI gave a blue oil in a 80% yield.[17] The oil was characterized by means of its trinitrobenzene complex (m. p. 147~148°C) and its picrate (m. p. 116~117°C), which were undepressed upon admixture with authentic samples[18] prepared from natural *S*-guaiazulene XVII. The infrared spectra of this oil and of natural *S*-guaiazulene are entirely identical.

Experimental

3-Methyl-6-isopropyltropolone (I).—To a mixture of hinokitiol (4-isopropyltropolone) (50 g.) and formaline (50 ml.), morpholine (50 ml.) was added. The generation of heat was observed. After being kept at room temperature for 1 hr., the mixture was heated at 60°C for 30 min. and then kept in a refrigerator overnight. 3-Morpholinomethyl-6-isopropyltropolone (m. p. 50°C) was obtained in a more than 90% yield.

The Reduction of 3-Morpholinomethyl-6-isopropyltropolone.—To a palladium chloride solution (30 ml.) prepared by Vogel's method[19] Norit (3 g.) was added; then hydrogen was absorbed to this mixture. When a sodium salt aqueous solution of 3-morpholinomethyl-6-isopropyltropolone (40 g.) was added to the palladium-carbon mixture and catalytically reduced at room temperature, a total of 4.2 l. of hydrogen was absorbed. With the progress of the reduction, sodium salt of the reduction product, 3-methyl-6-isopropyltropolone (I), was deposited.

The first 1 molar equivalent of hydrogen was rapidly absorbed, but the absorption of the second 1 molar equivalent of hydrogen was rather slow; a total of 2 molar equivalents of hydrogen were absorped. In methanol or acidic methanol solutions, however, hydrogen absorption did not stop even after 2 molar equivalents of hydrogen had been absorbed, so the reduction of the tropolone nucleus must have been taken place.

After the hydrogen absorption had ceased, 2 N sodium hydroxide (50 ml.) and water (200 ml.) were added to the reduction mixture, and then the crystals and palladium-carbon were filtered and dissolved in 2 N sulfuric acid. The solution was extracted with chloroform, and palladium-carbon was filtered off. On the other hand, the alkaline filtrate was acidified with 6 N sulfuric acid and extracted with chloroform. The extracts were combined with the former chloroform extracts, washed with water twice, and dried over magnesium sulfate. When the chloroform was removed and the remaining residue distilled under reduced pressure, 3-methyl-6-isopropyltropolone (I) (25.2 g.) was obtained as a yellow oil in a 91.5% yield.

The Tosylation of I. — *p*-Toluenesulfonyl chloride (4.6 g.) was added to a solution of 3-methyl-6-isopropyltropolone (3.65 g.) dissloved in absolute pyridine (10 ml.). After the mixture had been kept overnight and the pyridine removed under reduced pressure, colorless crystals were obtained on the addition of water. The recrystallization of these crystals from benzene-cyclohexane (1 : 1) gave colorless needles (m. p. 86~87°C) (3.7 g.).

Found: C, 65.08; H, 5.95. Calcd. for $C_{18}H_{20}O_4S$: C, 65.05; H, 6.07%.

The Methyl Ether of I.—To I (25.2 g.) dissolved in ether (100 ml.) an excess of a diazomethane ether solution was added, and the mixture was kept at room temperature overnight. This reaction proceeded extremely slowly. After the ether had been removed and the residue had been distilled, the methyl ether, IIa and IIb, 26.8 g. was obtained in a 98% yield.

The Reaction of 2-Methoxy-4-isopropyl-7-methyltropone (IIa and IIb) with Malononitrile.—To a sodium methoxide solution prepared from absolute methanol (5 ml.) and sodium metal (100 mg.), malononitrile (360 mg.), and IIa and IIb, (400 mg.) were added successively; the mixture was kept at room temperature overnight. Then it was heated under reflux for 2.5 hr., and the resultant red solution was diluted with ethyl acetate and washed with a saturated sodium chloride aqueous solution three times and then dried over magnesium sulfate. After the removal of the solvent, there remained a red oil, which was then dissolved in benzene and chromatographed on alumina. From the benzene eluate, IVa or IVb (m. p. 140~141°C) was obtained in the form of yellow scales.

Found: C, 74.36; H, 6.63; N, 12.19. Calcd. for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.26; N, 12.38%.

UV λ_{max}^{MeOH} mμ (log ε): 242 (4.29), 295 (4.65).

From benzene-ethyl acetate (5 : 1), an eluate, III (250 mg., 48% yield) was obtained as orange prisms from ethanol. M. p. 184~185°C.

Found: C, 77.05; H, 6.19; N, 17.02. Calcd. for $C_{16}H_{15}N_3$: C, 77.08; H, 6.06; N, 16.86%.

UV λ_{max}^{MeOH} mμ (log ε): 235 (4.57), 315 (4.68), 325 (4.75), 390~400 (sh.).

The Hydrolysis of III. — *With Sulfuric Acid-Formic Acid.*—A mixture of III (350 mg.), 80% formic acid (2 ml.) and concentrated sulfuric acid (2 ml.) was heated at 85~95°C at 1 hr. The addition of water then afforded a red solution. A red crystalline substance (350 mg.) (m.p.>270°C) was obtained by neutralization (pH 4~5) with 2 N sodium hydroxide. Recrystallization from dimethylformamide gave Va (m.p.>270°C) in the form of red scales. The compound did not dissolve in a saturated sodium bicarbonate solution, but it did dissolve in 2 N sodium hydroxide.

Found: C, 69.29; H, 5.77; N, 14.23. Calcd. for $C_{17}H_{17}N_3O_2$: C, 69.13; H, 5.80; N, 14.23%.

UV λ_{max}^{MeOH} mμ (log ε): 315 (4.61), 362 (3.84), 380 (3.85), IR 3370, 3270, 3170, 3070, 1655, 1605, 1585, 1510 cm^{-1}.

With 100% Phosphoric Acid. — 100% phosphoric acid (5 ml.) prepared by the addition of an excess quantity of phosphoric acid anhydride to 85% phosphoric acid was added to III (720 mg.), and the mixture was heated at 100°C for 3.5 hr. After water had been added to the reaction mixture, it was neutralized with sodium bicarbonate and extracted with ethyl acetate. The combined ethyl acetate extract was washed with water and dried, and the solvent was removed, giving a red crystalline compound (420 mg.). Recrystallization from ethanol gave VIa (m. p. 157~158°C) as red prisms in a 65% yield.

Found: C, 80.39; H, 7.42; N, 12.79. Calcd. for $C_{15}H_{15}N_2$: C, 80.32; H, 7.19; N, 12.49%.

UV λ_{max}^{MeOH} mμ (log ε): 228 (4.30), 305 (4.76), 315 (4.82), 355 (3.91), IR 3400, 3300, 3200, 2150, 1640, 1540 cm^{-1}.

With 100% Phosphoric Acid at 120°C—A mixture of III and 100% phosphoric acid (3 ml.) was heated at 120°C for 5 hr., water was added, and the mixture was neutralized with sodium bicarbonate and extracted with benzene. The benzene extract was washed with water, dried, concentrated and chromatographed on alumina. The benzene eluate afforded a red oil. After this oil had been heated with acetic anhydride under reflux for 1 hr., the removal of the acetic anhydride gave a red crystalline compound. Recrystallization from dimethylformamide afforded blackish violet prisms (m. p. 250°C.)

Found: C, 88.48 (88.66); H, 8.13 (7.86); N, 3.85 (3.70). Calcd. for $C_{28}H_{31}N$: C, 88.14; H, 8.19; N, 3.67%.

The Acetylation of VIa.—A mixture of VIa (300 mg.) and acetic anhydride (4 ml.) was heated under reflux for 30 min.; the solvent was removed under reduced pressure, and then water was added. The filtered crystals were recrystallized from benzene (m. p. 182~184°C) VII as long red needles.

Found: C, 77.04; H, 6.88; N, 10.68. Calcd. for $C_{17}H_{18}N_2O$: C, 76.66; H, 6.81; N, 10.52%.

UV λ_{max}^{MeOH} mμ (log ε): 240 (4.30), 307 (4.75), 317 (4.85), 355 (3.90), 370 (3.93).

The Vilsmeier Reaction of VII.—To VII (260 mg.) dissolved in dimethylformamide (10 ml.) phosphorus oxychloride (300 mg.) was added and the mixture was heated at 90°C for 1 hr. The reaction mixture was poured into water (100 ml.) yielding a crystalline compound IX. The filtrate was neutralized with 2 N sodium hydroxide and extracted with ethyl acetate. From the ethyl acetate extract, VIII was obtained. The recrystallization of VIII from ethanol gave orange prisms (130 mg.) (m. p. 175~176°C).

Found: C, 73.88; H, 6.07; N, 9.85. Calcd. for $C_{18}H_{18}N_2O_2$: C, 73.45; H, 6.16; N, 9.52%.

UV λ_{max}^{MeOH} mμ (log ε): 232 (4.34), 252 (4.41), 287 (4.40), 322 (4.61).

The recrystallization of IX from dimethylformamide afforded red needles (50 mg.) (m. p. 232~233°C (decomp.).

Found: C, 73.48; H, 5.53; N, 9.71. Calcd. for $C_{18}H_{18}N_2O_2$: C, 73.45; H, 6.16; N, 9.52%.

UV λ_{max}^{MeOH} mμ (log ε): 240 (4.46), 320 (4.66), 335 (4.70), 370 (3.83), 390 (4.02), 415 (4.17).

The Hydrolysis of IX with 100% Phosphoric Acid.—A mixture of IX (150 mg.) and 100% phosphoric acid (7 ml.) was heated at 120~130°C for 5 hr., then it was diluted with water, neutralized with 2 N sodium hydoxide, and extracted with benzene. After the combined extract had been washed with water and dried, the removal of the solvent gave a reddish violet oil (XII). Picrate: m. p. >250°C, green needles.

Found: C, 55.74; H, 3.91; N, 11.34. Calcd. for $C_{23}H_{22}N_4O_9$: C, 55.42; H, 4.45; N, 11.24%.

The Hydrolysis of VIII. — To VIII (130 mg.) dissolved in methanol was added 2 N sodium hydroxide under reflux. After the methanol had been removed by heating on a water bath, a yellow crystalline compound was obtained on the addition of water. Recrystallization from methanol gave crange scales (X) (90 mg., m.p. 168~169°C).

Found: C, 76.03; H, 6.55; N, 11.32. Calcd. for $C_{16}H_{16}N_2O$: C, 76.16; H, 6.39; N, 11.10%.

UV λ_{max}^{MeOH} mμ (log ε): 230 (4.30), 252 (4.43). 282 (4.48), 335 (4.74).

The Condensation of X with Hydrazine.—An ethanol solution of XI and an excess quantity of hydrazine was heated for 10 min., and then water was added. After being kept overnight, a reddish crystalline product was obtained. Recrystallization from ethanol afforded XI as reddish brown needles (m. p. 158~160°C (decomp.)).

Found: C, 71.73; H, 6.79; N, 21.03. Calcd. for $C_{16}H_{18}N_4$: C, 72.15; H, 6.81; N, 21.04%.

UV λ_{max}^{MeOH} mμ (log ε): 260 (4.41), 300 (4.45), 310 (4.45), 350 (4.76) 400 (sh.).

The Deamination of III. — III (1 g.) was dissolved in a mixture of 86% formic acid (50 ml.) and concentrated sulfuric acid (10 ml.). To this solution sodium nitrite (400 mg.) in concentrated sulfuric acid (20 ml.) was added. The solution turned a bright reddish violet. After the addition of the sodium nitrite solution, the mixture was allowed to stand for 30 min., then a small amount of copper powder and 38% hypophosphorous acid (8 g.) were added. When the resultant mixture was kept in a refrigerator overnight, the solution turned red. After the solution had been stirred at room temperature for 5 hr. to complete the reaction, water was added. The reaction mixture was neutralized with 2 N sodium hydroxide and extracted with benzene. The combined benzene extract was concentrated to a proper volume and chromatographed on alumina. From benzene eluate, a red crystalline compound (500 mg.) was obtained. Recrystallization from ethanol gave XIII (53% yield) as red needles (m. p. 145~146°C).

Found: C, 82.11; H, 5.96; N, 11.80. Calcd. for $C_{16}H_{14}N_2$: C, 82.02; H, 6.02; N, 11.96%.

UV λ_{max}^{MeOH} mμ (log ε): 237 (4.71), 300 (4.55), 340 (3.89), 368 (4.02).

Attempts to Hydrolyze XIII. — a) XIII was dissolved in 100% phosphoric acid (1 ml.) and heated at 95~100°C for 2 hr., but no gas evolution was noticed. After being heated at 120~130°C for 2.5 hr., water was added. The reaction mixture was neutralized with 2 N sodium hydroxide and extracted with ethyl acetate. After the ethyl acetate had been removed, the residual oil was dissolved in benzene and chromatographed on alumina. From benzene eluate a blue oil was obtained. The infrared spectrum of this oil indicates the absence of a cyano group and this oil afforded its picrate of green needles, but its identity was not confirmed because of its small quantity. The ethyl acetate eluate gave a green oil, the infrared spectrum of which indicates the presence of a hydroxyl group (3400 cm^{-1}) and the absence of a cyano group. This oil gave a picrate, but its identity was not confirmed because of its small quantity.

b) XIII was dissolved in 10% sodium ethoxide-ethanol and heated at 95°C for 1 hr. The solvent was almost all removed. Water was then added to the residue, and it was extracted with ethyl acetate. From the ethyl acetate solution, the starting material was recovered.

c) A mixture of XIII, formic acid and concentrated sulfuric acid was heated for 1 hr. on a water bath. Only the starting substance was recovered.

The Synthesis of 1-Cyano-2-amino-*S*-guaiazulene (XV). — To VIa (550 mg.) dissolved in dimethylformamide (10 ml.), phosphorus oxychloride (1 g.) was added, and the mixture was kept overnight. Then the mixture was added to a heated ethanolic 2 N sodium hydroxide solution, ethanol (10 ml.) and hydrazine (2 ml.) were added, and the resultant mixture was heated for 30 min. on a water bath. After the addition of an ethylene glycol solution (5 ml.) of potassium hydroxide, which had been prepared by dissolving potassium hydroxide (5.6 g.) in ethylene glycol (25 ml.), the mixture was heated at 190~200°C with reflux for 1.5 hr. Then it was diluted with water and extracted with ethyl acetate, and the combined ethyl acetate extract was washed with water and dried. After the ethyl acetate had been removed, it was chromatographed on alumina. From the benzene-ethyl acetate (1 : 1) eluate, a red crystalline substance was obtained. Recrystallization from methanol afforded red scales (m. p. 120~121°C).

Found: C, 80.20; H, 7.63; N, 11.53. Calcd, for $C_{16}H_{18}N_2$: C, 80.63; H, 7.61; N, 11.76%.

UV λ_{max}^{MeOH} mμ (log ε): 230 (4.25), 310 (4.78), 320 (4.82), 355 (3.95), 395~400 (sh.), 420~430 (sh.).

The Deamination of XV. — XV (230 mg.) was dissolved into a mixture of ethanol (10 ml.) and concentrated sulfuric acid (0.4 ml.). Isoamyl nitrite (130 mg.) was added to the mixture under ice cooling, and it was stirred for 30 min. Then the mixture was added to boiling ethanol (10 ml.) and heated for 30 min. After neutralization with 2 N sodium hydroxide, the mixture was extracted with benzene. The benzene extract was washed with water and dried, and the benzene was removed. When the resulting residue was dissolved in cyclohexane - ether (4 : 1) and chromatographed on alumina, a crystalline compound (90 mg.) (m. p. 64~67°C) was obtained. Purification by sublimation gave XVI of bluish violet needles (m. p. 68.5~69.5°C).

Found: C, 86.12; H, 7.99; N, 5.97. Calcd. for $C_{16}H_{17}N$: C, 86.05; H, 7.76; N, 6.27%.

UV λ_{max}^{MeOH} mμ (log ε): 245 (4.44), 298 (4.58), 312 (4.47), 380 (3.98), 558 (2.75).

IR 2190, 1554, 1539, 1526, 1417, 1330, 1295 (doublet), 1208, 1160, 1123, 1097, 1055, 1020, 995, 953, 915 cm^{-1}.

The Hydrolysis of XVI. — A mixture of XVI (90 mg.) and 100% phosphoric acid (1 ml.) was heated at 98~99°C°. It first became a clear solution, but then a compound, which might be carbamoyl-*S*-guaiazulene, was separated out. After this temperature had been maintained for an additional 4 hr., water was added. The resultant solution was neutralized with sodium bicarbonate and extracted with petroleum ether. The combined extract was washed with water and dried, and the solvent was removed. When the residual oil was chromatographed on alumina using petroleum ether, a blue oil was obtained. This oil was dissolved in ethanol (2 ml.), of which 0.5 ml. was used for the preparation of its picrate. The picrate (m. p. 116~118°C) was obtained as blackish green needles. Similarly, from the ethanol solution (0.5 ml.), 1, 3, 5-trinitrobenzene complex (30 mg.) was obtained as green crystals. Recrystallization from ethanol afforded green needles (m. p. 147~148°C). They were both identical with the authentic sample obtained from *S*-guaiazulene as determined by mixed melting point determination.

The authors gratefully acknowledge financial help from the Sankyo Co., Ltd., to cover part of the expenses of the present work. They are also indebted to Miss Yoko Endo and Miss Yukiko Endo of this Institute for their elemental analyses.

*A Novel Method of Acetylation Using Acetoxypyridines**

By Yoshio UENO, Takao TAKAYA and Eiji IMOTO

(Received November 9, 1963)

Pyridoxine, cytosine, thymine, guanine and adenine, which play important roles in biological systems, have an azine or a diazine ring and also one or more hydroxyl and/or amino substituents. Though it had been known that the hydroxyl and the amino groups of these compounds are important in constructing the double spiral structure of nucleic acids by means of hydrogen bonds, the chemical meaning of these groups had not yet been known. A hydroxyl group and an amino group attached to such a heteroaromatic ring as an azine or a diazine have interesting properties. For example, 2- or 4-hydroxypyridine tends to from 2- or 4-pyridone. It may, therefore, be assumed that acyloxy derivatives of pyridine and pyrimidine behave as acylating reagents. Moreover, if so, it is expected that the hydroxyl and the amino groups of the basic components in nucleic acids will play their chemical role of offering an electrophilic reaction intermediate if they act chemically.

In this paper the satisfactory acetylation of alcohols, phenols, amines and acid compounds with 2- and 3-acetoxypyridines is reported.

Experimental

2-Acetoxypyridine.—This compound was prepared by the Tschitschibabin method[1] from acetyl chloride and the sodium salt of 2-hydroxypyridine,[2] which had been prepared from 2-aminopyridine. B. p. 110~112°C/10 mmHg.

3-Acetoxypyridine.—This compound was prepared from acetic anhydride and 3-hydroxypyridine by

* This article was presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

the Fischer method,[3] b. p. 92°C/9 mmHg.

The Acetylation of Butyl Alcohol. — *The Preperation of Butyl Acetate.*—Butyl alcohol (3.96 g.) and 3-acetoxypyridine (8.23 g.) were placed in a flask equipped with a condenser and a calcium chloride tube; the mixture was refluxed for 7 hr., then cooled, acidified with dilute hydrochloric acid and extracted with ether. The ethereal extract was washed with an aqueous solution of sodium bicarbonate and then with water, and dried with anhydrous sodium sulfate. After the ether had been distilled off, the residue was combined with 10 ml. of dry xylene and fractionated under atmospheric pressure to give 5.78 g. of butyl acetate. Yield, 93%. When butyl alcohol (6.07 g.) was acetylated with 2-acetoxypyridine (10.47 g.) in tetrahydrofuran (5 ml.) at 25°C for 3 hr. and when the reaction mixture was then treated in a way similar to that described above, the same yield (92%) of butyl acetate was obtained.

The Acetylation of Amines and Phenols. — *General Method.*—In a 50 ml. flask equipped with a condenser and a calcium chloride tube, an amine or a phenol was acetylated with acetoxypyridine under various conditions. The details of reaction conditions are summarized in Table I. After the solvent had been distilled under reduced pressure at room temperature, the residue was washed with 1 N hydrochloric acid or a 1 N sodium hydroxide solution according to the case and then washed with water several times. The acetyl derivative obtained was recrystallized from an adequate solvent. The product was identified with an authentic sample. In case the product was a liquid, such as acetobutylamide or acetodiethylamide, the aqueous hydrochloric acid solution was extracted with ether and the ethereal solution was dried over anhydrous sodium sulfate. After the ether had been distilled off, the residue was fractionated in a vacuum. In the case of urea, the residue was washed with absolute alcohol and the monoacetyl derivative was obtained.

3-Benzoxypyridine.—In a flask equipped with a condenser and a calcium chloride tube, benzoic acid (6.11 g.) and 3-acetoxypyridine (7.11 g.) were placed in 5 ml. of dry xylene, and the mixture was refluxed for 1 hr. After the acetic acid produced had been distilled off, ether was added to the residue. The ethereal solution was washed with an aqueous dilute solution of sodium carbonate and then with water. After drying over anhydrous sodium sulfate, the ether was distilled off and the residue was fractionated under reduced pressure. The fraction boiling at 168~171°C/12 mmHg was collected, m. p. 49~50°C. The yield of 3-benzoxypyridine was 85% on the basis of the 3-acetoxypyridine.

The Friedel-Crafts-type Acetylation of Anisole. —In a round-bottomed three-necked flask equipped with a condenser, a calcium chloride tube, a dropping funnel, a thermometer, and a sealed stirrer there were placed anisole (13.5 g.) and 3-acetoxypyridine (13.7 g.) in 50 ml. of dry carbon disulfide. Aluminum chloride (37 g.) was added to the stirred solution over a period of 15 min., with occasional cooling with water. The solution was then stirred under gentle reflux for 2 hr. After the carbon disulfide had been distilled under reduced pressure, the residue was poured onto ice containing hydrochloric acid. The decomposed mixture was extracted with ether, and the combined ether extracts were washed with water, with a 10% aqueous solution of sodium hydroxide and again water. After drying over sodium sulfate, the ether was distilled and the residue was fractionated under reduced pressure. The yield of acetylanisole was 76% on the basis of 3-acetoxypyridine. Acetyl derivatives of benzene and toluene were obtained in similar manners; the results are shown in Table II.

3 : 3-Acetoxypyridine

acetylated compounds with 2-acetoxypyridine were higher than those with 3-acetoxypyridine. *o*-Toluidine and *p*-nitroaniline did not react with 3-acetoxypyridine under reflux in xylene, but they did reacted with 2-acetoxypyridine to give the corresponding acetyl compounds without catalyzers under mild conditions. For example, *o*-acetotoluide was obtained in a 81% yield in refluxing tetrahydrofuran and in a 73% yield at 25°C in the same solvent. The acetyl derivatives of *p*-nitroaniline, β-naphthylamine, diphenylamine and β-naphthol were obtained in good yields with 2-acetoxypyridine under mild conditions. In the Friedel-Crafts-type acetylation, it was found that the main acetyl-substituted products of aromatic compounds were *p*-derivatives and that *o*-derivatives were very small in quantity. As may be seen from Table III, interesting results were obtained. The boron trifluoride etherate was found to be a good catalyzer for this acetylation. On the other hand, because cupric sulfate and cupric acetate were sparingly soluble in dry organic solvents, they were unsuitable as catalyzers. For example, *p*-nitroaniline was acetylated with 3-acetoxypyridine in chloroform containing boron trifluoride etherate, but it was not acetylated with either cupric sulfate or cupric acetate. The solvent effect was not clear in these experiments. The interexchange reaction between benzanilide and 2-acetoxypyridine did not proceed in refluxing xylene or tetrahydrofuran containing boron trifluoride etherate as a catalyzer. The effect of the temperature and the catalyzer on the reactivity of aniline was investigated with 3-acetoxypyridine. As is shown in Table IV, the yield was little changed above 25°C, but at 10°C it decreased to the extent of 40% of the yield.

Ultrasonic Studies of the Hydration of Various Compounds in an Ethanol-Water Mixed Solvent. I. Hydration of Inorganic Compounds

By Tatsuya YASUNAGA, Yasutomo HIRATA, Yoshihiko KAWANO and Masaji MIURA

(Received December 9, 1963)

The problem of the hydration of electrolytes in an aqueous solution has been studied in our laboratory for the past few years. One of the present authors[1] determined the amount of hydration by measuring the ultrasonic velocity and density on the basis of the assumption that the hydrated water molecules are incompressible because of the strong electrostatic interaction between the ion and the surrounding water. A theoretical study on this problem has also been reported by Yasunaga,[2] who assumed that the strength of interaction between the ion and the surrounding water molecules depends only on the distance between them for the ions of identical charge, and that the lower limit of the strength of interaction is that of a hydrogen bond in ice.

In general, the definitions of hydration in the various methods hitherto reported are somewhat arbitrary, and the discordance among the data of hydration numbers found in the literature suggests the need of further research. The hydration numbers obtained by various methods are compared in Table III.

It has been known that the velocity of sound in an ethanol-water mixture[3] shows unusual behavior withre spect to its concentration dependence as do such other physical properties as viscosity, volume contraction, heat capacity, heat of mixing, and sound absorption. According to Parshad,[4] a maximum in the plot of the velocity of sound against the concentration is shifted to the lower concentration side by the addition of electrolytes.

In the present study, an attempt is made to determine the degree of the hydration of electrolytes by using this phenomenon, assuming that the shift of the peak is caused only by the decrease in the amount of free water in the solution.

Theoretical

As has been mentioned above, the plot of the velocity of sound against the concentration of ethanol in water exhibits a peak, the maximum of which is shifted toward the lower concentration side by the addition of an electrolyte. Now it is assumed that this shift is caused only by the hydration, and that there is no interaction between the electrolyte dissolved and the ethanol. Therefore, the amount of hydration can be estimated from the relationship:

K_2CO_3	0.095 g./100 g. solution of 90.65% ethanol (23~26°C)
$BaCl_2$	0.014 g./100 g. ethanol 97% (15°C)

$$\frac{W_{alc.0}}{W_{w.0}} = \frac{W_{alc}}{W_w - W_x} = a \qquad (1)$$

where W_{alc}, W_w and W_x are the amounts of ethanol, total water and hydrated water at the peak point respectively, and the subscript 0 refers to the values at infinite dilution with respect to the electrolyte. This equation is derived on the basis of a working hypothesis that the position of the maximum is determined only by the ratio of the amounts of ethanol and free water.

Experimental

Apparatus.—The velocity of sound was measured with an ultrasonic interferometer. A partially-exploded diagram of the interferometer-cell is show in Fig. 1. A vertical glass tube 15 cm. long and 3.8 cm. in diameter is sealed with a glass plate of 4.213 mm. thick, without grease at the bottom, below which is placed a gold plated x-cut quartz crystal with a resonance frequency of 5 Mc.

The reflector is made of a plane glass plate, which moves vertically without and rotation, and its position is determined within an accuracy of 0.002 mm. with a micrometer with a travelling range of 5 cm.

The electronic circuits are given in Fig. 2. The temperature change of the frequency was minimized by keeping the quartz crystal of the main oscillator in a thermostat. The frequency of the oscillator was measured in each experimental run with the standard frequency of the JJY station. The drift of frequency was less than 10 c./day.

The velocity of sound in water as measured with the present apparatus is given in Table I, together with the data found in the literature. The present result is in good agreement with those results, especially with those of Owen and Simons, and with those of Gucker and Haag, who used interferometers of a similar type.

Materials.—Sodium chloride, potassium chloride, potassium carbonate, and barium chloride were used

as the electralytes. The mutual interaction between the ion and ethanol for these electrolytes is negligible, as is seen from their solubilities in ethanol as shown in Table II. Guaranteed pure reagents were used without further purification. Ethanol was purified by the usual method to a purity of 99.86%.

Results

The velocities of sound in the solutions of sodium chloride, potassium chloride, potassium carbonate and barium chloride in the mixture of ethanol and water are shown in Figs. 3—6. The concentration of ethanol at the maximum velocity of sound decreased with the increase in the concentration of electrolytes, as has

been reported by Parshad.[4] The concentration of ethanol at the maximum velocity of sound is plotted against that of the electrolyte in Fig. 7. The degrees of hydration at various concentrations of the electrolytes calculated from these data by using Eq. 1 are shown in Fig. 8. The degree of hydration of sodium chloride and potassium chloride decreased slightly with the increase in the concentration, while that of potassium carbonate and that of barium chloride were constant over the range of concentration studied. The values for the degree of hydration at infinite dilution, as obtained from Fig. 8 by extrapolation, are

shown in Table III, where the data found in the literature are appended. As may be seen in Table III, the present result is slightly higher than the other data.

The results obtained for the mixtures of sodium chloride and potassium chloride are shown in Figs. 7, 8 and 9. As may be seen in the figures, the degree of hydration in the mixture of two electrolytes is just the arithmetic sum of those of the individual ions.

Discussion

The significant points in the present results are as follows. 1) The degree of hydration is independent of the concentration. The slight deviation from constancy for the concentrated solutions of sodium and potassium chloride can be ascribed to the ion association. 2) The degree of hydration of a mixture of two electrolytes is additive. 3) The amounts of hydration are in good agreement with those

obtained by various methods. These facts confirm, at least empirically, the validity of our assumption that the position of the maximum of sound velocity is determined by the relative concentration of free water.

The extension of the research with different types of compounds is in progress; this will shed light on the problems of hydration and of the solution properties of a three-component system.

Preparation of Some Bis(fluorodimethylsilyl)alkanes

By Makoto KUMADA, Kiyomi NAKA and Yoshihiro YAMAMOTO

(Received January 31, 1964)

Sommer and his co-workers[1] observed that certain organosilicon structures undergo the selective cleavage of one methyl group from each trimethylsilyl grouping, Me_3Si, as methane, when treated with concentrated sulfuric acid. It has also been well established that the demethylation reaction takes place smoothly, even in heterogeneous systems. For example, Sommer and Ansul[2] found that 1,4-bis(trimethylsilyl)butane can be converted into 2,7-dimethyl-2,7-difluoro-2,7-disilaoctane by sulfuric acid cleavage, followed by hydrolysis and then by treatment with boron trifluoride etherate.

$$n\mathrm{Me_3Si(CH_2)_4SiMe_3} \xrightarrow[2)\ H_2O]{1)\ H_2SO_4} \left[-\mathrm{Si(Me)_2(CH_2)_4Si(Me)_2-O-}\right]_n + 2n\mathrm{CH_4}$$

$$\mathrm{FMe_2Si(CH_2)_4SiMe_2F} \xleftarrow{BF_3\cdot Et_2O} \left[-\mathrm{Si(Me)_2(CH_2)_4Si(Me)_2-O-}\right]_n$$

Kumada and his co-workers[3] observed that hexamethyldisilane behaves towards concentrated sulfuric acid in a manner similar to that of the above silahydrocarbon except that the demethylation reaction in this case proceeds in two distinct steps. Thus, chloro(or fluoro)-pentamethyldisilane or 1,2-dichloro(or 1,2-difluoro)tetramethyldisilane can be obtained selectively if the reaction mixture is treated with ammonium chloride (or fluoride) when, respectively, one or two equivalents of methane have been evolved.

$$\mathrm{Me_3SiSiMe_3} \xrightarrow[2)\ NH_4X]{1)\ H_2SO_4} \begin{cases} \mathrm{Me_3SiSiMe_2X} + \mathrm{CH_4} \\ \mathrm{XMe_2SiSiMe_2X} + 2\mathrm{CH_4} \end{cases}$$

In the present study we have established that the demethylation by sulfuric acid, followed by fluorination by the same method as above, can successfully be used for the method generally applicable to the preparation of bis(fluorodimethylsilyl)alkanes (Eq. 1), important intermediates for the preparation of hybrid paraffin-siloxanes.

$$\mathrm{Me_3SiRSiMe_3} \xrightarrow[2)\ NH_4F\cdot HF]{1)\ H_2SO_4} \mathrm{FMe_2SiRSiMe_2F} + 2\mathrm{CH_4} \qquad (1)$$

The starting compounds selected for the present study were eight bis(trimethylsilyl)-alkanes and one chlorine-substituted compound: bis(trimethylsilyl)methane (I), 1,1-bis(trimethylsilyl)ethane (II), 1,2-bis(trimethylsilyl)ethane (III), 1,3-bis(trimethylsilyl)propane (IV), 2,2-bis(trimethylsilyl)propane (V), 1,4-bis(trimethylsilyl)butane (VI), 1,5-bis(trimethylsilyl)pentane (VII), 1,6-bis(trimethylsilyl)hexane (VIII) and bis(trimethylsilyl)-chloromethane (IX). The respective normal products, bis(fluorodimethylsilyl)alkanes, are as follows: bis(fluorodimethylsilyl)methane (X), 1,1-bis(fluorodimethylsilyl)ethane (XI), 1,2-bis(fluorodimethylsilyl)ethane (XII), 1,3-bis(fluorodimethylsilyl)propane (XIII), 2,2-bis(fluorodimethylsilyl)propane (XIV), 1,4-bis(fluorodimethylsilyl)butane (XV), 1,5-bis(fluorodimethylsilyl)pentane (XVI), 1,6-bis(fluorodimethylsilyl)hexane (XVII) and bis(fluorodimethylsilyl)chloromethane (XVIII). The reaction conditions employed for the demethylation and the yields of fluorinated products are listed in Table I; the physical properties, together with analytical data for $FMe_2SiRSiMe_2F$, are shown in Table II.

c) Reported value:[1] b. p. 176°C.

The mixture of a silahydrocarbon and sulfuric acid was stirred vigorously in a vessel connected to a gas-collecting apparatus. The reaction system was heterogeneous initially, but it became homogeneous as the reaction went on. In the $Me_3Si(CH_2)_xSiMe_3$ series of compounds, it was necessary to increase the reaction temperature along with an increase in the value of x in order to cause the demethylation to occur at a reasonable rate. At the temperatures indicated in Table I the reaction appeared to be completed within a few hours.

In agreement with the observation by Sommer and Ansul[2] of the cleavage of 1,4-bis(trimethylsilyl)butane (VI) by sulfuric acid, some percentage of the reaction gave a cleavage between silicon and the R grouping, while Si-Me cleavage was the main reaction in most cases. Less than a theoretical amount of methane (2 mol. of methane per mole of $Me_3SiRSiMe_3$) was evolved; accordingly, the fractional distillation of fluorinated products gave trimethylfluorosilane and alkyldimethylfluorosilanes, $HRMe_2SiF$, in some and nearly equal yields in most cases. With compound I, however, a small amount of a liquid believed to be tetramethylsilane was also detected.

Apart from the detailed reaction mechanism, undoubtedly these products were formed through the two different courses indicated by

Eqs. 2a-2b and 3a-3b:

$$Me_3SiRSiMe_3 \xrightarrow{H_2SO_4} Me_3Si(HSO_4) + HRSiMe_3 \quad (2a)$$

$$HRSiMe_3 \xrightarrow{H_2SO_4} HRSiMe_2(HSO_4) + CH_4 \quad (2b)$$

$$MeSiRSiMe_3 \xrightarrow{H_2SO_4} Me_3SiRSiMe_2(HSO_4) + CH_4 \quad (3a)$$

$$Me_3SiRSiMe_2(HSO_4) \xrightarrow{H_2SO_4} Me_3Si(HSO_4) + HRSiMe_2(HSO_4) \quad (3b)$$

Apparently tetramethylsilane is a product in reaction 2a; this volatile (b. p. 27°C) and paraffin-like compound leaves the reaction system without being attacked by concentrated sulfuric acid. Compounds of the $HRSiMe_2F$ type are probably produced through both courses, 2a-2b and 3a-3b.

Since the results in Table I are over-all ones from complicated reactions, heterogeneous and homogeneous, we cannot discuss the mechanism of silicon-carbon cleavage in detail. However, the following listing by relative ease of Si-R cleavage may be established on the basis of the yields of products:

$$CH_2,\ CHMe > (CH_2)_2 > (CH_2)_3 > (CH_2)_4,$$
$$(CH_2)_5,\ (CH_2)_6 > CHCl > CMe_2$$

These results seem to be fairly well explained in terms of electronic and steric effects of substituents on the methylene carbon to be attacked by the acid.

In order to learn more about the reaction path, further investigation into the homogeneous reaction using compounds such as $Me_3SiRSiMe_2OEt$ is being undertaken.

Experimental

Materials.—All the compounds used (I—IX) are known and prepared by known methods with the exception of compounds III and VIII, the preparation of which is described below. In the following list, the references given after the compounds are to the source or method of preparation: I,[4] b. p. 132~134°C, n_D^{20} 1.4172; II,[5] b. p. 160~161°C, n_D^{20} 1.4331; IV,[6] b. p. 170°C, n_D^{20} 1.4224; V,[7] b. p. 178°C, n_D^{20} 1.4459; VI,[2] b. p. 191°C, n_D^{20} 1.4272; VII,[5] b. p. 88°C/12 mmHg, n_D^{20} 1.4310; IX,[5] b. p. 71°C/21 mmHg, n_D^{20} 1.4491.

1,2-Bis(trimethylsilyl)ethane (III).—To a Grignard solution prepared from 40 g. (0.33 mol.) of Me_3SiCH_2Cl and 7.8 g. (0.33 g. atom) of magnesium turnings in ether, 7 g. of anhydrous cobaltous chloride was added in several portions. To the resulting black solution 40 g. of Me_3SiCH_2Cl was added, and the reaction mixture was kept under reflux for 40 hr. After hydrolysis, an organic layer was separated, dried and fractionally distilled to give 21 g. of unchanged Me_3SiCH_2Cl and 14.3 g. (a 34% yield on the basis of the Me_3SiCH_2Cl unrecovered) of 1,2-bis(trimethylsilyl)ethane; b. p. 149~150°C, n_D^{20} 1.4202, d_4^{20} 0.7506 (reported:[9] b. p. 152°C, n_D^{20} 1.4204, d_4^{20} 0.7536).

1,6-Bis(trimethylsilyl)hexane (VIII).—This compound was prepared by the following sequence of reaction:

$$CH_2=CHCH_2CH_2CH=CH_2 + 2MeSiHCl_2 \rightarrow Cl_2MeSi(CH_2)_6SiMeCl_2$$
XIX
$$XIX + 2MeMgBr \rightarrow VIII$$

In a 100-ml. three-necked flask fitted with a thermometer, a dropping funnel and an efficient reflux condenser, there was placed 25 g. (0.35 mol.) of diallyl and 0.5 ml. of a 0.1 M $H_2PtCl_6 \cdot 6H_2O$ solution in isopropyl alcohol.[10] The exit of the apparatus was sealed with mercury so that the reaction might be carried out at temperatures higher than the boiling points of the starting materials. To the mixture 76 g. (0.66 mol.) of methyldichlorosilane was added drop by drop under reflux conditions. The reaction temperature gradually increased to 140~150°C over a period of 13 hr. Fractional distillation gave two products: 5-hexenylmethyldichlorosilane (b. p. 91°C/26 mmHg; 26 g., in a 41% yield based on the diallyl used (Found: Cl, 35.96. Calcd. for $C_7H_{14}Cl_2Si$: Cl, 36.20%)) and 1,6-bis(dichloromethylsilyl)hexane (XIX) (b. p. 155~156°C/13 mmHg; 42 g., yield 44% (Found: Cl, 44.91. Calcd. for $C_8H_{18}Cl_4Si_2$: Cl, 45.46%)).

To a Grignard solution containing about 1 mol. of methylmagnesium bromide 68 g. (0.22 mol.) of compound XIX was added over a 2/3-hr. period. The reaction mixture was allowed to stand overnight, refluxed for 1 hr. and then hydrolyzed with dilute hydrochloric acid. After a work-up in the usual way, the product was fractionally distilled to give 33 g. (66% yield) of 1,6-bis(trimethylsilyl)hexane; b. p. 101°C/7 mmHg, n_D^{25} 1.4322, d_4^{25} 0.773 (reported:[8] b. p. 109.5°C/16 mmHg, n_D^{25} 1.4298, d_4^{25} 0.772).

The Demethylation, Followed by Fluorination, of Silahydrocarbons.—The technique followed in detail that used in the demethylation, followed by the fluorination, of hexamethyldisilane.[3] The organic products were fractionally distilled through a small Stedman column rated at about 20 theoretical plates to give, in most cases, trimethylfluorosilane (b. p. 16°C), alkyldimethylfluorosilanes and bis(fluorodimethylsilyl)alkanes (see Tables I and II).

Summary

It has been established that the demethylation of bis(trimethylsilyl)alkanes of the

general formula $Me_3SiRSiMe_3$ by concentrated sulfuric acid, followed by fluorination with ammonium hydrogenfluoride, can successfully be used for the method generally applicable to the preparation of bis(fluorodimethylsilyl)-alkanes, $FMe_2SiRSiMe_2F$. Although Si-Me cleavage was the main reaction in most cases, some part of the reaction gave a cleavage between silicon and the R grouping. The ease of the cleavage of R from silicon was found to decrease in the following order :

CH_2, $CHMe > (CH_2)_2 > (CH_2)_3 > (CH_2)_4$, $(CH_2)_5$, $(CH_2)_6 > CHCl > CMe_2$

*Studies of Polybutene. I. Determination of the End-groups and the Molecular Weight by the Infrared Method**

By Kazuyoshi IIMURA, Ryūichi ENDŌ and Masatami TAKEDA

(Received February 1, 1964)

A practical method for the determination of the molecular weight of commercial liquid polybutenes of a low molecular weight has been developed by an infrared technique. Moreover, the types of unsaturated terminal groups of the polymer chain have been ascertained. However, the application of this method to polymers of a higher molecular weight would be difficult, because of the undetectably weak relative-intensity of the band assignable to the end-group.

Experimental

Materials.—The samples of the commercial polybutenes used in this investigation are Indopol from Amoco, Oronite from California Chemicals, and Polyvis from Cosden. Benzene was washed with sulfuric acid and water, and distilled after drying over calcium chloride. The treated benzene was purified by fractional distillation over sodium wire before use.

Technique.—The molecular weight of the samples was determined by a cryoscopic method, using benzene as the solvent, and also by an iodine-value method[1] reported on in a preceding paper. The infrared absorption was measured by a Hitachi EPI-2 infrared spectrometer with an NaCl optical system. A group-type analysis was applied in the determination of the content of the end group and of the molecular weight. In this case, the absorption coefficient of the band characteristic of the type of structure must usually be determined. In the present work, however, this procedure was eliminated by applying the data of the absorption coefficients, reported by McMurry and Thornton,[2] of the bands caused by the structural types in question; the proportionality of the absorption coefficient can be held between the data reported by McMurry and our measurements.

Results and Discussion

The Molecular Weight of the Polybutenes.—Table I gives the molecular weight obtained by the iodine-value method on the assumption that each polymer molecule contains only one unsaturated double bond at the end, and those obtained from the cryoscopic method. As may be seen in the table, there is a close agreement in molecular weight between the two methods. This fact justifies the assumption indicated above when the molecular weight is determined by the iodine-value method.

TABLE I. THE MOLECULAR WEIGHT OF POLYBUTENES

Sample	Cryoscopic method	Iodine-value method
Polyvis 3	650	660
Polyvis 5	710	690
Polyvis 10	900	870
Polyvis 30	1300	1150

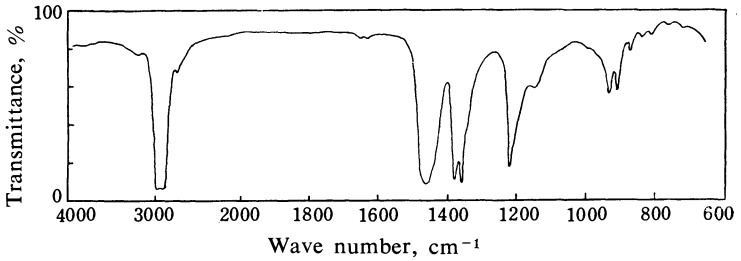

Fig. 1-a. Infrared spectrum of Polyvis 10.

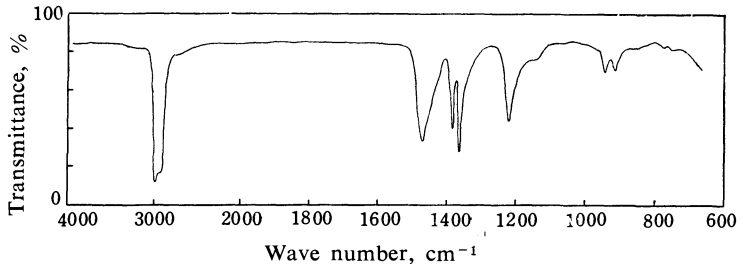

Fig. 1-b. Infrared spectrum of polyisobutylene (Vistanex LM-MH).

The Structures of the Polybutenes. — The infrared spectra of eleven samples are all identical to that of polyisobutylene except in the double-bond stretching and the out-of-plane =CH deformation regions. For example, the infrared spectra of Polyvis 10 and polyisobutylene (Vistanex LM-MH from the Esso Standard, $\bar{M}_w$: 10000~11700) are shown in Fig. 1. The absorption caused by the unsaturated double bonds is observed in all samples. The two weak absorption bands at 1660 and at 1640 cm^{-1} can be assigned to the C=C stretching vibrations. The disappearance of the bands at 892 and at 830 cm^{-1} on the iodation of the samples (cf. Fig. 2) suggests that these bands arise from the CH out-of-plane bending vibration at the C=C bond. The bands at 1660 and 830 cm^{-1} are assigned to the vibration of the tri-substituted ethylenic double bond, while those at 1640 and 892 cm^{-1} have been assigned to the vibration of the vinylidene-type double bond by Dainton and Sutherland[3] and by other investigators.[4-6]

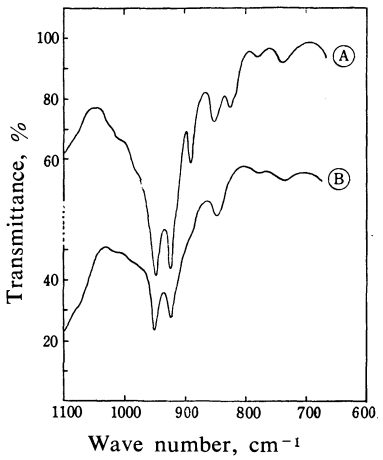

Fig. 2. Infrared spectra of Polyvis 10 before and after treating with I_2; A: original, B: treated with I_2.

From this finding, together with that obtained in the first section, it would seem that the commercial polybutenes are low molecular weight polyisobutylene, and that they are mixtures of two types of polymer chains consisting of one vinylidene-type end-group per one polymer molecule and one tri-substituted ethylenic end-group per another polymer molecule.

The Quantitative Determination of the End-groups.—In the infrared study of low molecular weight polyisobutylene, Dainton and Sutherland[3] and Flett and Plesch[6] have suggested that the termination of the polymer occurs mainly in the vinylidene-type unsaturation. In the sample used in this investigation, however, a considerable amount of the tri-substituted ethylenic end-group exists in the polymer chain, together with the vinylidene-type end-group.

The measurement of the absorption intensities of the bands at 892 and 830 cm^{-1}, which

3) F. S. Dainton and G. B. B. M. Sutherland, *J. Polymer Sci.*, **4**, 37 (1949).

5) W. S. Gallaway and M. J. Murray, *J. Am. Chem. Soc.*, **70**, 2584 (1948).
6) M. St. C. Flett and P. H. Plesch, *J. Chem. Soc.*, **1952**, 3355.

are assigned to the CH out-of-plane vibration of the vinylidene-type end-group and that of the tri-substituted ethylenic end-group respectively, gives the concentration of the end-groups. The absorption coefficients of the bands at 892 and 830 cm^{-1} have been determined as 14×10^4 mol./ml./cm. and 4.0×10^4 mol./ml./cm. respectively by McMurry and Thornton.[2] Using these values, it is possible to obtain the content of the end-groups from the measured intensity ratio of the bands.

If the intensities of the bands at 830 and 892 cm^{-1} are proportional to the concentrations of the respective end-groups, the following relation can be proved:

$$C_{830}/C_{892} = (k_{892}/k_{830}) \times (D_{830}/D_{892}) = (14/4.0) \times (D_{830}/D_{892}) \quad (1)$$

where C is the molar concentration of the end-group, k is the absorption coefficient, and D is the optical density of the band at the wave numbers shown by the subscript. The ratio of the contents of the tri-substituted ethylenic end-group to that of the vinylidene-type end-group is given by C_{830}/C_{892}. The contents calculated from C_{830}/C_{892} are listed in Table II.

TABLE II. END-GROUP CONTENT

Sample	D_{830}/D_{892}	C_{830}/C_{892}	V	T
Polyvis 3	0.431	1.51	0.40	0.60
Polyvis 5	0.427	1.49	0.40	0.60
Polyvis 10	0.461	1.61	0.38	0.62
Polyvis 30	0.437	1.53	0.40	0.60
Indopol L-10	0.306	1.07	0.48	0.52
Indopol H-35	0.436	1.53	0.40	0.60
Indopol H-50	0.490	1.72	0.37	0.63
Iodopol H-100	0.623	2.18	0.31	0.69
Indopcl H-300	0.402	1.41	0.41	0.59
Oronite 24	0.573	2.01	0.33	0.67
Oronite 32	0.520	1.82	0.35	0.65

Note: V provides a vinylidene-type end-group. T provides a tri-substituted ethylenic end-group.

Unlike the results obtained by Dainton and Sutherland[3] and by Flett and Plesch[6] on their samples, the tri-substituted ethylenic end-group is predominant in our samples.

The Determination of the Degree of Polymerization by the Infrared Method.—The band at 855 cm^{-1} is caused by the $R\text{–}CH_2\text{–}C(CH_3)_2\text{–}CH_2\text{–}R$ group in the polyisobutylene chain, and its absorption coefficient is estimated as 0.2×10^4 mol./ml./cm.[2] As has been described in the second section, if we assume that these samples are mixtures of two kinds of polyisobutylene chains, one with the tri-substituted ethylenic end-group and the other with the vinylidene end-group, the contribution from the dimethyl branching of these two chains to the intensity of the band at 855 cm^{-1} must be considered. That is, the number-average degree of polymerization, $\bar{P}_n$, of the samples can be calculated from the following formulas:

$$\bar{P}_n = \{(V\times D_{855}\times k_{892})/(D_{892}\times k_{855})\}+1 \quad (2)$$

or

$$\bar{P}_n = \{(T\times D_{855}\times k_{830})/(D_{830}\times k_{855})\}+1 \quad (3)$$

where V is the content of the vinylidene-type end-group and T is that of the tri-substituted ethylenic end-group. The degree of polymerization, therefore, can be obtained from the content of the end-group by applying Eq. 2 or 3.

Table III gives the degree of polymerization obtained by the above method and those obtained from the cryoscopic and iodine-value methods. There is considerable agreement between the results obtained by the three methods. These experimental results demonstrate that the infrared technique can be used as a practical and rapid method for the determination of the types and numbers of the end-group in the commercial polybutenes and the molecular weight of polymers.

TABLE III. DEGREE OF POLYMERIZATION OBTAINED BY INFRARED AND OTHER METHODS

Sample	Infrared		Cryo-scopic	Iodine-value
Polyvis 3	10.9[a]	10.8[b]	11.6[c]	11.8[c]

A Cobalt(III) Complex with Trimethylenediaminetetraacetate

By Nobuyuki TANAKA and Hiroshi OGINO

(Received February 3, 1964)

The preparation and the properties of the cobalt(III) complexes with ethylenediaminetetraacetate (edta) have been extensively investigated. The cobalt(III) complexes with propylenediaminetetraacetate (pdta) and *trans*-1, 2-cyclohexanediaminetetraacetate (cydta) have also been reported on.[1,2] In these complexes, the chelate rings around the central cobalt(III) ions are all five-membered.

This paper will present the synthesis of a cobalt(III) complex with trimethylenediaminetetraacetate (trdta, $(^{-}OOCH_2C)_2N(CH_2)_3N(CH_2COO^{-})_2$) in which a six-membered chelate ring involving two nitrogen atoms is formed. The infrared, visible and ultraviolet absorption spectra of the complex, as well as those of edta-, pdta- and cydta-cobalt(III) complexes, are also presented and discussed.

Experimental

Preparation.—H_4pdta,[1] H_4hdta[3] (hexamethylenediaminetetraacetic acid, $(HOOCH_2C)_2N(CH_2)_6N(CH_2COOH)_2$), Na[Coedta]·$4H_2O$,[4] K[Copdta]·$H_2O$[1] and K[Cocydta]·$3H_2O$[2] were preparaed in essentially the same way as has been reported in the literature. The H_4edta and H_4cydta used were purchased from Dojindo & Co., Ltd.

Trimethylenediaminetetraacetic acid: Twenty-eight grams of monochloroacetic acid in 25 ml. of water was cooled in an ice-bath and then 16.5 g. of potassium hydroxide dissolved in 30 ml. of water was added drop by drop with stirring, followed by the addition of 5 g. of trimethylenediamine. The resulting solution was heated for 1 hr. After cooling, the pH of the solution was adjusted to 2.3 with concentrated hydrochloric acid. The solution was filtered and evaporated on a water-bath to a volume of 40 ml. Then, the deposited potassium chloride was removed and the solution kept in a refrigerator until white powder appeared. This powder was collected and washed with water, alcohol and ether. The filtrate was concentrated on a water-bath, and the same procedure was repeated to recover the compound from the solution; yield, 6 g. The compound was recrystallized from aqueous alcohol and dried at 110°C.

Found: C, 43.24; H, 6.06; N, 9.23. Calcd. for $C_{11}H_{18}N_2O_8$: C, 43.14; H, 5.92; N, 9.15%.

Schwarzenbach and Ackermann[5] reported that H_4trdta did not precipitate upon the acidification of the condensation-mixture of monochloroacetic acid, sodium hydroxide and trimethylenediamine. In this study, however, H_4trdta was successfully crystallized by the careful adjustment of the pH of the condensation-mixture (pH 2.3).

K[Cotrdta]·$2H_2O$: 6.1 g. of H_4trdta, 12 g. of potassium acetate and 5.0 g. of cobalt(II) acetate tetrahydrate were dissolved into 100 ml. of water, to which 2 g. of active charcoal and 4 ml. of 30% hydrogen peroxide were then added. Air was passed through the mixture for 50 hr. at room temperature. Then the solution was filtered and the filtrate evaporated to 25 ml. on a water-bath. During the evaporation the solution was bubbled with a current of air. After the solution had been cooled to 0°C, the reddish violet crystals deposited were collected and washed with alcohol and ether. The compound was recrystallized from water by the addition of alcohol and dried over a silica gel desiccator.

Found: C, 30.27; H, 3.93; N, 6.26; H_2O, 8.13. Calcd. for K[Co($C_{11}H_{14}N_2O_8$)]·$2H_2O$: C, 30.28; H, 4.16; N, 6.42; H_2O, 8.26%.

Apparatus.—The crystalline water of the complexes was determined by a Shimadzu RT-2 recording thermobalance. The infrared spectra were measured with a Hitachi EPI-2G recording infrared spectrophotometer by the potassium bromide disk method. The visible and ultraviolet spectra were obtained by using a Hitachi EPU-2 spectrophotometer at room temperature.

Results and Discussion

Infrared Absorption Spectra.—The carboxyl stretching bands of H_4edta and the related compounds are shown in Fig. 1. In Table I are summarized the frequencies of the absorption bands of these compounds. The values obtained for H_4edta and H_4pdta almost agree with those reported in the literature.[6,7] It has been known that the ionized COO^{-} stretching band occurs at 1610~1550 cm^{-1} and the unionized COOH stretching band at 1725~1700 cm^{-1}.[8] The compounds investigated in

this study show similar absorption spectra, except that H_4cydta gives an additional strong and sharp absorption band at 1587 cm^{-1}, a band which can be assigned as ionized COO^-. This may be the evidence for the fact that H_4cydta forms a so-called "zwitter ion" in the solid state.

The coordinated $COO^-\cdots M$ stretching bands of the cobalt(III)-trdta and the related complexes are listed in Table II. The values obtained for the cobalt(III)-edta and the cobalt(III)-pdta complexes agree with that reported by Busch and Bailar[9] and those by Gillard[10] and Swaminathan and Busch[11] respectively. Busch et al. found that the cobalt(III)-edta complex gave a single and strong carboxylate band at higher frequencies than those of the free COO^- band, and they considered this to be the indication of the covalent character of the metal-carboxylate bond.[9,12] The results given in Table II indicate that the character of the metal-carboxylate bond in the cobalt(III) complexes with trdta, pdta and cydta closely resembles that in the cobalt(III)-edta complex. Although the carboxylate band of K[Cotrdta]·$2H_2O$ split into two absorption peaks at 1661 cm^{-1} and 1639 cm^{-1} (Fig. 2), both peaks are considered to be associated with the coordinated carboxyl groups. This strongly suggests that a quadrivalent trdta anion in the cobalt(III) complex is hexadentate.

TABLE II. INFRARED ABSORPTION OF Co(III)-trdta AND THE RELATED COMPLEXES (cm^{-1})

Compound	$COO^-\cdots M$
K[Cotrdta]·$2H_2O$	1661(sh), 1639

K[Copdta]·H_2O	1653

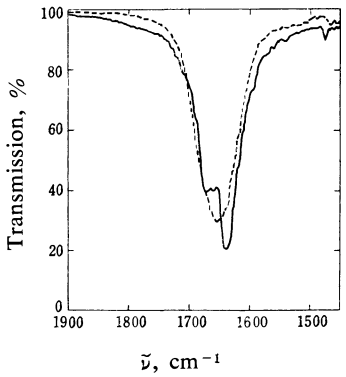

Fig. 2. Infrared absorption spectra of K[Copdta]·H_2O (dotted line) and K[Cotrdta]·$2H_2O$ (full line).

Visible and Ultraviolet Absorption Spectra.— The characteristic numerical data of the visible and ultraviolet spectra for the cobalt(III) complexes with trdta and the related complexes are presented in Table III, from which it can be seen that the absorption spectra of Na[Coedta]·$4H_2O$, K[Copdta]·H_2O and K[Cocydta]·$3H_2O$ are essentially identical, while those of K[Cotrdta]·$2H_2O$ are somewhat different. The intensities of the first and the second absorption bands of K[Cotrdta]·$2H_2O$ are smaller than, and the wavelength of the first band of K[Cotrdta]·$2H_2O$ is longer than, those of the other three complexes. Furthermore, as may be seen in Fig. 3, the broadening of the first band is observed with K[Cotrdta]·$2H_2O$. Yamatera predicted from the molecular orbital calculations that the first band of a complex of the $[CoA_4B_2]$ type splits into two components.[13] The broadening of the first band of K[Cotrdta]·$2H_2O$ seems to support Yamatera's prediction. Although the broadening or splitting of the first band was not

Summary

The synthesis of a new cobalt(III) complex, K[Cotrdta]·$2H_2O$ (trdta, $(^-OOCH_2C)_2N(CH_2)_3N(CH_2COO^-)_2$), has been carried out. The infrared, visible and ultraviolet absorption spectra indicate that a quadrivalent trdta anion in this complex is hexadentate. The infrared, visible and ultraviolet absorption spectra of the cobalt(III) complexes with ethylenediaminetetraacetate, propylenediaminetetraacetate and *trans*-1,2-cyclohexanediaminetetraacetate have also been observed and discussed.

