The Permeabilities of Hydrogen, Sodium and Calcium Ions in Mixed Solvents across Ion-exchange Membranes

By Manabu SENŌ and Takeo YAMABE

(Received July 19, 1963)

The ion-exchange equilibria in mixed solvents exhibit some different behaviors from those in aqueous solutions. For example, the selectivity coefficient, K_H^{Na}, of the ion exchange of sodium for hydrogen ions increases remarkably with the decrease in the dielectric constants of the media.[1,2] On the other hand, it has been revealed that the selective permeability of ions across ion-exchange membranes is primarily ruled by the concentrations and the mobilities of ions in the membrane phase.[3,4] In this paper, the permeabilities of hydrogen, sodium and calcium ions across ion-exchange membranes in mixed solvents will be examined and discussed. The aim of this investigation is to disclose the behavior of ions in mixed solvents and to give some information on the mechanism of the ion transportation across the membranes.

Experimental

The electrodialysis apparatus is a cell with two compartments separated by a cation-selective membrane and equipped with silver-silver chloride electrodes. The solvent systems examined were water-methanol, water-ethanol and water-acetone, from which the sample solutions were prepared by adding nearly the same equivalent quantities of two kinds of chlorides, hydrogen chloride-sodium chloride, sodium chloride-calcium chloride. The total concentration was nearly 0.1 N. The membranes used were heterogeneous, prepared from pulverized ion-exchange resins (Amberlite IR-120), poly(vinyl chloride), dioctyl phthalate and cyclohexanone.

The electrodialyses were carried out for 90, 60 and 30 min. under the current densities of 5, 10 and 30 mA/cm^2, respectively. From the analytical data for sample solutions, the coefficient, T_B^A, of the permselectivity of ion A for ion B are calculated by

$$T_B^A=\left(\frac{m_A}{m_B}\right)\Big/\left(\frac{C_A}{C_B}\right)$$

where m is the quantity of ions transferred across the membrane and C is the mean concentration in the compartment from which ions flow out. In these calculations, the effect of the concentration diffusion has been disregarded, based on the results of the preliminary experiments.

The electric conductivity of the membranes in each ionic form was measured by the use of a universal bridge, Yokogawa BV-Z-103B. The method, each membrane being sandwiched directly between two mercury electrodes, was employed.

Results and Discussion

The experimental results are shown in Figs. 1 and 2. The premselectivity coefficients, T_{Na}^H

and T^{Ca}_{Na}, decrease upon the addition of the organic solvents. The decrease is approximately linear with the increasing contents of the organic solvents, but it shows a tendency to converge to a limiting value at higher organic contents, especially in the water-ethanol system.

The increase in the current densities decreases the permselectivity coefficients, T^{H}_{Na} and T^{Ca}_{Na}. The effect is pronounced at the lower current densities. An example is shown in Fig. 3.

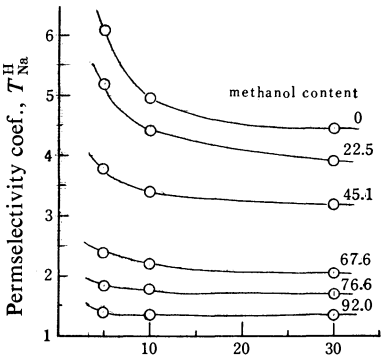

Fig. 3. Dependence of T^{H}_{Na} on current densities.

It is considered that the transport of ions across ion-exchange membranes is effected by both the number of movable ions and the mobility of the ions in the membrane. That is, the coefficient of the permselectivity, T^{A}_{B}, is split into two terms, the mobility terms and the concentration term:

$$T^{A}_{B}=\left(\frac{\bar{u}_A}{\bar{u}_B}\right)\left(\frac{\bar{C}_A}{\bar{C}_B}\Big/\frac{C_A}{C_B}\right)$$

It may readily be shown that, in the limiting region of the lowest current densities, the concentration term approaches the separation factor, S^{A}_{B}, of the ion-exchange equilibria. Moreover, the conductivity ratio, $\kappa_{ACl}/\kappa_{BCl}$, estimated from the electric conductivity of the membranes in each ionic form should be nearly equal to the mobility ratio, if all the ions in the membrane are active in the transportation. The measured values of the separation factor and the conductivity ratio and the product of these values are shown in Tables I and II.

The product, $S^{A}_{B}\cdot\kappa^{A}_{B}$, has characteristics similar to those of T^{A}_{B}. It is considered that the quantitative disagreement between the two values is largely due to the facts that, firstly, the true equilibrium is not attained in the transport process and, secondly, the conductivity ratio estimated from the conductivities of the membranes in each ionic form does not give the true values in the mixture systems. The former results in a concentration ratio nearer to unity, while the latter results in a conductivity ratio nearer to unity, because the slower ions are

accelerated by the faster ions and vice versa. The effect of partial immobilization pointed out by the present authors[3] is included in the conductivity ratio.

When an ion in the membrane phase has a stronger attractive interaction with the membrane matrix, the concentration of this ion in the membrane phase is higher and its mobility is lower. The concentration and the mobility terms have the opposite effects on the permselectivity.

The decrease in the separation factors, S_{Na}^{H} and S_{Na}^{Ca}, shows that the attractive interaction of hydrogen and calcium ions with the resin matrix becomes smaller than that of sodium ions upon the addition of the organic solvents. This is probably caused by the decrease in the dielectric constant, which results in stronger electrostatic interaction for the smaller hydrated ions. Thus, the permselectivity is in the order $H \gg Ca > Na$ in aqueous solutions, and in the order $H > Na > Ca$ in mixed solvent solutions. This behavior is observed more clearly in solutions with the higher contents of organic solvents or with the solvent of the lower dielectric constant.

The effect of the partial immobilization gives the complicated feature to the conductivity ratio. In the present investigation, the decrease in the conductivity ratio upon the addition of the organic solvents seems to be primarily a result of the partial immobilization. Further investigation is required in this respect.

Under the present experimental conditions, the hydrated state of ions seems not to be affected greatly by the addition of the organic solvents, except for the addition of methanol over 80 percent, where the concentration term changes reversely and the decrease in the permselectivity becomes small.

Microwave Spectrum of s-Trioxane

By Takeshi OKA, Katsura TSUCHIYA, Suehiro IWATA and Yonezo MORINO

(Received July 27, 1963)

The microwave spectrum of formaldehyde in the ground vibrational state has been extensively studied.[1,2] In order to analyze the microwave spectrum of formaldehyde in the excited vibrational states, however, it is necessary to observe weak spectral lines. *s*-Trioxane is the cyclic trimer of formaldehyde; microwave investigation of this molecule was first started because it was suspected to exist as an impurity in the sample of formaldehyde evolved by heating paraformaldehyde vapor. After making some measurements, this possibility has been eliminated. No trace of *s*-trioxane line was observed in the formaldehyde sample. However, rather strong spectral lines were observed for pure *s*-trioxane, and the spectroscopy has been continued to determine the molecular structure, the dipole moment and the vibration-rotation constants in the excited vibrational states of this molecule.

A preliminary report on the microwave spectrum of this molecule was published by Amble in 1951,[3] but no other work seems to have been reported. The molecular structure of *s*-trioxane has been examined by electron diffraction.[4] There are also vibrational and dipole moment studies of this molecule.[5] These previous works report that the *s*-trioxane molecule is a chair-form symmetric top both COC and OCO angles nearly tetrahedral.

Experimental

s-Trioxane was prepared by heating paraformaldehyde and dilute sulfuric acid in an oil bath.[6] The product was purified by sublimation. A commercially-available sample was also used. Purified *s*-trioxane is a colorless crystalline compound and is stable. The vapor pressure is large enough to observe the spectral lines at room temperature, but measurement at dry-ice temperature was impossible because of the low vapor pressure of the sample. The spectrograph used was a conventional one, with 100 kc. Stark modulation.

Spectrum

s-Trioxane is an oblate symmetric top, and the R-branch transitions, $J=1\leftarrow0$, $2\leftarrow1$ and $3\leftarrow2$, fall in the centimeter-wave region. Although this molecule is rather heavy and has low frequency vibrations, it gives fairly strong spectral lines because of the large dipole moment and so the spectral lines of ^{13}C isotopic species could be observed in the natural abundance. The dipole moment is directed along the axis with the largest moment of inertia, and c-type transitions are observed for the isotopic species.

TABLE I. OBSERVED FREQUENCIES OF *s*-TRIOXANE (IN Mc./sec.)

Transition	Observed frequency
$(^{12}CH_2{}^{16}O)_3$	
$J=1\leftarrow0$	10546.46 ± 0.05
$J=2\leftarrow1$	21092.97
$J=3\leftarrow2$	31639.36
$(^{12}CH_2{}^{16}O)_2(^{13}CH_2{}^{16}O)$	
$3_{30}\leftarrow2_{20}$	31354.0 ± 0.2
$3_{21}\leftarrow2_{11}$	31203.0 ± 1

The observed frequencies are listed in Table I. The assignment of the $3_{30}-2_{20}$ transition was confirmed by the Stark behavior of the line. The $3_{21}-2_{11}$ transition was measured with rather large uncertainty because of the weakness and the large Stark shift of the line. The $3_{31}-2_{21}$ transition could not be separated from the excited vibrational lines of the normal

∠OCO	111°10′±1°	109°	110°±1°	112°±3°

species. Weak lines with $K=2$ were not observed. The rotational constants have been determined from these frequencies, as Table II shows.

Molecular Structure

If the position of the six hydrogen atoms relative to the carbon atoms and the C_{3v} symmetry are assumed, the molecular structure of *s*-trioxane is expressed by three independent parameters. They have been determined by using the rotational constant, B, of the normal species and A and B of the ^{13}C isotopic species. It was assumed that the hydrogen atoms are attached to the carbon atoms at the tetrahedral angle, with three hydrogen-carbon bonds parallel to the symmetry axis. The carbon-hydrogen distance was assumed to be 1.09±0.005 Å. The coordinate system are taken so that the symmetry axis coincides with the z axis and one carbon atom (C_1) lies in the xz plane (Fig. 1).

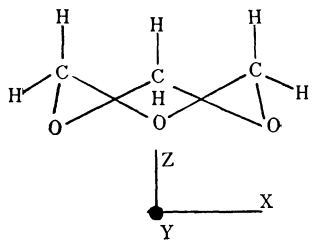

Fig. 1. The *s*-trioxane molecule.

The x and z coordinates of the carbon atom, C_1, have been determined by the substitution method[7] from the formula:

$$z^2_{C_1}=\frac{\Delta I_{aa}}{\mu}\left[1-\frac{\Delta I_{bb}-\Delta I_{aa}}{I_{aa}-I_{cc}}\right]$$

$$x^2_{C_1}=\frac{\Delta I_{bb}-\Delta I_{aa}}{\mu}\left[1+\frac{\Delta I_{aa}}{I_{aa}-I_{cc}}\right] \quad (1)$$

where ΔI_{aa} and ΔI_{bb} are the changes in the moments of inertia due to the isotopic substitution and $\mu=M\Delta C/(M+\Delta C)$, with M the total mass and ΔC the difference between the masses of ^{12}C and ^{13}C. There is no experimental data for I_{cc}, but, since the latter term in the bracket of Eq. 1 is much smaller than one, the value of I_{cc} calculated from a reasonable structure was used.

The z coordinates of the oxygen atoms have been determined from the condition of the center of gravity;

$$m_C z_C+m_O z_O+m_H(2z_C+2/3r)=0 \quad (r=1.09) \quad (2)$$

The x coordinate of the oxygen atom, O_1, is determined from the moment of inertia of the normal species by the formula:

$$I_{bb}=3\,[m_C(x^2_{C_1}/2+z^2_{C_1})+m_O(x^2_{O_1}/2+z^2_{O_1})+m_H(x^2_{C_1}+2\sqrt{2x_{C_1}}r/3+2z^2_{C_1}+4z_{C_1}r/3+14r^2/9)] \quad (3)$$

The molecular structure thus determined is shown in Table III, together with the previous results.

The uncertainty of the molecular structure was estimated from the probable error of the experimental rotational constants and the uncertainty in the assumed hydrogen parameters. Although the uncertainty in the z coordinate is rather large, it is reduced in the C–O bond length and COC and OCO angles. The COC angle is smaller than the OCO angle by about 3 degrees. The C–O distance is shorter than the corresponding distances in trimethylene oxide (1.449±0.002 Å[8]) and methanol (1.434 Å[9]), but it is close to that of dimethyl ether (1.410±0.003 Å[10]).

Excited Vibrational States

In addition to the spectral lines of *s*-trioxane in the ground vibrational state, many vibrational satellites were observed, as shown in Table IV and Fig. 2. They were found to be the rotational lines of molecules in the excited states of four normal vibrations. Two of them were assigned to the degenerate E species, since they clearly showed l-type doubling. The l-type doubling constants, q_l, were determined from the splitting, as is shown in Table V. These two vibrations come from the COC and OCO bending vibrations, with a strong coupling with the torsional motion. They are named $\nu_E(1)$ and $\nu_E(2)$, as shown in Fig. 2. Since the frequency of $\nu_E(1)$ is

TABLE IV. OBSERVED FREQUENCIES OF *s*-TRIOXANE IN THE EXCTED VIBRATIONAL STATES (IN Mc./sec.)

Vibrational assignment	$J=1\leftarrow0$	$J=2\leftarrow1$	$J=3\leftarrow2$
$v_E(2)=1$	10553.76	21108.28	31699.4* 31661.95 31623.8*
Ground state	10546.46	21092.97	31639.36
$v_E(1)=1$	10536.17	21086.47* 21072.67 21057.47*	31633.1* 31609.4 31582.8*
$v_E(1)=2$	10526.46	21052.97	31579.3
$v_E(1)=3$	10517.21	21033.65	31550.0
$v_A(1)=1$	10520.73	21040.89	31561.0
$v_A(2)=1$		21025.73	31536.8

Experimental errors for the frequencies of the ground state and $v_E(1)=1$ state are 0.1 Mc./sec. For the weaker transitions except l-type doublets, the experimental errors are 0.6 Mc./sec. For the l-type doublets the experimental errors are larger. It is possible that experimental errors are as large as 2 Mc./sec.

* l-Type doublets

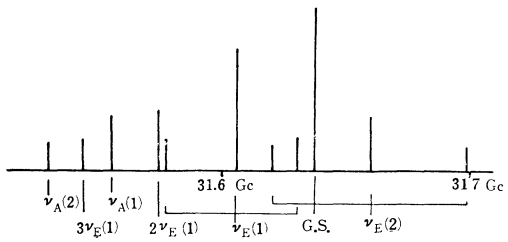

Fig. 2. $J=3\leftarrow2$ transition of *s*-trioxane.

small, the excited states up to $v_E(1)=3$ have been clearly observed. Up to $v_E(1)=3$, there is no indication of the inversion of the ring and the spacings between the satellites are normal.

The other two satellites must be assigned to the totally symmetric A_1 species, since no more low frequency degenerate vibration is expected. One of them, named $\nu_A(1)$, is fairly strong; it is evident that it corresponds to the totally symmetric vibration with the lowest frequency. The other one is rather weak and appears far from the ground state line. It is probable that the line corresponds to another totally symmetric vibration, but we cannot disregard the possibility that this might be due to the $\nu_A(1)+\nu_E(1)$ state. The values of α and q_l for the various vibration are listed in Table V.

TABLE V. MOLECULAR CONSTANTS FOR THE EXCITED STATES (IN Mc./sec.)

Vibrational state	B_v	α_s	q_l
$v_E(2)=1$	5276.95	− 3.72	7.50
$v_E(1)=1$	5268.16	4.95	12.60
$v_E(1)=2$	5263.23		
$v_E(1)=3$	5258.45		
$v_A(1)=1$	5260.25	12.98	
$v_A(2)=1$	5256.28	16.95	

Statistical Spin Weights of the Rotation-vibrational States

The statistical spin weights of the rotational state of symmetric top molecules in the ground vibrational state has been worked out by Wilson.[11] In order to ascertain the statistical spin weights of the rotation-vibrational states of symmetric top molecules, it is necessary to extend his theory.

The rotational subgroup for the molecule with C_{3v} symmetry is C_3, the character table of which is shown in Table VI. Since ^{12}C and ^{16}O are Bose particles with spin zero, the symmetry of the spin-wave function of *s*-trioxane is determined solely from the hydrogen atoms. It can be shown, by directly applying Wilson's method,[11] that the wave function of *s*-trioxane has the symmetry of $24A+20(E_1+E_2)$. The symmetry of the rotational wave function is classified by the value of K as:[11]

TABLE VI. CHARACTER TABLE FOR C_3 SYMMETRY

C_3	E	C_3	C_3^2
A	1	1	1
E_1	1	$e^{2\pi i/3}$	$e^{4\pi i/3}$
E_2	1	$e^{4\pi i/3}$	$e^{2\pi i/3}$

$$K=0 \qquad (2J+1)A$$
$$K=3p\,(p\neq0) \qquad 2(2J+1)A$$
$$K=3p+1 \qquad (2J+1)E_1$$
$$K=3p-1 \qquad (2J+1)E_2$$

In discussing the symmetry of rotation-vibrational states, K is the quantum number for the total angular momentum along the symmetry axis, including the vibrational angular momentum. The symmetry of the vibrational part of the wave function which is multiplied to the rotational wave function can be specified by l, the quantum number of the vibrational angular momentum along the symmetry axis, as follows:[12,13]

$$l=0 \qquad A$$
$$l=3p\,(p\neq0) \qquad 2A$$

11) E. B. Wilson, Jr., *J. Chem. Phys.*, 3, 276 (1935).
12) L. D. Landau and E. M. Lifshitz. "Quantum Mechanics Non-Relativistic Theory," Addison-Wesley Publishing Company, Reading, Massachusetts.
13) J. T. Hougen, *J. Chem. Phys.*, 37, 1433 (1962).

$$l=3p+1 \qquad E_2$$
$$l=3p-1 \qquad E_1$$

The symmetry of the total rotation-vibrational wave function, including spin, can be obtained by taking a direct product of these three parts.

Any operation in the C_3 point group applied to the trioxane molecule corresponds to an even exchange of the nuclei, so the total wave function must be totally symmetric. Thus, the spin weights of the states are derived as shown in Table VII.

Table VII. Spin weight for the rotation-vibrational states of *s*-trioxane

	$K=0$	$K=3p$	$K=3p+1$	$K=3p-1$
$l=0$	24	48*	20	20
$l=3p$	48*	96*	40	40
$l=3p+1$	20	40	24*	20
$l=3p-1$	20	40	25	24*

* These states may show doubling if some terms in the vibration rotation Hamiltonian are large.

Low Frequency Vibrations in *s*-Trioxane

Since the spin weight of each quantum state has been obtained, it is possible to estimate the frequencies of the low frequency vibrations *s*-trioxane from the observed relative intensities of the vibrational satellites. The relative intensities were measured for the three transitions, $J=1\leftarrow0$, $2\leftarrow1$ and $3\leftarrow2$, but the data from $J=1\leftarrow0$ gives the most reliable value because of the simple Stark effect. The frequencies thus obtained are listed in Table VIII, together with the infrared results. Because of the rather large experimental errors in the intensity measurement, the uncertain in the vibrational frequencies are large. However, the assignment is in agreement with the infrared results for the lowest three frequencies. The frequency of $\nu_A(2)$ has not yet been definitely determined.

Table VIII. Low frequency vibrations of *s*-trioxane (in cm^{-1})

	Present work	Stair and Nielsen
$\nu_E(1)$	290 ± 40	307
$\nu_E(2)$	490 ± 30	472
$\nu_A(1)$	470 ± 30	524
$\nu_A(2)$	650 ± 100	748

Thermal Decomposition

In order to test the thermal stability of *s*-trioxane, the absorption cell was heated to about 250°C, but no trace of a formaldehyde line was observed. The observation was accomplished by using the $32_{5,27}\leftarrow32_{5,26}$ transition line of formaldehyde, which comes close to the $J=1\leftarrow0$ line of *s*-trioxane.[1] It can be said, therefore, that *s*-trioxane is stable up to this temperature.

Dipole Moment

The dipole moment of *s*-trioxane has been determined from the second order Stark shift of the $J=3\leftarrow2$ line. This absorption line splits into a triplet when a strong electric field ($\sim$1000 V./cm.) is applied. From the spacings of the triplet, the dipole moment has been determined to be 2.07 ± 0.04 Debye. If tetrahedral angles are assumed between the bonds in *s*-trioxane, the dipole moment of this molecule can be experessed by the bond moment along the C–O axis and that along the C–H axis as

$$\mu = 2(\mu_{CO} + \mu_{CH})$$

The experimental value gives $\mu_{CO}+\mu_{CH}=1.04$ Debye. This value should be compared with that of methanol for which $\mu_{CO}+\mu_{CH}=0.88$ Debye.

The authors wish to express their appreciation to the Fund of the Toyo Rayon Foundation for the Promotion of Science and Technology for the grant which made this research possible.

Planar Quadri-co-ordinate Complexes of Cobalt(II) with Schiff Bases Derived from Salicylaldehyde

By Hiroaki NISHIKAWA and Shoichiro YAMADA

(Received August 2, 1963)

The chemistry of transition-metal complexes with Schiff bases derived from salicylaldehyde is considered to involve a number of interesting problems of fundamental importance in the field of co-ordination chemistry.[1-3] The copper(II) and nickel(II) compounds of this type have been studied in some detail, but there have been very few systematic studies of cobalt(II)-complexes with *N*-alkylsalicylideneiminate ions. Thus, the configuration of quadri-co-ordinate cobalt(II)-complexes of this kind was in dispute when the present study was started. There are some cobalt(II)-complexes in which the steric requirements alone determine the configuration of the complex, allowing only one of two possibilities, that is, a planar or a tetrahedral co-ordination. As a step to the elucidation of the structure of cobalt(II)-complexes with Schiff bases, the present paper is concerned with those compounds whose structure is necessarily planar because of the steric conditions imposed by the ligands, and with the determination of the main characteristics of their spectroscopic properties. The electronic spectra of the planar cobalt(II)-complexes have never been unanimously characterized; it is thought that their establishment will be useful for the discussion of the structure of, and the chemical bond involved in, cobalt(II)-complexes.

Experimental

Materials. — *Bis(salicylaldehyde)ethylenediiminatocobalt(II)*[4] (Fig. 1, A) was prepared previously[5] by adding an aqueous solution of cobalt(II) acetate to an ethanolic solution of bis(salicylaldehyde)-ethylenediimine under reduced pressure. The crystals of the compound obtained by this method, however, are generally so small that they are very susceptible to oxygenation. In the present work, a different method was devised for preparation of the compound in larger cystals, which were bound to be more inert in the atmosphere. A suspension of bis(salicylaldehyde)cobalt(II) dihydrate (2.0 g.) in methanol (400 ml.) was boiled in a flask. While this was boiling and while the vapor of methanol filled the flask, a theoretical amount of ethylenediamine was added to the orange-colored solution; then the flask was closed tightly. When the mixture was kept at room temperature for a few hours, needle-like crystals first started to separate out; these were soon changed, in the solution in the absence of oxygen, into dark-violet, prism-like crystals, which were finally collected. The nature of the red crystals which separated at first and which then disappeared was not characterized in the present study. The dark-violet crystals obtained according to this method are hardly oxygenated at all, even when filtered in the air. They are slightly soluble in chloroform and benzene.

Found: C, 59.3; H, 4.36; N, 8.90. Calcd. for $C_{16}H_{14}O_2N_2Co$: C, 59.1; H, 4.34; N, 8.61%.

Bis(salicylaldehyde)propylenediiminatocobalt(II) (Fig. 1, B) was prepared as reddish-brown, needle-like crystals by a new method similar to that for "salcomine" which was devised by the present authors. The crystals, which are readily oxygenated in the atmosphere, are slighty soluble in ethanol, chloroform and benzene.

Found: C, 59.4; H, 4.90; N, 8.00. Calcd. for $C_{17}H_{16}O_2N_2Co$: C, 61.2; H, 5.13; N, 7.93%.

Bis(salicylaldehyde)-α, α'-dimethylethylenediiminatocobalt(II) (Fig. 1, C) was previously reported by Diehl.[6] In the present work, a different method was devised. Under reduced pressure, bis(salicylaldehyde)-cobalt(II) dihydrate and a slight excess of α, α'-dimethylethylenediamine were reacted in a water-ethanol mixture for several minutes. Then the solution was evaporated in vacuo to give an orange, crystalline powder. The micro-crystals, which are stable in the atmosphere, are soluble in common organic solvents.

Found: C, 60.5; H, 5.45; N, 7.47. Calcd. for $C_{18}H_{18}O_2N_2Co$: C, 61.2; H, 5.13; N, 7.93%.

Bis(salicylaldehyde)-α, α'-diphenylethylenediiminatocobalt(II) (Fig. 1, D) has not been reported yet. In the present study, this compound was synthesized from bis(salicylaldehyde)cobalt(II) dihydrate and α, α'-diphenylethylenediamine according to a method similar to that used for bis(salicylaldehyde)-α, α'-dimethylethylenediiminatocobalt(II). Recrystallization of the crude product from chloroform yielded pure, red crystals, which are quite stable in the atmosphere. These crystals are soluble in ethanol,

chloroform and benzene, and they are stable in solution as well as in the solid state.

Found: C, 71.6; H, 4.99; N, 5.47. Calcd. for $C_{28}H_{22}N_2O_2Co$: C, 70.4; H, 4.64; N, 5.86%.

Bis(salicylaldoximato)cobalt(II) was prepared by a new method, one invented for the present work in order to obtain crystals of a larger size by avoiding undesirable oxygenation during the process. Prior to the synthesis, the fiask was evacuated, and it was eventually filled with ethanol vapor. Cobalt(II) chloride and salicylaldoxime were dissolved in warm ethanol in the molar ratio of 1:2.2, and a methanolic solution of lithium methylate (2.0 mol.) was added drop by drop to the solution. Red-brown crystals separated out immediately, and they were collected. The crystals obtained are slightly soluble in common organic solvents.

Found: C, 50.7; H, 3.59; N, 8.04. Calcd. for $C_{14}H_{12}N_2O_4Co$: C, 50.8; H, 3.65; N, 8.46%.

Bis(salicylaldiminato)cobalt(II) was prepared by the following two methods: (i) Bis(salicylaldehyde)-cobalt(II) dihydrate (2.0 g.) was suspended in 200 ml. of ethanol in a flask at 60~65°C. A concentrated aqueous ammonia (9 ml.) was added to the solution in the flask which was evacuated, and the reaction mixture was kept at this temperature for about one and a half hours to give orange, plate-like crystals. The crystals were filtered, washed with a mixture of a concentrated aqueous ammonia and methanol, and dried in vacuo. (ii) Bis(salicylaldehyde)cobalt(II) dihydrate (2.5 g.), ammonium chloride (2.5 g.) and methanol (100 ml.) were placed in a flask, which was evacuated until the solution in it started boilig.

Then the flask was closed and warmed to 65°C while being stirred, and lithium methylate prepared from lithium metal (0.28 g.) and methanol (20 ml.) was added drop by drop into the flask. Orange, plate-like crystals separated out immediately; they were filtered while hot, washed with a mixture of concentrated aqueous ammonia and methanol, and dried in vacuo.

The crystals are readily soluble in pyridine, but insoluble in other common organic solvents.

Found: C, 56.0; H, 4.05; N, 9.38. Calcd. for $C_{14}H_{12}N_2O_2Co$: C, 56.2; H, 4.04; N, 9.36%.

6) H. Diehl and T. S. Chao, *Iowa State Coll. J. Sc.*, **22**, 126 (1947).

The crystals prepared by the above-described methods are obviously different from those reported previously. Fomerly Endo[7] claimed to have isolated bis(salicylaldiminato)cobalt(II) dihydrate from hydrosalicylamide and cobalt(II) acetate. Our experiments using his procedures yielded a substance with the same properties as those described in the literature. The substance, however, gave an analytical value for nitrogen, an appreciable deviation from the formula of bis(salicylaldiminato)-cobalt(II) or its hydrate. Moreover, observation under a microscope indicates that the product consists of two kinds of crystals. It is likely that a mixture is obtained by this procedure. The most remarkable difference seems to be that the product obtained by the Endo's method was reported to be stable in boiling chloroform, whereas the product obtained by the method reported here was quite sensitive to air.

Measurements.—The electronic absorption spectra of the compounds in solution were determined with a Beckman DU spectrophotometer. Since all the compounds are more or less sensitive to oxygen in the air, the measurements were carried out in a nitrogen atmosphere. Examination was made after every measurement to see whether or not any change occurred in the solution. In general, Beer's law was obeyed in the concentration range of the present measurements, which varied between 10^{-2} and 10^{-5} mol./l.

Results and Discussion

Bis(salicylaldehyde)ethylenediiminatocobalt-(II) and Its Derivatives.—Judging from the steric requirement of the ligand (Fig. 1, A), bis(salicylaldehyde)ethylenediiminatocobalt(II) is considered to have a quadri-co-ordinate, planar complex of the *cis*-$[Co(N)_2(O)_2]$ type. The visible and ultraviolet spectrum of "salcomine" in solution has previously been reported, but the measurement did not cover the whole region of the ligand field bands.[8] In the present study, therefore, the measurements were carried out in the atmosphere of nitrogen and were extended to a much lower frequency region than that previously reported. The results of the measurements are shown in Fig. 2. In the region of the higher frequency, there appear intense absorption bands; these are regarded as resulting mainly from the ligand group in the complex. These absorption bands, however, do not extend beyond $60\times10^{13}sec^{-1}$ (500 mμ), so that a considerable part of the ligand field band region is left uncovered. In the lower frequency region, the main features of the ligand field bands of "salcomine" are definitely different from those of cobalt(II)-complexes with a sexa-co-ordinate octahedral

1. $Co(O\cdot C_6H_4\cdot CH:N\cdot CH_2\cdot CH_2\cdot N:CH\cdot C_6H_4\cdot O)$, (salcomine); 2, $Co(O\cdot C_6H_4\cdot CH:N\cdot CH(CH_3)\cdot CH(CH_3)\cdot N:CH\cdot C_6H_4\cdot O)$; 3, $Co(O\cdot C_6H_4\cdot CH:N\cdot CH(C_6H_5)\cdot CH(C_6H_5)\cdot N:CH\cdot C_6H_4\cdot O)$.

or a quadri-co-ordinate tetrahedral configuration. Thus, the spectrum of "salcomine," which has a sharp peak at about 25×10^{13} sec^{-1} (1200 mμ), may be considered to represent the main features characteristic of cobalt(II)-complexes with a planar configuration.

Bis(salicylaldehyde)propylenediiminatocobalt-(II) is regarded, on the basis of the steric condition (Fig. 1), as taking a quadri-co-ordinate, cis-planar configuration. The ligand field bands (Fig. 3) of bis(salicylaldehyde)-propylenediiminatocobalt(II) are quite similar to those of "salcomine," both show a sharp absorption peak at about 25×10^{13} sec^{-1} (1200 mμ).

Bis(salicylaldehyde)-α, α'-disubstituted ethylenediiminatocobalt(II) complexes (Fig. 1) are also considered, on the basis of the steric condition of the ligands, to take a planar co-ordination around the cobalt(II) ion. Thus, compouds C and D (Fig. 1) both show spectra quite similar to that of "salcomine," as is shown in Fig. 2. The sharp peaks in the near-infrared region of the complexes shown in Fig. 1 do not differ much from one another (Table I).

It is of significance that the quadri-co-ordinate cobalt(II)-complexes with a planar configuration, examined in the present study, exhibit characteristic ligand field bands, with

a sharp peak at about 25×10^{13} sec^{-1} (1200 mμ). Since this is remarkably different from that which is observed for sexa-co-ordinate octahedral or quadri-co-ordinate tetraherdal complexes of cobalt(II), this difference may be diagnostic in the discussion of the configuration of cobalt(II)-complexes.

It is also characteristic that the oscillator strength of this sharp peak in the near-infrared region is very small. Although an unambiguous assignment of the band is difficult at the time, the quite small oscillator strength of the band seems to indicate that this peak may be ascribed to a spin-forbidden d-d transition. On the basis of the energy level diagram provided by Cotton and Holm,[9] the peak may tentatively be ascribed to an electronic transition from $^2B_{2g}$ to $^4A_{2g}$ or ^4E_g.

The Configuration of Bis(salicylaldoximato)- and Bis(salicylaldiminato)-cobalt(II).—The co-ordination around the cobalt(II) ion in bis-(salicylaldoximato)-cobalt(II) is either planar or tetrahedral. From the magnetic moment of 2.6 B. M. for the compound in the solid state,[10] it was formerly assumed that the compound had a planar configuration.[11] This compound is exceedingly susceptible to oxidation, and a specimen obtained by the conventional method of preparation often contains oxygen molecules absorbed from the atmosphere.[12] It is not quite certain whether or not, in the former studies of the magnetic moment, due care was exercised in this respect; reexamination of the problem, preferably using evidence of another sort, was thought to be desirable. In the present work, the pure specimen of bis(salicylaldoximato)cobalt(II) has been prepared with the utmost care to prevent the undesirable oxygenation, and the

spectrum of the compound in solution has also been determined in an inert atmosphere. The qualitative spectrum thus determined is shown in Fig. 3. In spite of the great care paid to the determination of the spectrum, a slight oxidation is noticeable in the determined spectrum, which shows an inflation at about 45×10^{13} sec^{-1}. The spectrum, however, is regarded as being accurate enough for the purpose and the nature of the present discussion. The spectrum has a sharp peak, at about 28.4×10^{13} sec^{-1}, which is characteristic of the quadri-co-ordinate square-planar complex of cobalt(II). It may, therefore, be concluded that bis(salicylaldoximato)cobalt(II) has a quadri-co-ordinate planar configuration around the cobalt(II) ion. A comparison of the absorption maximum of the sharp peak in the near-infrared region reveals that the ligand field of the salicylaldoximate ion in the planar cobalt(II)-complex is stronger than that of salicylaldiminate or bis(salicylaldeyde)ethylenediiminate.

It will be shown in forthcoming papers that, with *N*-alkyl- and *N*-aryl-salicylideneimine, most quadri-co-ordinate cobalt(II)-complexes take a tetrahedral configuration, unless the steric condition of the ligands demands a planar co-ordination. It is to be noted that bis(salicylaldoximato)- and bis(salicylideneiminato)-cobalt(II) take a quadri-co-ordinate planar configuration; this is especially noteworthy in view of the fact that these ligands, which are similar in their bonding ability to salicylaldoximate or bis(salicylaldehyde)ethylenediiminate, except for the steric factor, do not necessarily demand a planar configuration for cobalt(II).

One of the necessary conditions for the cobalt(II)-complex to take a planar co-ordination is that the field produced by the ligands in the complex be stronger than a certain threshold value, below which the complex is assumed to take a tetrahedral co-ordination with the ligands. Another cause for the formation of the planar cobalt(II)-complex may be the steric conditions favorable for the square-planar co-ordination of the metal-ion. Thus, if bis(salicylaldoximato)cobalt(II) is assumed to be a planar trans-complex, a strong hydrogen bond of an O—H—O type may be possible. This is probably one of the factors which favor the planar co-ordination of salicylaldoximato-complex of cobalt(II). In this connection, it is of significance that a strong hydrogen bond of an O—H—O type has been reported to exist in bis(salicylaldoximato)nickel(II).[13]

The crystals of bis(salicylaldiminato)cobalt(II) are readily oxidized in the air, and their solubility in solvents is generally low, so that the measurement of the spectrum was not very easy. With precautions to prevent oxidation, the qualitative absorption spectra of the compound in chloroform and in ethyl methyl ketone were determined; the results are given in Fig. 3 and Table I. The spectra in the two different solvents coincide essentially with each other in all important points.

Bis(salicylaldiminato)cobalt(II) in non-co-ordinating solvents has a quadri-co-oridinate, planar configuration; the spectrum of this compound, which shows a sharp peak at about 24.8×10^{13} sec^{-1}, is regarded as characteristic of the quadri-co-ordinate, planar cobalt(II)-complex.

As will be described in a forthcoming paper, bis(*N*-*n*-alkylsalicylideneiminato)cobalt(II) complexes, which are derived by substituting *n*-alkyl groups for the hydrogen atoms of bis(salicylaldiminato)cobalt(II), take a tetrahedral co-ordination around the cobalt(II) ion. This remarkable change in configuration, caused by a change of a substitutent, may be due partly to the fact that the ligand field produced by the salicylideneiminate group is stronger than that produced by the *N*-*n*-alkylsalicylideneiminate group. In addition to this there may be cited the possibility that hydrogen bonding of an N—H—O type would be formed in bis(salicylideneiminato)cobalt(II) when the complex is trans-planar.

In the light of the findings of the present

13) L. L. Merritt, C. Guare and A. E. Lessor, *Acta Cryst.*, **9**, 253 (1956).
14) J. F. Fackler, *Inorg. Chem.*, **2**, 266 (1963).

work, the configuration of bis(acetylacetonato)-cobalt(II) may be discussed. The complex has a magnetic moment correspondig to three unparied electrons, and a planar configuration would be ruled out by the conventional argument of magnetism. The complexes of cobalt(II), whose configurations have been firmly established as planar, are all of a low-spin type, with a magnetic moment corresponding to one unpaired election. On the basis of theoretical consideration, however, Cotton and Holm[6] claimed that bis(acetylacetonato)cobalt-(II) was a rare example of a planar cobalt-(II)-complex of a high-spin type. Its electronic absorption spectra, its ligand field bands in particular, are quite different from the spectra of the typical planar cobalt(II)-complexes studied in the present work. Thus, the square-planar configuration of bis(acetylacetonato)-cobalt(II) is to be rejected; there is no warrant for assuming the existence of planar cobalt(II)-complexes of a high-spin type, none of which have ever been established with reasonable certainty. It has also been pointed out recently that the association of the cobalt-(II)-complexes occurs to some extent, a sexa-co-ordination around the cobalt(II)-ion being thereby completed[14].

Summary

In order to establish the electronic absorption spectra of quadri-co-ordinate, square-planar cobalt(II)-complexes, the absorption spectra of bis(salicylaldehyde)ethylenediiminato- and bis-(salicylaldehyde)propylenediiminato-cobalt(II) in solution have been determined, with the utmost care taken to avoid undesirable oxidation of the complexes. These compounds show characteristic ligand field band, with a comparatively sharp peak in the near-infrared region.

Bis(salicylaldehyde)-α-α'-dimethylethylenediiminato- and bis(salicylaldehyde)-α,α'-diphenylethylenediiminato-cobalt(II) have deen prepared, and their spectra examined. These also show characteristic ligand field bands, with a sharp peak in the near-infrared region.

Bis(salicylaldoximato)- and bis(salicylaldiminato)-cobalt(II) have been prepared, and their spectra examined. On the basis of the results obtained above, it has been concluded that these two complexes take a quadri-co-ordinate, planar configuration.

The authors are very grateful to the late Professor Ryutaro Tsuchida for his interest in this work, and to Professor Yoshiharu Izumi and Dr. Kensaku Morihara of the Institute for Protein Research for their advice on the syntheses of the organic ligands. Syntheses and Structures of Acetylformoin and Its Related Compounds. IV. Solvent Effects on a Tautomerism

By Yo MIYAGI

(Received August 7, 1963)

A condensation of the benzoin type of an α-ketoaldehyde RCOCHO yields a formoin, the most primitive structure of which is RCOCH·(OH)COCOR :

$$2\ \mathrm{RCOCHO} \xrightarrow{\mathrm{CN^-}} \mathrm{RCOCH(OH)COCOR}$$

The formoins which had been synthesized were listed in a previous paper.[1] The conditions of the condensation of methylglyoxal were studied by Görlich,[2] while the products other than the formoin were isolated by Franzen.[3] The possible structures for the formoin are I—V.[4-7]

The present author and his co-workers have

studied the structures and the chemical behavior of several formoins. Acetylformoin[8] has been proved to have an enediol structure II ($R=CH_3$) in the solid state and in chloroform solution. Benzoylformoin,[8] neopentoylformoin[1] and isobutyrylformoin[9] are furanones IV ($R=C_6H_5$, $C(CH_3)_3$ and $CH(CH_3)_2$ respectively) in the solid state. Isobutyrylformoin[9] has structure IV in tetrahydrofuran solution and structure II in chloroform solution.

Most of these conclusions have been deduced from infrared spectral data. Structure II is characterized by a broad, weak band of the OH stretching absorption and by an intense band of the C=O stretching absorption at a lower frequency, around 1620 cm^{-1}.[10] On the other hand, in structure IV, a rather broad but distinct band arises in the region of the OH stretching absorption, while the C=O and C=C stretching absorption bands are observed around 1690 and 1600 cm^{-1} respectively. Furthermore, these assignments are supported by some of the chemical behavior of formoins.

Results

The ultraviolet and infrared spectra of isobutyrylformoin was found to depend remarkably on the solvent in which it is measured, suggesting a tautomerism between structures II and IV in solution.[9] An ultraviolet absorption arises at 305 mμ ($\varepsilon=7350$) in tetrahydrofuran, and at 360 mμ, with a great enhancement of the intensity ($\varepsilon=14200$), in chloroform (Fig. 1). It has been concluded that the 305 mμ band is attributable to structure IV and the 360 mμ one to structure II, since the infrared spectra had established structure II for chloroform solution and structure IV for tetrahydrofuran solution.

The ultraviolet spectra of isobutyrylformoin were measured in some other solvents. Since the 305 mμ band arises in ethanol and ether (Fig. 2), structure IV may be considered to predominate in these solvents. A slight but distinct tailing beyond 350 mμ in tetrahydrofuran and ether indicates the existence of a

10) The enol form of a β-diketone, $-C=C(CH)-C(=O)-$, constitutes a conjugate chelation, which gives a broad, weak hydroxyl band and a widely shifted, intense carbonyl band: see, for example, L. J. Bellamy, "Infrared Spectra of Complex Molecules," Methuen, London (1958), pp. 104, 147.

small amount of structure II. In acetonitrile, isobutyrylformoin shows the 305 mμ band with a somewhat decreased intensity (ε=6000) and a shoulder at 360 mμ (ε=2950), suggesting an equilibrium between structures II and IV.

The above findings necessitate a reinvestigation of the structures of other formoins in solution. In the ultraviolet spectrum of acetylformoin in ethanol, the 303 mμ band is dominant (Fig. 3). In tetrahydrofuran there

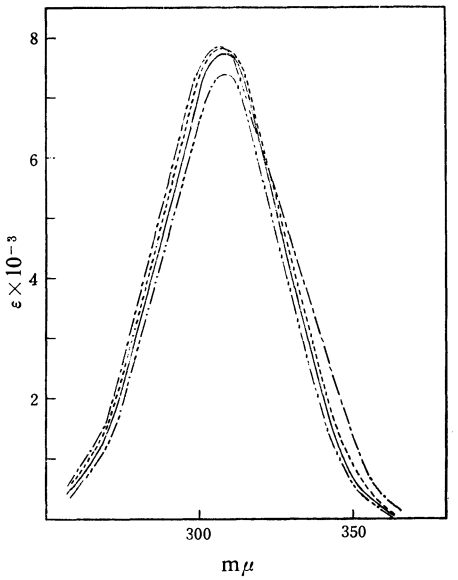

Fig. 4. Ultraviolet spectra of neopentoylformoin in tetrahydrofuran (——), acetonitrile (– – – –), ethanol (— — —) and ether (------).

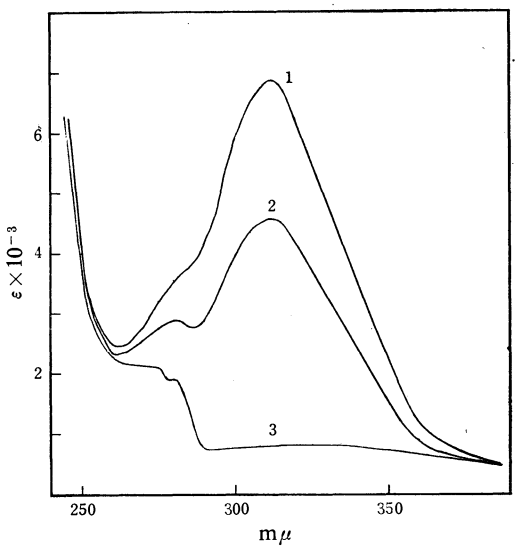

Fig. 5. Ultraviolet spectra of neopentoylformoin in chloroform: 1, in vacuo; 2, 5 hr. after breaking the seal; 3, 1 day after breaking the seal.

is an intense absorption at 303 mμ (ε=7100), with a shoulder around 360 mμ. Thus, in the former solvent, structure IV, and in the latter solvent, an equilibrium between IV and II, may be established. In chloroform an ultraviolet absorption also arises at 355 mμ with an enhancement of the intensity, indicating structure II.

The infrared spectrum of isobutyrylformoin in chloroform (Fig. 8) is very similar to those of acetylformoin in chloroform and in the solid state (Fig. 9). As has been stated in previous papers,[8,9] these spectra are characteristic of structure II: a broad weak band of the OH stretching absorption and an intense one of the C=O stretching absorption at 1620 cm^{-1}. The infrared spectrum of acetylformoin in carbon tetrachloride makes these characteristics more distinct: it becomes more apparent that the OH absorption is broad and weak, because of the disappearance of the C–H stretching absorption of the solvent, which makes the OH band ambiguous. The insolubleness of isobutyrylformoin in this solvent fails to give such a characteristic spectrum as that of acetylformoin in this solvent.

Neopentoylformoin has spectral characteristics consistent with structure IV in ethanol, tetrahydrofuran, ether, acetonitrile and even in chloroform. In the first three solvents, neopentoylformoin shows an ultraviolet absorption at 308 mμ (ε=ca. 7000). In tetrahydrofuran and ether no such tailing beyond 350 mμ is observed as in acetyl- and isobutyrylformoin (Fig. 4). In acetonitrile an absorption arises also at 307 mμ without any shoulder around 360 mμ.

The infrared spectra in ether, tetrahydrofuran and acetonitrile are characteristic of structure IV: the C=O, C=C and OH stretchching absorptions are located at 1705, 1630 and ca. 3300 cm^{-1} respectively (Fig. 10).

Neopentoylformoin is rapidly oxidized in chloroform, so the ultraviolet spectrum in this solvent was measured in a cell sealed in vacuo. There occurs an absorption at 311 mμ with a slight shoulder around 275 mμ; when the sealed cell is opened, the 311 mμ band decreases and the shoulder at 275 mμ can be recognized as an absorption band (Fig. 5). Though the origin of this band has not been found, the dominating 311 mμ band suggests structure IV for neopentoylformoin in chloroform.

The spectra of benzoylformoin indicates structure IV for solution. In tetrahydrofuran it shows an infrared spectrum characteristic of structure IV (Fig. 11); the OH and C=O stretching absorptions arise at 3240 and 1705 cm^{-1} respectively, while the C=C stretching

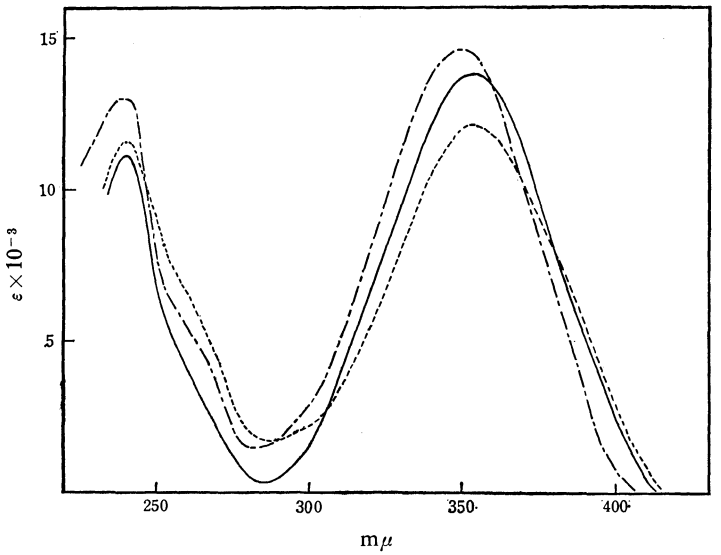

Fig. 6. Ultraviolet spectra of benzoylformoin in tetrahydrofuran (——), ether (— — —) and ethanol (------).

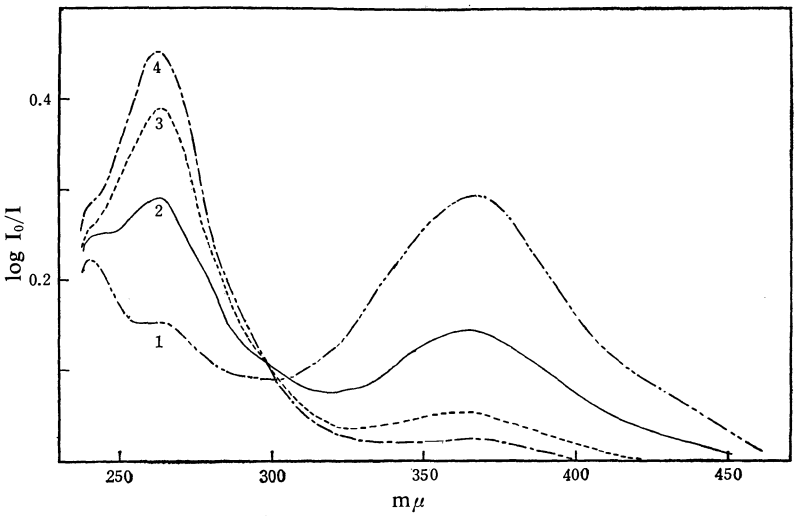

Fig. 7. Ultraviolet spectra of benzoylformoin in chloroform: 1, in vacuo; 2, 2 hr. after breaking the seal; 3, 4 hr. after breaking the seal; 5, 1 day after breaking the seal.

absorptions are located at 1615 and 1595 cm^{-1}. The ultraviolet spectrum of benzoylformoin in tetrahydrofuran is quite identical with those in ether and ethanol (Fig. 6); the absorptions are observed at 354 and 240 mμ. Since structure IV is established for tetrahydrofuran solution by the infrared spectral evidence mentioned above, the two ultraviolet absorptions at 354 and at 240 mμ should be attributed to structure IV. It may be elucidated as follows: the absorption arising from the chromophore, C=C–C=O of IV, is shifted to longer wavelengths by conjugation with a phenyl group.

Benzoylformoin is also rapidly oxidized in chloroform; the ultraviolet spectrum in this solvent was measured in a sealed cell in vacuo. The absorption arises at 370 and at 240 mμ. The lapse of time does not change the spectrum. Opening the sealed cell decreases the 370 and 240 mμ bands. However, Eistert[11] has pointed out a spectral change which might be attributed to a reaction of benzoylformoin with the ethanol present in chloroform as a stabilizer.

Discussion

The above results are summarized in Table III. This tautomerism is apparently affected by two factors: the substituent R and the solvent. Some conclusions may be deduced as follows:

i) In benzoyl- and neopentoyl-formoin, structure IV is dominant in any solvent;

ii) In acetyl- and isobutyryl-formoin, a tautomerism between II and IV occurs in solution; in an A-type solvent,*1 structure IV is dominant, while in a B-type*1 solvent, structure II prodominates;

iii) In the solid state, benzoyl-, neopentoyl- and isobutyryl-formoin have structure IV; only acetylformoin has structure II.

*1 A-type solvent: ethanol, ether and tetrahydrofuran. B-type solvent: chloroform and carbon tetrachloride.

The discussion of the cause of the tautomerism will be restricted here to the case of solution. It may be reasonable to consider that a tautomer predominating in a solvent is stabililized by a solvation. The most likely explanation is as follows: all A-type solvents have an oxygen atom carrying lone pair electrons, which may be supposed to take part in the formation of hydrogen bondings with the hydroxyl group of formoins, as in Fig. 17, and so the formoins are greatly stabilized. A B-type solvent has no such lone pair electrons with the ability to form a hydrogen bonding and structure IV can not be stabilized by such a solvation as above.*2 Consequently, in chloroform acetyl- and isobutyryl-formoin have more

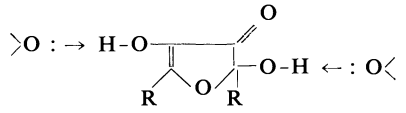

Fig. 17

a B-type solvent, chloroform. However, in this solvent structure IV can not be stabilized so much as in an A-type solvent because of the absence of the solvation,*2 so both formoins are easily oxidized.

The solubility*3 of the formoins seems to have a correlation with their structures. While acetylformoin is very soluble in chloroform and carbon tetrachloride (B-type solvents), the other three formoins are only slightly soluble in chloroform and quite insoluble in carbon tetrachloride. This difference may be explained in terms of the solvation energy and the interaction of molecules in the solid state.*4

All the formoins except acetylformoin show slight but definite discrepancies (about 20 cm^{-1}) in the C=O and C=C stretching absorption bands of structure IV between the solid state and solutions in A-type solvents. On the other hand, the C=O stretching absorption of

*3 This investigation often encounters a difficulty with low solubilities of the formoins in solvents desirable for the spectroscopic measurement (carbon tetrachloride, heptane, cyclohexane; i. e., B-type solvents).

*4 In general, the solubility is proportional to $e^{-\Delta H/RT}$, where ΔH is the energy change in dissolving and is further expressed:

$\Delta H = \Delta H_V - \Delta H_S$

ΔH_V; heat of vaporization

ΔH_S; solvation energy

acetylformoin in the solid state (structure II) arises at the same position as that in a B-type solvent. In other words, the positions of the infrared absorptions of structure IV are different in the solid state and in the solution, while that of structure II is identical in both states. It means that the intermolecular bonding in the solid state is strong in structure IV, but not so strong in structure II. This is easily understandable, because the intermolecular chelation is very intense in structure II. A large intermolecular bonding in the solid state suggests a large value of the heat of vaporization (ΔH_v) : the ΔH_v value of structure IV is larger than that of structure II. As has been mentioned previously, the solvation to structure IV is large in an A-type solvent. This means that the ΔH_s value of structure IV

is large in the A-type solvent but small in B-type solvents, while that of structure II in B-type solvents is small.

In spite of its small ΔH_S value, acetylformoin has a large solubility in the B-type solvent because it has structure II in the solid state; in other words, it has a small ΔH_V value. A combination of a large ΔH_V value and a small ΔH_S value results in low solubilities of the other three formoins in B-type solvents.

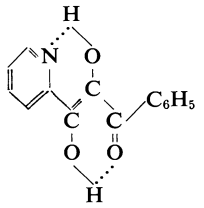
IV V

Further Results

***O*-Alkyl Derivatives of Benzoylformoin.**—Benzoylformoin undergoes a series of reactions as follows: it suffers methanolysis with methanolic hydrogen chloride to give a mono-*O*-methyl benzoylformoin, which is further methylated with dimethyl sulfate to give di-*O*-methyl benzoylformoin. A hydrolysis of the latter compound yields a second mono-*O*-methyl benzoylformoin, which is soluble in chloroform.

Blatt[5a] has stated that second mono-*O*-methyl benzoylformoin was IX. However, structure X may also be possible. A careful study of the ultraviolet and infrared spectra of this compound was undertaken (Figs. 12 and 14). Its ultraviolet spectrum in chloroform is almost identical with that in ethanol and is similar to that of di-*O*-methyl benzoylformoin,*5 the structure of which was established as VIII by chemical evidences. Moreover, there have been found no differences between the infrared spectrum in chloroform (a B-type solvent) and that in tetrahydrofuran (an A-type solvent): the C=O and C=C stretching absorptions arise around 1705 and 1610 cm^{-1} respectively. In structure IX, a partial structure OH·····O constitutes a conjugate $-\overset{|}{C}=C(OCH_3)-\overset{||}{C}-$ chelation. If second mono-*O*-methyl benzoylformoin were IX, it would show a broad weak band of the OH stretching absorption and of the C=O stretching absorption around 1620 cm^{-1} and the ultraviolet absorption at 340 mμ would be shifted to longer wavelengths. For instance, 1-benzoyl-2-α-pyridylethenediol (XII)[12] shows a broad band of the OH stretching absorption, the C=O stretching absorption band at 1603 cm^{-1}, and an ultraviolet absorption at 405 mμ ($\varepsilon = 15940$).

These results indicate that the structure of second mono-*O*-methyl benzoylformoin is X in both types of solvents. Here again a tautomerism between IX and X does not arise.



VI VII VIII X or IX

*5 The introduction of a glycosidic ether linkage does not bring about a shift of the ultraviolet absorption. However, that of an enol ether linkage results in a shift of the 354 mμ band to 340 mμ. A similar shift was observed in di-*O*-methyl neopentoylformoin (Fig. 13).

12) B. Eistert and H. Munder, *Ber.*, **91**, 1415 (1958).

Alcoholysis of Isobutyrylformoin.—There is an interesting experimental observation: neo-

XII

pentoylformoin and benzoylformoin undergo methanolysis with methanolic hydrogen chloride to give quantitatively mono-*O*-methyl derivatives. On the other hand, the color of the methanolic hydrogen chloride solutions of isobutyryl- and acetyl-formoin is yellow at first; it turns black while the alcohol and the acid being evaporated under reduced pressure. The residues are black syrups, from which the isolation of mono-*O*-methyl derivatives failed.*6

No differences were observed between the ultraviolet spectrum of neopentoylformoin in ethanol and those in methanolic hydrogen chloride (the concentration of hydrogen chloride, 8 and 17 wt. %), and the latter spectra show no absorptions beyond 350 mμ. On the other hand, the ultraviolet spectra of isobutyrylformoin in methanolic hydrogen chloride (Fig. 16) differ greatly from those of neopentoylformoin. In 0.5% methanolic hydrogen chloride, a band arises at 269 mμ besides the 304 mμ band of a slightly decreased intensity ($\varepsilon=5100$). The absorption band of 7% methanolic hydrogen chloride, arising at 300 mμ, seems to be a overlapping band of the two above bands of a 0.5% solution. In a greatly concentrated solution, the absorption has a remarkably increased intensity. It may be considered that the band located at 269 mμ in 0.5% solution is shifted to longer wavelengths and that its intensity is remarkably enhanced to overlap with the 304 mμ band of 0.5% solution, which may be attributed to the enone chromophore of the formoin.

In methanolic hydrogen chloride solutions of acetyl- and isobutyryl-formoin, it may be considered that some chemical reaction other than etherification occurs, probably a condensation involving C-H bonds of the substituent R. The ultraviolet absorption at 269 mμ arising in the 0.5% methanolic hydrogen chloride solution of isobutyrylformoin may be attributed to this condensation product, the amount of which may increase with the increment in concentration of hydrogen chloride, thus enhancing the intensity of the ultraviolet absorption. Though the attempts to isolate the condensation product have not been successful, the above explanation may be reasonable, because a condensation of a ketone having hydrogen atoms attached to α-carbon atoms occurs under acidic conditions.*7)

Isobutyrylformoin in methanolic hydrogen chloride shows at 360 mμ an additional absorption band, the intensity of which increases also with the increment in the concentration of hydrogen chloride. This band may be ascribed to the condensation product or to the shift of the equilibrium toward structure II upon the decrease in the solvation of methanol: in methanolic hydrogen chloride the proton forms an oxonium ion, $CH_3\text{-}O^+H_2$, to deprive methanol of the ability to solvate.

In an alcoholic solution of an acid, the protonated ketone shows an additional absorption band at a longer wavelength.[13] However, the 360 mμ band arising in a methanolic hydrogen chloride solution of isobutyrylformoin is not attributable to the protonated ketone. If this were the case, neopentoylformoin would show an absorption at 360 mμ in methanolic hydrogen chloride.

Conclusion

When R is methyl or isopropyl (i. e., acetyl- or isobutyryl-formoin), a tautomerism between structures II and IV occurs in solution. When R is phenyl or *t*-butyl (i. e., benzoyl- or neopentoyl-formoin), structure IV predominates in both types of solvents. In a B-type solvent, acetyl- and isobutyryl-formoin have structure II, the more stable tautomer. In an A-type solvent, they have structure IV, a tautomer stabilized by the solvation depicted in Fig. 17.

The above sequence of investigation suggests two assumptions: structure IV is generally more stable than structure II, although when R is methyl or isopropyl, the latter becomes more stable than the former; structure II is, in general, more stable than structure IV, although the former structure becomes unstable when R is phenyl or *t*-butyl. The former assumption is apparently reasonable because γ-

*6 Steinbauer and Waldman[6] isolated mono-*O*-methyl acetylformoin in a 30% yield. The author isolated a trace of a solid product by pouring a methanolic hydrogen chloride solution of isobutyrylformoin into cold water. The product is probably the mono-*O*-methyl derivative because it shows ν_{OH} at 1960, and $\nu_{C=C}$ at 3160, $\nu_{C=O}$ at 1620 cm^{-1} in Nujol.

*7 For example, diacetyl gives a trimer when shaken with concentrated hydrochloric acid at 0°C (R. M. Cresswell, W. R. D. Smith and H. L. S. Wood, *J. Chem. Soc.*, **1961**, 4882). The self-condensation of acetone in the presence of hydrochloric acid gives mesityl oxide, phorone and isophorone (J. B. Conant and N. Tuttle, "Organic Syntheses," Coll. Vol. I, 346 (1948)).

13) See, for example, J. F. Thomas and G. Branch, *J. Am. Chem. Soc.*, **75**, 4793 (1953); M. H. Palmer and D. S. Urch, *J. Chem. Soc.*, **1963**, 174.

and δ-oxy-aldehydes or ketones prefer hemiacetal or hemiketal forms; for example, aldoses and ketoses exist as pyranoses and furanoses. However, structures II and IV involve conjugation, so that the above analogy may not always hold true.

Experimental

Formoins.—All formoins were prepared by the usual method of the benzoin condensation described in previous papers.

Acetylformoin.[8]—Yellow needles, purified by vacuum sublimation; m. p. 82~83°C.

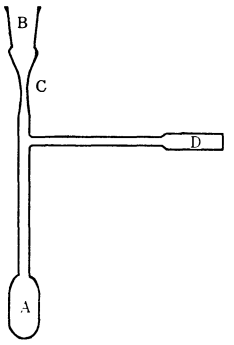


Fig. 18

Isobutyrylformoin.[9]—Colorless needles, recrystallized by adding water to an alcoholic solution; m. p. 87~93°C.

Neopentoylformoin.[1]—Colorless needles, recrystallized from isopropanol; m. p. 170~171°C.

Benzoylformoin.[8]—yellow needles, recrystallized from ethanol; m. p. 186~188°C.

First Mono-*O*-methyl Benzoylformoin (VII).—Benzoylformoin (4 g.) was dissolved in ca. 10% methanolic hydrogen chloride (80 ml.) (slightly warmed). After they had stood overnight, the solvent and the acid were evaporated off under reduced pressure. The residue was washed with cold water and dried in vacuo. The recrystallization was carried out from 50 ml. of ethanol: yellow needles; 3 g.; m. p. 180~182°C.

Found: C, 72.15; H, 4.91. Calcld. for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

By the addition of 10 ml. of water to the mother liquor, 1 g. of the product was collected; m. p. 176~182°C.

Di-*O*-methyl Benzoylformoin (VIII).—First mono-*O*-methyl benzoylformoin (2.5 g.) was dissolved in a solution of 0.7 g. of sodium methoxide in 50 ml. of methanol. After the addition of 15 g. of methyl iodide, the solution was refluxed for 3 hr. After it had stood overnight, the solvent was evaporated off under reduced pressure. Water and ether were added to the residue. The product was obtained as yellow needles by evaporating ether from the ethereal layer and then recrystallized from 2 ml. of methanol: 2.1 g.; m. p. 79.5~80.5°C.

Found: C, 72.85; H, 85.29. Calcd. for $C_{15}H_{16}O_4$: C, 72.96; H, 5.44%.

Second Mono-*O*-methyl Benzoylformoin (X).—This compound was prepared by the method of Blatt:[5a] m. p. 120~124°C.

Found: C, 72.19; H, 5.01. Calcd. for $C_{17}H_{14}O_4$: C, 72.33; H, 5.00%.

Mono-*O*-methyl Neopentoylformoin.[1]—Colorless needles; recrystallized from isopropanol; m. p., 100.5~101°C.

Di-*O*-methyl Neopentoylformoin.[1]—Colorless liquid; b. p., 107~108°C/5 mmHg.

The Ultraviolet Spectra of Neopentoyl- and Benzoyl-formoin in Chloroform.—A definite quantity (3 ml.) of a tetrahydrofuran solution of neopentoylformoin (ca. 5×10^{-5} M) was placed in bottle A, which was then attached to a vacuum line through ground joint B. The solvent was distilled off under 10^{-4} mmHg. Chloroform (3 ml.) was placed in a flask attacthed to the vacuum line, and chloroform was distilled into bottle A which was cooled by liquid air under 10^{-4} mmHg. The thin glass tube C was sealed. After the contents of bottle A reached room temperature, it was poured in cell D and the spectrum was recorded. Consequently, the molecular extinction coefficient was nearly correct. In the case of benzoylformoin, about 0.5 mg. of crystals was placed in bottle A and chloroform was distilled in by the same method as above: the intensity in Fig. 7 is arbitrary.

Spectra.—The infrared spectra were recorded with a Koken model DS-301 and IR-S spectrophotometer. The ultraviolet spectra were recored with a Shimadzu model QR-50 spectrophotometer.

The author wishes to express his thanks to Professor Ryozo Goto of Kyoto University for his kind guidance and encouragement throughout the work, and to Professor Saburo Nagakura of The University of Tokyo and Dr. Yoshiki Matsui of Shionogi & Co. for their discussions.

*The Cationic Copolymerization of Styrene and Isobutene in Liquid Sulfur Dioxide**

By Masashi IINO and Niichiro TOKURA

(Received August 10, 1963)

Recently, there have been published many investigations of the solvent effect on the monomer reactivity ratios as a means of examining the reaction mechanism operating during a cationic polymerization.[1a-g]

A study of the cationic copolymerization of styrene and *p*-bromostyrene presented in a previous paper[3] by the present authors has demonstrated that:

(1) The monomer reactivity ratios in liquid sulfur dioxide are $r_1=0.8$ and $r_2=0.4$ respectively, where r_1 is the ratio of styrene and r_2 is that of *p*-bromostyrene.

(2) In nitrobenzene, $r_1=1.8$ and $r_2=0.3$.

(3) The values of the reactivity ratios in the mixed solvent systems (equivolume) of liquid sulfur dioxide-benzene, liquid sulfur dioxide-nitrobenzene and liquid sulfur dioxide-carbon tetrachloride are almost the same within the range of experimental error as those in liquid sulfur dioxide itself (in case 1).

The absence of any distinct difference in monomer reactivity ratios, *r*'s, among these solvent systems is due perhaps to the similarity of the reactivities of styrene and *p*-bromostyrene. The purpose of the present investigation is to make clearer the behavior of liquid sulfur dioxide in the cationic copolymerization of styrene and isobutene, which are different from each other in monomer structure and in reactivity.

Lately, Higashimura and his coworkers[1g] have reported, of the cationic copolymerizations of styrene-isobutene in various organic solvents, that the isobutene monomer, which is usually more reactive than styrene in cationic polymerization, gets less reactive as the dielectric constants of the systems become lower.

Overberger et al.[1c] have found the same relation between dielectric constant and monomer reactivity ratios in the copolymerization of *p*-chlorostyrene and isobutene.

However, it is doubtful whether the reactivity of the monomer will be explained only by the differences in the dielectric constants of the solvent, since in liquid sulfur dioxide behavior considerably different from that of usual organic solvents have been seen in cationic polymerization.[2a,b]

Experimental

Materials. — The purification of styrene, liquid sulfur dioxide, benzene, nitrobenzene and ethylene dichloride was carried out according to the procedures described in a previous paper.[3] Isobutene used was fractionated after the removal of water with sodium-wire. It was confirmed by gas chromatography that its purity was 99%; it contained about one per cent propane. Stannic chloride was distilled under reduced pressure in a nitrogen stream and sealed into an ampoule. Nitromethane was dehydrated over the phosphorus pentoxide and distilled.

Polymerization. — The charge of isobutene into the reaction tube was carried out according to the same procedure as that employed previously (using a pressure buret), and the other details of the polymerization employed here were the same as those employed in the previous paper[3] with the exception that stannic chloride was used as an

initiator. Moreover, this polymerization resulted in a heterogeneous system, a polyisobutene or isobutene-rich copolymer being insoluble in liquid sulfur dioxide.

Analyses of Copolymers.—The quantity of styrene in the copolymer was determined on the basis of infrared spectrometry using a Hitachi EPI-S infrared spectrometer, with ν_{max}, 700 cm^{-1}, as the key band. Carbon disulfide was used as the solvent; the thickness of the sodium chloride cell was 0.516 or 0.525 mm. The copolymer used for the measurement was purified by precipitation from carbon disulfide. Beer's law held strictly, as may be seen in Fig. 1.

Results

The r_1 and r_2 Values on Using Liquid Sulfur Dioxide as the Solvent. — The experimental conditions were as follows; total volume of styrene and isobutene, 10.0 ml.; liquid sulfur dioxide, 10.0 ml.; polymerization temperature, −78°C (dry ice-methanol bath); concentration of stannic chloride, 2.1×10^{-3} mol./l.

Figures 2 and 5a show the feed-copolymer composition curve and the results obtained

from the intersection method respectively.

The reactivity ratios of $r_1 = 1.1$ and $r_2 = 3.1$, where styrene and isobutene are M_1 and M_2 respectively, were obtained from Fig. 5a.

The r_1 and r_2 Values in the Mixed Solvent Systems of Liquid Sulfur Dioxide-Benzene, Liquid Sulfur Dioxide-Nitrobenzene, Liquid Sulfur Dioxide-Nitromethane and Liquid Sulfur Dioxide-Ethylene Dichloride. — In each solvent system, the composition in feed was as follows: total volume of styrene and isobutene, 10.0 ml.; liquid sulfur dioxide, 11.5 ml.; and the added solvent, 4.0 ml.

Figures 3 and 4 show the composition curve and r_1 and r_2 were obtained by the intersection method respectively. Figure 5 illustrates the results obtained by the intersection method in each solvent system of liquid sulfur dioxide, liquid sulfur dioxide-benzene, and liquid sulfur dioxide-nitrobenzene.

Discussion

The results described above are summarized in Table I.

In liquid sulfur dioxide, the rate of the polymerization of isobutene is far larger than that of styrene. A comparison of the two monomers is shown in Table II.

In the case of styrene polymerization, $\alpha =$ 3.2, and only 3% of the catalyst at the maximum (without transfer) was used, whereas the α value of isobutene is 43%, suggesting that the initiation rate of the latter was very fast in liquid sulfur dioxide when stannic chloride was used as the catalyst.

As has been mentioned before, in the usual cationic copolymerization,[1g] the value of r_2 decreases but r_1 increases as the dielectric constant of the system is reduced, and the product, $r_1 \times r_2$, is approximately unity. A similar tendency was also observed in the cationic copolymerization of *p*-chlorostyrene and isobutene.[1c] On the contrary, as may be seen in Table I, the results obtained here have proved there to be no definite relation between r values and the dielectric constants of the systems, the order of the dielectric constants of the solvents being: liq. SO_2+nitromethane > liq. SO_2+nitrobenzene > liq. SO_2 > liq. SO_2+ethylene dichloride > liq. SO_2+benzene, whereas, r_2 values vary in the order liq. SO_2 > liq. SO_2+nitromethane > liq. SO_2+benzene > liq. SO_2+ethylene dichloride > liq. SO_2+nitrobenzene; r_1 values are classified in two groups, one being $r_1 \fallingdotseq 1$ in liq. SO_2, liq. SO_2+nitromethane and liq. SO_2+ethylene dichloride and the other being $r_1 \fallingdotseq 0.5$ in liq. SO_2+nitrobenzene and liq. SO_2+benzene.

The differences in r_1 values in the two groups may be ascribed to the differences in the monomer reactivities in these two sets of solvent systems. The values of the products, $r_1 \times r_2$ cover a wide range from 0.4 in liquid sulfur dioxide-nitrobenzene to 3.4 in liquid sulfur dioxide.

The r_1 values show no difference in the series of solvent mixtures, liquid sulfur dioxide, liquid sulfur dioxide+nitromethane and liquid sulfur dioxide+ethylene dichloride, wherein $r \fallingdotseq 1$, while r_2 values differ as the solvents are varied. Obviously the differences in reactivities of the carbonium ions derived from the isobutene moiety of the growing end in each solvent may be responsible for these phenomena.

In liquid sulfur dioxide, styrene can give a high molecular weight polymer, whereas isobutene can not. Figure 6 illustrates the correlation between the composition of the feed

and the intrinsic viscosity of the copolymer in the copolymerization. That the η values here can give the measurement of the degrees of polymerization for polymers of styrene, isobutene, and the copolymers of the two on the same basis has been demonstrated elsewhere.[4] Isobutene polymerizes heterogeneously in liquid sulfur dioxide, and the solubility of the polyisobutene is extremely meager.

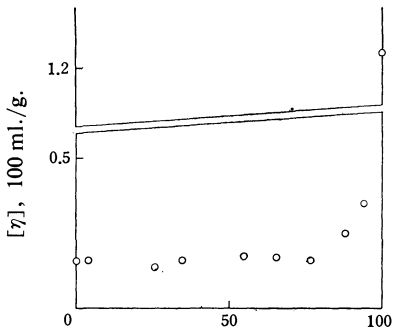

Fig. 6. Relationship between styrene concentration in feed and the intrinsic viscosity* of the copolymer.
* Viscosity was measured in toluene at 30°C.

Though the molar per cent of styrene in feed is about 70%, the η values of the copolymers are as small as in the case of polyisobutene, which suggests that though isobutene is a more reactive monomer than styrene, the growing of the isobutene carbonium ion end is likely to be easily terminated in liquid sulfur dioxide. A controlled polymerization of isobutene in liquid sulfur dioxide (an experiment to be reported on in the near future) also proved the formation of a very low molecular weight polymer. Polyisobutene cannot remain in the solution and separates out on the surface of liquid sulfur dioxide, the polymerization being terminated by keeping away monomers in the solution and eliminating any catalyst fragments. The present authors would like to recall the fact that the classical Edeleanu process for petroleum refining by using liquid sulfur dioxide is based on the scarce solubility of paraffins in liquid sulfur dioxide. At the experimental temperature (−78°C), the higher polymers of isobutene may be insoluble. This means that if the copolymer's propagating end consists of two or more sequences of isobutene units, the copolymer may be separated out and a heterogeneous copolymerization may occur. In mixed solvent systems, the sequence length of isobutene units may also be affected by the added solvents. It should be also noticed that styrene has a stronger solvation than isobutene with liquid sulfur dioxide because the former has a benzene nucleus. However, the present authors have not yet examined precisely the correlation between the reactivities and the solubilities of the monomers and the carbonium ions in each mixed solvent; further study is called for.

4) S. Okamura, T. Higashimura and K. Takeda, *Kobunshi Kagaku*, **18**, 389 (1961).

Summary

The copolymerizations of styrene and isobutene in liquid sulfur dioxide and in mixtures of liquid sulfur dioxide with nitromethane, ethylene dichloride, nitrobenzene and benzene have been carried out at −78°C. The r_1 and r_2 values have been estimated by the intersection method. When M_1 stands for styrene and M_2 for isobutene, r_1 and r_2 are 1.1 and 3.1 in liquid sulfur dioxide. The r_2 values vary, as the added solvent is changed. Two sets of r_1 values, approximately unity and 0.5, have been found. The meager solubility of polyisobutene and isobutene sequence in the copolymer may be responsible for the findings.

The authors are indebted to the Seitetsu Kagaku K. K. for the donation of liquid sulfur dioxide and to the Ministry of Education for a grant-in-aid for this project.

The Theory of the Indicator Transition in Chelatometry

By Genkichi NAKAGAWA and Motoharu TANAKA

(Received August 12, 1963)

Though various theories have been proposed for the indicator transition in chelatometry, the discussion seems to have been restricted more or less to particular cases; we find hardly any general treatments applicable to every case of chelatometry.[1-5]

In our preceding paper[1] a formula has been proposed for the indicator transition in the chelatometry of a metal using the NY-HA system as an indicator. In the present investigation the effect of a second metal is considered theoretically, and general equations are proposed for the indicator transition in the chelatometry of a metal in the presence of a second metal using HA or the NY-HA system as an indicator.

Theoretical Consideration

The Derivation of the Expressions of the Indicator Transiton.—*Chelatometry Using HA as an Indicator.*—In order to secure a distinct indicator transition in the vicinity of the equivalence point of the chelatometry of M_I, it is necessary for reaction 1.1 to proceed in favor of the right side and, at the same time, for reaction 1.2 to proceed in favor of the left side.

$$M_I' + A' \rightleftarrows M_IA \qquad (1.1)^{6}$$

$$M_IY + A' \rightleftarrows M_IA + Y' \qquad (1.2)$$

From the constant of the (1.1) equilibrium, i.e., the conditional stability constant of M_IA,

$$[M_I]' = \frac{[M_IA]}{[A]'K_{M_IA'}} \qquad (1.3)$$

The constant of the (1.2) equilibrium, which is equal to $K_{M_IA'}/K_{M_IY'}$, is given by the following:

$$\frac{K_{M_IA'}}{K_{M_IY'}} = \frac{[M_IA][Y]'}{[M_IY][A]'}$$

Hence,

$$[Y]' = \frac{[A]'}{[M_IA]}\frac{[M_IY]K_{M_IA'}}{K_{M_IY'}} \qquad (1.4)$$

Stoicheometric relationships 1.5 through 1.8 hold throughout the titration:

$$C_{M_I} = [M_IY] + [M_IA] + [M_I]' \qquad (1.5)$$

$$C_Y = [M_IY] + [M_{II}Y] + [Y]' \qquad (1.6)$$

$$C_{M_{II}} = [M_{II}Y] + [M_{II}]' \qquad (1.7)$$

$$C_A = [M_IA] + [A]' \qquad (1.8)$$

The side reaction coefficient of the protonation and the formation of $M_{II}Y$, $\alpha_{H,M_{II}(Y)}$, is given by 1.9:

$$\alpha_{H,M_{II}(Y)} = \frac{[M_{II}Y] + [Y]'}{[Y]} \qquad (1.9)^{7}$$

When Eq. 1.9 is substituted into Eq. 1.6,

$$C_Y = [M_IY] + [Y]\ \alpha_{H,M_{II}(Y)} \qquad (1.10)$$

When Eqs. 1.4 and 1.10 are combined,

$$C_Y = [M_IY]\left(1 + \frac{[A]'}{[M_IA]}\frac{K_{M_IA'}\alpha_{H,M_{II}(Y)}}{K_{M_IY}}\right) \qquad (1.11)$$

By substituting Eqs. 1.3 and 1.5 into 1.11, we have

$$C_Y = \left(C_{M_I} - [M_IA] - \frac{[M_IA]}{[A]'}\frac{\beta_{(M_I)}\alpha_{H(A)}}{K_{M_IA}}\right) \times \left(1 + \frac{[A]'}{[M_IA]}\frac{K_{M_IA}\alpha_{H,M_{II}(Y)}}{K_{M_IY}\alpha_{H(A)}}\right) \qquad (1.12)$$

The indicator transition, ϕ, is defined as:

$$\phi = \frac{[A]'}{C_A} \qquad (1.13)$$

Designating $C_Y/C_{M_I} = a$, we obtain Eq. 1.14 from 1.8, 1.12 and 1.13:

$$a = 1 - \frac{1-\phi}{\phi}\frac{\beta_{(M_I)}\alpha_{H(A)}}{C_{M_I}K_{M_IA}} + \frac{\phi}{1-\phi}\frac{K_{M_IA}\alpha_{H,M_{II}(Y)}}{K_{M_IY}\alpha_{H(A)}} - \frac{C_A}{C_{M_I}}\left(1-\phi + \phi\frac{K_{M_IA}\alpha_{H,M_{II}(Y)}}{K_{M_IY}\alpha_{H(A)}}\right) - \frac{\beta_{(M_I)}\alpha_{H,M_{II}(Y)}}{C_{M_I}K_{M_IY}} \qquad (1.14)$$

2) J. M. H. Fortuin, P. Karsten and H. L. Kies, *Anal. Chim. Acta*, **10**, 356 (1954).
3) H. Flaschka and S. Khalafalla, *Z. anal. Chem.*, **156**, 401 (1957).
4) C. N. Reilley and R. W. Schmid, *Anal. Chem.*, **31**, 887 (1959).
5) H. Flaschka, *Talanta*, **1**, 60 (1958).
6) A is assumed to form a 1:1 chelate with M_I.
7) From the formation constant of $M_{II}Y$, we have $\alpha_{H,M_{II}(Y)} = K_{M_{II}Y}[M_I^I] + \alpha_{H(Y)}$
For a more detailed discussion of the concept of the ligand buffer, as well as for the calculation of $\alpha_{H,M_{II}(Y)}$, cf. M. Tanaka, *Anal. Chim. Acta*, **29**, 193 (1963).

Equation 1.14 is a quantitative expression of the indicator transition in the chelatometry of M_I in the presence of M_{II}, using HA as an indictor. Under conditions favorable for the titration, the last term of Eq. 1.14 may be neglected, and, when $C_A \ll C_{M_I}$, the fourth term on the right side of Eq. 1.14 may also be neglected. Therefore,

$$a=1-\frac{1-\phi}{\phi}\frac{\beta_{(M_I)}\alpha_{H(A)}}{C_{M_I}K_{M_IA}}+\frac{\phi}{1-\phi}\frac{K_{M_IA}\alpha_{H,M_{II}(Y)}}{K_{M_IY}\alpha_{H(A)}} \quad (1.15)$$

Near the equivalence point $[M_{II}Y]$ is negligibly small compared with $[M_{II}]'$ in Eq. 1.7, so

$$\alpha_{H,M_{II}(Y)}=K_{M_{II}Y}C_{M_{II}}/\beta_{(M_{II})}+\alpha_{H(Y)}$$

When the formation of $M_{II}Y$ is not appreciable, $\alpha_{H,M_{II}(Y)}=\alpha_{H(Y)}$. The substitution of this relationship into Eq. 1.15 gives an equation for the indicator transition in the absence of a second metal, M_{II}.[4,5]

Chelatometry Using the NY-HA System as an Indicator.—The indicator transition of a chelatometry using the NY-HA system as an indicator should be discussed for the following two cases separately:

a) $K_{M_I'Y'}>K_{N'Y'}$, e.g., the titration of calcium with EDTA, using the Mg-EDTA-Erio T system as an indicator, and b) $K_{N'Y'}>K_{M_I'Y'}$, e. g., the titration of aluminum with EDTA using the Cu-EDTA-PAN system as an indicator.

a) $K_{M_I'Y'}>K_{N'Y'}$. — This case corresponds to the so-called partial replacement titration, in which we consider the following two equilibria:

$$N' + A' \rightleftharpoons NA \quad (2.1)$$

$$NY + A' \rightleftharpoons NA + Y' \quad (2.2)$$

From the constants of equilibria 2.1 and 2.2, we have

$$[N]'=\frac{[NA]}{[A]'K_{N'A'}} \quad (2.3)$$

$$[Y]'=\frac{[A]'}{[NA]}\frac{[NY]K_{NA'}}{K_{NY'}} \quad (2.4)$$

Stoicheometric relationships 2.5 through 2.8 hold throughout the titration:

$$C_{M_I}=[M_IY]+[M_I]' \quad (2.5)$$

$$C_Y=[M_IY]+[NY]+[M_{II}Y]+[Y]' \quad (2.6)$$

$$C_N=[NY]+[NA]'+[N]' \quad (2.7)$$

$$C_A=[NA]+[A]' \quad (2.8)$$

N being added as NY, the total concentration of the complexan used as the titrant, C_Y', is given by $C_Y'=C_Y-C_N$. Therefore, from Eqs. 2.5, 2.6 and 2.7, we obtain

$$C_Y'=C_{M_I}-[M_I]'-[N]'+[Y]\alpha_{H,M_{II}(Y)}-[NA] \quad (2.9)$$

From the formation constants of M_IY and NY,

$$\frac{[M_IY]}{[M_I]'K_{M_I'Y}}=\frac{[NY]}{[N]'K_{N'Y}}$$

Therefore,

$$[M_I]'=\frac{C_{M_I}[N]'K_{N'Y}}{K_{M_I'Y}(C_N-[N]')+[N]'K_{N'Y}} \quad (2.10)$$

Substituting Eq. 2.10 into 2.9, we have

$$a=C_Y'/C_{M_I}=1-\frac{[N]'}{C_{M_I}}\times\left(1+\frac{C_{M_I}K_{N'Y}}{K_{M_I'Y}(C_N-[N]')+[N]'K_{N'Y}}\right)+\frac{[Y]\alpha_{H,M_{II}(Y)}}{C_{M_I}}-\frac{[NA]}{C_{M_I}} \quad (2.11)$$

When $K_{M_I'Y'}>K_{N'Y'}$ and $a>1-C_N/C_{M_I}$, we can neglect the second term in the parentheses of the second term on the right side of Eq. 2.11. Therefore, by combining Eqs. 2.3, 2.4 and 2.11, we obtain

$$a=1-\frac{1-\phi}{\phi}\frac{\beta_{(N)}\alpha_{H(A)}}{K_{NA}C_{M_I}}+\frac{\phi}{1-\phi}\frac{K_{NA}\alpha_{H,M_{II}(Y)}C_N}{K_{NY}\alpha_{H(A)}C_{M_I}}-\frac{C_A}{C_{M_I}}\left(1-\phi+\phi\frac{K_{NA}\alpha_{H,M_{II}(Y)}}{K_{NY}\alpha_{H(A)}}\right)-\frac{\beta_{(N)}\alpha_{H,M_{II}(Y)}}{K_{NY}C_{M_I}} \quad (2.12)$$

In a favorable condition for the titration, we can neglect the last term on the right side of Eq. 2.12, and, C_{M_I} being generally much greater than C_A, we can also neglect the fourth term. Therefore, we have

$$a=1-\frac{1-\phi}{\phi}\frac{\beta_{(N)}\alpha_{H(A)}}{K_{NA}C_{M_I}}+\frac{\phi}{1-\phi}\frac{K_{NA}\alpha_{H,M_{II}(Y)}C_N}{K_{NY}\alpha_{H(A)}C_{M_I}} \quad (2.13)$$

In the vicinity of the equivalence point, $\alpha_{H,M_{II}(Y)}=K_{M_{II}Y}C_{M_{II}}/\beta_{(M_{II})}+\alpha_{H(Y)}$ in Eq. 2.13, and when the formation of $M_{II}Y$ is not appreciable, $\alpha_{H,M_{II}(Y)}=\alpha_{H(Y)}$.

It should be remembered that Eq. 2.13 holds for $a>1-C_N/C_{M_I}$. For $a<1-C_N/C_{M_I}$, however, Eq. 2.13 does not hold; we can not neglect the second term in parentheses on the right side of Eq. 2.11. In this case, most Y being combined with M_I, $[N]'\simeq C_N$. Therefore, from Eq. 2.3,

$$1-\phi=\frac{C_NK_{N'A'}}{C_NK_{N'A'}+1}$$

The maximum coloration of the indicator is

determined by this equation. It then follows that, in order to secure a full coloration of NA before the equivalence point, the $C_N K_{N'A'}$ value should be much greater than unity.

b) $K_{N'Y'} > K_{M_I'Y'}$.—We shall consider the following two equilibria, the constants of which are denoted as K_1 and K_2:

$$NY + M_I' + A' \overset{K_1}{\rightleftharpoons} M_IY + NA$$

$$K_1 = \frac{[M_IY]\,[NA]}{[NY]\,[M_I]'\,[A]} = \frac{K_{M_I'Y} K_{NA'}}{K_{NY}} \quad (2.14)$$

$$NY + A' \overset{K_2}{\rightleftharpoons} NA + Y'$$

$$K_2 = \frac{[NA]\,[Y]'}{[NY]\,[A]'} = \frac{K_{NA'}}{K_{NY'}} \quad (2.15)$$

From expressions 2.14 and 2.15, we have

$$[M_I]' = \frac{[M_IY]\,[NA]}{[NY]\,[A]'K_1} \quad (2.16)$$

$$[Y]' = \frac{[A]'\,[NY]K_2}{[NA]} \quad (2.17)$$

The following stoicheometric relationships, 2.18 through 2.22, hold throughout the titration:

$$C_{M_I} = [M_IY] + [M_I]' \quad (2.18)$$

$$C_Y = [M_IY] + [M_{II}Y] + [NY] + [Y]' \quad (2.19)$$

$$C_{M_{II}} = [M_{II}Y] + [M_{II}]' \quad (2.20)$$

$$C_N = [NY] + [NA] + [N]' \quad (2.21)$$

$$C_A = [NA] + [A]' \quad (2.22)$$

N being generally added as NY, the total concentration of the complexan used as the titrant, C_Y', is given by the following:

$$C_Y' = C_Y - C_N \quad (2.23)$$

When N does not form any appreciable complexes other than NY and NA, [N]' can be neglected in Eq. 2.21. Therefore, by combining Eqs. 1.9, 2.19 and 2.23, we have

$$C_Y' = [M_IY] + [Y]\,\alpha_{H,M_{II}(Y)} - [NA] \quad (2.24)$$

Substituting Eq. 2.17 into 2.24,

$$C_Y' = [M_IY] + \frac{[A]'}{[NA]} \frac{[NY]\,K_2 \alpha_{H,M_{II}(Y)}}{\alpha_{H(Y)}} - [NA] \quad (2.25)$$

On the other hand, from Eqs. 2.16 and 2.18,

$$C_{M_I} = [M_IY]\left(1 + \frac{[NA]}{[A]'} \frac{1}{[NY]\,K_1}\right) \quad (2.26)$$

By combining Eqs. 2.25 and 2.26, we have

$$C_{Y'} = C_{M_I} \Big/ \left(1 + \frac{[NA]}{[A]'} \frac{1}{[NY]\,K_1}\right) + \frac{[A]'}{[NA]} \frac{[NY]\,K_2 \alpha_{H,M_{II}(Y)}}{\alpha_{H(Y)}} - [NA] \quad (2.27)$$

Under conditions favorable for titration, $[NA]/[A]'\,[NY]\,K_1$ is much smaller than unity in the vicinity of the equivalence point. Since C_{M_I} is generally much greater than C_A, the fourth term on the right side of Eq. 2.27 can be neglected. Moreover, when C_N is much greater than C_A, [NY] may be regarded as C_N. Therefore,

$$a = 1 - \frac{1-\phi}{\phi} \frac{K_{NY} \beta_{(M_I)} \alpha_{H(A)}}{K_{M_IY} K_{NA} C_N} + \frac{\phi}{1-\phi} \frac{K_{NA} \alpha_{H,M_{II}(Y)} C_N}{K_{NY} \alpha_{H(A)} C_{M_I}} \quad (2.28)$$

In the vicinity of the equivalence point, $\alpha_{H,M_{II}(Y)}$ is given by the following:

$$\alpha_{H,M_{II}(Y)} = K_{M_{II}Y} C_{M_{II}} / \beta_{(M_{II})} + \alpha_{H(Y)}$$

and, when the formation of $M_{II}Y$ is not appreciable, $\alpha_{H,M_{II}(Y)} = \alpha_{H(Y)}$.

A General Discussion of the Indicator Transition in the Vicinity of the Equivalence Point of Chelatometry.—In Eqs.1.15, 2.13 and 2.28, ϕ is a value expressing the indicator transition, and the second term is mainly concerned with the color transition before the equivalence point, while the third is mainly concerned with the color transition after the equivalence point.

Equations 1.15, 2.13 and 2.28 can be rewritten as the following general form:

$$a = 1 - \frac{1-\phi}{\phi} f_1 + \frac{\phi}{1-\phi} f_2$$

Thus the indicator transition near the equivalence point in any chelatometry is determined by a combination of f_1 and f_2 values; the lower the values of f_1 and f_2, the sharper the indicator transition.

Now it should be noted that the value of $f_1 f_2$ is independent of the indicator characteristics and is given by the following:

$$f_1 f_2 = \frac{\alpha_{H,M_{II}(Y)} \beta_{(M_I)}}{K_{M_IY} C_{M_I}}$$

Thus, if $K_{M_{II}'Y'}$ is sufficiently low, a distinct indicator transition will be obtained even for a high value of $C_{M_{II}}/C_{M_I}$. From Eqs. 1.15, 2.13 and 2.28, it can easily be seen that M_{II} hardly affects the indicator transition *before* the equivalence point. However, the higher the value of $\alpha_{H,M_{II}(Y)}$ or $K_{M_{II}'Y'} C_{M_{II}}$, the less distinct the indicator transition *after* the equivalence point. ϕ or $1-\phi$ versus a diagrams drawn for various combinations of f_1 and f_2 values facilitate the establishment of the optimum conditions for a given problem; the computation of f_1 and f_2 values for a given

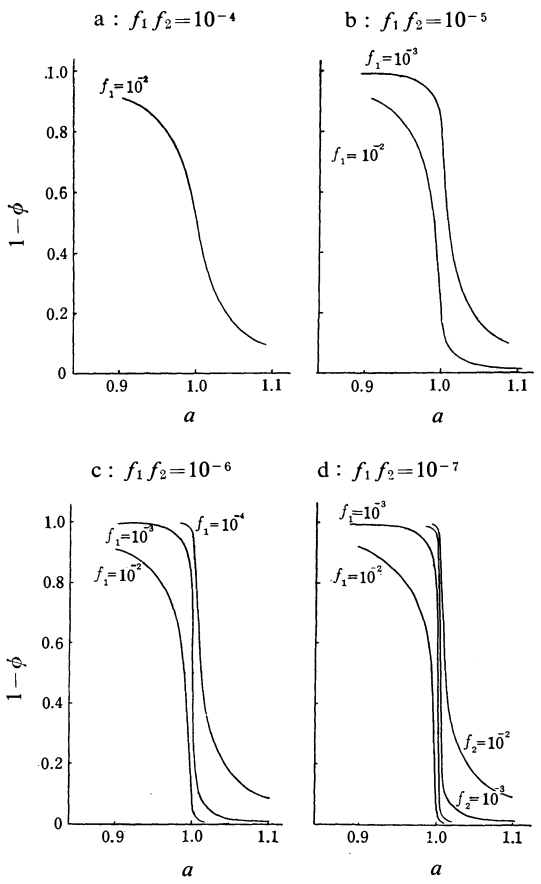

Fig. 1. Theoretical indicator transition for various couples of f_1 and f_2.

system makes possible the prediction of the indicator transition (Fig. 1).

We would like to emphasize that Eqs. 1.15, 2.13 and 2.28 make possible a theoretical consideration of the indicator transition in any type of chelatometry using HA or the NY-HA system as an indicator.

Applicability of the Theory

The above theory has been confirmed experimentally in some familiar examples of the titration of alkaline earths with EDTA, using Erio T as an indicator.

HA as an Indicator.—The titration of magnesium with EDTA, using Erio T as an indicator.

a) In the absence of a second metal.

Condition: $C_{M_I} = C_{Mg} = 10^{-3}$ M; $C_{M_{II}} = 0$; pH $= 10$.[8] Using log $K_{MgY} = 8.69$ and log $K_{MgA'}$ (pH $= 10$) $= 5.44$,[9] f_1 and f_2 are computed thus:

$$f_1 = \frac{1}{K_{MgA'} C_{Mg}} = 10^{-2.44}; \quad f_2 = \frac{K_{MgA'}}{K_{MgY'}} = 10^{-2.80}$$

From these values, a distinct indicator transition is anticipated in the vicinity of the equivalence point (cf. Fig. 1).

b) In the presence of sodium.

When $C_{M_{II}} = C_{Na} = 1$ M, f_1 is the same as in a) and, from log $K_{NaY} = 1.66$,

$$f_2 = \frac{K_{MgA'}}{K_{MgY'}} (K_{NaY'} C_{Na} + 1) = 10^{-1.56}$$

Thus the discoloration of Mg-Erio T after the equivalence point will become somewhat sluggish. However, the visual titration of magnesium in the presence of 1 M sodium is possible.[10]

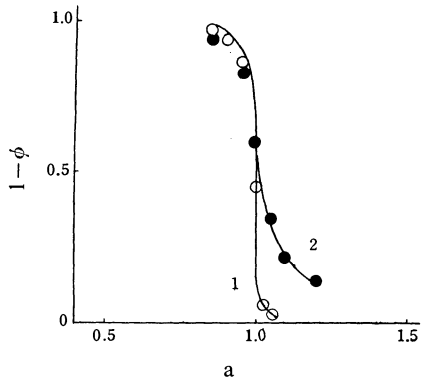

Fig. 2. Indicator transition of the titration of magnesium using Erio T as an indicator.
—— Theoretical indicator transition:
Curve 1: Na=0, Curve 2: Na=1 M
○● Experimental values:
○: Na=0, ●: Na=1 M

Figure 2 shows the results of the photometric titration of magnesium, using Erio T as an indicator, as well as the theoretical indicator transition curve. The experimental results agree well with the theoretical curves after the equivalence point. The discordance between the observed and the theoretical curves before the equivalence point may be attributable to the decomposition of Erio T, which is accelerated in the presence of sodium.[11]

The purity of commercial preparations of Erio T is often very low, and the decomposition of impure Erio T is particularly fast. A method for the purification of Erio T has

8) At a pH value of 10 neither hydrolysis nor the ammine formation of magnesium needs to be taken into consideration.

9) G. Schwarzenbach, "Die komplexometrische Titration," Ferdinand Enke Verlag, Stuttgart (1955). p. 27.

10) Using an indicator such as Erio T, of which the contrast of metallized and unmetallized indicator is sufficiently large, visual titration is possible with values of f_1 and f_2 up to about $10^{-1.5}$.

11) G. Nakagawa and M. Tanaka, unpublished results.

been described[12]; in the present investigation, however, we employed Erio T purified by the following simplified procedure: 20 g. of commercial Erio T (Dojindo Chemical Co., Kumamoto) are washed five times with 50 ml. of 2 N hydrochloric acid. The desalted dye is then air-dried and recrystallized from dimethylformamide. Though the obtained dimethylammonium salt of Erio T is not very pure, it is satisfactory for all practical purposes.

The NY-HA System as an Indicator.—*i) Partial Replacement Titration, $K_{MI'Y'} > K_{N'Y'}$.*—The titration of calcium, with EDTA using the MgY-ErioT system as an indicator.

a) In the absence of a second metal.

Condition: $C_{MI} = C_{Ca} = 10^{-3}$M; $C_{MII} = 0$; pH $=10$. Using the values log $K_{CaY} = 10.70$, K_{MgY} and $K_{MgA'}$ (pH$=10$), f_1 and f_2 in Eq. 2.13 are computed:

$$f_1 = \frac{1}{K_{MgA'} C_{Ca}} = 10^{-2.44}$$

$$f_2 = \frac{K_{MgA'} C_{Mg}}{K_{MgY} C_{Ca}} = 10^{0.20} C_{Mg}$$

f_1, f_2 and $(1-\phi)_{max}$ values for various values of C_{Mg} are given in Table I.

Table I. f_1 and f_2 for various values of C_{Mg} in the chelatometry of calcium using MgY-Erio T system as an indicator

C_{Mg}, M	log f_1	log f_2	$(1-\phi)_{max}$
10^{-3}	−2.44	−2.80	0.996
10^{-4}	−2.44	−3.80	0.965
10^{-5}	−2.44	−4.80	0.734

From Table I it may easily be deduced that about 10^{-4}M of magnesium will give the best results.

b) In the presence of sodium.

The indicator transition is considered for the chelatometry of calcium in the presence of 1M sodium using C_{Mg} of 10^{-4}M, which gives the best indicator transition in the absence of a second metal. f_1 and $(1-\phi)_{max}$ are the same as in i a), and

$$f_2 = \frac{K_{MgA'} C_{Mg}}{K_{MgY'} C_{Ca}} (K_{NaY'} C_{Na} + 1) = 10^{-2.57}$$

It is evident that calcium is successfully titrated in the presence of 1M sodium.

ii) $K_{N'Y'} > K_{MIY'}$.—The titration of barium with EDTA, using the MgY-Erio T system as an indicator.

a) In the absence of a second metal.

Condition: $C_{MI} = C_{Ba} = 10^{-3}$M; $C_{MII} = 0$; pH $=10$. Calculation gives the following values:

$$f_1 = 10^{-4.51}/C_{Mg} \text{ and } f_2 = 10^{0.20} C_{Mg}$$

12) H. Diehl and F. Lindstrom, *Anal. Chem.*, **31**, 414 (1959).

f_1 and f_2 for various values of C_{Mg} are given in Table II. Table II also shows that 5×10^{-3}M of magnesium will give the best indicator

Table II. f_1 and f_2 for various values of C_{Mg} in the chelatometry of barium using MgY-Erio T system as an indicator

C_{Mg}, M	log f_1	log f_2
10^{-2}	−2.51	−1.80
5×10^{-3}	−2.21	−2.10
2×10^{-3}	−1.81	−2.50
10^{-3}	−1.51	−2.80
10^{-5}	−0.51	−3.80

○● Experimental values:
○: Na$=0$, ●; Na$=1$ M

transition; this is not, however, very satisfactory.

The discussion given under i), agrees well with that of Schwarzenbach.[13]

b) In the presence of sodium.

A similar consideration has been made for $C_{Mg}=5\times10^{-3}$M, $C_{Na}=0.1$ N. The computed values of f_1 and f_2 are as follows:

$$f_1=10^{-2.21} \text{ and } f_2=10^{-1.68}$$

Judging from these values, it is anticipated that the presence of 0.1M sodium may be tolerable in the visual titration of barium, using MgY-Erio T as an indicator. However, a larger amount of sodium will make the indicator transition sluggish.

Figures 3 and 4 show the results obtained for calcium and barium. The experimental results agree well with the theoretical indicator transition after the equivalence point. As has been indicated, the discordance between the observed and the theoretical curves before the equivalence point may be attributable to the decomposition of Erio T.[14]

It is true that the difference in ionic strength or the addition of an organic solvent may modify the constants involved, but in the ordinary range of the usual experimental conditions the modification of the constants rarely exceeds one logarithm unit. Therefore, for most cases, the titration can be predicted on a sound theoretical basis by the proposed equations.

Summary

General equations have been proposed for the indicator transition in the chelatometry of a metal in the presence of other metals, using HA or the NY-HA system as an indicator. The validity of these equations has been confirmed experimentally in several examples of practical importance. If the constants involved are all available, it is possible, by the aid of the proposed equations, to predict the optimum conditions for any type of chelatometry.

List of Symbols

Symbols used are summarized below in the order of appearance in the text. Most of them are of current use in the literature, but in order to avoid confusions they are defined once when appeared for the first time.

- M, N Metal
- Y Complexan
- NY Chelate of metal N with complexan Y
- HA Metallochromic indicator
- M′ Metal M not combined with Y and A
- Y′ Y not combined with M_I
- [M]′, etc. Concentration of M′, etc.
- K_{MY}, etc. Stability constant of MY, etc.
- $\alpha_{H(Y)}$ Side reaction coefficient of protonation of Y.
- $\alpha_{H(A)}$ Side reaction coefficient of protonation of A: $\alpha_{H(A)}=[A]'/[A]$
- $\alpha_{H,M_{II}(Y)}$ Side reaction coefficient of protonation and chelation with M_{II} of Y
- $\beta_{(M)}$ Side reaction coefficient of complex formation of M with auxiliary complexing agents: $\beta_{(M)}=[M]'/[M]$
- $K_{M'Y'}$ etc. Conditional stability constant of MY: $K_{M'Y'}=K_{MY}/\alpha_{H(Y)}\beta_{(M)}$, $K_{M'Y}=K_{MY}/\beta_{(M)}$, $K_{MY'}=K_{MY}/\alpha_{H(Y)}$
- C_M, etc. Total concentration of M, etc.
- $C_{Y'}$ Total concentration of Y used as titrant
- a Fraction titrated: C_Y/C_{MI}
- ϕ Indicator transition: $[A]'/C_A$

A New Method for the Colorimetric Determination of Hypophosphate Ions with the Molybdenum(V)-Molybdenum(VI) Reagent

By Norimasa Yoza and Shigeru Ohashi

(Received August 12, 1963)

This work was undertaken to establish a method for the colorimetric determination of hypophosphate ions in the presence of hypophosphite, phosphite, and orthophosphate ions. No colorimetric methods specific to hypophosphate ions have yet been reported. Hypophosphate ions can be determined indirectly by oxidizing them to orthophosphate ions and then by employing conventional method for the colorimetric determination of orthophosphate ions. However, this procedure can not be employed in the presence of hypophosphite or phosphite ions. In a previous paper[1] it has been mentioned that hypophosphoric acid does not give any colored products when it is treated with ammonium molybdate(VI) in a perchloric acid solution.

Lucena-Conde and Prat[2] have proposed a new reagent for the colorimetric determination of orthophosphate ions. This reagent is an acid solution of a mixture of molybdenym(V) and molybdenum(VI) and reacts with orthophosphoric acid to form a blue complex. In the present paper this reagent is called the molybdenum(V)-molybdenum(VI) reagent. During the course of a series of investigations of lower oxo acids of phosphorus, it was found that hypophosphoric acid reacts with this molybdenum(V)-molybdenum(VI) reagent to form a blue complex and that this reaction can be applied to the colorimetric determination of hypophosphate ions in the presence of hypophosphite, phosphite, and orthophosphate ions. The properties and composition of the blue complex due to hypophosphoric acid were compared with those of the blue complex due to orthophosphoric acid by means of spectrophotometry and the solvent extraction method.

The term "heteropoly blue" has commonly been used for the blue complex of orthophosphoric acid with molybdenum.[3] For the sake of convenience, the present authors employ the term "hypophosphoric heteropoly blue" for the blue complex produced by the reaction of hypophosphoric acid with the molybdenum molybdenum(VI) reagent and the term "orthophosphoric heteropoly blue" for the blue complex due to orthophosphoric acid.

Experimental

Apparatus.—A Shimadzu photoelectric spectrophotometer, QB-50, with 1.00 cm. cells was employed.

Reagents.—Disodium dihydrogen hypophosphate hexahydrate was supplied by Blaser and Worms. Sodium hypophosphite monohydrate, disodium phosphite pentahydrate, potassium dihydrogen orthophosphate, and the other reagents used were commercial reagents of the purest grade. The molybdenum(V)-molybdenum(VI) reagent was prepared by the procedure described by Lucena-Conde and Prat.[2] The concentrations of the constituents of this reagent were 0.08 M for molybdenum(V), 0.12 M for molybdenum(VI), 10 N for sulfuric acid, and 3 N for hydrochloric acid.

The Procedure for the Determination of Hypophosphate.—A suitable amount of an approximately neutral solution of a given sample was placed in a 25 ml. volumetric flask and diluted to about 20 ml. with water. After 2 ml. of the molybdenum(V)-molybdenum(VI) reagent had been added, the solution was shaken well. Then, the volume was adjusted to the mark with water and again the solution was well shaken. After the solution had been kept at room temperature for 30 min., the absorbance at 670 mμ was measured. A reagent blank was used as a reference solution.

The Procedure for the Determination of Molybdenum in Organic Extracts.—The molybdenum contained in "hypophosphoric and orthophosphoric heteropoly blue" extracted in an organic phase was determined by Lueck and Boltz's method.[4] An *n*-butyl alcohol phase which separated from an aqueous phase was washed three times with an equal volume of 1 N sulfuric acid to remove an excess of molybdate in the organic phase. By shaking the organic phase with a buffer solution of 0.5 M aqueous ammonia and 0.5 M ammonium chloride, the molybdate in the organic phase came into the aqueous phase. The absorbance at 230 mμ due to molybdate(VI) ions was measured.

Results and Discussion

Reactions at 95°C.—Lucena-Conde and Prat have investigated the color reaction of ortho-

phosphoric acid with the molybdenum(V)-molybdenum(VI) reagent and its application to the determination of orthophosphate ions. In this case it is necessary to heat a test solution at 95°C for 1 hr. in order to ensure complete color development. Under the same conditions, the reactions of hypophosphorous, phosphorous, and hypophosphoric acid with the molybdenum(V)-molybdenum(VI) reagent were examined. As is shown in Fig. 1, hypo-

A: Hypophosphorous and phosphorous acid, each 62.0 μg. as P in 25 ml.
B: Orthophosphoric acid, 12.4 μg. as P in 25 ml.
C: Hypophosphoric acid, 25.9 μg. as P in 25 ml.
D: A mixture of orthophosphoric acid, 12.4 μg. as P, and hypophosphoric acid, 25.9 μg. as P in 25 ml.
Reaction temp.; 95°C, Reaction time; 1 hr.

phosphorous and phosphorous acid do not give any color reactions, while hypophosphoric acid gives "hypophosphoric heteropoly blue," the absorption spectrum of which has two maximums, at 590 and at 670 mμ. "Orthophosphoric heteropoly blue" gives a spectrum, with a maximum at 820 mμ, which is identical with the spectrum of the well-known blue complex produced by the reduction of molybdophosphoric acid. Curve D in Fig. 1 was obtained for a mixture of orthophosphoric and hypophosphoric acid, the quantities of which are equal to those used in the cases of curves B and C respectively. The sum of the absorbances of curves B and C is quite identical with curve D. It is well known that hypophosphoric acid is hydrolyzed by heating it with mineral acid to form phosphorous and orthophosphoric acid.[5] However, the facts mentioned above indicate that hypophosphoric acid is not hydrolyzed by heating it in an acid solution at 95°C for 1 hr. if the molybdenum(V)-molybdenum(VI) reagent is also present.

Reactions at Room Temperature.—The reactions of hypophosphorous, phosphorous, hypophosphoric, and orthophosphoric acid with the molybdenum(V)-molybdenum(VI) reagent at room temperature were examined. As was to be expected, hypophosphorous and phosphorous acid do not cause any color reactions. Hypophosphoric acid forms "hypophosphoric heteropoly blue." As is shown in Fig. 2, there is no difference among the shapes of absorption spectra of "hypophosphoric heteropoly blue" produced from hypophosphoric acid of various concentrations at room temperature (curves A, C, E, and F) and at 95°C (curves B and D). Therefore, it has been concluded that the species of "hypophosphoric heteropoly blue" produced under the various conditions mentioned above are quite identical with one another. Orthophosphoric acid gives a faint blue color (curve G in Fig. 2), the intensity of which is highly dependent on the reaction temperature.[2]

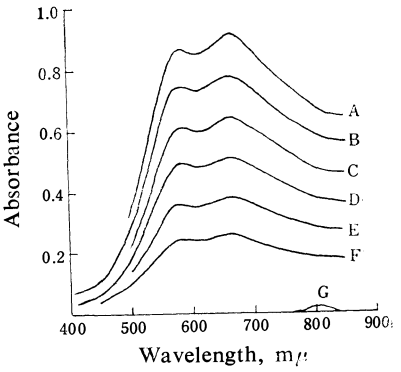

Fig. 2. Absorption spectra of "hypophosphoric heteropoly blue" produced under various conditions and an absorption spectrum of "orthophosphoric heteropoly blue" produced at room temperature.
A, C, E, and F: Hypophosphoric acid, 45.5, 32.5, 19.5, and 13.0 μg. as P in 25 ml., respectively. Reaction temp.; room temp. Reaction time; 30 min.
B, and D: Hypophosphoric acid, 39.0 and 26.0 μg. as P in 25 ml., respectively. Reaction temp.; 95°C, Reaction time; 1 hr.
G: Orthophosphoric acid, 12.4 μg. as P in 25 ml. Reaction temp.; room temp. Reaction time; 30 min.

The Effect of Reagent Concentration.—Varying quantities of the molybdenum(V)-molybdenum(VI) reagent and hypophosphoric acid, 32.4 μg. as phosphorus, were allowed to react at room temperature for 30 min. When the reagent amount was 0.5, 1.0, 2.0 or 4.0 ml., the

5) J. R. Van Wazer "Phosphorus and Its Compounds," Interscience Publishers, Inc., New York (1958), p. 410.

absorbance at 670 mμ was 0.551, 0.620, 0.620, or 0.621 respectively. Hence, 2 ml. of the reagent is sufficient to ensure the color development.

The Effect of Acid Concentration.—If 2 ml. of the molybdenum(V)-molybdenum(VI) reagent is added to an approximately neutral solution of a sample and diluted to 25 ml. with water, the final acidity will be 1.04 N. The reaction of hypophosphoric acid with the reagent at room temperature was studied at various final acidities, which were regulated by the addition of sulfuric acid or sodium hydroxide. When a final acidity is lower than 0.3 N, a reagent blank is blue. On the other hand, the higher a final acidity is, the lower the reaction rate becomes. For instance, when a final acidity is 2.0 N, it took about 2 hr. for the complete color development. When a final acidity lies between 0.6 and 1.4 N, the complete color development is attained within 30 min. The resulting blue color is stable for at least 3 hr.

A recommended procedure for the determination of hypophosphate ions is described in the experimental section. A calibration curve obtained by this procedure follows Beer's law, as Fig. 3 shows. A molar extinction coefficient of "hypophosphoric heteropoly blue" at 670 mμ is 3.04×10^4 on the assumption that a molecule of the blue complex contains a molecule of hypophosphoric acid.

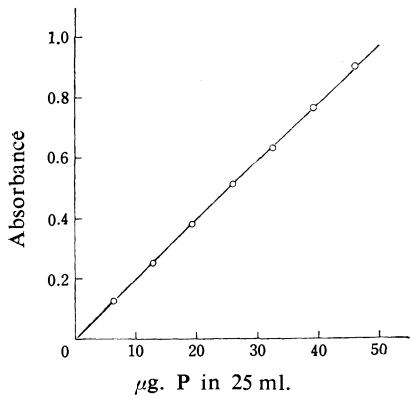

Fig. 3. Calibration curve for hypophosphate ions, at 670 mμ.

Interference.—The effect of several ions on the determination of hypophosphate ions is indicated in Table I. The presence of a large excess of hypophosphite, phosphite, orthoarsenate, and metasilicate ions caused no interference. The presence of orthophosphate ions likewise caused no serious interference if its quantity was less than or comparable with the quantity of hypophosphate ions. Wolframate ions caused a serious interference because they form a blue product by reaction with the reagent.

The Solvent Extraction of "Hypophosphoric and Orthophosphoric Heteropoly Blue."—"Hypophosphoric and orthophosphoric heteropoly blue can be extracted into *n*-butyl alcohol, isobutyl alcohol, tributyl phosphate, or cyclohexanone. Chloroform, carbon tetrachloride, hexane, benzene, xylene, cyclohexane, *n*-butyl acetate, and ethyl ether are not good extractants for both heteropoly blues. "Orthophosphoric heteropoly blue" produced by the reduction of molybdophosphoric acid shows a similar behavior in the solvent extraction.[6] When aqueous solutions of "hypophosphoric and orthophosphoric heteropoly blue" produced by reaction with the molybdenum(V)-molybdenum(VI) reagent are shaken with an equal volume of *n*-butyl alcohol, the blue complexes are completely extracted into the organic phase. When *n*- or iso-butyl alcohol diluted with benzene is used as an extractant, the difference between the extractability of the two heteropoly blues can be observed as is illustrated in Fig. 4. "Hypophosphoric heteropoly blue" is less extractable than "orthophosphoric heteropoly blue." Absorption spectra of both heteropoly blues in *n*-butyl alcohol are shown in Fig. 5.

Lueck and Boltz[4] have described a method for the determination of the molybdenum(VI) content in an organic extract of molybdophosphoric acid. This method was applied in the present investigation to the determination of molybdenum combined with hypophosphoric acid and orthophosphoric acid in both heteropoly blues. When organic extracts of both heteropoly blues were shaken with a buffer solution of ammonia and ammonium chloride, the blue colors disappeared. It was found that no molybdenum remains in the organic phase after this

treatment and that molybdenum(V) is oxidized to molybdenum(VI) by shaking it with the buffer solution in air. The resulting molybdenum(VI) in the aqueous solution can be determined by measuring the absorbance at 230 mμ (Fig. 6). The relations between the contents of molybdenum and phosphorus in both heteropoly blues are shown in Fig. 7. From these data, the mole ratios of molybdenum (a sum of molybdenum(V) and molybdenum(VI)) to hypophosphoric and orthophosphoric acid in both heteropoly blues were calculated to be approximately 9 and 12 respectively.

Summary

It was found that hypophosphoric acid reacts with the molybdenum(V)-molybdenum(VI) reagent at room temperature as well as at 95°C to form a blue complex, the absorption spectrum of which has maximums at 590 and 670 mμ. Although orthophosphoric acid reacts with this reagent at 95°C to form a blue complex, it gives only a faint blue color at room temperature. Hypophosphorous and phosphorous acid do not give any colored products when treated with this reagent. Therefore, the

reaction of hypophosphoric acid with this reagent at room temperature can be applied to the colorimetric determination of hypophosphate ions in the presence of hypophosphite, phosphite, and orthophosphate ions. The differences in the absorption spectra and solvent extraction behavior between the two blue complexes due to hypophosphoric and orthophosphoric acid (" hypophosphoric heteropoly blue " and " orthophosphoric heteropoly blue ") have been described. The mole ratios of molybdenum to hypophosphoric and orthophosphoric acid in the blue complexes were found to be approximately 9 and 12 respectively.

The authors wish to express their hearty thanks to Professor Jun Yoshimura for the kind suggestions made in the course of this work. The authors also wish to thank Dr. Bruno Blaser and Dr. Karl-Heinz Worms for supplying the sodium hypophosphate used in this study.

The Reactions of Lower Oxo Acids of Phosphorus with the Molybdenum(V)-Molybdenum(VI) Reagent

By Norimasa YOZA and Shigeru OHASHI

(Received August 14, 1963)

In a previous paper[1] it has been found that hypophosphoric acid reacts with the molybdenum(V)-molybdenum(VI) reagent to form a blue complex, while hypophosphorous and phosphorous acid do not produce any color reactions. Orthophosphoric acid also reacts with this reagent to form a blue complex, as has been pointed out by Lucena-Conde and Prat.[2] The blue complexes due to hypophosphoric and orthophosphoric acid are called "hypophosphoric heteropoly blue" and "orthophosphoric heteropoly blue" respectively.[1] The present investigation deals with the color reactions of various lower oxo acids of phosphorus with this reagent. The data obtained indicate that the mechanism of these reactions are closely related to the structural units of the lower oxo acids of phosphorus and their hydrolysis reactions. The abbreviated notations proposed by Blaser and Worms[3] will be used for the oxo acids of phosphorus in this paper. For instance, hypophosphorous, phosphorous, hypophosphoric, and orthophosphoric acid are represented by the notations, ^{1}P–, ^{3}P–, ^{4}P–^{4}P–, and ^{5}P–acid respectively. The Arabic numerals attached to the phosphorus atoms represent the oxidation numbers of the phosphorus atoms.

Experimental

Reagent. — All the reagents used in this work have been described in previous papers.[1,4]

The Procedure for the Color Reactions. — A suitable aliquot of a neutral solution of a given sample (about 10^{-4} M) was taken in a 25 ml. volumetric flask, diluted to approximately 20 ml. with water, and treated by each of the following three procedures. After the volume of the solution had been adjusted to the mark with water, the absorption spectrum was measured by the use of a Shimadzu photoelectric spectrophotometer, QB-50, with 1 cm. cells.

Procedure I. — The sample solution was allowed to react with 2 ml. of the molybdenum(V)-molybdenum(VI) reagent for 30 min. at room temperature.

Procedure II. — The sample solution was allowed to react with 2 ml. of the molybdenum(V)-molybdenum(VI) reagent for 1 hr. at 95°C.

Procedure III. — The sample solution was allowed to react with a mixture of 1 ml. of 1 M sodium hydrogen sulfite solution and 2 ml. of the molybdenum(V)-molybdenum(VI) reagent for 1 hr. at 95°C.

Results and Discussion

As has been pointed out in a previous

1) N. Yoza and S. Ohashi, This Bulletin, **37**, 33 (1964).
2) F. Lucena-Conde and L. Prat, *Anal. Chim. Acta*, **16**, 473 (1957).
3) B. Blaser and K.-H. Worms. *Z. anorg. u. allgem. Chem.*, **300**, 225 (1959)
4) S. Ohashi and N. Yoza, This Bulletin, **36**, 707 (1963).

paper,[1] $^{4}_{4}$P–P–acid reacts with the molybdenum-(V)-molybdenum(VI) reagent under the conditions of procedures I and II to form hypophosphoric heteropoly blue, the absorption spectrum of which has two maxima, at 590 and 670 mμ, while ^{1}P– and ^{3}P–acid do not give any colored products under the conditions of either procedures I or II. ^{5}P–Acid reacts with this reagent under the conditions of procedure II to form orthophosphoric heteropoly blue, the absorption spectrum of which has a maximum at 820 mμ. Under the conditions of procedure I, the rate of the reaction is so slow that ^{5}P–acid gives only a faint blue color. If the quantity of ^{5}P–acid is comparable to that of $^{4}_{4}$P–P–acid, the absorbance due to orthophosphoric heteropoly blue is negligibly small compared with that due to hypophosphoric heteropoly blue.

In the course of this investigation, it was found that ^{1}P– or ^{3}P–acid is quantitatively oxidized with sodium hydrogen sulfite to ^{5}P–acid when heated in an acid solution at 95°C. The sulfite is reduced to elemental sulfur in the course of this reaction. Therefore, when ^{1}P– or ^{3}P–acid is treated by procedure III, orthophosphoric heteropoly blue is produced quantitatively. Since the elemental sulfur produced coagulates, it does not interfere with the measurement of the absorbance of the blue color.

The reactions of twelve lower oxo acids of phosphorus as well as of ^{5}P–acid with the molybdenum(V)-molybdenum(VI) reagent were carried out by procedures I, II, and III. All the blue products were either orthophosphoric or hypophosphoric heteropoly blue, or a mixture of them. The quantities of both the heteropoly blues were calculated from the absorbances of the spectra. All the results are summarized in Table I. The final acidity of the reaction mixture is approximately 1 N with respect to the sulfuric and hydrochloric acid in all cases.[1] Since the molecular structures of orthophosphoric and hypophosphoric heteropoly blue have not been determined, it is assumed, for the sake of convenience, that one mole of each heteropoly blue contains one mole of ^{5}P– or $^{4}_{4}$P–P– units.

The Reactions with Procedure I. — One mole of ^{3}P–O–$^{4}_{4}$P–P–, (–$^{4}_{4}$P–P–O–)$_2$–ring, $^{4}_{4}$P–P–O–$^{4}_{4}$P–P–, or ^{5}P–O–$^{4}_{4}$P–P–acid, which contains one or two

^{5}P–Acid	0	0	0	1.01	0	1.00

Mole ratios of the products to the starting compounds are shown.

$^{4}_{4}$P–P–Mo ; Hypophosphoric heteropoly blue

^{5}P–Mo ; Orthophosphoric heteropoly blue

$^{4\ 4}$P–P–units in its structure, produces one or two moles of hypophosphoric heteropoly blue when procedure I is used. These results suggest that all the four oxo acids undergo hydrolysis to form $^{4\ 4}$P–P–acid, which reacts successively with the molybdenum(V)-molybdenum(VI) reagent. One mole of $^{4\ 3\ 4}$P–P–P–acid produces one mole of hypophosphoric heteropoly blue. Therefore, it is evident that $^{4\ 3\ 4}$P–P–P–acid is hydrrolyzed by procedure I according to Eq. 1, not Eq. 2:

$$^{4\ 3\ 4}\text{P–P–P–Acid} \rightarrow {}^{4\ 4}\text{P–P–Acid} + {}^{3}\text{P–Acid} \quad (1)$$

$$^{4\ 3\ 4}\text{P–P–P–Acid} \rightarrow {}^{2\ 4}\text{P–P–Acid} + {}^{5}\text{P–Acid}$$

$$\rightarrow 2\,{}^{3}\text{P–Acid} + {}^{5}\text{P–Acid} \quad (2)$$

As has been discussed in a previous paper,[5] $^{4\ 3\ 4}$P–P–P–acid is hydrolyzed also in a perchloric acid solution according to Eq. 1. One mole of $(-{}^{3}\text{P}-)_6$–ring acid produces approximately 0.8 mol. of hypophosphoric heteropoly blue. Although the reaction mechanism of the hydrolysis of $(-{}^{3}\text{P}-)_6$–ring acid has not been clarified, the data obtained here indicate at least that $^{4\ 4}$P–P–acid is one of the main intermediate products in the hydrolysis of $(-{}^{3}\text{P}-)_6$–ring acid. ^{1}P–, ^{3}P–, $^{3\ 3}$P–O–P–, $^{2\ 4}$P–P–, $^{3\ 5}$P–O–P–, and ^{5}P–acid do not give any colored products when procedure I is used, because of the impossibility of its producing $^{4\ 4}$P–P–acid.

The Reactions Using Procedure II.—The final products in the hydrolysis of ^{3}P–O–P–P–, $^{4\ 3}$P–P–P, $^{4\ 4}$P–P–, $(-{}^{4\ 4}\text{P–P–O}-)_2$–ring, $^{4\ 4}$P–P–O–P–P–, and ^{5}P–O–P–P–acid are ^{3}P– and ^{5}P–acid when they are boiled in mineral acid.[6,7] As for $(-{}^{3}\text{P}-)_6$–ring acid, the final products in the hydrolysis with mineral acid are ^{1}P–, ^{3}P– and ^{5}P-acid.[8] However, when procedure II is used, $(-{}^{3}\text{P}-)_6$–ring, ^{3}P–O–P–P–, $^{4\ 4}$P–P–P–, $(-{}^{4\ 4}\text{P–P–O}-)_2$–ring, and $^{4\ 4}$P–P–O–P–P–acid give hypophosphoric heteropoly blue, the absorption spectra of which are quite identical with those of the blue products obtained from the respective compounds by procedure I. One mole of ^{5}P–O–$^{4\ 4}$P–P–acid produces a mixture of one mole of orthophosphoric heteropoly blue and one mole of hypophosphoric heteropoly blue when procedure II is used. These results indicate that $^{4\ 4}$P–P–acid produced by the hydrolysis of the lower oxo acids of phosphorus mentioned above reacts preferentially with the molybdenum(V)-molybdenum(VI) reagent and that the resulting hypophosphoric heteropoly blue is remarkably stable under the conditions of procedure II.

One mole of ^{3}P–O–^{5}P–acid produces one mole of orthophosphoric heteropoly blue when procedure II is used, because ^{3}P–O–^{5}P–acid is hydrolyzed to form ^{3}P– and ^{5}P–acid. ^{1}P–, ^{3}P–, ^{3}P–O–^{3}P–, and $^{2\ 4}$P–P–acid do not give any colored products when procedure II is used.

The Reaction Using Procedure III.—One mole of ^{3}P–O–^{3}P–acid produces two moles of orthophosphoric heteropoly blue when procedure III is used, because ^{3}P–O–^{3}P–acid is hydrolyzed in the course of procedure III to form ^{3}P–acid. When procedure III is used, $^{4\ 4}$P–P–, $(-{}^{4\ 4}\text{P–P–O}-)_2$–ring, $^{4\ 4}$P–P–O–$^{4\ 4}$P–P–, and ^{5}P–O–$^{4\ 4}$P–P–acid give the same products as in the case of procedure II, because there is no ^{1}P– or ^{3}P–acid in the hydrolysis products of these oxo acids. Since one mole of ^{3}P–O–$^{4\ 4}$P–P– or $^{4\ 3\ 4}$P–P–P–acid is converted into one mole of $^{4\ 4}$P–P–acid and one mole of ^{3}P–acid in the first step of its hydrolysis, the reaction products of ^{3}P–O–$^{4\ 4}$P–P– or $^{4\ 3\ 4}$P–P–P–acid obtained by procedure III exhibit the absorption spectra due to an equimolar mixture of orthophosphoric and hypophosphoric heteropoly blue. One mole of ^{3}P–O–^{5}P–acid produces, of course, two moles of orthophosphoric heteropoly blue when procedure III is used. $^{2\ 4}$P–P–Acid produces orthophosphoric heteropoly blue with a small amount of hypophosphoric heteropoly blue when procedure III is used. Since the hydrolysis product of $^{2\ 4}$P–P–acid in mineral acid is ^{3}P–acid, it is reasonable that the main product obtained by procedure III is orthophosphoric heteropoly blue. The small amount of hypophosphoric heteropoly blue may be due to the redox

reaction between sulfite and $\overset{2\ 4}{\text{P–P}}$–acid, where a part of the $\overset{2\ 4}{\text{P–P}}$–acid is oxidized to $\overset{4\ 4}{\text{P–P}}$–acid. One mole of $(\overset{3}{\text{–P–}})_6$–ring acid produces a mixture of orthophosphoric and hypophosphoric heteropoly blue when procedure III is used. The data indicate that the mechanism of the hydrolysis of $(\overset{3}{\text{–P–}})_6$–ring acid varies with small differences in the reaction conditions. The results obtained for $(\overset{3}{\text{–P–}})_6$–ring acid by using procedures II and III suggest that $\overset{5}{\text{P}}$–acid, as one of the final products in the hydrolysis of $(\overset{3}{\text{–P–}})_6$–ring acid by the action of mineral acid, may be derived from $\overset{4\ 4}{\text{P–P}}$–acid as one of the intermediate products. $(\overset{3}{\text{–P–}})_6$–Ring acid forms a larger quantity of hypophosphoric heteropoly blue when procedure III is used than when procedure III is used. This fact may suggest that certain intermediate products, e. g., $\overset{2\ 4}{\text{P–P–}}$ or $\overset{2\ 3\ 4}{\text{P–P–P}}$–acid (a hypothetical compound), in the process of the hydrolysis of this ring acid, are oxidized with sulfite to $\overset{4\ 4}{\text{P–P}}$–acid or some other compounds that give $\overset{4\ 4}{\text{P–P}}$–acid as the result of hydrolysis.

Summary

The reaction of twelve lower oxo acids of phosphorus and orthophosphoric acid with the molybdenum(V)-molybdenum(VI) reagent have been carried out under the conditions prescribed by three different procedures: (1) the reactions for 30 min. at room temperature, (2) the reactions for 1 hr. at 95°C, and (3) the reactions in the presence of sodium hydrogen sulfite for 1 hr. at 95°C. The absorption spectra of the reaction products have been measured. It has been found that the blue products obtained by these reactions are orthophosphoric heteropoly blue and/or hypophosphoric heteropoly blue in all cases and that mechanisms of these reactions are closely related to the structural units of the lower oxo acids of phosphorus and their hydrolysis reactions.

The authors wish to express their hearty thanks to Professor Jun Yoshimura for the kind suggestions he made in the course of this work. The authors also wish to thank Dr. Bruno Blaser and Dr. Karl-Heinz Worms for supplying the samples used in this study.

Some Benzonorbornadiene Derivatives[1)]

By Hiroshi TANIDA, Ryonosuke MUNEYUKI and Teruji TSUJI

(Received August 21, 1963)

Bicyclo [2, 2, 1] heptane and the compounds with this skeleton have received wide attention in the past few years. They have been employed so often as a suitable model for developing modern organic theory because of their special fixed stereochemistry and because of the high strain of the ring system. Of particular interest are the demonstration of anchimeric assistance or homoconjugation in solvolytic displacement reactions,[2)] and that of trans-annular interaction between the double bond and the carbonyl group of dehydronorcamphor.[3)] Along with these developments in the theoretical field, remarkable progress was made in the syntheses of bridged ring compounds. Particularly, the success of the syntheses of norbornane derivatives condensed with an aromatic nucleus have opened a new area of organic chemistry. Norbornadiene I prepared by the Diels-Alder reaction of cyclopentadiene and acetylene[4)] is commercially available now,

benzonorbornadiene II is easily obtained by the cycloaddition of benzyne to cyclopentadiene,[5] and dibenzobicyclo[2, 2, 1]heptadiene III can be prepared by the condensation of norbornadiene with butadiene, followed by dehydrogenation.[6] They may be likened to a series of benzene, naphthalene and anthracene.

I II III

One of our chief objectives in investigating the chemistry of these systems has been to gain some insight into the nature of the homobenzylic conjugation.[1] Toward this end, we have studied the cycloaddition of substituted benzynes in the preparation of β-substituted benzonorbonadiens. This paper describes a convenient and steady method for the generation of benzynes, which carry several kinds of substituents, by the development of Wittig's procedure.[5] Furthermore, we would like to demonstrate that Wittig's procedure is very often more convenient than the decomposition of the zwitterionic diazonium salts of anthranilic acid derivatives,[7] a method which has recently been advocated, for use in syntheses.

Results and Discussion

One of the conditions necessary for the cycloaddition of benzynes generated via metal aromatics is the fragmentation of suitably ortho-substituted di-halobenzenes under an aprotic solvent. According to the Huisgen addition-elimination mechanism[8] for the formation of benzynes, the Wittig process is assumed to be composed of two steps, the metallation and the subsequent elimination of metal halogenide. Huisgen proposed that the rate-determining step was generally in the metalation reaction and that the rate of the elimination of halogen anions was in the order of iodine >bromine>chlorine≫fluorine. Several kinds of *o*-dihalobenzene have been prepared on the basis of the above discussions.

4-Bromo-3-iodoanisole IV, prepared from 6-bromo-*m*-anisidine V,[9] was proved to be a good source for the generation of 4-methoxybenzyne. Racemic 4'-methoxybenzonorbornadiene VI was obtained in a 40% yield by the reaction of IV with cyclopentadiene and magnesium. 3-Bromo-4-flourotoluene VII was prepared from 2-bromo-*p*-toluidine by the Schiemann reaction, and its cycloaddition to cyclopentadiene was satisfactorily carried out, yielding 4'-methylbenzonorbornadiene VIII in a 54% yield. The benzyne reaction of 2-bromo-4-chloroflourobenzene IX, obtained by the Schiemann reaction of 2-bromo-4-chloroaniline, proceeded successfully with cyclopentadiene by the elimination of bromine and fluorine, giving 4'-4-chlorobenzonorbornadiene X in a 55.6% yield. The position of the substituents on the benzene nucleus of the benzonorbornadienes obtained was unequivocally established by the conversion into the 2-substituted naphthalenes through the route of benzoyloxylation at the 7-position, hydrolysis and the Oppennauer oxidation.[1,10]

Attempts to generate cyanobenzyne, which is interesting in view of the fact that the benzyl has a strongly electronegative group, failed when either 3-bromo-4-fluorobenzonitrile XI or 3-bromo-4-iodobenzonitrile XII was used.[11] Compound XI did not react with magnesium in tetrahydrofuran. The reaction of XII with magnesium afforded 3-bromobenzonitrile as an isolable product, while no reaction with lithium occurred.

Of particular interest was the reaction of 2, 5-dibromo-1-iodobenzene XIII with cyclopentadiene and magnesium. Gas chromatography of the product, which had been distilled under reduced pressure, indicated the existence of seven compounds. The residue not distillated presumably consisted of high molecular substances. The identities of the main four compounds, *p*-dibromobenzene XIV, 3-bromoiodobenzene XV, the desired 4'-bromobenzonorbornadiene XVI and benzonorbornadiene XVII, were confirmed by retention time analysis in gas chromatography. The estimation of their relative yields was carried out on the basis of the peak area, as Table II shows. Furthermore, XIV, XVI and XVII were isolated and identified by mixed melting point determination and by a comparison of the infrared spectra. The formation of XVII is probably due to the further reaction of XVI with magnesium. No evidence of the formation of *o*-bromoiodobenzene was obtained. This fact may imply that the rate of formation of phenyl anion was enhanced by ortho halogen.[12] The percentage of the benzyne formation would be more than the total yield of XVI and XVII because of the polymerization of benzynes.

The formation of considerable amounts of XIV and XV suggests that the metalation reaction took place without the subsequent elimination. The above experiments of XII gave an analogous result. Contrary to Huisgen's popular mechanism, Zieger and Wittig[13] recently reported that, in the case of the reaction of 3-chloro-4-dimethylaminophenylsulfone XVIII with *n*-butyllithium and furan, XVIII was metalated very rapidly and completely at a low temperature such as $-80°C$, but that the elimination of lithium chloride proceeded at a measurable rate, giving a k_1 value of $0.094 \sim 0.064\ min^{-1}$ at 0°C. Therefore, we think that Huisgen's discussions and Wittig's finding are probably valid in terms of their own experiments and, that which step, metalation or elimination, is the rate-determining step depends primarily upon the particular case. The benzyne formation will substantially be a two-step reaction.

The ultraviolet spectra data, listed in Table I, exhibits the transannular interaction of the double bond and the benzene ring in the benzonorbornadiene derivatives prepared here. It is interesting to note the absorption maximum[14] around 230~240 mμ, which may correspond to the π-π^* band of the styrene derivatives. The spectral data and electronic structures of these compounds will be discussed in detail later.

TABLE I. UV SPECTRA OF BENZONORBORNADIENE DERIVATIVES

λ_{max} in mμ, log ε in parentheses, solvent is cyclohexane, except for the 4'-bromo compound in *n*-hexane.

Experimental[15]

4-Bromo-3-iodoanisole.—Into a mixture of 20.2 g. (0.10 mol.) of 6-bromo-*m*-anisidine,[16] 47 ml. of concentrated hydrochloric acid and 31 g. of cracked ice, a solution of 7.6 g. (0.11 mol.) of sodium nitrite in 31 ml. of water at 0~3°C was slowly stirred over a ten-minute period. Stirring was kept up for additional fifteen minutes. The deep orange solution which resulted was filtered, slowly stirred at approximately 10°C into a solution of 57 g. (0.344 mol.) of potassium iodide in 187 ml. of water, and left to stand overnight at room temperature. The violet oil which separated was extracted with ether, wahed with 10% aqueous sodium hydroxide, water and 5% aqueous sodium bisulfite, and then dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was distilled at 124~126°C (2 mmHg) to give 15.9 g. of the expected product as a yellow oil, in a 60% yield; n_D^{25} 1.6493.

11) XI (m. p. 57~58°C) was prepared in the following way: VII→3-bromo-4-fluorobenzaldehyde (b. p. 120°C) (21 mmHg), n_D^{24} 1.5795→the oxime (m. p. 104~104.5°C)→XI. XII (m. p. 137~138.5°C) was prepared from 3-amino-4-iodobenzonitrile by the Sandmeyer reaction.

13) H. Zieger and G. Wittig, *J. Org. Chem.*, **27**, 3270 (1962).

14) No maximum was observed in benzobicyclo[2, 2, 2]-octadiene, according to a private communication from Dr. K. Kitahonoki. Cf. K. Kitahonoki and Y. Takano, *Tetrahedron Letters*, **24**, 1597 (1963).

15) All melting points and boiling points are uncorrected.

16) H. H. Hodgson and R. J. H. Dyson, *J. Chem. Soc.*, 1935, 946.

Found: C, 27.09; H, 1.99; Br, 25.25. Calcd. for C_7H_6OBrI: C, 26.86; H, 1.93 Br, 25.55%.

3-Bromo-4-fluorotoluene (VII).—B. p. 186°C; n_D^{25} 1.5281. Found: C, 44.70; H, 3.27. Calcd. for C_7H_6BrF: C, 44.47; H. 3.20%.

2-Bromo-4-chlorofluorobenzene (IX).—B. p. 90°C (30 mmHg); n_D^{19} 1.5549. Found: C, 34.51; H, 1.58. Calcd. for C_6H_3BrClF: C, 34.41; H. 1.44%. were prepared from the corresponding amino compounds by the Schiemann procedure of Roe.[17]

4'-Methoxybenzonorbornadiene (VI).—A three-necked flask, equipped with a stirrer, a pressure-compensated dropping funnel, a gas inlet tube, and a reflux condenser with a Drierite tube, was charged with 4.1 g. (0.158 mol.) of magnesium turning and flushed with dry nitrogen for 30 min. to remove the air completely. In the dropping funnel there was then placed a solution of 44 g. (0.141 mol.) of 4-bromo-3-iodoanisole and 9.5 g. (0.143 mol.) of fresh-distilled cyclopentadiene in 240 ml. of anhydrous tetrahydrofuran. A part of the solution from the funnel was dropped to cover the magnesium and heated to boiling. When a vigorous reaction commenced, the stirrer was started and the remaining main part of the solution was added at such a rate that the temperature in the flask was kept at 60~65°C (this took about 50 min.), after which the mixture was refluxed gently for 30 min. After removal of the solvent under slightly reduced pressure, the residue was poured into a mixture of a saturated aqueous solution of ammonium chloride and 300 ml. of ether. The ether layer was separated, washed repeatedly with 5% aqueous sodium bisulfite and water, and dried over sodium sulfate. The ether extracts were distilled under reduced pressure to obtain 9.7 g. (40%) of a colorless oil at b. p. 99~100°C (4 mmHg). The oil contained a small amount of impurity, presumably 4-bromoanisole. Elution chromatography by Florisil, hexane and benzene gave completely pure 4'-methoxybenzonorbornadiene (n_D^{23} 1.5642) after of 4-bromoanisole had been eluted as a forerun. Found: C, 84.03; H, 7.16; O, 9.11. Calcd. for $C_{12}H_{12}O$: C, 83.69; H, 7.02; O, 9.29%.

4'-Methylbenzonorbornadiene (VIII).—By means of the above procedure, 42 g. of VII, 14.7 g. of cyclopentadiene and 6 g. of magnesium turning in 270 ml. of dry tetrahydrofuran, 18.6 g. (53.6%) of VIII as a colorless oil was obtained; b. p. 110~112°C (22mm Hg); n_D^{24} 1.5541.

Found: C, 93.09; H, 6.77, Calcd. for $C_{21}H_{18}$: C, 93.29; H,6.71%.