Kinetic Energies of Fragment Ions from n-Butane Resulting from Electron Impact

By Miyako INOUE and Akibumi DANNO

(Received February 10, 1964)

Fragment ions from polyatomic molecules produced by electron impact sometimes possess considerable kinetic energy, the so-called initial energy, which may amount to several electron volts. In early studies the initial energy of ions was measured to determine the ionization potential of ions from their appearance potential. Recently, however, the kinetic energy has come to be of importance in itself, because it provides valuable information on the molecular structure and on the primary processes of the radiation chemistry.

The kinetic energy of fragment ions from *n*-butane produced by electron impact has been studied by many workers. Using the retarding potential method, Fox and Hipple[1] reported that fragment ions of a small mass and those formed by complex dissociation processes always had a high kinetic energy. Taubert[2] carried out a systematic measurement of the kinetic energy of fragment ions from some paraffins and mono-olefines; varying the repeller voltage, he showed that more abundant fragment ions normally have lower kinetic

1) R. E. Fox and J. A. Hipple, *Rev. Sci. Instr.*, **19**, 462 (1948).
2) R. Taubert, "Advances in Mass Spectrometry," p. 486 (1959).

energies. Mohler et al.[3] observed some ions of a high kinetic energy from polyatomic molecules, and they proposed that these ions are produced from the decomposition of doubly-charged molecule-ions. On the other hand, Washburn and Berry[4] attempted to estimate the initial energies of various ions from *n*-butane, using a discrimination method.

Conventional mass spectrometers exhibit a phenomenon called "discrimination," in which ions having initial energies tend to fail to pass through the slit system of the ion-source and the analyzer tube because of the effect of the velocity components perpendicular to the principal motion through the system. On the basis of his experiments, Berry[5] pointed out that the initial velocity distribution could be obtained from the discrimination data and that it was possible to utilize the discrimination effect to determine the average value of initial kinetic energies; he studied theroretically and experimentally the effects of discrimination using the slit system of a mass spectrometer.

The purposes of the present work are two: (a) To investigate the influence of the initial kinetic energy of ions on the relative intensity of the mass spectrum. We studied the difference between the discrimination for ions produced from rare gases in which the initial energy was in equilibrium with the thermal energy, and that for some fragment ions produced from *n*-butane, ions which were believed to have a certain amount of initial energy. (b) On the basis of the information gained about the discrimination effect of the ions with some kinetic energy, the amount of kinetic energy for fragment ions is estimated and the mechanisms of dissociation processes from doubly-charged molecule-ions are considered.

Experimental

A model 21-103-C C.E.C. mass spectrometer was used in the present research. The temperature of the ion-source was kept at 250°C as determined by a thermocouple. The energy of the ionizing electrons was 70 V. and the current was 9.5 μamp. in all experiments. In the instrument, the ions formed in the electron beam are forced through the first slit by a weak repeller voltage and are accelerated in the region between the first and second slits by a high voltage. Between the second slit and the collector slit, the ions travel at a constant speed, but they are caused to move in a circular path by the uniform magnetic field. The mass analyzer tube which is immersed in the magnetic field is a 180° type.

As the instrument is the electric-field scanning type, the ion-accelerating voltage varies in inverse proportion to the mass-chage ratio, *m/e*, of the ions. To determine the discrimination curve, the relative intensity of various ions was measured by scanning accelerating voltage at several magnetic fields.

The samples used in this experiment were standard samples for mass spectrometric analysis and were 99.9% pure.

Experimental Results

The Effect of the Initial Energy on the Relative Intensities of the Mass Spectrum.—The discrimination efficiency is defined as the ratio of the number of ions of a given mass passing through the collector slit in a unit of time to the number of ions initially produced by electron impact. Since the discrimination efficiency depends on the initial energy of ions, on the accelerating voltage, on the repeller voltage, and on the geometry of the

At the normal repeller voltage and at the fixed geometry of the slit system, the measured relative abundance for ions with an initial energy was measured as a function of the ion-accelerating voltage. Table I shows the relative abundance of fragment ions from *n*-butane at two different magnetic fields. The second column of the table shows the relative intensity for fragment ions preduced at a lower magnetic field (the magnetic current was 255 mamp), while the third column shows those at a higher magnetic field (the magnetic current was 300 mamp). The relative intensities for most of the fragment ions, such as the ions of $m/e=$ 58, 42 and 29, are nearly independent of the magnetic field strength and are all about the same, varying only within a few per cent. On the other hand, the relative intensities for

certain ions, such as the ions of m/e =39, 40 and 26, are considerably dependent on the field strength. For instance, the change in relative intensity at the two different magnetic field strengths is about 7% for m/e=39 and about 10% for m/e=26.

Table II shows the relative intensities for krypton isotopes at two different magnetic field strengths. The relative intensities for each isotope ion at the different field strengths are nearly equal, but they have a small dependence on the field strength; that is, the relative intensity of isotopes gradually increases at a high magnetic field as the mass-charge ratio of the ions increases.

Figure 1 shows the relation between the relative intensity of the isotopes of krypton and argon and the accelerating voltage. In this experiment, the accelerating voltage was determined by using the relation between the accelerating voltage and the magnetic field strength, which was adjusted by means of the magnetic current. Although there is a great difference between the mass of argon (m=40) and krypton (m=80), the relative intensities of both ions lie on the same discrimination curve, since the ions for argon and krypton are produced with no initial energy but have only thermal energy which is determined by the temperature of the ions-source, From this finding, it may be concluded that the ions which have only thermal energy but whose mass-charge ratios are different receive the same discrimination effect.

In this instrument, since ions are analyzed by the electric-field scanning, the ions are accelerated by the voltage obtained from the following eqation:

$$V_1/V_2=(B_1/B_2)^2 \qquad (1)$$

where V is the accelerating voltage, B is the magnetic field strength, and the subscripts represent two different magnetic fields. Since the accelerating voltage decreases with an increase in the mass-charge ratio of ions, the discrimination efficiency for ions with the same mass increases with an increase in the magnetic field strength, as is shown in Fig. 1. This is a reason why the sensitivity ratios for krypton isotopes measured at different magnetic fields increase with an increase in the mass of ions, as is shown in Table II.

The relative intensities for fragment ions from n-butane were measured at different magnetic fields. Figure 2 shows the discrimination curves for several ions of n-butane. In this figure, the discrimination curves for argon, carbon dioxide and propane ions which were produced with no initial energy are also shown. The relative intensity of the most abundant ion (m/e=43) from n-butane lies on the same discrimination curve as argon, carbon dioxide and propane ions. On the other hand, the curves for the fragment ions, such as ions of m/e=37, 39 and 40, are seen to be extremely steep compared with the former curves. It is reasonable to conclude that these ions are produced with certain amounts of initial energy from the dissociation processes. Furthermore, from the slope of the curves it may be seen that the initial energy for the ion of m/e=37 is greater than those of ions of m/e=39 and 40.

From the effect of discrimination, it may be concluded that the relative intensity of fragment ions with initial kinetic energies greater than the thermal energy is markedly dependent on the conditions of measurement, such as the accelerating voltage or the magnetic field strength.

The Kinetic Energy of the Fragment Ions from n-Butane.—Since the discrimination efficiency for ions with an initial energy markedly depends on the accelerating voltage and on the geometry of the slit system, there is a possibility of utilizing the discrimination effect to determine the average value of initial energies. Berry[5] pointed out that the collection efficiency, N, namely, the ratio of the number of ions of a given mass-charge ratio passing through the collector slit in a unit of time to the number of ions passing the second slit is given by the following equation:

$$N=\frac{1}{2}\left[(1+k)-\frac{L}{w}\sqrt{\frac{V_0}{V}}\right] \qquad (2)$$

where k, w and L are constants determined by the geometry of the slit system, V is the accelerating voltage, and V_0 is the initial energy of the ions. When the initial energy of ions is not so large as the thermal energy, the discrimination effect at the second slit is not so appreciable that the above equation can be applied. On the basis of the results of Figs. 1 and 2, Eq. 2, seems to give a good approximation for the collection efficiency of these ions, because the discrimination effect for ions with the same kinetic energy is not dependent on the mass of ions, as is shown in Figs. 1 and 2, and because the discrimination curves for fragment ions linearly decrease with an increasing $1/\sqrt{V}$, as is shown in Fig. 2.

On the basis of Eq. 2, the kinetic energy for a given ion can be estimated as in Fig. 3. Line (a) in the figure shows a discrimination curve for the A^+ ion with the known kinetic energy of V_{oa}. The dotted lines on both sides of the line are extrapolations of the observed points to $V\rightarrow\infty$, or to the relative intensity, $\rightarrow$0. The line (b) shows a discrimination curve

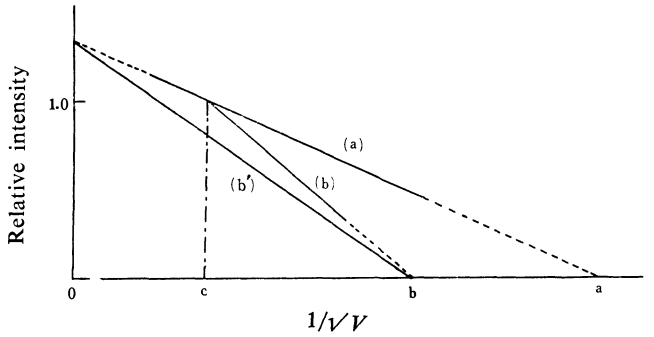

Fig. 3. Calculation of the kinetic energy for ions having initial energy by a graphical method.

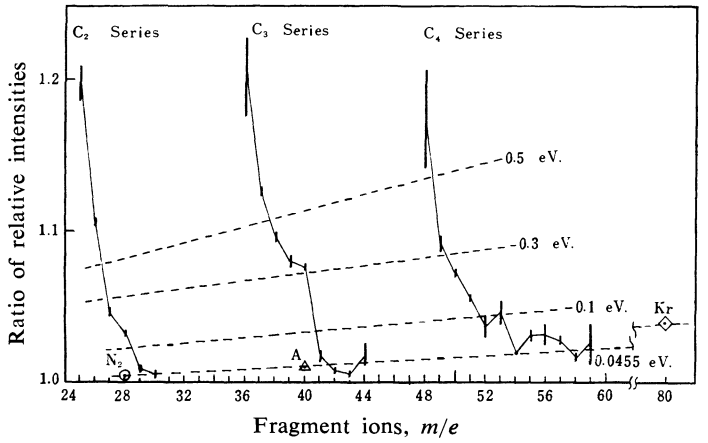

Fig. 4. Ratio of relative intensities at two different magnetic fields and kinetic energies for fragment ions from *n*-butane. Low magnetic field strength was 2386 G and the high field strength was 2807 G.

for the B^+ ion with the unknown kinetic energy of V_{ob}, and the relative intensity for B^+ is normalized at a point C, which is usually the highest voltage obtained. To compare the kinetic energies for the A^+ and B^+ ions, line (b) must be transferred to line (b'), which is normalized at $1/\sqrt{V}=0$. Line (b') is easily obtained as shown in Fig. 3. Let the slopes of lines (a) and (b') be t_a and $t_{b'}$; then the kinetic energy of the B^+ line is given by the following equation:

$$V_{ob}=(t_{b'}/t_a)^2 V_{oa} \qquad (3)$$

Since the kinetic energy of the argon ion of $m/e=40$ is in equilibrium at the wall of the ion-source and is estimated to be 0.0455 eV. at 250°C, the kinetic energy for the fragment ion of $m/e=40$ is estimated to be about 0.31 eV. from the results of Fig. 2 and from the relation of Eq. 3.

The ratio of the relative intensities for a given ion at two different magnetic fields, or at two difierent accelerating voltages of V_1 and V_2, provides information about the initial energy of the ion. Figure 4 shows the ratio of relative intensities for fragment ions from *n*-butane obtained by successive operations (to eliminate an error arising from the pressure drop). In this figure, the dotted lines show the iso-energy curve obtained by the above method for ions with difierent initial energies. The curves for ions of N_2^+, Ar^+ and Kr^+ were obtained with this instrument. The other curves for 0.3 and 0.5 eV. were calculated from Eq. 3, assuming that the kinetic energies for N_2^+, Ar^+ and Kr^+ were thermal energy. From the results of Fig. 4, some information about the initial energy for fragment ions from *n*-butane is obtained: (1) All ions produced from *n*-butane by the scission of CH_3 or C_2H_5 have lower kinetic energies, energies which are comparable with the thermal energy. (2) The ions which are represented by the following formulas have high kinetic energies;

$$C_nH_m^+, \quad n=2,3,4 \quad m=0,1,\ldots,n+1 \qquad (4)$$

In general, the kinetic energy of these ions increases with a decrease in the number of hydrogen atoms; that is, as the number of scissions of the C–H bond increases, the initial

energy for the ions rapidly increases.

Discussion

Fragment ions from *n*-butane produced by electron impact are divided into C_2, C_3 and C_4 series depending on the number of carbon atoms in the ions. The $C_4H_{10}^+$ ion is the parent ion, but its relative intensity is small compared with that of the $C_3H_7^+$ ion, which is the most abundant. This result indicates that the $C_4H_{10}^+$ ion is so unstable that the ion decomposes further into a number of fragment ions as soon as it is formed.

The initial energies obtained in the present experiment for various fragment ions are summarized in Table III. The fragment ions in the second and third columns of the table have only thermal energy. On the other hand, the ions in the fourth and fifth columns have initial kinetic energies larger than the thermal energy. With regard to the relative abundances, in the C_3 series, the intensities of the $C_3H_7^+$ and $C_3H_5^+$ ions are larger than those of the $C_3H_6^+$ and $C_3H_4^+$ ions, and in the C_4 series the intensities of the $C_4H_9^+$ and $C_4H_7^+$ ions are larger than those of the $C_4H_8^+$ and $C_4H_6^+$ ions. In general it is found that the relative intensities of ions with odd numbers of hydrogen atoms are larger than those with even numbers of such atoms. Therefore, it is reasonable to conclude that the fragment ions in a series are formed by splitting hydrogen molecules successively.[6]

However, in the C_2 series the above relation does not hold, because the relative intensity of the $C_2H_4^+$ ions is quite large; it is, in fact, of nearly the same order as that of the $C_2H_5^+$ and $C_2H_3^+$ ions. Moreover, with regard to the initial energies, the $C_2H_5^+$ ion has only thermal energy, while the $C_2H_4^+$ and $C_2H_3^+$ ions have certain amounts of initial energy. Therefore, it is not always true that the less abundant ions have higher initial energies, as Taubert[2] proposed.

It was pointed out by Berry[5] and Mohler et al.[3] that the CH_3^+ ion from *n*-butane produced by electron impact possessed an initial energy of several electron volts. Mohler et al. proposed the mechanism leading to the high initial energy of the CH_3^+ ion. The ion with a high kinetic energy comes from the dissociation of the doubly-charged molecule-ion, because the Coulomb repulsion of these two charges can dissociate the molecule and most of this Coulomb energy will appear as kinetic energy of the fragment ions. The maximum kinetic energy of the CH_3^+ ion was measured as 1.6 eV. by Berry and as 2.2 eV. by Mohler et al. If the high energy of the CH_3^+ ion is produced by the dissociation of doubly charged molecules, the remaining fragment ions will also possess a high kinetic energy.

On the basis of the above assumption, the process for producing the kinetic energies for the $C_3H_3^+$ and $C_3H_4^+$ ions may be explained as follows:

$$(C_4H_{10})^{2+} \rightarrow CH_3^+ + 2H_2 + C_3H_3^+$$
$$\rightarrow CH_4^+ + H_2 + C_3H_4^+$$

When the kinetic energy for the CH_3^+ ion is selected as 1.6 eV., the kinetic energy for the $C_3H_3^+$ ion formed by the above dissociation

6) F. H. Field and J. L. Franklin, "Electron Impact Phenomena," Academic Press Inc., New York (1957), p. 88.

process is calculated as 0.61 eV. On the other hand, the kinetic energy for the $C_3H_4^+$ ion is estimated as 0.64 eV., provided that the kinetic energy of the CH_4^+ ion is of the same magnitude as that of the CH_3^+ ion.

In the case of the C_2 series, the processes for producing the kinetic energies for the $C_2H_3^+$ and $C_2H_4^+$ ions may also be explained by the same assumption:

$$(C_4H_{10})^{+2} \rightarrow C_2H_3^+ + 2H_2 + C_2H_3^+$$
$$\rightarrow C_2H_4^+ + H_2 + C_2H_4^+$$

The kinetic energies for the $C_2H_3^+$ and $C_2H_4^+$ ions are measured as about 0.25 eV. and 0.15 eV. respectively.

In the present experiment, however, the initial energy distribution for ions could not be obtained, although the average energy for mixtures of thermal and high energy ions was obtained. The discrimination effect is larger for high energy ions than for low energy ions. Therefore, the observed values of 0.35 eV. for the $C_3H_3^+$ ion and of 0.31 eV. for the $C_3H_4^+$ ion may turn out to be somewhat smaller than the actual kinetic energy. Using a deflection method, Berry obtained the maximum value of the initial energy for the $C_3H_3^+$ ion as 1.2 eV.[5]; its average value is calculated to be about 0.3 eV. Therefore, the present results are in good agreement with his result. Moreover, these results indicate that a considerable portion of the $C_3H_3^+$ ions is produced by the dissociation of doubly-charged molecule-ions.

Summary

The discrimination effect on the fragment ions from *n*-butane produced by electron impact has been investigated using a conventional mass spectrometer. From the effect of discrimination, it has been concluded that the relative intensity of fragment ions with initial energies larger than their thermal energy is markedly dependent on the conditions of measurement. On the basis of the information gained about the effect of discrimination on ions, the amount of the kinetic energy for fragment ions from *n*-butane has been estimated. From the results of our experiments, it is reasonable to consider that considerable portions of $C_3H_3^+$, $C_3H_4^+$, $C_2H_4^+$ and $C_2H_3^+$ ions are produced with high kinetic energies from the dissociation of the doubly-charged molecule-ion, according as the high kinetic enegy of the CH_3^+ ion is produced.

The authors wish to express their sincere thanks to Dr. Tsutomu Watanabe and Mr. Masamitsu Washino for their valuable discussions, and also to Mr. Hitoshi Hashimoto for assisting in the experimental work described in this paper.

NOTES

Terpenoids. VII. The Isolation of Sandaracopimarinol from the Wood Oil of "Sugi"[*1]

By Shizuo NAGAHAMA[*2]

(Received September 19, 1963)

A recent investigation by Kondo, Imamura and Suda[1] showed the presence of isopimaric acid, sugiol, xanthoperol, ferruginol, β-sitosterol and a new diterpene alcohol, phyllocradanol, in the heartwood extractive of Sugi (*Cryptomeria japonica* D. Don.).

An acetone extract of the sawdust of Sugi wood gave an oil which afforded sandaracopimarinol[2] together with some of the compounds cited above. This is the first time sandaracopimarinol has been found in a natural source. Since sandaracopimaric acid[3] has already been found in the exudates of Sugi, the existence of sandaracopimarinol in the wood is of interest in view of a biogenetic pathway.

A diterpene hydrocarbon with a conjugated diene system was also isolated.

Experimental

The Isolation of an Oily Mixture.—Sawdust of Sugi (12 kg.) collected at a saw-mill on Mt. Seburi, near Fukuoka City, was extracted with hot acetone for 20 hr. The acetone was evaporated off, and the remaining oil was stirred into a tenfold volume of petroleum ether. The petroleum ether solution was then successively washed with a saturated aqueous sodium hydrogen carbonate, 5% sodium hydroxide, and water. After evaporation of the solvent from the solution, the volatile oil (6.35 g.) was removed by steam distillation. The residue was extracted with petroleum ether, which was evaporated off after drying over sodium sulfate, yielding a neutral material (36 g.). This substance was divided by simple distillation into three parts: fraction a, b. p. 110~117°C/4 mmHg (5.5 g.); fraction b, b. p. 177~185°C/4 mmHg (5.5 g.); and fraction c, residue (about 25 g.).

The Separation of Fraction b.—The fraction was chromatographed on an alumina column (100 g.). Petroleum ether eluted an oily diterpene hydrocarbon (1.88 g.) which gave a single peak on gas chromatograph.[*3]

Found: C, 88.04; H, 11.94. Calcd. for $C_{20}H_{32}$: C, 88.16; H, 11.84%.

n_D^{25} 1.5272, λ_{max} 241.5 mμ, ε 12300. ν_{max} 1628, 886 cm^{-1}.

A mixture of petroleum ether and ether (1 : 1) eluted a carbonyl compound (0.06 g.), and ether containing 1% methanol eluted an alcohol fraction (total: 3.40 g.), from which phyllocradanol (0.6 g., m. p. 187.5~188.5°C, recrystallized from methanol) and sandaracopimarinol were isolated (see below).

The Separation of the Residue c.—The residue was chromatographed on another alumina column (190 g.). The results are shown in Table I.

TABLE I

Fr.	Solvent	Volume cc.	Yield g.
1	Petroleum ether	100	0.67
2	Petroleum ether	250	0.22
3	Petroleum ether+Ether (1%)	50	0.12
4	Ether	50	3.35
5	Ether	50	2.25
6	Ether	450	3.47
7	Ether+Methanol (1%)	300	0.82
8	Ether+Methanol (1%)	100	0.90
9	Ether+Methanol (5%)	150	3.59
10	Methanol	300	1.87

Fraction 1 was the same diterpene hydrocarbon that was obtained from fraction b. The presence of an ester was recognized in fractions 2 to 5. Ferruginol was separated from fraction 4 by further chromatography and was identified by infrared spectrum measurement.

[*3] The author is indebted to Professor Yoshio Kitahara and Dr. Akira Yoshikoshi for the gas chromatography and elementary analysis of this hydrocarbon.

Fractions 6 to 9 contained mainly sandaracopimarinol and phyllocradanol. A crude sandaracopimarinol fraction (970 mg.) obtained from fraction 9 was treated with excess acetic anhydride and was left overnight.*4 A petroleum ether extract gave the residue (1.05 g.), which was chromatographed on an alumina column. Petroleum ether eluted the acetate of sandaracopimarinol (495 mg.), and ether eluted phyllocradanol (286 mg.). The saponification of the acetate with ethanolic potassium hydroxide afforded crude sandaracopimarinol (m. p. 40~62°C). 3, 5-Dinitrobenzoate, m. p. 150.5~151.5°C (from a petroleum ether - benzene mixture). Pure sandaracopimarinol, m. p. 63~65°C, $[\alpha]_D$ −11° (*c* 2.34, chloroform), was obtained by the saponification of the 3, 5-dinitrobenzoate.

A crystalline ketone (m. p. 85°C, 0.03g.) was obtained from fraction 6. Fraction 10 solidified on standing and recrystallization from methanol afforded β-sitosterol (m. p. 136~137°C, 435 mg.).

The Oxidation of Sandaracopimarinol.—The alcohol (530 mg.) in acetone (100 cc.) was oxidized with a Jones reagent[4] (about 3 cc.) in 30 min. The mixture was poured into water and extracted with ether. The crude acid (84 mg.) separated in the usual manner was recrystallized from acetone and was purified by silica gel chromatography to afford sandaracopimaric acid (m. p. 171~175°C (from acetone)). No depression was observed by mixed melting point test with an authentic sample. The infrared spectra of the two samples were superimposable.

*4 On the acetylation of the distilled diterpene alcohol fraction, most of the phyllocradanol was precipitated from the acetic anhydride solution.

4) A. Bowers, T. G. Halsall and E. R. H. Jones, *J. Chem. Soc.*, **1953**, 2555.

The author wishes to express his gratitude to Professor Ernest Wenkert, Indiana University, U. S. A., for the authentic sandaracopimaric acid and to Professor Tamio Kondo of this University for the other authentic samples. Thanks are also due to Professor Emeritus Saburo Akiyoshi for his interest and encouragement, to Assistant Professor Masashi Sumimoto of this University for his valuable discussions, and to Dr. Tamaki Kubota for material.

The Selective Nuclear Hydrogenation of Benzyl-type Alcohols. On the Effect of the Solvent

By Yoshiyuki ICHINOHE and Hirotoshi ITŌ

(Received December 16, 1963)

It has been well known that the aromatic nuclear catalytic hydrogenation of benzyl-type oxygen compounds is accompanied by the hydrogenolysis of carbon-oxygen linkage.[1] In recent years, studies concerning the selective nuclear hydrogenation have been described by many investigators. Especially, Nishimura[2] reported that the catalytic hydrogenation of benzyl alcohol (I) by means of Adams' platinum oxide catalyst gave cyclohexylcarbinol (II) in a high yield of 88% at ordinary temperature and pressure in ethanol containing a trace of glacial acetic acid. However, no report on the effect of the solvent has been made.

In order to prepare 1,4-dihydroxymethylcyclohexane (III), an important intermediate of synthetic fiber,[3] we studied the selective nuclear hydrogenation of *p*-xylylene glycol (IV), which had not yet been described. Since IV has two carbon-oxygen linkages susceptible to hydrogenolysis, the hydrogenation of IV to III seemed to be more difficult than that of I to II.

We now wish to report that we have been able to synthesize compound III in an almost quantitative yield at ordinary temperature and high hydrogen pressure in *t*-butanol containing a trace of glacial acetic acid by the use of Adams' platinum oxide catalyst.

It has been found that alcohols used as solvents strongly influence the selectivity of the nuclear hydrogenation of benzyl-type alcohols. The selectivity increases in the following order of the solvent alcohols: prim-<sec-<tert-alcohol. This effect of solvents may be caused by some affinity between the solvent and the catalyst. Supposing that there exist active centers of nuclear hydrogenation and of hydrogenolysis on the surface of the

** Hydrogen up-take became extremely slow and almost stopped at these points.

catalyst, the larger the electron density of the oxygen atom of an alcohol the stronger may be the poisoning with the alcohol which occurs on the active centers of hydrogenolysis, which are supposed to be of an electrophilic character. Therefore, the nuclear hydrogenation is considered to occur selectively.

The experimental data on the hydrogenation of I and IV are shown in Table I. Hydrogenations were carried out in a magnetic, mechanically-stirred autoclave (600 r.p.m.) made of SUS-32 stainless steel.

Runs No. 1 and No. 2, the conversion rates of which were 30 and 100% respectively, show no difference in selectivity, so it seems that subreactions are concurrent.

In tests using various alcohols as solvents, the initial rate of hydrogen absorption in the hydrogenation of IV decreased in the following order; prim->sec->tert-alcohol (cf. Fig. 1).

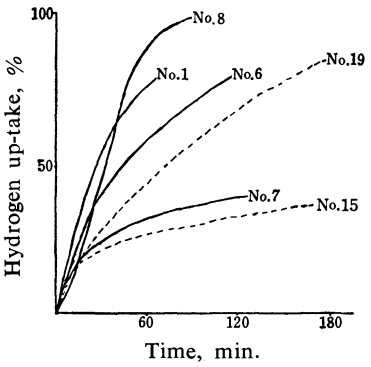

Fig. 1. Effect of solvent on the rate of hydrogen absorption.
Full lines; hydrogenation of IV
Broken lines; hydrogenation of IV

However, the absorption rates of primary and secondary alcohols show a tendency to decrease after the hydrogen absorption goes over 30~40% of the theoretical amount. On the contrary, no such tendency was observed in *t*-butanol. The selectivity of the nuclear hydrogenation diminished in the order: tert->sec->prim-alcohol. Dioxane seemed to make the selectivity higher than primary alcohol, but hydrogen absorption was very slow at the initial stage, and it soon stopped entirely. In the case of I, where the reaction was slower than in the case of IV, the solvent effect was similar to that in the case of IV, and II was obtained in a quantitative yield by the use of *t*-alcohols as the solvent.

The effects of hydrogen pressure on the hydrogenation of IV were studied in about 15 kg./cm^2 and 90 kg./cm^2. The selectivity was higher at the higher pressure, when either ethanol or *t*-butanol was used as the solvent.

In *t*-butanol, the initial rate of hydrogen up-take at the higher pressure was about twice as great as that at the lower pressure, while in ethanol, under the increased hydrogen pressure, the hydrogen up-take was slower and stopped when less than 30% of the theoretical amount.

In the hydrogenation of IV with platinum-rhodium catalysts of the Adams type, the reaction proceeded slowly, both in ethanol and in *t*-butanol, and it stopped halfway (Nos. 5 and 10)*. An analogous result was obtained with the use of a platinum-palladium catalyst of the Adams type (No. 11). On adding 30% of II to I at the starting of a repeated test of No. 14, no hydrogen absorption occurred. When the influence of added organic acids was investigated in *t*-butanol, acetic acid was bound to be the most effective. When a weaker acid was added, the rate of hydrogen absorption was extremely slow; when a stronger acid was added it was fast, but the selectivity was lower (Nos. 8, 12 and 13). Thus, it is necessary to add a proper organic acid in order to accelerate the hydrogenation without inviting hydrogenolysis.

The hydrogenation of IV with palladium, palladium-carbon or nickel on a kieselguhr catalyst gave no III; with Raney nickel (W-2), it gave just a trace of III.

p-Xylylene glycol diacetate (V) more easily underwent hydrogenolysis than IV, and its aromatic nucleus was scarcely be hydrogenated without inviting an extensive hydrogenolysis, as Table II shows.

The authors wish to express their deep thanks to Dr. Nobuto Ohta, Chief of the Department of Organic Synthetic Chemistry, Government Chemical Industrial Research Institute, Tokyo, for many helpful discussions and suggestions during this work.

The Assignment of the Methyl Proton Signals in the NMR Spectrum of Hibaene[*1]

By Yoshio KITAHARA and Akira YOSHIKOSHI

(Received December 26, 1963)

Hibaene, a diterpene isolated from the essential oil in the leaves of *Thujopsis dolabrata* Sieb. et Zucc., has been shown[1] to have structure I.

In order to assign the methyl proton signals in the NMR spectrum of hibaene, the chemical shifts have been compared with those of dihydrohibaene (II), isophyllocladene (III), and phyllocladane (IV).

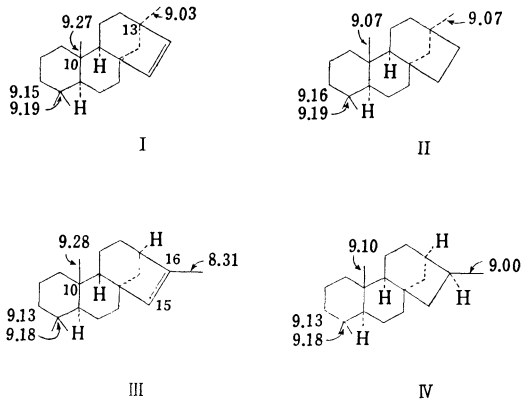

Fig. 1. Chemical shifts of methyl protons.

Hibaene shows four methyl proton signals;[*2] on the other hand, in dihydrohibaene[1] (II), the positions of some of the methyl group signals are displaced in comparison with those of hibaene. This is considered to be due to some of the methyl groups in hibaene being influenced by the anisotropy effect of the double bond. Such effects have been observed, for example, in Δ^7-steroids.[2]

The signals at τ, 8.31 (J=2 c. p. s.) of isophyllocladene[3] (III) and at τ, 9.00 (J=6 c. p. s.) of phyllocladane[4] (IV) appear as doublets; they are, therefore, to be assigned to the C_{16}-methyl group, which is coupled with the C_{15}-proton in III and with the C_{16}-proton in IV. Because there is no change in the chemical shifts of the peaks at τ, 9.13 and 9.18 of III compared to the corresponding peaks of IV, it is deduced that these signals are due to the *gem*-dimethyl group. The remaining methyl signal at τ, 9.28 in III corresponds, therefore, to the C_{10}-angular methyl group; the corresponding signal in IV appears at a lower field (τ, 9.10). The C_{10}-angular methyl group in III is recognized to be shielded by the anisotropy of the double bond.

By applying the results of the above assignments to the spectra of I and II, the methyl proton signals were assigned as follows: (a) the signals at τ, 9.15 and 9.19 of I and at τ, 9.16 and 9.19 of II originate from their respective *gem*-dimethyl groups; (b) the signal at τ, 9.07 of II is due to the C_{10}-angular methyl-group; this is shielded in the the case of I and appears at a high field (τ, 9.27); (c) consequently, the signal at τ, 9.07 of II is assigned to the C_{13}-methyl group in II; this signal appears at a low field (τ, 9.03) in the case of I because of deshielding.

The results of these assignments are depicted in Fig. 1. The C_{10}-angular methyl and the C_{13}-methyl group in I are subject to bond anisotropy effects of the opposite sign, a finding which is in agreement with what would be expected from an inspection of the molecular models.

We wish to thank Dr. Shizuo Nagahama of Kyushu University for the donation of isophyllocladene, and the Shionogi Research Laboratories, Shionogi and Co. for the measurement of the NMR spectra.

*The Synthesis of 3α-Chloro-5, 6α-epoxy-5α-cholestane**

By Michio SHIOTA and Taeko TOYOTA**

(Received December 28, 1963)

One of the present authors (M. S.) and his co-workers have previously reported on a study of the formation and the reactions of 3α-chloro-5, 6β-epoxy-5β-cholestane.[1] This paper will describe a study of the synthesis of an isomeric epoxide, 3α-chloro-5, 6α-epoxy-5α-cholestane.

6β-Chloro-5α-cholestane-3β, 5-diol[2] (I) was chlorinated with phosphorus oxychloride and pyridine.[3] The elementary analysis and infrared spectrum of the product II showed that one of the hydroxyl groups in I was replaced by chlorine. The chlorohydrine II was not acetylated with acetic anhydride and pyridine at room temperature, and it differed from 3β, 6β-dichloro-5α-cholestan-5-ol derived from 3β-chloro-5, 6α-epoxy-5α-cholestane.[4] From these observations it was concluded that the chlorohydrin II is 3α, 6β-dichloro-5α-cholestan-5-ol. The configuration at C_3 was further confirmed by a study of the reactions of the epoxide derived from II.

The chlorohydrin was treated with alkali to afford 3α-chloro-5, 6α-epoxy-5α-cholestane (III). The epoxide was converted into II with hydrochloric acid, and the reaction of III with boron trifluoride-ether complex[5] gave 6-ketone. Whereas 3α-chloro-5, 6β-epoxy-5β-cholestane failed to be reduced with lithium aluminum hydride at the boiling point of ether,[1] the epoxide III was reduced with the reagent to give 3α-chloro-5α-cholestan-5-ol.[3] Hydrolytic cleavage was also effected to give 3α-chloro-5α-cholestane-5, 6β-diol. These reactions confirmed that the epoxide is 3α-chloro-5, 6α-epoxy-5α-cholestane.

Experimental***

3α, 6β-Dichloro-5α-cholestan-5-ol (II). — To a stirred solution of 1 g. of 6β-chloro-5α-cholestane-3β, 5-diol in 25 ml. of pyridine, 10 ml. of freshly distilled phosphorus oxychloride was added over a period of 30 min. at room temperature. Stirring was continued for another hour at room temperature, and then the product was isolated according to the procedure of Shoppee.[3] A pale yellow, oily residue was dissolved in 50 ml. of *n*-hexane, and the solution was stirred with 2 g. of silica gel for 30 min. at room temperature. The removal of the solvent from the filtered solution afforded a colorless crystalline residue. Recrystallization from acetone gave 180 mg. of 3α, 6β-dichloro-5α-cholestan-5-ol (m. p. 118~119.5°C) $[\alpha]_D$ 0° (*c* 2.23, $CHCl_3$).

Found: C, 70.86; H, 10.04. Calcd. for $C_{27}H_{46}Cl_2O$: C, 70.87; H, 10.13%.

The acetylation of the chlorohydrin with acetic anhydride and pyridine at room temperature was attempted, but the starting material was recovered unchanged. 3β, 6β-Dichloro-5α-cholestan-5-ol (m. p. 149~150°C) derived from 3β-chloro-5, 6α-epoxy-5α-cholestane was different from II.

3α-Chloro-5, 6α-epoxy-5α-cholestane (III). — A mixture of 130 mg. of II, 9 ml. of ethanol and 0.4 ml. of 15% aqueous sodium hydroxide was heated under reflux for 30 min. The solvent was then removed under reduced pressure, and the product was isolated with ether in the usual way. Two recrystallizations from methanol gave 72 mg. of the colorless crystalline product, which sintered at 158°C and melted at 160~162°C. Filtration through alumina, followed by recrystallization from methanol, did not raise the melting point. $[\alpha]_D$ −37.7° (*c* 3.18, $CHCl_3$). It gave no yellow color with tetranitromethane and showed no hydroxyl infrared absorption. Infrared absorptions at 1261, 1036 and 875 cm^{-1} (KBr disk) seemed to indicate the 5,6-epoxy group.

Found: C, 76.95; H, 10.29. Calcd. for $C_{27}H_{45}ClO$: C, 77.01; H, 10.77%.

The Reduction of the Epoxide III with Lithium Aluminum Hydride.—The epoxide was reduced with lithium aluminum hydride at the boiling point of ether in the usual way to give 3α-chloro-5α-cholestan-5-ol in an almost quantitative yield (m. p. 118~120°C (lit.,[3] m. p. 118~119°C)).

The Reaction with Boron Trifluoride-Ether Complex. — Freshly-distilled boron trifluoride-ether complex (4 drops) was added to a solution of 50 mg. of III in 5 ml. of dry benzene. After the mixture had been allowed to stand at room temperature for 20 min., it was treated with aqueous sodium bicarbonate and washed with water. The removal of the solvent from the dried solution gave a brown oily residue (52 mg.), which showed hydroxyl and ketonic infrared absorptions. The attempted crystallization of the oil from various

*** All melting points are uncorrected

solvents was not successful. The oily material was heated with 3 drops of concentrated hydrochloric acid in 10 ml. of ethanol to give a semicrystalline product, from which 3α-chloro-5α-cholestan-6-one was isolated in about a 50% yield by recrystallization from acetone. From this result, it was inferred that the oily product contained 3α-chloro-5β-cholestan-6-one,[4] a rearrangement product of the epoxide III, which was isomerized to 5α-6-one by treating it with hydrochloric acid.

The Hydrolytic Cleavage of the Epoxide III. — A mixture of 60 mg. of III, 4 ml. of acetone and 0.1 ml. of a 5% phosphomolybdic acid solution (in acetone) was kept at 28~30°C for 2.5 hr.[6] The solution was then treated with ammonia solution to remove phosphomolybdic acid, and the product was isolated with ether. An oily residue (60 mg.) was crystallized from methanol to give a crystalline product (30 mg.). Recrystallization from methanol gave 3α-chloro-5α-cholestane-5, 6β-diol in needles (20 mg.) (m. p. 130~134°C). The acetylation of the diol afforded an acetate (m. p. 129~130°C). The acetate was identified by comparing it with the acetate derived from 6β-acetoxy-5α-cholestane-3β, 5-diol.

6β-Acetoxy-3α-chloro-5α-cholestan-5-ol from 6β-Acetoxy-5α-cholestane-3β, 5-diol. — 6β-Acetoxy-5α-cholestane-3β, 5-diol[7] (1 g.) was chlorinated with 10 ml. of freshly-distilled phosphorus oxychloride in 25 ml. of pyridine as described above. An oily product was crystallized from methanol to give 650 mg. of a crude crystalline product (m. p. ca. 118°C). Two recrystallizations from acetone-methanol gave 350 mg. of 6β-acetoxy-3α-chloro-5α-cholestan-5-ol (m. p. 129~131°C). $[\alpha]_D$ −34.9°C (*c* 1.65, $CHCl_3$).

Found: C, 72.41; H, 10.17. Calcd. for $C_{29}H_{49}ClO_3$: C, 72.39; H, 10.27%.

The acetate was identical with the acetate derived from the hydrolytic cleavage product of 3α-chloro-5, 6α-epoxy-5α-cholestane (mixed melting point test and infrared spectrum).

The Reaction of Enamines with Acetonecyanohydrin

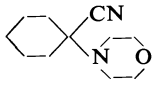
By Yujiro NOMURA, Takiko SHIMURA and Yoshito TAKEUCHI

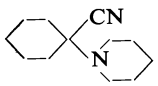
(Received December 29, 1963)

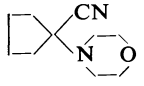
Betts and Davey[1] reported that the alkoxy group in the enol ethers (I) of 2-phenylcyclohexane-1, 3-dione was replaced by a cyano group by a reaction with acetonecyanohydrin, yielding 2-phenyl-3-cyano-2-cyclohexen-1-one (II). In connection with the resemblance of the properties of enol ethers and enamines, the reaction of the enamines (III) of cycloalkanone with acetonecyanohydrin has been investigated and found to yield aminonitrile (IV).

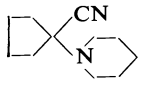
(I) (II)

(III) (IV) (V)









No further reaction to cyanocycloalkene (V) could be observed, even when IV was treated with thionyl chloride in pyridine.[2] Thus, the reaction of 1-morpholino-1-cyclohexene, 1-piperidino-1-cyclohexene, 1-morpholino-1-cyclopentene and 1-piperidino-1-cyclopentene with acetonecyanohydrin in chloroform in the presence of triethylamine gave 1-cyano-1-morpholinocyclohexane (VI) (m.p. 44～45°C), 1-cyano-1-piperidinocyclohexane (VII) (m. p. 67～68°C), 1-cyano-1-morpholinocyclopentane (VIII) (m. p. 53～54°C), and 1-cyano-1-piperidinocyclopentane (IX) (b. p. 88°C/3 mmHg) respectively. Of these aminonitriles, VIII and IX are new substances.

The identity of these products was confirmed by a comparison with authentic samples prepared by the condensation of cycloalkanone-cyanohydrin with morpholine or piperidine. The infrared spectra of these aminonitriles (VI—IX) in a carbon tetrachloride solution had an absorption at 2225～2230 cm^{-1}, indicating the presence of a cyano group.

TABLE I. AMINONITRILES PRODUCED BY THE REACTION OF ENAMINE WITH ACETONECYANOHYDRIN

Aminonitrile	No.	Yield %	B. p. °C/mmHg	M. p. °C	IR cm^{-1}	N % Calcd.	N % Found
	VI	74 (almost quanti.)	127~133/4[a]	44~45[a] (45)	2230 1122 (2230) (1120)	14.42	14.31
	VII	57 (47)	(120~121/3)	67~68[b] (67~68)	2230	14.57	14.80
	VIII	55 (almost quanti.)	98~99/2.5	53~54 (52~53)	2225 1117	15.54	15.61
	IX	48 (50)	88/3 (104/4)	n_D^{19} 1.4908 ($n_D^{20.8}$ 1.4901)	2225	15.71	15.70

a) The reported[3] boiling point of VI is 120°C/1 mmHg, and the melting point is 35°C. It was prepared by the catalytic reduction (Pd-charcoal) of 1-cyano-1-morpholino-2-iodocyclohexanein methanol in the presence of triethylamine.

b) The reported[4] melting point of VII is 59°C. It was prepared from piperidine hydrochloride, sodium cyanide and cyclohexanone in an aqueous ethanol solution.

Experimental

All temperatures are uncorrected. The infrared spectra were determined with a Nihon Bunko Model Koken DS 301 spectrophotometer.

The Reaction of Enamines with Acetonecyanohydrin.—To a solution of enamine (0.1 mol.) and triethylamine (0.1 mol.) in 100 ml. of chloroform, one molar equivalent of acetonecyanohydrin was added. After the exothermic reaction had subsided, the mixture was heated under reflux for two hours. The solution was then cooled and poured into 300 ml. of water which had been neutralized with 6 N hydrochloric acid (Congo red). The layers were separated, and the aqueous layer was extracted with three 50 ml. portions of ether. The combined chloroform layer and ether extracts were washed with dilute hydrochloric acid and then with water. After the solution had been dried over anhydrous magnesium sulfate and the solvent had been removed, the crude aminonitrile appeared; this was purified by distillation at reduced pressure or by recrystallization from ethanol.

The aminonitriles obtained by this procedure are listed in Table I along with the results obtained by the condensation of cycloalkanonecyanohydrin with morpholine or piperidine (in parentheses).

The Reaction of Phthalic Anhydride with Cyanoacetic Acid

By Toshio HAYASHI

(Received January 18, 1964)

Yale reported that the reaction of phthalic anhydride with malonic acid, in the presence of pyridine, gave *o*-acetophenonecarboxylic acid in a good yield.[1] The present author has attempted a similiar reaction using cyanoacetic acid in place of malonic acid, expecting to obtain *o*-carboxy-*α*-cyanoacetophenone (I). However, the reaction of phthalic anhydride with cyanoacetic acid in pyridine, in addition to unaltered phthalic anhydride and a small quantity of phthalic acid, yielded a new, bright yellow compound (II) (m. p. 221~222°C, $C_{12}H_6ON_2$).

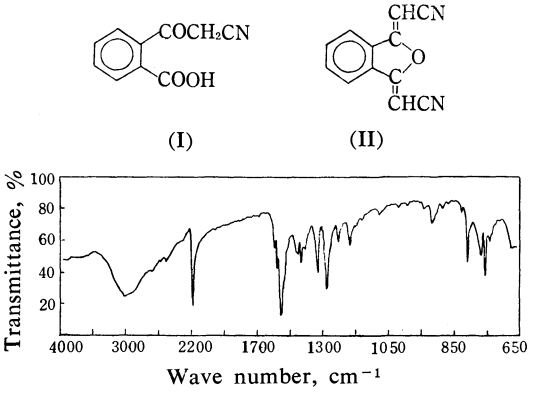

Fig. 1. Infrared spectrum of II in KBr disk.

The infrared spectrum of II (Fig. 1) unexpectedly lacks an absorption band in the C=O stretching region; on the other hand, it does show a sharp and strong band at 2208 cm^{-1} indicating the presence of a conjugated cyano group, and a strong absorption at 1576 cm^{-1}, which is regarded as the C=C stretching frequency which is shifted to the lower wave number region by conjugation with the benzene nucleus and with the cyano group. The enhanced intensity of this band is possibly due to the substitution of a hydrogen atom by an oxygen atom on one of the carbon atoms constituting the double bond. It also shows the out-of-plane deformation band of hydrogen atom of the tri-substituted double bond at 821 cm^{-1} and that of hydrogen atoms of the ortho-di-substituted benzene ring at 768 cm^{-1}. Biscyanomethylenephthalan (II) is the most probable structure to explain all the facts mentioned above. All attempts to hydrolyze II according to the usual method failed giving further evidence that the cyano groups are conjugated with double bonds.

Experimental

Biscyanomethylenephthalan (II).—A finely-powdered mixture of 26.5 g. (0.18 mol.) of phthalic anhydride and 18.0 g. (0.21 mol.) of cyanoacetic acid was heated with 20 ml. of pyridine on a water bath for 1.5 hr. Carbon dioxide was evolved throughout the heating. The clear red solution, on dilution with 200 ml. of water, results in the separation of a colorless solid (m. p. 124~126°C). When this was filtered and dried, it was identified as unaltered phthalic anhydride by a mixed melting point determination with an authentic sample. After the filtrate had been treated with 20 ml. of concentrated hydrochloic acid and allowed to stand for three days at room temperature, the precipitates which formed were filtered and identified as phthalic acid. To the filtrate 20 ml. of concentrated hydrochloric acid was again added and the mixture allowed to stand for additional three days. Clusters of yellow plates appeared on the sides of the flask. These were filtered off; weight 2.3 g. One crystallization of this sample from aqueous ethanol gave bright yellow plates (m. p. 221~222°C).

Found: C, 74.09; H, 2.88; N, 14.03. Calcd. for $C_{12}H_6ON_2$: C, 74.22; H, 3.11; N, 14.03%.

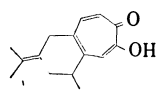
The Synthesis of Procerin



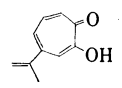
By Yoshio KITAHARA and Tadahiro KATO

(Received January 23, 1964)

In the course of his investigation of the tropolone constituents of *Juniperus procera Hochst*, Buneberg found a propolone, $C_{15}H_{18}O_2$, of a new sesquiterpene type to which he gave the name of procerin. From the chemical and physical experimental facts, the same author proposed structure I for it.[1] However, the synthesis of procerin has not yet been published.

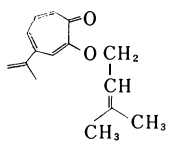
(I)

(II)



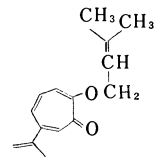
Nootkatin (II)[2,3] which has structure similar to that of procerin, has already been synthesized by Kitahara and Funamizu[4] by applying the Claisen rearrangement reaction. We have expected that procerin may be synthesized by the application of the above method to β-dolabrin (III).

The reaction of the silver complex salt of dolabrin and γ,γ-dimethyl allyl bromide in ether afforded the corresponding allyl ether (IV) of III in a 60% yield. IV was anticipated to be a mixture of two isomers, i. e., IVa and IVb, although several efforts to separate them were all unsuccessful.

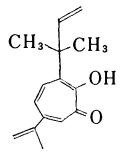


After a mixture of IVa and IVb had been heated in xylene to perform the Claisen rearrangement, the tropolone part was placed in an alkaline solution; this was extracted with ether after an acidification. From the sodium bicarbonate-soluble fraction of the ether solution, III was recovered in a 6.5% yield, while the sodium carbonate-soluble part of it gave a white crystalline compound V (m. p. 68~69°C), whose infrared spectrum is entirely the same as that of natural procerin. Furthermore, the results of the microanalysis of V and its copper complex (m. p. 199~200°C) are satisfactory for procerin and for its copper complex respectively.

We have not isolated the compound VI, which might be formed by the rearrangement which occurs at the ortho position.



Since the synthesis of III had already been carried out, the total synthesis of procerin has now accomplished.



(III)

(IVa)

(IVb)

(VI)

Experimental

Silver Salt of Dolabrin (III). — Dolabrin (III) (1.62 g.) was dissolved into water (300 ml.), and the solution was neutralized with 2 N sodium hydroxide, using phenolphthalein as an indicator. To the solution was added silver nitrate (1.8 g.) in an aqueous solution (50 ml.). The separated yellow precipitate (2.5 g., 97%) were filtered off and dried at 100°C at reduced pressure for 2 hr., using phosphoric acid anhydride.

γ,γ-Dimethyl Allyl Ether IV of III.—(A) well-dried silver complex (2.5 g.) was suspended in absolute ether (30 ml.), and into this suspension γ,γ-dimethyl allyl bromide (1.5 g.) was stirred at room temperature. After being stirred for 1 hr., it was heated under reflux for 2 hr., the separated silver bromide was filtered off, and the ether was removed. Distillation of the resultant residue under reduced pressure afforded a yellow oil (IVa and IVb) (1.27 g., 60%), which has a slight color reaction to a ferric chloride solution.

The Claisen Rearrangement Reaction of γ,γ-Dimethyl Allyl Ether (IV). — A solution of IV (1.27 g.) in xylene (3 ml.) was refluxed for 3 hr. under a nitrogen atmosphere; then the solution was diluted with ether (20 ml.) and extracted with 0.1 N aqueous sodium hydroxide. The sodium hydroxide solution was acidified with sulfuric acid and extracted with ether. The combined ether

solution was extracted three times with a saturated sodium bicarbonate aqueous solution, which was then separated from the ether solution (E_1). The combined sodium bicarbonate solution was washed with ether once, and the ether washing was combined with E_1. The sodium bicarbonate solution was acidified and extracted with ether. The ether extract gave a white crystalline compound (60 mg.) (m. p. 50~53°C), which was identified as dolabrin by mixed melting point determination. E_1 was extracted with a saturated sodium carbonate aqueous solution, which was then separated from the ether solution (E_2). The sodium carbonate solution was washed with ether once, and the ether washing was combined with E_2. The separated sodium carbonate solution was acidified and extracted with ether. The ether solution gave a white crystalline compound (70 mg., 5.5%) (m. p. 68~69°C).

The Instability of Carbon Tetrachloride as a Solvent in the Study of Acid-Base Reactions

By Tai-ichi SHIBUYA* and Yasumasa I'HAYA

(Received January 28, 1964)

Barrow and Yerger[1] studied the acid-base reactions between acetic acid and diethylamine in carbon tetrachloride and chloroform, which are usually recognized as non-dissociating solvents, and reported that an interesting ion-pair with the structure:

(I)

is formed in carbon tetrachloride, but not in chloroform. This conclusion mainly followed from the fact that a new infrared absorption band appears just midway between the monomer and dimer carbonyl-stretching vibration bands of acetic acid in the carbon tetrachloride solution.

We reinvestigated the same system and also the benzoic acid-diethylamine reaction. We observed the same intermediate band as Barrow and Yerger reported, but we also found a new feature, that its intensity increases continuously as time passes. This is schematically shown in Fig. 1. It was also found that a crystalline substance gradually precipitates in the cell and that the solution becomes first yellow and then blue after the solution is taken out of the cell. This was seen over a wide range of concentrations of acids and diethylamine. It can be concluded that the crystalline substance is diethylamine hydrochloride from the fact that its infrared absorption spectrum and melting point agree very well with those of pure diethylamine hydrochloride. This compares favorably with the report of Collins.[2]

We also noticed that diethylamine in the carbon tetrachloride solution itself always shows a weak absorption band at 1741 cm^{-1}, the intensity of band increasing very much in about half an hour and a crystalline substance precipitating in the ordinary cell with a spacer of lead-amalgam. The crystalline substance in this case also was confirmed to be diethylamine hydrochloride. We have, therefore, concluded that the 1741 cm^{-1} band should *not* be assigned to the carbonyl group of the ion-pair (I). Since diethylamine hydrochloride does not show any infrared absorption in the carbonyl-stretching frequency region, the 1741 cm^{-1} band has to be ascribed to another substance, one which is supposed to be produced

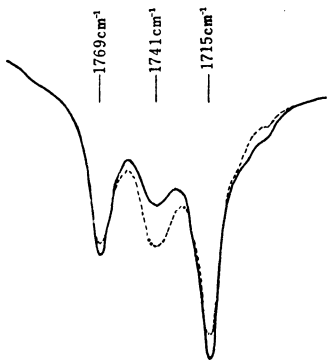

Fig. 1. Non-reproducibility of the infrared absorption curve for the system of 0.001 M acetic acid — 0.001 M diethylamine in the carbon tetrachloride solution. The time interval between first run (solid curve) and second run (dotted curve) is about 2 min. 1769 cm^{-1} band: free carbonyl stretching; 1715 cm^{-1} band: bound carbonyl stretching.

through organic reactions involving a process producing hydrogen chloride. As Ard and Fontaine reported,[3] the mixed solution of diethylamine and carbon tetrachloride, when used as an infrared solvent, tends to become opaque in an ordinary cell with a lead-amalgam spacer, but it is kept transparent for a while in a cell with a polyethylene spacer. We confirmed that this unknown organic reaction is promoted by the existence of a lead-amalgam—the solution rapidly becomes yellow, and soon a sticky, dark brown liquid floats on the surface of the solution, while the amount of the crystalline substance produced increases. We found that carbon tetrachloride acts on triethylamine in the same way as on diethylamine. The previous results obtained for acid-base reactions in carbon tetrachloride by infrared spectroscopy[1] seem, therefore, to be quite disputable, even qualitatively.

The Appearance of Free Radicals during Grignard Reactions

By Kazuhiro MARUYAMA*

(Received February 14, 1964)

Although ionic mechanisms are generally assumed for most Grignard reactions, I have been able to observe free radicals during the course of the addition of Grignard reagents to certain ketones by ESR techniques. Such aromatic ketones as benzophenone, 4-chlorobenzophenone, 4-aminobenzophenone, 4-methoxybenzophenone, 4, 4'-dimethoxybenzophenone, acetophenone and *p*-bromoacetophenone produce free radicals in their reactions with C_2H_5MgI, C_6H_5MgBr and p-$CH_3C_6H_4MgBr$ in tetrahydrofuran (THF).[1] Some aliphatic ketones (such as pentamethylacetone and hexamethylacetone) and benzonitrile also produce free radicals in the reaction.

The ESR measurements were carried out as follows: The carbonyl compounds and the Grignard reagent (each at about 10^{-3} mol.) were mixed at a dry-ice-acetone temperature in the absence of air and moisture. The sapmle was then inserted into a cavity which had previously been cooled with a stream of boiling liquid nitrogen, and the ESR spectrum was measured.

* Present address: Department of Chemistry, Faculty of Science, Kyoto University, Kyoto.

1) The Grignard reagents were prepared from reagent grade magnesium turnings for a Grignard reagent and the corresponding halides.

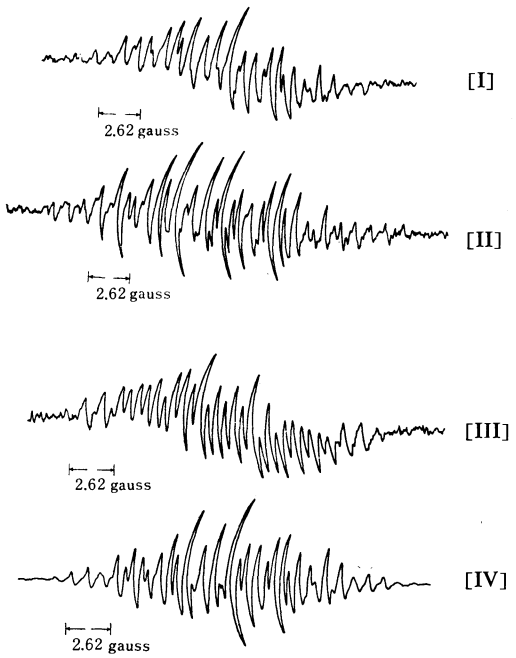

Fig. 1. The ESR spectra obtained during the course of some Grignard reaction.
[I] Benzophenone/phenylmagnesium bromide reacting system at −25°C
[II] Benzophenone/*p*-tolylmagnesium bromide reacting system at −25°C
[III] *p*-Chlorobenzophenone/phenylmagnesium bromide reacting system at −20°C.
[IV] Benzophenone-magnesium ketyl at −20°C

Benzophenone and 4-chlorobenzophenone give well-resolved hyperfine spectra during the course of the reactions with the Grignard reagents mentioned (Fig. 1). The other compounds give a single line. Although it is clear that the free radical in each Grignard reaction is not the ketyl which is obtained through the reduction of the corresponding carbonyl compound with Mg/Hg, a comparison of their ESR spectra and visible absorption spectra indicate that they are quite similar.

Table I. Absorption maximum in the visible absorption spectra of carbonyl/Grignard reacting systems and of the corresponding ketyls

Carbonyl compound	Carbonyl/Grignard system in THF	Ketyl in THF
Benzophenone	555 mμ	615 mμ
4-Chlorobenzophenone	570 mμ	623 mμ

It was also found that the amount of the free radical which is produced in the course of the Grignard reaction depends on the concentration of the Grignard reagent (Table II).