4'-Chlorobenzonorbornadiene (X)—It was prepared from XI, cyclopentadiene and magnesium in the same manner as the above. It is a colorless oil with a boiling point of 112~112.5°C (10 mmHg); n_D^{21} 1.5763. The yield was 55.6%.

Found: C, 74.44; H, 5.20; Cl, 20.25. Calcd. for $C_{11}H_9Cl$; C, 74.79; H, 5.14; Cl, 20.07%.

The Reaction of 2, 5-Dibromo-1-iodobenzene (XIII) with Magnesium and Cyclopentadiene.—With 75 g. of XIII, 16.5 g. of cyclopentadiene and 6.05 g. of magnesium turning in 300 ml. of tetrahydrofuran, the above procedure was carried out. The ether extracts were distilled up to 132°C (10 mmHg) to obtain 26.4 g. of a mixture of oil and crystals. The composition of the distillate was investigated by gas chromatography. The components and the relative yields are shown in Table II. 4'-Bromobenzonorbornadiene (XVI), fractionated by preparative gas chromatography, has a b. p. of 127 ~129°C (10 mmHg); n_D^{29} 1.5910.

Found: C, 59.96; H. 4.24. Calcd. for $C_{11}H_9Br$: C, 59.76; H, 4.10%.

Table II. The components of the reaction product of 2, 5-dibromo-1-iodobenzene with magnesium and cyclopentadiene

1	Benzonorbornadiene	25.4%
2	*p*-Dibromobenzene	28.6%
3	3-Bromoiodobenzene	6.6%
4	x(unidentified)	1.6%
5	4'-Bromobenzonorbornadiene	21.1%
6	y(unidentified)	4.9%
7	z(unidentified)	11.8%

*The Electron Spin Resonance of an Irradiated Single Crystal of Potassium Hydrogen Maleate**

By Machio IWASAKI and Koichi ITOH

(Received August 22, 1963)

Although the electron spin resonance (ESR) of many irradiated single crystals of organic molecules has been reported on in the past five years, few attempts have been made to examine molecules containing conjugate systems. It has been found by I. Miyagawa** that the ESR spectra of several dicarboxylic acids, such as formic acid, fumaric acid, and maleic acid, were very weak, while very much stronger spectra were obtained from saturated carboxylic acids. The common characteristics of these dicarboxylic acids are that all molecules in a crystal are linked by intermolecular hydrogen bonds and that each molecule has a conjugate system. The odd electrons or holes produced in a crystal by irradiation may easily migrate throughout the entire crystal through the conjugate systems and the intermolecular hydrogen bonds, accompanied by the recombination and disappearance of the odd electrons or holes. In this respect, potassium hydrogen maleate (KHM) is an especially interesting case. In this molecule the intermolecular hydrogen bonds are broken by the substitution with potassium as:

Unlike maleic acid, this molecule gave strong and sharp spectra, supporting the interpretation of the phenomenon mentioned above. This paper will deal with the identification of the radical produced in a single crystal of this interesting molecule.

Experimental Procedure

Single crystals of potassium hydrogen maleate and its deuterium-exchanged compound (KOOCCH=CHCOOD) were grown from aqueous and heavy water solutions respectively by the slow cooling method. The purity of the deuterium-exchanged compound was tested by means of its infrared spectra. The single crystals obtained were typical orthorhombic crystals, the crystal axes of which were identified by taking vibration photographs of the X-ray diffraction. The crystal structure of KHM has been completely analyzed by Darlow and Cochran,[1] giving the orthorhombic space group Pbcm, with four molecules per unit cell and cell dimensions of $a=4.578$Å, $b=7.791$Å and $c=15.953$Å. The results of the ESR will be compared with their crystal analysis in a later paragraph of this paper.

The single crystals were irradiated at room temperature with an X-ray source operating at 30 kV. and 15 mamp. The ESR of irradiated single crystals was measured mainly at 24 kMc./sec. for various orientations of the crystal in the magnetic field at room temperature. As a reference for the spectroscopic splitting factor, the sharp resonance of DPPH was used. The separations of the hyperfine structures were measured by a proton resonance with a side-band technique.

Experimental Results

The ESR spectra first observed at 9 kMc./sec. showed a marked second order effect,[2] making the spectra somewhat complicated, but the

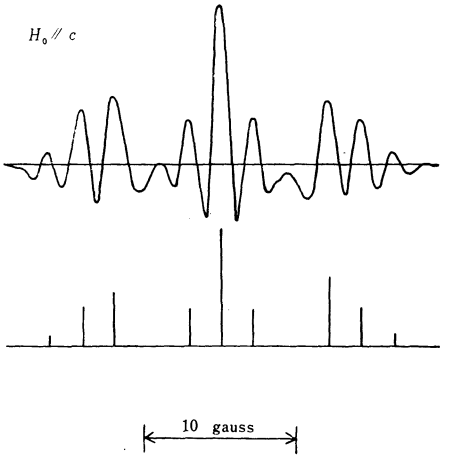

Fig. 1. Electron spin resonance curves at 9 kMc./sec. of an X-irradiated single crystal of potassium hydrogen maleate with the static magnetic field parallel to the c-axis. The vertical lines indicate the theoretical positions and intensities.

one observed at 24 kMc./sec. showed practically no second order effect, making the spectra simple enough to interpret very easily and accurately. Therefore, the measurements for various orientations of the crystal were mainly carried out at 24 kMc./sec. Figure 1 depicts the ESR spectrum measured at 9 kMc./sec. for the orientation of the crystal in the magnetic field parallel to the crystal c-axis. The hyperfine structure of the spectrum was interpreted on the basis of the theory of the second-order effect[2], giving a good agreement with observed results. The vertical lines under the absorption lines indicate the theoretical spectral positions and their intensities.

The spectra observed at 24 kMc./sec. for orientations of the crystal in the magnetic field parallel to the three crystallographic axes consist of three lines, the relative intensities of which are 1 : 2 : 1. If the crystal is rotated around the a- or b-axis, fixing the magnetic field in the (bc) or (ca) plane of the crystal respectively, the triplet is resolved into a quartet consisting of the pair of doublets expected for two non-equivalent protons with a spin of 1/2 (see Figs. 2 and 3). This suggests that, for these orientations, the unit cell contains only one radical having two chemically-equivalent protons, and that the two protons

are not magnetically equivalent for the field along the intermediate directions of the crystal axes. However, if the crystal is rotated around the c-axis, fixing the magnetic field in the (ab) plane of the crystal, the single triplet is resolved into a pair of triplets, the *g*-factors of which are different from each other (see Fig. 4). This means that, for this orientation of the crystal, there are two magnetically non-equivalent radicals. In this case, the triplets were not resolved into a quartet as in the case of the rotation around the a- or b-axis. Therefore, two coupling protons in a radical are magnetically equivalent for any orientation produced by the rotation around the c-axis.

From the interpretation of the observed spectra, it is concluded that there are four coupling protons in a unit cell. The principal values and the direction cosines of the hyperfine tensors for these protons determined from the angular dependence of the coupling constants are tabulated in Table I. The principal values and the direction cosines of the *g*-tensors were determined from the angular dependence of the center of the hyperfine patterns and are also listed in Table I.

The ESR of an irradiated single crystal of potassium deuterium maleate (KDM) was also measured in order to get some additional information about the structure of the free radical. The observed spectra, however, was not any different in the coupling values from the one for KHM. The line widths for both compounds were very narrow and in both the distance between maximum slopes was 1—2 gauss. Although slightly sharper lines were observed for KDM, it was shown by a comparison of the spectra for rotations around the a-, b-, and c-axes that the largest difference between the line widths of the two compounds was only 0.5 gauss.

Analysis of the Results and Discussion

These features of the observed spectra suggest that the radical is produced by the removal of OH hydrogen, and that the coupling protons are two vinylene protons which can be chemically equivalent because of the following resonance:

Two vinylene protons are always equivalent for the orientations of the crystal in the magnetic field in the (ab) plane, so the (ab) plane should be perpendicluar to the C=C bond. Furthermore, it is expected from the experimental results that the two kinds of molecules in a unit cell are oriented in such a way that the (ca) or (bc) plane of the crystal makes an equal angle to the two planes of molecules corresponding to the two magnetically-non-equivalent radicals.

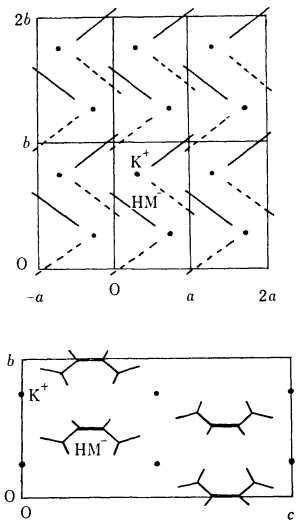

Fig. 5. Projection of the structure of potassium hydrogen maleate to the c- and a-axes.

Shown in Fig. 5 is the arrangement of the four molecules in the unit cell as determined by Darlow and Cochran.[1] It may be seen that the orientations of the molecules expected from the observed ESR spectra are entirely consistent with the crystallographic results. The direction cosines of the C–H bond and the directions perpendicular to it can be calculated from the crystallographic data and compared with those of the principal axes of the hyperfine tensor. As Tables I and II indicate, the direction for the smallest element approximately coincides with the C–H bond direction, while that for the largest coincides with the direction perpendicular to the C–H bond in the molecular plane. This finding indicates that the origin of the hyperfine structure is two vinylene protons, and that the structure of the free radical produced is not very much deformed from the parent molecule as far as the vinylene portion of the molecule is concerned.

The results listed in Table I indicate that the smallest principal element of the *g*-tensor has its axis perpendicular to the molecular plane and that the other two pincipal elements are approximately equal and are directed in the molecular plane. This means that the spin density is in a p-orbital of the carbon,

which has its direction perpendicular to the molecular plane.

The nuclear hyperfine interaction constant, A, of the $\diagdown$·C—H$\diagup$ fragment consists of an isotropic Fermi term, A_f, and an anisotropic dipole-dipole interaction term, A^{μ}. The isotropic term, A_f, is determined from the three principal elements by $(A_1+A_2+A_3)/3$ to be 6.4 gauss for the present free radical. With this value, the spin density on the vinylene carbon atom is found to be 0.26, employing 25 gauss as the A_f value for unit spin density. The anisotropic hyperfine interaction for π-eletron free radicals has been estimated by McConnell and Strathdee,[3] who gave the principal elements the values of 15.4, −1.7, and −13.6 gauss along the C–H bond, along the density axis of the p-orbital, and perpendicular to those two respectively. For the present radical these principal values should be reduced by 74% to 3.9, −0.4, and −3.5 gauss respectively. Since A_f is known to be negative in sign,[4] adding the observed isotropic component, $A_f=-6.4$ gauss, to the theoretical anisotropic components yields −2.5 gauss for the total coupling constant along the C–H bond, −6.8 gauss along the p-orbital, and −9.9 gauss perpendicular to the C–H bond in the molecular plane. These values are in very good agreement with the observed principal elements of the hyperfine tensor shown in Table I. Figure 6 indicates the directions of the principal axes, A_1, and A_3; A_2, which is not indicated, is perpendicular to the molecular plane.

suggest that no nuclear spin except two vinylene protons exists in the present radical. The difference of line width in both compounds when the OH proton exists in the produced radical was estimated on the basis of the following assumptions: (1) the radical has the same geometrical structure as that of the parent molecule;[1] (2) the spin density in the vinylene carbon atom is +0.26; (3) the remaining spin density, +0.48, is equally assigned to the most distant side oxygen atoms from the OH protons; (4) each spin density is located on the nucleus as a point spin density; (5) the Fermi term of the OH proton-coupling constant is assumed to be −0.1 gauss, which gives the smallest possible total coupling constant; (6) the contributions from the neighboring molecules to the line width are disregarded. As nothing is known about the quantities in assumptions 3 and 5, they are assumed to give the lowest possible value for differences in line widths as far as these quantities are concerned. Thus, the principal elements of the coupling constant for the OH proton were estimated to be +1.5, −1.5, and −0.3 gauss for the direction perpendicular to the C=C bond in the molecular plane, for that perpendicular to the molecular plane, and for that parallel to the C=C bond respectively. When the OH proton is substituted with deuteron, the line widths are expected to be reduced at least by 1.0, 1.0, and 0.2 gauss for the principal directions. A comparison of these calculated values with the observed ones excludes the possibility that the radical which gives the observed absorption has an OH hydrogen atom as does the parent molecule.

It is interesting to note that the discrepancy between the observed direction of the C–H bond in the radical and the calculated direction from the X-ray crystallographic data of the parent molecule may be responsible for the loss of the bridge hydrogen bond. Darlow[5] pointed out that this intramolecular hydrogen bond produces strain in the bond angles of this molecule. The C=C–C angle in unstrained molecules[5] is about 121.5±1.0°, while the same angle in the present molecule[1] is 130.4 ±0.2°, the strain angle being 8.9±1.0°. Therefore, if the strain is removed by the loss of the bridge hydrogen, the C=C–C angle will be closed by about 8.9°, accompanied by a change in the C=C–H angle which will amount to about a half of this strain, that is, to 4.5°. Thus, the C=C–H angle will change from 115.8° (X-ray value) to 120.3° in the unstrained radical. The observed C=C–H angle in the radical, 121°, is in good agreement with the expected value, 120.3°.

It is of interest that simple LCAO calculation shows that the unpaired electron must be a π-electron for the proposed radical produced by the removal of the OH hydrogen during irradiation. It is assumed in the calculations that the Coulomb integral to the ring oxygen is smaller than the side oxygen for the following reasons. (1) According to the X-ray data, the side C–O distance is shorter than the ring C–O in the parent molecule (see Fig. 6). (2) In the radical produced upon the removal of the OH hydrogen, the ring O···O distance becomes so short that the β_{OO} can not be ignored. Instead of including β_{OO}, the contribution from the β_{OO} may be replaced by taking the smaller value of the Coulomb integral for the ring oxygen. With $\alpha_O(\text{ring}) = \alpha_C + 1.8\beta_C$, $\beta_{CO}(\text{ring}) = 0.85\beta_C$, $\alpha_O(\text{sid}) = \alpha_C + 1.2\beta_C$, and $\beta_{CO}(\text{side}) = 0.95\beta_C$, the energy level of the highest-filled π-orbital was found to be higher than that of a pπ lone-pair electron on an oxygen atom by $0.71|\beta_C|$, where α_C is the Coulomb integral and β_C is the resonance integral of a pπ electron in a C=C bond. The unpaired electron which should be formed on the oxygen atom by the removal of the OH hydrogen atom is equivalent to one of the σ lone-pair electrons. The energy level of the latter electron is equal to that of a pπ lone-pair electron on the same atom for a simple LCAO approximation. Thus, to minimize the energy of the radical, an electron in the highest-filled orbital is relocated at the half-filled σ lone-pair orbital, the remaining π electron becoming an unpaired electron. The spin density on the vinylene carbon atom was found to be +0.28, which is in very good agreement with the +0.26 estimated from the proton-coupling constant.

After finishing our work, we found that Heller and Cole[6] had obtained a similar results. However, our results may be more accurate than those of (HC), since their results were derived mainly from measurements at 9 kMc./sec. These two independent measurements are in very good agreement with each other. The discrepancies between the principal values in Table I and those given by (HC) are within 0.2 gauss and 2.5° for the values and directions of the principal elements of the proton-coupling constant respectively, and within 0.0012 and 1° for those of the g-factor respectively.

The authors are greatly indebted to Professor Ichiro Miyagawa of Duke University for his

Electron Paramagnetic Resonance Studies of Titanium(III) Ions with Complexing Compounds

By Shizuo FUJIWARA and Maurice CODELL

(Received August 28, 1963)

The nuclear hyperfine structure of titanium-(III) was first observed by Waters and Maki[1] using titanium(III) complexes formed by the interaction of equimolar quantities of titanium-(III) chloride in methanol and sodium methylate in methanol and slightly more than two equivalents of hydrogen fluoride in methanol to one equivalent of titanium(III) chloride in methanol. The spectra which were obtained in the methanol solution at $-45°C$ consisted of eight lines, which is in accordance with the predictions of Jeffries[2] who determined through nuclear magnetic resonance measurements that ^{47}Ti and ^{49}Ti have spins of 5/2 and 7/2 respectively. The spectrum obtained by Waters and Maki is highly unsymmetrical, with peak intensities decreasing at higher fields.

A symmetrical hyperfine spectrum of titanium(III) was obtained by McGarvey[3] at 77°K using a single crystal of aluminum acetylacetonate containing a small amount of titanium acetylacetonate. A signal for titanium(III) in solution has been observed by Shien and Boss[4] using the $(\pi\text{-}C_5H_5)_2Ti(C_2H_5)$ complex in toluene at 300°K, and by Avvakumov, Garif'yanov and Semenova[5] using supercooled solutions of $TiCl_3\cdot 6H_2O$ and $Ti_2(SO_4)_3\cdot 4H_2O$ in alcohol and glycerine at 200, 77°K, and 300°K. The g values were measured, as were the g values at 200 and 77°K of the solid salts, used in the above solutions[6] (see Table II). The hyperfine spectrum of titanium(III) arises from the interaction of the unpaired 3d electron with the nucleus. The eight lines of the hyperfine pattern are formed by the contributions of the ^{47}Ti and ^{49}Ti isotopes with spins of 5/2 and 7/2 respectively; two of them are overlapped by the large central line from ^{46}Ti, ^{48}Ti, and ^{50}Ti with zero spins.

It was decided to investigate the EPR spectra of other titanium(III) solutions at about 9000 Mc. in order to determine if the hyperfine spectra could be obtained in an aqueous solution and at room temperature. Because of their known ability to form chelate complexes, we chose the complexing agents listed in Table I, which also lists the conditions for preparing the samples.

The spectra obtained in this investigation are the first examples of the hyperfine structure of the complexes of paramagnetic ions to be observed in aqueous solutions.

The features of the simple and hyperfine spectra of several of the chelate compounds were considerably changed by varying the pH values by varying the quantities of complexing agents.

Results and Discussion

The spectra for the titanium(III)-NTA complex is unique in showing practically no change when the pH values are changed from 3 to 10.2. At lower pH values the hyperfine structure diminishes in intensity, until at pH 1.90 very little of the hyperfine structure is discernible. The disappearance of the hyperfine pattern may result from 3d-electron exchange among titanium ions or from the rapid relaxation of titanium nuclear spins.

TABLE I. PREPARATION OF SAMPLE SOLUTIONS

Complexing agent	Name	Formula	pK_{a_i} $i=1,2,3,4$	Quantity added per 10 ml.	Control of pH by addition of	Additional reagent
NTA	Nitrilotriacetic acid	$N(CH_2COOH)_3$	1.9, 2.5, 9.7	0.3 g.	NH_4OH	
HEID	Hydroxyethyl-iminodiacetic acid	$N(CH_2COOH)_2 \cdot CH_2CH_2OH$	2.2, 8.7	0.3 g.	NH_4OH	
BHEG	Bis-(2-hydroxyethyl)-glycine	$N(CH_2CH_2OH)_2 CH_2COOH$	8.08	0.3 g.	NH_4OH	(1) Tartaric acid (2) No tartaric acid
TEOHA	Triethanolamine	$N(CH_2CH_2OH)_3$	7.90	—	Complexing agent itself	Tartaric acid
DEA	Diethylamine	$NH(CH_2CH_3)_2$	11.0	—	Complexing agent itself	Tartaric acid
NBA	*N*-Butylamine	$H_2N(C_4H_9)$		—	Complexing agent itself	Tartaric acid
EDTA	Ethylendiamine-tetraacetic acid disodium salt	$C_2H_4 \cdot \{N(CH_2COOH) \cdot (CH_2COONa)\}_2$	2.2, 8.0, 5.2, 10.3	0.3 g.	NH_4OH	(1) Tartaric acid (2) No tratraic acid
AAC	Acetylacetone	$CH_3COCH_2COCH_3$		3 ml. saturated soln.	NH_4OH	
TEA	Triethylamine	$N(CH_2CH_3)_3$	10.8	—	Complexing agent itself	Tartaric acid

The titanium(III)-NTA spectra are unsymmetrical and similar to those obtained by Waters and Maki. The other complexes studied exhibited remarkable changes at higher pH ranges. The stability of this complex probably results from the three carboxyl groups of NTA, which allows the molecule to enter into a three-dimensional system with titanium(III) with little probability of interaction with the nitrogen of NH_4 when an excess of ammonium hydroxide is added. In less stable titanium(III) complexes, titanium-(III) hydroxide tends to precipitate at higher pH values.

The cause of the unsymmetrical hyperfine structure of this spectrum may be deduced from the suggestion made by McConnell[7] and confirmed experimentally by Rogers and Pake[8] regarding the observed broadening of the hyperfine spectrum of VO(III) ions in an aqueous solution. This condition can also exist with the solutions used in this investigation.

$$1/T_2 \approx \lambda_c(\Delta g \beta H_0 + b m_I)^2/h^2$$

where b is $A_{\parallel} - A_{\perp}$; the other symbols possess their usual meanings. The above equation generally predicts a different width contribution for each hyperfine line. The minimum width should occur for the m_I value which causes the bracket to approach a minimum.

The spectra for the titanium(III)-HEID complex show a hyperfine structure which is far less intense than but which has the same unsymmetrical features as the previously-discussed complex. This hyperfine structure is only discernible at pH ranges from about 5.0 to 7.9. At appreciably higher or lower pH values, no hyperfine structure is exhibited by the complex. Since HEID contains only two carboxyl groups, the three-dimensional system which was thought to be obtained with the NTA complex is less likely to be obtained with this complex.

With BHEG, which contains only one carboxyl group, no hyperfine structure is obtained at any pH value. This complex is not as stable as either of the above complexes, and titanium(III) hydroxide begins to precipitate at a pH of approximately 9.0. Upon the addition of tartaric acid, however, the precipitation is prevented and a signal at higher pH values can be obtained.

complex is especially interesting because of the different spectra obtained with and without the addition of tartaric acid. With no tartaric acid, the spectra (Fig. 3) shows a less hyperfine structure, but evidence for more than one complex is clearly seen. Two peaks are observed for all pH values but are more pronounced at the pH values of 7 and 8. With the addition of tartaric acid, the spectrum exhibits an observable hyperfine structure in which each component of the hyperfine lines is broadened at higher pH values. At pH 9.5, another peak without a hyperfine structure appears at higher

fields. At pH 10.1, the increase in the intensity of the second peak indicates a change in the equilibrium mixture of the two complexes.

The principles of the complex formation of titanium(III) with TEOHA (Fig. 5), TEA (Fig. 6), DEA (Fig. 7), and NBA (Fig. 8) are similar. A hyperfine structure is seen with all the complexes. The spectra clearly show the presence of two different complexes for each complexing agent. The concentration of one complex with respect to the other depends upon the amount of complexing agent which has been added, rather than upon the pH of the solution. This is shown with the different equilibrium mixtures of complexes obtained using different concentrations of titanium(III) with TEOHA at pH 7.7 (Fig. 5). Since the concentration of titanium(III) in one case is double that of the other, a different complex is dominant. The g values for this group (Table II) are all 1.974$\pm$0.002, which is excellent evidence for the fact that the orbital character of the ground electronic doublet of titanium(III) remains the same with these compounds for all pH values. Similar conditions appear to exist with NTA, HEID, BHEG, and EDTA, as is shown in Table II, where g varies from 1.950 to 1.962. The g value for titanium(III) acetylacetonate is 1.946, which is a fairly sizable shift from that of the other complexes. It is interesting to note that the g values are little changed with different complexing agents and varying pH values. This shows that the contributions of the spin orbit coupling are little changed despite the fact that different colors are obtained.

The titanium(III) used in this investigation was a commercial grade in hydrochloric acid and contained zinc in excess of a 1 : 1 ratio to titanium. Recent work has shown that zinc is necessary in order to obtain spectra with

complexing agents which do not contain carboxyl groups. Somewhat similar spectra can be obtained with a mixture of titanium(III), tartaric acid and zinc.

Summary

The EPR spectra of a number of titanium-(III) complex compounds have been obtained at room temperature and in aqueous solutions; these compounds show either a hyperfine structure alone or a mixture of hyperfine and simple structures. The g values for the various complexes have been determined and compared. This technique should provide a simple method for studying the state in solution of the complexes of several other metals and their isotopes.

The authors acknowledge with gratitude the excellent suggestions made by Dr. Kozo Nagashima and Mr. Yuzuru Fujiwara of this department.

The Use of NMR Spectroscopy as a Structural Probe in Ferrocene Chemistry[1]

By Yoichiro NAGAI, John HOOZ and Robert A. BENKESER

(Received August 30, 1963)

Electrophilic substitution reactions in the ferrocene systems give rise, in most instances, to complex isomeric mixtures,[2] such that separation and structural characterization often constitute a perplexing problem. Several methods have been employed for structure determination, of which the most generally useful has proved to be infrared spectroscopy. In particular, the "9, 10μ" Rule[3] has been an invaluable aid for distinguishing between homoannularly- and heteroannularly-substituted ferrocene derivatives.

Classic methods of structure proof involving either independent syntheses[2] or degradative (e.g., bromination,[4] forced catalytic hydrogenation[4,5] and chemical reduction[6]) schemes appear to be limited to mono- or symmetrically-substituted ferrocene types. Unequivocal syntheses are hampered by the relative inaccessibility of the appropriately substituted cyclopentadiene (except in the simplest cases),[7] whereas degradative methods frequently bring about mixtures of substituted cyclopentadienes and cyclopentanes, the structures of which are also frequently unestablished.

Relative yield data[8] and arguments based on analogy to the benzenoid analogs[9] have also been offered as evidence in support of structures. Another proposal of practical use has been advanced[10] that the relative adsorbabilities of disubstituted ferrocenes on the alumina column provided to effect their separation constitute a useful primary indication of structure. Thus, it has been found that, for a variety of alkyl- and arylferrocenes, the order of the elution of isomers from an alumina column is $1,2>1,1'>1,3$.

Ultraviolet spectroscopic data have been

employed[8,11] to distinguish between homoannular isomers; the absorption for the 2-isomer is more intense, but it appears at a shorter wavelength than that of the 3-isomer.

Recently, it has been suggested that infrared absorptions may serve to define the structures of homoannularly-disubstituted ferrocene derivatives;[12] a 1, 3-structure exhibits two bands in the region between 10.8 and 11.2 μ, whereas the 1, 2-isomer possesses only one band, near 10.9 μ.

It can be seen from Table VIII,[13] however, that it is difficult to distinguish between the 1, 2 and 1, 3-structures of the acylalkyl series by a simple application of this generalization.

Another attempted correlation,[14] in which the infrared absorption at 7.80 μ was said to be characteristic of a 1, 3-disposition of groups, has been questioned recently.[15] It will be noted from Table VIII that the 1, 1' compounds, as well as several of the 1, 2-types, show absorption very near 7.80 μ.

In many cases, a judicious combination of all these methods has been employed.[11] However, relatively little use has been made of NMR spectroscopy to distinguish between various structural types.[16]

It is the purpose of this paper to report that NMR spectroscopy can provide an unequivocal and universal probe for determining the structure of many substituted ferrocenes.

Results and Discussion

In connection with another study[17] we have had occasion to acylate the homologous series of alkylferrocenes. The isomeric acetylmethyl- and acetylethyl-derivatives are known, whereas the isopropyl- and *t*-butyl-derivatives have not yet been reported. Each of these compounds could be conveniently prepared by a modification of the mild acylation procedure described by Hauser and Lindsay.[18] The resulting isomeric acetylalkylferrocenes were separated by column chromatography (Merck neutral alumina). For the methyl, ethyl and isopropyl-derivatives, the course of the separation was conveniently followed by vapor phase chromatographic analysis.[19]

Incomplete resolution of the vapor chromatogram for the mixture of 1, 1'- and 1, 3-acetyl-*t*-butylferrocenes required that a different criterion of purity be employed (cf. Experimental). Interestingly, the order of the increasing retention times (VPC) of isomers within a given set parallels the order of increasing adsorbability on the alumina column initially employed for their separation, i.e., 1, 2-<1, 1'<1, 3-acetylalkylferrocene.

A preliminary determination of the chemical shifts[20] for a variety of monosubstituted ferrocenes revealed that the 2- (or 5-) and 3- (or 4-) protons[21] were shielded only slightly by alkyl substituents (ca. 0.09~0.14 p.p.m. relative to ferrocene), whereas electron-withdrawing substituents (e.g., acetyl, carbomethoxy) displayed a pronounced deshielding effect. These results are analogous to those already described for the benzenoids.[22]

For the homoannular acetylalkylferrocenes, there is one "ortho" proton (relative to the acetyl group) for the 1, 2-isomer, whereas for the 1, 3-structure there are two such positions. It was reasoned qualitatively that if any small shielding effects imposed by alkyl groups were outweighed by the more substantial deshielding effect caused by electronegative functions, NMR spectroscopy should provide a useful probe for elucidating homoannular positional isomers. That this indeed proved to be the case is convincingly demonstrated by the data in Table I. (See also the N.M.R. illustrations.)

All 1-acetyl-1'-alkylferrocenes exhibit similar patterns for the ring protons.[23] When the

16) K. L. Rinehart et al. (*J. Am. Chem. Soc.*, **82**, 4111 (1960).) made use of this method, as did M. Rosenblum et al. (*J. Am. Chem. Soc.*, **85**, 316 (1963).), to study the conformation of alkyl-bridged ferrocenes. Apparently the only use of NMR to distinguish between homoannularly-substituted isomers is the recent report by Rinehart and his coworkers, which was contemporaneous with our preliminary communication. [R. A. Benkeser, Y. Nagai and J. Hooz, This Bulletin, **36**, 482 (1963).].

19) There is relatively little mention in the literature of the use of VPC for ferrocene compounds. Perhaps the reason for such an aversion resides in the fact that ferrocene and many of its derivatives are solids. That such a view is unwarranted is clearly demonstrated by the successful analysis of numerous ferrocene compounds in our laboratory.

20) The nuclear magnetic resonance spectra were determined in a carbon tetrachloride solution employing a Varian A-60 spectrometer. Tetramethylsilane served as an internal standard. Chemical shifts are reported to the estimated center of a singlet or multiplet. Peak areas were determined by electronic integration.

21) The 2- (or 5-) and 3- (or 4-) protons represent the positions "ortho" and "meta" to the substituent. In the discussion of the spectra of acetylalkylferrocenes presented below, the acetyl group is assigned position one.

1) The data listed are "tau" values, using tetramethylsilane as an internal standard.
2) The values in parentheses are relative intensities. All measurements were made on a Varian A-60 analytical spectrometer.
3) Column "*a*" values refer to the H in the 2- and 5-position relative to the acetyl group.
4) Column "*b*" values refer to the H in the 3- and 4-position relative to the acetyl group.
5) Column "*c*" values refer to the H on an unsubstituted ring.
6) Column "*d*" values refer to the H on an alkylated ring.

spectrum of acetyl- and the appropriate alkylferrocene is inspected, it may be seen that the only reasonable assignment for the ring protons of 1, 1'-isomers is to ascribe the two low-field resonances (each of an intensity of two) to the acetylated ring. The lower resonance (column a, Table I) is due to 2- and 5-H (relative to the acetyl group), and the higher field triplet, to 3- and 4-H. Within this set, the alkylated ring protons possess chemical shifts that are only slightly different from the alkylated ring protons of the parent alkylferrocene.

Unsubstituted ring protons of all 1-acetyl-2-alkylferrocenes are singlets, exhibiting a deshielding order from methyl (5.95 tau) through *t*-butyl (5.85 tau). Of greater interest to the present investigation, however, was the appearance of the disubstituted ring protons as three complex peaks, indicating three non-equivalent protons. The most deshielded multiplet (column a, Table I) was reasonably assigned to 5-H, by analogy with acetylferrocene itself. The high-field multiplet (column b, Table I, higher entries) was assigned to 3-H by inspection of the alkylated ring protons of the parent alkylferrocene, whereas the mid-field multiplet (the lower of the two tau values in column b, Table I) was assigned to 4-H. The general appearance of three complex peaks of the intensity 1 : 1 : 1[24] was in itself diagnostic of a 1, 2-disubstituted ferrocene, bearing an alkyl and an electronegative moiety.

Furthermore, clinching evidence in support of these assignments is provided by the model have space compound, 1, 2-(α-ketotetramethylene)-ferrocene.[25] Infrared absorptions at 9 and 10 μ eliminate the possibility of the 1, 1'-structure, and a 1, 3-disposition is seemingly impossible on structural grounds. The NMR spectrum showed three peaks[26] on the low-field side of the unsubstituted ring (intensities 1 : 1 : 1); this is in complete agreement with the above assignments for the 1-acetyl-2-alkylferrocenes. In this instance, any structural assignments based upon only infrared generalizations might prove ambiguous, as will be shown later (Table VIII).

The 1, 3-structures presented an entirely different NMR pattern. The spectra of all

23) We are concerned here only with ring proton spectra. The alkyl groups behaved normally, although it should be mentioned that the gem-dimethyl groups of the 1-acetyl-2-isopropylferrocene displayed two nonequivalent methyl groups, each split into a doublet by the methine hydrogen.

24) Alternatively, since the shoulders of the 3-H multiplets were frequenly hidden under the wings of the 4-H multiplet, one may consider the intensities as 1 : 2 (in order of increased shielding). The difference in chemical shifts between 5-H and 4-H was greater than that between 4-H and 3-H (see in particular the 1-acetyl-2-*t*-butyl entry).

25) K. L. Rinehart, Jr., et al., *J. Am. Chem. Soc.*, **84**, 3263 (1962).

26) The tau values obtained in a carbon tetrachloride solution are 5.28 (5-H), 5.60 (4-H), 5.66 (3-H), 5.88 (unsubstituted ring protons), and 7.68 ($-CH_2-$).

1, 3-isomers displayed two peaks on the low field side of the respective unsubstituted ring in the ratio of 2 : 1. (The peak of intensity 2 was in all cases more deshielded than the intensity 1 peak.) Each peak appeared as an unresolved multiplet. In these isomers there are two unsubstituted positions adjacent to an acetyl group, the other position being adjacent only to an alkyl function. There can be little doubt, therefore, that the peaks of intensity 2 correspond to the two protons (2-H and 5-H) adjacent to the acetyl group. The somewhat higher-field peak (intensity 1) is due to 4-H. The latter proton for each 1, 3-isomer possesses a chemical shift not widely different from the 4-H of the corresponding 1, 2-isomer.

These structural assignments receive further support from the trend of the chemical shifts of the α-protons of the alkyl groups attached to the ferrocene ring (see Table II). It may be seen from the table that the frequencies for the α-protons of the 1, 1'-isomers are only slightly different from those of the respective parent hydrocarbons.

TABLE II. CHEMICAL SHIFTS FOR α-PROTONS[1] OF ALKYL GROUPS ON FERROCENE RINGS[2-4]

Substituent	α-H(Me)	α-H(Et)	α-H(*i*-Pr)
R (alkyl)	8.04	7.71	7.41
1-Ac-1'-R	8.09	7.73	7.43
1-Ac-2-R	7.67	7.28	6.59
1-Ac-3-R	7.97	7.62	7.34

1) The α-protons referred to in this table are those located on the carbon atom of the alkyl group which is attached to the ferrocene ring.
2) The data listed are "tau" values, using tetramethylsilane as an internal standard. A Varian A-60 analytical spectrometer was used for all the measurements.
3) Ac in the table refers to the acetyl group.
4) The spectra of all the compounds listed in this table, as well as all those in Table I, were obtained in a solvent of carbon tetrachloride.

For the homoannularly-substituted acetylmethylferrocenes, the α-proton of one isomer is deshielded 0.37 p. p. m., whereas that of the other is deshielded 0.07 p. p. m. (relative to methylferrocene). Consequently, due to the shielding effect on the α-protons induced by their proximity to the acetyl group, the former isomer must possess the 1, 2-, and the latter, the 1, 3-structure.

The same trends are manifest for the homoannularly-substituted acetylethyl- and acetylisopropylferrocenes, the largest deshielding (relative to the corresponding alkylferrocene) occurring for the 1, 2-isomer.

Interestingly enough, it was observed that the chemical shifts for ring protons of those acetylalkylferrocenes could be calculated with a reasonable degree of accuracy (average deviation: 0.04 p. p. m.) employing a simple additivity relationship[27] akin to that developed by Shoolery[28] for acyclic systems.

Shielding constants, measuring the effect of a substituent at a given position (in a given solvent),[29] are tallied relative to the chemical shift for the ring protons of ferrocene itself in Table III.

It is evident from Table I that an acetyl group deshields "ortho" hydrogens by -0.61 p.p.m. and "meta" hydrogens by -0.30 p.p.m. The alkylated ring protons of isopropylferrocene appear as a singlet at 6.04 tau, so that an isopropyl group shields both "ortho" and "meta" hydrogens by $+0.10$ p.p.m. A set of shielding constants calculated in this manner appears in Table III. Using these values, a chemical shift for the ring protons of an acetyl-isopropylferrocene may be calculated. For example, the 5-H resonance of the 1, 3-isomer is obtained from: $5.94+(-0.61+0.10)=5.43$ tau (versus 5.41 tau, observed). Tables IV to VII list predicted and observed tau values for the ring protons in the acetylalkylferrocenes,

TABLE III. SHIELDING CONSTANTS (p.p.m.)

Group	2-Position	3-Position	1'-Position
Me	+0.12	+0.07	+0.07
Et	+0.09	+0.09	+0.05
i-Pr	+0.10	+0.10	+0.04
t-Bu	+0.14	+0.14	+0.04
Ac	−0.61	−0.30	−0.06
CO_2Me[a]	−0.66	−0.21	−0.07

a) Carbomethoxyferrocene absorbs at 5.28 tau (2- and 5-H); 5.73 tau (3- and 4-H) and 5.87 tau (the unsubstituted ring protons).

27) A simple additivity rule was also observed for various alkylcarbomethoxy and alkyldicarbomethoxyferrocenes, the NMR spectra of which will be described later.
28) Ref. 22, p. 59.
29) The simple additivity observed and the conclusions drawn are to be considered limited to carbon tetrachloride solutions. NMR spectra of acetylalkylferrocenes were also determined in benzene solvent, which proved far less satisfactory than carbon tetrachloride. In general, chemical shifts were higher in benzene. The spectra of all the 1, 3-isomers possessed the 2 : 1 intensities of substituted ring protons already noted in carbon tetrachloride. However, the greater differential shielding (in benzene) caused an overlap of 4-H and 5-H for the 1, 2-isomes when R = *i*-Pr and *t*-Bu; consequently, the 1, 2-structure also displayed a 2 : 1 intensity relationship in the region of interest, which could lead to ambiguity. For this reason, carbon tetrachloride is the preferred solvent. Since the proton frequencies are solvent-dependent, no general conclusions regarding the additivity of substituent effects may as yet be drawn. It is not unreasonable, however, to employ shielding constants characteristic of substituents in a given solvent as a first approximation. This approach has been used by Taft et al. (*J. Am. Chem. Soc.*, **85**, 709 (1963).) to determine substituent constants in a study of the NMR spectra of meta-substituted fluorobenzenes.

a) For these compounds, all protons of the unsubstituted ring appear as a singlet and are simply designated as 1'-.

and in several 1,1'-dicarbomethoxy-2- and 3-alkylferrocenes.[30]

This very simple but valuable method of prediction should serve as a useful guide for the elucidation of many other ferrocene derivatives.

Summary

All of the acetylalkylferrocenes have been synthesized and obtained in a highly pure state. The infrared and NMR spectrum of each of these compounds has been determined, and the results tabulated.

It has been shown that NMR spectroscopy provides a convenient tool in elucidating the structure of substituted ferrocenes. It is particularly useful in distinguishing between 1,2- and 1,3-disubstituted structures, a situation where infrared has its greatest limitations.

A series of shielding constants has been developed for a variety of ferrocene substituents. These enable one to predict with considerable precision the chemical shifts of a variety of protons bonded to the ferrocene nucleus.

Experimental

Alkylferrocenes.—These materials were prepared by procedures described elsewhere.[31]

Acetylferrocene.—This was prepared following the directions of Hauser and Lindsay,[18] with the exception that boron fluoride-etherate was used instead of the boron fluoride-ethyl acetate complex.

Acetylation of Alkylferrocenes.—The acetylation procedure was identical for all alkylferrocenes. A solution of 0.05 mol. of the appropriate alkylferrocene and 10.2 g. (0.1 mol.) of acetic anhydride in 100 ml. of methylene chloride was cooled to 0°C. To this solution was added 21.3 g. (0.15 mol.) of boron fluoride-etherate with stirring. A nitrogen sweep was employed throughout. The mixture was stirred at 0°C for 30 min. and at room temperature for 2 hr. The contents of the flask were decomposed with water and extracted with methylene chloride. The organic layer was dried over calcium chloride. The residue obtained after removal of

30) The observed values for the latter compounds are taken from the Ph. D. thesis of J. L. Bach, Purdue University, June, 1963.

1,2-(α-Ketotetramethylene)	11.22(m)	—	9.96(s)	9.02(s)	—	7.80(s)

a) Spectra of crystalline materials were determined as Nujol mulls, those of liquids, as capillary films. A Perkin-Elmer Model 221 spectrophotometer was used.
b) s=strong, m=medium, w=weak
c) Rosenblum's correlations (Ref. 12) hold with a slight modification. Actually, in most cases, both the 1,2- and 1,3-isomers exhibit two bands in the region between 10.7 and 11.25 μ. It may be said, however, that for these bands a stronger absorption appears at a shorter wavelength with the 1,2-structure, while with a 1,3-disposition a more intense peak lies at a higher wavelength. An exceptional case is 1,2-(α-ketotetramethylene)-ferrocene.
d) The "9, 10 μ" rule holds in every case.

the solvent was chromatographed on an alumina (Merck, neutral grade) column.

The development and elution of methylacetyl-isomers were carried out with pentane-ether mixtures (approximately 1 : 1 by volume). A faster moving band was separated from the major band. The first compound eluted was 1-acetyl-2-methylferrocene (1.34 g.) (m. p. 62.5~63.5°C) (lit.[32] 62.2~63.2°C).

Found: C, 64.82; H, 5.77; Fe, 23.39. Calcd. for $C_{13}H_{14}OFe$: C, 64.49; H, 5.83; Fe, 23.07%.

The second isomer eluted from the column was 1-acetyl-1'-methylferrocene (2.74 g.) (m. p. 42~43°C) (lit.[32] 42.7~43.2°C). Found: C, 64.45; H, 5.75; Fe, 23.30%.

The third isomer eluted from the column was 1-acetyl-3-methylferrocene (1.16 g.) (m. p. 61.5°C) (lit.[32] 57.5~61.5°C). Found: C, 64.54; H, 6.00; Fe, 23.30%.

The ethylacetyl-isomers were separated in the same manner as above. The first compound eluted was 1-acetyl-2-ethylferrocene (0.94 g.) (m. p. 44.5°C) (lit.[3b] 42.5~44.5°C).

The second isomer eluted from the column was 1-acetyl-1'-ethylferrocene (1.59 g.) (b. p. 128°C/0.2 mmHg) (lit.[3b] m. p. 12.5~13.2°C).

Found: C, 65.97; H, 6.24; Fe, 21.56. Calcd. for $C_{14}H_{16}OFe$: C, 65.65; H, 6.30; Fe, 21.80%.

The third isomer eluted from the column was 1-acetyl-3-ethylferrocene (0.55 g.) (b. p. 144°C/0.8 mmHg) (lit.[3b] m. p. 11.6~12.6°C). Found: C, 66.13; H, 6.69; Fe, 22.19%.

The separation of the isomeric acetyl-isopropylferrocenes was more laborious than that of the methyl- or ethyl-acetyl analogs. Using a pentane-ether (ca. 9 : 1 by volume) mixture, a faster-moving band could be separated from the major broad band. The first compound eluted was 1-acetyl-2-isopropylferrocene (1.03 g.) (b. p. 145°C/1 mmHg).

Found: C, 67.21; H, 7.00; Fe, 21.10. Calcd. for $C_{15}H_{18}OFe$: C, 66.69; H, 6.71; Fe, 20.67%.

Elution was continued using a pentane-ether mixture, gradually enriching the ether content. The major band became broader than it was at the beginning, but no discrete bands were formed. Thus, ten fractions of ca. 100 ml. each were taken. The separation was conveniently checked by VPC (F and M Model 500 vapor fractometer; DEGS column; 15 feet×1/4 inch; 215°, at a flow rate of helium of 60 ml./min.). From the first two cuts 1-acetyl-1'-isopropylferrocene (2.04 g.) was obtained (b. p. 146°C/1 mmHg.). Found: C, 66.60; H, 6.25; Fe, 20.43%.

From fractions 9 and 10 1-acetyl-3-isopropylferrocene (0.99 g.) was obtained (b. p. 143°C/1 mmHg). Found: C, 66.81; H, 6.61; Fe, 20.90%.

The separation of the *t*-butylacetylferrocenes (1,1'- and 1,3-isomers) was accomplished only with great difficulty. Elution with pentane-ether mixtures (ca. 9 : 1 by volume), gradually enriching the ether content, developed a discrete, faster-moving band, followed by a broad and unresolved major band. The first compound eluted was 1-acetyl-2-*t*-butylferrocene (0.38 g.) (m. p. 99~100°C).

Found: C, 67.83; H, 7.19; Fe, 19.55. Calcd. for $C_{16}H_{20}OFe$: C, 67.62; H, 7.09; Fe, 19.65%.

No discrete separation of the major band could be effected. A total of ten fractions were taken of ca. 100 ml. each. The course of the separation in this instance could not be followed by vapor phase chromatographic analysis, since a wide variety of column materials proved ineffective in separating the 1,1'- and 1,3-isomers. A method based on infrared spectroscopy was employed. Earlier frac-

tions were characteristically devoid of the "9, 10μ" absorption bands. This indicated the presence of 1,1'-disubstituted products. Although these fractions did possess strong absorption bands at 7.85 and 8.97 μ, they had no absorption at 8.0 μ.[33] The first four fractions were combined and rechromatographed in the same manner. From the latter first fraction 1-acetyl-1'-*t*-butylferrocene (1.22 g.) was isolated (b. p. 144°C/3 mmHg). Found: C, 67.15; H, 7.02; Fe, 19.99%.

The middle fractions of the original chromatograph possessed an infrared absorption at 7.85 μ, but a band started appearing at 8.0 μ. The "9, 10 μ" bands also started appearing, with the 9 μ band possessing a shoulder on the low wavelength side. The last fractions taken indicated the total disappearance of the 7.8 μ band, but a strong absorption at 8.05 μ. The "9,10 μ" bands appeared at 9.05 and 9.95 μ respectively. In this manner there was obtained 3.09 g. of 1-acetyl-3-*t*-butylferrocene, melting at 83.5~84.5°C. Found: C, 67.77; H, 7.00; Fe, 19.59%.

1,2-(α-Ketotetramethylene)-ferrocene. — This compound was prepared according to the directions of Rinehart and his coworkers[25] (m. p. 86~87°C) (lit.[25] 87.5~88.5°C).

33) The correlation of 10.8 and 11.2 μ bands for a 1,3-disposition of substituents[12] could not be employed since the 1,1'-structure absorbs in this region.

Colloid Chemical Studies of Starching Materials. V. Rheological Properties of Concentrated Polyvinyl Alcohol Solutions

By Masayuki NAKAGAKI* and Takako NISHII

(Received September 3, 1963)

In a previous paper,[1] the dynamic viscosity and rigidity of starch solutions measured by a top-drive coaxial rheometer have been reported, and the results have been discussed[2] on the basis of Rouse's theory[3] as modified to take the intermolecular association into account. On the other hand, the structural viscosity of dilute solutions of polyvinyl alcohol has also been reported on previously[4]. These papers have, however, been chiefly interested in the anomalous viscosity due to the intermolecular association.

In the present paper, the viscoelastic behaviour of concentrated solutions of polyvinyl alcohol will be studied by means of a rotation viscometer, together with the rheometer previously used for starch solutions, and the results will be discussed on the basis of Rouse's theory, considering the change in intermolecular association in the solutions.

Experimental

Sample.—The polyvinyl alcohols used in these experiments are the same as those used in a previous paper.[5] They are Gohsenol GH-17 (degree of saponification $S=88.1\%$, average degree of polymerization $P=1700$), GH-23 ($S=87.5\%$, $P=2300$), NH-17 ($S=98.8\%$, $P=1700$), and NH-26 ($S=99.4\%$, $P=2600$).

To prepare aqueous solutions of polyvinyl alcohol, 90 g. of the polymer was put in 600 g. of distilled water, together with 0.18 ml. of Shinetsu Silicone Antifoaming Agent KM-65, and the whole was heated at 95°C for 30 min. (in the case of NH-17 and NH-26) or 1 hr. (in the case of GH-17 and GH-23) while being stirred well with a glass rod. After the solution had cooled to room temperature, the film which had formed on the surface of the solution was removed and kept in a closed vessel. The concentration was determined by measuring the weight of the polymer which remained after a known weight of the solution had been dried.

For the dynamic measurement, a solution put in the rheometer was covered with liquid paraffine and the measurements were made for the same solution 20, 60 and 110 hr. after the preparation of the solution. For the measurement of the steady-flow viscosity, a solution kept in a closed vessel for 20, 60 and 110 hr. was put in the rotation viscometer for each measurement.

Oscillation Rheometer.—A top-drive coaxial rheometer used was the same as has been reported on in a previous paper.[1] All measurements have been made in a thermostat at 30°C.

Rotation Viscometer.—A coaxial rotation viscometer of the Couette type was newly constructed. An inner cylinder 30 mm. in diameter ($2r_1$), 75 mm. long, and weighing 461.72 g. was hung in an outer cylinder 42 mm. in inner diameter ($2r_2$) and 90 mm. deep with a steel wire 490 mm. long, the torsional constant of which was $k_0=1.036\times10^5$ (dyn. cm.). The sample solution was put into the gap between the inner and outer cylinders, and the inner cylinder was held to dip into the solution by $h=65$ mm. The outer cylinder set in a thermostat at 30°C was rotated. The rate of the rotation, Ω (r. p. m.), was variable between 6 r. p. m. to 190 r. p. m. by means of thirty combinations of gears. The velocity gradient, g (sec^{-1}), was calculated by the following relation:

$$g=\frac{2\pi r_2}{60(r_2-r_1)}\quad \Omega=0.367\,\Omega \tag{1}$$

By measuring the angle of the deflection of the inner cylinder, θ (degree), the steady-flow viscosity of the solution can be calculated by the equation:

$$\eta=\left(\frac{k_0}{24\,\pi\,h}\right)\left(\frac{1}{r_1^2}-\frac{1}{r_2^2}\right)\frac{\theta}{\Omega} \tag{2}$$

All data are given in c. g. s. units.

Theoretical

In a previous paper,[2] the viscoelastic behavior of starch solutions has been discussed on the basis of a modified Rouse equation:

$$\left.\begin{aligned}\eta&=(F/\sqrt{\omega})\alpha\\ G&=G_0+F\sqrt{\omega}\beta\end{aligned}\right\} \tag{3}$$

where ω is the angular frequency, τ is the relaxation time, F is a constant, and α and β are functions depending on $\omega\tau$ only. The values of the functions have been given in that previous paper.[2]

In the case of polyvinyl alcohol solutions, however, the viscoelastic behaviour is different from that of starch solutions, especially in the low frequency region, where the polyvinyl alcohol solutions showed the following features: (1) The dynamic viscosity, η, is almost constant (except for NH-26), and (2) the dynamic rigidity, G, is nearly equal to zero; that is, $G_0\fallingdotseq0$.

Since the α function tends to the following value when $\omega\tau\ll1$,

$$\alpha=(\sqrt{2}\,\pi/3)\sqrt{\omega\tau}=1.48020\sqrt{\omega\tau} \tag{4}$$

the value of η at $\omega\to0$, designated by η_0, is given by:

$$\eta_0=1.48020\,F\sqrt{\tau} \tag{5}$$

Therefore, the following equations can be used for polyvinyl alcohol solutions:

$$\left.\begin{aligned}\eta/\eta_0&=A(\omega\tau)\\ G/\eta_0&=B(\omega\tau)/\tau\end{aligned}\right\} \tag{6}$$

where $G_0=0$ was used. Here, A and B are the functions of $\omega\tau$ only, as defined by the following:

$$\left.\begin{aligned}A&=\alpha/1.48020\sqrt{\omega\tau}\\ B&=\sqrt{\omega\tau}\,\beta/1.48020\end{aligned}\right\} \tag{7}$$

The theoretical relations of $\log(\eta/\eta_0)$ and $\log(G/\eta_0)$ relative to $\log\omega$ can be drawn for various values of τ (sec.), as shown in Fig. 1.

In order to compare the experimental with the theoretical values, the experimentally-obtained values were plotted on $\log\eta$ and $\log G$ vs. a $\log\omega$ chart with the same scale as the theoretically-drawn Fig. 1, and the chart was superposed on Fig. 1 by sliding it along the ordinate. In order to obtain the best fit, attention must be paid to the values of η at low frequencies. The values of η_0 can then be read off from the position of the ordinate at the best fit, and the value of τ (sec.) can

be obtained from the location of the experimental $\log\eta$ and $\log G$ curves, paying attention especially to the point of intersection of these curves, that is, the points marked by open circles in Fig. 1.

Results and Discussion

Dynamic Viscosity and Dynamic Rigidity.— The experimental values of η and G obtained by the oscillation rheometer at 30°C are shown in Fig. 2 for a 11.51% GH-17 solution, in Fig. 3 for a 12.38% GH-23 solution, and Fig. 4 for a 11.09% NH-17 solution. All these correspond well with the theoretical curves drawn by Eq. 6 with the parameter values cited in Table I. The length of time between the preparation of the solutions and the measurement did not make much difference in the η and G values.

The viscoelastic behavior of NH-26 was fairly different from that of other samples. The viscosity changed with the time which elapsed from the preparation of solutions to the measurement. If one pays attention to the frequency value at which the curves of η and G intersect, the values $\eta_0=100$ and $\tau=0.015$ are obtained, as is cited in Table I. The theoretical η and G curves for these parameter values, calculated by Eq. 6 and shown in Fig. 6 by broken lines, do not however, correspond well with the experimental values, especially at the small ω values, where the experimental η values are much greater than the η_0 value, probably because of the association of polymer molecules. If it is assumed that the degree of association is the greater, and the η value is the greater, the smaller the frequency, ω, the fraction of the highly-associated component x_1 could, of course, be calculated for various frequency values by using the method already described in a previous paper.[2] In the present paper, however, it is assumed that, because of the existence of the highly-associated component, the average τ value is the greater, the smaller the ω value. The ω dependency of τ is calculated as follows. It can be shown that the following equation should be used when $\omega\tau\ll1$;

$$\tau\fallingdotseq(\eta/1.48020\,F)^2 \tag{8}$$

where F is a constant which is believed to be independent of ω and τ. The value of $F=551$ is obtained from Eq. 5 on the basis of $\eta_0=100$ and $\tau=0.015$. The frequency dependence of τ obtained by Eq. 8 for NH-26 is shown in Fig. 5. By using the τ values

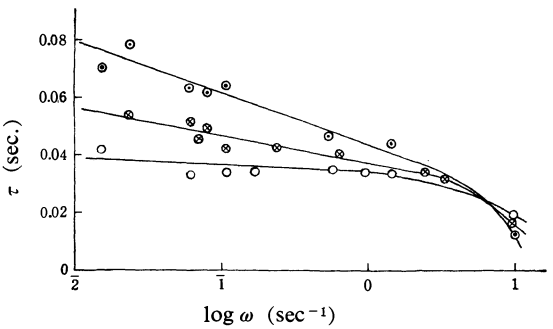

Fig. 5. Apparent relaxation time of NH-26 after 20 hr. (○), 60 hr. (⊗) and 110 hr. (⊙).

corresponding to the solid lines in Fig. 5 drawn by assuming that the $\tau-\log\omega$ relation is linear for $\omega\leqq1$, the values of η and G calculated from Eq. 6, instead of from the approximate Equation 8, are shown in Fig. 6 by solid lines. Thus, it is concluded that the "structure" due to the intermolecular association is developed in the NH-26 solution; that the average relaxation time, τ, and, therefore, the dynamic viscosity, η, are increased with the lapse of time after the preparation of the solution, and that the structure is destroyed and that η is decreased with the increase in the frequency, ω.

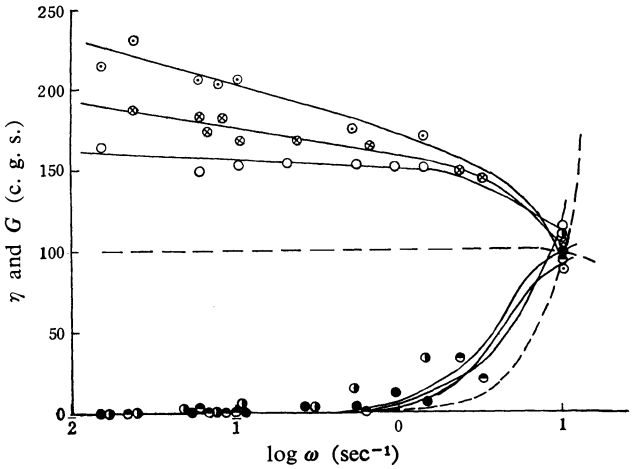

Fig. 6. Dynamic measurements for NH-26. η after 20 hr. (○), 60 hr. (⊗), 110 hr. (⊙), G after 20 hr. (●), 60 hr. (◓) and 110 hr. (◑). Broken curves are for $\eta_0=100$, $\tau=0.015$.

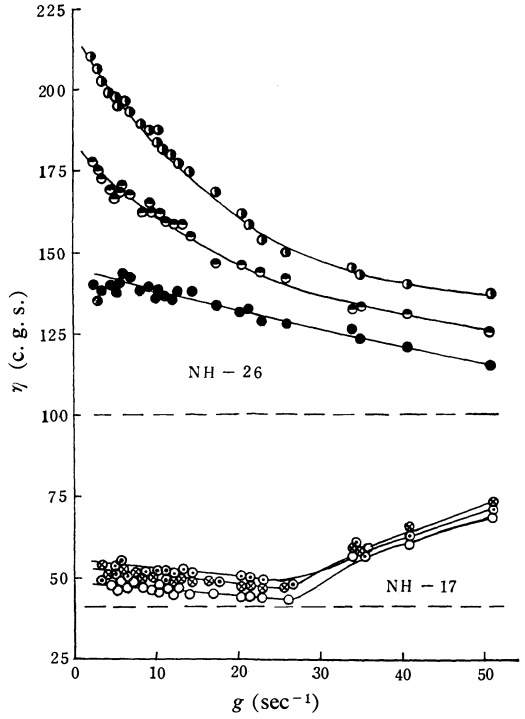

Fig. 8. Steady-flow measurements for NH-17 after 20 hr. (○), 60 hr. (⊗) and 110 hr. (⊙) and for NH-26 after 20 hr. (●), 60 hr. (◓) and 110 hr. (◑).

Steady-flow Viscosity.—The steady-flow viscosities measured by a coaxial rotational viscometer at 30°C are shown in Fig. 7 for GH-17 and GH-23 and in Fig. 8 for NH-17 and NH-26. The order of magnitude of the steady-flow viscosity values agrees with the values of η_0 in Table I obtained dynamically by the oscillation rheometer and shown in Figs. 7 and 8 by horizontal broken lines. There are, however, several important points of disagreement between the dynamic and steady-flow measurements.

The discussions in the present paper are essentially based on Rouse's theory, a theory which is presumed by some people[6] to be applicable to the steady-flow viscosity, too, if one substitutes the frequency, ω, in the dynamic measurement as is in the original Rouse equation with the velocity gradient, g, in the steady-flow measurement. The present authors, however, do not agree with this conventional substitution; they believe that the steady-flow

6) E. g., J. D. Ferry, M. L. Williams and D. M. Stern, *J. Phys. Chem.*, **58**, 987 (1954).

viscosity is equal to η_0. The steady flow viscosity should, therefore, be Newtonian except in the case of NH-26, for which the structural change with ω is observed in the course of dynamic measurement.

The solution of NH-26 showed structural viscosity as expected and as shown in Fig. 8. However, the steady-flow viscosities of GH-17, GH-23 and NH-17 also showed dependencies not only on the velocity gradient but also on the time after the preparation of the solution, as Figs. 7 and 8 show. Neither of these dependencies could be expected on the basis of the dynamic measurements reported in the preceding paragraph.

The steady-flow viscosity of the relatively low molecular weight samples, GH-17 and NH-17, increase with the velocity gradient, g, when the g value exceeds 30 sec^{-1}. In this region of g, the solutions, therefore, behave as if they are dilatant. This dilatant behavior might be due to a certain unexpected factor involved in the method of measurement, although the authors can not think of any fault in the experiment.

As for the structural viscosity of polyvinyl alcohol solutions, it has been reported[4] that the apparent viscosity is linear to the reciprocal of the rate of flow ($1/Q$), and that the limiting value of viscosity, η_N, extrapolated to ($1/Q \rightarrow 0$) is independent of the history of the solution.

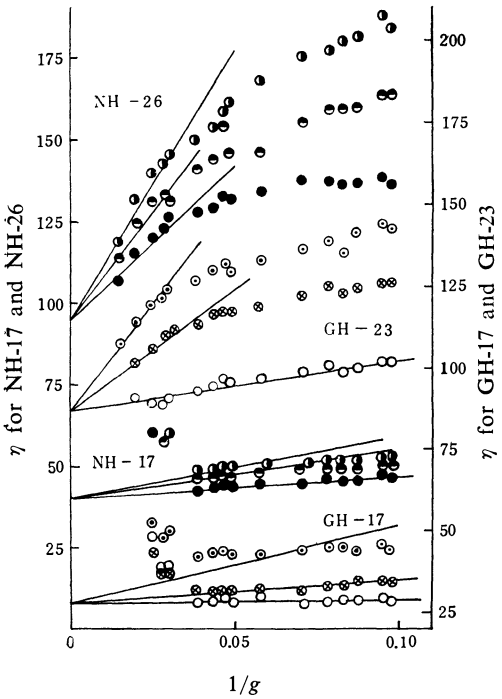

Fig. 9. Relation between η and $1/g$ for the samples after 20 hr. (○, ●), 60 hr. (⊗, ◓) and 110 hr. (⊙, ◑).

The empirical relation translated to the present notation is:

$$\eta = \eta_N + G_y/g \tag{9}$$

For the concentrated solutions discussed here, however, this relation holds not over the whole range of $1/g$, but only in the range of small $1/g$ values, excluding the dilatant behavior of GH-17 and NH-17. The results are shown in Fig. 9, while the values of the parameters, η_N and G_y, are given in Table I. The value of η_N is independent of the time which has elapsed before the measurement and is in good agreement with the dynamically-obtained η_0 value. The G_y has the dimension of rigidity and corresponds to the yield value of Bingham flow, although the behavior of the solution is not Bingham-like because the value of η is smaller than that expected from Eq. 9 in a high ($1/g$) region. The increase in G_y with time suggests the development of structure in the solutions.

An Examination of Parameter Values.—As has been shown in a previous paragraph, the viscoelastic behavior of polyvinyl alcohol solutions may be described fairly well with Eq. 6, which is essentially based on Rouse's theory. On examining the values of parameters, however, it appears that the theory is not very good in explaining all the results. First of all, the value of F calculated by Eq. 5 and given in Table I is a constant throughout the experiments any on one sample, but it is not a constant common to all the samples. The same has been observed in the case of starch solutions reported on before.[2] On the other hand, the theoretical expression of F is, as has already been shown in a previous paper:[2]

$$F = nN\sigma\sqrt{kT}/4\sqrt{3}\sqrt{B} \tag{10}$$

where n is the number of molecules in a unit volume of the solution, N is the number of segments contained in one polymer molecule, σ is the length of the segment, and B is the mobility of the end of a segment. If the polymer molecules aggregate in the solution, and if the average number of molecules to form one aggregate is m, then n and N in Eq. 10 should be replaced by (n/m) and (mN) respectively, but this replacement does not make any difference in Eq. 10 because $(n/m)\cdot(mN)$ is equal to nN. Therefore, F should be a constant independent of the degree of intermolecular association, and it should be a constant for various samples of the polymer composed of the same monomeric unit. Contrary to this theoretical expectation, however, the experimental values of F for various samples do not equal each other. This is

probably due to the change in $\sigma/\sqrt{B}$. However, the situation is supposed to be complicated in concentrated polymer solutions because of various reasons such as are, for example, described below: (1) The manner of the intermolecular aggregation might be different. If the molecules associated head to tail to form a linear aggregate, Rouse's theory may be applied without further modification, but if the molecules associate with intermediate segments to form a "star"-shaped aggregate, the viscoelastic behavior will be different from that expected by Rouse's theory derived for linear molecules. (2) If the possibility of intramolecular interaction can be expected, the interaction will change not only $\sigma/\sqrt{B}$ but also the effective number of segments, N. These changes will, of course, explain the variation in the value of F.

At any rate, it seems to be necessary to presume that the molecular aggregates are formed in the solutions of all samples, and that the aggregation is the cause of the non-Newtonian behavior of the steady-flow viscosity, but that the structural change of the aggregates is not dominant, except for NH-26, within the extent of the range of the frequency used for the dynamic measurement. Although this view still can not explain why the time dependence of η was not observed in the dynamic measurement, one of the reasons might be that the solution kept in the apparatus was used for successive measuments in the case of the dynamic experiment, while a part of a solution kept in a reservoir was placed in the apparatus for each steady-flow experiment.

Although it is not clear whether it is theoretically valuable or not, it may be worthwhile to point out here the entirely empirical fact that the value of η_0/P^2 is fairly constant, as is shown in Table I, where P is the degree of polymerization of the polymers.

Summary

The dynamic viscosity, dynamic rigidity and steady-flow viscosity at 30°C have been measured for 11~12% solutions of four specimens of polyvinyl alcohol, GH-17, GH-23, NH-17 and HN-26, 20, 60 and 110 hr. after the preparation of the solutions.

In the dynamic measurement by a top-drive coaxial oscillation rheometer, the relations of η and G vs. ω did not depend on time and have all been explained by Rouse's theory except for NH-26, the latter showing time and ω dependencies of the structure. In the steady-flow measurement by a coaxial rotation viscometer, the viscosity of all the polymers showed both time and velocity gradient dependencies.

*The Photometric Determination of Traces of Platinum in Electrolyte using Copper Sulfide as a Collector**

By Yûsuke UJIHIRA and Shizo HIRANO**

(Received February 15, 1963)

In recent years, considerable interest has been aroused concerning the behavior of platinum dissolved from platinum anode during electrolysis. Consequently, a simple, sensitive and accurate method for the determination of microgram quantities of platinum is required.

To determine the platinum content in electrolyte, a preliminary separation step is necessary because of the presence of macro amounts of diverse ions and the need to reduce the solution to a small volume.

Several papers have been published for this purpose.

Wölbling[1] reported the adsorption of platinum with activated charcoal, Beamish[2] separated microgram quantities of platinum from

* Presented at the 14th Annual Meeting of the Chemical Society of Japon, Tokyo, April, 1961.

** Present address: Applied Chemistry Department, Faculty of Engineering, Tôyo University, Kawagoe, Saitama.

1) H. Wölbling, *Z. angew. Chem.*, **45**, 1720 (1932).

2) F. E. Beamish and A. G. Marks, *Anal. Chem.*, **30**, 1464 (1958).

macro amounts of iron, nickel and copper by the use of a cation-exchange resin, Salyards[3] concentrated minute quantities of platinum by precipitation with stannous chloride from a hydrochloric acid solution containing 1 mg. of tellurium, Bufatin[4] precipitated platinum sulfide using 10 mg. of copper as a carrier, and Poluektov[5] developed a method for the concentration of platinum with mercury-mercuric chloride.

In this paper, the authors will describe the separation of trace amounts of platinum by the use of carrier precipitation with 1.5 to 3.0 mg. of copper sulfide and subsequent photometric determination by the stannous chloride method.

A photometric stannous chloride method for the determination of platinum in a hydrochloric acid solution has been described by Ayres and Mayer[6,7] and by Maziekien and his coworker,[8] and the nature of the platinostanno-chloro-complex has been studied by Ayres[9] and Mayer.[10]

In order to reduce interference by diverse ions in the photometric step, the authors studied the color development of the platinostanno-chloro-complex in an aqueous solution and in ethyl acetate.

The separation of platinum from the interfering elements by this carrier precipitation method is simple, and traces of platinum are determined photometrically by mean of the stannous chloride ethyl acetate extraction method, which has the sensitivity required.

This method has been developed specifically for the determination of platinum in electrolytes for the electrolysis of sodium chlorate, but it can be applied equally well to most aqueous solution samples.

Experimental

Apparatus. — A Hirama photoelectric filter photometer, model II, was used for all measurements of the absorbancy, matched 1 cm. glass cells also being used.

Materials. — A standard platinum solutions was prepared by dissolving 0.998 g. of pure platinum metal in aqua regia and evaporating it to dryness. Then 5 ml. of concentrated hydrochloric acid and 0.1 g. of sodium chloride were added to the residue, and the resulting solution was evaporated again to dryness. The residue was dissolved in 20 ml. of hydrochloric acid (1 : 1) and diluted to 100 ml. with water.

This solution was diluted with hydrochloric acid (1 : 0) to give a solution containing 9.8 μg.-Pt/ml.

A copper solution was prepared by dissolving 1.964 g. of reagent grade copper sulfate in 500 ml. of water. This solution contained 1 mg. of copper per 1 ml.

An ammonium nitrate solutions was prepared by dissolving 80 g. of analytical reagent grade ammonium nitrate in 1000 ml. of water.

Aqua regia was prepared by mixing one portion of concentrated nitric acid and three portions of concentrated hydrochloric acid.

A stannous chloride solution was prepared by dissolving 23 g. of analytical reagent grade stannous chloride dihydrate in 30 ml. of concentrated hydrochloric acid and diluting it to 100 ml. with water.

The ethyl acetate used was of the analytical reagent grade, as were the hydrochloric acid and nitric acid used.

Method. — To determine the recovery of trace quantities of platinum from hydrochloric acid solutions with copper sulfide, an aliquot of the standard platinum solution was placed in a 100 ml. beaker and diluted to 50 ml. with 0.5 to 3.0 N hydrochloric acid. After the addition of 1 to 2 ml. of the copper sulfate solution, a fairly rapid stream of hydrogen sulfide was passed into the solution for 10 min.

This solution was heated to near the boiling point and kept at this temperature for 10 min.; then the gas was passed again for 10 min. The precipitate was filtered off through a paper filter (Toyo Roshi No. 5C (ϕ 5.5 cm.)) and then washed successively with 10 ml. of hydrochloric acid (1 : 10), 10 ml. of the ammonium nitrate solution and a few milliliters of water.

The precipitate and the filter paper were ignited in a casserole, and the residue was dissolved in 0.4 ml. of aqua regia. This solution was transferred to a 50 ml. Terex beaker, and the same treatment was repeated with another 0.5 ml. of aqua regia. The casserole and rod were then washed several times with a few milliliters of hydrochloric acid (1 : 1), and the washings were drawn into the same beaker.

The solution was evaporated to dryness on a water bath without prolonged heating, the residue was dissolved in 2.0 ml. of hydrochloric acid (1 : 7), and 0.5 ml. of the stannous chloride solution was added. The colored solution was transferred to a glass-stoppered test tube and was shaken for 1 min. with 2.5 ml. of ethyl acetate.

The color intensity of the organic phase was measured at 420 mμ with a photometer.

The investigation of the photometric stannous chloride method and the tests of the effect of diverse ions were made as follows unless otherwise stated.

The desired volume of the standard platinum solution, and, if necessary, of a diverse ion solution was placed in a 50 ml. Terex beaker and

evaporated to dryness on a water bath. The residue was dissolved in 4 ml. hydrochloric acid (1 : 7), and 1.0 ml. of the stannous chloride solution was added. One half of the volume of this solution was extracted with an equal volume of ethyl acetate. The intensities of the resulting color in the aqueous solution and in ethyl acetate were measured at 420 mμ.

Results and Discussion

The recovery of platinum from a solution with copper sulfide is shown in Table I. Table I indicates that 1 mg. of copper is sufficient for gathering microgram quantities of platinum from a 3 N hydrochloric acid solution. This amount of copper does not interfere at all with the photometric step.

Though the carrier precipitation with copper sulfide is somewhat lacking in selectivity, a trace amount of platinum is completely collected and separated from macro amounts of salt or other diverse ions (especially chromium).

Filtration of the precipitate by a sintered glass filter is unsuitable because of the difficulty of dissolving copper sulfide completely in nitric or hydrochloric acid.

The decomposition of the precipitate and of the filter paper was attained by burning them in a casserole. Their ashes are easily dissolved in 0.4 ml. of aqua regia.

amounts of sodium chloride, sodium chlorate and sodium bichromate.

Twenty-five milliliters of a sample solution was taken in a 200 ml. beaker, then concentrated and hydrochloric acid was carefully added. The quantities and the speed of the addition of the acid were experimentally selected to avoid the spraying of the sample solution by the rapid evolution of chlorine gas.

After evolution had ceased, the solution was warmed to ensure the complete decomposition of the oxidizing substances. Then platinum was isolated by carrier precipitation with copper sulfide and was determined photometrically by the stannous chloride method described previously.

The results of eight determinations of micro amounts of platinum in electrolytes sodium chlorate electrolysis are shown in Table V. The results are in good agreement with those obtained by other methods of analysis. The blank value obtained by running the full procedure corresponded to less than 0.1 μg. of platinum.

Summary

A method of separation has been developed for the photometric determination of trace amounts of platinum in electrolytes for the electrolysis of chlorate by the use of carrier precipitation with copper sulfide.

After a sample solution had been treated with concentrated hydrochloric acid, the preliminary separation of platinum was made by carrier precipitation with copper sulfide, and, following the ignition of the precipitate, the ashes was introduced into a hydrochloric acid solution. The orange-colored substance which was produced by the addition of the stannous chloride solution was extracted into ethyl acetate, and the color intensity of the ethyl acetate phase was measured at 420 mμ.

The recovery of platinum was quantitative, and the removal of macro amounts of salt and divers ions was satisfactory.

Experiments using synthetic sample solutions indicate that trace quantities of platinum in electrolytes for the electrolysis of sodium chlorate could be determined by this method with an accuracy of from 5 to 10% in the range between 0.02 and 0.00 p.p.m.

The authors wish to express their grateful thanks to Dr. Atsushi Mizuike of the University of Tokyo for his continuous interest and encouragement throughout this investigation.

The Direct Spectrophotometric Determination of Iron with Dibenzoylmethane in the Organic Phase

By Yoshimi UMEZAKI

(Received August 21, 1963)

In the preceding paper,[1] the author has described a spectrophotometric determination of uranium with dibenzoylmethane (DBM) in the organic phase. Since DBM reacts with iron(III) to form a colored complex, iron may be determined in a way similar to that used for uranium. Shigematsu and Tabushi[2] have reported a spectrophotometric determination of iron with DBM after forming an iron-DBM complex in an aqueous solution and after extracting the complex into butyl acetate. This method, however, is too greatly subject to interference by diverse ions.

As the extraction of iron(III) with methyl isobutyl ketone (MIBK) in a hydrochloric acid solution is an excellent method for separating iron from interfering ions, this extraction method is, as a preliminary separation, employed in various methods of determination for iron.[3] Recently, Jackson and Phillips[4] have reported a spectrophotometric determination of iron with *o*-phenanthroline after the MIBK extraction. In this case, iron extracted in MIBK is stripped by an aqueous solution and reduced to iron(II), and then the color is developed.

This paper describes a simple, sensitive and selective spectrophotometric determination of iron(III) with DBM in the organic phase after the MIBK extraction.

Experimental

Apparatus.—Absorbance measurements were made with a Hitachi spectrophotometer, Model EPV-2A, using 1-cm. glass cells.

Reagents.—*Standard Iron Solution.*—A stock solution containing 100 μg. of iron(III) per ml. was prepared by dissolving iron(III) chloride in a 0.1 N hydrochloric acid solution. Standardization was made by titration with a 0.01 M EDTA solution.

Dibenzoylmethane Solution.—A 0.5% solution was prepared by dissolving 0.5 g. of dibenzoylmethane in 100 ml. of methanol.

Solutions of Diverse Ions.—Reagents grade salts, usually the chlorides, were used for testing the interference of cations. Anions were tested by the addition of sodium or potassium salts.

Traces of iron involved in the reagents were removed when necessary with an anion exchange resin column.

Procedure.—Transfer 5.0 ml. of a slightly acidic sample solution containing less than 40 μg., preferably 10 to 30 μg., of iron(III) to a 50 ml. separatory funnel. Add 5.0 ml. of concentrated hydrochloric acid and 3.0 ml. of MIBK. Shake vigorously for about 1 min. After the phases have separated, discard the aqueous layer. Run the organic phase through a small plug of filter paper* in the stem of the separatory funnel into a dried small vessel. Transfer 2.0 ml.** of the extract to a 10 ml. volumetric flask. Add 2.0 ml. of a 0.5% DBM solution and 0.5 ml. of pyridine, and dilute with methanol to the mark. Measure the absorbance at 410 mμ (or 425 mμ) against a blank.

Results and Discussion

Absorption Spectra.—The absorption spectra of the blank and the iron complex are shown in Fig. 1, together with those of copper, tin, vanadium and molybdenum. The maximum absorbance of the iron complex is observed at 410 mμ.

The Effect of the Diluent.—Since the iron-DBM complex is insoluble in methyl or ethyl alcohol, MIBK was primarily used as a diluent. In this case, however, an extremely large amount of DBM was necessary in order to ensure full color development, and this induced large blank values. In the study of the color reaction of the complex, it was found that the absorbance of the complex was markedly affected by the choice of diluent, as has been reported by Mann and White[5] for the *in situ* spectrophotometric determination of chromium with diphenylcarbazide. The comparison of some diluents, shown in Fig. 2, revealed that methanol is best for this purpose,

while ethanol is barely satisfactory. No precipitation of the complex occurred in this combination of solvents (MIBK : pyridine : methanol=2 : 0.5 : 7.5). The effect of diluents on the color development of the complex apparently parallels the magnitude of the dielectric constants of the solvents. If this assumption is true, water, which has the highest dielectric constant, should be most effective. In fact, the addition of water instead of methanol up to 2 ml. gave a light pink color even before the addition of pyridine, though its use is not adequate for the standard procedure because a large amount of water causes precipitation.

Pyridine Concentration.—Pyridine was chosen as a miscible base in order to neutralize the acid extracted simultaneously into the organic phase and in order to ensure the full color development of the complex. The role of pyridine is not clear; it is not certain whether it only neutralizes the acid or whether it forms some adducts with iron-DBM as in cobalt-TTA and pyridine.[6]

As Fig. 3 shows a very small amount of pyridine is sufficient for full color development; 0.5 ml. was used in practice.

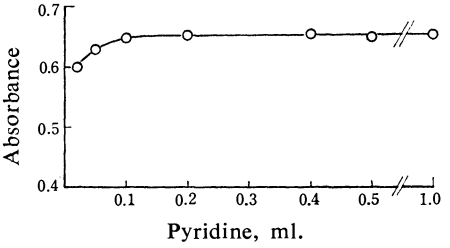

Fig. 3. Effect of pyridine.
30 μg. of Fe(III) present in aq. soln. 0.5% DBM×2 ml.

DBM Concentration.—As Fig. 4 shows, 2 ml. of a 0.5% DBM solution is sufficient in the methanol system.

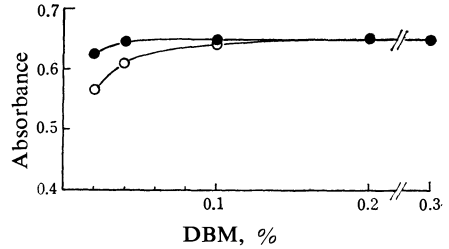

Fig. 4. DBM concentration.

● Methyl alcohol was used as diluent.
○ Ethyl alcohol was used as diluent.

The Effect of the Volume of the Aqueous Solution.—Since MIBK dissolves in water to some extent and vice versa, any change of the volume ratio of the two phases should be avoided as much as possible. In the recommended procedure, 3 ml. of MIBK decreases its volume to 2.1 to 2.2 ml. after passing through the filter paper plug. The effect of the volume of the aqueous solution was ex-

6) J. P. Fackler, *Inorg. Chem.*, 2, 266 (1963).

TABLE I. EFFECT OF VOLUME OF AQUEOUS SOLUTION (20 μg. of iron(III) present)

Volume of aq. soln. ml.	Absorbance
8.0	0.429
9.0	0.436
10.0	0.437
11.0	0.437
12.0	0.441

amined with varying volumes of the sample solution using 3 ml. of MIBK. As Table I shows, a variation of the volume by $\pm$1 ml. for 10 ml. of the sample solution does not yield any appreciable error.

The Effect of the Acidity of the Aqueous Solution.—Since the volume of the extract decreases with the increasing acidity of the aqueous solution, a relatively severe control of the acidity is desired. As is shown in Table II, the range of permissible variation in the acidity is narrow; i. e., about $\pm$0.15 N corresponds to a 1% error.

TABLE II. EFFECT OF ACIDITY OF AQUEOUS SOLUTION (20 μg. of iron(III) present)

Acidity of aq. soln. N	Absorbance	
	2 ml. extract	Whole extract
5.3	0.422	0.524
5.9	0.437	0.523
6.5	0.456	0.527
7.1	—a)	0.511
7.7	—a)	0.487

a) Volume of extract was less than 2 ml.

When the adjustment of the acidity is rather difficult, the use of the entire extract instead of a 2 ml. portion is preferable.

Stability and Sensitivity.—The color develops almost instantaneously on the addition of the reagent and pyridine, and it is stable for a long time provided the container is sealed.

The sensitivity of this reaction is 0.0046 μg. Fe/cm^2 for $-\log T=0.001$ (2 ml. extract) and 0.0038 μg. Fe/cm^2 (whole extract).

Beer's Law.—Beer's law is obeyed up to 40 μg. of iron in an aqueous solution in the recommended procedure, as Fig. 5 shows.

The Mole Ratio.—The mole ratio of the complex was studied by the method of continuous variations; it is clear that, in the lower concentration of DBM, the ratio of iron to the reagent is 1 : 2, as is shown in Fig. 6. How-

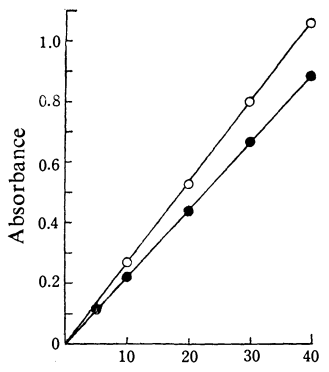

Fig. 5. Calibration curve.

ever, the absorption spectrum of this species is slightly different, there being no peak at 410 mμ, from that of the species obtained in a higher concentration of the reagent, which presumably has a mole ratio of 1 : 3, judging from its close resemblance to the absorption spectrum of iron-DBM in butyl acetate reported by Shigematsu and Tabushi.[2] The absorption spectra of these species change gradually with an increasing concentration of DBM; the change is hardly observed when this ratio exceeds 1 : 40, as Fig. 7 shows.

The Effect of Diverse Ions.—The effect of diverse ions on the determination of iron is summarized in Table III.

a) Precipitate was produced in the organic phase.
b) Measured at 425 mμ.

Goto et al.[7] reported that antimony(III, V), arsenic(III, V), tin(IV), selenium(IV), tellurium(IV), germanium(IV), chromium(VI), vanadium(V) and molybdenum(VI) are also extracted, more or less, with MIBK from a hydrochloric acid solution. Of these ions, arsenic, antimony, selenium and germanium do not interfere with the determination of iron, whereas tellurium, vanadium, chromium, molybdenum and tin do cause interference more or less. However, these interferences are reduced or eliminated by reduction (for chromium, chromium(VI) to chromium(III)) or by the measurement of the absorbance at a longer wavelength, where the absorbances due to these elements decrease rapidly, as Fig. 1 shows.

Among the ions which are not extractable, copper(II), uranium(VI) and tungsten(VI) interfere more or less. However, the interference with these ions is not so serious that the presence of 10- (for uranium and tungsten) to 50-fold (for copper) is permissible. Of the cations tested, the interference with vanadium is the most serious.

Sulfate, acetate and phosphate do not interfere, whereas nitrate interferes, especially in its higher concentration, where both the volume of the MIBK extract and the amount of the co-extracted acid become larger; this spoils the experimental conditions.

Summary

A method has been described for the direct spectrophotometric determination of up to 40 μg. of iron(III) with DBM in the organic phase.

An orange complex, which is formed with the addition of DBM and pyridine to the MIBK extract of iron, has a maximum absorbance at 410 mμ. The effect of the diluent on the color reaction has been studied; methanol has been selected as the best diluent of those tried. The color reaction conforms to Beer's law and has a sensitivity of 0.0046 μg. Fe/cm² for $-\log T = 0.001$. The effects of diverse ions on the determination of iron have been studied; it has been found that this method is simple and is sensitive and selective to iron.

The Condensation of Acetonitrile with Formaldehyde

By Yoshiro OGATA, Yasuji IZAWA and Yasuo OSUMI

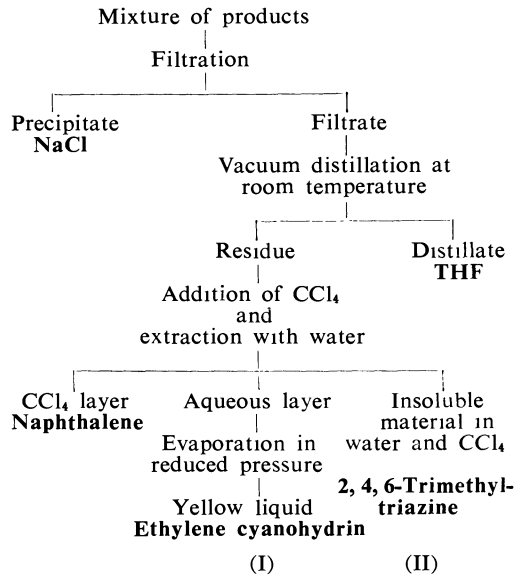
(Received June 3, 1963)

The condensations of nitriles with aldehydes have been reported with both acidic and basic catalysts. Examples of an acid-catalyzed condensation are the formation of methylenebisamides or that of triacyltrihydrotriazines.[1,2] In base-catalyzed condensations, the nitriles with an active methylene group, such as cyanoacetic acid,[3] ethyl cyanoacetate[4,5] and malononitrile[6], can easily be converted to the corresponding α, β-unsaturated nitriles. It has been shown that the reaction of acetonitrile with aldehyde is difficult with ordinary base catalysts, but that it reacts with benzaldehyde or benzophenone, using sodium amide as a catalyst, yielding β-hydroxynitriles, i. e., β-hydroxy-β-diphenylpropionitrile, respectively.[7] However, the aldol-type condensation of acetonitrile with such aliphatic aldehydes as formaldehyde has not yet been reported.

The present paper will describe the aldol-type condensation of acetonitrile with formaldehyde in tetrahydrofurane (THF), using as a base catalyst sodium naphthalene complex, which has been proved to be effective for the alkylation of nitriles with aldehydes.[8] Although the reaction was complicated by side reactions, β-hydroxynitrile (ethylene cyanohydrin) was identified in the reaction product by gas chromatography and spectrography.

$$HCHO + CH_3CN \xrightarrow{Na\cdot C_{10}H_8} \underset{|}{\overset{OH}{HCH}}\text{-}CH_2CN$$

In the reaction product, 2, 4, 6-trimethyltriazine was also detected. A similar reaction using a SiO_2-NaOH catalyst[8a] at 280~300°C was unsuccessful.



Experimental

Materials.—Acetonitrile (first grade) was dried over anhydrous potassium carbonate and fractionally distilled (b. p. 81~82°C). Naphthalene was of the first grade. THF (first grade) was dried over sodium for a few days and distilled over sodium hydroxide in an all-glass apparatus protected from the moisture in the air by a calcium chloride tube (b. p. 66°C).

Preparation of Sodium Acetonitrile.—Sodium acetonitrile was prepared according to the Horner-Güsten method;[8] 5.0 g. (0.2 mol.) of sodium was added to a solution of 25.6 g. (0.21 mol.) of naphthalene in 200 ml. of THF, and the mixture was stirred at room temperature for about 3 hr. in an atmosphere of nitrogen. The solution was then added slowly to a solution of 25.6 ml. (0.2 mol.) of acetonitrile in 100 ml. of THF at −8 and −10°C.

Reaction of Sodium Acetonitrile with Formaldehyde.—Gaseous formaldehyde was preparaed by dropping liquid paraffin slurry, containing 12 g. of paraformaldehyde, into a preheated flask at 115~140°C. The gaseous formaldehyde was bubbled into the THF solution of sodium acetonitrile for one hour at room temperature and then for an additional 0.5 hr. to ensure the completion of the reaction. The resulting yellow and viscous liquid was carefully neutralized with concentrated hydrochloric acid. Instead of gaseous formaldehyde, paraformaldehyde and trioxane could be used, but the yields were poorer (see Table I).

Ehtylene cyanohydrin in the products was isolated according to the following scheme:

Table I. Reaction of acetonitrile with formaldehyde

Aldehyde	Reaction time hr.	Reaction temp. °C	$HOCH_2CH_2CN$ yield, %
Gaseous formaldehyde	2(1)[a]	0~5	6.0
Gaseous formaldehyde	2(1)[a]	15	6.4
Gaseous formaldehyde	2(1)[a]	20	7.7
Paraformaldehyde	2	30	0
Paraformaldehyde	2	50	1.0
Trioxane	2	50	2.8

a) The figures in the parenthesis are the bubbling time (hr.) of gaseous formaldehyde.

Identification of Ethylene Cyanohydrin.—Both infrared spectrography and gas chromatography showed that the main component in the products (I) was identical with an authentic sample of ethylene cyanohydrin, prepared from ethylene chlorohydrin and sodium cyanide. The wave numbers (cm^{-1}) of the characteristic absorption bands of ethylene cyanohydrin and the product sample are as follows: 3400 (ν_{OH}), 2920 (ν_{CH_2}), 2260 (ν_{CN}), 1410 ($\delta_{CH_2(CN)}$), 1060 (ν_{CO})cm^{-1}.[9]

Figure 1 presents the gas chromatography curves on the authentic and resulting ethylene cyanohydrin; these also support our findings.

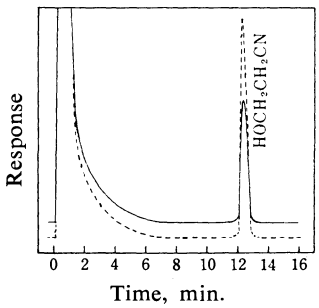

Fig. 1. Gas chromatography curves on ethylene cyanohydrin.
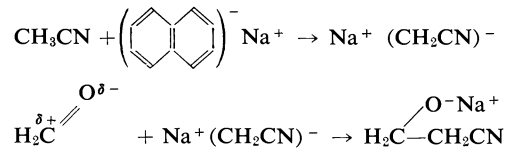
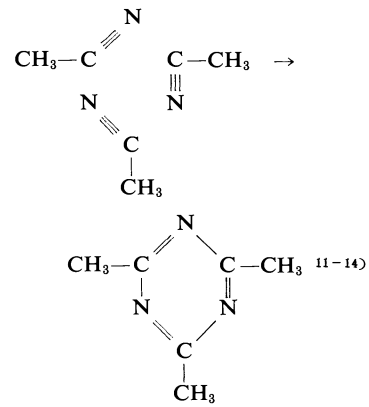
Partition liquid: PEG 4000, 25 wt.%/Celite 545, 80~100 mesh
Column length: 2 m.
Column temp.: 203°C
Carrier gas: He 49 ml./min.
Detection current: 150 mamp.
——: EtOH solution of I
- - -: Addition of pure ethylene cyanohydrin to the above solution.



It was found both by a qualitative test of nitrogen (alkali fusion) and by ultraviolet absorption spectrography that the insoluble material (II) in water and carbon tetrachloride contained 2, 4, 6-trimethyltriazine, since it has the characteristic absorption band at 254 mμ (256 mμ[10]) in ethanol.

The yields on the basis of used acetonitrile, together with the reaction conditions, are presented in Table I.



The yields of ethylene cyanohydrin in these experiments were estimated by gas chromatography. The yields, high (6.0~7.7 %) with gaseous formaldehyde, tended to be lower (1.0~2.8%) with paraformaldehyde and trioxane.

Discussion

The present fiindings show that formaldehyde can be reacted with acetonirile through the aldol-type condensation to form ethylene cyanohydrin. The reaction appeares to proceed by way of the attack of the carbanion of acetonitrile on the carbonyl carbon of formaldehyde.

The above reaction was successful with a strong base catalyst such as sodium naphthalene, but it appears that the reaction does not occur with a weaker base because of the difficulty of forming carbanion. The base-catalyzed polymerizations of acetonitrile may also occur—for instance, the trimerization of acetonitrile:

2, 4, 6-Trimethyltriazine

In fact, we could identify 2, 4, 6-trimethyltriazine.

9) E. F. Dupre, A. C. Armstrong, E. Klein and R. T. O'Conner, *Anal. Chem.*, 27, 1878 (1955).
10) T. L. Cairns, A. V. Larchar and B. C. McKusick, *J. Am. Chem. Soc.*, 74, 5633 (1952).

The poor yield of ethylene cyanohydrin may be due to the formation of such polymers of acetonitrile as cyamethine, *N*-(2, 6-dimethyl-*N*-(2, 6-dimethyl-4-pyrimidyl)-acetamidine, and 2, 4, 6-trimethyltriazine, the hydrolysis of acetonitrile and/or the base-catalyzed condensation of formaldehyde.[10] The other aliphatic aldehydes, e. g., acetaldehyde, are easily subject to aldol condensation by themselves; hence, the reaction with acetonitrile was found to be difficult.

Summary

The condensation of acetonitrile with formaldehyde using sodium naphthalene as a base catalyst has been studied. The results showed that formaldehyde reacted with acetonitrile through the aldol-type condensation to form ethylene cyanohydrin (1.0~7.7%). 2, 4, 6-Trimethyltriazine was detected as one of the by-products.

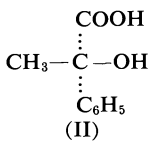
The Anomalous Adsorption of Enantiomers of Mandelic Acid and Atrolactic Acid on the Optically-Active Adsorbent



By Masaaki OHARA, Kosuke OHTA and Takao KWAN

(Received July 1, 1963)

The present paper is concerned with the selective adsorption of enantiomers of mandelic acid (I) and atrolactic acid (II) on a starch column.

(I)

(II)

As has been described in a previous paper,[1] the (−) isomer of mandelic acid is eluted from a starch column earlier than the (+) isomer. A similar selectivity in the adsorption was found with the homologues of mandelic acid except with atrolactic acid (II), where the (+) isomer was eluted earlier than the (−) isomer. The apparently anomalous selectivity in the adsorption of these enantiomers will be discussed here.

Experimental and Results

Racemic mandelic acid or atrolactic acid (0.5 g.) in 50% aqueous methanol was adsorbed at room temperature on a starch column 1.6×60 cm. and chromatographed with the same solvent. The optical rotation of the eluted was measured by a Zeiss-Kreis polarimeter. The concentration of the acid in the fraction was determined by absorption at 257 mμ.

In Fig. 1 the specific rotations of mandelic acid as well as of atrolactic acid are plotted against the fraction numbers. The observed angle of rotation, α, and the concentration of the adsorbates, c, in g. per 100 ml. of an aqueous methanol solution are given for some of the fractions.

As shown in the figure with atrolactic acid the (+) isomer is eluted earlier, while with mandelic acid the (−) isomer is eluted earlier, in accordance with the previous observation.[1] Over 90% of the acids were recovered in either case. Judging from the reversal order of the elution of the enantiomers of mandelic acid

TABLE I. THE ELUTION OF SEVERAL HOMOLOGUES OF MANDELIC ACID ON A STARCH COLUMN (15~18°C)

Racemate	The sign of the isomer eluted earlier	The sign of the isomer eluted later
Mandelic acid	(−)	(+)
Atrolactic acid	(+)	(−)
Methyl mandelate	(−)	(+)
Acetyl mandelic acid	(+)	(−)
β-Phenyl lactic acid	(+)	(−)
Tropic acid	(−)	(+)

1) M. Ohara, I. Fujita and T. Kwan, This Bulletin, 35, 2049 (1962).

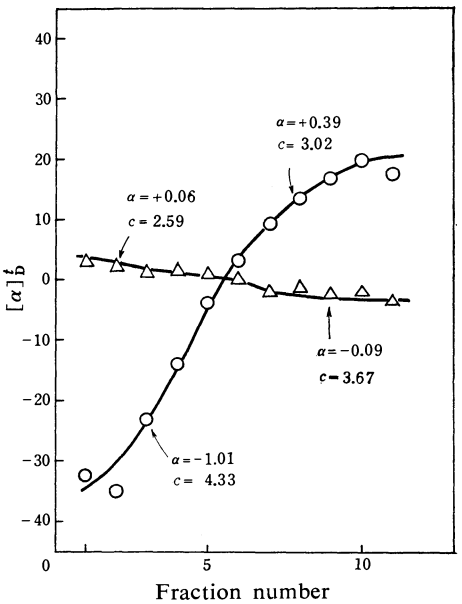


Fig. 1. The specific rotation $[\alpha]_D^t$ of mandelic acid and atrolactic acid against fraction numbers (t, 15~18°C).
○ Mandelic acid
△ Atrolactic acid

and atrolactic acid, it can be considered that the adsorption affinity of mandelic acid and that of atrolactic acid are reversed with respect to their enantiomers.

(+) mandelic acid > (−) mandelic acid

(+) atrolactic acid < (−) atrolactic acid

Several homologues of mandelic acid were investigated in a similar manner. The order of appearance is shown in Table I.

Optical isomers with the same sign can not always be assigned to the same configuration. In Table I it may be seen that atrolactic acid, acetyl mandelic acid and β-phenyl lactic acid are different with respect to the sign of the isomer eluted earlier. The literature shows, however, that the (+) isomers of the latter two have the same configuration as the (−) isomer of mandelic acid.[2,3] On the other hand, optical isomers of mandelic acid and atrolactic acid with the same sign have generally been assigned to the same configuration.[3-6] Therefore, the fact that the (+) isomer of atrolactic acid is eluted earlier may be considered peculiar with regard to the relative adsorption affinity of enantiomers or may raise some question of the configurational interaction between the adsorbate molecule and the surface of starch.

Discussion

The configurational relation of the enantiomers of mandelic acid and its homologues has been established so far by the chemically correlative method. For instance, Brewster[5] clarified the configurational correlation of mandelic acid with atrolactic acid by means of a diastereoisomer, i. e., *threo*-1, 2 diphenyl propanediol. Support for this conclusion was provideded by Cram and his co-workers[6] through a similar stereochemical course. The physical method was also applied in determining the configurational relationship; the change in the molecular rotation of several of their derivatives were investigated,[3] leading to results consistent with the chemical method. Another physical method, the quasi-racemate one, was also tried, but it was found ineffective.[7]

On the other hand, the so-called adsorption affinity method has sometimes been proposed; in this method the adsorbability of one optical isomer in preference to its enantiomer was investigated on a certain optically-active adsorbent. For instance, it was adopted by Beckett and his co-workers[8] in such systems as quinine-quinidine or cinchonine-cinchonidine adsorbed on quinine-pretreated silica gel. They were successful in correlating the configuration of the adsorbent to the strongly-adsorbed epimers. In this case, the adsorbent molecule is similar to the adsorbate molecule in size. Thus the method may resemble the quasi-racemate method.[7]

In contrast, in cases where adsorbents are macromolecules, the adsorption affinity may be conceptually included in the biological method in view of the specificity-like enzyme action. An investigation of the adsorbed configuration of enantiomers along such lines may be found the work of Balandin and his co-workers.[9]

Now, the observed reversal order of elution with mandelic acid and atrolactic acid seems to be incosistent with their *established* configurational correlations; one has to seek an interpretation of the *anomalous* selectivity in the relative configuration of the adsorbate-adsorbent complex. On the other hand, if we assume that the substitution of H for CH_3 with mandelic acid has little effect on the

adsorption on starch, then the *established* relation between the sign and the configuration with enantiomers of mandelic acid and atrolactic acid will be false.

Two tentative explanations to this anomaly have been proposed. One is that the true configurational relationship of enantiomers is a reverse one, being consistent with the order of adsorption affinity. Another is associated with the structure-sensitive properties of starch.

When the above-mentioned configuration relationship is admitted as having been established, the relationship between the adsorption affinity and the configuration of the enantiomers is reversed.

In the latter explanation, when a three-point adsorption model, as was mentioned by, for instance, Ogston,[10] is adopted and when the common functional groups (-OH, -COOH, and $-C_6H_5$) are responsible to the adsorption force, it is impossible to expect the reversal effect in the adsorption of the enantiomers of mandelic acid and atrolactic acid. Perhaps a kind of multiple interaction would have to be assumed between the adsorbate and the surface of the starch.

At present it is difficult to determine what kind of interaction is responsible for the specific adsorption of mandelic acid and atrolactic acid.

The Rheological Properties of Concentrated Suspensions. III. Dynamic Properties and Their Correlations with Stationary Flow Properties

By Masaharu TAKANO

(Received August 9, 1963)

In a previous paper[1] the construction and principles of a versatile rheometer have been described. The dynamic properties of concentrated suspensions at lower frequencies and stationary flow properties at very low rates of shear may be measured with this apparatus. Preliminary investigations of the dynamic properties of concentrated suspensions have been reported on in another previous paper.[2]

It is the purpose of the present paper to examine the concentration dependence of dynamic properties and their correlations with stationary flow properties and to prove the validity of theoretical considerations based on a network model.[3]

Experimental

Materials.—The fillers used in this work were barium sulfate of a chemical grade and barium sulfate coated with sodium stearate; both of these have very narrow size distributions. The mediums used were linseed oil and polyisobutylene whose number average molecular weight is 858. The characteristics of the materials are listed in Table I.

The Preparation of Suspensions.—The filler was dried at 110°C in a vacuum of 20 mmHg for three hours prior to the preparation of suspensions. Suspensions were prepared by ten "tight" passes of the mixed components through a three-roll paint mill, with a roll 5 cm. in diameter, 10 cm. long and with revolution velocities of 18, 60 and 170.5 r.p.m. The additive was adsorbed to the filler before the preparation of suspensions. Suspensions prepared in such a manner were kept at 30°C for six days before being measured.

Apparatus and Methods.—The apparatus used in this work has been described in detail in a previous paper.[1] The apparatus can be used as a rotational viscometer and as an oscillatory viscoelastometer under the same geometrical conditions. For this work, stationary flow properties at very low rates of shear and dynamic properties at lower frequencies (below 1 c.p.s.) were measured.

In simple shear experiments, the shearing stress, S, and the apparent rate of shear, $\dot{\gamma}$, at the surface of the inner cylinder were given as follows:

$$S=T/2\pi R_i^2 L=k\theta/2\pi R_i^2 L \quad (1)$$

$$\dot{\gamma}=2\omega/\{1-(R_i/R_o)^2\} \quad (2)$$

3) M. Takano, This Bulletin, to be published.

TABLE I. CHARACTERISTICS OF MATERIALS

Material	Viscosity* at 30°C poises	Density at 30°C g./cm³	Particle size μ $(\bar{R})$	$(\bar{R^2})^{1/2}$	$(\bar{R^3})^{1/3}$
Barium sulfate	—	4.50	0.075	0.079	0.082
Linseed oil	59.3	0.960	—	—	—
Polyisobutylene	154.0	0.883	—	—	—

* Measured by a capillary viscometer.

TABLE II. EXPERIMENTAL CONDITIONS

Radius of outer cylinder	R_o	1.400 cm.	
Radius of inner cylinder	R_i	1.250 cm.,	1.000 cm.
Depth of outer cylinder		8.365 cm.	
Length of inner cylinder	L	5.000 cm.,	4.000 cm.
Maximum angular deflection of inner cylinder	θ_o	below 4 degrees	
Region of frequency	ν	from 0 to 1 c. p. s.	
Torsional constant	k	from 0 to 8.55×10^3 dyn.-cm./deg.	
Amplitude of shear strain (at wall of inner cylinder)	γ_{max}	below 0.685,	below 0.285
Amplitude of shear stress (at wall of inner cylinder)	S_{max}	below 11.7 dyn./cm²,	below 55.0 dyn./cm²
Range of revolution velocity of outer cylinder		from 0 to 400 r. p. m.	

where R_i and R_o are the radii of the inner and outer cylinders respectively; L is the length of the inner cylinder; T, the torque; k, the torsional constant of the inner cylinder; θ, the angular deflection of the inner cylinder, and ω, the angular velocity of the outer cylinder.

In dynamic measurements, the basic equation of the motion of the inner oscillatory unit is:[1,4,5]

$$(M+m+C)\mathrm{d}^2\theta/\mathrm{d}t^2+\{(\eta'/A)+B\}\mathrm{d}\theta/\mathrm{d}t+(G'/A)\theta=T \quad (3)$$

$$T=Ki_d-k\theta \quad (4)$$

where M, C, B and K are the instrument constants; m is the moment of inertia of the sample; A the shape factor; i_d, the current through a torque motor which gives torque to the inner cylinder, and η' and G' are the dynamic viscosity and the dynamic modulus of the sample respectively. When the moment of inertia of sample m is negligibly small compared to $(M+C)$ and the current, i_d, changes sinusoidally, the dynamic viscosity and the dynamic modulus are given by the following equations:[1,4,5]

$$\eta'=A[\{K'(f_{d_0}/f_{\theta_0})\sin d\}/\omega-B] \quad (5)$$

$$G'=A[K'(f_{d_0}/f_{\theta_0})\cos d-k+(M+C)\omega^2] \quad (6)$$

where f_{d_0} and f_{θ_0} are the amplitudes of the recorded curves of the current, i_d, and of the deflection, θ, respectively; K' is the instrument constant, and d, the phase lag between the current and the deflection.

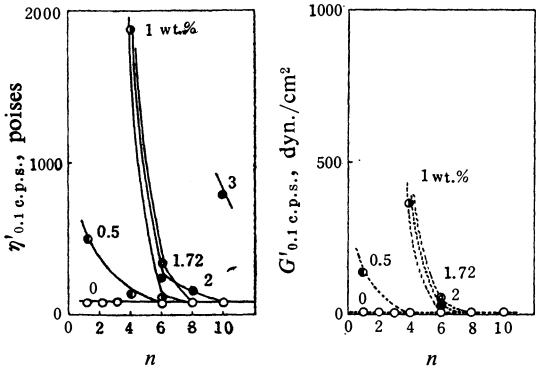
The shape factor A and the phase lag d are given as follows:

$$A=(1/4\pi L)\{(1/R_i)^2-(1/R_o)^2\} \quad (7)$$

$$d=\cos^{-1}\{f^2_{\theta_0}+f^2_{d_0}-f^2_{s_0})/2f_{\theta_0}f_{d_0}\} \quad (8)$$

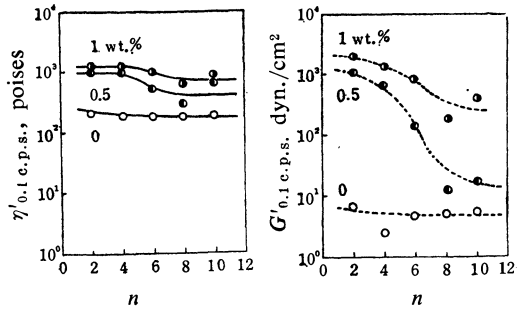
where f_{s_0} is the amplitude of recorded curve of difference between the current and the deflection.[1]

The dimensions of the assemblies of coaxial cylinders and the experimental conditions are listed in Table II. The temperature was maintained at 30 ± 0.2°C during measurements. For Newtonian liquids, the dynamic experiments and the simple shear measurements were made within a range of error of $\pm10\%$.



Experimental Results and Discussion

The Influence of the Conditions of Mixing and Resting.—The rheological behavior of a disperse system is closely related to the state of the flocculation of its particles and is influenced by the conditions of preparation and resting.



For the study of the influence of mixing conditions, a small quantity of suspension was taken out after each pass through the mill and examined rheometrically. Figure 1 shows the relation between the dynamic properties of suspensions of barium sulfate in linseed oil and in polyisobutylene, with and without water added, and the number of passes through the mill.

In suspensions of barium sulfate in linseed oil with water added, the higher dynamic viscosity and dynamic modulus observed at the earlier stages of milling decrease rapidly with milling to limiting values which are almost independent of the amount of water. Without

Concentration dependence of the dynamic properties: ○, barium sulfate in polyisobutylene, at 0.02 c.p.s. ◐, barium sulfate in polyisobutylene, with 0.5 wt. % water added, at 0.02 c.p.s. ◑, barium sulfate in polyisobutylene, with 1.0 wt. % water added, at 0.02 c.p.s. ◎, barium sulfate in linseed oil, with or without water added, at 0.20 c.p.s.

Data for suspensions which have been passed ten times through the mill and rested for three hours will be compared below.

The Concentration Dependence and Frequency Dependence of Dynamic Properties. — The dynamic viscosity and the dynamic modulus of suspensions are shown in Figs. 3 and 4 as functions of the frequency and of the concentration. Stationary flow curves of suspensions in polyisobutylene at various concentrations are illustrated in Fig. 5.

The linseed oil and polyisobutylene used in this work are viscoelastic by themselves. In a previous paper[3] it has been pointed out theoretically that the dynamic properties of concentrated suspensions are given approximately by the sum of the viscoelasticities of the medium and network-structures formed by suspended particles.

Assuming a suspension as a Maxwell body, we can get the apparent relaxation time, τ_a, from the following equation:

$$1/\eta'_s(\omega) = 1/\eta'_s(0) + (\tau_a^2/\eta'_s(0))\omega^2 \quad (9)$$

where $\eta'_s(\omega)$ is the dynamic viscosity of the suspension at the angular frequency ω. Figure 6 shows the relation of $1/\eta'_s(\omega)$ to ω^2 for suspensions of barium sulfate in linseed oil. The apparent relaxation times obtained experimentally for various suspensions are listed in Table III. The apparent relaxation time generally increases with an increase in the concentration, as is shown in Fig. 7. In linseed oil, the apparent relaxation time of the suspension shows a slight change with the concentration. In polyisobutylene, on the other hand, the apparent relaxation time increases abruptly above a critical concentration, at which a network structure is formed by the particles in the medium.

The concentration dependence of dynamic properties at a given frequency is shown in Fig. 8 and in Table IV. In polyisobutylene, the dynamic viscosity and dynamic modulus of a suspension increase abruptly above a critical concentration. The mean free energy of the activation for breaking links between particles, ΔF, and the mean number of links to be broken for the separation of two neighboring particles, σ', can be evaluated from the critical concentration ϕ'_{crit}.[3,6] In suspensions of barium sulfate in polyisobutylene, the energy of interaction, ΔF, has the order of $33 \sim 34\,kT$, while the mean number of links,

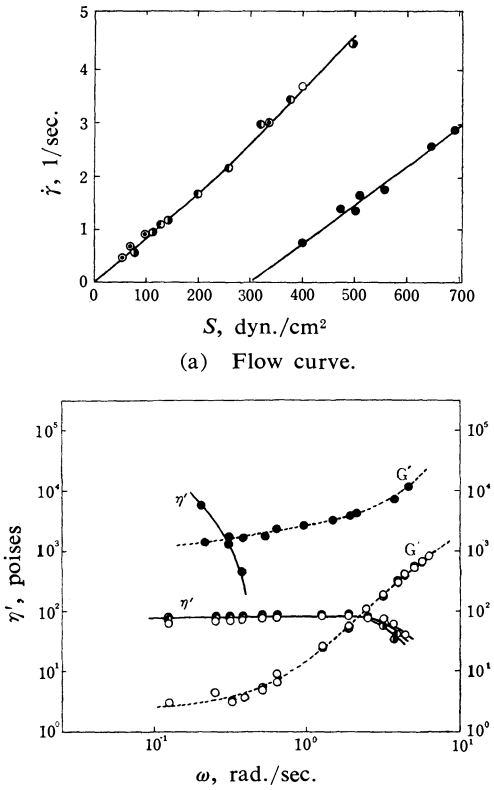
TABLE V. CRITICAL CONCENTRATION AND THE INTERACTION PARAMETERS IN SUSPENSIONS OF BARIUM SULFATE IN POLYISOBUTYLENE (30°C)

Concn. of water (wt. % based on barium sulfate)	0	0.5	1.0
ϕ'_{crit} in η' (vol. %)	2.0	0.8	0.8
ϕ'_{crit} in G' (vol. %)	2.0	1.2	1.2
$\Delta F/kT$ in η' ($\sigma'=1$)	33.3	34.2	34.2
$\Delta F/kT$ in G' ($\sigma'=1$)	33.3	33.3	33.8
σ' in η'	1.49_1	1.49_2	1.49_2
σ' in G'	1.49_1	1.49_2	1.49_2
$\Delta F/kT$ in η' ($\sigma'=1.49$)	32.9	33.8	33.8
$\Delta F/kT$ in G' ($\sigma'=1.49$)	32.9	33.4	33.4

σ', is 1.49, as Table V shows. These values coincide well with those evaluated from the stationary flow properties.[6] In suspensions of barium sulfate in linseed oil, the concentration dependence of the dynamic viscosity and the dynamic modulus are given by the following equations (at 0.20 c.p.s.):

$$\eta'_s(0.20) = \eta'_m(0.20)\exp(5.53\,\phi) \qquad (10)$$



$$G'_s(0.20) = G'_m(0.20)\exp(3.92\,\phi) \qquad (11)$$

where $\eta'_m(0.20)$ and $G'_m(0.20)$ are the dynamic viscosity and the dynamic modulus of an unfilled medium at 0.20 c.p.s. respectively, and where ϕ is the volume fraction of the filler. The increase in the apparent relaxation time with the concentration can be explained qualitatively by the difference in the concentration dependences between the dynamic viscosity and the dynamic modulus.

The Influence of Additions of Water and Sodium Stearate on the Dynamic Properties.— Dynamic properties also change upon the addition of additives which have an influence on the energy of interaction between particles, as is shown in Tables III, IV and V.

In relatively polar linseed oil, the dynamic viscosity and dynamic modulus of a concentrated suspension with water added increase in the earlier stages of milling, as is shown in Fig. 1. However, it is shown in Figs. 1, 8, 9 and Table IV that the dynamic properties decrease to limiting values upon milling, that these properties are slightly influenced by the amount of water, and that they are increased by coating particles with sodium stearate. The apparent relaxation time is also slightly influenced by the addition of water, as is illustrated in Table III.

In non-polar polyisobutylene, the dynamic viscosity and dynamic modulus of a concentrated suspension are increased by the addition of water independently of milling, as is shown in Figs. 1, 8, 10 and Table IV. The apparent relaxation time at lower concentrations also increases upon the addition of water, as Fig. 7 and Table III show. The critical concentration above which the dynamic properties increase appreciably is lowered, and the energy of interaction between particles, is increased by the addition of water, as is shown

in Fig. 8 and Table V. The dynamic viscosity and dynamic modulus are decreased by coating particles with sodium stearate.

The change in the dynamic properties by additives must be attributed to the influence of the additive on the interactions between particles: van der Waals-London attractions,[7,8] capillary forces due to interfacial tension between additive and medium,[9-11] the repulsion of two electric double layers,[12] the entropic repulsion of adsorbed molecules of the medium on the surfaces of particles,[8,13] contractive forces arising from the elastic property of a medium when the medium is viscoelastic by itself,[14] and others. The diffusion of water into the polar medium must also be taken into account.

In the present experiments, it seems that capillary forces originating from the presence of water do not have a decisive effect on the interaction between particles at a stationary state of dispersion. The interfacial tension between water and linseed oil is larger than that between water and polyisobutylene, as shown in Table VI. Besides, it seems that water is adsorbed on the surfaces of particles

TABLE VI. INTERFACIAL TENSION (26.3°C)

Interface	Interfacial tension* dyn./cm.
Water-Air	71.2

Polyisobutylene-Water	39.5

* Measured by Du Noüy's surface tension meter.

without diffusion into the medium. If water adheres to the surfaces of particles, contractive forces originating from the viscoelastic properties of the medium may be decreased by the addition of water. In a previous paper,[3] the following equation has been derived for the frequency dependence of the dynamic viscosity:

$$1/\{\eta'_s(\omega)-\eta'_m(\omega)\}=a+b\omega^2 \qquad (12)$$

where

$$a=\lambda_2^2\pi R_1/\boldsymbol{h}\exp(\Delta F/\boldsymbol{k}T)\,\sigma'(\phi-\phi'_{crit}) \qquad (13)$$

$$b=\boldsymbol{h}\pi R_1\exp(\Delta F/\boldsymbol{k}T)/4g_2^2\lambda_2^2\sigma'(\phi-\phi'_{crit}) \qquad (14)$$

In Eqs. 13 and 14, $\boldsymbol{h}$ and $\boldsymbol{k}$ are the constants of Planck and Boltzmann respectively; R_1 is the diameter of particles; λ_2, the distance by which particle moves whenever the secondary links between particles are broken reversibly; T, the absolute temperature; ΔF, the mean free energy of activation for breaking the links between particles; g_2, the mean stiffness of the secondary links, and σ', the mean number of links to be broken for separating two particles at very small deformations. If there are no

contractive forces arising from the viscoelastic property of the medium, the values of a and b must be effectively independent of the frequency. Figure 11 shows the relation of $1/\{\eta'_s(\omega)-\eta'_m(\omega)\}$ to ω^2. However, it has been assumed that the dynamic viscosity of a medium involving particles at the volume fraction ϕ is given by the following equation:[15]

$$\eta'_m(\omega)=\eta'_{mo}(\omega)(1+2.5\phi+7.17\phi^2+16.2\phi^3)$$

where $\eta'_{mo}(\omega)$ is the dynamic viscosity of an unfilled medium. The dependence of b on the frequency apparently decreases on the addition of water. Such a tendency is observed both in polar and in non-polar media.

The magnitude of the van der Waals-London attraction between two spherical particles can be approximately evaluated as in a previous paper.[6] The change in dynamic properties by additives can be explained at least qualitatively by considering van der Waals-London attractions between particles.[6] However, other forces must also be taken into account, particularly such forces as the contractive forces of the medium. In a polar medium, the repulsion of two electric double layers may have an influence on the interaction between particles. In a medium with a high molecular weight, the entropic repulsion of adsorbed macromolecules may be considered between particles.

The Correlation between Dynamic Properties and Stationary Flow Properties. — In unfilled media and pseudo-plastic suspensions, the apparent viscosity at lower rates of shear coincides with the dynamic viscosity at lower frequencies. In plastic suspensions, however, the former does not generally coincide with the latter.

In plastic suspensions, the apparent viscosity at lower rates of shear may be higher or lower than the dynamic viscosity at lower frequencies when they are compared with each other on the same time scale. Figures 12 and 13 show the shear-rate dependence of the apparent viscosity, along with the frequency dependence of dynamic viscosity and dynamic modulus. In a series of suspensions of barium sulfate in polyisobutylene, the apparent viscosity in simple shear experiments is lower than the dynamic viscosity on the same time scale. Such a tendency is observed independently of the presence of water. In suspensions of barium sulfate in linseed oil, with a large quantity of water added, the apparent viscosity is higher than the dynamic viscosity on the same time scale.

These correlations between the apparent viscosity and the dynamic viscosity are at least qualitatively explained by the network model described in the previous paper.[3] The dynamic viscosity at very small deformations, $\eta'_s(\omega)$, and the apparent viscosity, η_a, are given by the following equations:

$$\eta'_s(\omega)=\eta'_m(\omega)+(2/\pi R_1)g_2\{\tau_2/(1+\tau^2{}_2\omega^2)\}\sigma'(\phi-\phi'_{crit}) \quad (15)$$

$$\eta_a=S/\dot{\gamma}=\eta_{pl}+S_o/\dot{\gamma} \quad (16)$$

where η_{pl} and S_o are given as follows:

$$\eta_{pl}=\eta_m+(R_1^2/3)(g_1+g_2)\tau_2\{(6/\pi R_1^3)+(3\eta\dot{\gamma}/kT\pi\phi_c)\}\sigma(\phi-\phi_{crit}) \quad (17)$$

$$S_o=(R_1^2/3)g_1\gamma_1\{(6/\pi R_1^3)$$

15) V. Vand, *J. Phys. and Colloid Chem.*, 52, 277, 300 (1949).

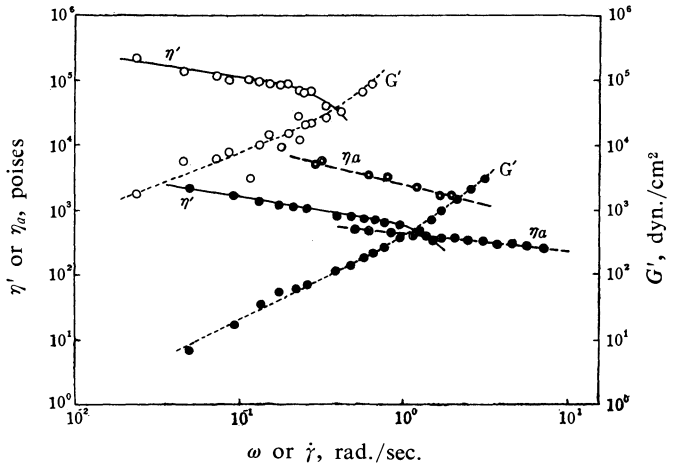

Fig. 13. Correlation between the dynamic properties and the apparent viscosity in suspensions of barium sulfate in polyisobutylene: ●◉, 10 wt. % suspension with 1.0 wt. % water added (yield value, 130 dyn./cm²); ○◎, 30 wt. % suspension with 1.0 wt. % water added (yield value, 1500 dyn./cm²).

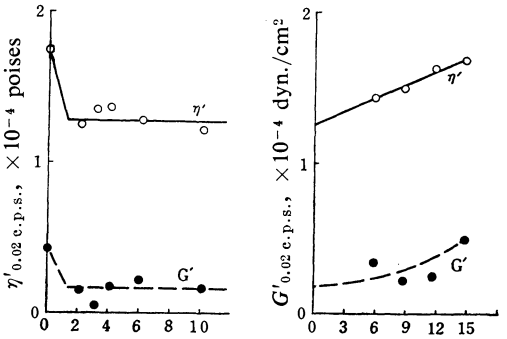
$$+(3\eta\dot{\gamma}/\boldsymbol{kT}\pi\phi_c)\}\sigma(\phi-\phi_{crit}) \qquad (18)$$



where g_1 is the mean stiffness of the primary links; τ_2, the relaxation time of the secondary links; γ_1, the mean strain of the primary links in the stationary flow; ϕ_c, the mean fraction of the volume occupied by particles in a multiple flocculate, and σ and ϕ_{crit} are the mean number of links to be broken for separating two particles and the critical concentration above which stationary links between particles would appear respectively at the shear-rate of $\dot{\gamma}$.[3] Equations 17 and 18 can be approximated by the following equations at very low rates of shear;[3]

$$\eta_{pl}=\eta_m+(g_1+g_2)\tau_2(2/\pi R_1)\sigma'(\phi-\phi'_{crit}) \qquad (17')$$

$$S_o=(2/\pi R_1)g_1\gamma_1\sigma'(\phi-\phi'_{crit}) \qquad (18')$$

In pseudo-plastic suspensions, the apparent viscosity at a zero rate of shear must be equal to the dynamic viscosity at zero frequency because, in Eqs. 17′ and 18′, γ_1 and g_1 are effectively zero and $\eta'_m(0)$ is generally equal to η_m.

In plastic suspensions, the apparent viscosity must be infinite at a zero rate of shear if a remarkable change in the structure of the network is not effected by shearing forces, whereas the dynamic viscosity has a finite value on the same time scale. Such a case is encountered in suspensions of barium sulfate in linseed oil, with a large quantity of water added. However, if the network is broken appreciably by shearing forces, the apparent viscosity may occasionally be lower than the dynamic viscosity at a finite rate of shear, as in suspensions of barium sulfate in polyisobutylene, since in Eqs. 17 and 18 σ is decreased and ϕ_{crit} is increased by shearing forces.[3] Figure 14 shows the fall of dynamic properties by shearing actions and their restoration by resting the solution in a 20 wt. % suspension of barium sulfate in polyisobutylene. The abscissas represent the number of repeated revolutions at a given rate of shear (3.78 sec^{-1}) and the resting time after 30 revolutions. In this system, it seems that the network is easily broken down by shearing actions and that it takes at least fifteen minutes for the restoration of the broken network-structure. The discrepancy between the apparent viscosity and the dynamic viscosity at lower rates of shear seems to be related to the sensitivity of the network structure to shearing forces and

(a) Structure break down with shearing actions ($\dot{\gamma}=3.78$ sec^{-1}).

(b) Structure restoration after 30 revolutions.

Fig. 14. Change in the dynamic properties with shearing conditions in 20 wt. % suspension of barium sulfate in polyisobutylene.

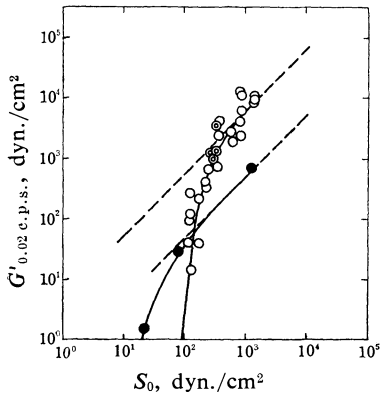


Fig. 15. Correlation between the dynamic modulus and the yield value: ○, suspensions of barium sulfate in polyisobutylene; ●, suspensions of barium sulfate in linseed oil, with water added; ◎, suspensions of barium sulfate coated by sodium stearate in linseed oil.

to the time necessary for the restoration of broken structures. Besides, it is likely that the discrepancy between viscosities is independent of the magnitude of yield value in stationary flow experiments, as is shown in Figs. 12 and 13.

The correlation of the dynamic modulus at a frequency of 0.02 c. p. s. and the yield value obtained by extrapolation to zero shear-rate in stationary flow experiments are shown in Fig. 15. The dynamic modulus apparently increases with an increase in the yield value.

According to theoretical considerations based on a network model,[3] the dynamic modulus, $G'_s(\omega)$, is given by the following equation at very small deformations:

$$G'_s(\omega) = G'_m(\omega) + (2/\pi R_1)\{g_1 + g_2\tau_2^2\omega^2/(1+\tau_2^2\omega^2)\}\sigma'(\phi - \phi'_{crit}) \quad (19)$$

where $G'_m(\omega)$ is the dynamic modulus of a medium involving particles. If the dynamic modulus of the medium is negligibly small compared to that of the network structure formed by particles at lower frequencies and if the network is not changed by shearing forces, the dynamic modulus at lower frequencies must be approximately proportional to the yield value given by Eq. 18′ at very low rates of shear. Consequently, the slope in Fig. 15 must be approximately equal to unity. In the experimental results, the slope seems to approach unity only at higher concentrations, where stronger network structures may be formed by particles. The deviation from the theoretical prediction at lower concentrations seems to be connected with the amplitude dependence of the dynamic modulus. If the network structure is sensitive to shearing forces, it is likely that the network is broken down irreversibly at lower concentrations and that the dynamic modulus decreases with an increase in the amplitude of oscillation, since measurements are made with a constant amplitude of the activating current, i_{d_0}.

In suspensions of barium sulfate in polyisobutylene, the time dependence of the apparent viscosity resembles that of the dynamic viscosity, as is shown in Fig. 13. However, it is dangerous to attribute two behaviors to the same mechanism. As has been described in a previous paper,[3] the dependence of the apparent viscosity on the rate of shear is connected with the structural changes of the network caused by shearing forces, whereas the frequency dependence of the dynamic viscosity originates mainly from the relaxation of the network structures formed by particles in the medium. For the elucidation of the correlation between the dynamic properties and stationary flow properties of concentrated suspensions, further investigation of the amplitude dependence of rheological properties is necessary.

The Amplitude Dependence of Dynamic Properties.—In unfilled media and non-flocculated systems, the dynamic properties fall well within the linear viscoelasticity at smaller amplitudes of oscillation.

In flocculated systems, however, the dynamic viscosity and the dynamic modulus inevitably decrease with an increase in the amplitude of oscillation.[16-18] Figure 16 shows the amplitude dependence of the dynamic properties in a 10 wt. % suspension of barium sulfate in polyisobutylene, with 0.5 wt. % water added. In Fig.

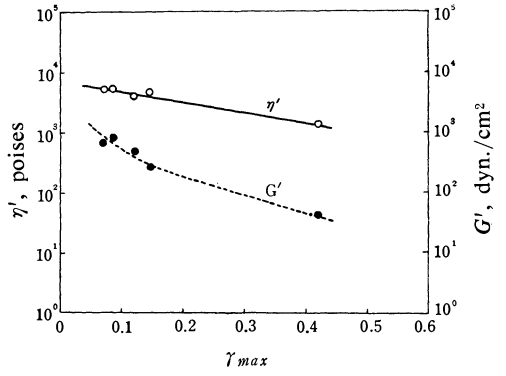

Fig. 16. Amplitude dependence of the dynamic properties in a 10 wt. % suspension of barium sulfate in polyisobutylene, with 0.5 wt. % water added, at 0.02 c.p.s.

18) A. R. Payne, *J. Appl. Polymer Sci.*, **3**, 127 (1960).

16, the maximum shear strain at the wall of the inner cylinder, γ_{max}, is calculated as follows:[19]

$$\gamma_{max,\, r=R_i} = 2\theta_o R_o^2/(R_o^2 - R_i^2) \qquad (20)$$

The amplitude dependence of the dynamic modulus is more remarkable than that of the dynamic viscosity. The amplitude dependence of the dynamic properties in flocculated systems is caused by the structural change in the network formed by particles and by the non-linearly elastic nature of the links between particles. In a previous paper,[3] it has been theoretically pointed out that the dependence of the dynamic viscosity on amplitude mainly originates from the structural change in the network, while that of the dynamic modulus originates from both the structural change and the non-linearly elastic nature of the links between particles. According to theoretical considerations based on a network model,[3] we obtain the following approximation at lower frequencies:

$$\{G'_s(\omega) - G'_m(\omega)\}_{\dot{\gamma},f}/\{G'_s(\omega) - G'_m(\omega)\}_{\dot{\gamma},f\fallingdotseq 0} \fallingdotseq \{(g_1)_{\dot{\gamma},f}/(g_1)_{\dot{\gamma},f\fallingdotseq 0}\}\{\eta'_s(\omega) - \eta'_m(\omega)\}_{\dot{\gamma},f}/\{\eta'_s(\omega) - \eta'_m(\omega)\}_{\dot{\gamma},f\fallingdotseq 0} \qquad (21)$$

where the subscripts s and m represent the values of the suspension and the medium respectively, and $\dot{\gamma}$ and f represent the experimental conditions of the rate of shear and the shearing forces. In flocculated systems, since $G'_m(\omega)$ and $\eta'_m(\omega)$ may be negligibly small compared to $G'_s(\omega)$ and $\eta'_s(\omega)$, we have, approximately:

$$\{G'_s(\omega)\}_{\dot{\gamma},f}/\{G'_s(\omega)\}_{\dot{\gamma},f\fallingdotseq 0} \fallingdotseq \{(g_1)_{\dot{\gamma},f}/(g_1)_{\dot{\gamma},f\fallingdotseq 0}\}\{\eta'_s(\omega)\}_{\dot{\gamma},f}/\{\eta'_s(\omega)\}_{\dot{\gamma},f\fallingdotseq 0} \qquad (22)$$

Consequently, the difference between the amplitude dependences of dynamic properties, as shown in Fig. 16, may be regarded as a measure of the non-linearity of the elastic nature of the links between particles.

The experimental data given in this paper were obtained with a given amplitude of torque acting on the inner cylinder. The amplitude of the deflection of the inner cylinder was consequently decreased with an increase in the frequency. As a result of these features in dynamic properties and dynamic experiments, the apparent relaxation time of suspensions may be slightly shorter than those evaluated in the present experiments. Dynamic properties were measured with as small an amplitude as possible.

Summary

The dynamic properties and stationary flow properties of suspensions of barium sulfate in polyisobutylene and in linseed oil have been measured by the use of an electrically-recording rotational rheometer.

The concentration dependence, the influence of mixing conditions, the effects of the addition of water and of sodium stearate on the dynamic viscosity and the dynamic modulus, and the correlation of the dynamic properties with stationary flow properties have been examined experimentally.

In suspensions of barium sulfate in linseed oil, the dynamic viscosity and dynamic modulus increase monotonously with an increasing concentration, and no critical concentration is observed up to the highest concentration. The apparent relaxation time shows a slight increase with an increase in the concentration of particles.

In suspensions of barium sulfate in polyisobutylene, the dynamic viscosity and dynamic modulus increase abruptly above a critical concentration. The apparent relaxation time also increases remarkably above the critical concentration. The mean free energy of the activation for breaking links between particles and the mean number of links to be broken for the separation of two neighboring particles have been evaluated as 33~34 kT and 1.49 respectively.

The influence of additives on dynamic properties resembles that on stationary flow properties and can be explained qualitatively by assuming a van der Waals-London attraction between particles. However, in a viscoelastic medium, contractive forces arising from the elastic property of the medium seems to be altered by the addition of additives.

For pseudo-plastic systems, the dynamic viscosity coincides with the apparent viscosity at lower frequencies. However, for plastic systems, the apparent viscosity may be higher or lower than the dynamic viscosity at lower frequencies, depending on the sensitivity of the network structures formed by particles and on the time necessary for the restoration of broken structures. The dynamic modulus at lower frequencies increases with an increase in the yield value, while the former increases proportionally to the latter at higher concentrations also.

The non-linearity of dynamic properties has been observed as a feature of their amplitude dependence. The change in the dynamic modulus is more remarkable than that in the dynamic viscosity.

The experimental results described above at least qualitatively agree with the theoretical predictions based on a network model.

The author wishes to express his cordial thanks to Professor Hirotaro Kambe for his invaluable advice and the encouragement extended to the author. Thanks are also due to the author's colleagues in the Aeronautical Research Institute, the University of Tokyo, for their stimulating discussions.

The Rheological Properties of Concentrated Suspensions. IV. The Viscoelastic Properties of Concentrated Dispersions in Molten Polymers

By Masaharu TAKANO and Hirotaro KAMBE

(Received August 9, 1963)

The effects of fillers on the equilibrium modulus of solid polymers and on the viscosity of molten polymers have been studied extensively.[1-4] The viscoelastic properties of filled polymers have also been much investigated.[5-7] However, these investigations have mainly been concerned with properties in the transition region from flexible to glasslike consistency and have not attempted to extend the experiment to the molten state. Very little work has been done on the viscoelastic properties of filled molten polymers.

In the transition region, it has been observed experimentally that if particles are dispersed homogeneously and too apart from each other to be bridged by single polymer molecules, the relaxation spectrum of the polymer is essentially unaffected by the filler on the high frequency side, although it is broadened on the lower frequency side because of the suppression of the molecular motion of the polymer by dispersed particles.[6-8] In suspensions of finer particles, however, the aggregation of the particles may also complicate circumstances. In such a case, when particles approach each other, each particle may be bonded to others by single polymer molecules and the whole system may act as a highly crosslinked polymer.[3,8,9] Furthermore, additional forces, e. g., van der Waals-London attraction, should also be considered between particles. It is evident that the concentration dependence of dynamic properties cannot be described in terms of the volume-filling properties alone in concentrated dispersions of fine particles.[4,8,10]

It is the purpose of this paper to examine experimentally the dependence of the dynamic properties of concentrated dispersions in the molten polymer on the concentration, the particle size and the amplitude of oscillations.

We have studied the dynamic viscosity and the dynamic modulus of disperse systems containing fillers of various particle sizes. In order to eliminate complex chemical crosslinking, we chose an uncrosslinked polyethylene containing non-interacting fillers, that is, small glass spheres, barium sulfate powder and calcium carbonate powder.

Experimental

Materials.—The medium used in this work is a melt of a low density polyethylene, "Sumikathene F-70-6," whose number average molecular weight is 28000, with a melt index of 7, a melting temperature of 109~112°C, and a density of 0.921 g./cm^3 at 23°C.

The fillers used in this work are two kinds of barium sulfate, two kinds of calcium carbonate,

and four kinds of glass spheres with various particle sizes. Calcium carbonate and barium sulfate powders were chosen because of their approximately spherical shapes and the narrow distributions of particle sizes. Besides, their dielectric constants are nearly equal to those of glass spheres and may be regarded as chemically inactive to polyethylene. The particle sizes were determined microscopically or electron-microscopically. Details of the size analyses, expressed on a statistical basis, are listed in Table I. The statistical diameters are defined as follows :[11]

Number average diameter : $d_n = \sum nd / \sum n$

Mean surface diameter : $d_s = (\sum nd^2 / \sum n)^{1/2}$

Mean volume diameter : $d_v = (\sum nd^3 / \sum n)^{1/3}$

Mean volume-surface diameter :

$$d_{vs} = (\sum nd^3 / \sum nd^2)$$

where n is the number of particles contained in a small size range, the mid value of which is d. The mean diameters were determined by measuring one hundred particles.

The Preparation of the Suspensions.—The fillers were dried at 110°C, in a vacuum of 20 mmHg, for three hours. Polyethylene was milled at 105± 2°C for two minutes prior to mixing it with particles through a plastic roll-mill, the roll of which was 3 inches in diameter, 7.5 inches long, and with revolution velocities of 18 and 20 r. p. m. After the filler had been added to the molten polyethylene, the suspension was milled for seven minutes and finished as a sheet about 2 mm. thick. A circular disk 2 cm. in diameter was cut off from the sheet and used as a specimen. The effect of the oxidation and shear degradation of polyethylene during milling on the dynamic properties seemed to be negligibly small compared to the effect of the filler. The dynamic viscosity, η', and the dynamic modulus, G', of milled polyethylene are not altered from those of raw polyethylene after 10 min. milling.

Apparatus and Methods. — The cone-and-plate rheometer used in this work has been described in detail in previous papers.[12-14] The apparatus can be used essentially as a rotationally oscillatory viscoelastometer, at small deformations. A feature of the rheometer is the completely automatic electrically detecting and recording system. The oscillatory torque is supplied to the shaft of the movable cone by a torque motor. The clearance between the cone and the plate is sufficiently large so that the dispersed particles do not interfere with the measurements. The dimensions of the assemblies of cone-and-plate and of coaxial coni-cylinders are as follows :

(a) Cone and plate : the angle between cone and plate is 9°58′, the radius of the cone is 1.002 cm. and the tip of the cone is truncated by 1/100 mm.

(b) Coaxial coni-cylinders : the angle between the conical end of the inner cylinder and the plane bottom of the outer cylinder is 19°58′, the radii of the inner and outer cylinders are 0.501 cm. and 0.951 cm. respectively, the depth of the outer cylinder is 0.683 cm. and the tip of the inner cone is truncated by 1/100 mm.

Since the assemblies are made so small in size, as has been described above, great care must be paid to the accuracy of the distance between cone and plate. The distance between the truncated cone tip and the stationary plate was held at 1/100 mm., within a margin of error of ±2/1000 mm., by using a micrometer unit with an electric contact. The shape factor was determined experimentally. The dynamic viscosity and the dynamic modulus were calculated from the amplitude ratio and the phase lag between the recorded curves of torque and deflection.

Experiments were made at a torsional constant of 2.39×10^4 dyn.-cm./rad. In this case, the moment of inertia of the oscillatory unit was 50± 0.5 dyn.-cm.-sec^2/rad., the amplitude of the angular deflection of the cone was below 4 degrees, and the amplitude of the torque could be varied from 0 to 3×10^3 dyn.-cm. The dynamic viscosity, η', and the dynamic modulus, G', were measured at frequencies from 1/100 to 75/100 c. p. s. The temperature was varied from 155 to 230°C within a margin of error of ±1°C. During the experiments a stream of hot nitrogen gas was supplied to the atmosphere in order to avoid the rapid oxidation of the specimen.

Experimental Results

The Thixotropic Behavior of Filled Systems.—In such a highly viscous medium as molten polyethylene, the state of the dispersion of particles seems to be determined essentially by the mechanical conditions of milling. The dynamic viscosity and the dynamic modulus of filled systems changed almost not at all during measurements in suspensions of glass spheres and in those of calcium carbonate of larger particle sizes. Table II and Fig. 1 show the time dependence of dynamic properties in a suspension of calcium carbonate. In suspensions of barium sulfate of finer particles, however, the dynamic viscosity and the dynamic modulus increased with time under periodic strains. Figure 2 shows the change in dynamic properties with time in such a filled system. Measurements were made with a given amplitude of torque, 1.8×10^3 dyn.-cm., in an atmosphere of nitrogen gas. The increase in the dynamic viscosity and in the modulus is not due to any chemical changes in the specimen but to structural changes in the network formed by the agglomeration of particles in such a highly viscous medium. No gel fraction could be obtained practically

in hot tetralin. Furthermore, the dependence of dynamic properties on the amplitude was examined, since dynamic properties at lower frequencies are very sensitive to structural change in a network formed by particles.[15-17] Table III shows typical data of the amplitude dependence of dynamic properties in various suspensions. The maximum shear strain, γ_{max}, is defined as follows:[18] in an assembly of cone and plate,

$$\gamma_{max}=\theta_o/\beta$$

and in an assembly of coaxial cylinders,

$$\gamma_{max}=2\theta_o R_o^2/(R_o^2-R_i^2)$$

where θ_o is the amplitude of deflection; β, the angle between cone and plate, and R_i and R_o, the radii of the inner and the outer cylinder respectively.

Whereas in the dynamic properties of suspensions at lower concentrations the linearity of viscoelasticity holds well, the dynamic properties of concentrated suspensions depend on the amplitude, even at very small deformations.[15,19] The dynamic viscosity and modulus seem to fall off with an increase in amplitude beyond a kind of yield strain whose magnitude depends on the concentration and on the particle size of the filler. These phenomena coincide with a common characteristic of thixotropic systems, the breaking of certain linkages strained beyond their elastic limits.

As the viscoelastic properties depend on their mechanical history in such thixotropic systems, great care must be paid to the mechanical conditions of preparation and experimentation. In suspensions of glass spheres and of calcium carbonate of larger particle sizes, the dependence of the dynamic modulus on the amplitude of oscillation is more remarkable than that of the dynamic viscosity, as is shown in Table III and Fig. 3. According to theoretical considerations based on a network model,[17] the decrease in dynamic viscosity is mainly due to structural changes in the network formed by particles, while the decrease in dynamic modulus is due to both the structural change in the network and the nonlinear characteristics of the links between particles.

The Dependence of Dynamic Properties on the Concentration and Frequency.—As has been described above, dynamic properties depend on the amplitude of oscillation as well as on the frequency and concentration of filler, especially

in thixotropic systems. In such filled systems, therefore, it is very difficult to obtain the exact frequency dependence of dynamic properties, independent of the amplitude. Figures 4—7 show the frequency dependence of the dynamic viscosity and the dynamic modulus obtained by a given amplitude of torque in the range of $1.6 \sim 2.0 \times 10^3$ dyn.-cm. at various concentrations and in various suspensions.

In suspensions of glass spheres, the amplitude dependence of the dynamic properties may be ignored within the range of experimental error of $\pm 10\%$, as shown in Table III. In suspensions of calcium carbonate and barium sulfate of smaller particle sizes, the dependence of the dynamic properties on the amplitude exceeds the range of experimental error because of their thixotropic nature. In the latter case, therefore, the frequency dependence curve represents only a qualitative tendency.

However, it is evident that the dynamic modulus at lower frequencies increases with an increase in the concentration of filler, and that the superposition of the frequency dependence curves with respect to the concentration

of filler can not be made as simply as was done in polymer solutions by Ferry.[20] Table IV shows the concentration dependence of the dynamic properties of suspensions of glass spheres, calcium carbonate and barium sulfate at a given frequency, 0.02 c. p. s. In order to confirm the reproducibility of these data, some suspensions were prepared twice; the dynamic viscosity and modulus were then measured under nearly the same mechanical conditions. In thixotropic suspensions, it is essentially impossible to obtain the limiting values of dynamic properties independent of the mechanical history. In thixotropic suspensions of calcium carbonate-I, the particles are relatively large and the restoration of the network broken by shearing forces requires a long time; therefore, the dynamic viscosity and modulus of these systems fall off appreciably after large deformations. The data listed in Table IV were obtained with as small a strain as possible. In suspensions of barium sulfate-II, the dynamic viscosity and modulus increase with time, as has been described above; therefore, data were obtained after heating the suspension for about two hours. By conditioning the system in such a way, the scattering of data could be reduced tolerably. Figures 8 and 9 show the dependence of the dynamic viscosity and the dynamic modulus at a given frequency, 0.02 c. p. s., on the volume fraction of the filler. The volume fraction of the filler has been calculated by assuming that the density of molten polyethylene is 0.76 g./cm^3 at 200~210°C;[21,22] the thermal expansion of the filler may be ignored, as the volume expansion of the filler is negligibly small compared to that of the polymer.

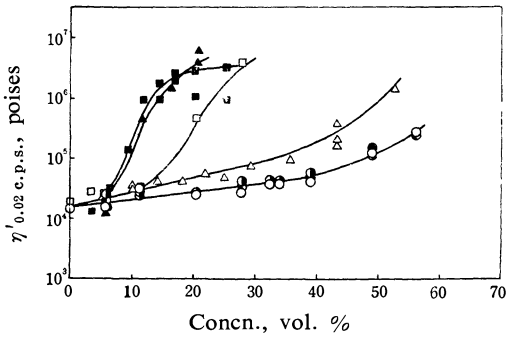

Fig. 8. Dependence of the dynamic viscosity on the concentration, at 0.02 c. p. s., in various suspensions: ○, glass sphere-I; ◑, glass sphere-II; ◐, glass sphere-III; ●, glass sphere-IV; △, calcium carbonate-I; ▲, calcium carbonate-II; □, barium sulfate-I; ■, barium sulfate-II.

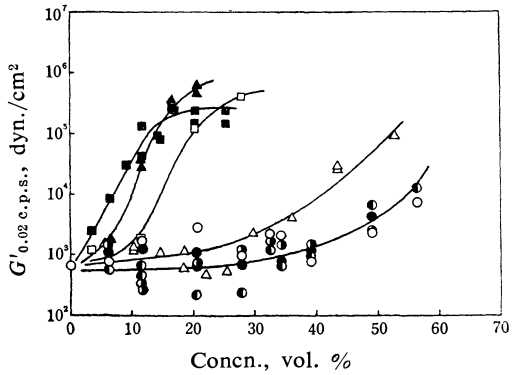

Fig. 9. Dependence of the dynamic modulus on the concentration, at 0.02 c. p. s., in various suspensions: ○, glass sphere-I; ◑, glass sphere-II; ◐, glass sphere-III; ●, glass sphere-IV; △, calcium carbonate-I; ▲, calcium carbonate-II; □, barium sulfate-I; ■, barium sulfate-II.

In suspensions of glass spheres, the concentration dependence of the dynamic viscosity at a frequency of 0.02 c. p. s. closely follows a generalized Robinson formula:[23,24]

$$\ln(\eta'/\eta'_0) = K\phi/(1-S'\phi)$$

where η'_0 is the dynamic viscosity of an unfilled polymer; ϕ, the volume fraction of the filler, and K and S', 2.5 and 1/0.74 respectively. The concentration dependence of the dynamic modulus resembles that of the dynamic viscosity.

In thixotropic suspensions of calcium carbonate and barium sulfate, the concentration dependence of the dynamic viscosity can not be represented by such a simple formula. The dynamic viscosity and the modulus increase more remarkably with an increase in the concentration. In suspensions of finer particles, the dynamic viscosity and the modulus suddenly increase beyond a sort of critical concentration. In suspensions of glass spheres of larger particles, no such critical concentration could be observed up to the highest concentration used in our experiments. In suspensions of calcium carbonate of an intermediate particle size, also, no such critical concentration could be observed. It is evident that the critical concentration depends on the particle size and that the effect of a filler on the dynamic properties of molten polymer can not be described in terms of the volume-filling properties alone. Although the filler used in

the present experiment has a perfectly or approximately spherical shape, the shape of particles also seems to have a great influence on the concentration dependence of dynamic properties, as our other experiments have discovered.

The Dependence of Dynamic Properties on the Temperature. — According to the experimental results described above, it is evident that particles aggregate in concentrated suspensions of finer particles, whether they are covered by polymer molecules or not. An examination of the temperature dependence of dynamic properties will present information on the nature of links between particles. Figures 10 and 11 show the temperature dependence of the dynamic viscosity at a frequency of 0.02 c. p. s. The coefficients of the temperature dependence of the dynamic viscosity calculated from the slopes of the above curves are listed in Table V. However, these values are not the true activation energies

for a viscous flow at zero rate of shear, because the dynamic viscosity depends on the frequency and the temperature. Therefore, they are only approximate values of the activation energies for flow. The values in parentheses have been approximately calculated from the temperature dependence of the shift factor as determined by the frequency dependence curves at 200 or 210°C and by the dynamic properties at a frequency of 0.02 c. p. s. at various temperatures. As Table V shows, the apparent coefficients of the temperature dependence for a viscous flow in various suspensions agree approximately with that of unfilled polyethylene. Consequently, in suspensions of finer particles, it is likely that dispersed particles are covered by polymer molecules and are bridged by single molecules at higher concentrations.

Discussion

As is shown in Figs. 8 and 9, the dynamic properties depend appreciably on the particle size of the filler. The effect of particle size on the melt viscosity and on the elasticity of rubber has been discussed by Furukawa[4] and Bueche[3] in detail. However, according to Furukawa's theory, the logarithmic relative viscosity of filled molten polymer must be proportional to the specific surface area and to the volume ratio of dispersed particles to polymer:

$$\ln(\eta/\eta_0) = (a+b/\boldsymbol{RT})(1+SM/\alpha A\rho)X$$

where η and η_0 are the viscosities of filled and unfilled polymers; a and b are constant; M is the molecular weight of the polymer; ρ, the density of the polymer; α, the surface area occupied by an adsorbed polymer molecule; $\boldsymbol{R}$, the gas constant; A, Avogadro's constant; S, the specific surface area per unit volume, and X, the volume ratio of the filler to the polymer. The dynamic viscosity at lower frequencies may be approximately equal to the melt viscosity. Figure 12 shows the relation of the relative dynamic viscosity at a frequency of 0.02 c. p. s. to the volume ratio of the filler. The linear relation expected by Furukawa's theory can not be observed, even in the suspensions of glass spheres of larger particle sizes. This means that the effect of the filler on the dynamic viscosity at small strains can not be described only in terms of an increase in the volume of particles caused by adsorbed polymer molecules but that it is rather closely connected with the network structure formed by particles bridged by single polymer molecules. Bueche has suggested that the effective number, ν, of polymer segments

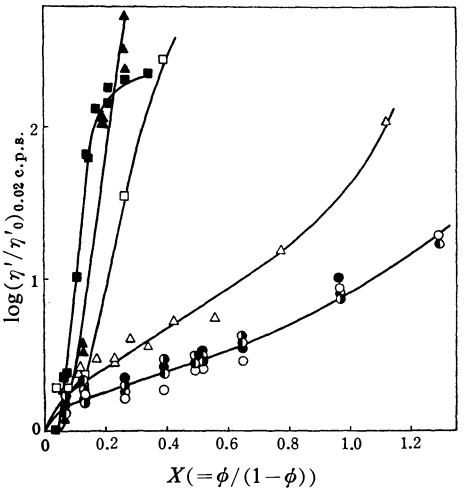

Fig. 12. Relation between the relative dynamic viscosity at 0.02 c.p.s. and the volume ratio of filler to polymer: ○, glass sphere-I; ◑, glass sphere-II; ◐, glass sphere-III; ●, glass sphere-IV; △, calcium carbonate-I; ▲, calcium carbonate-II; □, barium sulfate-I; ■, barium sulfate-II.

which can act as a molecular spring is given by the following equation:

$$\nu = N\{(1-1/N)^n - (1-n/N)\}$$

where N is the number of linear polymer molecules and n, the number of points of adherence. In the case of spherical particles with the radius r, we have:[3]

$$n = 3fv_2/r$$

and

$$N = \rho v_1/m$$

where f is the number of points of adherence per unit area; m, the mass of a polymer molecule, and v_1 and v_2 the volume fractions of the polymer and the filler respectively. Bueche's theory predicts that the first few filler particles will be relatively ineffective and that at higher concentrations the number of molecular springs will approach[3]

$$\nu = n - N = 3fv_2/r - \rho v_1/m$$

The critical volume ratio beyond which dynamic viscosity and modulus increase appreciably is, therefore, given by:

$$X_c = \rho r/3mf = A\rho r/3Mf$$

As $\rho = 0.76$ and $M = 2.8\times10^4$ in the present experiments, we have

$$X_c = 2.73\times10^{18}d/f$$

and

$$1/f = 3.66\times10^{-19}X_c/d$$

where d is the mean volume-surface diameter of the particles.

In suspensions of barium sulfate-II and -I, the values of X_c are 0.06 and 0.12 respectively, as shown in Figs. 8 and 9. Therefore, the surface area necessary for one point of adherence, $1/f$, are 25 Å^2 and 12Å^2 for barium sulfate-II and -I respectively. In suspensions of calcium carbonate-II, X_c is 0.06, and so the value of $1/f$ is 55Å^2. The value of $1/f$ seems to be decreased by a decrease in the particle size. If we assume that the surface area necessary for one point of adherence, $1/f$, is 10Å^2 for particles larger than that of calcium carbonate-I, the critical volume ratio, X_c, is expected to be 0.72 in suspensions of calcium carbonate-I. In suspensions of glass spheres, the critical volume ratio, X_c, is expected to be near to the closest packing.

Furthermore, if particles are covered by polymer molecules and are bridged partially by single molecules, it is expected that the dynamic viscosity and the modulus will increase as the mean distance between the surfaces of the particles approaches the molecular dimension of the polymer. Assuming that the particles of calcium carbonate and barium sulfate have also a perfectly spherical shape, we can calculate the mean distance between the surfaces of particles, δ_m, by the following equation:

$$\delta_m = d\{(\phi_c/\phi)^{1/3} - 1\}$$

where ϕ_c is the volume fraction at the closest packing, 0.7405. Figure 13 shows the relation of the relative dynamic viscosity at a frequency of 0.02 c. p. s. to the mean distance between the surfaces of the particles at the various concentrations, 6.1, 11.4, 20.5 and 27.9 vol. %. The root-mean square end-to-end separation of polyethylene, the number average molecular weight of which is 28000, is 97Å, and the end-to-end separation at maximum extension is 2540 Å.[25] The relative dynamic viscosity apparently increases as the mean distance between the surfaces of particles approaches the molecular dimension of the polymer. Therefore, it may be concluded that the dispersed particles are covered by polymer molecules and that in suspensions of finer particles they are partially bridged by single molecules.

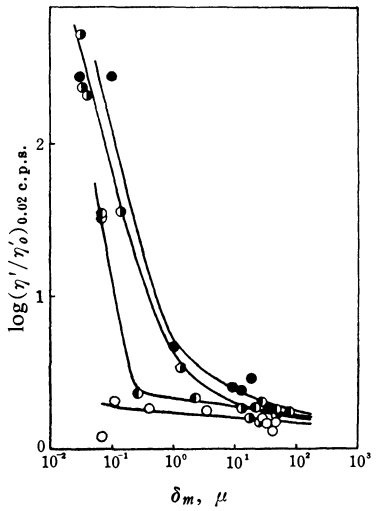

Fig. 13. Relation between the relative dynamic viscosity at 0.02 c. p. s. and the mean distance between surfaces of particles: ○, 6.1 vol.%; ◐, 11.4 vol.%; ◑, 20.5 vol.%; ●, 27.9 vol.%.

If particles sufficiently approach each other, the van der Waals-London attraction may also be considered among neighboring particles. The energy of interaction between two neighboring particles covered by polymer molecules is given by the following equation;[26]

$$\Delta F = (A_m^{1/2} - A_p^{1/2})^2 d/24(\delta + 2\Delta)$$

where A_m and A_p are the Hamaker parameters of the medium and of the particles respectively, Δ is the thickness of the layer of bound polymer molecules, and δ, the distance of the closest approach of the covered surfaces. The magnitudes of the Hamaker parameters A_m and A_p evaluated from the dielectric constants of the polymer and of the particles are approximately 2×10^{-12} and 6×10^{-13} ergs.[27]

Therefore, the energy of interaction due to the van der Waals-London attraction is

$$\Delta F = 1.70\times10^{-14} d/(\delta + 2\Delta)$$

and the additional shear modulus due to the van der Waals-London attraction, ΔG, is

$$\Delta G \fallingdotseq N_a(d+2\Delta)(d^2\Delta F/d\delta^2)/3$$
$$= 1.13\times10^{-14} N_a(d+2\Delta)d/(\delta+2\Delta)^3$$

where N_a is the number of links between particles per unit cross-sectional area which transmit forces from one part of the sample to the other. If all the dispersed particles are involved in a flocculate, N_a is given approximately by $2\phi\sigma(d+2\Delta)/\pi d^3$; thus we have

$$\Delta G \fallingdotseq 7.20\times10^{-15}\phi\sigma(d+2\Delta)^2/d^2(\delta+2\Delta)^3$$

where σ is the parameter depending on the network structure and with values in the range of 1~3.[17] When the thickness of the layer of a bound polymer, Δ, is negligibly small compared to the diameter of the particles, we have approximately:

$$\Delta G \fallingdotseq 7.20\times10^{-15}\phi\sigma/(\delta+2\Delta)^3$$

25) P. J. Flory, "Principles of Polymer Chemistry," Cornell University Press, Ithaca, New York (1953), p. 415.
26) M. J. Vold, *J. Colloid Sci.*, **16**, 1 (1961).
27) M. Takano and H. Kambe, This Bulletin, **36**, 1424 (1963).

In this case, the additional shear modulus due to the van der Waals-London attraction is independent of the particle size, and if particles approach each other within 100Å at a concentration of 10 vol. %, the magnitude of the additional shear modulus, ΔG, may be in the order of $10^2 \sim 10^3$ dyn./cm^2. This order seems to be sufficiently small compared to the observed order of the modulus, $10^4 \sim 10^6$ dyn./cm^2. Therefore, the van der Waals-London attraction seems to be of secondary importance in the forces between particles.

Summary

The dynamic viscoelastic properties of molten polyethylene with various fillers have been measured in nitrogen gas at frequencies from 0.01 to 0.75 c. p. s. The dynamic viscosity and dynamic modulus have been measured at the temperatures of 150~230°C.

Glass spheres, calcium carbonate powder and barium sulfate powder have been used as fillers. The average diameter of the particles covers the range of 0.04~91 μ. The polyethylene used was one of a low density, "Sumikathene F-70-6," whose number average molecular weight is 28000.

The dynamic viscosity and modulus of molten polyethylene are increased by the addition of fillers. The viscoelastic properties at low frequencies depend differently on the concentration in each suspension. In suspensions of glass spheres of the larger particle sizes (particle diameter: 24.0, 32.3, 49.5 and 91.1 μ), the concentration dependence of the dynamic viscosity, η', follows a generalized Robinson's formula:

$$\ln(\eta'/\eta'_0) = K\phi/(1-S'\phi)$$

where η'_0 is the dynamic viscosity of polyethylene; ϕ, the volume fraction of the suspended particles, and K and S', 2.5 and 1/0.74 respectively, regardless of the particle size. In suspensions of calcium carbonate of the intermediate particle size (particle diameter: 2.4 μ), the dependence of the dynamic viscosity on the concentration and on the amplitude of oscillation is observed more remarkably than that in suspensions of glass spheres. In suspensions of calcium carbonate and barium sulfate of the smaller particle sizes (particle diameter: 0.04, 0.08 and 0.27 μ), the dynamic viscosity and modulus increase appreciably above a critical concentration of the filler, a point which depends on the particle size. Beyond this critical concentration, the particles seemed to be linked with each other by single polymer molecules.

The dynamic viscosity and modulus at lower frequencies increase remarkably as the mean distance between the surfaces of particles becomes less than the molecular dimension of the polymer. In suspensions of the larger particles of glass spheres, this critical concentration can not be observed up to the highest concentration.

The temperature dependence of the dynamic viscosity at lower frequencies approximately agrees with that of unfilled polymers.

The dependence of dynamic properties on the time and on the amplitude of oscillations is observed in suspensions of calcium carbonate and in those of barium sulfate of comparatively small particles. In the barium sulfate suspensions of the finest particles, the dynamic viscosity and modulus increase with time under periodic strains and decrease with the increase in the amplitude of oscillations. The amplitude dependence of the dynamic modulus is more remarkable than that of the dynamic viscosity generally. In such thixotropic suspensions, the dynamic properties were measured with as small a strain as possible.

One of the present authors (M. T.) especially wishes to express his gratitude to the Japan Society for the Promotion of Science for its financial support during the work described in the present paper.

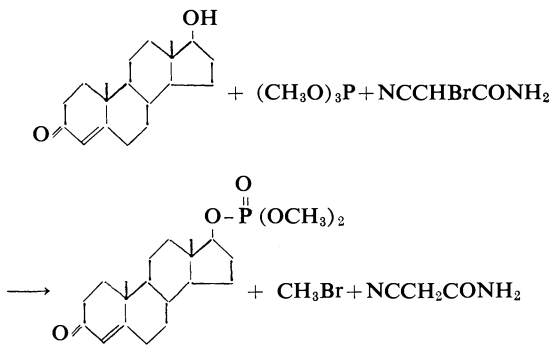
Synthesis of Testosterone Dimethyl Phosphate, Bornyl Phosphate and Adenosine 5'-Phosphate

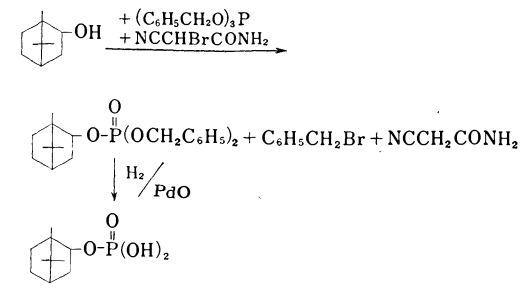
By Tsujiaki HATA and Teruaki MUKAIYAMA

(Received June 19, 1963)

A previous paper described a useful method for the selective phosphorylation of alcohols and the diesters of phosphoric acid by means of α-bromocyanoacetamides and trialkyl phosphites to yield phosphates and pyrophoshates.[1]



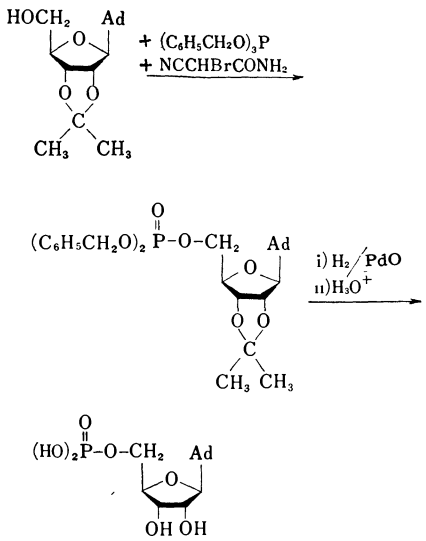
A selective phosphorylation can be effected successfully by this method without isolating the intermediate, enol-phosphate (I) or imidoyl phosphate (II), since it reacts exclusively with nucleophilic reagents, such as alcohols, phenols, diesters of phosphoric acid and amines, under mild conditions.



HY: alcohol or diester of phosphoric acid or amine

In the present paper, a successful application of this method to the synthesis of a steroid phosphate, a terpene phosphate and a nucleotide is described.

Müller and his co-workers[2] reported that testosterone dimethyl phosphate was obtained by the oxidation of the dimethyl ester of androst-5-ene-3β, 17β-diol 17-phosphate with chromic acid. It has now been found that testosterone dimethyl phosphate is obtained in a good yield from testosterone and the phosphorylating reagents, i. e., monobromocyanoacetamide and trimethyl phosphite. When trimethyl phosphite was added to a solution of one mole of testosterone and one mole of monobromocyanoacetamide in dry ether at $-40°C$, testosterone dimethyl phosphate was obtained in a 62% yield.



In the next place, a synthesis of bornyl phosphate, which had been reported to be synthesized from borneol and phosphorus oxychloride,[3] by means of the afore-mentioned phosphorylating reagents was tried. It was obtained in a 60% yield by the reaction of borneol with monobromocyanoacetamide and tribenzyl phosphite, followed by hydrogenolysis to remove the benzyl group.

Finally, it was established that adenosine 5'-phosphate[4] was successfully synthesized. Adenosine 5'-phosphate was obtained in a 62% yield when one mole of 2', 3'-isopropylideneadenosine was treated with one mole of monobromocyanoacetamide and one mole of tribenzyl phosphite, followed by hydrogenolysis and hydrolysis.

Ad: Adenine

Experimental

Testosterone Dimethyl Phosphate.—Into a solution of testosterone (0.20 g.) and monobromocyanoacetamide (0.11 g.) in 20 ml. of dry ether, trimethyl phosphite (0.08 g.) in 10 ml. of dry ether was stirred drop by drop at −40°C. A white precipitate, cyanoacetamide, separated. The solution was kept at room temperature overnight and then filtered. After the removal of methyl bromide and ether, testosterone dimethyl phosphate was obtained as a colorless crystalline solid weighing 0.17 g. (62%) and melting at 144~149°C. The crude product was recrystallized from ether (m. p. 152°C).

Bornyl Phosphate.—Into a solution of borneol (1.54 g.) and monobromocyanoacetamide (1.63 g.) in 100 ml. of dry ether, tribenzyl phosphite (3.80 g.; purity 80%) was stirred drop by drop at room temperature. The solution was further stirred for 2 hr. and then left to stand overnight. After removal of the ether, the residual material was dissolved in aqueous alcohol (50 ml. of 50%), and the solution was shaken with hydrogen at atmospheric pressure over an Adams palladium oxide catalyst, the theoretical amount of hydrogen for the removal of two benzyl groups being taken up in 100 min. The catalyst was removed by filtration, the solution was evaporated to dryness at 40°C under reduced pressure, and the crude bornyl phosphate (1.40 g., 60%) was recrystallized from benzene-petroleum ether (m. p. 155~156°C), alone and in admixture with an authentic sample.

Adenosine 5'-Phosphate.—To a solution of 2', 3'-isopropylideneadenosine (0.31 g.) and tribenzyl phosphite (0.44 g.; purity 80%) in 15 ml. of anhydrous dimethylformamide, monobromocyanoacetamide (0.33 g.) in 10 ml. of anhydrous dimethylformamide was added drop by drop with shaking at room temperature. The solution was then kept at room temperature for 3 days and the solvent evaporated at 30~35°C under reduced pressure (3~4 mmHg). The residual syrup was dissolved in aqueous alcohol (30 ml. of 50%), and the solution was shaken with hydrogen at atmospheric pressure over an Adams palladium oxide catalyst. The absorption of the hydrogen was rapid, the theoretical amount for the removal of two benzyl groups being taken up in 60 min. After the catalyst had been removed by filtration, the filtrate was evaporated at 30°C under reduced pressure to a faintly yellow syrup. The syrup was dissolved in dilute sulfuric acid (5 ml. of a 0.1 N solution), and the solution was set aside for 2 days to effect the hydrolysis of the isopropylidene residue, The sulfuric acid was neutralized with a calculated amount of barium hydroxide (5 ml. of a 0.1 N solution). Barium sulfate was removed by centrifugation, aqueous ammonia (0.1 N) was added to pH 10, and then a saturated solution of barium chloride was added. The precipitate was collected by centrifugation and washed with two portions (10 ml.) of water. The crude barium salt of adenosine 5'-phosphate was suspended in a small amount of water, and dilute hydrochloric acid (1 N) was added to pH 2. The adenosine 5'-phosphate did not crystallize instantly, but, on standing overnight at 0°C, it separated as needles (0.23 g., 66%) (m. p. 187~190°C). Recrystallized from water, it melted at 191°C; the R_f value was 0.70.* The melting point was not depressed in admixture with natural adenosine 5'-phosphate (m. p. 191~192°C).

A Cobalt Complex Catalyst for the Linear Dimerization of Butadiene

By Taro SAITO, Yasuzo UCHIDA and Akira MISONO

(Received April 26, 1963)

We have found that the selective dimerization of 1, 3-butadiene to 3-methyl-hepta-1, 4, 6-triene is carried out by a complex catalyst composed of triethylaluminum and cobalt complexes such as cobalt(III) acetylacetonate, cobalt salicyl aldehyde, a cobalt chloride pyridine complex, and cobalt chloride. Some of the results using cobalt(III) acetylacetonate have been previously reported.[1] The order of mixing cobalt acetylacetonate, butadiene and triethylaluminum had a great effect on the rate of formation of the butadiene dimer; the best results were obtained when cobalt acetylacetonate, butadiene and triethylaluminum were mixed in that order. These results suggest that the coordination of butadiene to cobalt is affected by the mixing order of the monomer and catalyst components and has an important influence on the dimerization of butadiene.

In this paper, an explanation for the formation of an active complex will be attempted by means of the results from infrared spectra, magnetic susceptibility and electron spin resonance spectra.

Experimental

Reagents. — Benzene was purified by washing it with concentrated sulfuric acid and then distilling it with metallic sodium in an atmosphere of nitrogen gas.

Triethylaluminum (made by the Ethyl Corp., U. S. A.) was used in the experiments without further purification.

Cobalt acetylacetonate was synthesized according to the method described in "Inorganic Syntheses."[2]

Infrared Analysis. — The infrared spectra of the samples were found by means of a Nihon-Bunko double-beam spectrometer model 401 G for the sodium chloride region and model 201 for the potassium bromide region.

Known amounts of cobalt acetylacetonate, butadiene (benzene solution) and triethylaluminum (benzene solution) were introduced into a glass tube in an atmosphere of nitrogen gas, and a part of the solution was transfused into a 0.1 mm.-path. length sodium chloride cell with a glass syringe.

TABLE I. THE PREPARATION METHOD OF THE SAMPLES EMPLOYED

1) Infrared analysis

Magnetic Susceptibility. — The Gouy method was adopted for observing the magnetic susceptibility of the compounds placed between the poles of an electric magnet with a value of 25000 gauss; a quartz sample tube was also employed. The measurement were carried out at 10°C. The samples were prepared in the way described in the above section.

Electron Spin Resonance Spectra. — The spectra were recorded in the X-band (9400 Mc.) with 100 kc. modulation by means of a Nihon-Denshi Model JES-3B ESR spectrometer. The method of sample preparation was the same as that described above; the conditions of sample preparation for each experiment are shown in Table I.

Results and Discussion

When triethylaluminum reacts with cobalt acetylacetonate in the presence of butadiene, the resultant solution shows a marked catalytic activity in the linear dimerization of butadiene, whereas the solution prepared by the reaction of cobalt acetylacetonate and triethylaluminum without butadiene is considerably inactive. Thus, the order of mixing the catalyst and butadiene components is very important in obtaining the active catalyst.[1)]

Infrared spectra were recorded for each solution of a different mixing order of the components. In the infrared spectrum in the sodium chloride region, the decrease in the absorptions of the CH- and CH_2-wagging vibrations of butadiene, at 1008 and 908 cm^{-1} respectively, was very marked in the sample prepared by adding triethylaluminum last (Fig. 1-1). This result indicates that butadiene molecules are strongly bound in that case. Triethylaluminum is assumed to play the role of reducing cobalt to the state in which butadiene molecules readily coordinate to cobalt. On the other hand, when triethylaluminum is added before butadiene (Fig. 1-3), a complex is formed to which butadiene molecules hardly coordinate at all. Figure 1-2 displays the intermediate state.

Infrared spectra in the potassium bromide region were recorded to elucidate the bond structure between the transition metal and the oxygen atoms of acetylacetone ligands. Nakamoto[3)] has reported on the infrared spectra in the potassium bromide region of acetylacetonates of trivalent metals. He assigned the 466 and 490 cm^{-1} bands to Co–O and Al–O stretching vibrations respectively. In the present investigation, the reaction mixtures of cobalt acetylacetonate, butadiene and triethylaluminum in both orders of mixing (Figs. 2-6 and 2-7) showed the Al–O band at

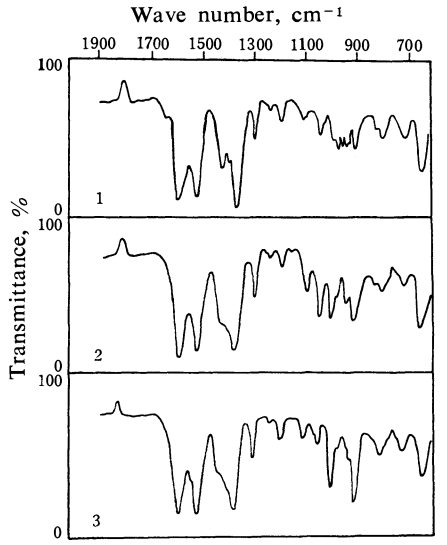

Fig. 1. IR spectra of the solutions prepared by different orders of mixing.

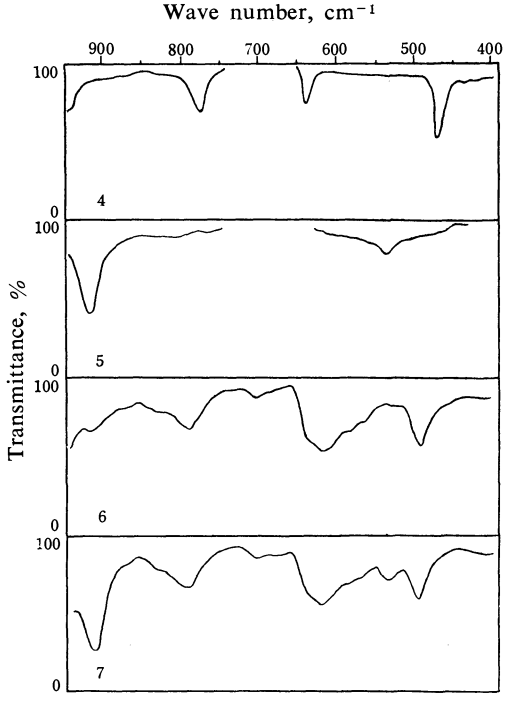

Fig. 2. IR spectra of the solutions prepared by different orders of mixing.

490 cm^{-1} instead of the Co–O band at 466 cm^{-1}, indicating that the acetylacetone ligands of cobalt acetylacetonate come to be coordinated to aluminum as the result of the ligand exchange reaction effected by triethylaluminum.

By evaporating the solvent and low-boiling materials from the reaction solution of cobalt acetylacetonate, butadiene and triethylaluminum in benzene, a catalytically-active solid

3) K. Nakamoto, *J. Am. Chem. Soc.*, **83**, 1066 (1961).

was obtained. By sublimation of the solid, it was confirmed that one sublimate was aluminum acetylacetonate. The sublimation residue was cobalt metal. These results support the theory that the reduction of the cobalt and ligand exchange reaction between cobalt and aluminum take place.

The magnetic susceptibilities of these reaction solutions were measured to determine the number of unpaired electrons of cobalt. Calculations based on the assumption that the sum of $w_i\chi_{gi}$ equals the χ_g value of the solution, where w_i is a weight fraction and χ_{gi} is a gram susceptibility of a component, indicated that the reaction product of cobalt acetylacetonate, butadiene and triethylaluminum mixed in that order is slightly paramagnetic, while, on the other hand, the product prepared by mixing cobalt acetylacetonate, triethylaluminum and butadiene in that order is strongly paramagnetic. Although the calculations are not decisive enough, because of the obscurity of the structure of the complex formed, to determine unequivocally the exact number of unpaired electrons of cobalt the reaction product of cobalt acetylaluminum with triethylaluminum in the presence of butadiene is probably diamagnetic. (The paramagnetism is due to the partial reaction of cobalt acetylacetonate and triethylaluminum without butadiene.) It is considered to be a diamagnetic complex formed by the removal of the acetylacetone ligands of cobalt acetylacetonate by triethylaluminum, with the simultaneous π-bonding of butadienes to cobalt.

The electron spin resonance spectra support the noticeable relation between the paramagnetism and the mixing order of the catalyst and butadiene components. The strong paramagnetism of the sample agrees very well with the results of the magnetic susceptibility measurement.

It may be suggested on the basis of these experimental results that the active catalyst complex for the dimerization is probably a π-complex of cobalt. Triethylaluminum deprives cobalt acetylacetonate of acetylacetone ligands, and simultaneously butadiene molecules coordinate to cobalt to form the active catalyst complex for the dimerization. Butadiene molecules coordinated to cobalt are considered to form a dimer, and the coordination force of the dimer is so much weaker than that of butadiene that the formed dimer is removed from the cobalt by ligand exchange with the butadiene in the solution. Dimerization will proceed until butadiene is consumed by repeated coordination, dimerization and detachment by ligand exchange processes.

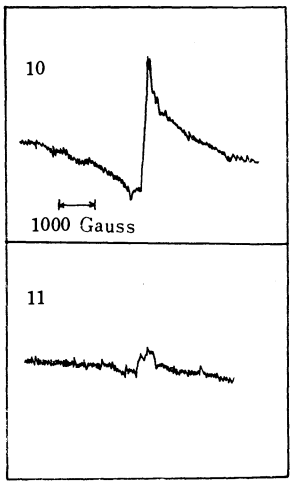

Fig. 3. ESR spectra of the solutions prepared by different orders of mixing.

Summary

In the linear dimerization of butadiene, the mixing order of butadiene and catalyst components, cobalt acetylacetonate and triethylaluminum affects the activity of the catalyst. When cobalt acetylacetonate and triethylaluminum react in the presence of butadiene, the solution possesses marked catalytic activity. In the infrared spectrum of this system, the intensity of the absorption peaks of the CH- ($1008\,cm^{-1}$) and CH_2- ($908\,cm^{-1}$) wagging vibrations of butadiene decrease significantly as compared with the case when butadiene is added last. In both cases, the absorption of Co–O ($466\,cm^{-1}$) disappered and that of Al–O ($490\,cm^{-1}$) was found. These results indicate that triethylaluminum reduces cobalt acetylacetonate and coordinates butadiene to cobalt. When butadiene is absent, triethylaluminum and cobalt acetylacetonate react to form a complex to which butadiene coordinate scarcely at all afterwards. The former solution shows a weak paramagnetism ($\mu_{eff}=1.4$), while the latter shows a strong paramagnetism ($\mu_{eff}=4.0$). From these results, the catalyst of the reaction is considered to be a diamagnetic complex of cobalt coordinated by butadiene.

Studies of the Photoreduction of Thiazine Dyes in Aqueous Solutions

By Masao KOIZUMI, Hiroshi OBATA and Shigenari HAYASHI

(Received August 14, 1963)

In 1961 Usui, Obata and Koizumi[1] found that methylene blue in suitable buffer solutions, without any reducing agents added, is photoreduced to leuco dye by the visible light. According to them, the quantum yield of photoreduction reaches as much as 10^{-3} in the phosphate buffer, but it is to be noted that the formation of leuco dye is accompanied by some degree of demethylation and a slight decomposition of the dye. Following this paper, Usui and Koizumi[2] attempted a kinetic treatment and found that in the borate buffer solution the reaction proceed approximately as of the first order with respect to the dye, while in the phosphate buffer solution, the reaction is a simple second order one with respect to the dye. It seemed that there is some difference between the reaction mechanisms of these two cases, but this was not conclusive in view of the rather tentative nature of the treatment.

The present paper is concerned with one, examining whether other kinds of dye show a similar photoreduction or not, and two, studying further the kinetic nature of the reaction in question.

The result is that, so far as we have examined, there are no kinds of dye other than thiazine dyes that show such a reaction. It seems that the reaction is specific for thiazine dyes. As to the second question, another example was found which behaves in a manner similar to methylene blue in the phosphate buffer solution. From the present investigation it has become more certain that in suitable cases the photoreduction of thiazine dyes process in a simple second order with regard to the dye.

I. A Search for Other Dyes which Display a Similar Photoreduction.—The following dyes were examined, each in plain aqueous, borate and phosphate buffer solutions.

a) Indophenol dye
  1) 2, 6-Dichlorophenol indophenol (Merck or Wako-junyaku)

b) Thiazine dyes
  2) New methylene blue (Tokyo-kasei)
  3) Methylene green (Tokyo-kasei)
  4) Toluidine blue (Tokyo-kasei)
  5) Thionine

c) Oxazine dyes
  6) Nile blue (Tokyo-kasei)
  7) Capri blue (Tokyo-kasei)

d) Phenazine dye
  8) Neutral red (Merck)

Experimental

Purification.—All the dyes were recrystallized from an ethanol solution several times. Sodium borate, sodium monohydrogen phosphate, and potassium dihydrogen phosphate (all G. R.) were recrystallized 3~4 times from an aqueous solution.

Apparatus and Procedures.—The sample solution in a spherical ampule (2 cm. radius) was evacuated 5~7 times by freezing and thawing and then poured into a reaction cell, which consisted of a spectrophotometer cell (1×1×4 cm.) and the upper part of which was connected to the above ampule by a glass tube. The experiment was performed in a thermostat at 30°C. The light source was a 500W/100V. projection lamp which usually operated at 75V. A suitable combination of filters were used for each system. At various time intervals, the sample cell was taken out and the absorption spectra were measured with a Hitachi spectrophotometer. The pH of the buffer solution was measured with a Hitachi pH-meter.

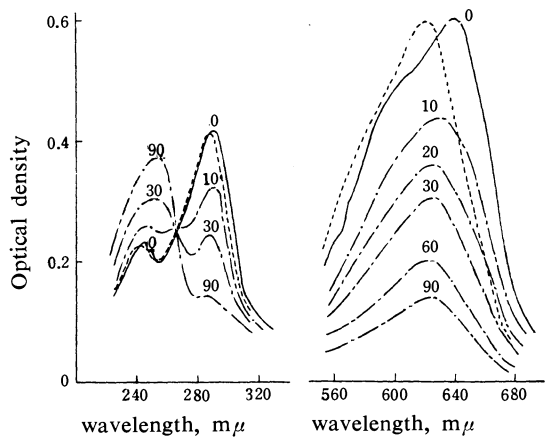

Fig. 1. Spectral change of toluidine blue in the photobleaching; dye conc. 2×10^{-5} M, phosphate buffer 1.0×10^{-2} M, pH 7.7. Numbers denote the time of illumination (min.); dotted line, after the introduction of air into the bleached solution.

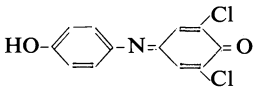
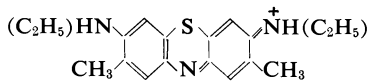


1) Y. Usui, H. Obata and M. Koizumi, This Bulletin, **34**, 1049 (1961).
2) Y. Usui and M. Koizumi, ibid., **34**, 1651 (1961).

The following two tests were employed to decide whether or not the bleaching is due to photoreduction; 1) the measurement of the absorption spectra of the illuminated sample in the visible and ultraviolet regions, and 2) the recovery of color by the introduction of air. For example, when a phosphate buffer solution of toluidine blue is illuminated, the spectra decline in the visible region and a new absorption band appears at 255 mμ with an isosbestic point at 266~7 mμ, this band being just the same as that of the chemically-prepared leuco dye. This is shown in Fig. 1.

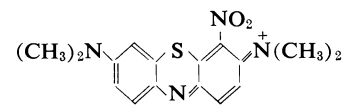
Furthermore, when air is introduced after the reaction, the absorption spectra in the visible region increase again, as is shown by a dotted curve. From these facts one can conclude that the photoreduction occurs in the case of toluidine blue. The phenomena described above are not observed in the case of irreversible decomposition.

Results



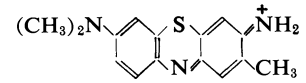
i) 2,6-Dichlorophenol Indophenol (2,6-DPIP)

This dye was studied because it has an oxidation-reduction potential as high as 0.217 V. (at pH=7). Its absorption spectra in the aqueous solution have three peaks, at 270, 310 and 600 mμ, while the reduced dye (prepared chemically) has one peak, at ~265 mμ.



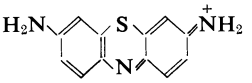
The stock solution must be kept in a refrigerator.[3] The dye was scarcely bleached at all by the visible light in the deaerated condition. Thus, the plain aqueous solution and the borate buffer solution (pH=9.2, 8.0), as well as the phosphate buffer solution (pH=8.9, 5.7), showed no change of absorption spectra even when illuminated as long as 430 min.

ii) New Methylene Blue (NMB)



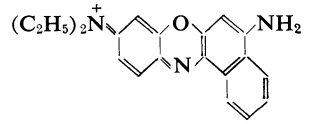
The absorption spectra have two peaks, at 285 and 630 mμ. The dimer peak exists at 585 mμ. The bleaching occurred, but very slowly, without any accompanying shift. The influence of the buffer solution on the rate was rather small. When the air was introduced after the reaction, 40~50% of the dye was restored.

iii) Methylene Green (MG)



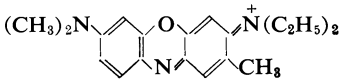
The λ_{max} lies at 275 and 650 mμ. The bleaching was moderately fast, with a shift of the maximum from 650 to 610~620 mμ. A new band appeared at 260 mμ. The rate increased in the order: plain aqueous solution <borate < phosphate. The introduction of air after the reaction restored 50~60% of the dye. The quantum yield of bleaching was ca. 3×10^{-4}.

iv) Toluidine Blue (TB)



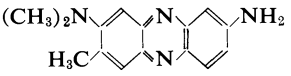
The photobleaching was rather rapid, with a shift of λ_{max} from 640 to 620 mμ. The order of the rate was: water <borate <phosphate. The introduction of air after the reaction recovered about 85% of the dye in case of the borate buffer solution, while in the phosphate buffer practically a 100% recovery was realized.

v) Thionine (Th)



A gradual photoreduction occurred. The details will be described elsewhere.

vi) Nile Blue



The rate of bleaching was very slow, and there was scarcely any recovery of dye by the introduction of air. It is to be noted that the borate buffer solution, when kept in the dark, showed a remarkable change in the absorption spectra and orange needle-like crystals precipitated.

vii) Capri Blue

The absorption spectra have two peaks, at 260 and 655mμ. The bleaching was very small, even with a 600 min. illumination. There was no effect of buffering on the rate, and no shift of the peak. The air-introduction recovered 20~30% in all cases examined.

viii) Neutral Red

This dye has two peaks, at 275 and 530 mμ. The plain aqueous solution and the phosphate buffer solution, when illuminated, showed a very small change in the absorption spectra. In the case of the borate buffer, the absorp-

tion spectra changed remarkably immediately after the buffer solution had been added to the dye solution (the resultant pH was 8~9), and in addition, some precipitate was produced. It is to be added that, in the plain aqueous solution (pH≈6), mere evacuation caused a shift of λ_{max} from 530 to 465 mμ, and the introduction of air restored the original absorption spectra. The above absorption spectra in the evacuated solution resembled those of the phosphate buffer solution (pH≈7). These phenomena seem to deserve further study.

ix) Résumé

Table I summarizes the results so far obtained. In this table, the numbers in parentheses denote the oxidation-reduction potential and the signs ◎, ○ and × represent, respectively, that the reaction is prominent, moderate and practically non-existent.

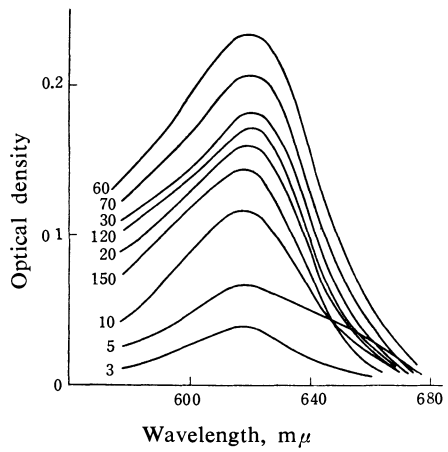
From the above table one can say that the reaction in question is rather specific for thiazine dyes; it is notable that the reaction is especially prominent when there is an accompanying demethylation. The effect of the buffer solution is quite similar to that observed in methylene blue, the rate increasing in the order of plain aqueous solution<borate buffer<phosphate buffer. The magnitude of the reaction cannot be correlated with the oxidation-reduction potential. Generally, the photoreduction is more or less accompanied with the irreversible decomposition of the dye, which prevents the complete recovery of the oxidized form. Toluidine blue, however, is very fortunately an exception, the recovery of this dye in the phosphate buffer solution being practically 100%. This dye is therefore expected to be particularly suitable for quantitative studies, including kinetic studies. These will be described in II. As to toluidine blue in the phosphate and borate buffer solutions, the detection of hydrogen peroxide was undertaken by the method of Meloan, Manck and Huffman,[4] but the sensitivity was not good enough for our purposes.

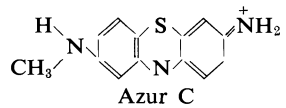
4) C. E. Meloan, M. Manck and C. Huffman, *Anal. Chem.*, 33, 104 (1961); 32, 791 (1960).

II. Kinetic Studies, Chiefly of Toluidine Blue

The most reliable data obtained from the experiment concern the change of the absorbance at λ_{max}. However, a slight shift of λ_{max}, accompanied by a fall in absorbance, makes it necessary to examine the interrelation between these two quantities.

From the analogy of methylene blue, there is scarcely any doubt that the shift in the present case is due also to demethylation from the side dimethylamino groups. Therefore, the absorption spectra at various times of illumination were analysed by the minimum ratio method of Blaisdell. This gives the absorption spectra of the demethylated dye which is shown in Fig. 2. It is clear that the demethylated product consists only of one species, with a maximum at 620 mμ. In view of the





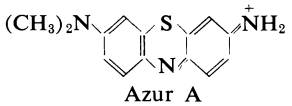


Fig. 2. Absorption spectra of the demethylated product (oxidized form) obtained by the Blaisdell method.

fact that the difference of λ_{max} between azur A and azur C is ca. 20 mμ, it is very reasonable

Azur C

Azur A

to consider that only one methyl group is detached in the case of toluidine blue. Table II gives the absorbance of the remaining toluidine blue at various times of illumination, D_0-D_t, and the absorbance of the demethylated product, D'_t.

From the above table one can see that, at an earlier stage of reaction, the ratio of the absorbance of the demethylated product to the total decrease in the absorbance of the original dye is near 0.5 in the case of phosphate, while in the case of borate it is less than 0.3. If one takes into account the fact that the restoration of dye by the introduction of air is almost complete in phosphate,

TABLE II

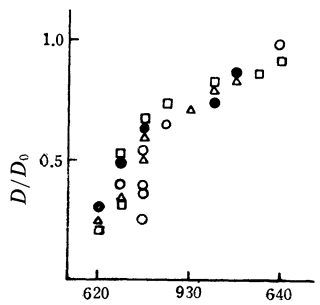
210	0.144	0.34	0.094

it appears that, in this case, demethylation participates in the photoreduction, probably in the ratio of one to one.



In Figs. 3 a, b and c the values of D/D_0, where D and D_0 are, respectively, the absorbance at the maximum wavelength at time t and at time $t=0$, are plotted against λ_{max} at various times. The figure concerns the phosphate buffer solution. From the results one may say that, in the case of the phosphate buffer, the shift accompanies the decline in almost the same ratio always, irrespective of the concentration of dye, the temperature, or the intensity of the exciting light.

Such a situation does not hold in the case of the borate buffer, where the relation between the shift and the bleaching is different from case to case. The increase in dye concentration and pH seems to favor the shift much more than the bleaching. Some data are shown in Fig. 4. These results, quite similar to those obtained for methylene blue, suggest some differences, between the processes occurring in the phosphate and borate buffer solutions.

On the basis of the above results it seems quite rational to undertake the kinetic treatment for the phosphate buffer based on the

decline of the absorption spectra of the remaining dye. This treatment, of course, concerns both photoreduction and demethylation, but these two processes, as has been mentioned above, go parallel in the case of toluidine blue in the phosphate buffer, irrespective of the experimental conditions. If demethylation plays an essential role in the photoreduction, as will be suggested later, the present treatment is most satisfactory. It must be added that the inner filter effect of the demethylated product will not cause much error because in a later stage, where the effect is expected to become notable, the concentration of the total dye (oxidized form) becomes much smaller.*

It must be added that the composition of the product consisting of demethylated dye and leuco dye obeys very rapidly the oxidation-reduction equilibrium and that a part of demethylated oxidized dye, after being produced by the reaction, will turn into the leuco form, while the corresponding quantity of leuco toluidine blue goes back to the oxidized form. These phenomena have already been treated to some extent in a previous paper;[1] the present finding that the recovered dye after the introduction of air has exactly the same λ_{max} as that of the remaining dye prior to aeration clearly demonstrates the existence of such an equilibrium as that discussed in the previous paper. In the following treatment, however, the effect of this phenomenon on the reaction rate will be disregarded in favor of a first approximation (see Appendix).

i) The Rate Formula.—A simple second-order rate formula was found to hold for the concentration of the remaining toluidine blue. However, as is shown in Fig. 5, the rate constant decreases as the concentration of dye increases. Some examples of the second order rate constant at various dye concentrations are given in Table III.

TABLE III. KINETIC DATA AND THE CONDITION OF THE SOLUTION

Phosphate buffer, pH=7.71
Na_2HPO_4 9.0×10^{-3} M
KH_2PO_4 1.0×10^{-3} M

Dye concn. $\times10^{-5}$ M	k $\times10^{-2}$ mol^{-1} l. sec^{-1}
0.7	3.07
0.9	2.03
1.4	0.935
1.8	0.735
2.1	0.534
2.7	0.375
3.6	0.238

A plot of $1/k$ against C_0 and a plot of $1/kC_0$ against C_0 are given in Figs. 6 a and b. The latter gives a good linear plot. Therefore, one can write the following equation as an experimental rate formula:

$$-\frac{dc}{dt}=kC^2=\frac{\alpha C^2}{\beta C_0(\gamma C_0+\delta)} \quad (1)$$

or $$\frac{1}{kC_0}=\frac{\beta\gamma}{\alpha}C_0+\frac{\beta\delta}{\alpha} \quad (2)$$

* If the concentration of the two components, C_1 and C_2, are very small, the quantity of light absorption by one component is $\varepsilon_1\times C_1\times I_0$, irrespective of the other components.

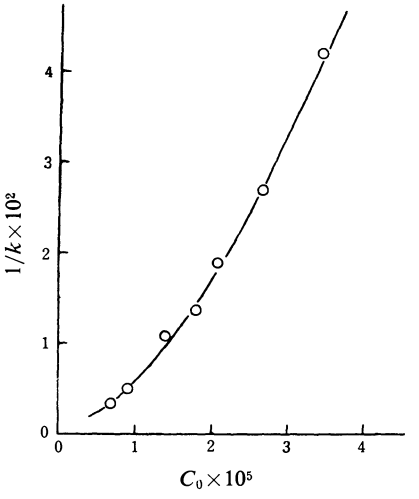

Fig. 6a. Relation of velocity constant to the initial dye concentration in phosphate buffer.

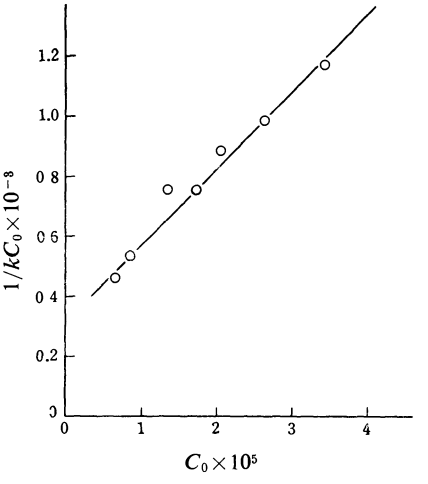

Fig. 6b. Relation of the velocity constant to the initial dye concentration in phosphate buffer.

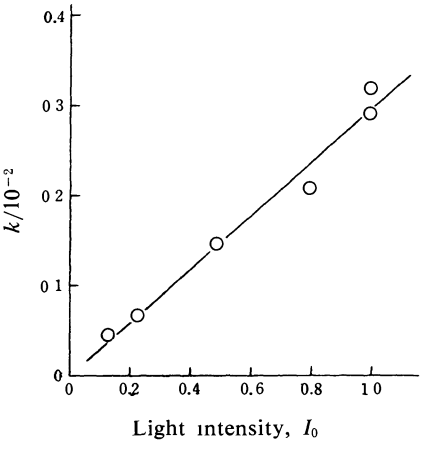

Fig. 7. Effect of incident light intensity on the rate constant in phosphate buffer.

From the above experimental data, one obtains;

$$\beta\gamma/\alpha=2.4\times10^7 \text{ mol. l. sec}^{-1}$$

$$\beta\delta/\alpha=0.3\times10^3 \text{ sec}^{-1}$$

ii) The Effect of Intensity.—The intensity of the illuminating light was varied by means of neutral filters, the transmission of which is 80, 49, 23 and 13%. The results are shown in Table IV and Fig. 7.

TABLE IV

Dye, ca. 2.5×10^{-5} M; Phosphate, 1.0×10^{-2} M

I_0	k $\times10^2$ mol^{-1} l. sec^{-1}
1.0	0.285
1.0	0.320
0.8	0.205
0.8	0.195
0.49	0.142
0.23	0.065
0.13	0.045

iii) The Effect of pH.—This is rather small, as Table V shows:

TABLE V

Dye, 1.8×10^{-5} M

pH	$k\times10^2$ mol^{-1} l. sec^{-1}	log k
9.10	1.18	2.07
7.71	0.735	1.87
7.00	0.595	1.78
5.93	0.239	1.38

iv) Temperature Effect.—Table VI.

TABLE VI

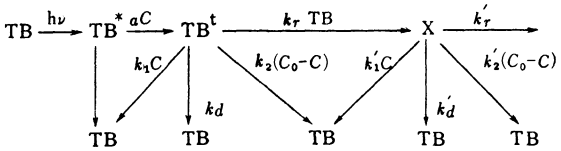
Dye, 2.1×10^{-5} M; pH=7.74

Temp., °C	$k\times10^2$ mol^{-1} l. sec^{-1}
20	0.421
30	0.534
40	0.627

From the above data, the apparent activation energy was evaluated as 4.2 kcal.

v) Quantum Yield (γ).—The following values were obtained. In the phosphate buffer (pH=7.74) and at 1.0×10^{-5} M of dye, $\gamma=6\times10^{-4}$. In the borate buffer (pH=9.40) and at 1.7×10^{-5} M of dye, $\gamma=4.4\times10^{-4}$. (The light quanta absorbed is 4.0×10^{14} sec^{-1} cc^{-1})

vi) Kinetic Results for Other Systems.—In the case of toluidine blue in a borate buffer, a simple second-order rate formula could not reproduce the experimental results. This is natural, since in this case there is an accompanying irreversible reaction and since, moreover, the degree of demethylation depends on



the experimental conditions. Most of the other cases could not be treated by a simple second-order rate formula either. An example for which a simple second-order rate formula holds approximately, however, was methylene green in a phosphate buffer solution.

Discussion

Usui and Koizumi tentatively applied, and with some success, the second-order rate formula to the photoreduction of methylene blue in a phosphate buffer. At that time they supposed that the success was rather fortuitous because the overall reaction, consisting of reversible and irreversible bleaching and, furthermore, of demethylation, was so complicated that the treatment could not be expected to be more than approximate. Now in the case of toluidine blue in a phosphate buffer, for which the second-order rate formula proved to hold satisfactorily again, the situations, though still complicated, are considered to be much better than in the case of methylene blue. Thus, first, the recovery of dye by the introduction of air being almost complete, there is no irreversible decomposition of dye occurring in this case. Second, the shift of λ_{max} is much less than that of methylene blue and corresponds to the elimination of one methyl group. Lastly, the fact that the quantity of demethylation is about half of the total decrease in the original dye, irrespective of the experimental conditions, suggests that demethylation is coupled in some way with the photoreduction. In view of these results, there is scarcely any doubt that a bimolecular process with regard to the dye is taking place in this case. Furthermore, the fact that the rate is proportional to the light intensity indicates that the photoreduction in this case occurs between some excited species and the ground state dye.

It must be added here that, for the simple second-order rate formula to hold, the absorption of light must be proportional to the concentration of dye, and so the concentration of dye must be low enough. Some of the experimental results for cases in which the concentration is rather large do not fulfil the above condition in an early stage of the run, and it seems rather strange that the same rate formula still appears to hold in this region.

Disregarding this point for the moment, however, the scheme will be discussed below on the basis of the experimental rate formula. The following scheme, which is somewhat different from that proposed before,[1] can interpret the present experimental rate formula. Although of course, the scheme is not conclusive, yet the authors believe that, in view of various facts, some of which will be published in a following paper,[5] the scheme is established almost definitely, at least in its essential point, i. e., in the point that it involves a bimolecular process with regard to dye. The success of the following analysis also favors the scheme.

In this scheme, C_0 and C are the concentration of TB at time $t=0$ and t, and aC is the rate of the production of the triplet dye, the absorption of light being assumed to be proportional to the concentration of dye. a can be written alternatively as $I_0 \times \varepsilon \psi_{S-T}$, and where I_0 is the incident light intensity, ε the molar absorbance, and ψ_{S-T}, a probability of intersystem crossing to the triplet state. Further, in the above scheme, the triplet dye is assumed to disappear via the following four processes; spontaneous deactivation k_d, reaction and deactivation with the ground state dye (the rate constant of the former being written k_r and the total sum of the reaction and deactivation, k_1), and, lastly, the deactivation by some reaction product, perhaps leuco dye. The effect of leuco dye was experimentally confirmed as in the case of methylene blue. The reaction between the triplet dye and the ground state dye will produce another transient species, X, which perhaps consists of half-hydrogenated dye and half-oxidized dye. If these two components can separate away or if the half-oxidized state is removed by a suitable (reducing) agent, then a net photoreaction will result. The rate constant connected with this net reaction will be written as k'_r. Most of X in the absence of any reducing agent will, however, return to two ground state dye molecules spontaneously (k'_d) or by interacting with the ground state dye, $k'C$, or with the leuco dye, $k'_2(C_0-C)$.

From the above scheme one can write:

$$-\frac{dc}{dt}=\frac{ak_rk_r'C^2}{\{k_d+k_1C+k_2(C_0-C)\}\times\{k_d'+k_1'C+k_2'(C_0-C)\}} \quad (1)$$

If one assumes here that the deactivation of the triplet dye and X is encounter-rate-determining, one may approximately put:

$$k_1 \approx k_2 \qquad k_1' \approx k_2' \quad (2)$$

If one further assumes that $k_dk_d' \approx 0$, then;

5) S. Kato, M. Morita and M. Koizumi, This Bulletin, 37, 117 (1964).

$$-\frac{dc}{dt}=\frac{ak_r k_r' C^2}{k_2k_2'C_0^2+(k_2k_d'+k_2'k_d)C_0}=kC^2 \quad (3)$$

$$k=\frac{ak_r k_r'}{k_2k_2'C_0^2+(k_2k_d'+k_2'k_d)C_0} \quad (4)$$

These are just the same form as the experimental rate formula.

From 4,

$$\frac{1}{kC_0}=\frac{k_2k_2'}{ak_rk_r'}C_0+\frac{k_2k_d'+k_2'k_d}{ak_rk_r'}$$

Hence, the experimental parameters $\beta\gamma/\alpha$ and $\beta\delta/\alpha$ can be expressed as follows:

$$\frac{\beta\gamma}{\alpha}=\frac{k_2k_2'}{ak_rk_r'} \qquad \frac{\beta\delta}{\alpha}=\frac{k_2k_d'+k_2'k_d}{ak_rk_r'}$$

From the experimental values of $\beta\gamma/\alpha$ and $\beta\delta/\alpha$, one can estimate the rate constants for each elementary reaction as follows. Thus, if one tentatively assumes that $k_2\approx k_2'\approx 10^{10}$ mol^{-1} l. sec^{-1}, then:

$$10^{20}=2.4\times 10^7\, ak_rk_r'$$

$$10^{10}(k_d+k_d')=3.2\times 10^2 ak_rk_r'$$

Hence,

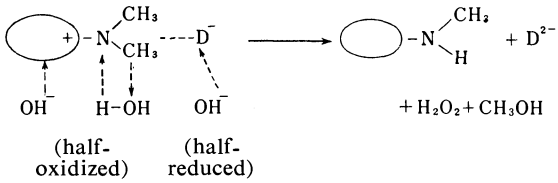
$$k_d+k_d'\approx 1.3\times 10^5\ sec^{-1}$$

$$ak_rk_r'\approx 4\times 10^{12}$$

The values of k_d+k_d' are consistent with the results of the flash experiment, which gives, for methylene blue in the buffer solution, $k_d\approx 10^5\ sec^{-1}$ and about a one order smaller value of k_d'. From the quantity of light absorption, one puts

$$aC=a\times 10^{-5}=\frac{4\times 10^{17}}{6\times 10^{23}}\phi_{S-T}$$

and so a may be approximately $7\times 10^{-2}\phi_{S-T}$ sec^{-1}. Therefore,



$$\phi_{S-T}k_rk_r'\approx 6\times 10^{13}$$

According to Oster, ϕ_{S-T} is ca. 0.21 for methylene blue; if one uses the same value, k_r and k_r' may be, respectively, of the order 10^{10} mol^{-1} l. and 10^4 sec^{-1}, as is to be expected. Thus, the above scheme, although it involves some processes which must be verified, can lead to the experimental rate formula. The most dubious point to be ascertained is the deactivation of both D^t and X by the ground state dye and by leuco dye, which takes place as an encounter-rate-determining process.

Putting together the above kinetic analysis and the fact that the quantities of demethylation and the photoreduction are about equal, irrespective of the experimental conditions, it seems natural to consider that, in the case of toluidine blue in a phosphate buffer, the triplet dye interacting with the ground state dye produces a transient species which consists perhaps of the half-oxidized and half-reduced form, that a part of the former is demethylated, and that a corresponding quantity of the latter goes to leuco dye. Thus, it may be said that the reduction is promoted by the coupling with demethylation. The scheme will hold more or less for the photoreduction of thiazine dyes in general. The transient electron transfer between the triplet dye and the ground state dye is somewhat similar to that which Lindqvist[6] proposed for the photoreduction of xanthene dyes on the basis of the flash experiments.

It is quite unknown how the formation of leuco dye and demethylation occur. The following is only to show one conceivable scheme.

Writing X as $D^+\cdots C^-$ (D^+ and D^- are, respectively, the half-oxidized and the half-reduced state):

Such a scheme seems to be reasonable since demethylation will afford some quantity of free energy, which will in turn make the decomposition of water energetically feasible; further, this is consistent with the well-known fact that demethylation easily occurs in the oxidative condition. If the transient electron transfer between the triplet dye and the ground state dye occurs generally in thiazine dyes, then one may suppose that some reducing agents, especially weak ones, will selectively attack the half-oxidized form. Therefore, the overall rate formula is expected to be approximately of the second order with regard to dye. From such a point of view, we have reexamined the data of the photoreduction of methylene blue by means of trimethylamine.[7]

It was found that the application of the simple second-order rate formula $-dC/dt=kC^2$ can satisfactorily reproduce most of the experimental results, at least in the initial stage, until 60% or more photoreduction proceeds. The later part deviates in most cases in the concave direction upward; this suggests the participation of the first-order reaction. Some examples are shown in Table VII.

As has been shown above, the second-order

6) L. Lindqvist, *Arkiv. för Kemi*, **16**, 79 (1960).

TABLE VII

Borate buffer pH=9.2
Trimethylamine 5×10^{-4} M

Exciting light	Concn. of MB($\times10^{-5}$)	$k\times10^{-4}$ l. mol^{-1} sec^{-1}	$kC_0\times10^2$ min^{-1}
λ=662 mμ	1.57	0.21	3.3
	1.20	0.38	4.55
	0.57	0.83	4.73
	0.28	1.58	4.43
λ=685 mμ	1.50	0.48	7.2
	1.17	0.63	7.25
	0.55	1.36	7.47
	0.30	2.40	7.2

rate constant in this case is inversely proportional to the initial concentration of dye. If one assumes that trimethylamine attacks the half oxidized component of X very effectively, then the mechanism can be written as follows:

Hence,

$$-\frac{dc}{dt}=\frac{ak_rC^2}{k_1C+k_d+k_2(C_0-C)}$$

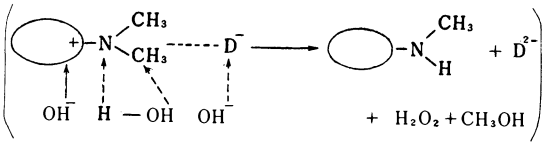
If one puts $k_1\approx k_2$ and $k_d\approx0$, then:

$$-\frac{dc}{dt}=\frac{ak_rC_2}{k_2C_0}$$

Thus, the above experimental results have been interpreted. It is to be added that no shift and, hence, no demethylation occurs in this case, and so there is less ambiguity in the kinetic treatment than in the case of toluidine blue in the phosphate buffer. One reason why Obata and Koizumi misinterpreted the results was that the second-order rate formula was very difficult to understand at that time. Of course, some reducing agents will attack D^t directly, and in such cases an overall rate formula will be simply proportional to the absorption of light. Further, it is expected that in some cases the two mechanisms will work simultaneously.

We are now reinvestigating various so-called reducing agents from this point of view. According to our preliminary experiments, EDTA is an example of a reducing agent which directly attacks the triplet dye, while allyl thiourea, ethanol, and trimethylamine belong to the other class.

Summary



Judging from the experiments performed in our laboratory, the photoreduction of dye without the addition of any reducing agent takes place only in thiazine dyes, and the reaction is particularly prominent when demethylation occurs simultaneously.

The reaction proceeds in the following way:

$$D + h\nu \rightarrow D^*$$

$$D^* \rightarrow D^t$$

$$D^t + D \rightarrow X \quad (X=D^-\cdots\cdots D^+)$$

The part in parentheses is still doubtful. The above conclusion is consistent with the results of the flash experiment which will be described in a following paper. It has been proposed that some reducing agents attack D^t directly, while others attack the half-oxidized state.

Appendix

When the photoreduction occurs in such a way that a part of half-oxidized state is demethylated and an equal quantity of the half-reduced form is fixed as a leuco dye, then some of the former will turn into leuco dye, while the same quantity of the latter returns to the oxidized dye. Such an interchange will decrease the rate to some extent. If one takes a special case where 1) demethylated dye is not photoreduced at all, and 2) the ratio of the oxidized form to the reduced form is exactly the same for the original dye and the demethylated dye, the rate formula will have to be modified to some extent.

Putting the concentration of the original dye, demethylated dye, as x_1, x_2, and that of each reduced form as y_1, y_2, all at time t, one can write:

$$x_1+x_2+y_1+y_2=C_0 \quad (1)$$

$$x_2=y_1 \quad (2)$$

and

$$\frac{y_1}{x_1}=\frac{y_2}{x_2}=\frac{y_2}{y_1}=K \quad (3)$$

Hence,

$$y_1=Kx_1,\ y_2=Ky_1=K^2x_1,\ x_2=Kx_1 \quad (4)$$

Suppose that the coupled reaction of leuco dye formation and demethylation (process i) obeys the following rate formula:

$$-\frac{dx_1}{dt}=f(x_1) \quad (5)$$

then, due to the oxidation-reduction equilibrium between the original and demethylated dye (process ii), the rate formula observed experimentally will be altered as follows: From 5, x_1 decreases during

Δt by $\Delta x_1 = f(x_1)\Delta t$, while x_2 and y_1 increase by $f(x_1)\Delta t/2$ during the same period. However, by process ii a certain portion of the increase of x_2 (oxidized demethylated) and y_1 (reduced methylated) turns into a reduced demethylated form (y_2) and into an oxidized methylated form (x_1). This quantity, $\Delta' x_1 = |-\Delta' x_2| = |-\Delta' y_1| = \Delta y_2$, can be calculated using relation 3 as follows, because Eq. 3 is considered to hold instantaneously:

$$\frac{x_2 + \frac{f(x_1)}{2}\Delta t - \Delta' x_1}{y_2 + \Delta' x_1} = \frac{x_1 - f(x_1)\Delta t + \Delta' x_1}{y_1 + \frac{f(x_1)}{2}\Delta t - \Delta' x_1}$$

From this, using relation 4,

$$f(x_1)\Delta t\left\{\frac{x_2+y_1}{2} + y_2\right\} = \Delta' x_1\{x_1+y_1+x_2+y_2\}$$

Thus,

$$\Delta' x_1 = \frac{2y_2+x_2+y_1}{2C_0} f(x_1)\Delta t$$

This is the amount which returns to the original dye during Δt due to the equilibration of the oxidized and reduced forms. Hence, the net rate of reaction is written as follows:

$$-\frac{dx_1}{dt} = \left\{1 - \frac{2y_2+x_2+y_1}{2C_0}\right\} f(x_1)$$

This can be rewritten as follows by means of relation 4:

$$-\frac{dx_1}{dt} = \left\{1 - \frac{K(K+1)x_1}{C_0}\right\} f(x_1) \qquad (6)$$

From Eqs. 1 and 4,

$$K = \sqrt{\frac{C_0}{x_1}} - 1$$

Therefore, Eqs. 6 becomes:

$$-\frac{dx_1}{dt} = \sqrt{\frac{x_1}{C_0}} f(x_1) \qquad (7)$$

Thus, in the above ideal case the resultant rate formula has the factor $\sqrt{x_1/C_0}$.

However, the above treatment concerns an ideal case under very specified conditions; in most cases it is believed that demethylated dye will also be photoreduced. It is believed that the correction term involved in Eq. 6 may be neglected and that the original rate formula will still hold approximately.

Studies of the Transient Intermediates in the Photoreduction of Methylene Blue

By Shunji KATO, Masaharu MORITA and Masao KOIZUMI

(Received August 14, 1963)

In the preceeding paper[1] some kinetic work has been reported on the photoreduction of thiazine dyes which proceeds in the absence of any reducing agent in the deaerated buffer solutions, especially in the phosphate buffer.

In connection with these, the photoreduction of methylene blue by means of trimethylamine as a reducing agent has been re-examined.

The most characteristic feature of these reactions is that the essential process in the reaction is the interaction of the excited state dye with the ground state dye, perhaps producing semiquinone and half-oxidized dye; it seems that this is rather more common than it was at first supposed to be.

Further investigations now under way in our laboratory show that the photoreduction of methylene blue by allylthiourea (ATU) and other mild reducing agents often obeys a similar rate formula; the only clear-cut exception that has ever been found is the photoreduction by EDTA, in which the rate formula is satisfactorily of the first order of dye.

In order to get more direct insight into the mechanism of such reactions, studies of the transient intermediates by the flash-technique have been undertaken. The aim of the present paper is to report on the general features and behavior of the transient intermediates observed in an aqueous solution of methylene blue. The transient spectra at various pH values, especially in borate and phosphate buffer and also in the solutions containing various reducing agents, such as trimethyl-amine (TMA), allylthiourea (ATU), EDTA and $K_4 \cdot [Fe(CN)_6]$, have been compared. The decays of the chief transient spectra has also been investigated.

Experimental

Materials. — *Methylene Blue.* — Merck's special grade sample was recrystallized four times from an

1) M. Koizumi, H Obata and S Hayashi, This Bulletin, 36, 108 (1964).

aqueous solution and dried in vacuo. The ε_{max} value in the aqueous solution was 72000. All the inorganic reagents were submitted to recrystallization or repeated distillation.

ATU.—Three recrystallizations from water.

EDTA. — A G. R. reagent was used without further purification.

The Preparation of the Sample Solution.—After it had been evacuated more than five times with freezing and thawing, the solution was poured into a reaction cell and was sealed. The experiments were performed at room temperature. The spectra before and after the flash experiment were taken by a Hitachi autorecording spectrophotometer or a Kotaki spectrophotometer. The concentration of dye was usually 0.5×10^{-5} M$\sim1.0\times10^{-5}$ M.

Apparatus. — Two quartz flash lamps filled with xenon were used for the photolysis. The electrode distance was 10 cm. The input energy was varied from 31.5 to 180J by changing the capacitance 10 μF$\sim$40μF and applied voltage, 2500$\sim$3000 V. Hoya O-54 filters were inserted between the light source and the reaction cell so as to cut off $<$540 mμ. A spectro-flash was worked at 10 μF and 3000 V. The time interval between the photolysis flash and the spectro-flash was controlled by a delay circuit in the range from 20 μsec. to 0.8 sec.

The half-width of the photolysis flash was about 40 μsec.

Transient spectra were taken on Fuji Neopan plates with a Shimadzu QF-60 quartz spectrograph.

In measuring the decays of the transient absorption spectra, the sample was irradiated by a xenon lamp (20 V., 7.2$\sim$8.0 amp.) instead of the spectro-flash used above, and the monitoring light beam at a fixed wavelength was received by a photomultiplier through a slit attached to the spectrograph. The signal was recorded with an Iwasaki synchroscope SS 5151 through a cathode follower.

The reaction cells were of Shibata SB glass tubes, 10 cm. long and 7 mm. in diameter, to both ends of which were cemented plane quartz plates. A shorter cell, 2.5 cm. long, was used in order to measure the transient decrease of the main absorption band of methylene blue.

Results

Transient and Permanent Bleaching by Flash Illumination. — In general, illumination by a flash causes transient bleaching to a large extent, the magnitude depending upon the intensity of the flash, but it produces only a rather small quantity of permanent bleaching unless no suitable reducing agent is present.

First the effect of the flash intensity upon the quantity of the transient bleaching in the plain aqueous solution and in the phosphate buffer solution will be described. The results were quite similar. At 125J the transient bleaching was almost complete, whereas at 31.5J a considerable quantity of the ground state dye remained. Figure 1 shows the results in the plain aqueous solution. In Fig. 1., $\Delta D'$ is the

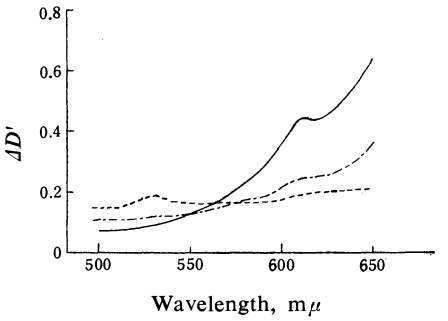

Fig. 1. The transient bleaching of the dye at different input energies.
——: Before flash, —·—·: 31J flash
----: 125J flash

difference in plate blackness between the sample and pure water, a difference which is proportional to the absorbance of the sample.

The quantity of the transient intermediate corresponds quite well to the above results, as is shown in Fig. 2. In this figure, and also in Figs. 3, 4, 5, 6, 7 and 8, ΔD is the difference in the blackness of two plates, one of which was measured at a given time after the photolysis flash and the other, about five minutes later.

This value is proportional to the absorbance of the transient species. The amount of permanent bleaching by one flash of 125J in the phosphate buffer was about 4%, while in the plain aqueous solution it was about 3%, the difference between the two solutions being rather small in comparison with that for the steady illumination. There is no doubt that most of the transient species returns to the ground state dye. About 10% of the dye was permanently bleached by six flashes in the case of the phosphate buffer (pH $\sim$8.12), while the introduction of air restored the color of the dye almost completely. There was no shift of the main peak, in contradiction to the results for the steady illumination.

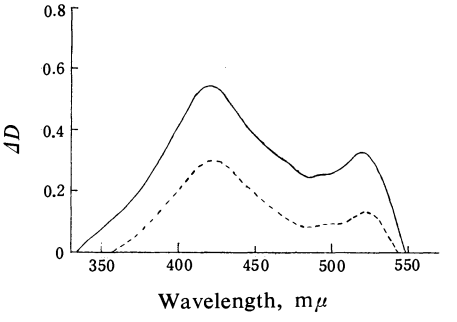

Fig. 2. The absorption spectra of transient species in a plain aqueous solution at different input energies.
——: 125J, ----: 31J

The addition of a 350-fold concentration of TMA (3.53×10^{-3} M) to the dye produced about a 40% permanent bleaching by one flash of 125J, but the quantity of bleaching per flash decreased for successive flashes. Along with the permanent bleaching, a new peak became apparent at 258~260 mμ. The introduction of air after almost complete bleaching led to a 100% recovery of the dye and the disappearance of the absorption in the ultraviolet region.

There was no shift of the main peak. Comparing these results with the ones in the steady illumination, the general features are quite similar, though there are some differences in details.

When the degassed 0.01 N hydrochloric acid solution of methylene blue was mixed with the degassed solution of ATU, the bleaching occurred even in the dark, and only a very little recovery of color was observed upon the introduction of air. The addition of a few drops of a 3% hydrogen peroxide solution and subsequent shaking restored the initial color. The above-mentioned decolorization did not occur appreciably when the solution was not acidic. Further studies by means of the steady illumination seem to be desirable.

By the addition of a 100-fold quantity of EDTA (10^{-3} M) to that of methylene blue, flash illumination brought about remarkable permanent bleaching, as was expected on the basis of the steady illumination results reported by Oster.[2] The quantity of bleaching per flash was larger in the phosphate buffer solution with a high pH than in the plain aqueous solution, the degree of permanent bleaching in the former reaching about 80%. The product with the absorption peak at 258 mμ is considered, without doubt, to be leuco dye, just as in the case of TMA. The introduction of air caused a 100% recovery of the dye. No shift of the main peak was observed in the course of either bleaching or recovery

Although the photoreduction of methylene blue by EDTA, ATU, and other mild reducing agents has been studied extensively by many workers,[3] including Oster,[2] using a steady illumination, the present results by flash illumination seem to require a reinvestigation by the steady illumination; this is now being undertaken in our laboratory from a somewhat different point of view.

Transient Spectra in the Absence of Any Reducing Agent. — All the transient spectra described below are those at 20 μsec. after the main flash and are for the energy input of 125J unless otherwise described.

In an acidic solution of 0.01 N hydrochloric acid the transient absorption spectra spread over 330~540 mμ, peaking at 375 mμ, as is shown in Fig. 3. Its lifetime is so short that it seems to survive only while the photolysis flash is still on; i. e., τ is estimated to be less than 30 μsec. These results agree quite well with those of Parker,[4] and there is scarcely any doubt that this transient species is the triplet dye.

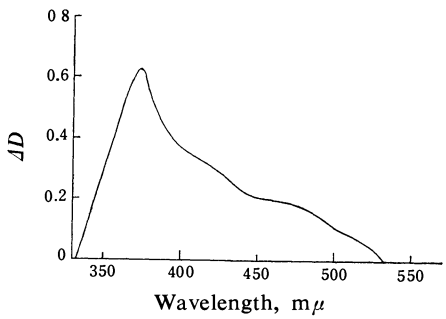

Fig. 3. The absorption spectrum of transient species in a 0.01 N HCl solution.

In the plain aqueous solution, the main absoption spectra spread from 340 to 550 mμ, with rather sharp peaks at 415 and 520 mμ, as is shown by the full line in Fig. 4. Besides, there is a weak transient absorption in ultraviolet, at 260~280 mμ and in the infrared region near 800 mμ. At 100 μsec., however, the shape of the spectra changes to some extent, as is shown by the broken line in Fig. 4. This implies that there are at least two transient species in the region near 415 mμ,

each with a different lifetime. The shorter one will most certainly be a triplet, but it is possible that even at 20 μsec., the spectra are still a superposition of the two. The transient spectra in a borate and in a phosphate buffer solution (pH 8.2) are quite similar to those in the plain aqueous solution, with two peaks at 415 and 520 mμ.

The fact that in a strong acidic solution a peak exists at 375 mμ, while at a higher pH ($\geqq$7) a peak shifts to 415 mμ, irrespective of the presence of buffering substances, strongly suggests the existence of an acid-base change in the transient species, almost certainly a change in the triplet dye. Hence, the systematic study of the dependence of the transient spectra on pH was made from pH=2.2 to 10.2. For lower pH values, sodium acetate-hydrochloric acid or only hydrochloric acid was used, while for higher pH values, the sodium acetate-sodium hydroxide system was used. As had been expected, the variation in the spectra is very regular, with a clear isosbestic point at 400 mμ.

Figure 5 gives the relation between the differences in the plate blackness, differences which are certainly proportional to the absorbance, and the pH at three wavelengths, 415, 375 and 400 mμ. From these results one gets pK=6.7.

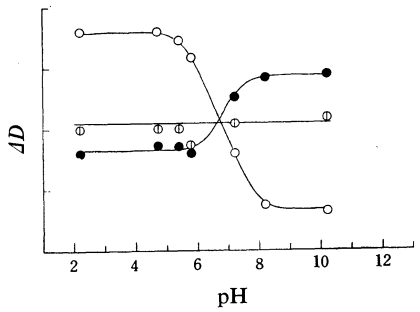

Fig. 5. The acid-base equilibrium of transient species. The change in the difference of plate blackness at various wavelengths, observed 20 μsec. after flashing, as a function of the pH value.

The Transient Spectra in the Presence of Some Reducing Agents.—The transient spectra of the solution containing a 350-fold concentration of TMA compared to that of dye are shown in Fig. 6. Broadly speaking, they are similar to those for the plain aqueous solution or for the buffered solutions, with the absorption in the 250~280 mμ region, with a peak at 260~263 mμ, and in the 340~540 mμ region, with two peaks at 415~420 mμ and at 520 mμ. A slight difference is that the height at 520 mμ is less prominent in comparison with that of a solution containing no amine. The

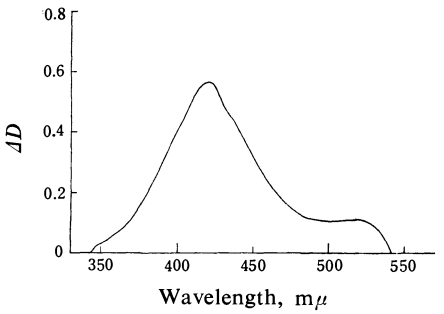

Fig. 6. The absorption spectrum of transient species in the plain aqueous solution containing 3.53×10^{-3} M TMA.

general features are also similar to those in a borate buffer solution (pH=8.2) to which TMA has been added, except that the 520 mμ peak is a little more prominent, all the spectra resembling those of the plain aqueous solution rather more.

The transient spectra of the solution to which ATU has been added are also similar to those of the plain aqueous solution of methylene blue, with two peaks at 415 and 520 mμ.

The addition of a 100-fold quantity of EDTA (1.0×10^{-3} M) to that of methylene blue causes a notable change in the transient spectra as compared with those of the plain aqueous solution. Thus, the peak at 520 mμ becomes less prominent and a shoulder appears near 370~380 mμ, although the other peak still exists at 415~420 mμ (Fig. 7). With 3000 times more EDTA than dye (dye, 1.3×10^{-5} M, EDTA, 4.0×10^{-2} M), the peak near 520 mμ completely disappears and the transient spectra extend from 340 to 475 mμ. Moreover, the shape of the spectra changes appreciably in the course of time, as is shown in Fig. 8. The curve is rather flat in the neighborhood of the maximum at 20 μsec., but at 200 μsec., two maxima, at 375 and 413 mμ, become apparent.

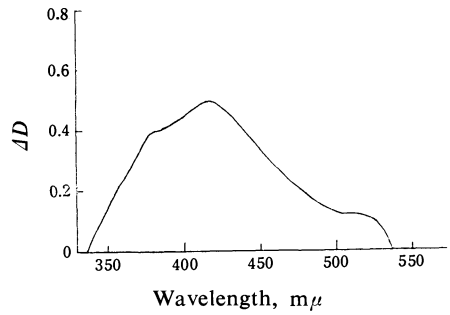

Fig. 7. The absorption spectrum of transient species in the plain aqueous solution containing 1.0×10^{-3} M EDTA.

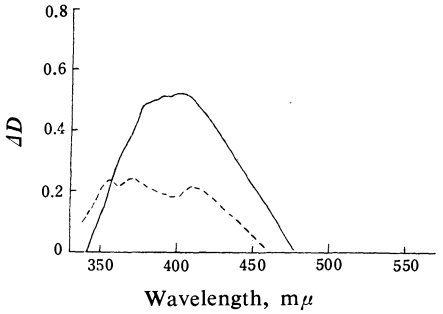

Fig. 8. The absorption spectra of transient species in the phosphate buffer solution (pH 8.1) containing 4.0×10^{-2} M EDTA.
——: 20 μsec. after flashing
----: 200 μsec. after flashing

When a concentration of $K_4[Fe(CN)_6]$ 50 times that of the dye is added to the plain aqueous solution of methylene blue, the transient spectra extend from 340 to 540 mμ, with a peak at 413 mμ. The peak at 520 mμ is completely lacking.

When leuco methylene blue (0.9×10^{-5} M) is added to the solution of methylene blue (1.5×10^{-5} M), the intensity at 415 mμ about doubles and the peak at 520 mμ is completely absent.

Lastly, when various amounts of oxygen are added to the solution, the transient absorption still appears in the 340~540 mμ region at 20 μsec.; on the other hand, at 100 μsec. the peak at 415 mμ declines remarkably, while quite a strong absorption is still existent in the ~520 mμ region.

Table I summarises the peaks of the transient spectra observed 20 μsec. after flashing in the visible region for various systems. s, m and w mean, respectively, that the intensity is strong, moderate and weak.

TABLE I

Solution	Peak

The Decay of the Transient Spectra.—In an 0.01 N hydrochloric acid acidic solution, the decay at 375 mμ obeyed the simple first order rate formula, giving a lifetime of about 30 μsec.

For the plain aqueous solution, the decays were examined at 415, 520 and 800 mμ. The initial part of the decay at 415 mμ obeyed the first order law approximately, giving a τ-value of 60~90 μsec. The same was true for the entire decay at 800 mμ, τ being 70~90 μsec. The approximate agreement of τ-values justifies the assignment of these two to the same transient species, most certainly to the triplet state. The latter part of the decay at 415 mμ showed a gradual deviation from the first order plot, but it seemed to fit another first order plot and a rough estimation gave a τ-value of about a few hundred μsec. The latter part of the decay at 520 mμ gave a τ-value of 200~260 μsec., roughly coinciding with the value for 415 mμ. Figure 9 shows a decay at 415 mμ.

It is very remarkable that the decay at 415 mμ for borate and phosphate buffer solution shows a clear hump at the earlier period as shown in Fig. 10. It is very difficult to express this decay curve analytically, but it is quite certain that the transient species survives longer than in the plain aqueous solution. It is to be noted that the above hump in the decay curve disappears when the energy input

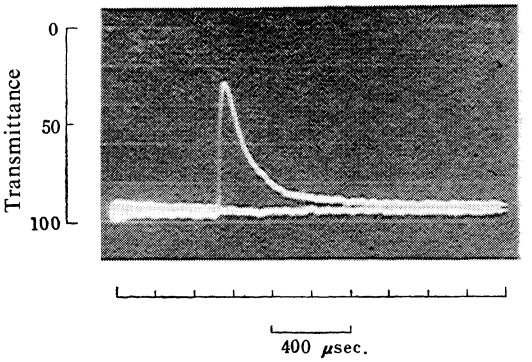

Fig. 9. The change in the transmittance at 415 mμ in the plain aqueous solution of 0.7×10^{-5} M methylene blue (input energy 125J).

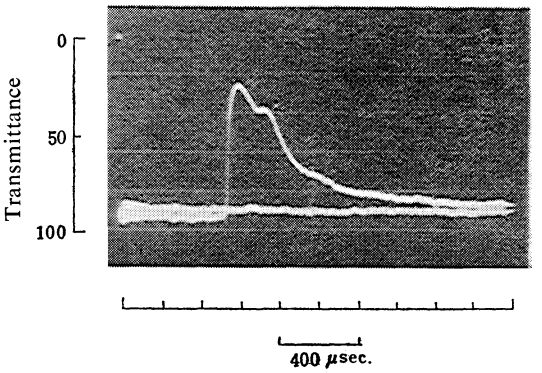

Fig. 10. The change in the transmittance at 415 mμ in the borate buffer solution (pH 8.2) of 0.7×10^{-5} M methylene blue (input energy 125J).

of the main flash is decreased to 31.5J. As has been mentioned before, almost all the dye turns into transient species at 125J, while at 31.5J more than half of the dye remains in the ground state. There is no doubt that the different results are due to these different situations (see Discussion).

The decay curve at 415 mμ when TMA or ATU was added displayed a small hump similar to that in the buffer solution.

Another notable finding is that the decay curve at 415 mμ when EDTA was added was simply monotonous. Although the entire decay curve did not obey the simple first order law, its earlier portion and the later one gave the lifetimes of the respective transient species, as respectively, about 170 μsec. and about 430 μsec.

Summarizing the results of the decay at 415 mμ, one can say that the decay is anomolous, with a hump in the early stage when there are two peaks at 415 and 520 mμ in the transient spectra, the only exception being the plain aqueous solution. On the other hand, the decay in question is simply monotonous when the peak at 520 mμ is low or is not present in the transient spectra.

When various amounts of oxygen were added to the solution, the decay at 520 mμ became slower with the increase in the oxygen concentration.

Discussion

Broadly speaking, the general features of the flash photobleaching correlate well with those of the steady-light photobleaching. Thus, in the evacuated state the bleaching is reversible; i. e., the introduction of air restores the color of the dye, indicating that the product is lecuo dye.

However, there are a few discrepancies which suggest that some different processes are occurring in the flash experiment. For example, n the presence of oxygen the bleaching is rreversible in the steady illumination, while n the case of a flash there is not any slight leaching observed, even by ten successive lashes. Further, the addition of amine to the hosphate buffer solution of methylene blue ncreases the steady-light bleaching more than enfold, while in the flash experiment the uantity of bleaching only doubles that in the bsence of amine, even when a large amount f amine is added.

There is scarcely any doubt that all the ansient spectra observed in the present investigation are due to some intermediates from ye in the photoreduction.

In the acidic solution there is only one intermediate, with a peak at 375 mμ with $\tau \approx$ 30 μsec. As has already been reported by Parker,[4] there is scarecely any doubt that this is due to the triplet state.

In the neutral solution quite different spectra than those of the acidic solution come into existence, and they show a rather complicated behavior. Thus in the plain aqueous solution, for example, the peaks at 415 and 520 mμ do not decline in a parallel way, the former declining a little faster at an early stage while at a later stage it seems that both decline at approximately the same rate. From the earlier part of the decay at 415 mμ, τ is estimated to be several ten μsec., while from the later part it is estimated as a few hundred μsec. Further, the decay curve at 415 mμ displays a notable anomaly in the phosphate and borate buffer and τ becomes a little longer.

From these facts there is no doubt that there are at least two transient species existing in this wavelength region. The one with the shorter τ may be a basic species of the triplet state. The effect of pH value on the transient spectra shown in Fig. 5 strongly supports this view. It seems worth mentioning that the pK-value obtained, pK=6.7, coincides with the sharp change in the rate of photoreduction observed by Oster[2] in steady-light photoreduction by EDTA.

However, it is questionable what kind of molecular change corresponds to this spectra change, because there is no corresponding different species existent in the ground state from pH $\approx$0 to pH $\approx$11. Although the acid-base property in the singlet excited state often differs from that in the ground state so greatly that the pK of the former is several units apart from that of the latter, there is no such difference in the triplet, according to Jackson and Porter.[5] Their results, however, are concerned with rather a limited group of compounds; it is possible that different types of substances behave differently. At any rate, we must in the future decide whether the 375 mμ band belongs to the protonated triplet bivalent cation and the 415 mμ band to the univalent cation, or whether the 375 mμ band is the univalent cation and the 415 mμ band a neutral molecule with OH^- attached, or whether quite a different interpretation must be made. Here, we would like to attribute tentatively the 375 and 415 mμ bands (with shorter τ) to two different species of the triplet. The fact that the transient species in the infrared region has τ=70~90 μsec., which is about equal to that of the earlier stage of

5) G. Jackson and G. Porter, *Proc. Roy. Soc.*, **260**, 13 (1961).

415 mμ absorption, also supports the triplet hypothesis.

As to the transient species which follow the triplet state, it is notable that there are two peaks, at 415 and 520 mμ, and that these transient spectra sometimes behave in a like manner, while in other cases they behave quite differently. Thus, when TMA or ATU is added, two peaks are observed, while when EDTA is added only the 415 mμ band appears; the 520 mμ band then becomes very weak or completely disappears. It is very natural, therfore, to consider that the two are produced by the same process in some cases but that only 415 mμ is produced in other cases and that the 415 mμ band is more intimately connected with the bleaching, because an effective reducing agent such as EDTA produces only this species.

In connection with this finding, it must be recalled that in the case of TMA and ATU, the rate formula for the steady illumination reaction closely approximates the second order law, while in case of EDTA the first order rate law holds.

From the above results it may be inferred that in the former case the excited dye (triplet, D^t), interacting with the ground state dye, D, produces semiquinone and a half-oxidized state, while in the latter case, the excited dye, by reacting with a reducing agent, produces only semiquinone. On this basis, the 415 and 520 mμ bands may be attributed respectively, to semiquinone and a half-oxidized state.

This hypothesis is further supported by the fact that the addition of leuco methylene blue greatly increases the peak at 415 mμ and completely eliminates the peak at 520 mμ. This implies that leuco dye, interacting with the triplet dye, produces semiquinone by the reaction $D^t + DH_2 \rightarrow DH + DH$ and that this occurs quite efficiently. It must be added here that the inhibiting action of leuco dye often referred to in the steady illumination experiment[1] is almost certainly due to such a reaction. The dehavior of the system containing oxygen also supports the above hypothesis. Thus, the finding that the absorbance by the existent oxygen at 415 mμ rapidly decreases while the decay at 520 mμ becomes slower is easy to understand if one considers that the former is a half-reduced form and the latter, a half-oxidized form.

It is well known that an analogous mechanism has been proposed by Lindqvist[6] for fluorescein on the basis of his extensive studies by the flash technique, but there have been no such examples reported since then.

As additional support for the above view, mention may be made of the features of the decay curves. The most conspicuous result is that in some cases a clear hump appears in the early stage of the decay. Such a phenomenon can be explained only if a certain transient species with a certain value of ε changes to another species with a negligible ε and is then transformed again into a third species with a rather large ε. The most plausible process satisfying the above conditions is considered to be the following one; the triplet dye with a certain value of ε goes back to the ground state, and the ground state dye thus produced, interacting with the remaining triplet dye, produces some new species with a larger ε. Thus D^t, at first, will perhaps go to the ground state by $D^t + D^t \rightarrow 2D$ or by a monomolecular process, but as the ground state dye accumulates, the $D^t + D \rightarrow 2D$ process will begin to make a greater contribution; accompanying this, the $D^t + D \rightarrow X(D^+ \cdots D^-)$ reaction will also occur. The later part of the above scheme is just the one proposed for the case when the second order rate formula is applied to the steady illumination experiment. Although exact analysis is very difficult, the conditions needed for the hump to appear may be something like the one described below.

Denoting a loosely-combined pair of semiquinone and a half-oxidized state as X and identifying the concentration of the triplet dye D^t, the ground state dye D, and X by, respectively, $[D^t]$, [D] and [X], the above scheme and the corresponding rate formulas may be written as follows, on the assumption that at $t=0$, $[D^t]_0 = a$, $[D]_0 = 0$, and $[X]_0 = 0$:

$D^t \rightarrow D$ k_1

$D^t + D \rightarrow 2D$ (deactivation) k_2

$D^t + D \rightarrow X$ (reaction) k_3

$X \rightarrow$ leuco dye or ground state dye k_4

$$-\frac{d[D^t]}{dt} = k_1[D^t] + k_2[D^t][D] + k_3[D^t][D]$$

$$\frac{d[D]}{dt} = k_1[D^t] + k_2[D^t][D] - k_3[D^t][D]$$

$$\frac{d[X]}{dt} = k_3[D^t][D] - k_4[X]$$

The absorbance of the system at 415 mμ [Ab] can then be given as follows if the molecular extinction coefficients of D^t, D, and X are, respectively, ε_1, $\varepsilon_2 = 0$ and ε_3:

$$[Ab] = l\{\varepsilon_1[D^t] + \varepsilon_3[X]\}$$

and

6) L. Lindqvist, *Arkiv för Kemi*, **16**, 79 (1960).

$$\frac{d[Ab]}{dt} = l\left\{\varepsilon_1\frac{d[D^t]}{dt} + \varepsilon_3\frac{d[X]}{dt}\right\}$$
$$= l\{-\varepsilon_1 k_1[D^t] - \varepsilon_1 k_2[D^t][D] - \varepsilon_1 k_3[D^t][D] + \varepsilon_3 k_3[D^t][D] - \varepsilon_3 k_4[X]\}$$

where l is the length of the reaction system.

At the earliest stage of the decay, $[D] \approx 0$; hence, $d[Ab]/dt < 0$, as is naturally expected.

For the hump to appear, $d[Ab]/dt > 0$ must hold in some region of the decay curve.

This requires

$$(\varepsilon_3 k_3 - \varepsilon_1 k_2 - \varepsilon_1 k_3)[D^t][D] > \varepsilon_1 k_1[D^t] + \varepsilon_3 k_4[X]$$

When X disappears very fast, a steady state condition may hold with regard to X and it will be possible to put $k_3[D^t][D]$ as approximately equal to $k_4[X]$. In this case the above condition never holds. However, if X is much more stable than D^t, then, by putting approximately $k_4 \approx 0$, the above conditions change as follows:

$$\varepsilon_3 > \varepsilon_1\left(\frac{k_2}{k_3} + \frac{k_1}{k_3[D]} + 1\right) \quad (1)$$

In fact, k_1 is $\sim 10^5\ sec^{-1}$, while k_4 may be put approximately as $\sim 10^3\ sec^{-1}$ from the later part of the decay curve. The situation is considered not to be very different from the above conditions. Provided that $k_1 \approx 10^5$, $k_2 \approx k_3 \approx 10^{10}$, and $[D] \approx 10^{-6}$ M, then (1) requires that $\varepsilon_3/\varepsilon_1 > 10$.

Thus it is expected in general that there are rather few chances for such a hump to appear, but it is not inconceivable. Borate and phosphate buffer solutions and solutions to which TMA or ATU has been added, are supposed to satisfy the above condition when the exciting light intensity is great enough. However, in the plain aqueous solution, in which X has a rather short lifetime, the condition would fail.

Further, when the intensity of the exciting light is small, the deactivation of X by the remaining ground state dye is large, as is expected from the steady illumination results, and so condition 1 can not hold again. In the case of EDTA, for which the rate formula is of the first order, D^t is directly reduced by EDTA, and so it is quite natural that the decay is simply monotonous.

To sum up, the results obtained in the flash experiments can be very satisfactorily correlated with the results obtained in the steady illumination experiments from the view point that the photoreduction of thiazine dyes in a neutral or an alkaline solution proceeds, in some cases, by a bimolecular process, $D^t + D \rightarrow D^- + D^+$ and, in other cases, by a direct electron transfer from the reducing agent to D^t.

It is to be hoped that more quantitative studies on the rate will be made and that the rate constant for each elementary reaction will be evaluated.

Summary

The intermediate species which are produced in the course of the photoreduction of methylene blue have been investigated by flash photolysis in plain aqueous, borate and phosphate buffer solutions with and without reducing agents. In an acidic solution, an absorption band with the lifetime of 30μsec. appears at 375 mμ, while in neutral and basic solutions, two bands appear, at 415 and 520 mμ, with lifetimes of 70~90 μsec. The bands at 375 and 415 mμ are considered to be due, respectively, to the acidic and basic forms of the triplet state, since the transient spectra change with pH, making an isosbestic point.

The band at 415 mμ is overlapped by another one with a lifetime longer by several hundred microseconds; this is presumed to be semiquinone. The intensity of the band at 520 mμ decreases upon the addition of reducing agents and increases upon the introduction of oxygen.

Hence, this band may be due to the half-oxidized form of the dye. These results support the reaction scheme that the excited state of the dye reacts with the ground state, which has been proposed in the investigation of steady light photobleaching.

*Entropy and Molecular Motion in the Condensed Phases of Tetrahedral Molecules**

By Hideaki CHIHARA and Takako SHINODA

(Received August 29, 1963)

Much attention has been paid to the molecular motion in a class of compounds which were named plastic crystals by Timmermans,[1] who illustrated that crystals composed of molecules more or less spherical in shape have small entropies of fusion (less than 5 e.u.) and exhibit plasticity below their melting point. Evidence has been accumulated by studies of X-ray diffraction, nuclear magnetic resonance, dielectric absorption, etc. to indicate that molecules in the plastic crystals are capable of rotational motion, if not completely free. Since the entropy is a measure of the degree of disorder, it will also give us some clue to the state of molecular motion in solids, a clue which would complement the deductions from other types of experiments.

Plastic crystals usually have a transition accompanying a large entropy change comparable to or greater than the entropy of fusion. The sum of the two entropies is close to what one expects from Walden's rule (13 e.u.).[2] This forms the basis of the interpretation that such crystals melt in two successive processes; the rotational degrees melt at the transition point, while the translational degrees melt at the triple point. However, this is an over-simplified model, as is evident from detailed studies. For example, the X-ray diffraction[3] of Si_2Me_6 indicates that the molecular axis is statistically oriented along one of the body-diagonals of the cubic unit cell; therefore, the disorder is not considered perfect. The nuclear magnetic resonance study of CMe_4 by Gutowsky et al.[4] found the potential barrier hindering molecular reorientation in the plastic phase (called phase I hereafter) to be 1.0 kcal./mol.; it also showed that the molecular rotation is not free. One should then be able to see some consequences of the hindrance of rotation in the thermodynamic quantities.

A comparison of the entropy of fusion of, say, face-centered cubic carbon tetrachloride (2.401 e.u.) with that of an inert gas solid (3.395 e.u. for argon) provides a clue to this problem. The fact that the fusion of argon requires a larger entropy change than does the fusion of carbon tetrachloride is just the contrary to what one would anticipate on the basis of the over-simplified model. The situation may conveniently be visualized in terms of diagrams of the degree of disorder in different phases; such diagrams are drawn in Fig. 1

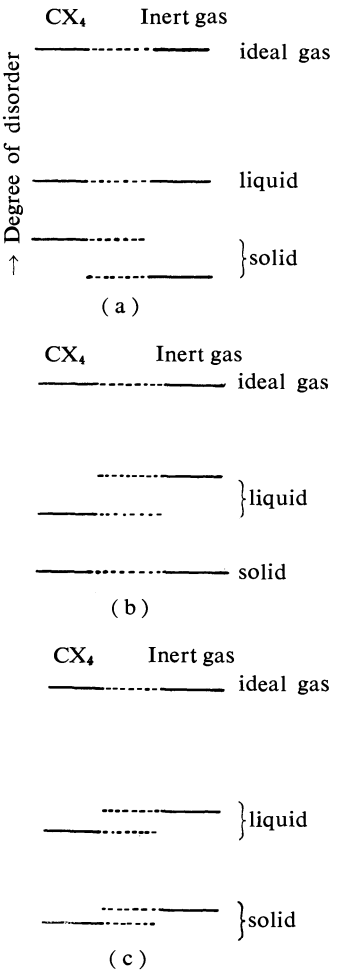

Fig. 1. A schematic representation of the degree of disorder in different phases of CX_4 type molecules and inert gases. (a) and (b) are extremely idealized situation, (c) is the actual situation.

* Presented before the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

on the analogy of the more familiar energy-level scheme. The fact that carbon tetrachloride has a smaller entropy of fusion than an average inert gas solid may be accounted for in two extreme ways: (a) carbon tetrachloride molecules would move more freely than argon in the solid state if fusion in general could remove all the positional and orientational constraints in the solid to give any liquid the same degree of disorder (see Fig. 1a), and (b) the motion of carbon tetrachloride molecules would be less free in the liquid if both carbon tetrachloride and argon possess the same degree of disorder in the solid just before they melt (Fig. 1b). Of course, there are other possibilities, such as an intermediate between those two extremes, in which both of the carbon tetrachloride "levels" are displaced with respect to the corresponding argon "levels". In what follows, the actual level scheme will be shown to correspond to the one given in Fig. 1c. It will also be shown that the displacement of the solid levels may be explained by the hindered rotation of carbon tetrachloride molecules in the solid and that the displacement of the liquid levels may be explained by a simple cluster model of the carbon tetrachloride liquid. Effective values of the hindering potential barriers were derived for carbon tetrafluoride, carbon tetrachloride and neopentane in connection with a consideration of the possible orientations of molecules in crystals.

The Entropy of Sublimation and Molecular Motion in Solid. — Let us take the state of ideal gases at the triple points as the state of perfect disorder; neither the solid nor the liquid state is by itself in general a state of a well-defined degree of order. The degree of disorder in a solid at the same temperature will then be quantitatively expressed by its entropy of sublimation at the triple points. Since we are interested in the difference in behavior between inert gas molecules (suffix 1) and tetrahedral molecules (suffix 2), we shall fix our attention upon the difference in the entropies of sublimation:

$$(\Delta S_2-\Delta S_1)^{S\to G}=(T_2{}^G-T_2{}^S+R_2{}^G-R_2{}^S)-(T_1{}^G-T_1{}^S) \quad (1)$$

where T and R are the entropies of the translational (including configurational) and the rotational degrees of freedom respectively, and where the superscripts G and S refer to the ideal gas at atmospheric pressure and at the solid states respectively. Here it has been assumed that the intramolecular contribution to the entropy remains unaltered in the process of the phase change involved. A rearrangement of Eq. 1 gives

$$R_2{}^G-R_2{}^S=(\Delta S_2-\Delta S_1)^{S\to G}+\{(T_1{}^G-T_1{}^S)-(T_2{}^G-T_2{}^S)\} \quad (2)$$

We now assume that the bracketed term on the right hand side may be disregarded if we choose a hypothetical inert gas whose molecular weight is the same as for the particular CX_4; in other words, we assume that the degree of disorder is the same with respect to the configuration and motion of the molecular centers of mass, the molecular masses and the crystal structures being identical.

Table I lists the thermochemical values*1 relevant to the present calculation. A value of $\Delta S_1{}^{S\to G}$ was read off Fig. 2 for an appropriate molecular weight. The $(R_2{}^G-R_2{}^S)$ value thus obtained can be interpreted in various ways. An obvious way is that the rotational motion of CX_4 molecules is restricted in the solid state. The motion could either be a reorientation or a hindered rotation.*2

TABLE I. TRIPLE POINTS AND ENTROPY CHANGES (e.u.) AT THE TRIPLE POINTS

	Triple point, °K	$\Delta S^{S\to L}$	$\Delta S^{L\to G}$	$\Delta S^{S\to G}$	Ref.
Ne	24.57	3.26	16.23	19.49	5
Ar	83.810	3.395	18.15	21.54	6,13
Kr	115.776	3.386	18.38	21.77	7,25

CCl_4	250.3	2.401	24.52	26.92	11
CMe_4	256.53	3.03	20.70	23.73	12

*1 The entropies of vaporization at the triple points were computed from literature values of the entropy of vaporization at the boiling point (or at 25°C) and of the heat capacities of liquid and ideal gases. The entropies were corrected for the non-ideality of the gas and for the work of expansion from the triple point pressure to the standard pressure. The value for carbon tetrabromide was not obtained because its liquid heat capacity is not completely known.

*2 It seems that there has been some confusion or an indiscriminate use of the terms, reorientation and hindered rotation; thus it would be appropriate to define the words here, at least for the present purposes. By hindered rotation, it is meant that the molecules can rotate in one or the other direction over potential barriers with an average total energy sufficient to surmount the barrier; the rotational energy level is, therefore, above the top of the hindering barrier, On the other hand, if the average total energy is numerically less than the hindering potential, the molecule will normally oscillate in the potential well, with only occasional go-over when the molecule has acquired greater energy through statistical fluctuation. This we call reorientation. The frequency of the reorientation depends on the temperature and on the height of the potential barrier.

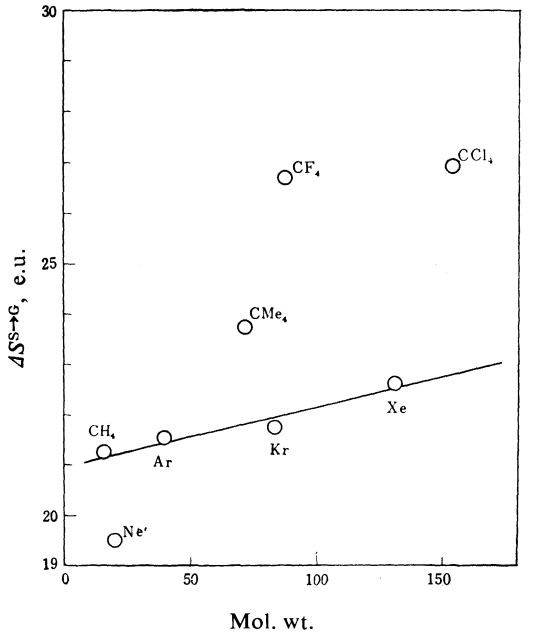

Fig. 2. Entropy of sublimation plotted versus molecular weight. A hypothetical inert gas of the same molecular weight is chosen to compare with a particular CX_4.

Our knowledge of the crystal structures of these compounds is not very complete. Their structure in the plastic phases is all face-centered cubic, at least with regard to the spatial arrangement of the center of gravity of the molecules; the one possible exception is carbon tetrafluoride, the structure of which is not yet known. It is reasonable, however, to assume that carbon tetrafluoride is isomorphous with carbon tetrachloride. The orientation of molecules in the lattice was not determined with certainty. For instance, the X-ray diffraction intensities from carbon tetrachloride[14] in its phase I can not be accounted for by a model of fixed molecular orientations, but they are appropriate to a model of rotating molecules even though the rotation is not perfectly free. For neopentane,[15] the temperature factor of the X-ray diffraction is so large that an almost free rotation of the molecules is suggested. The nuclear magnetic resonance experiments[16] (except carbon tetrachloride) give more direct information as to the mode of molecular motion in phase I (relative to X-ray studies), and it is strongly suggested that molecules are undergoing general rotation or three-dimensional reorientation (no distinction seems possible). Gutowsky[4] was able to derive the barrier height hindering the reorientation of the neopentane molecule as 1.0 kcal./mol. The crystal structure of phase II of these solids is even less well known. Mones and Post[15] reported that neopentane is weakly birefringent below the transition point and that it is probably tetragonal (close to cubic, however, $a_0=11.2$Å, $c_0=11.5$Å). It is generally agreed that methane is very close to cubic at lowest temperatures. Its zero-point configuration was studied by Nagamiya[17] and by James and Keenan[18]; the latter made a careful analysis of the stability of various orientations of molecules. Although James and Keenan's model for the structure of phase II of CD_4 is extremely idealized, their zero-point configuration is much more reliable*3 in the sense that it is the result of the self-consistent calculation of static lattice energy. We shall use this configuration as the basis of the present analysis.

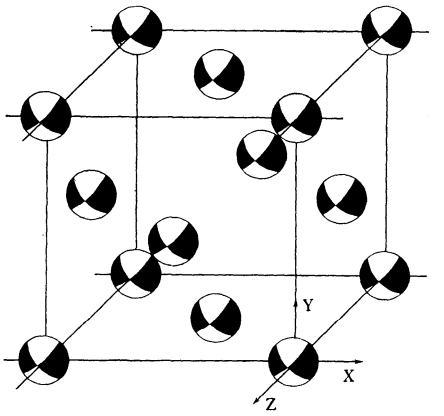

Fig. 3. Zero-point configuration of CD_4 crystal derived by James and Keenan, taken from Fig. 7 of Ref. 16. Black spots represent D atoms.

The James and Keenan structure for the phase III of CD_4 is reproduced from their paper in Fig. 3. We shall assume that this structure represents the features of the molecular orientational arrangement in all CX_4 molecules to be considered in this paper. In

CMe_4	18.33	28.3	3.8	1.3

the James and Keenan structure, the centers of the mass of molecules form a face-centerd lattice and one of the molecular C_2 axes is parallel with one of the crystallographic axes, while the others make an angle of 45° with two other crystallographic axes. The structure of the plastic phase is, of course, related to this zero-point configuration, the latter, however, being tetragonal rather than cubic. The structure of Fig. 3 can be rendered as a cubic symmetry, and, at the same time, as a rotational disorder if the plastic phase structure is assumed to be a hybrid of three such configurations in which crystal axes are permuted. As a first approximation, we shall assume that molecular rotation is a superposition of three independent plane rotations; the potential barrier hindering the rotation thus lies at 90° from the orientation of the minimum potential energy in three directions, in an adiabatic approximation in which the orientations of neighboring molecules are fixed. Such tetragonality disappears at the transition point in accordance with the excitation of the molecular rotational degrees of freedom or reorientation. A Similar consideration will apply to other CX_4 molecules.

i) Reorientation Mechanism.—First we will consider a model in which molecules reorient themselves in order that the crystal may possess the cubic symmetry. Molecules are in the state of harmonic libration (torsional oscillation) of frequency in potential minima and occasionally jump over the potential barrier. There are two distinguishable configurations*4 per molecule which contribute to the entropy R_2^S, which now becomes

$$R_2^S = 3R\,[x\exp(-x)/\{1-\exp(-x)\} - \ln\{1-\exp(-x)\}] + R\ln 2 \qquad (3)$$

where $x = h\nu/kT$

The values of ν and their corresponding potential barriers, V_0, were derived from $(R_2^G - R_2^S)$ by the use of Eq. 3 and $V = (1/2)V_0(1-\cos 2\theta)$ and are given in Table II. For methane, the $(R_2^G - R_2^S)$ is very close to zero, and, therefore, the molecules are rotating almost freely in phase I (at the triple point), in agreement with Staveley's analysis of the heat capacity.[20] There are no literature values available to compare with the ν and V_0 values derived here except for the ν of carbon tetrachloride in the low temperature phase, which was estimated to be 36.5~38 cm^{-1} by Gutowsky and McCall[21] from their measurements of chlorine nuclear quadrupole resonance frequencies as a function of temperature. The present value of 24.8 cm^{-1} for carbon tetrachloride is not unreasonable for the high temperature phase.

ii) Hindered Rotation Mechanism. — If one assumes the superposition of three plane rotators of CX_4 molecules in a solid in a potential field of the type

$$V = (1/2)V_0(1-\cos 2\theta) \qquad (4)$$

which is equivalent to assuming the rotation around the two-fold axes of a molecule, its contribution, R_2^S, to the entropy can be calculated by the help of Pitzer's table.[22] The values of the hindering potential, V_0, which correspond to the $(R_2^G - R_2^S)$ values for three degrees of freedom of rotation, are listed in Table II.

For the three compounds, carbon tetrafluoride, carbon tetrachloride and neopentane, the potential barrier in the reorientation mechanism is, as we have seen in Table II, comparable in magnitude with the heat of sublimation (2.4, 6.7 and 6.1 kcal./mol., respectively), and it is larger than the barrier for the hindered rotation mechanism by a factor of about three. Therefore, we consider that mechanism ii), the hindered rotation mechanism, is the more likely one. There is another reason for believing so: a consideration of the nuclear magnetic resonance of carbon tetrafluoride. Aston and others[16] showed that the

*4 Starting with the zero-point configuration, in which two of the diad axes of neighbor molecules make an angle of 45° with, say, the b and c axes of the lattice, a central molecule has two distinguishable orientations. The cubic symmetry of the crystal lattice is then acquired if the neighbor molecules take three different orientations wihch are obtained by the permutation of the crystal axes, a, b, and c. The original zero-point configuration, therefore, appears at the probability of 1/3, and there are three permutations of the crystal axes. The total number of distinguishable configurations will thus be $(2\times 1/3\times 3)^N = 2^N$.

22) K. S. Pitzer, "Quantum Chemistry," Constable and Company, Ltd., London (1953), p. 498.

rigid lattice width of the fluorine resonance absorption in carbon tetrafluoride is about 12 gauss, which narrows in two distinct steps, at 55~65°K and at the transition point. They suggested, on the basis of their calculation of second moments, that carbon tetrafluoride molecules begin to rotate first around their two-fold axis at about 55°K and then rotate about all axes at higher temperatures. Now it is of some interest to examine what consequences in the nuclear resonance may be anticipated if we apply the familiar equation of the absolute reaction rate theory[23]

$$\nu \approx (kT/h) \exp(-V_0/kT) \tag{5}$$

to derive the frequency at which the molecules would jump over the potential barrier, V_0. The substitution of $V_0=3.4$ kcal./mol. and $T=89.47$°K leads to $\nu \doteqdot 9.2\times10^3\ \mathrm{sec}^{-1}$. This value of ν indicates that the motional narrowing will not occur until higher temperatures (97°K) because the rigid lattice width, 12 gauss, corresponds to $4.8\times10^4\ \mathrm{sec}^{-1}$ for the fluorine nucleus[24]. On the other hand, $V_0=1.0$ kcal./mol. gives $\nu \approx 7\times10^{10}\ \mathrm{sec}^{-1}$, which is sufficiently rapid to cause motional narrowing; the narrowing would occur at 30°K if the same potential barrier height persisted at such a temperature.

The fore-going analysis gives support to the view that the rotation of tetrahedral molecules in their plastic phase is not free, except possibly in the case of methane.

A Model for Liquid Carbon Tetrachloride at Its Triple Point

It remains to be examined how the displacement (in Fig. 1c) of the "level" of carbon tetrachloride with respect to the inert gas liquid "level" can be explained. The model we will now present is perhaps one of the simplest, but yet, we hope, it represents the feature of the structure of liquid at the triple point. We shall here consider carbon tetrachloride as an example.

It may be assumed that liquid carbon tetrachloride consists of clusters (embryos of crystallites), each containing n molecules, and that the arrangement and motion of the centers of mass of clusters are in the same degree of disorder as in an inert gas liquid. The molar entropy of liquid carbon tetrachloride will, then, be

$$S_2^{\mathrm{L}} = \frac{1}{n}(T_2+R_2+C_2)_{\mathrm{cluster}} + \frac{1}{n}(3n-6)s_l + R_2^{\mathrm{L}} + I_2 \tag{6}$$

where C_2 is the configurational entropy, s_l is the internal entropy (per degree of freedom) of a mole of clusters, R_2 is the molar entropy of molecular rotation, and I_2 is the intramolecular contribution to the entropy. The rotational modes of clusters related to R_2 (cluster) are nearly equivalent to a mode of intra-cluster vibration at the limit of a long wavelength and may, therefore, be approximated by additional degrees for intra-cluster modes:

$$S_2^{\mathrm{L}} = \frac{1}{n}(T_2+C_2)_{\mathrm{cluster}} + \frac{1}{n}(3n-3)s_l + R_2^{\mathrm{L}} + I_2 \tag{7}$$

The entropy of vaporization at the triple point is given by

$$\Delta S_2^{\mathrm{L}\to\mathrm{G}} = (T_2^{\mathrm{G}}+R_2^{\mathrm{G}}) - \frac{1}{n}(T_2+C_2)_{\mathrm{cluster}} - \frac{1}{n}(3n-3)s_l - R_2^{\mathrm{L}} \tag{8}$$

The corresponding expression for an inert gas is

$$\Delta S_1^{\mathrm{L}\to\mathrm{G}} = T_1^{\mathrm{G}} - (T_1^{\mathrm{L}}+C_1^{\mathrm{L}}) \tag{9}$$

Now, if we adopt the free volume model for the liquid,

$$T_1^{\mathrm{L}}+C_1^{\mathrm{L}} = R\left(-\ln N + \frac{5}{2} + \ln N\omega_1 + \frac{3}{2}\ln(2\pi mk/h^2) + \frac{3}{2}\ln t_1\right) \tag{10}$$

and

$$\frac{1}{n}(T_2+C_2) = \frac{R}{n}\left\{-\ln(N/n) + \frac{5}{2} + \ln(N\omega_2/n) + \frac{3}{2}\ln(2\pi mnk/h^2) + \frac{3}{2}\ln t_2\right\} \tag{11}$$

where a hypothetical inert gas was chosen so that it would have the same molecular mass, m, as carbon tetrachloride. The triple point, t_1, is also a hypothetical temperature for this value of m and was determined from a plot of the triple point temperature vs. the molecular weight. In the absence of a better alternative, an assumption, $n\omega_1=\omega_2$, was made concerning the free volumes, ω_1 and ω_2. Cancelling common terms between Eq. 10 and Eq. 11, we obtain, from Eqs. 8 and 9:

$$\Delta S_2^{\mathrm{L}\to\mathrm{G}} = (T_2^{\mathrm{G}}+R_2^{\mathrm{G}}) - \frac{1}{n}\left[(T_1^{\mathrm{G}} - \Delta S_1^{\mathrm{L}\to\mathrm{G}}) - \frac{3R}{2}\ln t_1 + \frac{3R}{2}\ln t_2 + \frac{5R}{2}\ln n\right] - \frac{1}{n}(3n-3)s_l - R_2^{\mathrm{L}} \tag{12}$$

23) S. Glasstone, K. J. Laidler and H. Eyring, "The Theory of Rate Processes." Princeton University Press (1941), Chapter IV.

24) E. R. Andrew, "Nuclear Magnetic Resonance," Cambridge University Press (1955), p. 167.

The intra-cluster entropy, s_l, may be approximated by the translational lattice entropy of solid T_2^S:

$$3s_l = T_2^S = T_2^G + R_2^G - R_2^S - \Delta S_2^{S\to G} \quad (13)$$

Finally, the estimation of R_2^L was made comparing the potential barriers hindering molecular rotation in a liquid with that in a solid at the triple point. The difference in the potential barrier arises from the difference in the average intermolecular distances (6.0Å in liquid and 5.897Å in solid). A good approximation to that part of intermolecular interaction which depends on the relative spatial orientation of molecules would be to use an effective cube octupole to represent a carbon tetrachloride molecule, thus taking into account the electric charge distribution and, to some extent, the shape of the molecule or the steric effect, because molecular dipole and quadrupole moments vanish by virtue of the tetrahedral symmetry of the molecules. The dispersion energy also depends on the relative molecular orientation and, therefore, contributes to the potential barrier; however, we shall incorporate the non-spherical part of the dispersion interaction into the effective octupole moment. Such interaction leads to the relation:

$$V_0(\text{liquid})/V_0(\text{solid}) = \{r(\text{solid})/r(\text{liquid})\}^7 \quad (14)$$

and the hindering potential barrier in liquid carbon tetrachloride at the triple point is found to be 2.1 kcal./mol. This value of V_0 gives R_2^L through the help of Pitzer's table.

The substitution of numerical values ($t_1 = 180°K$, $T_2^G = 40.13$ e.u., $R_2^G = 23.09$ e.u., $R_2^L = 19.42$ e.u., the other values have been taken from Tables I and II) into Eq. 12 gives, for the calculated entropy of vaporization of carbon tetrachloride at its triple point, t_2:

$$\Delta S_2^{L\to G} = 25.25 \text{ e.u.}$$

if one assesses on n the number 13, the number of nearest neighbor molecules in addition to the one at the center. This value, 25.25 e.u., is in excellent agreement with the observed value, 24.52 e.u.

Discussion

It has been suggested in the preceding sections that the small entropies of fusion of CX_4 molecules are the consequences of two effects combined; i. e. in the solid state the molecules are in the state of hindered rotation, and thus they possess a smaller degree of disorder than in an average inert gas solid, while in the liquid state they have still smaller degree of disorder than inert gas liquids. Thus, Fig. 1c shows what the actual situation looks like: both solid and liquid levels of CX_4 are lower than the corresponding levels of an inert gas in such a manner that the separation between the solid and liquid levels of CX_4 is smaller than that for inert gas. The interpretation that has been put forward in the present paper is based on the use of inert gases as the reference substance with which to compare tetrahedral molecules in regard to their behavior in condensed phases. Such a method of comparison is particularly useful because some of the properties of condensed phases are difficult to calculate from first principles. Thus, a straightforward calculation of the thermodynamic properties of liquids in terms of molecular distribution functions is a formidable task except for monatomic liquids. Also, the configurational entropy of a liquid can be estimated only to a certain limit, even in model theories. In the present treatment, such terms have been crossed out by similar terms for inert gases, and this is considered to be a major reason for the good agreement between the observed and calculated entropies of vaporization of carbon tetrachloride. Although the so-called free volume model was adopted for the liquid, the approximation imposed by the model was largely eliminated by virtue of the nature of the method of comparison. The present model of the liquid carbon tetrachloride is, of course, a statistical one. The clusters are constantly being formed and demolished. The number 13 for n should also be regarded as an average value.

One thing that has not been considered here is the effect of vacancy formation and self-diffusion in the solid at high temperatures. In the cases of argon and krypton, the measurements of heat capacity near the triple point were used to derive the equilibrium concentration of Schottky vacancies in the solid, which amounted to 2~3% at the triple points[25,26]. The contribution of the vacancy formation to the entropy would, however, be small even if there were no lattice relaxation; the difference between an inert gas and CX_4 solids would then be by far smaller. Self-diffusion in the solid will acquire an entropy of R if it is fully excited. The calculation of the entropy of diffusion in the intermediate state is not easy; here again there is a definite merit in the comparison method.

It is interesting to note that the potential barrier height hindering molecular rotation is

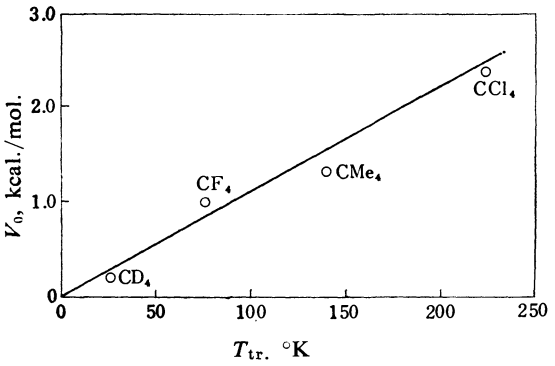

Fig. 4. Relation between the potential barrier hindering molecular rotation and the transition point.

related to the transition temperature in the solid, as is shown in Fig. 4. The point for CD_4 given by James and Keenan is also included in the figure. The points lie on a straight line which passes through the origin. While the entropy of fusion becomes larger in the order CF_4, CCl_4, CD_4 and CMe_4, the transition point becomes higher in the order CD_4, CF_4, CMe_4 and CCl_4, and so does the hindering potential. It is believed that such a linear relation between V_0 and the transition temperature justifies the treatment of a solid developed in the present paper. The apparently irregular order of the entropies of fusion has thus been straightened out.

Summary

By a comparison of the entropies of sublimation at the triple points of carbon tetrafluoride, carbon tetrachloride and neopentane with those of inert gas solids, it has been shown that these molecules are in the state of hindered rotation rather than of reorientation in the solid at the respective triple points, with heights of the potential barrier of 1.0, 2.4 and 1.3 kcal./mol. respectively. The hindering potential has been shown to be proportional to the transition temperatures of these solids.

A simple model for the structure of liquid carbon tetrachloride has been presented to account for its entropy of vaporization; the model consists in assuming nearest neighbor crystallite embryos in the liquid.

The authors are grateful to Professor Isamu Nitta of Kwansei Gakuin University, and to Professor Syûzô Seki and Dr. Hiroshi Suga of Osaka University for discussing the models with us.

SHORT COMMUNICATION

The Polymerization of 1, 1-Dichloro-2-vinylcyclopropane

By Takako TAKAHASHI, Iwao YAMASHITA and Takaharu MIYAKAWA

(Received October 21, 1963)

The ring-opening polymerization of cyclopropane derivatives has attracted keen interest recently. However, only a few reports that the oligomers of cyclopropane[1] and alkyl- or aryl-cyclopropanes[2] have been obtained have appeared. We have studied the polymerization of 1, 1-dichloro-2-vinylcyclopropane (I).

The compound I was prepared by the method of Woodworth and Skell.[3] We carried out bulk or solution polymerization in a nitrogen atmosphere with a sealed tube. I failed to polymerize when such usual ionic catalysts as $BF_3 \cdot (C_2H_5)_2O$, $AlCl_3$, $TiCl_4$, Et_3Al-$TiCl_4$ and Na (in liq. NH_3) were used, although in some

* Measured by the cryoscopic method in benzene.

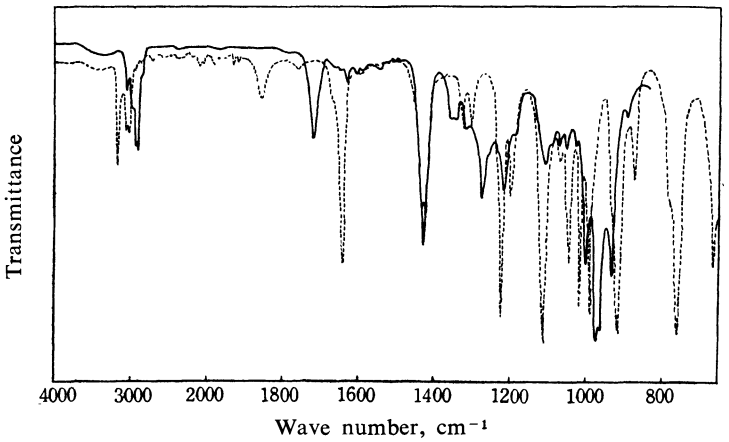

Fig. 1. Infrared spectra: (a) solid line, polymer obtained by benzoyl peroxide in CCl_4 paste; (b) dotted line, 1, 1-dichloro-2-vinylcyclopropane.

cases a trace of a solid product was obtained. When, however, benzoyl peroxide or α, α'-azobisisobutyronitrile was used as a catalyst, a polymeric product was obtained. For instance, when the bulk polymerization of I was carried out by benzoyl peroxide (5% wt.) for 40 hr. at 80°C, a crude polymer (with an average molecular weight* of about 1000) was obtained in a 36% yield. The curde polymer was dissolved in benzene, purified by pouring the solution into a large excess of methanol, and dried in vacuo. The purified polymer was powdery white, it melted at 70°C, its molecular weight* was about 7000, and its reduced viscocity was 0.025 (measured on a solution of 0.037 g. of polymer in 100 ml. of benzene at 30°C).

The chlorine content of the polymer (48.18 %) was found to be comparable with that of the monomer (calcd. 51.76%). Therefore, almost no dehydrochlorination or dechlorination took place in the polymerization process. The near-infrared spectrum of the polymer had no absorption band at 1.63 μ that might be assigned to the 1, 1-dichlorocyclopropane ring. The infrared spectra of I and the polymer obtained by benzoyl peroxide are shown in Fig. 1. In the spectrum of the polymer, the absorption bands of the cyclopropane ring (1020 cm^{-1}) and of the end vinyl group (990 cm^{-1}, 910 cm^{-1}) almost disappeared and that of the trans-double bond (965 cm^{-1}) was observed. Three peaks, 1720 cm^{-1}, 1270 cm^{-1}, and 1110 cm^{-1}, might be due to those of the benzoate group, which is an initiator fragment attached to the polymer's end. The presence of this end group was confirmed by the fact that, in the infrared spectrum of the hydrolysis product of the polymer, these absorption bands were absent. The polymer obtained by the use of α, α'-azobisisobutyronitrile had the absorption band of the immonium group (1800 cm^{-1}) in place of that of the benzoate group.

The infrared spectrum of unreacted monomer was in agreement with that of I.

On the other hand, 1, 1-dichloro-2-ethylcyclopropane gave no polymer when radical catalysts were used.

These facts might suggest that the polymerization of I mainly occurs by opening both the double bond and the cyclopropane ring, as is shown in the following scheme. This scheme is similar to those that have been proposed for the 1, 4-polymerization of conjugated dienes.

$$CH_2{=}CH\text{-}\overset{2}{C}H\text{—}\overset{3}{C}H_2 \rightarrow$$
$$\qquad\qquad\quad \diagdown\overset{1}{C}Cl_2$$
(I)

Effect of Solvation on the Menschutkin Reaction in Liquid Sulfur Dioxide[1,2]

By Niichiro TOKURA and Yasuhiko KONDO

(Received July 8, 1963)

When the Menschutkin reaction in liquid sulfur dioxide was recently carried out,[2] it was indicated that the reaction in liquid sulfur dioxide is extremely slow compared to that in such nucleophilic dipolar solvents as dimethylformamide or dimethylsulfoxide. In the light of the facts that liquid sulfur dioxide is one of the best ionizing solvents[3] and that the product is an ion-pair (alkylammonium cation and halide anion), and judging from extensive previously-reported discussions,[4] the Menschutkin reaction should be very fast in liquid sulfur dioxide. The reasons for such a discrepancy perhaps lie both in the strong solvation of the solvent (liquid sulfur dioxide) to amines and the fact that the rate-determining step of the reaction may be the step of attack by the base on the alkyl halide.

In contrast to the cationic polymerization and the Beckmann rearrangement in liquid sulfur dioxide, which are very fast and in which unsolvated carbonium ions are favored,[2] the Menschutkin reaction is one of the reactions in which the unsolvated base (or anion) is favored. In both cases, the unsolvated or *bare* species (ion or substrate) is a predominating factor in carrying out the reactions rapidly. That a borderline case between S_N1 and S_N2 reactions has been observed by Ingold[5] in a substitution in liquid sulfur dioxide which would otherwise be an S_N1 reaction is to be understood as the result of the fact that the rate-determining ionization of alkyl halide is not followed by the fast step of the combination of alkyl carbonium ion with an anion or a base, since the base or the anion is solvated by sulfur dioxide and since the second step is also occasionally a slow step.

The organic reaction in a solution is a reaction of polymolecularity in the sense that the solvent molecule always has some interaction during the course of the reaction, as has already been pointed out by Winstein[6] and Ingold[6b]. In the present paper, the reaction of methyl iodide with *N, N*-dimethylaniline, pyridine, triethylamine, *N, N*-dimethylbenzylamine or their *o*-methyl-substituted derivatives has been undertaken in order to further elucidate the effect of the solvation of liquid sulfur dioxide on the bases as compared with that of nitrobenzene or methanol.

Experimental

Materials. — Methyl iodide was washed with a sodium thiosulfate solution, water, a sodium carbonate solution and water successively, then dried and distilled; b. p. 42.5~43°C. *N, N*-Dimethyl-*o*-toluidine was synthesized from *o*-toluidine-bromohydrate and methanol at 145~150°C,[7] and the twice-distilled product boiling at 181~182°C was used. *N, N*-Dimethylaniline and triethylamine were refluxed with acetic anhydride and distilled respectively. The bases were dried over potassium hydroxide and redistilled; b. p., *N, N*-dimethylaniline; 189°C, and triethylamine; 89.5~90.1°C. Pyridine was dried with potassium hydroxide and barium oxide successively and distilled; b. p. 115.5°C. *N, N*-Dimethylbenzylamine was dried over potassium hydroxide and distilled; b. p. 177~177.5°C. α-Picoline and 2,6-dimethylpyridine were purified as the following; a double salt from the base, hydrochloric acid and mercuric chloride was recrystallized three times from a dilute hydrochloric acid solution and decomposed with a sodium hydroxide solution. The product was extracted with benzene, dried with potassium hydroxide and barium oxide successively, and distilled; α-picoline; b. p. 129~131°C, and 2,6-dimethylpyridine; b. p. 143.0~143.1°C. Liquid sulfur dioxide was dried with phosphorus pentoxide and distilled. Nitrobenzene and methanol were purified by known methods.

Kinetic Procedure. — The method described in a preceding paper[2] was used. A potentiometric titration was used to estimate the amount of iodide anions produced.

Results and Discussion

The Kinetical Order of the Reaction.—Methyl iodide was used as the alkyl halide since it is believed to be ionizable only with difficulty, since the reaction may thus be conveniently carried out by a S_N2 mechanism, and since it has the least steric hindrance to a coupling with the nitrogen atom of the amines. However, as may be seen in Table I, the kinetical order of the reaction (methyl iodide with pyridine) varied from second order to first order as the molar ratio, [base]/[halide], exceeded unity. When the base was used excessively against the halide, the reaction rate followed the first order rate law, the first order in methyl iodide, and the zero-th order in pyridine.

These phenomena are reported to be often encountered in cases wherein a one-to-one intermediate complex is formed reversibly in a reaction course.[8] In the reaction of methyl iodide and pyridine, the intermediate may be,

Pyridine···Me···I

The formation of such an intermediate is consistent with the experimental fact that the

	$\Delta S^{\ddagger}$	−10.3	—	−26.5

* $\Delta E^{\ddagger}$, kcal. mol^{-1}, $\Delta S^{\ddagger}$, e. u.

ionizing power of the solvent has little influence on the reaction rate.[2] Therefore, the reaction rates were followed in the range of the molar ratio, in which the second order rate law was dominating, and in the initial stage of the reaction. A typical run with triethylamine is shown in Fig. 1.

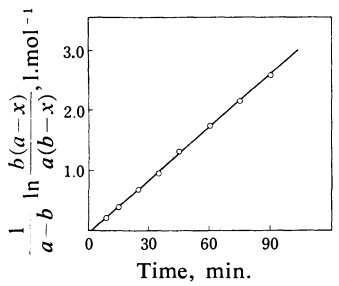

Fig. 1. A typical run in liquid sulfur dioxide. Temp. 60°C, triethylamine: 0.431 mol.l^{-1}, methyl iodide: 0.301 mol.l^{-1}

The Effect of Bases on the Reaction Velocity.—The results are indicated in Tables II and III.

In general, the rate of the Menschutkin reaction is in the order.

nitrobenzene > methanol > liquid sulfur dioxide

in liquid sulfur dioxide, however, the rate is slower than in methanol or in nitrobenzene. In nitrobenzene, the order of the relative rates of the bases is dependent upon the K_b values of the respective bases:

N, *N*-dimethylbenzylamine > triethylamine > pyridine > *N*, *N*-dimethylaniline

and in methanol, the order is:

N, *N*-dimethylbenzylamine > triethylamine > *N*, *N*-dimethylaniline > pyridine

whereas in liquid sulfur dioxide, the order is reversed:

pyridine > triethylamine > *N*, *N*-dimethylaniline > *N*, *N*-dimethylbenzylamine

Moreover, the difference in the relative rates is small (in the range of 0.34~5.18) in liquid sulfur dioxide, whereas in nitrobenzene the relative rates are scattered throughout the 1~338 range and in methanol, the 1~29.8 range. Thus in liquid sulfur dioxide the rate constants are leveling, while in nitrobenzene they are differentiating. A comparison of the Arrhenius parameters is givin in Table IV.

As may be seen in Table IV, both the energy and the entropy of the activation are larger in liquid sulfur dioxide. The entropy of the activation of triethylamine is the largest (−7.5 e. u.). This is very consistent with the very small value of the dissociation constant, (0.007 in benzene[13]) of the triethylamine-sulfur dioxide complex and suggests the effect of sulfur dioxide solvation on the reaction velocity. The release of the solvated sulfur dioxide may be necessary in the reaction sequences. The inverse order of the relative rates in liquid sulfur dioxide may perhaps be ascribed to the following reasons. First, in sulfur dioxide, the stronger the bases, the more will be the solvation by sulfur dioxide molecules; thus, the attacking rate may be modified according to their strength as bases. The dissociation constant of the pyridine-sulfur dioxide complex is as large as 4.0[13] (571 times that of the triethylamine-sulfur dioxide complex), while the K_b values also reflect the above relation. In methanol the hydrogen bonding may be operative, and in nitrobenzene some interaction with the bases may be considered; however, these solvents are less solvating to the bases than is liquid sulfur dioxide.