Although the mechanism of the free radical formation can not be clarified by only the ESR technique, the facts described above seem to suggest that the free radical is of the ketyl type and that it is produced through the reduction of ketone by a species such as $(MgX)_2(RMgX)_n$ or $(MgR)_2(RMgX)_n$ which might exist in the Grignard reagent.[2)]

The scope of the formation and the problem of the structure of such free radical species are now under study.

2) There is no conclusive information about the components of Grignard reagents. The existence of an equilibrium such as $2RMgX \rightleftarrows RMgR\ MgX_2 \rightleftarrows RMgR + MgX_2$ is generally believed in, but this is not enough to explain the complex behavior of Grignard reagents. The Polarographic Behavior of Hydroxylycoctonine

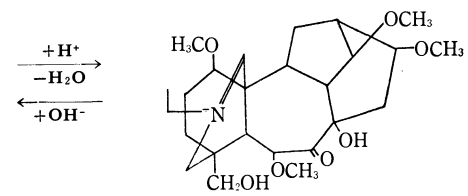
By Shozo YAMADA

(Received February 19, 1964)



Hydroxylycoctonine[1,2] exhibited well-defined polarographic waves in an acidic medium. As is shown in Table I and in Fig. 1, the first wave was observed in the pH range of 2~8 and the second in the pH range of 5~8; the heights of both waves became smaller as the pH became greater, and the waves entirely disappeared at pH values greater than 8.

A slope of 10 mV. per unit change of pH in the $E_{1/2}$~pH curve, a slope of 80 mV. in the log (i/i_d-i)~E curve at pH 1.9, and an $E_{1/4}-E_{3/4}$ value of 100 mV. at pH 1.9 were obtained, these values confirming the irreversibility of

2) O. E. Edwards and L. Marion, *Can. J. Chem.*, 30, 627 (1952).

the electrode process. The irreversibility was observed also in the a.c. polarography of hydroxylycoctonine.

Applying Ilkovic equation with the D value estimated from the molecular weight, $n=2.0$ was obtained.

From the $i_d \sim$pH curve the apparent pK_a of hydroxylycoctonine was assumed to be 5.8; this value was concordant with the reported pK_a (5.8) in a 50% methanol solution.[3]

The limiting current of the wave was confirmed to be diffusion-controlled from the relationship between the height of the mercury column and the limiting current height; it was linearly proportional to the concentration between 0 and 0.27 mmol./l. at pH 1.9.

This polarographic behavior of hydroxylycoctonine can be readily interpreted from the defined structures[3,4] of hydroxylycoctonine (I) and its anhydronium salt (II). Therefore, it is considered that the first wave of the polarogram is due to the $>C=N^+<$ bond and the second to the ketone group in II,* which is formed in an acidic medium.

Similar behavior was observed also in the polarography of acetylanhydrolycoctonine** and of anhydrolycoctonine.***

Further details of the experiment will be published shortly.

Eine π-Dien-Eisentricarbonyl-Komplexverbindung als ein öllöslicher Hydrierungskatalysator

von Ikuei OGATA und Akira MISONO

(Eingegangen am 26. Februar, 1964)

Das π-C_{18}-Dien-carbonsäure-ester-eisentricarbonyl, welches immer bei der Hydrierung des als Fettsäurezusammensetzung Diensäure enthaltenden Öles mit Eisenpentacarbonyl entsteht und bisher für ein Nebenprodukt oder für einen Zwischenkörper im Hydrierungsvorgang gehalten wurde,[1] erwies sich, dass es als ein aktiver Katalysator mit grösserer Aktivität als Eisenpentacarbonyl selbst auf die Hydrierung der CC-Doppelbindung von ungesättigten Fettsäureestern wirkt und sich selbst dabei allmählich—in der Monoen-Körper-Hydrierung ziemlich schneller—zersetzt.

Jeder Versuch wurde mit der einem 0.4～0.8 Gew. % metallischen Eisen entsprechenden Komplexverbindung, welche durch die in der letzten Arbeit[2] berichtete Methode hergestellt wurde, in einem kleinen Edelstahlautoklaven durchgeführt. Das Reaktionsprodukt wurde zur Entfärbung in Äther mit Salzsäure (1 : 1) geschüttelt, und seine Fettsäurezusammensetzung wurde als Methylester durch Gaschromatographie gemessen. Einige Versuchsergebnisse sind in der folgenden Tabelle zusammengestellt.

Bei geeigneten Reaktionsbedingungen verlief die Hydrierung ziemlich selektiv und die Umwandlung von Dien-Körpern, besonders von Konjugierter, in Monoen war bevorzugt. Dabei trat im Vergleich zu Arbeiten mit Festkatalysator verhältnissmässig geringfügige Transisomerisierung ein. Als Eigentümlichkeit des homogenen Katalysators waren die Selektivität und die Geschwindigkeit bei der Hydrierungsreaktion davon unabhängig, ob die Probe als Methylester order als Glycerid zu der Reaktion verwendet wurde. Freie Fettsäuren dagegen, die unter den Versuchsbedingungen kein Komplex bilden, wurden nicht reduziert und verhalten sich wie ein Katalysatorgift, wie es bereits bei der Hydrierung mit Eisenpentacarbonyl bemerkt wurde. Andererseits wurde aber reines Methyloleat hydriert,[3]

obgleich unter den gleichen Umständen auch keine Komplexbildung beobachtet wurde. Das System, welches das im gesättigten Fettsäureester und unter Wasserstoffatmosphäre durch thermische Zersetzung von Eisencarbonylen erzeugte kolloidale Eisen enthält, zeigte keine katalytische Aktivität für die Hydrierung.

Zur Aufklärung dieses Ergebnisses können wir vermuten, dass die Bildung von π-Dieneisentricarbonyl-Komplex keine notwendige Voraussetzung für die weitere Hydrierungsreaktion ist, sondern dass der Komplex in ein Eisencarbonylradikal wie $Fe(CO)_3$ dissoziiert, das auch aus Eisenpentacarbonyl in beschränkten Zuständen erzeugt werden könne und alsbald ins unbekannte aktive Eisencarbonylwasserstoffradikal wie $HFe(CO)_3$[4] übergehen und die Hydrierung verursachen werde. Der Reaktionsmechanismus mit freien Säure ist noch nicht klar.

The Intermolecular Dehydration Reaction of Benzhydrols in Dimethyl Sulfoxide

By Takeo SATO, Akihiko TAKATSU and Kazuo HATA

(Received February 29, 1964)

It has been shown[1] that the treatment of α-(bromomesityl)-benzyl alcohol (Ib) with polyphosphoric acid gives α-(bromomesityl)-benzyl ether (IIb). This mild reaction, which takes place when the mixture is warmed on a water bath for 15 minutes, constitutes the first example of the intermolecular dehydration of alcohol by means of polyphosphoric acid.

I II

a, R=phenyl
b, R=bromomesityl

The current interest in dimethyl sulfoxide as an efficient dehydrating agent, which gives olefins from aliphatic tertiary alcohols or secondary and tertiary benzylic alcohols[2] and substituted tetrahydrofurans from 1, 4-glycols,[3] has lead the present authors to reinvestigate the ether formation reaction of compound Ib in dimethyl sulfoxide.[4] The same reaction was also applied to benzhydrol (Ia) and 9-hydroxyfluorene.

Benzhydrol (0.010 mol.) was heated in dimethyl sulfoxide[5] (0.20 mol.) at 165~170°C for 8 hours under an atmosphere of nitrogen. The dilution of the reaction mixture with water, followed by the filtration and recrystallization of the crystalline product, afforded a 87.5% yield of bis(diphenylmethyl) ether (IIa) (m. p. 108~109°C; ν_{max}^{KBr} 1050, 737 and 698 cm^{-1}). The shorter reaction period employed apparently lowered the yield to 62.5% (4 hr.), whereas the longer heating did not affect the yield since 80% of IIa was obtained after 24 hr. α-(Bromomesityl)-benzyl alcohol (Ib) in the form of colorless prisms (m. p. 65~67°C) (Found: C, 62.77; H, 5.51. Calcd. for $C_{16}H_{17}OBr$: C, 62.96; H, 5.61%) was obtained in a 95% yield by the reduction of benzoylbromomesitylene[6] with a lithium aluminum hydride slurry in ether. It formed an acetate as colorless prisms (m. p. 99~100°C) (Found: C, 62.07; H, 5.21. Calcd. for $C_{18}H_{19}O_2Br$: C, 62.26; H, 5.51%). The treatment of Ib in dimethyl sulfoxide at 165~170°C for 16 hours, followed by the isolation procedure

4) After the completion of the present study, two reports along this line appeared: V. J. Traynelis, W. L. Hergenrother, H. T. Hanson and J. A. Valicenti, *J. Org. Chem.*, **29**, 123 (1964); V. J. Traynelis and W. L. Hergenrother, *J. Am. Chem. Soc.*, **86**, 298 (1964).

5) Dimethyl sulfoxide was dried over potassium hydroxide and fractionally distilled through a Vigreux column under a current of nitrogen; b. p. 84~84.5°C/18 mmHg, n_D^{20} 1.4791.

6) J. F. Hyde and R. Adams, *J. Am. Chem. Soc.*, **50**, 2503 (1928).

described above, afforded 20% of the crude ether as colorless prisms (m. p. 156~158°C), the same compound as the product of dehydration reaction by polyphosphoric acid.[1] By a combination of fractional crystallization and chromatography on alumina it gave α-(bromomesityl)-benzyl ether (IIb) (m. p. 176~177°C) (Found: C, 64.51; H, 5.51. Calcd. for $C_{32}H_{32}OBr_2$: C, 64.86; H, 5.44%), together with a low melting compound (m. p. 152~154°C), probably the structural isomer.

As a related compound, 9-hydroxyfluorene was heated in dimethyl sulfoxide for 24 hours at 165~170°C. It, however, gave 9-fluorenone as a major product (56%), with only a 14% yield of 9-fluorenyl ether. Benzyl alcohol has also been found to give an oxidation product on prolonged heating (20 hr.) in dimethyl sulfoxide at the same temperature; benzaldehyde was obtained in a 15.7% yield, characterized as 2,4-dinitrophenylhydrazone, about 60% of the starting alcohol being recovered by distillation.

The Trans-Configuration in Dimethyltin and Dimethyllead Bis(acetylacetonates)

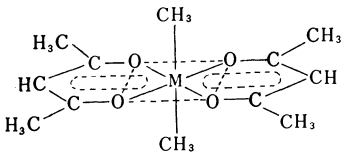
By Yoshikane KAWASAKI, Toshio TANAKA and Rokuro OKAWARA

(Received March 4, 1964)

Recently, a series of diorganotin bis(8-hydroxyquinolinates) and diorganotin (2,2'-bipyridyl)dichlorides have been characterized by the authors[1] and others[2]; all of these compounds seem to have a chelate structure containing a hexa-coordinated tin atom. It is not clear, however, whether they have a cis- or a trans-configuration with regard to the methyl groups. It seemed that it would be interesting to identify one of the isomers which is of either a cis- or a trans-configuration among similar compounds with a hexa-coordinated tin atom.

We have, therefore, prepared dimethyltin and dimethyllead bis(acetylacetonates). Dimethyltin bis(acetylacetonate). M. p. 177～178°C. Found: C, 41.03; H, 5.83; Sn, 34.25. Calcd. for $C_{12}H_{20}O_4Sn$: C, 41.54; H, 5.81; Sn, 34.21%. Dimethyllead bis(acetylacetonate). M. p. 163～163.5°C. Found: C, 33.10; H, 4.58; Pb, 47.53. Calcd. for $C_{12}H_{20}O_4Pb$: C, 33.10; H, 4.60; Pb, 47.58%.

The infrared spectra of these compounds were measured as mulls in Nujol and in hexachlorobutadiene, using a Hitachi EPI-2G grating infrared spectrophotometer for 2～25 μ and a Leitz infrared spectrophotometer equipped with CsBr optics for 15～33 μ. Furthermore, the Raman spectrum of dimethyltin bis(acetylacetonate) was measured in the solid state, using a Nippon Yūki-gōsei Raman spectrograph. The absorption bands and the Raman lines in the 300～600 cm^{-1} region of these spectra are shown in Table I, together with the assignment of the M–C and M–O stretching vibrations. The assignment of the remaining bands will be discussed elsewhere.



The most interesting characteristic of the infrared spectrum of dimethyltin bis(acetylacetonate) is that the only strong antisymmetric stretching vibration of the Sn–C bond was observed at 556 cm^{-1}, while the symmetric one disappeared. On the other hand, the latter was observed at 508 cm^{-1} in the Raman spectrum, as Table I shows. In the infrared

2) D. Blake, G. E. Coates and J. M. Tate, *J. Chem. Soc.*, **1961**, 756; D. L. Alleston and A. G. Davies, ibid., **1962**, 2050.

spectrum of dimethyllead bis(acetylacetonate), similarly, the only antisymmetric stretching vibration of the Pb–C bond was found at 541 cm^{-1}. Considering the selection rules of the infrared and the Raman spectra, two methyl groups in these compounds will be in the trans-position with the central tin or lead atom. The absorption bands due to the ligand of the tin or lead chelate are similar to those of copper acetylacetonate,[3] in which four Cu–O bonds are considered to be equivalent. The four Sn–O or Pb–O bonds in these acetylacetonates seem, therefore, to be nearly equivalent. From these facts, the most probable structure of dimethyltin and dimethyllead bis(acetylacetonates) is considered to be:

Trans-dimethylmetal bis(acetylacetonates)
M=Sn, Pb

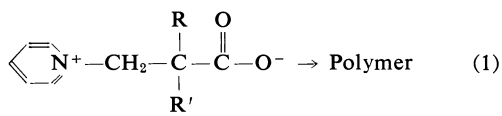
A Molecular Orbital Interpretation of the Ring-opening Polymerization



By Kenichi FUKUI, Hiroshi KATO, Teijiro YONEZAWA and Seizo OKAMURA

(Received March 9, 1964)

One of the most interesting problems in ring-opening polymerization is that of the fission of a particular bond in a definite catalyst. No quantum mechanical interpretation of the results, however, has yet been proposed. In this short communication, it will be shown that the reactivity indices for σ electron systems, that is, the delocalizability (D_r) and the frontier electron density (f_r) proposed in our previous paper,[1] are useful in explaining the experimental results of ring-opening polymerizations of β-propiolactone derivatives by Watanabe, Hayashi and Okamura.[2] It will be pointed out that, in β-propiolactone derivatives (I), the bond fission takes place at the β C–O bond with a basic catalyst such as pyridine:

(I)

(1)

The rate of the polymerization in these derivatives is found to decrease as follows:

α,α-bischloromethyl β-propiolactone >
α-ethyl, α-chloromethyl β-propiolactone >
α-methyl, α-chloromethyl β-propiolactone >
β-propiolactone > α,α-dimethyl
β-propiolactone

With an acid catalyst such as BF_3OEt_2, the order of the reaction rate is reversed; hence, it may be supposed that the magnitude of the σ electron density at the β-carbon atom may be correlated with the experimental results presented above.

We have tentatively treated these compounds by the C–C skeleton method[3] for the sake of simplicity. The values of the parameters used may be summarized as follows:

Coulomb integrals:

$$C(sp^3)=\alpha,\ C(sp^2)=\alpha+0.1\beta,$$
$$\text{and } O(\text{etheric})=O(\text{ketonic})=\alpha+0.3\beta.$$

Resonance integrals:

$$C(sp^3)\text{–}C(sp^3)=\beta,\ C(sp^3)\text{–}C(sp^2)=\beta,$$
$$C(sp^3)\text{–}O(\text{etheric})=0.6\beta,$$
$$C(sp^2)\text{–}O(\text{etheric})=0.7\beta,$$
$$C(sp^2)\text{–}O(\text{ketonic})=1.2\beta,$$

3) H. Yoshizumi, *Trans. Faraday Soc.*, **53**, 125 (1957): K. Fukui, H. Kato and T. Yonezawa, This Bulletin, **33**, 1197 (1960).

$C(sp^3)-C(sp^3)=0.34\beta$,
$C(sp^2)-C(sp^2)=0.40\beta$,
$O-O=0.30\beta$,
} between two hybridized orbitals of the same atom.

In order to characterize the electronic effect of the substituent group at the α-carbon atom in β-propiolactone, two symbols are employed. M denotes an electron-repelling group, and X, an electron-attracting group. We make use of one parameter to represent their electronic effect. The value of the Coulomb integral of M is taken tentatively to be -0.2 (for ethyl)* and to be 0 (for the methyl group), and that of X, to be $+0.2$ and $+0.4$ for the chloromethyl group. The values of the resonance integral for C–M and C–X are taken to be β.

Since it is evident from our frontier electron concept that the frontier orbital of pyridine for an electron acceptor is the highest-occupied lone-pair orbital of nitrogen, we can assume a weak interaction between the nitrogen lone-pair electrons in pyridine and the σ orbital in β-propiolactone derivative molecules at the transition state. Hence, $D_r^{(N)}$ and $f_r^{(N)}$ are employed as the reactivity indices. In Fig. 1, the calculated values of $f_r^{(N)}$ with respect to several lactones are listed. The position of

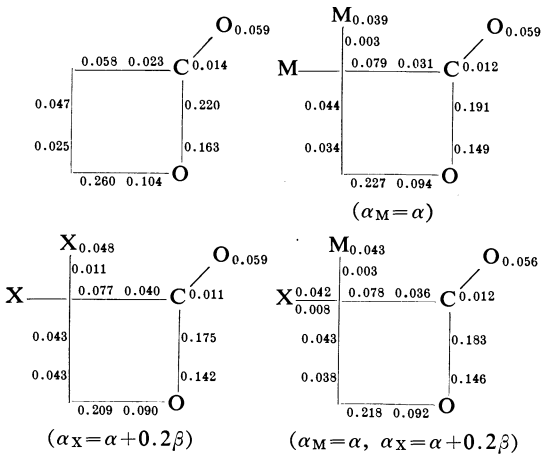

Fig. 1. Values of $f_r^{(N)}$ of some β-propiolactone derivatives.

* Altough this value may be too large, it is adopted just for the convenience of calculation.

Table I. Calculated values of $D_r^{(N)}$ at σ orbital (1) in various β-propiolactone derivatives

$X^{a)}=+0.4$, $X=+0.4$	1.570
$X=+0.2$, $X=+0.2$	1.538
$M=0$, $X=+0.2$	1.536
$M=0$, $X=+0.2$	1.522
$M=-0.2$, $X=+0.4$	1.519
M none, X none	1.510
$M=0$, $M=0$	1.510
$M=-0.2$, $M=-0.2$	1.489

a) X and M denote the values of the Coulomb integral of X and M respectively.

the largest $f_r^{(N)}$ is common with respect to all of these compounds and is the orbital 1 (cf. Eq. (1). This finding is compatible with the experimental evidence.[2] The calculated $D_r^{(N)}$'s of σ orbitals at the β-C atom in the C–O bond are shown in Table I. In view of this finding the more repulsive the substituent group is, the lower is the reactivity of the compound. In the case of the electron-attracting substituent, the more attracting the substituent group is, the higher is the reactivity. This theoretical results is approximately consistent with the experiment which is indicated in Reaction (1).

Accordingly, it may be seen that $D_r^{(N)}$ and $f_r^{(N)}$ are appropriate indices for discussing the reactivity of ring-opening polymerization.

For the case of acidic catalysts, the electrophilic reactivity indices, $D_r^{(E)}$ and $f_r^{(E)}$, can be used. These results will be published in the near future.

The calculation has been carried out on a KDC-I digital computer at Kyoto University.

The Solubility and Anion Exchange Behavior of Heavy Lanthanide Elements in a Potassium Carbonate Solution

By Tomitsugu TAKETATSU

(Received March 13, 1964)

In a previous paper,[1] the present author reported that several lanthanide elements dissolved in a potassium carbonate solution were adsorbed on an anion exchange resin and that both the amount dissolved and that adsorbed increase with the increase in atomic number. However, it was impossible to distinctly detect the order of these amounts dissolved and adsorbed, as well as the position of yttrium among those of lanthanide elements, because of the lack of data for heavy lanthanide elements.

This study treats the behavior of tripositive lanthanide elements other than cerium and promethium. Since the solubilities of lanthanum and praseodymium are small and since the convenient concentration for an anion exchange measurement can not be obtained, both these elements are eliminated from the measurement. From the results obtained, it was observed that there was a distinct difference between the heavy lanthanide elements (Er, Tm, Yb, Lu and Y) and the other light elements. The standard solutions were prepared by dissolving the pure oxides (purity more than 99.8~99.9%) in dilute hydrochloric acid. The quantities of these lanthanide elements and the volumes of the potassium carbonate solutions used in this experiment were identical, i. e., ca. 2×10^{-4} mol. and 5 ml. for the measurement of the solubility (S), and ca. 2×10^{-5} mol. and 20 ml. for that of the distribution coefficient (K_d, cc./g.) respectively. The anion exchange resin used was 1 g. of Dowex 1, X-8, in the carbonate form, of the size of 50~100 mesh.

Figure 1 shows that, when the amount dissolved is more than about 3×10^{-5} mol./ml., the solubility increases with the increase in atomic number, and that, on the other hand, when the amount is less than that, the slope of the curve $\log S$ vs. $\log CO_3^{2-}$ in the heavy lanthanide elements obviously differs from that in other light elements. It may be thought that the order of the solubility varies with the concentration of potassium carbonate. Figure 2 shows the logarithmic plot of the K_d values of four representative lanthanide elements against various concentrations of potassium carbonate. All the curves of $\log K_d$ vs. $\log CO_3^{2-}$ obtained in this experiment give a linearity,

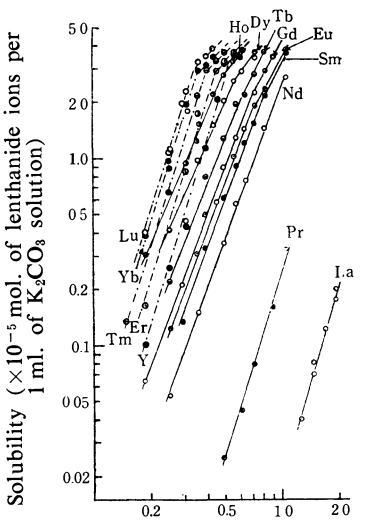

Fig. 1. Relation between the solubility of lanthanide elements and the concentration of potassium carbonate at 20°C.

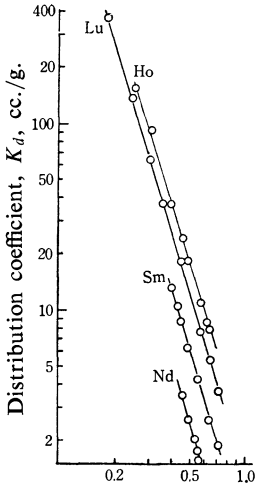

Fig. 2. Distribution coefficient of lanthanide ions between Dowex 1 and potassium carbonate solution at about 20°C.

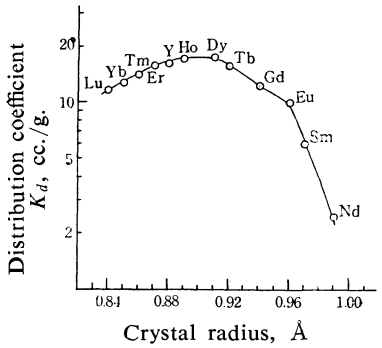

Fig. 3. Relation between the K_d value in a 0.5 M potassium carbonate solution and the crystal radius of tripostive lanthanide ions at about 20°C.

and the lines are parallel to one another, with a negative slope. The relation between the K_d values in a 0.5 M potassium carbonate solution and the crystal radii of tripositive lanthanide ions given by Zachariasen[2] is shown in Fig. 3. These K_d values increase with the increase in atomic number from neodymium to dysprosium or holmium; on the other hand, the values decrease with the increase from erbium to lutetium. The position of yttrium is found to be between erbium and holmium. It is interesting to consider that the maximum K_d value corresponds with the maximum magnetic susceptibility of the lanthanide element.

The details of the experimental procedure will be presented and the findings discussed elsewhere.

Some Stable Sigma-bonded Alkyl Derivatives of Nickel

By Hiroshi YAMAZAKI and Nobue HAGIHARA

(Received March 23, 1964)

In recent years a variety of compounds has been reported in which an aryl or ethynyl group is attached to nickel[1-3] by means of a sigma-bond. However, alkyl derivatives have not been isolated because of their instability, though evidence has been obtained about their formation in solution.[1,4] We now wish to report the preparation of stable sigma-bonded alkyl derivatives of nickel.

The treatment of a solution of methyl magnesium iodide in ether with a solution of triphenylphosphine-π-cyclopentadienyl nickel chloride[5] (decomp. p. 138~139°C. Found: C, 65.53; H, 4.82%.) in benzene under cooling, followed by hydrolysis with aqueous ammonium chloride, chromatography on alumina, and recrystallization from hexane resulted in the formation of dark green crystals of triphenylphosphine-π-cyclopentadienylmethylnickel, (π-C_5H_5)Ni(PPh_3)CH_3 (Yield, 67%; m. p. 115~118°C (decomp.). Magnetic measurement: diamagnetic, $\chi_{mol} = -149 \times 10^{-6}$. PMR: 2.56$\tau$ (C_6H_5); 4.94 τ (C_5H_5); 10.82 τ (CH_3), doublet (J=6 c. p. s.). Found: C, 71.64; H, 5.99; mol. wt. (cryoscopic in benzene), 387. Calcd. for $C_{24}H_{23}PNi$: C, 71.86; H, 5.78%; mol. wt., 401.).

The crystals are stable enough to handle in the air. They are soluble in most organic solvents, although poorly soluble in alcohols; they decompose immediately in carbon tetrachloride. The green solution in benzene is fairly stable under nitrogen, but unstable in the air.

Triphenylphosphine-π-cyclopentadienylethylnickel, (π-C_5H_5)Ni(PPh_3)C_2H_5, was also obtained by a similar procedure (green crystals; yield, 61%; decomp. p. 90~100°C (without melting). PMR: 2.56 τ (C_6H_5); 4.94 τ (C_5H_5); 9.46 τ (C_2H_5), unresolved broad peak. Found: C, 72.64; H, 6.15. Calcd. for $C_{25}H_{25}PNi$: C, 72.33; H, 6.07%). The crystals can be handled in the air, but their solution is less stable than that of the methyl derivative.

More stable phenyl, ethynyl and phenylethynyl derivatives were also prepared by the

The Fractionation of Polypropylene by Extraction with Boiling Hydrocarbons with Increasing Boiling Points

By Akio Nakajima and Hiroshi Fujiwara

(Received July 16, 1963)

The fractionation of polypropylene is generally carried out either by the fractional solution method in a column or by the fractional extraction method in a Soxhlet-type apparatus. As to the column method, two techniques are known: the gradient elution fractionation is achieved at a given temperature by making use of solvents with gradually increasing solvent power, or the increasing temperature fractionation is performed with a given solvent at increasing temperatures. According to the findings on column techniques by Wijga and others,[1] the gradient elution method at a temperature (150°C) sufficiently near the melting point of the polymer separates fractions only according to molecular weight, whereas the increasing temperature method fractionates the polymer mainly according to tacticity. On the other hand, in the fractional extraction in a vapor-jacketed Soxhlet apparatus with boiling solvents with increasing boiling points, separation is considered to be conducted mainly by tacticity. However, in the reports[2-4] published so far, the solvents used for a series of fractional extractions of polypropylene have been comparatively few in number and, moreover, detailed information on the solubilities of polypropylene in these solvents has not been reported.

One of the present authors[5] previously fractionated polyethylene and its thermally degradated product by extraction with boiling hydrocarbons with increasing boiling points in a range from 45°C to 95°C, and pointed out that both the degree of crystallinity (density and melting point) and the molecular weight of the fractionated fraction increase with an increase in the boiling point of the hydrocarbons. Accordingly, this method of fractionation may be regarded as promising for polypropylene also.

In this study, 17 hydrocarbon fractions, mainly based on normal paraffins, with different boiling temperatures in the range from 35°C to 135°C, were used for the fractional extraction of polypropylene in a Soxhlet-type apparatus. With this method, successive fractionations are carried out with hydrocarbons, with different carbon numbers and with different solubilities, at different extraction temperatures corresponding to their boiling temperatures. Thus, fractionation, in this case, is conducted by two parameters. We will discuss the characteristic features of this method in comparison with other methods of fractionation and will also investigate the correlation between the solubility parameters of the solvents at their extraction temperatures and those of polymer fractions extracted at these temperatures, working with experimental findings on molecular weight, degree of crystallinity, tacticity, melting point, and extraction temperature.

Experimental

Material.—The polypropylene used was Moplen AS. Moplen AS pellets were dissolved in a low-boiling-range fraction of kerosene at 140~145°C and precipitated in powder form by cooling the solution to room temperature; then the solvent was evaporated in vacuo at 60°C. The powdered polypropylene thus obtained was used for the fractionation experiments.

Solvents for Extraction.—Purified petroleum ether, petroleum benzine and high-boiling-range ligroin were fractionated by fractional distillation to obtain hydrocarbon fractions with a sharp boiling range. 17 hydrocarbon fractions covering boiling temperatures of 35~130°C were prepared. The boiling temperature range of each hydrocarbon fraction is shown in the second column of Table I. Gas chromatographic examinations of these fractions disclosed that the main components in the fractions were normal paraffin hydrocarbons with carbon number from 5 to 8.

Fractionation Apparatus.—The fractional extraction was carried out in a vapor-jacketed Soxhlet-type apparatus, as is shown in Fig. 1, consisting of a extraction cell equipped with a G-1 glass filter, condensers and a solvent container. The outside of the apparatus was covered with asbestos to keep the temperature constant. With this apparatus, the extraction temperature (see Table I) were kept constant within ±0.3°C.

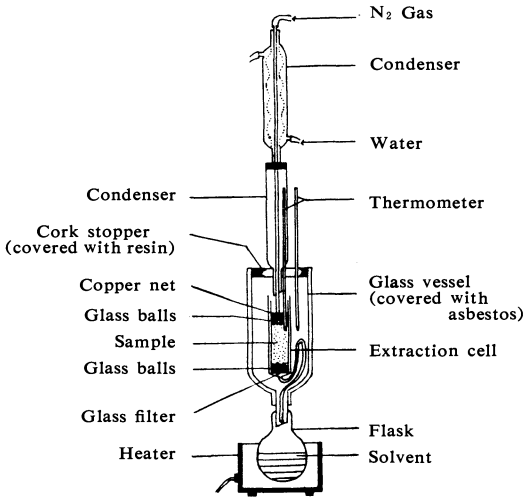

Fig. 1. Extraction apparatus.

Fractionation.—Fifteen grams of a sample was placed in the extraction cell. The extraction of each fraction was performed in 10 hr. by circulating the solvent under flushing (100 cc./min.) nitrogen. The amount of solvent placed in the flask was 400 ~500 ml., and the time needed for one cycle of solvent circulation through the cell was about 10 min. In cases of extractions at above 100°C, 2, 6-di-*t*-butyl-*p*-cresol was added (0.5% of the amount of solvent) to prevent the thermal decomposition of the polymer. The polymer fractions extracted below 100°C were recovered by evaporating the solvent, while those extracted above 100°C were collected in acetone to remove the stabilizer, filtered, and dried in a vacuum oven. The amount of fractions extracted is given in the fifth column of Table I.

Molecular Weight Determination. — The molecular weights, M, of the fractions were estimated by determining the limiting viscosity numbers in decalin, including a small amount of 2, 6-di-*t*-butyl-*p*-cresol, at 135°C, with the equation:[6]

$$[\eta] = 1.10 \times 10^{-4} M^{0.8} \quad (1)$$

where the limiting viscosity number, $[\eta]$, is given in dl./g. units. The viscosity measurements were carried out in a nitrogen atmosphere.

Density Measurement.—Samples were molded in film form under the same conditions and were thoroughly annealed at temperatures suited to the fractions. Density measurements were then carried out by the flotation method in a water-methanol system at 30°C. The degree of crystallization at 30°C, X_c, was estimated by means of Eq 4.

Infrared Spectra. — Samples were dissolved in ligroin with a high boiling point and then cast in films, ca. 20 μ thick, by evaporating the solvent. Infrared absorption spectra were obtained for these films by using a Shimadzu spectrometer (Type AR-275-2S). The ratio of optical densities at 995 cm^{-1} and 974 cm^{-1}, D_{995}/D_{974}, was used to estimate the isotacticity X_i of the samples according to the method of Luongo.[7]

Melting Point Measurement.—The melting points of the samples were determined by visual observations on sufficiently-annealed samples sealed in capillary tubes by raising the temperature at a rate of about 1°C/hr.

Results and Discussion

Fractionation. — Table I shows the boiling temperatures of the solvents, the extraction temperatures, the main components of the solvents, the amounts of the polymer fractions extracted, the limiting viscosity numbers, the degrees of polymerization (P), the densities

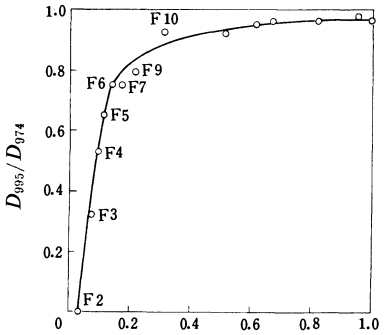

Fig. 4. Integral weight fraction plotted against D_{995}/D_{974}.

(d^{30}), the optical density ratios, and the melting points of the fractions.

In Figs. 2, and 4, the integral weight fraction is plotted against the limiting viscosity number, the density, and the optical density ratio of the fractions respectively. A characteristic feature of the curve shown in Fig. 2 is that the limiting viscosity number of the fractions is almost constant up to about a 0.2 integral weight fraction. This means that the fractionation in the low molecular weight range did not occur according to the molecular weight of the polymer. On the other hand, the curve shown in Fig. 3 or 4 means that the fractionation in the low molecular weight range (F1–F9) was rather determined by the crystallinity or tacticity of the fractions, but that the fractions above F10 were fractionated according to molecular weight and have almost the same crystallinity or tacticity. The integral weight fraction at above 0.3 is abruptly increased with an increase in the density or in the optical density ratio. This behavior is similar in the low molecular weight range to the results obtained for increasing temperature fractionation by the column technique and in the high molecular weight range to those obtained by the gradient elution method. Compared with the increasing temperature method, the maintenance of a constant temperature in the method used here was much easier. Between the melting points of the fractions and the extraction temperatures, a linear relationship was obtained, as is shown in Fig. 5. Presumably, the extraction was carried out at or near the critical solution temperatures of the corresponding polymer fractions. To confirm this,

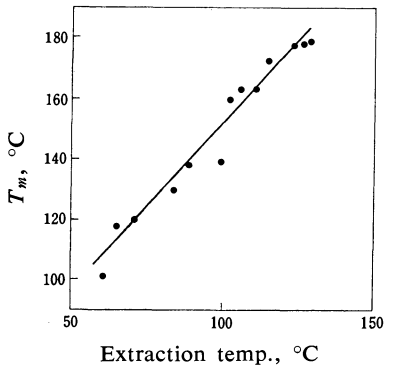

Fig. 5. Melting points of the fractions plotted against the extraction temperature.

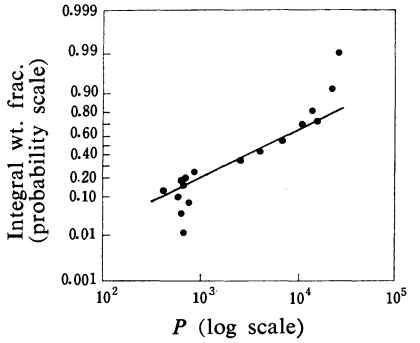

Fig. 6. Integral weight fraction plotted on logarithmic paper. P denotes the degree of polymerization.

some experiments were undertaken. In Fig. 6, the integral weight fraction is plotted against the degree of polymerization on logarithmic probability paper after Wesslau.[8] A straight line was obtained from about a 0.1 to a 0.8 integral weight fraction. Taking into account the fact that the fractionation up to a 0.3 integral weight fraction is carried out according to the degree of crystallinity, it may be concluded that the molecular weight distribution of the sample is given approximately by a log-normal molecular weight distribution except in a sufficiently high molecular weight range. From the slope of the straight line, the ratio of the weight average to the number average degree of polymerization, P_w/P_n, is obtained by using the expression:

$$P_w/P_n = \exp \sigma^2 \qquad (2)$$

were σ is the standard deviation of the Gaussian distribution of the weight fractions against the logarithm of the molecular weight of the fractions; it is determined by the equation: $\sigma = [\sqrt{2\pi}P(\mathrm{d}I/\mathrm{d}P)_{P=P_0}]^{-1}$, in which I denotes the integral weight fraction and P_0 is the degree of polymerization at $I=0.5$. The value of P_w/P_n obtained was 13, which falls in the range of $P_w/P_n=12\sim35$ found[1] for some commercial polypropylene samples.

The Characterization of the Fractions.—Before discussing the solubility of polypropylene, we should refer to the stereoregularity and crystallinity of the fractions. Luongo,[7] after taking into account the fact that the degree of crystallinity of samples with the same tacticity is scarcely affected by the method of sample preparation, obtained a relationship between the tacticity of polypropylene and the D_{974}/D_{995} value from data obtained for a series of mixtures composed of a 100% isotactic and a 100% atactic sample. In this study, the isotacticity, X_i, was obtained from D_{974}/D_{995} using Luongo's method.

On the other hand, the crystallinity, X_c, was calculated from the density of the fractions at 30°C by using the relation:

$$\frac{1}{d} = X_c\frac{1}{d_c} + (1-X_c)\frac{1}{d_a} \qquad (3)$$

in which d_c and d_a are the densities of crystalline and amorphous polypropylene respectively. With $d_c=0.936$, which was obtained by Natta et al.[9] from X-ray data, and with $d_a=0.850$, also obtained by Natta et al.,[10] Eq. 3 becomes:

$$X_c = 11.68 - (9.966/d) \qquad (4)$$

The linear relationship shown in Fig. 7 was obtained between X_i and X_c, from which it is known that the intermediate fractions are different in their tacticities. The extrapolated value of X_c to $X_i=1$ is about 0.8. Since X_i indicates the fraction of maximum crystallizable component, the result means that about 80% of a crystallizable component is really crystallized.

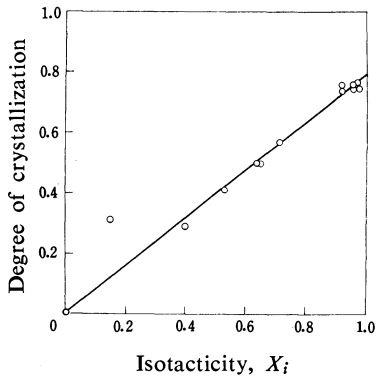

Fig. 7. Relation between the degree of crystallization and the isotacticity of the fractions.

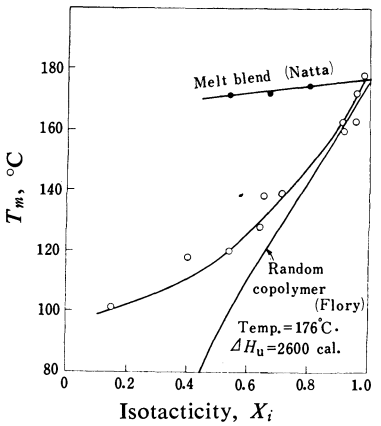

Fig. 8. Melting point-isotacticity relation.

Figure 8 shows the relation between the melting points of the fractions and their isotacticities, together with the results obtained on melt blends of amorphous and crystalline polymers by Natta.[11] Obviously, the melting points of our fractions are much lower than those of melt blends of the same isotacticity. This may mean that our intermediate fractions are composed of copolymers which are built up of components of *d*- and *l*-configurations. Now, we shall apply Flory's[12] equation, proposed for a random copolymer composed of

8) H. Wesslau, *Makromol. Chem.*, **20**, 111 (1956).
9) G. Natta, P. Corradini and M. Cesari, *Lincei-Rend. Sc. fis. mat. e nat.*, **22**, 11 (1957).
10) G. Natta, F. Danusso and G. Moraglio, *Angew. Chem.*, **69**, 686 (1957).

12) P. J. Flory, *J. Chem. Phys.*, **17**, 223 (1949).

crystalline and amorphous components, to the polypropylene fractions. For the present case, the melting point depression should be a function of X_t, instead of the mole fraction of crystalline component in the case of the random copolymer. Thus, we have:

$$\frac{1}{T_m}-\frac{1}{T_m{}^0}=-\frac{R}{\Delta H_u}\ln X_t \qquad (5)$$

in which T_m and $T_m{}^0$ donote the melting point of the fractions and that of $X_t=1$ respectively, and in which ΔH_u indicates the heat of the melting of the polymer.

The curve, T_m against X_t, calculated with $T_m{}^0=176$°C and $\Delta H_u=2600$ cal./mol., a value obtained by Danusso,[13] is given also in Fig. 8. A comparison between the observed and calculated curves shows that the two coincide at higher values of X_t, but at lower values of X_t the observed melting points are higher than the calculated ones for a random copolymer. Such results may suggest that these fractions are composed of stereoblock copolymers (as designated by Natta), which are built up, in a somewhat different fashion in the low X_t range from usual random copolymers, of sequences of *d*- and *l*-configurations of various lengths. In other words, the distribution of such stereoregular-sequence length may differ from that of crystalline-sequence length in random copolymers.

The Fractionation Mechanism in Connection with Solubility Parameters of Solvents.—The solvents used for extraction and the polymer are both aliphatic hydrocarbons, so the solvent-polymer interaction may be approximated by the geometrical mean of the solvent-solvent interaction and the polymer-polymer interaction. Thus, we may discuss the mechanism of the extraction fractionation in connection with the solubility parameter of the solvent, δ_s, and of the polymer, δ_p. Since the partial molar heat of dilution, $\Delta\bar{H}_1$, for the polymer solution is related[14] to the heat parameter, κ_1, by the equation:

$$\kappa_1=\frac{\Delta\bar{H}_1}{RTv_2{}^2} \qquad (6)$$

where v_2 denotes the volume fraction of the polymer in solution, the equation given by Hildebrand;[15]

$$\Delta\bar{H}_1=V_1(\delta_s-\delta_p)^2v_2{}^2 \qquad (7)$$

is rewritten in the form:

$$\frac{\kappa_1}{V_1}=(\delta_s-\delta_p)^2/RT \qquad (8)$$

in which V_1 represents the molar volume of the solvent, and in which the solubility parameter of solvent, δ_s, is calculated by the equation:[16]

$$\delta_s=\frac{\Delta H_v-RT}{V_1} \qquad (9)$$

where ΔH_v is the heat of the vaporization of the solvent at temperature T. Our extraction fractionation was carried out at the boiling points of hydrocarbons with different boiling points. Now we shall estimate the solubility parameters of solvents at their boiling points. It is possible to estimate the heat of vaporization from the boiling point, provided the liquid is nonpolar, by the aid of the "Hildebrand rule." Between the heats of vaporization at the normal boiling point, $\Delta H_{v,b}$ (cal./mol.), and the normal boiling points, T_b (°K), the following relation was found by Scott:[17]

$$\Delta H_{v,b}=17.0\,T_b+0.009\,T_b{}^2 \qquad (10)$$

Thus, we can estimate δ_s at the boiling point of the solvent, the temperature regarded as the extraction temperature, with Eqs. 9 and 10 if the molal volume of the liquid at the boiling point is known.

In Table II, the boiling point, T_b, the molar volume, V_1, of the liquid at T_b, and the solubility parameter of the solvent at T_b are listed. The numerical values of V_1 for the solvents used here were obtained in the following way. At first, the values of V_1 at the boiling points of *n*-pentane, *n*-hexane, *n*-heptane and *n*-octane were calculated using the equation proposed by Sakurada and one of the present authors:[18]

$$V_1=1.143+0.00089\,t+\frac{1}{(0.50-0.00110\,t)n} \qquad (11)$$

where n is the number of carbon atoms in normal paraffin and t is the temperature in °C. Plotting these V_1-values against the boiling temperatures of the corresponding paraffins, we obtained the V_1 values of the solvents used here by interpolation. The δ_s values of normal paraffins at their boiling points are plotted against their boiling points in Fig. 9 (the broken line less sloped). In Fig. 9 also the δ_s values of normal paraffins at temperatures up to their boiling points are plotted against the temperatures (the broken lines more sloped). Our extractional fractionation is carried out along the former broken line; on the other hand, the increasing temperature

method, using a given solvent and the column technique, is performed along a curve as shown by the latter broken lines. In both cases, δ_s decreases with an increase in the temperature; however, the slopes of the curves are different.

TABLE II. SOLUBILITY PARAMETERS OF SOLVENTS AT BOILING POINTS

No.	T_b, °C	V_1 at T_b	δ_s at T_b
1	36.0	118	6.90
2	50.0	128	6.80

17	128.5	188	6.39

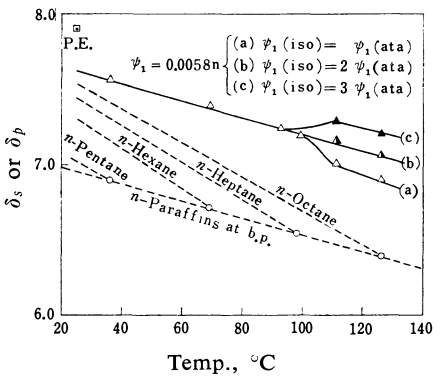

Fig. 9. Cohesive energy density of solvent, δ_s (broken line), and of polymer, δ_p (solid line), as a function of temperature.

Now we would like to speculate about the solubility parameter of the polymer, δ_p. We assume that extraction is carried out at the critical solution temperature, T_c, of the extracted polymer fraction with regard to the hydrocarbon used for extraction. According to Flory,[14] the heat parameter, κ_1, is related to the entropy parameter, ψ_1, and the free energy parameter, χ_1, by $\chi_1 = 0.5 + \kappa_1 - \psi_1$, and the value of χ_1 at the critical temperature is expressed by the equation:

$$\chi_{1,c} = \frac{(1+x^{1/2})^2}{2x} \tag{12}$$

Accordingly, by combining these equations with Eq. 8, we obtain:

$$(\delta_s - \delta_p)^2_{T=T_c} = \frac{RT_c}{V_1}\left[\frac{1}{2x} + \frac{1}{x^{1/2}} + \psi_1\right] \tag{13}$$

where x means the ratio of the molar volume of the polymer to that of the solvent. As the entropy parameter, ψ_1, is independent of the temperature, if ψ_1 is known for the corresponding solvent-polymer system, then we can calculate the δ_p at $T=T_c$ from Eq. 13.

So far we do not have any information about the ψ_1 of polypropylene in aliphatic hydrocarbons. However, the results obtained by Fox[19] for the ψ_1 of polyisobutylene-aliphatic hydrocarbon systems may serve as a reference. The relationship obtained between ψ_1 and the number of carbon atoms in aliphatic hydrocarbons, n, is

$$\psi_1 = 0.0058\, n \tag{14}$$

The δ_p values, calculated from Eq. 13 by the use of the ψ_1 values obtained by assuming Eq. 14 for polypropylene, are plotted against the temperature as curve a in Fig. 9. The curve shows that δ_p is abruptly changed at the fraction (F10) extracted near 100°C. This change in δ_p may be due to the change in T_c arising from the marked effect in tacticity. As is obvious from Fig. 3, the densities of the fractions above F10 are quite high and are almost all the same. Previously we pointed out, on the basis of experiments on polymethyl methacrylate in several solvents,[20] that the ψ_1 of the isotactic polymer is always larger than that of the atactic polymer. If we apply this fact for polypropylene and assume $\psi_1(\text{iso}) = 2\psi_1(\text{atac})$ and $\psi_1(\text{iso}) = 3\psi_1(\text{atac})$, then we obtain curves b and c in Fig. 9. In these estimations, we regarded the fractions extracted at above 100°C as isotactic and used the ψ_1(iso) value, and the fractions extracted at below 100°C as atactic and used the ψ_1(atac) value, the value calculated by Eq. 14. In the case of curve b, δ_p was nearly linearly decreased with the temperature, but in the case of c, the δ_p of the fractions above F10 were located higher than those given by curve b. If we extrapolate the linear portion of these curves for higher fractions, then we have, at a given temperature, $\delta_p(\text{iso}) \gtrless \delta_p(\text{atac})$ according to the condition of a, b, and c. In the present polymer-solvent system, the case c means that the energy interaction between the crystalline segment and the solvent is larger than that between the amorphous segment and the solvent. Such a case is the same as the model

20) I. Sakurada, A. Nakajima, O. Yoshizaki and K. Nakamae, *Koll-Z.*, **186**, 41 (1962).

introduced by Oyama[21] for a crystalline polymer solution. Thus, the condition as given in c seems most probable so far as Eq. 14 is concerned.

So far as Eq. 14 is concerned, the δ_p value of polypropylene at 25°C is estimated as 7.6. This value may be compared to $\delta_p=7.9$ for polyethylene[21] and $\delta_p=8.05$ for polyisobutylene.[22] Taking into account the value obtained here for polypropylene at 25°C, the solubility parameter, δ_s, of *n*-octane or *n*-nonane at 25°C is very close to that of polypropylene at that temperature.

Some Novel Reactions of 1, 1-Diphenyl-3, 3-dibromoprop-1-ene

By Fumio TODA and Hisaya TANI

(Received November 27, 1963)

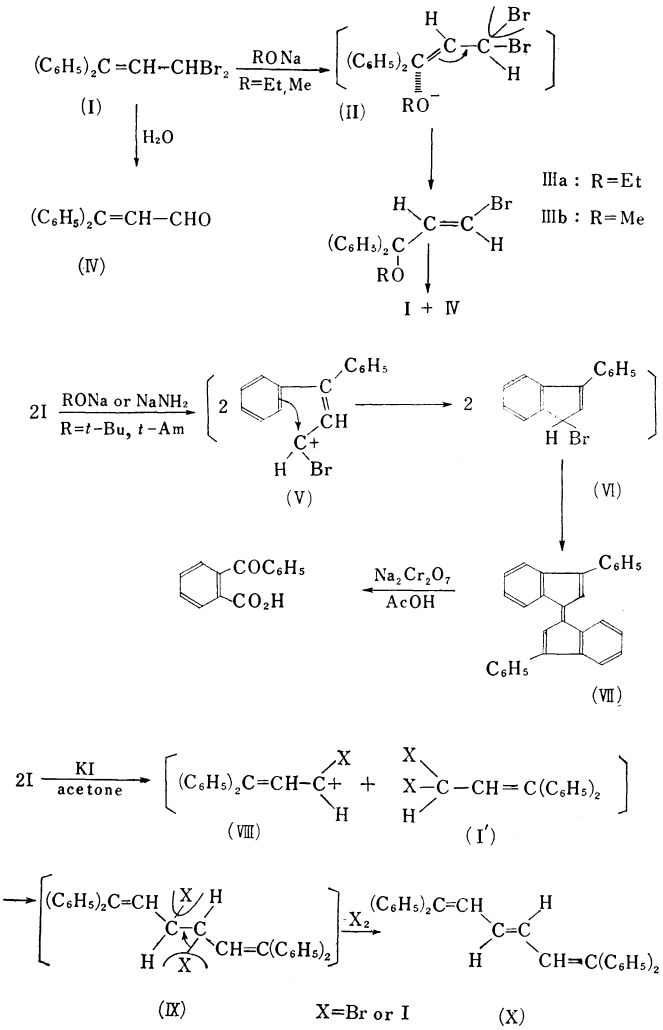
In previous papers,[1] the synthesis of 1,1-diphenyl-3,3-dibromoprop-1-ene (I) from 1,1-diphenylprop-2-yn-1-ol and phosphorus tribromide in acetic acid has been reported.

During the course of the studies of the reactions of the *gem*-dibromide (I), some novel reactions were found. The present paper deals with these reactions and will discuss the reaction mechanism.

The treatment of the *gem*-dibromide (I) with sodium ethoxide in ethanol resulted in *trans*-1,1-diphenyl-1-ethoxy-3-bromoprop-2-ene (IIIa) in a 33% yield. The structure of the compound IIIa was determined by infrared and ultraviolet spectral determination. The ultraviolet spectrum of IIIa is almost identical with that of benzene, indicating the absence of conjugation between benzene nuclei and the double bond. The infrared spectrum of IIIa shows the presence of a non-conjugated trans double bond, an ethoxy group and ether linkage (Fig. 2).

As is shown in the Scheme, this reaction may be attributable to the S_N2' mechanism. At the transition state, the less hindered intermediate (II) most reasonably produces the trans-compound (IIIa).

Although the crystals of IIIa were fairly stable for several days in the absence of air, IIIa was converted into an oily material in about one hour in the presence of air. Some parts of the oil gradually solidified, and the solid was identified as the *gem*-dibromide (I) by mixed melting point determination with an authentic specimen. The unsolidified oil was determined to be 3,3-diphenylprop-3-en-1-al (IV) by infrared spectroscopy. It may be most reasonable to consider the mechanism of this reaction to be the disproportionation of IIIa. The aldehyde IV was also obtained by the hydrolysis of I.[1]



A lower homologue of IIIa, IIIb, obtained by the similar treatment of I with sodium methoxide in methanol, behaved in the same way as IIIa. The less hindered methoxy compound IIIb was less stable than IIIa.

In contrast with the reactions with sodium methoxide or sodium ethoxide, the reaction of I with sodium amide in liquid ammonia resulted in the formation of 3,3'-diphenyl-bis-(1-indenylidene) (VII) in a 50% yield. The compound VII was also obtained, by the treatment of I with sodium *t*-butoxide or sodium *t*-amyloxide, in a 40% yield in both cases. The electronic spectrum (Fig. 1) of the bis(1-indenylidene) (VII) is typical of fulvene derivatives and is similar to that of 3,3'-dibromo-bis(1-indenylidene).[2] The oxidation of VII with potassium bichromate in acetic acid gave *o*-benzoylbenzoic acid. Satisfactory analysis and consistent infrared (Fig. 2) and NMR spectra were also obtained for the compound VII.

As is shown in the Scheme, the formation of VII can be interpreted as the result of the ionic dimerization of the cyclic compound VI produced by the intramolecular cyclization of

2) F. Straus, R. Kuhnel and R. Haensel, *Ber. dtsch. Chem. Ges.*, **66**, 1847 (1933).

the cationic intermediate V initially formed from I.

The heating of the *gem*-dibromide (I) with potassium iodide in acetone for two hours led to *trans*-1, 1, 6, 6-tetraphenylhexa-1, 3, 5-triene (X) in a 74% yield. The ultraviolet (Fig. 1) and infrared (Fig. 2) spectra of X are identical with that recorded by Kuhn and Fischer[3] for X prepared by the partial hydrogenation of 1, 1, 6, 6-tetraphenylhexapentaene. The triene melted at 204°C with or without the addition of an authentic sample, kindly supplied by Professor Richard Kuhn.

On the basis of the experimental finding that the *trans*-triene was obtained exclusively, the following mechanism may be put forward. As is shown in the Scheme, an S_N2 attack of a cationic intermediate VIII on a *gem*-dihalide (I') leads to a dihalogeno compound IX, in which two halogens are located in meso-form fashion, and the intermediate IX finally gives *trans*-triene (X) by the trans-elimination of halogens.

During the reaction of I with potassium iodide, an ionic salt containing an iodide anion formulated as $[C_{30}H_{24}\cdot H_2O]^+I^-$ was isolated as purple black needles; m. p. 155°C. The salt was easily converted into the triene (X) by treatment with ethanol. The structure of this salt is being investigated.

Experimental*

1, 1-Diphenyl-1-ethoxy-3-bromoprop-2-ene (IIIa). —I (1.0 g.) was dissolved in 30 ml. of a 1% solution of sodium ethoxide in ethanol. The mixture was refluxed for 30 min., thus causing sodium bromide

to be deposited. The reaction mixture was poured into water, and the oily material was extracted with ether. The ether layer was washed with water and dried over sodium sulfate. The oily substance obtained by the evaporation of the ether gradually solidified. Recrystallization of the solid from aqueous ethanol yielded IIIa as colorless needles (0.3 g. (33%), m. p. 60°C). IR: KBr disk, 2980 (ethoxy), 1620 (double bond), 1060 (ether) and 952 cm^{-1} (trans). UV: $\lambda_{max}^{Dioxane}$, 253 (470) and 259 mμ (ε, 530).

Found: C, 64.28; H, 5.30; Br, 25.96. Calcd. for $C_{17}H_{17}BrO$: C, 64.35; H, 5.36; Br, 25.24%.

When treated with 2,4-dinitrophenylhydrazine,

IIIa gave directly 2,4-dinitrophenylhydrazone of 3,3-diphenylprop-3-en-1-al quantitatively (m. p. 200 °C (lit.[4] 196°C)).

On being kept standing for an hour, IIIa was degraded into an oily material, some of which was converted into rhombic plates. The crystals melted at 75~78°C and were identified as the *gem*-dibromide (I) by mixed melting point determination.

1,1-Diphenyl-1-methoxy-3-bromoprop-2-ene (IIIb).—By the same treatment employed for the preparation of IIIa, IIIb was obtained from I and sodium methoxide as colorless needles (30%); m. p. 58°C. IR: KBr disk, 1615 (double bond), 1075 (ether) and 970 cm^{-1} (trans).

Found: C, 63.21; H, 5.01. Calcd. for $C_{16}H_{15}BrO$: C, 63.70; H, 5.01%.

IIIb behaved similarly to IIIa but was less stable.

3,3'-Diphenyl-bis(1-indenylidene) (VII), Sodium Amide Method.—To a stirred suspension of sodium amide (3.9 g., 0.1 mol.) in liquid ammonia (100 ml.), a solution of I (8.5 g., 0.024 mol.) in tetrahydrofuran (20 ml.) was added drop by drop over a period of 10 min. After the stirring had then been continued for a further hour, the reaction mixture was decomposed with ammonium chloride (7.0 g.). The solid which remained after the evaporation of the ammonia was extracted with benzene (200 ml.). The benzene solution was washed with water and dried over sodium sulfate. The recrystallization from ethyl acetate of the crude crystals obtained by the evaporation of the solvent from the benzene solution afforded VII as purple red needles (2.3 g. (50%); m. p. 208°C). UV: $\lambda_{max}^{Dioxane}$, 249 (39400), 325 (14800), 400 (27800), 418 (30700) and 500 mμ (shoulder) (ε, 12000).

Found: C, 94.31; H, 5.35. Mol. wt., 380. Calcd. for $C_{30}H_{20}$: C, 94.70; H, 5.30%. Mol. wt., 380.

3,3'-Diphenyl-bis(1-indenylidene) (VII), Sodium *t*-Butoxide Method.—The *gem*-dibromide (I) (0.5 g.) was added to 30 ml. of a 5% solution of sodium *t*-butoxide in *t*-butyl alcohol. The mixture was heated at 90°C. for 10 min. After the reaction mixture had been decomposed by the addition of water, the crude solid which remained was collected by filtration and washed with water and methanol. Two successive recrystallizations of this dried solid from ethyl acetate yielded VII as purple red needles (0.1 g. (40%); m. p. 208°C); these did not show any depression of melting point when mixed with the authentic sample obtained above.

The same treatment of I with sodium *t*-amyloxide in *t*-amyl alcohol also gave VII in a 40% yield.

The Potassium Bichromate Oxidation of VII.—A mixture of VII (0.2 g.), potassium bichromate (1.0 g.) and acetic acid (20 ml.) was heated at 90°C for 30 min. and then refluxed for a further hour. After cooling, the reaction mixture was poured into dilute hydrochloric acid. The crude crystals which separated were collected by filtration and dissolved in ether. The ether solution was extracted with aqueous sodium bicarbonate. Crystals obtained from the acidified alkaline layer were recrystallized from petroleum ether (b. p. 60~70°C) to give *o*-benzoylbenzoic acid as colorless needles (0.1 g. (43%); m. p. 127°C (lit.[5] 127°C)). The substance showed no depression of its melting point on admixture with an authentic specimen.

***trans*-1,1,6,6-Tetraphenylhexa-1,3,5-triene (XI).**—A mixture of I (0.50 g.), finely powdered potassium iodide (0.75 g.) and acetone (20 ml.) was heated under reflux for 2 hr. After the acetone had been removed, the residue was decomposed with water and extracted with ether. The ether layer was washed with aqueous sodium thiosulfate and water, and dried over sodium sulfate. The crude crystals obtained by the evaporation of the solvent were suspended in ethanol and heated for 10 min. The yellow solid collected by filtration was recrystallized from ethyl acetate to yield XI as bright yellow needles (0.2 g. (74%); m. p. 204°C). A mixed melting point determination with an authentic sample, kindly supplied by Professor Richard Kuhn, showed no depression. IR: KBr disk, 977, 968 cm^{-1} (trans) UV: $\lambda_{max}^{Dioxane}$, 355 (shoulder) (42100), 370 (51200) and 390 mμ (shoulder) (ε, 37100).

Found: C, 93.34; H, 6.35. Calcd. for $C_{30}H_{24}$: C, 93.71; H, 6.29%.

The authors wish to express their thanks to Professor Richard Kuhn for supplying a sample of *trans*-1,1,6,6-tetraphenylhexa-1,3,5-triene. They are also indebted to Professor Yasuhide Yukawa and Professor Shigeru Oae for their valuable discussions.

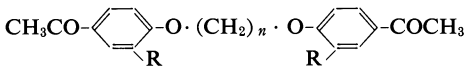
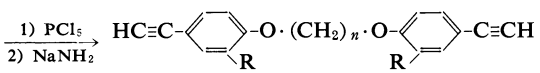
Oligomers and Polymers Containing Triple Bonds. III. Derivatives of α,ω-Bis(4-ethynylphenoxy)alkane[1]



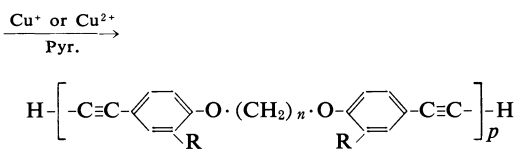
By Hisaya TANI, Ken MURAYAMA and Fumio TODA

(Received December 7, 1963)

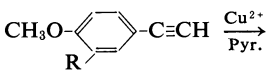


In previous papers[2,3] the oxidative polymerization of conjugated diethynyl compounds to produce conjugated linear polymers containing triple bonds has been reported.

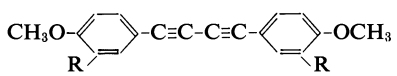
The present paper deals with the oxidative polymerization of non-conjugated diethynyl compounds, α,ω-bis(4-ethynylphenoxy)alkanes (II: R=H) and α,ω-bis(4-ethynyl-2-methylphenoxy)alkanes (II: R=CH_3). In connection with the polymerization, the relation among the kinds of catalysts, the degree of polymerization and the crystallinity of polymers and that between the degree of polymerization and the length of the polymethylenic chain of the monomeric compound (*n*) have been studied.



(I)



(II)



(III)

R=H: n=1, 2, 3, 4, 5, 6 and 10

R=CH_3: n=1, 2, 3, 4, 5 and 6

(IV)

(V) R=H, CH_3

The influence of a methyl group substituted at the benzene ring on the degree of polymerization and on the crystallinity has also been investigated.

Following the method employed for the preparation of α,ω-di(2-ethynylphenoxy)alkane,[4] sodium 4-acetylphenoxide or sodium 4-acetyl-2-methylphenoxide was treated with α,ω-dibromoalkanes in boiling dimethylformamide to produce the diketones (I: R=H or R=CH_3), usually in moderate yields. These diketones were then converted to the chlorinated compounds with phosphorus pentachloride, followed by dehydrochlorination with sodium amide in liquid ammonia to give the diethynyl compounds (II).

The oxidative polymerization of the diethynyl monomers (II) using cupric or cuprous salt in pyridine afforded the corresponding polymers, which were insoluble in common organic solvents. Under some conditions, however, some linear oligomers were produced; for example, when the polymerization of a monomer (II: R=CH_3, n=6) was carried out using cupric salt in pyridine-methanol, the linear dimer (III: R=CH_3, n=6) was obtained as colorless crystals. Although the polymers were stable at temperatures below 150°C, when heated above 200°C in a air bath they turned brown and finally black.

The infrared spectra of most of the polymers show the ethynyl absorption band at ca. 3300 cm^{-1} (Fig. 1); this provides evidence for the linear structure of the polymers. Another confirmatory piece of evidence for the structure involving diphenyldiacetylene and diphenoxyalkane linkages was obtained by comparing the infrared spectra of the polymers with those of standard compounds involving the monomers II, the linear dimer (II: R=CH_3, n=6, p=2), 4,4'-dimethoxydiphenyldiacetylene (V: R=H) and 4,4'-dimethoxy-3,3'-dimethyldiphenyldiacetylene (V: R=CH_3).

The degree of polymerization of the polymer (III) was estimated by comparing the intensity of the ethynyl absorption maximum with that of the corresponding monomer (II),[1,2] as represented by the example shown in Fig. 1.

Although some polymers (III: R=CH_3, n=1, 3, 5) do not show any ethynyl band at ca.

3300 cm^{-1}, their degrees of polymerization are assumed to be higher than 36, since the monomer (II: R=H, n=1, 3 and 5) with an odd number of n yielded higher polymers than those obtained from the monomers (II: R=H, n=2, 4, 6 and 10) showing even mumbers of n, as is shown in Figs. 2 and 3 as well as in Tables I and II, moreover, the polymer (III: R=CH_3, n=4) was estimated to have 36 degree of polymerization according to the spectral estimation cited above.

The high crystallinity of the polymers (III) shown by the X-ray diagrams and the fact that the larger the degree of polymerization, the higher is the crystallinity of the polymer, indicate that the polymers are substantially linear and are arranged in a regular manner.

The degree of polymerization (p) is scarcely affected by the kind of catalyst or by the length of the methylenic chain of the monomer (n), but it is strikingly influenced by whether n is odd or even (see Figs. 2 and 3, Tables I and II).

Experimental*

α,ω-Bis(4-acetylphenoxy)alkanes (I: R=H, n=1, 2, 3, 4, 5, 6 and 10).—Sodium 4-acetylphenoxide prepared from 4-acetylphenol (15.8 g., 0.12 mol.) and a nearly equivalent amount of sodium ethoxide in ethanol, was dried under reduced pressure, mixed with dibromomethane (11.5 g., 0.066 mol.), a small amount of potassium iodide and dimethylformamide (27 ml.), and then heated under reflux for 3 hr. The cooled reaction mixture was poured into ice-water, and the solid which deposited was collected by filtration, washed with water and then recrystallized from ethanol to afford I, R=H, n=1, (15.2 g., 89%) in the form of colorless needles (m. p.

* Melting points are not corrected.

104～105°C). IR: Nujol mull, 1680 (CO), 1275 (=C-O-) and 820 cm^{-1} (*p*-disubstituted benzene).

Found: C, 71.95; H, 5.64. Calcd. for $C_{17}H_{16}O_4$: C, 71.82; H, 5.67%.

A similar treatment of sodium 4-hydroxyacetophenone with α,ω-dibromoalkanes (n=2,3,4,5,6 and 10) yielded the following ketones:

I: R=H, n=2, colorless needles (14%), m. p. 165 °C.

Found: C, 72.40; H, 6.03. Calcd. for $C_{18}H_{18}O_4$: C, 72.46; H, 6.08%.

I: R=H, n=3, colorless needles (21%), m. p. 126 °C.

Found: C, 72.96; H, 6.44. Calcd. for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45%.

I: R=H, n=4, colorless leaflets (60%), m. p. 145.5 ～146.5°C.

Found: C, 73.44; H, 6.79. Calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79%.

I: R=H n=5, colorless leaflets (62%), m. p. 89～90°C.

Found: 74.06; H, 7.16. Calcd. for $C_{21}H_{24}O_4$: C, 74.09; H, 7.11%.

I: R=H, n=6, colorless leaflets (57%), m. p. 123 ～124.5°C.

Found: C, 74.21; H, 7.93. Calcd. for $C_{22}H_{26}O_4$: C, 74.55; H, 7.39%.

I: R=H, n=10, colorless leaflets (67%), m. p. 105 °C.

Found: C, 75.95; H, 8.35. Calcd. for $C_{26}H_{34}O_4$: C, 76.06; H, 8.34%.

α,ω-Bis (4-ethynylphenoxy) alkanes (II: R=H, n=1,2,3,4,5,6 and 10).—A mixture of I: R=H, n=1 (14.2 g., 0.05 mol.), phosphorus pentachloride (27 g., 0.13 mol.) and phosphorus oxychloride (20 ml.) was heated at 70°C for 2 hr. The crude chloride which remained after the removal of the solvent under reduced pressure was dissolved in dry ether (100 ml.), and the solution was added to sodium (10 g., 0.43 g. atom) amide in liquid ammonia (500 ml.). After the ammonia had been evaporated, the residue was decomposed with water and extracted with ether. The ethereal solution was washed with water, dried over magnesium sulfate, and evaporated. The crude crystals thus obtained were recrystallized from ethanol to give II, R=H, n=1, (7.4 g., 60%); m. p. 85.5～86°C. IR: Nujol mull, 3295 (-C≡CH), 2095(-C≡C-), 1220 (=C-O-) and 813, 833 cm^{-1} (*p*-disubstituted benzene).

Found: C, 82.19; H, 4.88. Calcd. for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%.

Further purification of the compound for oxidative polymerization was carried out by means of column chromatography on alumina from carbon tetrachloride.

By the same method as that employed for II, R=H, n=1, the following diethynyl compounds were prepared:

II: R=H, n=2, colorless needles (37%), m. p. 170.5 °C.

Found: C, 82.80; H, 5.54. Calcd. for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%.

II: R=H, n=3, colorless needles (36%), m. p. 124 ～124.5°C.

Found: C, 82.35; H, 5.83. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%.

II: R=H, n=4, colorless needles (47%), m. p. 118.5 ～119°C.

Found: C, 82.26; H, 6.42. Calcd. for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

II: R=H, n=5, colorless needles (70%), m. p. 97～98.5°C.

Found: C, 82.68; H, 6.59. Calcd. for $C_{21}H_{20}O_2$: C, 82.86; H, 6.62%.

II: R=H, n=6, colorless leaflets (32%), m. p. 111～111.5°C.

Found: C, 82.18; H, 7.10. Calcd. for $C_{22}H_{22}O_2$: C, 82.98; H, 6.96%.

II: R=H, n=10, colorless leaflets (56%), m. p. 110 ～111.5°C.

Found: C, 82.34; H, 7.98. Calcd. for $C_{26}H_{30}O_2$: C, 83.38; H, 8.07%.

α,ω-Bis(4-acetyl-2-methylphenoxy)alkanes (I: R=CH_3, n=1,2,3,4,5 and 6).—In the same manner as that described in the preparation of II, R=H, n=1, 2-methyl-4-acetylphenol (30 g., 0.2 mol.) was first converted to its sodium derivative and then treated with dibromomethane (17.4 g., 0.1 mol.) and a small amount of potassium iodide in dimethylformamide (100 ml.) to afford I, R=CH_3, n=1. Recrystallization from ethanol gave colorless needles (10.3 g., 33%), m. p. 132.5～133.5°C. IR: Nujol mull, 1680 (CO), 1275 (=C-O-) and 815 cm^{-1} (1,2,4-trisubstituted benzene).

Found: C, 73.12; H, 6.44. Calcd. for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45%.

A similar treatment of sodium 2-methyl-4-acetylphenoxide with α,ω-dibromoalkanes yielded the following ketones:

I: R=CH_3, n=2, colorless needles (25%), m. p. 167～167.5°C.

Found: C, 73.34; H, 6.77. Calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79%.

I: R=CH_3, n=3, colorless leaflets (52%), m. p. 108.5～109.5°C.

Found: C, 73.98; H, 7.13. Calcd. for $C_{21}H_{24}O_4$: C, 74.09; H, 7.11%.

I: R=CH_3, n=4, colorless leaflets (64%), m. p. 114.5～115.5°C.

Found: C, 74.45; H, 7.34. Calcd. for $C_{22}H_{26}O_4$: C, 74.55; H, 7.39%.

I: R=CH_3, n=5, colorless leaflets (52%), m. p. 81.5～82.5°C.

Found: C, 74.98; H, 7.58. Calcd. for $C_{23}H_{28}O_4$: C, 74.97; H, 7.66%.

I: R=CH_3, n=6, colorless leaflets (76%), m. p. 87～88°C.

Found: C, 75.21; H, 7.90. Calcd. for $C_{24}H_{30}O_4$: C, 75.36; H, 7.91%.

α,ω-Bis(4-ethynl-2-methylphenoxy)alkanes (II: R=CH_3, n=1,2,3,4,5 and 6).—I, R=CH_3, n=1 (7.8 g., 0.025 mol.) was chlorinated with phosphorus pentachloride (11.5 g., 0.055 mol.) in phosphorus oxychloride (20 ml.) at 60°C for 2 hr., and the crude product was treated in the manner shown in the preparation of II, R=H, n=1, to yield II, R=CH_3, n=1, which was then recrystallized to give colorless needles (3 g., 44%), m. p. 138.5～139 °C. IR: Nujol mull, 3260 (-C≡CH), 2100 (-C≡C-), 890 (isolated H) and 815 cm^{-1} (1,2,4,-trisubstituted benzene).

Found: C, 82.63; H, 5.80. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%. Further purification was carried out by column chromatography on alumina from carbon tetrachloride.

Using the method employed for I, R=CH_3, n=1, the following diethynyl compounds were prepared:

II: R=CH_3, n=2, colorless needles (20%), m. p. 166~167°C.

Found: C, 82.73; H, 6.25. Calcd. for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

II: R=CH_3, n=3, colorless plates (46%), m. p. 67.5~69°C.

Found: C, 82.68; H, 6.63. Calcd. for $C_{21}H_{20}O_2$: C, 82.86; H, 6.62%.

II: R=CH_3, n=4, colorless needles (38%), m. p. 103~104°C.

Found: C, 82.70; H, 6.97. Calcd. for $C_{22}H_{22}O_2$: C, 82.98; H, 6.96%.

II: R=CH_3, n=5, colorless needles (34%), m. p. 87~88°C.

Found: C, 82.69; H, 7.24. Calcd. for $C_{23}H_{24}O_2$: C, 83.10; H, 7.28%.

II, R=CH_3 n=6, colorless leaflets (71%), m. p. 91.5~93°C.

Found: C, 83.10; H, 7.61. Calcd. for $C_{24}H_{26}O_2$: C, 83.20; H, 7.56%.

3-Methyl-4-methoxyphenylacetylene (IV: R=CH_3).—A mixture of 3-methyl-4-methoxyacetophenone[5] (8.8 g., 0.053 mol.), chloroform (25 ml.), and phosphorus pentachloride (15.5 g., 0.074 mol.) was heated at 60°C for 2 hr. After the chloroform had been removed under reduced pressure, the crude product was suspended in dry tetrahydrofuran (100 ml.), and the suspension was stirred drop by drop to sodium (6 g., 0.265 g. atom) amide into liquid ammonia (300 ml.). The stirring was continued for a further 1.5 hr. After the ammonia had evaporated, the residue was decomposed with water and extracted with ether. The ethereal layer was washed with water and dried over sodium sulfate. The removal of the solvent afforded IV, R=CH_3 (3.5 g., 44%) as an oily material which partly solidified when kept standing at room temperature. The recrystallization of the solid from ethanol yielded the pure substance in the form of colorless plates; m. p. 75~77°C. IR: Nujol mull, 3295 (-C≡CH), 2095 (-C≡C-), 2850 (-OCH_3) and 898, 820 cm^{-1} (1,2,4-trisubstituted benzene).

Found: C, 82.41; H, 6.82. Calcd. for $C_{10}H_{10}O$: C, 82.16; H, 6.90%.

3,3'-Dimethyl-4,4'-dimethoxydiphenyldiacetylene (V: R=CH_3).—A mixture of IV, R=CH_3, as the crude oil (1.8 g.), cupric acetate monohydrate (1.8 g.) and pyridine (20 ml.) was stirred at 55°C for 2 hr. The solvent was removed in vacuo and the residue was decomposed with water and extracted with ether. The ethereal layer was washed with water, dried over sodium sulfate and evaporated. On recrystallization of the residue from acetone V, R=CH_3, was obtained in a very high yield in the form of colorless needles (m. p. 163~165°C). IR: Nujol mull, 2140 (-C≡C-) and 890, 810 cm^{-1} (1,2,4-trisubstituted benzene). UV: $\lambda_{max}^{Ethanol}$, 262 (56700), 268 (58000), 281 (41000), 300 (37400), 319 (45000) and 342 mμ (ε, 36900).

Found: C, 82.51; H, 6.18. Calcd. for $C_{20}H_{18}O_2$: C, 82.73; H, 6.25%.

4-Methoxyphenylacetylene (IV: R=H) and 4,4'-Dimethoxydiphenyldiacetylene (V: R=H).—4-Methoxyacetophenone[6] (3 g., 0.02 mol.) was treated with phosphorus pentachloride (5 g., 0.024 mol.) and then with sodium amide (0.086 mol.) in liquid ammonia to yield IV, R=H, as an oil which was used for the following coupling reaction without further purification, though it was still somewhat inhomogeneous. IR: liquid, 3300 (-C≡CH), 2850 (-OCH_3), 2140 (-C≡C-) and 835 cm^{-1} (p-disubstituted benzene). In the same manner as that employed for IV, R=CH_3, IV, R=H, was coupled giving quantitatively diacetylene V, R=H, in the form of colorless needles (m. p. 143.5°C). IR: Nujol mull, 2130 (-C≡C-) and 843, 822 cm^{-1} (p-disubstituted benzene). UV: $\lambda_{max}^{Ethanol}$, 267 (27700), 281 (28700), 299 (34000), 317(44000) and 341 mμ (ε, 36700).

Found: C, 82.10; H, 5.37. Calcd. for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%.

The General Procedure for the Oxidative Polymerization of II.—A mixture or II, pyridine and cupric acetate monohydrate or cuprous chloride was stirred under the conditions summarized in Tables I and II. The precipitate formed was collected by filtration, washed successively with dilute hydrochloric acid, water and methanol, and then dried in vacuo.

The Linear Dimer of 1,6-Bis(4-ethynyl-3-methylphenoxy)hexane (II: R=CH_3, n=6).—When the oxidative coupling of II, R=CH_3, n=6, was carried out in methanol-pyridine (30:1) with cupric acetate monohydrate, a small amount of the linear dimer (III: R=CH_3, n=6, p=2) was produced. along with a large amount of an insoluble polymer, Colorless leaflets, m. p. 114~116°C. IR: Nujol mull, 3305 (-C≡CH), 2130, 2090 (-C≡C-) and 885, 815, 805 cm^{-1} (1,2,4-trisubstituted benzene). UV: $\lambda_{max}^{Ethanol}$, 269 (32200), 282 (34300), 298 (40400), 318 (40400) and 340 mμ (ε, 39800).

Found: C, 83.24; H, 7.29. Mol. wt., 699 (camphor). Calcd. for $C_{48}H_{50}O_4$: C, 83.44; H, 7.30%. Mol. wt., 695.

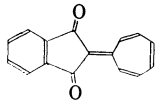
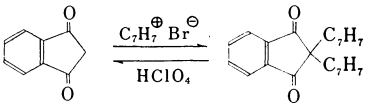
The Synthesis and Reaction of Sesquifulvalene-1, 4-quinone[1]



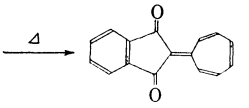
By Yoshio KITAHARA, Ichiro MURATA and Takashi ASANO*

(Received December 20, 1963)

One of the non-alternant hydrocarbons, sesquifulvalene (I), has been synthesized recently by Prinzbach and Rosswog[2] and found to be less stable than was expected from the molecular orbital theory.[3-6] On the other hand, Roberts[7] has pointed out that such



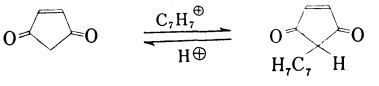
(I) (II)



(III)

unsaturated cyclic hydrocarbons would be expected to form stable quinone derivatives. In this paper we will report on the synthesis and the chemical properties of the following five-membered ring quinone derivatives of sesquifulvalene; sesquifulvalene-1, 4-quinone (II) and 2, 3-benzosesquifulvalene-1, 4-quinone (III).

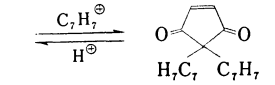
The reaction of indane-1, 3-dione (IV)[8] with 2 mol. equiv. of tropylium bromide (V) in an aqueous solution afforded 2, 2-ditropylindane-1, 3-dione (VI)[9] in a good yield. The two tropyl groups in compound VI were easily cleaved,[10] by the action of perchloric acid, to yield IV and tropylium perchlorate. The thermal decomposition[11] of VI gave 2, 3-benzosesquifulvalene-1, 4-quinone (III) as red needles.



(IV) (VI)

(III)

When cyclopentene-3, 5-dione[12] was allowed to react with 2 mol. equiv. of V, 4, 4-ditropylcyclopentene-3, 5-dione (VIII) was obtained in a very low yield; however, by adjusting the reaction mixture to pH 7 with sodium hydrogen carbonate, VIII could be obtained in an almost quantitative yield.



When an attempt was made to obtain sesquifulvalene-1, 4-quinone (II) by the thermal decomposition of VIII, the only product isolated was a reddish-brown resinous substance. This reaction will be discussed later. On the other hand, it is to be expected that II would be produced by the dehydrogenation of 4-tropylcyclopentene-3, 5-dione (IX). The preparation of this compound IX from VII was attempted, but even when 1 mol. equiv. of V was used, no monotropyl compound IX could be detected. The following equilibrium is supposed to be involved in the tropylation of cyclopentene-3, 5-dione (VII):

This means that, if 1 mol. equiv. of acid were to be used in the reaction, even though VIII were formed, the action of the protons would be expected to cause cleavage in VIII and thus to shift the equilibrium towards the monotropyl compound IX. In fact, when the tropylation was carried out in the presence of a 1 mol. equiv. of hydrogen bromide, an oily substance resulted, and on dehydrogenation with chloranil in xylene, the oil gave II as red plates (m. p. 180~181°C). The possibility that the rearrangement to a benzene derivative might take part in the reaction was excluded by the finding reported below. The expected rearrangement product of II is 4-benzylidene-cyclopentene-3, 5-dione (structure shown below). This compound has already been synthesized by DePuy as pale yellow needles (m.p. 146~146.5°C[13]) and is obviously different from the product (II) (m. p. 180~181°C), obtained above.

The thermal decomposition of 1, 2-dichloro-4, 4-ditropylcyclopentene-3, 5-dione (XI), which was derived from 1, 2-dichlorocyclopentene-3, 5-dione (X),[14] gave 2, 3-dichlorosesquifulvalene-1, 4-quinone (XII) in a good yield.

(X) (XI)

(XII)

All the sesquifulvalene quinone derivatives synthesized as above are red to reddish-orange crystals with high melting points; they are quite stable to air, heat and light.

It is noteworthy that the double bond at the 2, 3-position of the parent compound II is comparatively reactive. Thus, it reacted with bromine in chloroform to give a dibromide XIII as an adduct, and with cyclopentadiene in benzene, even at room temperature, a Diels-Alder reaction occurred to yield an adduct XIV; furthermore, by the action of diazomethane it afforded a pyrazoline derivative XV.

The highly unsaturated nature of the unsubstituted 2, 3-double bond in II accounts for the fact that, in the case of the 2, 3-benzo and 2, 3-dichloro derivatives where the 2, 3-position is substituted, the thermal decomposition of the ditropyl compounds, VI and XI, give III and XII respectively in good yields. Under the same conditions, however, only resinous products were obtained from VIII. This can be understood because, in the latter case, addition would occur between sesquifulvalene-1, 4-quinone and cycloheptatriene,[15] both of which would be formed during the thermal decomposition of VIII.

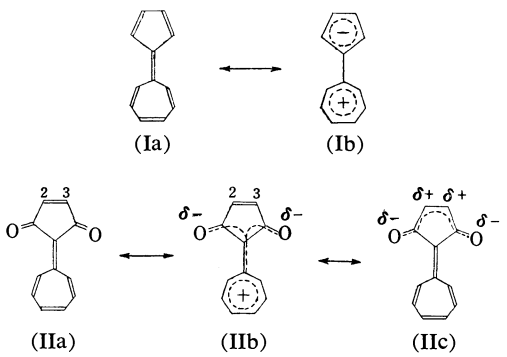
The ultraviolet absorption maxima[16] and the carbonyl-stretching frequencies[17] of the sesquifulvalene-1, 4-quinones and their 2, 3-adducts are shown in Tables I and II.

Table I. Ultraviolet absorption maxima: mμ (log ε)

II	III	XII
222 (4.35)	247 (4.43)	230 (4.20)
253 (4.16)	257 (4.40)	255 (4.36)
420 (4.37)	452 (4.57)	422 (4.42)
$\Delta\lambda$ 0	+32	+2
XIII	**XIV**	**XV**
225 (4.30)	227 (4.27)	225 (4.33)
267 (4.21)	264 (4.15)	266 (4.23)
452 (4.43)	450 (4.42)	451 (4.42)
+32	+30	+31

Table II. C=O Stretching frequencies: cm^{-1}; KBr-disk

II	III	XII	XIII	XIV	XV
1643	1645	1660	1627	1620	1618
$\Delta\nu$ 0	+2	+17	−16	−23	−25



With reference to the 2, 3-adducts, XIII, XIV and XV it is significant that their ultraviolet absorption maxima at the longest wavelength show a bathochromic shift of about 30 mμ, and that their carbonyl-stretching frequencies, in the infrared spectra, are decreased by about 20 cm^{-1} compared with those of the 2, 3-unsaturated compounds, II and XII.

It appears to be rather strange that, despite the decrease of conjugation due to the 2, 3-positions being saturated in the adducts, the absorption maxima are shifted towards longer

15) The product from the thermal decompostion of VIII; it had the characteristic odor of cycloheptatriene, although none of this compound was actually isolated.
16) The ultraviolet spectra were recorded on a Hitachi photoelectric spectrometer model EPU-2 and are for methanol solutions.
17) The infrared spectra were measured on a Perkin-Elmer model 21 spectrometer and are for KBr-disks.

wavelengths. This apparent discrepancy could be explained as follows.

In sesquifulvalene (I), there appears to be quite a large contribution by the ionic structure Ib, a dipolar species possessing a positive seven-membered ring and a negative five-membered ring; for this reason a large dipole moment is expected.[4]

A contribution by the ionic structure may also naturally be expected in II. However, in this case the negative charge is not delocalized over the whole five-membered ring, as is the case in the species Ib; rather, it is probably localized on the two more electronegative oxygen atoms and a charge distribution as depicted in IIb is obtained. The charge transfer between the seven-membered ring and the two oxygen atoms seems to be rather strongly inhibited by the charge transfer IIc which occurs between the double bond at the 2, 3-position and the oxygen atoms. Naturally, the conditions for the transfer of the charge from the seven-membered ring become more favorable when the 2, 3-double bond is removed by the addition of bromine, cyclopentadiene, or diazomethane. The shifts in the ultraviolet and infrared spectra are thus understandable. This speculation is also supported by dipole moment measurements.[18]

Experimental

2, 2-Ditropylindane-1, 3-dione (VI).—Tropylium bromide (3.4 g., 0.02 mol.) in water (50 ml.) was stirred in, drop by drop over a period of 10 min., into a solution of indane-1, 3-dione (1.46 g., 0.01 mol.) in acetonitrile (25 ml.) at room temperature; stirring was then continued for a further 5 hr. The crystalline deposit was filtered off (3.15 g., 97.2%, m. p. 164~166°C) and recrystallized from ethanol to afford colorless prisms of VI (m. p. 167.5~168°C).

IR ν_{max}^{KBr} : 3015, 1728, 1699, 1590, 765 cm^{-1}. UV λ_{max}^{MeOH} $m\mu$ (log ε) : 227 (4.69), 252 (4.31).

Found: C, 84.29; H, 5.41. Calcd. for $C_{23}H_{18}O_2$: C, 84.64; H, 5.56%.

The Reaction of 2, 2-Ditropylindane-1, 3-dione with Perchloric Acid.—To a stirred solution of 2, 2-ditropylindane-1, 3-dione (0.65 g., 0.002 mol.) in 5 ml. of glacial acetic acid 60% perchloric acid (0.4 ml., 0.004 mol.) was added at room temperature; crystals were deposited almost immediately. After the mixture had been allowed to stand for 3 hr., the crystals of tropylium perchlorate (0.68 g., 89.4%) were filtered off. Its infrared absorption spectrum coincided with that of authentic tropylium perchlorate.

The filtrate was then diluted with water (300 ml.) and extracted with ether. The ether layer was washed with water, dried, and evaporated to yield crystals (0.25 g., 85.6%; m. p. 124~127°C), which showed no depression on a mixed melting point test with indane-1, 3-dione.

2, 3-Benzosesquifulvalene-1, 4-quinone (III).—2, 2-Ditropylindane-1, 3-dione (1.0 g., 0.00307 mol.), in a test tube fitted with a side arm which was connected via a dry-ice trap to a vacuum pump, was heated, under reduced pressure, in an oil bath at 175°C for 30 min. During this time an oil was observed to distil into the trap. After distillation of the oil had ceased, the pressure was kept at 2 mmHg for a further 10 min. The oil in the trap was then refluxed with maleic anhydride in xylene for 4 hr. The recrystallization of the crystalline product from carbon tetrachloride gave colorless rods (m.p. 98~100°C). No depression in the melting point was observed when a mixed melting point test was carried with the maleic anhydride adduct of cycloheptatriene.

The residue which remained in the test tube after the above thermal decomposition was a red solid (0.70 g., 97.5%; m. p. 194~200°C) which, after four recrystallizations from benzene, afforded red needles of III (m. p. 244~245°C).

UV λ_{max}^{MeOH} $m\mu$ (log ε) : 247 (4.43), 257 (4.40), 452 (4.57). IR ν_{max}^{KBr} : 1645, 1628, 1590, 760 cm^{-1}.

Found: C, 81.71; H, 4.13. Calcd. for $C_{16}H_{10}O_2$: C, 82.04; H, 4.30%.

4, 4-Ditropylcyclopentene-3, 5-dione (VIII).—(a) Tropylium bromide (1.71 g., 0.01 mol.) in water (30 ml.) was stirred drop by drop during 10 min. into a solution of cyclopentene-3, 5-dione (0.96 g., 0.01 mol.) in water (20 ml.). After the reaction mixture had been allowed to stand for 3 hr. at room temperature, the resulting precipitate was taken up in ether. The ether layer was washed with water, dried over magnesium sulfate, and then evaporated. The residue, dissolved in benzene, was chromatographed on an alumina column (1× 10 cm.). From the combined yellow benzene eluates 0.55 g. of crystals was obtained (m. p. 118~121°C). Recrystallization from cyclohexane gave yellow prisms (m. p. 121~122°C).

UV λ_{max}^{MeOH} $m\mu$ (log ε) : 225 (4.17), 250 (3.90). IR ν_{max}^{KBr} : 3015, 1735, 1696, 740 cm^{-1}.

Found: C, 82.45; H, 5.84. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84%.

(b) Tropylium bromide (3.42 g., 0.02 mol.) in 75% ethanol (15 ml.) was added, in one lot, to a

18) S. Katagiri, I. Murata, Y. Kitahara and H. Azumi, to be published.

stirred solution of cyclopentene-3,5-dione (0.96 g., 0.01 mol.) in ethanol (20 ml.) at room temperature. After being stirred for 10 min., the solution was adjusted to pH 6.5~7.0 with saturated aqueous sodium hydrogen carbonate. The precipitated crystals of 4,4-ditropylcyclopentene-3,5-dione (2.58 g., 93.5%; m. p. 118~120°C) were then filtered off.

Sesquifulvalene-1, 4-quinone (II).—To a stirred solution of cyclopentene-3,5-dione (1.92 g., 0.02 mol.) in water (40 ml.) 3.2 g. of 48% hydrobromic acid was added; then to this mixture, a solution of tropylium bromide (3.42 g., 0.02 mol.) in water (50 ml.) was stirred in drop by drop over a period of 30 min. The yellow oil which separated was extracted into ether, and the ether solution was washed with water, dried over magnesium sulfate, and then evaporated. The residual oil (3.7 g.), without further purification, was dissolved in xylene (40 ml.). Chloranil (4.8 g.) was added to the solution, and the solution was refluxed for 3 hr. and then allowed to stand overnight. The precipitated tetrachlorohydroquinone was filtered off, and the filtrate was concentrated under reduced pressure. The benzene-soluble fraction of the residue was chromatographed on an alumina column (2×15 cm.). The red benzene eluate yielded red crystals (0.37 g., 10% yield based on tropylium bromide; m. p. 172~175°C). Recrystallization from benzene afforded red plates of II (m. p. 180~181°C).

UV λ_{max}^{MeOH} mμ (log ε): 222 (4.35), 253 (4.16), 420 (4.37). IR ν_{max}^{KBr}: 3060, 1643, 1515, 1262, 849 cm^{-1}.

Found: C, 78.41; H, 4.26. Calcd. for $C_{12}H_8O_2$: C, 78.25; H, 4.38%.

1, 2-Dichloro-4, 4-ditropylcyclopentene-3, 5-dione (XI).—Tropylium bromide (12.1 g., 0.0708 mol.) in acetonitrile (150 ml.) was stirred drop by drop into a solution of 1,2-dichlorocyclopentene-3,5-dione (5.5 g., 0.033 mol.) in acetonitrile (50 ml.) at room temperature. Pyridine (5 ml.) was then added, and stirring was continued for a further 30 min. The yellow crystals (11.2 g., 97.3%) which precipitated on the addition of water (500 ml.) had a m. p. of 98~100°C; recrystallization from methanol afforded yellow plates of XI (m. p. 103~104°C).

IR ν_{max}^{KBr}: 3020, 1757, 1712, 1584, 1200 cm^{-1}.

Found: C, 66.21; H, 4.20. Calcd. for $C_{19}H_{14}O_2Cl_2$: C, 66.11; H, 4.09%.

2, 3-Dichlorosesquifulvalene-1, 4-quinone (XII).—1,2-Dichloro-4,4-ditropylcyclopentene-3,5-dione (1.72 g., 0.005 mol.) was pyrolysed in a test tube with a side arm at 150°C under reduced pressure. During the reaction, the material in the tube melted, then began to bubble, and finally resolidified after about 10 min. Methanol was added to the residue, and the red crystals (1.1 g., 86.9%; m. p. 250°C (decomp.)) which were obtained in filtering the suspension were recrystallized from benzene to give reddish-orange scales of XII (m. p. 263°C (decomp.)).

UV λ_{max}^{MeOH} mμ (log ε): 230 (4.20), 255 (4.36), 422 (4.42). IR ν_{max}^{KBr}: 1660, 1615 cm^{-1}.

Found: C, 57.07; H, 2.59. Calcd. for $C_{12}H_6O_2Cl_2$: C, 56.95; H, 2.39%.

The Reaction of Sesquifulvalene-1, 4-quinone (II) with Bromine.—Bromine (0.08 g.) in chloroform (1 ml.) was added to a stirred solution of sesquifulvalene-1,4-quinone (0.09 g.) in chloroform (4 ml.) with ice-cooling. The crystalline orange precipitate (0.12 g; m. p. 80~95°C) which was produced was then filtered off and recrystallized from ethanol to yield golden-yellow scales of XIII (m. p. 148°C (decomp.)).

UV λ_{max}^{MeOH} mμ (log ε): 225 (4.30), 267 (4.21), 452 (4.43). IR ν_{max}^{KBr}: 1627 cm^{-1}.

Found: C, 42.51; H, 2.42. Calcd. for $C_{12}H_8O_2Br_2$: C, 41.89; H, 2.34%.

The Reaction of Sesquifulvalene-1, 4-quinone (II) with Diazomethane.—Ethereal diazomethane was stirred into an ice-cold solution of sesquifulvalene-1,4-quinone (0.09 g.) in a mixture of benzene (4 ml.) and ether (50 ml.). Orange crystals began to be formed within a few minutes; the mixture was then allowed to stand for 30 min., after which time the crystals (0.08 g.; m. p. 290°C) were filtered off and recrystallized three times from ethanol to afford orange needles of XV (m. p. 290°C).

UV λ_{max}^{MeOH} mμ (log ε): 225 (4.33), 266 (4.23), 451 (4.42). IR ν_{max}^{KBr}: 1618 cm^{-1}.

Found: C, 68.67; H, 4.33; N, 12.08. Calcd. for $C_{13}H_{10}O_2N_2$: C, 69.01; H, 4.46; N, 12.38%.

The Reaction of Sesquifulvalene-1, 4-quinone (II) and Cyclopentadiene.—A solution of sesquifulvalene-1,4-quinone (0.09 g.) and freshly-distilled cyclopentadiene (0.07 g.) in benzene (6 ml.) was set aside for 24 hr. in a tightly-stoppered flask at room temperature. The residue remaining after the removal of the benzene was treated with light petroleum, and the insoluble residue (m. p. 182~183°C) was recrystallized from benzene; red prisms of XIV (m. p. 188~189°C) were obtained.

UV λ_{max}^{MeOH} mμ (log ε): 235 (3.82), 289 (3.83), 450 (4.43). IR ν_{max}^{KBr}: 1620 cm^{-1}.

Found: C, 81.51; H, 5.25. Calcd. for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

Radiolysis of Solid Glycine

By Gisuke MESHITSUKA, Kotaro SHINDO, Atsuko MINEGISHI, Hiroshi SUGURO and Yoshiharu SHINOZAKI

(Received January 8, 1964)

The mechanism of radiation-induced reactions in a glycine aqueous solution has been extensively studied in many laboratories.[1,2] The radiolysis of solid glycine, however, has not been investigated thoroughly; although some of the radicals produced have been examined from the ESR spectra of irradiated solid glycine,[3,4] there has been insufficient interpretation of the spectra.

In the present work, products are measured after dissolving irradiated solid glycine in water, and mechanisms for the primary reaction of solid glycine radiolysis and for the secondary reaction, giving final products, are proposed with reference to the results of ESR studies.

Experimental

Materials. — Glycine (Yuki Gosei Kogyo Co., Special grade) was purified by recrystallization from water at least four times. Sodium chromotropate (Merck, Reagent) and *p*-dimethylaminobenzaldehyde (Daiichi Kagaku Yakuhin Co., Special grade) were used without further purification as reagents for the analysis of the products.

Irradiation.—Glycine powder (100~200 mesh) in glass vessels was evacuated for 8 hr. at 110°C in vacuo ($<10^{-4}$ mmHg) and then sealed. A 3000-curie cobalt source was used for γ-ray irradiation. The dose range employed was 0.5×10^{20} eV. g^{-1} to 2.7×10^{21} eV. g^{-1} at dose rates of $9.5\times10^{18}\sim4.1\times10^{19}$ eV. $g^{-1}\,hr^{-1}$. Dosage was determined by the Fricke-dosimeter technique with a $G(Fe^{3+})$ value of 15.6.

Analysis. — Hydrogen collected by conventional techniques directly from the irradiated solid samples was analyzed with a gas chromatograph (Shimadzu, GC-1A) and a mass spectrometer (Hitachi, RMU-5B).

All the other products, volatile bases, organic acids, formaldehyde etc. were analyzed from the solutions after dissolving the irradiated samples in water in and out of the presence of oxygen.

Nitrogen-containing Products.—The total amount of the volatile bases (NH_3, CH_3NH_2) was measured by two different methods, the Kjeldahl method and separation with an anion-exchange resin. In the latter case, Dowex 1 resin (OH form, 100~200 mesh, 8% crosslinked) was used. Aqueous solutions of the irradiated glycine were poured onto the top of the column (40 cm. high by 2 cm. in diameter), and the effluents were collected in the excess of sulfuric acid and back-titrated with sodium hydroxide, using phenolphthalein as an indicator. The results of the two methods agreed well. In some runs, a radiofrequency titration method was also applied.

Methylamine was identified and measured by an infrared absorption spectrum of methylamine hydrochloride obtained by evaporating the effluents after neutralization with hydrochloric acid. Methylamine was measured also from extinction at 540 mμ induced by the reaction with lactose.[5] The amount of ammonia was obtained by substracting the amount of methylamine from that of the total volatile base.

The amount of hydrazine tested colorimetrically with *p*-dimethylbenzaldehyde[6] was negligibly small. Amino acids were not detected by the use of an amino acid analyzer or by paper chromatography.

Acids and Formaldehyde.—Organic acids were separated from glycine and other products with cation exchange resin Dowex 50 (H form, 50~100 mesh, 8% crosslinked). Aqueous solutions of the irradiated glycine were poured onto the column (40 cm. high, 2 cm. in diameter), and the effluents were titrated with sodium hydroxide, using cresol red as an indicator, under an atmosphere of nitrogen. In some runs, the effluents were degassed by conventional techniques to remove the carbon dioxide and then titrated in order to measure the real amount of organic acids. The amount of carbon dioxide was obtained from the decrease in the total of acid produced by the degassing. The components of the organic acid were identified as glyoxilic acid and acetic acid from the infrared absorption spectra of the sodium salts obtained by freeze-drying after titration.

Glyoxilic acid was measured by techniques modified from the method used for the analysis of formaldehyde by MacFadyen.[7] The irradiated glycine (0.01~0.05 g.) was dissolved in 0.5 ml. of water and 5 ml. of 2 N hydrochloric acid; 0.05 ml. of sodium chromotropate (0.1 g. ml^{-1}) and 5 ml. of concentrated sulfuric acid were then added, and

the mixture was boiled for 30 min., cooled, and diluted to 10 ml. with water. From the absorption spectra of the solution, glyoxilic acid was measured by the extinction at 440 mμ.

The amount of acetic acid was obtained by subtracting the amount of glyoxilic acid from the total of organic acid. A small amount of formaldehyde was measured by the same method as glyoxilic acid from the extinction at 568 mμ.

Results and Discussion

Yields.—Figures 1 and 2 show the relations between the amounts of the products and the irradiation doses. All products except H_2 increase linearly with the dose. Hydrogen shows a plateau from a relatively low dose. Figure 1 shows that oxygen dissolved in water,

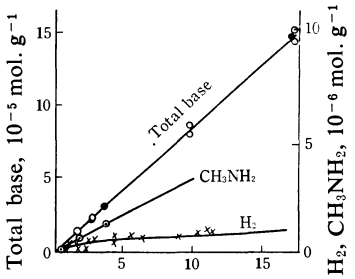

Fig. 1. The yields of basic products and H_2 from glycine irradiated by ^{60}Co γ-rays. Total base was obtained by dissolving the sample in oxygen containing water (○) or degassed water (●).

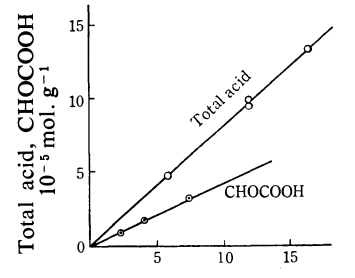

Fig. 2. The yields of acidic products from glycine irradiated by ^{60}Co γ-rays.

TABLE I. YIELDS OF PRODUCTS

Product	G
H_2	~0.2
NH_3	4.8
CH_3NH_2	0.2
$CHOCO_2H$	2.5
CH_3CO_2H	2.3
CO_2	~0.2
HCHO	trace (~0.0_3)

which is used to dissolve the irradiated samples, does not remarkably affect the yields of the total base. The yields of the products obtained from the slopes of Figs. 1 and 2 are listed in Table I. The initial yield of H_2 was estimated to be approximately 0.2 from the initial slope of the curve.

Mechanism. — From the studies of ESR spectra of the irradiated solid glycine, some evidence concerning radicals in irradiated solid glycine was obtained.[8] The results were interpreted by assuming that the free radicals primarily produced are NH_2 and $CH_2CO_2^-$, with a trace of $\overset{+}{N}H_3CHCO_2^-$, and that NH_2 and $CH_2CO_2^-$ slowly decrease to produce $\overset{+}{N}H_3CHCO_2^-$ and an unknown radical (presumably $\overset{+}{N}H_2CH_2CO_2^-$).

Irradiated glycine was dissolved in water, immediately after irradiation or after having been kept at room temperature for a long time. In the latter case, the radicals originally produced should have completely changed. Nevertheless, the chemical analysis of the final products of the two cases gave the same results.

The CH_3NH_2 obtained ($G=0.2$) appears to be due to a direct molecular dissociation of the glycine molecule, as was proposed by Garrison[2] in the radiolysis of aqueous solutions.

From these results, the following mechanism of the radiolysis of solid glycine may be proposed:

$$\overset{+}{N}H_3CH_2CO_2^- \rightsquigarrow H^+ + NH_2 + CH_2CO_2^- \quad (1)$$

$$\overset{+}{N}H_3CH_2CO_2^- \rightsquigarrow CH_3NH_2 + CO_2 \quad (2)$$

$$\overset{+}{N}H_3CH_2CO_2^- \rightsquigarrow \overset{+}{N}H_3CHCO_2^- + H \quad (3)$$

$$H + \overset{+}{N}H_3CH_2CO_2^- \longrightarrow H_2 + \overset{+}{N}H_3CHCO_2^- \quad (4)$$

With an increasing dose, radicals are accumulated (the estimated value is, for instance, 10^{-5} mol. g^{-1} at a dose of 1×10^{20} eV. g^{-1}) and scavenge H atom to give a plateau of the H_2 yield.

$$H + R \longrightarrow RH \quad (5)$$

The primary process 1 seems to be not so simple; it may contain dissociative electron-capture mechanism to give the same resultant radicals. The results of the investigation of this point will be published elsewhere.

When the irradiated glycine is dissolved in

8) G. Meshitsuka, Y. Shinozaki and K. Shindo. *Annual Report, Tokyo Metropolitan Isotope Center*, 2, 181 (1963).

water, particular radicals, NH_2 and $CH_2CO_2^-$, abstract H from the glycine molecule to produce ammonia, acetic acid and $\overset{+}{N}H_3CHCO_2^-$:

$$NH_2 + \overset{+}{N}H_3CH_2CO_2^- \longrightarrow NH_3 + \overset{+}{N}H_3CHCO_2^- \quad (6)$$

$$CH_2CO_2^- + \overset{+}{N}H_3CH_2CO_2^- \longrightarrow CH_3CO_2^- + \overset{+}{N}H_3CHCO_2^- \quad (7)$$

Hydrogen abstraction may occur at the amino group to form $\overset{+}{N}H_2CH_2CO_2^-$, but it is probable that the radical changes to a more stable radical, $\overset{+}{N}H_3CHCO_2^-$, by the H atom migration:

$$\overset{+}{N}H_2CH_2CO_2^- \longrightarrow \overset{+}{N}H_3CHCO_2^- \quad (8)$$

Glycine radicals give NH_3, $CHOCO_2H$, HCHO and CO_2 by the following reactions, as proposed in the radiolysis of aqueous solutions:[2]

$$2\overset{+}{N}H_3CHCO_2^- \longrightarrow \overset{+}{N}H_2CHCO_2^- + \overset{+}{N}H_3CH_2CO_2^- \quad (9)$$

$$\overset{+}{N}H_2CHCO_2^- + H_2O \longrightarrow NH_3 + CHOCO_2H \quad (10)$$

$$\longrightarrow NH_3 + HCHO + CO_2 \quad (11)$$

Reaction 9′ has been proposed by Garrison[2] in the radiolysis of oxygen-containing aqueous solutions:

$$\overset{+}{N}H_3CHCO_2^- + O_2 \longrightarrow \overset{+}{N}H_2CHCO_2^- + HO_2 \quad (9')$$

However, oxygen in water does not have any remarkable effect on the yields of the total base. It seems, therefore, that $\overset{+}{N}H_3CHCO_2^-$ reacts mainly in the disproportionation reaction 9 instead of in reaction 9′, even in the presence of dissolved oxygen. If the scavenging reaction 5 holds, $G(CH_3CO_2H)$ should be a little higher than $G(CHOCO_2H)$. On the contrary, however, the results show $G(CHO\cdot CO_2H)$ to be a little higher than $G(CH_3CO_2H)$, indicating that reaction 9′ also occurs to a small extent.

According to the mechanism, the following relationships may be expected:

$$G(\text{total acid}) = G(\text{total base})$$

$$G(NH_3) = G(CHOCO_2H) + G(CH_3CO_2H)$$

$$G(CO_2) = G(CH_3NH_2) + G(HCHO)$$

As Table I shows, the experimental results satisfy these relationships well. The yields of the primary processes are estimated as follows:

$$G(1) = G(CH_3CO_2H) = 2.3$$

$$G(2) = G(CH_3NH_2) = 0.2$$

and $G(3) = G(H_2) \sim 0.2$

Summary

Solid glycine has been radiolyzed by ^{60}Co γ-rays in vacuo at room temperature, and all the products except H_2 have been measured after dissolving the irradiated samples in water. The hydrogen has been collected and measured directly from the irradiated solid samples. All products except H_2 increase linearly with the dose, while H_2 shows a plateau from a relatively low dose. The yields of products are as follows: $G(H_2) \sim 0.2$, $G(NH_3) = 4.8$, $G(CH_3NH_2) = 0.2$, $G(CHOCO_2H) = 2.5$, $G(CH_3CO_2H) = 2.3$, $G(CO_2) \sim 0.2$, and $G(HCHO) \sim 0.03$. The mechanisms of the primary process and the reactions to give final products have been proposed with reference to the results of the ESR studies.

A Study of the Sorption of Metal Ions by Cotton Cloth

By Reiko KOGA, Yoshiharu SHINOZAKI, Gisuke MESHITSUKA and Toshizo TITANI

(Received January 8, 1964)

The interactions of cellulose with metal ions in aqueous solutions have long been known. For example, cellulose can react with metal ions in such strong alkaline media as Schweizer's solution. In connection with the structure and the nature of cellulose, mechanisms for the sorptions of metal ions by cellulose have been discussed by various workers.[1-5] Some of them ascribe the sorption phenomena to an acidic action of hydroxyl groups and a complex formation,[4] and some, to an ion-exchange reaction of the carboxyl groups which exist in cellulose.[3,5]

The present paper will study, by means of the tracer technique, the sorption phenomena of metal ions by cotton cloth in the aqueous media. In the neutral and the acidic region, the exchange mechanism by the carboxyl grou s has again been confirmed. Since it has been another object of this work to obtain information on the decontamination of metal ions from cotton cloth, the relative affinities of metal ions, i. e., Cu^{2+}, Co^{2+}, Zn^{2+}, Ca^{2+}, Sr^{2+}, Cs^{+}, K^{+} and Na^{+}, to cotton cloth have also been determined.

Experimental

Materials.—The cotton print cloth (Nitto Boseki K. K.) was purified by extracting it with hot ethanol and boiling for 2.5 hr. in a 1% sodium hydroxide solution. The residual sodium hydroxide was removed from the cotton by washing it with distilled water; it was then acidified with dilute acetic acid, again neutralized with dilute aqeous ammonia, and finally washed with deionized distilled water. The cotton thus obtained was dried and stored. The Cu-value was found to be 0.048.

Commercial metal salts (reagent grade) were used without further purification. The water employed was treated with ion exchange resin and distilled. Radioisotopes, ^{45}Ca, ^{60}Co and ^{137}Cs, were diluted to the proper activity level for use.

Procedures. — *The Determination of Uptake.* — Weighed samples of cotton cloth, about 4.5 cm^2 in apparent area (ca. 0.05 g.), were immersed into 20 ml. of a metal salt solution of a known concentration containing the radioisotope as a tracer and shaken for 2 hr. at a desired constant temperature (usually 25°C) in most cases. Then the cotton sample was taken out of the solution, pressed between two sheets of filter paper, and reweighed to determine the amount of the moisture retained in the sample. The activity of the air-dried sample was measured by a Geiger-Mueller counter or a scintillation counter, while the total number of metal ions taken up by the sample was calculated by means of the calibration curve which had been obtained in the preliminary experiment for the sample soaked with a known number of the metal ions. The real amount of sorbed metal ions was obtained by correcting for the moisture retained in the sample. In this correction it was assumed that the concentration of the metal ion in the retained moisture was the same as that in the bulk solution.

The Determination of Rates of Sorption. — The rates of the sorption of Co^{2+} were determined at 2, 4.7, 25 and 38°C by measuring the uptake at appropriate intervals by a method similar to that mentioned above until equilibrium was achieved.

pH Adjustment.—In the studies of the pH dependence, hydrogen ion concentrations were changed by adding hydrochloric acid to solutions while keeping the amount of metal hydroxide constant.

The Determination of Relative Affinities. — The maximum uptakes of Co^{2+} from mixed solutions of Co^{2+} and any one of the following ions, Cu^{2+}, Zn^{2+}, Ca^{2+}, Cs^{+}, K^{+} and Na^{+}, were determined. The initial concentrations of the two ions in the mixed solutions were the same (10^{-3} M). An affinity series was determined from the order of the maximum uptake of Co^{2+}. A similar experiment was undertaken for mixed solutions of Ca^{2+} and any one of the following ions, Cu^{2+}, Co^{2+}, Zn^{2+}, Cs^{+}, K^{+} and Na^{+}.

Results and Discussion

pH Dependence. — The equilibrium uptakes of Co^{2+}, Ca^{2+} and Cs^{+} by cotton cloth exhibit a marked dependence upon the hydrogen ion concentration of the media, as is shown, for instance, for Ca^{2+} in Fig. 1. The uptake becomes perceptible around pH 3 and increases rapidly with the increasing pH, with an intermediate approximate plateau in the neutral region. This suggests two mechanisms for the

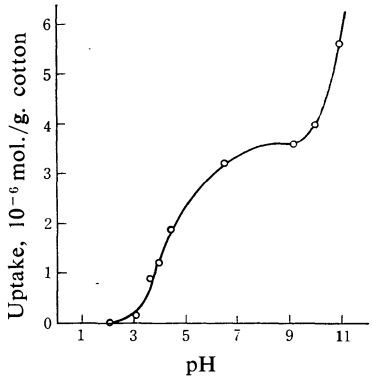

Fig. 1. pH dependence of Ca^{2+} uptake on cotton cloth.
$[Ca^{2+}]=1.1\times10^{-3}$ M, 25°C

sorption, one effective in the acidic and neutral regions, and the other only in the strongly alkaline region. The former is a cation exchange mechanism of the carboxyl groups, in accordance with Michie's[5] observation that the uptake of copper is proportional to the carboxyl content and with Demint and Arthur's[3] study of the exchanging properties of γ-ray irradiated cotton.

The latter mechanism is an acidic action of the hydroxyl groups in cellulose. Complex formations of this groups have long been known in strongly alkaline media, such as Schweizer's solution. In the strongly alkaline region, however, cotton shows a swelling which may increase the active sites. This renders the interpretation difficult. Therefore, the following experiments are restricted to the sorption in the acidic and neutral regions.

The Rate of Sorption. — The rates of the sorption of Co^{2+} were measured at various temperatures and at various concentrations of Co^{2+} at pH ca. 4.7. As is shown in Fig. 2, the uptakes increase with time approaching the equilibrium values.

According to the mechanism of cation exchange between the hydrogen ion of the caboxyl groups, H^+, and the metal ions, M^+, the following rate expression may be expected

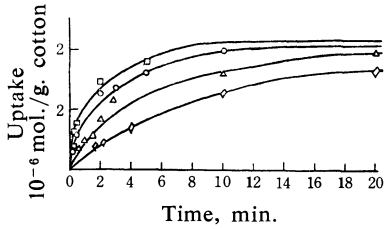

Fig. 2a. Uptake of Co^{2+} at various temperatures.
($[Co^{2+}]=1\times10^{-4}$ M)
2°C (◇), 4.7°C(△), 25°C (○), 38°C (□)

to hold as a first approximation;

$$dx/dt=k_1(a-x)[M^+]-k_2x[H^+] \qquad (1)$$

where x is the uptake at time t, a is the total number of sites available for ion exchange, and k_1 and k_2 are rate constants. Equation 1 was derived by assuming a hypothetical homogeneous solution. Further, it can be assumed that $[H^+]$ and $[M^+]$, practically speaking, do not change during the sorption under our experimental conditions. Thus, from Eq. 1, a linear relationship for $\ln(1-x/x_e)$ vs. t plots follows, where x_e is the equilibrium uptake. The experimental results under the various conditions are illustrated in Fig. 3. The deviation from linearity in Fig. 3 indicates that the simplified model mentioned above is not accurate. The actual process is a heterogeneous one. Possibly, delayed transporting phenomena of the metal ions from the surface into the inner sorption site of the cotton are responsible for the non-linearity obtained.

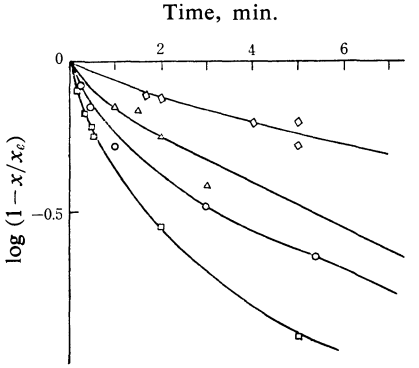

Fig. 3. $\log(1-x/x_e)$ vs. t plots.
2°C (◇), 4.7°C (△), 25°C (○), 38°C (□)

However, as the limiting case of Eq. 1, the following relation may be applied for an initial stage of the sorption;

$$(dx/dt)_0=k_1a[M^+] \qquad (2)$$

where $(dx/dt)_0$ means the initial velocity. $(dx/dt)_0$ can be obtained from the 'initial

slopes of curves in Fig. 2. Equation 2 is satisfied as illustrated in Fig. 4, as far as the change of $[M^+]$ is concerned in the sorption of Co^{2+}. k_1 can be calculated from the slope of the straight line in Fig. 4, using the maximum uptake, a, obtained in the equilibrium experiments.

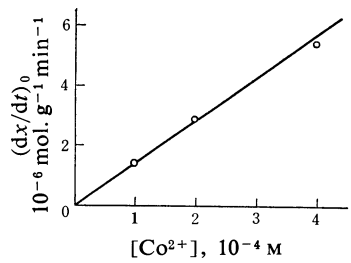

Fig. 4. Initial rates of Co^{2+} uptake at various concentrations (25°C).