Effect of *o*-Methyl Substituents.—An intimate relation between the rate and the solvation has been further clarified by study of the ortho-substituent effect. The effect of the *o*-methyl substituent of *N*, *N*-dimethylaniline or pyridine on the reaction rate has been examined in liquid sulfur dioxide and has been compared

	$\Delta S^{\ddagger}$, e. u.	−31.9		−16.1	

with that in methanol (cf. Tables V, VI and VII).

A dramatical difference is observed in the ortho-effect between the rates in liquid sulfur dioxide and in methanol. As may be seen in Table VI, $k_{o\text{-Me}}/k_H$ is the ratio of the rate constants of the *o*-methyl-substituted and the unsubstituted bases. In liquid sulfur dioxide, the ratios are 0.346 (*N*, *N*-dimethyl-*o*-toluidine), 0.988 (α-picoline) and 0.696 (2, 6-dimethylpyridine) respectively, while in methanol the ratios are greatly depressed: 0.035 (*N*, *N*-dimethyl-*o*-toluidine), 0.330 (α-picoline) and 0.0252 (2, 6-dimethylpyridine) respectively, a leveling effect being again prevalent in liquid sulfur dioxide.

In methanol, both the activation energy and the entropy of activation increase when the methyl group is introduced in the ortho-position. In liquid sulfur dioxide, both the parameters decrease upon the introduction of the *o*-methyl substituent, as is shown in Table VII. The

above results may also be well interpreted as due to the effect of solvation by liquid sulfur dioxide. The *o*-methyl group in dimethylaniline or in the pyridine ring is expected to lower the basicity of the base, either by hydrogen bonding (chelate formation as in Fig. 2) or by partial inhibition of the resonance by the steric hindrance of the methyl group.[14] In liquid sulfur dioxide, the reduction of

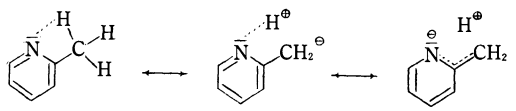

Fig. 2

solvation may compensate for the basicity depression by the *o*-methyl group and thus eliminate the difference or level off the rate constants, as may be seen in Table VI. An alternative explanation is that the solvation of sulfur dioxide to the nitrogen atom of the base is competitive against the chelation or the resonance inhibition. The lack of the linear dependence of the activation energy difference on the heat of the vaporization of the base in liquid sulfur dioxide, as will be described below, seems to support both views.

The Heat of Vaporization and the Difference in the Activation Energy. — If the basicity depression of an *o*-methyl substituted base is to be ascribed to the chelation effect, the reaction rate of the Menschutkin reaction should have some linear dependence on the heat of the vaporization of the base, since it is a well-established fact[15] that the boiling point of *o*-methylaniline is lower than that of *p*-methylaniline because of the same chelation, as Fig. 2 shows. In Fig. 3, the difference, $\Delta E^*_{o\text{-Me}} - \Delta E^*_{H}$, was plotted against the difference of the heat of evaporation of the *p*- and *o*-methyl derivative, $\Delta H_p - \Delta H_o$. In methanol, a linear plot is obtained, where ΔH_p, ΔH_o, $\Delta E^*_{o\text{-Me}}$ and ΔE^*_{H} are the heat of the vaporization of the *p*-methyl derivative, that of the *o*-methyl derivative, the activation energy of *o*-methyl, and that of the unsubstituted bases respectively.

As may be seen in Fig. 3, in liquid sulfur dioxide the plots are scattered, while in methanol a linear dependence between the differences in activation energies and in heats of evaporation is observed.

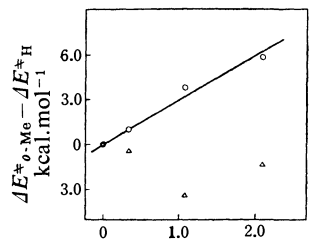

Fig. 3. Dependence of difference of activation energies on difference of heat of evaporation.

a) Landolt-Börnstein Tabellen
b) Calculated from the relationship between vapor pressure and temperature

The Isokinetic Relation. — Although a linear relationship has never been obtained in liquid sulfur dioxide between the activation energy and the heat of vaporization, it seems likely that a similar reaction mechanism is taking place throughout the reaction in liquid sulfur dioxide. The plots of ΔE^* against ΔS^* gave a linear isokinetic relation[16] (Fig. 4), whose slope indicates that the isokinetic temperature is 350°K. The temperature is very close to the experimental condition (30~75°C), again proving the leveling effect of liquid sulfur dioxide.

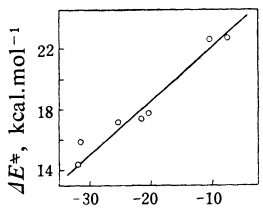

Fig. 4. Isokinetic relationship in liquid sulfur dioxide, methyl iodide with various bases.

Summary

1) The effect of the solvent solvation has been compared in the reaction between methyl

14) J. W. Smith, *J. Chem. Soc.*, **1961**, 31.
15) E. Pimental and A. L. McClellan, "The Hydrogen Bond," W. H. Freeman Co., New York (1960), p. 8.
16) J. E. Leffler, *J. Org. Chem.*, **20**, 1202 (1955).

iodide and various bases in liquid sulfur dioxide, methanol and nitrobenzene. The reaction rate in liquid sulfur dioxide is very much depressed, and the differences in the relative rates among bases are reduced in sulfur dioxide (a leveling effect) as compared to the other two solvents.

2) The order of the relative rates is reversed in liquid sulfur dioxide; pyridine>triethylamine > *N*, *N*-dimethylaniline > *N*, *N*-dimethylbenzylamine, whereas in methanol and in nitrobenzene, *N*, *N*-dimethylbenzylamine is the fastest of the bases. The reasons for this have been discussed.

3) The effect of the *o*-methyl substituent of the bases on the reaction rate has been examined. In liquid sulfur dioxide, the rate ratios $k_{o\text{-Me}}/k_{H}$ are again leveling, while in methanol the ratios are differentiating. The solvation of sulfur dioxide has been considered to be the reason.

4) An isokinetic relation between $\Delta E^{\ddagger}$ and $\Delta S^{\ddagger}$ has been observed, and the isokinetic temperature calculated as 350°K; however, no linear dependence was obtained between $\Delta E^{\ddagger}_{o\text{-Me}} - \Delta E^{\ddagger}_{H}$ and $\Delta H_{p} - \Delta H_{o}$.

Solvent Effect on the Rearrangement of Cyclohexanoneoxime-p-toluenesulfonate. The Ionizing Power of Liquid Sulfur Dioxide[1,2]

By Niichiro TOKURA, Tetsuyo KAWAHARA and Sachio IKEDA

(Received July 20, 1963)

In liquid sulfur dioxide, the Beckmann rearrangement has been reported to take place with unusual rapidnesss,[3] at a low temperature[4] and without any side reaction,[5] giving a product of an extreme purity.[3,4] The Beckmann rearrangement was elucidated first by Kuhara in 1906, when he observed that benzophenoneoxime-benzenesulfonate rearranges spontaneously and that the product formed is hydrolyzed to yield benzanilide.[6,7] He studied this rearrangement under varying conditions, thus finding out that the reaction rate depends both on the acid strength and on the easiness of the cleavage of the N–O bond of the oximeester to an ion-pair, $=N^+ \ ^-O-$. Lately the mechanism of the reaction has been generally accepted as depicted in Chart 1, according mainly to the studies of Chapman,[7] Pearson[8] and Huisgen[9].

In a recent paper, Heldt[10] has found that the first order rate of the rearrangement of cyclohexanoneoxime-*p*-toluenesulfonate depends on the ionizing power of the solvents. The solvents used were acetic acid, chloroform, methanol and ethanol. The present authors have also attempted to study the solvent effect on the rearrangement, paying special attention to the ionizing power of liquid sulfur dioxide.

The results confirm that sulfur dioxide is an excellent solvent for the rearrangement,

although no distinct solvent effect could be deduced to show the relationship between the rate of rearrangement and the ionizing power of the solvent. The ionizing powers of liquid sulfur dioxide, nitromethane, ethylenedichloride and ethyl methyl ketone have also been estimated according to the method of Kosower.[11]

Experimental

Materials.—Cyclohexanoneoxime was prepared according to the known method; m.p. 90.5~91.0°C. Commercial *p*-toluenesulfonylchloride was dissolved in carbon tetrachloride and then precipitated by petroleum ether. Liquid ammonia was dried with sodium wire and distilled. Liquid sulfur dioxide was dried with phosphorus pentoxide and distilled. Benzene, carbon tetrachloride, petroleum ether (b.p. 30~60°C), acetone and chloroform were purified according to the known methods.

The acetonitrile of the first grade materials was dehydrated with phosphorus pentoxide and distilled; b. p. 82.0°C. Pyridine was dehydrated with potassium hydroxide and then with barium oxide, and distilled over barium oxide; b.p. 115.0°C. Ethylenedichloride was dehydrated with calcium chloride and then with phosphorus pentoxide, and distilled; b.p. 83.0~83.7°C. Ethyl methyl ketone was dried over phosphorus pentoxide and fractionated; b.p. 79.3~79.8°C.

Preparation of Cyclohexanoneoxime-*p*-toluenesulfonate.—The preparative method of Heldt,[10] was modified. Into a cooled, three-necked flask, 200 ml. of liquid ammonia was introduced. 3.26 g. of sodium wire was rapidly stirred in, and then a trace of ferric nitrate was added as a catalyst. The color of the solution changed from blue to dark green in 60 min. The excess ammonia was evaporated, and a solution consisting of 15.7 g. of cyclohexanoneoxime in 70 ml. of dry benzene was added to the mixture while the temperature of the flask was kept below 35°C. After the addition of the oxime, the mixture was stirred for a further 16 hr. at room temperature. Then the precipitate was filtered, washed eight times with dry benzene, and dried under reduced pressure; yield, 16 g.

To a slurry of 16 g. of sodium oximate thus prepared in 30 ml. of benzene, 17 g. of *p*-toluenesulfonyl chloride in 70 ml. of dry benzene was added, and the mixture was stirred for two hours at 25~30°C. The precipitate was filtered, dissolved in dry carbon tetrachloride, treated with active carbon, and again filtered. Petroleum ether was added to the filtrate to cause a white clouding, and the mixture was allowed to stand in an ice box for 24 hr. The precipitate formed was separated and dried under reduced pressure; m.p. 57°C (lit.,[10] m.p. 56.8~58°C).

Found: N, 5.28. Calcd. for $C_{13}H_{17}NO_3S$: N, 5.24%.

Apparatus and Procedure. — *Ionizing Power (Z-Value[11]) of Solvents, Including Liquid Sulfur Dioxide.* —The ultraviolet absorption spectra were measured by an Hitachi Model EPU-2A type spectrophotometer using 1-ethyl-4-carbomethoxypyridiniumiodide (m. p. 111°C) (lit.,[11] 111~112°C) as the reagent. The c-t band was estimated in a quartz cell 10 mm. wide at 25°C. A specially-designed pressure cell with quartz windows (0.36 mm. wide) was used for liquid sulfur dioxide.

Kinetic Procedure.—The change of the concentration of oxime-*p*-toluenesulfonate was followed by the infrared spectrometry of Heldt.[10] An Hitachi Model EPI-S double beam spectrometer was used, with a specially-designed pressure cell (KCl width: 0.077 mm.) for liquid sulfur dioxide and with a cell (NaCl width: 0.1 mm.) for the other solvents. The absorption at 857 cm^{-1} (a frequency due to the N-O stretching vibration of oxime) was used.[10] Beer's law was obeyed throughout the experiment. The base line method was used for the estimation of the absorbancy.

The first order reaction dominated in each solvent, the rate constants of which were obtained from the linear plot of the time, t, vs. $\log a/(a-x)$, where a is the initial concentration of the ester and $(a-x)$ is the concentration at the time, t. The reaction was measured at 21.5°C. An example of the results obtained is shown in Fig. 1. From this plot, k (in acetone) is estimated as 1.92×10^{-5} sec^{-1}. The maxima at 857 cm^{-1} showed little shift when solvents of different natures were used.

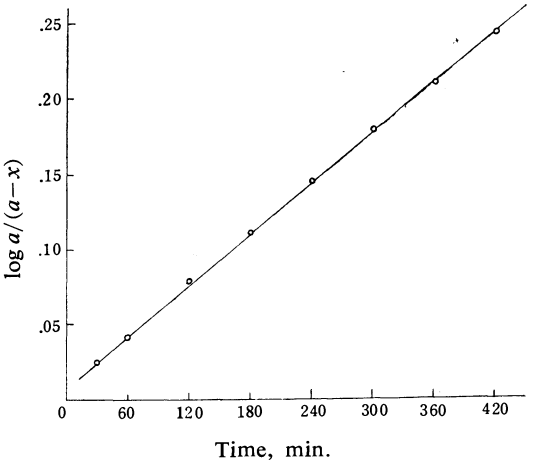

Fig. 1. A typical plot of $\log a/(a-x)$ vs. time. Rearrangement of cyclohexanoneoxime-*p*-toluenesulfonate in acetone at 21.5°C. Oxime-ester, 0.2260 mol./l.

Results and Discussion

The Ionizing Power of Liquid Sulfur Dioxide. —The absorption maximum of the charge-transfer band of 1-ethyl-4-carbomethoxypyridiniumiodide (7.27×10^{-4} mol./l.) in liquid sulfur dioxide was at 3650Å, with an apparent ε value of 2.83×10^{4}. The Z-value of liquid sulfur dioxide was calculated from the E(kcal./mol.) $=2.859\times10^{-3}\times\tilde{\nu}$ equation[11] to be 78.3.

Charge Transfer Bands in Various Mixtures

11) E. M. Kosower, ibid., **80**, 3267 (1958).
12) "Organic Syntheses," Coll. Vol. 2, 76 (1943).

of Liquid Sulfur Dioxide and Acetone.—As is shown in Fig. 2, the λ_{max}'s of the charge-transfer bands of 1-ethyl-4-carbomethoxypyridiniumiodide were estimated in various mixtures of liquid sulfur dioxide in acetone, from 0 (acetone only) to 100% surfur dioxide (21.38 mol./l.). The c−t band in acetone (4354 Å) dropped abruptly upon the addition of a slight amount of liquid sulfur dioxide, a specific solvation by liquid sulfur dioxide being observed.

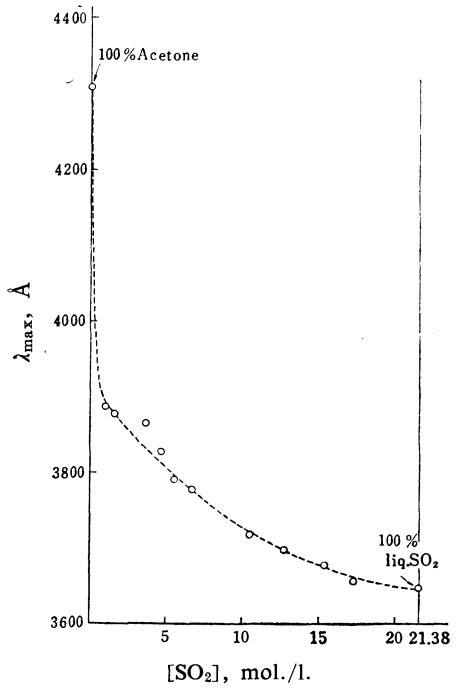

Fig. 2. Maxima of charge transfer band of 1-ethyl-4-carbomethoxypyridiniumiodide in various mixtures of acetone and liquid sulfur dioxide.

TABLE I. THE RATE CONSTANTS OF THE REARRANGEMENT IN MIXTURES OF LIQUID SULFUR DIOXIDE AND ACETONE AT 21.5°C

The Rate Constants in Various Mixtures of Liquid Sulfur Dioxide and Acetone.—The rate constants of the rearrangement of the oxime-ester in various mixtures of liquid sulfur dioxide and acetone, from 0 (acetone only) to

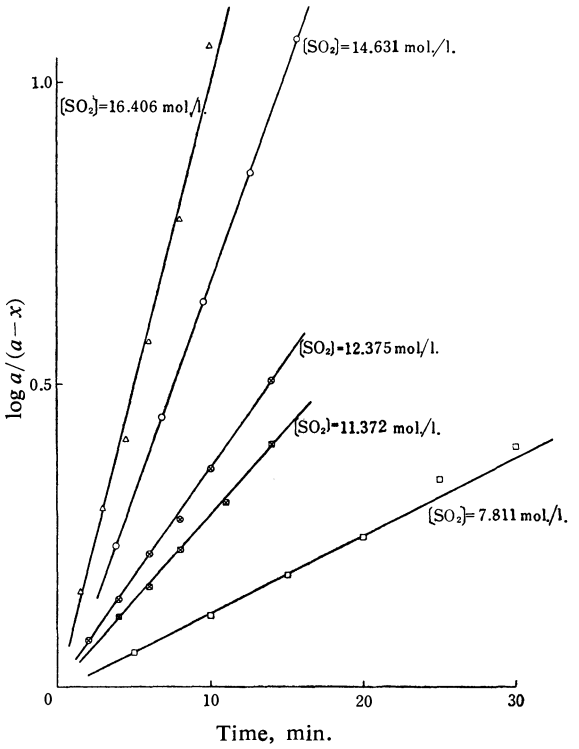

Fig. 3. Some examples of rate-runs in mixtures of acetone and liquid sulfur dioxide. 21.5°C

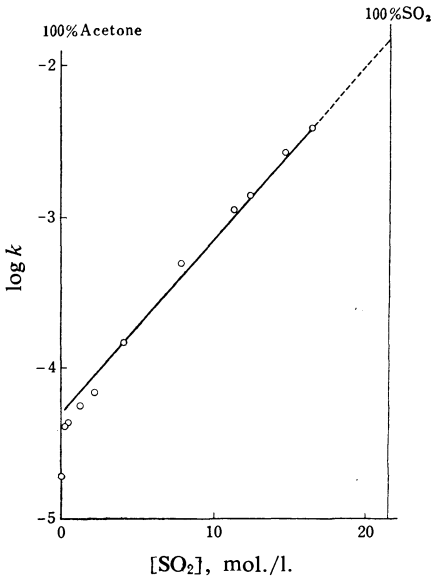

Fig. 4. The plot of log k vs. liquid sulfur dioxide concentration in acetone.

16.406 mol./l. (76.74 mol.%) of liquid sulfur dioxide in acetone are estimated and listed in Table I, some of the $\log a/(a-x)$ vs. t plots being shown in Fig. 3.

A linear plot of the $\log k$ vs. lquid sulfur dioxide concentration in acetone was obtained as in Fig. 4. The rate constant in liquid sulfur dioxide (100%) is obtained, by extrapolation of this plot to 100 % (21.38 mol./l.) liquid sulfur dioxide, as $k=1.6\times10^{-2}$ sec^{-1}.

The *Z*-Values of Nitromethane, Ethylenedichloride and Ethyl Methyl Ketone.—The same method was applied in estimating the *Z*-values of the solvents which were not measured in Kosower's papers. The results are listed in Table II.

TABLE II. *Z*-VALUES OF SOLVENTS

Solvent	λ_{max}, Å	ε_{max}	*Z*-Value
Nitromethane	3750	389	76.2
Ethylenedichloride	4400	703	64.4
Ethyl methyl ketone	4320	825	66.0

The Rate Constants in Various Solvents. The Correlation of the Rates with the Dielectric Constants. — The rearrangements were also carried out in various solvents, such as methanol, acetic acid, nitromethane, ethanol, acetonitrile, pyridine, chloroform, acetone, ethylenedichloride, ethyl methyl ketone and carbon tetrachloride. The rate constants were estimated from linear plots of $\log a/(a-x)$ vs. t, which are depicted in Fig. 5. These results, together with those with liquid sulfur dioxide, are listed in Table III; among them, the values of k at 21.5°C in chloroform, acetic acid, methanol and ethanol are calculated from the results of Heldt.[10] No correlation is found either between $\log k$ and the dielectric constant, D, or between $\log k$ and the dipole moment of

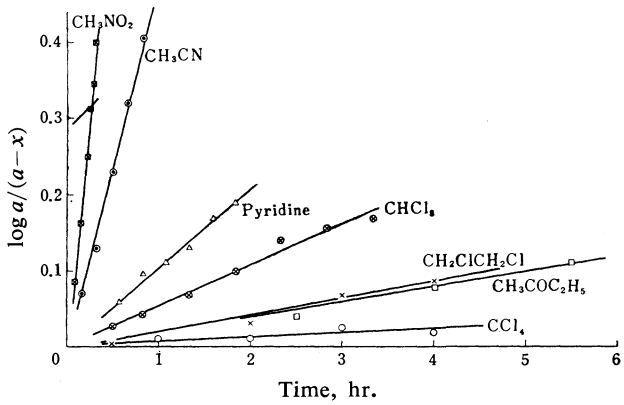

Fig. 5. The rate constants in various solvents. 21.5°C

the solvent. Figures 6 and 7 show the plots of log k vs. $1/D$ and log k vs. $(D-1)/(2D+1)$ respectively. The rate constants decrease in the following order: liquid sulfur dioxide> methanol>acetic acid>nitromethane>ethanol > acetonitrile > pyridine>chloroform>acetone >ethylenedichloride > ethyl methyl ketone > carbon tetrachloride. The fastest rate, in liquid sulfur dioxide, is eighty times that in methanol, 480 times that in chloroform and 1.6×10^4 times that in carbon tetrachloride at 21.5°C.

The rate in the mixtures of liquid sulfur dioxide in acetone was dependent on the molarity of liquid sulfur dioxide, as may be seen in Fig. 4, and relation 1 is observed:

$$\log k = \text{const.} \times [SO_2] \qquad (1)$$

which means that the higher the concentration of liquid sulfur dioxide in acetone, the smaller will be the activation free energy of the reaction.

The Ionizing Power of the Solvent. The

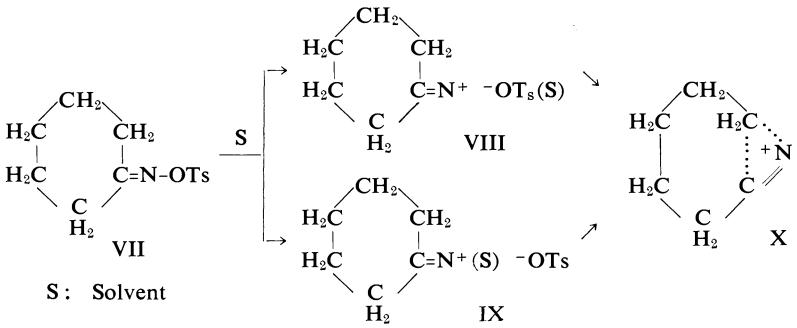

Chart 2

Correlation of *Z*-Values with the Rate Constants of the Rearrangement.—As is visualized in Figs. 6 and 7, no dependency of $\log k$ on $1/D$ or on $(D-1)/(2D+1)$, the latter relation being well-known as Kirkwood's relation,[13] is observed. Although Chapman[14] has revealed that the added solvents accelerated the Beckmann rearrangement in carbon tetrachloride and that the rates were dependent on the dipole moments of the added solvents, no linear correlation is seen between the $\log k$ and the dipole moment of any of the solvents used in this experiment. The relationship of $\log k$ against *Z*-value is also a disappointing one (Fig. 8).

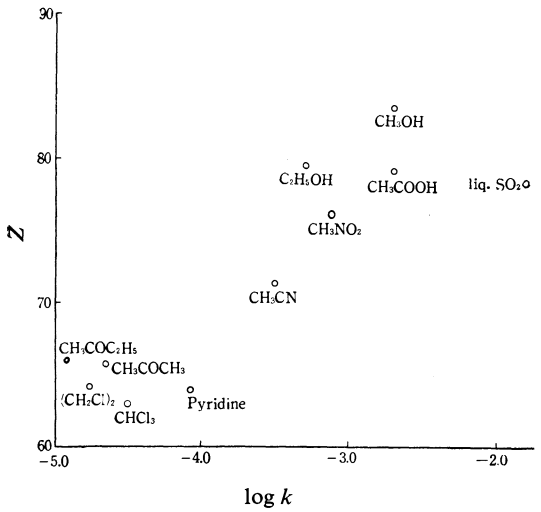

Fig. 8. Correlation of $\log k$ vs. *Z*-value.

The assertion of Heldt[10] that $\log k$ was dependent on the *Z*-value must be amended, for only four solvents were used in his work. An inspection of Fig. 8 will enable us to understand that the $\log k$ vs. *Z* relation is not linear but consists of a broad zigzag band; the explanation of such a result must await further study. For instance, the *Z*-value of ethanol is larger than that of acetonitrile, and that of methanol is larger than the *Z*-value of acetic acid; the $\log k$'s of ethanol and acetonitrile or those of methanol and acetic acid are very close to each other. In chloroform the rate is faster than in acetone, whereas the *Z*-value of acetone is larger than that of chloroform. The comparatively small *Z*-value of liquid sulfur dioxide (78.3) is unexpected in view of the largest rate constant in this solvent.

In a preceding paper[15] by one of the present authors, a proposal has been made regarding the reasons for the unusual rapidness of the Beckmann rearrangement and the cationic polymerization, and for the unexpected dullness of the Menschutkin reaction in liquid sulfur dioxide, in which the presence and the importance of the unsolvated *(bare)* carbonium ion in liquid sulfur dioxide have been emphasized. The rapidness of these reactions is largely a result of the ability of the solvent, (1) to ionize the covalent linkage to an ion-pair and (2) to prevent the harmful attachment (association) of counter anion or nucleophilic species to carbonium ions or cations by the strong solvation of the solvent (liquid sulfur dioxide) on anions or nucleophiles.

It is generally accepted that the formation of an aza-cyclopropenium cation (X) is the intermediate step in the Beckmann rearrangement.[8,9] The fact that the rearragement is always a *trans*- and intramolecular-migration supports this view. Since the results indicated here suggest that the ionizing power of the solvents is important but not the final word in the elucidation of the solvent effect on the rearrangement, another source for such behavior should be sought.

As is illustrated in Chart 2, to attain the intermediate X, two extreme cases of the solvent solvation may be considered. When the solvent is an electrophile, the anion

($^-$OTs anion) may be strongly solvated and the intermediate X may easily be formed concertedly or by ionization via VIII. However, when the solvent used is a nucleophile, the solvation of the cation (=C=N$^+$) by the solvent may be predominant, as is seen in IX, the formation of X being thus retarded or inhibited. If such is the case, the migrating group (α carbon atom) should have enough driving force to push away the nucleophilic solvent to obtain the intermediate X. Acetone, pyridine and acetonitrile are to be classified as nucleophilic solvents, whereas sulfur dioxide is to be considered an electrophilic solvent. However, the ionizing powers of ethanol and methanol are large; these solvents are biphilic (both electrophilic and nucleophilic), and the behavior of these solvents towards the oximeester is of a complicated nature. The effect of the strong ionizing power on the rate of the rearrangement may perhaps be compensated for partly by the nucleophilicity of these hydroxyl solvents. There remain many problems to be solved concerning the ionizing power of solvents. Many suggestions which have intended to classify the solvents by their ionizing powers such as dielectric constants, *Y*-values[16] or *Z*-values are not satisfactory. The consistent relations between such ionizing powers of the solvents and the rate of the reactions in the solvents are only observed among the solvents with similar natures. Meanwhile, the superiority of liquid sulfur dioxide as the solvent in many reactions is probably largely due to its electrophilic and non-nucleophilic nature.

Summary

The Beckmann rearragement of cyclohexanoneoxime-*p*-toluenesulfonate has been carried out in various solvents and the results have been discussed. The rate in liquid sulfur dioxide is the fastest among the solvents examined. The plots of the log k vs. ionizing powers of the solvents are not linear. The electrophilic solvation of liquid sulfur dioxide on the *p*-toluenesulfonate anion is important if the reaction is to be carried out rapidly and if an intermediate bridged cation, an azacyclopropenium cation, is to be obtained.

The Velocity of Ascending Air Bubbles in Aqueous Solutions of a Surface Active Substance and the Life of the Bubble on the Same Solution

By Satiko OKAZAKI*

(Received July 19, 1963)

The surface tension and the adsorption from an aqueous solution of a surface active substance have been studied by many authors with refererence to the problem of surface activity. However, from the practical point of view, the properties of the system in the dynamic state[1-4] are more important than those in equilibrium, as in the cases of emulsification, dispersion, foaming, detergency and wetting. Unfortunately, the studies of such dynamic properties are very few, especially concerning the mechanism of surface activity. In this connection, it is important to study the phenomena of the ascending of air bubbles in an aqueous solution of a surface active substance.

Concerning these phenomena, an empirical formula for the velocity of bubbles ascending in a liquid and various effects upon the velocity, for instance, the effects of the size and the shape of the bubble, of the circulation of gas inside the bubble, of impurities in the solution, and of bubbles rising in succes-

sion have been reported.[5-8] However, as to the actual conditions of the system under which the above formula can be applied or the effects appear, the results reported by vavious authors are not concorbant. Garner and Hammerton,[5] for instance, made an experiment with vaseline-contaminated bubbles and confirmed a retarding action of the hydrocarbon film on the bubble surface for the ascending velocity; Stuke[8] also reported an extreme sensitivity of the ascending velocity of bubbles to the presence of a surface active substance in the solution. However, the results and the explanations of these findings differ greatly. The present author has, therefore, made a similar experiment for the aqueous solutions of surface active substances and has also measured the density, the viscosity, the compressibility, the surface tension, and the stability of bubbles for the same solution in order to elucidate the phenomena.[9,10] The present report will discuss these results in detail.

Experimental, Results and Discussion

Materials.—For the study of the surface active substances, sodium dodecyl sulfate (SDS) and isoamyl alcohol were selected as two typical substances for producing stable and unstable aqueous foams respectively. SDS was prepared and purified by the usual method. In order to eliminate any possible error due to aging, the solution of SDS was prepared and kept overnight in a stoppered glass bottle before use. The sample of isoamyl alcohol was purified by the distillation of a commercial product over calcium oxide.

The Ascending Velocity of Bubbles in the Solution of a Surface Active Substance. — The velocity of an air bubble ascending in an aqueous solution of a surface active substance was measured in a glass cylinder (9 cm. in diameter and 50 cm. high) which had been filled with an aqueous solution of SDS or isoamyl alcohol to the depth of 40 cm.[9,10] By means of a capillary tube varying in size, air bubbles were produced at the center of the bottom of the cylinder and were made to ascend through the liquid. Special care was taken to keep the orifice of the capillary clean by drawing it anew in each run. Each bubble was made to ascend separately, allowing a time interval of at least three seconds between successive bubbles, this interval is needed to avoid the error due to the streaming bubble effect,[5] which will be discussed later. The uniform velocity portion of the bubbles was measured for the varying distances from 10 to 40 cm., to the accuracy of 1/10 sec.

Ascending air bubbles were also caught under a watch glass which was held near the surface of the solution, and their radii were measured by a microscope equipped with an ocular scale.

The measurements were mainly conducted at room temperatures ranging from 20 to 25°C. The temperature fluctuation of this range did not obscure the results obtained.

The ascending velocity, V, of the bubble in an aqueous solution of SDS is plotted against its radius, r, in Fig. 1. We can see in this diagram that in the region of $r<0.03$ cm. all of the plots for different concentrations of the SDS solution fall on one straight line, while in the region of $0.03<r<0.07$ cm. they break into separate and nearly straight lines of different inclinations for different concentrations of SDS.

The inclination is largest for pure water, decreases with the increase in the concentration of SDS, and is smallest for 10^{-3} molar and 10^{-4} molar SDS, which give a common straight line without a break point at $r=0.03$ cm. We can further confirm this by the visual observations that above a certain critical radius the bubble fluctuates and that all of the polts deviate from the lineality rather abruptly.* In our experiments this critical radius is about 0.07 cm. for all solutions, independent of their concentrations (as shown by a dotted vertical line in Fig. 1). In Fig. 2 a similar relation

between V and r is shown for an isoamyl alcohol solution. All these findings are similar as a whole to what was briefly reported by Stuke,[8] while it differs in some respects from what was reported by Garner and Hammerton.[5]

It can be noticed at once that the ascending velocity of air bubbles in water is retarded by the presence of SDS, even in such a small concentration as 10^{-6} molar. This is rather surprising, considering the physico-chemical properties of the solution of a surface active substance in such a dilution where the properties are not practically different from those of pure water, as will be mentioned later. We can further see in Fig. 1 that a straight line expressing V—r relations up to $r=0.03$ cm. for all concentrations of SDS solution, and up to $r=0.07$ cm. for 10^{-3} and 10^{-4} molar SDS solutions, together with the deviation from this linearity above $r=0.07$ cm. for the latter solutions, show an apparent coincidence with the results obtained by Garner[5] for the ascending bubble contaminated with vaseline, where he insists that the linearity indicates the spherical shape of the rising bubble and that the deviation from the linearity above $r=0.07$ cm. is explained by the deformation of the bubble due, in his case, to the hydrocarbon film on the bubble surface. However, before the results of his experiment are accepted, a marked difference should be pointed out between his results and ours for the rising velocity of air bubbles in distilled water, as is shown in Fig. 1. To check this point, the $V-r$ relation for a rigid spherical bubble will be established independent of these measurements.

The Ascending Velocity of a Rigid Spherical Bubble.—The V—r relation for a rigid spherical bubble is calculated by using an entirely empirical formula[7] and is plotted as solid circles in Fig. 1. This curve coincides with the V—r relation of a 10^{-5} molar SDS solution and is somewhat greater than those of 10^{-3} and 10^{-4} molar SDS. This may predict a possible deformation from a sphere of rising bubble of $r<0.07$ cm. in 10^{-3} and 10^{-4} molar SDS solutions. However, is also probable that the uncertainty is due to the empirical nature of the equation,[7] which has no adjustable constnats relating to the dimensions of the apparatus used. Thus, it was further necessary to make an experiment in our own apparatus to obtain an actual V—r relation of the rising velocity of a rigid spherical bubble which exactly fits our experimental conditions.

For this purpose the present author has measured the falling velocity of rigid glass spheres, the density being 2.37, in water and in the solution under experimental conditions similar to those which held in the measurement of the rising bubble velocity, from which the rising velocity, V, and the radius, r, of an air bubble considered to be a rigid sphere, with the same drag coefficient and Reynolds number, were calculated.[11] The V—r relation thus obtained is plotted with

* The present discussion is mainly concerned with the phenomena occuring in the region of $r<0.07$ cm. in order to avoid the complications coming from the bubble fluctuation. The discussion is also restricted to the bubble radius far greater than about 0.008 cm., a point which corresponds to the upper limit of the Stockes velocity region of this system. Ref. 7, p. 24.

circles and curve 1 in Fig. 3, where the V—r curves for the actual air bubble in the aqueous solution of SDS shown in Fig. 1 are reproduced.

Now in the range of $r<0.07$ cm., the V—r curve for the rigid spherical bubbles obtained from a glass sphere experiment and the curves for the actual air bubbles in concentrated aqueous solutions of 10^{-3} and 10^{-4} molar SDS coincide with each other, while the curve for 10^{-5} molar SDS is somewhat higher.

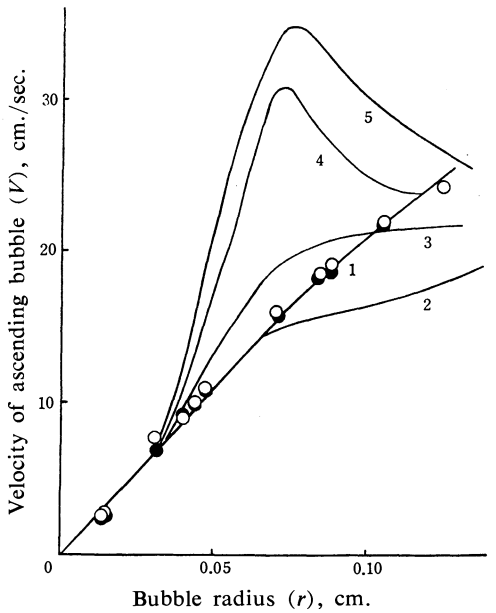

Fig. 3. Velocity of air bubbles ascending in the aqueous solutions of SDS.
(1) Rigid spherical bubble in distilled water (○) and in 1.0×10^{-3} molar SDS solution (●), actual air bubble in aqueous SDS of (2) 1.0×10^{-3} and 1.0×10^{-4} molar, (3) 1.2×10^{-5} molar, (4) 1.0×10^{-6} molar solution and (5) in distilled water.

This shows the rigid spherical nature of the rising bubble in 10^{-3} and 10^{-4} molar SDS. It may also be inferred that, though our V—r curves for 10^{-3} and 10^{-4} molar SDS actually coincide with Garner's curve (shown in Fig. 1), they do not represent the rising velocity in distilled water, as Garner insisted; rather, they correspond to the spherical bubble rigidly covered with the adsorbed film, and the effect of vaseline-contamination is considered to appear already in the region of $r<0.07$ cm. His explanation of the rising velocity of the bubble of $r>0.07$ cm. mentioned above may also be invalid. Since, as has been mentioned above, this critical radius of 0.07 cm. is largely independent of the SDS concentration and is equal to the value in distilled water, such a critical radius and the retardation of the rising velocity of bubbles beyond this radius is likely to be explained mainly by the hydrodynamic effect prevailing even in distilled water. The fairly good coincidence of our critical value with those of Garner[5] and Coppock[12], who used different substances or worked under widely differing conditions, also confirms this.

The Ascending Velocity of Bubbles in a Dilute Solution.—As for the extremely sensitive effect of 10^{-5} and 10^{-6} molar SDS solutions in retarding the ascending velocity of bubbles in the region of $0.03<r<0.07$ cm., the following factors may be pointed out in explanation;

(1) A change in the physical properties of the solution, a change which affects the hydrodynamic properties of the solution.

(2) The streaming bubble effect.

(3) The contamination or adsorbed film on the bubble surface.

As for 1, the density, velocity, compressibility, and surface tension were measured for these solutions and distilled water as shown in Table I. None of the data of this table can, however, in any way explain the retardation of the ascending velocity since there is no difference in the magnitude of these properties between pure water and a SDS solution.

Next we may take account of the streaming bubble effect, that is, the acceleration of an ascending bubble by another one rising just above it.[5] It has been reported that, at the speed of one bubble per second, the rising velocity of bubbles in a series is about three times as large as that of a solitary bubble,[13] and that the apparent increase in the rising velocity due to such an effect is less than 1%

● 1.0×10^{-3} molar aqueous SDS

only when the time interval between two neighboring bubbles exceeds three seconds.[5] In our experiment, however, the time interval of the successive bubbles is longer than three seconds, as has been mentioned above, so the possibility of the streaming bubble effect can be eliminated.

We may, therefore, concentrate on the effect of the third factor. The effect of surface contamination is considered to appear in two ways, namely, by deforming bubbles and by inhibiting both the circulation of gas taking place inside and the liquid flow at the surface of ascending bubbles in pure water.[6] Of these two possibilities, the former seems not to occur in all solutions of the concentration studied, since in 10^{-3} and 10^{-4} molar SDS, the ascending bubble can be treated as a rigid sphere, as has already been mentioned, and deformation from the sphere, if any, should result in a V—r line of the inclination less than this, as in the case of the retardation at $r>0.07$ cm. This is, however, just opposite to what was observed.

Therefore, the inhibition of gas circulation or liquid flow remains as the only possible explanation for the remarkable retardation of the ascending velocity of the bubble. Here, it is interesting to note that our V—r curves between $0.03<r<0.07$ cm. are very similar in shape to what was obtained by Nawab[14] for the effect of the emulsifier film surrounding emulsion droplets upon the emulsion viscosity, where not only the viscosity of the liquid of the external phase but also that of the internal phase, namely, the emulsion droplets, have an influence upon the emulsion viscosity. Both of these phenomena may be similarly explained by the adsorbed film on emulsion droplets or bubbles, which acts to retard or inhibit the circulation or flow inside and at the surface of the droplets or bubbles. In the studies of circulation in sedimenting fluid spheres, the inhibition of the internal circulation by the addition of surface active impurities to the external phase has been confirmed, from which the rigid nature of the adsorbed film surrounding the liquid droplets has been inferred.[15] The movement inside the ascending bubble was reported to start in pure water at a bubble radius as small as 0.02 cm. and to reach a maximum speed at the radius of 0.125 cm.[5] Bond[16] calculated the effect of circulation inside the bubble in increasing the ascending velocity of a spherical bubble from a Stokes law velocity without internal gas circulation. The adsorbed film of a surface active substance is also inferred to dissipate the kinetic energy at the bubble surface through the relaxation effect.[5] A similar explanation for the retardation is possible by introducing the concept of surface transport proposed by Sutherland.[17] Thus, we are of the opinion that the increase in the ascending velocity beyond the velocity of a rigid spherical bubble in pure water at $0.03<r<0.07$ cm. is chiefly aided by the gas circulation inside the bubble, and that the sensitive action of retarding the rising velocity of bubbles in an aqueous SDS solution is to be ascribed to the adsorbed film of the surface active substance, which acts to reduce or inhibit both the movement of liquid at the surface and the circulation of gas inside the bubbles.

17) W. E. Ewers and K. L. Sutherland, *Austr. J. Sci. Res.*, A5, 697 (1952).

A similar explanation is possible for the system of an isoamyl alcohol solution, as may be understood from the similar V—r curves in Fig. 2.

Dynamic Surface Tension, Surface Viscosity, and Bubble Life.—As for the remarkable effect of SDS on the ascending velocity of the bubble, it has already been stated that all the static properties of the solution fail to explain the phenomena. Now let us take into account such surface properties as the surface viscosity or the dynamic surface tension, as Bryn and Garner suggested.[5]

The dynamic surface tension was measured by using a stalagmometer.[18] This enabled us to regulate the dropping speed and thus facilitated the detection of the aging of the solution which might occur during the bubble ascension. In order to estimate the surface tension of a relatively fresh surface of a solution, the age of the drop surface was decreased by increasing the dropping speed. Precautions were taken to eliminate the error due to the dropping speed by conducting a similar experiment with pure water. The results obtained are shown in Fig. 4. This figure again shows no difference in surface tension between pure water and 10^{-5} or 10^{-6} molar SDS, at least for the aqueous surface aged more than two seconds, though an apparent slight time effect can be seen for the 10^{-4} molar SDS solution. Concerning the effect of surface viscosity, we did not actually make any measurements, but its order of magnitude may also be very small for the 10^{-6} and 10^{-5} molar SDS solutions; at least this can be expected from the data of McBain.[19] This quantity too, therefore, may not be sensibly different from that of water. Thus, we can find no difference in either the static or the dynamic properties of the system between pure water and 10^{-5} molar SDS to elucidate the phenomena as far as the above measurements are concerned.

However, the ascending bubble has been estimated to have a surface zone of considerable thickness in which the viscosity of the liquid is not normal,[20] and there is ample reason to believe that the surface viscosity or flow resistance near the bubble surface, though directly undetectable in magnitude, sensitively affects the ascending velocity of bubbles in water. In this connection it is important to measure the stability or the life of bubbles on the aqueous surface, which has also been known to be sensitively affected by the adsorbed layer of the surface.[21] The life time of bubbles was measured in a glass vessel 10 cm. in diameter. As is shown in Fig. 5, the stability of bubbles at the surface of the SDS solution becomes perceptible and gradually increases when the concentration exceeds 10^{-6} molar, the whole appearance of the stability concentration curve being very similar to the concentration dependence of the retardation of the ascending velocity of the bubble, which is also shown in Fig. 5. It is known that the drainage of liquid in the bubble film is one of the factors determining the life time of bubbles.[22] Particularly in our very dilute solution of SDS, where the surface tension is not sensibly different from that of pure water and where the strength of the bubble film due to the solute adsorption is almost imperceptible, the bubble life is affected chiefly by the rate of drainage, which is in turn influenced by the surface viscosity or the resistance to surface flow.[17] Thus, the surface viscosity affects the rate of drainage and, therefore, the life of sessile bubbles at a liquid surface, just as it affects the velocity of the ascending bubbles. The common cause of resistance to flow and a similar high sensitivity to surface active substances makes the two phenomena very similar, as may be seen in Fig. 5.

The probable mechanism of the resistance to flow may be such that, on the surface of

the ascending bubble, there may occur some uneven distribution of the adsorbed solute molecules of the surface active substance arising from the sweeping action of liquid flow around the ascending bubble. Accordingly, during ascension, a surface pressure difference, though slight, is produced on the bubble surface, which sets up the force to oppose the liquid flow near the bubble, as Sutherland pointed out in terms of the surface transport.[17] This may cause a decrease in its ascending velocity.

Here one should further refer to the electrophoretic velocity of a highly purified paraffin oil (Nujol) droplet in water.[23] In has been reported that the mobility of Nujol in water alone is $-4.35\,\mu$/sec./V./cm., but that the addition of as little as 7.5×10^{-5}% of pyridinium salt reduces the mobility to zero. In spite of this marked change in mobility, the lowering of the interfacial tension is appreciable at a concentration below 0.01% of this salt. This suggests the important rôle of the change in a diffuse electrical double layer surrounding the oil droplet. In our case of an ascending bubble, similar conditions may also be considered to exist which act to retard its motion. However, the effect of inorganic ions on the ascending velocity of the bubble is rather opposite in its action in this respect, at least so far as our experiment is concerned.[10] Further detailed studies should be made of this point.

Summary

1) The velocity of an air bubble ascending in water is remarkably retarded by the addition of a minute amount of sodium dodecyl sulfate (SDS) or isoamyl alcohol. With an air bubble with a radius ranging from 0.03 to 0.07 cm., the decrease in velocity is perceptible even in a 10^{-6} molar SDS solution, while it tends to a limiting value in 10^{-3} and 10^{-4} molar SDS solutions, where the rising velocity is about half as large as that in pure water.

2) To elucidate this retardation, the static properties of the solution, such as surface tension, density and compressibility, and the dynamic properties, such as viscosity and the change in surface tension with time, have been measured. However, no difference could be found in these properties between pure water and a 10^{-5} molar SDS solution to account for the retardation phenomena.

3) The rising velocity of a bubble considered to be a rigid sphere calculated by using an empirical formula fails to explain the results, since the formula does not fit our experimental conditions. The rising velocity of a rigid spherical bubble calculated from the observed data of a falling velocity of glass spheres in water in our apparatus is found to be in good agreement with that in 10^{-3} and 10^{-4} molar SDS solutions.

4) It has been concluded that, in all concentrations of the solution studied and for the bubble with a radius less than 0.07 cm., the bubble rises as a sphere and that the air circulation inside the bubble is closely related to the rising velocity of the bubble. The air circulation, which is strongest in the rising bubble in pure water, is hindered in 10^{-5} and 10^{-6} molar SDS solutions by the formation of an adsorbed film of SDS on this bubble, and the rising velocity is also thereby retarded. The circulation is actually suppressed, and the bubble rises as a rigid sphere in 10^{-3} and 10^{-4} molar SDS solutions. The retardation of the rising velocity of bubbles with radii larger than 0.07 cm. is due to the deformation of the bubbles from a sphere.

5) The life time of bubbles on an aqueous solution is affected by the surface active substance as sensitively as in the case of the effect of the same substance on the velocity of the rising bubble. Both phenomena are explained by the common factor of the retardatoin of the flow around the bubble surface.

The author wishes to express her gratitude to Professor Tsunetaka Sasaki for his kind direction and valuable criticism. The cost of this research has been defrayed by a grant of the Ministry of Education given to Professor Sasaki. The author also wishes to thank Mr. Kiyoshi Tamura of our laboratory for his measurements of compressibility and density.

A Novel Rearrangement of α, β-Unsaturated Ketones[1]

By Sachihiko Isoe and Masao Nakazaki

(Received July 25, 1963)

In the course of studies of Plancher's rearrangement, the smooth conversion of 1b-methyl-5, 6-dihydro-11b-benzo[c]carbazole (I) and spirocyclopentane-1, 3'-pseudo-2'-phenylindole (II) into 6a-methyl-5, 6-dihydro-6a-benzo[a]carbazole (III) and 11-phenyltetrahydrocabazolenine (IV) respectively by heating them with polyphosphoric acid at 150~188°C, have been reported.[2,3] (Fig. 1)

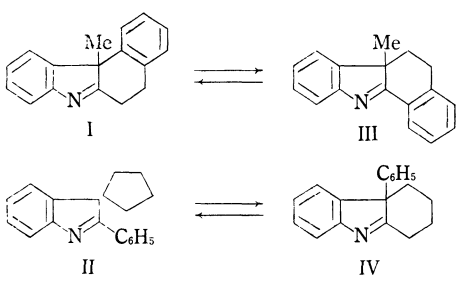

Fig. 1

A twofold Wagner-Meerwein type mechanism has been proposed to explain these facile rearrangements, and an analogous mechanism may be advanced for the well-known rearrangements of various carbonyl compounds, an example of which is illustrated in Fig. 2.[4]

Hitherto, however, the same type of rearrangement has not been demonstrated involving the twofold Wagner-Meerwein shift in more complex systems, e. g., mono-, bi-, and tri-cyclic α, β-unsaturated ketones.

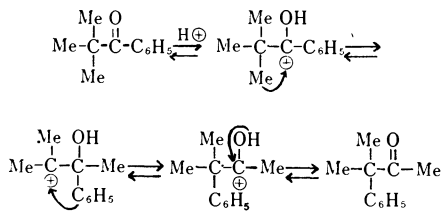

Fig. 2

This contribution is concerned with the syntheses of various α, β-unsaturated ketones which have electronic features analogous to those of the indolenines I and II, and with their interconversions with polyphosphoric acid.

Syntheses of α, β-Unsaturated Ketones.[5]—The α, β-unsaturated ketones (6-phenyl-spiro[4, 5]-dec-6-en-8-one (V), 3-keto-10-phenyl-$\Delta^{4,5}$-octalin (VI), 3-keto-10a-methyl-2, 3, 9, 10, 10a, 1-hexahydrophenanthrene (VIIIa), 3-keto-4, 10a-dimethyl-2, 3, 9, 10, 10a, 1-hexahydrophenanthrene (VIIIb), 4, 4-dimethyl-3-phenylcyclohex-2-enone (Xa) and 2, 4, 4-trimethyl-3-phenylcyclohex-2-enone (Xb)) were synthesized by the usual Robinson annelation method, but the syntheses of the two unsaturated ketones, VIIa and IXa, seem to call for special comment.

5) According to the nomenclature of A. M. Paterson and L. T. Capell, "The Ring Index," Reinhold Pub. Corp., New York (1940).

In an attempt to obtain 2-keto-4a-methyl-2, 3, 4, 4a, 9, 10-hexahydrophenanthrene (VIIa), 1-methyl-2-tetralone was condensed with methiodide of 1-diethylaminobutan-3-one in the presence of potassium *t*-butoxide. Although the oily product, (b. p. 152~156°C/1 mmHg) showed a carbonyl absorption band at 1715 cm^{-1} in an infrared spectrum, it also exhibited a peak at 3390 cm^{-1} (hydroxy group). Most simply interpreted, this implies that the product may have the structure XI (Fig. 7)

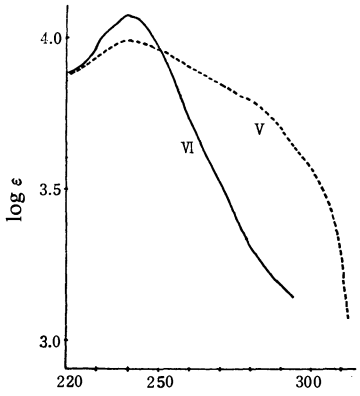

Fig. 4

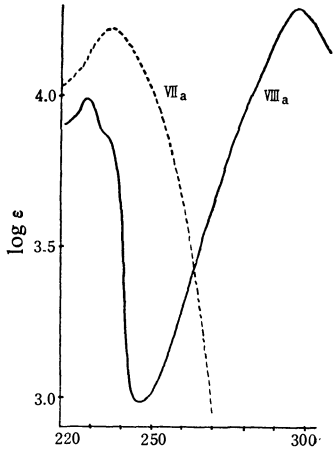

Fig. 5

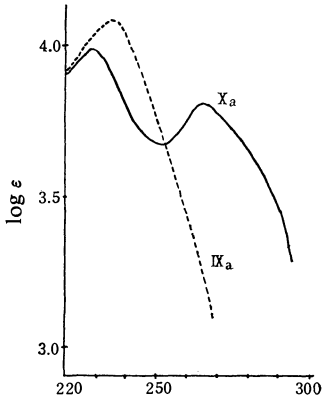

Fig. 6

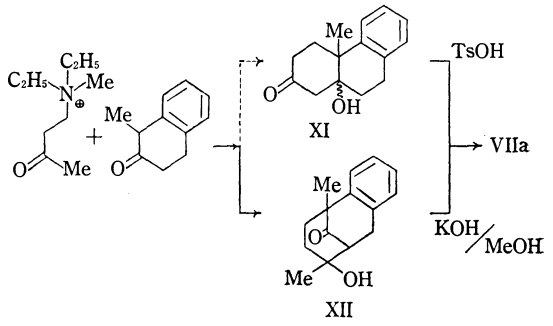

Fig. 7

(4a-methyl-10a-hydroxy-3, 4, 4a, 9, 10, 10a - hexahydrophenanthrene), the cis isomer (m. p. 157~158°C), of which has been synthesized by Wenkert and Stevens[6] via another route. They succeeded in converting *cis*-XI into VIIa (m. p. 89~91°C), by dehydration with toluenesulfonic acid, but our product was found to be recovered unchanged by this procedure. These facts, together with the steric hindrance around the carbonyl group (2, 4-dinitrophenylhydrazone could not be prepared by the usual procedure), suggest the ketol structure XII. This view is supported by the smooth conversion of the oil into VIIa upon heating it with methanolic potassium hydroxide. Recently, Johnson et al.[7] provided ample evidence that a bridge-ring ketol like XII is a common intermediate in Robinson's annelation reaction.

Another perplexing situation arose when

7) W. S. Johnson, J. J. Korst, R. A. Clement and J. Dutt, ibid., **82**, 614 (1960).

2-phenylbutan-3-one and methiodide of 1-diethylaminobutan-3-one were condensed in the presence of sodium amide in an attempt to secure IXa. (Fig. 8). The product, an oil (b. p. 112~116°C/1 mmHg), showed the expected absorption in infrared region (1661 cm^{-1}, for α, β-unsaturated ketone), but the carbonyl group was found very reluctant to give a semicarbazone, indicating that the carbonyl group is sterically hindered. Apparently, the ring closure took place to give the unsaturated ketone XIII (route B in Fig. 8) instead of the expected IXa (route A).[8,9] As an alternative synthetic route to IXa, the *t*-butyl chromate oxidation of 2, 3-dimethyl-3-phenylcyclohexene was attempted, and this process eventually afforded IXa in a fairly good yield. The structure of the ketone IXa thus obtained was supported by the ease with which semicarbazone and 2, 4-dinitrophenylhydrazone were formed, as well as by its ultraviolet absorption, λ_{max} 236 mμ (log ε 4.08), which is very close to the expected value calculated by Woodward's rule.[10]

Table I summarizes the properties of the unsaturated ketones, while Fig. 4, 5 and 6 reproduce the ultraviolet absorption spectra of the V, VI, VIIa, VIIIa, IXa and Xa ketones.

Rearrangements of the α, β-Unsaturated Ketones.—Having secured these α, β-unsaturated ketones, we can proceed to explore their interconversion by acid. The heating of the ketone V with polyphosphoric acid at 150~160°C for 10 min. gave rise to the formation of VI in a 60% yield; identification was established by comparison of an infrared spectrum with synthetic VI and by a mixed melting point determination of their semicarbazones. Under the same conditions, the ketone VIIa rearranged smoothly to the ketone VIIIa, whereas the ketone IXa was recovered unchanged after heating it with polyphosphoric acid at 150~160°C for 4 min. A more vigorous treatment, 170~175°C for 6 min., apparently caused a considerably deep-seated decomposition of IXa, and the ketone recovered exhibited, in addition to the original absorption maximum at 228 mμ, a shoulder at 270 mμ in an ultraviolet spectrum. The detection of the semicarbazone of Xa in the crude semicarbazone (m. p. 205~209°C) derived from the recovered ketone was unsuccessful; we obtained only the semicarbazone (m. p. 215°C) of the starting material, IXa. Attempts to convert VI and VIIIa back to V and VIIa respectively under various conditions (ethanolic hydrochloric acid, zinc chloride in ethanol and polyphosphoric acid at 150°C) failed.

Discussion

The facile rearrangements, V→VI and VIIa → VIIIa, are parallel with the conversions, I→III and II→IV, demonstrated in indolenine compounds, and an analogous mechanism involving a twofold Wagner-Meerwein-type shift can be advanced (Fig. 2). At first sight, the directions of the rearrangements of V and VII seem contradictory; the one leading to the α, β-unsaturated ketone VI with no conjugation with the phenyl group, while the other leading to VIIIa, conjugated with the phenyl goup. However, an inspection of the molecular models of these compounds explained this seeming discrepancy. In the compound V, a considerable steric repulsion between the spiropentan group and the phenyl group forces the phenyl group to pivot around, out of the plain of the α, β-unsaturated ketone group. This can be see from a comparison of the ultraviolet absorption of the compound V and that of VIIIa, which has the phenyl group fully conjugated with the α, β-unsaturated carbonyl group because of the coplanarity of the two groups. (Figs. 4 and 5; Table I). Thus, the tendency to be released from the steric compression would be the driving force of the V→VI rearrangement. The compound VIIa suffers no such non-bonding interaction, and the driving force may simply be a gain in delocalization energy earned by going to the compound VIIIa. As was demonstrated elegantly by the successful optical resolution of 4, 5-disubstituted phenanthrene derivatives,[11] the substitutions at the 4- and 5-positions of the phenanthrene force the plane of the aromatic molecule to twist. In the compound VIIIb which has an extra methyl group at the 4 position of VIIIa, the non-bonding interaction between the methyl group and the hydrogen atom at the position 5 also causes the molecule to twist, and the molecule can no more enjoy the most stable conformation, in which both A and B rings (VIIIb in Fig. 3) have *quasi* chair forms, with the phenyl group coplanar with the plain of the α, β-unsaturated carbonyl system. This effect can account for the observed hypsochromic shift in an ultraviolet spectrum of VIIIb (Table I; compare with the compound VIIIa), and would compensate for the mesomeric stabilization, shifting the equilibrium toward VIIb, in the reverse

8) Cf. G. G. Walker, ibid., **77**, 3664 (1955).

9) Unfortunately, after we submitted our preliminary report,[1] this fact attracted our attention. Consequently, the physical contsants given in the report for the compound IX are actually for the compound XIII.

c) Decomposition point

direction from that of VIIa→VIIIa. Contrary to this expectation, heating VIIb with polyphosphoric acid gave the starting material unchanged.

So far, the direction of the rearrangements is in a line with that established in the corresponding indolenine derivatives. However, the unsaturated ketones, IXa, Xa and Xb, were found recovered unchanged after heating them at 160~170°C with polyphosphoric acid for 6 min., and they decomposed under a more drastic treatment. On the other hand, in the corresponding indolenines,[12] an equilibrium mixture consisting of 70% 2,3-dimethyl-3-phenylindolenine and 30% 3,3-dimethyl-2-phenylindolenine was obtained from both compounds upon heating them with polyphosphoric acid at 150°C.

Special interest arises in the conversion of VIIa→VIIIa, since derivatives of VIIa have frequently been employed as intermediates in the syntheses of various steroids as well as of tricyclic diterpenes.[13]

Experimental*

6-Phenyl-spiro[4, 5]dec-6-en-8-one (V). — Into a solution of potassium *t*-butoxide prepared from 100 cc. of *t*-butanol and 4.0 g. of potassium, 17.4 g. of cyclopentyl phenyl ketone[14] (b. p. 135~137°C/10 mmHg; m. p. of the 2,4-dinitrophenylhydrazone, 142°C) were added; the mixture was then refluxed for 2~3 min. in an atmosphere of nitrogen. After a solution of the quarternary ammonium salt[15] prepared from 14.3 g. of 1-diethylamino-3-butanone and 14.3 g. of methyliodide in 60 cc. of absolute ethanol had been added to the chilled and stirred solution over a one-hour period, the stirring was continued for 10 hr. at room temperature. The solvent and diethylmethylamine were removed, and the residue was diluted with water and then extracted with ether. The ether solution was washed with 3 N hydrochloric acid and dried over anhydrous sodium sulfate. Removal of the solvent gave an oil which was distilled in a vacuum to give 8.5 g. of recovered cyclopentyl phenyl ketone and 5.3 g. of the unsaturated ketone V (b. p. 151~153°C/2 mmHg).

The semicarbazone was recrystallized from ethanol to yield crystals; m. p. 228~229°C (decomp.).

Found: C, 72.34; H, 7.65; N, 14.71. Calcd. for $C_{17}H_{21}ON_3$: C, 72.05; H, 7.47; N, 14.83%.

3-Keto-10-phenyl-$\Delta^{4,5}$-octalin (VI).—VI was prepared from 2-phenylcyclohexanone (b.p. 136~137°C/6 mmHg)[17] following Boekelheide's procedure.[16] B. p. 153~156°C/2 mmHg. The semicarbazone was recrystallized from ethanol to afford crystals (m. p. 229~230°C (decomp.)).

2-Keto-4a-methyl-2, 3, 4, 4a, 9, 10-hexahydrophenanthrene (VIIa).—A solution of 8 g. of 1-methyl-2-tetralone (b. p. 100°C/1 mmHg; the semicarbazone,

16) V. Boekelheide, *J. Am. Chem. Soc.*, **69**, 790 (1947), reported b.p. 136~140°C/0.5 mmHg, semicarbazone, decomp. p. 230~232°C.
17) M. S. Newman and M. D. Farbman, ibid., **69**, 1550 (1944).

m. p. 196~198°C.)[18] was added to a solution of potassium *t*-butoxide prepared from 2.7 g. of potassium and 62 cc. of *t*-butanol, and the reaction mixture was refluxed for 4 min. in an atmosphere of nitrogen. After a solution of the methiodide of 1-diethylamino-3-butanone prepared from 10.8 g. of the amine and 10.8 g. of methyl iodide in 37 cc. of ethanol had been added drop by drop over a 20 min. period, the mixture was stirred for 8 hr. at room temperature and then was allowed to stand for 10 hr. at the same temperature. The mixture was poured into water and extracted with ether. The ether solution was washed with 4 N hydrochloric acid and water, dried over anhydrous sodium sulfate, and freed of the solvent. The residue was distilled in a vacuum to yield 1.0 g. of the recovered 1-methyl-2-tetralone (b. p. 70~76°C/1 mmHg) and 5.6 g. of the ketol XII (b. p. 152~156°C/1 mmHg). An infrared spectrum indicated major peaks at 3390 and 1715 cm^{-1}. To a solution of 12.5 g. of the ketol XII in 30 cc. of methanol, was added 30 cc. of 50% methanolic potassium hydroxide, and the mixture was refluxed for 1 hr. Water was added, and the aqueous mixture was extracted with ether. The ether solution was separated, washed with water, and dried over anhydrous sodium sulfate, and the solvent was evaporated. When the residure was recrystallized from petroleum ether and benzene, colorless crystals separated (m. p. 86~89°C) which weighed 0.7 g. Recrystallization from petroleum ether and ether yielded crystals; m. p. 89~91°C (reported 89~91°C).[6,19]

Found: C, 84.60; H, 7.67. Calcd. for $C_{15}H_{16}O$: C, 84.87; H, 7.60%.

The semicarbazone was recrystallized from ethanol to yield crystals (m. p. 223°C (decomp.)).

Found: C, 71.67; H, 7.30; N, 15.41. Calcd. for $C_{16}H_{19}ON_3$: C, 71.34; H, 7.11; N, 15.60%.

The 2, 4-dinitrophenylhydrazone melted at 200~201°C, after recrystallization from ethyl acetate (reported 203~204°C).[6,19]

Found: C, 64.12; H, 5.27; N, 14.40. Calcd. for $C_{21}H_{20}O_4N_4$: C, 64.27; H, 5.14; N, 14.26%.

3-Keto-10a-methyl-2, 3, 9, 10, 10a, 1-hexahydrophenanthrene (VIIIa).—To a chilled solution of potassium *t*-butoxide prepared from 8.6 g. of potassium and 200 cc. of *t*-butanol, 29.0 g. of 2-methyl-1-tetralone[20] (b. p. 88~90°C/1 mmHg; the semicarbazone, decomp. p. 201°C) were added in an atmosphere of nitrogen. The solution was refluxed for 3 min. and then chilled in an ice bath. A solution of the quarternary ammonium salt prepared from 35 g. of 1-diethylamino-3-butanone and 35 g. of methyl iodie in 120 cc. of ethanol was added to the stirred solution over a one-hour period. The reaction mixture was then allowed to stand at room temperature for 10 hr. After the solvent had been removed, the residue was diluted with water and extracted with ether. The ether solution was washed twice with 3 N hydrochloric acid and then with water and dried over anhydrous sodium sulfate. Removal of the solvent yielded an oil which was distilled to give 4.3 g. of the recovered 2-methyl-1-tetralone (b. p. 150°C/1 mmHg) and 16.3 g. of the unsaturated ketone VIIIa (b. p. 155~156°C/1 mmHg), which crystallized on standing at room temperature. Recrystallization from petroleum ether afforded crystals (m. p. 62~63°C).

Found: C, 85.23, H, 7.68. Calcd. for $C_{15}H_{16}O$: C, 84.87; H, 7.60%.

The semicarbazone which was prepared by the usual procedure decomposed at 248°C after recrystallization from ethanol.

Found: C, 71.16; H, 7.00; N, 15.90. Calcd. for $C_{16}H_{19}ON_3$: C, 71.34; H, 7.11; N, 15.60%.

The 2,4-dinitrophenylhydrazone was recrystallized from ethyl acetate (m. p. 232~233°C).

Found: C, 64.70; H, 5.16; N, 14.75. Calcd. for $C_{21}H_{20}O_4N_4$: C, 64.27; H, 5.14; N, 14.28%.

3-Keto-4, 10a-dimethyl-2, 3, 9, 10, 10a, 1-hexahydrophenanthrene (VIIIb).—To a chilled solution of potassium *t*-butoxide prepared from 5.5 g. of potassium and 125 cc. of *t*-butanol, 17 g. of 2-methyl-1-tetralone were added in an atmosphere of nitrogen. The solution was refluxed for 3 min. and then cooled in an ice bath. A solution of the quaternary ammonium salt prepared from 24 g. of 1-diethylamino-3-pentanone and 22 g. of methyl iodide in 75 cc. of ethanol was added into the solution over a 20 min. period. The temperature was gradually raised to room temperature and kept at this temperature for 2.5 hr. The mixture was refluxed for 1 hr., and the solvent was removed. The residue was diluted with water and extracted with ether. The ether extract was washed with 3 N hydrochloric acid and water, and then dried over anhydrous sodium sulfate. The solvent was removed and the residue distilled to yield two high boiling fractions: (1. b. p. 155~162°C/2 mmHg, 11.5 g.; 2. b. p. 168~182°C/2 mmHg, 4.4 g.), besides a low boiling fraction (b. p. 100~125°C/2 mmHg), which consisted mainly of the recovered 2-methyl-1-tetralone. The combined high boiling fractions were distilled to afford 12.0 g. of the unsaturated ketone VIIIb (b. p. 160~162°C/2 mmHg). The semicarbazone was prepared by the usual procedure and was recrystallized from ethanol (decomp. p. 220~221°C).

Found: C, 72.34; H, 7.42; N, 14.39. Calcd. for $C_{17}H_{21}O_4N_3$: C, 72.08; H, 7.42; N, 14.83%.

The 2, 4-dinitrophenylhydrazone was recrystallized from ethyl acetate to give dark red needles (m. p. 188~189°C).

Found: C, 64.88; H, 5.54; N, 13.95. Calcd. for $C_{22}H_{22}O_4N_4$: C, 65.01; H, 5.40; N, 13.79%.

3, 6-Dimethyl-6-phenylcyclohex-2-enone (XIII).—To a slurry of sodium amide prepared from 4.6 g. of sodium in 150 cc. of ether, a solution of 29.6 g. of 3-phenyl-2-butanone[21] (b. p. 105~107°C/17 mmHg) was added, and the mixture was refluxed for 1 hr. (ammonia gas evolved). To the reaction mixture was added a solution of the quaternary ammonium salt prepared from 15 g. of 1-diethylamino-3-butanone, 15 g. of methyl iodide and 60 cc. of ethanol over a one-hour period., and then the

mixture was refluxed for 6 hr. with stirring. The mixture was poured into water and extracted with ether. The ether solution was washed with 4 N hydrochloric acid and then with water. Drying and removal of the solvent yielded a residue which was distilled in a vacuum to give 14.5 g. of the recovered 3-phenyl-2-butanone and 5.3 g. of an oil (b. p. 112~116°C/1 mmHg). The semicarbazone could not be prepared by the usual method, but 2, 4-dinitrophenylhydrazone could be obtained with Brady's reagent. Recrystallization from ethanol-ethyl acetate gave orange red needles (m. p. 204~206°C).

Found: C, 63.29; H, 5.27; N, 14.99. Calcd. for $C_{20}H_{20}O_4N_4$: C, 63.15; H, 5.30; N, 14.73%.

2,3-Dimethyl-3-phenylcyclohex-1-ene.—A stream of methyl bromide gas was passed through a stirred suspension of 3 g. of magnesium in 100 cc. of ether until the magnesium disappeared. After a solution of 12 g. of 2-methyl-2-phenylcyclohexanone[17] in 50 cc. of ether had been added over a 30 min. period, the reaction mixture was refluxed for 1 hr. The Grignard complex was decomposed with diluted aqueous hydrochloric acid and extracted with ether. The ether solution was washed with water, dried, and evaporated. To the viscous residue 0.1 g. of iodine was added, and the mixture was heated at 100°C for 30 min. and then distilled to give a dark brown oil (b. p. 124~126°C/13 mmHg). The distillate was diluted with ether, washed with an aqueous sodium hyposulfite solution to remove the iodine, and washed with water. Removal of the solvent and distillation yielded 7.9 g. of oil (b. p. 118~119°C/10 mmHg).

3, 4-Dimethyl-4-phenylcyclohex-2-enone (IXa).—A solution of 7.9 g. of 2, 3-dimethyl-3-phenylcyclohexene in 50 cc. of carbon tetrachloride was stirred at 80°C, and then a mixture of 175 cc. of a *t*-butyl chromate solution[22] (which corresponds to 32 g. of chromic anhydride), 53 cc. of acetic acid, and 21.6 g. of acetic anhydride was added. After having been stirred at this temperature for 8 hr., the solution was cooled and the excess oxidation reagent was decomposed with a solution of 35 g. of oxalic acid in 350 cc. of water. The mixture was then passed through a layer of Hyflo super cells to remove a sludgy material. After having been separated from the carbon tetrachloride layer, the aqueous solution was extracted with carbon tetrachloride three times. The combined carbon tetrachloride solutions were washed with water, 5% aqueous sodium carbonate, 2 N sodium hydroxide and water successively. Drying and removal of the solvent gave a residue, which was distilled to yield 2.1 g. of the recovered hydrocarbon (b. p. 130°C/10 mmHg) and 3.0 g. of the unsaturated ketone IXa (b. p. 163~164°C/10 mmHg). The semicarbazone was recrystallized from ethanol (decomp. p. 217~218°C).

Found: C, 69.87; H, 7.30; N, 16.12. Calcd. for $C_{15}H_{19}ON_3$: C, 70.00; H, 7.44; N, 16.33%.

The 2, 4-dinitrophenylhydrazone was recrystallized from ethyl acetate to afford orange red needles (m. p. 146~147°C).

Found: C, 62.95; H, 5.30; N, 14.82. Calcd. for $C_{20}H_{20}O_4N_4$: C, 63.15; H, 5.30; N, 14.73%.

4, 4-Dimethyl-3-phenylcyclohex-2-enone (Xa).—To a solution of potassium *t*-butoxide prepared from 4.0 g. of potassium and 100 cc. of *t*-butanol, 14.8 g. of isopropyl phenyl ketone (b. p. 97~99°C/13 mmHg, 2, 4-dinitrophenylhydrazone, m. p. 161~162°C) were added, and the solution was refluxed for 3 min. in an atmosphere of nitrogen. A solution of the quarternary ammonium salt prepared from 14.3 g. of 1-diethylamino-3-butanone and 14.3 g. of methyl iodide in 60 cc. of ethanol was added over a period of 35 min., and the reaction mixture was then allowed to stand at room temperature for 11 hr. After having been refluxed for 20 min., the mixture was concentrated and diluted with water. The aqueous solution was extracted with ether, and the ether extracts were washed with 3 N hydrochloric acid and then with water. Drying and removal of the solvent afforded a viscous oil which distilled in a vacuum to yield 10.0 g. of the recovered ketone (b. p. 100°C/13 mmHg) and 2.5 g. of the unsaturated ketone Xa (b. p. 124~126°C/2 mmHg). The semicarbazone was recrystallized from ethanol to give crystals (decomp. p. 242°C).

Found: C, 69.83; H, 7.47; N, 16.24. Calcd. for $C_{15}H_{19}ON_3$: C, 70.00; H, 7.44; N, 16.33%.

The 2, 4-dinitrophenylhydrazone was recrystallized from ethanol-ethyl acetate (m. p. 198~199°C).

Found: C, 63.12; H, 5.43; N, 14.99. Calcd. for $C_{20}H_{20}O_4N_4$: C, 63.15; H, 5.30; N, 14.73%.

2, 4, 4-Trimethyl-3-phenylcyclohex-2-enone (Xb).—To a solution of potassium *t*-butoxide prepared from 5.8 g. of potassium and 120 cc. of *t*-butanol, 17.5 g. of isopropyl phenyl ketone were added, and the mixture was refluxed for 3 min. After a solution of the quarternary salt[23] prepared from 24 g. of 1-diethylamino-3-pentanone and 22 g. of methyl iodide in 70 cc. of ethanol had been added over a period of 45 min., the mixture was cooled in an ice bath for 4 hr. and then refluxed for 1 hr. After the solvent had been removed, the reaction mixture was diluted with water and extracted with ether. The ether solution was washed with 3 N hydrochloric acid and water, and then dried over anhydrous sodium sulfate. The ether was removed and the residual liquid distilled to give 7.2 g. of a colorless liquid (b. p. 172~175°C/27 mmHg). The semicarbazone was recrystallized from ethanol to afford crystals (decomp. p. 239~240°C).

Found: C, 70.73; H, 8.02; N, 15.36. Calcd. for $C_{16}H_{21}ON_3$: C, 70.82; H, 7.80; 15.49%.

The 2, 4-dinitrophenylhydrazone was recrystallized from ethanol-ethyl acetate to yield red needles (m. p. 247~248°C (with decomposition)).

Found: C, 63.99; H, 5.56; N, 14.40. Calcd. for $C_{21}H_{22}O_4N_4$: C, 63.94; H, 5.62; 14.21%.

Interconversion between V and VI.—*a) V→VI.*—To a polyphosphoric acid prepared from 8 cc. of 85% phosphoric acid and 12.5 g. of phosphorous pentoxide, 2.5 g. of the unsaturated ketone V were added, and the mixture was heated at 150~155°C for 10 min. Ice water was added to the reaction mixture, and the turbid solution was extracted with ether. The ether extract was washed with an

aqueous sodium carbonate solution and then with water. Removal of the solvent gave a liquid which distilled to give 1.0 g. of a liquid (b. p. 149~152°C/2 mmHg). An infrared spectrum of the product and that of VI were indistinguishable. The semicarbazone was prepared to give crystals (m. p. 229°C (with decomposition)). The mixed melting point with the semicarbazone of the starting ketone (decomp. p. 228~229°C) was 215°C (with decomposition), while the mixed melting point with the semicarbazone of VI (decomp. p. 229~230°C) was 228°C (with decomposition).

b) *VI→V.*—A mixture of 2.0 g. of VI and 20 g. of polyphosphoric acid was heated at 100°C for 30 min. and then at 150°C for 5 min. The reaction mixture was poured into ice water and extracted with ether. Evaporation of the solvent and distillation gave 1.5 g. of an oil (b. p. 140~150°C/2 mmHg). Identification of the product with the starting material was established by comparison of their infrared spectra and by a mixed melting point determination of their semicarbazones.

Interconversion between VIIa and VIIIa.—*a*) *VIIa→VIIIa.*—A mixture of 0.7 g. of the ketone VIIa and 20 g. of polyphosphoric acid was heated in an oil bath; the temperature was raised rapidly to 165°C and then kept at this temperature for 3 min. After the reaction mixture had been poured quickly into water, the mixture was extracted with ether. The ether solution was washed with water and with a 5% sodium carbonate solution. Drying and removal of the solvent gave an oil which distilled to afford 0.55 g. of a viscous oil (b. p. 157~163°C/1 mmHg). The product crystallized upon standing at room temperature and was recrystallized from petroleum ether to yield crystals (m. p. 60~61°C), the identification of which with VIIIa was established by a comparison of their infrared spectra and by mixed melting point determination. The identification was further confirmed by the mixed melting point, 248°C (with decomposition) of the semicarbazone of the produt, with the semicarbazone of VIIIa (decomp. p. 248°C).

b) *VIIIa→VIIa.*—A mixture of 2.0 g. of VIIIa and 30 g. of polyphosphoric acid was heated at 160°C for 3 min. and then poured into ice water. The mixture was extracted with ether, and the ether solution was washed with aqueous sodium carbonate and then with water. Drying and removal of the solvent gave a residual oil which distilled to yield 1.9 g. of a liquid (b. p. 165~170°C/1 mmHg). The product which crystallized upon standing at room temperature was recrystallized from petroleum ether to afford crystals, (m. p. 62 63°C). The mixed melting point with the starting material was 62~63°C.

Reaction of VIIIb with Polyphosphoric Acid.—A mixture of 3.0 g. of the ketone VIIIb and 30 g. of polyphosphoric acid was heated at 160°C for 15 min. Upon the usual work-up, 2.5 g. of VIIIb were recovered. Identification was established by an infrared absorption spectrum.

Interconversion between IX and Xa.—*a*) *IX→Xa.*—A mixture of 2.0 g. of the ketone IX and 25 g. of polyphosphoric acid was heated at 150~160°C for 4 min. The reaction mixture was poured into water and extracted with ether. The ether solution was washed with aqueous sodium carbonate and with water. Removal of the solvent and distillation of the residue gave 1.6 g. of an oil (b. p. 160~163°C). Although the infrared spectrum was found indistinguishable with that of the starting material, the ultraviolet spectrum showed a peak at 228 mμ, with a shoulder at 270 mμ. The semicarbazone prepared from the product decomposed at 203~209°C after one recrystallization from ethanol. This was found contaminated with a very small number of needles. Four recrystallizations from ethanol raised the decomposition point to 215°C, which was unchanged upon admixture with the semicarbazone of the starting material.

b) *Xa→IX.*—A mixture of 2.3 g. of Xa and 30 g. of polyphosphoric acid was heated at 150~160°C for 10 min. Upon the usual work-up, 1.5 g. of the starting material was recovered; identification was established by a comparison of the infrared spectrum and the melting point (m. p. 190~193°C) of the 2, 4-dinitrophenylhydrazone.

Reacton of Xb with Polyphosphoric Acid.—A mixture of 3.0 g. of ketone Xb and 35 g. of polyphosphoric acid was heated at 160~170°C for 6 min. From the reaction mixture, 2.5 g. of the starting material (b. p. 115~117°C/2 mmHg) was recovered; identification was established by comparing the infrared spectra and the melting points (decomposed at 240~241°C) of the semicarbazone of the starting material with those of the reaction product.

The authors are very grateful to the Nitto Kasei Co. for its financial support. A part of the cost of this research was also defrayed by a grant-in-aid for fundamental scientific research from the Ministry of Education, to which the authors' thanks are due.

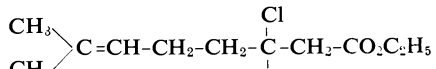
Stereoselective Synthesis of Nerol

By Yasuhide YUKAWA, Terukiyo HANAFUSA and Kaneko FUJITA

(Received July 27, 1963)

It is well known that geraniol and nerol are the most fundamental acyclic monoterpenoid alcohols and that both are geometric isomers. Their geometric configurations were mainly elucidated by the following chemical and physical evidence. Zeitschel[1] showed in 1906 that when fifty grams each of geraniol, linalool and nerol were cyclized to α-terpineol with dilute sulfuric acid, the yields of the reaction were 0.35 g., 1.75 g. and 2.5 g. respectively. Judging from the ease of cyclization, he assumed that the isohexenyl group and the hydroxymethyl group in geraniol (I) were trans to each other and that these groups in nerol were cis, based upon the ease of the cyclization.

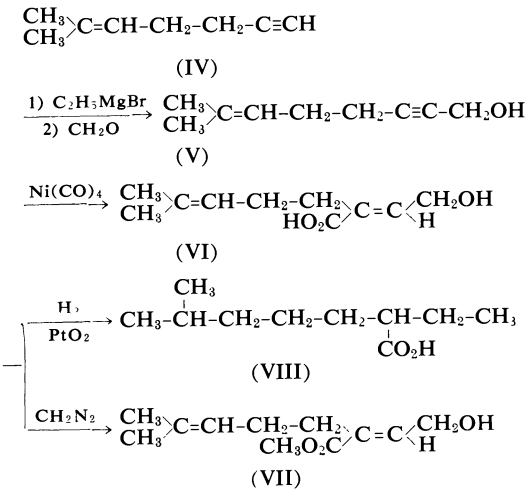


(I)

(II)

Recently Jeffery[2] has established by X-ray crystallographic study that geranyl amine hydrochloride derived from geraniol has a structure which agrees with the chemically-assigned configuration. Thus, geraniol, in which relatively bulky groups are trans, may be thermodynamically more stable than nerol, and this may be correlated to the fact that the melting point of geranyl derivatives is higher than that of neryl compounds.[3,4]

Two synthetic methods of nerol have been reported in the literature. One[5] is the isomerization of geraniol to nerol; this reaction involves the addition of hydrogen iodide to geraniol and the subsequent elimination of the acid with alcoholic sodium hydroxide to give nerol. In the other,[6] nerol is obtained by the lithium aluminum hydride reduction of *cis*-geranic acid, which has been prepared by the elimination of hydrogen chloride with pyridine from the chloroester III. Both routes to form

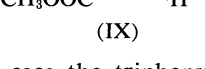


(III)

the double bond concerned are base-catalyzed eliminations; it seems probable that a major product would be a more thermodynamically stable isomer in these reactions. In the syntheses of nerol, thus, an ambiguity still remains.

In this paper we wish to report the stereoselective synthesis of nerol allophanate, starting with an acetylenic compound.

Results and Discussion



The starting material, 6-methyl-5-hepten-1-yne (IV), was prepared from γ-butyrolactone and acetylene according to Eschenmoser's procedure[7] and was converted into 7-methyl-6-octen-2-yn-1-ol (V) by the reaction of its Grignard compound with paraformaldehyde. The acetylenic alcohol V was reacted with nickel carbonyl in a solvent mixture of alcohol, acetic acid and water at 70°C to give unsaturated hydroxylic acid VI, which did not lactonize on being heated to 120°C for 5 hr. The catalytic hydrogenation of this acid VI over platinum oxide afforded 2-ethyl-6-methylheptanoic acid (VIII), with hydrogenolysis of

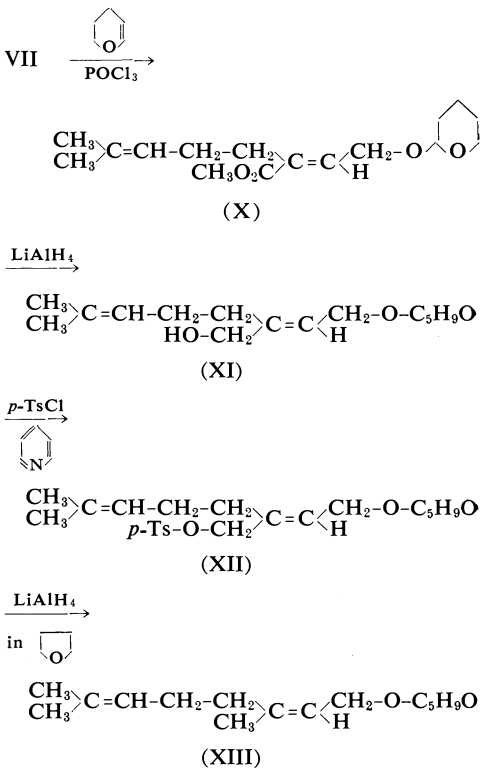
the allylic hydroxyl group, which was characterized as its anilide (m. p. 66~67°C[8]). If the carboxylation of the acetylenic alcohol V with nickel carbonyl occurred in the β-position of the hydroxyl group, the hydrogenation of this reaction product should give 2, 7-dimethyloctanoic acid, which is an isomer of VIII. However, it is reported that its anilide melted at 93°C.[8] Since it has been established[9,10] that this carboxylation of the acetylenic compound, developed by Jones,[9] results in the formation of α, β-unsaturated carboxylic acid, in which the carboxyl function and the hydrogen atom introduced are on the same side of the double bond, these evidences confirm the correctness of the above formulation.



The esterification of the unsaturated hydroxylic acid VI smoothly proceeded using diazomethane to give an unsaturated ester VII. During the subsequent reduction of the ester function to the methyl group it is necessary to protect the hydroxyl function in a form unaffected by reducing agents. In our previous investigation,[10] 4-methoxycarbonyl-3-hexen-1-ol (IX) was converted into triphenylmethyl ether of IX in order to prevent the elimination of the hydroxyl function during hydrolysis and decarboxylation. It was found, however, that

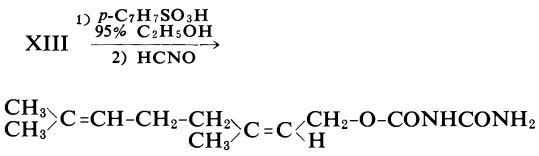
(IX)

in this case the triphenylmethoxy group in the trityl ether of VII was replaced by a hydrogen atom during the course of the reduction of the ester function to the methyl group. Recently we reported[11] that the reaction of dihydropyran with catechol furnished protection to the hydroxyl group in catechol to give the di-(tetrahydropyranyl)ether of catechol, which was stable in basic media and which was readily hydrolyzed with dilute mineral acid. This procedure has also been employed in the study of aliphatic unsaturated hydroxylic compounds.[12]

The ester VII was treated with dihydropyran and a catalytic amount of phosphorous oxychloride to afford tetrahydropyranyl ether X. The ester function of the tetrahydropyranyl derivative X was transformed into the hydroxymethyl group with lithium aluminum hydride in a cold ethereal solution. The reaction of the resulting alcohol XI with *p*-toluenesulfonyl chloride in pyridine gave a sulfonate XII, which was further reduced with lithium aluminum hydride in tetrahydrofuran under reflux. In some reactions of allylic derivatives, allylic rearrangement may occasionally occur. However, it has proved by a study using ^{14}C as a tracer[13] that allylic rearrangement does not occur when the *p*-toluenesulfoxyl group in an allylic situation is replaced with nucleophilic reagents. This procedure has ordinarily been employed in the transformation of the hydroxymethyl group to the methyl group.[14]

(X)

(XI)



(XII)

(XIII)

The reduction product was purified by alumina chromatography, and the pure tetrahydropyranyl ether XIII was eluted with petroleum ether. It has been reported that the hydrolysis of tetrahydropyranyl ether has been carried out by the action of warm dilute mineral acid, a boiling aqueous oxalic acid solution, 2, 4-dinitrophenylhydrazine in 2 N hydrochloric acid or *p*-toluenesulfonic acid in aqueous alcohol.[15] In this case it was experimentally found that the last of these reagents

was the most satisfactory. The tetrahydropyranyl ether XIII was treated with a small amount of *p*-toluenesulfonic acid in 95% ethyl alcohol at 55°C for one-and-a-half hours to give an oil, into which cyanic acid was then introduced at room temperature. The allophanate XIV was obtained as colorless needles after one recrystallization each from benzene and from petroleum ether. It was much more soluble in benzene or petroleum ether than in

(XIV)

geranyl allophanate and melted at 84~86°C. The melting point was not raised by further recrystallization and was not depressed upon admixture with geranyl allophanate (m. p. 110°C).

Other investigators[3,4,16,17] have also recorded that the crystalline derivatives of nerol are much more soluble in ordinary solvents than that of geraniol, that the melting points of neryl derivatives are lower than that of geranyl derivatives, and that they did not depress upon admixture with geranyl compounds. It is evident that the allophanate XIV is neryl allophanate since its behavior agrees with these results.

As has been described above, Mondon[6] has reported obtaing *cis*-geranic acid by the reaction of chloroester III with pyridine and by the hydrolysis of the resulting ester. Its *S*-benzylthiourea adduct recrystallized from dioxane melted at 133°C, while the adduct of *trans*-geranic acid, prepared by the oxidation of geraniol, melted at 141~143°C after recrystallization from dilute alcohol. However, it was found that these two adducts were the same compound. The adduct of *cis*-acid melted at 141~143°C when it was recrystallized from dilute alcohol, and the reduction product of *cis*-acid purified by Mondon's procedure was geraniol, which was characterized as its allophanate (m. p. 107~110°C). These results agree with the generality that the base-catalyzed elimination of hydrogen halide from a halogeno compound gives a more thermodynamically stable isomer at a higher rate.[18]

Experimental

7-Methyl-6-octen-2-yn-1-ol (V). — 6-Methyl-5-octen-1-yne (IV) (16 g.), prepared according to Eschenmoser's procedure, was added to an ethereal solution of ethylmagnesium bromide prepared from ethyl bromide (22 g.) and magnesium (5 g.) in ether (150 ml.). The reaction mixture was heated under reflux for 2 hr., after which paraformaldehyde (22 g.) was stirred in efficiently at −5°C over a 1 hr. period. After being stirred for 2 hr. at 0°C, the mixture was decomposed with a saturated aqueous ammonium chloride solution. The ether extracts were washed with water and dried over anhydrous magnesium sulfate. This compound (12 g.) was obtained as an oil (b. p. 93~95°C/3 mmHg, n_D^{23} 1.4761). Its phenyl urethane did not solidify.

3-Carboxy-7-methyl-2, 6-octadien-1-ol (VI).—A solution of nickel carbonyl (7.5 ml.) in absolute ethyl alcohol (15 ml.) was added dropwise at 65~70°C with stirring under an inert atmosphere into a solution of the acetylenic alcohol (V) in ethyl alcohol (32 ml.) acetic acid (6.5 ml.), and water (3 ml.). After being heated under reflux for 2 hr., the mixture was treated with 5% sulfuric acid (35 ml.) and ether (100 ml.) at 0~5°C. The water layer was repeatedly extracted with ether. The combined ether was extracted with saturated aqueous sodium hydrogen carbonate until the pH value in an alkaline solution did not change (twelve times). The alkaline layer was acidified with dilute hydrochloric acid. Continuous ether extraction from the acidic solution afforded, after removal of the solvent, this acid VI (6.9 g.) (b. p. 145~147°C).

Found: C, 65.19; H, 8.75. Calcd. for $C_{10}H_{16}O_3$: C, 65.38; H, 8.43%.

The compound was redistilled unchanged under reduced pressure and did not change on being heated at 120°C for 5 hr.

2-Ethyl-6-methylheptanoic Acid (VIII). — The acid VI was hydrogenated in ethyl acetate over platinum oxide under atmospheric pressure. 3.5 equivalents of hydrogen were absorbed over a 6 hr. period. The product was then extracted with a 10% aqueous sodium carbonate solution. After acidification with 2 N hydrochloric acid, the saturated acid VIII was extracted with ether in a 63% yield. This compound was distilled at 105°C/20 mmHg and showed no band in the region of 3000~4000 cm^{-1}.

Found: C, 69.14; H, 11.70. Calcd. for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%.

The anilide of this acid melted at 66~67°C; this agrees with Suzuki's finding.[8]

3-Methoxycarbonyl-7-methyl-2, 6-octadien-1-ol (VII).—A solution of diazomethane prepared from *N*-nitrosomethylurea (15 g.) in ether (30 ml.) was introduced into a solution of the unsaturated acid (VI) (6.9 g.) in an ice-salt bath. After it had been left standing overnight, the reaction mixture was shaken with 2 N hydrochloric acid, with a saturated aqueous sodium hydrogen carbonate solution, and with water successively. The ester VII (5 g.) was distilled at 128~129°C/3 mmHg; n_D^{28} 1.4737.

Found: C, 66.77; H, 9.59. Calcd. for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%.

3-Methoxycarbonyl-7-methyl-2,6-octadienyl Tetrahydropyranyl Ether (X). — A few drops of phosphorous oxychloride were added to a mixture of the ester VII (5 g.) and dihydropyran in an ice bath. After it had stood at room temperature for 3 hr., the reaction mixture was added to a 20% aqueous sodium carbonate solution. Ether extraction gave, after removal of the solvent, the ether X (4 g.) (b. p. 120~121°C/0.1 mmHg).

Found: C, 68.20; H, 9.37. Calcd. for $C_{16}H_{26}O_4$: C, 68.05; H, 9.28%.

3-Hydroxymethyl-7-methyl-2, 6-octadienyl Tetrahydropyranyl Ether (XI).—A solution of the above ether X (4 g.) in absolute ether (50 ml.) was stirred, at −10°C, into a solution of lithium aluminum hydride (0.6 g.) in absolute ether (30 ml.). The reaction mixture was heated under reflux for a short time. After ethyl acetate (1 ml.) had been added to the mixture in an ice-salt bath, 2 N hydrochloric acid (30 ml.) was introduced. An ethereal layer was washed with water and dried over anhydrous magnesium sulfate. This compound XI (2.8 g.) was distilled at 130~137°C/0.3 mmHg.

Found: C, 70.25; H, 10.30. Calcd. for $C_{15}H_{26}O_3$: C, 70.83; H, 10.30%.

The Sulfonate of XI (XII).—A solution of XI (2.8 g.) in dry pryridine (30 ml.) was stirred, at −1~−3°C, into a solution of *p*-toluenesulfonyl chloride (4.5 g.) in the solvent. After having been stirred for 3 hr. at room temperature, the mixture was poured into cold dilute hydrochloric acid. Chloroform extraction afforded this compound XII as an viscous oil after evaporation of the solvent under reduced pressure. The sulfonate was easily soluble in chloroform or tetrahydrofuran, only but with difficult in ether, and it was not further purified.

Neryl Tetrahydropyranyl Ether (XIII).—A solution of the above sulfonate XII in tetrahydrofuran (50 ml.) was stirred into a solution of lithium aluminum hydride (1 g.) in tetrahydrofuran (50 ml.) in an ice-salt bath. The reaction mixture was heated under reflux for 10 hr. After having been cooled, the mixture was decomposed with ethyl acetate (4 ml.), water (10 ml.) and 2 N hydrochloric acid (50 ml.) successively. The water layer was extracted with ether. The combined ether solution was then washed with a 20% sodium carbonate solution and an aqueous saturated sodium chloride solution. After removal of the solvent, the residue was purified by alumina column chromatography. Elution with light petroleum (600 ml.) gave neryl tetrahydropyanyl ether XIII (0.4 g.) (b. p, 150°C (bath temp.)/0.3 mmHg). The infrared spectrum of this compound resembled that of the geranyl derivative.

The Allophanate of Nerol (XIV).—A solution of the neryl tetrahydropyranyl ether (XIII) (0.4 g.) and *p*-toluenesulfonic acid (0.05 g.) in 95% ethyl alcohol (8 ml.) was heated to 52~58°C for one and a half hours. The mixture was then extracted with light petroleum after having been added to water. An organic layer was washed with a 10% aqueous sodium carbonate solution and water, and then dried over magnesium sulfate. After removal of the solvent, the cyanic acid generated from the thermal decomposition of cyanuric acid (0.5 g.) was introduced into the residue in an ice bath. The solids thus produced were washed with light petroleum and recrystallized once from benzene and once from light petroleum. The allophanate XIV (0.1 g.) was obtained as needles, which melted at 84~86°C by themselves and which melted at 84~88°C on admixture with the allophanate of geraniol. The melting point was not raised by further recrystallization.

Found: C, 59.03; H, 8.39; N, 11.72. Calcd. for $C_{12}H_{20}O_3N_2$: C, 59.98; H, 8.46; N, 11.66%.

Reduction of the Triphenylmethyl Ether of VII.—A mixture of VII (4 g.), triphenylmethyl chloride (7 g.) and pyridine (3 g.) in benzene (70 ml.) was heated under reflux for 4 hr. After removal of the solvent under reduced pressure, the residue was extracted 4 times with light petroleum (100 ml.). The trityl ether (5.4 g.) was obtained as a viscous oil after having been purified by alumina column chromatography.

A solution of the substance (5 g.) in absolute ether (30 ml.) was ordinarily reduced with lithium aluminum hydride in an ice bath. The reaction products were chromatographed on alumina. 3-Hydroxymethyl-7-methyl-2, 6-octadienyl triphenylmethyl ether (1.8 g.) was eluted, using 30% benzene-light petroleum as a syrup, a syrup which was decomposed on distillation, even under highly reduced pressure.

Found: C, 84.30; H, 7.92. Calcd. for $C_{29}H_{32}O_2$: C, 84.42; H, 7.82%.

The reduction procedure of this compound was analogous to that described in the reduction of XI through its sulfonate XII with lithium aluminum hydride. The products were chromatographed on alumina. An olefin was eluted with light petroleum and seemed to be 2, 6-dimethyl-2, 6-octadiene judging from its boiling point (100~110°C (bath temp.)/20 mmHg), its analytical datum and its infrared spectrum.

Found: C, 87.49; H, 11.63. Calcd. for $C_{10}H_{18}$: C, 86.88; H, 13.12%.

The other product was eluted with 50% benzene-light petroleum as plates; the m. p. was 150~155°C, which was not depressed when the product was admixed with triphenylmethyl alcohol.

Geranyl Tetrahydropyranyl Ether.—This compound (3.5 g.) (b. p. 122~124°C/5 mmHg) was prepared from geraniol (3 g.) and dihydropyrane (3 g.) in a manner similar to that described in the synthesis of X.

Found: C, 76.05; H, 10.70. Calcd. for $C_{15}H_{26}O_2$: C, 75.63; H, 10.92%.

Hydrolysis of Geranyl Tetrahydropyranyl Ether.—1) A mixture of the ether (1 g.) and oxalic acid (0.5 g.) in water (5 ml.) was heated while being stirred at 100°C for 1.5 hr. Steam distillation gave the starting material (0.6 g.) unchanged; this was confirmed by its infrared spectrum.

2) A mixture of the ether (1 g.) in 2 N sulfuric acid (10 ml.) was slowly distilled with steam to give an alcohol, but its allophanate melted at 70~80°C.

3) The ether was shaken with excess 2, 4-dinitrophenylhydrazine in 2 N hydrochloric acid for 7 hr. The ether was recovered unchanged.

The Reduction of *cis*-Geranic Acid.—*cis*-Geranic acid was prepared from III following Mondon's procedure. Its *S*-benzylthiuronium salt melted at 133°C on recrystallization from dioxane and at 141~143°C on recrystallization from dilute alcohol. The purified acid through the *S*-benzylthiuronium salt was reduced with lithium aluminum hydride by Mondon's procedure. The reduction product (b. p. 86~87°C/4 mmHg) was converted into its allophanate, which melted at 107~110°C after having been recrystallized from benzene. The melting point was not depressed when the product was admixed with geranyl allophanate.

Summary

Nerol, acyclic monoterpene alcohol, has been stereoselectively synthesized using as an intermediate the unsaturated hydroxylic acid VI, in which the carboxyl and the hydroxymethyl groups are evidently in the cis-relation.

The authors wish to express their thank to Mr. Tsuguyo Shishido for his microanalysis and to Miss Kayo Kabazawa for her infrared spectroscopy. They are also indebted to the Shiono Koryo Co., Ltd., and to the Hagihara Laboratory for their kind assistance throughout this work.

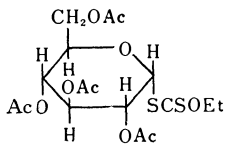
The Rotatory Dispersion and Stereochemistry of Organic Compounds. V.[1] *On Anomeric Pyranoses with a Xanthate Group*

By Yojiro TSUZUKI, Koko TANABE, Masuo AKAGI and Setsuzo TEJIMA

(Received July 27, 1963)

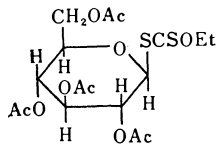
In a previous paper[1] it was shown that some of the rotatory contribution of the hydroxyl groups in glucose can be studied by means of rotatory dispersion with its derivatives which contain a xanthate group. The present paper will report on similar, comparative studies made of a variety of newly-synthesized xanthates with a pyranose configuration, namely:

2, 3, 4, 6-Tetra-*O*-acetyl-α-D-glucopyranosyl ethylxanthate (compound I),



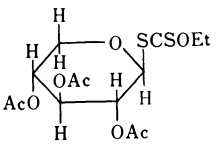
2, 3, 4, 6-Tetra-*O*-acetyl-β-D-glucopyranosyl ethylxanthate (compound II),

2, 3, 4-Tri-*O*-acetyl-β-D-xylopyranosyl ethylxanthate (compound III),

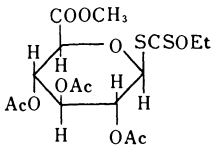


Methyl 2, 3, 4-tri-*O*-acetyl-β-D-glucopyranuronate 1-ethylxanthate (compound IV),

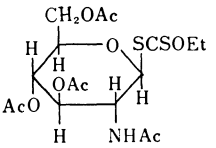
2-Acetamido-2-desoxy-3, 4, 6-tri-*O*-acetyl-β-D-glucopyranosyl ethylxanthate (compound V),



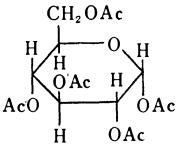
6-Desoxy-6-ethylxanthogen-α-D-glucopyranose tetraacetate (compound VI),



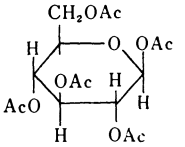
(I) -Et=-C_2H_5
-Ac=-$COCH_3$



(II)



(III)



(IV)

(V)

(VI)

(VII)

6-Desoxy-6-ethylxanthogen-β-D-glucopyranose tetraacetate (compound VII).

1) Y. Tsuzuki, K. Tanaka and K. Tanabe, This Bulletin, 35, 1614 (1962).

Results and Discussion

The RD curves of these compounds are shown in Figs. 1, 2 and 3. Figure 1 shows distinctly the difference between α- and β-anomers. The rotatory background of the α-form I is, as expected, more positive, but its Cotton effect is negative in sign, the peak being 380 mμ, whereas the β-form II shows a stronger, positive Cotton effect (the peak being 381 mμ, the trough, 334 mμ).

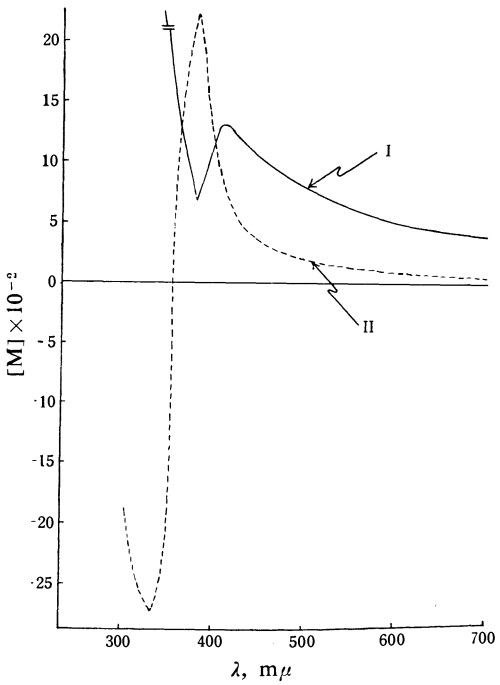


Fig. 1. RD of α- and β-1-xanthogen glucose.

Figure 2 shows the effects of the C_2 and C_5 groups on the rotatory contribution in the β-xanthate series, which exhibit, without exception, obviously positive Cotton effects. Since, in D-glucose and D-xylose and their derivatives, the C_2 group is expected to contribute to the positive rotation, it is possible that the glucosamine derivative V, being a β-configuration, is distinguished from others in high rotation. Its molecular amplitude (the difference of [M] between peak and trough) is also far greater. It is observed that the C_5 effect is insignificantly small when it carries no chromophoric group. The [M] values of these compounds are almost identical above the absorption region, irrespective of the C_5 groups (H, $COOCH_3$, CH_2OCOCH_3); however in molecular amplitude there are little grades of difference which might be of some significance as to the configuration and the group of optically-active absorption, but at present the authors can not consider this point since the sign of the rotatory contribution of the C_5 group has not yet been elucidated. It should, however, be pointed out that all the peaks are situated near 380 mμ, the troughs at 334 mμ, and λ_0, the optically-active absorption maximum, at 360 mμ.

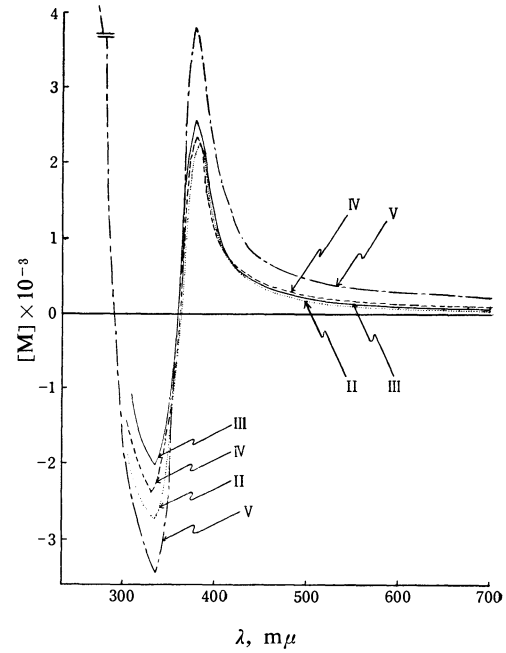

Fig. 2. RD of β-1-xanthates.

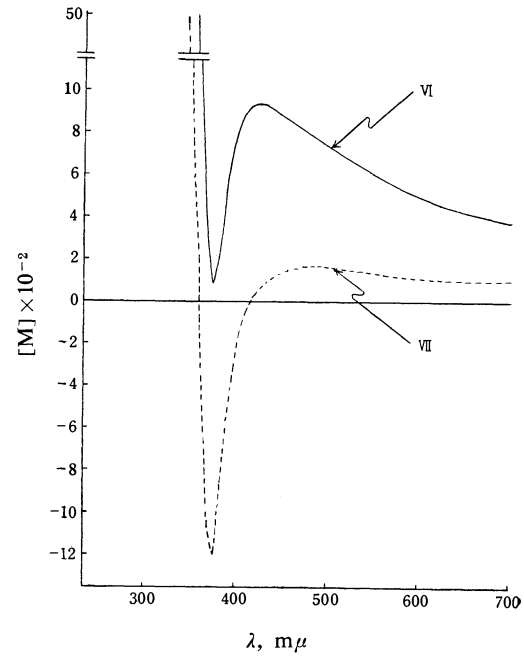

Fig. 3. RD of 6-xanthogen α- and β-acetylglucose.

TABLE I. RD COSTANTS AND UV ABSORPTION MAXIMA

Compound	Rotatory dispersion				Molecular amplitude	Ultraviolet absorption			
	Peak		Trough			R-band		K-band	
	mμ	[M]	mμ	[M]	$\times 10^{-1}$	mμ	ε	mμ	ε
I	380 (negative)	+686°	—	—	—	363	32.0	276	4280
II	381	+2220°	334	−2720°	494°	363	36.4	275	10400
III	378	+2510°	335	−2010°	452°	364	42.5	275	9750
IV	378	+2270°	330	−2320°	459°	360	40.0	274	3330
V	378	+3780°	335	−3340°	712°	360	42.3	276	11400
VI	375 (negative)	+98.7°	—	—	—	356	49.7	279	13100
VII	376 (nagative)	−1190°	—	—	—	356	40.4	279	12900

It can readily be seen from Fig. 3 that the negative Cotton effects are both due to the C_6-xanthate groups, the α-anomer VI showing the RD curve of the greater positive rotation, as expected. The negative peaks are in both cases situated at 375 mμ.

Some characteristic constants of the Cotton effects are collected in Table I, together with those of the ultraviolet absorption, which were measured with a self-recording spectrophotometer of the Hitachi EPU-II type.

The values of λ_0 practically coincide with those of the absorption maximum of the weak band due to the $-\overset{\overset{S}{\|}}{C}-S$ group. The absorption maxima of the strong K-band due to the $>C=S$ moiety are also inserted in the table, although the latter may have no direct relation with the optical activity in these cases.

Expression by the Two-term Drude Equation and the Physical Meaning of the Dispersion Constants

In the expectation that the dispersion data would conform, at least approximately, to the two-term Drude equation:

$$[M] = \frac{A_1}{\lambda^2 - \lambda_1^2} + \frac{A_2}{\lambda^2 - \lambda_2^2}$$

the authors carried out very complicated calculations by means of the least square method using an electronic computer of the Fuji FACOM 201 type. The results are shown in Table II. The agreement between the observed and the calculated values of rotation is tolerably good, the difference between them being mostly only a few per cent outside the absorption region, although in the neighborhood of the absorption center it sometimes rises to even fifty per cent.

TABLE II. DISPERSION CONSTANTS FOR D-GLUCOSE DERIVATIVES (BY THE TWO-TERM DRUDE EQUATION)

Compound	A_1	A_2	λ_1^2	λ_2^2
I	167.77	−6.544	0.211^2	0.370^2
VI	204.39	−29.83	0.202^2	0.353^2
VII	67.13	−19.90	0.209^2	0.366^2

As may be seen in Table II, the values of λ_2 thus calculated from the dispersion data are in the neighborhood of 360 mμ and practically coincide with the corresponding absorption maxima of the R-band shown in Table I; therefore, their physical meaning is self-evident. The strength and sign of the rotatory contribution of the chromophor is embodied in the term of A_2, which is, in these compounds, negative in sign and relatively small as compared to A_1, an important factor in the residual rotation. The negative sign of A_2 is natural, since the negative Cotton effects of compounds VI and VII are obviously to be attributed to their xanthate groups attached to the C_5 conformation of the L-type.[2]

The cotton effect is especially feeble in compound I, the value of A_2 being particularly small, probably because it is overwhelmed by the strong background of the dextrorotatory α-configuration.

On the contrary, all the β-ethylxanthates (compounds II, III, IV, and V) show distinctly positive Cotton effects, although the optically-active xanthate group is situated in the β-configuration. This apparent anomaly may also be accounted for by the idea of the inversion of the sign of rotation, as has been suggested in a previous paper.[1]

With these β-ethylxanthates the dispersion

2) In a previous, preliminary paper (This Bulletin, 35, 1617) the authors (Y. T. and K. T.) provisionally interpreted the apparently positive, feeble Cotton effect of a derivative of D-glucose 6-benzylxanthate in terms of the inversion of the sign of rotation, but it is now realized that the Cotton effect should be judged as negative, considering the position of the negative peak. Reinvestigation of this point, together with recalculation, is being made; the results will be published in due time.

data conform more suitably to the following abbreviated two-term expression of the Drude equation:

$$[M] = \frac{A}{\lambda^2} + \frac{B}{\lambda^2 - \lambda_c^2}$$

The results of calculations are shown in Table III. The agreement with the experimental results is not yet satisfactory, the difference between them often exceeding several percentage points, even outside the absorption region. It may be advisable to study them more fully, but at present the authors think they can preliminarily offer some interesting stereochemical information.

TABLE III. DISPERSION DATA FOR β-ETHYLXANTHATES (BY AN ABBREVIATED TWO-TERM DRUDE EQUATION)

Compound	A	B	λ_c^2
II	−13.68	27.33	0.369^2
III	−2.38	23.28	0.361^2
IV	−3.88	33.43	0.357^2
V	46.23	39.62	0.362^2

As may be seen in Table III, the values of λ_c are again nearly 360 mμ, practically in good accord with the corresponding absorption maxima of the R-band shown in Table I. In contrast to the former cases (Table II), the values of B are positive, showing that the sign of the Cotton effects is definitely positive. The first term, A/λ^2, of the equation is the sum of the rotational contributions from the other optically-active centers. In the first three compounds (II, III, IV), the sign A is negative, presumably because the basically strong levorotation of the β-configuration predominates, while in the last compound V, the acetamino group of the D-configuration is, as has already been mentioned, likely to overwhelm the other, partial rotations.

Experimental

The rotatory dispersion was measured with a Rudolph spectropolarimeter, mostly at 22.5~22.6°C over the wavelength region of 270 to 700 mμ. Under each compound several values of the specific rotation will be described so as to indicate the main features of the RD curve.

As the light source a xenon lamp was used. The length of the layer was 1 dm., but below 380 mμ 0.1 dm.

2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl Ethylxanthate[3] (Compound I).—Syrup. $[\alpha]_D = +133.2°$ (*c* 1.1, chloroform).[3] The RD was measured at 22.6°C in tetrahydrofuran (T.H.F.) *The Gamma Ray-Induced Addition of Acetaldehyde to Cyclohexene and Normal Hexene**

By Motoyoshi HATADA, Jun'ichi TAKEZAKI and Kozo HIROTA

(Received July 31, 1963)

In the present series of research papers[1] radiation-induced telomerizations have been studied, making gaseous olefins (ethene, propene and isobutene) the taxogens and acetaldehyde, the telogen, respectively; i. e., several methyl-alkyl ketones have been synthesized by the following reaction:

$$RCH{=}CH_2 + CH_3CHO \xrightarrow{\sim} CH_3CO(RC_2H_3)_nH \quad (n=1, 2,.....) \quad (1)$$

However, since these research papers, as well as that published by others,[2] have been mainly interested in finding a new method of synthesizing ketones, the results are not suitable for a detailed discussion of the reaction mechanism. Especially, because of the small solubilities of gaseous olefins in acetaldehyde, the composition of the liquid part of the sample was not exactly the same as that of the gaseous part, resulting in a difficulty of drawing definite conclusions.

Such being the situation, it will be interesting to study the system where a liquid olefin perfectly soluble in acetaldehyde is used as the taxogen. Therefore, normal hexene-1 and/or cyclohexene is adopted as the taxogen in the present research. Thus, the reactivity of olefins other than α-olefins can be investigated at the same time. Second, according to the method of research hitherto published, it was difficult to discuss the point if the initial process 2 could be regarded as a single reaction brought about by irradiation.

$$CH_3CHO \xrightarrow{\sim} CH_3\dot{C}O + H \quad (2)$$

In order to solve this problem, gaseous products are analyzed, as well as liquid products on samples the initial composition of which covers the entire range.

The research carried out along these lines will be reported on with reference to the reaction mechanism of this telomerization in general.

Experimental

Materials.—The acetaldehyde used was prepared from commercial acetaldehyde by the method described in previous reports.[1] Commercial cyclohexene was used after purification by distillation. Commercial *n*-hexene-1 was used without further purification. No impurity was detected in cyclohexene by gas chromatographic analysis, while the total amount of impurities in *n*-hexene-1 was found to be 5%. Mixtures of hexene and acetaldehyde were prepared and charged in vacuo into glass ampoules by a procedure reported on already.[1]

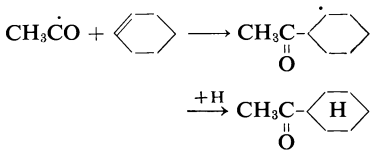
Irradiation.—The mixtures were irradiated at room temperature or at higher temperatures up to 180°C with gamma rays from a cobalt-60 source installed in our laboratory. The dose rate, which was determined by the use of a Frick dosimeter, was varied over the range from 1.4 to 9.7×10^4 r/hr.

The Analysis of the Liquid Products.—The liquid part of the irradiated mixture was subjected to both gas chromatographic and mass spectrometric analyses. The gas chromatograph used was an apparatus (the Shimadzu Model GCIA), the analytical conditions being as follows: column length, 5.25 m.; adsorbent, high vacuum oil; column temperature, 152°C; flow rate of the carrier gas (helium), 150 cm³/min.

The Analysis of the Gaseous Products.—The gaseous product was collected with an automatic töpler pump and was analyzed with a mass spectrometer (Hitachi RMU-5).

Results and Discussion

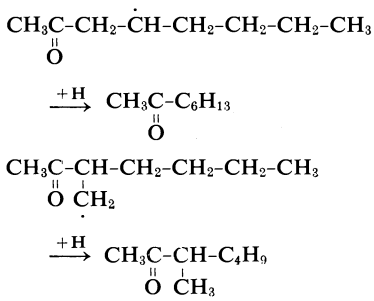
a) The Identification of the Liquid Products.—Only one new peak appeared in the gas chromatogram of the liquid part in the irradiated samples besides the peaks of acetaldehyde and cyclohexene. The fraction corresponding to this peak was collected and identified as methyl cyclohexyl ketone (McHK) by mass spectrometry. This substance is an addition product or a 1 : 1 telomer of acetaldehyde to cyclohexene. However, Mayo et al.[3] had reported that cyclohexanol was produced as the main product in the ultraviolet-irradiated



* Chain Telomerization Induced by Radiation. V. (A part of this paper was presented at the 14th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1961).

1) K. Hirota, M. Hatada et al., a) This Bulletin, **33**, 1682 (1960); b) ibid., **34**, 1644 (1961); c) ibid., **36**, 817 (1963); d) The IV Isotope Symposium (Japan), No. R-7 (1961), Kyoto.

2) C. E. Stoops and C. L. Furrow, *J. Org. Chem.*, **26**, 3264 (1961).



3) P. de Mayo, J. B. Stothers and W. Templeton, *Can. J. Chem.*, **39**, 488 (1961).

mixture of acetaldehyde and cyclohexene, especially when the latter was present in excess. However, no peak was found in the gas chromatogram of the present experiment over the region where the peak of cyclohexanol might be expected to appear. Therefore, the addition of the acetyl radical to cyclohexene will be the main process in the γ-ray irradiated system, as is shown by Eq. 3:

(3)

By a similar process, methyl *n*-hexyl ketone (MnHK) and methyl isohexyl ketone (MiHK) were found to be produced from the irradiated mixture of acetaldehyde and *n*-hexene-1. Both ketones are evidently the addition products of acetaldehyde and *n*-hexene-1. Apparently the mechanism of producing them will be the same as has been explained in the mixtures of aldehyde and lower olefins;[1] e. g., according as the acetyl radical attaches to the carbon-1 or the carbon-2 of *n*-hexene-1, followed by the addition of a hydrogen atom, MnHK or MiHK respectively, may be obtained as is shown below.

(4)

In both reactions, such products, which correspond to the higher telomers, could not be identified, partly because of their high boiling point as well as because of their small quantity caused by the difficulty of reaction. However, assuming the reaction to proceed by the mechanism already proposed, the methyl hexyl ketones mentioned above will be called 1 : 1 telomers hereafter.

b) The *G* Values of the Formation of Telomers.—In Fig. 1, the yield of the McHK produced in the mixture of acetaldehyde and cyclohexene is plotted vs. the irradiation time, keeping the dose rate at 7.4×10^4 r/hr. It is shown that, approximately, the yield increases linearly with the increasing dose. Similar curves could be obtained for the yields of MnHK and MiHK in the mixture of acetaldehyde and normal hexene, the *G* values of each

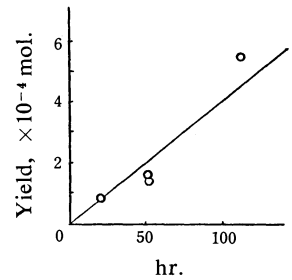


Fig. 1. The amount of McHK formation vs. irradiation time.

telomer were calculated from these curves. Generally speaking, MnHK was always produced most easily. This point will be discussed further in b).

However, it is noteworthy that *G*(MnHK) is larger than the value to be expected from *G*(1 : 1 telomer) of the mixtures of ethene,[4] propene[1] and/or isobutene[5] with aldehyde, because the *G*(1 : 1 telomer) decreases as the carbon number of the taxogens increases. Such a contradictory result may be explained by the possibility that the liquid part of the mixture contains much less olefin than would be estimated from its initial charge in the samples, as has been mentioned in the introduction.

The main components of the gas produced at room temperature by irradiation on the mixture of cyclohexene and acetaldehyde were found to be carbon monoxide, methane and hydrogen, as in the case of propene and acetaldehyde.[1a]

c) The Effect of the Dose Rate on *G*(Telomer)'s.—The *G*(telomer)'s thus obtained are plotted vs. dose rate *I* in logarithmic scales in Fig. 2, where the total dose is kept at 2.25×10^6 r, while the dose rate ranges from 10^4 to 10^5 r/hr. From the inclination of the lines, the *G*(McHK) is shown to increase in inverse proportion to the square root of *I*, while both *G*(MnHK) and *G*(MiHK) increase to the three-fourth power of *I*; i. e., the relation is expressed by a formula:

$$\log G = \text{Const.} - \alpha \log I \qquad (5)$$

where $\alpha=0.5$ for McHK and $\alpha=0.75$ for MnHK and MiHK respectively.

The fact that α has a value somewhat larger than 0.5 in the latter system suggests that a minor part of the reaction chain terminates in a monomolecular mechanism, as may be observed in the ionic mechanism.

Dose 1×10^7 r
△ MnHK ○ McHK □ MiHK

d) The Effect of the Composition of the Feed on the G(Telomer)'s.—In Fig. 3, the G(1 : 1 telomer)'s obtained at the same dose rate (9.7×10^4 r/hr.) are plotted vs. the mole per cent of olefin in the feed. The curves thus drawn for the three telomers show a similar shape, with a maximum at ca. 5 mol.% of olefin concentration.

These curves may appear in the situation where some part of the acetyl radicals is consumed to form by-products and does not contribute to the production of methyl hexyl ketones.

The G(MnHK)$>$$G$(McHK)$>$$G$(MiHK) relation, mentioned in b), exists over the entire concentration range; i. e., MnHK is produced the most favorably, while MiHK is produced the least. This relation, contrary to Markownikoff's rule, may be an indication that telomerization proceeds by a radical chain mechanism, since the addition of the polar substance to the double bonds is known to follow Markownikoff's rule. Moreover, it will be noted that the G(MnHK)$>$$G$(MiHK) relation is concordant with the fact[2] that 1-olefin is more reactive than 2-olefin to aldehyde.

e) The Temperature Dependency on the G(Telomer).—The G(telomer)'s obtained at various temperatures take maximum values in both systems, e. g., at 70~80°C, as Figs. 4 a and 4 b show. Such maxima have already been observed in other systems where the taxogens were lower olefins,[2-4] but it could not be made clear that this decrease of G(telomer)'s in the high temperature region comes either from the instability of radicals or from the decrease in the solubility of the taxogens. Since hexenes are perfectly soluble in acetaldehyde, the decrease of G at the higher temperature may be ascribed to the decomposition of the acetyl radical because, the decomposition

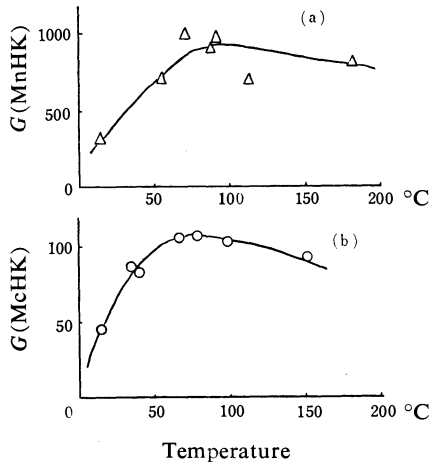

Fig. 4. G(Telomer)'s vs. irradiation temperature.
△ MnHK ○ McHK

$$CH_3\dot{C}O \rightarrow \dot{C}H_3 + CO \qquad (6)$$

with the activation energy of 15 kcal.,[6] proceeds more favorably at the higher temperature. Such an explanation will also be reasonable on the basis of the experimental finding that the shapes of both curves are the same, irrespective of the taxogen.

In order to determine the overall activation energy of formation, the logarithmus of the $G(1:1$ telomer)'s was plotted against $1/T$. The activation energies thus determined in the region of room temperature were 4.3 kcal./mol. for MnHK and 3.7 kcal./mol. for McHK respectively. They practically correspond to the activation energy of the propagation step, if a bimolecular termination of the propagating radical with a negligibly small activation energy is assumed. However, it is noteworthy that the values actually observed are smaller in this system than those in the system where the taxogens were ethene (5.0 kcal.)[4] or isobutene (6.5 kcal.).[5] The values may be ascribed to the decrease in the solubility of lower olefins with the temperature, so that their initial concentration in the liquid part of the samples decreased more than in the feed.

f) Gases Produced by Irradiation on the Mixture of Cyclohexene and Acetaldehyde.—As has already been mentioned, hydrogen, methane and carbon monoxide were the main gaseous products. They were produced in almost equal amounts, as is shown by Fig. 5, by the irradiation of samples rich in acetaldehyde, although the latter two components decrease with an increase in the cyclohexene fraction in the initial mixture. These may be explained easily by the decomposition of acetaldehyde: $CH_3CHO \rightarrow CH_4+CO$, and the primary process may be the one designated by Eq. 6, as well as by the direct scission of the C–C bond.

$$CH_3CHO \rightsquigarrow \dot{C}H_3 + CHO \qquad (7)$$

The slight difference between $G(CH_4)$ and $G(CO)$ may be caused by the recombination of methyl radicals into ethane, whose formation is favorable in the aldehyde-rich region, $G(C_2H_6)$ being, however, experimentally difficult to determine.

The $G(H_2)$~composition curve has a minimum in the middle region. This is because hydrogen is produced as the by-product of the telomerization as well as by the decomposition of cyclohexene, the $G(H_2)$ value of cyclohexene-rich samples was 1.3, which agreed well with that ($G(H_2)=1.2$) obtained by Freeman[7] in the γ-ray irradiation on pure cyclohexene. On the other hand, hydrogen may be produced by the decomposition of acetaldehyde, e.g., $CH_3CHO \rightarrow H_2+CH_2C{=}O$. Since $G(H_2)$ nearly equal to $G(CO)$ in the acetaldehyde-rich region, the $G(H_2)$ produced from acetaldehyde in the middle region may may be given approximately by the value of $G(CO)$. If so, $G(H_2)$-$G(CO)$ as shown by the dotted line α in Fig. 5 can be regarded as the $G(H_2)$ from cyclohexene only.

In short, considering the magnitude of $G(H_2)$, $G(CO)$ and $G(CH_4)$ in Fig. 5, radiation-induced decompositions of aldehyde and cyclohexene may be said to proceed parallel with the telomerization.

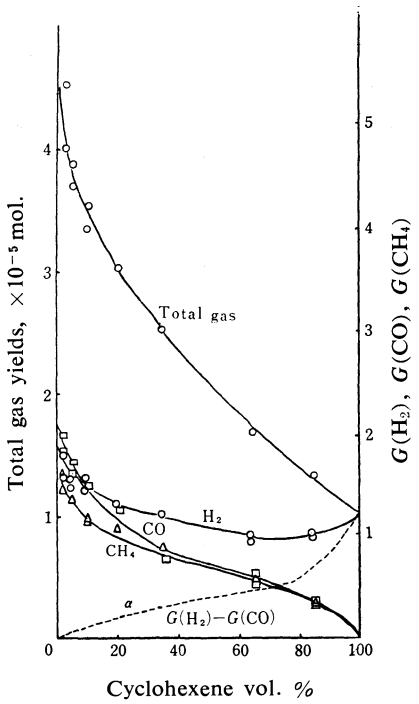

Fig. 5. G(gases) vs. cyclohexene vol. % in the feed.

g) The Effect of Benzene and Cyclohexane Added to the System.—Since benzene is known to act as a scavenger of hydrogen atoms, the dilution of the samples with benzene may give us knowledge of the fate of the hydrogen atoms produced in Eq. 2. The experiment is interesting from the viewpoint of increasing the yield of telomers, because the hydrogen produced in Eq. 2 might be captured, otherwise it would act as a terminating agent.

The experiment was carried out on various mixtures of aldehyde (A), cyclohexene (B) and benzene (C), keeping the amounts of A and B+C respectively constant. As is shown by the full line in Fig. 6, the G(McHK) became, contrary to expectation, slightly smaller upon the addition of benzene over the whole range of composition expressed by the electron fraction than that denoted by the dotted line

6) Cf. E. W. R. Steacie, "Atomic and Free Radical Reactions," 2nd ed., Reinhold Publishing Corp., New York (1954).

which was calculated under the assumption that benzene plays the role of a mere diluent.

It might be possible that the above tendency comes, rather, from an energy transfer to benzene molecules from excited cyclohexene molecules, which can easily react with acetyl radicals. If this be true, the addition of cyclohexane to the feed might increase the G(McHK), because cyclohexene would behave also to some extent as an energy acceptor from the excited cyclohexane. This reasoning may be justified by the fact that cyclohexane is regarded as acting as an energy donor in the cyclohexane-benzene mixture.[7,8] However, as the broken line in Fig. 6 shows, in the systems where cyclohexane was added to the mixture, a curve was obtained which is also concave upward but slightly different in shape from the systems where benzene was added. In order to explain these findings, it is not necessary to assume that the excitation of the cyclohexene molecule is important in the production of methyl hexyl ketones.

○ Benzene △ Cyclohexane

In summarizing the conclusions obtained from c) to g), it can be said that the mechanism of the telomerization of the aldehyde-olefin mixture is generally expressed by the radical mechanism hitherto proposed.[1]

Summary

By the radiation-induced telomerization of acetaldehyde-hexene mixtures, McHK has been produced when cyclohexene is used, while MnHK and MiHK have been produced when normal hexene is used. The G(MnHK) at room temperature has been found to be 400 (dose rate $=9.7\times10^4$ r/hr.), which is larger by a factor of ten than the G(MiHK) and the G(McHK). Irrespective of the dose rate, a G(MnHK)$>G$(McHK)$>G$(MiHK) relation always exists.

It has been found that: (i) the G(MnHK) value, as well as the G(MiHK) and the G(McHK) values, increases with the rise in temperature, they all show however, maxima at 70~80°C, because of the thermal decomposition of the acetyl radical, (ii) sharp maxima are shown in the curves of G(telomer) vs. initial composition at 5 mol.% of hexenes, (iii) the analytical data of the gaseous products establish that the radiation-induced decomposition of aldehyde and hexene occurs in parallel with the telomerization, and (iv), upon the addition of benzene or cyclohexane to the system, the G(telomer)'s decrease slightly in both systems, suggesting that they act as diluents rather than as agents of the energy transfer.

A part of the expenses has been defrayed by a grant (1961) given by the Science and Technology Agency, to which the authors' thanks are due.

The Thermal Decomposition of Ammonium Polymolybdates. I

By Eikoh MA

(Received August 6, 1963)

When a normal ammonium molybdate solution is acidified, various polyanions of increasing degrees of condensation are obtained according to different acidifications and other conditions.[1] Gmelin[2] has reported the existence of nine kinds of molybdates with different mole ratios of R_2O: MoO_3. In ammonium polymolybdates of various compositions, the structures of the heptamolybdate (paramolybdate) ion and the octamolybdate (tetramolybdate) ion have been crystallographically investigated by Lindqvist.[3] Little is known about the crystal structures of the rest. The present paper is concerned with four of them, ammonium di-, hepta-, tri- and octa-molybdate; the thermal decomposition of each has also been studied.

The thermal decomposition of ammonium heptamolybdate has previously been studied by several authors, Duval[4] using thermogravimetric analysis and Hegedüs et al.,[5] using X-ray diffraction techniques besides thermogravimetric analysis. Funaki and Segawa[6] reported the thermal decomposition of several kinds of polymolybdates, but they gave no description on the experimental method employed. A differential thermal analysis of the thermal decomposition of ammonium tetra-, para- and normal-molybdate has been reported by Rode and Tverdokhlebov.[7] Rode and Tverdokhlebov, however, adopted for heptamolybdate (paramolybdate) an empirical formula, $5(NH_4)_2O\cdot 12MoO_3\cdot 12H_2O$, which has been proved incorrect; an alternative formula, $3(NH_4)_2O\cdot 7MoO_3\cdot 4H_2O$, had long been supported by crystallographic studies.[8] The tetramolybdate in their paper, $(NH_4)_2O\cdot 4MoO_3\cdot 2H_2O$, is essentially identical with octamolybdate, $(NH_4)_4Mo_8O_{26}\cdot 4H_2O$, the crystal structure of which has been determined by Lindqvist. Previous works of crystallographic significance seem to have been ignored in their paper. The behaviors of ammonium polymolybdates in the thermal decomposition are comparable with those of ammonium polytungstates, since they are both ammonium salts of the polyacid of transition elements in the sixth group of the periodic table. Reference may be made to a previous work on the thermal decomposition of ammonium paratungstate.[9] In the present paper the thermal decomposition of ammonium polymolybdates is treated by means of thermogravimetric analysis, ammonia determination and omegatron mass-spectrometry; in a succeeding paper studies by means of differential thermal analysis and X-ray diffraction techniques will be reported.

Experimental

Chemical Analysis.—Samples of ammonium dimolybdate, heptamolybdate, trimolybdate and octamolybdate were first identified as such by determining their compositions through chemical analysis. The quantity of molybdenum was determined by the gravimetric method, using lead acetate, and that of ammonia, by the Kjeldhal method. The results were found to be in agreement with the empirical formulae, $(NH_4)_2O\cdot 2MoO_3$ for dimolybdate, $3(NH_4)_2O\cdot 7MoO_3\cdot 4H_2O$ for heptamolybdate, $2(NH_4)_2O\cdot 8MoO_3\cdot 2H_2O$ for octamolybdate, and $(NH_4)_2O\cdot 3MoO_3\cdot xH_2O$ for trimolybdate, where x depends upon conditions of preparation.*

X-Ray Analysis.—Samples of ammonium heptamolybdate and octamolybdate, the lattice constants of which had been known,[10] were further identified as such by crystallographic data of single crystals using rotation photographs. The unit cell dimensions for ammonium heptamolybdate are: $a=8.382$ Å $b=36.125$ Å, $c=10.464$ Å and $\beta=116°0'$, while those for octamolybdate are: $a=7.76$ Å, $b=9.75$ Å, $c=9.78$ Å, $\alpha=97°2'$, $\beta=100°5'$ and $\gamma=98°$. X-Ray diffraction patterns were taken by a Guinier focussing camera using Cu$K\alpha$ radiation. The

The Determination of Evolved Ammonia.—When a sample was heated in a furnace, the ammonia which evolved was carried into 1 N sulfuric acid by a stream of air and of nitrogen at 30 l./hr.; it was determined by titration using methyl orange as an indicator. By continually titrating it during the thermal decomposition, smooth curves of ammonia evolution were obtained, as Fig. 1 shows. The heating rate employed was 3°C/min.

Thermogravimetric Measurement.—Thermogravimetric measurement was performed in air at a heating rate of 3°C/min. by an automatic thermobalance.

Analysis by an Omegatron Mass-spectrometer.—Omegatron mass-spectrometric analysis was performed with about 30 mg. of a sample at 10^{-5} Torr, in the mass range between 1 and 50 and in the temperature range between room temperature and 400°C. The resolution of the omegatron was $M/\Delta M=56.5$ (calcd.) and 56.0 (obs.) at mass 28. It was possible to detect a partial pressure of 10^{-11} Torr by the omegatron. The measurement was performed at about every 50°C of elevation while the sample was being evacuated by oil diffusion pumps with an activated charcoal trap, the temperature being held constant during the measurement. Every time the sample was heated in a furnace, the pressure rose to 10^{-3} Torr at first because of the vigorous decomposition. However, since the omegatron measuremont was favorable at a pressure lower than 10^{-4} Torr, measurement was performed only when the pressure decreased to 10^{-5} Torr and became as constant as possible.

* By X-ray examination, the sample of ammonium trimolybdate was found to have changed into ammonium octamolybdate in about half a year when left undisturbed.

Results

The Evolution of Ammonia.—It is important, in the pyrolysis study of ammonium salts, to determine continuously the ammonia which is liberated during the thermal decomposition. Figure 1 shows the ammonia evolution curves.

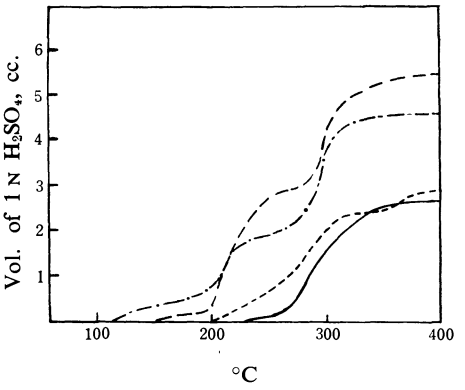

Fig. 1. Ammonia evolution curves.
——— Ammonium dimolybdate
—·—·— Ammonium heptamolybdate
——— Ammonium octamolybdate
-------- Ammonium trimolybdate

Heptamolybdate begins to evolve ammonia at the lowest temperature, about 120°C. Dimolybdate begins to evolve ammonia next, around 150°C; rapid evolution subsequently begins around 200°C. Octamolybdate and trimolybdate begin to evolve ammonia only above 200°C. By contrast, the evolution of ammonia is complete in all at almost the same temperature, 360~375°C. Each of the ammonia evolution curves of heptamolybdate and dimolybdate has three well-defined stages. X-Ray study illustrates that three different structures correspond to the respective stages, as will be discussed later.

Weight-decrease Curves. — Weight-decrease curves drawn by an automatic thermo-balance are shown by the solid lines in Figs. 3, 4, 5 and 6. It is noticeable that heptamolybdate and dimolybdate begin to decompose rapidly at 110 and 200°C respectively, their weight-decrease curves forming sharp inflections. Octamolybdate and trimolybdate, by contrast, decompose gradually at the beginning of heating. The end-points of decomposition are very clearly defined for all the molybdates. Decomposition is complete in all at almost the same temperature of 360~375°C. Heptamolybdate, dimolybdate and trimolybdate decompose in three stages, and octamolybdate in two stages.

Observation by Means of an Omegatron Mass-spectrometer.—Omegatron mass-spectrometer has been found to be effective in the

pyrolysis study in this research.[11] An example of the results obtained by the omegatron is given in Fig. 2. The observed mass numbers and the ionic species corresponding to them are as follows: 2 (H_2^+), 14(N^+, N_2^{2+}, CO^{2+}), 15 (NH^+), 16 (NH_2^+), 17 (NH_3^+, OH^+), 18 (H_2O^+), 19 (H_3O^+), and 28 (N_2^+, CO^+).

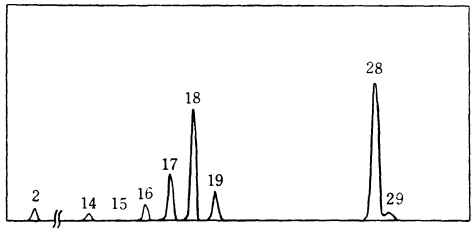

Fig. 2. Mass-spectrum of gases evolved from ammonium heptamolybdate at 395°C. Sensitivity of mass 2 is three times that of other masses.

Mass 29 seems to be a fragment of residual gas, but it is unidentifiable. The mass spectra were treated in the following way:

1) Since the observed intensities of the ionic current are proportional to the square root of the mass numbers, an appropriate adjustment was made.

2) Since one-fifth of H_2O^+(18) is known to appear as OH^+ in the same place as NH_3^+ (17) is observed, it was subtracted from the intensity of NH_3^+.

3) NH^+ and NH_2^+ are considered to be fractions of NH_3^+. These fractions, added to NH_3^+ (17) and then with one-fifth of H_2O^+ (18) subtracted, gave the sum of ammonia.

4) H_3O^+ (19), OH^+ (17) and H_2O^+ (18) gave the sum of water.

5) N^+ (14), N_2^{2+} (14) and N_2^+ (28) gave the sum of nitrogen.*

6) The partial pressure of water, ammonia and nitrogen were calculated for each temperature and, for the sake of comparison, were re-estimated as values at the same total pressure. Thus Fig. 7 was obtained.

The final product obtained in the omegatron at 10^{-6} Torr and at 400°C consisted of purple-black oxides of molybdenum, in which MoO_3, Mo_9O_{26} and Mo_4O_{11} are predominant and Mo_8O_{23} is only auxiliary.

Discussion

Since one molecule of water accompanies every two molecules of ammonia when they are liberated from the salt, the ammonia evolution curves, NH_3 curves, shown in Fig. 1, must be represented as $(NH_4)_2O$ curves. By superimposing the latter on the weight-decrease curves obtained by the automatic thermo-balance, the dotted lines in Figs. 3, 4, 5 and 6 are obtained. With ammonium

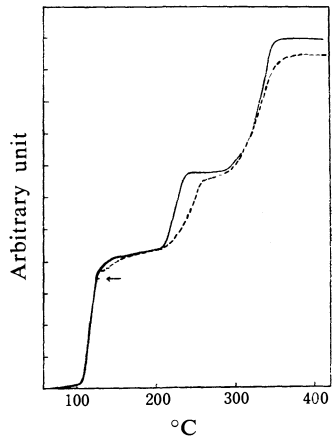

Fig. 3. Weight-decrease curve (solid line) and $(NH_4)_2O$ curve (dotted line) of ammonium heptamolybdate.

heptamolybdate tetrahydrate (Fig. 3), a fairly good coincidence as to the shape and height of the curves between 130 and 360°C is noticeable. The three stages in the $(NH_4)_2O$ curve correspond to those in the weight-decrease curve. Therefore, the weight decrease from 130°C up to 360°C may be correlated with the evolution of ammonia and water accompanying it. Consequently, the weight decrease from room temperature up to 130°C is correlated with the dehydration of crystals. The theoretical value of four molecules of the water of hydration is shown by an arrow mark; it is in good agreement with the observed value. We might conclude that dehydration begins very slowly at room temperature, that around 115°C dehydration becomes rapid, and that it is almost complete at 130°C. The discrepancy between the weight-decrease curve and the $(NH_4)_2O$ curve above 360°C is due to the formation of nitrogen from ammonia, which will be discussed below. Indeed, the observed values of the quantitative determination of ammonia always fall short of the theoretical values.

The four molecules of water of hydration are not included in the crystal structure of the discrete heptamolybdate ion, $Mo_7O_{24}^{6-}$.[12] The crystal structure of heptamolybdate does not break down until 130°C, when most of

11) M. Onchi and E. Ma, *J. Phys. Chem.*, **67**, 2240 (1963).

* CO^+ (28) and CO^{2+} (14) as background are evacuated to negligible amounts, Moreover, the pattern coefficient of the 28 peak justifies its identification as nitrogen.

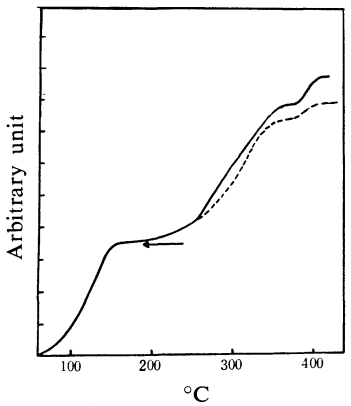

Fig. 6. Weight-decrease curve (solid line) and $(NH_4)_2O$ curve (dotted line) of ammonium trimolybdate.

the water is lost. As the dehydration does not proceed step by step, some part of the water may be regarded as of the zeolitic type.

Since ammonium dimolybdate is not hydrated, the weight-decrease curve is approximately equal to the $(NH_4)_2O$ curve, and the decomposition begins at a temperature higher than that in the case of heptamolybdate. (Fig. 4).

In the case of trimolybdate, dehydration is complete around 150°C, and the crystal structure changes into octamolybdate above 200°C.

In the case of ammonium octamolybdate dihydrate, dehydration is complete around 280°C, and the crystal structure of octamolybdate does not break down until around 360°C. Therefore, some of the water molecules are tenaciously held up to 280°C. Consequently, they must be water molecules of a different type. (Figs. 5 and 6).

The step-by-step decompositions indicate that water and ammonia, presumably as ammonium ions in the crystal, are bonded with the molybdate ions in different strengths, and that there should be a further difference in bonding strength in ammonia. To each stage of the weight-decrease curves, there should be a corresponding crystal structure. Studies of structural change will be reported on in a succeeding paper.

The ultimate discrepancy between the weight-decrease curves and the $(NH_4)_2O$ curves in Figs. 3, 4, 5 and 6 may be assumed to be referrable to the formation of nitrogen from ammonia, as has been mentioned above. In order to confirm this, the process of the thermal decomposition was analyzed by means of omegatron, taking ammonium heptamolybdate as an example.

The most significant information provided by the omegatron was that the existence of nitrogen in the process of thermal decomposition was definitely established. Water, ammonia and nitrogen are plotted on the ordinate of the same arbitrary unit in Fig. 7, which, therefore, provides an estimate of the relative values of these gases. The sudden decrease in

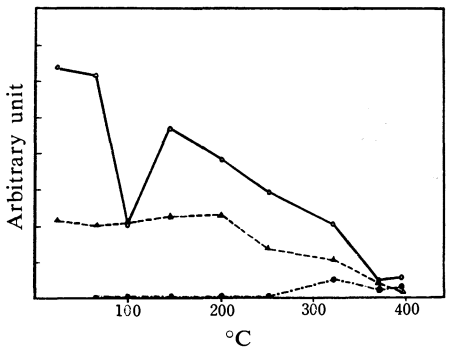

Fig. 7. Partial pressure vs. temperature
—— Water ---- Ammonia
—·—·— Nitrogen

water quantity at 100°C might be due to the end of dehydration. Nitrogen formation began around 250°C and reached a maximum around 320°C. Consequently, it became of interest to determine whether hydrogen also existed. Molecular hydrogen was also successfully detected by the omegatron. The formation of hydrogen goes on in a way quite similar to that of nitrogen, i. e., beginning to form around 250°C and reaching a maximum around 320°C. The hydrogen is not to be considered to come from water. In Fig. 8 the amounts of nitrogen and hydrogen are plotted on ordinates of different arbitrary units. Neither H_2O^+ nor H_3O^+ has a tendency to increase when nitrogen is being yielded.

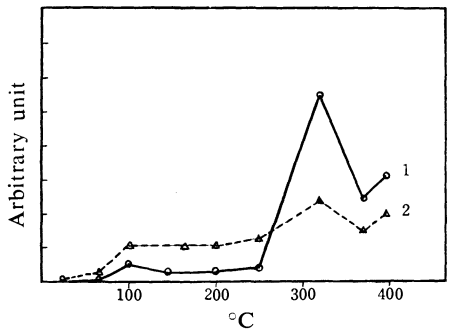

Fig. 8. Partial pressure vs. temperature.
1) Nitrogen 2) Hydrogen

These findings might be interpreted as meaning that ammonia is oxidized to nitrogen by the molybdenum oxide resulting from the thermal decomposition. Thus the molybdenum oxide is reduced to a lower oxide. An alternative interpretation is that ammonia is decomposed into nitrogen and hydrogen at the surface of molybdenum oxide through its catalytic action. The detection of hydrogen by the omegatron may support the latter interpretation. The amount of nitrogen at 320°C is more than ten times the amount at 250°C, while the amount of hydrogen at 320°C is less than ten times that at 250°C. Therefore, a larger amount of nitrogen must be yielded through oxidation than through decomposition. The formation of nitrogen from ammonia was detected in vacuo by the omegatron. Similar considerations apply to the formation of nitrogen from ammonia in air. It takes place even more vigorously if it is yielded through oxidation. Since the precise mole ratios of the nitrogen and hydrogen formed in vacuo have not yet been determined, quantitative argument will be deferred pending further investigation.

Figure 7 shows that water is evolved more abundantly than ammonia throughout the process; this is contrary to the theoretical expectation, and the cause is not certain. One possible explanation is as follows: When the sample was heated in a furnace while being evacuated, it decomposed vigorously at first and the pressure rose to 10^{-3} Torr. The omegatron measurement was performed, however, only when the pressure decreased to 10^{-5} Torr, when the evolution of the gases was almost in equilibrium. Accordingly, the composition of evolving gases might be different from that at 10^{-3} Torr.

Summary

The thermal decomposition of ammonium di-, hepta-, tri- and octa-molybdate has been investigated by means of thermogravimetric analysis, ammonia determination and the use of an omegatron mass-spectrometer. Both weight-decrease curves and ammonia evolution curves exhibit stepwise decomposition, indicating that there should be a difference in bonding strengths of water and of ammonia, presumably as ammonium ions in the crystal, with molybdate ions. Hepta-, di- and trimolybdate decompose in three stages, and octamolybdate in two stages. A certain crystal structure should correspond to each stage. Dehydration precedes deammoniation. Dehydration is complete at about 130, 150 and 280°C with hepta-, tri- and octa-molybdate respectively. Deammoniation is complete in all at the same temperature of 360~375°C. The existence of nitrogen above 250°C in vacuo has been established. Nitrogen is yielded in the process of the thermal decomposition through oxidation as well as through the catalytic decomposition of ammonia. Nitrogen reached a maximum around 320°C. As evidence for the formation of nitrogen through decomposition, hydrogen was also detected above 250°C, and was found to reach a maximum at about 320°C, although in a much smaller quantity.

The author wishes to express his deep gratitude to Professor Kumasaburo Kodera and to Professor Sukeji Kachi of Kyoto University for their continued interest in this investigation and for their valuable suggestions. He is also greatly indebted to Dr. Minoru Ozasa of the Matsushita Electronics Corporation for courtesies extented to him and for fruitful discussions. He wishes to thank Dr. Masaru Onchi of Kyoto University for measurement using the omegatron mass-spectrometer.

*Thermoanalytical Studies of the Thermal Stability of High Polymers. II. The Differential Thermal Analysis and Thermogravimetric Analysis of Some Polyethylenes**

By Shoichi IGARASHI and Hirotaro KAMBE

(Received August 7, 1963)

Previous investigations of the thermal decomposition of high polymers have dealt almost entirely with isothermal experiments using thermobalance[1-5] to record the change in the weight of the sample at elevated temperatures. Recently the melting behavior and thermal changes of high polymers during oxidation or degradation have been investigated by differential thermal analysis,[6-10] and the thermal stability of linear polymers has been studied by thermogravimetric analysis.[11-17]

Although Paulik et al.[12] reported some thermoanalytical results on polyethylenes obtained by using the Derivatograph, the kinetic parameters for the thermal decomposition of polyethylenes were not determined. Anderson and Freeman[11] evaluated the activation energy and order of reaction for the thermal decomposition of a high-pressure polyethyene from the derivative thermogravimetric analysis curve, in which the rate of the weight loss of the sample is plotted against the temperature of a furnace at a constant rate of heating.

In the first paper of this series[18] an automatic recording thermobalance for studying the thermal stability of high polymers was described and a thermoanalytical study of the thermal decomposition of a commercial low-pressure polyethylene was presented.

It is the purpose of this paper to examine the thermal stability of some polyethylenes, when they are heated at a constant rate of 1°C/min., by differential thermal analysis and by thermogravimetric analysis, both in air and in a nitrogen atmosphere.

Experimental

Materials.—The polymers used were the low-pressure polyethylenes Hizex 5000 and 7000, supplied by the Mitsui Chemical Co., and the high-pressure polyethylenes Sumikathene MF-40 and F-70-6, produced by the Sumitomo Chemical Co. The materials were purified by precipitation using xylene as a solvent and methyl alcohol as a precipitant at room temperature and were then dried at about 60°C in vacuo for about 24 hr.

The melting point of the paraffin used is 56.0~56.5°C.

Differential Thermal Analysis.—The apparatus which has been described in the previous paper[19] was used. Concentric cylindrical sample cells of stainless steel were used; they were essentially similar to that described by Vold.[20] The diameter and the depth of the sample cell are 1.5 cm. and 5 cm. respectively. The sample was put into the gap between the external sample holder and the concentric internal cylinder. Within the hollow of the internal cylinder, a two-junction chromel-constantan thermocouple was inserted in order to measure the temperature difference between the sample and the reference substance. The thermoelectric output was amplified and recorded on the chart of an electric recorder.

The temperature of the vertical electric furnace was automatically controlled so as to increase at a constant rate of about 1°C/min., and it was measured by means of another thermocouple of chromel-alumel and recorded on the same chart.

The sample weight used was about 1 g., a calcined alumina was used as the inert reference substance.

Experiments were carried out both in air and in a nitrogen atmosphere.

Thermogravimetric Analysis. — An automatic recording thermobalance, which had been designed and constructed in our laboratory[18] using a calibrated phosphor-bronze spring and a linear variable differential transformer, was used to record the change in the weight of the sample, while the furnace temperature was continuously elevated at a constant rate of about 1°C/min., in air and in a nitrogen atmosphere. The temperature of the cylindrical electric furnace was controlled by an electronic program controller.

The temperature of the sample was measured by means of a chromel-alumel thermocouple located near the sample glass crucible; the output of this thermocouple was recorded. The diameter and the depth of the crucible were 1.1 cm. and 1.0 cm. respectively. The sample weight used was about 90 mg.

Results and Discussion

Differential Thermal Analysis.—Typical results of the differential thermal analysis curves for some polyethylenes are shown in Fig. 1. In these curves the differential temperature between the sample and the reference substance is plotted against the reference temperature.

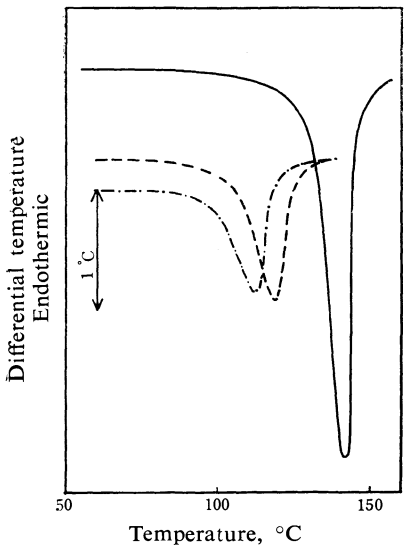

Fig. 1. Differential thermal analysis curves for polyethylenes. Solid line, Hizex 7000; dashed line, Sumikathene MF-40; chain line, Sumikathene F-70-6.

A low-pressure polyethylene, Hizex 7000, displayed a sharp endothermic peak over the range from 120 to 145°C. Two high-pressure polyethylenes, Sumikathene MF-40 and F-70-6, showed a small peak over the ranges from 103 to 118°C and from 103 to 112°C respectively. It is evident that each endothermic peak corresponds to a melting point of the polymer.

The area of a peak in the differential thermal analysis curve is proportional to the amount of the absorbed (or evolved) heat in the sample, and it can be calibrated by a known heat. When the heat of fusion for benzoic acid was used as a standard for calibration, the heats of fusion for these polymers were obtained as follows: 51 cal./g. for Hizex 7000, 42 cal./g. for Hizex 5000, 24 cal./g. for Sumikathene MF-40 and 22 cal./g. for Sumikathene F-70-6. Dividing these values by the heat of fusion for a perfectly crystalline polyethylene (i.e., 66 cal./g.[21]), the crystallinity of each sample was obtained. These values are listed in Table I. It is clear that the

Table I. Differential thermal analysis of polyethylenes

Polymer	M. p. °C	Heat of fusion cal./g.	Crystallinity %	Entropy of fusion e. u./g.
Sumikathene				
F-70-6	103~112	22	33	0.057
MF-40	103~118	24	36	0.062
Hizex				
5000	122~140	42	64	0.102
7000	120~145	51	77	0.123

crystallinity of the branched high-pressure polyethylene is smaller than that of the low-pressure polymer. The results are in agreement with the work of Ke.[6] In Table I the crystallinity of the polymer is shown to be smaller than the reported values of Hizex 5000 and 7000 (e.g., 80~90%). However, according to the theory of differential thermal analysis,[22] the area of a peak depends not only on

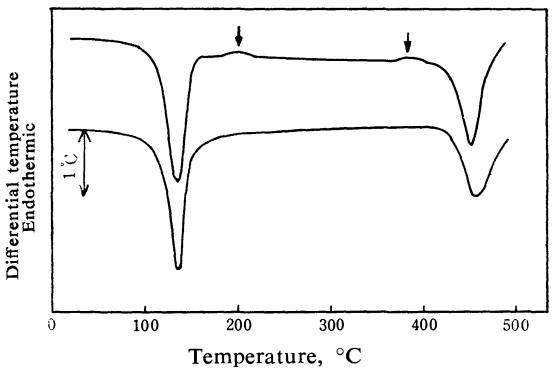

Fig. 2. Differential thermal analysis curves for low-pressure polyethylene Hizex 5000. Upper curve, in air; lower curve, in a nitrogen atmosphere.

22) W. J. Smothers, "Differential Thermal Analysis: Theory and Practice," Chemical Publishing Co., Inc., New York (1958), p. 85.

the amount of the absorbed heat, but also on the thermal conductivity of the sample. Since the latter value is not kept constant over the melting range in the polymer, it should be noticed that the latent heat (or crystallinity) obtained from the data of the differential thermal analysis may be the apparent value.

In his earlier work Ke[6] observed that the crystallinity of commercial polyethylene estimated by differential thermal analysis agreed well with the reported one determined by the X-ray method; however, he has recently reported[7] that there was a considerable discrepacy between the two crystallinities of the ethylene copolymers. Therefore, it may be suggested that this discrepancy between the crystallinity evaluated by differential thermal analysis and the reported value may be due to the difference in methods.

Figure 2 shows the differential thermal analysis curves for a low-pressure polyethylene, Hizex 5000, in air and in a nitrogen atomsphere from the ambienat temperature to approximately 500°C. The upper curve in Fig. 2 shows two endothermic peaks at 135 and 457°C. The former peak for the melting of the sample agrees with the literature value of 135°C. The latter peak at 457°C is due to the thermal decomposition of polyethylene, which will be discussed in the following section.

Two small exothermic peaks, indicated by arrows, show the oxidation of polyethylene, because these exothermic peaks are not observed in the lower curve in a nitrogen atmosphere.

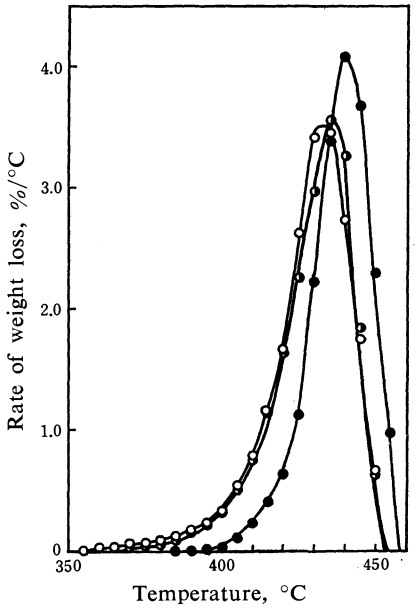

Fig. 3. Thermogravimetric analysis curves for polyethylenes in a nitrogen atmosphere. (●), Hizex 7000; (◑), Sumikathene MF-40; (○), Sumikathene F-70-6.

In the differential thermal analysis curve of low-pressure polyethylene in the presence of air, a small exothermic peak has been observed by Paulik et al.[12] in the range from 190 to 250°C. Danusso et al.[9] have also reported that, after the melting of the polyethylene, an exothermic peak due to oxidation was observed in the differential thermal analysis curve in air.

By a gas-flow-type differential thermal analysis apparatus recently constructed in our laboratory, it has been observed that the crystallinity of polyethylene decreases abruptly in the first exothermic stage (ca. 180°C). The results will be reported elsewhere.

Thermogravimetric Analysis in Nitrogen. — The thermogravimetric analysis curves for Hizex 7000, Sumikathene MF-40 and Sumikathene F-70-6 in a nitrogen atmosphere are shown in Fig. 3. These curves, in which the rate of weight loss (%/°C) is plotted against the temperature, were obtained by a graphical differentiation of the curve of weight loss as a function of the temperature.

From Fig. 3 it is clear that thermal decomposition for each sample takes place in one stage. The weight losses of the two high-pressure polyethylenes, Sumikathene MF-40 and F-70-6, commence at approximately 360°C, and the weight losses for these polymers reach a maximum rate (ca. 3.5%/°C) at about 435°C. However, the thermal decomposition of the low-pressure polyethylene, Hizex 7000, takes place over the range from 380 to about 455°C. The temperature at which the thermal decomposition of high-pressure polyethylene commences is obviously higher by about 20°C

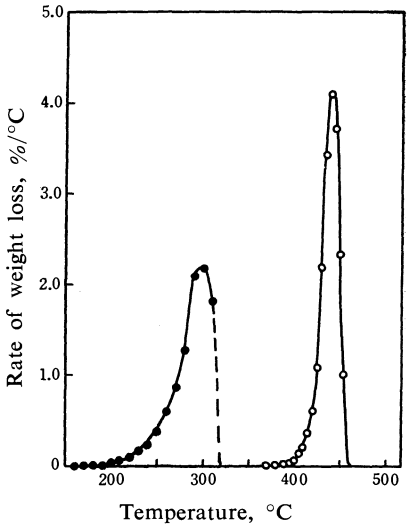

Fig. 4. Thermogravimetric analysis curves for paraffin and Hizex 7000 in a nitrogen atmosphere. (●), paraffin; (○), Hizex 7000.

than that of low-pressure polyethylene.

The above results obtained from the thermogravimetric measurements support the conclusion that a branched polyethylene is thermally more unstable than a linear one in isothermal experiments[5] because thermal decomposition is initiated at the branched point with a tertiary hydrogen atom.

Paulik et al.[12] have reported thermogravimetric studies of polyethylenes including low-pressure, medium-pressure and high-pressure samples in air and in a nitrogen atmosphere. However, they have not described the thermal stability of these polymers in a nitrogen atmosphere. It seems to be impossible in a nitrogen atmosphere for the Derivatograph to clarify the differences in the chemical structure of commercial polyethylenes.

In Fig. 4 the derivative thermogravimetric analysis curves for paraffin (m. p. 56.0~56.5°C) and polyethylene (Hizex 7000) are shown. Figure 4 shows that the weight loss of paraffin begins slowly at about 180°C and that that of polyethylene begins at 380°C. The degradation products were collected into the trap which was set below the sample crucible. The melting points of the trapped products for paraffin and polyethylene were 55.0~55.5°C and 51.0~67.0°C respectively. Since the melting point of the trapped products for paraffin corresponds well with the original one, it is confirmed that the weight loss of paraffin is mainly due to the vaporization of the sample. When the melting point of the trapped paraffin is compared with that of the degradation products for polyethylene, it is also confirmed that the thermal decomposition of polyethylene occurs at the peak appearing in the derivative thermogravimetric analysis curve.

Madorsky et al.,[23] when investigating the degradation products for polyethylene by means of a mass spectrometer, have found that the products contained very little monomer but mainly paraffins and olefins with up to about fifty carbon atoms. As has been mentioned above, the degradation products for Hizex 7000 melts over a wide range in temperature. This means that the products contain a number of hydrocarbon members.

The apparent activation energy and the order of reaction for the thermal decomposition of polymers in a nitrogen atmosphere were evaluated from the derivative thermogravimetric analysis curve by the method of Freeman and Carroll.[24] They derived the following equation:

$$\Delta \log(dW/dT)/\Delta \log W_r = n - (E/2.3R) \times \Delta(1/T)/\Delta \log W_r$$

where dW/dT is the rate of change in weight, n is the order of reaction, E is the apparent activation energy, R is the gas constant, T is the absolute temperature, and W_r is the weight of the reactant at the temperature, T. If we plot $\Delta \log(dW/dT)/\Delta \log W_r$ against $\Delta(1/T)/\Delta \log W_r$, we obtain a linear plot with an intercept, n, on the ordinate and slope equal to $E/2.3R$. This plot for the thermal decomposition of the low-pressure polyethylene Hizex the 7000 is shown in Fig. 5. Thus we found that $E=73.6$ kcal./mol. This agrees with the value of 72 kcal./mol. for the polymethylene of Madorsky.[4] The order of reaction for this stage was not clear. The results are listed in Table II.

decomposition of the polymer takes place in three stages; the initial, 3% zero-order reaction, the second, 3 to 15% zero-order stage, and the final, first-order reaction, occurring above 35% degradation. The energies of activation for the stages are 48 kcal./mol., 61 kcal./mol. and 67 kcal./mol. respectively.

Thermogravimetric Analysis in Air. — The thermogravimetric analysis curves for Hizex 7000, Sumikathene F-70-6 (unpurified) and Sumikathene F-70-6 (purified) in air are shown in Fig. 6. The curves are different from that obtained in a nitrogen atmosphere (Fig. 3).

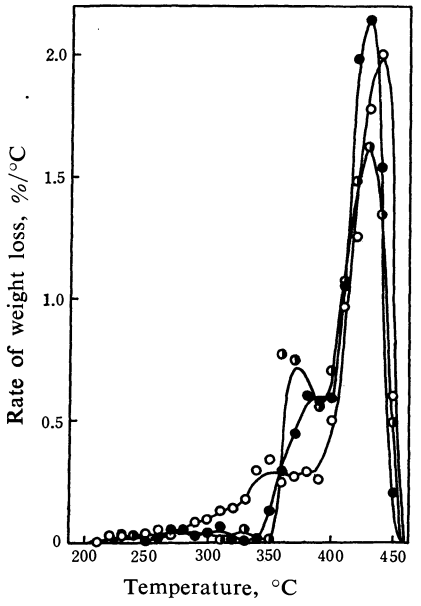

Fig. 6. Thermogravimetric analysis curves for polyethylenes in air. (●), Hizex 7000; (◑), Sumikathene F-70-6 (unpurified); (○),Sumikathene F-70-6 (purified).

The weight loss of Sumikathene F-70-6 commences at about 200°C, and that of Hizex 7000, at 250°C. The maximum rates of weight loss of these polymers occur at about 430°C. In these curves it seems that the oxidative degradation takes place in three stages: the first, up to approximately 350°C, the second from 350 to about 390°C, and the third from 390 to about 455°C.

When the curve for the purified Sumikathene is compared with that for the unpurified one, it is found that the weight loss for the first stage of the latter is smaller than for that of the former. This may indicate the effect on the theraml stability exerted by an antioxidant added to the commercial polymer. In the lower-temperature range the weight loss is mainly due to the degradation at the branching point in the polymer molecule. In accordance with this, the weight loss of the less-branched Hizex 7000 in this stage is smaller than that of Sumikathene. In a previous paper[25] it has also been recognized that the chain branching and the unsaturation have a marked effect on the weight loss at the first stage of the oxidative degradation of the irradiated polyethylene.

Paulik et al.[12] observed from the Derivatograph of the low-pressure polyethylene that the weight gain of the sample took place in the range from 160 to 200°C and that the rapid oxidative weight loss occurred over the range from 320 to about 400°C.

Since the oxidative degradation of the polymer may begin at its surface, the influence of the surface area of the sample on the weight loss in the thermogravimetric analysis was examined. For this purpose the sample crucible, the surface area of which is 1.63 times that of the crucible usually used, was utilized for low-pressure polyethylene. As a result, it was recognized that the weight loss at the low-temperature stage increased to 1.4 times the value obtained with the usual crucible.

Summary

The thermal stability of polyethylenes has been studied by differential thermal analysis and by thermogravimetric analysis in air and in a nitrogen atmosphere.

25) S. Igarashi, I. Mita and H. Kambe. *J. Appl. Polymer Sci.*, in press.

The crystallinities of some polyethylenes have been evaluated from the data of differential thermal analysis. These values are smaller than the reported value. This discrepancy may be due to differences in the methods.

In the differential thermal analysis curve for low-pressure polyethylene Hizex 5000 in air, two small exothermic peaks due to oxidation were observed at about 200 and at about 390°C. The endothermic peaks at 135 and at 457°C correspond to the melting and to the thermal decomposition points of polyethylene.

In thermogravimetric analysis in a nitrogen atmosphere, the thermal decomposition of low-pressure polyethylene takes place over the range from 380 to about 450°C, and that of high-pressure polyethylene, from 360 to about 450°C. In the presence of air, the oxidative degradation of low-pressure and high-pressure polyethylenes occurs in three stages: the first from about 200 to 350°C, the second from about 350 to 390°C, and the third from about 390 to 455°C.

It has been concluded that the thermal stability of high-pressure polyethylene is smaller than that of low-pressure polyethylene. This may be attributed to the difference in branching of commercial polyethylenes.

Studies of the Organic Reactions of Metal Carbonyls. I. The Isomerization of Alkyl- and Acylcobalt Carbonyls

By Yoshinobu TAKEGAMI, Chikao YOKOKAWA, Yoshihisa WATANABE and Yasukazu OKUDA

(Received August 9, 1963)

Heck and Breslow[1] obtained two isomeric products by the carbonylation of, for instance, methyl acrylate or 1-pentene with cobalt hydrocarbonyl. This seems to indicate that the addition of the carbonyl group to the olefinic bonds has taken place at both carbon atoms of the C=C double bond. It is possible, however, to assume that the alkyl- and/or acylcobalt carbonyls which are formed in the course of this type of reaction have been isomerized.

In the present program, in order to check the possibility of this isomerization, the reactions of some alkyl (*n*-propyl iodide, ethyl α-bromopropionate) and acyl halides (*n*-butyryl- and iso-butyryl halide) with potassium cobalt tetracarbonyl have been carried out. By means of the results of the structural determination of the products, it has been established that the isomerization mentioned above does indeed take place.

Experimental

The Preparation of Cobalt Hydrocarbonyl. — The aqueous solution of potassium cobalt tetracarbonyl was prepared by Blanchard's method.[2] After the acidification of this solution with hydrochloric acid, cobalt hydrocabonyl was extracted by toluene. Into a 2 l. bottle 250 ml. of an aqueous solution containing 160 g. of potassium hydroxide and 20 g. of potassium cyanide were placed. After the air in the bottle had been replaced with carbon monoxide, the solution containing 50 g. of cobalt(II) chloride hexahydrate and 250 ml. of water was added. The bottle was connected to a reservoir of carbon monoxide and shaken mechanically for 10 to 20 hr. at room temperature under the atmospheric pressure of carbon monoxide. After 17 to 20 l. of the carbon monoxide had been absorbed, a yellow solution of potassium cobalt tetracarbonyl was formed. This solution was stored in a dark and cool place under a carbon monoxide atmosphere. About 250 ml. of this solution and 400 ml. of toluene[3] were then placed in a 1 l. four-necked flask, fitted with a dropping funnel, a stirrer and a rubber stopple, and flashed with carbon monoxide. Seventy to eighty milliliters of concentrated hydrochloric acid were gradually but vigorously stirred in at 0°C. By the use of a hypodermic syringe, the cobalt hydrocarbonyl solution in toluene thus formed was transferred into another bottle, which was then filled with carbon monoxide and kept at −70°C.

1) R. F. Heck and D. S. Breslow, *J. Am. Chem. Soc.*, **83**, 4023 (1961).

2) A. A. Blanchard and P. Gilmont, ibid., **62**, 1192 (1940).

3) In some cases *n*-heptane was used instead of toluene (cf. Tables).

The concentration of this solution was determined by the analytical method proposed by Sternberg,[4] using 20 ml. of the sample. By diluting it with toluene, a 0.09 M solution was prepared and used for the reaction.

The Reaction of Alkyl Halides with Potassium Cobalt Tetracarbonyl. — A 100 ml., four-necked flask, fitted with a 50 ml. dropping funnel, a stirrer and a rubber stopple, was connected with a gas buret, and the air in the system was replaced with carbon monoxide or nitrogen. By the use of a syringe, 50 ml. of the cobalt hydrocarbonyl solution was put into the flask; then the solution was titrated with a 1/2 N alcohol[5] solution of potassium hydroxide in the presence of phenolphthalein. To the potassium cobalt tetracarbonyl thus formed, a desired amount of alkyl halide was introduced, and the reaction mixture was agitated at various temperatures for several hours. In the course of this reaction, the amounts of carbon monoxide absorbed were determined by following the change in the readings of the buret. In the case of the reaction of ethyl α-bromopropionate under a nitrogen atmosphere, gas formation was observed.

The Reaction of Acyl Halides with Potassium Cobalt Tetracarbonyl.—The solution of potassium cobalt tetracarbonyl, obtained by the procedure mentioned above, was evaporated to dryness[6] under reduced pressure at room temperature, and 50 ml. of anhydrous tetrahydrofuran or isopropyl ether were added. The solution[8] thus formed was mixed with 4.5 mmol. (equi-mole of potassium cobalt tetracarbonyl) of *n*-butyryl chloride or isobutyryl bromide, and the reaction was carried out as in the case of alkyl halides. In every case gas formation was observed.

Analytical Procedures.—After a desired reaction time, 30 ml. of a saturated solution of iodine in toluene[9] and 4 ml. of alcohol[10] were vigorously stirred into the reaction mixture at the same temperature as that for the reaction; the agitation was continued until gas ceased to evolve. By this treatment acylcobalt carbonyl was converted into the corresponding ester of carboxylic acid[1]. The solution of this ester was concentrated under reduced pressure (20 to 30 mmHg) and was then gas chromatographed. A column three meters long, filled with dilauryl phthalate on cerite, was used; the column temperature was varied between 100 to 150°C, depending on the boiling point of the sample, and the flow rate of the carrier gas (hydrogen) was set at 75 ml./min. The identification of the materials was made by means of a mixed melting point test with authentic samples.

Other Materials Used. — Methyl iodide, ethyl iodide, isopropyl bromide, *n*-butyl bromide, benzyl bromide, iodobenzene, bromobenzere, ethyl α-bromopropionate, *n*-butyryl chloride and isobutyryl bromide were commercial products, and all of them were proved to be sufficiently pure by gas chromatography. *n*-Propyliodide and isopropyl iodide were synthesized by the iodination of alcohols with iodide and red phosphor.[11]

Results

The Reactivity of Alkyl Halides with Potassium Cobalt Tetracarbonyl.—The reaction of *n*-propyl iodide with potassium cobalt tetracarbonyl is important in determining the isomerization mentioned at the beginning of this paper. No detailed observation had, however, been reported on the reaction of alkyl halide homologs higher than ethyl halide. Therefore, some alkyl or aryl halides have been reacted with potassium cobalt tetracarbonyl, and the amounts of carbon monoxide absorbed have been determined as the measure of their reactivity. It is believed[12] that the carbon monoxide absorption occurs as a result of the following reactions; the alkylcobalt tetracarbonyl ($RCo(CO)_4$), which is formed at the initial stage of the reaction, is converted to acylcobalt tricarbonyl ($RCOCo(CO)_3$), and the latter absorbs carbon monoxide to form acylcobalt tetracarbonyl ($RCOCo(CO)_4$).

The results for the reactions of ethyl iodide and *n*-propyl iodide illustrated in Fig. 1, in which the amounts of carbon monoxide

absorbed are plotted against the reaction time, indicate that these two halides scarcely reacted at 0°C, as it had already been observed,[13] but that they react fairly well at 25°C. For convenience of comparison, the results for methyl iodide and benzyl bromide are also given in Fig. 1.

Besides the halides mentioned above, isopropyl bromide, isopropyl iodide, *n*-butyl bromide, iodobenzene and bromobenzene were subjected to the reaction. It seems that none of them react; there was no absorption of carbon monxide nor any change in the color of the reaction mixtures when five times mole of halides were submitted to the reaction with potassium cobalt tetracarbonyl at 25°C for 2 hr.

The Reaction of *n*-Propyl Iodide and Ethyl α-Bromopropionate with Potassium Cobalt Tetracarbonyl.—*n*-Propyl iodide, which is the simplest compound for the study of the isomerization of alkyl- or acylcobalt carbonyls, and ethyl α-bromopropionate were subjected to react with potassium cobalt tetracarbonyl; the results are summarized in Table I. The latter was chosen as a sample for the secondary halide, because isopropyl iodide did not react with potassium cobalt tetracarbonyl. Methyl α-bromopropionate was submitted to this same type of reaction by Heak and Breslow,[13] but they did not identify the reaction products.

From *n*-propyl iodide only *n*-propyl *n*-butyrate should be produced if no isomerization takes place, but the product contained *n*-propyl isobutyrate besides *n*-butyrate. This formation of the isomeric esters was observed under the atmospheres of both carbon monoxide and nitrogen, but it seems that isobutyrate was formed easily under the nitrogen atmosphere. On the other hand, it was evident that no isomerization of alkyl halide took place in the course of reaction, because no isopropyl iodide was detected in the reaction product, while the amount of *n*-propyl iodide remained unchanged. These findings lead to the conclusion that the isomerization of alkyl- or acylcobalt carbonyls takes place.

In the reaction of ethyl α-bromopropionate, carbon monoxide was absorbed at −25°C and 0°C under a carbon monoxide atmosphere, but, on the contrary, gas evolution was observed at 25°C under a carbon monoxide or nitrogen atmosphere. The reaction at −25°C under a carbon monoxide atmosphere gave only diethyl methylmalonate, but at 0°C and 25°C both isomeric products (diethyl methylmalonate and diethyl succinate) were formed. Diethyl methylmalonate (A) was predominant in the reaction product at 0°C, but diethyl succinate (B) was the main product at 25°C. The ratio of B/A was just reversed at 0°C and at 25°C. These tendencies are also observed in a nitrogen atmosphere. Because no ethyl β-bromopropionate is formed in these reactions, it can be concluded that the isomerization of alkyl- or acylcobalt carbonyls takes place.

The Reaction of *n*-Butyryl Chloride and Isobutyryl Bromide with Potassium Cobalt Tetracarbonyl.—In order to check the possibility of the isomerization of acylcobalt carbonyls, *n*-butyryl chloride and isobutyryl bromide were made to react with potassium cobalt tetracarbonyl; the results are summarized in Table II. It is evident in all the conditions examined, that *n*-butyryl chloride gave only *n*-propyl *n*-butyrate, but that isobutyryl bromide gave *n*-butyrate besides isobutyrate. It is clear also that *n*-butyrate is predominant when the reactions are carried out in tetrahydrofuran, especially under a nitrogen atmosphere.

These findings seem to indicate that isoacylcobalt carbonyl is easily isomerized to form *n*-acylcobalt carbonyl, but that the reverse isomerization, *n*-acylcobalt carbonyl to isoacylcobalt carbonyl, is extremely difficult.

Comparing the findings concerning acyl halides with those concerning alkyl halides and summarizing the characteristic behavior observed in the course of these two types of reaction, in conclusion it may be said that:

Both isoalkyl- and isoacylcobalt carbonyls are isomerized easily to form large amounts of *n*-structural products,[14] and *n*-alkylcobalt carbonyl is also isomerized to result in a relatively small amount of iso-structural products.[14] On the other hand, *n*-acylcobalt carbonyl gives no iso-structural product. These findings appear to be related to the general tendency for the *n*-structural products to increase as the reaction temperature rises.

In all the experiments described here, the yields of the expected products (esters) are not good; this is because the intermediates, i. e., alkyl- or acylcobalt carbonyls, are very reactive and because some side reactions have taken place. Actually, it is clear that some side reactions occur, because in the reactions of ethyl α-bromopropionate in toluene and of acyl halide in tetrahydrofuran, organic crystalline substances were isolated from the concentrated reaction mixtures, and in the case of acyl halides, a relatively large amount of unknown substances was detected in the gas

(A) R-C-C-CO (B) R-C-C
CO

chromatograms.

As has already been described, the reactions studied in this program are complicated, and their details are not yet solved, but the conclusion, that the isomerization of alkyl- or acylcobalt carbonyl takes place, is unquestionable.

Discussion

It has been postulated by Breslow and Heck[12] that the mechanism of the reaction of organohalides with potassium cobalt tetracarbonyl can be represented as follows:

$$RX + KCo(CO)_4 \rightarrow RCo(CO)_4$$
$$\rightleftarrows RCOCo(CO)_3 \xrightarrow[CO]{} RCOCo(CO)_4$$
$$RCOX + KCo(CO)_4 \rightarrow RCOCo(CO)_4$$

They did not consider any possibility of isomerization during the course of the reaction sequences mentioned above.[15] Our experiments, however, have shown clearly that isomerization does occur at some step of the reaction. On the basis of our finding that the isomerization of acylcobalt carbonyl is accelerated under a nitrogen atmosphere and on the basis of the equilibrium established previously,[16] $RCOMn(CO)_5 \underset{CO}{\overset{\Delta}{\rightleftarrows}} RMn(CO)_5 + CO$, it may reasonably be concluded that [the isomerization species is the carbon monoxide-lacking complex in the reaction sequences described above: i. e., alkylcobalt tetracarbonyl and/or acylcobalt tricarbonyl.

Thermally-induced Changes in Poly-α-amino Acids Containing Methyl Sidechains[1]

By Tadao HAYAKAWA

(Received August 9, 1963)

Poly-α-amino acids containing α-methyl sidechains have been synthesized by the Leuchs method. These acids include poly-L-alanine, poly-DL-alanine, poly-α-aminoisobutyric acid, copoly(DL-alanine, L-glutamic acid) and copoly-(α-aminoisobutyric acid, L-glutamic acid). Copolymers have been coagulated in an aqueous solution by heat; other changes in the properties of both polymers and copolymers have been studied by the methods or measurements of specific rotation, specific viscosity, differential thermal analysis and infrared absorption spectra. The effects have been interpreted as being due to changes in the secondary structure. The poly-α-amino acids containing the alanine residue show changes in these properties at about 60°C, while the polymers containing the α-aminoisobutyric acid residue show such changes at about 50°C. The infrared absorption spectra indicate a change from the α to the β form.

It has been reported that poly-ε-aminocaproyl-DL-alanine,[2] poly-ε-aminocaproyl-α-aminoisobutyric acid[3] and poly-ε-aminocaproyl-L-proline[4] are slightly soluble in water and that these solutions are reversibly coagulated by heat; they precipitate from an aqueous solution upon being heated and redissolve upon being cooled. Kurtz et al.[5] observed the same phenomenon with poly-L-proline. Elliott[6] reported the thermal conversion of poly-DL-alanine from the α to the β formin an aqeuous solution. The β-form can be converted into the α-form by treating it with formic acid.[6]

Methyl groups of alanine or α-aminoisobutyric residues and tetrahydropyrrole rings of proline residues may contribute to the alteration of the secondary structure of the polypeptide chain upon being heated possibly resulting in the coagulation phenomenon. These groups may also be important in the heat denaturation of protein. This paper reports on the effect of heat upon various properties of poly-α-amino acids containing α-methyl groups. The polymers studied were poly-L-alanine (I), poly-DL-alanine (II), poly-α-aminoisobutyric acid (III), copoly(DL-alanine, L-glutamic acid) (IV), and copoly(α-aminoisobutyric acid, L-glutamic acid) (V). They were prepared by the Leuchs method[7] (Table I), glutamic acid being protected as the γ-benzyl ester during the synthesis.

The properties of the polymers studied, or the methods of studying the reversible heat coagulation, were specific rotation, specific viscosity, differential thermal analysis and infrared absorption spectra.

Experimental

The polymers studied and their solubilities in water are listed in Table I.

Poly-L-alanine (I).—This was prepared by the usual method.[7] The L-alanine was suspended in dry dioxane and treated with dry phosgene, and the resulting Leuchs anhydride was polymerized in benzene at 80°C for 48 hr. The polymer was insoluble in all the solvents tested except dichloroacetic acid. The intrinsic viscosity was measured with an Ostwald viscosimeter in dichloroacetic acid at 30±0.01°C. $[\eta]=[\eta_{sv/c}]_{c\to 0}=0.0216$, ml./g.

Poly-DL-alanine (II).—This was prepared in the same way as was poly-L-alanine. The molecular weight was determined by *N*-terminal analysis by titration with perchloric acid in glacial acetic acid. Mol. wt.=5000.

Poly-α-aminoisobutyric Acid[8] (III).—α-Aminoisobutyric acid (6.0 g.) was suspended in 300 ml. of dry dioxane, and dry phosgene was passed in at 50°C. It was almost completely dissolved after ten hours. Carbon dioxide was then passed in to remove the excess phosgene, and the solvent was removed under reduced pressure. The residual crystals were treated with petroleum ether, filtered and dried. The Leuchs anhydride was recrystallized from ethyl acetate-petroleum ether; yield, 5.0 g. The Leuchs anhydride (5.0 g.) was dissolved in 100 ml. of dry dioxane and polymerized with a sodium methylate initiator at room temperature. After a week, the solvent was removed, and the residue was treated with water, filtered and dried; yield, 2.2 g. (66.7%).

This polymer was insoluble in all the solvents tested except dichloroacetic acid. The intrinsic viscosity was measured in dichloroacetic acid in the same way as was the poly-L-alanine at 30±0.01°C. $[\eta]=[\eta_{sp/c}]_{c\to 0}=0.00187$, ml./g.

Copoly(DL-alanine, L-glutamic acid) (VI).—The method of preparing IV-2, IV-3, IV-4, and IV-5 samples has been reported earlier.[8] The IV-1 sample was prepared in the same way.

Found: N, 14.00; Calcd. for $1C_3H_5ON$-$1C_5H_7O_3N$: N, 14.00%.

The molecular weight was determined by the *N*-terminal titration of the intermediate, copoly(DL-alanine, γ-benzyl-L-glutamate); mol. wt.=19000.

Copoly(α-aminoisobutyric acid, L-glutamic acid) (V).—Mixtures of α-aminoisobutyric acid NCA and γ-benzyl-L-glutamate NCA were each dissolved in dry dioxane in the ratios of 1 : 1, 2 : 1, 5 : 1, 10 : 1 and 20 : 1. Each mixture was polymerized for several

days at room temperature, using sodium methylate as the initiator. The mixture in each case was then heated on a boiling water bath for one hour, and the solvent was removed under reduced pressure. The residue was treated with much water, filtered, and dried. The molecular weight was determined by endgroup titration. Portions of these copolymers were hydrolyzed with 6 N hydrochloric acid, and the component amino acids were assayed from paper chromatograms after ninhydrin staining by means of the densitometer (Table II).

These copolymer were debenzylated with glacial acetic acid and hydrogen bromide at 50°C in the usual way[10] (Table III).

TABLE III. COPOLYMERS OF α-AMINOISOBUTYRIC ACID AND L-GLUTAMIC ACID

	Mole ratio	N, % Found	N, % Calcd.

Discussion

Reversible Heat Coagulation.—It was not possible to test the water-insoluble poly-L-alanine (I), poly-α-aminoisobutyric acid (III), copoly(DL-alanine, L-glutamic acid) (IV) (1)–(2) and copoly(α-aminoisobutyric acid, L-glutamic acid) (V) (1)-(2) for reversible coagulation by heat. The water-soluble poly-DL-alanine and copoly(DL-alanine, L-glutamic acid)

(V-5) were also not coagulated by heat, possibly because of their high solubility in water. Other slightly-soluble copolymers, IV-3, IV-4, V-3, V-4 and V-5, were reversibly coagulated by heating and cooling. The relationship between the turbidity and the temperature is shown in Figs. 1 and 2. The turbidity increased with an increase in the temperature, the polymers of group IV, which contains DL-alanine, reaching a constant value at about 60°C, and those of groups V, which contains α-aminoisobutyric acid, reaching one at about 50°C. However, the ascending and descending temperature curves did not coincide. When the glutamic acid residues were converted to sodium salts, the water solubility of these

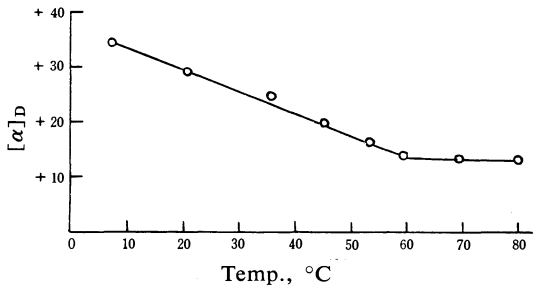

Fig. 3. Optical rotation of poly-L-alanine I (c=1.31, dichloroacetic acid).
(Measured after keeping for 15 min. at each temp.)

samples increased, and they were no longer heat-coagulable.

Specific Rotation.—The effect of the temperature on the optical rotation of these polymers is shown in Figs. 3, 4 and 5. The levorotation of poly-L-alanine (I) (Fig. 3), measured in dichloroacetic acid, decreased with a rise in the temperature, reaching, however, an almost constant value at about 60°C. The sodium salt of copoly IV also exhibited the same critical temperature, as Fig. 4 shows. The sodium salt of copolymer V had a critical temperature of about 50°C, as is shown in Fig. 5. These optical properties are complementary with the reversible heat coagulation phenomena. It is possible that the structure of the polymer chain which has methyl side-chains may be altered by heating, and that this may cause delicate changes in the solubility. The poly-α-amino acids containing the alalyl residue seem to undergo a change (or

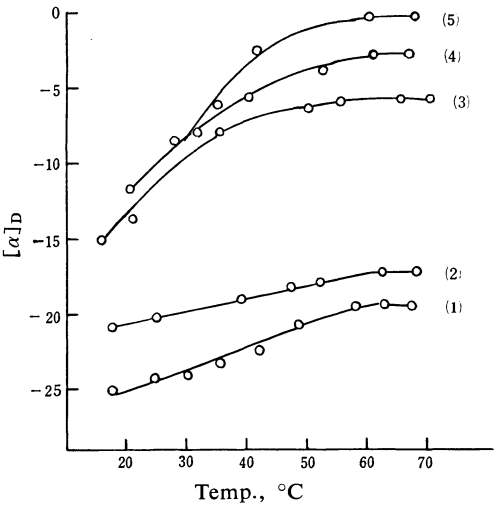

Fig. 4. Optical rotation of copoly(DL-ala, L-glu-Na) IV in water (1) C=5.00, (2) c=5.00, (3) c=5.00, (4) c=3.46, (50) c=1.71.

(Measured after keeping for 15 min. at each temp.)

changes) in their secondary structure at about 60°C, while the polymers containing α-aminoisobutyryl residues show their initial response at about 50°C.

In order to verify these phenomena, specific viscosity determinations, differential thermal analyses and infrared spectra were performed on poly-L-alanine (I), poly-DL-alanine (II), and poly-α-aminoisobutyric acid (III).

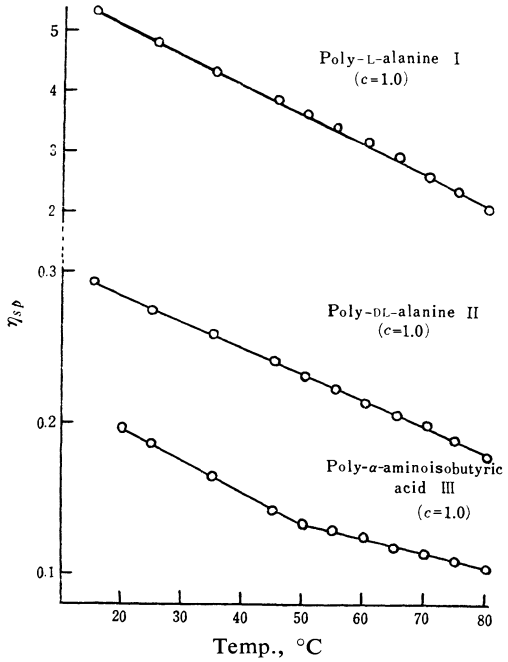

Fig. 6. Specific viscosity in dichloroacetic acid.
(Measured after keeping for 30 min. at each temp.)

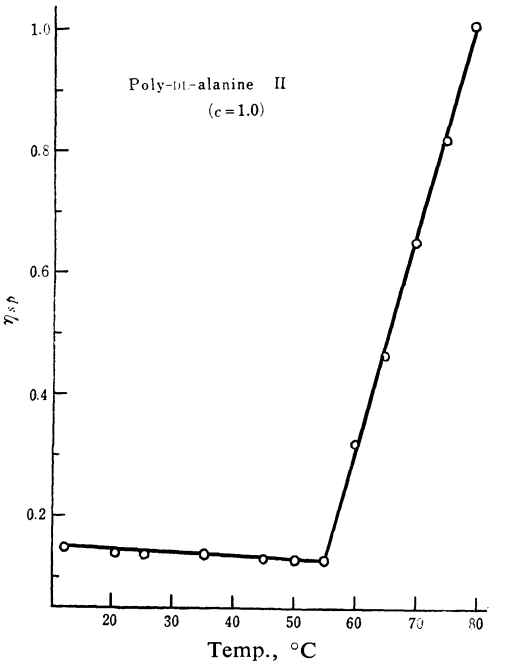

Fig. 7. Specific viscosity in water.
(Measured after keeping for 2 hrs. at each temp.)

Specific Viscosity.—The specific viscosities of I, II and III in 1% dichloroacetic acid solutions were measured in an Ostwald viscosimeter at varying temperatures, as is shown in Fig. 6. The specific viscosity decreased with a rise in the temperature. The viscosity of I and II decreased linearly, while the viscosity of III was observed to have a transition point at 50°C. In a dichloroacetic acid solution, the change in viscosity was not great. II was water-soluble; the specific viscosity in an aqueous solution is shown in Fig 7. The measurements of viscosity were carried out after the substance had stood for two hours at each temperature. In this case, the specific viscosity decreased slightly until the temperature reached 55°C but it increased rapidly when the temperature exceeded 55°C. This finding is consistent with Ebata's report,[11] in which the aqueous solution of poly-ε-aminocapryol-DL-alanine showed a minimum viscosity at about 55°C, with an increase at higher temperatures. This effect may be due to the influence of alanine residues in the polymer. The aqueous solution of II at more than a 4% concentration formed a gel at 60°C or a higher temperature, as has been reported by Elliott.[6]

Differential Thermal Analyses.—The differential thermal analytical data for I, II and III are shown in Fig. 8. With polymer I, an endothermal change was observed from 38 to 120°C, with polymer II, from 60 to 160°C, and with polymer III, from 50 to 120°C. The

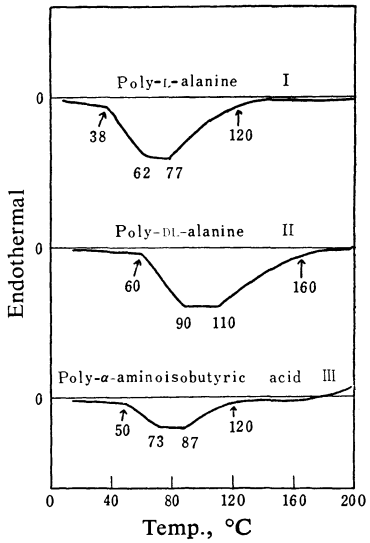

Fig. 8. Differential thermal analyses.

11) M. Ebata, This Bulletin, 33, 899 (1960).

maximum endothermal change was observed from 62 to 77°C, from 90 to 110°C and from 73 to 87°C, respectively, for the polymers I, II and III. The endothermal changes of poly-DL-alanine (II) and poly-α-aminoisobutyric acid (III) started at 60 and 50°C respectively, they are in good agreement with the viscosity and heat coagulation curves.

Infrared Analyses.—The infrared absorption spectra of I, II and III that were measured at room temperature were compared with the spectra that were measured at the maximum endothermal value temperature in the differential thermal analyses, i.e., at 62°C for I, at 100°C for II and at 80°C for III (Fig. 9). The

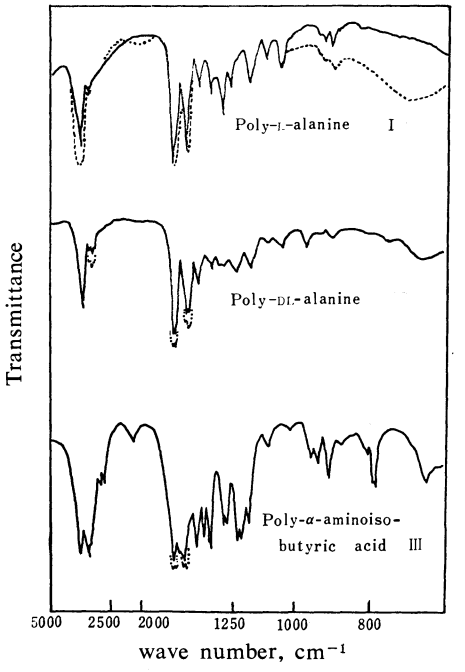

Fig. 9. Infrared absorption spectra.

observations were carried out after two hours at the above-mentioned temperatures. The dotted lines in Fig. 9 depict the spectra observed at higher temperatures, which are different from those measured at room temperature. At high temperatures, poly-L-alanine (I) (film) showed a wider absorption at 3300 cm^{-1}, (νNH) and a broader absorption at about 2070 cm^{-1} than the spectra measured at room temperature. In a region longer than 1000 cm^{-1}, the absorption spectra showed a different pattern, which may be due to the conformational changes in the polymer. These differences observed in the absorption spectra disappeared when the sample was cooled to room temperature. The absorption bands at 1660 cm^{-1} (Amide I) and at 1550 cm^{-1} (Amide II) appeared slightly broader when they were measured at a higher temperature. This effect may be due to the shift from the α to the β form. These phenomena were observed more clearly with poly-DL-alanine (II) (film) and poly-α-aminoisobutyric acid (III) (pellet). The absorption bands at 1630 cm^{-1} and at 1530 cm^{-1} in II were relatively weak at room temperature, but they were significantly stronger at 100°C. This behavior may be explained by the shift from the α to the β conformation of the peptide chain. With III, only the 1660 cm^{-1} and 1550 cm^{-1} bands were exhibited at room temperature. At higher temperatures, however, these bands were split, the former into 1660 cm^{-1} and 1630 cm^{-1} and the latter into 1550 cm^{-1} and 1530 cm^{-1}. This might represent a shift to the β-form from the α-form, as has been postulated above. The absorption due to methyl at 2960 cm^{-1} in I and II was strong at a high temperature, and the absorption with III, at about 3000 cm^{-1} was very strong because of the additional methyl group. Again, a conformational change from the α-form to the β-form is assumed to occur at a high temperature.

Conclusion

Poly-α-amino acids containing alanine and α-aminoisobutyric acid, i.e., containing one and two α-methyl groups respectively, have been synthesized. From the findings of coagulation phenomena, specific rotation, specific viscosity and differential thermal analysis, these poly-α-amino acids containing the alanine residue and the α-aminoisobutyric acid residue may be understood to undergo steric structural changes at about 60°C and 50°C respectively. The difference in critical temperature between the above two polymers can be explained by the presence of one more methyl group per residue in the polymer from α-aminoisobutyric acid. From the infrared results a conformational change at high temperature from the α- to the β-form has been inferred.

The author wishes to express his thanks to Professor Junzo Noguchi of Hokkaido University and to Professor Sidney W. Fox and Dr. Kaoru Harada of Florida State University for their helpful suggestions.

Syntheses of α-Amino Acid Menthyl Esters

By Kaoru HARADA and Tadao HAYAKAWA

(Received August 20, 1963)

l-Menthol[1] has been used as an optically-active moiety in many kinds of stereochemical studies.[2] However, few α-amino acid menthyl esters have been prepared[3] because the conventional esterification methods, such as the hydrogen chloride or sulfuric acid methods, fail to give satisfactory results.

In this paper a new method of preparing α-amino acid menthyl esters is described. The method involves a direct esterification of α-amino acids with menthol, using a Dean and Stark distillation tube[4,5] in azeotropic distillation. *p*-Toluenesulfonic acid was used as a catalyst, and benzene or a benzene-toluene mixture was used as the solvent.[5] The α-amino acid menthyl esters thus prepared were isolated as hydrochlorides; they are abbreviated as amino acid M. HCl.

DL-, D- and L-Amino acid M. HCl's were prepared. It was found that the solubility of D-amino acid M. HCl was generally smaller than that of L-amino acid M. HCl. The fractionation of the diastereomers of DL-amino acid M. HCl during the isolation and recrystallization was checked by comparing the $[\alpha]_D$ value of the DL-amino acid M. HCl with those of the synthesized L- and D-amino acid M. HCl's. The $[\alpha]_D$ values of L-phenylalanine M. HCl and D-phenylalanine M. HCl were $-20.8°$ and $-75.1°$ respectively, so the calculated $[\alpha]_D$ value of DL-phenylalanine M. HCl should be $-48.0°$. The $[\alpha]_D$ values of isolated DL-phenylalanine M. HCl were found to be $-51.4°$ and $-55.2°$, before and after recrystallization respectively (Table I). These results showed that the fractionation of diastereomers occurred during the isolation and recrystallization steps. Table I shows that the yield of D-amino acid M. HCl is generally twice as high as that of L-amino acid M. HCl. This means that the rate of the esterification of D-amino acids with menthol is faster than that of L-amino acids. This suggests the possibility of the fractionation of D- and L-amino acid M. HCl's during the synthesis of these esters.

The menthyl esters of D-phenylalanine and D-methionine were resolved by seeding the supersaturated DL-amino acid M. HCl solution with D-phenylalanine M. HCl and D-methionine M. HCl respectively. The 89% optically-active D-phenylalanine M. HCl and the 65% optically-active D-methionine M. HCl were each isolated in one seeding procedure.

Generally, D- and L-amino acid M. HCl's showed sharp melting points, whereas DL-amino acid M. HCl's showed relatively broad melting points because the DL compounds were a mixture of diastereomers. L-Leucine M. HCl and D-leucine M. HCl did not crystallize, so they were converted to *N*-benzoyl derivatives. D-Alanine and L-alanine M. HCl showed similar $[\alpha]_D$ values (L, -67.3; D, -70.9). These compounds were also converted to *N*-benzoyl derivatives (Table II), which also exhibited similar $[\alpha]_D$ values (L, -57.7; D, -43.2). The free α-amino acid menthyl esters were stable and did not form diketopiperazine derivatives after standing a few days at room temperature. It was difficult to apply the esterification method to the hydroxy amino acids (serine, threonine and phenylserine) or to the basic amino acids (arginine and histidine). The reaction conditions, yields, physical properties and elemental analyses are shown in Tables I and II.

These results might be useful in providing standards for the field of stereochemistry or in the asymmetric synthesis of α-amino acid menthyl esters.

Experimental

L-Phenylalanine Menthyl Ester Hydrochloride.—8.26 g. (0.05 mol.) ($[\alpha]_D^{27} = -33.4$, H_2O, *c* 1.50) of L-phenylalanine, 12.0 g. (0.077 mol.) of *l*-menthol ($[\alpha]_D^{27} = -50.0$, abs. EtOH, *c* 3.5), and 12.0 g. 0.063 mol.) of *p*-toluenesulfonic acid monohydrate were mixed with 100 ml. of a benzene-toluene mixture (7 : 3) and refluxed with a Dean and Stark distillation apparatus[4,5] in azeotropic distillation for 24 hr. The nascent water was then removed azeotropically. The insoluble materials (unreacted

1) *l*-Menthol was used throughout in this study; m. p. 42~44°C, $[\alpha]_D^{27} = -50.0°$ (*c* 3.50, in abs. EtOH).

a) Recrystallization solvent: E-PE=ether and petroleum ether; Et=ethyl acetate and ether
b) All melting points are uncorrected.
c) All samples were measured in abs. ethanol at 26~27°C. All samples exhibited negative rotations.

L-phenylalanine and its *p*-toluenesulfonate) were removed by filtration, and the solvent was evaporated to about 30 ml. in vacuo. To this was added about 30 ml. of ether, and then the acidic material was extracted with 8% sodium hydrogen carbonate. The organic layer was washed once with water and dried with anhydrous sodium sulfate. To this dried solution, dry hydrogen chloride gas was introduced to precipitate the L-phenylalanine M. HCl. The crystals were filtered and washed with ether and petroleum ether. Yield, 5.45 g. (32%); $[\alpha]_D^{27}=-21.8°$ (*c* 0.623, in abs. EtOH). This was recrystallized from ethyl acetate and ether.

***l*-Menthyl *N*-Benzoyl L-Leucinate.**—3.28 g. (0.025 mol.) ($[\alpha]_D^{27}=+15.3°$, 5 N HCl, *c* 2.01) of L-leucine, 6.0 g. (0.0385 mol.) of menthol, and 6.0 g. (0.0315 mol.) of *p*-toluenesulfonic acid monohydrate were mixed with 50 ml. of a benzene-toluene mixture (7 : 3) and refluxed with the Dean and Stark distillation apparatus[4,5] for 24 hr. The reaction mixture was then filtered and the solvent removed in vacuo to about 20 ml. Then 20 ml. of ether was added to the solution, and this was extracted with 8% sodium hydrogen carbonate three times. The organic layer was dried with anhydrous sodium sulfate. Dry hydrogen chloride was introduced into the free menthyl ester solution. No hydrochloride of the menthyl ester crystallized. The solvent was removed, and the syrupy ester hydrochloride was dissolved in ether. The ether solution was extracted with 8% sodium hydrogen carbonate to make the free ester. The ethereal solution of the free menthyl ester was dried with anhydrous sodium sulfate. A part of the solution was titrated in an aqueous condition with 0.1 N hydrochloric acid, using methyl red as an indicator to determine the free ester content (0.015 mol., 60%). The solution was then strongly agitated, together with a slight excess of benzoyl chloride (2.39 g., 0.017 mol.) and triethylamine (1.82 g., 0.018 mol.) in ice water. The reaction mixture was washed with 5% sodium hydrogen carbonate, 0.5 N hydrochloric acid, and water. The ethereal solution was dried with anhydrous sodium sulfate. To this solution, petroleum ether was added to precipitate the *N*-benzoyl L-leucine menthyl ester. Yield, 3.84 g. (0.0103 mol.); 75% from free ester. $[\alpha]_D^{27}=-61.0°$ (*c* 0.960, in abs. EtOH). This was recrystallized from ether and petroleum ether.

Benzoyl D-, L- and DL-Alanine Menthyl Ester.—The benzoylation of the D-, L- and DL-alanine menthyl esters was carried out by the use of sodium ethoxide and benzoyl chloride in absolute alcohol. The yields of the benzoyl derivatives were 85.2, 63.2 and 86.2% respectively. Physical and analytical data are shown in Table II. The *p*-nitrobenzoyl glycine menthyl ester was also prepared by the use of sodium ethoxide and *p*-nitrobenzoyl chloride in absolute alcohol; yield, 55.0%.

The Fractionation of Diastereomers of the DL-Phenylalanine Menthyl Ester.—Two grams of DL-phenylalanine M. HCl was dissolved in 100 ml. of hot ethyl acetate and filtered. About 3 mg. of powdered D-phenylalanine M. HCl in 5 ml. of absolute ether was then added to the filtrate and kept at room temperature for 3 hr. The D-rich crystals obtained weighed 0.40 g.; $[\alpha]_D^{27}=-72.1°$ (*c* 1.25, in abs. EtOH) (D : 94.5%; L : 5.5%). To the mother liquor 80 ml. of ether was added, and the resulting solution was seeded with D-phenylalanine M. HCl. After standing for 3 hr. at room temperature, an additional 0.52 g. of a D-rich fraction was obtained. $[\alpha]_D^{27}=-64.4°$ (*c* 1.05, in abs. EtOH) (D : 80.3%; L : 19.7%). By use of the seeding procedure, the first D-rich crystals were fractionated and obtained as pure D-phenylalanine M. HCl. 0.22 g. $[\alpha]_D^{27}=-75.6$ (*c* 1.29, in abs. EtOH).

The fractionation of DL-methionine M. HCl (1.0 g.) followed essentially the same pattern. However, crystallization was carried out by lefting it stand in the cold for three days. 0.32 g. of D-rich crystals were obtained. $[\alpha]_D^{27}=-59.7°$ (D : 82.7%; L : 17.3%). From the mother liquor, an additional 0.30 g. of D-rich fraction was obtained by evaporation, $[\alpha]_D^{27}=-54.6°$ (D : 55.6%; L : 44.4%).

This work was supported by National Aeronautics and Space Administration Grant No. NsG-173-62. Contribution No. 18 of the Institute for Space Biosciences. The authors

wish to express their sincere appreciation to Professor Sidney W. Fox of Florida State University for his advice. Thanks are also extended to Mr. David Joseph for his measurements of the optical rotation.

The Synthesis and Configurational Analysis of 2-Amino-1,3-cyclohexanediol

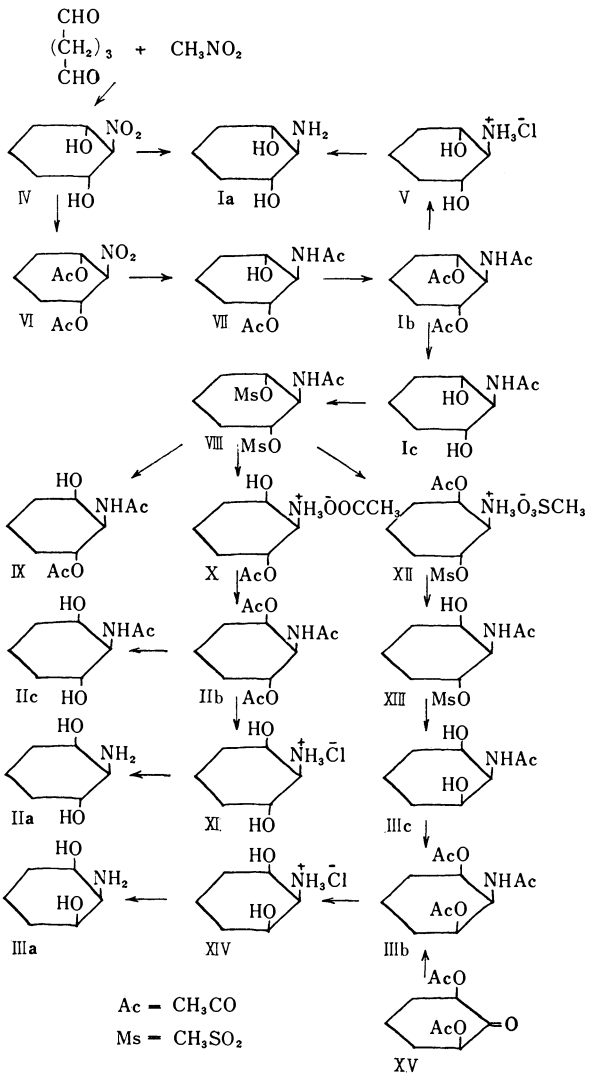
By Tetsuo SUAMI and Seiichiro OGAWA

(Received August 10, 1963)

Interest in inosamine and inosadiamine has been stimulated by their occurrence in certain antibiotics. The previous studies of 2-amino-cyclohexanol derivatives[1,2] have stimulated our interest in the synthesis of alicyclic compounds which have three neighboring groups. An attempt to prepare 2-amino-1, 3-cyclohexanediol was abandoned by McCasland et al. because of the poor yield of a corresponding nitrodiol.[3] Very recently, however, Lichtenthaler[4] synthesized two diastereomeric 2-amino-1, 3-cyclohexanediols (trans and DL-isomers) through the nitrodiol obtained by the cyclization of glutaraldehyde with nitromethane.

In the present paper, synthetic routes to another diastereomeric 2-amino-1, 3-cyclohexanediol (cis isomer) will be described, and its structure assignment will be made by means of the proton magnetic resonance spectrum of its acetyl derivative.

The cyclization of glutaraldehyde with nitromethane in the presence of sodium carbonate gave 2-nitro-1, 3-cyclohexanediol (IV).[4] Hydrogenation with Raney nickel, T4,[5] gave 2α-amino-1β, 3β-cyclohexanediol (Ia) in a 63% yield. In order to establish the configurational purity of Ia, paper chromatography was employed. The compound, Ia, consumed 1.91 mol. of the periodate in an aqueous solution in 20 hr., showing a single spot (R_f 0.59) in 1-butanol-ethanol-water (2 : 1 : 3), and also a single spot (R_f 0.45) in 1-butanol-acetic acid-water (4 : 1 : 5). These data provide strong, if not conclusive, evidence that Ia is a single isomer.



The acetylation of IV with acetic anhydride and a small amount of concentrated sulfuric acid gave di-*O*-acety-2-nitro-1, 3-cyclohexanediol (VI).[4] VI was hydrogenated with Raney nickel, T4,[5] to give 2α-acetamido-*O*-aecty-1β, 3β-cyclohexanediol (VII) in a 75% yield; this might be obtained through the O→N migration of an acetyl group[6] during the course of reduction. VII was further acetylated to give the triacetyl derivative of Ia, Ib, in a 83% yield. Under Kunz's conditions,[7] Ib was selectively deacetylated; this showed the presence of two hydroxyl groups. The *N*-acetyl derivative Ic was recovered from the neutralized solution of Kunz's hydrolysis. Ic did not consume any periodate in an aqueous methanol solution in 50 hr. These data are consistent with a cyclic structure with one acetamido group between two hydroxyl groups.

To obtain the other diastereomers of Ia, an inversion reaction of its mesyl derivative was employed. When a cyclohexane ring containing vicinal mesyloxy and acylamido groups in the trans position was treated with sodium acetate in refluxing aqueous 2-methoxyethanol, the replacement of the mesyloxy group takes place with Walden inversion through an intermediary oxazolinium ion to give *cis*-acylamido alcohol.[8] On the other hand, when vicinal mesyloxy and acylamido groups are in the cis position, the replacement of the mesyloxy group takes place at a considerably slower rate.[9]

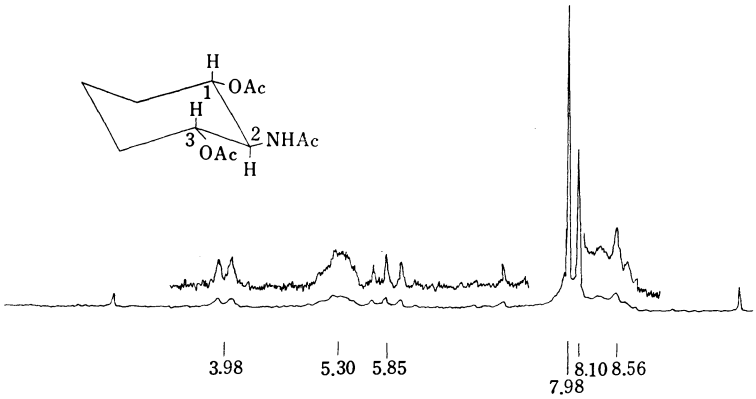
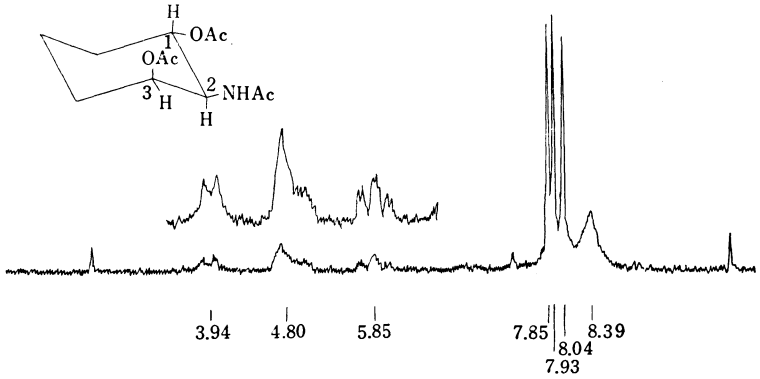
The compound, Ic, gave a dimesyl derivative (VIII) by reaction with mesyl chloride in pyridine.[4] The displacement of both mesyloxy groups of VIII gave DL-*O*-acetyl-2α-amino-1α, 3β-cyclohexanediol acetate (X) when the reaction with two moles of sodium acetate was carried out in boiling water for 1 hr. The fact that the replacement of two mesyloxy groups in VIII took place at a considerably higher rate showed that the C-1 and C-3 mesyloxy groups were both situated in the trans position to the C-2 acetamido group.[9] X gave a triacetyl derivative IIb melting at 146°C in a 74% overall yield, after acetylation. Studies of a detailed reaction mechanism in this reaction are in progress.

When IIb was hydrolyzed with 6 N hydrochloric acid, DL-2α-amino-1α,3β-cyclohexanediol hydrochloride (XI) melting at 117°C was obtained. The free base IIa melting at 113°C was recovered from XI with a sodium hydroxide solution. A paper chromatography of IIa showed a single spot (R_f 0.49) in 1-butanol-acetic acid-water (4 : 1 : 5).



When VIII was refluxed in water for a few minutes, without adding any sodium acetate, DL-*O*-acetyl-*O*-mesyl-2α-amino-1α, 3β-cyclohexanediol methanesulfonate (XII) was produced in a 74% yield. In this reaction, the replacement of the mesyloxy group yielded an oxazolinium ion which was attacked by water to give *cis*-acetamido alcohol as usual. Then the acetyl group could migrate from nitrogen to oxygen in an acidic medium to yield XII, which could not have a further inversion because of the lack of an acetamido group adjacent to the mesyloxy group.

When treated with sodium hydroxide solution, XII gave DL-2α-acetamido-*O*-mesyl-1α, 3β-cyclohexanediol (XIII) in a 73% yield. Accordingly, it must involve the O→N migration of the acetyl group.[6] Since XIII had the mesyloxy group situated in the trans position to the vicinal acetamido group, a further inversion was expected. XIII was refluxed in 95% aqueous 2-methoxyethanol for 5 hr. to yield the *N*-acetyl derivative IIIc melting at 121.5°C with an inversion of the configuration. IIIc was acetylated to give the triacetyl derivative IIIb melting at 179°C.



IIIb was also obtained via a different synthetic route starting from *cis*-2, 6-diacetoxycyclohexanone (XV). XV was prepared by the oxidation of cyclohexanone with lead tetraacetate in boiling benzene.[10] The structure and configuration of XV were established by converting it to 1α, 2α, 3α-cyclohexanetriol of a known configuration.[11] Anderson and Lardy[12] found that the primary amine obtained from the phenylhydrazone or oxime of *scyllo*-inosose practically consisted of a single isomer, when glacial acetic acid was used as a solvent and Adams platinum oxide, as a catalyst. Therefore, the reduction of *cis*-2, 6-diacetoxycyclohexanone oxime was carried out using the procedure of Anderson and Lardy.[12] Then the crude reduction product was treated with acetic anhydride in pyridine to obtain the compound, which was identical with IIIb. However, the yield was unexpectedly low. Since the starting material, XV, had a known configuration, the only point requiring to be clarified was the configuration of the newly-introduced amino group. The steric selectivity of the reduction condition employed in this

Fig. 1. NMR spectra in deuteriochloroform at 60 Mc.
Peak positions are given in τ-values.

synthesis seemed ample enough to enable us to assign IIIb as all-cis configuration.

IIIb was hydrolyzed with 6 N hydrochloric acid to give 2α-amino-1α, 3α-cyclohexanediol hydrochloride (XIV) melting at 161.5°C. The free base IIIa melting at 128°C was obtained from XIV by an ordinary method. A paper chromatography of IIIa showed a single spot (R_f 0.44) in 1-butanol-acetic acid-water (4 : 1 : 5).

The above consideration of the configuration of IIIb has been fully substantiated by means of its proton magnetic resonance spectra, as will be described below.

The protons of the acetoxy and acetamido groups of Ib and IIb have already been assigned by Lichtenthaler.[4] In the present study, the NMR spectrum of the compound, IIIb, gave two sharp signals of a 2 : 1 relative intensity (cf. Fig. 1-C), as was to be expected from the two equatorial acetoxy groups (τ of 7.95) and the axial acetamido group (τ of 7.99).

Lemieux et al.[13] assigned the configurations of two diastereomeric 2-acetoxy-1, 3-dimethoxycyclohexanes on the basis of the fine structure of an axial proton on C-2 in their NMR spectra. In the present experiments, the axial proton on C-2 of Ib was coupled with the two axial protons on the neighboring carbon atoms (C-1 and C-3) ; the signal for this proton should be a triplet with an intensity of 1 : 2 : 1 (J_{aa}=8~11.5 c.p.s.).[14] As Fig. 1-A shows, Ib was readily recognized as a trans isomer by the triplet centered at 5.85 with a 1 : 2 : 1 relative intensity (observed J=10.5 c.p.s.). In the case of IIb, the proton on C-2 was coupled with an axial proton (C-1 or C-3) and an equatorial proton (C-3 or C-1). Since the coupling between an equatorial proton and an axial proton was considerably weaker than that between two axial protons, the signal for the proton on C-2 could be anticipated to be a quartet. However, the sextuplet at 5.85 in the observed spectrum of IIb shown in Fig. 1-B could not be interpreted without counting the spin-spin coupling between the proton on C-2 and the proton on the nitrogen atom.[15] The spin-spin coupling constant between the proton on C-2 and the proton on the nitrogen atom in the trans orientation was about 9.0 c.p.s. (observed value); this value was close to that of the observed J_{aa}.

Also in the case of IIIb, it could be distinguished from the others by its lack of an axial proton on C-2. In Fig. 1-C, the signal for the proton on C-2 appears in a lower field (centered at 5.60) ; it can be recognized that this proton is in an equatorial position.

The signal of the protons on C-1 and C-3 was not well resolved, but the width of the signal presented some information on the configurations. The spin-spin coupling constant was greater between two axial protons than between axial-equatorial, or two equatorial protons.[16] Therefore, the most narrow peak width observed in Fig. 1-C was consistent with the assigned configuration of IIIb. The peak widths are listed in Table I.

Table I. Chemical shifts expressed in τ-values

Protons (C-1 and C-3)		Peak width c.p.s.
Ib	5.30	30
IIb	4.80	30
IIIb	5.17	17

The other six protons showed a signal at 8.32~8.56, as was expected from the ring protons of cyclohexane in the chair conformation.[17]

As a result of these considerations of the NMR spectra and the chemical evidence, it has been concluded that the compound IIIb (m. p. 179°C) has the cis configuration, and Lichtenthaler's assignmets for the Ib and IIb compounds have been further confirmed. All three predicted diastereomers of 2-amino-1, 3-cyclohexanediol have now been synthesized.

Experimental

All melting points are corrected, and unless noted otherwise, they were measured in a liquid bath. The melting points marked with asterisks were measured on a Mitamura-Riken micro hot stage. The NMR spectra of all the acetyl derivatives were determined at a frequency of 60 Mc. with a Japan Electron Optics instrument JNM-C-60 in deuteriochloroform containing tetramethylsilane as an internal reference. The peak positions are given in τ-values. The infrared spectra were recorded in potassium bromide pellets.

2α-Nitro-1β, 3β-cyclohexanediol (IV). — By the method of Lichtenthaler,[4] the cyclization of glutaraldehyde with nitromethane gave IV in a 59.5% yield ; m. p. 161.5~163.5°C (recrystallized from ethyl acetate). (Reported m. p. 159~161°C).[4] (Found : C, 44.92 ; H, 6.70 ; N, 8.71%).

2α-Amino-1β, 3β-cyclohexanediol (Ia).—A mixture of 5.0 g. of IV and 50 ml. of absolute ethanol was hydrogenated at room temperature under 40 p. s. i. g. of initial hydrogen pressure with a Raney

nickel T4 catalyst,[5] obtained from 7.0 g. of Raney nickel alloy, in a Parr shaker-type hydrogenation apparatus for 1 hr. After the catalyst had been removed by filtration, the filtrate was evaporated under reduced pressure. The residue was recrystallized from absolute ethanol to yield 2.3 g. (56%) of needles melting at 190.5~193.5°C (decomp.). The second crop of the product (0.25 g.) was obtained from the mother liquor. The total yield was 62.5%. Recrystallization from ethanol gave an analytically pure sample melting at 191.5~193.5°C (decomp).

Found: C, 54.77; H, 9.72; N, 10.74. Calcd. for $C_6H_{13}NO_2$: C, 54.94; H, 9.99; N, 10.68%.

Paper Chromatography. — 1-Butanol-ethanol-water (2 : 1 : 3) gave a single spot of R_f 0.59 (R_f of D-glucosamine hydrochloride : 0.33) in ascending development at 23°C. The spot was developed with ninhydrin. Both the pure crystals and the crude product gave a single spot in the same R_f region, and no other spot was observed.

Also, an upper layer of 1-butanol-acetic acid-water (4 : 1 : 5) gave one spot of R_f 0.45 in acending development at 25°C (R_f of D-glucosamine hydrochloride : 0.14).

Periodate Oxidation.—A mixture of 100 mg. of Ia was treated with 100 ml. of a 0.1 M sodium metaperiodate solution at 24°C. Iodometric titrations with sodium arsenite[18] revealed that 1.91 mol. of periodate had heen consumed per mole of Ia in 20 hr.

Di-*O*-acetyl-2α-nitro-1β, 3β-cyclohexanediol (VI).—The acetylation of IV with a mixture of acetic anhydride and a small amount of concentrated sulfuric acid gave a crude product in a 79% yield.[4] (Found: C, 49.02; H, 6.05; N, 5.60%).

***N, O*-Diacetyl-2α-amino-1β, 3β-cyclohexanediol (VII).**—A mixture of 10 g. of VI and 120 ml. of absolute ethanol was hydrogenated, as described in the hydrogenation of IV, to yield 6.6 g. (75.2%) of pale yellow crystals. The crude product was recrystallized from benzene to yield 5.4 g. (61.6%) of colorless needles melting at 126~130°C. An analytical sample was further recystallized from benzene; it melted at 130.5~131.5°C.

Found: C, 55.62; H, 8.24; N, 6.63. Calcd. for $C_{10}H_{17}NO_4$: C, 55.80; H, 7.96; N, 6.51%.

IR: 3420 (OH), 1626, 1566 (amide) and 1745 (ester) cm^{-1}.

Triacetyl-2α-amino-1β, 3β-cyclohexanediol (Ib).—A 2.0 g. portion of the crude product of VII was acetylated with 20 ml. of acetic anhydride and 20 ml. of pyridine at room temperature overnight. The mixture was then evaporated under reduced pressure. The product was recrystallized from ethanol to give 1.98 g. (83.0%) of needles melting at 152~152.5°C.

Found: C, 56.17; H, 7.20; N, 5.56. Calcd. for $C_{12}H_{19}NO_5$: C, 56.02; H, 7.44; N, 5.44%.

The product was identified with the triacetyl derivative[4] on the basis of a mixed melting point determination and infrared spectra.

2α-Acetamido-1β, 3β-cyclohexanediol (Ic). — Ib gave 2.15 mol. of acetic acid on hydrolysis under Kunz's conditions.[7]

18) J. M. Bobbitt, "Advances in Carbohydrate Chem.," Vol. XI, Academic Press, Inc., New York (1956), pp. 1—41.

The neutralized hydrolyzate was evaporated in vacuo and the residue was extracted with acetone. The combined acetone extract was evaporated to yield a crude product of *N*-acetyl derivative Ic. The product was recrystallized from ethanol to yield 48 mg. (28.2%) of crystals melting at 208.5~210°C. (Found: C, 55.60; H. 8.64; N, 8.31%). A mixed melting point determination with an authentic sample[4] was undepressed.

The porduct (200 mg.) did not consume any periodate in 50 hr. in a mixture of 40 ml. of a 0.1 M sodium metaperiodate solution and 10 ml. of methanol at 26°C.

2α-Amino-1β, 3β-cyclohexanediol Hydrochloride (V).—A mixture of 200 mg. of Ib and 10 ml. of 6 N hydrochloric acid was refluxed for 6 hr. The hydrolyzed solution was evaporated under reduced pressure to dryness, the residue was dissolved in 2 ml. of absolute ethanol, and 6 ml. of absolute ether was added. The mixture was stored in a refrigerator to yield 100 mg. (77%) of needles melting at 143.5~145.5°C. The mixed melting point determination with an authentic sample[4] was undepressed.

The free base, Ia, was regenerated from V by dissolving a 374 mg. portion of V in 30 ml. of a 0.5 N sodium hydroxide solution. The mixture was evaporated, and the residue was extracted with absolute ethanol to yield 217 mg. (74%) of crystals melting at 188.5~190.5°C (decomp.)., the melting point being undepressed upon adimxture with Ia.

2α-Acetamido-di-*O*-mesyl-1β, 3β-cyclohexanediol (VIII).—Ic gave VIII by a reaction with mesyl chloride in pyridine[4] in an 80% yield. Recrystallization from 95% ethanol afforded colorless needles melting at *153~154°C (Found: C, 36.86; H 5.96; N, 4.27; S, 19.43%).

DL-*N,O*-Diacetyl-2α-amino-1α, 3β-cyclohexanediol (IX).—VIII was refluxed with sodium acetate and 95% aqueous 2-methoxyethanol for 6 hr. to yield IX in a 36% yield.[4] The crude product was recrystallized from ethanol-ether to yield colorless plates melting at *148~152°C (Found: C, 55.96; H, 7.98; N, 6. 43%).

DL-*O*-Acetyl-2α-amino-1α, 3β-cyclohexanediol Acetate (X).—A mixture of 5.0 g. of VIII, 2.75 g. of anhydrous sodium acetate, and 100 ml. of water was refluxed for 1 hr. Then the mixture was evaporated under reduced pressure to dryness. The residue was extracted with boiling acetone repeatedly. The combined acetone extract was evaporated under reduced pressure to yield a crystalline residue. The residue was washed with a small amount of cold acetone to give 1.3 g. (20%) of colorless needles melting at 104~113°C. Recrystallization from acetone afforded needles melting at 130.5~132°C; these were shown by infrared spectrum and elementary analysis to be DL-*O*-acetyl-2α-amino-1α, 3β-cyclohexanediol acetate.

Found: C, 51.33; H, 8.44; N, 6.14. Calcd. for $C_{10}H_{19}NO_5$: C, 51.49; H, 8.21; N, 6.01%.

IR: 3200 (OH), 1725 (ester), 1638 (NH_3^+), 1547 and 1403 (COO^-) cm^{-1}.

DL-Triacetyl-2α-amino-1α, 3β-cyclohexanediol (IIb).—A mixture of crude X, obtained from 5.0 g. of VIII, 25 ml. of acetic anhydride, and 25 ml.

of pyridine, was left to settle at room temperature overnight and then heated at 80°C for 1 hr. The mixture was evaporated under reduced pressure and the residue was dissolved in 100 ml. of chloroform. The chloroform solution was washed with cold water, dried over anhydrous sodium sulfate, and then evaporated in vacuo to dryness. Crystallization of the residue with a mixture of benzene and petroleum ether gave 2.9 g. (74%) of the product melting at 140.5~143.5°C. Recrystallization from benzene afforded colorless crystals melting at 144.5~146.5°C.

Found: C, 55.81; H, 7.35; N, 5.39. Calcd. for $C_{12}H_{19}NO_5$: C, 56.02; H, 7.44; N, 5.44%.

DL-2α-Acetamido-1α, 3β-cyclohexanediol (IIc).—IIb was treated with methanol saturated by ammonia to give the crude product in a 74% yield.[4] (Found: C, 55.65; H, 8.37; N, 8.46%).

DL-2α-Amino-1α, 3β-cyclohexanediol Hydrochloride (XI).—A mixture of 0.3 g. of IIb and 15 ml. of 6 N hydrochloric acid was refluxed for 7 hr. The mixture was evaporated under reduced pressure to dryness. The residue was dissolved in 4 ml. of absolute ethanol, and absolute ether was added. The mixture was kept in a refrigerator to yield 0.13 g. (67%) of crystals melting at 111~117°C. The product was recrystallized from absolute ethanol-ether to yield needles melting at 115~117°C after sintering at 110°C.

Found: C, 42.89; H, 8.40; N, 8.18; Cl, 21.33. Calcd. for $C_6H_{14}NClO_2$: C, 42.99; H, 8.42; N, 8.36; Cl, 21.15%.

DL-2α-Amino-1α, 3β-cyclohexanediol (IIa).—A 517 mg. portion of XI was treated, as described in the regeneration of Ia from V, to yield 400 mg. (98%) of a crude product which crystallized gradually in a vacuum desiccator. The crude product was recrystallized from absolute ethanol-ether to give hygroscopic crystals melting at *112~113°C.

Found: C, 54.81; H, 10.01; N, 10.89. Calcd. for $C_6H_{13}NO_2$: C, 54.93; H, 9.99; N, 10.68%.

Paper Chromatography.—A nupper layer of 1-butanolacetic acid-water (4 : 1 : 5) gave a single spot of R_f 0.49 in ascending development at 25°C.

DL-*O*-Acetyl-*O*-mesyl-2α-amino-1α, 3β-cyclohexanediol Methanesulfonate (XII).—A mixture of 5.0 g. of VIII and 70 ml. of water was refluxed for a few minutes to give a clear acidic solution (pH 1.0). After standing ovenight, the solution was evaporated under reduced pressure. The residue was recrystallized from ethanol to yield 3.6 g. (68%) of crystals melting at *173~174°C. A second crop of the product (0.3 g.) was obtained from the mother liquor. The total yield of the crude product was 74%. The product was recrystallized from ethanol to yield needles melting at *174.5~175°C.

Found: C, 34.80; H,6.23; N, 3.97; S, 18.11. Calcd. for $C_{10}H_{21}NO_9S_2$: C, 34.57; H, 6.09; N, 4.03; S, 18.46%.

IR: 1740 (ester) 1622 (NH_3^+), 1355, 1170 (mesyloxy), 1200 and 1045 (SO_3^-) cm^{-1}.

DL-2α-Acetamido-*O*-mesyl-1α, 3β-cyclohexanediol (XIII). A 2.0 g. portion of XII was dissolved in 6 ml. of water, and the pH was adjusted with a 10% potassium hydroxide solution to 11. Then the solution was cooled in an ice bath to give a white crystalline precipitate. After cooling at 0°C for 1 hr., the product was collected by filtration, washed with ethanol, and dried to yield 1.05 g. (72.5%) of crystals melting at *118~119°C. A sample was recrystallized from ethanol for analysis; it melted at *118~118.5°C.

Found: C, 43.17; H, 7.07; N, 5.61; S, 12.69. Calcd. for $C_9H_{17}NO_5S$: C, 43.01; H, 6.82; N, 5.58; S, 12.78%.

IR: 3540 (OH), 1643, 1542 (amide), 1340, 1175 (mesyloxy) and 960 (cyclohexane) cm^{-1}.

2α-Acetamido-1α, 3α-cyclohexanediol (IIIc).—a) A mixture of 0.55 g. of XIII, 0.6 g. of anhydrous sodium acetate, 0.5 ml. of water, and 10 ml. of 2-methoxyethanol was refluxed for 5 hr. The mixture was evaporated under reduced pressure to dryness. After drying, the residue was extracted with 10 ml. of boiling acetone five times, and the combined acetone extract was evaporated under reduced pressure to give an oily residue. Trituation of the residue with a mixture of ethanol and ether gave 0.30 g. (79%) of crystals melting at *118~120°C. Two recrystallizations from acetone afforded colorless needles melting at *120~123°C.

Found: C, 55.21; H, 8.97; N, 8.31. Calcd. for $C_9H_{15}NO_3$: C, 55.47; H, 8.73; N, 8.09%.

b) A 203 mg. portion of IIIb was added to 10 ml. of methanol saturated with ammonia. The mixture was kept at room temperature overnight and evaporated under reduced pressure to obtain a crystalline residue. The product was recrystallized from ethanol to yield 117 mg. (85.6%) of crystals melting at 119~123°C. A mixed melting point determination with an authentic sample was undepressed.

Triacetyl-2α-amino-1α, 3α-cyclohexanediol (IIIb).—a) The crude IIIc, obtained from 2.2 g of XIII, was treated with a mixture of 20 ml. of acetic anhydride and 20 ml. of pyridine for 24 hr. The mixture was evaporated in vacuo, and the residue was recrystallized from benzene to give 1.6 g. (71%) of colorless needles melting at 175.5~177.5°C. An analytical sample was obtained by recrystallization from benzene; m. p. 177.5~179°C.

Found: C, 56.23; H, 7.56; N, 5.45. Calcd. for $C_{12}H_{19}NO_5$: C, 56.02; H, 7.44; N, 5.44%.

b) A starting material, *cis*-2, 6-diacetoxycyclohexanone (XV), was prepared by the method of Cavill and Solomon.[10] A mixture of 2.97 g. of XV and 70 ml. of methanol was added to a mixture of 1.49 g. of hydroxylamine hydrochloride, 2.58 g. of sodium hydroxide, and 13 ml. of water under ice cooling. The mixture was kept in a refrigerator overnight and then evaporated. The residue was added to ethanol, and an insoluble salt was removed by filtration. The filtrate was evaporated in vacuo, and the residue was dissolved in 50 ml. of glacial acetic acid. The mixture was shaken with 0.57 g. of an Adams platium catalyst under an atmospheric pressure of hydrogen for 130 min. The crude hydrogenated product was then heated with pyridine and acetic anhydride for 3 hr. at 100°C. The crude product was dissolved in ethanol, and ether was added to give 0.53 g. (14.8%) of crystals melting at 170~176°C. The product was recrystallized twice from ethanol-ether to yield 0.33 g. (9.3%) of needles melting at 176.5~178°C.

A mixed melting point determination with an authentic sample was undepressed. The infrared spectrum of the product was superimposable on that of an authentic sample.

2α-Amino-1α, 3α-cyclohexanediol Hydrochloride (XIV).—A mixture of 2.0 g. of IIIb and 100 ml. of 6 N hydrochloric acid was refluxed for 6 hr. The mixture was then evaporated under reduced pressure to yield 1.21 g. (93%) of crystals melting at 156.5~160°C. The crude product was recrystallized from absolute ethanol-absolute ether to give needles melting at 160.5~161.5°C.

Found: C, 42.67; H, 8.46; N, 8.41; Cl, 21.38. Calcd. for $C_6H_{14}NClO_2$: C, 42.99; H, 8.42; N, 8.36; Cl, 21.15%.

2α-Amino-1α, 3α-cyclohexanediol (IIIa).—A 1.02 g. portion of the crude XIV was treated, as described in the regeneration of Ia from V, to yield 743 mg. (93%) of crystals melting at 78~83°C. The product was recrystallized from absolute ethanol-absolute ether to yield 322 mg. (40.5%) of crystals melting at 126~128°C.

Found: C, 54.65; H, 9.97; N, 10.84. Calcd. for $C_6H_{13}NO_2$: C, 54.93; H,9.99; N, 10.63%.

Paper Chromatography. — An upper layer of l-butanol-acetic acid-water (4 : 1 : 5) gave a single spot of R_f 0.44 in ascending development at 25°C.

The authors are grateful to Pofessor Sumio Umezawa and Professor Herbert E. Carter for their helpful advice and to Mr. Saburo Nakada for his microanalysis. Also, the authors are indebted to Miss Sunao Ohata for her measurement of the infrared spectra, to Miss Sumiko Uchida for her assistance in the analytical experiments, and to the Japan Electron Optics Co., Ltd., for the NMR spectra.

Studies of the Synthesis of Peptides Containing C-Terminal Glutamine. II. The Synthesis and Use of α-p-Nitrobenzyl γ-Methyl L-Glutamate

By Yasutsugu SHIMONISHI

(Received August 12, 1963)

In a previous paper,[1] it has been described how the usual synthetic methods of peptides containing *C*-terminal glutamine are attended with many difficulties, and how the introduction of a xanthyl group into the γ-amide nitrogen is effective in reducing these troubles. The present study is concerned with another approach to the same problem using α-*p*-nitrobenzyl γ-methyl glutamate as an intermediate. It is known that the *p*-nitrobenzyl ester derivative of an amino acid[2] is easily crystallizable; morever, its ester bond is quite stable to dry hydrogen bromide in hydrous organic solvents. The cleavage of the *p*-nitrobenzyl ester linkage is effected not only by means of alkaline hydrolysis but also by catalytic hydrogenolysis. Since the methyl ester linkage is stable to hydrogen bromide or hydrogenolysis, glutamine peptide can be prepared from the carbobenzoxy peptide of the glutamate by catalytic hydrogenation, followed by ammonolysis.

The starting material, *N*-carbobenzoxy-(α-*p*-nitrobenzyl, γ-methyl)glutamate (I), was prepared in a good yield from *N*-carbobenzoxy-(γ-methyl)glutamate and *p*-nitrobenzyl bromide in the presence of triethylamine. Substance I was treated with hydrogen bromide in glacial acetic acid to give α-*p*-nitrobenzyl γ-methyl glutamate hydrobromide (II). The hydrobromide II was stable and easily crystallizable. First, carbobenzoxy-glycine was coupled with this compound I to form peptide under several conditions. In the case of a mixed anhydride with isobutyloxycarbonic acid or an active ester with *p*-nitrophenol, the product was not pure, and purification was very difficult. It was finally found that dicyclohexylcarbodiimide was the most effective reagent in this case. The urea-derivative formed and the unreacted starting materials were separated easily, and carbobenzoxy-glycyl-(α-*p*-nitrobenzyl, γ-methyl)-glutamate (III) was obtained as crystals. There was no difficulty in obtaining glycyl-(γ-methyl)-glutamate, which was converted to glycyl-glutamine as expected (Fig. 1). The optical purity of the glycyl-L-glutamine was checked after hydrolysis with 6 N hydrochloric acid, and no difference was observed between the

optical rotation of the hydrolyzate and that of the artificial mixture of the same components. When this synthetic procedure was applied to several carbobenzoxy amino acids, the following depeptides were synthesized: L-alanyl-L-glutamine, L-valyl-L-glutamine, L-leucyl-L-glutamine, L-prolyl-L-glutamine, and L-phenylalanyl-L-glutamine.

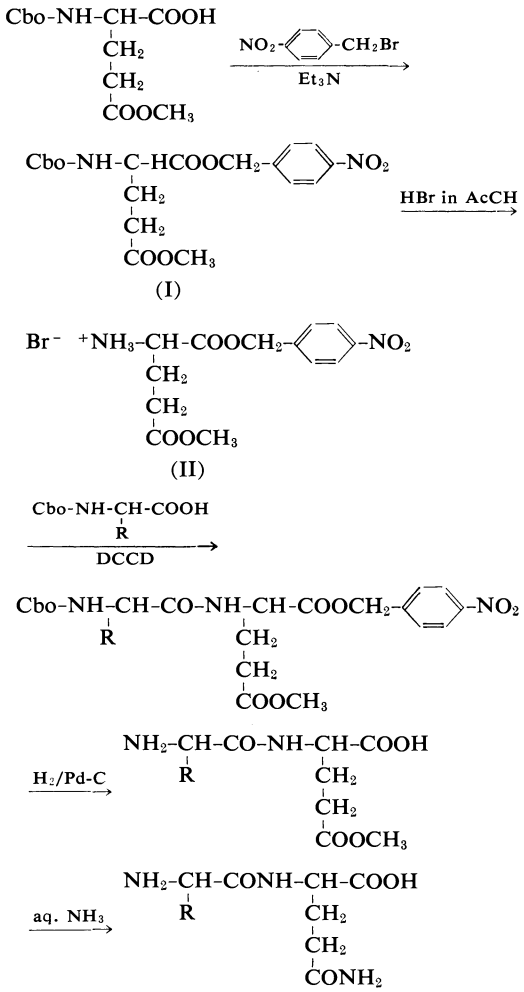

Fig. 1. Synthetic procedure.

Experimental*

***N*-Carbobenzoxy-(*α*-*p*-nitrobenzyl, *γ*-methyl)-L-glutamate (I).**—A mixture of carbobenzoxy-(*γ*-methyl) L-glutamate (59.0 g., 0.2 mol.), *p*-nitrobenzyl bromide (54.0 g., 0.25 mol.) and triethylamine (36.0 ml., 0.25 mol.) in ethyl acetate (800 ml.) was refluxed for 5 hr. The triethylamine hydrobromide which precipitated was removed by filtration, and the filtrate was washed with 0.2 N hydrochloric acid, 5% aqueous sodium bicarbonate, and water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to a residue, which was then triturated with petroleum benzine. The crude material (80.0 g.) was recrystallized as needles from ethyl acetate-petroleum benzine; yield, 70 g. (80%); m. p. 67~69°C; $[\alpha]_D^{28}$ −15.2° (*c* 3.21, methanol).

Found: C, 58.51; H, 5.22; N, 6.37. Calcd. for $C_{21}H_{22}O_8N_2$: C, 58.60; H, 5.15; N, 6.51%.

***α*-*p*-Nitrobenzyl *γ*-Methyl L-Glutamate Hydrobromide (II).**—This compound was prepared by Ben-Ishai's method.[3] Compound I (43.0 g., 0.1 mol.) was treated with 33% hydrogen bromide in glacial acetic acid (61.5 g., 0.25 mol.). During the course of the reaction, the hydrobromide of the decarbobenzoxylated product deposited as a crystalline mass. After this mixture had stood for an hour at room temperature, ether (1000 ml.) was added and the precipitates were filtered, washed with a sufficient amount of ether, and dried over sodium hydroxide pellets in vacuo. The crude material (37.0 g.) was recrystallized as fine needles from methanol-ether; yield, 31.0 g. (83%); m. p. 156°C; $[\alpha]_D^{27}$ +9.6° (*c* 5.02, methanol).

Found: C, 41.50; H, 4.59; N, 7.17; Br, 20.86. Calcd. for $C_{13}H_{17}O_6N_2Br$: C, 41.39; H, 4.54; N, 7.43; Br, 21.19%.

Carbobenzoxy-glycyl-(*α*-*p*-nitrobenzyl, *γ*-methyl)-L-glutamate (III).—A solution of II (22.6 g., 0.06 mol.) and triethylamine (8.2 ml., 0.06 mol.) in anhydrous chloroform (100 ml.) was cooled to −15°C. Solutions of carbobenzoxy-glycine (10.5 g., 0.05 mol.) in ethyl acetate (70 ml.) and of dicyclohexylcarbodiimide (10.3 g., 0.05 mol.) in ethyl acetate (30 ml.) were stirred into the above solution at −15°C, and the mixture was allowed to stand overnight at the same temperature. Dicyclohexyl urea and triethylamine hydrobromide were filtered off and washed with ethyl acetate. The combined filtrate and washings were washed with 5% aqueous sodium bicarbonate, 0.5 N hydrochloric acid, and a small amount of water, dried over anhydrous magnesium sulfate, and concentrated to dryness under reduced pressure. A residual oil was crystallized from ethyl acetate-petroleum benzine; wt., 22.5 g.; m. p. 105~106°C. The product was recrystallized from ethyl acetate-petroleum benzine; yield, 21.3 g. (87%); m. p. 106~108°C; $[\alpha]_D^{16}$ −15.1° (*c* 5.11, DMF**).

Found: C, 56.61; H, 5.23; N, 8.58. Calcd. for $C_{23}H_{25}O_9N_3$: C, 56.67; H, 5.17; N, 8.62%.

Carbobenzoxy-L-alanyl-(*α*-*p*-nitrobenzyl, *γ*-methyl) L-glutamate (IV).—To a solution of II (22.6 g., 0.06 mol.) and triethylamine (8.2 ml., 0.06 mol.) in anhydrous chloroform (100 ml.), a solution of carbobenzoxy-L-alanine (11.2 g., 0.05 mol.) in ethyl acetate (70 ml.) was added at −15°C. Then dicyclohexylcarbodiimide (10.3 g., 0.05 mol.) in ethyl acetate (30 ml.), which had been cooled to −15°C, was added with swirling. The mixture was kept overnight at −15°C and then treated as described above. The product was recrystallized from ethyl acetat-petroleum benzine as colorless needles; wt. 21.0 g. (87%); m. p. 132~138°C; $[\alpha]_D^{16}$ −11.9° (*c* 5.48, DMF).

* All melting points are uncorrected.

** DMF: dimethylformamide

Found: C, 57.26; H, 5.54; N, 8.25. Calcd. for $C_{24}H_{27}O_9N_3$: C, 57.48; H, 5.43; N, 8.38%.

Carbobenzoxy-L-valyl-(α-*p*-nitrobenzyl, γ-methyl)-L-glutamate (V). — To a solution of II (17.4 g., 0.046 mol.) and triethylamine (6.3 ml., 0.046 mol.) in anhydrous chloroform (120 ml.), which had been cooled to −15°C, carbobenzoxy-L-valine (9.7 g., 0.039 mol.) in ethyl acetate (50 ml.) was added. Then dicyclohexylcarbodiimide (8.0 g., 0.039 mol.) in ethyl acetate (50 ml.), which had been cooled to −15°C, was added. The mixture was kept at the same temperature overnight and then treated as described above. The crude product (17.7 g.; m. p. 133°C) was collected with ethyl acetate-petroleum benzine. Recrystallization of the crude material from ethyl acetate-petroleum benzine gave colorless needles (15.2 g., 75%; m. p. 138~140°); $[\alpha]_D^{16}$ −6.1°C (*c* 6.02, DMF).

Found: C, 59.02; H, 6.09; N, 7.92. Calcd. for $C_{26}H_{31}O_9N_3$; C, 58.97, H, 5.90; N, 7.94%.

Carbobenzoxy-L-leucyl-(α-*p*-nitrobenzyl, γ-methyl) L-Glutamate (VI). — Compound II (22.6 g., 0.06 mol.) and triethylamine (8.2 ml., 0.06 mol.) in an hydrous chloroform (100 ml.), carbobenzoxy-L-leucine (13.3 g., 0.05 mol.) in ethyl acetate (70 ml.), and dicyclohexylcarbodiimide (10.3 g., 0.05 mol.) in ethyl acetate (30 ml.) were treated by the procedure described above. The crude product which had been collected from ethyl acetate-petroleum benzine was recrystallized from ethyl acetate-petroleum benzine as colorless needles; yield 23.0 g. (85%); m. p. 109~113°C; $[\alpha[_D^{18}$ −14.8° (*c* 6.10, DMF).

Found: C, 59.35; H, 6.24; N, 7.97. Calcd. for $C_{27}H_{33}O_9N_3$: C, 59.66; H, 6.12; N, 7.73%.

Carbobenzoxy-L-prolyl-(α-*p*-nitrobenzyl, γ-methyl)L-glutamate (VII). — Carbobenzoxy-L-proline (12.5 g., 0.05 mol.) in ethyl acetate (70 ml.), II (22.6 g., 0.06 mol.) and triethylamine (8.2 ml., 0.06 mol. in anhydrous chloroform (100 ml.), and dicyclohexylcarbodiimide (10.3 g., 0.05 mol.) in ethyl acetate (30 ml.) were mixed at −15°C. The mixture was maintained overnight at the same temperature and treated as above. The crude material (25.0 g.) was collected with ethyl acetate-petroleum benzine and melted at 102~106°C. Recrystalization of the crude product from ethyl acetate-petroleum benzine gave colorles needless; yield 24.0 g. (91%); m. p. 104~107°C; $[\alpha]_D^{18}$ −33.4° (*c* 5.92, DMF).

Found: C, 59.27; H, 5.48; N, 8.15. Calcd. for $C_{26}H_{29}O_9N_3$: C, 59.19; H, 5.54; N, 7.97%.

Carbobenzoxyl-L-phenylalanyl-(α-*p*-nitrobenzyl, γ-methyl)L-glutamate (VIII). — Carbobenzoxy-L-phenylalanine (15.0 g., 0.05 mol.) in ethyl acetate (70 ml.), II (22.6 g., 0.06 mol.) and triethylamine (8.2 ml., 0.06 mol.) in anhydrous chloroform (100 ml.) and dicyclohexylcarbodiimide (10.3 g., 0.05 mol.) in ethyl acetate (30 ml.) were mixed at −15°C. The mixture was allowed to stand overnight at the same temperature. Ethyl acetate (100 ml.) was added to the reaction vessel, and the mixture was heated to boiling. The undissolved materials were removed by filtration and washed with a small amount of hot ethyl acetate. From the filtrate, a crystalline material was filtered and dried in a vacuum desiccator. The crude material (32.0 g., m. p. 147~148.5°C) was recrystallized as colorless fine needles from ethyl acetate; yield 25.9 g. (87%); m. p. 151~152°C; $[\alpha]_D^{18}$ −13.4° (*c* 5.43, DMF).

Found: C, 62.18; H, 5.53; N, 7.47. Calcd. for $C_{30}H_{31}O_9N_3$: C, 62.38; H, 5.41; N, 7.28%.

Carbobenzoxy-(γ-methyl)-L-glutamyl-(α-*p*-nitrobenzyl, γ-methyl)L-glutamate (IX).—To a solution of carbobenzoxy-(γ-methyl)L-glutamate (11.2 g., 0.038 mol.) in ethyl acetate (50 ml.), II (17.2 g., 0.046 mol.) and triethylamine (6.2 ml., 0.046 mol.) in anhydrous chloroform (80 ml.) was added. To the mixture, which had been cooled to −15°C, was added a cooled solution of dicyclohexylcarbodiimide (7.85 g., 0.38 mol.) in ethyl acetate (30 ml.). After the treatment of the reaction mixture in the same manner as descrired in the synthesis of IV, the crude material (19.8 g.) was obtained and recrystallized from ethyl acetate as needles; yield 18.5 g. (85%); m. p. 97~100°C; $[\alpha]_D^{18}$ −9.7° (*c* 6.51, DMF).

Found: C, 56.87; H, 5.58; N, 7.35. Calcd. for $C_{27}H_{31}O_{11}N_3$: C, 56.54; H, 5.45; N, 7.33.

Glycyl-(γ-methyl)L-glutamate (X).—Compound III (15.0 g., 0.031 mol.) was suspended in a mixture of methanol (200 ml.) and water (100 ml.), and then hydrogenated over a 3% palladium-charcoal catalyst (1.5 g.) for 6 hr. The catalyst was then filtered off and washed with water. The filtrate was evaporated to dryness, and the residue was dissolved in a small amount of hot water. The insoluble material was removed by filtration. When acetone was added to the filtrate, a crystalline material (6.0 g.) was obtained. Recrystallization from water-acetone gave colorless needles; yield 5.5 g. (82%); m. p. 178~179°C (decomp.); $[\alpha]_D^{19}$ −3.5° (*c* 5.11, water).

Found: C, 44.14; H, 6.57; N, 12.59. Calcd. for $C_8H_{14}O_5N_2$: C, 44.03; H, 6.47; N, 12.84%.

L-Alanyl-(γ-methyl)L-glutamate (XI). — Compound IV (15.0 g., 0.03 mol.) and 3% palladium-charcoal (1.5 g.) were suspended in a mixture of methanol (200 ml.) and water (100 ml.) and hydrogenated until the evolution of carbon dioxide stopped. The catalyst was then filtered off and washed with a small amount of hot water. The filtrate and washing were combined and concentrated under reduced pressure. A crude product (6.5 g., m. p. 186~187°C (decomp.)) was collected with acetone. Recrystallization of the crude material from water-acetone gave colorless needs; yield 6.2 g. (90%); m. p. 186°C (decomp.); $[\alpha]_D^{20}$ +8.0° (*c* 5.72, water).

Found: C, 46.37; H, 6.95; N, 12.03. Calcd. for $C_9H_{15}O_5N_2$: C, 46.54; H, 6.94; N, 12.06%.

L-Valyl-(γ-methyl)L-glutamate (XII).—Compound V (12.8 g.) and a 3% palladium-charcoal catalyst (1.5 g.) in a mixture of methanol (250 ml.) and water (80 ml.) were treated in the same manner as has been described above. Recrystallization of the crude material from water-acetone gave fine colorless needles; yield 4.3 g. (68%); m. p. 195~195.5°C; $[\alpha]_D^{20}$ +25.9° (*c* 6.07, water). L-Valyl-(γ-methyl)L-glutamate was submitted to elementary analysis after being dried over phosphorus pentoxide in vacuo at 110°C. The results of the analysis

were identical with the calculated values for the ester plus one and half moles of water, as is shown by the analytical data.

Found: C, 46.31; H, 7.99; N, 9.86. Calcd. for $C_{11}H_{20}O_5N_2 \cdot 3/2H_2O$: C, 46.00; H, 8.08; N, 9.76%.

L-Leucyl-(γ-methyl)L-glutamate (XIII). — Compound **VI** (15.0 g., 0.028 mol.) and a 3% palladium-charcoal catalyst (1.5 g.) in a mixture of methanol (200 ml.) and water (100 ml.) were treated in the same way as has been described above. The crude product (6.6 g.) was recrystallized from water-acetone as colorless needles; yield 5.3 g. (70%); m. p. 196~197°C (melted and decomposed with coloring); $[\alpha]_D^{20}$ +27.2° (*c* 5.62, water).

Found: C, 52.45; H, 8.06; N, 10.52. Calcd. for $C_{12}H_{22}O_5N_2$; C, 52.54: H, 8.08; N, 10.21%.

L-Prolyl(γ-methyl)L-glutamate (XIV). — Compound VII (15.0 g., 0.029 mol.) and a 3% palladium-charcoal catalyst (1.5 g.) were suspended in a mixture of methanol (200 ml.) and water (200 ml.) and treated in the same way. The crude product (5.1 g.) was obtained and recrystallized from water as colorless long needles; yield 4.8 g. (66%); m. p. 208°C (decomp.); $[\alpha]_D^{20}$ −38.5° (*c* 6.02, water).

Found: C, 47.82; H, 7.30; N, 10.14. Calcd. for $C_{11}H_{18}O_5N_2 \cdot H_2O$: C, 47.81; H, 7.17; N, 10.29%.

L-Phenylalanyl-(γ-methyl)L-glutamate (XV). — Compound VIII (15.0 g., 0.026 mol.) was suspended in a mixture of methanol (200 ml.) and water (50 ml.) and catalytically hydrogenated in the presence of 3% palladium-charcoal (1.5 g.). The crude material (8.0 g.) was recrystallized from water-acetone as prisms; yield 6.1 g. (77%); m. p. 228~232°C (decomp.); $[\alpha]_D^{20}$ +27.1° (*c* 6.09, water).

Found: C, 57.90; H, 6.72; N, 9.07. Calcd. for $C_{15}H_{20}O_5N_2$: C, 58.43; H, 6.54; N, 9.09%.

γ-Methyl-L-glutamyl-(γ-methyl)L-glutamate (XVI).—Compound IX (11.5 g., 0.02 mol.) and a 3% palladium-charcoal catalyst (1 g.) in a mixture of methanol (130 ml.) and water (60) ml. were treated in the manner described above. The crude product was recrystallized from water-acetone as colorless needles; yield 3.2 g. (53%); m. p. 153~154°C (decomp.); $[\alpha]_D^{20}$ +32.3° (*c* 5.75, water).

Found: C, 47.26; H, 6.51; N, 9.09. Calcd. for $C_{12}H_{20}O_7N_2$: C, 47.36; H, 6.63; N, 9.21%.

L-Glycyl-L-glutamine (XVII). — Compound X (2.0 g., 0.092 mol.) was dissolved in concentrated aqueous ammonia (100 ml.) The solution was then allowed to stand for 24 hr. at room temperature (about 15°C) and then concentrated to a syrup under reduced pressure at room temperature. After being flushed once with a small amount of water, the residue was crystallized from water-ethanol. The crude product (1.8 g.) was recrystallized as color less needles from water-ethanol; yield 1.8 g. (90%); m. p. 203~204°C (decomp.); $[\alpha]_D^{21}$ −1.6° (*c* 3.85, water); $[\alpha]_D^{20}$ −7.0° (*c* 3.29, N HCl).

Found: C, 37.95; H, 6.98; N, 19.52. Calcd. for $C_7H_{13}O_4N_3 \cdot H_2O$: C, 38.00; H, 6.84; N, 19.00%.

L-Alanyl-L-glutamine (XVIII). — Compound XI (3.5 g., 0.015 mol.) was dissolved in concentrated aqueous ammonia (150 ml.) and treated in the manner described above. The crude product (3.0 g.) was collected with water-ethanol and recrystallized from the same solvents as needles; yield 2.6 g. (74%); m. p. 215~216°C (decomp.); $[\alpha]_D^{24}$ −3.0° (*c* 3.31, N HCl). A sample for elementary analysis was dried over phosphorus pentoxide in vacuo for 20 hr. at 110°C.

Found: C, 44.50; H, 7.06; N, 18.85. Calcd. for $C_8H_{15}O_4N_3$: C, 44.23; H, 6.96; N, 19.35%.

L-Valyl-L-glutamine (XIX).—Compound XII (3.6 g., 0.014 mol.) in concentrated aqueous ammonia (140 ml.) was treated in the manner described above. The crude product (2.5 g.) was obtained and crystallized from water as needles; yield 2.2 g. (65%); m. p. 218~219°C (decomp.); $[\alpha]_D^{20}$ +15.8° (*c* 3.08, N HCl).

Found: C, 49.12; H, 7.78; N, 17.20. Calcd. for $C_{10}H_{19}O_4N_3$: C, 48.96; H, 7.81; N, 17.13%.

L-Leucyl-L-glutamine (XX).—Compound XIII (4.1 g., 0.015 mol.) was treated in the same manner described above. The crude product (3.5 g.) was obtained and recrystallized from water as colorless needles; yield 3.2 g. (84%); m. p. 236~237°C (decomp.); $[\alpha]_D^{19}$ +14.2° (*c* 3.57, N HCl).

Found: C, 50.68; H, 8.13; N, 16.10. Calcd. for $C_{11}H_{21}O_4N_3$: C, 50.95; H, 8.16; N, 16.21%.

L-Prolyl-L-glutamine (XXI). — Compound XIV (2.6 g., 0.01 mol.) in concentrated aqueous ammonia (100 ml.) was treated in the manner described above. Recrystallization of the crude product from water gave colorless needles; yield 2.0 g. (77%); m. p. 211~212.5°C (decomp.); $[\alpha]_D^{21}$ −52.2° (*c* 3.91, N HCl).

Found: C, 45.93; H, 7.31; N, 16.19. Calcd. for $C_{10}H_{17}O_4N_3 \cdot H_2O$: C, 45.97; H, 7.33; N, 16.08%.

L-Phenylalanyl-L-glutamine (XXII).—Compound XV (3.1 g., 0.01 mol.) in concentrated aqueous ammonia (100 ml.) was treated in the manner described above. The crude product (2.7 g.) was obtained and recrystallized from water as needles. The first crop of crystallization was 1.8 g. and the second crop was 0.8 g.; yield 2.6 g. (87%); m. p. 213~214°C (decomp.); $[\alpha]_D^{19}$ +17.3° (*c* 3.42, N HCl).

Found: C, 57.04; H, 6.42; N, 14.49. Calcd. for $C_{14}H_{19}O_4N_3$: C, 57.32; H, 6.53; N, 14.33%.

The Hydrolysis of Glycyl-L-glutamine Monohydrate. — Glycyl-L-glutamine monohydrate (104 mg.) was placed in a volumetric flask (3.04 ml.) filled with 6 N hydrochloric acid, and the solution was refluxed for 5 hr. After the hydrolysis, the volume of the solution was adjusted to exactly 3.04 ml. by adding 6 N hydrochloric acid, and the optical rotation of the solution was determined; $[\alpha]_D^{19}$ +31.3°. The optical rotation of a solution containing L-glutamic acid (68.1 mg.), glycine (34.7 mg.) and ammonium chloride (24.7 mg.) gave $[\alpha]_D^{19}$ +31.4°.

The author wishes to express his deep gratitude to Professor Dr. Shiro Akabori and Dr. Shumpei Sakakibara for their kind advice throughout this work. The author is also indebted to Misses Kiku Koike and Masako Kawakita of this Institute for performing elementary microanalyses.

*The Nitration of Some Derivatives of 1, 3, 5-Tri-t-butylbenzene**

By Setsuo WATARAI

(Received August 15, 1963)

In connection with the interesting problem of the possible existence of derivatives of *sym*-tri-*t*-butylbenzene with two or three functional groups, the nitration of some derivatives of 1, 3, 5-tri-*t*-butylbenzene has been undertaken.

Sym-tri-methyl-, or tri-isopropylbenzenes bearing three functional groups,[1] and *sym*-tri-*t*-butylbenzenes with one functional group[2] have already been known, but derivatives of the latter hydrocarbon bearing two or three functional groups have not yet been prepared. It has recently been suggested[3] that the steric requirements of the bulky *t*-butyl groups cause the distortion of the benzene ring in *o*-di-*t*-butylbenzene or in 1, 2, 4, 5-tetra-*t*-butylbenzene.

The nitration of 2, 4, 6-tri-*t*-butylphenol[4] has been shown to give various unusual nitration products. Among them, there were products in which original *t*-butyl groups were replaced by nitro groups, or, products of quinoid or quinolide structures, depending upon the conditions of nitration. Such a replacement of a *t*-butyl group by a nitro group has frequently been described in the literature[5] and has been found to be the case in the nitration of 2, 4, 6-tri-*t*-butylaniline.[6]

While 2, 4, 6-tri-*t*-butylnitrobenzene (I) can be obtained by a rather mild nitration of the corresponding hydrocarbon, the further nitration of I to a dinitro compound (m. p. 290~292°C) was found to require much more severe conditions using fum. nitric acid in sulfuric acid at 70°C. This dinitro compound II, when analyzed, is found to correspond to the molecular formula $C_{18}H_{28}O_4N_2$ and to have a molecular weight of 336 (Rast method), while still retaining three *t*-butyl groups.

The structure of II has been elucidated on the basis of the evidence given below.

The catalytic hydrogenations of the nitro compound II and the related nitro compounds shown in Fig. 1 were carried out under atmospheric pressure and at room temperature in the presence of the same amount of Raney nickel per each nitro group. II was found to resist hydrogenation very strongly, while all the nitro groups of *m*-dinitrobenzene (IIa) and of other *m*-di-nitro-*t*-butylbenzenes** (IIb and IIc) were readily reduced, absorbing theoretical quantities of hydrogen rapidly. On the other hand, the reduction of the nitro group substituted between the two ortho *t*-butyl groups in I proceeded very slowly, although it gave the expected reduced product. This experiment seems to indicate that both nitro groups in II are highly sterically hindered.

The steric hindrance of the nitro group was further supported by the infrared spectra of

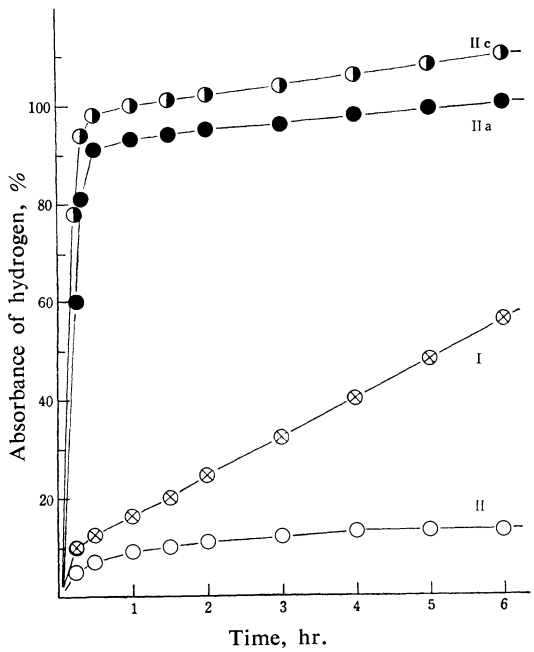

Fig. 1. Hydrogenations of *t*-butyl-*m*-dinitrobenzenes.

** The only curve of IIc is shown in Fig. 1, but almost the same one was also obtained in the case of IIb.

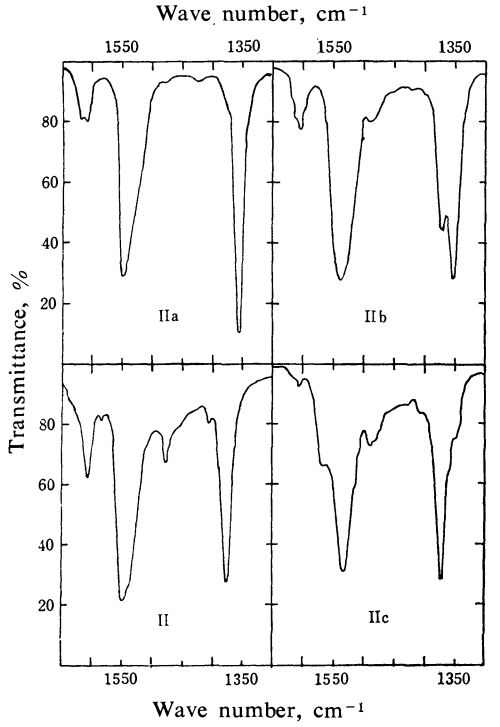

Fig. 2. Infrared spectra of *t*-butyl-*m*-dinitrobenzenes.

TABLE I. NO_2-STRETCHING VIBRATION BANDS OF *m*-DINITROBENZENES

m-Dinitrobenzenes	Band frequency cm^{-1}		Transmittance %	
	ν_a	ν_s	ν_1	ν_s
Unsubstituted, IIa	1545	1352	28.5	10.5
4-*t*-Butyl-, IIb	1537	1372 1354	28.0	44.0 27.5
4,6-Di-*t*-butyl, IIc	1535	1372	31.0	28.0
2,4,6-Tri-*t*-butyl-, II	1548	1375	22.0	28.0

N–O stretching vibrations shown in Fig. 2 and Table I. The most characteristic feature is the change in the N–O symmetric stretching vibration band of the dinitro-*t*-butylbenzenes from that of IIa. The shifts of these bands to higher frequencies, accompanied by the decreases in the apparent intensities relative to their N–O antisymmetric stretching bands, also suggest that the nitro groups in these compounds are sterically hindered.[7] Moreover, the N–O symmetric stretching band of IIb, in which only one nitro group is sterically hindered, splits into a doublet; on the contrary, that of II is a sharp singlet, as are those of IIa and IIc, in which the two nitro groups are indistinguishable.

On the basis of these data, the structure of II is assumed as 2,4,6-tri-*t*-butyl-*m*-dinitrobenzene.

An absolutely negative result for the high pressure catalytic hydrogenation of I over Raney nickel has been reported by other workers.[8] Indeed, we found I to be reduced very slowly in a low pressure and over this catalyst, as is shown in Fig. 1, but at a high pressure and over 50°C it was readily reduced under the same catalyst to afford almost quantitatively the corresponding aniline, 2,4,6-tri-*t*-butylaniline (III).

Nitration in acetic acid and acetic anhydride converted III into a di-*t*-butylnitroaniline (IV) in which a *t*-butyl group was replaced by a nitro group. The m.p. (256°C) of IV was distinctly different from that (89.5°C) of 2,4-di-*t*-butyl-6-nitroaniline,[9] one of the expected products in this dealkylnitration. Therefore, it was shown that the *t*-butyl group at the para-position of the amino group was replaced by the nitro group.

Several attempts to convert IV directly to a known 5-nitro-*m*-di-*t*-butylbenzene[9] by diazotization, under varying conditions, were unsuccessful. However, upon the reduction of the nitro group, the resulting diamine V could be converted, by oxidation with ferric chloride, to the known 2,6-di-*t*-butylbenzoquinone (VI).[10]

This experiment indicates that V is *p*-diamine and that, hence, IV is 2,6-di-*t*-butyl-4-nitroaniline. This result was in accordance with the assignment of the structure for IV made by other workers[6] on the basis of the rate constant of the catalytic deacetylation of the bisacetylamino compound derived from IV.

It is interesting to compare the present nitrations with those of the *sym*-tri-alkylbenzenes and with some of their amino derivatives.

Trinitro-derivatives have been obtained from mesitylene, triisopropylbenzene,[1b] and *t*-butyl-*m*-xylene[11] without any replacement of the alkyl groups; however, the introduction of more than two nitro groups into *m*-di-*t*-butyltoluene[12] has been shown to be unsuccessful. From mesidine, 2,4,6-tri-isopropylaniline,[1b] and 3,5-di-*t*-butyl-*o*-toluidine[12], only the usual nitration products have been reported.

Therefore, the failure to obtain the trinitro-derivative of *sym*-tri-*t*-butylbenzene, even with the application of drastic nitration conditions, may definitely be ascribed to the steric effect of the bulky *t*-butyl groups. The replacement

of the *p*-*t*-butyl group by the nitro group, in the case of the nitration of IV, also seems to be caused by the steric effect of these groups. Undoubtedly the *t*-butyl group activated by the electron-releasing substiuent, such as the *p*-amino group, is displaced with remarkable ease in the electrophilic substitution.[5]

Experimental

2, 4, 6-Tri-*t*-butylnitrobenzene (I), was prepared from 1, 3, 5-tri-*t*-butylbenzene[13] in the manner described in the literature;[2] 80% of yield, m. p. 200~203°C.

Found: C, 74.37; H, 10.13; N, 5.08. Calcd. for $C_{18}H_{29}O_2N$: C, 74.18; H, 10.13; N, 4.81%.

The Nitration of I: 2, 4, 6-Tri-*t*-butyl-*m*-dinitrobenzene (III).—A finely ground mononitro derivative (7 g. of I) was added in small portions to the stirred mixture of 13 ml. of fuming nitric acid (d=1.50) and 36 ml. of concentrated sulfuric acid at 20°C. The reaction mixture was subsequently heated to 80°C for 5 hr.; the product, when cooled, was then poured onto a large amount of ice. The yellow solid was collected, washed with water, dilute ammonia and water, and then dried. It weighed 6.6 g. and melted at 220~269°C.

Purification by recrystallization from benzene and by chromatography on alumina with benzene-ligroin (b. p. 80~100°C) gave pale yellow needles (m. p. 290~292°C). The molecular weight of this product was determined by the Rast method.

Found: C, 64.27; H, 8.42; N, 8.58%; mol. wt., 324.1. Calcd. for $C_{18}H_{28}O_4N_2$: C, 64.26; H, 8.39; N, 8.33%; mol. wt., 336.4.

The Reduction of I at a High Pressure: 2, 4, 6-Tri-*t*-butylaniline (III).—A suspension of 30 g. of I and a catalyst prepared from 20 g. of Raney-nickel-alloy in 300 ml. of ethanol was reduced with hydrogen (60 kg./cm^2) at 50~80°C for 3.5 hr. in a 500 ml. autoclave. After the catalyst had been filtered off, the solvent was distilled off; 22 g. of practically pure III with a m. p. of 143~145°C was thus obtained. One recrystallization from ethanol gave a sample melting at 145°C.

Found: C, 82.65; H, 11.79; N, 5.61%. Calcd. for $C_{18}H_{31}N$: C, 82.69; H, 11.95; N, 5.36%.

The Nitration of III: 2, 6-Di-*t*-butyl-4-nitroaniline (IV).—This was prepared in essentially the manner described in the literature,[6] except that the reaction was carried out at 40°C, because most of the starting material (about 70%) was recovered at −10~−12°C, as is mentioned in the literature.

To a solution of 5.2 g. of III in a mixture of 40 ml. of acetic anhydride and 20 ml. of glacial acetic acid, 22 ml. of a mixture of 1 vol. of nitric acid (d=1.52) and 19 vol. of glacial acetic acid was added drop by drop at 40°C; hereupon III crystallized out in yellow needles. While the stirring was continued, the crystals of III disappeared and other crystalline material IV was obtained in the reaction mixture. After a total reaction time of 4.5 hr., the product was collected and dried; 1.9 g. Upon treatment with water, the filtrate gave further crops; 0.1 g.

The recrystallization of this product (m. p. 240~247°C) from benzene-ethanol (10:1) gave IV as pale yellow leaf crystals; m. p. 256°C.

Found: C, 66.92; H, 9.00; N, 10.92%. Calcd. for $C_{14}H_{22}N_2O_2$: C, 67.17; H, 8.86; N, 11.69%.

2, 6-Di-*t*-butyl-*p*-diaminobenzene (V).—A suspension of 3.0 g. of IV in 100 ml. of ethanol was shaken with hydrogen at room temperature under atmospheric pressure over Raney nickel for 6 hr. The catalyst was then filtered off under a stream of nitrogen. After the filtrate had been saturated with dry hydrogen chloride, the solvent was distilled off under reduced pressure. The dihydrochloride of V separated in the crystalline state. This salt was collected, washed with dry ether, and dried; yield 3.4 g. (96%). Recrystallization from ethanol saturated with dry hydrogen chloride gave a colorless salt which melted at 204°C (decomp.).

Found: Cl, 23.42%. Calcd. for $C_{14}H_{26}N_2Cl_2$: Cl, 24.17%.

Through a treatment of the salt with a dilute alkali solution, the base was liberated; m. p. 94~95°C.

2, 6-Di-*t*-butyl-*p*-benzoquinone (VI).—A suspension of 1 g. of the above salt in a solution of 15 g. of ferric chloride crystals in a mixture of 7.6 ml. of water and 1 ml. of concentrated hydrochloric acid was stirred overnight at room temperature and was then heated on a water bath for 2 hr. The product was then collected through steam distillation. The yield was 0.6 g. of orange yellow crystals (VI); 80% of yield, m. p. 66.5~68.5°C. Recrystallization from aqueous ethanol gave a sample melting at 67.5°C; this sample showed no depression on admixture with an authentic sample synthesized from 2, 6-di-*t*-butylphenol.[10]

Found: C, 76.48; H, 9.12%. Calcd. for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

The Preparation of Other *m*-Dinitrobenzenes.—IIa, IIb and IIc were prepared by the standard procedures.

IIa, m. p. 90°C; IIb, m. p. 61~63°C; IIc, 165~166°C.

The Reduction of Dinitro Derivatives (Fig. 1).—A mixture of the purified dinitro compound (0.005 mol.) in 50 ml. ethanol was shaken with hydrogen for several hours at room temperature under atmospheric pressure in the presence of a catalyst prepared from 5 g. of Raney-nickel-alloy (5 g. of alloy for 0.01 mol., of I in 100 ml. ethanol) until no more hydrogen was absorbed. About 10~13% more than the stoichiometric quantity of hydrogen for the reduction of nitro groups was absorbed. II resisted hydrogenation very strongly; most of it was recovered.

Infrared Spectra.—The spectra of 0.02 M solutions in chloroform were measured in a 0.511 mm. cell on a Hitachi EPI-2 double-beam prism spectrometer (with a rock salt prism).

The frequencies (in wave numbers) and the transmittance (%) of the symmetric (ν_s) and antisymmetric (ν_a) stretching modes of the nitro-group are summarized in Table I.

The Synthesis of β-Ionylideneacetaldehyde

By Yozo Ishikawa

(Received August 16, 1963)

This paper will present a simple method to prepare β-ionylideneacetaldehyde, which is an important intermediate in the synthesis of vitamin A or its homologous compounds. *trans*-β-Ionylideneacetaldehyde (III) was obtained by the oxidation of vinyl-β-ionol (II) with manganese dioxide under an acidic condition. II was prepared by means of a Grignard reaction from β-ionone (I) and vinyl chloride.

II has been prepared by the reduction of ethynyl-β-ionol (IV)[1-4] derived from I and acetylene. Another method which utilizes the Grignard reaction of I with vinylmagnesium bromide has been reported,[4] but the yield of II is not so satisfactory (41%). The author obtained II in a 91% yield by means of the Grignard reaction of I with vinylmangnesium chloride.

1) K. Suga, Y. Ishikawa and S. Watanabe, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), to be published.

The synthesis of vinylmagnesium chloride by means of Normant's method[5] and the continuous preparation of the chloride have been reported by Ramsden et al.[8] and by Reimschuessel[7] respectively. The present author applied Ramsden's method, but vinyl chloride gas was passed into tetrahydrofuran at 15~20°C as the reaction proceeded more rapidly. The Grignard compound of I with vinylmagnesium chloride was allowed to react as usual, and the product distilled to give II.[8]

III may be prepared by the oxidation of β-ionylideneethanol (V), the isomerization product of II. Because of the tendency to give a "*retro*-compound,"[11-14] it is very difficult to obtain V by the allylic rearrangement

of II in spite of the easier oxidation of V with manganese dioxide to III ;[1] V has, therefore, usually been prepared by the reduction of β-ionylideneacetates. The author obtained *trans*-III in one step by treating II with manganese dioxide under an acidic condition.

To a solution of II in petroleum ether containing a small quantity of 50% sulfuric acid, manganese dioxide was added with vigorous agitation. The product was chromatographed on a silica-gel column. A hydrocarbon (A) and a carbonyl compound (B) were eluted with petroleum ether and benzene-ether (9 : 1) respectively. The properties of B agreed with the authentic data of *trans*-β-ionylideneacetaldehyde, which will be described later. The mechanism of this reaction is not clear as yet, but we can assume that as soon as II rearranges to V, oxidation occurs simultaneously.

The infrared absorption spectrum of A did not show the presence of either a hydroxyl or a carbonyl group. As the ultraviolet absorption spectrum shows the characteristic "*retro*-ionylidenetetraene" structure (λ_{max} 319 mμ ; ε, 52300), A may be considered to be, for the most part, "*retro*-compound (VI)."

Experimental[15]

β-Ionone (I).—The properties of I used in this experiment were as follows : d_{25}^{25} 0.943 ; n_D^{20} 1.5198 ; Acid value 0.1 ; λ_{max} 296 mμ ; ε, 9900 (lit.,[10] $\lambda_{max}^{96\%\ ethanol}$ 296 mμ ; ε, 10550) ; the 2,4-dinitrophenylhydrazone, m. p. 125°C ; λ_{max} 389 mμ ; ε, 21000.

Found : C, 61.40 ; H, 6.14 ; N, 15.21 ; Calcd. for $C_{19}H_{24}O_4N_4$: C, 61.29 ; H, 6.50 ; N, 15.05%.

Vinyl-β-ionol (II). — In a four-necked flask equipped with a thermometer, a dropping funnel, as gas inlet tube and a reflux condenser, 200 cc. of dry tetrahydrofuran, 13 g. (0.54 mol.) of magnesium, and a few crystals of iodine were placed. To this mixture 3.0 g. (0.03 mol.) of ethyl bromide was added drop by drop. When magnesium had been activated, the mixture was allowed to react with dry gaseous vinyl chloride at 40°C. After 30 min., the mixture was cooled to 15~20°C and vinyl chloride was passed through for an additional 9 hr. The reaction mixture turned dark brown and viscous. After the completion of the reaction, the gas inlet tube was removed, and 60 g. (0.31 mol.) of I in 60 cc. of tetrahydrofuran was stirred into this solution at 5~10°C. After having been stirred for another hour, the solution was heated to 40°C. The reaction mixture was decomposed with an ice-cooled ammonium chloride solution and extracted with ether. The ethereal layer was washed with a 2% aqueous solution of sodium hydrogen carbonate and water, and then dried over anhydrous sodium sulfate. Evaporation under reduced pressure gave 67 g. of a light yellow oil. By fractional distillation 57.4 g. of vinyl-β-ionol (II) was obtained (91.4% yield) : b. p. 113~115°C/2 mmHg (lit., 113~115°C/2 mmHg ;[4] 91~92°C/0.8 mmHg[3]) ; n_D^{20} 1.5045 (lit., n_D^{20} 1.5702 ;[4] 1.5022[3]) ; λ_{max} 237 mμ ; ε, 5700 (lit.,[3] λ_{max} 235 mμ ; 5700).

Found : C, 81.35 ; H, 10.91 ; Calcd. for $C_{15}H_{24}O$: C, 81.76 ; H, 10.98%.