An activation energy for the sorption of Co^{2+} was calculated from k_1 values at various temperatures (Fig. 5) to be 7.6 kcal./mol. It is interesting to note that this value is of the same order as the activation energies of the diffusion of metal ions in aqueous solutions.[6,7]

The facts may indicate that the diffusion of Co^{2+} to the cotton surface is the rate-determining step in the early stage of the sorption of the ion.

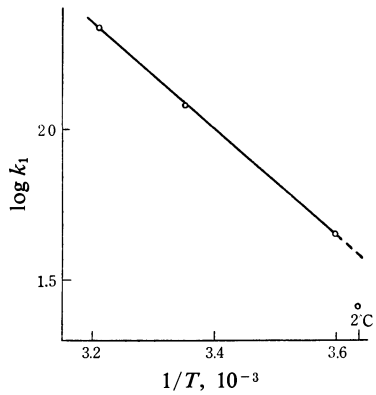

Fig. 5. Temperature dependence of initial rate constants of uptake of Co^{2+}.

The Concentration Dependence of the Uptake. —The equilibrium uptakes at various concentrations of Co^{2+} are expressed as a Langmuir-type sorption isotherm (Fig. 6).

Assuming a cation exchange mechanism,

$$RH + M^+ \rightleftharpoons RM + H^+$$

a Langmuir-type isotherm (Eq. 5) is derived as follows:

$$\frac{(RM)\,[H^+]}{(RH)\,[M^+]} = K_H^M \tag{3}$$

$$(RH) + (RM) = a \tag{4}$$

$$a = \frac{(RM)\,[H^+]}{K_H^M\,[M^+]} + (RM)$$

$$\frac{[M^+]}{(RM)} = \frac{[H^+]}{aK_H^M} + \frac{[M^+]}{a} \tag{5}$$

where (RH) and (RM) are the total number of sites per gram of cotton occupied by H^+ and M^+ respectively, and $[H^+]$ and $[M^+]$ are the concentrations of H^+ and M^+ respectively in the solution.

The total amount of available sites a mol. per gram of cotton can be obtained as the maximum uptake experimentally. The value, 4.2×10^{-6} mol./g. cotton, calculated for a from Fig. 6 is about 10^{-3} times the number of hydroxyl groups in cellulose. These results seem to indicate that some special group, possibly a carboxyl group, is responsible for the sorption phenomena in the acidic region.

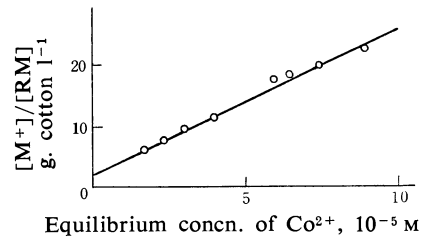

Fig. 6. Langmuir absorption isotherm of Co^{2+} (25°C).

The Heat of Sorption. — The heat of the sorption of Co^{2+} was determined to be ca. -2 kcal./mol. from the variation of uptake with temperature. Because of the small effect of the temperature on the uptake, it was difficult to ascertain the heat of sorption accurately. The low value of the heat of sorption may be an evidence for the exchange mechanism of the sorption.

The Affinities of Various Metal Ions.—When two kinds of metal ions, M_1^+ and M_2^+, coexist in the sorption system, the following exchange equilibria are to be expected;

$$RH + M_1^+ \rightleftharpoons RM_1 + H^+$$

$$RH + M_2^+ \rightleftharpoons RM_2 + H^+$$

$$RM_1 + M_2^+ \rightleftharpoons RM_2 + M_1^+$$

The relative affinity of these metal ions to the cotton can be given as;

$$K_{M_1}^{M_2} = \frac{K_H^{M_2}}{K_H^{M_1}} = \frac{\dfrac{(RM_2)\,[H^+]}{(RH)\,[M_2^+]}}{\dfrac{(RM_1)\,[H^+]}{(RH)\,[M_1^+]}} = \frac{(RM_2)\,[M_1^+]}{(RM_1)\,[M_2^+]} \tag{6}$$

6) J. H. Wang, *J. Phys. Chem.*, **58**, 686 (1952).
7) F. Fukuoka, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zassi*), **56**, 51 (1953).

where $K_{M_1}^{M_2}$ denotes the relative affinity of M_2^+ with respect to M_1^+. The uptake of the metal ions of 10^{-3} M on a RH ion exchanger was found to be almost equal the maximum uptake, a. Therefore, in this case the following relation holds.

$$a=(RM_1)+(RM_2) \tag{7}$$

Therefore, Eq. 6 can be written;

$$K_{M_1}^{M_2}=\frac{(a-(RM_1))\,[M_1^+]}{(RM_1)\,[M_2^+]} \tag{8}$$

Using ^{45}Ca or ^{60}Co as a tracer, K_{Ca}^{M} or K_{Co}^{M} were determined experimentally using Eq. 8, and then K_H^M was calculated using the value of K_H^{Ca} (=0.26) obtained from the studies of pH dependence. The results are given in Table I. This order nearly parallels that of the stabilities of metal complexes[8] and that of the catalytic activities of metal ions in the oxygen exchange reaction between lactose and water.[9]

TABLE I. RELATIVE AFFINITIES

Ion	Cu^{2+}	Zn^{2+}	Co^{2+}	Ca^{2+}	Sr^{2+}	Cs^+	K^+	Na^+
K_H^M	1.4	0.54	0.36	0.26	0.11	0.03	0.03	~0

The Decontamination of Radioactive Metal Ions from Cotton.—It can be expected that metal ions sorbed by cotton cloth may be effectively replaced by an ion which has a much stronger affinity to cotton. This was ascertained by the following experiments. Cotton cloth which had been contaminated by ions, ^{60}Co or ^{45}Ca, was immersed in a solution of Cu^{2+}. After the solution had been shaken for 2 hr., the residual contamination was measured. As Fig. 7 shows, of ^{60}Co or ^{45}Ca can be decontaminated very efficiently by using a Cu^{2+} solution. The solid lines show the theoretical values calculated by using these relative affinities; A: $K_M^M=1$, B: $K_{Co}^{Cu}=3.6$, and C: $K_{Ca}^{Cu}=5.3$. Thus, the order of relative affinities in Table I turns out to be useful as a guide for the decontamination problems.

Summary

The uptakes of the metal ions, Co^{2+}, Ca^{2+} and Cs^+, by cotton cloth have been determined by using the tracer technique. In the acidic and the neutral media, the isotherms were the Langmuir type, and the cation exchange mechanism of the special groups (probably the carboxyl group) has been confirmed. The heat and the activation energy for the sorption of Co^{2+} were -2 kcal./mol. and 7.6 kcal./mol. respectively (at pH ca. 4.7). In the alkaline media, the cotton cloth showed marked uptakes. The order of the affinity of various metal ions to cotton cloth was also determined as follows:

$$Cu^{2+}>Zn^{2+}>Co^{2+}>Ca^{2+}>Sr^{2+}>Cs^+, K^+>Na^+$$

The order is useful for the purpose of decontamination.

Studies of the Organic Reactions of Metal Carbonyl. IV. The Acceleration Effect of the Addition of Organic Compounds on the Reaction of Olefin Oxide with Cobalt Hydrocarbonyl and on the Hydroformylation of Olefin Oxide

By Yoshinobu TAKEGAMI, Chikao YOKOKAWA and Yoshihisa WATANABE

(Received January 16, 1964)

It has been demonstrated elsewhere[1,2] that olefin oxides react with cobalt hydrocarbonyl and carbon monoxide to form β-hydroxyacylcobalt carbonyls which can be converted to the corresponding esters of β-hydroxycarboxylic acid by cleavage with iodine and alcohol. On the other hand, the present authors have recently reported[3] that propylene oxide undergoes hydroformylation to form β-hydroxy-*n*-butyraldehyde as the major product.

The authors have found that the alcohol used in the cleavage reaction has an acceleration effect on the reaction of olefin oxide with cobalt hydrocarbonyl. The present investigation has aimed at examining in detail the effect of the addition of various organic compounds on these types of reaction. The results described in this paper indicate that some organic compounds, such as alcohol, ketone, ether and ester, accelerate remarkably the reaction of olefin oxide with cobalt hydrocarbonyl. A similar effect has been also observed in the hydroformylation of olefin oxide.

Experimental

Reaction Procedures.—The reactions of olefin oxide with cobalt hydrocarbonyl were carried out in the way described in a previous paper[2] using 50 ml. of a 0.09 M cobalt hydrocarbonyl solution in toluene. Various amounts of organic compounds were added at the beginning or during the reaction.

The hydroformylation of olefin oxide was investigated, in the manner which has been described previously,[3] in the presence of ethyl alcohol using dicobalt octacarbonyl as a catalyst.

Analytical Procedures.—The reaction products were analyzed by gas chromatography and by means of infrared spectra which had been taken on a Shimadzu model IR-27 infracord spectrophotometer. The details were given in previous papers.[2,3] The hydroformylation product of ethylene oxide was isolated as 2,4-dinitrophenylhydrazone and recrystallized from chloroform.

Meterials.—Ethylene oxide, propylene oxide, styrene oxide, epichlorohydrin and the other organic compounds employed in this study were commercial products, all of which were proved to be sufficiently pure by gas chromatography.

Results and Discussion

The Reactions of Propylene Oxide with Cobalt Hydrocarbonyl in the Presence of Various Organic Compounds.—All reactions were carried out at the mole ratio*1 of 1.6, at which the reaction without additives proceeds very slowly.[2] The results of the reactions in the presence of ethyl alcohol are summarized in Table I and in Figs. 1, 2 and 3. In Fig. 1 the amounts of carbon monoxide absorbed at 0°C are plotted against the reaction time. These gas absorption curves indicate a remarkable increase of the reaction rate upon the addition of a relatively small amount of ethyl alcohol. Without the additive (curve A),

A: without ethyl alcohol

only 0.1 mol.*2 of the gas was absorbed in three hours. When 0.5 mol.*3 of the alcohol was added (Exp. 1 and curve 1), 0.3 mol. of the gas was absorbed in 70 min. Additional amounts of the alcohol (0.5 and 1.0 mol.) also promoted the gas absorption. By the addition of 2.0 mol. of the alcohol (Exp. 2) in the beginning, the rate of the gas absorption was about one hundred and twenty times larger than that of the standard run. The increase in the rate of the gas absorption with the increase in the amount of the alcohol added seemed to cease, however, at the amount of 2.0 mol. since the rates of Exps. 3 and 4 (3.0 and 4.0 of the alcohol were added respectively) were comparable to that of Exp. 2. No gas absorption was observed in the systems of cobalt hydrocarbonyl and ethyl alcohol or of propylene oxide and ethyl alcohol.

The main product in these reactions was ethyl β-hydroxy-*n*-butyrate.*4 In addition to this ester and a small amount of β-hydroxy-*n*-butyraldehyde, there was no indication of the presence of other product in the gas chromatogram. The total yield of the ester and aldehyde, based on the amount of gas absorbed, is about 50% almost the same as that of the reactions without the alcohol.[2]

The acceleration effect of the alcohol was also observed at −30 and −45°C, as Fig. 2

*2,*3 Mole per mole of cobalt hydrocarbonyl used.
*4 This compound can be obtained from the corresponding acylcobalt carbonyl by cleavage with iodine and ethyl alcohol.[2]

*3 Ethyl β-hydroxy-*n*-butyrate

*4 Ethyl β-hydroxy-*n*-butyrate 0.40 and *n*-butyl β-hydroxy-*n*-butyrate 0.08

shows although the rate of the gas absorption decreased with a decrease in the reaction temperature. The yield of the ester increased at low temperatures; the total yields of the ester and aldehyde, based upon the amount of the gas absorbed, are about 70 or 80% at −30 and at −45 or −55°C respectively. The low yield of the ester at the relatively high reaction temperature seems to be partly due to the thermal instability of alkyl- and/or acyl-cobalt carbonyl.

From Fig. 3, it is evident that ethyl alcohol also has an acceleration effect in *n*-heptane. However, the effect seems to be about half of that for the reactions in toluene.

The effects of several organic compounds other than ethyl alcohol on this reaction at 0°C were examined; the results are summarized in Table II, in which the value of the gas absorption rate at the early stage of the reaction relative to the absorption rate in Exp. A is shown as a measure of the acceleration effect of the individual compound.

The results shown in Table II indicate that various kinds of organic compounds also have this effect, though their effects are considerably influenced by their structures. *n*- and *t*-butyl alcohols have an effects comparable to that of ethyl alcohol, but the effect of ethylene chlorohydrin is about one-twelfth that of ethyl alcohol. The compounds with functional groups other than an aliphatic hydroxy group, such as acetone, tetrahydrofuran, acetal, benzaldehyde, ethyl acetate and acetonitrile, also show the effect, but it is much smaller than that of ethyl alcohol. These facts seem to suggest that the compounds which have the effect are not limited to the above-mentioned compounds but may also include their homologues, i. e., alcohols, ketones, ethers, esters of carboxylic acids and nitriles.

The acceleration effect seems to be due to the basicity of these compounds. This consideration is supported by the following facts: phenol has no effect, and ethylene chlorohydrin, chloroacetone and acetylacetone have a smaller effect, than ethyl alcohol and acetone respectively. The chlorine atom and the acetyl group are considered to decrease the basicity of hydroxy and carbonyl groups with their nagative inductive effect.

The main product was ethyl β-hydroxy-*n*-butyrate in all of these cases. Even the reactions which were carried out in the presence of *n*- or *t*-butyl alcohol gave this ethyl ester*5 as a main product. This fact indicates that

*5 Ethyl alcohol was used in the cleavage reaction with iodine.

the alcoholysis of β-hydroxy-*n*-butyrylcobalt carbonyl did not occur in the course of the reaction. Thus, all of the additives appear to be acting as kinds of catalysts.

The Reactions of Styrene Oxide and Epichlorohydrin with Cobalt Hydrocarbonyl in the Presence of Ethyl Alcohol. — Styrene oxide was submitted to the reaction at −45°C; the results are summarized in Table III.

No gas absorption was observed in the reaction without ethyl alcohol under the conditions of Exp. 30, but a rapid gas absorption was observed in the presence of ethyl or propyl alcohol (Exp. 31—33), probably the carbonylation reaction was promoted by the addition of the alcohols. An ester-like compound was obtained as a main product after the cleavage of the reaction mixture with iodine and alcohol.*6 This ester may reasonably be considered to be β-phenyl-β-hydroxypropionate or α-phenyl-β-hydroxypropionate. As the minor by-products, α- and β-phenylethyl alcohols, which are the major products of the reaction without the alcohol at 0°C and at a relatively small mole ratio (1∼2),[2] were identified. These facts seem to support the supposition that the alcohol added accelerates the carbonylation reaction selectively. The low yield of the corbonylation product may be attributed to the instability of the corresponding acylcobalt carbonyl complex.

The results with epichlorohydrin are summarized in Table IV and in Fig. 4. The reactivity of epichlorohydrin is about several tenths that of propylene oxide;[2] at a relatively small mole ratio of epichlorohydrin (5∼6) no gas absorption was observed. Although the acceleration effect of the addition of alcohol has also been observed for the reaction of epichlorohydrin, the magnitude of this effect is smaller than those for propylene oxide and styrene oxide. The effect of the addition of ethyl alcohol was scarcely observed at a 1.5 mole ratio of epichlorohydin, even when 3 mol. of the alcohol, which is a sufficient amount in the reactions of propylene

*6 The infrared spectrum of the products in toluene had a band at 1730 cm^{-1} corresponding to a carbonyl group. The retention time of the product (ester) in gas chromatography increased as the molecular weight of the alcohol used in the cleavage increased. The retention time of the ethyl ester was longer than that of ethyl hydrocinnamate.

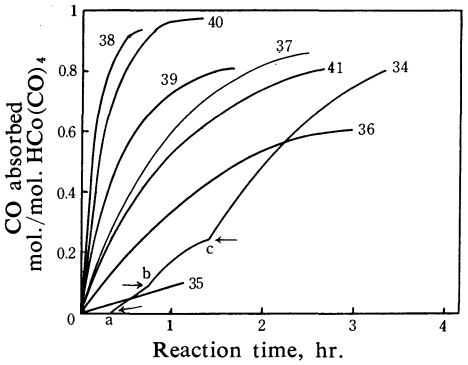

Fig. 4. CO absorption vs. time plots for the reactions of epichlorohydrin in the presence of ethyl alcohol.
a, b, and c: At these points, 1.5 mol. of epichlorohydrin per mole of $HCo(CO)_4$ was added.

oxide and styrene oxide, was added, but when additional amounts of epichlorohydrin were added successively, the acceleration of the gas absorption was clearly observed (Exp. 34 and and curve 34). At a 14.5 mol. ratio of epichlorohydrin at which a very slow gas absorption was observed without the alcohol (Exp. 35), a faster gas absorption evidently occurred when a larger amount of alcohol was added (Exp. 36—38).

The values of the gas absorption rate relative to the rate of Exp. 36 at an early stage of the reactions are shown in Table IV. At 14.5 and 5.8 mol. ratios, the rate increased proportionally with the increased amount of alcohol (Exp. 36—40). On the other hand, the rate increased with the increased amount of epichlorohydrin when the amount of the alcohol was fixed at 8.0 mol. (Exp. 38, 39 and 41). Thus, the rate of the gas absorption may be represented by the following equation:

$$\text{rate} = k\,[\text{epichlorohydrin}]\,[\text{ethyl alcohol}]$$

The main product of these reactions has been proved to be ethyl γ-chloro-β-hydroxy-*n*-butyrate from the considerations described previously.[2] Thus, this carbonylation reaction is also promoted by the addition of alcohol.

In the reactions of propylene oxide or styrene oxide, however, the relationship given by the above equation was not observed. This observation may be interpreted in terms of the fact that propylene oxide and styrene oxide are much more reactive, in other words, the same relationship may exist under well-controlled reaction conditions, such as a lower reaction temperature and a smaller concentration.

In the light of the above equation, ethyl alcohol seems to form some complex with epichlorohydrin and/or cobalt hydrocarbonyl as the first step of the reaction; this complex is considered to be more reactive than epichlorohydrin and/or cobalt hydrocarbonyl.

The Hydroformylation of Ethylene Oxide in the Presence of Ethyl Alcohol.—The effect of the addition of ethyl alcohol on the hydroformylation of ethylene oxide has been examined.

Although ethylene oxide seems to undergo hydroformylation at 80~90°C, even without ethyl alcohol,[3] only a little acrolein is obtained; some side reactions, such as isomerization, dehydration and polymerization may decrease the yield of the hydroformylation product considerably. By the addition of the alcohol (0.5~1.0 mol./mol.-ethylene oxide), however, the side reactions seemed to be considerably decreased, and then the hydroformylation product (β-hydroxypropionaldehyde*[7]) was obtained, though its yield was not good (at 80°C, about 15% of the amount of ethylene oxide used).

Summary

It has been observed that organic compounds with various kinds of functional groups have an accelerating effect on the reaction of olefin oxide with cobalt hydrocarbonyl and on the hydroformylation of olefin oxide.

1) The addition of a relatively small amount of ethyl alcohol promotes the carbonylation of propylene oxide with cobalt hydrocarbonyl until it is about 120 times faster than that of the standard run, carried out without alcohol. The amount of the alcohol necessary for this effect is about 2.0 mol./mol. $HCo(CO)_4$. As the reaction products, only compounds with a β-hydroxy-*n*-butyryl structure (ester and aldehyde) have been obtained.

2) The compounds other than ethyl alcohol, such as *n*- and *t*-butyl alcohol, ethylene chlorohydrin, acetone, tetrahydrofuran, ether, acetal, benzaldehyde, ethyl acetate and acetonitrile, also have the same effect on this reaction. Among these compounds, ethyl and butyl alcohols have the largest effect. On the other hand, phenol has no effect. The accelerating effect is considered to be due to the basicity of these compounds.

3) The reactions of styrene oxide and epichlorohydrin with cobalt hydrocarbonyl are also promoted by the addition of ethyl alcohol.

*[7] Identified by gas chromatography. 2,4-Dinitrophenylhydrazone. Found: C, 45.7; H, 3.39; N, 24.8. Cald. for $C_9H_8O_4N_4$: C, 45.8; H, 3.38; N, 23.7%. M. p. 164~166°C. A mixed melting point with the hydrazone of authentic acrolein gave no depression. β-Hydroxypropionaldehyde is dehydrated to give acrolein in the formation of the hydrazone.

A relatively small amount of the alcohol accelerates selectively, the carbonylation of styrene oxide which is comparatively readily hydrogenated with cobalt hydrocarbonyl.[2] For epichlorohydrin, the following relationship was observed to exist at an early stage of the reaction: rate of the gas absorption $=k$ [epichlorohydrin] [ethyl alcohol].

4) The hydroformylation of ethylene oxide seems to be selectively promoted by the addition of ethyl alcohol, which gives β-hydroxypropionaldehyde, in a low yield.

Crystal Structure of Salicylamide

By Yoshio SASADA, Tsunehiro TAKANO and Masao KAKUDO

(Received January 20, 1964)

The polymorphism observed in the crystals of most amides may be expected to correspond to the varied types of molecular arrangement connected by hydrogen bonds with each other.[1] Such variations in molecular linkage are due to the fact that the amide group is a bivalent donor and a bivalent acceptor of hydrogen bonding at the same time.

If a group attached to an amide group is a donor or an acceptor of hydrogen bonding, more different types of molecular association can be presumed, and this compound might show more crystallographic modifications. In fact, one of the authors has observed that pyrazinamide has four modifications and has determined, from the structure determination, that each modification has a characteristic molecular linkage by hydrogen bonds.[1-3]

The determination of the molecular arrangement in amide crystals will be of some interest in determining the relationship between the delicate balance of intermolecular interactions and the molecular geometry. As a part of a series of studies of the amide crystals,[1-4] this account will deal with the crystal structure of salicylamide obtained from X-ray analysis.

Experimental and Crystal Data

Crystals were obtained from an alcohol-water solution as colorless laths elongated along the b-axis. Twins were found frequently, and X-ray photographs showed that this twinning occurs with a common ba plane.

The crystal and physical data found are as follows:

Salicylamide: $C_7H_7NO_2$, m. p. 139°C
Monoclinic: $a=12.92\pm0.04$, $b=4.98\pm0.02$, $c=21.04\pm0.05$ Å, $\beta=91.8\pm0.4°$
Absent spectra: (hkl) when $h+k+l$ is odd, $(h0l)$ when h and l are odd, $(0kl)$ when $k+l$ is odd, $(hk0)$ when $h+k$ is odd, and $(0k0)$ when k is odd.
Space group: I $2_1/a-C_{2h}^6$
Eight molecules per unit cell
Volume of the unit cell: 1353.0 Å^3
Density (by floatation): 1.34_9 g. cm^{-3}
Density (calculated): 1.34_5 g. cm^{-3}
Linear absorption coefficient for Cu$K\alpha$ radiation: $\mu=9.73$ cm^{-1}
Total number of electrons per unit cell: $F(000)=576$

Using Cu$K\alpha$ radiation with a nickel filter, complete sets of relative intensities for $(h0l)$, $(h1l)$ and $(h2l)$ were obtained by the Weissenberg procedure. The specimen used was 0.04×0.02 cm. at right angles to the axis of rotation. Precession photographs were also taken using Cu$K\alpha$ radiation for the $(0kl)$ and $(hk0)$ zones. Intensities were estimated by visual comparison with a calibrated scale prepared using the same crystal. The multiple-film technique was applied to correlate strong and weak reflections, ranging in relative intensity from 5400 to 1. The maximum $2\sin\theta$ observed was 1.95. Within this range, 133 reflections were measured out of the 172 possible $(h0l)$.

Corrections for Lorentz and polarization factors were applied in the usual way, while that for absorption was neglected. The observed structure factors were first set onto an absolute scale by Wilson's method,[5] and the scale factor was further improved during the later stage of the refinement.

Structure Determination

Structure Projected on the (010) Plane.—It seemed reasonable to set up a planar molecular model of salicylamide on the basis of the information already obtained on some related crystal structures. The problem in the first step was to determine the arrangement of these hypothetical molecules in the unit cell. From the unit cell dimensions and the disposition of symmetry elements required by the space group, the molecule could not be inclined steeply with respect to the (010) plane but would lie approximately in the region with the dimensions of $a/4 \times c/4$. There are four possible arrangements of the symmetry elements, as Fig. 1 shows, and the hydroxyl and amide groups can be arbitrarily taken to point downward in this drawing. It was expected from the normal van der Waals radii and hydrogen bond distances that the atoms would be located only outside the circles centered on the symmetry elements shown in Fig. 1. The initial coordinates of the atoms in the molecule were chosen in the rather limited allowable region so as to give large calculated values for some strong reflections, such as (202). By the systematic use of the structure factor maps for reflections with a larger spacing than 2 Å, the coordinates were adjusted so that a fairly good agreement between observed and calculated structure factors was obtained. Ordinary Fourier syntheses followed. After four cycles of Fourier refinement, the (F_o-F_c) synthesis technique was applied twice in succession. Four hydrogen atoms were first placed on the molecular plane at a distance of 1.0 Å from the carbon atoms, and the hydrogen atoms of the hydroxyl and amino groups were located at positions which could reasonably be expected from the second difference map. At this stage, the discrepancy index, $R=\sum||F_o|-|F_c||/\sum|F_o|$, was 0.16. After that, the anisotropy in the thermal motion of each atom was taken into account in terms of $\exp\{-(h^2B_{11}+hlB_{13}+l^2B_{33})\}$. The anisotropic temperature factors were derived and refined from four successive (F_o-F_c) syntheses by the method of Takaki and Sakata.[6] The effect of secondary extinction was also allowed for. The discrepancy index thereby decreased to 0.087. The final atomic coordinates and the temperature factors of carbon, nitrogen and oxygen atoms are listed in Table I, while the observed and calculated structure factors are shown in Fig. 2. In the refinement stage, all calculations of the structure factors and Fourier syntheses were made on an automatic digital computer, NEAC 2203, using programs devised by Yoriko Ogawa of this laboratory. The final electron density distribution projected on the (010) plane is shown in Fig. 3.

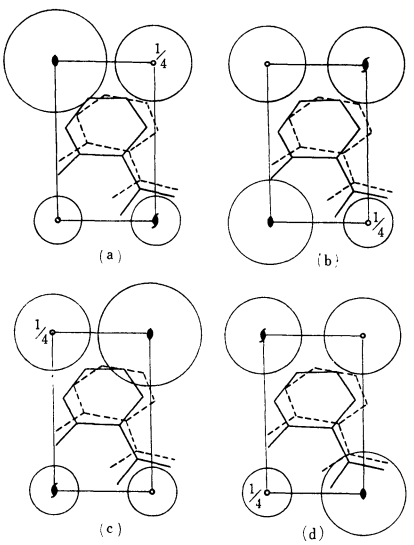

Fig. 1. Arrangement of symmetry elements and trial structure (solid line). Final projected structure is shown by broken lines. Correct arrangement of symmetry elements is (b).

complete intensity set for $(0kl)$, $(hk0)$ or (hkl) was taken and a serious overlapping of atoms was expected in the projections along the a and c axes, we attempted to refine the y-coordinates by the full-matrix least-squares technique for $(hk0)$ and $(0kl)$ intensity data, with fixed x and z coordinates obtained from the (010) projection. The structure projected on the (010) plane suggested that the relative arrangement of the symmetry elements in Fig. 1(c) is impossible because of too close van der Waals contacts around C_4. Arrangements (a) and (d) also seemed to be less probable. As the inclination of the molecular plane with respect to the (010) plane could be estimated, it was not difficult to choose approximate y-coordinates for the atoms referred to the arrangement (b) of the symmetry elements,

thus explaining some characteristic structure factors using the structure factor maps. The program of the full-matrix least-squares refinement was written in MALT language[7] and executed on an electronic computer NEAC 2206. After a few cycles of refinement, the discrepancy index decreased from 0.47 to 0.22. As the molecule suffered considerable deformation, however, the y-coordinates so obtained were adjusted to recover a reasonable molecular shape and were then again refined by the least-squares program. When this process was repeated several times, the discrepancy index reached 0.120. The overall isotropic temperature factor was 3.27.

The unsatisfactory convergence at the earlier stages of refinement may be due to the shortage of the intensity data and to the less accuracy of some of the structure factors. We had the feeling that in such a case a technique similar to that used in the analysis of 2-amino azulene[8] would be adequate, although we did not actually apply one.

Observed and calculated structure factors for (*hk*0) and (0*kl*) are shown in Fig. 4. To confirm the above-mentioned results further, we have calculated the structure factors for (*h*1*l*). The agreement between observed and calculated structure factors for (*h*1*l*) was fairly good, as Fig. 5 shows; the discrepancy index was 0.184.

Description of the Structure and Discussion

Molecular Structure.—Bond lengths and bond angles in salicylamide are shown in Fig. 6.

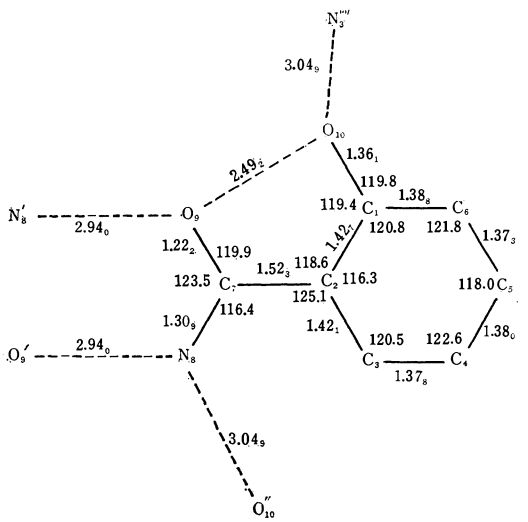

Fig. 6. Bond lengths (Å) and bond angles (°).

Although small fluctuations among the C–C bond lengths in the benzene ring are observed and the slight elongation of C_1–C_2 is probably of some significance, no detailed discussion will be given because of low degree of accuracy of the y-coordinates. The average C–C bond length in the benzene ring is 1.39_5 Å, and the average bond angle C–C–C is 120.0°, in good agreement with the standard value. The bond length, C_1–O_{10}, is 1.36_1 Å, which is nearly the same as the values observed in salicylic acid,[9] 1.36_1 Å, and in *p*-amino salicylic acid,[10] 1.37 Å. The dimensions of amide group found in the present compound are close to those found in the related compounds: for example, C–N= 1.31_2 Å and C–O=1.24_6 Å in α-pyrazinamide.[2]

The final (F_o-F_c) synthesis projected on the (010) plane is shown in Fig. 7; this was obtained using the structure factors calculated without the contributions from hydrogen. Electron density peaks corresponding to hydrogen atoms are easily recognized, although their heights and coordinates are not so accurate. The hydrogen atom attached to O_{10} lies near the line joining O_9 and O_{10}. The position of this hydrogen atom and the interatomic distance between O_9 and O_{10}, 2.49 Å, clearly show that an intramolecular hydrogen bond is formed between these atoms, as has been observed in salicylic acid[9] and *p*-amino salicylic acid[10] also.

The plane of the benzene ring (including C_7 and O_{10}) can be represented by the equation:

$$y=-0.0526\,x'-1.1098\,z'+9.6211$$

where x', y and z' are referred to the orthogonal axes a, b and c*, so that $x'=x+z\cos\beta^*$ and $z'=z\sin\beta^*$; the values of the coefficients were determined by means of the least-squares method. The perpendicular displacements of atoms from the mean plane, shown in Table

II, vary from 0.001 to 0.013 Å, the mean value being 0.007 Å. On the other hand, oxygen and nitrogen atoms in the amide group considerably deviate from the mean plane, and the angle between planes of amide and benzene ring is about 3°. In many related amide crystals,[3,4,11,12] it is observed that the amide group twists around the connecting C–C bond and that the planes of amide and ring make an angle of about 25°. This twist has been interpreted as the effect of steric hindrance between hydrogen atom in the amino group and that in the ortho position of the ring. In the present compound, however, it may be suggested that this kind of steric hindrance is balanced with the effects of the intramolecular hydrogen bond on another side of the amide group, together with other intermolecular forces, and that the whole molecule remains approximately planar. In this connection, it is of some interest that the C_2–C_7 distance in this molecule is longer than those in similar amide compounds.[3,4,11,12]

Crystal Structure.—The crystal structure of salicylamide is shown in Fig. 8, in which the hydrogen bond is represented by bold broken lines. The molecules are connected by two NH–O hydrogen bonds, the first set, 2.94 Å in length, forming a dimer across the center of symmetry, and the second set, 3.05 Å in length, joining such dimers into an endless chain extended along the a axis. As the latter set is located across the two-fold axis, the

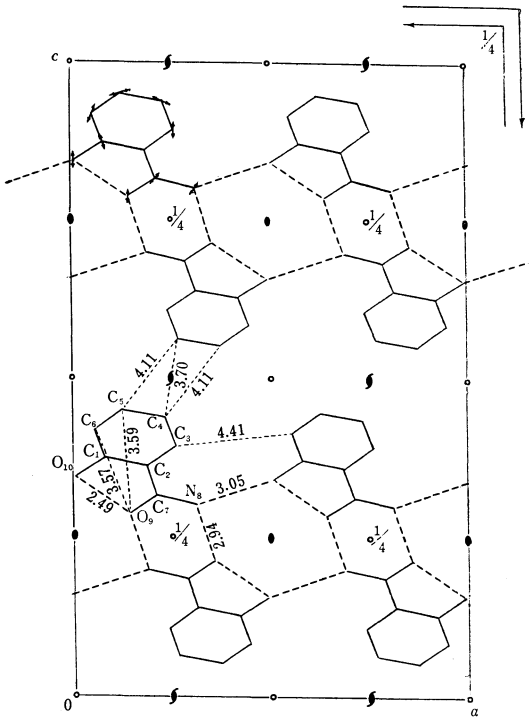

Fig. 8. Arrangement of molecules in the (010) projection with intermolecular distances (Å). Arrows show the direction of the maximum thermal oscillation of atoms.

12) B. R. Penfold and J. C. B. White, ibid., **12**, 130 (1959).

inclination of component dimers in a chain changes alternately. In α-pyrazinamide,[2] the atom in the ortho position is a donor of the hydrogen bond which connects the pyrazinamide dimers with each other. It might be said that in this sense the molecular linkage in α-pyrazinamide is similar to that found in the present crystal, although there are some differences between them.

McCrone and Hinch[13] have reported another modification obtained from melt. It is supposed that the molecular association in this modification might be of a type similar to that in β- or δ-pyrazinamide.[3]

The directions of the maximum thermal motions of atoms are illustrated by arrows in Fig. 8; they ase derived from the anisotropic temperature factors in Table I. The length of the arrow is proportional to the mean-square displacement of the atom by the thermal motion in this direction. By inspection it seems probable that the molecule is making an angular oscillation around the mass center of a single molecule, suggesting that the NH–O hydrogen bonds forming the dimer are not very strong, a similar situation having also been observed in the crystal of α-pyrazinamide.[2]

This molecular arrangements can reasonably explain the existence of the cleavage parallel to the ba plane and also the twinned crystals frequently obtained, in which the twinning plane is the ba.

The authors wish to express their thanks to Miss Yoriko Ogawa for her assistance in the experiments and for her computations using the electronic computer.

Pyrolysis of Fluorinated Organic Compounds. I. The Pyrolysis of 1, 2-Dibromo-1-chloro-1, 2, 2-trifluoroethane and Some Related Halogenated Ethane Derivatives

By J. D. PARK, R. W. LAMB[1] and J. R. LACHER

(Received January 17, 1964)

It is known that chemical bonds may be broken homolytically by heat to produce free radicals which may further react to produce other compounds. This study involves the homolytic scission of the least thermally stable bonds in CF_2Br–$CFClBr$ and related compounds. A temperature was selected for the pyrolysis which probably caused primarily carbon bromine bonds to be broken in the initiation steps of the reaction. The products were isolated and used as evidence to postulate reaction paths involving intermediate free radicals.

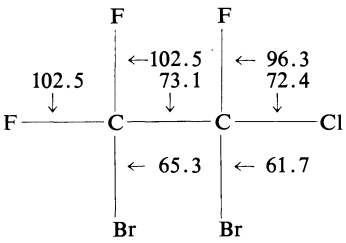
Results and Discussion

It was shown that pyrolysis of CF_2Br–$CFClBr$ (I) produced two major products, CF_2Cl–$CFClBr$ (II) and CF_2Br–$CFBr_2$ (III) in addition to starting material. The following reactions can be used to explain the products.

$$\mathrm{I} \xrightarrow{\text{heat}} \begin{cases} \rightarrow \dot{C}F_2\text{-}CFClBr + \dot{B}r \\ \rightarrow CF_2Br\text{-}\dot{C}FCl + \dot{B}r \end{cases} \quad \text{(initiation)} \quad (1)$$

$$\dot{C}F_2\text{-}CFClBr + \mathrm{I} \rightarrow CF_2Br\text{-}\dot{C}FBr + \mathrm{II} \quad (2)$$

$$CFBr\text{-}\dot{C}FCl + \mathrm{I} \rightarrow CF_2Br\text{-}CFCl_2\ (\mathrm{IV}) + CF_2Br\text{-}\dot{C}FBr \quad (3)$$



$$CF_2Br\text{-}\dot{C}FBr + \mathrm{I} \rightarrow CF_2Br\text{-}\dot{C}FCl \text{ or } \dot{C}F_2\text{-}CFClBr + \mathrm{III} \quad (4)$$

(propagation)

The bond dissociation energies (kcal./mol.) were calculated for the starting material I, according to the equation developed by Errede.[2]

1) Frank J. Seiler Research Laboratory, Office of Aerospace Research, United States Air Force Academy, Colorado. This paper represesnts part of a thesis submitted by R. W. Lamb to the Graduate School, University of Colorado, in partial fulfillment of the requirements of the Ph. D. degree, June, 1961.

2) L. A. Errede, *J. Phys. Chem.*, **64**, 1031 (1960).

Assuming that the ease of breaking a bond in the initiation step is a function of the bond dissociation energy, it is postulated that the initiation step in the pyrolysis of I involves primarily the rupture of carbon-bromine bonds as is shown in reaction 1.

A small amount of CF_2Cl-$CFBr_2$ (VI) was also shown to be present in the product which indicates the presence of the free radical, $\dot{C}F_2$-$CFBr_2$ or CF_2Cl-$\dot{C}FBr$, during the course of the reaction. Both of these free radicals could originate from the further reaction of the products obtained in reactions 2 and 3.

There was no IV · isolated in the product, therefore, the rate of reaction 3 must be slow compared to 2 and 4.

When a mixture of I and bromine was pyrolyzed, the same products were obtained in the same proportions as was obtained when elemental bromine was not used in the reaction. However, the yield was drastically reduced when I was pyrolyzed in the presence of nitric oxide as would be expected for a reaction involving free radicals.

When II was pyrolyzed, CF_2Cl-$CFCl_2$ (V), I and VI were the only products isolated. These products can be accounted for using the following reactions.

$$\text{II heat} \rightarrow CF_2Cl\text{-}\dot{C}FCl + \dot{B}r \quad \text{(initiation)} \quad (5)$$

$$\text{II} + CF_2Cl\text{-}\dot{C}FCl \rightarrow \text{V} + \dot{C}F_2\text{-}CFClBr \quad \text{or } CF_2Cl\text{-}\dot{C}FBr \quad (6)$$

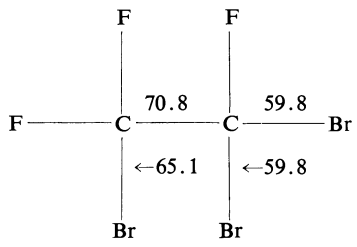
$$\text{II} + \dot{C}F_2\text{-}CFClBr \rightarrow \text{I} + CF_2Cl\text{-}\dot{C}FCl \quad (7)$$

$$\text{II} + CF_2Cl\text{-}\dot{C}FBr \rightarrow \text{VI} + CF_2Cl\text{-}\dot{C}FCl \quad (8)$$

(6), (7), (8): (propagation)

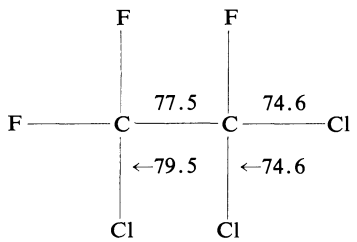
Pyrolysis of an equimolar mixture of III and V produced I, II and VI as the major products. Four different free radical intermediates are possible from the pyrolysis of III and V. The combination of these intermediates with a bromine or chlorine atom should lead to the formation of the products as follows :

$$\dot{C}F_2\text{-}CFCl_2 \xrightarrow{\text{Abstract Br}} \text{IV} \quad (9)$$



$$CF_2Cl\text{-}\dot{C}FCl \xrightarrow{\text{Abstract Br}} \text{II} \quad (10)$$

$$\dot{C}F_2\text{-}CFBr_2 \xrightarrow{\text{Abstract Cl}} \text{VI} \quad (11)$$



$$CF_2Br\text{-}\dot{C}FBr \xrightarrow{\text{Abstract Cl}} \text{I} \quad (12)$$

The products which were isolated furnish evidence for reactions 10, 11 and 12. Since IV could not be isolated from the pyrolysis, it appears that either appreciable amounts of $\dot{C}F_2$-$CFCl_2$ are not present during the reaction or reaction 9 is slow compared to 10, 11, and 12. It is presumed that the carbon-chlorine bond in the chlorodifluoromethyl moiety of V is not appreciably broken under the conditions of the reaction. This particular bond is known to be relatively strong because of the strong negative inductive effect of the two fluorine substituents.[3]

Using the equation developed by Errede,[2] a quantitative comparison of the strengths of the bonds in III and V can be made. The following model illustrates some calculated bond dissociation energies in kcal./mol.

III

V

It is presumed from the above calculated bond dissociation energies that the initiation step involves primarily the breaking of carbon-bromine bonds in III. Furthermore, the rate of production of CF_2Br-$\dot{C}FBr$ should exceed that of $\dot{C}F_2$-$CFBr_2$ because of the difference in the bond dissociation energies of the carbon-bromine bonds in III. Production of free radicals from V probably occurs during the propagation steps by the reaction of V with either $\dot{C}F_2$-$CFBr_2$ or CF_2Br-$\dot{C}FBr$. The high boiling liquid obtained from the pyrolysis of CF_2Br-$CFBr_2$ in the presence of nitric oxide was probably formed from the coupling of

3) R. K. Steunenberg and G. H. Cady, *J. Am. Chem. Soc.*, **74**, 4165 (1952).

free radicals, such as $CF_2Br-\dot{C}FBr$ or $\dot{C}F_2-CFBr_2$.

An infrared spectrum of the slightly blue product showed no absorption peak at 6.25 μ, where the nitroso should absorb. The nitroso blue color is very intense; therefore, the presence of a small amount of nitroso compound could be enough to give a slight coloration to the product, but not enough to show up on a gas chromatogram, or in an infrared spectrum. This small amount of nitroso compound is to be expected. Nitric oxide is a known free radical scavenger; therefore, it would be expected to react with the free radicals formed in the following manner:

$$CF_2Br-\dot{C}FBr + NO \rightarrow CF_2Br-\underset{\displaystyle NO}{\underset{|}{CFBr}} \quad (1)$$

$$\dot{C}F_2CFBr_2 + NO \rightarrow \underset{\displaystyle NO}{\underset{|}{CF_2}}-CFBr_2 \quad (2)$$

These reactions represent termination steps; therefore, the products should be present only in small amounts. No attempt was made to isolate and identify the high boiling compound, which was a minor product, when $CF_2Br-CFBr_2$ was pyrolyzed in the presence of nitric oxide.

Experimental

General Procedures.—All pyrolysis runs were made using the same general procedures. When the reactants were liquids, as was the case in all but one reaction, they were added from a 50 ml. burette into a pyrolysis tube enclosed in an electric furnace. In the one reaction involving a gaseous reactant and a liquid reactant, the same apparatus was used except that the gas was introduced into the line leading to the pyrolysis tube via a T-connection just below the burette.

The tube used for pyrolysis was a platinum-lined nickel tube with an outside inconel jacket about 24 inches long and 3/4 inches in diameter. A section of the tube about 12 inches long was enclosed in the furnace. In order to make a distinct boundary for the region of pyrolysis, tap water was circulated through copper coils wrapped around the tube at the ends of the furnace. The volume of the section of tube used for pyrolysis was required in order to calculate the contact time. The temperature of the reaction was measured with a chromel-alumel thermocouple, which was inserted into the furnace along with the pyrolysis tube. The contact time was calculated by dividing the volume of the pyrolysis tube by the rate of flow of the reactants through the tube.

Gas chromatography was used to determine the composition of mixtures of liquids. All percentages are given in weight percents.

1, 2-Dibromo-1-chloro-1, 2, 2-trifluoroethane.—1,2-Dibromo-1-chloro-1, 2, 2-trifluoroethane was prepared by bubbling chlorotrifluoroethylene through liquid bromine in the presence of actinic light. In a typical reaction, 290 g. (2.50 mol.) of olefin was added to 375 g. (2.34 mol.) of bromine over a four hour period. The distilled product obtained was 637 g. (92% conversion), b. p. 86.5°C/630 mmHg (lit.[4] 92~92.5°C/760 mmHg). Gas chromatography showed this material to be pure.

Pyrolysis of 1, 2-Dibromo-1-chloro-1,2,2-trifluoroethane.—*A) at 500°C.*—Exactly 155 g. (0.56 mol.) of $CF_2Br-CFClBr$ was pyrolyzed at 500°C at a contact time of about 26~27 sec. The reactant was added at a uniform rate over a total time of four hours. All of the products (150 g.) were collected in a trap maintained at room temperature. Fractionation through a Todd column yielded the following three main fractions: a) $CF_2Br-CFClBr$ (I), b. p. 86~87°C/630 mmHg (84%); b) $CF_2Cl-CFClBr$ (II), b. p. 63°C/630 mmHg (5.5%) and c) $CF_2Br-CFBr_2$ (III), b. p. 108°C/630 mmHg (7.9%).

II was shown to be $CF_2Cl-CFClBr$ by comparison of its infrared spectrum with that of an authentic sample obtained from the addition of chlorine to trifluorobromoethylene. Similarly, compound III was compared with an authentic sample obtained form the bromination of trifluorobromoethylene.

B) At 600°C.—Although a trap maintained at −80°C was in the exit line, nearly all the products were collected in the trap kept at room temperature. In a typical reaction, 382 g. of $CF_2Br-CFClBr$ was pyrolyzed over a 3.5 hr. period to yield 367 g. of product. The product was washed with 5% sodium bisulfite solution to remove some bromine, washed with water, and dried over magnesium sulfate. The product was filtered and fractionated through a 50 cm. Todd column. The following materials were isolated and identified: a) mixture A consisting of $CF_2Br-CFClBr$ and $CF_2Cl-CFBr_2$, b. p. 86~87°C/630 mmHg: n_D^{25} 1.4254 (33%); b) $CF_2Cl-CFClBr$ (14%) and c) $CF_2Br-CFBr_2$ (19%).

The yields of the various components were calculated from a chromatogram of the mixture of undistilled products. The isomers, $CF_2Br-CFClBr$ and $CF_2Cl-CFBr_2$ gave only one peak on the chromatogram; therefore, they were treated as one compound in calculating yields.

The infrared spectrum of the mixture was compared with the spectrum of $CF_2Br-CFClBr$ prepared by adding bromine to chlorotrifluoroethylene. The spectrum of the mixture contained all of the absorption peaks of $CF_2Br-CFClBr$ plus two additional peaks at 9.75 μ and 13.27 μ. This evidence indicated that mixture A consisted of the two positional isomers, $CF_2Br-CFClBr$ and $CF_2Cl-CFBr_2$. In order to verify this supposition, and to determine the relative amounts of each isomer, A was treated with zinc and the resulting gaseous olefins brominated. The two isomers reacted by the following paths giving two products, which were easily separated by fractionation:

4) R. N. Haszeldine, *J. Chem. Soc.*, 1952. 3423.

$$\left.\begin{matrix} CF_2Br\text{-}CFClBr \\ \\ CF_2Cl\text{-}CFBr_2 \end{matrix}\right\} \xrightarrow{\text{Zn in ethanol}} \left\{\begin{matrix} CF_2{=}CFCl \\ + \\ CF_2{=}CFBr \end{matrix}\right\}$$

$$\xrightarrow[\text{light}]{Br_2} \left\{\begin{matrix} CF_2Br\text{-}CFClBr \text{ b. p. } 86°C/630 \text{ mmHg} \\ + \\ CF_2Br\text{-}CFBr_2 \text{ b. p. } 107°C/630 \text{ mmHg} \end{matrix}\right.$$

The amount of each component was determined from a vapor phase chromatogram of the product. The product was found to be 73 mol. percent CF_2Br-$CFClBr$ and 27 mol. percent CF_2Br-$CFBr_2$.

Pyrolysis of a Mixture of 1, 2-Dibromo-1-chloro-1, 2, 2-trifluoroethane and Bromine at 600°C.—A mixture consisting of 535 g. (1.93 mol.) of CF_2Br-$CFClBr$ and 309 g. (1.93 mol.) of bromine was pyrolyzed at 600°C at a contact time of about 10 sec. The pyrolysis reaction was run over a period of fourteen hours and fifty minutes. The product was collected in a trap maintained at room temperature. It was then washed with a solution of 5% sodium bisulfide to remove the excess bromine, washed with water and dried over magnesium sulfate. The composition of the product was calculated from a gas chromatogram of the undistilled material. The individual peaks corresponding to each component of the products were identified by their retention times. The following products were obtained: a) mixture A consisting of CF_2Br-$CFClBr$ and CF_2Cl-$CFBr_2$ (32%); b) CF_2Cl-$CFClBr$ (13.6%) and c) CF_2Br-$CFBr_2$ (24%).

The reaction was repeated with a mixture consisting of 200 g. (0.72 mol.) of CF_2Br-$CFClBr$ and 109 g. (0.69 mol.) of bromine using a longer contact time (21.1 sec.). Apparently, there was very little change in the distribution of the pyrolyzates from that obtained above. The distribution was 27%, 13.6% and 19% for mixture A, CF_2Cl-$CFClBr$ and CF_2Br-$CFBr_2$, respectively.

Pyrolysis of a Mixture of 1, 1, 2-Tribromo-1, 2, 2-trifluoroethane and Nitric Oxide at 600°C.—Approximately 40 g. of CF_2Br-$CFBr_2$ was pyrolyzed in the presence of nitric oxide at 600°C over a 1.5 hr. period. The apparatus described under "General Procedures" was used, except that the nitric oxide was added at the rate of approximately 100 ml. per second. The product was all collected in the trap maintained at room temperature. It was washed with water, dried over magnesium sulfate, and filtered. The product was slightly blue, indicating a possible trace of a nitroso compound; however, the infrared spectrum of the product showed no absorption at the wavelengths, where the nitroso group should absorb. Calculations based on a gas chromatogram of the product indicate that it is approximately 92% starting material and 8.0% high boiling compound. The high boiling compound is probably a product of coupling of free radicals produced in the pyrolysis.

Pyrolysis of 1-Bromo-1, 2-dichloro-1, 2, 2-trifluoroethane at 600°C.—About 110 g. of CF_2Cl-$CFClBr$ was pyrolyzed at 600°C at a contact time of about 11 sec. over a period of one hour and thirty-five minutes. All of the product (102 g.) were collected in the trap, maintained at room temperature. It was washed with a solution of 5% sodium bisulfite to remove some bromine, washed with water and dried over magnesium sulfate. The product was fractionated through a Todd column. The pure products were obtained for identification from the distillation, but the yields were calculated from a chromatogram of the original mixture of products. The following products were identified. The yields given were based on the amount of starting material: a) CF_2Cl-$CFCl_2$ (10%); b) CF_2Cl-$CFClBr$ (43%), and c) mixture A consisting of CF_2Cl-$CFBr_2$ and CF_2Br-$CFClBr$ (9.5%).

Pyrolysis of a Mixture of 1, 1, 2-Tribromo-1, 2, 2-trifluoroethane and 1, 1, 2-Trichloro-1, 2, 2-trifluoroethane at 600°C.—A mixture consisting of 56 g. (0.17 mol.) of CF_2Br-$CFBr_2$ and 32 g. (0.17 mol.) of CF_2Cl-$CFCl_2$ was pyrolyzed at 600°C at a contact time of about 14 sec. The pyrolysis was run over a 1.5 hr. period. All of the product (49 g.) were collected in the trap kept at room temperature. It was washed with a solution of 5% sodium bisulfite to remove some bromine, washed with water, and dried over magnesium sulfate. The product was fractionated through a Todd column. The pure products were obtained for identification from the distillation; however, the yields were calculated from a chromatogram of the original mixture of products. The following products were isolated and identified from the reaction. The calculated yields were based on the total amount of material obtained from the pyrolysis: a) CF_2Cl-$CFCl_2$ (37.4%); b) CF_2Cl-$CFClBr$ (7.6%); c) mixture A consisting of CF_2Br-$CFClBr$ and CF_2Cl-$CFBr_2$ (14.5%) and d) CF_2Br-$CFBr_2$ (40.5%).

Dehalogenation of a Mixture of 1, 2-Dibromo-1-chloro-1, 2, 2-trifluoroethane and 1, 1-Dibromo-2-chloro-1, 2, 2-trifluoroethane.—About 166 g. (0.6 mol.) of a mixture of CF_2Cl-$CFBr_2$ and CF_2Br-$CFClBr$ was treated with zinc in ethanol to yield a mixture of $CF_2{=}CFBr$ and $CF_2{=}CFCl$. The reaction was carried out in a three-neck flask equipped with a stirrer, addition funnel, and a condenser. The halocarbons were added dropwise to a stirred suspension of powdered zinc in ethanol via an addition funnel. The exit line from the top of the condenser was collected to a dry-ice acetone trap, in which the olefins were collected. The olefins were used as a mixture in the next reaction, in which they were brominated.

Bromination of a Mixture of 1-Bromo-1, 2, 2-trifluoroethylene and 1-Chloro-1, 2, 2-trifluoroethylene.—Approximately 30 g. of a mixture, consisting of a mixture of $CF_2{=}CFCl$ and $CF_2{=}CFBr$, was passed from a trap through a glass frit into a glass flask approximately 6 cm. × 50 cm. The glass flask, which contained the bromine, was irradiated with light from a tungsten lamp to catalyze the reaction. The glass flask was equipped with a water-cooled condenser. The exit line was connected to a bubbler, which was connected to a dry-ice acetone-cooled trap to recover some unreacted olefin. The crude product was washed with a 10% sodium bisulfite solution to remove the excess bromine, washed with water, and dried over magnesium sulfate. Gas chromatography showed that the product (72 g.) consisted of a mixture of 78%

CF_2Br-CFClBr and 22% CF_2Br-$CFBr_2$.

Pyrolysis of CF_2Br-$CFBr_2$ in the Presence of Nitric Oxide.—A sample of CF_2Br-$CFBr_2$ was pyrolyzed at 350°C in the presence of nitric oxide. At this temperature, 93% of the starting material was recovered and the absence of blue color was noted. This indicated no nitroso compounds, such as CF_2NO-$CFBr_2$ and CF_2Br-CFBrNO, were formed.

When the pyrolysis was run at 600°C a great deal of decomposition took place. After washing the product with water and drying, it retained a blue color, indicating that some nitroso compounds could be in the product. However, a gas chromatogram of the product showed it to consist of 92% of CF_2Br-$CFBr_2$ and 8% of an unidentified high boiling liquid.

Summary

The synthesis of various halogenated ethane derivatives was performed by the pyrolysis of CF_2Br-CFClBr and other similar compound. The reactions were carried out in a platinum-lined tube at temperatures ranging from 350°C to 600°C alone and in the presence of nitric oxide or bromine. Various products were isolated and identified. A mechanism is postulated for the reaction.

We wish to take this opportunity to thank the Minnesota Mining and Manufacturing Co., St. Paul, Minnesota for partial support of this work through a grant-in-aid.

*Studies of Polybutene. II. On the Molecular Weight Distribution and the Solution Properties**

By Ryūichi ENDŌ, Kazuyoshi IIMURA and Masatami TAKEDA

(Received February 1, 1964)

Various commercial polybutenes have been obtained from several sources. Infrared study makes it seem that the polybutene is almost identical with a low-molecular-weight polyisobutylene.[1] Far fewer studies of the solution properties of the polymers with molecular weights ranging from 1000 to 10000 were carried out than on the usual high polymers, although recently the vapor pressure osmometer has become available for these low-molecular-weight polymers. Previous investigation of the polybutene has only dealt with its rheological property,[2] not with its solution property because of its extremely low molecular weight.

The present investigation has been undertaken to study the molecular weight and the molecular weight distribution of polybutene. Furthermore, according to the theory of Stockmayer and Fixman,[3] the unperturbed dimension of the polybutene fractions has been calculated from the relationship between the intrinsic viscosity and the molecular weight, and compared with the data reported by Fox and Flory[4] on low-molecular-weight polyisobutylene.

Experimental

Samples.—All the polybutenes employed were commercial products: Indopol of Amoco, Oronite of California Chemicals, and Polyvis of Cosden. All these samples except Indopol L-10 appeared as transparant viscous liquids.

The solvent and non-solvent were purified in the usual ways.[5]

Fractionation. — Fractional extraction has been applied with benzene as a solvent and methanol as a non-solvent. The fractionation was carried out using benzene-methanol mixtures, initially with a mixture rich in the non-solvent and finally with a mixture rich in the solvent, at room temperature. Then, the lowest-molecular-weight fraction was extracted from the sample. All the sample were divided into about eight or nine fractions.

Viscosity Measurement.—Samples were dissolved into benzene at room temperatures. The viscosities were measured with dilution in an Ubbelohde-type

viscometer at 30°C. The temperature of the double water bath, in which the viscometer was mounted vertically by using a specially-designed clamp, was maintained constant within ±0.005°C. Intrinsic viscosities were treated by the Huggins relation, and the data were calculated by the least-square method.

Molecular Weight Measurement.—The molecular weight of unfractionated samples was determined by the cryoscopic method in benzene. The molecular chain of polybutene is known to be a linear chain with one double bond at the end of the chain.[6]

Therefore, it is possible to determine the molecular weight of the same samples by the end-group analysis. The number of double bonds was determined using a modified Hübler method[7] in the following manner: about 1 g. of a sample was dissolved into 20 ml. of chloroform in a 500 ml. Erlenmeyer flask and added to a definite volume of an iodine solution ($I_2+Hg_2Cl_2$ in alcohol). The flask was then shaken frequently by hand. The reaction to the double bond with iodine was carried out in a dark oven at 30°C; the reaction mixture was kept there for 48 hr. (e. g., see Fig. 3). The molecular weight was calculated from the following equation (1);

$$\overline{M}_n = 1/[I_2] \quad (1)$$

The observed values agreed closely with that determined by the cryoscopic method. Since the amount of each fraction was limited, the molecular weight was determined mainly by the end-group analysis method.