The infrared absorption spectrum showed the characteristic bands of a tertiary hydroxyl group (3400 and 1100 cm^{-1}) and of a vinyl group (920 and 990 cm^{-1}). The infrared and ultraviolet absorption spectra were identical with those of the partial reduction product of ethynyl-β-ionol derived from β-ionone and acetylene.[1]

***trans*-β-Ionylideneacetaldehyde (III).** — To a solution of 5.00 g. (0.023 mol.) of vinyl-β-ionol in 150 cc. of petroleum ether, 1.3 cc. of 50% sulfuric acid and 50 g. of activated manganese dioxide were added under efficient agitation. The mixture was stirred for 72 hr. at room temperature. Upon the product had been worked up, 4.10 g. of a light yellow oil was obtained. This oil was chromatographed on a silica-gel column. From the petroleum ether-eluted fraction, a 0.69 g. of hydrocarbon (A) was obtained, while 1.77 g. (a 35.8% yield) of a carbonyl compound (B) was obtained from the benzene-ether (9 : 1).

The infrared absorption spectrum of B was super-imposable on that of the authentic sample ;[1] 1670 and 965 cm^{-1}. The ultraviolet absorption spectrum : λ_{max} 275, 326 mμ ; ε, 11000, 14000 (lit.,[16] λ_{max} 273, 326 mμ ε, 11800, 15600).

Semicarbazone.—Recrystallized from ethanol : m. p. and mixed m. p. 195°C ; λ_{max} 324 mμ ε, 34700 (lit.,[17] m. p. 195~196°C ; λ_{max} 323 mμ $E_{1cm}^{1\%}$ 1330).

Found : N, 14.85. Calcd. for $C_{16}H_{25}ON_3$: N, 15.26%.

2, 4-Dinitrophenylhydrazone. — Recrystallized from chloroform-ethanol : m. p. and mixed m. p. 198°C ; λ_{max} 410 mμ ; ε, 40000 (lit.,[16] m. p. 198°C ; λ_{max} 408 mμ ε 37000).

Found : C, 62.83 ; H, 6.35 ; N, 14.05. Calcd. for $C_{21}H_{26}O_4N_4$: C, 63.30 ; H, 6.58 ; N, 14.06%.

An attempt to isolate III by means of the addition product with sodium hydrogen sulfite[12] was unsuccessful.

The ultraviolet absorption spectrum of A showed the characteristic "*retro*-ionylidenetetraene" structure at λ_{max} 319 mμ (lit., $\lambda_{max}^{96\%\ ethanol}$ 313 mμ ;[12] $\lambda_{max}^{ethanol}$ 317 mμ[18]), suggesting the formation of a retro-form unsaturated hydrocarbon. The isolated A changed to a gummy substance within a few hours and became insoluble in the usual solvents, so its structure was not identified.

15) The UV absorption spectra were measured in ethanol, chloroform (the semicarbazone and the 2, 4-dinitrophenylhydrazone of (III)) or benzene (VI), and the IR absorption spectra, with liquid film. Elementary analyses were performed at the Institute of Physical and Chemical Research, Tokyo.

*The Electronic Effect of the Substituents on the Intramolecular Hydrogen Bonding of o-Aryloxybenzoic Acids**

By Michinori Ōki and Minoru Hirota

(Received August 19, 1963)

As early as 1955, Davies[1,2] reported the intramolecular hydrogen bonding of *o*-methoxybenzoic acid (II: $R=CH_3$); the enthalpy of the hydrogen bonding was then estimated to be 3.3 kcal./mol. It is also known that *o*-alkoxy- and *o*-aryloxybenzoic acids show some anomalous properties which may be attributed to intramolecular interaction.[3-5] In spite of this early discovery, however, systematic studies of this phenomenon are lacking and little is known about its nature. Since the authors are interested in the intramolecular hydrogen bonding of carboxylic acids, this work was undertaken as an extension of their earlier work.

An earlier study disclosed that the intramolecular hydrogen bonding of the alkoxy- and aryloxy-alkanoic acids is observed only when the alkoxyl or aryloxyl group is placed at the α-position of the carboxyl group to form five-membered rings by means of the hydrogen bond (III: $n=1$).[6] Therefore, we have to face a very interesting problem; "Why does the six-membered hydrogen bond system exist very stably in *o*-alkoxybenzoic acid, but not in β-phenoxy- or β-methoxy-propionic acid (III: $n=2$)?" In order to clarify the situation, various effects on the interaction must be studied. Thus, the electronic effect exerted by the substituent in the aryl group of *o*-aryloxybenzoic acid was investigated as a first step, the effect of the configuration being also discussed.

Experimental

The Preparation of Materials. — All the *o*-aryloxybenzoic acids were prepared from *o*-chlorobenzoic acid and the corresponding phenols by modifying Fritzsche's method[7] as described below.

Into a methanol solution (70 ml.) of sodium methoxide prepared from 4.6 g. (0.2 g. atom) of sodium, a mixture of phenol (9.4 g., 0.1 mol.) and *o*-chlorobenzoic acid (15.7 g., 0.1 mol.) was added with efficient stirring. As soon as the addition was over, about 0.5 g. of copper powder was added, and then the solvent was distilled off to dryness by immersing the flask in an oil bath kept at 150°C. The reaction mixture was heated up to 190~220°C in the oil bath, whereupon the abrupt initiation of the condensation was observed. After an hour, the reaction mixture was cooled and the entire mixture dissolved in water. After filtration, the filtrate was acidified to give crude *o*-phenoxybenzoic acid. Recrystallization from xylene-ligroin yielded 18.0 g. (84%) of the pure compound. Similarly, the following compounds were prepared (Table I):

Table I. Analytical data and physical constants of 2-(*p*-substituted phenoxy)-benzoic acids

p-Substituent	Analytical data: Calcd., % C	Calcd., % H	Found, % C	Found, % H	M. p. °C
Acetyl	70.30	4.72	70.34	4.83	182
Chloro	62.70	3.63	62.93	3.78	112
Methoxy	68.84	4.95	68.86	4.96	144

Measurement of the Spectra. — The infrared spectra were recorded with a Perkin Elmer 112G grating infrared spectrophotometer; the spectral slit widths were 1.0 cm^{-1} and 0.6 cm^{-1} for the O-H and C=O stretching regions respectively. The measurement was carried out in a carbon tetrachloride solution with a concentration of less than

0.002 mol./l. in the ν_{O-H} region and less than 0.0005 mol./l. in the $\nu_{C=O}$ region at 20~25°C. Each absorption curve was assumed to be a Lorentzian curve, and the integrated intensity was calculated from the equantion : [8,9]

$$A=2.30\times\frac{\pi}{2}\cdot\frac{1}{cl}\log\left(\frac{T_0}{T}\right)_{max}\times\Delta\nu_{1/2}$$

Since the spectral measurements were carried out under conditions which gave spectral slit widths less than one-tenth of the half-band width, the application of the equation is permissible.

Results and Discussion

The O–H stretching and the C=O stretching absorptions were determined with various *o*-(*p*-substituted phenoxy)benzoic acids; the results are summarized in Tables II and III.

Assignment of the Infrared Spectra.—Before the intramolecular hydrogen bonding is discussed, the assignment of the absorption bands should be carried out. The O–H and the C=O stretching absorption spectra of *o*-phenoxybenzoic acid are illustrated in Figs. 1 and 2 respectively. In the O–H stretching region, three absorption bands were found; the one at 3527.8 cm^{-1} is no doubt the absorption

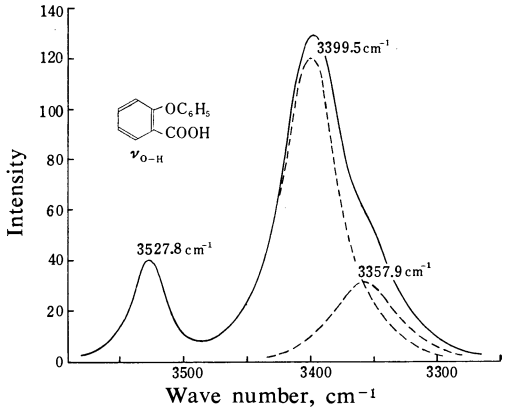

Fig. 1

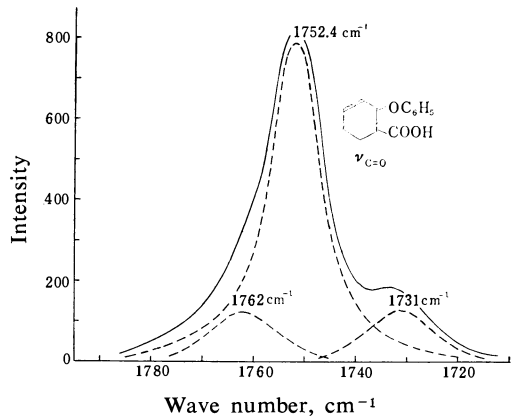

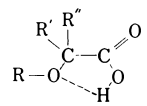

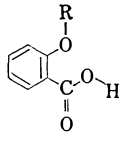

Fig. 2

caused by the monomeric cis-configuration (IIa), while the others may arise from the monomeric trans forms and/or the dimeric forms.

$RO(CH_2)_nCOOH$

III

The results obtained at various concentrations, however, exclude the latter possibility, and so the two absorption bands at 3399.5 cm^{-1} and 3357.9 cm^{-1} are both attributed to the hydrogen-bonded trans-configuration.

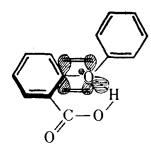
Then the measurement was carried out at various temperatures, with both the O–H and the C=O stretching absorptions (Table IV),

TABLE IV. THE TEMPERATURE DEPENDENCE OF THE INTENSITY RATIO (A_t/A_c) OF *o*-PHENOXYBENZOIC ACID

ν_{O-H} Region

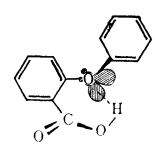
T, °K	$1000/T$	Absorption intensity		Intensity ratio
		ε_{cis}	ε_{trans}	$\varepsilon_t/\varepsilon_c$
296.7	3.37	43.0	122	2.83
307.0	3.26	47.2	125	2.65
317.2	3.15	53.5	125	2.32
325.5	3.07	62.8	129	2.09
339.2	2.95	64.4	124	1.93

$\Delta H = 1.89$ kcal./mol.



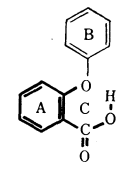
$\nu_{C=O}$ Region

T, °K	$1000/T$	Absorption intensity		Intensity ratio
		ε_{cis}	ε_{trans}	$\varepsilon_t/\varepsilon_c$
296.7	3.37	135	852	6.31
312.7	3.19	149	845	5.77
322.8	3.10	154	792	5.14
336.0	2.98	169	794	4.70
345.2	2.90	208	864	4.16



$\Delta H = 1.78$ kcal./mol.

and the enthalpy difference, ΔH, for IIa → IIb was determined to be 1.89 kcal./mol. from the results obtained in the O–H stretching region by assuming the above assignment. Here the 3357.9 cm^{-1} band is disregarded for the sake of simplicity. From the $\nu_{C=O}$ spectrum, the enthalpy difference is determined to be 1.78 kcal./mol. by assigning the band at 1731 cm^{-1} to the cis configuration and the band at 1752.4 cm^{-1} to the trans. The agreement of the two ΔH values supports the above assignment and also the reliabilty of the enthalpy difference value for this equilibrium. The much smaller ΔH value than that of *o*-methoxybenzoic acid indicates a weaker hydrogen bonding; this will be discussed later. The fact that the carbonyl absorption of the trans isomer appears at a higher frequency had already been interpreted as arising from the absence of intramolecular interaction between the hydroxyl and the carbonyl group in the same carboxyl group.[6,10]



The carbonyl band at 1762 cm^{-1} is assigned to the trans-configuration which causes the 3357.9 cm^{-1} band in the O–H stretching region, from the parallel change in intensity.* On the other hand, the higher C=O stretching band should be assigned to the structure which makes the less contribution to the resonance between the benzene nucleus and the carboxylic C=O group. Thus, the trans ν_{O-H} absorption at the higher frequency and the $\nu_{C=O}$ absorption at the lower frequency are attributed to the system IVa (The thick lines in IVa' indicate the planar conjugated system.), while the trans ν_{O-H} absorption at the lower frequency and the trans $\nu_{C=O}$ absorption at the higher frequency are attributed to the less probable conjugate system, IVb. In the IVa system, the hydrogen bond is formed by the lone pair electrons conjugating with the B ring (in IVa'), and the hydrogen-bonded ring system C is on the same plane with the ring system A, a pseudo-aromatic nature being expected. On the other hand, the hydrogen bond is formed by the participation of the lone pair electrons conjugating with the A ring in the IVb system, and the conjugated six-membered hydrogen bond system existing in IVa is partly destroyed.

IVa

IVb

IVa'

The diphenyl ether system is concluded to be non-planar, and the two stable rotational isomers are assumed by some authors.[11] It is obvious, in accordance with the postulation, that the existence of the two rotational isomers is also probable in this diphenyl ether system, that of *o*-aryloxybenzoic acids.

In the case of *o*-aryloxybenzoic acids, the shift of the ν_{O-H} absorption maxima caused

10) M. Ōki and M. Hirota, *Spectrochim. Acta*, 17, 583 (1961).

* The following may be added as another proof for this assignment. The introduction of a 3-alkyl group to 2-methoxybenzoic acid causes a ν_{O-H} shift to a lower frequency. It is assumed that the steric interference between 3-alkyl and 2-methoxyl groups causes the rotation of the C_{Ph}-O bond, leaving the CH_3O group intact; therefore, the hydrogen bonding may be strengthened because of the richer electron density of the oxygen atom. Therefore, a higher ν_{O-H} absorption corresponds to a more planar structure.

11) One of the latest reports on this problem is that of S. Fujiwara H. Shimizu, and Y. Morimo, *J. Chem. Phys.*, 34, 1467 (1961). See also K. Higashi and S. Uyeo, This Bulletin, 14, 87 (1939).

by the hydrogen bonding ($\Delta\nu_{max}$) is much larger than in the case of 2-aryloxyalkanoic acids, but the assignment established to the latter is qualitatively applicable.

The Substituent Effect on the Absorption Intensity.—The data in Tables II and III show the variation of the ratio (A_t/A_c) of the absorption intensity due to the trans isomer to that due to the cis isomer with the change in the electronic nature of the substituents; this result is illustrated by the $\log(A_t/A_c)$ vs. σ relation presented in Fig. 3. Table V also gives numerical values.

In general, the hydrogen bonding is favorable when the electron density of the hydrogen-accepting atom (the ether oxygen atom in this case) is large; therefore, the larger A_t/A_c ratio

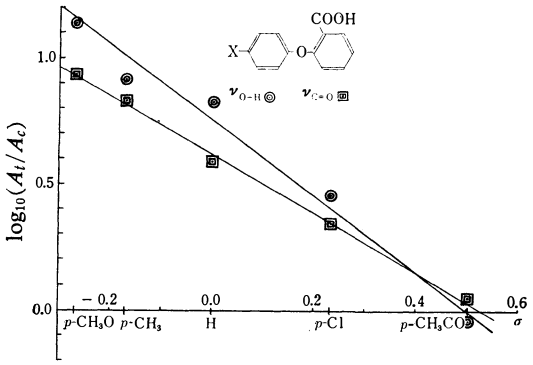


Fig. 3

Table V. The relation between the σ-constant and $\log(A_t/A_c)$ of o-(p-substituted phenoxy)benzoic acids

Substituent	σ-Constant	$\log(A_t/A_c)$ O–H Region	$\log(A_t/A_c)$ C=O Region
CH_3O	−0.268	1.137	0.933
CH_3	−0.170	0.910	0.830
H	0.000	0.826	0.589
Cl	0.227	0.456	0.344
CH_3CO	0.502	−0.044	0.053

is expected for the bases with electron-repelling substituents.

This tendency is observed in many hydrogen bond systems, and the same is observed with the spectra of o-aryloxybenzoic acids, in both the O–H and C=O absorption bands. This finding also supports the assignment of the $\nu_{C=O}$ absorptions, since the opposite inclination of the $\log(A_t/A_c)$ vs. σ plot would be expected from a wrong assignment.

Conclusions on the Nature of the Hydrogen Bonding.—The hydrogen bonding in o-aryloxybenzoic acid causes a much larger ν_{O-H} shift and enthalpy gain, and the hydrogen-bonded species are much more favorable than are α-aryloxyacetic acids and their homologs. This cannot be explained by the steric factor only. The pseudo-aromatic nature of the hydrogen bond system (the C ring in IVa') could explain the unusual stability of this hydrogen bonding. The pseudo-aromatic nature of the hydrogen bond system will be established in the following paper.[12]

Summary

The infrared hydroxyl and carbonyl absorptions of o-aryloxybenzoic acids have been reported and the assignment of each absorption band in these regions made. The higher carbonyl-stretching absorptin at about 1752 cm^{-1} has been attributed to the intramolecular hydrogen-bonded trans isomer from the following reasons: i) The A_t/A_c intensity ratio in the hydroxyl-stretching region increases as the Hammett σ-constant of the substituent decreases, and the same tendency is observed by assigning the carbonyl band at a higher frequency to the trans isomer; ii) From the measurement of the absorption intensity of 2-phenoxybenzoic acid at various temperatures, in both the hydroxyl and carbonyl regions, the authors have obtained nearly equal enthalpy difference values (1.89 and 1.78 kcal./mol. respectively) between the cis and trans isomers by assuming the above assignment.

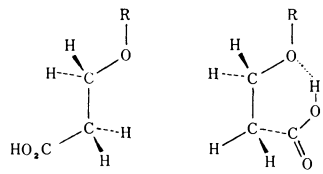
The Steric Requirements and the Nature of the Intramolecular Hydrogen Bonding of o-Methoxybenzoic Acid[*1]

By Michinori Ōki and Minoru Hirota

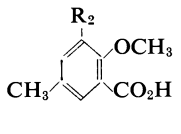


(Received August 19, 1963)

The existence of the six-membered intramolecular hydrogen bonding in *o*-aryloxybenzoic acids[1] and in *o*-methoxybenzoic acid[2] has already been established, but the reason why the six-membered hydrogen bonding is present in *o*-aryloxy- and *o*-alkoxybenzoic acids but not in *β*-phenoxy- and *β*-alkoxybenzoic acids has not yet been explained.

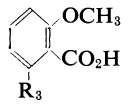
An answer to this question may be given by the entropy difference between the two systems. That is, the intramolecular hydrogen bonding is forced in *o*-alkoxybenzoic acids (such as I), while the rotational isomerism around the C–C single bond reduces the probability of the intramolecular hydrogen bonding in *β*-alkoxypropionic acid, since the most stable rotamer is IIa if there is no stabilization by the hydrogen bond formation.

Ia Ib



IIa IIb

An alternative answer to this question may be that the intramolecular hydrogen bonding in *o*-alkoxybenzoic acids is stabilized by resonance, since this kind of stabilization is present in many hydrogen bond systems, such as the enol form of acetylacetone and salicylaldehyde. The resonance-stabilized hydrogen bond systems usually have a characteristic electronic spectra in the ultraviolet region. Ultraviolet spectral studies of the intramolecular hydrogen bonding have been carried out with many ortho-substituted phenols by Burrawoy and his co-workers,[3] who concluded that the intramolecular hydrogen bonding causes a remarkable red shift of the so-called B-bands, which have the longitudinal transition moment. On the other hand, the ultraviolet spectral measurement is also a very useful tool for the estimation of the steric hindrance; extensive study in this field has been reported by Braude and his co-workers.[4]



Thus, the ultraviolet spectral technique, as well as the infrared spectral measurement, has been employed in order to study the nature of the intramolecular hydrogen bonding of *o*-alkoxybenzoic acid derivatives, and the spectral data have been interpreted from the stand-point of steric hindrance and that of the characteristic absorption of the conjugated system.

Experimental

Preparation of the Materials. — *Substituted 2-Methoxybenzoic Acids.* — To a solution of 25 g. of 2,4-dimethylanisole in 150 ml. of chloroform, an equi-molecular amount (29.5 g.) of bromine was added at such a rate that the large excess of bromine did not remain unreacted in the reaction mixture. The mixture was left to stand for 10 min. after the addition was over; then the solvent distilled off, and the residual liquid was distilled under reduced pressure. The liquid, which boiled at 130 ~134°C/15 mmHg, was almost pure 6-bromo-2,4-dimethylanisole. Yield: 32 g. (81%).

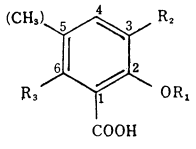
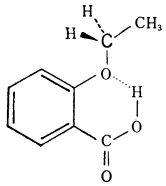
6-Ethyl	—	110	66.65	6.71	66.57	6.70

* The preparation of this compound had been reported[5] by means of the hydrolysis of the corresponding nitrile. However, the hydrolysis was found to be very slow and the reported melting point did not agree with the present results.



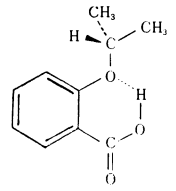
A solution of 32 g. of 6-bromo-2,4-dimethylanisole in 50 ml. of dry ether was added to 3.6 g. of magnesium in 100 ml. of ether, while the flask was externally heated to the boiling point. The heating was continued for 2 hr. after the completion of the addition; then the Grignard reagent was cooled to room temperature and treated with a large excess of solid carbon dioxide until the reaction mixture was saturated with carbon dioxide. The mixture was kept overnight and decomposed with hydrochloric acid. The ether layer was collected and, after washing with water, extracted with an aqueous sodium bicarbonate solution. The solution was heated to remove the ether in the solution and then acidified. The solid was dried and recrystallized from a xylene-petroleum mixture to give 17 g. (64%) of 2-methoxy-3,5-dimethylbenzoic acid (m. p. 90°C).

Other subtituted 2-methoxybenzoic acids were prepared in a similar manner; the results are tabulated in Table I.

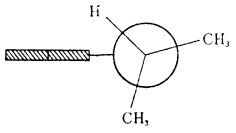


Spectral Measurement.—Ultraviolet spectra were measured with a Beckman model DU spectrophotometer, the samples being dissolved in an appropriate solvent to make up ca. 3×10^{-4} mol./l. solution. The details of the infrared spectral measurement have been reported elsewhere.[6]

Results and Discussion



To investigate the steric effect of the intramolecular hydrogen bonding of *o*-methoxybenzoic acid, various alkyl substituents were introduced to the oxygen atom at the 2-position (R_1 in IX), to the 3-position (R_2), and to the 6-position (R_3).*[2]



IX

X

XI

XII

The *O*-alkyl group R_1 is introduced to test the effect of the steric interference between the alkyl substituent and the hydrogen atom at the 3-position. The steric interference could be reduced if the alkyl substituent exists as an appropriate rotational isomer, as shown by X and XI. The infrared O–H stretching absorption spectra in the 3 μ region and the near-ultraviolet absorption spectra of 2-methoxy-, 2-ethoxy- and 2-isopropoxy-benzoic acids are shown in Tables II and III.

The results show that these acids apparently have two absorption bands in the O–H stretching region. One absorption at the higher frequency (about 3530 cm^{-1}) was assigned to the

cis form, and the other at the lower frequency, ranging from 3364.7 cm^{-1} to 3320.9 cm^{-1}, to the trans form. The infrared ν_{O-H} spectra of 2-methoxybenzoic acid, as illustrated in Fig. 1, show a somewhat asymmetric band at the lower frequency. The band is divided into two absorptions by assuming that it is the overlap of two Lorentzian curves, the treatment being that carried out in the previous paper*1 with *o*-aryloxybenzoic acids. The ν_{O-H} frequencies of the cis forms are nearly constant throughout this series, but the ν_{O-H} frequencies of the trans forms shift to the lower frequency as the substituent becomes bulky, while the A_t/A_c intensity ratio are invariant throughout the series. The integrated intensity (A) of the cis and the trans forms should be proportional to the amount of the energy absorbed by each form of the acid molecule and related to the populations of the molecules existing as the assigned isomeric forms. However, the existence of the dimer, though its proportion to the rest is very small, prevents the exact discussion of the absolute intensity values and of the intensity ratio, which is supposed to be proportional to the population of the cis and the trans forms. The intensity ratio would be more reliable and could be an important element in comparing the relative population ratio existing in the two states of the acid if the effect of the dimer were negligible. However, the invariance of the A_t/A_c ratios indicates that the bulkiness of the *O*-alkyl substituent does not influence the equilibrium constant between the two forms.

Figures 2 and 3 show the ultraviolet spectra of these acids in heptane and ethanol respectively, together with the spectra of 2-methoxy-5-methylbenzoic acid and methyl 2-methoxybenzoate in the same solvents. The ultraviolet spectra of 2-methoxybenzoic acid and its 5-methyl derivative in ether are also shown in Fig. 4. From a comparison of these spectra, it becomes clear that the spectra of these acids in heptane differs from those in other polar solvents which are capable of hydrogen bond formation. The characteristic feature of the absorption curves in heptane is its two-peaked envelope, the maxima of which are located at 286~288 mμ and at 293~295 mμ with 2-alkoxybenzoic acids. The band envelope of the spectrum of methyl 2-methoxybenzoate in heptane is quite different from that of the parent acid, while those in ethanol are similar to each other except for a considerable red shift caused by the esterification.

The peak at the shorter wavelength is attributed to the ordinary B-band of 2-methoxybenzoic acid, and the one at the longer wavelength, to the intramolecular hydrogen-bonded

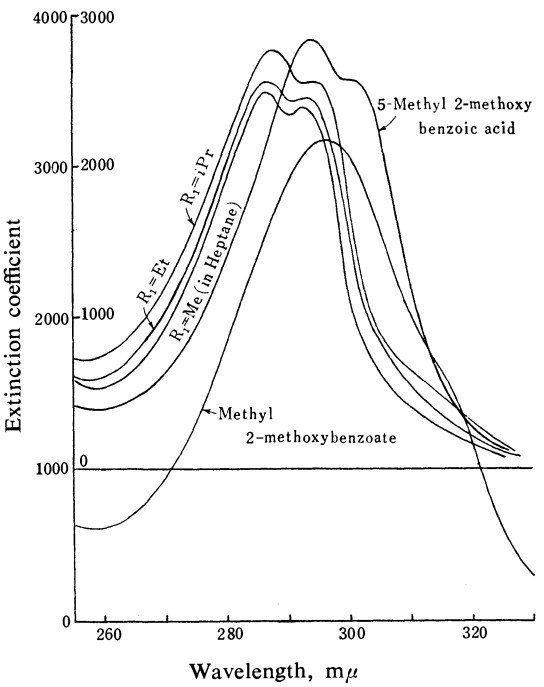

Fig. 2. The ultraviolet spectra of 2-alkoxybenzoic acids and related compounds in heptane.

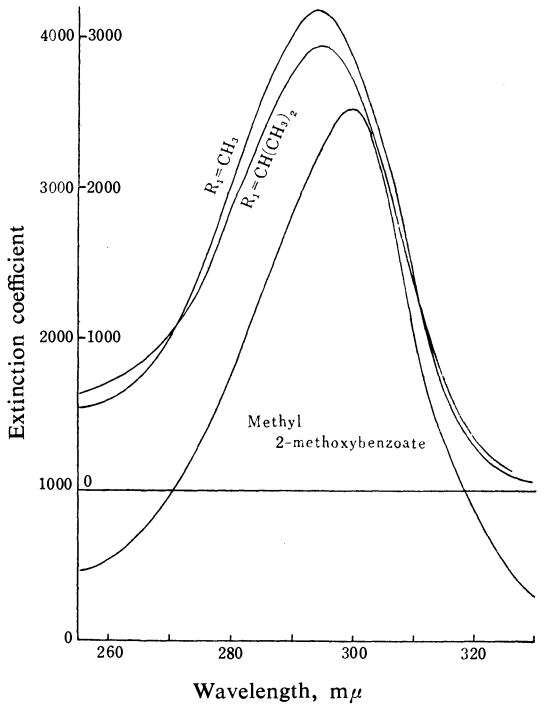

Fig. 3. The ultraviolet spectra of 2-alkoxybenzoic acids and methyl 2-methoxybenzoate in ethanol.

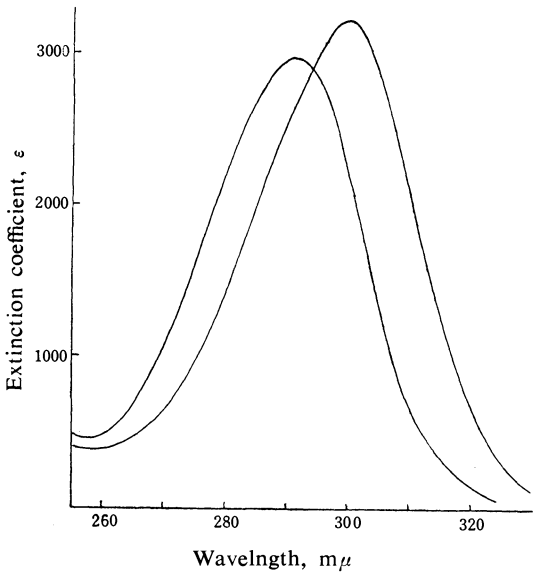

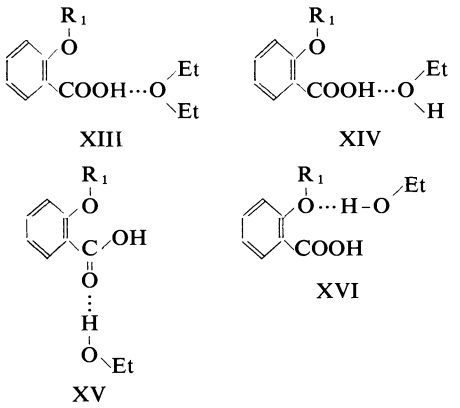

Fig. 4. The ultraviolet spectra of 2-methoxybenzoic acid (λ_{max}: 291 mμ) and its 5-methyl derivative (λ_{max}: 300 mμ) in diethyl ether.

structure (Ia); these assignments will be discussed below. Thus, additional evidence for the intramolecular hydrogen bonding was given from the ultraviolet spectral measurement. This two-peaked absorption pattern disappears in ether and in ethanol; this phenomenon is interpreted as stemming from the destruction of the intramolecular hydrogen bonding.

In ether, the intramolecular hydrogen bonded structure (Ia) is probably destroyed because intermolecular hydrogen bonding with ether is more favored than intramolecular hydrogen bonding. The enthalpy difference value for the intramolecular hydrogen bonding of 2-methoxybenzoic acid and for the association between acetic acid and dibutyl ether have been determined to be 3.3±0.5 kcal./mol.[2] and 4.56±0.3 kcal./mol.[7] respectively. Since the intermolecular hydrogen bonding enthalpy of this acid has not yet been obtained, the exact discussion cannot be given, but the above ΔH value for the intermolecular hydrogen bonding of carboxylic acid with ether and the advantage in entropy term in association (because the hydrogen acceptor is the solvent itselt) suggest the existence of the acid molecules as intermolecularly associated structures XIII.

In ethanol, the acid can associate with the solvent both as a hydrogen donor (XIV) and as a hydrogen acceptor (XV and/or XVI). However it has not been clearly established whether either or both of these types of hydrogen bonding exists in the solution. Ito, Tsukioka and Imanishi[8] determined the ultraviolet spectra of benzoic and *o*-toluic acids in various solvents as functions of the temperature and of the concentration, but they could not reach a decisive conclusion on the type of hydrogen bonding. At any rate, it seems quite natural to conclude that the intramolecularly hydrogen-bonded structure Ia is destroyed in ether and in ethanol. Since the two-peaked absorption pattern disappears in these solvents, the assignment of the absorption to the intramolecularly hydrogen-bonded form is justified. This relation between ultraviolet spectra and intramolecular hydrogen bonding is also observed in other series of acids investigated.

A red shift upon the esterification of *p*-substituted cinnamic acids has been observed by one of the authors[9] and interpreted as arising from the unfavorable effect of the hydroxyl group on the electron-attracting property of the carboxylic carbonyl group; a similar discussion is applicable in this case. The absorption band at ca. 300 mμ of 2-methoxybenzoic acid and its derivatives should be the B(benzenoid)-band according to the Gillam's classification.[10] From Burawoy's theory,[3] the B-band transition involves a charge migration from the terminal methoxyl group into the receiving termial carboxyl or methoxycarbonyl group in 2-methoxybenzoic acid and its methyl ester. In other words, the contribution of the polarized structure XVII plays an important role in this transition, although the electronegative character of the carboxylic hydroxyl group (the contribution of the structure XVIII) in the ground and ex-

cited states of the acid does not favor the contribution of the structure XVII.

XVII XVIII

The substituent at the 3-position is then introduced to test the necessity of the coplanarity of the methoxyl group with the benzene nucleus. Phenol and its derivatives are concluded to take the planar structure,[11,12] and the methoxyl group of 2-methoxybenzoic acid should take the S-trans configuration with respect of C_1, which carries the carboxyl group, in the absence of the steric hindrance created by the alkyl group at the 3-position. The slight steric effect on the resonance interaction of the methoxyl group with the 3-hydrogen atom is known[13], but it is estimated to be negligible by means of Braude's method[14] (XIX) for the estimation of the steric hindrance. On the other hand, a considerable steric hindrance is foreseen from the molecular chart (XX) by the introduction of the methyl group to the 3-position. The method uses covalent radii as a measure of the steric hindrance and so has a tendency to underestimate the steric hindrance.

The infrared ν_{O-H} absorption and near-ultraviolet absorption spectra of 2-methoxy-5-methylbenzoic acid (III) and its 3-alkyl(R_2)-derivatives (IV, V and VI) are listed in Tables II and III, together with those of other series of acids. The 5-methyl group is introduced for the convenience of synthesis. The infrared spectra of these compounds and their ultraviolet spectra in heptane are illustrated in Figs. 5 and 6 respectively. As is to be expected from the above consideration of the steric effect, the 3-alkyl group causes a considerable decrease in the A_t/A_c ratio, and it is concluded that an unfavorable effect is exerted by the 3-alkyl substituents. The A_t/A_c intensity ratios of 3-methyl (IV), 3-ethyl (V) and 3-isopropyl (VI) derivatives are 8.48, 7.91 and 6.11 respectively. This shows the gradual decrease in the A_t/A_c ratio as the substituent changes from methyl

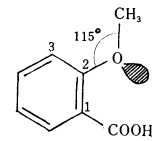
to isopropyl; therefore, the unfavorable steric effect on a hydrogen-bonded structure like Ia increases in this order. The ultraviolet spectra of these compounds show a gradual decreases in the characteristic absorptions which have two peaks at about 295 mμ when the alkyl group R_3 is changed from hydrogen to isopropyl. This agrees with the infrared results. The introdction of the 3-*t*-butyl group would be very interesting since the very bulky *t*-butyl group would force the methoxyl group to take the S-cis configuration with respect to C_1, which carries the carboxyl group and so prevents the acid from existing as a hydrogen-bonded structure like Ia, but 3-*t*-butyl-2-methoxy-5-methylbenzoic acid has not been obtained in a pure state. Examining the frequency difference data $\Delta\nu(\equiv\nu_{max}^{cis}-\nu_{max}^{trans})$ in the ν_{O-H} region, it is concluded that the increase is caused by the larger bulk of the 3-alkyl substituents. In general, a parallel relation is expected between the $\Delta\nu_{max}$ and A_t/A_c values if the nature and steric conditions of the hydrogen bonding are similar.



In this case, the 3-alkyl substituent hinders the coplanarity of the methoxyl group with respect to the benzene ring and destroys the conjugation between the p-π electrons of the methoxyl group and the π-electrons of the aromatic ring. The deviation from coplanarity causes, first, the alteration of the direction of the electron orbitals and, second, the localization of the electron on the oxygen atom, which is responsible for the higher electron density. On the other hand, the buttressing effect given by the 3-alkyl group causes the distance between the methoxyl oxygen and the carboxylic O–H group to be shorter than that in 2-methoxybenzoic acid. The C-O-H(C) angles of phenols and their alkyl ethers have been determined to be 115° from the dipole moment investigations[15]; the bond angle indicates that the alkoxyl oxygen takes a hybridized state between sp^2 and sp^3. Assuming that the oxygen atom takes a planar sp^2-like configuration, the four lone-pair electrons fill a p-π orbital which is perpendicular to the molecular plane and conjugate with the aromatic π-electrons and another sp^2-like orbital, the axis of which is planar with the other part of the molecule and divides the C_{Me}–O–C_{Ph} angle into two almost equal parts (XXI). The electron of the latter orbital is available to form a dative bond (hydrogen bond) with the carboxyl group. The steric hindrance is supposed to cause some twisting of the methoxyl group from the plane of the benzene ring without any appreciable change in hybridization. This twisting will reduce the probability of the hydrogen bond formation. The reduced probability of the hydrogen bonding and the shorter O···H–O distance are reflected in the decreased A_t/A_c ratio and in the larger $\Delta\nu_{max}$ values of the O–H stretching absorption bands. Another interpretation of the larger $\Delta\nu_{max}$ may be given by the increased electron density caused by the decreased contribution of the resonance form XXVII, resulting in the larger energy of hydrogen bonding. In any case, the introduction of the 3-akyl groups causes a considerable decrease in the relative population of the hydrogen-bonded species and an increase in $\Delta\nu_{max}$.

XXI

The introduction of the methyl or ethyl group to the 6-position causes the disappearance of the O–H stretching absorption of the hydrogen-bonded trans isomer and of the characterstic ultraviolet absorptions. The infrared and ultraviolet absorption spectra of these acids (VII and VIII) are shown in Figs. 7 and 8.

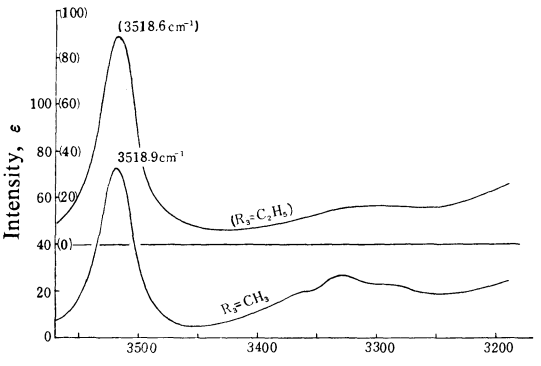

Fig. 7. The infrared ν_{O-H} spectra of 6-alkyl-2-methoxybenzoic acids.

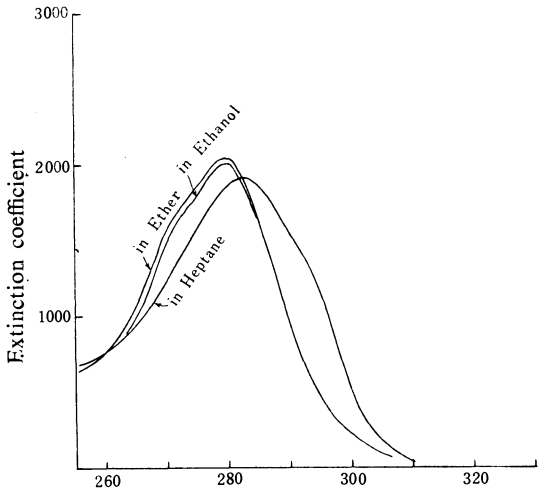
*3 These molecular diagrams were drawn according to the method reported by Braude and his co-workers.[14] In these figures, the following dimensions were used: C-C (aromatic) 1.40 Å, C-H 1.98 Å, Me covalent radius 1.39 Å, =O covalent radius 1.10 Å, and C-O-C angle 115°.[15]



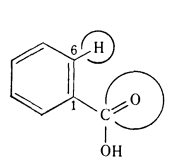


Fig. 8. The ultraviolet spectrum of 6-methyl-2-methoxybenzoic acid in various solvents.

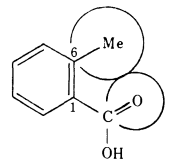
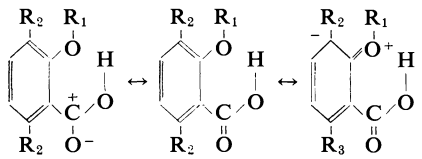


The ultraviolet spectrum of the 6-methyl acid VII in heptane and ether are almost identical, and, though the spectrum in heptane exhibits a small red shift, the band envelopes of the acid in every solvent investigated resemble one other. Consequently, it is concluded that the spectral behavior of 6-alkyl-2-methoxybenzoic acid differs from those of the acids of other series. A comparison of the infrared spectra of the 6-alkyl-2-methoxybenzoic acids indicates the existence of a broad and weak absorption in the hydrogen-bonded O–H stretching region when the alkyl group is methyl, but the characterization of the absorption band was impossible because of the low intensity, the diffuse band envelope and the very high background absorption, which is supposed to be the wing of either the C–H absorption or, less probably, the dimeric O–H absorption.

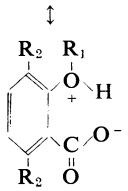
When the steric hindrance is estimated from the molecular diagram (XXIII) drawn by Braude's method,[14] a much smaller steric interaction is expected between the carbonyl oxygen and the 6-methyl group of 2-methoxy-6-methylbenzoic acid than the steric interference between the methoxyl and methyl groups of 2-methoxy-3-methylbenzoic acid (as is shown by XIX, XX, XXII and XXIII), but the actual steric effect is by far larger in the 6-alkyl acids. This indicates the important role of the planarity of the carboxyl group. In other words, the contribution of the resonance form XXV is much more important than that of the structure XXVII.

The importance of the resonance form XXV should be reflected in the polar C=O bond; the C=O stretching absorptions of these acids

XXII



XXIII



suggest this tendency. The infrared C=O stretching absorption data of some representative acids are tabulated in Table IV. The measurement of the spectra was carried out under almost the same conditions as that of the O–H spectra. The higher frequency of the

$\nu_{C=O}$ absorption attributable to the trans isomer is explained in terms of the absence of the hydrogen bond-like interaction shown by XXIX.[17] The frequency shift ($\Delta\nu_{max}$) in the $\nu_{C=O}$ region caused by this four-membered ring interaction is as large as 32 cm^{-1} for α-phenoxyisobutyric acid, to which no resonance contribution of the polar C^+-O^- structure is expected on the formation of the intramolecular hydrogen bond as XXIX.[17] On the other hand, the $\Delta\nu_{max}$ (C=O)*4 values for 2-methoxybenzoic and 3, 5-dimethyl-2-methoxybenzoic acids are 7 cm^{-1} and 13 cm^{-1} respectively, values being much smaller than that of α-phenoxyisobutyric acid. This implies the contribution of the polar structure C^+-O^-, even in the trans hydrogen-bonded isomer; as a result, the force constants of their C=O bond become less.

In view of the electronic theory, the results may be interpreted as follows. The structure of 2-methoxybenzoic acid may be expressed as the resonance hybrid of the canonical formulas XXIV, XXV, XXVI and XXVII when it takes the trans structure. The structure XXIV is the only structure without a charge separation, and its contribution is by far the greatest. Formulas XXV, XXVI and XXVII represent the canonical structures with the polarized carbonyl bond, with the charge transfer through the hydrogen bridge, and with the contribution of the electron-repelling property of the methoxyl group respectively. The strong hydrogen bond with a considerable lowering of the O–H stretching frequency is always accompanied by the weakening of the O–H bond to compensate the energy of the hydrogen bond, corresponding to the contribution of the charge transfer structure XXVI. The contribution of the polarized carbonyl structure XXV is concluded to be essential and to play a decisive part in the hydrogen bonding of this type. The importance of the structure XXV suggests that the stability of the planar hydrogen bond system in 2-methoxybenzoic acid is due to its pseudo-aromatic nature, which arises from the 10-π-electron system as illustrated by XXVIII, in which π-electrons are expressed by dots on the atoms to which the electrons originally belong.

The characteristic ultraviolet absorption bands for the intramolecularly hydrogen-bonded acids may be due to the electronic transition caused by this pseudo-aromatic system, but a more detailed investigation is needed before this hypothesis can be proven.

17) M. Ōki and M. Hirota, This Bulletin, 33, 119 (1960).

*4 To distinguish the $\Delta\nu_{max}$ in the O-H region from that of the C=O region, $\Delta\nu_{max}$(C=O) is used for the frequency difference between the absorption maxima of the two $\nu_{C=O}$ absorptions assigned to the cis and the trans structures.

Summary

The infrared and ultraviolet absorption spectra of derivatives of salicylic acid with alkyl substituents at the 2-*O*-, 3- and/or 6-positions have been measured, and much information on the nature of the intramolecular hydrogen bonding has been obtained from these data. The infrared O–H stretching absorption measurement shows that a substituent at the 6-position inhibits the formation of hydrogen bonding and that a substituent at the 3-position has some unfavorable steric effects.

These data imply the importance of the coplanarity of the carboxyl group with the benzene nucleus; moreover, a consideration of these data, together with the infrared C=O streching and ultraviolet spectral data, leads to the conclusion that the structure of the hydrogen-bonded trans isomer Ia may be expresed as a resonance hybrid among XXIV, XXV, XXVI and XXVII, the contribution of XXIV being the most important and that of XXV the next most important.

Infrared Spectroscopic Studies of Hexammine- and Pentammine-chromium(III) Complexes

By Nobuyuki TANAKA, Minoru KAMADA, Junnosuke FUJITA* and Eishin KYUNO**

(Received September 23, 1963)

Studies of the infrared spectra of the inorganic coordination compounds offer interesting information concerning the natures of the coordination bond and of the molecular structure. From this point of view, cobalt(III)-ammine complexes have been often investigated.[1-9] Chromium(III)-ammine complexes, on the other hand, have not been studied systematically. Indeed, Nakamoto et al.[9] reported on the effect of the outer ions on the infrared spectra of chromium(III)-ammine complexes. Their discussion, however, was mainly devoted to hexamminechromium(III) complexes.

In the present work, the infrared spectra of twenty-nine samples of hexammine and pentammine complexes of chromium(III) and cobalt(III) have been measured, and the shift of the observed bands with the change in the outer ions has been discussed.

Experimental

Preparation of Chromium(III)-Ammine Complexes. — Hexamminechromium(III) chloride and aquopentamminechromium(III) chloride were obtained, by the procedure given by King,[10] from the nitrates of the corresponding complexes, which had been prepared according to the method of Mori.[11] Bromides, iodides and perchlorates of hexammine- and aquopentamminechromium(III) complexes were prepared from the chlorides by the same method as reported by King.[10]

Halopentamminechromium(III) complexes were obtained by heating aquopentamminechromium(III) halide at 80~120°C for a few hours, and the outer ions of those complexes, if necessary, were converted by procedures similar to those used for hexamminechromium(III) complexes.

Some selected samples were deuterated by dissolving them in heavy water (D_2O). D_2O was subsequently removed by evaporation at reduced pressure, and the samples were dried in vacuo over P_2O_5.

Measurements of Infrared Spectra. — Infrared spectra were measured by using a Hitachi EPI-2G recording infrared spectrophotometer equipped with a potassium bromide foreprism and a grating double monochrometer. The potassium bromide disk method was employed for the measurement in the sodium chloride prism region, and both the potassium bromide disk and the Nujol mull methods, in the potassium bromide prism region. The values obtained by the Nujol mull method, however, were adopted for the determination of the wavelength of absorption peaks, because, in general, the spectra are clearer in the Nujol mull method than in the potassium bromide disk method.

The calibration of the frequencies was made with polystylene film, and with carbon dioxide and water vapor.

sodium chloride prism region are shown in Fig. 1. They, and the spectra of other hexammine- and pentamminechromium(III) complexes, give four main absorption bands. Since these bands shifted to lower frequencies upon the deuteration of ammonia, they were assigned to be N–H stretching, degenerated deformation, symmetric deformation and rocking vibrations.[3] All spectra of $[CrX(NH_3)_5]Y_{2,3}$, where X is NH_3, H_2O and halide ions, and Y, ClO_4^-, NO_3^- and halide ions, shifted to higher frequencies in the N–H stretching vibration and to lower frequencies in the other three deformation vibrations when the outer ions were changed to the order of chloride, bromide and iodide, as Table I shows.

Figure 2 shows the infrared spectra of several complexes in the potassium bromide prism region. From the assignment of the absorption bands of hexamminecobalt(III) ions,[8] the Cr–N stretching vibration is expected to be observed in this frequency region, but at somewhat lower frequencies than those of the corresponding cobalt(III) complex, because the coordination effect of chromium(III) is considered weaker than that of cobalt(III).[12] When the outer ions of hexamminechromium-(III) are halide ions, three bands appear in the potassium bromide prism region. All these bands were assigned to be Cr–N stretching vibrations for the following two reasons. First, as the Cr–N stretching vibration of hexamminechromium(III) complex belongs to the F_{1u} species if the ammonia molecule is taken as a single group, this band splits into three components because of the lowering of symmetry which is caused by the formation of a hydrogen bond between ammonia and halide ion and by the deformation in the crystal state. Second, these bands shifted to lower frequencies upon the deuteration of the coordinating ammonia. The frequency ratio of the band of the undeuterated complex to that of the deuterated complex (ν_{NH_3}/ν_{ND_3}) is 1.09 (Table II),

Table II. Observed frequencies of $[Cr(NH_3)_6]Cl_3$ and $[Cr(ND_3)_6]Cl_3$

Frequencies of $[Cr(NH_3)_6]Cl_3$ ν_{NH_3}, cm^{-1}	Frequencies of $[Cr(ND_3)_6]Cl_3$ ν_{ND_3}, cm^{-1}	ν_{NH_3}/ν_{ND_3}

which is in good agreement with the theoretical value (1.06) calculated from a harmonic oscillator consisting of a chromium(III) atom and ammonia (or deuterated ammonia) group.

In pentamminechromium(III) complexes, $[CrX(NH_3)_5]^{2,3+}$, similar phenomena were observed. A pentammine complex ion has C_{4v} symmetry, if the ammonia molecule is taken as a single group, and A_1- (Cr–X stretching, Cr–N symmetric stretching) and E-species (Cr–N asymmetric stretching) are infrared active. $[CrCl(NH_3)_5](ClO_4)_2$ gives two weak absorption bands, at 457 and 420 cm^{-1} (Fig. 2). When the outer ions were halide ions, three bands were observed in the potassium bromide prism region upon the split of E-species, as is shown in Table III. All these bands shifted to lower frequencies upon the deuteration of ammonia and when the outer ions were changed from

chloride to iodide. When the outer ions were nitrate and perchlorate, which do not form a strong hydrogen bond, the splitting of the band was not observed. From this spectral evidence, it was concluded that the absorption bands of $[CrX(NH_3)_5]^{2,3+}$ appearing in the potassium bromide prism region were all due to the Cr–N stretching vibration, not to the Cr–X stretching vibration.

Discussion

Table I shows that the absorption bands of hexammine- and pentamminechromium(III) complexes shift with the change in outer ions. It is well known that the band shifts because of the formation of a hydrogen bond of the X···H–N type,[5] where X indicates halide ions or oxyacids. The strength of the hydrogen bond between the anions and ammonia increases in the order of ClO_4^-, NO_3^-, I^-, Br^- and Cl^-. Table I shows that the N–H stretching band shifts to lower frequencies, while the deformation band shifts to higher frequencies in the order of the strength of the hydrogen bonding. The relation between the rocking vibration frequencies and outer halide ions is shown in Table IV. The differences in frequencies (Δ) between the chloride and the iodide are 7 cm^{-1} in $[Cr(NH_3)_6]^{3+}$ and 13 cm^{-1} in $[Cr(H_2O)(NH_3)_5]^{3+}$, and 26 and 20 cm^{-1}, respectively, in the corresponding cobalt(III) complexes.

The effect of outer ions was remarkable in the potassium bromide prism region, also. As Table III shows, spectra shift to lower frequencies when the outer ions are changed from chloride to iodide. As explanation of this experimental data, it is considered that the M–N stretching vibrations shift to higer frequencies with an increasing strength of hydrogen bond formation because the M–N stretching vibration is apt to couple with the NH_3 rocking vibration.

TABLE IV. EFFECT OF OUTER IONS ON THE FREQUENCIES OF THE ROCKING VIBRATION BAND OF NH_3 (cm^{-1})

Complex ion	Cuter ion

TABLE V. OBSERVED FREQUENCIES OF SPLIT IN THE Cr–N STRETCHING VIBRATION BANDS OF HEXAMMINE- AND HALOPENTAMMINECHROMIUM-(III) HALIDES

Complex ion	Outer ion			
	Cl	Br^-	I^-	NO_3^-
$[Cr(NH_3)_6]^{3+}$	39	35	26	0
$[CrCl(NH_3)_5]^{2+}$	40	37	31	0
$[CrBr(NH_3)_5]^{2+}$	47	44	—	14
$[CrI(NH_3)_5]^{2+}$	26	—	20	13

The M–N stretching vibration band splits into three components when the outer ions are halide ions. The magnitudes of the split are 39, 35 and 26 cm^{-1} in the chloride, the bromide and the iodide of hexamminechro-

mium(III) respectively. Table V summarizes the magnitude of the split in other complexes. In all cases, the magnitude of the split increases in the order of the iodide, the bromide and the chloride. From the facts that a stronger hydrogen bonding between an ammonia molecule and an outer ion results in a larger split of the M–N stretching vibration and that the M–N stretching vibration does not split in the perchlorate and the nitrate, it is expected that the main cause for the split and the shift of absorption band is the formation of the hydrogen bond.

Halopentamminechromium(III) complexes showed a tendency similar to that of hexamminechromium(III) complexes with regard to the split and the shift of absorption bands. These phenomena may be explained in the same way as were those of the hexamminechromium(III) complexes. Although the M–N stretching vibration did not split in $[Cr(NH_3)_6](NO_3)_3$, it did split to three components in $[CrX(NH_3)_5](NO_3)_2$, where X indicates halide ions. The magnitude of split, however, is smaller than that observed with the corresponding halides (Table V). This experimental result coincides with the view that a nitrate ion forms a weaker hydrogen bond with ammonia than a halide ion does. The differences in the M–N stretching frequencies between the chlorides and the iodides of $[CrX(NH_3)_5]^{2+}$ (X=halide ion) are almost equal; they are 18, 19 and 19 cm^{-1} when X is chloride, bromide and iodide ions respectively. It can be expected, from this fact, that coordinating halide ion has almost the same effect on the hydrogen bonding between the outer ion and the ammonia molecule. When coordinating halide ions were varied with the same outer ion, the M–N stretching bands shifted to slightly higher frequencies in the order of chloro-, bromo- and iodopentamminechromium(III) complexes, that is, 460, 462 and 463 cm^{-1} in the nitrates. This fact that the magnitude of shift is not appreciable may indicate that the effects of coordinating halide ions on the adjacent M–N bond are almost the same.

The spectra of aquopentamminechromium(III) complexes in the potassium bromide prism region were different from those of hexammine- and halopentamminechromium(III) complexes, because only one absorption band was observed, even in the case of the halides. If the ammonia molecule is taken as a single group, an aquopentamminechromium(III) ion has C_{4v} symmetry and, consequently, should give at least two absorption bands.

This discrepancy may be explained as follows: $[Cr(H_2O)(NH_3)_5]^{3+}$ has a similar structure to that of the complex that has O_h symmetry because the mass of the ammonia molecule is almost equal to that of water molecule.[2] Moreover, since the electronegativity of the oxygen atom of water is larger than that of the nitrogen atom of ammonia, water can more easily form a hydrogen bond with an outer ion than ammonia does. The effect of the outer ion on the ammonia of $[Cr(H_2O)(NH_3)_5]^{3+}$ is small, and, consequently, no split of the M–N stretching band occurs. The M–N stretching frequencies of $[Cr(H_2O)(NH_3)_5]^{3+}$ were found to be 478, 476 and 479 cm^{-1} in the chloride, the bromide and the iodide respectively. These experimental results support the above consideration.

Summary

Twenty-nine samples of hexammine and pentammine complexes of chromium(III) and cobalt(III) have been prepared, and their infrared spectra have been measured in the region of 2~25 μ. The absorption peaks of these complexes have been found to shift to higher frequencies in the N–H stretching vibrations, and to lower frequencies in the NH_3 deformation and the Cr–N stretching vibrations in the order of the chlorides, the bromides and the iodides. In a potassium bromide prism region, three absorption bands due to the Cr–N stretching vibrations have been observed in hexammine- and halopentamminechromium(III) halides, but only one in the aquopentamminechromium(III) complexes. The shifts of the absorption bands observed have been discussed from the standpoint of the hydrogen bond formation.

Polarographic and Coulometric Studies of cis-Dioxalatodiaquochromate(III)

By Nobuyuki TANAKA, Eiki ITABASHI, Reita TAMAMUSHI and Gen SATÔ*

(Received August 26, 1963)

In a previous paper,[1] the present authors reported on the polarographic behavior of various oxalato complexes of chromium(III) in acidic or neutral aqueous solutions. As for dioxalatodiaquochromate(III), no reduction wave was observed, in acidic solutions, at less negative potentials than the potential of the reduction of hydrogen ions, while a reduction wave was obtained in neutral solutions. In this paper, an extensive study of the reduction of *cis*-dioxalatodiaquochromate(III) in neutral aqueous solutions at the mercury electrode is presented. The mechanism of the reduction process is discussed on the basis of the experimental results obtained by direct current and alternating current polarography, the measurements of Kalousek polarograms and current-time curves, and the controlled potential electrolysis.

Experimental

Materials.—*cis*-Potassium dioxalatodiaquochromate(III) was prepared according to the method of Werner.[2] It was identified as a cis-form, and its chromium and oxalate contents were determined by the procedure given by Palmer.[3]

Found: Cr, 15.18; ox, 53.5. Calcd. for $K[Cr(ox)_2(H_2O)_2]2H_2O$: Cr, 15.33; ox, 51.89%. *cis*-Potassium dioxalatodiaquochromate(III) is stable for a few months in the solid state and for a few hours in solutions, unless it is exposed to light. All the other chemicals used were of a guaranteed reagent grade.

Polarography. — Current-voltage curves were recorded with a pen-recording polarograph, a Yanagimoto Galvarecorder Model PR-2 with an automatic potential scanner. A Yanagimoto Y-GR 2 Galvarecorder was used for recording alternating current (a. c.) polarograms. Kalousek polarograms were recorded with the same circuit as has previously been described.[4] The current-time ($i-t$) curves during the life of a mercury drop were recorded with a Rikadenki ER-J1 recorder equipped with an RLDC-201 preamplifier.

Measurements were made at 25.00±0.05°C unless otherwise stated. The characteristics of the dropping mercury electrode employed in this study are given in Table I. The cell equipment used was the same as has been reported on previously.[5] The potentials were referred to a saturated calomel electrode(SCE). The dissolved oxygen in the solution was removed by bubbling pure nitrogen gas through the solution. The current-potential curves presented in this paper are corrected for the residual current and for the ohmic (iR) drop across the electrolysis cell.

TABLE I. CHARACTERISTICS OF THE DROPPING MERCURY ELECTRODE

	Height of mercury reservoir cm.	Rate of flow of mercury, m mg./sec.	Drop time, t_d sec.
Electrode A*	50	1.499	3.32
Electrode B**	45	1.862	3.25

* Measured in a dearated 1.0 M KNO_3 solution containing 0.005% gelatin.

** Measured in a dearated 1.0 M KCl solution containing 0.005% gelatin.

Coulometry.—Controlled potential electrolysis[6] was carried out with a Yanagimoto automatic potentiostat, Model VE-3. The working electrode was a mercury-pool electrode whose surface area was approximately 20 cm^2. The anode was a platinum spiral electrode which was connected with the electrolytic solution through a salt bridge of potassium chloride. The electrolytic current was recorded with a Yanagimoto pen-recording Galvarecorder, Model GR-103. The electrical circuit of the equipment and the electrolysis cell used were the same as have been described previously by Tanaka et al.[7] The electrolytic solution was stirred by means of a magnetic stirrer and by bubbling pure nitrogen gas through the solution.

Results

The reduction wave of *cis*-dioxalatodiaquochromate(III) in potassium oxalate solutions changed considerably with time and was

affected by the concentration of potassium oxalate. According to Hamm and Perkins,[8] this is due to the reaction of *cis*-dioxalatodiaquochromate(III) with oxalate ions to form trioxalatochromate(III) :

cis-Dioxalatodiaquochromate(III) gives an ill-defined current-potential curve in potassium nitrate solutions, while a well-defined and reproducible reduction wave is observed in potassium chloride or potassium sulfate solutions (see Fig. 1). Therefore, most of the measurements were carried out in potassium chloride solutions.

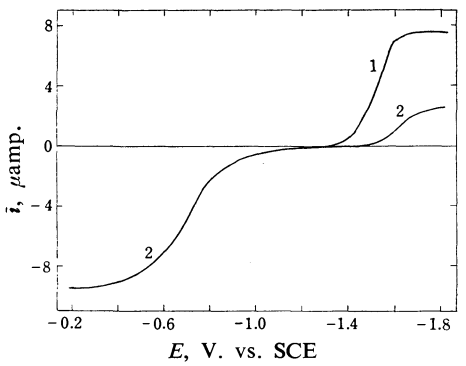

Fig. 1. A direct current polarogram (1) and a Kalousek polarogram (2) of 1.0 mM *cis*-$[Cr(ox)_2(H_2O)_2]^-$ in 0.3 M KCl solutions containing 0.005% gelatin. (Electrode A). For (2), the constant potential was applied at −1.80 V. vs. SCE.

In potassium chloride solutions, the limiting current was proportional to the concentration of the complex up to 2 mM and also to the square root of the effective height of the mercury reservoir. No well-defined wave was obtained in the absence of gelatin. The shape of the reduction wave was affected considerably by the concentration of gelatin. The reduction wave shifted to more negative potentials and its limiting current decreased with an increase in gelatin concentration (Table II).

Measurements were also made in potassium chloride and potassium sulfate solutions of various ionic strengths. The results obtained are presented in Table III. The effect of the temperature on the reduction wave is shown in Table IV; the temperature coefficient of the limiting current was found to be 1.8%/degree in the range of 0 to 35°C. On the a. c. polarogram a peak was observed at a little more negative potential than the half-wave potential of the corresponding d. c. polarogram. One of the typical Kalousek polarograms of *cis*-dioxalatodiaquochromate(III) in a 0.3 M potassium chloride solution containing 0.005%

gelatin is reproduced in Fig. 1, where the anodic wave is apparently separated from the cathodic wave. The current-time curves during the life of a mercury drop were recorded at various potentials and at various concentrations of gelatin. Some of the curves are shown in Fig. 2.

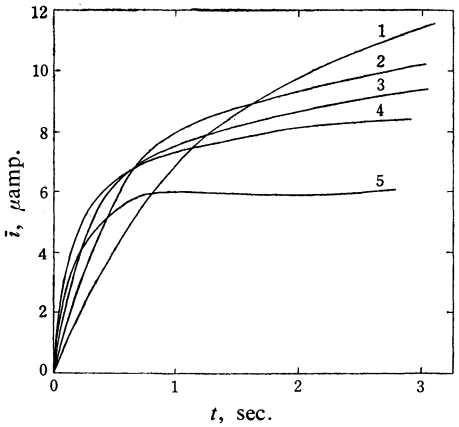

Fig. 2. Current-time curves of 1.0 mM *cis*-$[Cr(ox)_2(H_2O)_2]^-$ measured at −1.75 V. vs. SCE in 0.3 M KCl solutions containing various concentrations of gelatin: (1) 0%; (2) 0.001%; (3) 0.005%; (4) 0.01%; (5) 0.02% gelatin present. (Electrode B).

The number of electrons which are involved in the overall electrode reaction of *cis*-dioxalatodiaquochromate(III) was determined coulometrically by controlled potential electrolysis. The electricity Q (coulombs) required in the controlled potential electrolysis was determined by integrating the recorded current-time curves, with correction being made for the contribution of the residual current. The number of electrons, n, can be calculated from the relation

$$n=\frac{Q}{FN}\times\frac{(\bar{i}_l)_2}{(\bar{i}_l)_1-(\bar{i}_l)_2}$$

where N is the initial amount of *cis*-dioxalatodiaquochromate(III) present in the solution expressed in mole; F, the faraday, and $(\bar{i}_l)_1$ and $(\bar{i}_l)_2$, the limiting currents of the polarograms before and after the electrolysis respectively. The current-voltage curves after the electrolysis were different from those before the electrolysis, as Fig. 3 shows. This seemed due to the increase in the pH of the solution during the course of electrolysis. In the determination of $(\bar{i}_l)_2$, the pH of the solution after the electrolysis was adjusted with hydrochloric acid to be equal to that of the initial solution. The controlled potential electrolysis of *cis*-dioxalatodiaquochromate(III) was also complicated by the evolution of hydrogen gas at the cathode which was observed when the

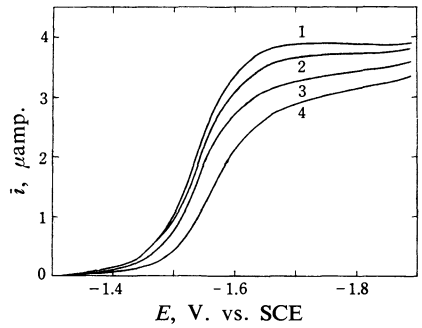

Fig. 3. Current-voltage curves of *cis*-$[Cr(ox)_2(H_2O)_2]^-$ in 0.3 M KCl solutions containing 0.005% gelatin before (1) and after (2-4) the controlled potential electrolysis. (Electrode B). The concentration of the complex and the pH of the initial solution were 0.50 mM and 5.29, respectively. The electrolysis periods and pH of the resulted solutions are: 2, 100 sec. (pH 5.49); 3, 180 sec. (pH 5.50); 4, 300 sec. (pH 5.82).

electrolysis was continued for a longer time. Under these conditions, a shorter period of electrolysis was more favorable for determining the quantity of electricity required for the reduction of *cis*-dioxalatodiaquochromate(III). Therefore, a procedure previously reported[7] was employed to determine the true value of n; the apparent n values obtained from the electrolyses of varied electrolysis periods were plotted against the electrolysis period to estimate the true value of n by the extrapolation of the plot to a zero time (Fig. 4). Fig. 4 indicates that the reduction process of *cis*-dioxalatodiaquochromate(III) at a mercury electrode in potassium chloride solutions is a three-electron process.

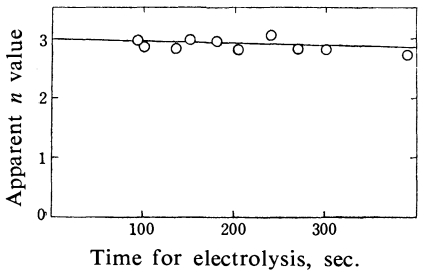

Fig. 4. Plot of apparent number of electrons involved in the reduction of *cis*-$[Cr(ox)_2(H_2O)_2]^-$ as a function of electrolysis period, being measured in 0.3 M KCl solutions containing 0.005% gelatin. The initial concentration of the complex was 0.50 mM. The controlled potential was −1.70 V. vs. SCE.

In order to examine the reduced species of *cis*-dioxalatodiaquochromate(III), current-voltage curves were measured, using a mercury

pool electrode with an area of approximately 1 cm^2 as a working electrode. An apparent anodic wave was observed when the working electrode was polarized at less negative potentials than −0.4 V. vs. SCE immediately after it had been polarized for 5 to 10 min. at the potentials where the reduction of the complex takes place. No anodic current, however, was observed at the DME inserted in the same solution. This result clearly indicated that the reduced substance was contained in the mercury of the electrode. The conventional chemical analysis of the mercury which had been used as the cathode in the electrolysis also showed the presence of chromium.

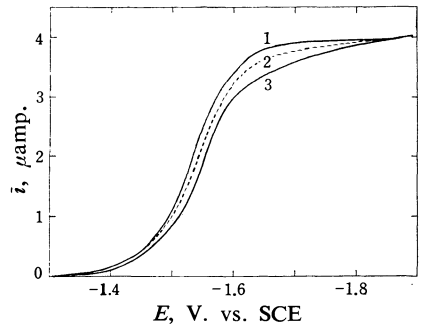

Fig. 5. Current-voltage curves of 0.5 mM *cis*-$[Cr(ox)_2(H_2O)_2]^-$ obtained in 0.3 M KCl solutions of various pH's containing 0.005% gelatin: 1, pH 5.3 (no NaOH added); 2, pH 5.6; 3, pH 5.9. (Electrode B).

Discussion

The experimental results indicate that the limiting current of *cis*-dioxalatodiaquochromate(III) in 0.3 M potassium chloride solutions containing 0.005% gelatin is diffusion-controlled. The diffusion coefficient is calculated to be 6.0×10^{-6} cm^2 sec^{-1} at 25°C by using the Ilkovič equation under the assumption that the number of electrons is equal to three. This value seems reasonable when it is compared with those of analogous complex ions, such as hexamminechromium(III) (8.5×10^{-6} cm^2 sec^{-1})[5] and aqopentamminechromium(III) (8.0×10^{-6} cm^2 sec^{-1}).[9]

The alternating current and the Kalousek polarograms suggest that the reduction process of *cis*-dioxalatodiaquochromate(III) in neutral solutions is totally irreversible in the polarographic sense. The relation between $\log\{\bar{i}/(\bar{i}_d-\bar{i})\}$ and the electrode potential, *E*, however, does not give a straight line. This complication makes the theoretical analysis of the current-potential curve less feasible.

The decrease in the limiting current with the decrease in the ionic strength of potassium chloride solutions is due to the migration effect, because *cis*-dioxalatodiaquochromate(III) is an anion. The potentials of the reduction wave are also dependent on the ionic strength of the solution; the half-wave potential shifts to more negative potentials as the ionic strength decreases (Table III). This can be explained, at least qualitatively, by considering the effect of the diffuse double layer on the irreversible reduction process.

As has been mentioned above, the shape of the reduction wave of *cis*-dioxalatodiaquochromate(III) gradually changes during the course of the controlled potential electrolysis. This is considered due to the increase in the pH of the solution, and is supported by the observation of the change in the reduction wave with the change in the pH of the solution. Figure 5 shows the current-potential curves obtained in 0.3 M potassium chloride solutions containing 0.005% gelatin at three different pH's, the adjustments being made with sodium hydroxide. It has been known that there exist the following equilibria in the aqueous solution of *cis*-dioxalatodiaquochromate(III):[10]

$$cis\text{-}[Cr(ox)_2(H_2O)_2]^- \rightleftharpoons cis\text{-}[Cr(OH)(ox)_2(H_2O)]^{2-} + H^+ \quad (pK=6.4)$$

$$cis\text{-}[Cr(OH)(ox)_2(H_2O)]^{2-} \rightleftharpoons cis\text{-}[Cr(OH)_2(ox)_2]^{3-} + H^+ \quad (pK=8.8)$$

The polarographic reduction wave of *cis*-hydroxodioxalatoaquochromate(III) appears at a potential about 200 mV. more negative than that of *cis*-dioxalatodiaquochromate(III).[1] Therefore, the change in the reduction wave of *cis*-dioxalatodiaquochromate(III) in solutions of pH 5~6 is considered to be due to the contribution of *cis*-hydroxodioxalatoaquochromate(III), whose concentration increases with an increasing pH.

The polarographic reduction wave of *cis*-dioxalatodiaquochromate(III) in potassium chloride solutions resembles the hydrogen wave. However, the appearance of a large anodic wave on the Kalousek polarogram (Fig. 1) eliminates the possibility that the reduction wave of *cis*-dioxalatodiaquochromate(III) is due to the discharge of hydrogen ions; hydrogen ions in potassium chloride solutions were found to give no apparent anodic wave on the Kalousek polarogram. The results obtained by controlled potential electrolysis

9) N. Tanaka, Y. Sato, R. Tamamushi and G. Satô, This Bulletin, **36**, 1059 (1963).

10) D. M. Grant and R. E. Hamm, *J. Am. Chem. Soc.*, **78**, 3006 (1956).

and coulometric analysis suggest that *cis*-dioxalatodiaquochromate(III) is reduced at the mercury electrode to chromium(0), probably to chromium amalgam.

From these results, it can be concluded that the reduction process of *cis*-dioxalatodiaquochromate(III) at the DME in potassium chloride solutions proceeds irreversibly according to this overall reaction;

$$cis\text{-}[Cr(ox)_2(H_2O)_2]^- + 3\ e \rightarrow Cr(0) + 2\ ox^{2-} + 2\ H_2O$$

Summary

The current-voltage curves of *cis*-dioxalatodiaquochromate(III) have been recorded at the dropping mercury electrode in various supporting electrolyte solutions. A well-defined wave with a half-wave potential of -1.52_2 V. vs. SCE was obtained in 0.3 M potassium chloride solutions containing 0.005% gelatin. The limiting current in this case was proved to be diffusion-controlled from its dependence on the effective pressure of mercury on the dropping mercury electrode and from the characteristics of the current-time curve during the life of a mercury drop. The electrode reaction of the complex was found to be irreversible by a study of both the characteristics of the Kalousek polarogram and the relation of $\log\{\bar{i}/(\bar{i}_d-\bar{i})\}$ against E.

The number of electrons involved in the reduction was determined by the controlled-potential coulometric method. The coulometric investigation showed that *cis*-dioxalotodiaquochromate(III) is reduced to the metal at the dropping mercury electrode. This conclusion was also supported by the detection of chromium from the surface of the mercury pool electrode used in the controlled potential electrolysis. The value of the diffusion coefficient of *cis*-dioxalatodiaquochromate(III), calculated for a three-electron reduction, was also reasonable in comparison with those of other chromium(III) complexes.

Analytical Studies Using the Convection Electrode. VII. The Use of the Pushed-out Mercury-drop Electrode

By Junsuke SUZUKI and Tokuro OZAKI

(Received August 27, 1963)

The "rotating disk" convection electrode of platinum wire has previously been devised as a new polarographic electrode by one of the present authors, and the current-voltage curves for the oxidation of iodide and the reduction of cadmium and thallum(I) have been studied. However, the platinum wire electrode, like the other solid electrodes, showed a poor reproducibility.[1] Therefore, using a mercury-coated platinum wire, polarographic waves for the reduction of cadmium and thallium(I) have been investigated and well-reproducible waves obtained.[2] In a neutral or almost neutralized medium, good results were achieved, but in a strongly alkaline or acidic medium, coated mercury on the platinum wire is often detached from the wire during the electrolysis and, in this case, the electrode loses its function as a mercury electrode. Consequently, the polarographic applications of this electrode were found to be limited to a narrow range of pH.

In order to correct these weak points, the authors prepared an electro-deposited mercury-drop electrode.[3] It has a small cup-shape vessel at the end of a glass tube and a small mercury drop electro-deposited on the tip of platinum wire sealed at the bottom of the vessel. The electro-deposited mercury-drop is never detached, even in strongly alkaline or acidic solutions. However, this electrode is difficult to construct and to manipulate, and, also, it takes much time to deposit a mercury drop electrolytically. In order to improve these points, the "pushed-out" mercury-drop

1) T. Ozaki and T. Nakayama, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 98 (1960).
2) T. Ozaki and T. Nakayama, ibid., **82**, 46 (1961).
3) T. Ozaki, *Bull. of Educ. Fac. of Shizuoka Univ.*, **11**, 133 (1960).

convection electrode (PMDCE) has recently been invented by the authors as a new polarographic electrode. This is much easier to construct and to manipulate than the electrodes mentioned above.

In the present paper, polarographic studies using this electrode on various depolarizers, i. e., cadmium, thallium(I) and lead, are reported, and the following points, among others, are examined: (1) the reproducibility of limiting currents or half-wave potentials, (2) the relation between the concentration and the wave height, (3) the relation between the stirring rate of the rotated disk and the wave height, and (4) the half-wave potential and its shift. The results are discussed in detail.

Experimental

Apparatus. — A Shimadzu RP-2 type polarograph was employed for the measurement of all the current-voltage curves. The curves were recorded with a chart speed of about 2 cm./min. and a rate of change of applied potential of about 100 mV./min. A rotating apparatus of a Shimadzu "rotated platinum electrode" was also used in all experiments. It can be rotated at 600, 800, 1000 or 1200 r. p. m. by shifting the gears. The rotated disk was fixed to the axis of the rotator. The disk was made of hard polyvinyl chloride resins and pulley shape.

Cell and Electrode. — The cell and the electrode used in this experiment are shown in Fig. 1. The cell was made of hard glass, while the electrode tube is composed of three parts: (A) a small cup-shape glass vessel (0.2 cm. in inside diameter, 0.3 cm. in outside diameter, and 0.4 cm. deep), (B) a glass capillary for inserting mercury, into A, and (C) a glass tube connecting it with the large mercury reservoir.

Small amounts of mercury are pushed-out into vessel A through B by the pressure caused by raising the mercury reservoir. When the reservoir is lowered, the mercury in vessel A is separated from the mercury in C and, accordingly, a mercury drop is formed in the vessel and the mercury remaining in the capillary B moves back to C.

(12) Cathode
(13) Outlet of H_2 gas

The electric connection of a mercury drop in vessel A with the mercury in C was made by mercury-plated platinum wire (0.01 cm. in diameter). The platinum wire prevents a mercury drop from falling out of A.

The solution containing the supporting electrolyte has a tendency to penetrate into the vessel. Therefore, the inside of the vessel is coated with silicone film.

The capillary B is constructed so finely as to separate the mercury drop in vessel A from the mercury in C in order to avoid the diffusion of an amalgamated metal from A to C.

The mercury drop prepared as mentioned above does not fall out of the vessel even under such severe experimental conditions as in 1 M sodium hydroxide or 1 M hydrochloric acid or at the rate of rotation of 1200 r. p. m.

Reagents.—Each solution of thallium(I), cadmium and lead was prepared from chemicals of an extra pure reagent grade without further purification. The other chemicals used are all of extra pure reagent grade.

Procedure. — The mercury drop is renewed in each polarographic measurement. The procedure is as follows.

Before the measurement of a current-voltage curve, the mercury reservoir is raised to the height of about 27 cm. A few mercury drops are made to fall out of vessel A because of the pressure created by raising the reservoir. When the last of these drops falls, the reservoir is brought down to the height of about 5 cm. The fall of mercury drops then stops, and, in vessel A, a mercury drop is formed. After that, a polarogram is recorded. The mercury drop can be renewed as the electrode by repeating the above process.

Dissolved oxygen is removed by passing H_2 gas through the solution or by adding small amounts of a sodium sulfite solution.

0.3 ml. of a 1 M sodium sulfite solution freshly prepared is added to 50 ml. of a 0.1 M potassium chloride solution containing thallium(I) or cadmium ions as depolarizers. A reduction wave is measured after 15 min. Also, after 50 ml. of 1 M sodium hydroxide or hydrochloric acid containing a lead depolarizer is poured into the electrolysis cell, a hydrogen gas stream is passed, at the rate of about 4 bubbles per second for about 1 hr., through the solution to remove the dissolved oxygen. These lead sample solutions are electrolyzed by the constant bubbling of hydrogen gas (by using gas-inlet pipe (2) in Fig. 1).

All the measurements were carried out at 16.5± 0.5°C.

Results

The Reproducibility of the Limiting Currents. — A mercury drop is pushed out into the vessel of the electrode before each measurement, so its surface area must always be kept

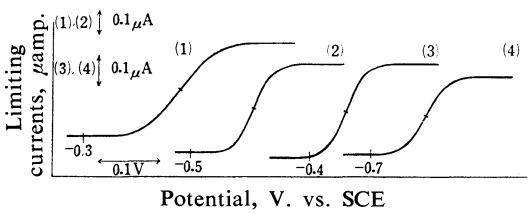

Fig. 2. Typical current-voltage curves of thallium, cadmium and lead (HCl and NaOH).
(1) 5×10^{-6} M Tl^+ in 0.1 M KCl
(2) 5×10^{-6} M Cd^{2+} in 0.1 M KCl
(3) 5×10^{-6} M Pb^{2+} in 1 M HCl
(4) 5×10^{-6} M Pb^{2+} in 1 M NaOH

constant. To test the reproducibility of the area, the limiting currents were measured with various depolarizers. Typical current-potential curves are shown in Fig. 2, while some of these results are given in Table I. The curves oscillated slightly, but this had no effect upon the results.

On the other hand, the limiting currents obtained by the renewal method of the electrode proposed by Marple et al.[4] are shown in Table II (the applied voltage and the time for the renewal were −0.4 V. vs. SCE and 5 min. respectively).

As is shown in Tables I and II, reproducibility with the PMDCE was slightly poor in comparison with the method of Marple et al.,[4] but it is considered that the surface area of the mercury drop can be kept fairly constant, because good reproducibilities of the limiting currents can always be obtained within a range of error of 2%.

The Reproducibility of Half-wave Potentials. — The half-wave potentials of various depolarizers were determined by the ordinary method; the results are listed in Table III. As is shown in Table III, the half-wave potentials have a good reproducibility.

The Relation between the Concentration of Depolarizers and the Limiting Currents. — The

relations between the limiting currents and concentration are shown in Table IV. It can be seen from Table IV that a satisfactory proportionality between the limiting currents and concentration is obtained.

The Effect of the Stirring Rate on Limiting Currents. — The dependence of the limiting currents on the stirring rate of the rotating disk was investigated by using a cadmium, thallium(I) or lead solution respectively. The results are shown in Fig. 3. It can be seen that no linear relation between the limiting currents and the stirring rate is obtained, although the currents decrease gradually with the increase in the stirring rate.

The Effect of the Stirring Rate on the Half-wave Potentials. — The effect of the stirring rate on the half-wave potentials of cadmium, thallium(I) and lead was investigated; the results are shown in Table V. It can there be seen that the change in the stirring rate of 600～1200 r. p. m. has no effect on the half-wave potentials.

The Effect of the Rate of Polarization. — It was observed with a stationary mercury-plated platinum electrode by Marple et al.[4] that the half-wave potential was shifted toward positive potentials as the rate of polarization was increased from 37 mV. to 222 mV. per minute.

Therefore, the effect of the rate of polarization was investigated with the PMDCE. The results are given in Table VI. It can be seen from Table VI that the limiting currents are increased with the increase in the rate of polarization and that, at the same time, the half-wave potentials are slightly shifted toward positive potentials, as Marple et al.[4] observed, in the cases of thallium(I) and lead (in 1 M sodium hydroxide). However, no change in the half-wave potential is observed on the other ions.

A comparison with the Dropping Mercury Electrode (DME). — The limiting currents obtained with the PMDCE (1200 r. p. m.) for thallium(I), cadmium, and lead (in 1 M hydrochloric acid and in 1 M sodium hydroxide) were, respectively, about eighteen, fifteen, sixteen and fourteen times as large as the corresponding diffusion currents obtained by the DME. The capillary of the DME used had an m value of 0.92 mg./sec. and a drop time of 5.1 sec./drop at −0.8 V. vs. SCE in a 0.1 M potassium chloride solution.

Discussion

Sensitivity. — Table VII lists the values of sensitivity, "S" ($S=i_l/nC$), which derived by Kolthoff and Jordan[5] to characterize the convection electrode, at the PMDCE; the values of $S/D^{2/3}$ (D: diffusion coefficient) are shown in column 4 of this table. If the limiting currents are completely controlled with convection, the S values of these depolarizers should be of the same value, because all measurements were carried out under the same hydrodynamic conditions. As is shown in Table VII, however, at the PMDCE the S values of these depolarizers are not equal, while the $S/D^{2/3}$ values agree well with one other. Therefore, it is found that the limiting currents change proportionally with two-thirds the power of the diffusion coefficient. Apparently both diffusion and convection contribute to the currents; i. e., the limiting currents depend on the diffusion coefficient and, at the same time, on the convection coefficient.[5]

The Relation between the Stirring Rate and the Limiting Currents. — The relation between the limiting currents and the speed of the rotation of the stirrer can generally be expressed by this equation:[6]

$$i_l = pr^a$$

where p is a constant, r is the number of rotations per minute of the stirrer, and a is a constant which is generally comprised between 0.4 and 1 and which depends on the geometric factors of the electrolytic cell, the stirrer and the electrode.

This relation was investigated with the PMDCE in the cases of cadmium, thallium(I) and lead. A logarithm of limiting current was plotted against a logarithm of the stirring rate of the stirrer. These plots are shown in Fig. 4, where the plots of various depolarizers give straight lines. The values of a in the above equation can be determined with the slope of a line in Fig. 4. The value of a

obtained is 0.50. This shows that the limiting currents change in proportion to the square root of the stirring rate.

Accordingly, the limiting currents at the PMDCE change linearly with the square root of the stirring rate and, at the same time, with two-thirds the power of the diffusion coefficient.[3] If it is assumed that the velocity of the stream on the surface of the electrode, which can hardly be measured, is proportional to the rate of the rotation of the disk, it seems that the limiting currents with the PMDCE conform to the equation of the limiting currents for the rotating disk electrode derived by Levich,[7] which is as follows:

$$i_l = knF'ACD^{2/3}\omega^{1/2}\nu^{-1/6}$$

where i_l=limiting currents, C=bulk concentration, ω=angular velocity of electrode, and ν=kinematic viscosity.

The relation between i_l and ν has not yet been investigated experimentally. This result is very similar to that obtained by Galus et al.[8] or by Galus and Adams.[9]

Half-wave Potentials. — Table VIII summarizes the half-wave potentials at the PMDCE and DME. As is shown in Table VIII, the half-wave potentials of various depolarizers at the PMDCE are slightly more negative than the corresponding half-wave potentials of DME. It seems probable that the rate of mass transfer becomes large as compared with the rate of electron transfer, as has been reported by Jordan,[10] or that δ_0, the effective thickness of the diffusion layer, is smaller, as has been pointed out by Delahay,[6] because of the convection effect caused by increasing the stirring rate. Table V shows the effect of the stirring rate on the half-wave potential; the results indicate that the half-wave potential is not affected by the stirring rate. It seems probable that a change in δ_0 can be almost disregarded in the range of a given stirring rate, as the relationship of the half-wave potential to δ_0 is of an exponential function.[3]

The effect of the concentration of reducible material on the half-wave potential is shown in Table IX. For cadmium, the half-wave potential is nearly the same at every concentration, but with the others, the half-wave potentials are shifted slightly toward positive potentials with the decreasing concentration of depolarizers. Such a shift can be found

reported also by Arthur et al.[11]

Plot of the Applied Potential against log $i/(i_l-i)$. — The logarithm of quantity (i/i_l-i) was plotted against the applied potential at the PMDCE. These plots for thallium, cadmium and lead how perfectly straight lines. Table X shows both the values of the slope (mV.) and the number of electrons, n calculated from it.

The data given in Table X show that the values of n decrease with an increase in the stirring rate. It is considered that the increase in the mass transfer due to the convection gives the increase in quasi-irreversibility.[10]

Summary

The limiting currents with the PMDCE depend on the factors of both convection and diffusion. The PMDCE is easy to prepare and to manipulate, and it has an excellent sensitivity. It can be used even in a strongly alkaline or acidic medium and can be reused many times with good reproducibility. Therefore, various applications to analytical chemistry can be expected.

The Synthesis of Oxygenated Organic Compounds from Methanol and Carbon Monoxide-Hydrogen Mixtures in the Presence of a Mixture of Cobalt Acetate and an Iodide Used as the Catalyst

By Tsutomu MIZOROKI and Mikitake NAKAYAMA

(Received August 30, 1963)

The treatment of methanol with carbon monoxide-hydrogen mixtures under the oxo reaction conditions results in the formation of ethanol. This is well known as the homologation of methanol. When cobaltcarbonyl or cobalt salts were used as catalysts in this reaction, small portions of the methanol were converted into ethanol.[1] However, Berty found that the yields of ethanol and other oxygenated compounds (acetaldehyde, methyl or ethyl acetate) were increased by adding a small amount of iodine as an additive for the cobalt acetate catalyst.[2]

In a preceding paper,[3] it was shown that, in a bathwise experimental run using a mixture of cobalt acetate and an iodide (LiI, NaI, KI and CaI_2) as the catalyst, acetic acid was synthesized in a 90% yield from methanol and carbon monoxide in a liquid phase under pressures from 300 to 500 kg./cm^2 and at temperatures from 210 to 240°C. However, when this reaction was carried out in a flow reactor under the same conditions except that the carbon monoxide contained 10% hydrogen, it was found that the amount of hydrogen was strikingly decreased, that this reaction was invariably accompanied by the formation of acetaldehyde and ethanol, and that the extent of methanol conversion into free acetic acid was less than 60%.[4] This led us to investigate the homologate of methanol with the same catalyst.

For acetic acid synthesis with a mixture of cobalt acetate and an iodide at the catalyst, it is necessary to add a considerable amount of water,[3] while for the formation of ethanol and other oxygenated compounds from methanol and carbon monoxide-hydrogen mixtures with the same catalyst, it in unnecessary to add water to methanol. This is very significant.

From a comparison of the effect of an iodide with that of iodine on the extent of methanol conversion into C_2-oxygenated compounds, we found that an iodide serves as an additive for increasing the yield of ethanol and other oxygenated compounds.

The present work was undertaken in order to study in detail the influence of an iodide

as an additive for a cobalt acetate catalyst on the reaction of methanol with carbon monoxide-hydrogen mixtures.

Experimental

Apparatus for Carrying out the Reaction.—In all experiments, the reaction was carried out in a titanium-manganese alloy autoclave (185 or 225 ml.). The complete apparatus used was essentially the same as that described in the preceding paper.[3]

When a solution of cobalt acetate and an iodide in methanol is heated without the addition of acetic acid, a precipitate is formed. However, in the presence of acetic acid*1 no precipitate is formed by heating, though the color of the solution changes from pale pink to blue or green. (These observations have been made by heating the solutions in a sealed, thick-walled glass tube.) In the latter case, the reaction between methanol and carbon monoxide-hydrogen takes place without an induction period being exhibited.

The experiments were carried out in the following way. The reaction vessel was heated in a shaking-type electric furnace (60 r. p. m.) after a mixture of methanol and acetic acid containing cobalt acetate and an iodide had been charged. After this solution had been maintained at a reaction temperature (between 160 and 240°C) for about one hour, the synthesis gases were introduced and continuously supplied from the pressure accumulator to keep the pressure (between 250 and 500 kg./cm^2) constant during the reaction. After a predetermined time of reaction, the heating and the addition of gases were stopped, the reaction vessel was allowed to cool to room temperature, and the gases and the liquid product were discharged.

Materials.—The methanol, acetic acid, cobalt acetate and iodides used were obtained from commercial sources. The synthesis gases were mixtures*2 of hydrogen from water electrolysis and carbon monoxide from formic acid decomposition, materials which had been compressed into the pressure accumulator.

Analytical Procedure. — The main components in the liquid product were determined by the gas-chromatographic procedure. A 2.5 meter glass column with carbo-wax 400 on a Johns-Manville C-22 fire brick was used at the temperature of 80°C with a hydrogen carrier at the gas flow rate of 70 ml. per minute. In this way, dimethyl ether, acetaldehyde, methyl acetate, ethyl acetate, methanol, ethanol, crotonaldehyde and water were quantitatively determined using pyridine as an internal standard. Since formic acid, propionic acid and their esters could not be detected in the liquid product, the amount of free acetic acid was determined by titration with an aqueous potassium hydroxide solution. The amount of each of these components as determined by this method was approximately in agreement with that obtained from the fractional distillation (Podbielniak 3500, Heli-Grid column).

Cobaltous ions and iodide ions were determined by EDTA and Volhard's methods respectively in the usual manner, but cobalt-carbonyl complex compounds in the liquid product were too unstable to be investigated.

Carbon monoxide, carbon dioxide, methane and hydrogen in gases were determined by absorption and combustion methods in the usual manner.

Results

A Comparison with Iodine. — In order to compare the effect on the extent of methanol conversion of an iodide as an additive for a cobalt acetate catalyst with the effect of iodine, the reaction was carried out by the use of sodium iodide and iodine under the same conditions. The volume of synthesis gases supplied during the reaction for maintaining the reaction pressure constant is plotted against the time in Fig. 1, while the conversion values of methanol into C_2-oxygenated compounds are presented in Table I.

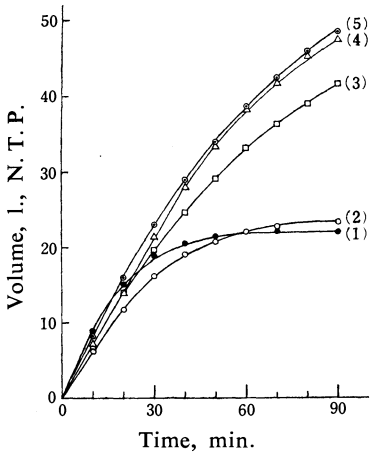

Fig. 1. The effect of iodine or sodium iodide as an additive for a cobalt acetate catalyst when a mixture of MeOH (1.62 mol.), AcOH (0.18 mol.) and $Co(AcO)_2 \cdot 4H_2O$ (9.0 mmol.) is treated for 90 min. under 300 kg./cm^2 and at 200°C. The added amounts of additives are (1) I_2 3.0 mmol., (2) I_2 6.0 mmol., (3) NaI 6.0 mmol., (4) NaI 12.0 mmol. and (5) NaI 18.0 mmol.

When iodine is used as an additive, the gas volume supplied becomes nearly constant after 30~40 min., the reaction ceases, and, as is shown in Table I, a considerable amount of dimethyl ether is formed. However, when sodium iodide is used instead of iodine, the reaction proceeds smoothly, the extent of methanol conversion to C_2-oxygenated compounds is about twice as much as that obtained with the use of iodine, and the amount of

*1 The amount of acetic acid in methanol is 5.0 to 10.0 mol. %.

*2 The amounts of CH_4, CO_2 and N_2 were less than 1.0 vol. %.

Total AcOH=free acetic acid+acetic esters
Total EtOH=ethanol+ethyl acetate
Total aldehyde=acetaldehyde+crotonaldehyde

ethanol in the product is relatively large. From these results, the addition of iodine as an additive for a cobalt acetate catalyst in this reaction is undoubtedly disadvantageous.

The infrared spectra of the high temperature fractions obtained from the fractional distillation of the product showed the presence of *n*-butanol, but its amount was too small to be quantitatively determined. A trace of dimethylacetal, also, was detected.

Lithium iodide, sodium iodide, potassium iodide and calcium iodide were used as additives, there was little difference between their effects on the reaction rates and the extent of methanol conversion into C_2-oxygenated compounds. The results obtained with the use of lithium iodide or sodium iodide will be described later.

The Effect of Pressure, the Composition of Synthesis Gases and Temperature.—The effect of reaction pressure on the extent of methanol conversion was examined by using the synthesis gases of 1-CO : 1-H_2. The results are presented in Fig. 2, in which the conversion values of methanol into aldehyde (acetaldehyde+crotonaldehyde), acetic acid*3 (acetic esters+free acetic acid) and ethanol (ethanol+ethyl acetate) are plotted against the pressure; the volume % of carbon monoxide and hydrogen in the discharged gases after reaction is plotted in the upper part.

The increase in pressure results in an increase in the extent of methanol conversion, but it has little more effect on the ratios of the yield of ethanol, acetaldehyde or acetic acid than that of the other. The amount of hydrogen in the discharged gases is much less than that in synthesis gases in every case. The loss of methanol by the formation of methane and dimethyl ether is less than 5%.

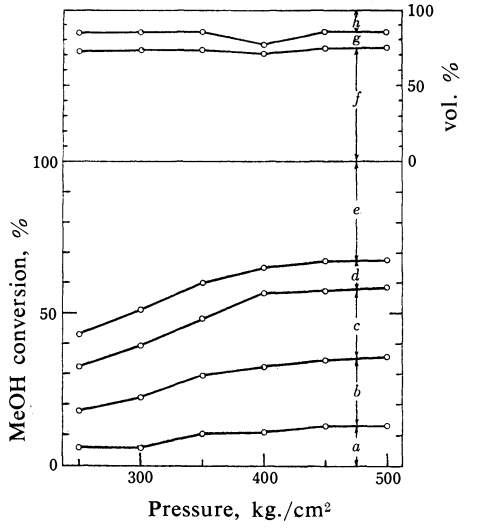

Fig. 2. The effect of pressure when a mixture of MeOH (1.425 mol.), AcOH (0.075 mol.), $Co(AcO)_2 \cdot 4H_2O$ (6.0 mmol.) and LiI (9.0 mmol.) is treated for 90 min. at 200°C.

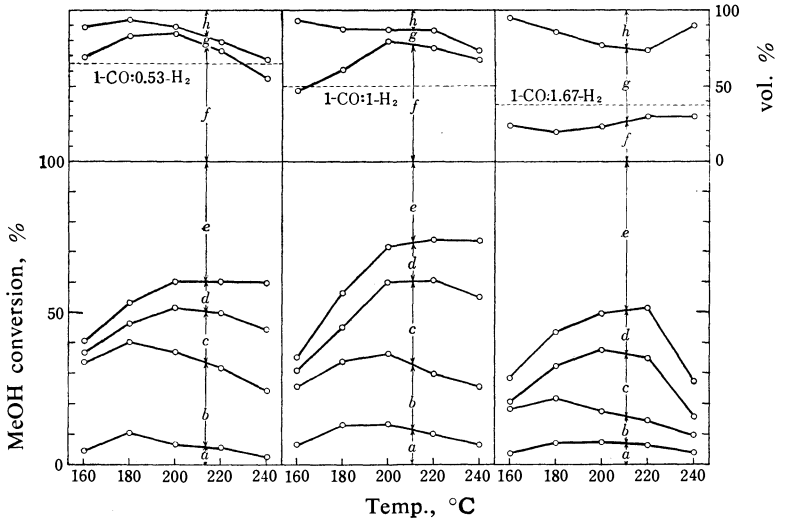

Fig. 4. The effect of temperature when a mixture of MeOH (1.425 mol.), AcOH (0.075 mol.), $Co(AcO)_2 \cdot 4H_2O$ (6.0 mmol.) and LiI (9.0 mmol.) is treated for 90 min. under 400 kg./cm².

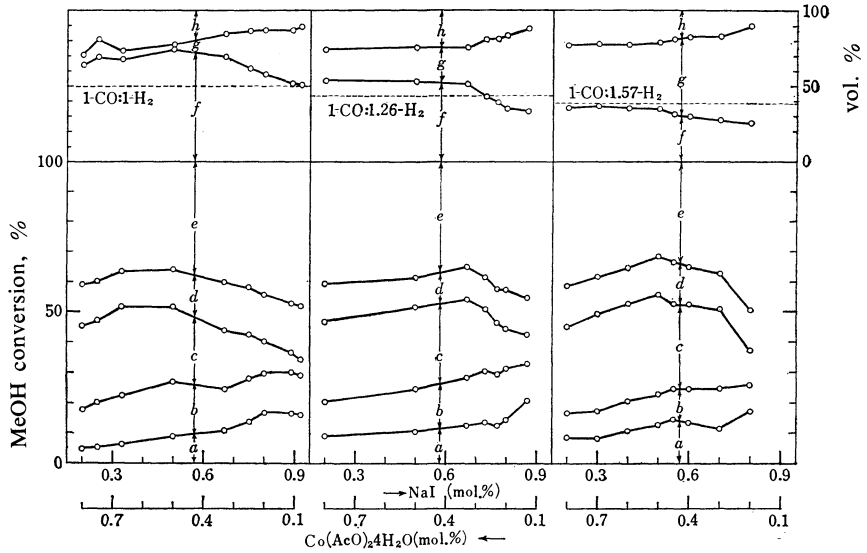

Fig. 5. Effect of the catalyst concentration at 200°C and the reaction time 90 min.

The effect of the composition of synthesis gases is represented in Fig. 3. Since the reaction was carried out at a constant pressure of 400 kg./cm^2, independently of the composition of synthesis gases, the partial pressures of hydrogen and carbon monoxide were different from each other. The evident formation of ethanol is expected to be favored in the presence of a large amount of hydrogen in this reaction, while the yield of ethanol does not increase as much as expected.

The effect of the temperature was examined at the pressure of 400 kg./cm^2 in the use of the synthesis gases of 1-CO : 0.53-H_2, 1-CO : 1-H_2 and 1-C : 1.67-H_2. The experimental results made at temperatures from 160 to 240°C are summarized in Fig. 4. At an elevated temperature, the amount of hydrogen reacting with methanol is more than that of carbon monoxide and the yield of ethanol consequently increases, although at a low temperature, the yield of acetaldehyde is relatively large. However, the increase in temperature beyond 220°C must be avoided, because then the amounts of methane, C_3- and higher oxygenated compounds increase and the methanol conversion decreases. A similar behavior with regard to temperature is observed in the synthesis of aldehydes and alcohols by oxo reactions.[5]

The Influence of the Catalyst Concentration. —For the purpose of obtaining more detailed information on the effect of the catalyst concentration, the variation of the values of the conversion of methanol into C_2-oxygenated compounds was examined by the use of a mixture of methanol (1.62 mol.) and acetic acid (0.18 mol.) over the range of the ratios of cobalt acetate to sodium iodide from 0.1 to 4.0, in which the sum of their concentrations was kept constant (1.0 mol. %). The reaction pressures were 300, 400 and 450 kg./cm^2 with the synthesis gases of 1-CO : 1-H_2, 1-CO : 1.26-H_2 and 1-CO : 1.57-H_2 respectively. The results are summarized in Fig. 5. The yield of ethanol evidently increases with an increase in the ratio of cobalt acetate to sodium iodide, while the yield of acetaldehyde increases with a decrease in it. It is very interesting to note that the composition of the discharged gases becomes approximately equal to that of synthesis gases at a certain ratio of an iodide to cobalt acetate. Such ratios of I^-/Co^{2+} were more than 10, 3 to 4 and 1 to 1.5 with the H_2/CO ratios of synthesis gases of 1.0, 1.3 and 1.6 respectively.

The experimental results made at the suitable catalyst concentration for each synthesis gas considered from the results of Fig. 5 are represented in Table II. They show that the extent of methanol conversion into ethanol and acetaldehyde considerably depends on the catalyst concentration.

Discussion

The possible reactions leading to the formation of acetaldehyde, ethanol and acetic acid can be represented by the following equations. However, the ease of the formation of these compounds considerably depends on the catalyst concentration, as has already been described.

		$-\Delta F°_{(25°C)}$[6] kcal./mol.	$-\Delta F°_{(200°C)}$[*4] kcal./mol.
$CH_3OH+CO+H_2$ $=CH_3CHO+H_2O$	(1)	16.1	9.8
$CH_3OH+CO+2H_2$ $=C_2H_5OH+H_2O$	(2)	25.9	11.0
$CH_3OH+CO=CH_3COOH$	(3)	21.3	11.8
$CH_3CHO+H_2=C_2H_5OH$	(4)	9.8	1.2

On the basis of the experimental results, we can postulate that, in the reaction of methanol with carbon monoxide-hydrogen mixtures, methanol is converted in the first place to acetaldehyde, that subsequently this is hydrogenated to ethanol or dimerized to other oxygenated compounds (2·acetaldehyde → ethyl acetate, 2·acetaldehyde → crotonaldehyde → n-butanol), and that the rates of the formation of methylacetate, acetic acid, C_3- and higher compounds are small, partly because the amounts of free acetic acid, C_3- and higher compounds present in the product are small and partly because the amount of hydrogen reacting with methanol is always larger than that of carbon monoxide.

It is well known that cobaltous salts react with carbon monoxide under high pressures to form dicobalt octacarbonyl, which undergoes a homomolecular disproportionation in methanol and which forms cobalt hydrocarbonyl in the presence of hydrogen[5]. However, only with these cobalt carbonyl catalysts, a small part of the methanol used is converted into C_2-oxygenated compounds under the oxo condition[1,5], although aldehydes are hydrogenated to alcohols or dimerized[7,8].

On the other hand, cobaltous halides form green or blue tetrahedral complex anions[9],

such as $CoCl_4^{2-}$, $CoBr_4^{2-}$ and CoI_4^{2-} in an organic solvent[10-12] (nitromethane, *N*, *N*-dimethylformamide or acetone). The same complex ions have been considered to be formed from cobalt acetate and litium or sodium iodide in glacial acetic acid.[13,14] In the experimental section, it was mentioned that cobalt acetate in methanol containing an iodide and acetic acid forms, at an elevated temperature, a greenish compound, which is presumably tetrahedral.

From these facts and experimental results, we can expect the catalytic action of cobalt acetate and an iodide in the reaction of methanol with carbon monoxide-hydrogen mixtures to be as follows: a part of the cobalt acetate forms a complex compound of the $[CoX_4(CO)H]^{2-}$ ($X=I^-$ or CH_3COO^-) type, which is similar in electronic configuration to cobalt hydrocarbonyl $HCo(CO)_4$, hydropentacyano cobaltate anion[15] $[Co(CN)_5H]^{3-}$, carbonyl ferrocyanic anion $[Fe(CN)_5CO]^{3-}$, etc. (Hieber[16] reported that solid cobaltous iodide reacted with pure carbon monoxide to form a dark brown crystalline carbonyl apparently represented by CoI_2CO, in which the cobaltous ion was probably surrounded by more than two iodide ions.) With this complex compound, a methanol reacts with a carbon monoxide and a hydrogen to form an acetaldehyde. The other part of the cobalt acetate froms cobalt hydrocarbonyl, with which the acetaldehyde produced is hydrogenated to ethanol or dimerized to ethyl acetate and other things. When a relatively large amount of an iodide is added, most of cobalt acetate forms $[CoX_4(CO)H]^{2-}$ according to the above expectation and the yield of acetaldehyde therefore increases, while in the presence of a large amount of cobalt acetate, a considerable amount of cobalt hydrocarbonyl is formed simultaneously and the yield of ethanol, therefore, apparently increase.

Summary

The reaction of methanol with carbon monoxide-hydrogen mixtures has been carried out in the presence of a mixture of cobalt acetate and an iodide as catalyst. The extent of methanol conversion into C_2-oxygenated compounds (acetaldehyde, ethanol and acetic esters) was 40 to 60% when the catalyst concentration ($Co(CH_3COO)_2 \cdot 4H_2O$ + an iodide) range was form 1.0 to 20 mol%; the temperature range was from 180 to 220°C; the pressure range was from 300 to 500 kg./cm^2 (the H_2/CO values in synthesis gases were 1.0 to 1.5), and the reaction time was 90 min. The amount of free acetic acid, C_3- and higher oxygenated compounds in the liquid product was small. The use of iodine instead of an iodide as an additive for the cobalt acetate catalyst is disadvantageous for this reaction. From the detailed investigation of the influence of the catalyst concentration on the extent of the conversion of methanol into C_2-oxygenated compounds, it has been shown that the formation of acetaldehyde is favored in the presence of a relatively large amount of an iodide and that an increase in cobalt acetate results in an increase in the yield of ethanol. It has been postulated that, under these conditions, methanol reacted with carbon monoxide and hydrogen to form acetaldehyde, which subsequently was hydrogenated to ethanol or dimerized to other oxygenated compounds.

The authors wish to express their thanks to Dr. Hiroshi Uchida for his invaluable advice and criticism.

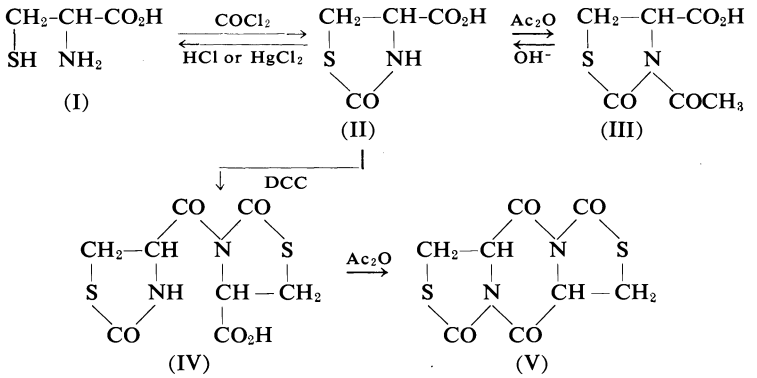
Syntheses and Properties of 2-Oxothiazolidine-4-carboxylic Acid and Its Derivatives[*1]

By Takeo KANEKO, Takeo SHIMOKOBE,[*2] Yoshimoto OTA,[*3] Ekido TOYOKAWA,[*4] Toshishige INUI and Tetsuo SHIBA



(Received September 9, 1963)

It has been shown that DL- or L-threonine is easily cyclized with phosgene to DL- or L-*trans*-5-methyl-2-oxo-oxazolidine-4-carboxylic acid in an alkaline solution without any configurational change at the either asymmetric center.[1] Cysteine may be similarly cyclized to 2-oxothiazolidine-4-carboxylic acid with phosgene beacause of the expected reactivity of the thiol group. Cook et al. have reported that the penicillamine methyl ester was also cyclized to the corresponding thiazolidone derivative with phosgene in the presence of sodium hydrogen carbonate.[2] This paper deals with the cyclization of L-cysteine with phosgene and with the properties of the cyclization product.

The cyclization of L-cysteine (I) to L-2-oxothiazolidine-4-carboxylic acid (II) with phosgene occured by means of the modified method as carried out in the cyclization of threonine.[1] The cyclized product II melted at 171~172.5°C and gave a strongly acidic aqueous solution. The racemic form of II (m. p. 155°C) was obtained from *S*-benzylthiocarbonyl-DL-cysteine by means of the action of alkali by Crawhall et al.[3] On hydrolysis in 6N hydrochloric acid or treatment with mercuric chloride, the starting L-cysteine (I) was recovered in its pure state. During this cyclization reaction, no configurational change took place.

When II was heated in acetic anhydride, L-3-acetyl-2-oxothiazolidine-4-carboxylic acid (III) and two other by-products were obtained. One of the two by-products, which was also obtained by the dehydration of the other with acetic anhydride, melted at 259~260°C and had the empirical formula $C_4H_3NO_2S$. The other (m. p. 215°C) possessed the empirical formula $C_8H_8N_2O_5S_2$ and was identified with the dehydration product of II by *N*, *N'*-dicyclohexyl carbodiimide (DCC). This second compound is probably 2-oxo-3-(2'-oxothiazolidine-4'-carbonyl-)-thiazolidine-4-carboxylic acid(IV), while the former seems to be the diketopiperazine-type compound, 1, 4, 5, 8-tetraoxo-2, 6-dithia-4a, 8a-diazaperhydro-*s*-indacene (V).

Therefore, if *N*-acetyl-L-cysteine[4] is similarly cyclized with phosgene, III will be obtained directly. The cyclization of *N*-acetyl-L-cysteine, however, was unsuccessful. The *N*-benzoyl-L-cysteine ethyl ester (VII) obtained by the reduction of the *N*, *N'*-dibenzoyl-L-cystine diethyl ester (VI) with zinc and hydro-

chloric acid was used. According to the method employed in the reaction of the *N*-benzyloxycarbonyl-DL-serine benzyl ester with phosgene by Bergel,[5] VII was treated with phosgene in benzene and thereby an expected *S*-chlorocarbonyl intermediate VIII was obtained. This intermediate was cyclized to 3-benzoyl-4-ethoxycarbonyl-2-oxothiazolidine (IX) when refluxed in xylene for 6 hr. by applying the method of Ben-Ishai.[6]

When III was treated in an aqueous solution with dilute sodium hydroxide, the separation of the acetyl group took place and II was recovered without any racemization. In a similar way, IX yielded II and benzoic acid under the same conditions.

It is expected that these results will be of use in discussing the synthetic and structural problems of cysteine peptides.

Experimental

L-2-Oxothiazolidine-4-carboxylic Acid (II).—To a cold solution of 24.2 g. (0.200 mol.) of L-cysteine ($[\alpha]_D$ +7.9° (1 N hydrochloric acid)) in 350 ml. of water, 50 ml. of 40% potassium hydroxide was added and cooled below −5°C in an ice-salt bath. A solution of 26.0 g. (0.262 mol.) of phosgene in 100 ml. of toluene and 100 ml. of 40% potassium hydroxide were simultaneously vigolously stirred into the solution over a 10~15 min. period. After the solution had been stirred for a half hour, the toluene layer was separated. The aqueous layer was extracted twice with ether and acidified to Congo red with concentrated hydrochloric acid. The acidic solution concentrated to dryness in vacuo, and the residue was extracted three times with 250 ml. of ethanol while hot. The extract was concentrated to dryness in vacuo, and residual oil was dissolved in 10 ml. of hot water. A crude II (23.2 g.) crystallized out after the solution had been left standing for several hours. After two recrystallizations from hot water, the pure substance was obtained. Yield, 14.5 g. (49%); m. p. 171~172.5°C, $[\alpha]_D^{16}$ −57.3° (*c* 2.7, water).

IR (Nujol mull): 3260 (amide), 2600, 1740, 1225 (carboxylic acid), 1625 (cyclic amide) cm^{-1}.

Found: C, 32.91; H, 3.47; N, 9.52; S, 21.40. Calcd. for $C_4H_5NO_3S$: C, 32.64; H, 3.42; N, 9.52; S, 21.79%.

L-3-Acetyl-2-oxothiazolidine-4-carboxylic Acid (III).—Eight and eight-tenth grams (0.06 mol.) of II was heated in 50 ml. of acetic anhydride until the II had been dissolved. After cooling at room temperature, the V which had separated was filtered off (0.55 g.) To a filtrate, 30 ml. of water was added and heated several times in order to effect the decomposition of the excess acetic anhydride. The solution was then concentrated to a half volume in vacuo, and the crystallized IV was filtered (2.4 g.) When the filtrate was again evaporated to dryness in vacuo, III crystallized out. The yield was 5.9 g. (52.1%). It melted at 152~154°C after recrystallization from ethyl acetate and light petroleum, and it gave $[\alpha]_D^{20}$ −136.4° (*c* 1.8, water-acetone (1 : 1)).

IR (Nujol mull): 2600, 1710 (carboxylic acid), 1730 (acetyl), 1650 (cyclic amide) cm^{-1}.

Found: C, 38.30; H, 3.59; N, 7.42. Calcd. for $C_6H_7NO_4S$: C, 38.08; H, 3.74; N, 7.40%.

2-Oxo-3-(2'-oxothiazolidine-4'-carbonyl-)-thiazolidine-4-carboxylic Acid (IV).—To a cold solution of 1.47 g. (0.01 mol.) of II in 40 ml. of *N*,*N*-dimethylformamide, 1.1 g. (0.005 mol.) of DCC was added drop by drop. After the mixture had been left standing overnight, the precipitated *N*,*N'*-dicyclohexyl urea was removed. The filtrate was acidified with 10 ml. of 6 N hydrochloric acid and extracted five times with 50 ml. of ethyl acetate. The extract was concentrated to dryness in vacuo, and when water was added to the residue, IV crystallized out. Yield, 0.9 g. (65%); m. p. 215°C (decomp.).

IR (Nujol mull): 3260 (amide), 2500, 1710 (carboxylic acid), 1625 (cyclic amide) cm^{-1}.

Found: C, 34.98; H, 3.08; N, 10.14. Calcd. for $C_8H_8N_2O_5S_2$: C, 34.77; H, 2.91; N, 10.13%.

1,4,5,8-Tetraoxo-2,6-dithia-4a,8a-diaza-perhydro-*s*-indacene (V).—A solution of 0.10 g. (0.0004 mol.) of IV in 10 ml. of acetic anhydride was heated under reflux for about 3 hr., when V began to appear. When it had then been cooled at room temperature for a few hours, V filtered off. Yield, 0.085 g. (91%); m. p. 259~260°C (decomp.)

IR (Nujol mull): 1747, 1675 (cyclic amide) cm^{-1}.

Found: C, 37.60; H, 2.50; N, 10.81. Cacld. for $C_8H_6N_2O_4S_2$: C, 37.20; H, 2.34; N, 10.84%.

L-Cysteine (I).—*By Hydrolysis with Hydrochloric Acid.*—A solution of 3.0 g. (0.02 mol.) of II in 20 ml. of 6 N hydrochloric acid was heated on steam-bath for 20 hr. I was isolated from the hydrolizate in the usual way. Yield, 1.0 g. (40%). All the properties of this sample were identical with those of an authentic sample.

Treatment with Mercuric Chloride.—To a suspension of 3.0 g. (0.02 mol.) of II in 50 ml. of water, a solution of 10.0 g. (0.037 mol.) of mercuric chloride in 80 ml. of water was added. After it had been shaken at 75°C for 15 min., this mixture was

6) D. Ben-Ishai, *J. Am. Chem. Soc.*, **78**, 4962 (1956).

allowed to stand at room temperature for 40 hr. A mercaptide which was precipitated was filtered and I was isolated from the mercaptide in the usual way. Yield, 0.8 g. (32%).

***N,N'*-Dibenzoyl-L-cystine Diethyl Ester (VI).**—Thirty grams (0.067 mol.) of *N,N'*-dibenzoyl-L-cystine[7] was esterified with hydrogen chloride in absolute ethanol in the usual way. Yield, 31.3 g. (78%). It melted at 183~185.5°C after recrystallization from absolute ethanol and gave $[\alpha]_D^{30}$ +13.3° (*c* 0.5, 99% ethanol).

Found: C, 56.96; H, 5.50; N, 5.33; S, 12.35. Calcd. for $C_{24}H_{28}N_2O_6S_2$: C, 57.14; H, 5.59; N, 5.55; S, 12.71%.

***N*-Benzoyl-L-cysteine Ethyl Ester (VII).**—To a suspension of 20 g. (0.037 mol.) of VI in 300 ml. of 50% ethanol, 20 g. of zinc dust and 50 ml. of acetic acid were added and heated with occasional shaking at 50~60°C for about 1 hr., or until the VI had been dissolved. After it had stood overnight at room temperature, the solution was evaporated to a small volume in vacuo under an atmosphere of nitrogen and extracted with benzene. The extract was evaporated to dryness in vacuo, and the residue was recrystallized from ethanol. Yield, 15 g. (70%); m. p. 85~89°C, $[\alpha]_D^{30}$ −30.6° (*c* 1.6, 99% ethanol).

Found: C, 56.38; H, 5.86; N, 5.32; S, 12.77. Calcd. for $C_{12}H_{15}NO_3S$: C, 56.91; H, 5.97; N, 5.53; S, 12.66%.

***N*-Benzoyl-*S*-chlorocarbonyl-L-cysteine Ethyl Ester (VIII).**—Phosgene was passed into a stirred suspension of 10 g. (0.036 mol.) of VII in 160 ml. of benzene at 5~10°C for 1 hr. VII was dissolved into a solution by additional stirring at room temperature for 2~3 hr. The next day, carbon dioxide was passed through the solution to remove the excess phosgene and the organic layer was evaporated to dryness in vacuo. The residue obtained was recrystallized from benzene. Yield, 10 g. (80%); m. p. 119~122°C (decomp.)

L-3-Benzoyl-4-ethoxycarbonyl-2-oxothiazolidine (IX). — Five grams (0.016 mol.) of VIII was refluxed in 100 ml. of xylene for about 6 hr., or until no hydrogen chloride had been evolved. After the removal of the solvent, the residue was recrystallized from benzene or xylene. Yield, 3.5 g. (79%); m. p. 130~132°C, $[\alpha]_D^{15}$ +18.0° (*c* 0.5, benzene).

IR (Nujol mull): 1735 (ester), 1710 (benzoyl), 1695 (cyclic amide) cm^{-1}.

Found: C, 55.94; H, 4.91; N, 4.88; S, 11.16. Calcd. for $C_{13}H_{13}NO_4S$: C, 55.91; H, 4.70; N, 5.02; S, 11.48%.

The Treatment of *N*-Acyl-thiazolidone Derivatives with Alkali. — a) To a solution of 0.38 g. (0.002 mol.) of III in 10 ml. of acetone and 10 ml. of water, 5 ml. (0.006 mol) of 1.25 N sodium hydroxide was added. After it had stood (and occationally been shaken) at room temperature for 1 hr., the mixture was acidified with 6 N hydrochloric acid and concentrated to drynes in vacuo. The residue was extracted with ethanol, and II was obtained from this ethanol extract. Yield, 0.24 g., (82%); m. p. 171~172°C (decomp.), $[\alpha]_D^{15}$ −57.8° (*c* 2.1, water). Its infrared absorption spectra were identical with those of the cyclized product of L-cysteine.

b) In a similar way, 3 g. (0.011 mol.) of IX were hydrolyzed with 1.2 g. (0.022 mol.) of potassium hydroxide in 40 ml. of 70% ethanol. After the removal of the benzoic acid, II was obtained. Yield, 0.9 g. (57%); m. p. 171~172.5°C (decomp.), $[\alpha]_D^{19}$ −56° (*c* 3.0, water).

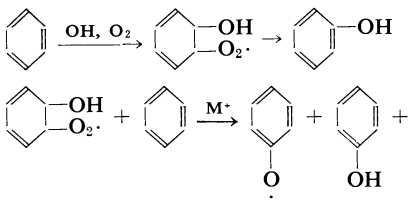
The Thermal and Radiation Oxidation of Benzene to Phenol in Aqueous Solutions Containing Metal Ions at Elevated Temperatures. IV. The Effect of Impurities in Benzene



By Nobutake SUZUKI and Hiroshi HOTTA

(Received September 9, 1963)

The oxidation of benzene to phenol catalyzed by metal ions has been studied in aqueous solutions under high oxygen pressure at elevated temperatures.[1,2] In a ferrous sulfate solution, phenol is produced in a good yield either with or without gamma-ray irradiation.[1] In a ferric sulfate solution, phenol is similarly produced by irradiation, but only above 180°C when not irradiated.[1] In a cupric sulfate solution, phenol is produced above 180°C either with or without irradiation.[2]

These facts have been interpreted as follows:[1,2] The chain processes of benzene oxidation are:

1) H. Hotta, A. Terakawa, K. Shimada and N. Suzuki, This Bulletin, **36**, 721 (1963).
2) H. Hotta, N. Suzuki and A. Terakawa, ibid., **36**, 1255 (1963).

(1)

(2)

$$PhO + PhH = PhOH + Ph \quad (3)$$

$$Ph + O_2 = PhO_2 \quad (4)$$

$$PhO_2 + PhH = PhO_2H + Ph \quad (5)$$

$$PhO_2H + M^{2+} = PhO_2 + H^+ + M^+ \quad (6)$$

$$PhO_2H + M^+ = PhO + OH^- + M^{2+} \quad (7)$$

$$2PhO_2 = 2PhO + O_2 \quad (8)$$

where Ph represents the phenyl radical, M^+, the ferrous or cuprous ion, and M^{2+}, the ferric or cupric ion. The OH radicals for the initiation reaction 1 are produced from the reactions:

$$H_2O \rightsquigarrow H, OH, H_2, H_2O_2 \quad (9)$$

$$M^+ + O_2 + H^+ = M^{2+} + HO_2 \quad (10)$$

$$HO_2 \text{ or } H_2O_2 \xrightarrow{M^+} OH \quad (11)$$

However, the phenol production above 180°C in non-irradiated ferric or cupric solutions cannot be interpreted in terms of the above reaction scheme because of a lack of reactions 9, 10 and 11. This fact suggests that there are some additional reactions above 180°C. Later, it has been found, as is shown in the present paper, that the results for carefully purified benzene are quite different from the previous results.[1,2] These observation will be interpreted in the present paper, together with the effect of impurities in benzene.

Experimental

Benzene was purified carefully by several methods, using mercury, sulfuric acid, sodium hydroxide, freezing, and distillation. The concentration of impurities in benzene with and without purification, analyzed by gas chromatography, using TCP-column at 70°C, is shown in Table I. Cyclohexane could not be separated by the present methods.

Benzene, with or without purification, was oxidized in neutral aqueous solutions of ferrous, ferric and cupric sulfates,[3] by means of the following procedure, as in the previous paper:[1] 1 cc. of benzene was put on 15 cc. of the aqueous phase in a hard-glass tube in a 50 cc. stainless-steel reactor under the oxygen pressure of 30 atm. Then this system was heated by a controlled procedure and kept for 30 min. at a given temperature. When it was irradiated, the dose was about 1.3×10^4 r of cobalt-60 gamma-rays for 25 min.

After cooling, it was analyzed by the same methods as in the previous papers.[1,2] A large portion of the iron species was precipitated above 160°C.

3) The initial concentration of metal ions was 0.01 M, except for the experiments shown in Fig. 4 and Table II.

Results and Discussion

The Ferrous Sulfate Solution. — The total amounts of phenol produced in the solution of 0.01 M ferrous, ferric and cupric sulfates[3] with (circle marks) and without (triangle marks) radiation are plotted against the reaction temperature in Figs. 1, 2 and 3 in order to compare purified (solid marks) and unpurified (open marks) benzene.

The yield of phenol from unpurified benzene is larger than that from purified benzene, even in the ferrous solution. This indicates that some peroxides are forced rseadily to initiae the chain process from the impurities in unpurified benzene, which is more readily oxidized than benzene. That is, the reaction

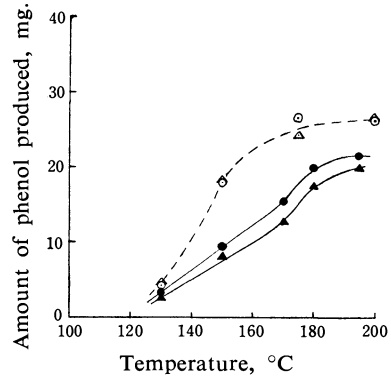


Fig. 1. Amounts of phenol produced in the irradiated (⊙ and ●) and non-irradiated (△ and ▲) neutral 0.01 M ferrous sulfate solutions, from purified (solid marks) and unpurified(open marks) benzene.

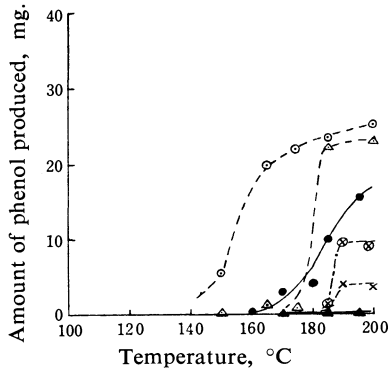

Fig. 2. Amounts of phenol produced in the neutral 0.01 M ferric sulfate solutions; circle and triangle marks are the same as in Fig. 1. The results in the non-irradiated solution for purified benzene containing toluene (3.3×10^{-3} M) and thiophene (4×10^{-4} M) are shown by ⊗ and × respectively.

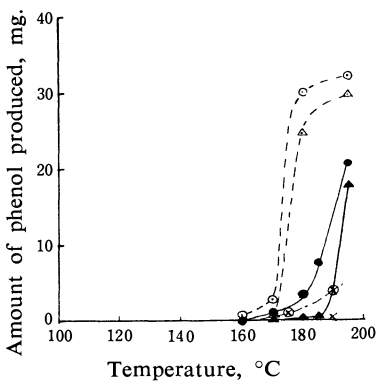

Fig. 3. Amounts of phenol produced in the neutral 0.01 M cupric sulfate solution; circle and triangle marks are the same as in Fig. 1. The results for purified benzene in the 0.01 M cupric sulfate—0.01 M ferric sulfate solution are show by ⊗ and × for the irradiated and non-irradiated cases respectively.

$$RH \xrightarrow{OH,\ O_2} \text{peroxide } (R'O_2) \qquad (12)$$

(RH: impurities in benzene)

should be assummed to be a faster initiation process than reaction 1 for cases of unpurified benzene. R' is not necessarily equal to R. It is known that a small of organic additives promotes the oxidation of benzene to phenol in the gaseous phase.[4]

The results in the ferrous sulfate solution, seen in Fig. 1, can be interpreted by means of the present reaction scheme.

The Irradiated Ferric Sulfate Solution.—The results in the irradiated ferric sulfate solution, shown by open and solid circles in Fig. 2, can also be interpreted by means of reaction 12. The remarkable decrease in the phenol yield upon purification indicates that the initiation process is reaction 12 rather than reaction 1. Even for purified benzene, the chain process might be initiated by the oxidation of cylohexane, which cannot be separated by the purification described previuosly. Accoring to Bach,[5] the yield of radiation oxidation is in the order of *n*-heptane>toluene>cyclohexane> benzene. Therefore, reactions 13—15:

$$R'O_2 + PhH = R'O_2H + Ph \qquad (13)$$

$$R'O_2H + M^{2+} = R'O_2 + H^+ + M^+ \qquad (14)$$

$$R'O_2H + M^+ = R'O + OH^- + M^{2+} \qquad (15)$$

should form the initial process instead of reactions 1 and 2. Phenyl radicals are consumed as in the previous scheme. Hydroxycyclohexadienyl peroxide, detected by Dorfman et al,[6] may not take a major part in the chain process at elevated temperatures; it does only as a precursor to phenol, as is shown in reaction 1. The greater part of the OH radicals from reactions 9, 10 and 11 are consumed by reaction 12 rather than by reaction 1, at least at the initial stage. The rate of the chromic acid oxidation of benzene is very slow in comparison with that of other compounds.[7]

When there are a large number of ferrous ions, as in the ferrous solution, reaction 2 may play some part in the initiation process (see Fig. 1). At any rate, it is certain that ferrous ions are indispensable to the chain process at lower temperatures in either reaction 2 or 12, for scarcely any phenol is produced below 160°C from purified benzene in Fig. 2, even when it is irradiated. It may also be concluded from a comparison of the results of purified benzene in the irradiated ferrous and in the same ferric solutions that the yield of OH radicals by in reaction 10 is much larger than that by reaction 9.

Since almost all of the iron species are ferrous in the solution after oxidation reaction, it is supposed that the rate of reaction 6 is faster than that of reaction 7. As phenyl peroxides are accumulated by reaction 6, they are converted to phenoxy radicals for reaction 3 by reaction 8.

Only a small amount of phenol is produced, even from unpurified benzene, at 200°C in an irradiated aqueous phase containing no metal ions, as is shown in Table I of Part II.[1] This is due to the lack of reactions 14 and 15, which regenerate $R'O_2$ and R'O.

The Non-irradiated Ferric Sulfate Solution.—As shown by open and solid triangles in Fig. 2, in the non-irradiated ferric sulfate solution, phenol is produced in a good yield above 180°C from unpurified benzene in spite of the lack of reactions 9, 10 and 11 to give OH radicals for reaction 12. On the other hand, purified benzene is hardly oxidized to phenol at least up to 200°C. Therefore, the initiation process for this case is attributed to the formation of hydroperoxides by oxygen from the impurities:

$$RH \xrightarrow{O_2} RO_2H \qquad (16)$$

The hydroperoxides are isolated for the oxiation of the compounds listed in Table I.[8,9] Since the hydroperoxides are built up to some

TABLE I. IMPURITY CONCENTRATIONS AND THEIR EFFECT

Impurity	Concn., M		Yield of phenol, mg.[a]	
	before purification	after purification	I[b]	II[c]
Carbon disulfide	4×10^{-4}	0	3.6	3.6
n-Hexane	4×10^{-4}	0	1.1	1.1
Cyclohexane	6.7×10^{-3}	6×10^{-3}	0.1	<0.1
Cyclohexene	$<2 \times 10^{-5}$e	0	0.4[d]	2.5
Thiophene	$<6 \times 10^{-4}$e	0	3.1[d]	3.0
Toluene	3.3×10^{-3}	0	9.9	3.4
Xylene	0	0	—	—

Note:

a) The amount of phenol produced at 190°C in the non-irradiated neutral ferric sulfate solution.
b) For benzene containing the same amount of the respective impurity as unpurified benzene.
c) For benzene containing 4×10^{-4} M of the respective impuritiy.
d) For benzene containing the amount of the upper limit before purification, noted by e, as an impurity.

extent above 180°C, they can propagate the chain process, as has been mentioned with regard to reaction 12. The rate of reaction 12 must be larger than that of reaction 16, especially at temperatures lower than 170°C, in view of the difference in unpurified benzene with and without irradiation.

To compare the relative promotive effect of the respective impurities, they were added separately, in portions as large as are present in unpurified benzene, to purified benzene. The amounts of phenol produced from this benzene at 190°C are shown in column I of Table I. The effect of toluene (3.3×10^{-3} M, ⊗) and thiophene (4×10^{-4} M, ×) were examined at other temperatures also, as Fig. 2 shows. Moreover, they are compared by adding an equal amount of 4×10^{-4} M, as is shown also in column II of Table I.

Although cyclohexane seems not, judging from Table I, to promote the production of phenol, its hydroperoxide is also actually isolated.[8] Therefore, a small amount of phenol production for non-irradiated purified benzene, as is seen in Fig. 2, may be attributed not to a trace amount of ferrous ions in the ferric solution, as was assumed in Part II,[1] but to cyclohexane as an impurity.

The Cupric Sulfate Solution.—All the results for the 0.01 M cupric sulfate solution, shown by circles and triangles in Fig. 3, are consistent with the above conclusions.

For the results of unpurified benzene, it is noticeable that the tendency is almost the same in the non-irradiated solution as for ferric sulfate, seemingly supporting reaction 16 as the common process. The lack of the production of phenol below 160°C for the irradiated case is attributed to the lack of cuprous ions because of the fast rate of cuprous oxidation if it is produced, as has been discussed in Part III.[2] On the other hand, phenol is produced in a good yield above 180°C. This is due to the build-up of indispensable cuprous ions over cuprous oxidation with the rise in temperature, which accelerates not only the formation of hydroperoxides but also their thermal decomposition by cupric ions.

Phenol is produced remarkably well at 200°C from purified benzene, even in the non-irradiated solution, in contrast to the case of ferric sulfate. This is due to the difference between the ion concentrations in the solution; that is, hardly any cupric sulfate is precipitated, even at 200°C, but ferric sulfate is almost all precipitated, up to less than 10^{-4} M. In fact, the yield of phenol decreases with a decrease in the cupric concentration, as is shown in Fig. 4, which gives the results of purified benzene in the non-irradiated aqueous

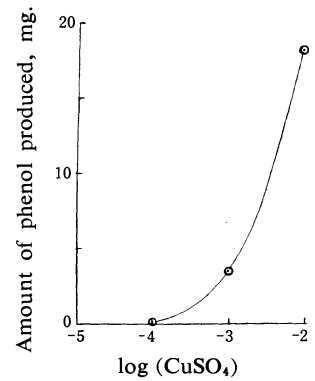

Fig. 4. Amount of phenol produced at 198°C purified benzene in the non-irradiated aqueous solution as a function of the concentration of cupric sulfate in M.

TABLE II. DEPENDENCE OF SULFATE CONCENTRATION

Composition of aq. soln., M				Amount of phenol produced (198°C) mg.	Ferrous concentration after reaction M
$CuSO_4$	$Fe_2(SO_4)_3$	Na_2SO_4	Total SO_4		
0.001	0	0	0.001	3.52	—
0.001	0.00005	0	0.00115	4.08	5.3×10^{-5}
0.001	0.0005	0	0.0025	1.50	5.1×10^{-5}
0.001	0	0.0015	0.0025	1.68	—
0.001	0.005	0	0.016	0.24	6.6×10^{-5}
0.001	0	0.015	0.016	0.50	—

solution of cupric sulfate. Such dependence of the cupric concentration was reported for unpurified benzene by Terakawa et al.[10]

The Cupric-Ferric Sulfate Solution.—As is shown in Fig. 3, the yield of phenol decreases in the irradiated (⊗) and non-irradiated (×) cupric sulfate solutions when 0.01 M ferric sulfate is added. The same fact is also shown for unpurified benzene in Fig. 3 of Part III.[2] For these cases, the concentration of iron species is no mere than 10^{-4} M at elevated temperatures due to precipitation, but the greater part of sulfate groups are still in the solution. On the other hand, the yield of phenol is suppressed in the concentrated sulfuric acid solution, as is seen in Fig. 1 of Part III.[2] This decrease in the yield is supposed to be attributable to the decrease in the cupric ion concentration due to the suppression of the dissociation of cupric sulfate effected by the addition of sulfate groups. To confirm this assumption, purified benzene was oxidized at 198°C without radiation in an aqueous solution of 0.001 M cupric sulfate by adding various amounts of ferric or sodium sulfate so as to give the equivalent sulfate concentration for both cases. The results, shown in Table II, indicate that the amounts of phenol produced are dependent on the total concentration of sulfate, but are independent of the kind of cation apparently supporting the above assumption.

Summary

The yield of phenol from the oxidation of unpurified benzene catalyzed by metal ions in an aqueous solution is much larger than from that of purified benzene. Phenol is produced in a good yield at temperatures lower than 160°C only in an oxygenated solution, in which OH radicals are produced, either with or without irradiation. Therefore, the autoxidation of impurities in benzene, initiated by OH radicals, is the initiation reaction of the chain oxidation process. On the other hand, phenol is also produce above 180°C even when OH radicals are not produced. Therefore, it is considered that the hydroperoxides of impurities are formed at higher temperatures without the OH radical by means of their autoxidation. Moreover, the yield of phenol in a cupric sulfate solution decreases remarkably with an increase in the sulfate concentration.

Spectroscopic and Theoretical Studies of Charge-Transfer Type Molecular Complexes between Monoölefins and Metal Ions: Selective Complex Formation Abilities of Copper(I), Silver(I) and Mercury(II) Ions

By Haruo Hosoya and Saburo Nagakura

(Received September 10, 1963)

Since Mulliken[1] developed the quantum-mechanical concept of the electron donor and acceptor with relation to the mechanism of molecular complex formation, both experimental and theoretical studies have been successively and successfully accomplished by many authors.[2] Rather little, however, is known about molecule-ion type complexes, such as the silver cation complexes with olefins and aromatic hydrocarbons; many problems are yet unsolved for this type of molecular complexes. Some of them are as follows:

i) Among the closed shell-type metal ions, why can only the copper(I), silver(I) and mercury(II) ions form stable complexes with monoölefins? [3,4]

ii) To what extent do the d-orbital electrons of these ions play a role in the complex formation,[5] and what kind of role is it?

iii) Do these monoölefin-metal ion complexes really show charge-transfer absorption bands? [6-8]

iv) Counter negative ions of silver salts affect the stability of the monoölefin-silver ion complexes. That is, the stability decreases in the order of $AgClO_4 > AgNO_3 \gg AgCl$, Ag_2SO_4.[7,8] How do we explain the difference in stability?

v) Is there any relation between the olefin-silver ion complex and the olefin-bromonium ion complex, which is known to be a reaction intermediate for the bromine addition reaction? [9]

The aim of the present study is to settle some of these problems as definitely as possible. In order to accomplish this purpose, we undertook to measure the ultraviolet, infrared and Raman spectra of the cyclohexene-silver perchlorate complex under various conditions, and to carry out some theoretical studies of the electronic energy levels of the complex. Furthermore, the stability of monoölefin-metal ion complexes will be discussed in detail in connection with the solvation energies of various metal ions.

Experimental

Materials. — Cyclohexene was distilled from cyclohexanol over a small amount of concentrated sulfuric acid. The distillate was dried with sodium metal and purified by repeating fractional distillation. Silver perchlorate of E. P. grade was used without further purification, since the infrared spectrum showed no marked difference between the cyclohexene complex with silver perchlorate recrystallized from acetone and that with the commercial silver perchlorate. Silver chloride precipitated from the mixture of aqueous silver nitrate and sodium chloride was dried over phosphorus pentoxide in the dark. Anhydrous cadmium perchlorate was synthesized from cadmium carbonate and perchloric acid, followed by dehydration at 100°C in vacuo.[10] Commercial silver nitrate, silver sulfate, potassium perchlorate, sodium perchlorate and magnesium perchlorate were used without further purification.[11]

Methanol, ethanol and tetrahydrofuran used as solvents were purified according to the standard methods.[12,13] Deuterated water (99.8%) was purchased from Asahi Kasei Co.

The cyclohexene-silver perchlorate complex was obtained by mixing the component substances directly and was recrystallized from ethanol.[14]

11) Cyclohexene was found immissible with aqueous $KClO_4$, $NaClO_4$, $Mg(ClO_4)_2$ and $Cd(ClO_4)_2$. The white crystals of cyclohexene-silver perchlorate were soluble in methanol, ethanol and tetrahydrofuran, but were insoluble in water, carbon tetrachloride and *n*-heptane. The mixture of cyclohexene with acetonitrile or concentrated sulfuric acid became turbid. The cyclohexene-silver perchlorate complex became yellowish the moment it came in contact with potassium bromide, indicating decomposition into silver bromide.

The cyclohexene-silver nitrate complex was crystallized from an ethanol solution of cyclohexene and silver nitrate at 0°C.[14]

Measurements of Ultraviolet Absorption Spectra. —A Cary recording spectrophotometer model 14 M was used for measuring ultraviolet spectra, fused quartz cells of 1 mm. light-path length being used. All the measurements were carried out at a constant temperature (20°C). The relatively strong absorption of the silver ion prevents us from measuring the spectra of solutions with concentrations higher than 0.1 N. The spectrum of cyclohexene was measured in aqueous silver perchlorate solutions with various concentrations and in a relatively concentrated aqueous cadmium perchlorate solution.

Measurements of Infrared and Raman Spectra. —A Hitachi EPI-2 infrared spectrophotometer, with a rock salt prism attached, was used for the infrared absorption measurements. Some of the solution spectra in the regions of 6 μ and 14 μ were measured with polyethylene bags. An envelope ca. 20×30 mm^2 was made from two sheets of polyethylene film 0.08 mm. thick, with no adhesive reagent but with moderate heating. The bag was then filled with a liquid sample and held by a commercial cell-window holder more or less tightly in order to avoid the wrinkling of the film and the vaporization of the solvent.

Raman spectra were measured with a Cary recording Raman spectrophotometer model 81 located at the Government Chemical Industrial Research Institute.[15]

Experimental Result for the Cyclohexene-Silver Perchlorate Complex

The Ultraviolet Absorption Spectrum of the Complex. — The absorption spectra measured with the cyclohexene-silver perchlorate-water system are shown in Fig. 1, whose ordinate represents the apparent molar extinction coefficients, ε's, the definition of which will be given later. As may be seen in Fig. 1, the ultraviolet absorption spectrum of cyclohexene in an aqueous silver perchlorate solution gradually but definitely increases its intensity with the increment of the salt concentration; in spite of less accuracy partly because of the relatively strong absorption of silver perchlorate ($\varepsilon=800$ at $\lambda_{max}=210$ mμ). This absorption change clearly shows that a new band appears at 220~230 mμ for the cyclohexene-silver perchlorate-water system. On the other hand, the spectrum of cyclohexene in an aqueous solution of 2 N cadmium perchlorate, like that of free cyclohexene, shows no absorption band above 220 mμ.

From a consideration of the equilibrium

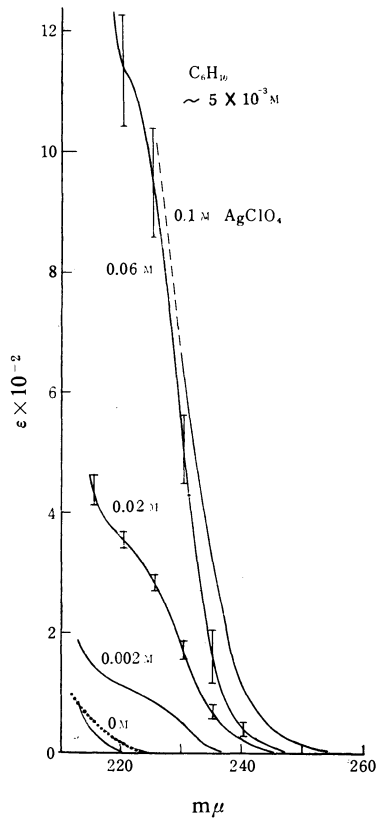

Fig. 1. Ultraviolet absorption spectra of cyclohexene in aqueous solutions of various concentrations of silver perchlorate (——) and of 1 mol./l. cadmium perchlorate (·····). Vertical lines represent the possible errors due to absorption by aqueous silver perchlorate solutions.

constant described below, we can safely conclude that the new band at about 220~230 mμ is due to the one-to-one complex of monoölefin and silver salt. This seems to mean that we could find Mulliken's[6] charge-transfer absorption band, which Salomon[7] and others[8] were unable to find for this system. Further details on the nature of this band will be discussed in a later part of the present paper.

Let us make a rough estimation of the equilibrium constant, K, for the system;

$$C_6H_{10} + AgClO_4 \rightleftharpoons C_6H_{10}\cdots Ag^+ClO_4^-$$

$$d-x \quad a-x \quad x \text{ (in mol./l.)}$$

$$K=x/(a-x)(d-x) \qquad pK=-\log K \qquad (1)$$

The apparent molar extinction coefficient of the complex, ε, can be defined by the following equation:[16]

15) The authors wish to express their hearty thanks to Miss Yuriko Matsubayashi of the Government Chemical Industrial Research Institute, Tokyo, for measuring the Raman spectra.

16) $\varepsilon=(I_T-I_A)/d$, where I_T and I_A are the optical densities of the cyclohexene-silver perchlorate-water system and the aqueous solution of silver perchlorate respectively; they can be represented by the following equations: $I_T=\{x\varepsilon_C+(a-x)\varepsilon_A\}$ (for $\lambda>220$ mμ) and $I_A=a\varepsilon_A$.

$$\varepsilon = x(\varepsilon_C - \varepsilon_A)/d \qquad (2)$$

where ε_C and ε_A are the molar extinction coefficients of the complex and silver perchlorate respectively at a certain wavelength. Setting d as a constant value, ε is dependent on the salt concentration (a), as is shown in Fig. 1, through the unknown parameters K and ε_C. By trial and error calculations, we actually estimated the pK and ε_C values in such a way that the dependence of ε on a can be explained as well as possible. The results are as follows:

$$pK = 0 \sim -2$$

$$\varepsilon_C = 10^3 \sim 10^4 \quad \text{for} \quad 220 \sim 230\ m\mu$$

Although the pK value obtained by the present authors is not accurate because of the superposition of the strong absorption of silver perchlorate, it is consistent with the value (pK = −1.9) obtained by Winstein and Lucas[3] from distribution experiments.

The Infrared and Raman Spectra of the Complexes. — The infrared absorption spectra of the Nujol and hexachlorobutadiene mulls of the solid complex of (cyclohexene)$_2$-$AgClO_4$[14] are shown in Fig. 2,[17] together with that of pure liquid cyclohexene. The former two spectra are in fairly good agreement with each other in the region where both solvents are transparent. The wave numbers of the observed bands of the complex are tabulated in Table I, compared with those of pure cyclohexene. The olefinic C–H out-of-plane bending band at 716 cm^{-1} shifts to a higher frequency, 748 cm^{-1}, in the complex. It is reported that this type of band in monoölefinic steroids also shifts to higher frequencies with the increasing strain in the ring.[18] The 900 and 1350 cm^{-1} bands intensified by the complex formation are assigned to C–H out-of-plane and in-plane bendings respectively. Although the assignment of the broad and weak 1900 cm^{-1} band has not yet been established, it is interesting to note that the frequency shift of +33 cm^{-1} is the same as that of 900 cm^{-1} band (+32 cm^{-1}). The olefinic C–H stretching band at 3020 cm^{-1} of free cyclohexene is weakend to

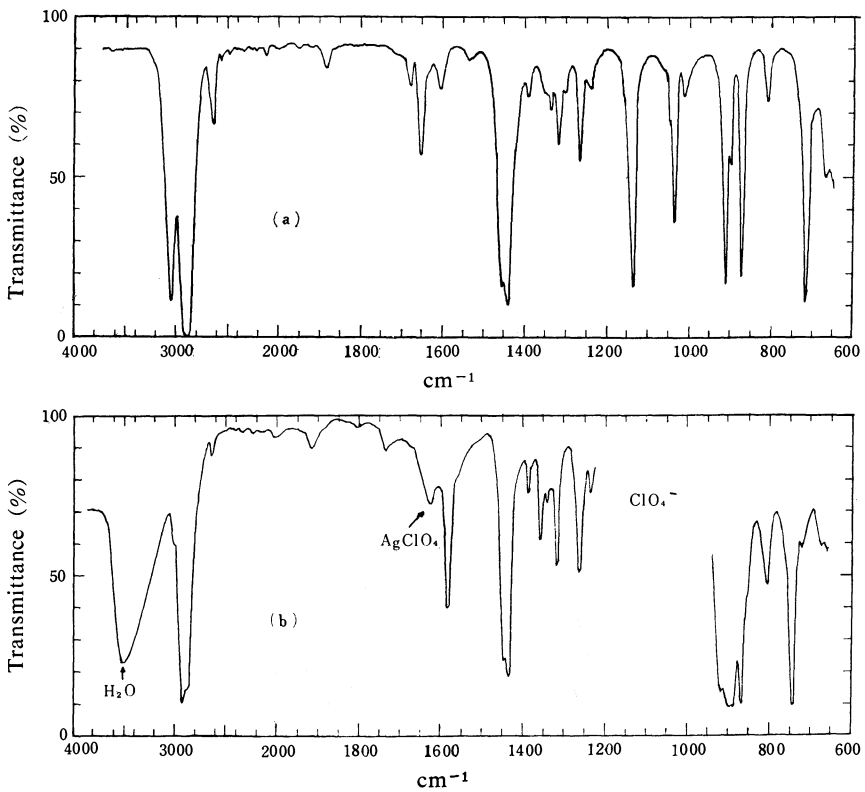

Fig. 2. Infrared absorption spectra of (a) pure cyclohexene and (b) the Nujol and hexachlorobutadiene mulls of the solid complex of $(C_6H_{10})_2 \cdots AgClO_4$.[17]

17) The Spectrum of the complex shown in Fig. 2b was synthesized by a complimentary combination of the spectra in Nujol and hexachlorobutadiene mulls. Accordingly, its absolute intensity is somewhat uncertain.

18) H. B. Henbest, G. D, Meakins and G. W. Wood, *J. Chem. Soc.*, **1954**, 800; H. B. Henbest, G. D. Meakins, B. Nicholls and R. A. L. Wilson, ibid., **1957**, 997.

* Masked by the solvent absorption.

a considerable extent and shifts to a lower frequency, 3000 cm^{-1}, by the complex formation. The band of the complex is so weak that there may be another possibility of its further shift down into the aliphatic C-H stretching frequency region. This fact suggests that the complex formation causes an increase in the strain or a decrease in the s-character in the carbon valence orbital of the C-H bond.

The change in the C=C stretching band is the most prominent. As may be seen in Fig. 3, where the infrared absorption spectra of the complex measured under various conditions are shown, the 1653 cm^{-1} in free cyclohexene

is lowered to 1582 cm^{-1} by the complex formation. The result was confirmed by the Raman spectrum measured with the complex under various conditions. This is also consistent with the observation by Taufen et al.[19,20] that the frequency of the ν(C=C) Raman band of cyclohexene is 1575 cm^{-1} in a concentrated silver nitrate solution. The weaker broad peak near 1625 cm^{-1} in the infrared absorption of the complex also appears in the spectrum of the Nujol mull of silver perchlorate and can not be attributed to the absorption of the complex.

All of these changed bands of the complex are pertinent to the C=C double bond part. This probably indicates that the silver ion attacks the C=C bond, weakening its double bond character and giving rise to some strain in the olefinic part. Table II summarizes the observed infrared and Raman bands in 6 and 14 μ regions of cyclohexene under various conditions.[21] It is striking that the perturbed C=C stretching frequencies are almost the same in the solid complex (1582 cm^{-1} for $(C_6H_{10})_2\cdots AgClO_4$) and in the complex in solution (1585 cm^{-1} for $C_6H_{10}\cdots AgClO_4$). This seems to suggest that the complex is in a similar state in a solid and in a solution.

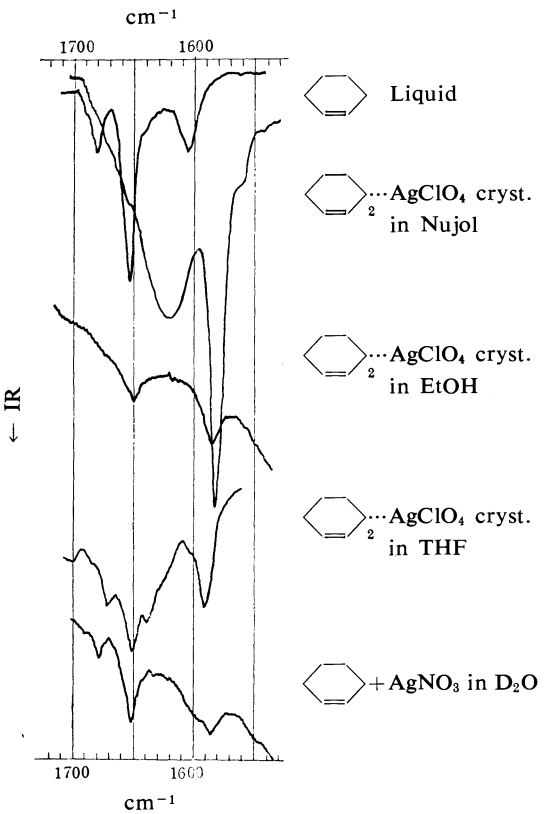

Fig. 3. Infrared absorption spectra of the 6 μ region of cyclohexene under various conditions.

A Theoretical Consideration of the Cyclohexene-Silver Perchlorate Complex

In the present theoretical study, the geometry of the cyclohexene-silver ion complex was assumed to be shown in Fig. 4 by analogy with those of the benzene-silver perchlorate[22a] and cycloöctatetraene-silver nitrate[22b] complexes. The electronic states of the complex were calculated by considering the interaction among the ground configuration and the several excited configurations caused by local excitations within the components and by charge-transfers between them.[23,24]

Component AO's and MO's.—For the olefinic part, besides the $2p\pi$ bonding (φ_1) and $2p\pi^*$ antibonding (φ_2) orbitals, the $3s\sigma$ bonding (φ_3) orbital was taken into account. These molecular orbital wave functions can be represented as follows:

$$\varphi_1=(\chi_1^{2p}+\chi_2^{2p})/\sqrt{2(1-S_{2p\pi})} \quad (3)$$

$$\varphi_2=(\chi_1^{2p}+\chi_2^{2p})/\sqrt{2(1-S_{2p\pi})} \quad (4)$$

$$\varphi_3=(\chi_1^{3s}+\chi_2^{3s})/\sqrt{2(1+S_{3s})} \quad (5)$$

Concerning the silver ion, two of the five 4d orbitals, $4d_{zx}$ (χ_d) and $4d_{z^2}$ (χ_e) and 5s (χ_s) orbitals were considered,[25] the x, y and z axes being taken as shown in Fig. 4. The component orbitals φ_1, φ_3, χ_e and χ_s are symmetric ($S=A_1$), while φ_2 and χ_d are antisymmetric ($A=B_2$) with respect to the σ_v plane. All the atomic orbitals are of the Slater type.

20) This is the only spectroscopic result reported hitherto about this type of complex.

21) All cyclohexene molecules interact with silver perchlorate in the solid complex, while in alcoholic and tetrahydrofuran solutions the complex and the free components are in equilibrium. The cyclohexene-silver nitrate complex is also in equilibrium with free components in (deuterated) water. Contrary to this, Taufen et al.[18] obtained no Raman band of free cyclohexene in its aqueous silver nitrate solution.

24) J. Tanaka, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zassi)*, **78**, 1636 (1957); **79**, 1373 (1958); S. Nagakura, *Mol. Phys.*, **3**, 105 (1960); H. Hosoya, J. Tanaka and S. Nagakura, This Bulletin, **33**, 850 (1960); H. Hosoya, J. Tanaka and S. Nagakura, *Tetrahedron*, **18**, 859 (1962).

25) The $4d_{x^2-y^2}$ orbital with A_1 symmetry character is excluded from the calculation, because of its smaller overlap with φ_1 or φ_2 (see Figs. 5 and 6 in Ref. 62). The remaining $4d_{xy}$ and $4d_{yz}$ orbitals can not interact with the φ_1, φ_2 and φ_3 MO's of the olefinic part because of their different symmetry properties.

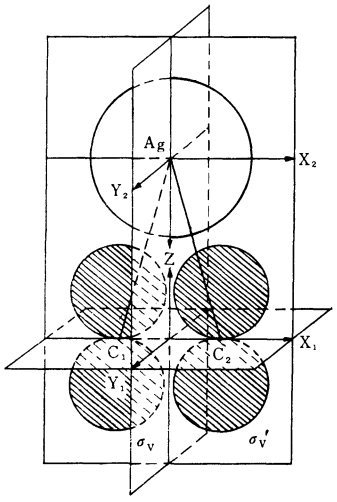

Fig. 4. The geometry of the monoölefin-metal ion complex. For $C_6H_{10}\cdots Ag^+$ the C_1-C_2 and the two Ag-C distances are 1.34 and 2.50Å, respectively.

Configurations and Their Energies.—Five symmetric (ψ_N, ψ_P, ψ_Q, ψ_R and ψ_S) and three antisymmetric (ψ_V, $\psi_{Q'}$ and $\psi_{S'}$) singlet configurations were taken into consideration. These configurations are given in Table III and Fig. 5. Among them, ψ_N, ψ_P and ψ_Q correspond to the no-bond, σ-type charge-transfer and π-type charge-transfer structures[5] respectively. The ψ_S (d-s transition) is the configuration in which one of the 4d orbital electrons of silver ion is excited to the 5s orbital. The importance of ψ_R (corresponding to the Rydberg transition in the olefinic part) has hitherto been overlooked; its inclusion is one of the important characteristics of the present theoretical treatment.[26]

The energy of the no-bond configuration, E_N, being taken as the standard, E_V and E_R can be taken to be equal to the observed transition energies corresponding to the N→V ($\pi\rightarrow\pi^*$ 6.79 eV.) and N→R (Rydberg 5.92 eV.) transitions of cyclohexene respectively.[27] E_S and $E_{S'}$ (5.71 eV.), the so-called singlet d-s separation energy, were obtained from the

26) The important role of the $3s\sigma$ bonding orbital in the charge-transfer process will be explained in a coming paper about the mechanism of "trans-addition."

TABLE III. ELECTRONIC CONFIGURATIONS FOR THE $C_6H_{10}\cdots d^{10}$ TYPE METAL ION COMPLEXES

Symmetric

$\psi_N=(1\bar{1}d\bar{d}e\bar{e})$ [a]	
$\psi_P=1/\sqrt{2}\{(1s\bar{d}de\bar{e})+(s\bar{1}d\bar{d}e\bar{e})\}$	Charge-transfer (σ-type)
$\psi_Q=1/\sqrt{2}\{(1\bar{1}d2e\bar{e})+(1\bar{1}2d\bar{e}e)\}$	Back charge-transfer (π-type)
$\psi_R=1/\sqrt{2}\{(13d\bar{d}e\bar{e})+(3\bar{1}d\bar{d}e\bar{e})\}$	Rydberg
$\psi_S=1/\sqrt{2}\{(1\bar{1}d\bar{d}es)+(1\bar{1}d\bar{d}s\bar{e})\}$	d-s Transition

Antisymmetric

$\psi_V=1/\sqrt{2}\{(12\bar{d}d\bar{e}e)+(2\bar{1}d\bar{d}e\bar{e})\}$	N → V Transition
$\psi_{Q'}=1/\sqrt{2}\{(1\bar{1}d\bar{d}e2)+(1\bar{1}d\bar{d}2\bar{e})\}$	Back charge-transfer (π-type)
$\psi_{S'}=1/\sqrt{2}\{(1\bar{1}ds\bar{e}e)+(1\bar{1}s\bar{d}e\bar{e})\}$	d-s Transition

a) The complete form is expressed as follows:

$$(1\bar{1}d\bar{d}ee)=\frac{1}{\sqrt{6!}}\sum_P(-1)^P P\begin{Bmatrix}\varphi_1(1) & \varphi_1(2) & \chi_d(3) & \chi_d(4) & \chi_e(5) & \chi_e(6)\\ \alpha(1) & \beta(2) & \alpha(3) & \beta(4) & \alpha(5) & \beta(6)\end{Bmatrix}$$

atomic spectral data collected by Moore.[28] The energies of the three charge-transfer configurations were calculated by means of the following equations:

$$E_P=I_{C_6H_{10}}-A_{Ag^+}+0.8\cdot S_{Ag^+}$$
$$=9.00-7.58+4.45=5.87\text{ eV}.$$
$$E_Q=E_{Q'}=I_{Ag^+}-A_{C_6H_{10}}-2e^2/R-0.8\times 3/4S_{Ag^+}$$
$$=21.49+0.10-11.52-3.34=6.73\text{ eV}.$$

where the I's and A's are ionization potentials and electron affinities respectively. $A_{C_6H_{10}}$ was assumed to be -0.10 eV. so as to make the sum $I+A=8.90$ eV. for alternant hydrocarbons.[29] S_{Ag^+}, the hydration energy of the silver ion, was calculated by Oshida and Horiguchi.[30] R is the distance between the silver ion and one of the olefinic carbon atoms, 2.50 Å. A detailed description of the derivation of these equations will be given later in this paper.

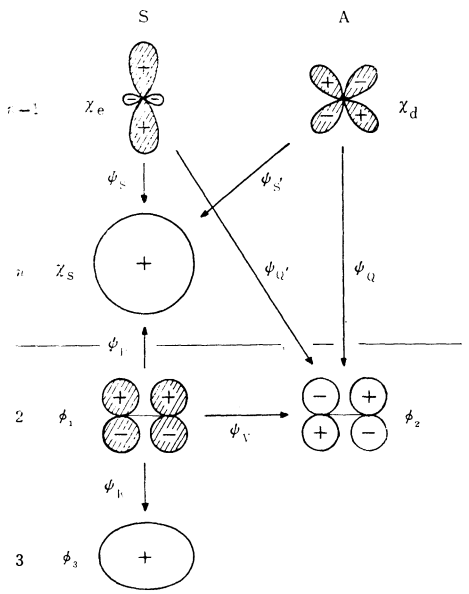

Fig. 5. Schematic representation of the component orbitals and the electron configurations important for the ground and lower excited states of the monoölefin-d^{10} type metal ion complex. These atomic or molecular orbitals are shaded which are doubly occupied in the ground configuration ψ_N. The letters $n-1$ and n for the metal ion and 2 and 3 for the monoölefin indicate the principal quantum numbers of the orbitals in the respective row, while the letters S (symmetric) and A (antisymmetric) represent the symmetry properties, with respect to the σ_V plane, of the orbitals in the respective column. The configurations represented by the vertical arrow have the same symmetry property as the ground configuration does and contribute to lower its energy.

Configurational Interaction.—The off-diagonal matrix elements of the total electronic Hamiltonian were accounted for only by means of the core resonance integral β.[31] For example:

$$H_{NP}=1/\sqrt{2}\int(1\bar{1}d\bar{d}ee)H\{(1s\bar{d}de\bar{e})+(s\bar{1}d\bar{d}e\bar{e})\}d\upsilon$$
$$=\sqrt{2}\int\varphi_1 H^{(1ddee)}\chi_s\,d\upsilon=\sqrt{2}\beta_{1s}^{(1ddee)}$$

29) N. S. Hush and J. A. Pople, *Trans. Faraday Soc.*, **51**, 600 (1955).

30) I. Oshida and D. Horiguchi, *Bull. Kobayashi Inst. Phys. Res.*, **5**, 61 (1955) (in Japanese); *J. Phys. Soc. Japan*, **11**, 330 (1956).

31) Generally speaking, the off-diagonal matrix elements comprise non-zero terms due to two-center Coulomb repulsion integrals. For example, $H_{RS}=(13\mid se)=\int\varphi_1^*(1)\times\varphi_3(1)(e^2/r_{12})\chi_e^*(2)\chi_S(2)d\upsilon$ contains non-zero Coulomb repulsion integral terms. However, this can be disregarded, as is clear from the following consideration. H_{RS} can be represented approximately by $\mu_{13}\cdot\mu_{es}/R$, where $\mu_{13}=e\int\varphi_1 r\varphi_3 d\upsilon$ and $\mu_{es}=e\int\chi_e r\chi_S d\upsilon$. The latter quantity is zero because it corresponds to the transition moment between s and d orbitals within the silver atom. The $H_{VS'}=(12\mid ds)$ value can also be disregarded.

Table IV. Effective charges and ionization energies of electrons for various states of cyclohexene obtained from spectroscopic results

Electronic configuration[a]	Ionizing electron	Slater's μ factor[38]	Ionization energy, eV.	Remark[b]
(11)	1	1.625	9.00	$=I_{C=C}$
(112)	2	1.45	−0.10	$=A_{C=C}$
(12)	2	1.625	2.21	$=I_{C=C}-\Delta E_{N\to V}$
(13)	3	0.483	3.08	$=I_{C=C}-\Delta E_{N\to R}$
(112)	1	1.45	6.69	$=\Delta E_{N\to V}+A_{C=O}$

a) 1, 2 and 3 are the molecular orbitals φ_1, φ_2 and φ_3, respectively.
b) I: Ionization potential;[33,34] A: Electron affinity (assumed); ΔE: Transition energy[27]

where $\beta_{1s}^{(1dd\epsilon e)}$ is the core resonance integral between the φ_1 and χ_s orbitals in the core potential field of $\boldsymbol{H}^{(1ddee)}$, which is the common part in the two configurations, ψ_N and ψ_P. According to Mulliken,[32] this value is approximated as proportional to the product of the overlap integral, $S_{1s}^{(1dd\epsilon e)}$, and the mean ionization potential, $\bar{I}$.

$$\beta_{1s}^{(1dd\epsilon e)}=C\cdot S_{1s}^{(1dd\epsilon e)}\cdot\bar{I}$$
$$=C\cdot S_{1s}^{(1dd\epsilon e)}\{I(11\to1)+I(ddees\to ddee)\}/2 \quad (6)$$

Here C is a constant, and $I(11\to1)$ and $I(ddees\to ddee)$ are the ionization potentials of cyclohexene and of the silver atom respectively.

The first ionization potential of cyclohexene was determined to be 9.00 eV. from the data of Watanabe[33] and others.[34] The values of the ionization energies for the other states of cyclohexene were estimated by combining the first ionization potential value with the spectroscopic data (see Appendix I). These values are summarized in Table IV, while the values for the metal ion part were taken from Moore's table.[28] The overlap integrals were mostly calculated from the published tables[35-37] but partly, where necessary, from our new tables (see Appendix II) by assuming appropriate effective charges for the Slater-type AO's.[38] The formulae for the iterative degradation of overlap integrals between the various types of d-orbitals and the olefinic p-orbitals into simpler forms are listed in Appendix III. The proportional constant, C, was evaluated to be -1.0,[39] by taking into account the following relation for ethylene:

$$\beta=C\cdot S\cdot I_C=-3.125$$
$$=-1.003\times0.270\times11.54 \text{ (eV.)}$$

where β is the value adopted by Pariser and Parr[41] and I_C, the $2p\pi$ valence state ionization potential of a carbon atom.[42] The non-zero off-diagonal elements thus obtained are included in Table IX.

The Stabilization Energy and the CT-R Band of the Cyclohexene-Silver Perchlorate Complex. —The secular equations constructed from the matrix elements evaluated as mentioned above were solved by the aid of an IBM 7090 electronic computer. Among the evaluated energy levels and wave functions, those for the lowest three levels are tabulated in Table V (see also Fig. 6).

According to the present theoretical study, the complex is stabilized by charge-delocalization by about 1.05 eV., with the 7.4 and 6.9 per cent contributions of the ψ_P and ψ_Q charge-transfer configurations respectively. The Rydberg configuration contributes to the ground state by 2.0 per cent. The in-phase mixing of the widely extended $3s\sigma$ orbital with the $2p\pi$ bonding orbital corresponds to the polarization of the latter electronic cloud toward the silver ion, especially in the outer skirts.

38) J. C. Slater, *Phys. Rev.*, **36**, 57 (1930).
39) If Eq. 6 be taken as proven, two problems still remain. One is whether the use of Slater-type wave functions for the silver 4d and 5s orbitals gives correct values for the overlap integrals, S's, which in principle should be calculated with the SCF orbitals. According to the test calculation by Mulliken et al.,[35] there arose no serious dircrepancy between the $S(2p\sigma C, 2p\sigma C)$ values calculated with Slater-type and SCF functions, especially for the bond length region around 2 Å (the S(SCF)/S(Slater) ratio being 1.4~0.7). By the use of numerical tables for metal s-orbitals calculated by Hartree et al.[40] with the SCF method, the $S(2p\sigma C(\text{Slarer}), 4sZn^+(\text{SCF}); 2.06 \text{ Å})$ value was numerically calculated and compared with the $S(2p\sigma C(\text{Slater}), 4sZn^+(\text{Slater}); 2.06 \text{ Å})$ value. The agreement was found unexpectedly well (the ratio being 1.2=0.21/0.17).
The other is whether the semi-empirical parameter, C, is applicable to the intermolecular lateral overlaps. In the present study, we have made calculations for the three cases of $C=-0.6$, -0.8 and -1.0.

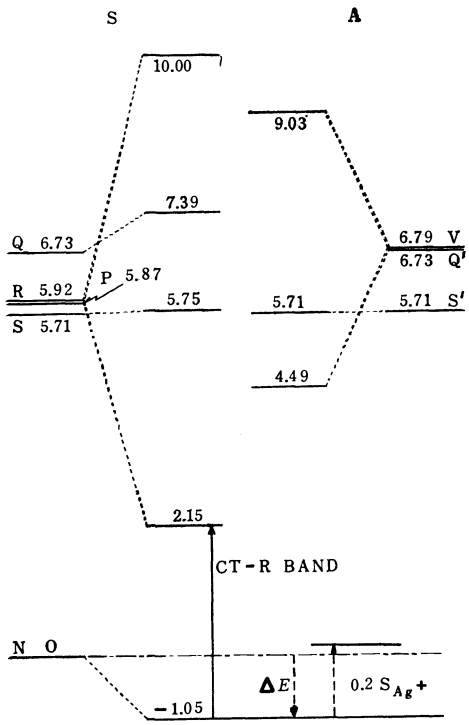

Fig. 6. Energy diagram (in eV.) for the $C_6H_{10}\cdots Ag^+$ complex in water showing configuration interaction, stabilization (ΔE) and destabilization ($0.2\cdot S_{Ag^+}$), and CT-R transition.

The stabilization energy of 1.05 eV. should not be taken literally, since the silver ion is destabilized by the replacement of a portion of the hydrated water molecules by a non-polar olefin molecule. This energy may be estimated to be about two-tenths of the hydration energy of a silver ion, because the solid angle spanning the cyclohexene molecule from the silver ion in this geometry is just two-tenths of the whole angle. Since the hydration energy of the silver ion is 5.56 eV.,[30] the destabilization energy due to the destruction of the water sheath may be estimated to be 1.11 eV. This is consistent with the electrostatic calculation by Eley and Evans[43] that the enegy requirement for removing one water molecule from the hydration sphere of the silver ion is larger than 20 kcal./mol. (=0.87 eV.). The most important point in the present treatment is that the olefinic π-electron stabilization energy (1.05 eV.=24.2 kcal./mol.) is comparable to the lost hydration energy (1.11 eV.=25.6 kcal./mol.).

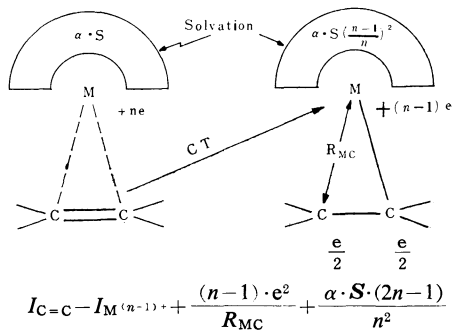
The lowest excited state, with 42 and 39 per cent contributions by the ϕ_P and ϕ_R configurations respectively, is only 3.2 eV. higher than the ground state. The poor agreement between the observed (~5.4 eV.) and calculated (~3.2 eV.) values may possibly be attributed to the use of the macroscopic hydration energy (see later) obtained from the Born-Haber cycle instead of the structure-dependent microscopic hydration energy, and to the lack of detailed quantitative knowledge about the electronic states of larger atoms with d-electrons and intermolecular interaction energies. However, as is evident in Table VI, for calculation with C values varying from −0.6 to −1.0, the lowest excited state is invariably 2 eV. lower than the next higher excited state (V state) and its character is invariant. Namely, ϕ_P and ϕ_R contribute to the lowest excited state by almost the same amount, 40 per cent. The new band at about 230 mμ for the cyclohexene-silver ion complex is, then, determined to have the mixing character of charge-transfer from the olefin to the silver ion and the Rydberg transition in the olefin part (CT-R band).

43) D. D. Eley and M. G. Evans, *Trans. Faraday Soc.*, **34**, 1093 (1938).

A Theoretical Consideration of the Selective-Complex Formation Abilities of Copper(I), Silver(I) and Mercury(II) Ions[44]

In order to clarify the reason why some of the closed shell (d^{10} and p^6)-type metal ions form stable complexes with olefins, while the others can not, we undertook to calculate the stabilization energy due to the electron delocalization for the systems containing various metal ions and cyclohexene, assuming reasonable geometrical configurations. A hypothetical monoölefin-metal ion complex is assumed to have the C_{2v} symmetry property (for the π-electronic part), with R_{MC} equal to $r_{M^{n+}}+1.32$ Å, where 1.32 Å is a constant determined in such a way that R_{MC} for the case of silver ions is equal to 2.50 Å.[51] The ionic and metallic raddii of silver ions are 1.18 and 1.34 Å, while the covalent radius of carbon atoms and the half thickness of aromatic molecules proposed by Pauling[52] are 0.77 and 1.70 Å respectively. That the sum of the respective mean values is equal to 2.50 Å is indeed a fortuitous coincidence, but it may be the ground for some possible additivity relationship.

Since the energy evaluations of the charge-transfer configurations are important in discussing the stabilities of various monoölefin-metal ion complexes, first of all a detailed description will be given of the evaluation of the charge-transfer configurational energy.



The Estimation of Charge-Transfer Configuration Energies. — The hydration energy of the metal ion may be thought to diminish greatly in the charge-transfer configuration compared with that of the ground configuration. Therefore, in the evaluation of the charge-transfer configuration energy, we must reasonably estimate the magnitude of the change of hydration energy. The solvation energy of a metal ion is known to be roughly proportional to the square of the charge number. If the solvated molecules are assumed not to change their positions during an electron transfer in the solvated cage, the decrease in solvation energy is approximately equal to

$$\alpha\,[n^2-(n-1)^2]/n^2\cdot S_{M^{n+}}=\alpha(2n-1)/n^2\cdot S_{M^{n+}}$$

where $S_{M^{n+}}$ is the solvation energy of a metal ion, M^{n+}, and α is a universal parameter representative of effective solvation by the olefin molecules. The energy necessary for an electron transfer from the olefin to the ion may then be estimated as follows:

$$H_{PP}=I_{C=C}-I_{M^{(n-1)+}}+(n-1)e^2/R_{MC}+\alpha\cdot S_{M^{n+}}\cdot(2n-1)/n^2 \qquad (7)$$

where $I_{C=C}$ and $I_{M^{(n-1)+}}$ indicate the ionization potentials of the olefin and the metal ion (or atom) $M^{(n-1)+}$, the latter quantity being identical to the electron affinity of the ion M^{n+}. The third term is the repulsion energy between charges of the metal and carbon atoms (see Fig. 7). In the above treatment, the change in the solvation energy of the olefinic part is disregarded, since the resulting net charge is divided into two carbon atoms and since, moreover, they are shielded by the other carbon and hydrogen atoms to a considerable extent. Even if it can not completely be disregarded, it may conceivably be included in the unknown parameter, α, the determination of which is the next problem.

$$I_{C=C}-I_{M^{(n-1)+}}+\frac{(n-1)\cdot e^2}{R_{MC}}+\frac{\alpha\cdot S\cdot(2n-1)}{n^2}$$

Fig. 7. Estimation of the charge-transfer configurational energy H_{PP}.

We have plotted the $(2n-1)\cdot S_{M^{n+}}/n^2$ $(=X)$ values for twenty-five d^{10} and p^6-type metal ions and for the halogen cations Br^+ and I^+ against the sum (Y) of the first three terms in Eq. 7 by using the following values: $I_{C=C}=9.00$ eV. for cyclohexene;[33] $I_{M^{(n-1)+}}$, from Moore's table;[28] $R_{MC}=1.32+r_{M^{n+}}$ Å, where the $r_{M^{n+}}$'s were taken from the table of ionic radii by Stockar;[53] the $S_{M^{n+}}$ value was taken from the table of hydration energies by Oshida and Horiguchi[30] (see Table VII). It may easily be shown that, for a fixed α value, the points for the metal ions with the same charge-transfer

44) The complexes considered here differ from such square planar Zeise salts as $K[(C_2H_4)\cdot PtCl_3]$[45], such transition metal carbonyl-olefin complexes as $C_5H_8\cdot Fe(CO)_3$[46] or such mercury ion-olefin addition compounds as $HO\cdot CH_2CH_2\cdot HgCl$,[47] which are shown to have true or nearly covalent metal-carbon bonds by the evidence of X-rays,[48] infrared absorption,[49] NMR spectroscopy[50] and from some other chemical properties.

a) $X=S_{M^{(n-1)+}}\cdot(2n-1)/n^2$ (eV.)

b) $Y=9.00-I_{M^{(n-1)+}}+(n-1)\cdot e^2/R_{MC}$ (eV.), $R_{MC}=1.32+r_{M^{n+}}$ (Å)

c) These values are $H_{P''P''}$'s, since $H_{P''P''}$ is smaller than H_{PP} for these ions.

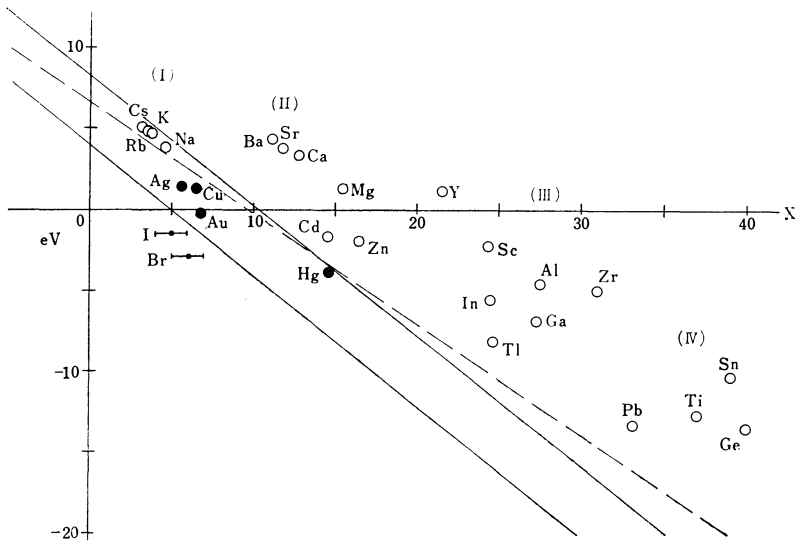

Fig. 8. Determination of α. The two parallel lines have α equal to 0.8, while the broken line 0.7. The Roman numerals indicate the charge numbers of the ions. The ions are classified into three groups:

○ without an ability of complex formation,

● with an ability of complex formation, and

I–•–I with a tendency for further addition reaction.

energy, $H_{PP}=Y+\alpha\cdot X$, lie exactly on a straight line with the slope $-\alpha$ and intercepting the Y axis at $Y=H_{PP}$. The Cu^+, Ag^+, Au^+ and Hg^{2+} ions, together with alkali metal ions, were found distinguishable from the others, since the points for the former ions lie beneath the line with α equal to about 0.8; this indicates that the former ions have lower H_{PP} values than the latter do. In spite of their higher electron affinities the trivalent and tetravalent ions show larger H_{PP} values. This is because the third and fourth terms of Eq. 7, namely, the electrostatic repulsion and solvation energy terms, become larger for these ions and compensate for the smaller value of the $I_{C=C}-I_{M^{(n-1)+}}$ term.

It is interesting to note that the plots for Br^+ and I^+ ions lie in the region for beneath the line, indicating their low H_{PP} values and, accordingly, the possibility of further addition reaction.

Similarly, the energies for the back charge-transfer H_{QQ}'s for twelve d^{10}-type metal ions were evaluated by the following equation:

$$H_{QQ}=I_{M^{n+}}-A_{C=C}-(n+1)e^2/R_{MC}-0.8\cdot S_{M^{n+}}(2n+1)/(n+1)^2 \quad (8)^{54)}$$

where $A_{C=C}$ is the electron affinity of cyclohexene, -0.10 eV. (estimated). Again, Cu^+, Ag^+, Au^+ and Hg^{2+} have much lower H_{QQ} values than do any other metal ions (see Table VIII). This fact is also closely related to the selected abilities of Cu^+, Ag^+ and Hg^{2+} for complex formation with monoölefins.

TABLE VIII. EVALUATION OF H_{QQ} VALUES

$R_{MC}=1.32+r_{M^{n+}}$ (Å)

The Estimation of Stabilization Energies for Various Monoölefin-Metal Ion Complexes.—The stabilization energies were estimated on the basis of charge-transfer configurational energies evaluated by the above-mentioned method.

The component MO's and AO's are the same as those for the silver complex. The effective charges and orbital energies were determined according to the Slater rule,[38] and by the atom ionization potentials and atomic spectral data,[28] respectively.

In this calculation, only the singlet symmetric (with respect to the yz plane), $^1A_1$, configurations are considered, because we are concerned with rough estimations of stabilization energies due to charge delocalization and of the loss in hydration energies. The H_{PP}'s for the d^{10}- and p^6-groups and the H_{QQ}'s for the d^{10}-group were estimated by the method described in the preceding section. H_{RR} is again 5.92 eV. Since, for the p^6-group ions, the energy separations between the ns- and np-orbitals are generally small (a few eV.), another charge-transfer configuration, $\psi_{P'}$ namely, the one caused by the charge-transfer from φ_1 to χ_{npz} (χ_p) was considered. For Sc^{3+}, Y^{3+}, Ti^{4+} and Zr^{4+}, with $(n-1)$d but not ns-orbital as the lowest vacant one, an extra charge-transfer configuration, $\psi_{P''}$, namely, the one caused by the charge-transfer from φ_1 to $\chi_{(n-1)dz^2}$ ($\chi_{e'}$; see Fig. 9) was considered. These configurational energies, $H_{P'P'}$ and $H_{P''P''}$'s, were determined by the algebraic addition of the doublet p-s ($(n-1)p^6\cdot ns\rightarrow(n-1)p^6\cdot np$) and d-s ($(n-1)p^6\cdot ns\rightarrow(n-1)p^6\cdot(n-1)d$) separation energies of $M^{(n-1)+}$ ion (or atom) to the H_{PP} values. The H_{SS}'s for the

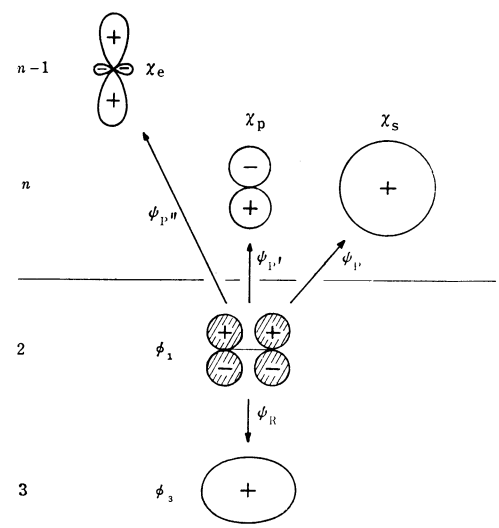

Fig. 9. Schematic representation of the component orbitals and the electron configurations (symmetric) of the hypothetical monoölefin-p^6 type metal ion complex. See the caption of Fig. 5.

54) The choice of $(2n+1)/n^2$ instead of $(2n+1)/(n+1)^2$ for the coefficient of $0.8\cdot S_{M^{n+}}$ in the last term was proved to give abnormally lower energies for H_{QQ}.

d^{10} group were determined as the singlet d-s separation energies ($d^{10}\rightarrow d^9\cdot s$) of M^{n+} ions. The offdiagonal elements were calculated in a manner similar to that used for a silver complex ($C=-1.0$). The non-zero matrix elements thus obtained for many metal ion complexes are tabulated in Tables IX and X. By solving the secular equations constructed from the matrix elements for each metal ion complex, the stabilization energy due to charge delocaliztion, ΔE, was evaluated. The results are shown in Table XI.

A Comparison of the Delocalization Energies Evaluated for Various Metal Ion Complexes.— In Table XI the $|\Delta E|$ values are compared with the $0.2\cdot S_{M^{n+}}$ values corresponding to the loss of hydration energy. As is evident from these results, the copper(I), silver(I), gold(I) and mercury(II) ions are distinguished from other closed shell-type metal ions with very small values of $(0.2\cdot S_{M^{n+}}-|\Delta E|)/0.2\cdot S_{M^{n+}}$ and are correlated with the very selective complex formation abilities except for the case of the gold(I) ion. The reason why the stable monoölefin-Au^+ complex can not exist may be due to the infrequent occurrence of the monovalent ion itself.

The fact that ψ_P and ψ_Q contribute to the ground state of copper(I), silver(I) and mercury(II) complexes by almost the same amounts seems to show the importance of the π-type back charge-transfer mechanism.[5] This may be supported by the fact that the p^6 group metal ions without outer d-electrons can not form stable complexes with monoölefins. The overlap integrals between the olefinic carbon, 2pz AO, and χ_s and χ_d have been shown not to deviate substantially from ion to ion, while the energies of the two charge-transfer configurations seem to correlate well with the complex formaton ability. It is interesting to note that a good correlation is also found with the smaller d-s separation energy (H_{SS}) for copper(I), silver(I) and mercury(II) ions

Table XI. Delocalization and destabilization energies of the hypothetical complexes of the C_6H_{10}···closed shell type metal ions

Ion	Delocalization energy $\lvert\Delta E\rvert$ eV.	Destabilization energy $0.2\cdot S_{M^{n+}}$ eV.	$\frac{0.2\cdot S_{M^{n+}}-\lvert\Delta E\rvert}{0.2\cdot S_{M^{n+}}}$

(see Table IX). As Orgel[55] has pointed out, the mixing of χ_{dz^2} orbital with a χ_s orbital facilitates the extension of the diagonal valency character.[56] The difficulty polyvalent ions have in forming complexes with olefins can be explained as follows. The destabilization energies ($0.2\cdot S_{M^{n+}}$) of metal ions in the same periodic row are proportional to the square of the charge number (n), whereas the competing delocalization energies (ΔE) were found to be roughly proportional to the three-halves order of the charge number (see Table XI). The reason why, among the divalent ions, mercury(II) ion alone has a selective complex formation ability is not attributed to the difference in its hydration energies or ionic radii but to the instability of its d^{10} state and, hence, its large electron affinity relative to other ions.

Although our calculations appear to be based on some bold assumptions and on arbitrarily numerical parameters, the results obtained here, specifically for the importance of the $3s\sigma$ orbital in the lowest excited state and for the selective complex-formation abilities of copper(I), silver(I) and mercury(II) ions, are invariant. Since both the method of the "composite molecule" and the concepts of charge-transfer and hybridization can be derived as consequeces of a mathematical development describing a true state in terms of quantities with clearer physical meanings, another approach, e.g., the LCAO MO method, to this problem would give similar results.

The Effect of Olefins and Negative Ions upon the Stability of Monoölefin-Metal Ion Complexes. — A similar calculation was made for the ethylene-silver ion complex. The ionization potential (10.52 eV.)[33] and the electron affinity (−1.81 eV.)[29] of the ethylene molecule and therefore, H_{PP} (7.49 eV.) and H_{QQ} (8.44 eV.) are different from those of cyclohexene. H_{VV} and H_{RR} are the observed $N\rightarrow V$ and $N\rightarrow R$ transition energies, 7.65 and 7.11 eV. respectively.[57,58] These four diagonal elements are larger than those for the cyclohexene complex. The other diagonal and all of the off-diagonal elements are just the same as were used for the cyclohexene complex.

With $C=-1.0$, the delocalization energy was evaluated to be 0.841 eV., which is smaller than that of the cyclohexene complex by 0.21 eV. This seems to mean that the silver ion complexes with ethylene and other simple monoölefins with higher ionization potentials may be more unstable than the cyclohexene-silver ion complex.

Although the effect of the anions of silver salts is disregarded in the present treatment, this is not the case experimentally. The cyclohexene-silver nitrate complex is stable only at a low temperature and no cyclohexene complexes have ever been known with silver salts other than the perchlorate and nitrate.[59] The different stabilities of these complexes seem to depend on the strengths of the interaction between the metal ions and the negative ions. Hence, the inability of silver chloride and sulfate to form complexes with cyclohexene may be explained by assuming that these anions have a strong affinity for silver cations.

Summary

The ultraviolet, infrared and Raman spectra of the cyclohexene-silver perchlorate complex

55) L. E. Orgel, "An Introduction to Transition-Metal Chemistry," Methuen & Co., London (1959), p. 67.

56) Winstein and Lucas[3] showed the existence of olefin-silver complexes with a 2:1 ratio in aqueous media. The solid complex also has the same composition ratio.[14] In both cases, a silver ion is supposed to be stacked in between two olefin molecules.[9]

57) P. G. Wilkinson and R. S. Mulliken, *J. Chem. Phys.*, **23**, 1895 (1955); G. Reid, ibid., **18**, 1299 (1950); D. F. Evans, *J. Chem. Soc.*, **1960**, 1735.

58) R. S. Mulliken, *J. Chem. Phys.*, **33**, 1596 (1960).

59) The possible existence of cyclohexene-silver fluoborate is anticipated.

TABLE XII. ELECTRONIC TRANSITION ENERGIES (IN eV.) OF CYCLOHEXENE AND ETHYLENE WITH VIBRATIONAL PROGRESSIONS (IN PARENTHESES, IN cm^{-1})

	V_{peak}	R_{OO}	T_R	T_{peak}
Cyclohexene	6.79	5.92 (1450)	4.9 (900)	3.8 (1200~1300)
Ethylene[27,57,58]	7.65 (850)	7.11 (1375)	6.4 (1400)	4.6 (~1000)
Electronic configration and spin multiplicity of the upper state	$^1(12)$	$^1(13)$	$^3(13)$	$^3(12)$

have been measured under various conditions. A new band has been found in the 220~230 mμ region for the complex in an aqueous solution; it has been found to have the mixing character of the charge-transfer from the olefin to the metal ion and of the Rydberg transition within the olefin molecule. The equilibrium constant (pK) has been evaluated spectrophotometrically as 0~−2 for the equilibrium

$$C_6H_{10} + Ag^+ \rightleftharpoons C_6H_{10}\cdots Ag^+$$

The 1653 cm^{-1} ν(C=C) and 716 cm^{-1} δ(=C–H) bands of pure cyclohexene have been found to shift to about 1585 and 745 cm^{-1} respectively by means of complex formation with silver perchlorate, both in solids and in solutions. This and other facts concerning the vibration spectrum of the complex show that the C=C bond is weakened by the complex formation.

The very selective complex formation ability of Cu^+, Ag^+ and Hg^{2+} toward monoölefins has been explained by the calculation in which we explicitly took into account the charge number, the ionization potential, the electron affinity, the ionic radius, the hydration (solvation) energy, and the various atomic excitation energies of the ions. It has been pointed out that the roles of the d-electrons of the metal ion and the 3sσ-electrons of the olefin molecule are important in the ground state and the lowest excited state respectively, while the effect of the hydration (or lattice) energy is important in both states.

Appendix I

The Various Electronic States of Cyclohexene.—The 209 mμ (5.92 eV.) band of cyclohexene was found, on the longer wavelength side, to have progressions with a vibrational frequency interval of about 1450 cm^{-1}. This band may possibly be assigned to be the Rydberg transition (N→R) on the basis of a comparison with the 7.11 eV. band of ethylene with 1375 cm^{-1} spacing so assigned by Mulliken.[57,58] Potts[27] observed the N→V transition of cyclohexene at 183 mμ (6.79 eV.), but he undertook no vibrational analysis. By measuring the spectrum of pure liquid cyclohexene with 1 cm. and 10 cm. cells, we have observed two different kinds of vibrational progressions in the longer wavelength region, namely, one around 4.9 eV. with 900 cm^{-1} spacings and another around 3.8 eV. with 1200~1300 cm^{-1} spacings. The former and the latter have tentatively been assigned to the Rydberg triplet (T_R) and the $\pi\rightarrow\pi^*$ triplet transition (T) respectively on the basis of the expected parallelism with the ethylene bands. There are doubts, however, about this assignment, because the magnitudes of their spacings are quite the reverse of those for ethylene and cyclohexene. Both triplet bands show the expected O_2-intensification and N_2-weakening, the effect being more pronounced for the longer wavelength one. Table XII lists the observed four transition energies of cyclohexene, along with the assignment for ethylene bands by Mulliken.[58]

Appendix II

Tables of Overlap Integrals.—The overlap integrals of the S(3s, 3s), S(3s, 5s) and S(2pπ, 5pπ) types were calculated according to the standard method.[35-37,60] The results are shown in Table XIII—XV.

For evaluating the matrix elements, we need to estimate the overlap integrals involving d- and p-orbitals in the assumed geometrical conformation of the complex. Let us consider the case in which the two xz planes of the metal (M) and carbon (C) atoms coincide with each other and in which the line (MC) joining the atoms is inclined at an angle α to the z axis. The overlap integrals for the various combinations shown in Fig. 10 between the d-orbitals of the atom M and the p_z-orbital of the atom C are expressed as linear combinations of $S(\sigma, \sigma)$ and $S(\pi, \pi)$ forms for which published

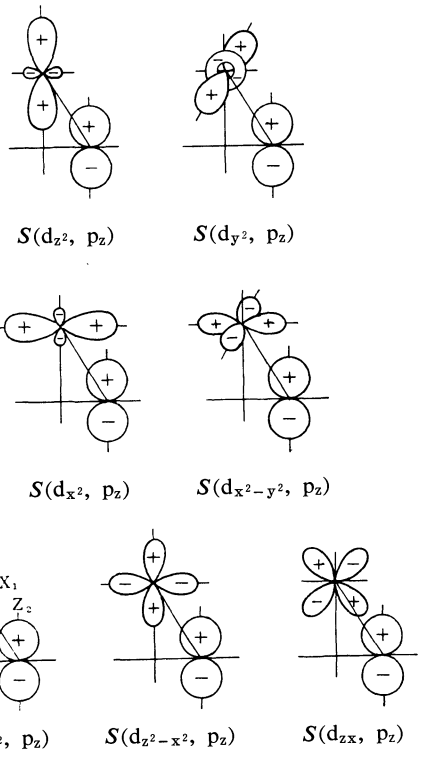

Fig. 10. Various combinations of the d-orbitals of a metal atom and the p_z orbital of a carbon atom.

tables[35-37] are available. The results are as follows:

$$S(d_{x^2}, 2p_z) = -1/4 \cdot \cos\alpha (3\cos 2\alpha - 1) \cdot S(d\sigma, 2p\sigma) - \sqrt{3}/2 \cdot \sin\alpha \cdot \sin 2\alpha \cdot S(d\pi, 2p\pi)$$

$$S(d_{y^2}, 2p_z) = -1/2 \cdot \cos\alpha \cdot S(d\sigma, 2p\sigma)$$

$$S(d_{z^2}, 2p_z) = 1/4 \cdot \cos\alpha (3\cos 2\alpha + 1) \cdot S(d\sigma, 2p\sigma) - \sqrt{3}/2 \cdot \sin\alpha \cdot \sin 2\alpha \cdot S(d\pi, 2p\pi)$$

$$S(d_{x^2-y^2}, 2p_z) = \sqrt{3}/4 \cdot \sin\alpha \cdot \sin 2\alpha \cdot S(d\sigma, 2p\sigma) + 1/2 \cdot \sin\alpha \cdot \sin 2\alpha \cdot S(d\pi, 2p\pi)$$

$$S(d_{y^2-z^2}, 2p_z) = -\sqrt{3}/2 \cdot \cos^3\alpha \cdot S(d\sigma, 2p\sigma) + 1/2 \cdot \sin\alpha \cdot \sin 2\alpha \cdot S(d\pi, 2p\pi)$$

$$S(d_{z^2-x^2}, 2p_z) = \sqrt{3}/2 \cdot \cos\alpha \cdot \cos 2\alpha \cdot S(d\sigma, 2p\sigma) - \sin\alpha \cdot \sin 2\alpha \cdot S(d\pi, 2p\pi)$$

$$S(d_{xy}, 2p_z) = S(d_{yz}, 2p_z) = 0$$

$$S(d_{zx}, 2p_z) = \sqrt{3}/2 \cdot \cos\alpha \cdot \cos 2\alpha \cdot S(d\sigma, 2p\sigma) + \sin\alpha \cdot \cos 2\alpha \cdot S(d\pi, 2p\pi)$$

It should be emphasized here that, unlike the p-orbitals, the d-orbitals are not vectoricaly decomposed into their x, y and z components; some authors[61] have wrongly evaluated the overlap integrals involving d-orbitals with distorted conformations. General formulations, their derivations, and the necessity for using auxiliary d_{x^2}, d_{y^2}, $d_{y^2-z^2}$ and $d_{z^2-x^2}$ functions will be described elsewhere.[62]

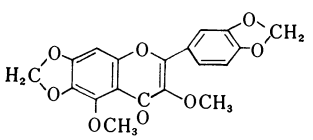
Synthetic Studies of the Flavone Derivatives. III.[1] *The Synthesis of 3, 7-Dimethoxy-5, 6 ; 3', 4'-bismethylenedioxyflavone, an Isomer of Meliternatin*

By Kenji FUKUI, Takashi MATSUMOTO and Sachiko MATSUZAKI

(Received September 12, 1963)

In a previous paper,[1] meliternatin (I)' which had been isolated from the bark of *Melicope ternata* by Briggs and Locker,[2] was synthesized. In this case, I was obtained from a ketone which had been prepared with the Hoesch condensation of 3-methoxy-4, 5-methylenedioxyphenol and methoxyacetonitrile. The structure of the ketone was expected to be either 2-hydroxy-6, ω-dimethoxy-4, 5-methylenedioxyacetophenone (II) or 2-hydroxy-4, ω-dimethoxy-5, 6-methylenedioxyacetophenone (III). According to the Allan and Robinson method, a flavone was prepared with piperonylic anhydride from the ketone. If the structure of the ketone is II, the flavone must 3, 5-dimethoxy-6, 7 ; 3', 4'-bismethylenedioxyflavone (I), which has been proposed by Briggs et al[3] as the structure of meliternatin. An unambiguous synthesis of 3, 7-dimethoxy-5, 6 ; 3', 4'-bismethylenedioxyflavone (IV) must be made in order to settle this question. In the present paper, therefore, the synthesis of IV is described.



The treatment of 6-hydroxy-3, 5, 7-trimethoxy-3', 4'-methylenedioxyflavone (V)[4] with anhydrous aluminum chloride afforded a demethyl compound, which gave a dark green color ferric

1) K. Fukui and T. Matsumoto. This Bulletin, **36**, 806 (1963).

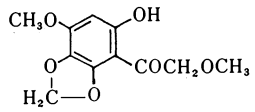
chloride reaction and a diacetate. It is well known that the demethylation of flavonols under the above-mentioned condition occurs at the 5-position[3-7] or occasionally at the 3-position.[3] Therefore, this demethyl compound should be either 5, 6-dihydroxy-3, 7-dimethoxy-3' 4'-methylenedioxyflavone (VI) or 3, 6-dihydroxy-5, 7-dimethoxy-3', 4'-methylenedioxyflavone (VII). As the compound was methylated with diazomethane to yield melisimplin (VIII; 5-hydroxy-3, 6, 7-trimethoxy-3', 4'-methylenedioxyflavone),[4,8,9] it is clear that the demethyl compound has one hydroxy group at the 5-position which is not methylated with diazomethane. On the basis of this result, VI is postulated as its structure.

VI has previously been prepared;[9] our product differs in melting point from that previously reported, but the color reaction with ferric chloride, the elementary analysis and the infrared spectrum (hydroxy bands, 3615 and 3483; carbonyl band, 1659; methylenedioxy band, 926 cm^{-1}) all confirm our assignment of structure to the material. Therefore, the preparation of VI from 2, 5-dihydroxy-4, ω-dimethoxyacetophenone (IX) via the intermediates, 6-hydroxy-3, 7-dimethoxy-3', 4'-methylenedioxyflavone (X) and 5-formyl-6-hydroxy-3, 7-dimethoxy-3', 4'-methylenedioxyflavone (XI), according to the published procedure,[9] was reexamined. The VI obtained was identified with the above demethyl compound by a mixed melting point determination and by an infrared spectral comparison. The melting points of some compounds (VI, X and XI) differed from those previously reported,[9] as is shown in the Experimental section.



The methylenation of VI with methylene iodide afforded 3, 7-dimethoxy-5, 6; 3', 4'-bismethylenedioxyflavone (IV). IV did not agree

with meliternatin in its properties. The structure of meliternatin has, therefore, been established as 3, 5-dimethoxy-6, 7; 3', 4'bismethylenedioxyflavone (I).[1,2]

Experimental*

2,5-Dihydroxy-4, ω-dimethoxyacetophenone (IX). —This ketone was prepared by a method reported in the literature;[10] m. p. 148~149°C (reported m. p. 145~146°C[10]).

6-Hydroxy-3, 7-dimethoxy-3', 4'-methylenedioxyflavone (X).—From the ketone IX, X was obtained in the form of colorless needles according to a procedure previously reported[9]; m. p. 253~254°C (reported m. p. 213~214°C[9]). X gave a negative ferric chloride reaction in ethanol. IR: 3384(OH), 1624(C=O), 1037(=C-O-C), 929 (O-CH_2-O) cm^{-1}.

Found: C, 62.94; H, 4.14. Calcd. for $C_{15}H_{14}O_7$: C, 63.16; H, 4.12%.

The acetylation of X gave the acetate (m. p. 201~202°C, reported m. p. 202°C[9]) in the form of colorless rectangular plates. IR: 1757(OAc), 1621 (C=O), 1037(=C-O-C), 934 (O-CH_2-O) cm^{-1}.

* All melting points are uncorrected; the infrared spectra were measured in Nujol.
10) L. R. Row and T. R. Seshadri, *Proc. Indian Acad. Sci.*, **21A**, 155 (1945).

Found: C, 62.57; H, 4.26. Calcd. for $C_{20}H_{16}O_8$: C, 62.50; H, 4.20%.

5-Formyl-6-hydroxy-3, 7-dimethoxy-3', 4'-methylenedioxyflavone (XI).—From the flavone X, XI was obtained in the form of yellow needles according to a procedure previously reported;[9] m. p. 262～263°C(decomp.) (reported m. p. 248～249°C[9]). XI gave a brown ferric chloride reaction in ethanol. IR: 1647, 1619(C=O), 1038(=C-O-C), 929 (O-CH_2-O) cm^{-1}.

Found: C, 61.39; H, 3.99. Calcd. for $C_{19}H_{14}O_8$: C, 61.62; H, 3.81%.

5, 6-Dihydroxy-3, 7-dimethoxy-3', 4'-methylenedioxyflavone (VI).—*a) From 6-Hydroxy-3, 5, 7-trimethoxy-3', 4'-methylenedioxyflavone (V).*—A solution of V[4] (1.0 g.) and anhydrous aluminum chloride (13.5 g.) in anhydrous ether (60 ml.) was refluxed for 10 hr. After the reaction mixture had been poured into ice-water and kept for several hours at room temperature, the precipitate was collected and refluxed with a solution of acetic acid (55 ml.) and concentrated hydrochloric acid (30 ml.) for 20 min. The resulting precipitate was collected and recrystallized from ethanol to give VI in the form of yellow needles (m. p. 187～188°C) (reported m. p. 218～219°C[9]), which gave a dark green ferric chloride reaction in ethanol; yield, 0.4 g. IR: 3615, 3483(OH), 1659(C=O), 1035(=C-O-C), 926 (O-CH_2-O) cm^{-1}.

Found: C, 60.34; H, 4.03. Calcd. for $C_{18}H_{14}O_8$: C, 60.34; H, 3.94.

The acetylation of VI gave the acetate (m. p. 231～233°C) (reported m. p. 226～227°C[9]), which gave a negative ferric chloride reaction in ethanol. IR: 1771(OAc), 1631(C=O), 1032(=C-O-C), 925 (O-CH_2-O) cm^{-1}.

Found: C, 59.76; H, 4.16. Calcd. for $C_{22}H_{18}O_{10}$: C, 59.73; H, 4.10%.

b) From 5-Formyl-6-hydroxy-3, 7-dimethoxy-3', 4'-methylenedioxyflavone (XI).—From the aldehyde XI, VI was prepared in the form of yellow needles (m. p. 187～188°C) according to a procedure previously reported.[9] This substance was identified with a specimen, prepared by the above-mentioned method a), by a mixed melting point determination and by an infrared spectral comparison.

Milisimplin (VIII).—The treatment of VI (60 mg.) in acetone (20 ml.) with an ethereal solution of diazomethane gave VIII as yellow needles (m. p. 233～234°C) (reported m. p. 234～235°C[9] and 235～236°C[4,8]) from ethyl acetate; yield, 20 mg. This substance gave a green ferric chloride reaction in ethanol. IR: 1667(C=O), 1037(=C-O-C), 925 (O-CH_2-O) cm^{-1}.

Found: C, 61.08; H, 4.36. Calcd. for $C_{19}H_{16}O_8$: C, 61.29; H, 4.33%.

3, 7-Dimethoxy-5, 6; 3', 4'-bismethylenedioxyflavone (IV).—A mixture of VI (350 mg.), methylene iodide (1.1 g.) and anhydrous potassium carbonate (4.0 g.) in anhydrous ethyl methyl ketone (50 ml.) was refluxed for 26 hr. on a steam bath. The reaction mixture was filtered from the precipitates, and ethyl acetate (70 ml.) was added to the filtrate. The solution was washed with a 5% aqueous sodium hydroxide solution and then with water. The solvent was distilled off, and the residue was recrystallized from acetone and then from aqueous acetic acid to give IV in the form of pale yellow needles (m. p. 233～234°C), which gave a negative ferric chloride reaction in ethanol: yield, 60 mg. IR: 1650～1643 (C=O), 1041 (=C-O-C), 930 (O-CH_2-O) cm^{-1}.

Found: C, 61.33; H, 3.99. Calcd. for $C_{19}H_{14}O_8$: C, 61.62; H, 3.81%.

Stability Order in Metal Chelate Compounds. II.[1] *5-(p-Sulfophenylazo)-salicylate Complexes**

By Yukito MURAKAMI and Makoto TAKAGI

(Received September 16, 1963)

In accordance with the work reported, up to the present time it is understood that the stability of metal chelate compounds and their stability order with respect to nuclear metal atoms are functions of the geometrical and electronic structures of a ligand molecule and of the character of the resultant coördinate bonds as well.

In continuation of an investigation which may contribute to the clarification of these relationships, 5-(*p*-sulfophenylazo)-salicylic acid has been used as a chelating agent in the present work. Recently, 5-(*p*-sulfophenylazo)-salicylic acid was employed as a reagent to detect the presence of magnesium,[2] aluminum, beryllium,[3] gallium and indium[4] for analytical purposes; nevertheless, no quantitative study of the interaction of this ligand with any metal ion has been reported up to the present time.

Since the stability constants of metal-salicylate and metal-5-sulfosalicylate complexes have been evaluated,[5-7] the substituent effect of the *p*-sulfophenylazo group, which is situated at the 5-position in the parent molecule, on the chelate formation may be compared with those of other substituents among the chelate derivatives.

Experimental

5-(*p*-Sulfophenylazo)-salicylic Acid.—The coupling reaction of the diazotized sulfanilic acid with salicylic acid in equimolar amounts was carried out in alkaline aqueous media. Acidification of the reaction mixture with hydrochloric acid resulted in the formation of a precipitate. This precipitate was then recrystallized several times from water or aqueous ethanol, giving a 90% yield of yellow-orange needles. These fine crystals were found to be the dihydrated monosodium salt of 5-(*p*-sulfophenylazo)-salicylic acid (I), which was dehydrated above 180°C and decomposed above 250°C. The estimated molecular weight was 380.7 by potentiometric titration (calcd. 380.3).

Found: C, 41.06; H, 3.55; N, 7.44. Calcd. for $C_{13}H_{13}N_2O_8SNa$ (dihydrate): C, 41.05; H, 3.44; N, 7.36%.

The dihydrate form I was transformed to the corresponding monohydrate at 110°C under reduced pressure (5 mmHg); it was also identified by reductive cleavage to sulfanilic acid and 5-aminosalicylic acid.

The synthesized material I was used to prepare a stock solution for potentiometric titrations after the establishment of the purity by means of potentiometric titration with a standard base.

Metal Solutions.—The bivalent metal nitrates, $Zn(NO_3)_2 \cdot 6H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Co(NO_3)_2 \cdot 6H_2O$, $Mg(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, and manganese sulfate, $MnSO_4 \cdot nH_2O$, of analytical grade were purchased from the Wako Pure Chemical Industries, Ltd. The nona-hydrated ferric nitrate, $Fe(NO_3)_3 \cdot 9H_2O$, was a pure grade reagent of the same company. Aqueous stock solutions of these metal salts were standardized for metal ion concentration by the usual procedures of chelatometric titration.

Potentiometric Measurements.—The apparatus and procedures for potentiometric measurements have been mentioned elsewhere.[8] In the present work, the temperature and ionic strength of a titrating solution were maintained, respectively, at 25.0 $\pm$0.1°C and 0.10 M with potassium nitrate. Since the solubility of the ligand in aqueous media at μ=0.10 M in potassium nitrate was observed to be very low, the ligand concentration for potentiometric measurements had to be maintained in a relatively low range (approximately 2×10^{-3} M or less). The measurement of each metal chelate system was checked by repeated titrations to avoid any significant error which might be caused by the low concentration of the system.

Calculation of Acid Dissociation Constants.—The dissociation constants of the dibasic acid I are defined as follows:

$$K_{H_2L}=\frac{[H^+][HL^{2-}]}{[H_2L^-]}, \qquad K_{HL}=\frac{[H^+][L^{3-}]}{[HL^{2-}]}$$

These constants were evaluated in a manner similar to that mentioned in a previous paper.[1]

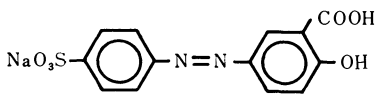
TABLE I. ACID DISSOCIATION CONSTANTS OF SALICYLIC ACID AND ITS DERIVATIVES

Ligand	5-(*p*-Sulfophenylazo)-salicylic acid	5-Sulfosalicylic acid[6,7]		Salicylic acid[6]
μ	0.10	0.1	0.15	0.15
t°C	25.0 ±0.1	25	20	20
pK_{H_2L}	2.38±0.02	2.49	2.62	2.98
pK_{HL}	11.04±0.02	12.00	11.95	13.61



The Calculation of Stability Constants.—Because of the hydrolytic behavior of the chlates of nickel(II), cobalt(II) and manganese(II), only potentiometric data of a limited range were used for the evaluation of the stability constants of these chelate systems. Such ranges were: 6~9.5, 6~9.5 and and 7~9.3 in $-\log[H^+]$; up to 1.35, 1.30 and 0.85 in $\bar{n}$-value* for nickel(II), cobalt(II) and manganese(II) respectively. No such limitations were required for alkaline earth metal chelates, even though an $\bar{n}$-value did not exceed 1.3 over the whole pH range studied. In these regions of $\bar{n}$-value, the main chelate species existing in the system were considered to be the 1 : 1 and 2 : 1 (lignd to metal) chelates. Therefore, the stability constants for each chelate system were evaluated in accordance either of two methods, namely, (1) the intersection method[1,8] or (2) the lineation method.[8] The two stability constants, K_1 and K_2, are defined as follows:

$$K_1=\frac{[ML]}{[M][L]}, \qquad K_2=\frac{[ML_2]}{[ML][L]}$$

On the other hand, the $\bar{n}$-value already exceeded 1.2 at a=0** in the potentiometric titration of the iron(III) chelate system. Thus, the only stability constant evaluated was for the 2 : 1 chelate.

Results and Discussion

Acid Dissociation Constants. — A titration curve of the monosodium salt of 5-(*p*-sulfophenylazo)-salicylic acid (II) is shown in Fig. 3.

II

The titrating solution was pale yellow-orange below a=1 and became reddish in the region beyond a=1, where the reddish color deepened as the pH increased. The first dissociation process is clearly separated from the second; thus the carboxy-proton of the ligand is very acidic in comparison with the phenol-proton. The acid dissociation constants of ligand II evaluated in this work are shown in Table I, together with those of 5-sulfosalicylic acid[6,7] and of salicylic acid.[6] Both K_{H_2L} and K_{HL} values vary in a parallel manner among these ligands, and the acidity increases in the order: salicylic acid<5-sulfosalicylic acid<5-(*p*-sulfophenylazo)salicylic acid. Therefore, a *p*-sulfophenylazo group seems to be a more effective substituent in electron-withdrawing effect than a sulfonate group. Judging from these observations, a phenylazo group may transmit the electron-withdrawing effect of the para sulfonate group through resonance interaction and withdraw an electron from the salicylate group as well.

Interaction of Bivalent Metal Ions with 5-(*p*-Sulfophenylazo)-salicylate. — Titration curves are illustrated in Figs. 1 and 2 for the 5-(*p*-sulfophenylazo)-salicylate chelate systems of manganese(II), cobalt(II), nickel(II), zinc(II), magnesium(II) and calcium(II) for 10 : 1 and 4 : 1 molar ratios of ligand to metal ion.

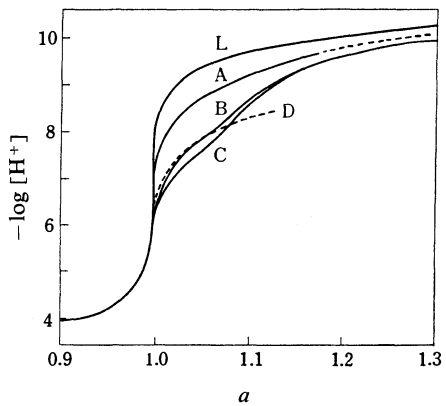


Fig. 1. Potentiometric titration of bivalent metal chelates of 5-(*p*-sulfophenylazo)-salicylate at total ligand concentration of 2.03×10^{-3} M with 10 : 1 molar ratio of ligand to metal ion: A, Mn; B, Co; C, Ni; D, Zn; L, ligand alone; a=moles of base added per mole of ligand; t=25°C; μ=0.10 M (KNO_3). Dotted lines represent non-equilibrated titration.

Since 5-(*p*-sulfophenylazo)-salicylate is considered to be a bidentate ligand, at most three moles of the ligand per mole of metal ion would be enough to satisfy the coördination sites of these bivalent metal ions. However, potentiometric titrations in the present work were carried out with an excess of the ligand

* n is referred to the Bjerrum formation function.
** a stands for the amount of base added per mole of ligand.

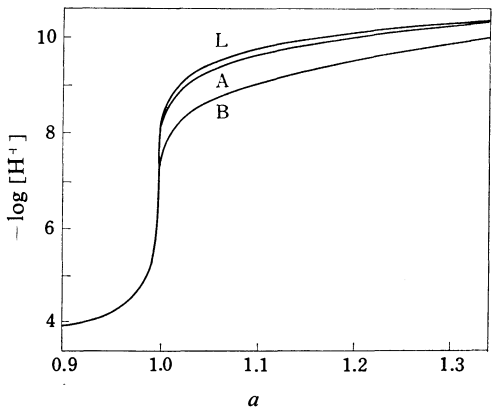

Fig. 2. Potentiometric titration of bivalent metal chelates of 5-(*p*-sulfophenylazo)-salicylate at total ligand concentration of 2.03×10^{-3} M with 4 : 1 molar ratio of ligand to metal ion: A, Ca; B, Mg; L, ligand alone; a=moles of base added per mole of ligand; t=25°C; μ=0.10 M (KNO_3).

in an attempt to avoid as much as possible both disproportionation and hydrolysis of metal chlates in a higher pH region.

Manganese(II), Cobalt(II), Nickel(II) and Zinc(II). — All the titration curves coincide well with that of the ligand alone in the lower buffer region, $a=0\sim1.0$, as is shown in Fig. 1. Thus, the only significant chemical process occurring in this region is the dissociation of a carboxyl-proton.

The depression of titration curves was observed beyond an a-value of 1.0 in comparison with the titration curve of the ligand alone. Such a depression became noticeable at pH 6.0 and above for cobalt(II) and nickel(II), and above pH 7.0 for manganese(II), as may be seen in Fig. 1. It is obvious that ligand II undergoes chelation with these bivalent metal ions in these higher pH regions. A small inflection region, which corresponds to the formation of a 1 : 1 chelate, was observed at $a=1.1$ for the nickel(II) chelate system and less significantly for the cobalt(II). Judging from the extent of the depression of titration curves among these bivalent metal chelate systems, the stability order with respect to metal ions is: manganese(II) < cobalt(II) < nickel(II). Meanwhile, the hydrolytic tendency of these metal chelates was found to be significant beyond $a=1.18$ for manganese(II) and beyond $a=1.3$ for cobalt(II) and nickel(II) in a manner similar to these observed for the salicylate and 5-sufosalicylate chelates of the same bivalent metals.[6,7]

Such hydrolytic behavior was much pronounced for the zinc(II) chelate system, and a pH drifting became significant in the region immediately beyond $a=1.0$. Further addition of a base resulted in the gradual formation of a precipitate. It seems, therefore, that the zinc chelate is much less stable than the corresponding cobalt and nickel chelates, since the hydrolytic tendency of zinc(II) was found to be comparable with these of cobalt(II) and nickel(II) ions.* On the other hand, the greater hydrolytic behavior** of the zinc(II) ion than that of the manganese(II) ion is responsible for the precipitation in the lower pH range, where the manganese chelate system did not form a precipitate.

Copper(II). — Titration of the copper(II) chelate system was carried out at various molar ratios of ligand to metal ion, ranging from 1 : 1 to 10 : 1 under the same experimental conditions as employed for other bivalent metal chelate systems. An appreciable pH-depression was observed, even in the a-range below 1.0. Equilibrium of the system was reached in a short period of time in a limited initial range of titration with a base; nevertheless, equilibrated potentiometric data were not obtained over most of the pH range studied due to the sluggish pH-drifting. Such a drifting tendency became increasingly pronounced as the pH was raised, even though no precipitate was noticed throughout the titration. Since the hydrolysis of copper ion alone is not significant in the lower pH region[9,10] the slow rate of the equilibration of the chelate system is conceivably due to the sluggish formation of chelate species. Because of such complex behavior of the copper chelate system, no quantitative interpretation of the data was possible.

Magnesium(II) and Calcium(II). — Neither drifting of pH nor precipitation was observed throughout the titration. These bivalent metal ions and the ligand undergo chelation in the region beyond $a=1.0$, as may be seen in Fig. 2. Both alkaline earth metal ions form much less stable chelates than the transition metal ions.

Interaction of Iron(III) with 5-(*p*-Sulfophenylazo)-salicylate. — Titration of a solution containing a 4 : 1 molar ratio of ligand to metal ion resulted in a large pH depression over the whole pH range and in two steep inflections, at 1.50 and 1.75, in a-value, as is shown in Fig. 3. No precipitate was observed at any time during the titration. The

* The estimated hydrolysis constants for zinc(II), cobalt(II) and nickel(II) are 8.7, 8.9 and 9.4 respectively in pK unit, at 30°C and μ=0.1 (S. Chaberek, Jr., R. C. Courtney and A. E. Martell, *J. Am. Chem. Soc.*, **74**, 5057 (1952)).

** The thermodynamic hydrolysis constants for zinc(II) and manganese(II) ions were 8.96±0.03 and 10.59±0.04 respectively in pK unit, at 25°C (D. D. Perrin, *J. Chem. Soc.*, **1962**, 2197, 4500).

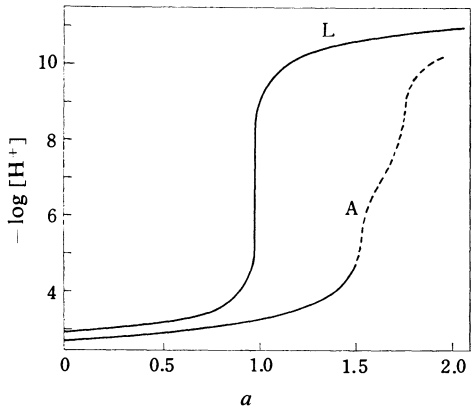

Fig. 3. Potentiometric titration of Fe(III)-5-(*p*-sulfophenylazo)-salicylate chelate system at total ligand concentration of 2.03×10^{-3} M with 4 : 1 molar ratio of ligand to metal ion: A, Fe; L, ligand alone; a=moles of base added per mole of ligand; t=25°C; μ=0.10 M (KNO_3). Dotted curve represents non-equilibrated titration.

former inflection corresponds to the formation of the 2 : 1 chelate, in addition to the liberation of a carboxy-proton of the uncoördinated ligand, while the latter most probably corresponds to the formation of the 3 : 1 chelate. Such a profound pH depression is to be ascribed to the greater stability of iron(III) chelates in comparison with that of other bivalent metal chelates. Similar results were obtained for the salicylate and 5-sulfosalicylate chelates.[6]

On the other hand, the sluggish pH drifting in the region beyond a=1.5 precludes the quantitative analysis of the chelating behavior of the system. Since 5-(*p*-sulfophenylazo)-salicylate demonstrated a strong affinity to ferric ion, the slow rate of the chelate formation would be responsible for such a pH drifting, and neither a hydrolytic reaction nor other complex reactions of the chelates would be the significant account. A similar conclusion was reached concerning the sluggish equilibration of the 4-sulfocatechol-iron(II) chelate system.[11]

The development of the deeper color for the ferric chelate system than for the ligand alone also provides evidence for the strong interaction of ferric ion with the ligand. The titrating solution was dark brownish in the lower buffer region (a<1.0). A reddish color gradually developed in the solution on approaching to the first inflection region, and this was further deepened as the pH was raised. However, the intensity of this reddish color gradually diminished in the second inflection region, and more apparently as the pH increased further. The hydrolysis of the chelate system, which may proceed extensively in this higher pH region, is most probably the cause of this color-fading.

Stability Constants.—The stability constants for the 5-(*p*-sulfophenylazo)-salicylate, as well as for the salicylate and 5-sulfosalicylate chelates, are listed in Table II. The stability order of these chelates in K_1 with respect to the ligands is shown in the increasing order: 5-(*p*-sulfophenylazo)-salicylate < 5-sulfosalicylate < salicylate. The decreased basicity of the donor group of the present ligand is responsible for the lower stability. The slightly greater

values of K_2 for the 5-(*p*-sulfophenylazo)-salicylate chelates than those for the corresponding 5-sulfosalcylate chelates are rather unexpected.

The stability order with respect to the bivalent metal ions in the present work may be put foward in an increasing manner as follows: calcium(II) < magnesium(II) < manganese(II) < (zinc(II)) < cobalt(II) < nickel(II) < (copper(II)). By referring to other analogous metal chelates listed in Table II, the following general stability order with respect to the bivalent transition metals may be afforded: manganese(II) < iron(II) < zinc(II) ~ cobalt(II) < nickel(II) < copper(II). Zinc(II) is placed below nickel(II) in stability, contrary to what was observed for the catechol chelates.

The pronounced color-deepening effect of the iron(III) chelate system indicates a strong electronic interaction among the ligand molecules and the metal atom through the coördinate bonds.

Summary

The interaction of 5-(*p*-sulfophenylazo)-salicylic acid with zinc(II), copper(II), nickel(II), cobalt(II), manganese(II), magnesium(II), calcium(II) and iron(III) has been investigated in aqueous media at 25.0±0.1°C and the ionic strength of 0.10 M. The stability constants for the 1 : 1 and 2 : 1 (ligand to metal) chelates of nickel, cobalt, manganese and magnesium, and for the 1 : 1 calcium chelate, as well as for the 2 : 1 ferric chelate, have been evaluated, and the resulting stability order with respect to the bivalent metals has been found to follow the sequence: calcium(II) < magnesium(II) < manganese(II) < (zinc(II)) < copper(II) < nickel(II) < copper(II). The stability sequence, zinc(II) < nickel(II), is contrary to that observed for the catechol chelates.

A *p*-sulfophenylazo group demonstrated an electron-withdrawing effect, the magnitude of which was slightly greater than that of a sulfonate group. However, the effect of the former group on the chelate-stability has been found to be comparable with that of the latter.

The present salicylate derivative is also a good chelating agent for iron(III) ion, even though the chelate system somehow becomes involved in a higher pH range.

The Electronic Structures and Spectra of Pentalene and Heptalene

By Takeshi NAKAJIMA, Yoshiko YAGUCHI, Ryoji KAERIYAMA* and Yuzo NEMOTO**

(Received September 25, 1963)

Recently Dauben and Bertelli[1] have reported the synthesis of the bicyclic nonbenzenoid aromatic hydrocarbon, heptalene (II), and discussed its physical and chemical properties. From the viewpoint of the molecular orbital theory, pentalene (I) is closely related to the hydrocarbon; pentalene has, however, so far defied synthesis, although the molecule has long been of interest since it was first postulated as a possible aromatic system by Armit and Robinson.[2] It should be noted that if the bridged bonds are disregarded, both these molecules are very similar to the planar cyclic polyenes with the general formula $C_{4n}H_{4n}$.

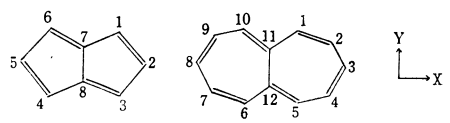

Fig. 1. Carbon skeleton, choice of axes, and numbering of pentalene and heptalene.

Early theoretical investigators,[3] presuming the molecular symmetry D_{2h} and using the simple MO and VB methods, have predicted appreciable π-electron delocalization energies for I and II and, on this basis, have suggested that the molecules may have a more or less

S., Paris (1955).

pronounced aromatic character. Craig and Maccoll[4] have, on the other hand, pointed out that the two methods are discordant, even as regards such a fundamental property as the symmetry of the ground state, and in a latter paper Craig[5] has classified molecules like I and II as pseudo aromatics. In addition, Longuet-Higgins[6] has suggested that pentalene may tend to be distorted in an asymmetrical (C_{2h}) manner and to undergo, at the limit, spontaneous decomposition to give two molecules of acetylene and one of butadiyne. Boer et al.[7,8] and Snyder,[9] on the basis of a modified MO theory, have recently shown that in I and II an asymmetrical (C_{2h}) structure is more favorable energetically than the symmetrical (D_{2h}) one. A more elaborate treatment, one which explicitly includes electron repulsion, has been proposed by Silvestri et al.,[10] who have examined the ground-state electronic properties of molecules I and II by a semiempirical self-consistent field method. These authors have, however, presumed molecular symmetry D_{2h} and have not been concerned with the electronic spectra.

It is the purpose of this paper to deepen our understanding of the aromatic characteristics of I and II through an attempt to examine the ground-state electronic properties and the electronic spectra in particular by means of a semiempirical SCF method. Calculations have been carried out for the two molecular symmetry models, D_{2h} and C_{2h}, of both I and II.

Method and Procedure

The SCF technique of Roothaan[11] was employed in conjunction with the Pariser-Parr approximations,[12] with slight modifications. In computing interaction terms for adjacent atoms, the internuclear distances at each step of the iterative process are predicted from the π-bond orders, p, with the aid of the formula;[13]

$$r(\text{in Å}) = 1.520 - ap \quad (1)$$

with

$$a = 0.186 \quad (2)$$

Nonneighbor internuclear distances are calculated assuming the rings to be regular, with the bond lengths taken to be 1.397Å. The Coulomb penetration and nonneighbor resonance integrals are all disregarded. The one-center electronic repulsion integral, (pp/pp), given in the Pariser-Parr theory as $I_c - A_c$ was taken to be $11.54 - 0.46 = 11.08$ eV.,[14] while the two-center repulsion integrals, (pp/qq), were determined by the extrapolation procedure of Pariser and Parr.

In addition, the resonance integral $\beta(r)$ is supposed to vary exponentially with r according to the relation:

$$\beta(r) = -2.38 \exp[b(1.397 - r)] \text{ eV.} \quad (3)$$

with

$$b = 2.5802 \text{ Å}^{-1} \quad (4)$$

This value of b is considerably smaller than that, 5.6864 Å^{-1}, obtained by Pariser and Parr. The b value of Pariser and Parr was determined from $\beta(r)$ values so adjusted as to reproduce the experimental spectral data for ethylene and benzene, the bond lengths of which were taken to be 1.35 and 1.39Å respectively. The present b value was obtained by the use of the same spectral data, but using the recently observed value, 1.333Å, for the bond length of ethylene[15] and 1.397Å for that of benzene.

It is perhaps interesting to note in this connection that the applicability of the Pariser-Parr parameterization to the calculation of ground-state electronic properties has not been clearly established. In fact, Pariser-Parr's formulation, with its original parameterization, if applied to benzene in conjunction with the SCF technique, gives the unexpected result that self-consistency is achieved for two symmetry types, D_{6h} and D_{3h}, and there is good reason for believing that in such a case the skew structure (D_{3h}) is more favorable energetically than the symmetrical one (D_{6h}).[16] This absurd result is undoubtedly due to too large a value of b having been assigned by Pariser and Parr. According to the present parameterization, the symmetrical structure turns out to be most stable.

The starting molecular orbitals employed were the Hückel-type ones obtained with $\beta_{single}/\beta_{double} = 1$ for the D_{2h} model and those obtained with $\beta_{single}/\beta_{double} = 0.55$ for the C_{2h} model. In general, some ten iterative procedures were followed to achieve four-place self-consistency.

					11—12	0.278

bond orders, and free valences for the two molecular symmetry types are summarized in Table I. In both I and II, the charge distributions for the asymmetrical models are remarkably smoothed out as compared with those for the symmetrical models. In contrast to this, the distributions of bond orders for the asymmetrical models are significantly uneven. The predicted bond lengths are 1.35 to 1.36Å for the double bonds and 1.46 to 1.48Å for the single bonds, the extent of bond length alternation being comparable to those in such chain polyenes as butadiene. From the viewpoint of the chemical reactivity, of particular notice is the fact that the free valences of the peripheral (secondary) carbon atoms of I and II, particularly for the asymmetrical models, are considerably larger than those for classical aromatic molecules (e. g., benzene, 0.40). Both of these molecules are thus expected to be highly susceptible to homolytic reactions. This is in agreement with the available experimental facts. Heptalene has been known readly to undergo polymerization by oxygen or mild warming.[1] In addition, the free valence numbers indicate that in I and II the highest reactivity should be expected at the ortho-positions. As regards II, this has also been confirmed experimentally.

The Total Electron Energy. — Now let us enquire which of the symmetrical and asymmetrical models is more favorable energetically. It has been emphasized[17,18] that a conclusion regarding the stability or the equilibrium configuration of a conjugated molecule cannot be based on π-electron calculations only; allowance for the effects of the σ-bond compression must also be made. Obviously the total electron energy should be considered in comparing the energetic stabilities of the two models. Using the assumptions of Longuet-Higgins and Salem,[17] the total binding energy of a conjugated molecule, taken to be the sum of π-bond energy and σ-bond energy, is given by

$$V=E_\pi+E_\sigma=(2/ab)\sum_{p<q}\bar{\beta}_{pq}+\sum_p q_p\bar{\alpha}_p+\text{const.} \tag{5}$$

in which we assume

$$\bar{\beta}(r)=\bar{\beta}_0\exp[\bar{b}(1.397-r)] \tag{6}$$

$$\bar{\alpha}_p=\bar{\alpha}_0+\omega(1-q_p)\bar{\beta}_0 \tag{7}$$

where ω is a proportionality coefficient here taken to be unity. Equation 6 differs from Eq. 3. $\beta(r)$ is the core resonance integral. On the other hand, $\bar{\beta}(r)$ should be interpreted as an effective resonance integral which includes an electron interaction term;* the value 4.5988

* Theoretical f values for pentalene were calculated using the predicted transition energies (in cm^{-1}) for ν in Eq. 8.

$Å^{-1}$ is taken for the parameter, $\bar{b}$.[13] The total energy values thus calculated indicate that in both I and II the asymmetrical structures are more favorable energetically than the symmetrical ones, the deformation energies which favor the structures being, respectively, -0.52 and $-0.58\bar{\beta}_0$, about 10 kcal./mol., if we take $\bar{\beta}_0=-16.5$ kcal./mol.[19] These figures are appreciable, and it is now clear that in I and II there exists a significant bond length distortion, one comparable in extent to those in linear chain polyenes. Such alternating bond lengths, if molecules I and II are treated as slightly perturbed hypothetical planar cyclooctatetraene and cyclodoecahexaene respectively, may be understood to be due to a pseudo Jahn-Teller effect.[20]

Electronic Spectra.—The calculated energies and oscillator strengths, f, for the lower singlet electronic transitions in I and II are summarized in Table II. No configuration interactions were allowed for (see below), and the theoretical f values were all obtained by the use of the well-known formula;

$$f_{th}=1.085\times10^{11}\nu Q^2 \qquad (8)$$

It may be noted that the f_{th} values calculated using Eq. 8 are usually about three times as large as the f_{obs} values.

It may be seen that, in both I and II, in passing from the symmetrical (D_{2h}) to the asymmetrical model (C_{2h}), the transition energies (particularly for the lowest (forbidden) transitions) increase, while the f_{th} values decrease, and in heptalene the C_{2h} model leads to numerical results in good agreement with experimental data. In this molecule the longest wavelength maximum is assigned to an electronic transition, $B_u\leftarrow A_g$, polarized approximately along the long axis (x), whereas the next maximum is assigned to a transition of the same type but with a moment roughly parallel to the short axis (y). The longest wavelength maximum is accompanied by an almost linearly decreasing absorption tail throughout the visible region. Such a tail may arise from a forbidden transition becoming partially allowed by molecular vibrations or twisting, and from transitions which take place according to the Franck-Condon process between a ground and an excited state having potential energy curves appreciably different in shape from each other. It has been shown[19] that in heptalene the potential energy curve for the lowest excited state differs considerably in shape from that for the ground state, the former having a single potential energy minimum, whereas the latter has a double minimum.

Recently hexaphenyl pentalene has been synthesized by Le Goff.[21] The absorption spectrum of this molecule shows a weak maximum at 13900 cm^{-1} (1.72 eV.) with $\log\varepsilon=1.95$ and followed by a long tail. This maximum may perhaps be assigned to the predicted forbidden transition, $A_g\leftarrow A_g$, in pentalene, which is allowed and shifted toward the red by the substitution.

In molecules I and II, if they are distorted in an asymmetrical mannar, a configuration interaction is possible between the ground and the lowest excited state, as the symmetry

groups of the two states are both A_g in distorted structures. Insofar as the distortion remains slight, this interaction may be of primary importance, and heavy mixing of the two states will occur, the ground state being substantially depressed in energy (pseudo Jahn-Teller effect).[6] However, in the asymmetrical structures here achieved, the interaction is of little importance, for the two states are well separated in energy from each other. In fact, in heptalene the lowering of the ground state energy caused by the interaction is calculated to be only about 0.1 eV. The SCF technique considerably reduces the effects of the configuration interaction.

Ionization Potentials. — In Roothaan's SCF formulation the ionization potentials are approximated by the orbital energies (Koopmans' theorem). Although this approximation has recently been criticized,[22-24] the orbital energies may still give at least an indication of the relative magnitude of ionization potentials. The orbital energies, $\varepsilon - W_{2p}$ (where W_{2p} is the ionization potential of the $2p\pi$-electron of the carbon atom) for the top occupied orbitals of I and II are calculated to be 1.55 (D_{2h}) and 0.84 (C_{2h}), and 3.20 (D_{2h}) 2.17 eV. (C_{2h}) respectively. It should be noted that, while in general $\varepsilon - W_{2p}$ values are negative for the top occupied orbitals (and for all other occupied orbitals), the values turn out to be positive in I and II. This indicates that the ionization potentials of these molecules are exceptionally small; in this sense they are unstable, the symmetrical structures being less stable than the asymmetrical ones.

Summary and Conclusion

The semiempirical SCF technique has been applied to pentalene and heptalene. Self-consistency has been achieved for the two symmetry types, D_{2h} and C_{2h}, and the total binding energy examination indicates that in both the molecules the asymmetrical structure (C_{2h}) is more favorable energetically than the symmetrical one (D_{2h}). The calculated uneven charge distributions, the high free valence values, and the low ionization potentials supply the reasons for the instability of these molecules. The theoretical spectral calculations for the asymmetrical structures are in good agreement with the available experimental data. It may be concluded that, in these molecules, there exists a remarkable bond length alternation, and that in this sense they cannot be considered aromatic. They show, rather, characteristics of cyclic polyolefins.

Kinetic Studies of Solvolysis. IX.[1] *The S_N1-type Cleavage of t-Butyl p-Substituted-phenyl Ethers and Optically-active α-Phenethyl Phenyl Ether by Hydrogen Halides in a Phenol-Dioxane Solvent**

By Kunio OKAMOTO, Ken-ichi TAKEUCHI and Haruo SHINGU

(Received June 12, 1963)

It has been well established experimentally that the mechanism for the cleavage of primary and secondary alkyl ethers by hydrogen halides is an S_N2-type displacement between a protonated ether (an oxonium ion-pair) and a hydrogen halide.[2] There have been, however, no publications concerning an unambiguous kinetic example of the S_N1-type cleavage for tertiary alkyl ethers, although the existence of such a cleavage has been suggested[3] on the basis of the rate sequence

of alkyl ethers.[4] It is anticipated that, unlike the S_N2-type cleavage, which obeys third-order kinetics,[5] the S_N1-type mechanism would display second-order kinetics, for in this mechanism the oxonium ion-pair cleaves unimolecularly.

In this paper typical examples of the S_N1-type cleavage are presented for the cleavages of *t*-butyl *p*-substituted-phenyl ethers and of α-phenethyl phenyl ether by a hydrogen halide in a phenol-dioxane solvent. In addition, the steric course and the mechanism are discussed in detail for the S_N1-type cleavage of optically-active α-phenethyl phenyl ether.

The Molecularity of the Hydrogen Chloride Cleavage of *t*-Butyl Phenyl Ether. — The hydrogen chloride cleavage of *t*-butyl phenyl ether was followed titrimetrically from 20 to 60% of completion in 20 wt. % phenyl-80 wt. % dioxane at 70.0°C. Assuming the S_N1-type mechanism for this cleavage, we calculated the rate constants from the second-order rate equation:

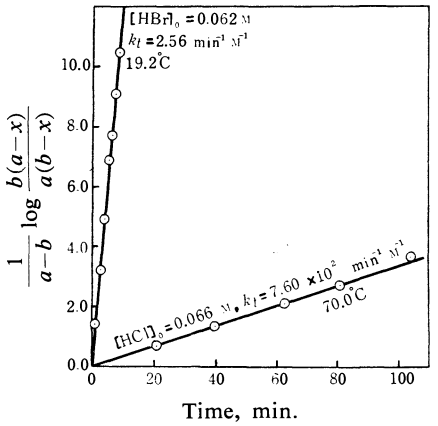

Fig. 1. Cleavage of *t*-butyl phenyl ether with hydrogen halides in 20 wt.% phenyl-dioxane.

TABLE I. SUMMARY OF RATES OF CLEAVAGE OF PHENYL ETHERS WITH HYDROGEN CHLORIDE IN PHENOL-DIOXANE

Compond	wt.% of phenol	Temp. °C	Initial concn. of the ether M	Initial concn. of HCl M	10^2k_t min.$^{-1}$ M^{-1}	10^2k_{tcorr} min.$^{-1}$ M	Conversion % of the ether

$$k_t=\frac{1}{t(a-b)}\ln\frac{b(a-x)}{a(b-x)} \quad (1)$$

where a is the initial concentration of the ether, b is the initial concentration of hydrogen chloride, and x is the concentration decrease in hydrogen chloride after the time lapse, t. Satisfactory second-order behavior was observed for each run; a representative run is illustrated in Fig. 1.

The values of the rate constants did not show any appreciable change between runs in various initial concentrations of hydrogen chloride, except for a slight increase probably due to the ionic strength effect of hydrogen chloride. These values are illustrated in Table I.

An examination of the extent of the completion of the reaction revealed that the consumption of hydrogen chloride did not exceed 91% of the starting ether after ten half-lives reaction time. This indicates that the major reaction is that of the cleavage, but also that there is, to a certain minor extent, a side reaction or a reverse reaction. Since the rate of the reverse reaction, i. e., the phenolysis rate of *t*-butyl chloride, was found to be negligibly small under these cleavage conditions, this incompleteness of hydrogen chloride comsumption may be ascribed to a concurrent side reaction. Although no attempt was made to clarify the characteristics of this side reaction, this seems to be rearrangement of the *t*-butyl group from ether-oxygen to the benzene-nucleus. This type of rearrangement has already been known in the hydrogen chloride cleavage of *t*-butyl phenyl ether in the absence of solvent at 20.0°C.[6]

In view of the fact that both the cleavage and the rearrangement proceed unimolecularly through the protonated ether, the ratio of the concentration decrease of hydrogen chloride to that of the ether at any reaction time should be equal to the ratio, r, of the concentration of the hydrogen chloride consumed by the ether at an infinite reaction time to the initial concentration of the ether. On the basis of this consideration, the ether concentration was expressed as $\{a-(x/r)\}$ instead of $(a-x)$ in Eq. 1, where a represents the initial concentration of the ether, and x represents the concentration decrease in hydrogen chloride after the time lapse, t. Thus, rate expression for the ether consumption:

$$-\mathrm{d}\{a-(x/r)\}/\mathrm{d}t=k_{t\mathrm{corr}}\{a-(x/r)\}(b-x) \quad (2)$$

gave a modified second-order kinetic equation:

$$k_{t\mathrm{corr}}=\frac{1}{(ar-b)}\ln\frac{b(ar-x)}{ar(b-x)} \quad (3)$$

The corrected second-order rate constants also gave good second-order behavior; these values are shown in Table I.

Hence, this cleavage is evidently a typical example of the S_N1-type ether cleavage, where an oxonium ion-pair, rapidly formed from the ether and hydrogen chloride, reacts intramolecularly by way of slow, unimolecular carbon-oxygen ionic fission.

Additional S_N1-type Characteristics of the Cleavage of *t*-Butyl Phenyl Ether.—The titrimetric rate constants (uncorrected), measured at 70.0°C in a series of solvents, i. e., dioxane 10 wt.% and 20 wt.% phenol-dioxane, increased with the phenol concentrations; this is illustrated in Fig. 2.

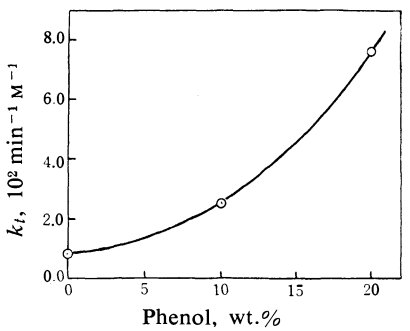

Fig. 2. Solvent effect in hydrogen chloride cleavage of *t*-butyl phenyl ether in phenol-dioxane.
$[\mathrm{ether}]_0=0.100$ M
$[\mathrm{HCl}]_0=0.059\sim0.066$ M, 70.0°C

Although the protonation of the ether might be promoted in the phenolic solvents by the relative decrease in dioxane concentration, it is more probable that the subsequent unimolecular cleavage would be greatly accelerated by an increase in phenol concentration. This kind of acceleration has already been found to be a normal pattern of the S_N1-type reaction in the phenolysis of *t*-butyl chloride.[6]

In addition, it was found that the titrimetric rate constants were markedly enhanced in the presence of added *p*-nitrophenol. This is illustrated in Fig. 3. This kind of phenomena has also been observed in the S_N1-type acetolysis of *t*-butyl bromide in acetic acid-carbon tetrachloride,[7] where it was interpreted as an acceleration of ionization due to hydrogen bonding. It may, therefore, be suggested that the similar acceleration by *p*-nitrophenol is effective in this cleavage.

The Substituent Effect for the Hydrogen Chloride Cleavage of *t*-Butyl *p*-Substituted-phenyl Ether.—The cleavage of *p*-tolyl *t*-butyl ether, followed titrimetrically in 20 wt. % phenol-dioxane at 70.0°C, obeyed good second-order kinetics. The titrimetric rate constants for *p*-chlorophenyl and *p*-nitrophenyl *t*-butyl ether, especially for the run with higher concentrations of the *p*-nitrophenol ether, showed a tendency to drift upward in the plot for the second-order rate constant. In view of the acceleration of the cleavage of *t*-butyl phenyl ether by *p*-nitrophenol, this upward drift may probably be ascribed to autocatalytic acceleration by the *p*-chlorophenol or *p*-nitrophenol liberated during the cleavage. The second-order rate constants of these ethers were calculated from the initial rates. The rate constants are shown in Table I.

The percentages for the completion of the hydrogen chloride consumption of the *p*-methyl-, *p*-chloro- and *p*-nitro-phenyl ethers amounted to 92 (at about 40 half-lives), 95.5 (at about 11 half-lives) and 94.3% (at about 10 half-lives) respectively. Using these values for *r*, we calculated the corrected rate constants from Eq. 3; they are shown in Table I.

The plot of the corrected rate constants vs. Hammett's σ-constants shows that there are no linear free-energy relationships involving these constants, as Fig. 4 illustrates. Since the reaction proceeds through an oxonium ion-pair formation, these substituents might display a counter effect for the oxonium ion-pair formation and the subsequent unimolecular cleavage. The para-nitro group may accelerate the cleavave and retard the protonation because of its electron-attracting effect, and the para-methyl group may show converse tendencies in each of the processes. This seems to be

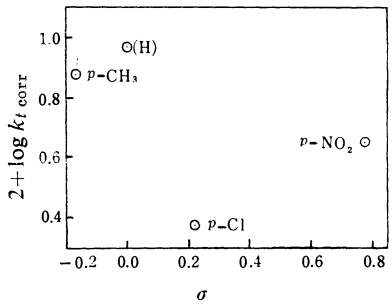

Fig. 4. Plot of $\log k_{t\,corr}$ vs. Hammett's σ constants for hydrogen chloride cleavage of *t*-butyl *p*-substituted-phenyl ether in 20 wt.% phenol-dioxane at 70.0±0.1°C.

the cause of the failure of Hammett's linear free-energy relationship for this reaction.

The Hydrogen Bromide Cleavage of *t*-Butyl Phenyl Ether. — Satisfactory second-order behavior was observed for the hydrogen bromide cleavage of *t*-butyl phenyl ether in 20 wt. % phenol-dioxane at 19.2°C; this is illustrated in Fig. 1. Although no attempt was made to correct to a side reaction, this result indicates that the reaction is of the S_N1-type. The rate constant is definitely higher than that of the hydrogen chloride cleavage. In view of the fact that the protonated ether can exist along with the anion as an oxonium ion-pair, it is unlikely that the enhancement of the rate by hydrogen bromide is due only to the ease of formation of the protonated ether. It is more reasonable to assume that the predominant cause of the enhancement is acceleration by the nucleophilic attack of the bromine ion, for the bromine anion is more nucleophilic than the chlorine ion. From this consideration it follows that the unimolecular cleavage of the oxonium ion-pair is of the "intramolecular" nature and that it is mechanistically similar to the S_Ni-type reaction.

The Hydrogen Chloride Cleavage of Optically-Active α-Phenethyl Phenyl Ether.—To substantiate the intramolecular cleavage of the oxonium ion-pair, the hydrogen chloride cleavage of (+)-α-phenethyl phenyl ether was followed polarimetrically in 50 wt. % phenol-dioxane at 30°C. The optical rotation associated with the disappearance of the (+)-ether decreased, and at the completion of the reaction (at about 14 half-lives) it reached a minus value, having crossed the zero line. Since the (+)-ether has the same configuration as the (−)-chloride,[8a] this result indicates that the configuration of the ether was retained after the cleavage. This is consistent with the previous

8) a) H. Hart and H. S. Eleuterio, *J. Am. Chem. Soc.*, **76**, 518 (1954); a) H. Hart and H. S. Eleuterio, ibid., **76**, 1379 (1954); c) H. Hart and R. J. Elia, ibid., **83**, 985 (1961).

observation that optically-active α-phenethyl phenyl ether is cleaved by hydrogen chloride in benzene,[8b] toluene,[8c] 3-pentanone[8c] and isobutanol;[8c] also, the rotation of the α-phenethyl chloride so formed shows that the process involves retention of the configuration, accompanied by a slight racemization.[8]

The polarimetric rate constant, k_p, was calculated from the rate equation 4:

$$\frac{-\mathrm{d(ether)}}{\mathrm{d}t} = k_p \ \mathrm{(ether)}\ \mathrm{(HCl)} \qquad (4)$$

by ploting d(ether)/dt, graphically calculated, against (ether) (HCl), where (ether) represents the ether concentration calculated from the polarimetric measurement and (HCl) represents the concentration of hydrogen chloride measured at a titrimetric run carried out under the same conditions. This is illustrated in Fig. 5.

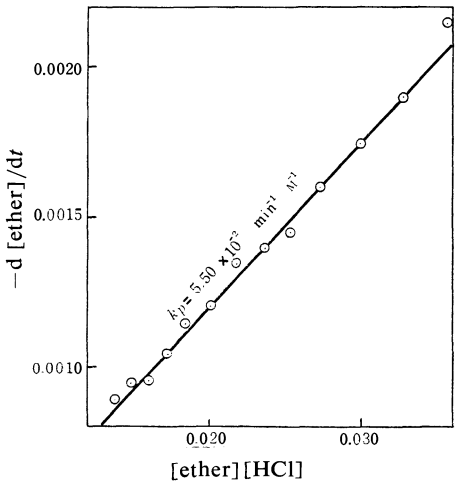

Fig. 5. Plot of −d[ether]/dt vs. [ether][HCl] for hydrogen chloride cleavage of (+)-α-phenethyl chloride in 50 wt.% phenol-dioxane at 30.0±0.1°C.

The titrimetric constant, $k_{t\ \mathrm{corr}}$, for this cleavage was also measured. The hydrogen chloride consumption at the completion of the reaction amounted to 75% of the starting ether. The rate of the reverse reaction was found to be negligibly small (2.3% of conversion at twenty half-lives of the cleavage). Evidently the incompleteness of hydrogen chloride consumption is due to a side reaction, probably a rearrangement of the oxonium ion-pair. Making a consideration analogous to the case of t-butyl phenyl ether, we estimated the concentration of the changed ether to be $x/0.75$, where x represents the concentration of the consumed hydrogen chloride at time t. The titrimetric rate constant was calculated from Eq. 5

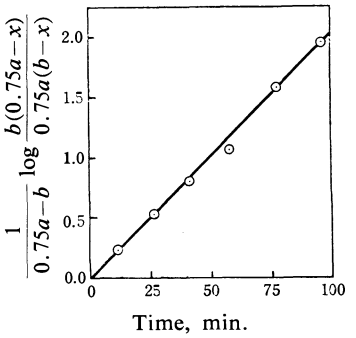
$$k_{t\ \mathrm{corr}} = \frac{1}{(0.75a-b)} \ln \frac{b(0.75a-x)}{0.75a(b-x)} \qquad (5)$$

This was derived from the rate expression

$$\frac{-\mathrm{d}\{a-(x/0.75)\}}{\mathrm{d}t} = k_{t\ \mathrm{corr}}\{a-(x/0.75)\}\ (b-x) \qquad (6)$$

where a represents the initial concentration of α-phenethyl phenyl ether and b represents the initial concentration of hydrogen chloride.

A good second-order titrimetric rate constant was obtained by a plot of $(1/0.75a-b)\log b(0.75a-x)/0.75a(b-x)$ vs. t,; this is illustrated in Fig. 6.



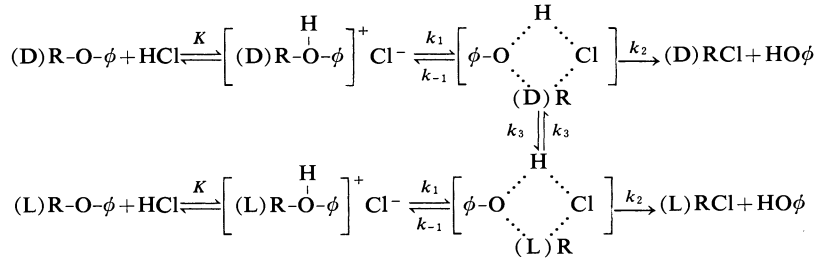


Fig. 6. Cleavage of α-phenethyl phenyl ether with hydrogen chloride in 50 wt.% phenol-dioxane at 30.0±0.1°C.
[ether]$_0$=0.200 M
[HCl]$_0$=0.212 M
$k_{t\ \mathrm{corr}}$=4.65×10^{-2} min^{-1} M^{-1}

As Table I shows, the polarimetric constant exceeds the titrimetric constant. This indicates kinetically that the racemization (or ionization) process of the oxonium ion-pair precedes the product-formation stage.

The Mechanism of the Hydrogen Halide Cleavage of *t*-Butyl and α-Phenethyl Phenyl Ether.—In the preceding sections the S_N1-type characteristics of the protonated ether have been clearly indicated on the basis of the molecularity, the solvent effect, and the acceleration by phenolic compounds for the cleavage reaction.

The intramolecular, S_Ni-like nature for this cleavage has also been suggested from the rate enhancement by hydrogen bromide for the cleavage of t-butyl phenyl ether and from the steric course revealed for the cleavage of optically-active α-phenethyl phenyl ether.

Since the optically-active product was obtained at the cleavage of optically-active α-phenethyl phenyl ether, the intermediate should retain the optical activity. Therefore, we can postulate two "parallel" series of two-stage reactions of the "antipodal," protonated ethers for the simplest expression of the ether

Scheme A

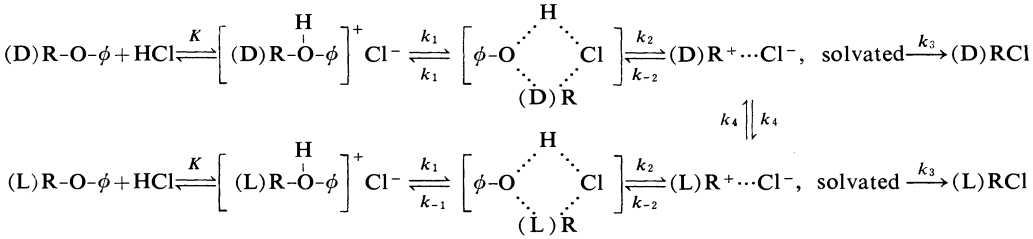
cleavage, as is depicted in Scheme A. The two parallel series of reactions of the antipodal substrates were previously postulated for the mechanism of the phenolysis of the optically-active α-phenethyl chloride.[1] In this mechanism the racemization is caused by way of interconversion between two antipodal intermediates. As a plausible structures for the intermediate; a quadrupolar type with a retained configuration; as has been suggested by Hart and Elia,[8b] may be assumed.

From Scheme A a quantitative explanation for the gap between the k_p and the k_t may be obtained by the following rate expressions:

$$k_p = Kk_1/(1+k_{-1}/(k_2+2k_3)) \qquad (7)$$

$$k_t = Kk_1/(1+k_{-1}/k_2)$$

In Eqs. 7 and 8, K, k_1, k_2 and k_3 represent the equilibrium constant for the protonated ether formation, the rate constant for the intermediate formation, the rate constant for the product formation, and the interconversion rate constant of the antipodal intermediates respectively,



However, it would be possible to explain this cleavage mechanism, especially for the α-phenethyl system, by a more complicated mechanism. Since it was concluded in the previous paper[1] that the phenolysis of α-phenethyl chroride in a phenol-benzene solvent, i.e., the reverse reaction of the ether cleavage, proceeded under a "three-stage" mechanism of the S_N1-type with two kinds of intermediates, there is a possibility that the cleavage in phenol-dioxane goes back through the same "three-stages" as those of the phenolysis in a phenol-benzene solvent, This hypothesis seems reasonable judging from the principle of microscopic reversibility. Thus, the "three-stage" cleavage of the protonated ether is shown in Scheme B. In this mechanism the first intermediates would be a quadrupolar type intermediate consisting of an RCl and a phenol molecule, and the second ones, an ion-pair derived from RCl and surrounded by a solvation shell. If these intermediates are compared with those postulated for the phenolysis,[1] the first group may be considered to be non-racemizable and the second, racemizable (see Part VIII of this series[1]). The overall rate expressions for the k_t and k_p in this scheme are given in Eqs. 9 and 10 respectively:

$$k_p = Kk_1/\left\{1+\frac{k_{-1}}{k_2}\left(1+\frac{k_{-2}}{k_3+2k_4}\right)\right\} \qquad (9)$$

$$k_t = Kk_1/\left\{1+\frac{k_{-1}}{k_2}\left(1+\frac{k_{-2}}{k_3}\right)\right\} \qquad (10)$$

Discrimination between mechanisms A and B seems to be impossible on the basis of the kinetic examination of the trend of the gap between the k_t and the k_p. Namely, the change of solvent composition or the addition of a scavenger for the intermediates may cause an increase in the k_2 in Eqs. 7 to 10 or in the k_3 in Eqs. 9 and 10, but this will lessen the gap between the k_p and the k_t in "both" of Schemes A and B.

Thus, the experimental descrimination between Schemes A and B needs further study, although the principle of microscopic reversibility seems to favor Scheme B, especially for the α-phenethyl system.

Scheme B

Experimental[9]

Materials.—The preparation of *t*-butyl phenyl ether has been described previously[6] (b.p. 89.0°C/35.5 mm Hg, Found: C, 79.80; H, 9.04. Calcd, for $C_{10}H_{14}O$: C, 79.95; H, 9.39). *t*-Butyl *p*-tolyl ether and *t*-butyl *p*-chlorophenyl ether, prepared in the respective phenol by a method similar to that used for *t*-butyl phenyl ether,[6] had b.p.'s of 86~87°C/15.2 mmHg. (Found: C, 80,23; H, 9.71. Calcd. for $C_{11}H_{16}O$: C, 80.44; H, 9.82%) and 84.0~85.5°C/9.0 mmHg respectively.

Found: C, 64.74; H, 6.89. Calcd. for $C_{10}H_{13}OCl$: C, 65.04; H, 7.09%.

t-Butyl *p*-nitrophenyl ether was obtained by means of the addition reaction of *p*-nitrophenol to isobutylene, To a mixture of 5.0 g of *p*-nitrophenol, 50 cc. of methylene chloride, and 0.55 cc. of 96% sulfuric acid, in a 200 cc., three-necked flask equipped with a thermometer, a cooled dropping funnel, and a drying tube, 12.0 g. of liquefied isobutylene were added in one portion at 0°C. After the mixture had stood for 20 hr. at 0~5°C, 40 cc. of 10% aqueous sodium carbonate was added to the reaction mixture to precipitate unchanged *p*-nitrophenol as the sodium salt. To the filtrate was added 10 cc. of ether, and the mixture was extracted with 10% aqueous sodium hydroxide, washed with water, dried and concentrated. The residue was fractionally distilled in vacuo, giving 1.91 g. (27.2% of theory) of *t*-butyl *p*-nitrophenyl ether; b.p. 103~110°C/2 mmHg.

Found: C, 62.02; H, 7.02. Calcd. for $C_{10}H_{13}NO_3$: C, 61,52; H, 6.71%.

(+)-α-Phenethyl phenyl ether was prepared from (+)-α-phenethyl chloride ($[\alpha]_D^{27°}$ 45.3°, homogeneous, 1 dm.) in the manner of Hart and Eleuterio[9a] (b.p. 106~110°/1 mmHg, $[\alpha]_D^{27°}$ 10.11±0.05°, homogeneous, 1 dm.). Aniline, phenol and dioxane (each of reagent grade) were dried and purified by fractional distillation; b.p. 42.0~43.0°C/1 mmHg, 178.5°C and 101.5°C respectively.

Kinetic Measurements.—The sealed ampoule technique was employed. The diminution of hydrogen chloride was followed by titration with standard sodium acetate in acetic acid, using crystal violet as an indicator. The polarimetric run was carried out in a manner similar to that previously described.[1]

Summary

1) Hydrogen chloride cleaves *t*-butyl phenyl ether at 70.0°C in 20 wt.% phenol-dioxane. The reaction is kinetically first-order in each reactant. The second-order rate constants show an increase with increasing phenol concentrations, and *p*-nitrophenol accelerates the reaction.

2) The hydrogen bromide cleavage of *t*-butyl phenyl ether at 19.2°C in 20 wt. % phenol-dioxane gives a second-order rate constant greater than that of hydrogen chloride.

3) The rate sequence of the hydrogen chloride cleavage of *t*-butyl *p*-substituted-phenyl ethers at 70.0°C in 20 wt.% phenol-dioxane is $H > p\text{-}CH_3 > p\text{-}NO_2 > p\text{-}Cl$, and there is no linear relationship between those rate constants and Hammett's σ constants.

4) The hydrogen chloride cleavage of (+)-α-phenethyl phenyl ether at 30.0°C in 50.0 wt.% phenol-dioxane obeys good second-order kinetics for both polarimetric and titrimetric runs. The value of the polarimetric rate constant exceeds that of the titrimetric constant, and from the final reading of the polarimetric run it has been concluded that the α-phenethyl chloride produced in the cleavage partly retained the configuration.

5) It has been concluded that the hydrogen halide cleavage of those phenyl ethers in phenol-dioxane proceeds through the protonated ether produced by a rapid equilibration between hydrogen halide and those ethers, and that the protonated ether reacts by an S_Ni-like mechanism. For the cleavage of the optically-active ethers, a detailed mechanism involving two parallel series of cleavage reactions of antipodal protonated ethers has been suggested wherein the partial racemization of the product is explained as resulting from the interconversion between the antipodal intermediates. For each series of S_Ni-type reactions, the possibility of a two-stage or three-stage mechanism has been discussed.

NOTES

Tetrodotoxin. III.[1] *A Revised Molecular Formula for Tetrodotoxin*

By Toshio GOTO, Sho TAKAHASHI, Yoshito KISHI and Yoshimasa HIRATA

(Received August 21, 1963)

The molecular formula of tetrodotoxin, a strongly toxic compound obtained from ovaries of swellfish (*Spheroides rubripes*), was said by Yokoo[2] in 1952 to be $C_{12}H_{17}O_{10}N_3$ on the basis of elementary analyses and the molecular weight determination by means of freezing point depression and the titration of its basic group. In 1953, Tsuda and Kawamura[3] reported on the analytical values of the toxin, but they did not give any definite molecular formula, since the values fluctuated considerably. Several years later, both Kakisawa et al.[4] and Tsuda et al.[5] gave a molecular formula, $C_{12}H_{19}O_9N_3$, based on elementary analyses and a titration equivalents.

Though it has previously been considered very difficult to purify tetrodotoxin (I), we have found that it can be purified through its nicely crystalline picrate II, which can be recrystallized from hot water. Acetylation of the toxin I with acetic anhydride and *p*-toluenesulfonic acid afforded, in a good yield, amorphous tetraacetyltetrodotoxin *p*-toluenesulfonate (III), which was further acetylated with acetic anhydride in the presence of pyridine to pentaacetylanhydrotetrodotoxin *p*-toluenesulfonate (IV).

The equivalent values of the purified toxin I determined by several runs of titration were between 311 and 324. The molecular weight of the crystalline pentaacetate IV was found to be 673±10 by means of the osmometer method[6] in a chloroform solution. These results, coupled with the analytical values of tetrodotoxin (I), the picrate II, and the acetates, III and IV, led to the molecular formula $C_{11}H_{17}O_8N_3$ for tetrodotoxin (I).

Experimental

Tetrodotoxin (I).—This toxin was purified by precipitating it with alcohol from its aqueous acetic acid solution according to the method of Tsuda and Kawamura[3] (samples 1 and 2), or through its crystalline picrate II, which had been treated with aqueous ammonia to precipitate the toxin (sample 3). The toxin I was obtained as microscopic crystals and darkened over 200°C without melting. Analytical samples were dried at 80~100°C for ca. 20 hr. in vacuo.

Found: (Sample 1) C, 40.21, 40.40; H, 5.62, 5.72; N, 12.52, 12.70;[7a] O, 41.43, 41.11, 41.00.[7b] (Sample 2) C, 40.62, 40.61; H, 5.75, 5.66; O, 41.73;[7c] titration equivalent (5 runs) 311 to 324. (Sample 3) C, 40.58, 40.87; H, 5.63, 5.94; N, 12.61, 12.60.[7d] Calcd. for $C_{11}H_{17}O_8N_3 \cdot \frac{1}{2}H_2O$: C, 40.24; H, 5.53; N, 12.80; O, 41.43%; mol. wt., 328.28.

Tetrodotoxin Picrate (II).—After this had been prepared from the toxin I and picric acid in water, it was recrystallized from water to give yellow needles which darkened over 200°C. An analytical sample was dried at 80~100°C for 20 hr. in vacuo.

Found: C, 36.25, 36.52; H, 3.95, 4.03; N, 14.24, 14.40.[7d] Calcd. for $C_{11}H_{17}O_8N_3 \cdot C_6H_3O_7N_3 \cdot H_2O$: C, 36.05; H, 3.92; N, 14.84%.

Tetraacetyltetrodotoxin *p*-Toluenesulfonate (III).—Tetrodotoxin (100 mg.) was suspended on a solution of *p*-toluenesulfonic acid hydrate (100 mg.) in acetic acid (2 ml.); the mixture was then allowed to stand overnight at room temperature. The resultant clear solution was evaporated to dryness under reduced pressure at 55°C (water-bath temp.), and the residue was treated with ice water containing sodium acetate (200 mg.) and then extracted

with chloroform (three times). The combined extracts were washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness. The residue was dissolved in chloroform and precipitated by the addition of petroleum ether. The precipitate (110 mg.) was further purified by dissolving it in benzene and precipitating it with ether. The analytical sample was a white amorphous powder; m. p. 162~164°C.

Found: C, 46.97; H, 5.27; N, 6.44.[7e] Calcd. for $C_{11}H_{13}O_8N_3(CH_3CO)_4 \cdot C_7H_8O_3S$: C, 47.34; H, 5.04; N, 6.37%.

Pentaacetylanhydrotetrodotoxin *p*-Toluenesulfonate (IV). — The tetraacetate III (500 mg.) was dissolved in a mixture of pyridine (2 ml.) and acetic anhydride (2 ml.), and the mixture was allowed to stand overnight at room temperature. The reaction mixture was evaporated at 55°C (bath temp.) under reduced pressure, and the residue was dissolved in chloroform. Ether was added to the solution to precipitate the product, which was then recrystallized from ethanol to give 200 mg. of white needles; m. p. 208~210°C.

Found: C, 48.83; H, 5.20; N, 5.81;[7e] C, 48.53, 48.80, 48.77; H, 4.77, 5.03, 5.40; N, 6.32;[7d] N, 6.13;[7a] O, 35.42;[7e] mol. wt., 673±10 (0.6418% solution in chloroform). Calcd. for $C_{11}H_{10}O_7N_3 \cdot (CH_3CO)_5 \cdot C_7H_8O_3S$: C, 49.19; H, 4.87; N, 6.15; O, 35.11%; mol. wt., 683.62.

The authors wish to thank the Fujisawa Pharmaceutical Co. Ltd., for collecting the ovaries of swellfish and also to express their appreciation to the Public Health Service, National Institute of Health, U. S. A., for its support of this work under Research Grant RG-7969.

The Isotopic Composition of Magnesium in Terrestrial Samples

By Makoto SHIMA*

(Received August 27, 1963)

The variation in the isotopic abundance of the stable isotopes of magnesium, one of the most common elements in the earth's crust and in meteorites, has received little detailed study. It has been reported on by Blewett and Jones (1936),[1] and by White and Cameron (1948),[2] using a commercial magnesium reagent. In dolomite samples, Daughtry, Perry and Williams (1962)[3] found a different magnesium 24-magnesium 26 ratio. However, on the whole it has been little studied.

Since some experimental difficulties were experienced in measuring the magnesium isotope ratio, the present study was begun with the hope of resolving these difficulties and with the thought that knowledge of the magnesium isotope ratio in the terrestrial sample might lead to useful geochemical findings.

The magnesium was mainly separated by the classical method of rock analyses. Dilute sulfuric acid and 50% hydrofluoric acid were added to two grams of the sample. After the calcium had been separated by the ordinary ammonium oxalate method, the magnesium was precipitated by oxine. After ignition, it was leached by hydrochloric acid. The ion exchange resin (Dowex 50-X12) was used for the purification of the magnesium of sodium and aluminum, which might disturb mass spectrometric analyses.[4] Magnesium oxide was mounted on the sample filament with phosphoric acid. The isotopic composition was measured in a mass-spectrometer, built by Nuclide Analysis Associates, with a 12-inch radius and a deflection of 60°. The ions, Mg^+, were produced by using a triple filament source made of tungsten ribbons. The beam current was amplified with an electron multiplier. In order to stabilize the ion beam, an advantage was gained by the use of phosphoric acid for mounting the magnesium oxide samples. The peak shape thus obtained is shown in Fig. 1.

There are several possible sources of error in the determination of magnesium isotope composition (Masses 24, 25 and 26) : isotopic fractionation in the sample preparation, mass discrimination in the ion production, instrument drift, and instability. The isotopic fractionation in the sample preparation and also the contamination were avoided by the use of

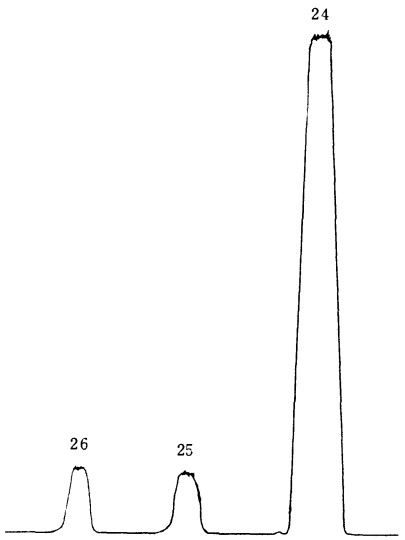

Fig. 1. The obtained peak shape of magnesium isotope.

the same chemical procedure and the same reagents as far as possible. The mass discrimination in the production of ions is not believed to be serious because the mass analyses were always repeated under the same conditions. Moreover, no variation in the isotopic ratio with time was observed during the course of the individual runs. The statistical uncertainty of each run—due principally to the instrumental effect—was usually within 2%. The difference in the average ratio on repeated runs was not significant.

The results of the measurement are shown in Table I. No mass correction factor is necessary for the relative ratio to be compared, because this study was designed to check the terrestrial magnesium samples with existed in the different formulae. On the basis of these preliminary results, no difference in the magnesium isotope composition of standard rocks, of sea water and of chemical reagents could be found. In other words, within the limits of the samples and of analytical error, no difference in the isotopic ratio among the terrestrial magnesium samples has been established. However, nothing decisive can be stated about the secondary dolomite which was reported by Daughtry et al. (1962).[3]

I am grateful to Dr. H. C. Urey for his encouragement throughout this work. I am also indebted to Dr. D. Schink for supplying me with samples.

The Formation of Methyl Methanethiolsulfonate, an Antibacterial Substance, from Dimethylsulfoxide

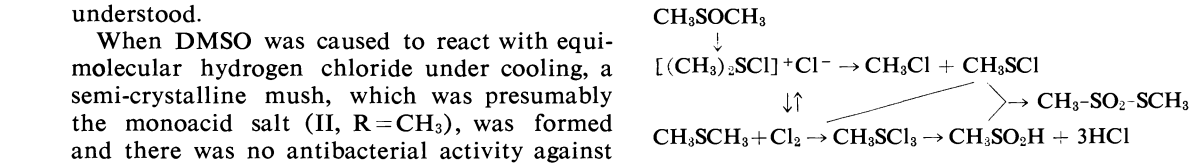
By Tsutomu TSUCHIYA, Setsuko IRIYAMA and Sumio UMEZAWA

(Received September 10, 1963)

When dimethylsulfoxide (DMSO) as a solvent is treated with an excess of hydrogen chloride and when the reaction product is subjected to paper bioautography, there is found an antibacterial spot which was presumed to be derived from DMSO; therefore, an attempt has been made to isolate the active substance from the reaction product of DMSO with hydrogen chloride. The purpose of this paper is to establish that the active substance is methyl methanethiolsulfonate.

Sulfoxides (I) are basic, as is indicated by their ability to form salts with strong acids, and it is known that sulfoxides are reduced by hydrogen halides to sulfides[1] (IV) via the diacid salts (III):

$$\underset{\text{(I)}}{R_2SO} \xrightarrow{HX} \underset{\text{(II)}}{R_2SO\cdot HX} \xrightarrow[-H_2O]{HX} \underset{\text{(III)}}{[R_2SX]^+X^-} \xrightarrow[-X_2]{} \underset{\text{(IV)}}{R_2S}$$



The reaction between DMSO and hydrogen chloride, however, is complicated and not fully understood.

When DMSO was caused to react with equimolecular hydrogen chloride under cooling, a semi-crystalline mush, which was presumably the monoacid salt (II, $R=CH_3$), was formed and there was no antibacterial activity against *Bacillus subtilis*. When DMSO was further treated with an excess of hydrogen chloride, however, a clear solution was obtained, and when the solution was allowed to stand, the temperature of the solution spontaneously rose to about 60°C and a considerable amount of gas was evolved. The low-boiling product collected was found to be mainly composed of hydrogen chloride and a water-insoluble component which was presumably dimethyl sulfide (IV, $R=CH_3$). The resulting solution was neutralized thoroughly with powdered sodium bicarbonate or pyridine and, as described in the experimental section, repeatedly treated with organic solvents to produce a crude product almost free from chlorine. This product was purified by vacuum-distillation to give methyl methanethiolsulfonate (CH_3–SO_2–SCH_3). The product purified gave analyses for methyl methanethiolsulfonate, and the boiling point and infrared absorption bands corresponded well with those reported for the compound prepared by a different method.[2]

Methyl methanethiolsulfonate has been found to have antibacterial and antifungal activities. This suggested that the methanethiolsulfonates have an antimicrobial interest. An antimicrobial test of a variety of methanethiolsulfonates is, therefore, under way.

Discussion

The inter-relationships of the products in the reaction of DMSO with hydrogen chloride may be represented by the accompanying diagram. All the inter-relationships except the formation of methanesulfenyl chloride ($CH_3\cdot SCl$) have been established.

The formation of methylsulfur trichloride (CH_3SCl_3) from methanesulfenyl chloride and chlorine was established by Douglass and coworkers.[3] The formation of methanesulfinic acid (CH_3SO_2H) by the hydrolysis of methylsulfur trichloride was found by Douglass and Farah.[2] The reaction of sulfenyl chloride with sulfinic acid was applied to the preparation of thiolsulfonate esters (R–SO_2–SR) by Stirling.[4] The formation of thiolsulfonate esters from sulfenyl chlorides and sulfinic acids was also concluded by Douglass and Farah[2] in the chlorination of alkyl disulfides.

Any mechanism which would account for the formation of methanesulfenyl chloride must involve the rupture of the sulfur-carbon bond,

1) Recent applications of the reaction to the preparation of sulfides have been described in the following papers: B. Iselin, *Helv. Chim. Acta*, **44**, 61 (1961); E. N. Karaulova and G. D. Gal'pern, *Zhur. Obshchei Khm.*, **29**, 3033 (1959); *Chem. Abstr.*, **54**, 12096 (1960).

2) I. B. Douglass and B. S. Farah, *J. Org. Chem.*, **24**, 973 (1959).

3) K. R. Brower and I. B. Douglass, *J. Am. Chem. Soc.*, **73**, 5787 (1951); I. B. Douglass, K. R. Brower and F. T. Martin, ibid., **74**, 5770 (1952).

4) C. J. M. Stirling, *J. Chem. Soc.*, **1957**, 3597.

and it seems reasonable to suppose that the diacid salt of DMSO decomposes into methanesulfenyl chloride and methyl chloride. This kind of decomposition is rather unusual and the major known product of the decomposition of the diacid salt of DMSO is dimethyl sulfide. Several instances of this kind of decomposition, however, have been found in the literature related to the chlorination of sulfides. An example is the formation[5] of 2-nitro-4-methylbenzenesulfenyl chloride from methyl 2-nitro-4-methylphenyl sulfide and chlorine. Moreover, Bordwell and Pitt[6] described that the presence of colored impurities in several of the products obtained by the chlorination of sulfides suggested contamination by sulfenyl chlorides.

Methanesulfenyl chloride probably was formed by the nucleophilic attack of chloride ions on the carbon in the chlorosulfonium ions.

Experimental

Methyl Methanethiolsulfonate.—DMSO was dried over potassium carbonate or potassium hydroxide and vacuum-distilled (b. p. 51°C/3.5 mmHg). DMSO (100 g.) was placed in a three-neck flask fitted with a sealed stirrer, a thermometer and a gas inlet tube. The flask and its contents were then cooled and a gentle stream of dry hydrogen chloride gas was admitted until about 60 g. hydrogen chloride had been absorbed. The temperature of the contents was not allowed to rise above 40°C. When about half of the hydrogen chloride had been absorbed, the contents crystallized. When the addition of hydrogen chloride was complete, however, a solution was obtained.

While the resulting solution was allowed to stand at room temperature, the temperature of the contents spontaneously rose to about 60°C and a considerable amount of gas evolved. The low-boiling product, collected in a bottle cooled in liquid air, mainly consisted of a water-insoluble liquid (about 15 g.) and hydrogen chloride. The water-insoluble liquid had a b. p. of about 37°C and was presumed to be dimethyl sulfide.

The solution left after the gas evolution was subjected to vacuum-distillation at about 50°C; when the vacuum reached 2 mmHg, the distillation was stopped. The viscous liquid (70 g.) left in the flask was thoroughly neutralized with sodium bicarbonate (about 50 g.) by mixing, and the mixture was allowed to stand at room temperature for 1 hr. The mixture was then extracted four times with 150 ml. portions of ethanol. The extracts were combined and allowed to stand for a while to give a small quantity of precipitate. After removal of the precipitate by filtration, the extract was distilled under reduced pressure to remove the solvent. The oily residue was again extracted with acetone (300 ml.), and the solvent was removed by distillation to give a yellowish, clear liquid (7.0 g.). The product was finally extracted three times with portions of 15 ml. of ether. The ether-insoluble part obtained was a viscous liquid and had a weak antibacterial activity against *Bacillue subtilis*.

The ethereal extract was distilled under reduced pressure to yield a colorless liquid of methyl methanethiolsulfonate, b. p. 82.5~83.5°C (2.5 mmHg)[7] at a bath-temperature of 100~120°C; yield, 3.5 g. The infrared spectrum showed strong absorptions at 1330, 1305, 1135, 958 and 750 cm^{-1}.

Found: C, 19.54; H, 4.99; S, 50.62. MW,* 117. Calcd. for $C_2H_6O_2S_2$: C, 19.04; H, 4.79; S, 50.81%. MW, 126.

The product inhibited the growth of *Trichophyton rubrum*, *Trichopyton asteroides*, *Bacillus subtilis* and *Escherichia coli* in the minimum concentrations of 15.6, 31.2, 125 and 125 mcg./ml. respectively. A detailed report on the antimicrobial spectrum and toxicity will be published elsewhere.

Summary

1) Methyl methanethiolsulfonate has been obtained from the reaction product of dimethyl sulfoxide with hydrogen chloride. Methyl methanethiolsulfonate has been found to have antifungal and antibacterial activities.

2) It has been suggested that methanesulfenyl chloride is formed from the diacid salt of DMSO and that it reacts with methanesulfinic acid to yield methyl methanethiolsulfonate.

SHORT COMMUNICATIONS

The Polarography of Lead(II) Ions in Fused Sodium Fluoride-Potassium Fluoride-Lithium Fluoride Ternary Eutectic

By Makoto SAITŌ and Shin SUZUKI

(Received October 18, 1963)

So far, it has not been possible to carry out the polarography of metal ions in a medium of fused fluoride salts because of the generally high melting points of fluoride salts and because of their strongly corrosive action. However, a good polarogram of a metal ion was obtained by using a eutectic mixture of sodium fluoride-potassium fluoride-lithium fluoride as the fused salt solvent, as proposed by Bergman et al.[1] The advantage of this solvent are its good thermal stability, the wide span of its electrolytic decomposition potential, its high conductivity and fluidity, and the commercial availability of its components as reagent-grade salts. Further, its melting point is the lowest of all the fluorides, and its chemical reactivity is such that a high pure alumina can be utilized as construction material. The properties of the solvent thus permit, in theory, a study of the electrochemistry of a wide variety of solutes with a minimum of interference from solvent effects and with only moderate experimental difficulty as high-temperature work goes.

In the present work, the dipping-type microelectrode, described in a previous report,[2] was modified for the fluoride bath, as is shown in Fig. 1, and the polarogram of the lead(II) ions in this solvent was obtained.

The fused salt was prepared in the following way: Sodium fluoride, potassium fluoride and lithium fluoride were separately dried in a vacuum desiccator at $10^{-2}\sim10^{-3}$ mmHg for 1~2 weeks. A mixture of 11.5 mol. % of sodium fluoride, 42 mol. % of potassium fluoride and 46.5 mol. % of lithium fluoride was placed in an alumina cell and heated in an electric furnace while being evacuated to $10^{-2}\sim10^{-3}$ mmHg. The temperature was raised to fuse the salts and was maintained at 850~900°C for 1.5~3.0 hr. The furnace temperature was then adjusted to 650±2°C.

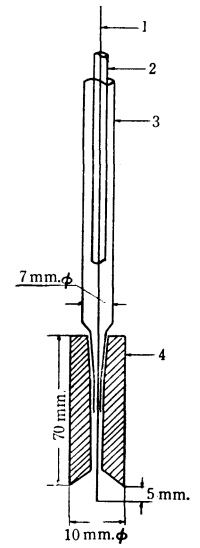

Fig. 1. Dipping type Mo microelectrode for fluoride bath.
1. Mo wire (0.3 mm. ϕ) 3. Quartz glass
2. Borosilicate glass 4. Graphite ring

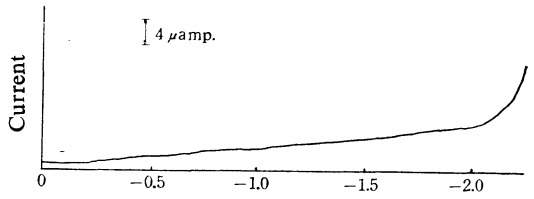

Fig. 2. Residual current curve of fused NaF-KF-LiF eutectic at 650°C.

The residual current curve obtained is shown in Fig. 2. The terminal voltage rise occurred at about −2.1 V. vs. the Mo anode.

1) A. G. Bergman and E. P. Dergnnov, *Compt. rend. acad. sci. U. R. S. S.*, **31**, 754 (1941).
2) H. Gotô, S. Suzuki and M. Saitô, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **84**, 332 (1963).

A typical polarogram of lead(II) ions is shown in Fig. 3; the wave form is similar to that described in a previous report.[2] The corresponding log plot is shown in Fig. 4. It was found that there is a linear relationship between the applied voltage and $\log(i_d-i)/i$, in spite of the fact that plotting the applied voltage against $\log(i_d-i)$ did not produce a straight line.

The half wave potential was -0.55 V. vs. the Mo anode.