Results and Discussion

Fractionation and Intrinsic Viscosity.—The solubility in a benzene-methanol mixed solvent was determined for Indopol L-10 as the lower, the Indopol H-35 as the medium, and for Indopol H-300 as the higher molecular weight sample respectively. The results are shown in Fig. 1. Figure 1 shows that the fractionation can be carried out with the mixed solvents by varying the volume fraction of benzene. Because these polymers have lower molecular weights, it seems likely that the fractionation is effected only by the difference in the dissolution energy of polymer molecules in mixed solvents and not by the entropy effect as in the usual high polymers. According to Brönsted's law of partition,[8] there exists a relation:

$$N_1/N_2 = \exp(-ME/RT) \quad (2)$$

where N_1 is the concentration of polymers in the solution phase, N_2 is the concentration of polymers in the gel phase, M is the molecular weight of dissolved polymers, and E is the dissolution energy of a monomer unit of polybutene. If the dissolution energy of some mixed solvent is a constant, the value of N_1/N_2 becomes smaller for the larger M. Generally, the value of N_1/N_2 increases with an increase in the dissolution energy or with the larger volume fraction of benzene in the mixed solvent. If the fractionation follows Eq. 2, a linear relation may be obtained between $\ln N_1/N_2$ and the dissolution energy, E, of mixed solvents.

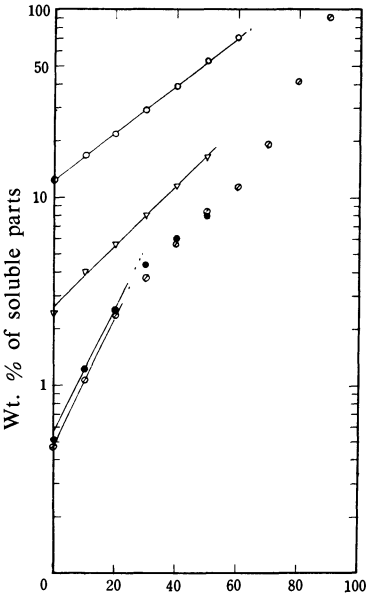

Fig. 1. Relation between the volume fraction of benzene in benzene-methanol mixed solvent and the weight fraction of soluble part.
○ L-10, ▽ H35, ⊘ H300, ● 32

For Indopol L-10, which is of the lowest molecular weight, a linear relation was obtained, but not for Indopol H-35 and Indopol H-300. A more general theory[9] it necessary for treating these samples. The fractions obtained from each sample are given in Table I(a)—(f). The reduced viscosities are plotted against the concentration for Indopol H-300 and Polyvis 3 in Fig. 2(a)—(b). It may be seen from Fig. 2 that the Huggins' relation holds for these samples up to higher concentrations, but for higher-molecular-weight polymers, the non-linear relation[10] appears in the range of higher concentrations. The intrinsic viscosities of unfractionated samples are shown in Table II.

Molecular Weight.—The molecular weight of unfractionated samples was determined by means of the cryoscopic method and are listed as $\bar{M}_{cry}$ in Table II. Figure 3 shows the plots of the iodine concentration against the reaction time. Therefore, the molecular weights with an end-group titration $\bar{M}_{end}$ were determined after 48 hr.; they are shown in Table I(a)—(f), and Table II. The agreement of $\bar{M}_{end}$ and $\bar{M}_{cry}$ is fair. Therefore, it has been proved that the molecular chain of polybutene has only one double bond in each chain.

Therefore, the molecular weight determination of fractions has been carried out mainly by end-group analysis, because it requires a smaller amount of sample than does the cryoscopic method.

The Relationship between Intrinsic Viscosity and Molecular Weight.—The intrinsic viscosity of fractions is plotted against the molecular weight in Fig. 4. The Mark-Houwink equation was determined by the least squares method to be:

$$[\eta] = 2.24 \times 10^{-4} \bar{M}_n^{0.72_2} \quad (3)$$

On the other hand, Fox and Flory[4] obtained for polyisobutylene with molecular weights from 1000 to 1300000:

$$[\eta] = 6.1 \times 10^{-4} \bar{M}^{0.56} \quad (4)$$

For comparison, a dotted line expressing Flory's equation (4) is also drawn in Fig. 4. The value of the exponent in Eq. 3 is larger than that in Flory's equation (4). Since it is known that the system of polyisobutylene

a) Determined by the end-group analysis.
b) Determined by the cryoscopic method.
c) Calculated from the molecular weight distribution.

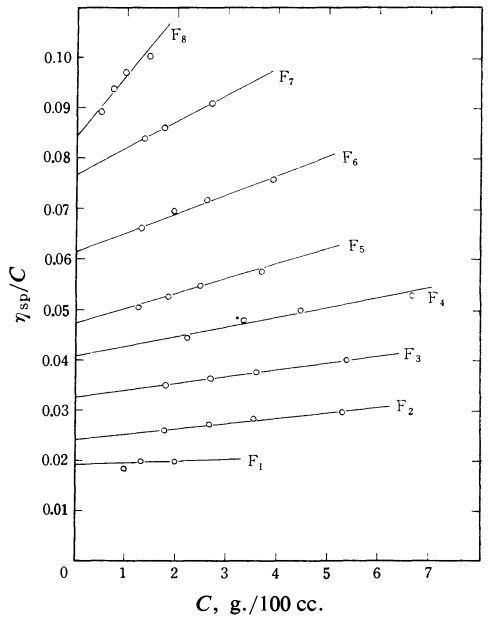

Fig. 2(a). Relation between the reduced viscosity and the concentration of Indopol H-300, at 30°C.

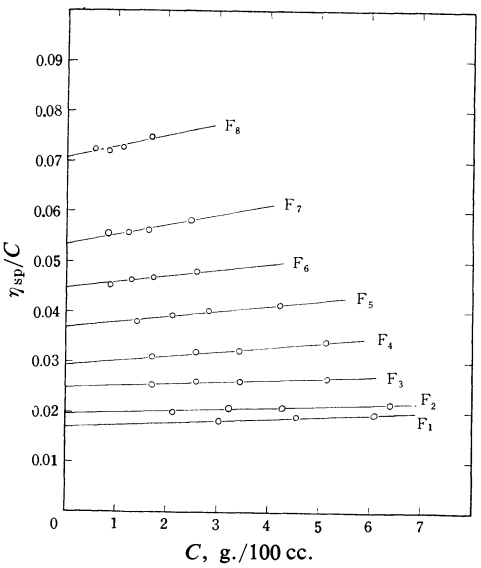

Fig. 2(b). Relation between the reduced viscosity and the concentration of Polyvis 3, at 30°C.

in benzene has the theta temperature at 25°C,[11] the obtained α for polybutene seems to be large. In polymerization, the branching of the polymer chain may occur mainly at the molecule with a higher molecular weight. Because the polyisobutylene has a higher molecular weight than polybutene, it seems that the branching exists in the molecular chain. Since polybutene seems to consist of linear chain molecules with molecular weights ranging from 240 to 7000, the value of the α of polybutene is thought to become larger than that of polyisobutylene.

Recently, Stockmayer and Fixman[3] have demonstrated a means to estimate the unperturbed dimension factor K from the intrinsic viscosity $[\eta]$ by means of the following equation:

$$[\eta] = KM^{1/2}\alpha_\eta^3 \tag{5}$$

$$[\eta] = KM^{1/2} + 0.51\Phi_0 BM \tag{6}$$

$$K = \Phi_0 A^3 \tag{7}$$

$$A^2 = \langle\bar{L}^2\rangle_0/M \tag{8}$$

where Φ_0 is the universal viscosity constant for chain polymers in theta solvents, B is the polymer-solvent interaction parameter, α_η is the viscosity expansion factor,[12] and $\langle\bar{L}^2\rangle_0$ is the mean square unperturbed end-to-end distance. Equation 6 gives the unperturbed molecular dimension, A^2, from the measured value of K without using the theta solvent. If the plots of $[\eta]M^{-1/2}$ against $M^{1/2}$ are extrapolated to zero molecular weight, we have the value of K. Experimental results are shown in Fig. 5. The value of K obtained

in the theta solvent is given[9] as 10.6×10^{-4}, as is shown on the ordinate axis by an arrow in Fig. 5. Although the experimental points are scattered widely, the value of K obtained from the present work shows a tendency to be smaller than 10.6×10^{-4}. This effect seems to arise from the end-effect of the molecular chain of polybutene because of its smaller molecular weight.[13]

Molecular Weight Distribution. — The end-group analysis is less reliable for the determination of the molecular weight of higher fractions. The molecular weight of all fractions was re-calculated by using Eq. 3 and is shown as $\overline{M}_v$ in Table I (a)—(f).

Integral distribution curves are expressed as

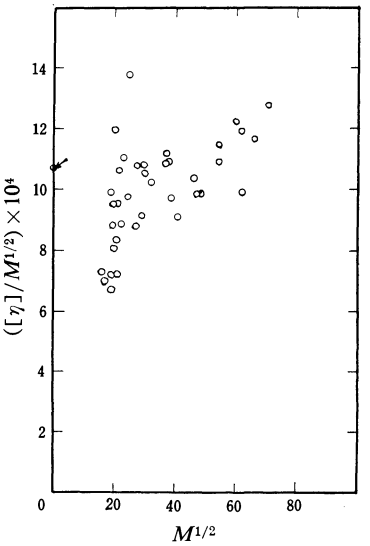

Fig. 5. Relation between $[\eta]M^{-1/2}$ and $M^{1/2}$. The arrow shows the value of K obtained in θ-solvent.

plots of the cumulative weight fraction against the molecular weight. The cumulative weight fraction corresponding to the molecular weight, M_i, of the i-th fraction, designated as W_i, is expressed by the following equation;

$$W_i = w_i/2 + \sum_{j=1}^{i-1} w_j \qquad (9)$$

where w_i and w_j are the weight fractions of the i-th and j-th fractions respectively. The integral distribution curves are then converted into the differential distribution curves (cf. Fig. 6 (a)—(f)). The number-average molecular weight $\overline{M}_n$, the weight-average molecular weight $\overline{M}_w$, the $\overline{M}_w/\overline{M}_n$ ratio and a variance, μ_2, were also calculated[14] for these distributions; they are shown in Table III. The calculated values of the number-average molecular weight, with the exception of Indopol L-10, are essentially identical with the observed values. The values of $\overline{M}_w/\overline{M}_n$, also with the exception of Indopol L-10, are equal to those of high polymers in general. Therefore, it is found that such a low-molecular-weight polymer keeps the inhomogeneity of molecular weight.

We have tried to fit Schulz's molecular weight distribution function[15] to our experimental results. This function is:

$$f(M) = M \ln^2 aa^M \qquad (10)$$

where M is the molecular weight and a is the probability of propagation for the active

molecule in polymerization. The parameters a in Eq. 10 were calculated from the observed distribution function; they are listed in Table IV. For comparison, theoretical curves expressing Eq. 10 are also given as dotted lines in Figs. 6(b), 6(c), 6(e) and 6(f). Some difference between the theoretical and the observed curves may be seen in Fig. 6(b). The theoretical curves are not drawn in Figs. 6(a) and 6(d) because the observed curves are not in good agreement with the theoretical ones. These disagreements are thought to be caused by their smaller molecular weights. Though the Indopol H-300 shown in Fig. 6(c) is of a higher molecular weight than the other three samples, the agreement between the observed curve and the theoretical one for it is not very good. In general, it is felt that the observed curves for the samples of Indopol series do not agree with the theoretical curves. On the other hand, the curves for the other samples shown in Figs. 6(e) and 6(f) are in close agreement with theoretical ones.

The ratio of the probability of termination to the probability of propagation, χ, is then calculated from the value of a; it is also shown in Table IV. For comparison, the value of a for polyisobutylene[16] is also listed in Table IV. Because the material gas of polybutene consists of mixed olefin with carbon numbers from two to six, it seems difficult to compare the mechanism of its polymerization directly with that of polyisobutylene. However, as the values of a are nearly equal to that of polyisobutylene, it may suggest that the polymerization mechanism of polybutene is similar to that of polyisobutylene.

The Synthesis of Lactones from ω-Chlorocarboxylic Acids

By Kazuo SAOTOME

(Received February 8, 1964)

Various intermediates for polymers have been prepared by Russian authors[1] from ω-chlorocarboxylic acids, which are the basic derivatives from the tetrachloroalkanes obtained by the telomerization of ethylene with carbon tetrachloride. However, the hydrolysis of these ω-chlorocarboxylic acid has been little studied.

In the present work, the author will report on the kinetics of the hydrolysis of δ-chlorovaleric and ω-chloroheptanoic acids in an aqueous solution. Joyce et al.[2] derived δ-valerolactone from δ-chlorovaleric acid by heating it with sodium hydroxide in methanol. δ-Chlorovaleric acid is easily hydrolyzed in an aqueous alkaline solution to δ-hydroxyvaleric acid, which is then immediately converted to δ-valerolactone by neutralizing the solution. When an aqueous solution of sodium δ-chlorovalerate is heated, the oily layer of δ-valerolactone appears. On the other hand, the hydrolysis product from sodium ω-chloroheptanoate in an aqueous solution remains ω-hydroxyheptanoic acid. Its polyester is produced by removing water from the solution.

The dimeric lactone of ω-hydroxyheptanoic acid was obtained by the thermal decomposition of the polyester according to the method of Spangel and Carothers.[3] The monomeric

lactone was also isolated from the lower-boiling by-products. Stoll and Rouve[4] early obtained the dimeric lactone by treating ω-hydroxyheptanoic acid in a large amount of benzene (the dilution method).

Practical methods for the preparation of δ-valerolactone from δ-chlorovaleric acid were investigated on the basis of the kinetic studies.

Experimental

The Hydrolysis of ω-Chlorocarboxylic Acids.—Sample solutions were prepared by neutralizing δ-chlorovaleric and ω-chloroheptanoic acids with a dilute aqueous solution of sodium hydroxide, using phenolphthalein as an indicator, while stirring and cooling the solutions with ice-water. The fresh solution was diluted to a given concentration and immediately subjected to the reaction in a thermostat. In the case of ω-chloroheptanoic acid, the reaction was carried out in a sealed ampoule. As the reaction proceeded, a portion of the solution was taken up and titrated with a standard solution of silver nitrate.

The Preparation of δ-Valerolactone.—1) A mixture of δ-chlorovaleric acid (136.5 g.) and an equivalent aqueous sodium hydroxide was heated while evaporating water with an aspirator. After the removal of the water, the residue was distilled under reduced pressure to afford δ-valerolactone; yield 92.0 g. (92%). Repeated distillation gave an analytically pure sample of δ-valerolactone; b. p. 75～76°C/3 mmHg, n_D^{25} 1.4555, d_4^{20} 1.0988 (lit. b. p. 88°C/4 mmHg, n_D^{20} 1.4600, 1.4503, d_4^{20} 1.0794, 1.094). The above sample was easily polymerized in the presence of acid catalysts. Its infrared spectrum shows, at 1725 cm^{-1}, a strong absorption band attributable to C=O stretching in lactone. 2) An aqueous solution (400 ml.) of sodium δ-chlorovalerate (1.0 mol.) was refluxed for 2 hr. After it had been cooled, the reaction mixture was extracted three times with benzene. The extract was distilled under reduced pressure to give δ-valerolactone; yield 92.5 g. (92.5%).

4) M. Stoll and A. Rouve, *Helv. Chim. Acta*, **18**, 1087 (1935).

The Thermal Decomposition of a Polyester-Sodium Chloride Mixture.—A solid mixture of the polyester and sodium chloride was prepared by evaporating water from the aqueous solution of sodium ω-chloroheptanoate. The mixture was decomposed by heating it with a niter-bath above 300°C under reduced pressure (1 mmHg) in the presence of various catalysts. By the repeated distillation of the decomposition product, two fractions were obtained: fraction I, b. p. 45～70°C/1 mmHg; fraction II, b. p. 115～130°C/1 mmHg. White crystals were precipitated by cooling the methanol solution of the fraction II with dry ice-methanol. Recrystallization from methanol afforded the dimeric lactone of ω-hydroxyheptanoic acid; m. p. 46°C (lit.[4] m. p. 41°C).

Found: C, 65.77; H, 9.37. Calcd. for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

This 16-membered dimeric lactone has a fairly strong musk odor. Its infrared spectrum indicates the characteristic absorption band at 1725 cm^{-1} due to the lactonic carbonyl. From these results, the crystalline product was proved to be the dimeric lactone of ω-hydroxyheptanoic acid.

The fractional distillation of fraction I afforded a liquid; b. p. 96～98°C/10 mmHg, n_D^{20} 1.4520. This was treated with potassium permanganate in an aqueous alkaline solution. The manganese dioxide produced was filtered out. From the ether extract of the filtrate, a crystalline product identified with pimelic acid (m. p. 103～104°C) was obtained.

The infrared spectrum of this fraction is similar to that of the dimeric lactone and shows the characteristic band at 1720 cm^{-1} due to the lactonic carbonyl. The above sample, after being allowed to stand for a few days, was converted into a polymer which was identified analytically with the polyester from ω-hydroxyheptanoic acid. These results indicate this fraction to be the monomeric lactone of ω-hydroxyheptanoic acid. Details of the reaction are shown in Table I.

The Thermal Decomposition of the Polyester.—A mixture of ω-chloroheptanoic acid (329 g.), potassium acetate (300 g.) and glacial acetic acid (400 ml.) was refluxed for 16 hr. The reaction mixture was then diluted with water and extracted with benzene. After being washed several times with water, the ether extract was distilled

under reduced pressure to give ω-acetoxyheptanoic acid (b. p. 147~150°C/1 mmHg, n_D^{20} 1.4430). The product (335 g.) was saponified with a small excess of sodium hydroxide in an aqueous methanol solution. The solution was acidified with hydrochloric acid and extracted with ether. The polyester of ω-hydroxyheptanoic acid was prepared by evaporating ether from the extract and by heating the residue a further 3 hr. under reduced pressure (about 3 mmHg). The polyester was decomposed as in the previous experiments. The results are given in Table II.

Results and Discussion

The Hydrolysis of ω-Chlorocarboxylic Acids. —The rate of hydrolysis was expressed by the following first-order equation:

$$dx/dt = k(A-x)$$

where A represents the initial concentration of the reactant, and x denotes the concentration of sodium chloride produced. The results are summarized in Tables III and IV.

In Table III, the rate constants at each temperature are calculated with a good constancy except for those at the beginning of the reaction. In the case of ω-chloroheptanoic acid, however, the rate constants tend to decrease as the reaction proceeds. Since the reaction product is in an equilibrium between δ-hydroxyvaleric acid and δ-valerolactone, a large change in pH valne, which is considered to affect the reaction rate, is prevented in the course of the reaction. On the other hand, the reaction solution of ω-chloroheptanoic acid becomes weakly acidic as the reaction proceeds.

The decrease in pH during the reaction, at any rate, is rather small, for the reaction system is a buffer solution. Therefore, the average values were employed for the calculation of rate constants.

The relation between the temperature and

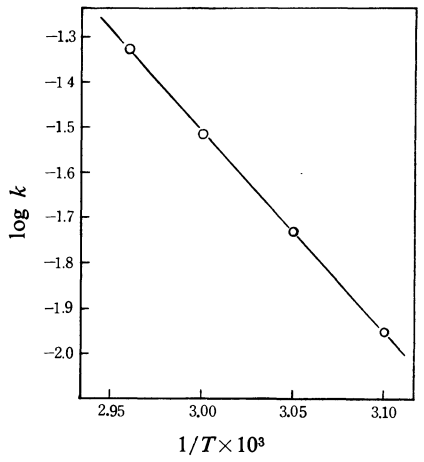

Fig. 1. Arrhenius plot for the hydrolysis of δ-chlorovaleric acid.
E=19900 cal./mol.

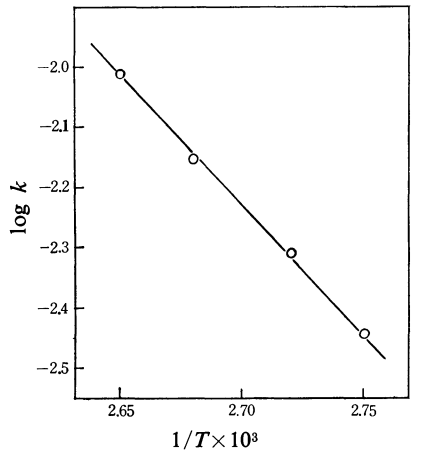

Fig. 2. Arrhenius plot for the hydrolysis of ω-chloroheptanoic acid.
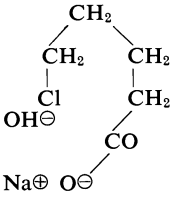
E=19700 cal./mol.

the rate constants is plotted in Figs. 1 and 2.

The energies and entropies of the activation in these reactions are calculated as: E=19900 cal./mol., $\Delta S^{\neq}=-14$ e.u. (δ-chlorovaleric acid); and E=19700 cal./mol., $\Delta S^{\neq}=-24$ e. u. (ω-chloroheptanoic acid). The rate equations are expressed as follows:

for δ-chlorovaleric acid:



$$dx/dt=3.5\cdot10^{11}\cdot e^{-19900/RT}(A-x)$$
$$(\text{mol. } l^{-1}\text{min}^{-1})$$

for ω-chloroheptanoic acid:

$$dx/dt=2.6\cdot10^{9}\cdot e^{-19700/RT}(A-x)$$
$$(\text{mol. } l^{-1}\text{min}^{-1})$$

While an equal value is obtained for the activation energies in these two reactions, a large difference is obterved between the activation entropies.

These facts suggest that the chlorine atom in δ-chlorovaleric acid is far more accessible to hydroxyl ions than that in ω-chloroheptanoic acid. The chlorine atom at the δ-position is considered to be located close to the ion-pair (−COO⊖ Na⊕), which accelerates the hydrolysis as below:

The large difference between the activation entropies in these reactions may be realized by the above explanation.

Summary

1) The kinetics of the hydrolysis of δ-chlorovaleric and of ω-chloroheptanoic acids in an aqueous solution of their sodium salts has been studied. The reason for the difference between the activation entropies has been discussed.

2) The methods for the preparation of δ-valerolactone from δ-chlorovaleric acid have been established.

3) By the thermal decomposition of the polyester from ω-hydroxyheptanoic acid, the dimeric lactone of the acid has been prepared, and the formation of the monomeric lactone has also been ascertained.

The Bromination of Aromatic Compounds with a Mixture of Peroxyacetic Acid and Bromine in Acetic Acid

By Yoshiro OGATA, Yoshiaki FURUYA and Kenji OKANO

(Received February 8, 1964)

It is well known that the bromination of aromatic compounds with molecular bromine is catalyzed by some electrophilic reagents such as ferric bromide and that, without these catalysts, the bromination of benzene is very slow. In the course of our study of some reactions using peroxycarboxylic acid, we discovered that peroxyacetic acid could accelerate the bromination of benzene. Although the yield of bromobenzene was not high (56%), the probable mechanism and attacking species of this reaction is of interest since the reaction mixture constitutes a homogeneous system suitable for a kinetic study. Thus far there have seemed to be two mechanisms for the bromination of aromatics; i. e., one is the rate-determining abstraction of bromide ions from the π-complex between an aromatic molecule and a bromine molecule, followed by the rapid elimination of the proton to give brominated aromatics;[1] the other is an attack of the bromonium ions formed from bromine and the electrophilic reagent on aromatics.[2] The present paper summarizes our data on the mechanism of bromination by a mixture of peroxyacetic acid and bromine in acetic acid. The data suggest a mechanism which involves the intermediary formation of acetyl hypobromite, CH_3COOBr. The mechanism was studied kinetically and, in addition, by the spectrophotometric detection of acetyl hypobromite.

Experimental

Materials.—Peroxyacetic acid was prepared by the reaction of acetic anhydride with hydrogen peroxide[3] and was stored as an acetic acid solution. Acetyl peroxide was prepared by dropping water into a suspension of sodium peroxide in an ethereal solution of acetic anhydride;[4] the ether was evaporated after the addition of acetic acid to prepare an acetic acid solution of acetyl peroxide for safe storage. Aqueous hypobromous acid was prepared by the addition of aqueous bromine to a suspension of an excess of mercuric oxide in water.[5] Acetyl hypobromite[7] was prepared by mixing an acetic acid solution of bromine and a suspension of silver acetate in acetic acid.

The Preparation of Bromobenzene.—An acetic acid solution of peroxyacetic acid was added slowly to a solution containing acetic acid, bromine and benzene. Aqueous sodium hydroxide was added to the resulting solution to remove unreacted bromine; the benzene layer was washed with water, dried and then distilled, yielding bromobenzene (b. p. 156~157°C). The trace of α-benzene hexabromide which was identified in the product is probably formed by the photochemical reaction. The results, including those of the other brominations, are shown in Table I. The yields were calculated on the basis of the original bromine.

Reaction Products Criterion.—Bromobenzene (b. p. 156~157°C) was identified by gas chromatography in comparison with an authentic sample. *p*-Chlorobromobenzene and *p*-dibromobenzene were identified by mixed melting point determinations with authentic samples; m. p. and mixture m. p., 66°C and 84°C, respectively. α-Benzene hexabromide was identified by a mixed m. p. determination (m. p. and mixture m. p. 214°C), together with a comparison of its infrared spectrum with that of an authentic sample prepared by the photochemical bromination of benzene.

A Typical Procedure for the Rate Measurements.—An acetic acid solution containing known amounts of benzene, peroxyacetic acid and sulfuric acid was brought to the constant temperature of 60°C. A known amount of an acetic acid solution of bromine was then added to the solution to start the reaction. Aliquots (each 5 ml.) were pipetted out at regular intervals and poured into ice-cooled aqueous 0.04 M phenol (50 ml.) to remove the bromine. After a few minutes, 5% aqueous potassium iodide (5 ml.) was added. The iodine liberated by peroxyacetic acid was titrated with 0.005 N aqueous sodium thiosulfate.

It was preliminarily confirmed that no appreciable reaction occurred between phenol and peroxyacetic acid under these conditions. The concentration of peroxyacetic acid was corrected by a blank test which estimated the extent of the decomposition of peroxyacetic acid alone (3~4% at 60°C for 100 min.).

Results and Discussion

Synthetic Experiments.—The results on the synthetic bromination of benzene are shown in Table I. The data show that the addition of a small quantity of sulfuric acid increases the yield of bromobenzene, and that the reaction is an electrophilic substitution. The formation of a small amount of α-benzene hexabromide suggests a radical attack in part; its formation is not due to the presence of diacetyl peroxide,[6] because no hexabromide was formed upon the addition of acetyl peroxide to the corresponding benzene solution of bromine.

TABLE I. BROMINATION OF SUBSTITUTED BENZENES

Molar ratio, $C_6H_5X : Br_2 : CH_3CO_3H = 1.28 : 0.11 : 0.27$
Reaction temp., 80~85°C
Reaction time, 2.5~4 hr.

Substituted group of C_6H_5X	Product	Yield, %
H	C_6H_5Br	31.1
	α-Benzene hexabromide	a small amount
$H(H_2SO_4)$[a]	C_6H_5Br	56.0
H[b]	C_6H_5Br	18.5
Cl	p-Cl-C_6H_4-Br	5.0
Br	p-Br-C_6H_4-Br	7.6
NO_2	—	0.0
CN	—	0.0

Molar ratio are as follows:
a) $C_6H_6 : Br_2 : CH_3CO_3H : H_2SO_4 : CH_3CO_2H = 1.0 : 0.1 : 0.14 : 0.135 : 0.5$
b) $C_6H_6 : Br_2 : CH_3CO_3H : CH_3CO_2H = 1.0 : 0.1 : 0.14 : 1.0$

Kinetics.—The rate data are shown in Table II. The table indicates that the rate is expressed as

$$-d[CH_3CO_3H]/dt = k_2[CH_3CO_3H][Br_2] \quad (1)$$

where k_2 is independent of the concentration of benzene and also independent of the acidity of the solution. Hence, the rate-determining step is the reaction of bromine and peroxyacetic acid to form reactive species which can react rapidly with benzene. It is known that bromine reacts with some oxidizing agents, e. g., mercuric oxide, to give bromine monoxide Br_2O, which may be formed in this reaction, but it should react rapidly with acetic acid or water to form acetyl hypobromite or hypobromous acid as follows:

$$CH_3CO_3H + Br_2 \overset{\text{slow}}{\rightleftarrows} CH_3CO_2H + Br_2O \quad (2)$$

$$Br_2O + H_2O \overset{\text{fast}}{\rightleftarrows} 2HOBr \quad (3)$$

$$CH_3CO_2H + HOBr \overset{\text{fast}}{\rightleftarrows} CH_3CO_2Br + H_2O \quad (4)$$

or

$$2CH_3CO_2H + Br_2O \rightleftarrows 2CH_3CO_2Br + H_2O \quad (5)$$

The rate-determining formation of bromine monoxide, followed by the rapid attack of acetyl hypobromite on benzene, was supported by the determination of the rate of the bromination of benzene with authentic acetyl hypobromite; i. e., the second-order rate constant was 3.20×10^{-2} M^{-1} sec^{-1} at 60°C, which was ca. 20 times as high as the rate constant of bromination with a mixture of bromine and peroxyacetic acid.

A Discussion of Active Attacking Species.—The ultraviolet spectrum of bromine showed a maximum at 266 mμ both in water (Fig. 1, curve 4) and in anhydrous acetic acid (curve 2), but neither an aqueous hypobromous acid solution (curve 5) nor an acetic acid solution of acetyl hypobromite (curve 3) showed a maximum at a wavelength longer than 250 mμ. The apparent maxima at ca. 243 mμ (curves 3 and 6 in Fig. 1) were found to be caused by the high absorption and, hence, too wide a slit width, which prevented scanning of the spectrophotometer, because the maxima shifted by changing the thickness of the layer for measurements and the maximum disappeared in a pure ethereal solution of acetyl hypobromite (curve 7). Hence, the maximum at 324 mμ for acetyl hypobromite reported by by Anber and Dostrovsky[7] is doubtful.

The molar extinction coefficient at 250 mμ for acetyl hypobromite is higher than that of hypobromous acid (curves 3 and 6 in Fig. 1); the extinction for acetyl hypobromite is comparatively stable, but that for hypobromous acid is decreased rapidly by the decomposition of the acid.

The addition of peroxyacetic acid to an acetic acid solution of bromine gave rise to an increase in extinction corresponding to that of acetyl hypobromite, the extinction being increased as the reaction proceeded.

The addition of water to an acetic acid solution of acetyl hypobromite results in a decrease in the extinction at 250 mμ (Figs. 1 and 2) and also in the appearance of a maximum at 266 mμ (bromine). These phenomena indicate the hydrolysis of acetyl hypobromite

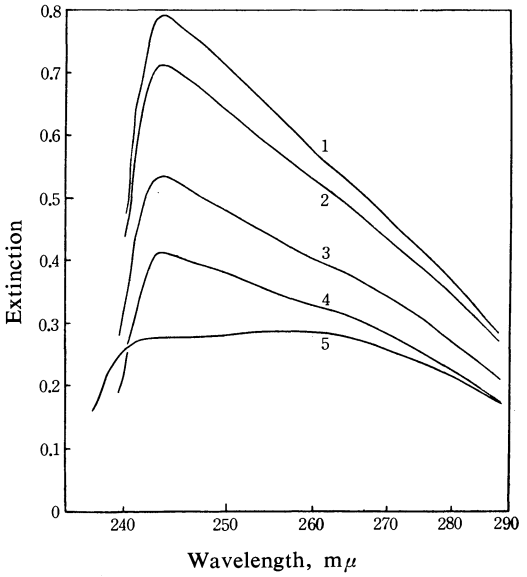
to hypobromous acid, followed by its rapid decomposition to give bromine. Moreover, the presence of a small percentage of water in an acetic acid solution of bromine gave the extinction corresponding to acetyl hypobromite (compare curves 1 and 2 in Fig. 1). Therefore, the following equilibria are probable:

$$Br_2O + H_2O \rightleftarrows 2HOBr$$

$$CH_3CO_2H + HOBr \rightleftarrows CH_3CO_2Br + H_2O$$

It is well known that bromine monoxide, Br_2O, or hypobromous acid readily decomposes to evolve oxygen and bromine; this must be the main cause of the poor yield of bromobenzene in the present reaction.

$$4HOBr \rightleftarrows O_2 + 2H_2O + 2Br_2$$



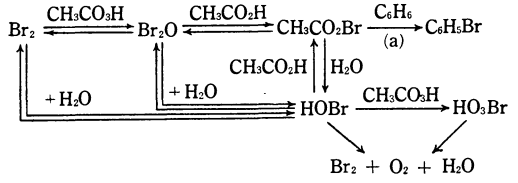


Fig. 2. Effect of the water content on the decomposition of 8.43×10^{-3} M acetyl hypobromite in acetic acid at 20°C.

Contents of water (%), (1) 0.18%; (2) 1.18; (3) 5.18; (4) 10.18; (5) 50.18

It was confirmed by gas chromatography (column, molecular sieve, 13X, 80~100 mesh, column temp., 32.5°C; carrier gas, helium 30 ml. min^{-1}) that a mixture of peroxyacetic acid and bromine in acetic acid evolved oxygen. Simultaneously, the mixture liberated bromine which could be titrated with 0.01 N sodium thiosulfate. In this reaction using both reactants in 0.04 M, the titer of peroxyacetic acid decreased to ca. 1/2 after 8 hr. at 50°C, while that of bromine held constant.

Over-all Mechanism. — These findings suggest the following mechanism for the over-all reaction:

A comparison of the electrophilicity of hypobromous acid with that of acetyl hypobromite strongly suggests that acetyl hypobromite, which has the electron-attracting carbonyl group, should be more powerful and a more probable agent for the electrophilic attack on the benzene ring.

The formation of acetyl hypobromite is slower than its reaction with benzene and is little influenced by the acidity of the solution. However, the addition of sulfuric acid to the reaction mixture appreciably increased the yield of bromobenzene (Table I), which implies that the bromination of benzene (step a) is done by protonated acetyl hypobromite.

Summary

Bromobenzene is obtained in a 56% yield when an acetic acid solution of peroxyacetic acid is slowly added to an acetic acid solution of bromine, benzene and a catalytic amount of sulfuric acid. The rate of the consumption of peroxyacetic acid has been expressed as $v=k_2[CH_3CO_3H][Br_2]$, where k_2 is independent of the concentration of benzene and of the acidity of solution. However, the rate of the formation of bromobenzene is accelerated by sulfuric acid and a more effective use of the attacking species is possible. A mechanism has been suggested which involves the rate-determining formation of bromine monoxide or acetyl hypobromite, followed by its rapid attack on benzene. The rate is slower with benzene substituted with electron-attracting groups. Some evidence for the formation of acetyl hypobromite has been obtained by ultraviolet spectrophotometry.

Long-range Proton Spin-Spin Interactions in Ketones. II. The Substitution Effect*

By Kensuke TAKAHASHI

(Received February 11, 1964)

A previous communication[1] has reported that multiplet structures have been observed in the spectra of the methyl group adjacent to the carbonyl group in ethyl methyl ketone and isopropyl methyl ketone. A similar multiplet structure was observed also in the $^{13}CH_3$ satellites of acetone by Holmes and Kivelson.[2] The aim of the present article is to get more extensive data to aid in understanding the mechanism of the long-range proton spin-spin interactions through the carbonyl groups in these ketones. In this paper we should like to present our experimental results and to discuss the substitution effect on such a long-range coupling in some substituted acetones. Some studies related to this problem have been

reported recently by Sasaki,[3] Wittstruck[4] and van Meurs.[5] In 2, 3-dihalopropenes, the solvent-dependence of the long-range coupling constants and rotational isomerism have been reported by Whipple.[6]

Experimental

The wiggle beat method[7] for measuring these small couplings was used in addition to the steady-state method used in the previous report.[1] The compounds examined were commercially-available products except for dibromoacetone, chloroacetone and phenylmercapto-2-propanone. Dibromoacetone was measured in the mixture with monobromoacetone and other small amounts of by-products which had been prepared by the bromination of acetone. Measurements were carried out with 5 mol.% solutions in carbon tetrachloride, which had been degassed and which contained small amounts of tetramethylsilane (TMS) as an internal reference. Spectra were obtained at a temperature of 22.8± 0.5°C, and at a frequency of 60 Mc.p.s. on a Varian 4300B spectrometer. The sweep rate of the magnetic field for chemical shift measurements was calibrated by measuring the displacement between the two peaks for a benzene-cyclohexane mixture (1 : 1 by volume). The value for this displacement in the present work is taken to be 5.746 p.p.m.[8]

Results and Discussion

The results of the measured coupling constants are shown in Table I, along with the values previously reported in measurements for the pure liquid state. In this table <0.2 shows no evidence of coupling; ~0.2 does show some evidence of coupling, but it is too small to resolve. For convenience, the chemical shifts are also given in the same table in p. p. m. with reference to TMS. In the case where the signal is split by the indirect spin-spin interaction, the chemical shift given in Table I is that for the center of the multiplet structure. The magnitude of the long-range coupling in question, as shown in Table I, seems to decrease as the electronegativity of the substituent, such as methyl, bromine or chlorine, increases; that is, the more the electronegativity of the substituent, the less the coupling constant seems to become. In the case of acetoin (No. 14 in Table I), the hydroxy-substituted compound of ethyl

8) The author wishes to express his thanks to Dr. M. Matsuoka (the Institute for Solid State Physics, the University of Tokyo) for measuring this displacement by the usual side-band technique; it is 232.50±0.25 c.p.s. at 40.462 Mc.p.s. and 24.0±0.1°C.

methyl ketone, there is no evidence of the coupling in question via the carbonyl group. This shows quite a decrease in the coupling as compared with that of ethyl methyl ketone. On the other hand, the sulfur compound of No. 8 holds a coupling of about 0.4 c. p. s. Consequently, it can be assumed that the introduction of an electronegative substituent, such as a halogen or hydroxyl group, causes the decrease in the coupling constant under consideration.

However, a further examination of the compounds listed under No. 16 in Table I shows no clear evidence of coupling. In these ketones, the first atom in the substituent is carbon, so that it may, from the consideration described just before, be expected to have a coupling of about 0.4 c. p. s. Similar is the case of 2, 5-hexanedione, No. 5 in Table I. Moreover, in the cases of the disubstituted acetones, isopropyl methyl ketone shows some decrease in coupling constant as compared with ethyl methyl ketone, but dichloro- and dibromoacetone show some increase as compared with chloro- and bromoacetone respectively.

For the sake of a plausible explanation of these results, first of all, it will be supposed that the internal rotation about the carbon-carbon bond in $CO-CHX_2$ may be more hindered than that in $CO-CH_2X$. The consideration of this kind of rotational hindrance brings the discussion to a consideration of the angular dependence of the long-range couplings in these ketones. Karplus[9] presented an approximate formula of the long-range coupling in some unsaturated hydrocarbons as follows:

$$A_{HH'}(\pi) = 2.1 \times 10^{-15} \sum (a_H \cdot a_{H'} / \Delta\pi)$$

where $\Delta\pi$ is the average singlet-triplet excitation energy in eV., and a_H is the hyperfine constant for a π-electron radical fragment in c. p. s. in ESR spectra. Holmes and Kivelson[2] have also shown an expression similar to the coupling observed in acetone, assuming the $CH_3-\dot{C}-\dot{O}$ triplet. The hyperfine constant a_H in radicals of the $CH_3-\dot{C}$ type has been found, both experimentally[10] and theoretically[11], to be positive and of the form:

$$a_H = A_0 + A_1 \cos^2\varphi$$

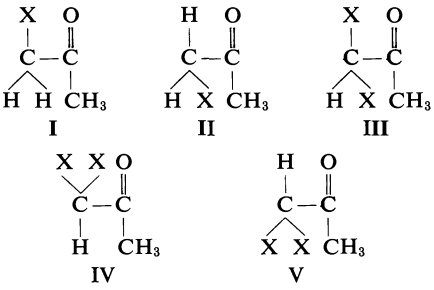
where φ is the dihedral angle between the H–C–$\dot{C}$ plane and the axis of the unpaired π-electron. The ESR data show us that A_0 is negligible as compared with A_1, so that it may be assumed to be $a_H \propto \cos^2\varphi$. This comes to $a_H = 0$ at $\varphi = 90°$. The absence of the coupling in the compounds of Nos. 16 and 17 prompts us to regard this assumption as reasonable. In these ketones, Nos. 16 and 17, if the conjugation between C=O and C=C bonds is supposed, φ will be nearly 90° and a_H will be approximately zero in ageement with the experimental results.

To predict the long-range coupling in ketones, depending upon the dihedral angle assumed above, it is necessary to average $a_H(\varphi)$ for all possible conformations, weighted with respect to the potential barrier hindering internal rotation. If such a barrier is significantly greater than RT, it is sufficient only to sum up the couplings for the conformation of some considerable rotational isomers. In each ketone, the NMR spectrum of the methylene or the methyl protons shows no differently-oriented conformations, only a single peak as a mean in the measurement at room temperature.

Now we will consider two extreme cases; the one is free rotation, and the other is a fixed conformation about the CO–CH bond as an axis. In each case, the factor $(\cos^2\varphi)$ of the long-range coupling in question, depending on the dihedral angle stated above, is shown in Table

Table II. $\cos^2\varphi$

No. of protons	3	2	1
Free rotation	1/2	1/2	1/2
Fixed conformation ($\varphi = 0 \sim 2\pi$)	1/2	1/4~3/4	0~1



II. In the case of the protons in CH_2 or CH_3, we took the average between the factors of two or three protons respectively. If we want to include some substituted acetones, the combination of two proton groups must be considered, as is shown in Table III. If any other constants remain approximately constant, the factor depending on the dihedral angle must play a significant role in the coupling. The variation of this factor appears rather large in the cases concerned with a smaller number of protons, such as the methine-methine system. The magnitude of the coupling observed in acetone is about 0.5 c. p. s., and if the methyl group in acetone is assumed to rotate freely around the CO–CH axis, the factor must be taken to be 1/4. Therefore, under these conditions, a coupling of about 2 c. p. s. may be observed in some cases. Further studies of some other ketones, such as cyclic ketones with limited conformations, would be of interest.

In chloroacetone, Mizushima[12] and Bellamy[13] suggested two rotational isomers, I and II, on the basis of their infrared and dipole moment studies. The carbonyl-stretching frequencies of this compound were observed at 1752 and 1726 cm^{-1} in a carbon tetrachloride solution,[13] corresponding to the two rotational isomers, the cis-form (I) and the trans-form (II) with respect to the Cl-atom and the CO group respectively. The former is more polar than the latter, so that a very marked change in the relative intensities of these bands was observed on passing from the solution in carbon tetrachloride to that in acetonitrile.[13] Similar is the case with dichloroacetone, as is shown in III, IV and V. In theses cases, the hyprefine constants,

which are considered to depend upon the dihedral angle, φ, in question, are as follows:

$$\bar{a}\,(\mathrm{Cl}) \fallingdotseq P_{\mathrm{I}}a(30°) + P_{\mathrm{II}}[a(30°) + a(90°)]/2$$
$$\fallingdotseq (1+P_{\mathrm{I}})\ a(30°)/2$$
$$\bar{a}'(\mathrm{Cl_2}) \fallingdotseq P_{\mathrm{III}}a'(30°) + (P_{\mathrm{IV}}+P_{\mathrm{V}})a'(90°)$$
$$\fallingdotseq a'(30°)$$

where P_i is the population of the i isomer (i. e., $P_{\mathrm{I}}+P_{\mathrm{II}}=1$ for chloroacetone and $P_{\mathrm{III}} \fallingdotseq 1$ for dichloroacetone; P_{IV} and P_{V} are supposed to be negligible in view of the band intensities of the carbonyl-stretching frequencies). From the consideration of electronegativity described before, it is rather difficult to explain the decrease in the coupling in chloroacetone as compared with dichloroacetone. However, it is possible to explain the experimental results if we consider the contribution of some rotational isomers. Even in the case of $a(30°) > a'(30°)$, $\bar{a}(\mathrm{Cl})$ depends upon the population of P_{I} in a very limited sense; therefore, $\bar{a}(\mathrm{Cl}) < \bar{a}'(\mathrm{Cl_2})$ is possible under some conditions.

Now we do not know enough to come to a final conclusion, but it must be noted about the long-range coupling in some substituted acetones, CH_3COCH_2X or CH_3COCHX_2, that (1) the more electronegative X is, the less the constant becomes, and that (2) this coupling is dependent upon the dihedral angle between the C–H bond and the π-orbital of carbon atom in the carbonyl group. From this standpoint, it is of interest of investigate the solvent or temperature effects of these coupling constants. Only a few compounds have been examined briefly in pure liquid and in a carbon tetrachloride solution.[14] The coupling constants in chloroacetone and bromoacetone seem to decrease upon dilution with carbon tetrachloride. This supports the assumptions of the dependence of the coupling constant on the dihedral angle and of the presence of the rotational isomers in these haloketones. These points are now under investigation.

The author wishes to express his gratitude to Professors Genjiro Hazato and Tsuneo Ikenoue for their continuous encouragement and valuable discussion, and to Mr. Akio Hanabuchi for his help in measuring the spectra.

Syntheses and Ultraviolet Spectra of Aromatic Azo Compounds. III. Methoxyazobenzene Derivatives

By Yujiro NOMURA, Hiroyuki ANZAI, Ryokichi TARAO and Kengo SHIOMI

(Received February 20, 1964)

In continuing our studies[1,2] of the synthesis of aromatic azo compounds by the reaction of diazonium salt with a Grignard compound, we wish in this paper to report on the synthesis of methoxyazobenzene derivatives.

Although several azobenzenes which have a methoxyl group at the ortho- or para-position with respect to the azo group are known, many other methoxyazobenzene derivatives have not hitherto been prepared.

Nine tolylazoanisoles (I—IX), six dimethoxyazobenzenes (X—XV), and six bromophenylazoanisoles (XVI—XXI) have been synthesized by the reactions of the zinc chloride double salts of diazonium chlorides with Grignard compounds following the procedure described in previous papers.[1,2] These azo compounds are listed in Table I, in which new compounds are asterisked. Although the yields of the azo compounds by this method were not always satisfactory, many of these azo compounds are also difficult to prepare by the method known hitherto.

The electronic absorption maxima of methoxyazobenzene derivatives are shown in Table II. It can be seen that the wavelengths of the *K*-bands of *m*-methoxyazobenzenes are shorter than those of the corresponding *o*- or *p*-isomers.

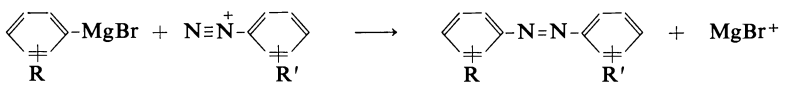
Experimental

2-(*o*-Tolylazo)anisole (I).—Following the procedure of a previous paper,[2] *o*-anisidine was diazotized and precipitated as the zinc chloride double salt by adding solid zinc chloride to the diazotized solution.

The suspension of 21.5 g. (0.09 mol.) of the dry powdered double salt in ether was vigorously stirred, and the ethereal solution of *o*-tolylmagnesium bromide prepared from 12 g. (0.07 mol.) of *o*-bromotoluene and the excess of magnesium was added slowly to it at the rate necessary to maintain reflux. After the mixture had been stirred for an additional 60 min. at room temperature, the deep red ether solution was separated by filtration with suction from the solid, which was then washed several times with ether. The ether filtrate and washings were combined and washed with dilute hydrochloric acid and then with water, dried over anhydrous sodium sulfate, and evaporated. The remaining crude azo compound (5.2 g.) was recrystallized twice from ethanol and then from petroleum ether (b. p. 40~60°C) to give orange crystals; m. p. 73.5~75°C; yield, 2.8 g. (18% theoretical based on *o*-bromotoluene).

2-(*p*-Tolylazo)anisole (III).—The brown red oil (2.6 g.) was obtained by the reaction of the zinc chloride double salt of *o*-methoxybenzenediazonium chloride (23.4 g., 0.098 mol.) with *p*-tolylmagnesium bromide (prepared from 0.07 mol. of *p*-bromotoluene). The oil was dissolved in petroleum ether (b. p. 40~60°C) and passed through a 40 cm. alumina column. The same solvent was employed as the eluent. Colorless crystals (0.1 g.) were isolated from the early fractions, which were identified as 4, 4'-dimethoxybiphenyl by melting point and mixed melting point determinations with an authentic sample. Deep red crystals (1.7 g., 11%) were obtained from the red elute; m. p. 56~57°C.

3-(*m*-Tolylazo)anisole (V).—The deep red oil (9.3 g.) was obtained by the reaction of the zinc chloride double salt of *m*-methoxybenzenediazonium chloride (23.9 g., 0.1 mol.) with *m*-tolylmagnesium bromide (prepared from 0.09 mol. of *m*-bromotoluene). The crude oil was extracted by petroleum ether (b. p. 40~60°C). The petroleum ether solution was evaporated and the remaining oil was distilled in vacuo to yield 4.1 g. (20%) of the azo compound (b. p. 168°C/6 mmHg), which could not be induced to crystallize.



Summary

1) Nine tolylazoanisoles, six dimethoxyazobenzenes, and six bromophenylazoanisoles have been synthesized by the reactions of Grignard reagents with zinc chloride double salts of diazonium compounds; thirteen of them are new compounds.

2) The ultraviolet and visible absorption spectra of the methoxyazobenzene derivatives have been measured, and some regularities of the absorption maxima have been observed in them.

* New compound

a) M. p. and b. p. are uncorrected.

b) Based on the bromo compound used to prepared the Grignard reagent.

c) Calcd. % of N for tolylazoanisole $C_{14}H_{14}N_2O$ (I—IX) : 12.38.
Calcd. % of N for dimethoxyazobenzene $C_{14}H_{14}N_2O_2$ (X—XV) : 11.56.
Calcd. % of N for bromophenylazoanisole $C_{13}H_{11}BrN_2O$ (XVI—XXI) : 9.62.

d) The reported[3] m. p. of VII is 59°C; it was prepared by the condensation of *o*-nitrosotoluene with *p*-anisidine.

e) The reported[4] m. p. of IX is 110～111°C; it was prepared by the condensation of *p*-nitrosotoluene with *p*-anisidine.

f) The reported[5] m. p. of X is 153～153.5°C; it was prepared by the decomposition of *o*-methoxybenzenediazonium chloride in the presence of cuprous chloride.

g) The reported[6] m. p. of XIII is 76～77°C; it was synthesized by the reduction of *m*-azoxyanisole, which was prepared from *m*-nitroanisole.

h) The reported[7] m. p. of XV is 162～163°C; it was prepared by the air oxidation of *p*-anisidine in pyridine containing cuprous chloride.

i) The repored[8] m. p. of XVIII is 62～63°C; it was synthesized by the methylation of 4-(*m*-bromophenylazo)phenol, which was prepared by the coupling of *m*-bromobenzenediazonium chloride with phenol.

j) The reported[9] m. p. of XIX is 83°C; it was synthesized by heating the mixture of *o*-nitroanisole and *p*-bromoaniline with powdered sodium hydroxide.

k) The reported[8] m. p. of XXI is 148～149°C; it was prepared by the methylation of 4-(*p*-bromophenylazo)phenol.

Syntheses and Ultraviolet Spectra of Aromatic Azo Compounds. IV. Naphthylazobenzene Derivatives

By Yujiro NOMURA and Hiroyuki ANZAI

(Received March 5, 1964)

In the previous papers[1-3] of this series it was shown that many azobenzene derivatives could be prepared conveniently by the reactions of the zinc chloride double salts of

TABLE I. NAPHTHYLAZOBENZENES PREPARED BY THE REACTION:

No.	Naphthyl	R	M. p., °C[a]	Yield, %[b]	Color	Found: N, %[c]

* New compound

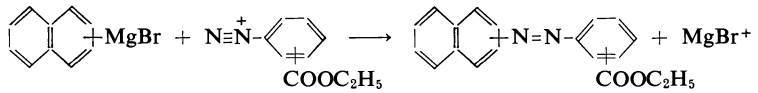
a) All temperatures in Tables I—III are uncorrected.

b) Based on the bromo compound used to prepare the Grignard reagent.

c) Calcd. % of N for naphthylazobenzene $C_{16}H_{12}N_2$ (I, II) : 12.06.
Calcd. % of N for naphthylazotoluene $C_{17}H_{14}N_2$ (III—VIII) : 11.29.
Calcd. % of N for naphthylazoanisole $C_{17}H_{14}N_2O$ (IX—XIV) : 10.68.
Calcd. % of N for naphthylazobromobenzene $C_{16}H_{11}BrN_2$ (XV—XX) : 9.00.

d) The reported m. p. of I is 63.5°C[4] or 70°C[5]. It was prepared by the deamination of 4-phenylazo-1-naphthylamine.

e) The reported[5] m. p. of II is 84°C. It was prepared by condensing nitrobenzene with β-naphthylamine in the presence of sodium hydroxide at 180°C.



f) The reported[4] m. p. of III is 52°C. It was synthesized by the deamination of 4-(*o*-tolylazo)-1-naphthylamine, which had been prepared by the coupling of *o*-toluenediazonium chloride with α-naphthylamine.

g) The reported[6] m. p. of V is 43~44°C. It was prepared by the reaction of *N*-sulfinyl-α-naphthylamine with *m*-tolylhydroxylamine.

h) The reported[7] m. p. of X is 92.5°C. It was prepared by condensing *o*-nitroanisole with β-naphthylamine in the presence of sodium hydroxide at 170~180°C.

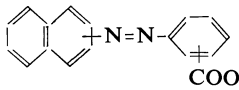
XXV*	α-	*p*-	[88.5~89]	4	Orange	9.43
XXVI*	β-	*p*-	[112.5~113.5]	trace	Orange	9.22

* New compound



a) Based on the α- or β-bromonaphthalene used to prepare the Grignard reagent.

b) Calcd. % of N for ethyl naphthylazobenzoate $C_{19}H_{16}N_2O_2$: 9.21.

c) The yield was poor, and analytically pure sample could not be obtained after distillation in vacuo. However, its structure was confirmed by hydrolyzing it to the free acid (XXVII of Table III).

d) Purified by column (alumina) chromatography.

TABLE III. NAPHTHYLAZOBENZOIC ACIDS

No.	Naphthyl	COOH	M. p., °C	Color	Found: N, %[a]
XXVII*	α-	*o*-	141~142	Orange red	10.21
XXVIII*	β-	*o*-	146~146.5	Orange yellow	10.01
XXIX	α-	*m*-	207 and >320[b]	Orange	9.97
XXX*	β-	*m*-	220~221	Orange yellow	10.02
XXXI*	α-	*p*-	234~234.5	Orange	10.02
XXXII*	β-	*p*-	220	Orange yellow	9.91

* New compound

a) Calcd. % of N for naphthylazobenzoic acid $C_{17}H_{12}N_2O_2$: 10.14.

b) XXIX melted at 207°C and solidified above its melting point to needles, which did not melt even at 320°C. The reported[8] m. p. of XXIX is 207°C. It was prepared by the deamination of *m*-(4-amino-1-naphthylazo)benzoic acid, which had been obtained by coupling *m*-carboxybenzenediazonium chloride with α-naphthylamine.

* Wavelength of shoulder.

diazonium chlorides with Grignard reagents. We would now like to report, in extension of this investigation, on the synthesis of naphthylazobenzenes and their derivatives by the same reaction.

α- and β-Naphthylazobenzene (I, II) and their eighteen derivatives (III—XX) carrying a substituent such as methyl, methoxyl, or bromine on a benzene ring have been prepared by the reactions of the zinc chloride double salt of α- or β-naphthalenediazonium chloride with substituted phenylmagnesium bromides. They are summarized in Table I, in which new compounds are asterisked.

Six ethyl naphthylazobenzoates (XXI—XXVI) have been obtained by the reactions of the zinc chloride double salt of ethoxycarbonylbenzenediazonium chloride with α- or β-naphthylmagnesium bromide. They are all new compounds and are listed in Table II. By the hydrolysis of ethyl naphthylazobenzoates, the corresponding free acids (XXVII—XXXII) were prepared; they are listed in Table III.

The electronic absorption spectra of these naphthylazobenzenes were measured in ethanol solutions; their maxima are listed in Table IV.

The K-band of the α-naphthylazobenzene derivatives shifts towards a wavelength longer by about 45 mμ than that of the corresponding β-isomers, in spite of the β-naphthyl dyes having a considerably greater intensity. A similar difference of spectra between α- and β-naphthylazobenzene was pointed out and discussed theoretically by Robin and Simpson.[9]

Experimental

The Preparation of Naphthylazobenzenes.—α- and β-Naphthylazobenzene (I, II) and their derivatives (III—XXVI) were prepared by the method used in a previous paper.[1] They have been summarized in Tables I and II.

***m*-(α-Naphthylazo)benzoic Acid (XXIX).**—One gram of ethyl *m*-(α-naphthylazo)benzoate was dissolved in 10 ml. of ethanol containing 0.2 g. of sodium hydroxide. The solution was refluxed on a water bath for an hour, diluted with 50 ml. of water, and acidified with dilute hydrochloric acid to precipitate *m*-(α-naphthylazo)benzoic acid, which was then recrystallized from ethanol. The yield (0.9 g.) was almost that theoretically expected.

Other naphthylazobenzoic acids were also prepared by the hydrolysis of the corresponding ethyl esters. They have been summarized in Table III.

The Measurement of Spectra. — The absorption spectra were obtained in 95% ethanol as a solvent on a Cary Model 14 M self-recording spectrophotometer with 1 cm. quartz cells.

Summary

1) α- and β-Naphthylazobenzene and their twenty-four derivatives with a substituent on a benzene ring have been synthesized by the reactions of Grignard reagents with zinc chloride double salts of diazonium salts. Twenty-one of them are new compounds.

2) Six naphthylazobenzoic acids have been prepared by the hydrolysis of the corresponding ethyl esters; five of them are new compounds.

3) The ultraviolet and visible absorption spectra of these naphthylazobenzene derivatives have been measured.

The Infrared Absorption Spectra of $(NH_2CONH-)_2$, $NH_2CONHNH_2$, $(NH_2CSNH-)_2$ and $NH_2CSNHNH_2$

By Mitsuo MASHIMA

(Received February 21, 1964)

The infrared absorption spectra of hydrazides containing the -CONHNHCO-[1] or $-CONHNH_2$[2] group have been investigated and the frequencies characteristic of those groups obtained by the present author. On the other hand, Suzuki[3,4] has discussed the frequency of the stretching vibration of the C=S bond adjacent to the C-N bond in thioamides in connection with the results of infrared measurements and normal vibration calculations. He has concluded that the band of thioformamide[3] at 843 cm^{-1} is associated with an almost pure C=S stretching vibration.

For the present study, the infrared spectra of hydrazine-*N*, *N'*-bis-carbonic acid amide, semicarbazide, hydrazine-*N*, *N'*-bis-thiocarbonic acid amide, thiosemicarbazide, acetyl-semicarbazide, formyl- and acetyl-thiosemicarbazide and the *N*-deuterated derivatives of these compounds were examined in the rock salt region. For the sake of comparison, semicarbazide hydrochloride and its *N*-deuterated derivative were examined spectroscopically. The frequencies obtained were tentatively assigned to the fundamental vibrational modes by comparing the spectra with those of related compounds.

Experimental

Hydrazine-*N*,*N'*-bis-carbonic Acid Amide (HCA): $(NH_2CONH-)_2$.—This compound was obtained by heating a mixture of urea (2 mol.) and hydrazine hydrate (1 mol.) in a sealed tube,[5] and it was purified by recrystallization from water (m. p. 267°C).

Semicarbazide (SC): $NH_2CONHNH_2$.—This compound was synthesized by heating the 1 : 1 (in mole) mixture of urea and hydrazine hydrate in a sealed tube,[6] and it was purified by recrystallization from ethanol (m. p. 96°C). Semicarbazide hydrochloride was prepared with hydrochloric acid and semicarbazide, and it was purified by recrystallization from water (m. p. 174°C). This hydrochloride was examined analytically.

Found: Cl, 30.4%. Calcd. for $NH_2CONHNH_2 \cdot HCl$: Cl, 31.8%.

Acetyl-semicarbazide (ASC): $CH_3CONHNH \cdot CONH_2$.—This compound was synthesized with acetic anhydride and semicarbazide,[7] and it was purified by recrystallization from ethanol (m. p. 165°C).

Hydrazine-*N*, *N'*-bis-thiocarbonic Acid Amide (HTCA): $(NH_2CSNH-)_2$.—This compound was synthesized with hydrazine sulfate and ammonium rhodanide[8] and was purified by recrystallization from water (m. p. 215°C).

Thiosememicarbazide (TSC): $NH_2CSNHNH_2$.—This compound was synthesized by the method presented by Freund and Imagat[9] and was purified by recrystallization from water (m. p. 180°C).

Formyl-thiosemicarbazide (FTSC): $HCONHNH \cdot CSNH_2$.—This compound was synthesized with thiosemicarbazide and formic acid[10] and was purified by recrystallization from water (m. p. 175°C).

Acetyl-thiosemicarbazide (ATSC): $CH_3CONH \cdot NHCSNH_2$.—This compound was synthesized with thiosemicarbazide and acetic anhydride[11] and was purified by recrystallization from water (m. p. 164°C).

The *N*-deuterated derivatives examined were prepared in a sealed tube in the presence of heavy water (99.8%). The excess of heavy water was evaporated in a vacuum.

The spectra of all of the compounds in the solid state were studied with KBr disks. A double-beam Hitachi infrared spectrophotometer, Type EPI-2, was used in the rock salt region.

Results and Discussion

The infrared spectra obtained are shown in Figs. 1 to 3.

The ν(C=O)*1 Frequency.—SC and HCA are considered to show a strong band which is mainly associated with the ν(C=O) vibration because, for urea[12] and oxamide[13], corresponding band has been found at 1686 and 1656 cm^{-1} respectively. In ASC, FTSC and ATSC,

the amide I band characteristic of monosubstituted amides is expected to appear. In fact, these bands are very easily identified in the spectra of those compounds. The ν(C=O) and amide I band are summarized in Table I.

The ν(C=S) Frequency.—This frequency has been found in the 1400~1150 cm^{-1} range in thioureas. This wide range has been ascribed to varying degrees of coupling with other vibrations.[14] Recently, Suzuki concluded that, judging from the normal vibration calculations, the ν(C=S) vibration in simple thioamides may couple with other vibrations; the band of thioformamide[3] at 830 cm^{-1} is associated with an almost pure ν(C=S) vibration, while the band of thioacetamide[4] at 718 cm^{-1} is due to a hybridized vibration mainly composed of the ν(C=S) motion. The spectra of HTCA, TSC, and ATSC are comparatively simple in the region 900~700 cm^{-1}, and they have only a moderately strong band near 830 cm^{-1}: 831 cm^{-1} of HTCA, 803 cm^{-1} of TSC, and 837 cm^{-1} of ATSC. In place of this band, their *N*-deuterated derivatives have two bands, near 910 and 730 cm^{-1}. It is of interest that the 830 $^{-1}$ band of thioformamide disappears on *N*-deuteration and that, in place of it, two bands appear, at 996 and 752 cm;[1-3] the latter two bands have been assigned to vibrations composed of the ν(C=S) and $r(ND_2)$ vibrations. The bands corresponding to these two bands may very easily be identified with the bands at 901 and 735 cm^{-1} for HTCA-d_6 and 910 and 743 cm^{-1} for ATSC-d_4, because they have only those two bands in this region. On the other hand, TSC-d_5 has three moderately strong bands, at 928, 792 and 700 cm^{-1}; of these, the first and last bands are considered to correspond to the two bands mentioned above. In this region the spectrum of FTSC is rather complicated, and it is comparatively hard to find the corresponding bands, but the band at 858 cm^{-1} may be taken as the ν(C=S) band because, on *N*-deuteration, it is displaced by new bands at 908*2 and 726 cm^{-1}.

The ν(C=S) frequencies in thioformamide and the compounds examined here are summarized in Table II, which also contains the bands associated with the hybridized vibrations, mainly composed of the ν(C=S) and $r(ND_2)$ vibrations. As may be seen in Table II, the ν(C=S) frequency in this class of compounds falls in the range of 860~800 cm^{-1}, which is rather lower than that of 1400~1150 cm^{-1} in thioureas and that in other classes of compounds containing the C=S bond.[14]

The $\beta(NH_2)$*1 Frequency.—For TSC and HTCA this frequency will be easily found because no band, except for one associated with the $\beta(NH_2)$ vibration, is considered to

14) L. J. Bellamy, "The Infrased Spectra of Complex Molecules," Methuen & Company, London (1958), p. 356.

*2 FTSC shows several bands in the region where the band mentioned in the text is considered to appear. By comparing the value of this frequency with those of HTCA, TSC, and ATSC, this frequency was used for the band considered just now.

appear in the region from 1650 to 1600 cm^{-1}. In fact, these compounds have a strong band at 1626 and 1617 cm^{-1} respectively. Since they disappear on *N*-deuteration, we can safely take them as $\beta(NH_2)$ frequencies. The $\beta(ND_2)$ frequency is easily found at 1150 cm^{-1} for TSC-d_6 and 1158 cm^{-1} for HTCA-d_6.

The bands at 1624 cm^{-1} for FTSC and 1633 cm^{-1} for ATSC may also be safely taken as $\beta(NH_2)$ bands. This assignment is supported by the spectroscopic observations for these compounds in the acetonitrile solution. In changes of state, the 1624 cm^{-1} band of FTSC shifts to 1618 cm^{-1} and the 1633 cm^{-1} band of ATSC, to 1613 cm^{-1}. These frequency shifts are, in direction and value, in accordance with those obtained for the $\beta(NH_2)$ bands of thioformamide[3] and thioacetamide.[4] HCA has a band at 1604 cm^{-1} which is accompanied with a shoulder band at 1622 cm^{-1}. They disappear on *N*-deuteration. Accordingly, they are taken as $\beta(NH_2)$ frequencies. In the remaining compounds, SC and ASC, the location of the $\beta(NH_2)$ band is very difficult to ascertain. As has been indicated above, TSC-d_5 and HTCA-d_6 have the $\beta(ND_2)$ band at ca. 1150 $^{-1}$. The corresponding band has been obtained at 1118 $^{-1}$ for $HCOND_2$,[15] 1145 cm^{-1} for $HCSND_2$,[3] 1189 cm^{-1} for CH_3COND_2,[16] and 1160 cm^{-1} for CH_3CSND_2[4]. Therefore, the $\beta(ND_2)$ band of the remaining five compounds is expected to appear near at 1150 cm^{-1}. It has been obtained as summarized in Table III.

Bands in the Region from 1590 to 1340 cm^{-1}. —In ASC, ATSC and FTSC, the amide II band is considered to appear in this region. Recently, Suzuki obtained amide II-like bands for *N*-methylthioamides: 1550 cm^{-1} of $HCSNH\cdot CH_3$ and 1564 cm^{-1} of $CH_3CSNHCH_3$.[17] On the other hand, the ν(C–N) vibration of the $CO(S)NH_2$ group is considered to give rise to a band in this region because the ν(C–N) frequency has been found at 1464 cm^{-1} for urea[12] and 1470 cm^{-1} for thiourea.[18]

In this region the observed frequencies of ASC, ATSC and FTSC are collected in Table IV(a). ASC has two strong bands at 1587 and 1542 cm^{-1}, one of which may be taken as the amide II band and the other as the ν(C–N) band. On *N*-deuteration, the amide II band usually moves to lower frequencies and the so-called amide II′ band occurs; e.g., $CH_3\cdot CONHCH_3$[19] shows the 1567 (amide II) and 1475 (amide II′) cm^{-1} bands. ASC-d_4 shows a relatively weak band at 1552 cm^{-1} and two strong bands at 1445 and 1410 cm^{-1}. The amide II′ band of $CH_3CONHCH_3$ has been ascribed to the ν(C–N) vibration interacting with other vibrational modes.[19] In ASC-d_4, it is considered that the ν(C–N) vibration interacts with at least the $\delta_a(CH_3)$ vibration, and two strong bands are shown as has been indicated above. The bands at 1443 and 1372 cm^{-1} of ASC may be safely assigned to the $\delta_a(CH_3)$ and $\delta_s(CH_3)$ vibrations respectively, because the values of frequency lie in the normal ranges for those vibrations of the C–CH_3 group. The band of ASC-d_4 at 1380 cm^{-1} may safely be ascribed to the $\delta_s(CH_3)$ vibration.

Since the bands at 1545 cm^{-1} for ATSC and 1540 cm^{-1} for FTSC correspond in fuequency to the amide II band of *N*-methylthioamides,[17] these bands may be taken as amide II bands. Two strong bands, at 1513 and 1437 cm^{-1}, of $HCSNDCH_3$[17] have been ascribed to the hybridized vibrations composed of the ν(C–N) and $\delta_a(CH_3)$ vibrations, while in $CH_3CSND\cdot CH_3$[17] the coupling occurs among the ν(C–N), $\delta_a(CH_3)_N$ and $\delta_a(CH_3)_C$ vibrations and three bands have been observed at 1515, 1483 and 1442 cm^{-1}. ATSC-d_4 and FTSC-d_4 also have strong bands at 1517 and 1515 cm^{-1} respectively; their frequency-values are in good accordance with those of the bands at 1513 cm^{-1} for $HCSNDCH_3$ and 1515 cm^{-1} for $CH_3CSNDCH_3$. Therefore, they seem to be bands characteristic of the –CSND– group (amide II′). The band of ATSC at 1485 cm^{-1} is displaced by a strong band at 1380 cm^{-1} on *N*-deuteration. The former may be associated with the amide II band; the latter is suitable in frequency to the $\delta_s(CH_3)$ vibration, but it appears more strongly than that vibration. Probably, the 1380 cm^{-1} band will be the $\delta_s(CH_3)$ band overlapped with the amide II′ band come from the CH_3COND– group. The band of FTSC at 1472 cm^{-1} moves to 1346 cm^{-1} on *N*-deuteration; they may be taken as the amide II and II′ bands respectively. In ATSC two bands at 1430 and 1379 cm^{-1} are easily associated with the $\delta_a(CH_3)$ and $\delta_s(CH_3)$ vibrations respectively. The band at 1374 cm^{-1} of FTSC corresponds to the band at 1384 cm^{-1} of FTSC-d_4, and these may safely be assigned to the δ(C–H) vibration.

In this region HCA shows three bands at 1505, 1465, and 1426 cm^{-1} which are displaced by two strong bands at 1506, 1473 cm^{-1} and a weak band at 1221 cm^{-1} on *N*-deuteration. For SC, the corresponding bands are found at 1577, 1484 and 1452 cm^{-1}. In the spectrum of SC-d_5, the location of the bands corresponding

to the 1506 and 1473 cm^{-1} bands of HCA-d_6 is very difficult to determine because of the presence of strong back-ground absorptions, while the band corresponding to the 1221 cm^{-1} band is easily found at 1259 cm^{-1}. HTCA and TSC show absorptions a little different from those of HCA and SC: HTCA has only two strong bands at 1517 and 1473 cm^{-1} which are displaced by strong bands at 1493 and 1374 cm^{-1} on *N*-deuteration; TSC has also two moderately strong bands at 1536 and 1491 cm^{-1} and TSC-d_5, at 1550 and 1407 cm^{-1}. A detailed assignment is difficult from the present observations only, but these bands may be taken as the amide II and ν(C–N) bands.

The Bands in the Region from 1340 to 700 cm^{-1}.—The observed frequencies of HCA, SC, HTCA, and TSC are collected in Table V(a). The band of HCA at 759 cm^{-1} is displaced by a band with two peaks at 771 and 758 cm^{-1} on *N*-deuteration. SC has a band at 767 cm^{-1} which moves to 772 cm^{-1} on *N*-deuteration; ASC has also a corresponding band at 783 cm^{-1} and ASC-d_4, one at 774 cm^{-1}, as is indicated in Table V (b). A band of urea[12] at 776 cm^{-1}, which moves to 785 cm^{-1} on *N*-deuteration, has been assigned to the $\pi(OCN_2)$*1 vibration. Therefore, the band near 770 cm^{-1} is considered to be one characteristic of these compounds and has been assigned to the $\pi(OCN_2)$ vibration.

HCA has, further, a moderately strong band at 1110 cm^{-1} and a weak band at 996 cm^{-1}; they are considered to be due to fundamental vibrational modes because they are displaced by two moderately strong bands, at 943 and 888 cm^{-1}, on *N*-deuteration. Urea[12] shows a band at 1150 cm^{-1} which has been assigned to the $r(NH_2)$ vibration of the A_1 and B_1 species: urea-d_4[12] has the $r(ND_2)$ bands at 1001 cm^{-1} (A_1) and 887 cm^{-1} (B_1). For oxamide,[13] the $r(NH_2)$ frequency has been obtained at 1103 cm^{-1} and the $r(ND_2)$ frequency at 927 cm^{-1}. The 1110 cm^{-1} band of HCA is determined to come from a vibration mainly due to the $r(NH_2)$ vibration by comparing the value of the frequency with those of the corresponding frequencies in urea and oxamide. In consequence, the 943 and 883 cm^{-1} bands of HCA-d_6 are considered to arise from the $r(ND_2)$ vibration strongly interacting with another vibration. Assuming the symmetry of C_{2h} for a molecule of HCA,*3 of a total of thirty-six (3N-6) normal vibrations, eighteen are infrared active; six of these are of species A_u, and twelve of species B_u. Seven of them will give rise to bands outside the region examined here. They may be deformation N–N–C and N–C–N vibrations (species B_u) or torsional N–C and N–N vibrations, wagging and twisting NH_2 vibrations and out-of-plane N–H deformation vibrations (species A_u); the τ(N–N–)*1 frequency of NH_2NH_2 is 377 cm^{-1},[20] the τ(C–N) frequency of $HCONHCH_3$[21] is 353 cm^{-1}, the δ(N–N–C) frequency of CH_3NHNH_2 is 433 cm^{-1},[22] and the δ(N–C–N) frequency of $NH_2 \cdot CONH_2$ is 556 cm^{-1}.[12] The π(N–H), $w(NH_2)$ and $t(NH_2)$*1 frequencies are considered to be found in this region,*4 but in the spectrum of HCA no band corresponding to them is observed. In consequence, eleven frequencies will be found for HCA in the region examined here. Of these only one has not yet been accounted for, the δ(O=C–N) frequency. Therefore, the 996 cm^{-1} band of HCA is considered to be due to that vibration, while the 943 and 888 cm^{-1} bands of HCA-d_6 may be ascribed to the hybridized vibrations composed of $r(ND_2)$ and δ(O=C–N) vibrations. The above assignment is supported by the fact that, for HTCA, no band corresponding to them is observed.

SC has four bands, not yet accounted for, at 1182, 1080, 996 and 946 cm^{-1}. In order to explain these bands, the spectrum of SC was compared with that of SC·HCl. Of the four, only the third band has no band corresponding in frequency to it in the spectrum of SC·HCl, and it moves to 834 cm^{-1} on *N*-deuteration. Therefore, it may be ascribed to a $\delta(NH_2)$ vibration of the hydrazine residue*5 contained in SC. The second and fourth bands are considered to correspond to the 1110 and 996 cm^{-1} bands of HCA, and they may be taken as the $r(NH_2)$ and δ(O=C–N) bands respectively. Since they are displaced by two bands at 917 and 891 cm^{-1} on *N*-deuteration, we can apply the same explanation to

*3 Since the infrared spectrum of diformylhydrazine has been reasonably explained with a model of the transplanar configuration of the -CONHNHCO- group (T. Miyazawa, T. Shimanouchi and S. Mizushima, *J. Chem. Phys.*, **24**, 408 (1956); T. Miyazawa, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **76**, 341 (1955)), that group contained in HCA may be assumed to have a similar structure. On the other hand, the spectrum of urea has been interpreted by means of a model of the planar structure of a molecule (see Ref. 12) and part of the $-NHCONH_2$ of a molecule of HCA is considered to have a planar configuration. In that case, HCA has the symmetry of C_{2h}.

*4 The π(N–H) frequencncy has been obtained at 720 cm^{-1} for *N*-methylformamide (see Ref. 21): the $w(NH_2)$ and $t(NH_2)$ frequencies have been found at 792 and 678 cm^{-1} for oxamide (see Ref. 13) and at 719 and 500 cm^{-1} for urea (see Ref. 12).

*5 In SC·HCl, HCl is considered to attach itself to the hydrazine residue because the NH_2 group of this residue is considered to be more basic in nature than that group of $-CONH_2$.

the latter two bands as was applied to the 943 and 888 cm^{-1} bands of HCA-d_6. The first band also has a partner band at 1180 cm^{-1} in the spectrum of SC·HCl and moves to 997 cm^{-1} on *N*-deuteration; it may be ascribed to a $\delta(NH_2)$ vibration of the hydrazine residue. This assignment will be considered further later in this paper.

HTCA has a moderately strong band at 1049 cm^{-1} which is disappears on *N*-deuteration; its frequency-value is suitable for it to be assigned to the $r(NH_2)$ vibration. The $r(ND_2)$ frequency of HTCA-d_6 has been considered previously (see Table II). The band at 1287 cm^{-1} of this compound shifts to 1028 cm^{-1} on *N*-deuteration and corresponds in frequency to the amide III band of HCSNH·CH_3[17] at 1297 cm^{-1}. Therefore, we can take it as the amide III band characteristic of the –CSNH– group.

TSC has four bands, at 1332, 1287, 1164 and 1001 cm^{-1}, all of which are displaced on *N*-deuteration. In this compound an $r(NH_2)$ vibration in the $-CSNH_2$ plane*6 and NH_2 deformation vibrations of the hydrazine residue will give rise to bands in the region just considered. Of the above four, the 1164 and 1001 cm^{-1} bands seem to be suitable in frequency for the $r(NH_2)$ and the NH_2 deformation vibrations respectively. In TSC-d_5 the 928 and 700 cm^{-1} bands have been assigned to the hybridized vibrations composed of the $r(ND_2)$ and ν(C=S) vibrations (see Table II). TSC-d_5 has a further band at 792 cm^{-1} which may be assigned to the ND_2 deformation vibration of the hydrazine residue. One of the 1322 and 1287 cm^{-1} bands of TSC is considered to correspond to the band at 1086 cm^{-1} of TSC-d_5 and may be taken as the amide III band.

The observed frequencies of ASC, FTSC and ATSC in this region are collected in Table V (b), except for the ν(C=S) frequency accounted for already. All of these compounds are considered to show the amide III band characteristic of the –CONH– group; ASC and ATSC show the bands due to the $r(CH_3)$ and ν(C–C) vibrations, and FTSC, the band due to the π(C–H) vibration. The bands at 1298 cm^{-1} of FTSC and 1265 cm^{-1} of ATSC may safely be taken as amide III bands because they disappear on *N*-deuteration, and their frequency-values are considered to be suitable for amide III bands. In ASC a band at 1197 cm^{-1} disappears on *N*-deuteration; we can take this as the amide III band. In the region where the $r(CH_3)$ and ν(C–C) vibrations will give rise to bands, three bands are found, at 1037, 1002 and 996 cm^{-1} for ASC and at 1058, 1045 and 990 cm^{-1} for ATSC. They may be ascribed to the $r(CH_3)$ and ν(C–C) vibrations or to the hybridized vibrations composed of those and the $r(NH_2)$, skeletal stretching vibrations. In ASC the above three bands are displaced by bands at 1043, 998 (relatively broad) and 931 cm^{-1}; those of ATSC are displaced by two bands, at 1058 and 1034 cm^{-1}, and a band with two peaks at 992 and 983 cm^{-1}. The 998 cm^{-1} band of ASC-d_4 and the doublet band of ATSC-d_4 may be regarded as the amide III′ band overlapping with a band arising from one of the hybridized vibrations indicated above. Now, ASC has three bands not yet accounted for, at 1313, 1121 and 700 cm^{-1}; the first and last bands are scarcely changed in frequency on *N*-deuteration, and, accordingly, they may be considered to come from skeletal stretching vibrations; the second shifts to 1089 cm^{-1}, but this is also due to a skeletal vibration. ATSC has two bands at 1318 and 1180 cm^{-1}; the latter is hardly changed on *N*-deuteration, while the former shifts to 1213 cm^{-1}. A detailed assignment of the two bands is not easy, but they are considered to come from skeletal vibrations. In the spectrum of FTSC, bands at 1093, 840 and 823 cm^{-1} are hardly changed on *N*-deuteration. Therefore, they may be ascribed to skeletal vibrations. In this compound the π(C–H) and $r(NH_2)$ vibrations will give rise to bands in this region. They may be associated with the relatively weak bands at 1029 and 1001 cm^{-1}. In FTSC-d_4 the band at 1019 cm^{-1} may be assigned to the π(C–H) vibration. A moderately strong band at 1223 cm^{-1} may be taken as the amide III band because it disappears on *N*-deuteration. In FTSC-d_4 the bands at 997 and 946 cm^{-1} are suitable in frequency for the amide III′ bands characteristic of the –COND– and –CSND– groups. The band at 733 cm^{-1} also disappears on *N*-deuteration and may be associated with the wagging or twisting NH_2 vibration.

The $\nu(NH_2)$ and ν(NH) Frequencies.—The frequencies observed above 2000 cm^{-1} and a tentative assignment of them are given in Tables VI (a), (b) and (c). As may be seen from Table VI (a), HCA and HTCA have two strong bands, near 3370 and 3190 cm^{-1}. They correspond in frequency to the $\nu_a(NH_2)$ band of 3335 cm^{-1} and the $\nu_s(NH_2)$ band of 3145 cm^{-1} for thioformamide[3] respectively. For formamide[15] the $\nu_a(NH_2)$ frequency has been found at 3330 cm^{-1} and the $\nu_s(NH_2)$ frequency, at 3190 cm^{-1}. Therefore, the bands near 3370 and 3190 cm^{-1} may safely be assigned to the $\nu_a(NH_2)$ and $\nu_s(NH)_2$ vibrations respectively.

*6 It may be assumed that this group is planar because the infrared spectrum of $HCSNH_2$ has been reasonably explained with a planar model of the molecule (see Ref. 3).

Table VII. The observed frequencies of SC·HCl in the region from 1600 to 700 cm^{-1}

	$NH_2CONHNH_3^+$	$ND_2CONDND_3^+$
$\delta_a(NH_3^+)$	1586(s)	
$\delta_s(NH_3^+)$	1529(m)	
Skeletal	1486(s)	1459(s)

		892(w)
$\pi(O=CN_2)$	768(m)	761(m)
$w(NH_2)$ or $t(NH_2)$	717(m)	

As has been mentioned already, it is assumed that a molecule of HCA has the point symmetry C_{2h}, so that only the ν(NH) vibration is infrared-active. The hydrazides[1] containing the -CONHNHCO- group show a band about 3200 cm^{-1} which has been associated with the ν(NH) vibration. On *N*-deuteration, the 3360 cm^{-1} band of HCA moves to 2565 cm^{-1}, while the 3190 cm^{-1} band is displaced by a doublet band with two peaks at 2390 and 2340 cm^{-1}. Therefore, it seems possible that the 3190 cm^{-1} band is the $\nu_s(NH_2)$ band overlapping with the ν(NH) band. Such a doublet band, which has two peaks at 2400 and 2320 cm^{-1}, is also found for HTCA-d_6.

SC and TSC are considered to show rather complicated absorption bands associated with the $\nu(NH_2)$ and ν(NH) vibrations because of the less symmetrical structure of their molecules. In fact, SC shows three strong bands at 3410, 3310 and 3200 cm^{-1} and TSC, at 3370, 3270 and 3190 cm^{-1} (see Table VI(b)). On *N*-deuteration, the SC 3410 cm^{-1} band of SC moves to 2580 cm^{-1}, and the 3370 cm^{-1} band of TSC, to 2560 cm^{-1}. SC·HCl also has a band at 3410 cm^{-1} which is displaced by a band at 2570 cm^{-1} on *N*-deuteration. Therefore, the band about 3400 cm^{-1} may be assigned to the $\nu_a(NH_2)$ vibration of the $-CONH_2$ group. On the other hand, no band corresponding to the band near 3300 cm^{-1} is observed in SC·HCl; therefore, this band may be associated with the $\nu(NH_2)$ vibration of the $-NHNH_2$ group. This assignment is supported by the fact that the hydrazides[2] contaning the $-CONHNH_2$ group show a band ca. 3300 cm^{-1}. The 3200 cm^{-1} band of SC is displaced by a doublet band with two peaks at 2410 and 2330 cm^{-1} on *N*-deuteration. This band corresponds in frequency to, and behaves on *N*-deuteration like, the 3190 cm^{-1} band of HCA; therefore, it may be the $\nu_s(NH_2)$ band of the $-CONH_2$ group overlapping with the ν(NH) band. TSC also has the corresponding band at 3190 cm^{-1} which is displaced by a doublet band, 2400 and 2330 cm^{-1}, on *N*-deuteration. The band of SC·HCl at 3220 cm^{-1} may be similarly explained because it is displaced by a doublet band, 2390 and 2320 cm^{-1}, on *N*-deuteration. SC·HCl further shows two strong bands at 2850 and 2640 cm^{-1} which are displaced by two bands at 2090 and 2020 cm^{-1} on *N*-deuteration; therefore, they may be associated with the NH_3^+ stretching vibrations.

ASC shows strong or moderately strong bands at 3440, 3310 and 3230 cm^{-1}; ATSC has corresponding bands at 3440, 3310, 3170 cm^{-1}. Of these three, the former two move to about 2600 and 2500 cm^{-1} on *N*-deuteration, while the third band corresponds in frequency to, and behaves on *N*-deuteration like, the bands about 3200 cm^{-1} of the compounds in Tables VI(a) and (b). Therefore, the band about 3200 cm^{-1} of ASC and ATSC may also be taken as the $\nu_s(NH_2)$ band overlapping with the ν(NH) band. On the other hand, the 3440 and 3310 cm^{-1} bands are considered to arise from the $\nu_s(NH_2)$ and ν(NH) vibrations respectively. For FTSC the corresponding bands are found at 3295, 3155 and 2970 cm^{-1}.

The Bands of SC·HCl.—The observed frequencies of this compounds have partly been accounted for in previous sections. Let us now consider the frequencies charateristic of the NH_3^+ structure. A number of investigations have been made of the infrared spectra of amino acids and their hydrochlorides. These compounds usually show two characteristic

bands in the 1600～1500 cm^{-1} region which are associated with the NH_3^+ deformation vibrations; many amino acids have a further band near 1300 cm^{-1} and their hydrochlorides, a band near 2000 cm^{-1}.[23] Mizushima and Nakagawa[24] have obtained the 1650～1560 cm^{-1} range for the $\delta_a(NH_3)$ frequency, the 1350～1150 cm^{-1} range for the $\delta_s(NH_3)$ frequency, and the 950～650 cm^{-1} range for the $r(NH_3)$ frequency in ammine complex salts. On the other hand, the corresponding frequencies of the NH_3^+ structure have been found at 1613, 1504, 1133 and 1109 cm^{-1} for glycine[25] and 1620, 1515 and 1497, and 1185 and 1112 cm^{-1} for *C*-deuterated glycine.[26]

The observed frequencies of SC·HCl in the region from 1600 to 700 cm^{-1} and their assignments are summarized in Table VII. In the range for the $\delta_a(NH_3)$ frequency indicated above, SC·HCl has only a strong band at 1586 cm^{-1}; this disappears on *N*-deuteration and so may be associated with the $\delta(_aNH_3^+)$ frequency. The band at 1529 cm^{-1} also disappears on *N*-deuteration and corresponds in frequency to the $\delta_s(NH_3^+)$ band of glycine. Therefore, it may be ascribed to the $\delta_s(NH_3^+)$ vibration. This hydrochloride shows two bands at 1215 and 1180 cm^{-1} in place of the 1182 cm^{-1} band of SC, and on *N*-deuteration those two bands shift to 1036 and 1005 cm^{-1} respectively. Their frequency-values are a little high, but they may be taken as $r(NH_3^+)$ frequencies. This assignment is consistent with the fact that these two bands appear in place of the 1882 cm^{-1} band of SC which has been ascribed to a $\delta(NH_2)$ vibration of the hydrazine residue. In SC·HCl-d_6 the two bands at 1160 and 1130 cm^{-1} are considered to arise from the $\delta_a(ND_3^+)$ and $\delta_s(ND_3^+)$ vibrations respectively.

Since three bands, at 1088, 933, and 768 cm^{-1} of SC·HCl and 918, 892 and 761 cm^{-1} of SC·HCl-d_6, have their partner bands in the spectra of SC and SC-d_5 respectively, these bands may be explained in the same way as those partner bands have been. It is especially interesting to see that the 1088 and 933 cm^{-1} bands of SC·HCl are displaced by two bands at 918 and 892 cm^{-1} on *N*-deuteration. In consequence, this observation supports the assignment presented already (see Table V(a)); i. e., the 1080 and 946 cm^{-1} bands of SC are associated with the $r(NH_2)$ and δ(O=C–N) vibrations of the $-CONH_2$ group, and the 917 and 891 cm^{-1} bands of SC-d_5, with the hybridized vibrations composed of the $r(ND_2)$ and δ(O=C–N) vibrations. The two bands at 1486 and 1387 cm^{-1} are displaced by bands at 1459 and 1441 cm^{-1} on *N*-deuteration, and these may be ascribed to skeletal stretching vibrations. A moderately strong band at 717 cm^{-1} disappears on *N*-deuteration and may be associated with a $w(NH_2)$ or $r(NH_2)$ vibration.

The weak band of SC·HCl at 1926 cm^{-1} seems to be one characteristic of the NH_3^+ structure, but it may be ascribed to a combination or overtone band because it is scarcely changed in frequency on *N*-deuteration.

Conclusions

(1) For HTCA, TSC, ATSC, and FTSC a ν(C=S) frequency has been obtained in the 860～800 cm^{-1} range which is rather lower than that obtained in other classes of compounds containing the C=S bond. In *N*-deuterated species, the ν(C=S) vibration interacts with the $r(ND_2)$ vibration and two bands which may be regarded as characteristic of the $-CSND_2$ group appear. In consequence, the conclusion obtained for thioamides[15,16] has been confirmed by the present observations.

(2) The spectra of HCA and SC are rather more like that of urea than those of hydrazides containing a –CONHNHCO– or –CONH·NH_2 group; the observed frequencies have tentatively been explained by comparing the spectra with the spectrum of urea.

(3) In ASC, ATSC, and FTSC the amide I, II, and III bands characteristic of the –CONH– group have without ambiguity been located. HTCA, TSC, ATSC, and FTSC show amide II- and III-like bands; these two bands are regarded as characteristic of the –CSNH– group, as previously been found for monosubstituted thioamides.[17]

(4) For SC·HCl the frequencies characteristic of the NH_3^+ structure have without much difficulty been obtained. By comparing the spectrum of SC·HCl with that of SC, the $r(NH_2)$ and δ(O=C–N) frequencies of the $-CONH_2$ group and two frequencies due to hybridized vibrations composed of the $r(ND_2)$ and δ(O=C=N) vibrations have been obtained.

The Electronic Structure of the α-Amino Acids of Proteins. II. Dissociation Constants

By Teijiro YONEZAWA,* Giuseppe DEL RE** and Bernard PULLMAN

(Received February 21, 1964)

In a previous paper[1] we obtained a satisfactory correlation between the charge distribution in the α-amino acids, as determined by a semi-empirical procedure derived from the molecular orbital method,[2] and the proton chemical shifts of these compounds. In the present paper we will report some approximate results concerning the dissociation constants of the same compounds.

The simplest α-amino acids dissociate according to the schemes:

$$RNH_3{}^+COOH \rightleftharpoons RNH_3{}^+COO^- + H^+ \quad (I)$$

and

$$RNH_3{}^+COO^- \rightleftharpoons RNH^2COO^- + H^+ \quad (II)$$

The pK's corresponding to these two dissociation processes are conventionally denoted as pK_1 and pK_2. Only these processes will be discussed in the present paper.

The Method

Simple electrostatic models[3] have already led to the conclusion that the dissociation constant of an acidic group is affected by the electrostatic effect of the neighbouring groups. We have assumed, therefore, that the energy variation involved in the dissociation process is given by two essential contributions: a) the change in the sum of the bond energies of the amino acid molecule in passing from the non-dissociated form to the dissociated form; and b) the change in the electrostatic energy of the proton because, in the final dissociated state, it is no longer subject to the attractions or repulsion of the other atoms of the molecule.

Several theoretical chemists have attempted to interpret dissociation constants on the basis of more or less refined calculations. They have, however, studied conjugated compounds almost exclusively and based their considerations on calculations for the π systems of such molecules. Therefore, their procedures cannot be directly applied to our problem. However, some of their considerations have, of course, a general significance. Thus, the basicity of conjugated molecules has been related to the chang in π energy during the dissociation[4] and to the value of the π charge of the protonated heteroatom[5]. The use of a combined index taking into account both the change in π energy and the change in the energy due to an additional electrostatic interaction has also been proposed[6] and shown to be particularly successful. Finally, it has been observed that taking the solvation into account leads to useful improvements.[7]

Only a classical electrostatic theory has been proposed,[3] as far as we know, in connection with saturated compounds.

We have adopted a point of view similar to that of Ref. 6. Already in Ref. 2, the method proposed in that paper was used for a semi-qualitative discussion of dissociation constants. In particular, the total σ-electron energy of a given molecule was calculated by adding the σ energies of the various bonds, according to the formulas;

$$E = \sum_{\substack{\text{bonds} \\ \mu\nu}} E_{\mu\nu} \quad (1)$$

where*

$$E_{\mu\nu} = 2\alpha + \{(\delta_\mu + \delta_\nu) + 2\varepsilon_{\mu\nu}\sqrt{1+Q^2{}_{\mu\nu}}\}\beta \quad (2)$$

and

$$Q_{\mu\nu} = \frac{\delta_\mu - \delta_\nu}{2\varepsilon_{\mu\nu}} \quad (3)$$

(The parameters α and β are the usual standard Coulomb and bond integrals; δ_μ and δ_ν are defined by the condition that $\alpha+\delta_\mu\beta$ and $\alpha+\delta_\nu\beta$ are the Coulomb integrals of the μ-th and ν-th atom respectively; $\varepsilon_{\mu\nu}\beta$ is the bond

* In Ref. 2 the factor 2 before $\varepsilon_{\mu\nu}$ had been ommitted in the formula for $E_{\mu\nu}$

integral of the $\mu\nu$ bond.)

If formula 1 is applied to a series of protonated molecules and to the corresponding free bases, one gets energy differences which can be expected to a first approximation to be linearly related to the pK's of the corresponding dissociation equilibria (of course, the changes in the solvation and nuclear repulsion energies are assumed to be constant).

These considerations have been taken as a starting point of the present paper. The ΔE's, however, have been calculated according to the refined formula:

$$\Delta E = E_\sigma(\text{final}) - E_\sigma(\text{initial}) - \sum_\mu \frac{Q_H Q_\mu e^2}{R_{H\mu}} \qquad (4)$$

Here E_σ(initial) denotes the energy of the protonated compound, and E_σ(final), that of the base. The third term corresponds to the electrostatic interaction between the proton and the other atoms in the protonated compound. Q_H is the net charge (in e units) of the proton; $Q\mu$, the net charge of μ-th atom, and $R_{H\mu}$, their mutual distance. The calculation of $R_{H\mu}$ was carried out using a formula proposed by Eyring,[8] and by Kirkwood and Westheimer.[9] This formula gives the root-mean square distance between the hydrogen and the atom located at the end of the n-th bond, assuming free rotation around the bonds. Let $\eta_{m\ m+1}$ be the cosine of the supplement of the angle between the m-th and $m+1$-th bond and l_k, the length of the k-th bond; then,

$$\overline{R_n}^2 = \sum_{k=1}^{n} l_k^2 + 2\sum_{k=1}^{n}\sum_{s=1}^{k-1} l_k l_s \prod_{m=s}^{k-1} \eta_{m\ m+1} \qquad (5)$$

A few remarks are important in connection with Eq. 4:

1) The net charge, Q_μ, of the μ-th atom must be calculated by adding the charge, $Q_\mu{}^\sigma$, due to the σ electrons to $Q_\mu{}^\pi$, the net charge due to the π electrons, if present:

$$Q_\mu = Q_\mu{}^\sigma + Q_\mu{}^\pi \qquad (6)$$

The net charges, $Q_\mu{}^\pi$, calculated for our compounds by the ordinary Hückel method are shown in Fig. 1.

2) ΔE should be given by the difference between the total energy of the final and initial molecules in Eqs. I and II the total energy of a molecule being:

$$E_\pi + E_\sigma + \sum_{\mu>\nu} \frac{Q_\mu Q_\nu e^2}{R_{\mu\nu}} \qquad (7)$$

(E_π and E_σ denote the total π and σ energies, and the third term denotes the core repulsion energy in the molecule). Equation 4 represents this ΔE only if the variation of the total π-electron energy is assumed to be constant, and only if one may reasonably assume that the variation of the third term can be written as:

$$\Delta\sum_{\mu>\nu} \frac{Q_\mu Q_\nu e^2}{R_{\mu\nu}} = C - \sum_\mu \frac{Q_H Q_\mu e^2}{R_{H\mu}} \qquad (8)$$

where C is a constant.

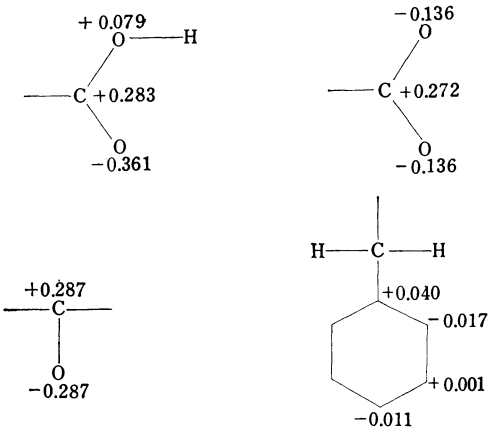

Fig. 1 The net charge of π-electrons in the conjugated parts of the amionacids.

3) The last term in Eq. 4 corresponds to the dielectric constant of the solvent being equal to 1. Different values have been adopted in classical theory,[3] but no serious modification could arise if we introduced the same kind of correction, as the change in the dielectric constant has always been taken to be small.

4) The contribution of the solvation energy is not taken into account.

5) The hyperconjugation effects, which may take place in certain amino acids, are ignored throughout all the calculations.

Results and Discussion

The results of the calculation are listed in Tables I and II, together with the experimental values of pK_1 and pK_2 for the various compounds. In the second columns of these tables, the variations of the total σ energies in the course of reactions I and II are given in units of $-\beta$. In the fourth columns the calculated values of the ΔE's (Eq. 4) are listed in units of eV.'s. The calculation of the ΔE's has required the determination of a value for $-\beta$. We have chosen 5.2 electron volts, a value not unreasonable for this type of property judging from other investigations of saturated compounds[10] and corresponding to a least-square

Alanine	−0.794	−0.363	−2.105	−1.742

fitting of the ΔE vs. pK_1 plot by a straight line.

As regards the relationship between the ΔE's and the pK_1's, Table I and Fig. 2 show that it corresponds to a straight line as far as could be expected with such drastic simplifications as have been introduced. In Table I, a remarkable contribution of the repulsion term is observed, for instance, in the case of β-alanine. This confirms that one cannot ignore the contributions of the third term of Eq. 4.

In the case of the pK_2's, the agreement between the experimental and theoretical results is less satisfactory (Table II and Fig. 3). For proline, which has the largest pK_2 value, we do obtain the largest calculated value of ΔE: this value, however, deviates to a large extent from the rough linear relationship observed for the other pK_2's.

It may be useful to consider the influence of some possible refinements in the calculations on these results. Thus, e. g., the present treatment introduces two kinds of approximations in connection with interatomic distances. First of all, the interatomic distances are calculated by means of Eq. 5, assuming that there is free rotation around the bonds; second, the repulsion term is assumed to consist only of those repulsions or attractions which take place between the hydrogen atom which is involved in the dissociation and the other atoms of the initial molecule, to the exclusion of the changes in other repulsion energies (Eq. 8).

As to the first approximation, one may note that, especially in reaction I, the Lewis acid from which the proton dissociates probably has a special steric conformation, so that the free rotation around the various bonds is hindered to some exten. In order to evaluate the changes brought about in the repulsion energy by the assumption of a fixed configuration, let us assign to the dipolar ion of reaction II the configuration shown in Fig. 4. The

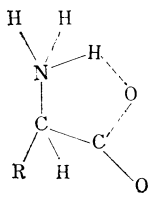

Fig. 4 Assumed conformation in $RNH_3^+COO^-$.

static repulsion terms, $\sum_{\mu}\frac{Q_{H}Q_{\mu}e^2}{R_{H\mu}}$, for this conformation of the glycine and alanine dipolar ions are given in Table III.

To check the validity of our second assumption, we have also evaluated the variation in the core repulsion energy, $\sum_{\mu>\nu}\frac{Q_{\mu}Q_{\nu}e^2}{R_{\mu\nu}}$, for the same molecules in a similar conformation of the anions, i. e., with a hydrogen bond between the $-COO^-$ group and the NH_2 group. Its values are also given in Table III, together with the values of $\sum_{\mu}\frac{Q_{H}Q_{\mu}e^2}{R_{\mu H}}$ corresponding to the freely rotating structure. Table III shows that the values of C (Eq. 8) become −1.759 and −1.742 for glycine and alanine respectively, they are thus approximately the same. These results strongly suggest that the above assumptions do not cause serious errors in connection with dissociation constants, therefore, e. g., the disagreement we have found between calculated and experimental values of the pK_2's may very probably be explained in a different way.

Another dubious point concerns the contribution of the solvation energy to ΔE, since this contribution is not taken into account in our calculation. No suitable method for estimating the extent of this contribution is available; therefore, we can only estimate it roughly with the help of the Hush-Blackledge and Daudel formula:[7,11]

$$E_s \simeq -\sum_{\mu} Q_{\mu}^2 \qquad (9)$$

where the solvation energy, E_s, is considered to be proportional to the sum of the squares of the net charges in the molecule. Formula 9 leads to nearly the same values of ΔE_s for all the aminoacids, so that no important improvement of the results can be expected for this correction.

Conclusion

The results reported in the present note seem to make possible another encouraging stop forward in the difficult process of correlating, by means of semi-empirical quantum

11) N. S. Hush and J. Blackledge, *J. Chem. Phys.*, 23, 514 (1955).

theoretical methods, the properties of α-amino acids. The particularly severe difficulties connected with the treatment of dissociation constants make the deviations from a linear relationship quite expected; therefore, it is gratifying that the overall correlation, especially of the pK_1's, is quite satisfactory.

Improvements should probably be looked for through refinements concerning the solvation effects and possibly through the inclusion of long-range exchange effects.

The Polarographic Behavior of Mercuric Diethyldithiocarbamate in a Ternary Solvent Mixture

By Taitiro FUJINAGA and Kazuo YAMASHITA

(Received February 21, 1964)

Sodium-diethyldithiocarbamate has long been used as one of the most useful analytical reagents in methods involving solvent extraction for the separation and concentration of the trace constituents of a sample.

As is well known, the method of solvent extraction has been widely applied to the analysis of trace elements, particularly in colorimetric determinations. However, in order to apply the extraction method to electrochemical analyses, either the sample solution has to be evaporated and the residue redissolved in water or, alternatively, the solution must be reextracted with water after a suitable adjustment of the physico-chemical conditions.

The present authors, in a previous paper,[1] proposed a third method, in which a ternary mixture is used as a solvent for the polarographic analysis after extraction; they applied the method to the determination of traces of lead in sodium chloride of analytical grade. In this procedure, the chloroform layer, into which the lead chelate of diethyldithiocarbamate had been extracted, was mixed directly with a solution consisting of ethylene glycol monomethyl ether (methyl-cellosolve), and aqueous hydrochloric acid as the supporting electrolyte. Even though chloroform is insoluble in water, the addition of methyl-cellosolve makes it possible to obtain a homogeneous solution. It was found that this homogeneous ternary mixture had a dielectric constant high enough to ensure the electrolytic dissociation of dissolved salts. The ohmic drop in this solution was about the same as that in a purely aqueous solution. Hence, it was possible to carry out the polarographic analysis directly, without any further treatment.

In the present work, the polarographic reduction of mercuric-diethyldithiocarbamate has been investigated in a ternary solvent mixture consisting of chloroform, methyl-cellosolve and water, in the presence of 0.5 M perchloric acid as a supporting electrolyte. In this solution, $Hg(DDTC)_2$ usually gives two d. c. cathodic waves, though a small anodic step appears at a more positive potential when the temperature is lowered below 15°C. The first cathodic step (step A in Fig. 1, curve 1) was found to be proportional to the bulk concentration of $Hg(DDTC)_2$ over the concentration range of 0.1 mM to 0.4 mM; it is probably due to the reduction of unadsorbed $Hg(DDTC)_2$. The height of the second step (step B in Fig. 1, curve 1), on the other hand, was almost constant and independent of the concentration of $Hg(DDTC)_2$ and, hence, seems due to the reduction of $Hg(DDTC)_2$ adsorbed onto the surface of the dropping electrode. Step B, therefore, represents a so-called anomalous polarographic step.[2] In the present case, the oxidised form of the depolarizer, $Hg(DDTC)_2$, is adsorbed strongly onto the electrode surface and, consequently, a post-step B appears at a more negative potential than the normal step A. Though many

1) T. Fujinaga, H. Brodowsky, T. Nagai and K. Yamashita, *Review of Polarography (Japan)*, 11, 217 (1963).

examples of anomalous waves[2-6] have been found for the adsorption of the reduced form which produces a prewave, examples of the present case have rarely been reported.

Experimental

The reagents and the apparatus used were the same as those reported on in the previous paper.[1] Throughout the experiments, two dropping mercury electrodes with the following characteristics were used: Electrode A: $m=0.73$ mg./sec., $t=3.75$ sec., and $h=65$ cm., and Electrode B: $m=0.64$ mg./sec., $t=4.63$ sec., and $h=65$ cm. in an air-free ternary solvent mixture at open circuit. The polarographic measurements were carried out in the absence of air; the potential values quoted refer to the saturated calomel electrode, which was connected to the electrolyte solution through an agar bridge (5% agar, 7.5% sodium perchlorate).

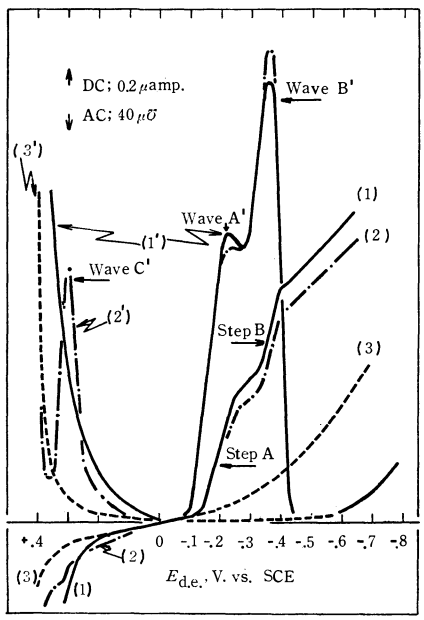

Fig. 1.

(1') A. C. polarogram of the same solution as in (1).
(2) D. C. polarogram of the same solution as in (1) at 10°C.
(2') A. C. polarogram of the same solution as in (1) at 10°C.
(3) D. C. polarogram of 0.5 M perchloric acid in the ternary mixture at 25°C
(3') A. C. polarogram of the same solution as in (3).

Results

It is well known that $Hg(DDTC)_2$ can be extracted completely into chloroform from an aqueous solution over a wide pH range.[7,8] The solution of $Hg(DDTC)_2$ in the ternary solvent mixture was prepared as follows: 1 ml. of an aqueous solution of 0.4% sodium diethyldithiocarbamate was added to 2 ml. of water which contained from 1 mM to 10 mM mercuric ions. To this solution 5 ml. of chloroform were added. After this mixture had been shaken for five minutes, 11 ml. of methyl-cellosolve and 1 ml. of concentrated perchloric acid were added and the solution was shaken until a clear solution was obtained. The proportion of water, methyl-cellosolve and chloroform in the final solution was 4 : 11 : 5 by volume.

D. C. Polarography.—With a solution of less than 0.1 mM $Hg(DDTC)_2$, only a single step is observed around −0.4 V. vs. SCE. When the concentration of $Hg(DDTC)_2$ is raised above 0.1 mM, however, two steps appear, one at −0.2 and the other at −0.4 V., as is shown by curve 1, Fig. 1.

85.2	0.928	3.10	52.5	90.0	83	0.63_2	9.8_7

Figure 2 illustrates the dependence of the heights of step A (1), step B (2) and of the total step height (3) on the concentration of $Hg(DDTC)_2$. The limiting currents of step A, step B and of the total step height were measured at −0.25 and at −0.40 V., respectively. The height of step B increases with the concentration of $Hg(DDTC)_2$ in a fashion corresponding to a Langmuir adsorption isotherm; it shows a limiting value when the concentration of $Hg(DDTC)_2$ reaches a value of 0.3 mM. The height of step A increases linearly with the concentration of $Hg(DDTC)_2$, but the step does not appear at concentrations of $Hg(DDTC)_2$ below 0.1 mM because of its adsorption onto the electrode surface which produces step B. The total wave height (curve 3) also increases approximately linearly with the concentration of $Hg(DDTC)_2$.

The electrocapillary curves obtained are shown in Fig. 3. In the presence of $Hg(DDTC)_2$, a marked decrease of the drop time is observed between +0.4 and −0.4 V. (curve 3). At more negative potentials than −0.4 V., the drop time in the presence of $Hg(DDTC)_2$ is equal to that in its absence (curve 2). This indicates that the substance is adsorbed between +0.4 and −0.4 V. and is desorbed from the electrode surface at about −0.4 V. The potential at which $Hg(DDTC)_2$ is desorbed corresponds to that at which step B appears.

The relationship between the heights of steps A and B and the concentration of $Hg(DDTC)_2$ also confirms the supposition that step B is due to the reduction of the adsorbed form of $Hg(DDTC)_2$, whilst step A is due to the reduction of the unadsorbed form. This assumption is also confirmed by experimental results to be reported on below.

The temperature coefficients of the heights of steps A and B and of their sum were +1.63%, +1.28% and +1.46% respectively in the 15~30°C range (Fig. 4).

The effect of the height of the mercury reservoir was also studied. The results are shown in Table I. The height of step B was

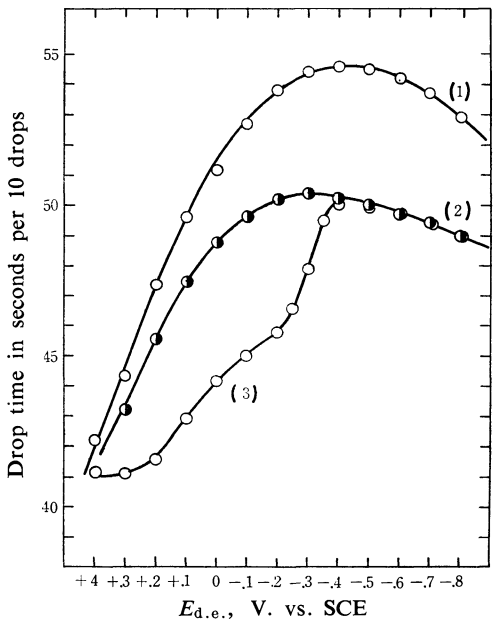

Fig. 3. Electrocapillary curves of (1) 0.5 M perchloric acid in water, (2) 0.5 M perchloric acid in ternary solvent mixtures and (3) 3×10^{-4} M concentration of $Hg(DDTC)_2$, h= 65 cm.; m=0.73 mg./sec.; t=3.75 sec.; T, 25°C.

approximately linearly proportional to h, whilst the total step height was approximately proportional to $h^{1/2}$. This agrees well with the assumption that step B is anomalous. The fact that surfactants, such as polyacrylamide (PAM 75) or gelatine, had little effect on the polarograms shows that $Hg(DDTC)_2$ is more strongly adsorbed than these surfactants.

A. C. Polarography.—A. C. polarograms obtained with a solution of 0.3 mM $Hg(DDTC)_2$ in the ternary solvent mixture are shown in Fig. 1. At 25°C, two a. c. waves were observed (curve 1', A' and B') at potentials corresponding to the two d. c. steps.

Below 15°C, however, a new a. c. wave (wave C') was observed at about +0.3 V., a

wave which corresponds to the small anodic wave in the d.c. polarogram (Fig. 1). The height of wave A′ increased linearly with the concentration of $Hg(DDTC)_2$ at concentrations below 0.5 mM (Fig. 5, curve 1). The calibration curves of waves B′ and C′ have the shape of a Langmuir adsorption isotherm (Fig. 5, curve 2, and Fig. 6). Hence, these two waves seem to be connected with the adsorption and desorption of $Hg(DDTC)_2$.

The effects of temperature are shown in Figs. 7 and 8. The height of wave A′ increases with the increasing temperature (Fig. 7, curve 1); the height of wave B′, however, decreases with the increasing temperature. This behavior shows that the a.c. current of wave B′ has both a tensammetric and a faradaic component

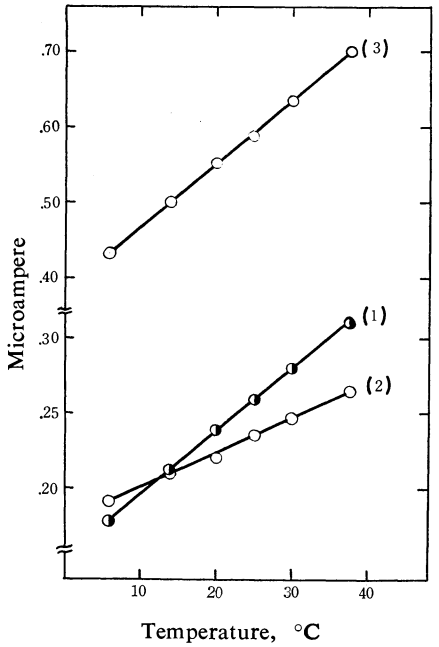

Fig. 4. Effect of temperature on heights of steps (1) A, (2) and (3) total step height in 0.5 M perchloric acid in the ternary solvent mixture, h=65 cm.; m=0.73 mg./sec.; t=3.75 sec.; T, 25°C.

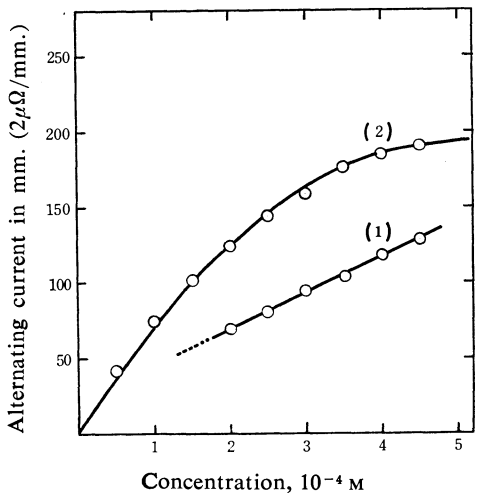

Fig. 5. Calibration curves of waves (1) A′ and (2) B′ of $Hg(DDTC)_2$ in 0.5 M perchloric acid in the ternary solvent mixture, h=65 m.; m=0.64mg./sec.; t=4.63 sec. at open circuit; T, 25°C; A.C. 15 mV. r.m.s.

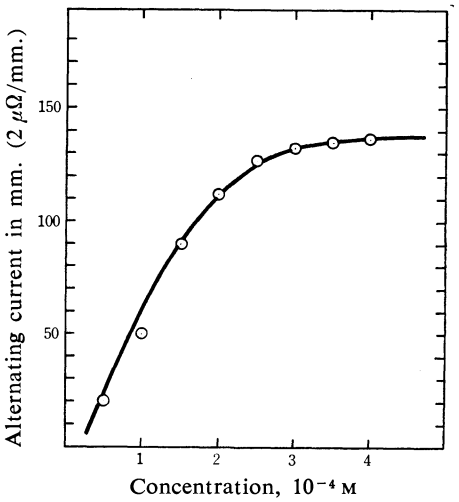

Fig. 6. Calibration curves of tensammetric wave (wave C′) of $Hg(DDTC)_2$ in 0.5 M perchloric acid in the ternary solvent mixture, h=65 cm., m=0.64 mg./sec., t=4.63 sec., at zero applied potential, T, 10°C; A.C. 15 mV. r.m.s.

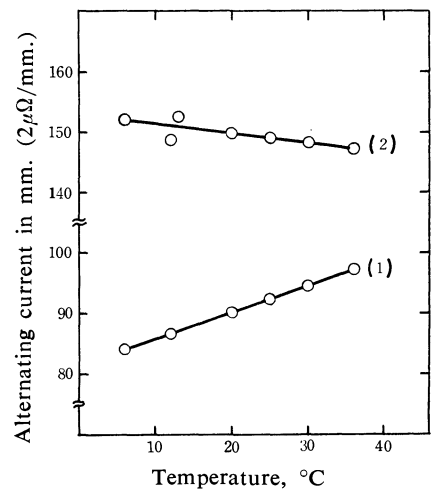

Fig. 7. Effect of temperature on the heights of A.C. waves (1) A′ and (2) B′; h=65 cm.; m=0.64 mg./sec.; t=4.63 sec.; T, 25°C; A.C. 15 mV. r.m.s.

("rearrangement current"[9]). The results obtained by the a. c. polarographic method are also in good agreement with the assumption that waves B and B′ are anomalous, that is, that they are due to the fact that the strongly adsorbed $Hg(DDTC)_2$ is reduced and desorbed from the electrode surface.

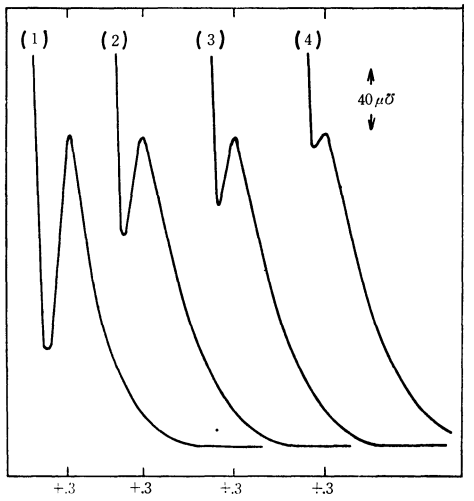

Fig. 8. Effect of temperature on the appearance of the tensammetric wave (wave C′) in 0.5 M perchloric acid in the ternary solvent mixture; h=65 cm; m=0.64 mg./sec.; t=4.63 sec.; A. C. 15 mV. r. m. s. (1) 10°C, (2) 13°C, (3) 14°C, (4) 15°C.

Discussion

The appearance of wave C′ in the a. c. polarogram in the absence of a d. c. polarographic step indicates that this a. c. wave is tensammetric in nature. The adsorption of $Hg(DDTC)_2$ onto the dropping mercury electrode, therefore, begins at this potential.

When the concentration of $Hg(DDTC)_2$ is small (below about 0.1 mM), all the molecules which diffuse to the electrode surface are adosorbed to be reduced at the B potential corresponding to step in d. c. polarography. If the concentration of $Hg(DDTC)_2$ becomes larger than that sufficient for the electrode surface to be completely covered with adsorbed molecules, unadsorbed molecules reach the electrode surface and are reduced, forming wave A. In d. c. polarography, wave B is called an anomalous polarographic wave. As has been pointed out already, the current of the a. c. wave B′ is a rearrangement current, that is, it contains both a faradaic and a tensammetric component; this is in good agreement with the postulate that it is due to the reduction of adsorbed $Hg(DDTC)_2$. Incidentally, we believe that this is one of the first instances where the existence of the theoretically-predicted rearrangement current has been proved experimentally.

If we assume that the reduction of $Hg(DDTC)_2$ proceeds according to:

$$Hg(DDTC)_2 + 2e = Hg + 2(DDTC)^- \qquad (1)$$

we would expect that the $(DDTC)^-$ anion so formed would give rise to an oxidation step. However, it has been reported by Bode[7] and by Gregg[10] that the $(DDTC)^-$ anion is decomposed immediately in a strongly acidic solution, such as 0.5 M perchloric acid, according to:

$$(C_2H_5)_2N\text{-}C\langle^{S^-}_{S} + H^+ = (C_2H_5)_2NH + CS_2$$

In fact, we did not observe an oxidation step of $DDTC^-$ ions in 0.5 M perchloric acid, though we did see one in a basic solution.

If the concentration of $Hg(DDTC)_2$ in the solution is large enough, the electrode surface is completely covered with a mono-layer of $Hg(DDTC)_2$ and the excess of $Hg(DDTC)_2$ produces step A.

The average current ($\bar{i}$) at the potential of wave A can be expressed as:

$$\bar{i} = \bar{i}_I - \bar{i}_B \qquad (2)$$

where $\bar{i}_I$ is the theoretical current, that is, that calculated from the Ilkovič equation under the assumption that $Hg(DDTC)_2$ is unadsorbed. $\bar{i}_I$ is defined by:

$$\bar{i}_I = 2Km^{2/3}t^{1/6}(C_0^* - C_0^0) \qquad (3)$$

where C_0^* is the concentration of $Hg(DDTC)_2$ in the bulk of the solution and C_0^0, that at the electrode surface, while $\bar{i}_B$ is the current corresponding to step B, i. e., the current due to the reduction of adsorbed $Hg(DDTC)_2$. $\bar{i}_B$ is practically independent of the concentration of $Hg(DDTC)_2$ and can be expressed by the following equation:

$$\bar{i}_B = 2Fz\Delta q \qquad (4)$$

where F: Faraday constant, z: maximum number of moles adsorbed per unit area, and Δq: the mean increase of the surface area per time unit ($\Delta q = 0.85\, m^{2/3}t^{-1/3}$).

From Eqs. 2 and 3, we obtain:

$$\bar{i} = 2Km^{2/3}t^{1/6}(C_0^* - C_0^0) - \bar{i}_B$$

$$C_0^0 = C_0^* - (\bar{i} + \bar{i}_B)/2Km^{2/3}t^{1/6} \qquad (5)$$

9) B. Breyer and H. H. Bauer, "Alternating Current Polarography and Tensammetry," Interscience Publishers, New York (1963), pp. 74, 268.

10) E. C. Gregg and W. P. Tyler, *J. Am. Chem. Soc.* 72, 4561 (1950).

Since, as has already been explained, $(DDTC)^-$ ions cannot exist in an acid solution, we can write:

$$\bar{i}=K'm^{2/3}t^{1/6}C_R{}^0$$

where $C_R{}^0$ is the surface concentration of $(DDTC)^-$.

Therefore,

$$C_R{}^0=\bar{i}/K'm^{2/3}t^{1/6} \quad (6)$$

Assuming that the redox reaction 1 occurs reversibly, the potential at any point of wave A is given by the Nernst equation:

$$E_{d.e.}=E_0-0.0295\log(C^\circ{}_{DDTC^-})^2/C^\circ{}_{Hg(DDTC)_2} \quad (7)$$

Solving Eqs. 5, 6 and 7, we obtain

$$E_{d.e.}=E_0'-0.0295\log(\bar{i}^2/(2C_0{}^*Km^{2/3}t^{1/6}-\bar{i}-\bar{i}_B))$$

where E_0' is equal to $E_0-0.0295\log(K/K'm^{2/3}t^{1/6})$ and is almost constant at a constant $m^{2/3}t^{1/6}$. $2C_0{}^*Km^{2/3}t^{1/6}$ is equal to the total limiting current and is given by the sum of $\bar{i}_B$ and $\bar{i}_A$ (average limiting current of step A).

Hence, we can write:

$$E_{d.e.}=E_0'-0.0295\log\bar{i}^2/(\bar{i}_A-\bar{i}) \quad (8)$$

Thus a plot of $E_{d.e.}$ vs. $\log\bar{i}^2/(\bar{i}_A-\bar{i})$ of wave A should have a slope of 29.5 mV. The experimental results agreed well with this prediction, as Fig. 9 shows; log-plots were found to have a slope between 28 and 31 mV. This fact suggests that the reduction of $Hg(DDTC)_2$ is a reversible, two-electron process.

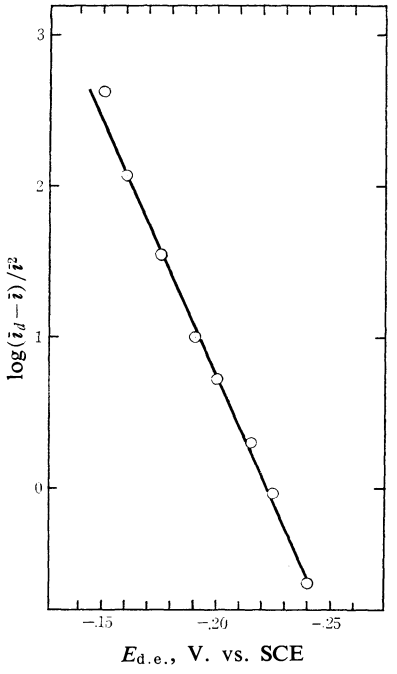

Fig. 9. Relationship between $\log(\bar{i}^2/\bar{i}_A-\bar{i})$ and $E_{d.e.}$ of the D. C. step A T, 25°C.

Relationship 4 makes it possible to evaluate directly the maximum number of molecules per unit area of the electrode surface. At a concentration of 0.3 mM of $Hg(DDTC)_2$, the number of moles of $Hg(DDTC)_2$ adsorbed per unit area of the electrode surface was calculated as:*

$$Z_1=5.7\times10^{-10}\ \text{mol./cm}^2$$

Similary, at a concentration of 0.1 mM, when wave A begins to appear:

$$Z_2=2.3\times10^{-10}\ \text{mol./cm}^2$$

From the value of Z_1, the area which one molecule of $Hg(DDTC)_2$ occupies is 30 Å^2/molecule, assuming that the adsorbed molecules form a monolayer. If we consider that $Hg(DDTC)_2$ is adsorbed vertically upon the electrode surface, this value seems reasonable, considering the area calculated from the crystal data reported by Simonsen and Wah Ho.[11] From the Z_2 value, the occupied area is found to be 75 Å^2/molecule; this value is in fairly good agreement with the value calculated by assuming that the chelate is adsorbed horizontally onto the electrode. We think that the difference between Z_1 and Z_2 might be due to a different orientation of the adsorbed chelate molecule at the electrode surface. However, it is also possible that the adsorbed film may be a multi- and not a monolayer.

The behavior of the $Hg(DDTC)_2$ dimethylformamide solution will be reported on in a subsequent paper.

$\bar{i}_B=(\bar{i}_{total})_{corr.}-\bar{i}_A$,

$(\bar{i}_{total})_{corr.}=(\bar{i}_{total})_{obs.}(t_A/t_B)^{1/6}$

where t_A=4.66 sec., $\bar{i}_A$=0.475 microampere at −0.29., t_B=4.97 sec., and $(\bar{i}_{total})_{obs.}$=0.905 microampere at −0.40 V.

Determination of Lead and Thallium(I) in Presence of Each Other by Amperometric Titrations

By D. S. JAIN and J. N. GAUR

(Received November 30, 1963)

Thallium in presence of lead has been determined by Winn[1] in urine by digesting a sample of urine with a mixture of sulphuric, perchloric and nitric acids. Thallium was oxidised to the trivalent state with bromine water and then extracted with a chloroform solution of dithiozone, while lead under these conditions, remained in the water phase. The chloroform extract was used for the polarographic estimation of thallium.

In supporting electrolytes which do not complex lead ions, the thallium and lead waves coincide. The half-wave potentials of lead and thallous ion in 1 M potassium nitrate has been found to be -0.38 V.[2] and -0.46V.[3] respectively against SCE at 25°C and thus their polarographic determination in presence of each other presents some difficulty, but by employing sodium or potassium hydroxide supporting electrolyte the half-wave potential of lead shifts to -0.76 V.[4] Thallium can thus easily be determined in presence of lead. In the present communication a method will be described by which lead and thallium (ous) can be determined in presence of each other amperometrically without oxidizing thallous to thallic ion.

Apparatus and Experimental

Heyrovsky LP55 polarograph was used. The dropping mercury electrode had the following characteristics: $m=2.12$ mg./sec., $t=3.6$ sec. (at -1.0 V. vs. SCE in 0.1 M potassium nitrate solution).

All measurements were done at 20°C, purified hydrogen was used for the removal of dissolved oxygen.

All reagents employed were of A. R. grade. Purity of the samples was checked by standard methods.

Determination of Lead in Presence of Thallium Ion.—The principles involved in the method are as follows: (i) Tl^+ does not form a complex with potassium ferrocyanide[5] in concentrations below 0.1 M, but lead does at all concentration; and (ii) when a potential of -0.4 V. vs. SCE is applied to a solution containing both lead and thallium ion, it is the thallous ion which can be reduced.

Solutions of different strength containing Pb^{2+} and Tl^+ were prepared in 1 M potassium nitrate. One thousandth percent solution of triton×100 was used as maxima suppressor in the final solution. The mixture was titrated with a standard potassium ferrocyanide solution at an applied voltage of -0.4 V. vs. SCE. Hydrogen was passed after every addition. Titrations were performed both by the direct and reverse methods. The results are recorded in Tables I and II.

Discussion

It has been found that the results obtained by the direct and reverse titrations of thallium by potassium ferrocyanide suggest an excellent method of determining lead in presence of thallium in small concentrations (0.01 M Pb^{2+} in 0.05 M Tl^+). The concentration of the thallium ion should not go beyond 0.1 M, since it reacts with potassium ferrocyanide. At pH 11.5 it has been possible to determine thallous ion in presence of lead by titration with potassium chromate. Under these conditions lead does not interfere. It is possible to determine accurately as small as 0.005 M Tl^+ in 0.1 M of Pb^{2+}.

Summary

A method has been described in which thallium(I) can be determined in presence of lead and vice versa. Thallium is determined amperometrically in presence of lead at pH 11.5 and is titrated with potassium chromate, while lead is determined in presence of thallium by titrating with potassium ferrocyanide. It is possible to determine small amounts of lead in large quantities of thallium and vice versa.

*The Inhibitive Behavior of the Fluoride Ion and the Destruction of Its Protective Film in the Corrosion of Magnesium in Neutral Solutions**

By Goro WADA and Seihei MAEKAWA

(Received December 25, 1963)

Fluoride ions accelerate the corrosion rate of aluminum in a manner quite similar to that of other halide ions.[1] Iron is corroded in a dilute solution of potassium fluoride as well as in a solution of potassium chloride, but its corrosion is suppressed in a solution of potassium fluoride more concentrated than 0.8 N.[2,3] The inhibitive action of chromate ions on the corrosion of zinc is considerably strengthened by the addition of fluoride ions.[4,5] Now, in the case of magnesium, the fluoride ion has been known to be a good inhibitor and to exhibit a somewhat different behavior from that of such other ionic inhibitors as the chromate, bichromate and nitrate ions.[6] In this paper, a mechanism for the formation of protective films by the fluoride ions and their destruction by corrosive ions will be presented on the basis of electrochemical kinetics.

Experimental

Materials. — The magnesium metal used was obtained from the E. Merck Chemical Company, Darmstadt, Germany, in the form of a ribbon 3.18 mm. in average width, 0.26 mm. in average thickness, and 99.93% pure. The impurities, as found by spectrographic analysis,[7] are shown in Table I.

TABLE I. IMPURITIES IN MAGNESIUM (%)

Fe	Mn	Cu	Al	Si	Ca	Zn
0.017	0.014	0.005_1	0.002_0	0.003_5	0.0003_7	<0.01
Sn	Sr	Ni	Cr	V	Ti	Pb
<0.005	<0.005	<0.001	<0.001	<0.005	+	−

After a magnesium specimen was cut in an appropriate length, the connection to the leading wire was sealed completely by paraffin so as not to come in contact with the corroding reagent. The effective surface area of magnesium acting as an electrode was determined by a micrometer microscope, considering its surface to be flat enough, or its roughness factor to be unity, and disregarding the edge effect in the course of reaction. The magnesium was cleaned by acetone just before the measurements.

Polarization Characteristics of Magnesium in Various Solutions. — The stationary potentials of magnesium at various external current densities in several corrosion media are shown in Fig. 1. The anodic polarization curves in corrosive media, such as the aqueous solutions of potassium chloride and potassium bromide, are almost horizontal, while those in solutions containing inhibitive reagents, such as potassium nitrate, potassium chromate and potassium fluoride, are displaced towards nobler potentials and have steeper slopes; especially in the case of potassium fluoride, the curve is quite vertical and the anodic current is markedly retarded.

On the other hand, all the cathodic polarization curves are very similar to one another.

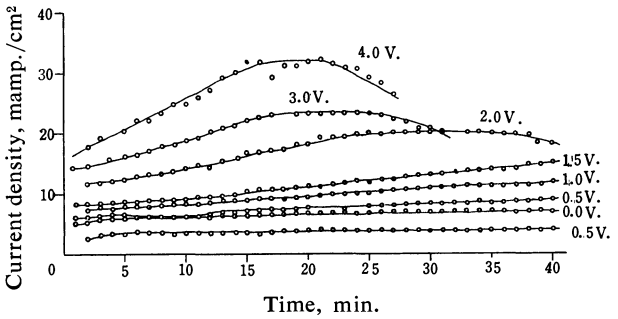

Fig. 2. Variations of anodic current densities with time at various potentials in a 0.001 N KCl solution at 20°C.

The Formation of Fluoride Films.—The inhibitive action of the fluoride ion on the corrosion of magnesium has been attributed to the formation of fine protective films composed of insoluble magnesium fluoride on the magnesium surface. Concerning this, the following facts were found in this experiment: a) 4.9 μg./cm^2 of the fluoride ion was deposited on the surface when magnesium was anodically polarized at 2 V. in a 0.1 N solution of potassium fluoride for 15 min., using a 0.1 N calomel electrode as the reference; b) 69.0 μg./cm^2 of the fluoride ion was also deposited when the magnesium was left alone in the same solution for 40 days. Provided that these amounts of deposited fluoride ions form homogeneous films of magnesium fluoride over the surface, their thicknesses would be about 280 Å in the case of a) and about 4000 Å in the case of b). In the experiment, the determination of small quantities of fluoride ion was carried out by the method of spectrophotometric titration using sodium alizarin monosulfonate.[8]

The quantity of electricity accumulated in the film during the 15 min. period was calculated to be about 0.03 coul./cm^2 from the observed current density-time relation,[9] while the theoretical quantity of electricity necessary to form the film in the case of a) is equal to about 0.025 coul./cm^2. Therefore, the current efficiency is nearly equal to unity for the formation of the magnesium fluoride film. Moreover, the result in the case of b) indicates that the magnesium fluoride film still continues to grow spontaneously by the diffusion of charged particles through the film, even in the natural, or externally unpolarized, state.[10]

The Destruction of Magnesium Fluoride Films by Corroding Reagents.—Figures 2 and 3 show the time variations in the potentiostatic external current densities observed at various electrode potentials

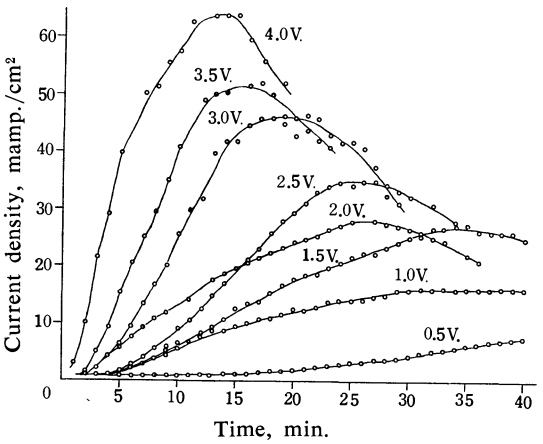

Fig. 3. Variations of anodic current densities with time at various potentials in a 0.001 N KCl+0.1 N KF solution at 20°C.

in the corrosive solutions, where magnesium had previously been covered with a magnesium fluoride film by treating it in a 0.1 N potassium fluoride solution under the same conditions as in the case of a) mentioned above.

In any case, the current density increases with time at the first stage, reaches a maximum, and then gradually begins to decrease. At the stage of increase, the destruction or the stripping of the magnesium fluoride film mainly occurs; at the stage of decrease, on the other hand, perhaps the surface is covered by the products of corrosion, the hydroxide of magnesium.

When fluoride ions coexist with chloride ions in the solution, the current density is rather larger than when the chloride ion alone is present. The fluoride ion itself must have the power to promote corrosion like other halide ions if magnesium fluoride were not insoluble.

Discussion

The Mechanism of Film Rupture.—As the fine film of magnesium fluoride covering the surface is quickly destroyed and stripped off by the attack of corrosive ions, the bare area of

8) W. P. Pickhardt, *Anal. Chem.*, 34, 863 (1962).

9) The electric current was quite large at the instant when magnesium was brought into contact with a 0.1 N potassium fluoride solution and afterwards reduced abruptly to an extremely low value.

10) Since the densities of magnesium fluoride and metallic magnesium are 3.17 and 1.74 g./cm^3, the atomic densities with respect to magnesium are 5.0×10^{-2} and 7.2×10^{-2} g.-atom/cm^3 respectively. Accordingly, there occurs as much as a 44% expansion in the volume of magnesium with the transformation from the metallic state into a magnesium fluoride film.

the surface, without the film, expands and, accordingly, the apparent current density increases. However, since the products of the corrosion, such as magnesium hydroxide soon begin to interfere with the contact of the bare area with the corroding reagent, the apparent current density begins to decrease after reaching its maximum. Now, if the fractions of three kinds of surface areas, namely the bare and those covered with magnesium hydroxide and magnesium fluoride, are denoted by s_1, s_2 and s_3 respectively, and if the true current densities at a certain potential, E, on the respective areas are denoted by i_1, i_2 and i_3, the following relations can be established, where I represents the averaged current density over the total surface:

$$s_1+s_2+s_3=1 \tag{1}$$

$$\frac{ds_1}{dt}+\frac{ds_2}{dt}+\frac{ds_3}{dt}=0 \tag{2}$$

$$I=s_1i_1+s_2i_2+s_3i_3 \tag{3}$$

$$\left(\frac{\partial I}{\partial t}\right)_E=i_1\left(\frac{\partial s_1}{\partial t}\right)_E+i_2\left(\frac{\partial s_2}{\partial t}\right)_E+i_3\left(\frac{\partial S_3}{\partial t}\right)_E \tag{4}$$

Judging from the nature of the surface, $i_1 \gg i_2$, and $i_3 \approx 0$. Therefore, Eq. 4 may be written as:

$$\left(\frac{\partial I}{\partial t}\right)_E=-i_1\left(\frac{\partial s_3}{\partial t}\right)_E-(i_1-i_2)\left(\frac{\partial s_2}{\partial t}\right)_E \tag{5}$$

In the cases as shown in Figs. 2 and 3, $s_1=s_2=0$ and $s_3=1$ at the beginning of the reaction, but s_1 has fluctuating values between zero and unity in the midst of the reaction and afterwards converges again to zero. Consequently, the slopes of the nearly straight lines appearing before and after the peaks in Figs. 2 and 3 are approximately expressed by Eqs. 6 and 7 respectively, and the condition corresponding to the maximum point is expressed by Eq. 8.

$$\left(\frac{\partial I}{\partial t}\right)_E \simeq -i_1\left(\frac{\partial s_3}{\partial t}\right)_E \quad \text{Initial stage} \tag{6}$$

$$\left(\frac{\partial I}{\partial t}\right)_E \simeq -(i_1-i_2)\left(\frac{\partial s_2}{\partial t}\right)_E \quad \text{Final stage} \tag{7}$$

$$-\left(\frac{\partial s_3}{\partial t}\right)_E \simeq \left(\frac{\partial s_2}{\partial t}\right)_E \quad \text{Maximum point} \tag{8}$$

The intrinsic anodic polarization characteristic curves for the respective kinds of areas are schematically shown in Fig. 4, where i_1 is, of course, by far the largest among the three throughout the whole range of the potential. The Tafel relation holds on the bare area as long as the potential is low, but i_1 gradually fails and reaches a saturation value which is controlled by the diffusion at the higher potentials.[11] The electrode potential on the mixed surface of the areas with different natures is denoted by E in Fig. 4, as "a compromise potential."[13]

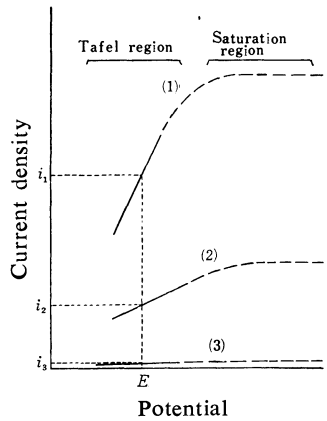

Fig. 4. Schematic diagram for the anodic polarization characteristic curves of different surface areas.
(1) Bare
(2) Covered with $Mg(OH)_2$
(3) Covered with MgF_2

Now, when the logarithms of the slopes of the initial and the final stages, $\log(\partial I/\partial t)_E$, in Figs. 2 and 3 are polotted against the potential, straight lines are obtained, as Fig. 5 shows. Therefore, recognizing that the potentials are high enough for i_1, i_2 and i_3 to be already saturated and hardly to vary with the potential, as can be seen in Fig. 4, the following relations can be derived:

$$R_F=\frac{A_F}{i_1}\exp\frac{\alpha_F FE}{RT} \tag{9}$$

$$R_O=\frac{A_O}{i_1-i_2}\exp\frac{\alpha_O FE}{RT} \tag{10}$$

where $R_F \equiv -(\partial s_3/\partial t)_E$, i.e., the rate of the destruction of the magnesium fluoride film; $R_O \equiv (\partial s_2/\partial t)_E$, i.e., the rate of the fomation of the magnesium hydroxide film; A_F and A_O are the characteristic constants; α_F and α_O are the transfer coefficients,[14] and F is the Faraday constant. Table II shows the transfer coefficients calculated from Fig. 5.

11) The anodic polarization curve of magnesium in a potassium chloride solution as shown in Fig. 1 is nearly horizontal. This was obtained by the steady-state method. If determination were performed on a fresh surface of magnesium by the rapid method, the curve should have a somewhat steeper slope in quite the same way as in the case of aluminum.[12]

Solution	α_F	α_O
0.001 N KCl	2.8×10^{-2}	0.41×10^{-2}
0.001 N KCl×0.1 N KF	2.3×10^{-2}	2.1×10^{-2}

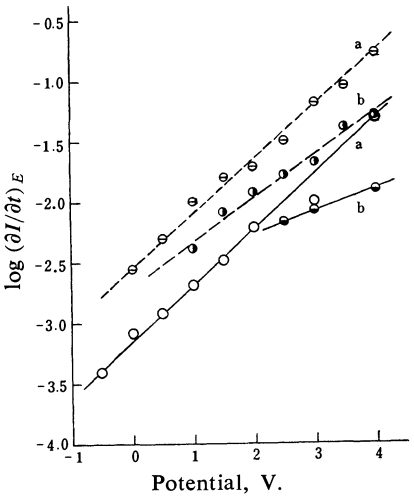

Fig. 5. Variations of $\log(\partial I/\partial t)_E$ of (a) the initial and (b) the final stages with the potential of magnesium.
—— 0.001 N KCl solution
---- 0.001 N KCl+0.1 N KF solution

In the reaction of the magnesium fluoride-film destruction, α_F's have values similar to each other irrespective of the presence of fluoride ions in the solutions, while in the magnesium hydroxide-film formation, the α_O's in the different solutions are quite different from each other. In the former reaction, a step which the existing ions do not seriously influence would be rate-determining, although it is not clear whether the reaction proceeds through a mechanical stripping-off of the film or through a chemical oxidation of fluoride ions. The films of magnesium hydroxide formed by the latter reaction, on the contrary, would all be different because of the adsorption of different ions.

The Activation Energy of the Destruction Reaction of the Magnesium Fluoride-film and That of the Cathode Reaction on the Same Surface.—The apparent activation energy of the reaction of the magnesium fluoride-film destruction at 0.5 V. in a 0.001 N KCl+0.1 N KF solution in the temperature range between 15 and 40°C was found to be nearly 19 kcal./mol. by plotting the logarithms of $(\partial I/\partial t)_E$ at the initial stage against the reciprocals of the temperature. This value is only one-fourth of the electron affinity of fluorine, 3.94 eV.[15] and seems to be too low if the destruction reaction involves a real electrochemical oxidation of fluoride ions. Therefore, it is probable that the destruction of the film is forced to occur through a mechanical stripping caused by the invasion of the corrosive reagent between the film and the metal. On the other hand, the apparent activation energies of the cathode reaction on the surface covered with magnesium fluoride, which had been formed beforehand in a 0.1 N potassium fluoride solution at 2.0 V. for 15 min., could be obtained from the temperature variations of the cathodic current density at −2.1V.; they are 3.0 kcal./mol. in a solution of 0.1 N potassium fluoride and 3.3 kcal./mol. in one KF 0.001 N KCl+0.1 N KF respectively.

As it could be ascertained that neither the reduction of Mg^{2+} ions nor the deposition of magnesium occurred at all through the magnesium fluoride film in the cathode reaction, it may be said, taking the very low values of both apparent activation energies into account, that the electric conduction through the film is not ionic but electronic. However, when the metal is polarized anodically, electricity is conducted through the magnesium fluoride-film neither by electrons nor by ions, in spite of the fact that the magnesium fluoride-film can grow by means of the diffusion of certain ions through the film, as has been mentioned. Thus the rectifying phenomenon by the magnesium fluoride-film can be recognized when the solution contains no other anions but fluoride ions.

Summary

Fluoride ions exhibit an anomalous inhibitive ability against the corrosion of magnesium; this may be attributed to the formation of a fine film of insoluble magnesium fluoride. This film conducts the cathodic current fairly well, but it conducts the anodic current not at all, as far as it is not destroyed. The cathode reaction through the magnesium fluoride film has a low apparent activation energy because of its electronic conduction, while, when magnesium is anodically polarized, the film is no longer electron-conductive and still permits to a lesser extent the diffusion of any other charged particles; consequently, this is a kind of rectifier in a solution containing potassium fluoride alone.

If a solution contains chloride ions in addition to fluoride ions, the matter is quite

15) "Kagaku Benran," Ed. by Chem. Soc. Japan, Maruzen, Tokyo (1952), p. 635.

different and fluoride ions rather promote the corrosion, like other halide ions. When magnesium, the surface of which has previously been covered with magnesium fluoride is anodically polarized in a solution containing only chloride ions or containing fluoride ions as well as chloride ions, the film soon begins to be destroyed at the initial stage, the bare area of high conductivity appears, and then the surface is gradually again covered with the bulky products, magnesium hydroxide, at the later stage. The destruction of the magnesium fluoride film may occur through a mechanical process regardless of the presence of fluoride ions.

The authors wish to thank Mr. Jujiro Nishijo, who helped in this investigation, and Dr. Nakaaki Oda of the Nippon Soda Co. Ltd. for his help in the special analysis of the magnesium sample.

Studies of Thio Acids. I. The Synthesis of Thiostearic Acid[*1]

By Yoshio HIRABAYASHI, Masateru MIZUTA and Tetsuro MAZUME[*2]

(Received December 26, 1963)

Many studies have been made of lower aliphatic thio acids, such as thioacetic acid and simple aromatic thio acids, and the knowledge recognized hitherto of the properties of thio acids has been mainly based on the properties of thioacetic acid or on those of thiobenzoic acid.[1,2] On the other hand, the studies of higher aliphatic thio acids have been very scanty, except for some short reports of the synthesis[3],[*3] of thiomyristic acid and thiopalmitic acid, and their properties have scarcely been studied at all.[4]

The authors made a series of studies for the purpose of obtaining extensive knowledge of higher aliphatic thio acids and examining the general properties of thio acids.

In this first paper of the present series, the synthesis of thiostearic acid from stearoyl chloride and sodium hydrogen sulfide will be described.

Stearoyl chloride prepared from stearic acid and thionyl chloride was added drop by drop into the ethanol solution of sodium hydrogen sulfide with heating. By the fractional crystallization of the crude product (Table I), thiostearic acid was obtained in the form of colorless crystals (m. p. 39.8~40.3°C), together with small amounts of distearoyl disulfide (m. p. 81.8~82.3°C), stearic acid, and ethyl stearate.

The separation of thiostearic acid from these by-products was achieved by fractional crystallization from petroleum ether or hexane; it was difficult to achieve by fractional distillation under reduced pressure or by fractional crystallization from other solvents.

The quantities of by-products depend upon the condition of the reaction. The yield of thiostearic acid was higher when the liquid temperature at dropping was higher, the time of dropping was shorter, the stirring was more vigorous, and the molar ratio of sodium hydrogen sulfide to chloride was larger. For example, the yields of thiostearic acid at the reaction temperatures of 40°C and 65°C were 25.2% and 53.3%[*4] respectively, other conditions being the same. The formation of ethyl

*1 Most of this study was presented at the 9th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1956.

*2 Present Address: Shimogamo-Kishimotocho, Sakyo-ku, Kyoto.

1) H. Gilman, "Organic Chemistry, An Advanced Treatise," Vol. I, John Wiley and Sons, Inc., New York (1949), p. 929.

2) D. S. Tarbell and D. P. Harrish, *Chem, Revs.*, **49**, 1 (1951).

3) V. Auger and M. Billy, *Compt. rend.*, **136**, 555 (1903).

*3 After the authors presented this study at the 9th Annual Meeting of the Chemical Society of Japan (1956), a report on thiostearic acid was found (F. J. Ritter, *Rubber Stickting, Delft, Commun.*, **No. 324**, 100 (1956); *Chem. Abstr.*, 50, 16168 (1956)). The synthetic method in the report corresponds well with the authors' method in this paper, but the melting point of the thiostearic acid obtained was reported to be 29~51°C, indicating the presence of an impurity.

4) K. S. Markley, "Fatty Acids," Intersience Publishers, Inc., New York (1947), p. 520.

*4 The yields were calculated for pure thiostearic acid separated from the crude product by recrystallization. If the sulfur contents (iodine method) in the crude product were attributed solely to thiostearic acid, the quantities of thiostearic acid in the crude product should be 72.2% and 90.9% respectively.

stearate made the separation of thiostearic acid difficult in fractional crystallization and gave a lower yield of thiostearic acid.

Distearoyl disulfide was obtained from the fraction with the higher melting point. Ethyl stearate was isolated from the mother liquor of the recrystallization of thiostearic acid by applying a method similar to the lead salt-alcohol method for the separation of solid fatty acids from liquid ones.

It is assumed that thiostearic acid and ethyl stearate were produced according to Eqs. 1—4 below and that distearoyl disulfide was produced as follows: in the preparation of a sodium hydrogen sulfide-ethanol solution, some sodium disulfide was produced, and then this reacted with stearoyl chloride to produce distearoyl disulfide.

$$RCOCl + C_2H_5OH \longrightarrow RCOOC_2H_5 + HCl \quad (1)$$

$$\left.\begin{array}{l} RCOCl + NaSH \longrightarrow RCOSH + NaCl \\ RCOSH + NaSH \rightleftarrows RCOSNa + H_2S \\ RCOSNa + RCOCl \longrightarrow RCOSOCR + NaCl \end{array}\right\} \quad (2)$$

$$\left.\begin{array}{l} 2\,NaSH \rightleftarrows Na_2S + H_2S \\ 2\,RCOCl + Na_2S \longrightarrow RCOSOCR + 2NaCl \end{array}\right\} \quad (3)$$

$$RCOSOCR + C_2H_5OH \longrightarrow RCOOC_2H_5 + RCOSH \quad (4)$$

$R = C_{17}H_{35}-$

The ultraviolet absorption spectrum of the obtained thiostearic acid in a cyclohexane solution is shown in Fig. 1, in which $\lambda_{max} = 221$ mμ and $\varepsilon_{max} = 1800$. An inflection is indicated at 260~280 mμ in the 0.1% solution,*5 but it is not observed in the 0.01% solution. In the infrared absorption spectra measured by the Nujol-mull method and by the potassium bromide-disk method (Fig. 2), an absorption band for the S–H group evidently appears at 2548 cm^{-1} as well as an absorption band for the C=O group at 1662 cm^{-1}, indicating that the synthesized thiostearic acid assumes the thiolic acid form; this is in accordance with the view of Sheppard[5] and Crouch[6] that thioacetic acid has the thiolic acid form.

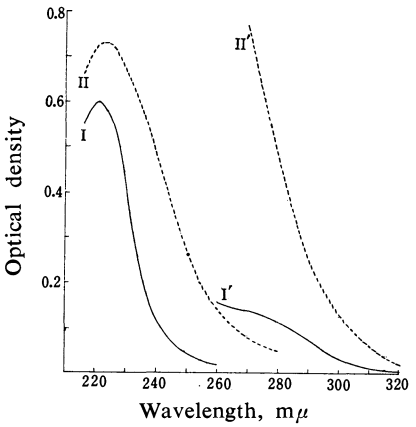

Fig 1. Ultraviolet absorption spectra of thiostearic acid (I, I') and distearoyl disulfide (II, II') in cyclohexane.
I, II, 0.01; I', II', 0.1% solution

Experimental

The Synthesis of Stearoyl Chloride.—Stearic acid (a product of the Nippon Yushi Co.) was recrystallized several times from methanol (neutralization value, 197.3; m. p. 70.0~70.5°C). When stearoyl chloride was synthesized by Ralston's process[7] from freshly-distilled thionyl chloride (85 g.) and stearic acid (105 g.), 100 g. of the fraction with the b. p. of 180~183°C/2.5 mmHg was retained.

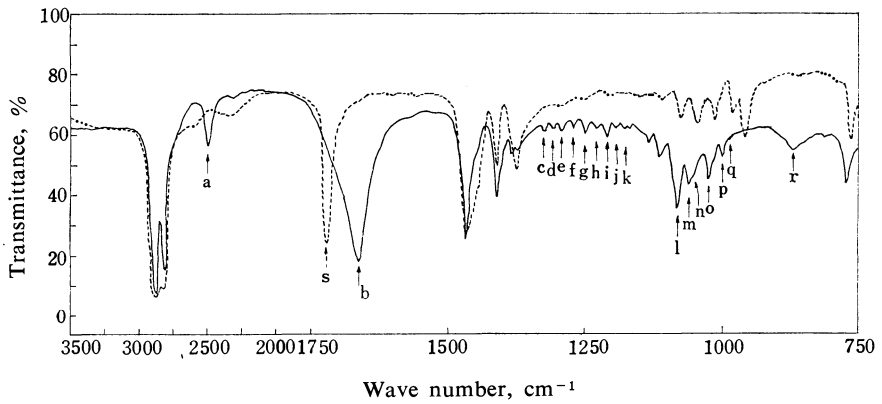

Fig. 2. Infrared absorption spectra of thiostearic acid (T) (——) in potassium bromide disk and distearoyl disulfide (J) (- - -) in Nujol mull.

*5 Ultraviolet absorption spectrum will be discussed later.

6) W. W. Crouch, *J. Am. Chem. Soc.*, 74, 2926 (1952).

7) A. W. Ralston and W. M. Selby, ibid., 61, 1019 (1939).

The Preparation of a Sodium Hydrogen Sulfide-Ethanol Solution. — Metallic sodium (10 g.) was dissolved in 150 ml. of absolute ethanol (previously distilled with the addition of metallic sodium), and then purified and dried hydrogen sulfide[8] was rapidly introduced into the solution until an excess of hydrogen sulfide was produced. The solution was colored a light yellow and was somewhat turbid.

The Synthesis of Thiostearic Acid.—Stearoyl chloride (31 g.) was vigorously stirred, drop by drop, into the above sodium hydrogen sulfide-ethanol solution at 40°C in 10 min. Then the mixture was refluxed on a water bath for 1 hr., followed by the separation of ethanol under a vacuum to obtain a white jelly residue. The residue was dissolved in 3 l. of water, acidified with dilute hydrochloric acid, and extracted with ether, and the ether layer was washed with water. An insoluble white matter suspended between the ether and the water was filtered off: 0.4 g. (A'). The ether layer was dried over anhydrous sodium sulfate, and the ether was expelled to obtain 27 g. of a crude product (light yellow colored; m. p. 32~34 °C; neutralization value 138.3; and sulfur content 7.7% (by the iodine method)). The crude product (23.0 g.) was recrystallized from hexane. The yields and melting points of several crystallization fractions are shown in Table I. These fractions were identified as follows:

TABLE I. YIELDS AND MELTING POINTS OF FRACTIONS OBTAINED BY RECRYSTALLIZATION OF CRUDE PRODUCT (23.0 g.)

Fraction	Yield, g.	M. p., °C
A	0.3	81.8~82.3
B	0.1	
C	1.1	69.5~70.0
D	1.6	51 ~55
E	5.8	39.8~40.3
F	4.5	31 ~35
G	8.4	30 ~31

(A): Obtained by the recrystallization of A' from benzene; colorless crystals.

Found: S, 0 (iodine method), 10.70 (Kitamura's method[9]). Calcd. for $C_{36}H_{70}O_2S_2$: S, 10.60%

This product did not show any depression in melting point when mixed with authentic distearoyl disulfide. Furthermore, the ultraviolet and infrared spectra of the two products were quite identical.

(C): Neutralization value 197.2. No depression in melting point was observed by mixing it with stearic acid.

(E): Colorless. Found: neutralization value 185.9; C, 72.03; H, 12.16; S, 10.57 (iodine method), 10.60 (Kitamura's method), 10.61 (Carius method). Calcd. for $C_{18}H_{36}OS$: neutralization value 186.7; C, 71.94; H, 12.07; S, 10.67%.

This fraction was thus identified as thiostearic acid $C_{17}H_{35}COSH$.

G): The neutralization value of 88.7, the sulfur content of 5.00% (iodine method) or 5.20% (Kitamura's method), and the melting point did not vary when recrystallization was repeated from hexane. A solution of this product (6 g.) in ethanol (20 ml.) was neutralized with a 0.1 N potassium hydroxide-ethanol solution. A soluton of lead acetate (0.4 g.) in ethanol (20 ml.) was added to the above solution, and the mixture settled for 3 hr. at room temperature. The solution was filtered, and then the filtrate was decomposed with dilute hydrochloric acid and extracted with ether; ethyl stearate (0.3 g.) was obtained: m. p. 33~34°C, saponification value 184.4. The precipitate was decomposed with dilute hydrochloric acid and extracted with ether to obtain a mixture of thiostearic acid and a small amount of stearic acid: m. p. 37.5~39°C, neutralization value 175.1, sulfur content (iodine method) 9.5%.

The Synthesis of Distearoyl Disulfide.—An iodine solution (0.1N) was added drop by drop into a mixture of thiostearic acid (3 g.) and ethanol (100 ml.) until coloring was observed; the reaction mixture was diluted by water, and the product (3 g.) was recrystallized from benzene to give 2.8 g. of the crystals with a m. p. of 81.8~82.3°C.

Found: C, 72.22; H, 11.83; S, 0 (iodine method), 10.70% (Kitamura's method). Calcd. for $C_{36}H_{70}O_2S_2$: C, 72.18; H, 11.78; S. 10.69%.

Infrared Absorption Spectra.—The infrared absorption spectra of thiostearic acid (T) and distearoyl disulfide (J) are shown in Fig. 2. A Hilger H-800 infrared spectrophotometer was used for measuring.

In T, the S-H stretching band is evidently indicated at 2548 cm^{-1} (a). The C=O stretching bands are indicated at 1662 (b) in T and at 1713 cm^{-1}(s) in J. In the spectrum of T measured by the potassium bromide disk method, absorption bands corresponding to the progression bands reported by Jones[10] appear at 1327(c), 1307(d), 1288(e), 1268(f), 1248(i), 1228(h), 1208(i), 1188(j) and 1172 cm^{-1} (k), but they are not evident in the spectrum measured by the Nujol mull method. Absorption bands appear at 1081(l), 1060(m), 1045(n), 1025(o), 996(p), and 977 cm^{-1} (q) in T, but their assignments are not evident. A low-intensity absorption band is indicated at 868 cm^{-1} (r) in T; this is probably due to the S-H group.

Ultraviolet Absorption Spectra. — They were measured by using a Shimadzu Quartz spectrophotometer, model QB-50, and silica cells (1 cm.).

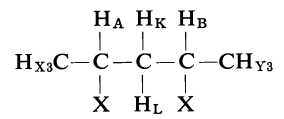
An Analysis of the NMR Spectra of the $ABKLX_3Y_3$ System



By Yuzuru FUJIWARA and Shizuo FUJIWARA

(Received December 27, 1963)

2, 4-Disubstituted pentane is often used as a model compound for vinyl-type polymers in investigating their physical and chemical properties. In the field of NMR, the analysis of the spectra of model compounds is of value in obtaining information concerning polymers. As disubstituted pentane has a much lower molecular weight than a polymer, the molecular motions are sufficient to give well-resolved spectra which permit unambiguous analysis. 2, 4-Disubstituted pentane has ten protons interacting with each other and belongs to the $ABKLX_3Y_3$ system. Analysis of the NMR spectra of this compound is simple in theory. However, the large number of included protons complicates the treatment. General formulas for NMR analysis are given for spin systems of three or less. For spin systems of four or more, the analysis is possible only in special cases or by numerical calculation. For the present analysis, the calculation was made by reducing the entire system to two six-spin systems and one four-spin system. The six-spin systems of the ABB'CC'D type[1] and the A_mBX_n type[2] were previously analysed, but the calculation of $AKLX_3$ type given below has not been previously reported.

The Analysis of $ABKLX_3Y_3$

2, 4-Disubstituted pentane has the following structure;

Suffixes have been assigned to protons. Though these ten protons interact with each other, the spin-spin coupling constants between methylene protons and methyl protons are likely to be negligibly small compared with the others and with the chemical shifts (as is the usual case), and it is not always necessary to consider all the protons in the calculation at the same time. This makes it possible to reduce the system to several simple subgroups. The specra of methyl protons are quite simple because they interact with only one methine proton, either H_A or H_B, and are of the AX_3 or BX_3 type. Methylene protons interact with two methine protons. Since they are not necessarily they are analyzed as the KL part in the ABKL system. Methine protons give the most complicated spectra to be analyzed since they are coupled with two methylene protons and three methyl protons. Therefore, this system is expressed as $AKLX_3$ or $BKLY_3$; the transitions concerned merely with A or B are taken into account. The calculation procedure was the usual one; the results are shown in Tables I to IV. The present calculation is confined to the case where the spin-spin coupling constants between methine and methylene protons are small compared with the corresponding chemical shift. Therefore, the large off diagonal terms are $H_{3,4}$, $H_{8,9}$, $H_{12,13}$, $H_{16,17}$, $H_{20,22}$ $H_{24,25}$, $H_{28,29}$, $H_{31,32}$, $H_{35,36}$, $H_{37,38}$, $H_{41,42}$, $H_{44,45}$, $H_{48,49}$, $H_{51,52}$, $H_{55,56}$ and $H_{59,60}$. The diagonalization of the energy matrix is effected by solving sixteen 2×2 determinants. The absence of a spin-spin coupling between methyl and methylene protons simplifies the spectrum, since it makes the parameters R_a, R_c, S_a, and S_c all equal, and R_b, R_d, S_b, S_d all equal.

Discussion

The spectrum of the KL part has an asymmetric form; the effect of the sings of the coupling constants and chemical shifts will now be discussed in relation to this spectrum. The change in sign of the geminal coupling constants between two methylene protons leads to the same spectrum because the resonance frequency and the intensity of the lines reverse themselves at the same time, so that the resultant spectrum remains identical. If the sign of the vicinal coupling constant between methine and methylene protons is reversed, the parameters C and the resonance position interchange between 1 and 4, and between 2 and 3, and no change in the resultant spectrum occurs, although the line assignment becomes different. These considerations enable one to conclude that the spectrum of the KL

$C_4=1/2[(\nu_{LK}+1/2J_{AK}+1/2J_{BK}-1/2J_{AL}-1/2J_{BL})^2+J^2_{KL}]^{1/2}$ $\theta_4=1/2\sin^{-1}J_{KL}/2C_4$

part does not contribute to the determination of the sign of the coupling constants through an approximation of this kind.

The sign of the chemical shift between K and L in a methylene group is determined when the relative magnitude of two vicinal coupling constants between methine and methylene protons are determined; i. e., the relative magnitude of the coupling constants decides the sign of the chemical shift. The change of the sign of the chemical shift results in an interchange of parameters between C_1 and C_4 and between C_2 and C_3, but the relative resonance positions are not altered, therefore the asymmetric spectrum is reversed against the field direction.

Another point of interest is that the present approximation makes the calculation fairly simple, though the application is limited to cases where the coupling constants between methine

and methylene protons are not very large compared with chemical shift. The perturbation method can be used in cases where the coupling constants are not very small but are still considerably smaller than the chemical shift. If the coupling constants are larger, a secular equation which includes determinants higher than 2×2 must be solved.

The present treatment may be applied to pentanes substituted by electronegative atoms or groups, such as halogens and OH, but it is not suitable for those groups which do not affect the electron density or the magnetic state surrounding methine hydrogen.

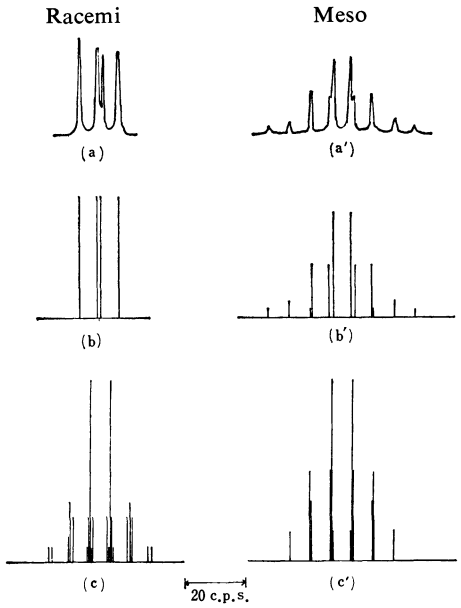

Fig. 1. NMR Spectra of 2,4-dichloropentane.
(a) and (a') : methylene spectra observed at 60 Mc.[3]
(b) and (b') : calculated methylene spectra
(c) and (c') : calculated methine spectra.

Example

The NMR spectra of 2,4-dichloropentane were analysed using the spin-decoupling technique[3]. This compound has two isomers (racemic and meso) and shows two corresponding spectra. The spectra of methylene protons and the results of analysis are shown in Fig. 1 and Table V respectively, where chemical shifts between methylene protons are estimated from the decoupled pattern with the assumption that the spin coupling constants between methylene protons are the same for both isomers.

The calculated spectra with the values in Table V are compared with the observed ones in Fig. 1.

Table V. Chemical shifts and coupling constants of 2,4,-dichloropentane

	Chemical shift ν_{LK}, c.p.s.	Coupling constant c.p.s.		
		CH_3-CH	CH_2	CH_2-CH
Racemi	0	6.7	14.5	5.8 7.1
Meso	15.6	6.7	14.5	7.0

The agreement of the methylene spectra is quite satisfactory. L=K for racemic compound and K≠L for meso one. The calculated spectrum of the methine proton in the racemic compound is more complicated than the simple sextet which appears for the meso compound. This is also in good agreement with the experimental results reported.[3] Another example of K≠L will be given in a succeeding paper.[4]

Added in Proof: Calculated spectrum of Fig. 1b was constructed from the values in Table V. Same spectrum can be obtained by using another set of parameters, $\nu_{LK}=0$, $J_{AK}=J_{BL}=10.8$ and $J_{AL}=J_{BK}=2.2$. In the latter case, Fig. 1c, should be replaced with a figure of different shape, that is also a complex sextet. The set seems to be a more plausible one.

The NMR Spectra of the Acetal of 2, 4-Pentanediol

By Yuzuru FUJIWARA and Shizuo FUJIWARA

(Received December 27, 1963)

2, 4-Pentanediol is a model compound of polyvinylalcohol (PVA), with the lowest molecular weight among this series and with optical isomers corresponding to the stereoregularity of the polymer. It has been shown, through a comparison of the reaction rate of the meso type of 2, 4-pentanediol (which corresponds to isotactic PVA) with that of the racemic type (which corresponds to syndiotactic PVA), that the rate of acetal formation from PVA and acetaldehyde depends upon the stereospecificity. The rate of the formation of the racemic acetal is about 20 times that of the meso type.[1] The reaction rate of PVA is of the same order as that of pentanediol, according to its tacticity. In determining the difference in reaction rates, two kinds of acetal were separated by gas chromatography and identified by NMR. The identification of these compounds was straightforward. A process for calculating the energy levels and transition probabilities of the $ABKLX_3Y_3$ system has been developed.[2] This process made it possible to accomplish the complete analysis of the NMR spectra of the compounds. Through this analysis, spin-spin coupling constants and chemical shifts are obtained, as well as information concerning the structures and conformations of the acetals.

Experimental

Acetal was formed by adding *p*-toluene sulfonic acid to a solution of 2,4-pentanediol and acetaldehyde at 60°C. After the water had been eliminated, the product was distilled. The acetal was allowed to pass through a gas chromatographic column 4 mm. in diameter and 2 m. long which was maintained at 100°C, using hydrogen as a carrier gas. This column was filled with Shimadzu DOP-A. The two species of acetal were completely separated. The first fraction was designated f_1, and the second one, f_2. The NMR spectra were measured at 60 Mc./sec. and 40 Mc./sec. at room temperature. The positions of spectral lines and coupling constants were determined by the usual side-band method.

Results and Discussion

The NMR spectra of f_1 and f_2 are shown in Fig. 1, and all lines have been assigned as shown, with consideration given to the position and the shape. f_1 has two doublets of methyl protons, one being about twice the size of the other, while f_2 has three doublets with almost equal intensity. Two different structures of acetal are formed in accordance with the structures of pentanediol (Fig. 2). Structure I comes from the meso type, and structure II, from the racemic type. Structure I has two methyl groups in equatorial positions at 4 and 6 carbons and one at 2 carbon. Structure II has one equatorial methyl group at 6, one axial methyl group at 4 and one at 2; i. e., the three methyl groups are not equivalent. This suggests that f_1 has structure I and f_2 has structure II. This identification is confirmed through the analysis of protons other than methyl groups.

The spectra of methine and methylene protons were analyzed by the method previously described;[2] the results are shown in Table I.

TABLE I. COUPLING CONSTANTS AND CHEMICAL SHIFTS FOR $ABKLX_3Y_3$ SYSTEM

	(A=B X=Y)		(A≒B X≒Y)	
	60 Mc.	40 Mc.	60 Mc.	40 Mc.
$\lvert J_{AK} \rvert$	10.73	10.73	11.26	11.26
$\lvert J_{AL} \rvert$	2.62	2.62	3.06	3.06
$\lvert J_{AX} \rvert$	6.20	6.20	6.14	6.14
$\lvert J_{KL} \rvert$	13.06	13.06	12.70	12.70
ν_{LK}	21.32	14.21	−25.94	−17.29
ν_{BA}	0	0	16.22	10.81
$\lvert J_{BK} \rvert$	10.73	10.73	7.02	7.02
$\lvert J_{BL} \rvert$	2.62	2.62	0.58	0.58
$\lvert J_{BX} \rvert$	6.20	6.20	6.80	6.80

in c.p.s.

The coupling constants and chemical shifts obtained were confirmed by comparison with the observed and calculated spectra at 60 and 40 Mc./sec. as shown in Figs. 3 to 6. Though some combination lines are missing because of their low intensity, the agreement is quite satisfactory. It is shown that, as expected, A is equivalent to B and X to Y for

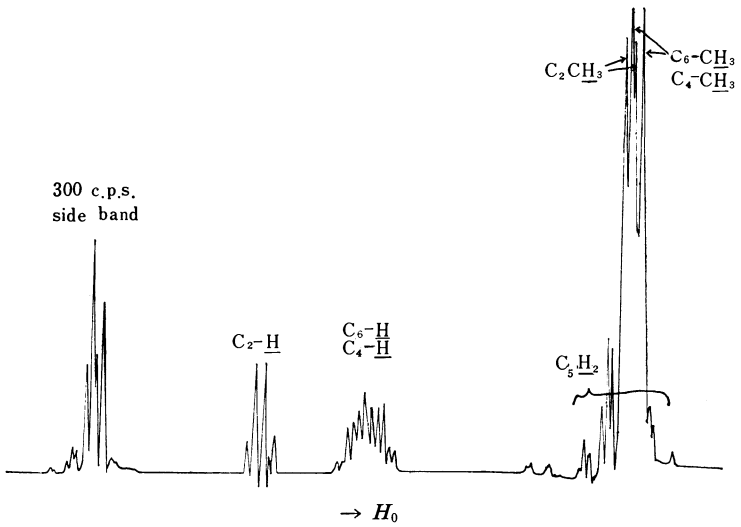

Fig. 1. a) NMR spectra of f_1 at 60 Mc./sec.

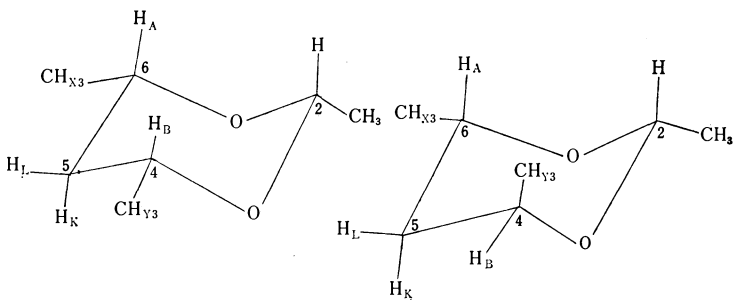

Fig. 2. Structures of acetals of 2,4-pentanediol.

f_1, but that A is not equivalent to B and X not to Y for f_2. It is noted that $J_{BK} \neq J_{BL}$ for f_2. Contrary to this finding, the structure suggests that $J_{BK}=J_{BL}$, because both couplings are vicinal ones in the gauche position. The discrepancy may result from strain in the structure caused by an outward slanting of the axial methyl. ν_{LK} is expected to be smaller for structure II than for structure I. However, experimental results show that the ν_{LK} for f_2 has a larger absolute value than f_1 and that the sign is negative. J_{AK} is quite large compared with J_{AL}, and it is not unlikely that both A and K are axial protons. Therefore the negative value of ν_{LK} means that the axial proton at 5 carbon appears at a lower field

than the equatorial one. This may be attributed partly to the structural strain mentioned above, and partly to the difference in magnetic anisotropy between oxygen and carbon. There is a slight possibility of missassignment of the spectrum due to one spectrum of this system being partly hidden by the large methyl signal, leading to such an apparent anomaly.

The methyl group at 2 is supposed to be equatorial, since if two kinds of methyl groups are positioned at 2 carbon, the methine proton at 2 must give two quartets; this is contradictory to the experimental findings.

A possible exchange between two chair forms is excluded by the fact of a large difference in the chemical shifts and coupling contants of the methylene protons, K and L; any such exchange would make the two protons nearly equivalent. This has been confirmed also by the temperature effects on the spectra. 1, 3-Dioxane undergoes ring inversion at temperatures higher than $-80°C$.[4] For 4, 4-dimethyl-1, 3-dioxane the incipient temperature is about $-50°C$.[4] 2, 4-Pentanediol-acetal (2, 4, 6-trimethyl-1, 3-dioxane) is supposed to have a higher incipient temperature because of high structural hindrance. The temperature change from $-77°C$ to $+150°C$ does not effect any change in the spectra of 2, 4, 6-trimethyl-1, 3-dioxane except for slight changes in the chemical shift. The same reasons may be given to explain the exclusion of the boat form of f_2.

As f_1, it can be said that only one stable form exists; this seems to be a chair form with all methyl groups in quatorial positions. This conclusion is consistent with energy considerations and with the structure of paraacetaldehyde.[3]

The authors wish to thank Messrs. Osamu Yamamoto of the Government Chemical Industrial Research Istitute, Shoichi Hayashi of The Institute of Physical and Chemical Research, and Naohiro Hayakawa of the Japan Atomic Energy Research Institute for their aid in obtaining the NMR spectra. They also wish to thanks Dr. Kiyoshi Fujii of the Kurashiki Rayon Co., Ltd., for preparing the samples.

A Study of the Reaction between Nitrosobenzene and the Grignard Reagent

By Kazuhiro MARUYAMA*

(Received January 25, 1964)

Although the ionic mechanism has generally been assumed for most Grignard reactions, it has been shown, as will be described below, that free radicals can be observed during the course of the reaction between nitrosobenzene and a Grignard reagent by the electron-spin resonance (ESR) technique. The reaction between nitrosobenzene and phenylmagnesium bromide was the subject of an extensive investigation by Wieland and his co-workers about fifty years ago,[1] and this reaction has been established as the usual synthetic method of diphenylhydroxylamine.

The present investigation is concerned mainly with reactions between nitrosobenzene and phenylmagnesium bromide, between *p*-nitrosotoluene and phenylmagnesium bromide and between nitrosobenzene and *p*-tolylmagnesium bromide. The free radical species produced during the reactions were determined from the hyperfine structures of their ESR spectra. The equilibrium among the reaction products will be discussed below.

Experimental

ESR Measurements.—An ESR spectrometer with an X-band and a 100 Kc. modulation was used in this work. The ESR measurement of the reaction