The concentration of lead(II) ions, in the range of 1.95~4.60 mmol./1000 g. fused salt, was found to be directly proportional to the limiting current.

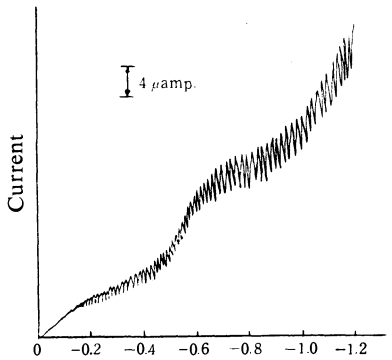

Fig. 3. Polarogram of Pb(II) ion in fused NaF-KF-LiF eutectic at 650°C.

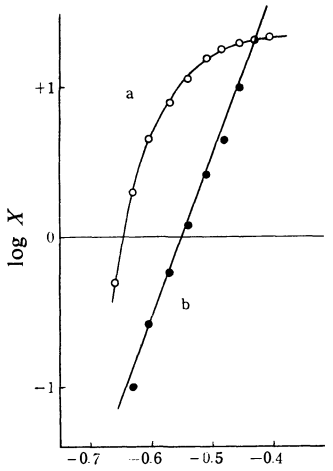

Fig. 4. Log plot of the current-voltage curve of Pb(II) ion.
a: $E\sim\log(i_d-i)$
b: $E\sim\log(i_d-i/i)$

Consequently, it is thought that the procedure described here may be useful for the study of the electrochemical behavior of metal ions in a medium of fused fluoride salt.

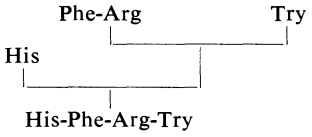
The Synthesis of an MSH-active Tetrapeptide, L-Histidyl-L-phenylalanyl-L-arginyl-L-tryptophan



By Hideo OTSUKA and Ken INOUYE

(Received November 7, 1963)

Hofmann and Yajima[1] and Pickering and Li[2] concluded that the key to the melanocyte-stimulating activity resided in the His-Phe-Arg-Try-Gly sequence (positions 6 to 10) in the α-MSH molecule. However, the requirement for the glycine is not yet clear.

We have now synthesized a tetrapeptide, L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophan (I), which exhibits the same level of MSH potency as do the pentapetides, L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine[3] and its D-phenylalanine analog.[4] From this observation it may be concluded that the glycine is not essential for the biological activity, and that the tetrapeptide is the smallest peptide fragment exhibiting MSH activity found so far. The outline of the synthetic route is:

N^G-Tosyl-L-arginine methyl ester (crystalline free base, m. p. 98~98.5°C, $[\alpha]_D^{25} = +14.8°$ (MeOH)) and *t*-butyloxycarbonyl-L-phenylalanine (prepared from the dicyclohexylamine salt; m. p. 210~212°C decomp., $[\alpha]_D^{25.5} = +28.9°$ (MeOH)) were coupled by the *N*,*N'*-dicyclohexylcarbodiimide (DCCI) method[5] to give *t*-butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginine methyl ester (II); amorph., $[\alpha]_D^{25} = -5.9°$ (MeOH). Found: C, 56.8; H, 7.0; N, 11.8; S, 5.6. Calcd. for $C_{28}H_{39}O_7N_5S$: C, 57.1; H, 6.7; N, 11.9; S, 5.4%. Compound II was converted into the corresponding acid (III) (amorph., $[\alpha]_D^{24} = +1.0°$ (MeOH). Found: C, 56.0; H, 6.8; N, 11.4; S, 5.8. Calcd. for $C_{27}H_{37}O_7N_5S$: C, 56.3; H, 6.5; N, 12.2; S, 5.6%.) by saponification or into the hydrazide (IV) (crystalline, m. p. 110~114°C, $[\alpha]_D^{24} = -6.3°$ (MeOH)). Found: C, 55.2; H, 7.2; N, 16.6; S, 5.5. Calcd. for $C_{27}H_{39}O_6N_7S$: C, 55.0; H, 6.7; N, 16.6; S, 5.4%. The coupling of the azide (derived from compound IV) with L-tryptophan benzyl ester (m. p. 71°C, $[\alpha]_D^{26.5} = +12.8°$ (MeOH); lit.[6] m. p. 71°C) gave a tripeptide, *t*-butyloxycarbonyl-L-phenylalanyl-N^G-tosyl-L-arginyl-L-tryptophan benzyl ester (V); amorph., purified on a silica gel column, $[\alpha]_D^{24.5} = -6.6°$ (MeOH). Found: C, 63.3; H, 6.4; N, 11.1; S, 3.7. Calcd. for $C_{45}H_{53}O_8N_7S$: C, 63.5; H, 6.3; N, 11.5; S, 3.8%. Compound V was, after the removal of the *t*-butyloxycarbonyl group by trifluoroacetic acid treatment, condensed by the DCCI method with N^α, N^{Im}-dicarbobenzoxy-L-histidine[7] to afford a tetrapeptide derivative, N^α, N^{Im}-dicarbobenzoxy-L-histidyl-L-phenylalanyl-N^G-tosyl-L-arginyl-L-tryptophan benzyl ester (VI); amorph., purified on silica gel, $[\alpha]_D^{24.5} = -10.9°$ (MeOH). Found: C, 64.3; H, 5.9; N, 11.9; S, 3.0 Calcd. for $C_{62}H_{64}O_{11}N_{10}S$: C, 64.4; H, 5.6; N, 12.1; S, 2.8%. The protecting groups of compound VI could be removed by treatment with sodium in liquid ammonia to give peptide I, which was, after purification on a carboxymethyl cellulose column, homogeneous with ninhydrin, Pauly, Ehrlich, and Sakaguchi reagents on paper chromatography ($R_f = 0.55$ in the system of *n*-butanol/acetic acid/water (4/1/2)) and on paper electrophoresis at pH 3.8, 6.6, and 11.1. $\lambda_{max}^{HCl} = 280.5$ mμ (ε, 5100), $[\alpha]_D^{24.5} = -5.4°$ (N HCl). Found: C, 55.3; H, 6.7; N, 18.0. Calcd. for $C_{32}H_{40}O_5N_{10} \cdot CH_3COOH \cdot 2H_2O$: C, 55.1; H, 6.5; N, 18.9%. The amino acid ratios[8] were $His_{1.00}$ $Phe_{1.00}$ $Arg_{1.03}$ ($Try_{0.79}$) (recovery 92.2%) in acid hydrolysate and $His_{1.00}$ $Phe_{1.03}$ $Arg_{0.97}$ $Try_{0.98}$ (recovery 92.5%) in LAP[9] digest. The MSH activity, as estimated by the method of Shizume and Lerner,[10] was 3.6×10^4 units per gram.[11]

The synthesis of compound V is the first instance in which the azide method could be successfully employed in the synthesis of arginyl peptide. When the Arg-Try bond was formed by means of the DCCI method, by the route shown above, the tetrapeptide obtained was contaminated by at least 10 to 15% of the racemate, but it exhibited the same hormonal potency.

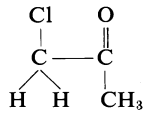
The Concentration Effect of the Long-range Proton Spin-spin Coupling Constant in Ketones

By Kensuke TAKAHASHI



(Received November 11, 1963)

A previous communication[1] has reported that the multiplet structures have been observed in the spectra of the methyl group adjacent to the carbonyl group in ethyl methyl ketone and in isopropyl methyl ketone. Such a coupling has also been investigated in some substituted acetones, CH_3COCH_2X or CH_3COCHX_2 (X=Cl and Br), and it has been pointed out: (1) the more electronegative X is, the less the coupling constant becomes, and (2) this coupling will be dependent upon the dihedral angle between the C–H bond and the π-orbital of the carbon atom in the carbonyl group.[2] Therefore, it is plausible to consider that the coupling will be dependent upon the population of the rotational isomers in each ketone. The four compounds have been examined briefly in the pure liquid and in a 5 mol. % solution in carbon tetrachloride, at 60 Mc. and 22.8±0.5°C. The experimental results are shown in Table I. Although the

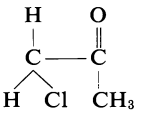


TABLE I. THE LONG-RANGE PROTON-PROTON COUPLING CONSTANTS IN KETONES (IN c. p. s.)

Compound	Pure	in CCl_4
$CH_3COCH(CH_3)_2$	0.45±0.05[1]	0.44±0.03
CH_3COCH_2Br	0.40±0.01	0.37±0.01[2]
CH_3COCH_2Cl	0.33±0.03	0.22±0.03[2]
$CH_3COCHCl_2$	0.24±0.03	0.30±0.01[2]

differences are very small, the variation of the coupling constants is clearly real. This result is acceptable on the basis of the following consideration about the rotational isomers. In chloroacetone, Mizushima[3] and Bellamy[4] suggested two rotational isomers, I and II, on the basis of the infrared and dipole moment studies. The carbonyl-stretching frequencies of this compound were observed at 1752 and 1726

I

II

cm^{-1} in a carbon tetrachloride solution,[4] corresponding to the two rotational isomers, the cis-form (I) and the trans-form (II) with respect to the Cl atom and the CO group, respectively. The former is more polar than the latter, so that a very marked change in the relative intensities of these bands was observed when the compound passed from the pure liquid to the solution in carbon tetrachloride. The contribution of each hydrogen in I and II, depending upon the dihedral angle (ψ), to the long-range coupling in chloroacetone is supposed to be:

$$a \sim P_{\mathrm{I}}[a(30°)+a(30°)]+P_{\mathrm{II}}[a(30°)+a(90°)]$$

$$a(\psi) \propto \cos^2\psi$$

where a corresponds to the hyperfine constant as defined by Karplus[5] and where P_i is the population of the i isomer. Therefore, the contribution of II is half that of I. The decrease in the coupling constant in a carbon tetrachloride solution may be caused by the increase in the population of II as compared with that of I. This kind of variation in the long-range coupling constants has not yet been reported in the literature. Detailed results will be published later in this Bulletin.

Tetraphenylallene- and Tetraphenylbutatriene-Iron π-Complexes

By Akira NAKAMURA, Pu-Jun KIM and Nobue HAGIHARA

(Received December 7, 1963)

Although a number of organometallic π-complexes of conjugated 1,3-diene systems have been reported,[1] no report on an example of the π-complexes of cumulene systems has been published as yet. We will now report a preparation which is believed to be the first example of the π-complexes of the cumulene systems.

The reaction of tetraphenylallene with an excess of iron pentacarbonyl in refluxing isooctane under nitrogen for 13 hr. proceeded with the evolution of a gas. After the removal of the solvent from the deep reaction mixture, a red semisolid was obtained. The semisolid crystallized from ethanol to give red crystals (I) (m. p. 102~103°C, decomp. 230°C) in 29% yield. The elemental analysis and molecular weight determination indicated the composition: (tetraphenylallene)$Fe(CO)_3$, (Found: C, 74.00; H, 4.45; mol. wt. (in benzene), 518. Calcd. for $C_{30}H_{20}FeO_3$: C, 74.39; H, 4.16%; mol. wt., 484).

Carbon monoxide (2.6 mol. equiv.) was evolved on the pyrolysis of I under nitrogen. The pyrolysis gave tetraphenylallene and 1,1-diphenyl-3-phenylindene.[2] The infrared spectrum of I showed the presence of terminal iron carbonyl groups (2060, 1999, and 1985 cm^{-1} in carbon tetrachloride) and phenyl groups. In the visible region it showed a maximum at 468 mμ (log ε: 2.91) and had an increasing absorption towards the shorter wavelengths. The compound I was found to be diamagnetic and was quite stable in air. It was soluble in *n*-hexane, benzene and ethanol.

Tetraphenylbutatriene was allowed to react with an excess of iron pentacarbonyl in ethylcyclohexane under nitrogen for 14 hr. at reflux. The evolution of a gas was accompanied by a change in color to deep red. Red crystals mixed with a small number of yellow ones were obtained on cooling. The product was purified by repeated crystallization from a benzene-*n*-hexane mixture. Pure red crystals (II) (decomp. 200°C) were obtained in 26% yield. The product was found to have the composition: (tetraphenylbutatriene)$Fe_2(CO)_5$. (Found: C, 64.90; H, 3.55; mol. wt. (in benzene) 500. Calcd. for $C_{33}H_{20}Fe_2O_5$: C, 65.16; H, 3.31 %; mol. wt., 608).

The amount of carbon monoxide which evolved upon pyrolysis indicated five CO groups present in a molecule of II. The pyrolysis gave tetraphenylbutatriene and 1-diphenylmethylene-3-phenylindene.[2] The infrared spectrum of II showed the presence of terminal iron carbonyl groups (2072, 2035, 1998, and 1988 cm^{-1} in carbon tetrachloride) and phenyl groups. The visible and ultraviolet spectra showed no maxima.[3] An increasing absorption towards shorter wavelengths was observed. This spectral evidence indicates the absence of tetraphenylbutatriene chromophore, which has a strong absorption maximum at 420 mμ. Therefore, the butatriene chromophoric system is destroyed by bonding with the iron carbonyl group. The compound II was diamagnetic and was stable in air. It was soluble in benzene and slightly soluble in *n*-hexane.

It is interesting to discuss how these cumulene systems interact with iron carbonyl groups. The bonding of the iron tricarbonyl group in I through the benzene nucleus is very unlikely since no examples of benzene iron tri- or dicarbonyl type compounds are known. The bonding through one of the double bonds of the allene system and a double bond of the benzene nucleus is also less probable as a possible steric hindrance. Therefore, we are left with the possibility of the bonding through two double bonds of the allene system. We believe that cumulated double bonds in a straight chain are responsible for stable bond formation. By similar reasoning and also from the spectral evidence, we judge that the bonding in II is probably through the butatriene system. The chemical approach to the structure determination seems to be inconclusive to us. It is hoped that structure elucidation by means of X-ray will clarify the nature of the bonding in these compounds.

*Tensammetric Waves in Oscillographic Square-wave Polarography**

By Koichi OKAMOTO

(Received October 10, 1963)

In previous papers[1-5] the oscillographic square-wave polarographic behavior of some reducible or oxidizable depolarizers has been reported on. Since the oscillographic square-wave polarograph can selectively eliminate the charging current by means of the gating and the positive feed-back techniques, as described in a previous paper,[1] the reduction or the oxidation waves obtained by this method may contain none of the charging current. On the contrary, the changes of the electric double layer at the electrode surface, according to the adsorption or desorption of surface-active substances, can be observed as tensammetric waves by this polarograph. This work will study the possibility of the observation of tensammetric waves by means of this polarograph and will compare the properties of the waves with those obtained by a conventional a. c. polarograph.

There are two experimental methods used in order to obtain the tensammetric waves by this equipment. One of them is the suitable regulation of the amount of the positive feed-back of an electrolytic current. Another method is the removal of the gating circuit from the electric circuit of the polarograph. In the present study the measurements were carried out under the optimum positive feed-back conditions.

In this paper the behavior of such surface-active substances as aliphatic alcohols and several synthesized surface active substances will be presented in relation to their behavior in the pen-recording sine wave a. c. polarograph. Moreover, the measuring method of the critical micelle concentrations of the synthetic surface-active substances will also be presented.

Experimental and Results

Apparatus.—The oscillographic square-wave polarograph reported on in a previous paper[1] was used. A pen-recording a. c. polarograph (Yanagimoto Model PA-102; frequency=50 c. p. s., amplitude=15 mV_{p-p}) was also used. The characteristics of the DME used were $m=0.529$ mg. sec^{-1}, $t=6.26$ sec. (open circuit) in a 1 N sodium sulfate solution.

The measurements were carried out at 25±0.5°C unless otherwise stated, and the potentials were referred to the external SCE, which was connected to the mercury pool anode through a 200 μF condenser. The dissolved air was removed by nitrogen gas. The degree of the positive feed-back of the electrolytic current was fixed at the optimum point for the base solution so as to completely eliminate its charging current, and then the studies with the sample solutions were carried out.

The Behavior of Aliphatic Alcohols.—In the oscillographic square-wave polarograph, the wave which appears at the potentials more positive than zero can not be observed because of the large charging current of the dissolution of the Hg-cathode, so only the waves appearing between 0 and −2 V. vs. SCE were studied.

The Summit Potentials and Currents.—Most of the aliphatic alcohols studied gave clear tensammetric waves, as is shown in Figs. 1—3; their summit potentials and currents are shown in Table I.

Generally speaking, the weakly surface-active alcohols, such as *n*- and isopropyl alcohols and *n*-butyl alcohol, show the broad waves, while the strongly surface-active alcohols, such as *t*-amyl alcohol and *n*-octyl alcohol, show the sharp waves.

With the oscillographic square-wave polarograph, the waves in the cathodic and the anodic sweep processes are very similar to each other, as is shown in Figs. 1 and 2. This is considered to correspond to the a. c. polarographic-reversible property of the adsorption-desorption reactions. Some exceptions were, however, observed, as in the case of *n*-octyl alcohol (Fig. 3). This may indicate an a. c. polarographic-irreversible property.

The Relation of the Concentrations to the Summit Potentials and Currents.—The findings on *t*-amyl alcohol are shown in Figs. 4 and 5. The summit potentials of their positive and negative tensammetric waves tend to approach each other as the concentration decreases, and the relationships between $(E_s^c - E_{ecm})^2$ or $(E_s^a - E_{ecm})^2$ and $\log C$ were linear, where

E_{ecm} is the electro-capillary maximum potential. In the present study, $E_{ecm} = -0.50$ V. vs. SCE was employed according to the electro-capillary curve. The summit currents increased to the limiting values as the concentration increased. However, the relation of $\log C$ to the summit current, i_s^c or i_s^a, was not linear. This relation of $\log C$ to i_s values is not the same as the finding reported by Senda[8] on the a. c. waves of *t*-amyl alcohol obtained by by a pen-recording a. c. polarograph.

Temperature Effects.—As Fig. 6 shows, the summit currents of *t*-amyl alcohol decreased with the rise in temperature, while the summit potential scarcely changed. These results may show the typical properties of the adsorption waves.

II, IV: Positive wave in anodic process

The Behavior of the Mixtures of Alcohols.—When the pen-recording a. c. polarograph is used the solution containing two or more surface-active substances gives the tensammetric wave of only one component which has the strongest surface activity.[6]

The polarographic behavior of the binary mixtures shown in Table II was studied.

The system of isopropyl alcohol - *n*-butyl alcohol showed waves similar to those of *n*-butyl alcohol. No wave of isopropyl alcohol could be observed. The summit potentials, however, of the mixture were slightly more negative than those of *t*-butyl alcohol, and the summit currents were not equal to those of *t*-butyl alcohol. A similar result was also obtained with an isopropyl alcohol - *t*-amyl alcohol system. The mixture of *t*-amyl alcohol and *n*-

octyl alcohol showed quite the same waves as those of *t*-amyl alcohol. However, the mixture of *n*-butyl alcohol and *t*-amyl alcohol gave a wave with a more positive summit potential and a higher summit current than those of the individual components.

The tensammetric wave of a mixed alcohol solution may correspond to the wave of the alcohol, the negative tensammetric wave of which appears at more negative potentials than that of the other alcohol. When the summit potentials of the alcohols in a mixture are, however, almost identical, a new wave appears as is observed in a *n*-butyl alcohol - *t*-amyl alcohol mixture.

The Synthetic Surface-active Agents. — A cationic agent (cetyltrimethylammonium chloride (CTACl)), and anionic agents (sodium

caprate (SC) and sodium laurylsulfate (SLS)) of the reagent grade were studied. Non-ionic agents (oleylpolyethyleneglycol ethers ($n=10$ and 12, OPEG), stearylpolyethyleneglycol ethers ($n=19$, 30 and 40, SPEG), laurylpolyethyleneglycol ether ($n=8$, LPEG) and nonylphenylpolyethyleneglycol ethers ($n=10.5$ and 12, NPPEG)) which had been synthesized in this laboratory were also studied.

The Summit Potentials and Currents. — The samples studied, except SLS, gave the waves at the potentials near to 0 and −2 V., as Fig. 7 shows. The numerical data are listed in Table III. The shape of the waves is very sharp, and their heights in the cathodic and the anodic processes were not generally equal.

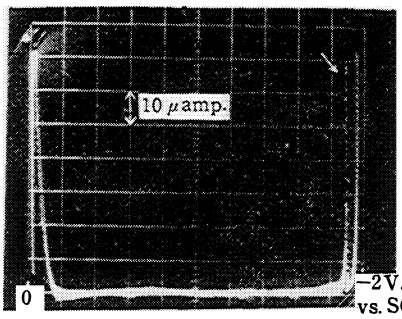

Fig. 7. 10^{-2} mol./l. oleylpolyethyleneglycol ether ($n=10$) in 0.5 M KCl, air free, 25°C.

The Relation of the Concentrations to the Summit Potentials and Currents.—The effect of the concentration change upon the cathodic waves of the non-ionic agent OPEG is shown in Fig. 8. The summit current increases to the limiting value as the concentration increases, and the potentials began to shift to more negative values at concentrations lower than ca. 2×10^{-4} mol./l.

The Influence of the Micelle Formation upon the Polarographic Waves of Some Metallic Ions. —In order to obtain the relation of critical micelle concentration (CMC) to the polarographic data, the values of the CMC of several agents were measured beforehand by the usual spectrophotometric method, using the color change of a dye.[7] The results are listed in Table IV.

The obscure negative shift of the summit potential of OPEG at the concentration of ca. 2×10^{-4} mol./l. (Fig. 8) was thought to correspond nearly to the CMC of OPEG, but the waves at such low concentrations can not be measured well. Therefore, the detection of the CMC from the concentration $-E_s$ or i_s curves is not a suitable method.

7) T. Nakagawa, *Shionogi's Ann. Rep.*, **8**, 31 (1958).

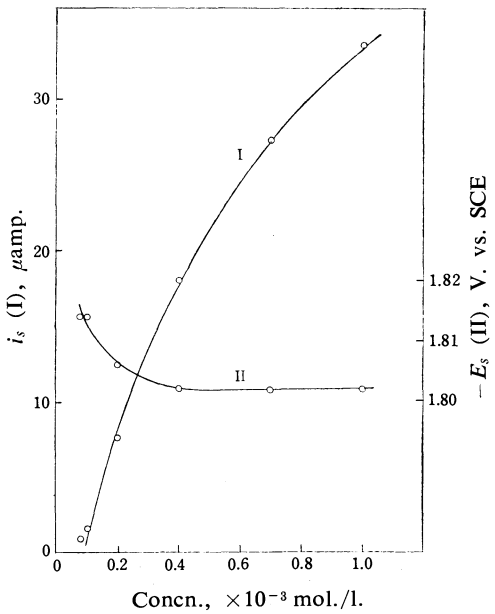

Fig. 8. Relation of i_s and E_s to concentration.
Oleylpolyethyleneglycol ether ($n=10$) in 0.5 N Na_2SO_4, 25°C, air free

The d. c. polarographic wave of a metallic cation is considerably affected by the addition of a surface-active agent, so the CMC of the agent can be detected by the change in the wave height or the half-wave potential of the metallic cation.[7] This change may mean a decrease in the reversibility of the electrode reaction of a metallic cation. The a. c. polarographic method is more sensitive than the d. c. method with respect to the response to the change in the reversibility of the electrode reaction. Therefore, the author's oscillographic method was also considered to be suitable for this purpose. Moreover, with this polarograph, since the cathodic and the anodic waves can be observed continuously, the change of the wave form can be observed more precisely than with the conventional pen-recording method.

The metallic ions used were lead(II) and zinc(II), which give a reversible and a quasi-reversible wave respectively. The surface-active agents used were CTACl, SLS, OPEG and NPPEG. The measurements were carried out in a deoxygenated 0.5 N sodium sulfate aqueous solution containing a constant amount of the metallic ions (2.5×10^{-4} mol./l. in lead(II) or 10^{-3} mol./l. in zinc(II)) and also various amounts of the surface-active agents. The degree of the positive feed-back of the electrolytic current was fixed at the optimum point for the solution of 0.5 N sodium sulfate containing only the metallic ions.

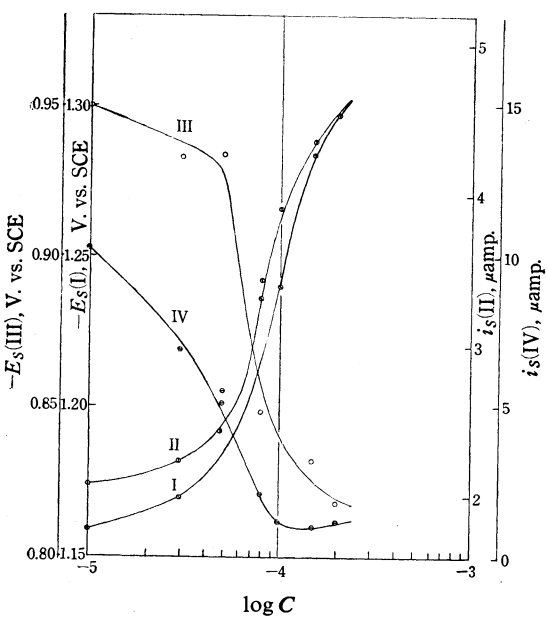

Fig. 11. Relations of i_s and E_s of waves of 1×10^{-3} mol./l. Zn(II) to concentration of CTACl, 25°C, air free, in 0.5 N Na_2SO_4.

I, II: Reduction wave
III, IV: Oxidation wave

Typical changes in the reduction and the oxidation waves of lead(II) and zinc(II) upon the addition of OPEG are shown in Figs. 9 and 10 respectively. In all the cases studied, the remarkable decrease in the summit currents and the shifts in the summit potentials were observed at the concentration near to the CMC. These relations are indicated in Fig. 11 in the case of the zinc(II)-CTACl system.

The nature of these changes can not be explained theoretically, but the inclusion of a metallic ion by the micelles or the increase in the thickness of the adsorption layer on the electrode surface upon the micelle formation may interfere with the electrode reaction of the metallic ions.

The concentration ranges where the summit potentials and currents of the metallic ions changed are summarized in Table IV. It appears that they represent the appoximate CMC values of the surface-active agents.

TABLE IV. THE CMC VALUES

Solvent: 0.5 N Na_2SO_4, 25±0.5°C

Compound	By oscillographic square wave polarograph $\times10^{-4}$ mol./l.	By spectrophotometric method $\times10^{-4}$ mol./l.
CTACl	0.4～1.8	2.0*1
SLS	2.0～5.0	1.5*2
OPEG-10	0.5～1.8	2.5*2
NPPEG-10.5	0.3～1.1	1.5*2

*1 Obtained from the shift of λ^{516}_{max} and ε^{516}_{max} of eosin yellow

*2 Obtained from the shift of λ^{547}_{max} of pinacyanol chloride

Discussion

The tensammetric waves of surface-active substances are said to correspond to the reversible wave in a pen-recording a. c. polarograph. This is also applicable to an oscillographic square-wave polarograph. As has been described in previous sections. the tensammetric wave could be observed very clearly and rapidly by means of the oscillographic method.

The values of the summit potentials of aliphatic alcohols obtained with the oscillographic method were almost always equivalent to those obtained with the pen-recording method as is shown in Table I. The summit current values, on the other hand, were found to be very much higher than those obtained by means of the pen-recording method. This may be mainly due to the difference between the frequencies of the a. c. potentials: the oscillographic method employs 3 kc./sec. and the pen-recording method employs 50 c.p.s. The sensitivity of the oscillographic square wave polarograph for the measurement of the adsorption-desorption wave is superior to that of the pen-recording polarograph.

The relation between the logarithm of the concentrations and the square of the summit potentials of *t*-amyl alcohol showed a linear relation similar to that in a pen-recording polarograph, as Fig. 4 shows.

When the concentration of a surface active substance is comparatively high, and when the concentrations at the electrode surface and in the bulk solution (C_n^0) can be thought to be equal, the relation of the summit potential to the bulk concentration may be expressed as $\ln C_n^0 \propto (E_s - E_{ecm})^2$, as was shown by Senda.[8] This relation seemed to be adaptable to the oscillographic polarographic waves of *t*-amyl alcohol.

The summit currents increased as the concentration increased, but the behavior of the positive tensammetric wave was not equal to that of the negative tensammetric wave (cf. Fig. 5). The relation between the $\log C$ and i_s of the negative wave is near to the linear relation.

The wave height in an anodic sweep process, as was observed on *n*-octyl alcohol (Fig. 3) and also on synthetic surface-active agents (Fig. 7), is not equal to that in a cathodic process. This may indicate the a. c. polarographically-irreversible property of their adsorption-desorption processes.

The critical micelle concentration of synthetic surface-active agents can be measured or detected by means of the measurement of the change, caused by the addition of the surface-active agents, in the summit potentials or the currents of such metallic ions as lead(II) and zinc(II). The mechanisms of the change in the form of the reduction or oxidation waves of the ions may possibly be studied by means of the author's polarograph.

8) M. Senda and I. Tachi, *Rev. Polarography*, **10**, 79 (1962).

Summary

The possibility of observing the tensammetric waves of surface-active agents by an oscillographic square wave polarograph has been investigated. Well-defined tensammetric waves of some aliphatic alcohols, as well as those of some synthetic surface-active agents, can be obtained both in the cathodic and anodic sweep processes. The summit potential values, measured by the oscillographic method and pen-recording method, are almost identical. The relations of the concentrations and temperature to the summit potentials obtained by the two methods are almost equivalent, also. However, the summit current observed by the oscillographic method is higher than that obtained by the pen-recording method, and also the relation of $\log C$ to i_s is not equivalent.

In order to measure the CMC of surface-active agents, the author had made use of the fact that, at the CMC of the agents, the form of the reduction or the oxidation wave of a metallic ion added to the solution of the agent changes remarkably. This method is thought to be superior to the conventional d. c. polarographic method, for the reduction and also the oxidation waves of a metallic ion can be observed, and the response to the change in the reversibility of the electrode reaction is much faster than with the d. c. method.

The author is much indebted to Professor Taichirō Fujinaga (Kyōto University) for his kind instruction and to Dr. Munetoshi Matsui and Dr. Akira Itō (both of this laboratory) for affording facilities for this investigation.

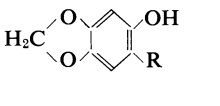
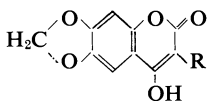
Synthetic Studies of Sesamol Derivatives. IV.[*1] *Preparation and Reaction of 2-Hydroxy-4, 5-methylenedioxyacetophenones*[*2]



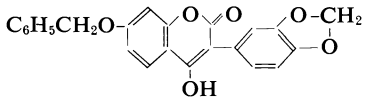
By Kenji FUKUI and Mitsuru NAKAYAMA



(Received July 30, 1963)

In continuation of a series of studies of sesamol derivatives, the present paper will report on the preparation of 2-hydroxy-4, 5-methylenedioxyacetophenones (I) and the reaction of I to give 4-hydroxycoumarins (II).

2-Hydroxy-4, 5-methylenedioxyacetophenone (Ia)[1] has been obtained by the Fries rearrangement of sesamol acetate in a poor yield (5%). A better result (35%) was obtained by means of the Hoesch reaction of sesamol (III) with acetonitrile. On the other hand, the acetylation of III with acetic acid and boron trifluoride to obtain the ketone Ia was extremely difficult, and it was unsuccessful with polyphosphoric acid. The failure may be due to an attack on the methylenedioxy system by the reagents which is not encountered in the Hoesch reaction. The Friedel-Crafts reaction of the methyl ether[2] of III also gave Ia (36%). By a similar Hoesch reaction employing methoxyacetonitrile and phenylacetonitrile, III was converted into 2-hydroxy-4, 5-methylenedioxy-ω-methoxyacetophenone (Ib)[3] and 2-hydroxy-4, 5-methylenedioxyphenyl benzyl ketone (Ic) respectively. 4-Hydroxyayapin (IIa) was obtained from Ia with ethyl carbonate,[4] but not with ethyl chloroformate.[5] The condensation of Ia with ethyl cyanoacetate[6] also gave IIa. On the other hand, either with ethyl carbonate or with ethyl chloroformate, Ib and Ic were converted into 3-methoxy- (IIb) and 3-phenyl-4-hydroxy-6, 7-methylenedioxycoumarin (IIc) respectively. 7-Benzyloxy-3-(3′, 4′-methylenedioxyphenyl)-4-hydroxycoumarin (IV) was obtained from 4-benzyloxy-2-hydroxyphenyl 3, 4-methylenedioxybenzyl ketone[7] with the former reagent.



These 4-hydroxycoumarins (II) exhibited fluorescence in alcohol, as did 3-substituted ayapin,[8] and the fluorescence of the acetate and the methyl ether of IIc was especially strong.

Ia R=$COCH_3$
Ib R=$COCH_2OCH_3$
Ic R=$COCH_2C_6H_5$
III R=H

IIa R=H
IIb R=OCH_3
IIc R=C_6H_5

IV

Experimental[*3]

2-Hydroxy-4,5-methylenedioxyacetophenone (Ia).—*The Hoesch Reaction.*—A mixture of III (5.0 g.),[9] acetonitrile (2.0 g.) and anhydrous zinc chloride (2.0 g.) in dry ether (30 ml.) was saturated with dried hydrogen chloride for 3 hr. at 0°C and then allowed to stand overnight. The ethereal solution was decanted from the greenish mass of ketimine hydrochloride which had separated. The residue was washed twice with dry ether (20 ml.) and then heated on a steam bath with water (30 ml.) for 0.5 hr. After cooling and standing, the resulting precipitates were collected and recrystallized from ethanol to give Ia in the form of pale yellow needles; m. p., 113~114°C (reported m. p. 114°C[1]); yield, 2.3 g. (35%). This was identical with an authentic sample[1] and gave a blue color with alcoholic ferric chloride solution. IR: 1634 (C=O); 1023, 918 (O-CH_2-O) cm^{-1}.

Found: C, 59.77; H, 4.53. Calcd. for $C_9H_8O_4$: C, 60.00; H, 4.33%.

The Boron Trifluoride Method.—With good cooling, a solution of III (5.0 g.) in acetic acid (40 ml.) was saturated with dried boron trifluoride for 3 hr., during which time care was taken to prevent the formation of solids. The resulting solution was heated at 80~90°C for 1.5 hr. and poured into a

saturated sodium acetate solution (100 ml.). After the solution had been extracted with ether, the ethereal solution was washed with a saturated sodium bicarbonate solution and water. The product was recrystallized from ethanol to give Ia; m. p. 112~113°C; yield, 0.3 g. (5%). It was identical with the above sample.

The Friedel-Crafts Reaction.—To a solution of anhydrous aluminum chloride (5.0 g.) in dry ether (50 ml.), sesamol methyl ether (b.p. 110~114°C/18 mmHg)[2] (3.0 g.) was added. Acetyl chloride (2.0 g.) was well stirred drop by drop into the solution for 0.5 hr., the stirring was continued another 5 hr. at room temperature, and the mixture was allowed to stand overnight. The ethereal solution was decanted from the dark-colored mass. Ice water containing dilute hydrochloric acid was cautiously added to the residue in order to dissolve the aluminum compounds. The crystalline product was collected and recrystallized from ethanol to give Ia (m.p. 112~113°C; 0.9 g.). The aqueous layer was extracted with ethyl acetate. After the extracted solution had been washed with water and saturated sodium bicarbonate solution, the solution was extracted with a 2 N sodium hydroxide solution. The aqueous layer was acidified with 2 N hydrochloric acid. The product was collected and recrystallized from ethanol to give Ia (m.p. 112~113°C; 0.4 g.). Total yield; 1.3 g. (36%). It was identical with the above sample.

The acetate was prepared by the pyridine-acetic anhydride method; m.p. 88~89°C (colorless prisms from ethanol), IR: 1731 (acetate); 1662 (C=O); 1027, 918 (O-CH_2-O) cm^{-1}.

Found: C, 59.35; H, 4.53. Calcd. for $C_{11}H_{10}O_5$: C, 59.46; H, 4.54%.

2-Hydroxy-4, 5-methylenedioxyphenyl Benzyl Ketone (Ic).—By a similar Hoesch reaction, Ic was obtained from III (5.0 g.), phenylacetonitrile (5.0 g.) and anhydrous zinc chloride (3.0 g.) in dry ether (120 ml.); m. p. 130~131°C (pale yellow prisms from ethanol); yield, 2.6 g. (28%). It gave a green color with an alcoholic ferric chloride solution. IR: 1649 (C=O); 1031, 923 (O-CH_2-O) cm^{-1}.

Found: C, 70.30; H, 4.87. Calcd. for $C_{15}H_{12}O_4$: C, 70.30; H, 4.72%.

The acetate; m.p. 124~125°C (colorless needles from methanol). IR: 1768 (acetate); 1692 (C=O); 1031, 923 (O-CH_2-O) cm^{-1}.

Found: C, 68.58; H, 4.97. Calcd. for $C_{17}H_{14}O_5$: C, 68.45; H, 4.73%.

4-Hydroxyayapin (IIa).—*The Ethyl Carbonate Method.*—A mixture of Ia (1.0 g.), ethyl carbonate (35 ml.) and pulverized sodium (1.5 g.) was warmed on a steam bath for 20 min. After the vigorous reaction had ceased, sufficient methanol was added to the cooled mixture to destroy the excess of sodium, and then the residue was added to ether (100 ml.). The extraction of the sodium salt of the product with water (100 ml.) and acidification of it with 2 N hydrochloric acid gave IIa, which formed colorless tiny needles from methanol; m.p. 274~275°C (decomp.); yield, 0.9 g. (79%). This dissolved in a sodium bicarbonate solution with effervescence. It did not give any color with an alcoholic ferric chloride solution. IR: 1706 (C=O); 1043, 934 (O-CH_2-O) cm^{-1}. UV: λ_{max}^{EtOH} mμ (log ε); 230.5(4.40), 254$_I$(3.80), 275(3.81), 285(3.88), 328(4.15).

Found: C, 58.15; H, 3.18. Calcd. for $C_{10}H_6O_5$: C, 58.26; H, 2.93%.

The Ethyl Cyanoacetate Method.—A mixture of III (10.0 g.), ethyl cyanoacetate (4.0 g.) and anhydrous zinc chloride (10.0 g.) in dry ether (120 ml.) was saturated with dried hydrogen chloride for 3 hr. at 0°C and then allowed to stand overnight. The ethereal solution was decanted from the dark-colored oil which had separated. The residue was washed twice with dry ether (20 ml.) and then treated with water (150 ml.). Upon being stirred, the ketimine hydrochloride separated as a dark violet mass (m. p.>300°C). It was hydrolyzed with 50% sulfuric acid (80 ml.) by heating it on a steam bath for 2 hr. The reaction mixture was added to a large quantity of water. The resulting precipitates were collected and recrystallized from methanol to give IIa; m.p. 270~272°C (decomp.); yield, 1.6 g. (11%). This was identical with the above sample.

The methyl ether was prepared by the methyl iodide-potassium carbonate method; m.p. 183~184°C (colorless needles from methanol). IR: 1728 (C=O); 1031, 921 (O-CH_2-O) cm^{-1}.

Found: C, 60.26; H, 3.83. Calcd. for $C_{11}H_8O_5$: C, 60.00; H, 3.66%.

3-Methoxy-4-hydroxy-6, 7-methylenedioxycoumarin (IIb).—*The Ethyl Carbonate Method.*—By a similar reaction, IIb was obtained from Ib (m.p. 136~138°C[3]) (0.5 g.), ethyl carbonate (20 ml.) and sodium (0.5 g.); m.p. 261~262°C (decomp.) (colorless needles from methanol); yield, 0.5 g. (89%). It dissolved in a sodium bicarbonate solution with effervescence. It did not give any color with an alcoholic ferric chloride solution. IR: 1699 (C=O); 1031, 937 (O-CH_2-O) cm^{-1}. UV: λ_{max}^{EtOH} mμ (log ε); 231(4.52), 256$_I$(3.90), 280(4.03), 289(4.11), 330(4.52).

Found: C, 55.72; H, 3.52. Calcd. for $C_{11}H_8O_6$: C, 55.94; H, 3.41%.

The Ethyl Chloroformate Method.—A mixture of Ib (1.0 g.), ethyl chloroformate (2 ml.), anhydrous potassium carbonate (5.0 g.) and acetone (50 ml.) was heated under reflux for 5 hr., poured into water, and acidified with concentrated hydrochloric acid. The resulting precipitates were collected and recrystallized from methanol to give IIb, m.p. 261~262°C (decomp.); yield 0.7 g. (62%). This was identical with the above sample.

The methyl ether; m.p. 161~162°C (colorless needles from methanol). IR: 1706 (C=O); 1031, 933 (O-CH_2-O) cm^{-1}.

Found: C, 57.66; H, 4.16. Calcd. for $C_{12}H_{10}O_6$: C, 57.60; H, 4.03%.

The acetate: m.p. 136~137°C (colorless needles from methanol). It gave a blue fluorescence in alcohol. IR: 1783 (acetate); 1721 (C=O); 1037, 931 (O-CH_2-O) cm^{-1}.

Found: C, 56.16; H, 3.75. Calcd. for $C_{13}H_{10}O_7$: C, 56.12; H, 3.62%.

3-Phenyl-4-hydroxy-6, 7-methylenedioxycoumarin (IIc).—By similar reactions, IIc was obtained from Ic; m. p. 267~268°C (decomp.) (colorless needles

from methanol); yield, 91% (the ethyl carbonate method) and 69% (the ethyl chloroformate method). It dissolved in a sodium bicarbonate solution with effervescence. It did not give any color with an alcoholic ferric chloride solution. IR; 1660 (C=O); 1040, 941 (O-CH_2-O) cm^{-1}. UV: λ_{max}^{EtOH} mμ(log ε); 225(4.41), 288(3.87), 336(4.30).

Found: C, 67.98; H, 3.78. Calcd. for $C_{16}H_{10}O_5$: C, 68.08; H, 3.57%.

The methyl ether; m.p. 189~190°C (colorless needles from methanol). It gave a blue fluorescence in alcohol. IR: 1703 (C=O); 1029, 926 (O-CH_2-O) cm^{-1}.

Found: C, 68.96; H, 4.19. Calcd. for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%.

*The Cationic Polymerization of Acrolein**

By Yoshio Toi and Yoshikazu Hachihama

(Received August 9, 1963)

Generally speaking, the ionic polymerization of acrolein[1,3] gives soluble polymers in organic solvents and the polymers have low molecular weights and melting points. The structures of the polymers are extremely different from those of the polymers obtained by radical polymerization;[1-9] contrary to the case of radical polymerization, which proceeds through the vinyl group, in the case of ionic polymerization the carbonyl group plays a more important role in the polymerization than does the vinyl group. Schulz and Passmann[10] reported on the behavior of acrolein in ionic polymerization in their recent work on anionic polymerization. In the present paper the cationic polymerization of acrolein will be studied. The kinetics of polymerization and the influence of the polymerization temperature on the structure of polymers will be investigated.

Experimental

Material. — Commercial acrolein was distilled, dried over anhydrous cupric sulfate, and distilled again immediately before the polymerization procedure; the distillate at b. p. 52.5~53.5°C was used as the acrolein monomer.

Polymerization Procedure.—The monomer and the solvent were precooled at the desired temperature under nitrogen in a glass tube with a rubber stopper; the initiator, boron trifluoride etherate, was stirred in via the rubber stopper with an injector. The mixture was kept at the desired temperature for the desired length of time. After

the polymerization, the resulting mixture was added to a large excess of a water-methanol mixture (3 : 1 vol.), and then the unreacted monomer, the solvent and most of the methanol were removed by distillation under reduced pressure until the polymer was precipitated as a white powder in a transparent aqueous solution. The polymer was filtered, washed with water and dried under reduced pressure at room temperature.

The Treatment of the Polymer. — *Aldehyde Content.*—The method reported by Bryant and Smith[11] was employed. 0.5 g. of polymer was dissolved in 25 ml. of dioxane, to this solution 10 ml. of a 0.5 N hydroxylamine hydrochloride water-methanol solution and 35 ml. of a bromophenol blue ethanol solution containing pyridine were added, and the resulting mixture was warmed at 70°C for three hours. After this treatment, the mixture was titrated with a 0.5 N sodium hydroxide methanol solution. A blank was run under the same conditions without the polymer. The aldehyde content was calculated from the amount of alkali consumed.

The Determination of the Unsaturation Value.—0.5 g. of the polymer was dissolved in 90 ml. of acetic acid and was hydrogenated in the presence of 0.2 g. of platinum black under the atmospheric pressure of hydrogen and at room temperature. The carbon-carbon double bond in the polymer was calculated from the volume of hydrogen gas consumed.

Ozone Degradation.—0.5 g. of the polymer was dissolved in 250 ml. of dry chloroform, and an oxygen-ozone mixture was passed through the solution for a long enough length of time at −50°C. After ozonization, the chloroform was removed from the solution under reduced pressure at room temperature. The ozonide which remained as a white powder was cleaved by treatment with 50 ml. of 3% aqueous hydrogen peroxide at 50°C to yield a transparent solution. The solution was distilled under reduced pressure to separate the volatile organic acid from the other products. The distillate was titrated with alkali, and the acidity was calculated as formic acid. It has been demonstrated by means of paper chromatography[12] that the distillate contains only formic acid. The R_f value of hydroxamate of formic acid was 0.49 when the mixture of 1-butanol, acetic acid and water (4 : 1 : 5 v/v) was used as the development solvent.

Molecular Weight.—For the measurement of the molecular weight of polymers, the cryoscopic method in acetic acid was employed.

Results

The polymerization of acrolein in an ethyl ether solution in the presence of a boron trifluoride etherate was made. Figure 1 shows the relationship between the concentration of the initiator ([C], mol./l.) and the overall rate of polymerization (R_p), which was calculated from the slope of the time-conversion curve shown by a straight line at the early stage of polymerization (<20% of conversion). The relationship between the monomer concentration ([M], mol./l.) and R_p is shown in Fig. 2. It is confirmed by Figs. 1 and 2 that

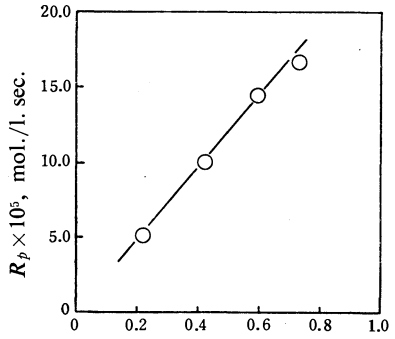

Fig. 1. Relationship between concentration of initiator and overall rate of polymerization.
Reaction temp.: 0°C
Concn. of monomer: 7.00 mol./l.
Solvent: ethyl ether

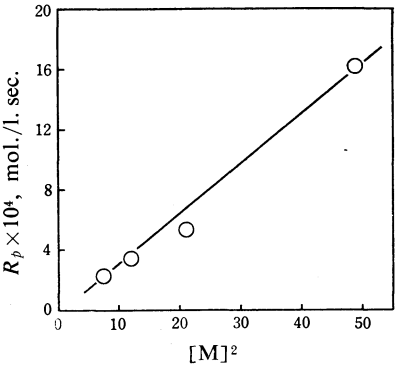

Fig. 2. Relationship between concentration of monomer and overall rate of polymerization.
Reaction temp.: 0°C
Concn. of initiator: 0.74 mol./l.
Solvent: ethyl ether

R_p is proportional to the first order of concentration of the initiator and to the second order of concentration of the monomer. From these results, the equation of the overall rate of polymerization is shown as Eq. 1:

$$R_p = K[C][M]^2 \qquad K: \text{constant} \qquad (1)$$

Equation 1 supports the theory that the initiation and termination reactions are bimolecular and monomolecular respectively. The temperature dependence on R_p is shown in Fig. 3. From R_p calculated from the slope

of the time-conversion straight line and Eq. 1, the rate constants (K) of the polymerization reaction were calculated as is shown in Table I. 4.5 kcal./mol. was calculated as the activation energy of the reaction from the slope of the straight line of the Arrhenius plot (Fig. 4).

The bulk polymerization in the presence of boron trifluoride etherate at $-78°C$ was made, while anionic polymerizations by potassium carbonate and triphenyl phosphine were also made. These results are shown in Table II. Polymers obtained by polymerizations initiated with these cationic or anionic initiators were soluble in ethyl ether, benzene, dioxane and acetic acid, etc., but were insoluble in water and *n*-hexane. The melting points of the polymers were 65~70°C.

The molecular weight of the polymer obtained by the solution polymerization with boron trifluoride etherate is given in Table III. The molecular weights of I, II and III (cf. Table II) are 643, 430 and 1270 respectively. The results of the elementary analysis of polymers are shown in Table IV. The infrared spectra of I, I-7 and II are shown in Fig. 5 (for reference, the spectrum of the polymer obtained by radical polymerization is shown in the same figure). At 1725 cm^{-1}, the absorption of the carbonyl group is observed. At 3080, 1645, 1410, 985 and 930 cm^{-1}, absorptions of the vinyl group are observed; these absorptions disappear or diminish in the spectra of hydrogenated polymers. In the spectra of II and I-7, a weak absorption of -C=C-O- is observed at 1250 cm^{-1}; this absorption disappears in a hydrogenated polymer. The aldehyde content and the carbon-carbon double bond in polymers were measured; these results are shown in Tables V and VI. Polymer I, which has a maximum double-bond content and a minimum aldehyde content compared with other polymers, was subjected to the ozonolysis. If the polymer has a double bond as vinyl group in a pendant of the polymer (as is shown in B), formic acid is produced as product of the ozone degradation as follows:

$$\begin{array}{l}\text{-CH-O-} \rightarrow \text{-CH-O-} + \text{HCOOH}\\ \quad\text{CH} \qquad\quad \text{COOH}\\ \quad\text{CH}_2\end{array}$$

(B)

On the other hand, if the polymer has a double bond in the main chain of the polymer as is shown in C, the formic ester of glycolic acid is produced as a product of the ozone degradation and this ester is saponified by the formic acid actually present in the mixture of the products, thus yielding a glycolic acid.

$$\text{-CH}_2\text{-CH=CH-O-} \rightarrow \text{O=CH-O-CH}_2\text{-COOH}$$

(C)

$$\rightarrow \text{HCOOH} + \text{HO-CH}_2\text{-COOH}$$

Formic acid was confirmed as the only volatile product by paper chromatography. Its acidity as determined by alkali titration was equivalent to 50% of the theoretical amount based on monomer units; this value is approximately in agreement with the degree of unsaturation as estimated by hydrogenation. In the nonvolatile product, glycolic acid was not identified by paper chromatography. It is confirmed by the above evidence that the

carbon-carbon double bond belongs to vinyl group in a pendant of the polymer; this is also supported by the infrared absorption spectra of the polymer.

Discussion

Understandably, acrolein is polymerized in a different orientation under suitable conditions; the polymers thus obtained contain the following structural units in some ratios:

$$CH_2{=}CH{-}CH{=}O$$

$$\underset{\text{(A)}}{-CH_2{-}\underset{\displaystyle CHO}{\underset{|}{CH}}-} \qquad \underset{\text{(B)}}{-\underset{\displaystyle \overset{\displaystyle CH}{\overset{\|}{CH_2}}}{\underset{|}{CH}}{-}O-} \qquad \underset{\text{(C)}}{-CH_2{-}CH{=}CH{-}O-}$$

Such behavior of acrolein is attributed to the conjugation of a carbonyl group with the vinyl group within its structure. In radical catalytic or gamma-rays-initiated polymerization, the polymers obtained belong to type A. For example, in the polymer obtained by the irradiation of gamma-rays at $-78°C$[13] or by redox polymerization,[5] the aldehyde content is 75~85% of the theoretical amount which is calculated as type A and the content of the carbon-carbon double bond is either not present or present in a negligibly small amount (4% in redox polymer[9]). On the other hand, in the polymer obtained by ionic polymerization, the aldehyde content is much less than that of the polymer given by radical polymerization, and the content of the carbon-carbon double bond increases. According to the recent work by Schulz[10] on anionic polymerization in the presence of sodium naphthalene, the polymer contains 70% of the theoretical amount of double bond and only 2% of the theoretical amount of the aldehyde group, and it is assumed that the polymer consists mainly of type B.

The similar behavior of acrolein upon polymerization is found in the cationic polymerization in the presence of boron trifluoride etherate. The polymer obtained at $-78°C$ has only 16% of the aldehyde group and 60% of the carbon-carbon double bond in the side chain, findings which are supported by the infrared spectrum, the hydrogenation and the ozone degradation of the polymer, so that the polymer consists of type B in magnitude and also contains some A. On the other hand, in the infrared spectra of the polymers obtained at a higher temperature, 0 or 20°C, a weak absorption of -C=C-O- at 1250 cm^{-1} is observed (Fig. 5), and in the polymer, the ratio of the amount of the aldehyde group to the carbon-carbon double bond is increased (Table IV). In the ionic polymerization of acrolein, the carbonyl's double bond plays an important role in the polymerization reaction, one which can be predicted from the fact that, in the acrolein molecule, the position of the maximum and minimum of π-electron density exist on the oxygen and carbon atoms of the carbonyl group respectively. This orientation of the polymerization reaction is more remarkable still at lower temperatures.

Summary

The cationic polymerization of acrolein with boron trifluoride etherate at various temperatures has been studied.

(1) The polymerization rate may be given as follows: $R_p = K[C][M]^2$, on the basis of the polymerization in an ethyl ether solution, and the activation energy of reaction is 4.5 kcal./mol.

(2) The structure of polymers depends very much on the polymerization temperature; the polymerization at the lower temperature gives a polymer containing the larger amount of the end vinyl group as a side chain, and the smaller amount of the aldehyde group.

The authors wish to express their thanks to the Nippon Kayaku Co., which supplied acrolein for this study.

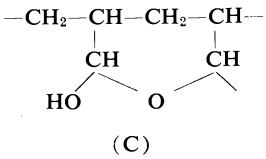
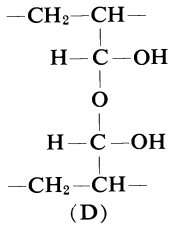
Polymerization of Acrolein Initiated by Gamma-rays

By Yoshio Toi, Toshikatsu Fujii and Yoshikazu Hachihama



(Received August 10, 1963)

It is known that acrolein is polymerized easily upon standing alone at room temperature, yielding an insoluble product. Moureu and Dufraisse[1] reported that the polymerization is greatly accelerated by heat and light. Scherlin[2] demonstrated the polymerization by Diels-Alder reaction under the action of heat. Thompson and Linnett,[3] and Blacet, Fielding and Roof[4] investigated the photochemical polymerization of acrolein in the vapor phase by irradiation with an ultraviolet light. Schulz, Kern and their co-workers[5-14] published a series of papers on the polymerization of acrolein in the presence of radical and ionic initiators. Under the action of gamma-rays at room temperature, acrolein is polymerized easily, yielding an insoluble polymer in common organic solvents.[15,16]



Generally the acrolein-polymer obtained by radical polymerization is assumed to consist of the following structural units, while the insolubility of the polymer is assumed to arise by means of the formation of intermolecular cross-linking as shown by D.

(A) (B)

(C)

(D)

In the present paper, the bulk polymerization at various temperature under irradiation by gamma-rays will be studied, and the influence of the polymerization temperature on the properties of the polymers obtained has been investigated.

Experimental

Material.—Commercial acrolein was distilled, dried over anhydrous cupric sulfate, and distilled again immediately before polymerization; the distillate at b. p. 52.5~53.5°C was used as acrolein monomer.

Polymerization Procedure.—The monomer was sealed under reduced pressure of nitrogen atmosphere in a glass tube after degassification and was kept at the desired temperature and for the desired length of time in the gamma-ray field with a constant dose rate. After irradiation, the resulting reaction mixture was transferred into a large excess of methanol; the polymer obtained as a precipitate was isolated, washed with methanol, and dried under reduced pressure at room temperature.

Analysis of the Polymer.—The measurement of the aldehyde content of the polymer was done as follows: 0.1 g. of the polymer and 0.4 g. of hydroxylamine hydrochloride were dissolved in 20 ml. of pyridine with a small amount of anhydrous sodium carbonate, and the mixture was warmed at 70°C for 3.0 hr. The polyoxime obtained in the reaction mixture was isolated by the precipitation method from water, dried under reduced pressure at room temperature, and subjected to an elementary analysis by nitrogen. The aldehyde content of the polymer was calculated from the nitrogen content of polyoxime.

The determination of the degree of unsaturation of the polymer (I-S-3) was made as follows; 1.0 g. of the polymer was dissolved in 20 ml. of pyridine, and to this solution 10 ml. of an aqueous solution in which 0.5 g. of sodium boron hydride has been dissolved was stirred in. The mixture was kept at room temperature for 20 hr. and was then dialyzed by water. From the dialyzed aqueous solution, the water was removed by distillation

under reduced pressure to isolate the product, and the resultant polyalcohol was dried under reduced pressure at room temperature. 0.5 g. of the polyalcohol obtained was dissolved in 90 ml. of acetic acid, and the experimenters tried to hydrogenate it in the presence of 0.2 g. of platinum black under atmospheric pressure and at room temperature. However, no hydrogenation of the polymer was observed.

Dosimetry. — A ceric solution was used for the dosimetry.

Results

Polymerization.—The conversion curves obtained in the gamma-ray-initiated polymerization of acrolein in bulk at various temperatures are shown in Fig. 1. It appears that the conversion increase proportionally to the irradiated dose in the early stages, but that after this stage the overall rate of polymerization increases acceleratively. This acceleration of the rate might be due to the fact that, in the higher range of conversion, above a ca. 10% precipitation of product in the reaction system appears. This behavior is more remarkable in polymerization at higher temperatures. Figure 2 shows the Arrhenius plot of the

overall rate of polymerization derived from the slope of the portion of the straight line of the conversion curve in the early stages. The overall activation energy, calculated from the slope of the straight line of Fig. 2, was 3.1 kcal./mol.

Properties of Polymer.—For convenience, the polymers obtained at −78°C, −20°C and 10°C are designated I, II and III respectively. I consists of the soluble part (I-S) and the insoluble part (I-InS) in pyridine at room temperature. The result of the separation of I-S from I by extraction with pyridine is shown in Table I. I-S is a white powder which is soluble in pyridine, dimethylformamide, and

dimethylsulfoxide at room temperature and is decomposed at about 320°C. The results of both the analysis of the aldehyde content and the measurement of the solution viscosity of I-S are shown in Table II. I-InS, which is insoluble at room temperature, becomes soluble at elevated temperatures, 120~150°C, in pyridine, dimethylformamide and dimethylsulfoxide. However, the polymer recovered from the solution by the reprecipitation method becomes insoluble again in the same solvents. The same behavior was reported in the polymer obtained by redox polymerization.[17] The variation in aldehyde content and solution viscosity induced by heat treatment in pyridine on I-InS was also investigated; the results are presented in Table III. The fact that the solution viscosity decreases with the increase in the duration of heat treatment supports the degradation of intermolecular cross-linking (D). The aldehyde content also decreases slightly as the duration of the heat treatment increases.

Table III. Aldehyde content and solution viscosity of I-InS after heat treatment*

Time min.	Nitrogen content %	Aldehyde content %	Inherent viscosity 0.5 g./dl.
60	17.00	86.4	0.49
100	16.46	83.5	0.44
140	14.67	74.5	0.42
180	15.11	76.6	0.35

* Sample: I-InS obtained in Exp. No. 3 of Table I.
Treatment: 0.25 g. of sample in 50 ml. of pyridine was heated at 150°C in sealed glass tube under nitrogen atmosphere.

Table IV. Fractionation of II and III by solubility in pyridine

Polymer	Conversion %	Soluble part[a] %	Soluble part at elevated temp.[b] %	Insoluble part[c] %
II	11.1	0.7 (85.2)[d]	99.3 (58.8)[d]	—
	25.8	—	77.5	22.5
III	15.8	—	21.6 (47.6)[d]	78.4
	33.4	—	14.5	85.5

a) Soluble in pyridine at room temperature
b) To be soluble in pyridine by treatment at 170°C for 1.0 hr.
c) Quite insoluble resinous compound
d) Aldehyde content (%)

In the case of II, a small amount of a soluble part is observed at a lower conversion, but most of II is soluble in pyridine only at elevated temperatures, 150~170°C, and with an increase in conversion the part of resinous compound which is entirely insoluble is increased. In the case of III, most of it is a resinous compound. The result of the separation of the parts of the polymer on II and III by extraction with pyridine are shown in Table IV.

Discussion

When acrolein is polymerized in bulk at various temperatures, at −78°C, −20°C and 10°C, by irradiation by gamma-rays, the resulting polymer precipitates in the reaction medium at a higher conversion because the polymer is not soluble in its own monomer, and the acceleration of the overall rate of polymerization is observed. However, in the early stage of polymerization, up to approximately 10% conversion, the reaction proceeds without any remarkable precipitation of the polymer and linear conversion curves are observed. The value of the overall activation energy, 3.1 kcal./mol., calculated from Fig. 2 is a reasonable value, one which supports the that theory, in the temperature range from 10°C to −78°C (the melting point of acrolein is −86.95°C), the polymerization of acrolein proceeds by a free radical mechanism. In the case of the radical polymerization of acrolein in dimethylformamide with azobisisobutylonitrile, the overall activation energy is 25.4 kcal./mol.[18] The G-values of the conversion in the early stage at each temperature are presented in Table V. The influence of the reaction temperature is important on the properties of the

Table V. G-value of conversion in bulk polymerization of acrolein

Temp., °C	Dose rate rads./sec.	G (conversion)
−78	1.76	9.85×10^{2}
−20	1.76	5.99×10^{3}
10	1.88	9.55×10^{3}

polymer obtained, especialy on the solubility of the polymer in organic solvents. That is, in the polymerization at −78°C most of the polymer obtained is soluble in pyridine, etc., but with an increase in the reaction temperature the soluble part of the polymer decreases extremely. The formation of intermolecular cross-linking, assumed to be the next reaction

18) Presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

of aldehyde after the polymerization reaction, is disturbed by taking a lower reaction temperature; the mechanism mentioned above is supported by the fact that the aldehyde content of the polymer obtained decreases with an increase in the reaction temperature (Tables II and IV). On the other hand, the monomer or polymer concentration in the polymerization system might be important on such a gel-formation, but not as important as the effect of temperature. Actually the percentage of the soluble part of I decreases greatly above an approximate 15% conversion (Table I). On the other hand, in the solution polymerization of acrolein by gamma irradiation[15,16] or radical catalysts,[8] the resulting polymers are not soluble in organic solvents at room temperature. For example, the polymerization of acrolein at 40~70°C by azobisisobutylonitrile in dimethylformamide, which can dissolve the polymer I-S, gives an insoluble polymer (the aldehyde content is 70~90%). That is, it is suggested that the influence of the polymerization temperature is predominant over other effects on the solubility of the polymer obtained. In the polymerization of acrolein initiated by gamma-rays, the reaction proceeds by a free radical mechanism through a carbon-carbon double bond. This theory is supported by the high aldehyde content and the very small content of the carbon-carbon double bond in the polymer, contrary to the existence of a double bond in the polymer obtained by ionic initiators. For instance, unlike I, which contains 75~85% of aldehyde and no unsaturation group, the polymer obtained by the bulk polymerization in the presence of boron trifluoride etherate at −78°C contains 16% of aldehyde and 62% of carbon-carbon double bond in the side chain.[18] The same behavior of acrolein on anionic polymerization, the predominant role of the carbonyl group on the polymerization reaction, was reported by Schulz and his coworkers.[14]

Summary

The bulk polymerization of acrolein initiated by gamma-rays at various temperatures has been studied. Most of the polymers obtained at −20° and 10°C are insoluble in organic solvents. On the other hand, most of the polymers obtained at −78°C are soluble in pyridine, dimethylformamide, and dimethylsulfoxide at room temperature. The aldehyde content of the soluble polymer is 75~85% of the theoretical amount, and its intrinsic viscosity is 0.32~1.20.

The influence of the polymerization temperature on the solubility of the polymer in organic solvents has been discussed, as has the polymerization mechanism.

The authors wish to express their thanks to the Nippon Kayaku Co., which supplied acrolein to this study.

Stereochemical Studies of Monoterpene Compounds. I. The Conformation of (+)-p-Menthane-3, 4-diol Obtained by the Performic Acid Oxidation of (+)-p-Menth-3-ene

By Takayuki SUGA, Tsuyoshi SHISHIBORI and Tamon MATSUURA

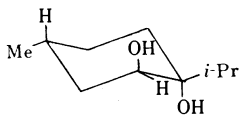
(Received August 9, 1963)

The hydroxylation of *p*-menth-3-ene with performic acid in the presence of water has been reported by Naves[1] to afford *p*-menthane-*cis*-3, 4-diol (m. p. 76~77°C) by a comparison of the melting point with that in the literature*1 cited as footnote 13 in Ref. 1. In the ring-opening reaction of *p*-menthane-3, 4-epoxide using dilute mineral acid, Tanaka[2] obtained a 3, 4-diol*2 with the same melting point (75~76°C) as that of the diol obtained by the

1) Y.-R. Naves, *Helv. Chim. Acta*, **42**, 1174 (1959).

*1 G. Wagner (1894) obtained (±)-*p*-menthane-3, 4-diol (m. p. 76.5~77°C) by the potassium permanganate oxidation of *p*-menth-3-ene. J. Böeseken (1923) showed that the hydroxylation of an olefin hydrocarbon by a permanganate reagent proceeds by cis addition. The reports by S. Tanaka (Ref. 2) and by H. Hock and S. Lang (Ref. 3) are also cited.

2) S. Tanaka, *Mem. Coll. Sci. Kyôto Imp. Univ. Series A*, **22**, 97 (1939) (*Chem. Zentr.*, **1940**, I, 688).



*2 (+)-*p*-Menth-3-ene ($[\alpha]_D$+107.24°) has been used for preparing the 3, 4-epoxide; the 3, 4-diol is presumed to be dextrorotatory.

potassium permanganate oxidation of *p*-menth-3-ene, while Hock and Lang[3] obtained a (±)-diol melting at 95°C from the 3, 4-epoxide and considered it to be trans. However, there has been no experimental evidence with respect to a spatial arrangement of the two hydroxyl groups. Generally, the hydroxylation[4] of an ethylenic compound with performic acid in the presence of water leads to *trans*-α-glycol by means of the ring opening of the epoxide which is the intermediate product. However, a few exceptions to this stereochemical course in this opening reaction are known.[4c,5] Therefore, we have investigated the conformation of *p*-menthane-3, 4-diol prepared by the same manner as in Naves' report,[1] particularly the hydroxyl groups in it.

(+)-*p*-Menth-3-ene (I) used was prepared by the pyrolysis of methyl (−)-menthylxanthate, but it was accompanied by (+)-*p*-menth-2-ene (28%). The hydroxylation of the sample hydrocarbon was carried out by hydrogen peroxide in an aqueous formic acid at 35°C, giving crude glycol in a 66% yield on the basis of the hydrocarbon. The crude glycol was separated into crystalline (+)-*p*-menthane-3, 4-diol (m. p. 76.5~77°C; a 71% yield based on the crude glycol) and oily (+)-*p*-menthane 2, 3-diol (29%) by elution chromatography on a silica-gel column; no other glycol, i. e., no *cis* or *trans*(diequatorial)-glycol, could be isolated in spite of a careful examination. Each of the diols was shown to be homogeneous by gas phase and chromatostrip chromatography.

(+)-*p*-Menthane-*trans*-3, 4-diol (V). — The crystalline diol was dextrorotatory and showed the same melting point as the previously-described 3, 4-diol,[3*] which is certainly optically inactive, because the *p*-menth-3-ene in Naves' report[1] was prepared from dihydro-α-terpineol by sulfuric acid dehydration. Treatment of the above crystalline diol with 10% sulfuric acid resulted in pinacolic dehydration affording a menthone mixture consisting of (−)-menthone (65%) and (+)-isomenthone (35%). Also, oxidation of the diol with *t*-butyl chromate gave (−)-4-hydroxymenthone. Thus it was confirmed that the hydroxyl groups are situated in both C_3- and C_4-positions.

The melting points of the *p*-menthane-3, 4-diol[4*] (m. p. 76.5~77°C) and its mono-3, 5-dinitrobenzoate (m. p. 150~150.5°C) differ from those of (+)-*cis*-4-hydroxymenthol (m. p. 80~81°C)[6a] and its mono-3, 5-dinitrobenzoate (m. p. 124~125°C)[6a,b] respectively. Moreover, the infrared spectrum of the diol in a highly dilute carbon tetrachloride solution, where intermolecular hydrogen bonding is out of the question, did not show any hydroxyl stretching absorption peak due to an intramolecular hydrogen bond, but only a free hydroxyl stretching absorption peak at 3630 cm^{-1}.[7] It has been established[8] that, at an ordinary temperature, the comparatively bulky isopropyl group in cyclohexane derivatives takes an equatorial conformation, because such conformation seems to be more energetically favored than an axial conformation. Accordingly, from the absence of an intramolecular hydrogen bonding in the 3, 4-diol, the two hydroxyl groups at C_3- and C_4-positions in it should be considered to take a diaxial conformation (V). It was thus shown that the predominant conformation of the hydroxyl groups in this crystalline *p*-menthane-3, 4-diol is in the diaxial trans position.

(V)

The methyl group in the sample *p*-menth-3-ene is considered to retain an equatorial orientation since the hydrocarbon was prepared from methyl (−)-menthylxanthate (1e, 3e, 4e)[9] by thermal decomposition proceeding by cis elimination[10] between the C_3-equatorial xanthate group and C_4-axial hydrogen. Moreover, it is generally accepted[4] that in the hydroxylation reaction of an olefin by performic acid in the presence of water, the intermediate epoxide with a cis configuration is immediately subjected to acid-catalyzed opening reaction by the reaction medium (in this case, formic acid), the opening reaction being initiated by protonation. Thus, the structure of protonated intermediate *p*-menthane-3, 4-epoxide is probably the II in Fig. 1. Generally, the acid-catalyzed opening reaction of cyclohexane epoxides containing no

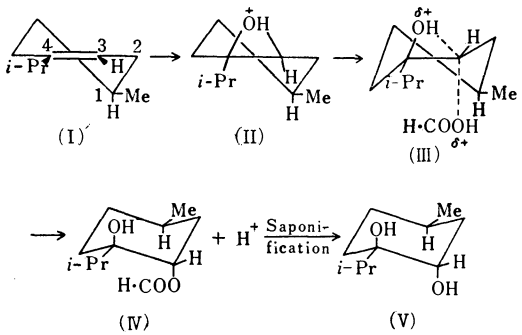

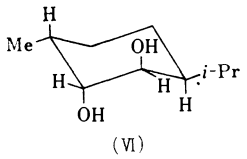

Fig. 1

group capable of exerting any marked polar or conjugative effect proceeds by the S_N2 attack of a reagent molecule from the axial side on the epoxide ring carbon atom, and the direction of the ring opening depends, consequently, on the steric factor.[4c] Therefore, the normal isomer corresponding to the attack of formic acid on the least-substituted carbon atom at the 3-position will be formed for the steric hindrance of the bulky isopropyl group, and the inversion of the configuration at the point of attack (the C_3-position) occurs because of the approach of the acid on the side opposite the displaced oxygen (cf. III). Thus, the opening reaction produces a monoformate of *p*-menthane-diaxial-3, 4-diol (IV), both alkyl groups of which are equatorial. Alkaline saponification of the formate affords only *trans*-diaxial-3, 4-diol (V).

(+)-*p*-Menthane-*trans*-2, 3-diol (VI).—This was isolated as a minor product and was a viscid oil. The infrared spectrum in a highly dilute carbon tetrachloride solution showed only one peak of a free hydroxyl stretching absorption at 3635 cm^{-1}.[11] This indicates the diaxial orientation of the two hydroxyl groups. Furthermore, the diol gave the same dinitrobenzoate as that of (+)-*trans*-2-hydroxyneomenthol.[11] Therefore, the 2, 3-diol was (+)-*trans*-2-hydroxyneomenthol (VI), which resulted certainly from the *trans*-*p*-menth-2-ene which coexisted in the sample of *p*-menth-3-ene.

(VI)

It appears that the hydroxylation of *p*-menth-2-ene takes place by the attack of formic acid on the C_2-position of *p*-menthane-2, 3-epoxide in the same way as with 3, 4-epoxide.

Experimental

Sample.—(+)-*p*-Menth-3-ene (I)[10a,12] (b. p. 168~169°C, n_D^{25} 1.4492, d_4^{25} 0.8080, $[\alpha]_D^{25}$ +114.8°) was prepared from (−)-menthol by the pyrolysis of methyl (−)-menthylxanthate (m. p. 40.5~41°C). According to the racemization procedure with *p*-toluenesulfonic acid,[13] the hydrocarbon was shown to be a mixture of (+)-*p*-menth-3-ene (72%) and (+)-*p*-menth-2-ene (28%). However, the isolation of pure *p*-menth-3-ene was so difficult that the hydrocarbon mixture was employed as the sample, without further purification.

Hydroxylation.—Into a mixture of the sample hydrocarbon (73 g.) and 77% aqueous formic acid (370 g.) 30% hydrogen peroxide (83 g.) was stirred drop by drop over a period of 0.5 hr. at 35°C, and then the mixture was maintained under the same conditions for a further 3 hr. The reaction mixture was treated as in Naves' report.[1] The crude glycol monoformate (84 g.) thus obtained was distilled to afford 63.2 g. of the main fraction boiling at 93~105°C/3 mmHg (reported :[1] b. p. 105°C/3 mmHg for *p*-menthane-3,4-diol monoformate). The infrared spectrum showed the peaks of ν_{OH} 3503, $\nu_{C=O}$ 1726, ν_{C-O-} 1188, and ν_{C-OH} 991 cm^{-1}. Hydrolysis of the formate with 14% ethanolic potassium hydroxide gave 47.8 g. of a crude glycol boiling at 99~110°C/3 mmHg; this was a viscid oil which solidified softly after being kept in a refrigerator. The gas chromatogram (3 m. column, Thermol-1 on quartz (150~200 mesh), 140°C, 50 ml. helium/min.) showed a main peak (t_R=16.3 min.) corresponding to the 3,4-diol and a small peak (t_R=20.2 min.) corresponding to the 2,3-diol. The crude glycol was chromatographed on silica-gel. The column was eluted with a mixture of ethyl acetate and *n*-hexane, and the elutes were separated into two fractions.

(+)-*p*-Menthane-*trans*-3, 4-diol (V).—The first elute gave 33.9 g. of a crystalline mass. Recrystallization of the mass from *n*-hexane gave white crystals with a m. p. of 76.5~77°C ($[\alpha]_D^{25}$ +27.5° (*c* 1, methanol) and +22.3° (*c* 1, chloroform)). The gas phase chromatogram on Thermol-1 packing showed only one peak; moreover, only one spot was observed on the chromatostrip chromatogram[14] (solvent: 20% ethyl acetate in *n*-hexane).

Found: C, 69.81; H, 11.48. Calcd. for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%.

Mono-3,5-dinitrobenzoate melted at 150~150.5°C (recrystallized from petroleum benzine) and showed $[\alpha]_D^{25}$ +36.8° (*c* 1, chloroform).

Found: N, 7.49. Calcd. for $C_{17}H_{22}O_7N_2$: N, 7.65%.

Pinacolic Dehydration.—A mixture of (+)-*p*-menthane-3,4-diol (0.5 g.) and 10% sulfuric acid (5 ml.) was refluxed for 2 hr. and then steam-distilled. The distillate gave a menthone mixture (0.36 g.). The infrared spectrum corresponded to

12) L. Tschugaeff, *Ber.*, **32**, 3332 (1899).
13) J. P. Wibaut, H. C. Beyerman and H. B. Van Leeuwen, *Rec. trav. chim.*, **71**, 1032 (1952).
14) J. G. Kirchner, J. M. Miller and G. J. Keller, *Anal. Chem.*, **23**, 420 (1951); J. M. Miller and J. G. Kirchner, ibid., **25**, 1107 (1953).

that[15] of a mixture of (−)-menthone and (+)-isomenthone. The composition (mentioned above) of the menthone mixture was calculated from its optical rotation value, $[\alpha]_D^{20}$ +15.2° (*c* 2, methanol), using $[\alpha]_D^{20}$ −25° (*c* 2, methanol) for (−)-menthone and $[\alpha]_D^{20}$ +90° (*c* 2, methanol) for (+)-isomenthone. Only (−)-menthone 2,4-dinitrophenylhydrazone (m. p. and mixed m. p. 145~145.5°C) was prepared.

Oxidation with t-Butyl Chromate (The Formation of 4-Hydroxymenthone).—A *t*-butyl chromate solution[16] was prepared from chromic trioxide (1.75 g.), *t*-butyl alcohol (3.5 g.) and benzene (20 ml.). The 3,4-diol (3.0 g.) in benzene (15 ml.) was oxidized with this oxidant at 25~30°C for 2 hr. Then a neutral reaction mixture (2.7 g.) obtained was fractionated into 1.3 g. of a keto alcohol (n_D^{25} 1.4641; d_4^{25} 0.9906; $[\alpha]_D^{25}$ −96.7°; IR (liq. film): 3493 (OH), 1709 (C=O), 1430 ($-CH_2-CO-$), 1154 (OH) cm^{-1}) and 1.3 g. of unchanged diol by elution chromatography on a silica-gel column using ethyl acetate—*n*-hexane as an eluant.

Treatment of the keto alcohol with 2 N hydrochloric acid solution of 2,4-dinitrophenylhydrazine gave (−)-4-hydroxymenthone 2,4-dinitrophenylhydrazone (m. p. 102.5~103°C; UV: λ_{max}^{alc} 360 mμ, ε=22400; Found: N, 15.73. Calcd. for $C_{16}H_{22}O_5N_4$: N, 15.99%). On the other hand, (±)-*p*-menth-3-en-5-one 2,4-dinitrophenylhydrazone (m. p. and mixed m. p. 147.5~148.5°C) was produced on treating it with an ethanol-sulfuric acid solution of 2,4-dinitrophenylhydrazine.[17]

(+)-*p*-Menthane-*trans*-2,3-diol (VI).—In the elution chromatography of the crude glycol described above, the second elute gave a viscid oil (13.8 g.), which was confirmed to be homogeneous by gas phase and chromatostrip chromatography as in the case of V. The oil showed $[\alpha]_D^{25}$ +37.2° (*c* 1, chloroform) (reported;[11] $[\alpha]_D^{20}$ +40.8°) and gave di-*p*-nitrobenzoate, m. p. 173.5~174°C (reported[11]: m. p. 174°C).

Measurement of the Infrared Spectra in the Hydroxyl Stretching Region.—The infrared spectra were measured by a Hilger H-800 double-beam spectrophotometer under the following conditions. Calcium fluoride prism. The wave number accuracy at 3500 cm^{-1}: ±3 cm^{-1}. Temperature: 20°C. Solvent: carbon tetrachloride. Cell: 20 mm. long. Sample concentration: 0.003 mol.

Summary

The conformational analysis of (+)-*p*-menthane-3, 4-diol, which had been obtained by the hydroxylation of (+)-*p*-menth-3-ene with performic acid in the presence of water, has been performed mainly by means of infrared spectra. It has been shown that the two hydroxyl groups at the C_3- and C_4-positions take a diaxial conformation, that they are, accordingly, trans to each other, and that the methyl group presumably holds an equatorial orientation. It has also been found that *p*-menthane-*trans*(diaxial)-2, 3-diol results from the *p*-menth-2-ene coexisting in the sample of *p*-menth-3-ene. A stereochemical course of the hydroxylation reaction has been discussed.

The microanalyses were performed by Mr. Toshiharu Takagi and Mr. Keiichi Kihara of the Tôyô Soda Co., Ltd., and the late Kazuko Iwata of the Faculty of Pharmacy of Kyoto University, to all of whom the authors' thanks are due. The present work was partly supported by a grant-in-aid of the Ministry of Education.

The Purification of Silicon Tetrachloride from Traces of Boron with N, N-Diphenylacetamide

By Masanao NAKAGAWA

(Received August 24, 1963)

During the past decade many studies have been made of the purification of silicon for use as a semiconductor and of its raw materials, particularly from traces of boron. The purification of silicon tetrachloride and trichlorosilane,[1,2] the raw materials, from the boron, however, has not been fully studied because of the lack of any appropriate method for chemical analysis, although a report[3] on it has recently been published.

In previous papers[4] it has been shown that the boron in silicon tetrachloride can be decreased by the addition of many Lewis bases, such as nitriles, amides, aniline derivatives and some others, followed by distillation. Among those bases, *N*, *N*-diphenylacetamide appeared to be a particularly effective reagent, because the amide gave a stable addition compound[5,6] with boron trichloride, with an equilibrium constant[7] of more than an order of 10^3, the heating of which up to 100°C evolves no detectable volatile boron compounds, as has also been reported previously.[8]

On the other hand, an analytical method[9] for traces of boron based on the extraction of a boron tetrafluoride ion-methylene blue complex, followed by spectrophotometric determination, appeared to be a useful and convenient method for the present study.

Thus, the present work was undertaken to clarify the effects of *N,N*-diphenylacetamide in the purification from boron (1 p.p.m. or 1 p.p.b. order) by a slight modification of the methylene blue method.

Experimental

Reagents.—Pure silicon tetrachloride was prepared by refluxing its crude chloride with copper powder (3%), followed by fractional distillation. Boron trichloride was obtained as a liquefied gas (a purity of 99.5%) in a steel cylinder from the American Potash and Chemical Corp. Carbon tetrachloride was distilled in the presence of phosphorus pentoxide. Dichloroethane, methylene blue and *N, N*-diphenylacetamide were purified by the normal procedure.

The Procedure for the 1 p. p. m. Order.—The standard solution of boron trichloride in carbon tetrachloride (1.125 M) was prepared by dissolving the vapor from the steel cylinder in the solvent; the concentration of the solution was determined by the titration, with a standard sodium hydroxide solution, of an aqueous solution obtained by hydrolyzing a portion of the solution in carbon tetrachloride.

The standard solution of boron in silicon tetrachloride (1.1 μg./ml.) was also prepared by diluting the standard solution in carbon tetrachloride (1.125 M) with pure silicon tetrachloride. The standard solution (25 ml.) and the amide (1/400 mol.)[10] were taken into a distillation flask (100 ml.), and, after having been stirred or refluxed for a stated number of times, the silicon tetrachloride was completely distilled off at 62~65°C, and dry nitrogen was passed through the flask overnight. The residue was hydrolyzed by stirring in a dilute sodium hydroxide solution (25 ml. of distilled water and 2 ml. of 5% sodium hydroxide) for 1 hr. The solution was filtered from the amide, and the filtrate was concentrated to about 5 ml.

The concentrate was diluted in a volumetric flask (25 ml.), and the solution (10 ml.) was taken into a polyethylene bottle (100 ml.) and acidified with phosphoric acid (1 ml. of a 1 : 10 solution). After the successive addition of hydrofluoric acid (5 ml. of a 5% solution) and distilled water (10 ml.), the bottle was tightly stoppered and kept at room temperature for 2 hr. Then ferrous ammonium sulfate (2 ml. of a 4% solution), distilled water (78 ml.) and methylene blue (2 ml. of a 1/1000 M aqueous solution) were successively added to the bottle, and the solution was vigorously shaken for 2 min. with dichloroethane (25 ml.). After the solution had stood for 30 min. the dichloroethane layer (1 ml.) was pipetted off and diluted with pure dichloroethane (5 ml.).

The dichloroethane solution was taken into a quartz cell (1 cm.), and the absorbance at 660 mμ

was measured by a Shimadzu QR-50 type photoelectric spectrophotometer. After the reagent blank with pure silicon tetrachloride had been subtracted from the absorbance, the amount of boron taken out with *N*, *N*-diphenylacetamide was obtained by the calibration curve made up with the standard aqueous solution of boron.

The Procedure for the 1 p.p.b. Order.—The standard solution of boron in silicon tetrachloride (0.009 μg./ml.) was prepared as has been described above, and the solution (100 ml.) was taken into a polypropylene beaker (100 ml.). After the addition of *N*, *N*-diphenylacetamide (0.1 g.), the beaker was placed in a vacuum desiccator equipped with two stopcocks, which were connected to a scrubbing bottle with concentrated sulfuric acid, through which dry air could be admitted, and to a vacuum pump via a phosphorus pentoxide column, two scrubbing bottles with a sodium hydroxide solution (1 : 2), and a calcium chloride column.

The vacuum desiccator was evacuated by heating it by two lamps (60 W.) above the desiccator, and the silicon tetrachloride was completely distilled off. The residue was taken out and hydrolyzed with distilled water (10 ml.). After the mixture had stood overnight in order to complete the hydrolysis the aqueous solution was filtered from the amide, and the beaker was washed two times with distilled water (5 ml.). The washing solution was also filtered by the filter paper previously used, and those filtrates were taken into a polyethylene bottle (100 ml.). The aqueous solution was submitted to extraction, followed by the measurement of the absorbance, which was as described previously except for the following points: dichloroethane, 10 ml., the shaking time for the extraction, 10 min., the quartz cell, 3 mm., and the absorbance was measured without the dilution of the extracts.

Results and Discussion

Figure 1 gives the calibration curve for the

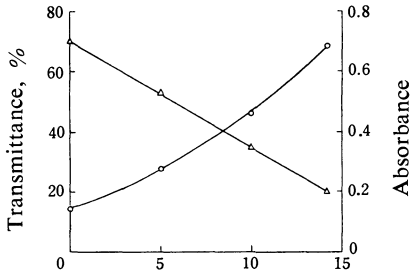

Fig. 1. Calibration curve for 1 p.p.m. order.

boron of the 1 p.p.m. order, which rather deviates from Beer's law, but which gives a good reproducibility and an accuracy within ±0.3 μg. The deviation observed might be due to certain interference by the amide slightly dissolved in the aqueous solution.

It had been reported[9] that the extraction oculd be well carried out with dichloroethane (25 ml.) and methylene blue (1/1000 M, 10 ml.). In the present study, however, a smaller amount of methylene blue (1/1000 M, 2 ml.) was used to decrease the blank value of the absorbance; the use of more was unfavorable for sensitive analyses.

The effects of the reaction factors on the recovery of boron (1 p.p.m. order) are shown in Fig. 2. The stirring at room temperature

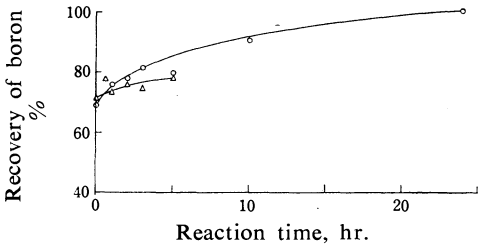

Fig. 2. Effect of the reaction time of the recovery of the boron (1.08 μg./ml.).
○ Stirring △ Refluxing

gave a slightly high recovery, and the stirring for 24 hr. led to a recovery of about 100%, which suggests that the boron contents in the silicon tetrachloride distilled off should be 0.06 μg./ml. or less, as could be estimated from the maximum experimental error involved.

Figure 3 represents the calibration curve for

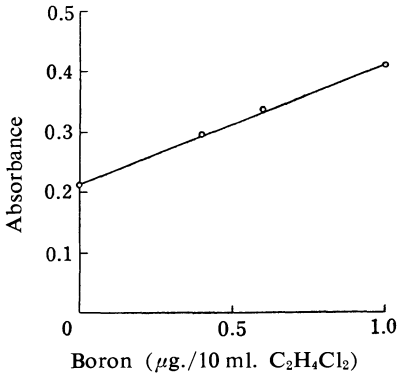

Fig. 3. Calibration curve for 1 p.p.b. order.

the 1 p.p.b. order, which obeys Beer's law. The analytical method herein used was sensitive, but the curve was less reproducible, and all the curves in the repeated experiments slightly varied parallel with one another from day to day. The lesser reproducibility appeared to be due to the slight variation in contamination involved. The respective calibration curve, therefore, was prepared in every experiment.

Table I reports on the recovery of the boron from the standard solution in silicon tetrachloride (100 ml. of 0.009 μg./ml.) by the vacuum

TABLE I. RECOVERY OF THE BORON OF 1 p.p.b. ORDER*

1	0.08	1.86	1.78	
2	0.14	1.07	0.93	
3	0.05	0.58	0.53	
4	0.17	0.93	0.76	
5	0.25	1.78	1.53	
Mean	0.14	1.2	1.1	1.2×100

* The recovery from the standard silicon tetrachloride soln. (100 ml. of 0.009 μg./ml.) with the amide (0.1 g.).

distillation carried out immediate after the addition of the amide (0.1 g.). Every numerical value given in the table varied, with some error, but the effects of the amide were apparent, and the amount of amide required was less than could be estimated by the equilibrium constant reported previously.[7]

The effects of the reaction factors were also studied, but similar results were obtained within the range of experimental error. For the purification, however, the stirring with amide, followed by the distillation, appeared to be more favorable, as could be expected by analogy with the results obtained with the solution of boron of the 1 p.p.m. order.

Summary

A standard solution of boron in silicon tetrachloride (1 p.p.m. or 1 p.p.b. order) has been distilled in the presence of *N*, *N*-diphenylacetamide. The residue of the distillation has been analyzed for boron by the spectrophotometric measurement of the methylene blue complex of boron tetrafluoride ions. The boron of an order of 1 p.p.m. has been about 100% recovered when the solution in silicon tetrachloride has been distilled after being stirred for 24 hr. with the amide. The recovery of the boron of an order of 1 p.p.b. has also been satisfactory. The silicon tetrachloride distilled off in the presence of the amide, therefore, believed to be almost free of boron.

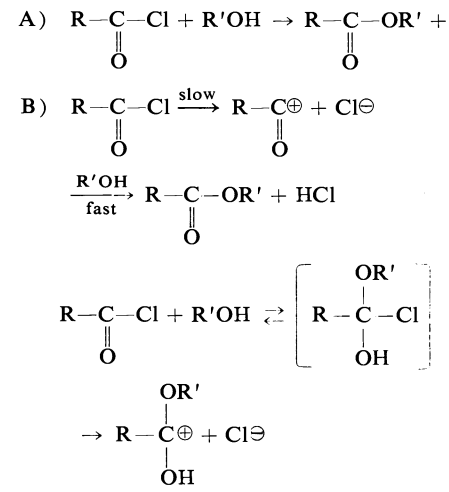
The Solvolysis of Acid Chlorides. A Presentation of the Problem and a Proposal for the Mechanism

By Hiroshi MINATO



(Received August 28, 1963)

The nucleophilic substitution reactions of derivatives of carboxylic acids, especially the hydrolysis of esters, have been studied very thoroughly, and the mechanism is well understood.[1] However, the investigations of the kinetics of the hydrolysis and alcoholysis of acid chlorides have not led to completely concordant conclusions, and a reasonable explanation for all the data available seems to be lacking. Hudson and his co-workers,[2-10] Gold, Hilton and Jefferson,[11] and Kelly and Watson[12] have suggested that aromatic acid chlorides may be hydrolyzed by either the S_N1 or the S_N2 mechanism, and Newman,[13] Gould[14] and Hine[15] have agreed with them. The two paths they proposed are as follows:

* Present address: International Christian University, Mitaka, Tokyo, Japan.

On the other hand, Bunton et al.[16,17] and Peeling[18] have suggested a two-stage process, excluding path B.

In order to resolve these two divergent views and to find a reasonable mechanism for the hydrolysis of acid chlorides the present investigation was undertaken.

Evaluation of the Two Mechanisms

The mechanism of Hudson et al. differs from the addition-ionization mechanism in that it has a path B in addition to a path A, the latter being essentially similar to the addition-ionization mechanism.

The evidence which has led some workers to propose path B is as follows:

a) The relative rates of the solvolysis of the following *p*-substituted benzoyl chlorides suffer an almost complete reversal in order as the reaction is transferred from 40/60 ethanol-ether (dielectric constant 13) to 50/50 water-acetone (dielectric constant 53),[4] as Table I shows. In 50% water-acetone, the solvolysis of only the *p*-nitro compound appears to have retained its bimolecular character.

Table I. Effect of solvent changes on relative solvolysis rates of *p*-substituted benzoyl chlorides

Medium	D	Relative solvolysis rate				
		p-NO_2	*p*-Br	H	*p*-Me	*p*-MeO
40% EtOH-ether	13	32	2.5	1	0.47	0.25
EtOH	22	22	2.1	1	0.70	0.81
50% H_2O-acetone	52	12	0.92	1	2.9	30

b) When the logarithms of the observed first-order rate constants of benzoyl chloride in water-acetone are plotted against the logarithms of water concentrations the "apparent order" in water varies from about 1.1～1.5 in 5～15% water to near 7 in 50% water.[3,11,12] The apparent order in water of the hydrolysis of 2, 4, 6-trinitrobenzoyl chloride in 10～30% water-90～70% acetone at 0°C is ca. 1. The apparent order in water of the hydrolysis of *p*-methoxybenzoyl chloride in 10～30% water -90～70% acetone at 0°C is ca. 3.5.[6]

c) The alcoholysis or hydrolysis of mesitoyl chloride is very fast, even faster than *p*-nitrobenzoyl chloride,[6,18,19] as Table II shows.

However, the following evidence seems to be against the path B):

a) Boehme[20] measured the hydrolysis of benzoyl chloride in 2～30% water-98～70% dioxane; his findings show that the apparent order in water at 2～5% water-dioxane is ca. 2.9. This cannot be explained by path B, which is considered to take place only at a higher water concentration, or at a higher dielectric constant.

b) Peeling[18] and Bunton et al.[17] found that the solvolysis of mesitoyl chloride is accelerated by the presence of alkali, as is shown in Table II. Although Brown and Hudson[6] reported that the hydrolysis rate of mesitoyl chloride in 5% water-acetone at 0.2°C did not change upon the addition of 0.001 M alkali, Bender and Chen[21] established that hydroxide ions do catalyze the hydrolysis of 4-substituted-2, 6-dimethylbenzoyl chlorides in 99% acetonitrile-water. This means that the solvolysis of mesitoyl chloride proceeds through a tetrahedral complex, at least in the presence of alkali.

Table II. Alcoholysis of substituted benzoyl chlorides in 80% alcoholic acetone at −10.75°C

21) M. L. Bender and M. C. Chen, *J. Am. Chem. Soc.*, **85**, 30 (1963).

c) In the reaction with diazomethane, benzoyl chloride is reactive, whereas mesitoyl chloride is inert.[22] If acylium ions are formed, mesitoyl chloride should react with diazomethane also.

d) Bunton et al.[17] found that the carbonyl oxygen of mesitoyl chloride suffers exchange with the oxygen of the solvent water. This indicates the existence of a tetrahedral intermediate of a finite life-time.[23] Their results are shown in Table III.

TABLE III. COMPARISON OF RATES OF EXCHANGE (k_e) AND HYDROLYSIS (k_h) OF SUBSTITUTED BENZOYL CHLORIDES AT 25°C

Substituents	% Water in the mixture with dioxane	$10^4 k_h$ sec^{-1}	$10^4 k_e$ sec^{-1}	k_h/k_e
H	5	1.2[20]	0	—
	25	7.57	0.30	25
	33	14.8	0.82	18
p-Me	5	0.346[4]	0	—
	25	6.22	0	—
	33	22.7	0.44	51
2,4,6-TriMe	5	33.5	1.1	31

e) The chlorine exchange between $Li^{36}Cl$ in dry acetone and mesitoyl chloride is much slower than with benzoyl chloride.[17] If acylium ions are formed, exchange should be faster with mesitoyl chloride. The slow exchange of chlorine atoms must be taking place through a tetrahedral intermediate.

f) Although mesitoyl chloride reacts with methanol or ethanol almost instantaneously at room temperature, it reacts with *t*-butyl alcohol or *t*-amyl alcohol much slower, and when mesitoyl chloride was mixed with a great excess of *t*-amyl alcohol at room temperature, about a 1 : 1 mixture of mesitoyl chloride and *t*-amyl mesitoate was observed by the infrared absorption method after 10 min.[24] The formation of *t*-butyl mesitoate from *t*-butyl alcohol and mesitoyl chloride is catalyzed by pyridine.[25] The reaction should not be catalyzed by pyridine if it proceeds via an acylium ion.

g) Although it is known that 2, 4, 6-trimethylbenzyl chloride ionizes in a liquid sulfur dioxide solution to a greater extent than does benzyl chloride,[26] conductance measurements on a solution of mesitoyl chloride in liquid sulfur dioxide indicated no appreciable ionization.[27]

h) The rate of the solvolysis of 2, 4, 6-trimethylbenzyl chloride and mesitoyl chloride are shown in Table IV. Table IV shows that 2, 4, 6-trimethylbenzyl chloride can not be solvolyzed by the S_N1 mechanism in 25% H_2O-acetone. In view of the evidence cited in g), it seems unlikely that mesitoyl chloride is solvolyzed by S_N1 in a poorer ionizing solvent than the solvent in which 2, 4, 6-trimethylbenzyl chloride failed to be solvolyzed by S_N1.

The evidence gathered above seems to indicate that the solvolysis of mesitoyl chloride does not proceed via an acylium ion but via a tetrahedral intermediate. If mesitoyl chloride is not solvolyzed by S_N1, it is reasonable to assume that other benzoyl chlorides are also solvolyzed by way of tetrahedral intermediates. A simple expression of an addition-ionization mechanism through a tetrahedral intermediate

TABLE IV. RATES OF SOLVOLYSIS OF 2,4,6-TRIMETHYLBENZYL AND MESITOYL CHLORIDES

Substance	Solvent	Temp.	Added material	$10^4 k_1$ sec^{-1}	$10^3 k_2$ M^{-1} sec^{-1}	Ref.
Trimethylbenzyl chloride	25%H_2O-acetone*	30	—	0.134	—	6

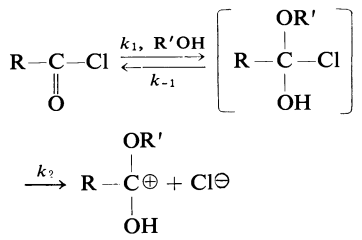
22) W. E. Bachman and J. Sheehan, unpublished results; cited from p. 227 of Ref. 13.

23) In 99% acetonitrile-water, which has a higher dielectric constant and a lower water content, Bender and Chen[10] observed no carbonyl oxygen exchange. The absence of exchange is, however, "not an infallible indication of an acylium ion intermediate," as Bender and Chen state. An explanation for their results is given later in the text.



24) Mesitoyl chloride was dissolved in respective alcohols, and the carbonyl absorption of the solution was determined in calcium fluoride cells against the pure alcohols at room temperature. In the cases of methyl and ethyl alcohols, only the ester absorption was observed at 5.77 μ, even immediately after mixing, while in the case of *t*-amyl alcohol, the height of the peaks due to *t*-amyl mesitoate (5.77 μ) and mesitoyl chloride (5.57 μ) was about the same at 10 min. after mixing.

is the following:

The rate of solvolysis is expressed by:

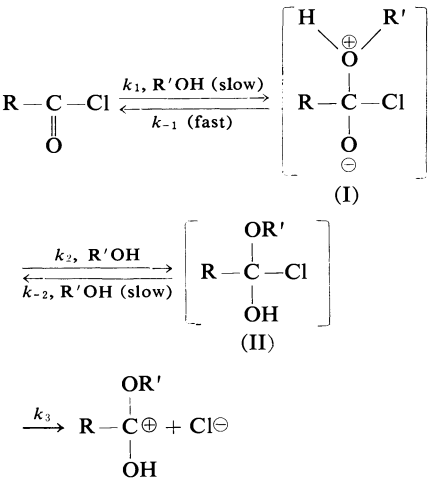
$$-\frac{d(RCOCl)}{dt}=\frac{k_1k_2(RCOCl)(R'OH)}{k_2+k_{-1}} \quad (1)$$

However, this simple mechanism fails to explain some of the data available. As is shown in Table III, the hydrolysis rate of *p*-toluyl chloride increases very much as the water concentration increases from 5% to 33%, yet k_h/k_e is very large, i.e., over 51. When k_h/k_e $(=k_2/k_{-1})$ is very large, Eq. 1 becomes

$$-\frac{d(RCOCl)}{dt}=k_1(RCOCl)(R'OH) \quad (2)$$

The observed increase of rate upon the increase in water concentration from 25 to 33% gives a value of 4.4 as an apparent order in water by plotting $\log k_1$ versus $\log(H_2O)$.

$$-\frac{d(RCOCl)}{dt}=k_{obs}(RCOCl)$$

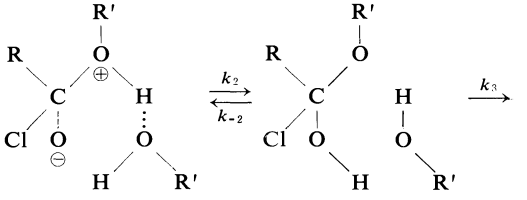


$$=\text{constant}\times(H_2O)^n(RCOCl)$$

$$n=\frac{\Delta(\log k_{obs})}{\Delta(\log(H_2O))}=\text{apparent order in } (H_2O)$$

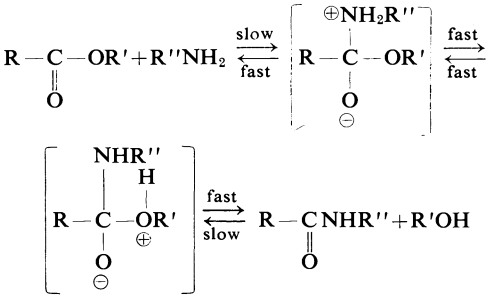
However, k_1 should not be so much dependent upon the concentration of water. Generally the substituted benzoyl chlorides with electron-releasing groups show a greater dependence upon the concentration of water, and this is incompatible with Eq. 1 or 2.

A Refined Addition-Ionization Mechanism



The Solvolysis of Aroyl Chlorides.—Therefore, the following mechanism[28] is proposed in order to explain the available data on the solvolysis of substituted benzoyl chlorides:**

With the usual steady-state assumptions for I and II, the rate of solvolysis is calculated as:



$$-\frac{d(RCOCl)}{dt}=\frac{k_1k_2k_3(RCOCl)(R'OH)^2}{k_{-1}k_3+k_{-1}k_{-2}(R'OH)+k_2k_3(R'OH)} \quad (3)$$

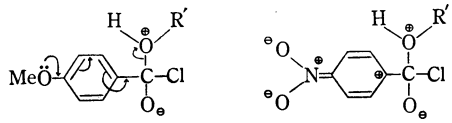
Although k_2 and k_{-2} could be an intramolecular proton transfer, it may be more plausible to go through a six-membered transition state with another solvent, since hydroxylic solvents exist as polymers.

Hudson and Saville[7] found that the alcoholysis of acetyl chloride and *p*-nitrobenzoyl chloride is much faster in ethanol-carbon tetrachloride than in an ethanol-ether mixture at the same ethanol concentration. Their results are shown in Table V. While ethanol exists as a polymer in carbon tetrachloride, it probably exists in ether as a hydrogen-bonded form with ether molecules. In carbon tetrachloride, the attack of ethanol on the acid chloride, is

28) This is somewhat analogous to the aminolysis of esters (Ref. 14, p. 330):

** A difficulty with this mechanism has been pointed out by a referee; that is, the mechanism proposed here may not be compatible with the linear relationship between σ^+ and ρ, or with the rather large negative ρ value observed for the hydrolysis of 4-substituted-2,6-dimethylbenzoyl chlorides.[21] However, the present author is not quite convinced by these results and the interpretations thereof, mainly because of the conditions employed for the kinetic and isotopic studies.

TABLE V. ETHANOLYSIS OF ACID CHLORIDES AT 20°C



Substance	(EtOH) mol./l.	10^4k_1 (min^{-1}) in CCl_4	in ether	k_{CCl_4}/k_{ether}
Acetyl chloride	0.172	369	4.8	77
	0.345	969	16.85	57.5
	0.69	2290	61.8	37.1
p-Nitrobenzoyl chloride	0.69	139	10.0	13.9

followed by a proton transfer through another ethanol molecule which is hydrogen-bonded to the reacting ethanol molecule. In ether, every ethanol molecule is linked to an ether molecule rather than to another ethanol molecule at low concentrations of ethanol, and thus the formation of intermediate I is not readily followed by a proton transfer; rather, it dissociates back to the starting materials. Since the dielectric constant of ether is even a little larger than that of carbon tetrachloride and since the mole fractions of ethanol in ether and carbon tetrachloride with the same concentration of ethanol are about the same, it is not at all possible to attribute the large difference in rate to the change in the dielectric constant of the medium. The hydrolysis rates of benzoyl chloride in 5% water-dioxane (dielectric constant 3.8) and 5% water-acetone (dielectric constant 22.2) are not very different (7.30×10^{-5} sec^{-1} and 5.45×10^{-5} sec^{-1}, respectively[4]). Thus, the data on the ethanolysis of acid chlorides in ether and in carbon tetrachloride seem to indicate the validity of the proposed intermediates, I and II.

As is shown in Table III, k_h/k_e is very large for benzoyl and *p*-toluyl chloride in 5~33% water-dioxane and for mesitoyl chloride in 5% water-dioxane at 25°C. When k_h/k_e is very large, i.e., $k_3 \gg k_{-2}$[R'OH], Eq. 3 becomes

$$-\frac{d(RCOCl)}{dt}=\frac{k_1k_2(RCOCl)(R'OH)^2}{k_{-1}+k_2(R'OH)} \quad (4)$$

k_{-1} is large in a solvent of low polarity and small in a solvent of high polarity. k_1 is large for *p*-nitrobenzoyl chloride and small for *p*-anisoyl chloride. k_{-1} is small for the former and large for the latter, since an electron-releasing group helps R'OH leave from I and an electron-withdrawing group prevents its departure. When the polarity of the medium

is low and/or an electron-releasing substituent is present, $k_{-1} \gg k_2$ (R'OH) may be realized. Then, Eq. 4 becomes:

$$-\frac{d(RCOCl)}{dt}=\frac{k_1k_2}{k_{-1}}(RCOCl)(R'OH)^2 \quad (5)$$

Although k_1 and k_2 also depend upon the polarity of the medium or on the concentration of water, the dependence of k_{-1} on the polarity of the medium may be far greater. Thus, an apparent order in water of 2 or more may be realized in these cases. We recall that the apparent order in water, *n*, is ca. 2.9 for benzoyl chloride in 2~5% water-dioxane at 25°,[20] and *n* is ca. 3.2 for *p*-anisoyl chloride in 10~30% water-90~70% acetone at 0°C.[6]

When the polarity of the solvent is rather high and electron-withdrawing substituents are present, it is possible that $k_{-1} \ll k_2$ (R'OH) is realized. Then, Eq. 4 becomes

$$-\frac{d(RCOCl)}{dt}=k_1(RCOCl)(R'OH) \quad (6)$$

n is ca. 1.15 for benzoyl chloride in 5~15% water-acetone at 25°C, ca. 0.8 for *p*-nitrobenzoyl chloride in 5~25% water-acetone at 0°C, and ca. 1.06 for 2, 4, 6-trinitrobenzoyl chloride in 10~30% water-acetone at 0°C.[5]

When the concentration of water becomes very large, k_{-2} becomes appreciable; the trend may be seen in Table III. Therefore, we have to consider Eq. 3 rather than 4, 5 or 6. k_3 is an ionization step and highly dependent on the polarity of the medium, and it is probable that the apparent order in water, *n*, is rather great. The *n* for benzoyl chloride in 25~40% water-acetone at 25°C is ca. 2.72 and in 50~75% water-acetone at 0°C is ca. 6.85.[3] The fact that no carbonyl oxygen exchange was observed with mesitoyl chloride in 99% acetonitrile-water[21] can be explained by this mechanism. The conversion of intermediate II to I is helped by water, and at the very low concentration of water, k_{-2} may be inappreciably small; the trend may be seen in Table III. Thus, the findings of Bender and Chen[21] (no oxygen exchange) is understandable, while at the higher concentration of water the exchange of oxygen is expected, and it was really found to take place.[17]

Thus, all the data available on the hydrolysis of aroyl chlorides[29] can be explained very well in terms of intermediates I and II, and Eqs. 3, 4, 5 and 6.

The Solvolysis of Acyl Chlorides and Chloroformates.—It is not certain whether or not acetyl chloride and chloroformates are solvolyzed via a tetrahedral intermediate, and there are no data available on the exchange of the

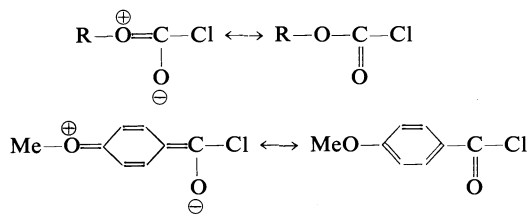
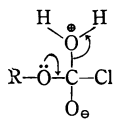
TABLE VI. SOLVOLYSES OF VARIOUS ACID CHLORIDES AT 25°C

Substance	Solvent	10^5k_1, sec^{-1}	Ref.
2,4,6-Trimethoxybenzoyl chloride	5% water-dioxane	830	16
2,4,6-Trimethylbenzoyl chloride	5% water-dioxane	335	16
2,6-Dimethoxybenzoyl chloride	5% water-dioxane	330	16
Acetyl chloride	5% water-acetone	668	29
p-Nitrobenzoyl chloride	5% water-acetone	169	3
Benzoyl chloride	5% water-acetone	7.71	3
p-Methoxybenzoyl chloride	5% water-acetone	3.0	3
Ethyl chloroformate	10% water-dioxane	0.39	19



oxygen of these compounds with a solvent. However, it is very probable that these substances are also solvolyzed by a similar mechanism. The rates of the solvolysis of various acid chlorides are compared in Table VI.

There have been several papers reporting on the solvolysis of acyl chlorides[30-35] and chloroformates,[20,36-39] but none of them present clear evidence with which one can decide the mechanism unambiguously.



Some workers presuppose, without good evidence, the appearence of an acylium ion during the solvolysis of acyl chlorides and chloroformates. However, the absence of this species may be clearly understood if one compares their rates with the rate of benzoyl chlorides and also the rates of the solvolysis of ethyl chloride, benzyl chloride and methoxymethyl chloride. The rate of the alcoholysis of ethyl chloride at 25°C is extremely slow, that of benzyl chloride is fairly fast, and that of methoxymethyl chloride is extremely fast.[40] Thus, the order is $CH_3CH_2Cl \ll C_6H_5CH_2Cl \ll CH_3OCH_2Cl$. This rate sequence is what is expected for an S_N1 reaction, based on the stability of the carbonium ions formed. On the other hand, the rate sequence for the solvolysis of acetyl chloride, benzoyl chloride and alkyl chloroformates is completely the opposite, that is, $CH_3COCl \gg C_6H_5COCl \gg C_2H_5OCOCl$, as Table VI shows. If an acylium ion is playing any significant role in the solvolysis of acyl chlorides or chloroformates, the rate sequence should be the opposite; that is, the chloroformates capable of forming the most stable acylium ion should be solvolyzed the most quickly and acetyl chloride should be solvolyzed the most slowly because of the unstabilized acetyl cation. Since what was found in various media by various workers is contrary to this, acyl chlorides and chloroformates must be solvolyzed, not via an acylium ion, but by way of the addition-ionization mechanism.

Acetyl chloride is more reactive than benzoyl chloride because of a lack of conjugation with the phenyl ring. If acetyl chloride follows the mechanism proposed for benzoyl chloride, k_1 is very large, k_{-1} is probably very large, and the rate may follow Eq. 5. The apparent order in water, n is found to be 2 in 1~5% water-acetone at 24.8°C,[30] 1.4 in 1~4% ethanol-carbon tetrachloride, and 2.0 in 1~40% ethanol-ether at 20°C.[7]

Chloroformates are less reactive than acetyl chloride because of resonance such as the following, and these compounds are somewhat analogous to *p*-anisoyl chloride.

If chloroformates follow the mechanism proposed for benzoyl chlorides, k_1 is rather small, k_{-1} may be very large, and the rate may follow Eq. 5:

The apparent order in water, n, is found to be 1.6~2.2 for ethyl chloroformate in 10~70%

water-dioxane at 25°C, and 1.1～1.4 for *t*-butylperoxy chloroformate in 20～100% methanol-carbon tetrachloride.[44] Leimu studied the rate of the methanolysis of chloroformates and found that β-chloroethyl chloroformate is solvolyzed 12.5 times faster than isopropyl chloroformate.[45]

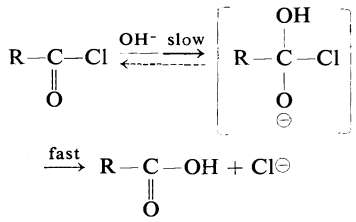
The Solvolysis of Aroyl Chlorides in the Presence of Alkali.—Although the solvolysis of acid chlorides in general is not catalyzed by the presence of acids, [2,31,46] it is much accelerated by the addition of alkali, as Table VII shows.

TABLE VII. EFFECT OF ALKALI ON THE SOLVOLYSES OF ACID CHLORIDES[6,18]

1) 80% alcoholic acetone at −10.75°C

	Benzoyl chloride	*p*-Nitrobenzoyl chloride	Mesitoyl chloride
10^6k_1 (sec^{-1})	4.97	212	521
k_2* ($M^{-1}\,sec^{-1}$)	3	2	0.34
k_2/k_1	6×10^5	6×10^5	650

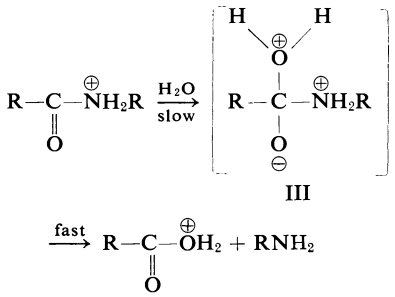
* $(OEt^{\ominus})=0.02$ M



2) 25% water-acetone at 0.2°C

	p-Nitrobenzoyl chloride	*p*-Anisoyl chloride	$\frac{k_{nitro}}{k_{anisoyl}}$
10^4k_1 (sec^{-1})	20.32	2.82	7.2
k_2* ($M^{-1}\,sec^{-1}$)	6.82	0.405	16.8
k_2/k_1	3360	1430	

* 0.003 M $OH^{\ominus}$



The relatively small increase of the rate on the addition of alkali to mesitoyl chloride is interesting. The slower rate of mesitoyl chloride than benzoyl and *p*-nitrobenzoyl chloride in alkali may be explained by the presence of steric hindrance and electron-releasing substituents.

When alkali is present, a probable mechanism may be the following:

If the alkaline solvolysis proceeds by this scheme, the rate increase upon the addition of alkali should be greater in a solvent of low polarity and greater for an acid chloride with electronegative substituents. Table VII is in agreement with this.

The basic hydrolysis of acid chlorides is somewhat analogous to the acid hydrolysis of amides:

In this case, an inappreciable oxygen exchange between solvent and amide is observed, and cation III seems to be an activated complex rather than an intermediate. There are no experimental data available on the isotope exchange in the alkaline solvolysis of acid chlorides, but the alkaline solvolysis of acid chlorides may possibly proceed through an activated complex, not an intermediate.

Mesitoyl Chloride. — The case of mesitoyl chloride is worthy of further comment. It is well known that mesitoic acid is resistant to esterification under ordinary conditions and that methyl mesitoate is saponified with difficulty.[47-48] However, Bender proved conclusively that the alkaline hydrolysis of methyl mesitoate proceeds through a tetrahedral intermediate, which goes to hydrolyzed acid 6.8 times faster than it goes back to the starting ester.[49] Acetomesitylene gives a 2,4-dinitrophenylhydrazone[50] and reacts with hydroxylamine to give acetomesidide.[51] Although these examples show that it is not impossible to form a tetrahedral intermediate for mesitoic acid derivatives, the very fast solvolysis of mesitoyl chloride[52] is yet to be explained.

From dipole moments,[53-54] ultraviolet absorption[55] or infrared absorption,[56] it is known

b) First order rate constants
c) Too fast to measure accurately

that steric hindrance by *o*-substituents can decrease the extent of conjugation between a benzene ring and a carbonyl group by preventing these groups from becoming coplanar. Bunton and Lewis[17] attributed the fast solvolysis rate of mesitoyl chloride to the failure of the carbonyl group to conjugate with the benzene ring. The solvolyses of some esters and acid chlorides are compared in Table VIII. The resistance of mesitoic acid towards esterification or of mesitoate towards hydrolysis is usually explained by the blocking effect of *o*-substituents. If mesitoyl chloride is reactive only because of the lack of conjugation between a carbonyl group and a benzene ring, as Bunton and Lewis maintain, it is difficult to explain why methyl mesitoate is not solvolyzed more easily than benzoate in a weakly acid solution, and why methyl mesitoate is solvolyzed 10^5 times more slowly than ethyl benzoate in an alkaline solution. It seems that the explanation must depend upon a factor peculiar to acid chlorides.

It is conceivable that the structure of mesitoyl chloride differs from those of benzoyl chloride and of mesitoate esters. Although the ortho substituents prevent the chlorocarbonyl group from becoming coplanar with the ring, the carbonyl group may remain colinear with the bonding-ring carbon atom as in the mesitoyl cation. The molecule may then be described by the resonance structures (IV).

IV

The fact that mesitoyl chloride is a non-conductor in sulfur dioxide[27] need not void this hypothesis. An incoming hydroxylic solvent can attack the carbonyl carbon from the direction of the *p*-orbital perpendicular to the ring without steric hindrance. The solvolysis still proceeds not by the direct displacement of chloride but rather by addition-ionization, since the isotope exchange experiment showed the existence of a tetrahedral intermediate. The tetrahedral intermediate formed in the hydrolysis of mesitoate esters, on the other hand, is formed very much more sluggishly because, as we postulate, the alkoxy-carbonyl group does not depart from the usual trigonal structure.

Summary

A mechanism has been proposed which seems to be consistent with all the experimental results obtained by various workers on the solvolyses of acid chlorides.

The author wishes to thank Professor Paul D. Bartlett of Harvard University for his encouragement and valuable advice, the members of Professor Bartlett's research group in 1958—1961 for their stimulating discussions, and the Bell Telephone Laboratories for a research fellowship in 1959—1961.

On the Configurations of α-Aminotricarballylic Acids

By Takeo KANEKO, Yasuo ARIYOSHI, Seiji ANDŌ*1 and Hakuji KATSURA

(Received September 10, 1963)

Greenstein et al.[1] have reported on the configuration of the α-asymmetric carbon atoms of α-aminotricarballylic acids and isocitric acids. Recently, the absolute configurations of isocitric acids have been confirmed wholly and undoubtedly by us[2] and by Patterson et al.[3] As a result, the conclusion suggested by Greenstein et al.[1] has been rectified. In this paper, the absolute configurations of α-aminotricarballylic acids will be characterized by confirming the stereostructures of their pyrrolidone derivatives. α-Aminotricarballylic acid (II) was prepared from ethyl acetamidocyanoacetate and diethyl monobromosuccinate by the method of Greenstein et al.,[4] and from diethyl formylsuccinate (I) by Strecker synthesis. The yields of the diastereoisomeric α-aminotricarballylic acids A*2 (II-A) and B*2 (II-B) were obtained at the rate of three to one in the former method, but at the rate of eleven to one in the latter method. The pyrrolidone derivative (III-B) of II-B afforded

N-acetyl acid anhydride (IV) when heated with acetic anhydride, but from that of II-A (III-A), no acid anhydride was obtained at all. From these results, III-B may be identified as cis, and III-A as trans; therefore, the stereostructures of II-A and II-B may be shown as in the figure. According to Greenstein,[4] (+)- and (−)-alloisocitric lactones were derived from (+)- and (−)-II-A respectively by the action of nitrite, and, similarly, (+)- and (−)-isocitric lactones were derived from)+)- and (−)-II-B. It is evident that the absolute configurations of the β-asymmetric carbon atoms of α-aminotricarballylic acids are identical with those of the correspoding isocitric acids, because there was no effect on the configurations of the β-carbon atoms in the treatment of α-aminotricarballylic acids with nitrite. The determination of the relative configuration between the β- and α-asymmetric carbon atoms of the diastereoisomeric DL-α-aminotricarballylic acids, therefore, is sufficient to clarify the absolute configurations, of the α-asymmetric carbon atoms of the amino acids. Consequently, the absolute configurations of these amino acids II-A and II-B may be shown as in Table I. This table shows that Lutz-Jirgensons' displacement rule[5] is applicable to these amino acids II-A and II-B, and that in the derivations from amino acids II to hydroxy acids III no Walden inversions are observed.

Experimental

Diethyl Formylsuccinate (I).—From diethyl succinate (50 g.) and ethyl formate (30 g.), I (b. p. 92~105°C/3 mmHg: 41~45 g., 70~77%) was prepared by the method described by Wislicenus.[6]

α-Aminotricarballylic Acid A (II-A) and Pyrrolidone Carboxylic Acid B (II-B).—To the addition product prepared from I (60.6 g.) and sodium hydrogen sulfite (37.5 g.), a solution of sodium cyanide (18 g.) in water (145 ml.) was added. Oily cyanohydrine was separated and added to a concentrated aqueous ammonium hydroxide solution (330 ml.). After the mixture had been allowed to react in a pressure bottle for 30 days at room temperature, the reaction mixture was concentrated and the

residue was refluxed with 6 N hydrochloric acid (800 ml.) for 7 hr. Inorganic salts were removed by extraction from the hydrolysate with cold ethanol (500 ml.), and chloride ions were removed by the aid of silver carbonate (38 g.); then the solution was treated with hydrogen sulfide. When the purified solution was concentrated and kept at 5°C for 20 hr., II-A (14 g.) deposited as a solid and was recrystallized from water.

Found: C, 37.77; H, 4.99; N, 7.23. Calcd. for $C_6H_9O_6N$: C, 37.70; H, 4.75; N, 7.33%.

Another crop (3 g.) was obtained by the concentration of the above filtrate.

The filtrate separated from II-A crystals was made to pH 5 with an aqueous sodium hydroxide solution, and a solution of copper acetate (65 g.) in hot water (650 ml.) was added to this solution to give blue crystals of copper salt (14 g.), which were collected after standing at room temperature for 20 hr. The copper was removed as copper sulfide, and the solution was refluxed with a large amount of water for 7 hr. When the solution was concentrated and kept at 5°C for 20 hr., III-B (1.5 g.) was obtained and recrystallized from water; m. p. 225°C (decomp.): lit.,[4] m. p. 230°C.

Found: C, 41.29; H, 4.16; N, 8.01. Calcd. for

$C_6H_7O_5N$: C, 41.62; H, 4.08; N, 8.09%.

Pyrrolidone Carboxylic Acid A (III-A).—From II-A (12 g.), III-A (8.5 g.) was obtained by the method described by Greenstein[4] and then recrystallized from water; m. p. 210°C: lit.,[4] 210°C. This sample contains one mole of the water of crystallization.

Found: C, 37.70; H, 4.73; N, 7.42; H_2O, 9.82 (dried at 90~100°C in vacuo for 18 hr.). Calcd. for $C_6H_7O_5N \cdot H_2O$: C, 37.70; H, 4.75; N, 7.33; H_2O, 9.43%.

Acid Anhydride (IV) of *N*-Acetyl-pyrrolidone Carboxylic Acid B.—III-B (2.7 g.) was dissolved in acetic anhydride (400 ml.) by heating it gently over a 30-min. period, and then the solution was heated at 120~140°C for 15 min. After some insoluble materials had been filtered off from the hot reaction mixture, the solution was cooled to room temperature. IV (2.1 g.) thereupon crystallized out, and yet another crop (0.3 g.; total, 2.4 g., 80%) was obtained by the cocentration of the filtrate; m. p. 225°C (decomp.). A sample (1 g.) was recrystallized from acetic anhydride and washed with acetone. The pure substance (0.7 g.) was obtained after drying it over phosphorus oxide in a vacuum desiccator; m. p. 225°C (decomp.).

Found: C, 48.68; H, 3.55; N, 7.11. Calcd. for $C_8H_7O_5N$: C, 48.74; H, 3.58; N, 7.11%.

When this sample (1 g.) was hydrolyzed with 2 N hydrochloric acid (30 ml.), III-B (m. p. 225°C (decomp): 0.4 g.) was recovered.

The R_f values of II-A and II-B, and III-A and III-B are shown in Table II.

Catalysis by Organic Semi-conductors. The Photo-oxidation of Isopropyl Alcohol in the Liquid Phase

By Hiroo INOUE, Shigeki HAYASHI and Eiji IMOTO

(Received September 12, 1963)

Some organic catalytic reactions in biological systems, especially oxidation and reduction, have been explained recently by means of a concept of an organic semi-conductor,[1] though no catalytic reaction of an organic semi-conductor has ever been studied *in vitro*. Zinc oxide, which is a typical n-type semi-conductor, is effective as a catalyzer for the oxidation of isopropyl alcohol to acetone with oxygen under ultraviolet-irradiation.[2] On the other hand, it has been reported by many workers[3] that some photo-oxidations of organic compounds with oxygen under ultraviolet or visible light irradiation are accelerated by various kinds of organic dyes, though there have not been many of the kinds of dye used as the catalyst for these photo-oxidations. Moreover, the property of a dye as an organic semi-conductor, chiefly the kind of charge-carrier, has been studied by Terenin[4] and others[5,6]; some of their results are shown in Table I in the present paper.

photo-oxidation of isopropyl alcohol to acetone with oxygen under ultraviolet or visible light irradiation.

Experimental

Materials.—Isopropyl alcohol was purified by a fractional distillation after dehydration on calcium oxide. The dyestuffs used as the catalyzer, auramine, safranine T, fluorescein, eosine Y, crystal violet, malachite green, rhodamine B and brilliant blue, were of a commercial grade and had been purified by recrystallization or by extraction. Condensed aromatic or aza-aromatic hydrocarbons, such as anthracene, perylene, violanthrone, isoviolanthrone, phenazine, acridine and indanthrene, were also of a commercial grade and had been purified by sublimation or the recrystallization method.

The Measurement of the Reaction Rate.—The rate of the oxidation of isopropyl alcohol with oxygen was determined by measuring the amount of oxygen absorbed. To make a solution with a catalyzer in an appropriate concentration, a weighed amount of a catalyzer was dissolved or dispersed into 10 ml. of isopropyl alcohol which had been placed in a test tube of a common quantity (inner diameter, 15 mm.; thickness of the wall, 0.5 mm.). After oxygen had been bubbled in for 5 min., the test tube was connected with a gas burette, the air space of which had previously been filled with oxygen, and placed in a thermostat at a distance from the light source, which was placed in the same thermostat. The light source used was a 200 W. tungsten lamp or a Toshiba mercury lamp SHEL-100, which irradiates the waves at 2500, 3200, 3600, 4400, 5500 and 5800 Å.

Analysis of the Acetone and Pinacol Produced.—The acetone and the pinacol formed in the reaction mixture, after they had cooled in dry ice, were analyzed with a gas chromatograph, Hitachi KGL-2, in which polyethylene glycol was used as an adsorbent and hydrogen gas as a carrier gas.

Results and Discussion

The Effects of Dyes on the Rate of Oxygen Absorption.—As is shown in Fig. 1, the amount of oxygen absorbed increased linearly with the reaction time after a certain induction period, no matter what kind of dye was chosen as the catalyzer. However, the absorption rates differed from dye to dye. They may be classified into two groups, one group with a large rate, and another group with a small rate. All the catalyzers which afford the large rate are the dyes which were identified as p-type semi-conductors by Terenin, while those which afford the small rate are ones which were identified as n-type semi-conductors by the same author. Although the magnitude of the induction period of each of the oxidations catalyzed by p-type dyes was not the same, all

the inclinations of the straight lines in Fig. 1 are parallel and are also parallel to that of the oxidation which proceeded without a dye. As Table II shows, the p-type dyes were gradually decolorized during the reaction and the decolorized dyes may not be effective in accelerating the production of hydrogen peroxide. Therefore, the curves of the oxygen absorption rate must have the same inclination after the induction period as in an oxidation without a dye. This means that the oxidation is a chain reaction carried out by means of the hydrogen peroxide which is produced by the reaction of dyes, isopropyl alcohol and oxygen, and p-type dyes are effective merely in producing hydrogen peroxide. On the other hand, the n-type dyes must not be effective in producing hydrogen peroxide.

The second remarkable difference between the reaction with an n-type dye and that with a p-type dye is the molar ratio of the acetone formed to the oxygen absorbed. As Table III

shows, the p-type dyes afforded a ratio larger than unity, while the n-type dyes afforded a ratio less than unity. Even when the crystal violet of an n-type dye was used as the catalyzer and the reaction system was irradiated at a nearer distance, 5~6 cm., from a light source, the amount of the acetone formed was yet very little.

Furthermore, it was astonishing that the reaction catalysed by a p-type dye produced mainly acetone, while that catalyzed by an n-type dye produced pinacol. The irradiation of isopropyl alcohol in an atmosphere of oxygen in the presence of crystal violet at the distance of 5~6 cm. from the light source for 210 hr. at 40~50°C produced about 7×10^{-4} mol. of pinacol per 10 ml. of isopropyl alcohol. Under the same conditions, eosine Y of a p-type produced only about 1.05×10^{-4} mol. of pinacol per 10 ml. of isopropyl alcohol, even after irradiation for two weeks.

The Effects of the Mixed Dyes on the Oxygen Absorption.—Eosine Y (a p-type dye) and rhodamine B (an p-type dye) were used together as the catalyzers of the oxidation, because it was expected that a combination of a p-type catalyzer and an n-type catalyzer might be effective because synergitic. Since the visible absorption spectrum of these mixed dyes was the sum of the absorption spectra of eosine Y and rhodamine B, it seems that there is no molecular interaction between eosine Y and rhodamin B in isopropyl alcohol.

As is shown in Figs. 2 and 3, the rate of oxygen absorption increased with the increase in the concentration of eosine Y at a constant concentration of rhodamine B; on the other hand, it did not vary with an increase in the concentration of rhodamine B at a constant concentration of eosine Y. This means that, contrary to our expectations, there was no synergitic action, even when two kinds of dyes were mixed. While the oxygen absorbed-reaction time curve rose steeply at the beginning of the reaction, as Fig. 2 shows, the inclination of the curve decreased gradually and at the final stage of the reaction approached

the inclination of that curve obtained with rhodamine B alone. This fact could be explained as follows. When eosine Y was used as the catalyzer together with rhodamine B, eosine Y was also decolorized gradually as much as 67.7% after 450 min. and 79% after 1168 min.; consequently, the oxidation rate was retarded.

The Effects of Dyes on the Rates of the Formation of Acetone.—When isopropyl alcohol was irradiated in an atmosphere of oxygen at 17~18°C for 20 hr. with a 200 W. tungsten lamp placed 15 cm. from the vessel, no acetone was detected. However, when a p-type dye was present in this system, acetone was produced, while, except for rhodamine B, no n-type dyes were effective (Fig. 4). Now, the rate of the formation of acetone was measured under the reaction conditions just cited. As is clear from the results shown in Fig. 5, each dye has its optimum concentration at which the

maximum rate was exhibited: eosine Y, 8×10^{-4} mol./l.; fluorescein; 7.5×10^{-4}; auramine and safranine T, $0.05\sim0.5\times10^{-4}$ mol./l., and rhodamine B, 0.08×10^{-4} mol./l. The order of the magnitude of these optimum concentrations was the same as that indicated in Fig. 1.

The Effects of Condensed Aromatic and Aza-aromatic Hydrocarbons.—An oxidation catalyzed by a condensed aromatic or aza-aromatic hydrocarbon was carried out in the presence of rhodamine B, which may be effective in suppressing the effects of hydrogen peroxide, and also, if necessary, in the presence of sodium palmitate, with which an insoluble aromatic hydrocarbon could be dispersed. The other experimental conditions were the same as those holding in the cases of dyes. As is clear from the results shown in Fig. 6, the compound

containing a few condensed benzene rings and a heteroatom is rather more effective than a compound containing many condensed benzene rings. It is uncertain whether this is caused by the difference between the dispersed and dissolved states of the catalyzer, or, substantially, by the difference in the excited energies. As Table IV shows, the molar ratio of the acetone produced to the oxygen absorbed was larger than unity. p-Type compounds were effective, but n-type compounds ineffective, similar to the cases of dyes. Furthermore, a compound which can easily take its triplet state seemed to be more effective. For example, phenazine, the density of the triplet of which was 10^3 larger than that of anthracene, was more effective than anthracene.

An Assumed Mechanism of the Sensitized Photo-oxidation of Isopropyl Alcohol.—Electrical conductivity is a property which should be attributed to a solid aggregate of molecules, and the catalytic action of a dye in a solution must result from the property of an isolated molecule. In spite of this inconsistency, the fact that electrical conductivity is very dependent on properties of the molecule itself has allowed us to classify dyes into two groups according to the type of electrical conductivity. As has been described above and as is summarized in Table V, p-type compounds are generally effective as a sensitizer of the photo-oxidation of isopropyl alcohol with oxygen, while n-type compounds are ineffective. Compounds containing a heteroatom are particularly effective. p-Type conductivity has been explained by Rosenberg[7] as the trapping of an excited electron at a triplet state, whereupon the hole formed migrates to an electrode. A hetero-

(7. B Rosenberg, *J. Chem. Phys.*, 37, 1371 (1962).

aromatic compound may be easily excited to its triplet state, as has been found true of quinoline and phenazine. In a heteroaromatic compound excited to a triplet state, an excited electron may be trapped and a hole may migrate to another compound. The migration of a hole from one compound to another compound means an oxidation. Now, the sensitized photo-oxidation of isopropyl alcohol with oxygen to acetone may proceed at first by the migration of a hydrogen atom of isopropyl alcohol to an excited p-type sensitizer. The formation of DH_2 by some reaction, for example, by reaction 3 or 4, involves the decoloration of the dye.

$$D \rightarrow D^* \quad (1)$$

$$(CH_3)_2CHOH + D^* \rightarrow (CH_3)_2\dot{C}OH + HD\cdot \quad (2)$$

$$(CH_3)_2CHOH + HD\cdot \rightarrow (CH_3)_2\dot{C}OH + H_2D \quad (3)$$

$$(CH_3)_2\dot{C}OH + HD\cdot \rightarrow (CH_3)_2CO + H_2D \quad (4)$$

Though the mechanism of the formation of hydrogen peroxide is not certain and is not within the scope of this paper, hydrogen peroxide must be produced from some radicals, such as HD· (5 and 6).

$$HD\cdot + O_2 \rightarrow D + HO_2\cdot \quad (5)$$

$$(CH_3)_2CHOH + HO_2\cdot \rightarrow (CH_3)_2\dot{C}OH + H_2O_2 \quad (6)$$

When a molecule of hydrogen peroxide is produced, it must oxidize a molecule of isopropyl alcohol to acetone by the following chain reactions (7—11), though this mechanism is merely speculative. This must also be the reason why the molar ratio of the acetone produced to the oxygen absorbed was larger than unity.

$$H_2O_2 \rightarrow HO\cdot + \cdot OH \quad (7)$$

$$(CH_3)_2CHOH + \cdot OH \rightarrow (CH_3)_2\dot{C}OH + H_2O \quad (8)$$

$$(CH_3)_2\dot{C}OH + O_2 \rightarrow (CH_3)_2CO + HO_2\cdot \quad (9)$$

$$(CH_3)_2CHOH + HO_2\cdot \rightarrow (CH_3)_2\dot{C}OH + H_2O_2 \quad (10)$$

$$(CH_3)_2\dot{C}OH + \cdot OH \rightarrow (CH_3)_2CO + H_2O \quad (11)$$

$$2(CH_3)_2CHOH + O_2 \rightarrow 2(CH_3)_2CO + 2H_2O$$

On the other hand, since a photo-excited sensitizer of the n-type could not abstract a hydrogen atom from isopropyl alcohol, it was ineffective as the catalyzer. The radical, $(CH_3)_2\dot{C}OH$, which is necessary for the formation of pinacol may be produced directly from isopropyl alcohol and oxygen.

Summary

The natures of organic semi-conductors have been correlated with the catalytic ability for the photo-oxidation of isopropyl alcohol to acetone with oxygen under ultraviolet or visible light irradiation. p-Type compounds are generally effective as sensitizers, but n-type compounds are ineffective. Heteroaromatic compounds are more effective than the parent aromatic compounds among p-type compounds. The molar ratio of the acetone formed to the oxygen absorbed is larger than unity in the case of p-type compounds and less than unity in the case of n-type compounds. Finally, it has been assumed that the migration of a positive hole in a p-type compound can be correlated with the migration of a hydrogen atom of isopropyl alcohol.

The Electrical Conductivity of Heterocyclic Compounds. Fluoridine and Triphenodioxazine

By Hiroo INOUE, Kazuo NODA and Eiji IMOTO

(Received September 12, 1963)

The electrical conductivity of aza-aromatic hydrocarbons has been studied by Akamatu and Inokuchi[1] and by others.[2] The photoconductivity of phenazine has also been reported on recently by Rosenberg,[3] MacGlynn[4] and others.[3] In this paper, for the purpose of investigating the effect of a heteroatom on the electrical conductivity of a heterocyclic compound, the dark- and photo-conductivities of fluoridine (1) and triphenodioxazine (2) will be compared with those of their parent aromatic compound, pentacene (3), the conductivity of which has been reported by Northrop and Simpson.[6]

(1) (2)

(3)

Experimental

Materials.—Fluoridine and triphenodioxazine were prepared according to the methods reported by Badger[7] and by Fierz-David[8] and were purified three times by sublimation at 200~250°C under a reduced pressure of 0.1 mmHg. Fluoridine purified is violet-green crystals, does not melt until 360°C, and is slightly soluble in organic solvents, but it is easily soluble in concentrated sulfuric acid, where it gives a pink-colored fluorescence, though no fluorescence is found in ethanol. The spectrum shows two absorption maxima, at about 517 and 552 mμ in dimethylformamide, and at about 541 and 579 mμ in ethanol, with red shifts of about 24~27 mμ from the bands in dimethylformamide, as is shown in Fig. 8. Triphenodioxazine is red crystals, does not melt until 360°C, and is a little soluble in xylene, giving a green fluorescence. The spectrum shows two absorption maxima, at about 474 and 508 mμ in dimethylformamide, and at about 479 and 510 mμ in ethanol, with red shifts of about 2~5 mμ from the bands in dimethylformamide, as Fig. 9 shows. That is, the effect of a solvent on the spectrum of triphenodioxazine is less remarkable than that of fluoridine.

1 Glass substrate, 2 terminal electrode, 3 organic thin layer, 4 epoxy-resin seal, 5 rubber stopper, 6 thermometer, 7 quartz tube, 8 copper-film

Apparatus.—The chamber used for the measurement of the electric conductivity is shown in Fig. 1. The resistance of materials, kept in a vacuum of 10^{-2} mmHg or less, was measured with the ultra-megohm meter.

The measurement of the electrical conductivity was performed by using conductivity cells of the following three types.

Surface-type Cell.—This cell was prepared by the sublimation of the sample in a thickness of a few microns on a transparent quartz plate (3×3 cm^2) which has aluminum or silver electrodes of a comb form that are separated from each other by a gap of 0.2 mm. or 0.5 mm., as in Fig. 2.

Sandwich-type Cell.—The sample was deposited by vacuum sublimation in a thickness of from three to eight microns on a quartz plate, which had previously been provided with an aluminum film as one electrode. Another film-electrode was formed by the sublimation of aluminum onto the surface of the specimen film. When Nessa glass was used

instead of the quartz plate, the initial sublimation of aluminum was omitted.

Bulk Specimen.—The d-c resistivity was measured under a pressure of 100 kg./cm² at an applied electric field of 1000 V./cm. according to the method described in previous papers.[9]

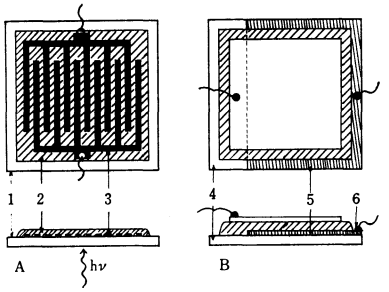

Fig. 2. Conductivity cell.
A Surface type, B sandwich type:
1 Quartz glass, 2 organic film, 3 aluminum film, 4 Pylex glass, 5 Nessa glass, 6 terminal electrode

Results

Dark-conductivities.—*Current/Voltage Relationship.*—The dark-currents of fluoridine and triphenodioxazine measured with sandwich- and surface-type cells were ohmic up to 10^4~10^5 V./cm. The relation between current and voltage is shown in Fig. 3. Even when the electrodes are reversed, identical results were obtained.

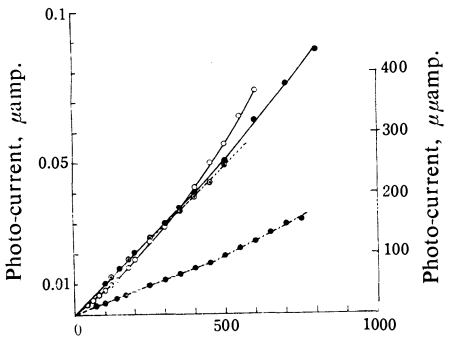

Fig. 3. Current/voltage relationship in the absence of oxygen.
—●— Surface type for fluoridine (μamp.)
---●--- Sandwich type for fluoridine (μμamp.)
—○— Surface type for triphenodioxazine (μμamp.)
---⊙--- Sandwich type for triphenodioxazine (μamp.)

Resistivity/Temperature Relationships.—The resistance of the surface- and sandwich-type cells and of the bulk specimens was measured at a range of 20~140°C under a reduced pressure of 0.1~0.01 mmHg, after the temperature had been kept for about 1/2~1 hr. at 115~120°C for triphenodioxazine and at 130~140°C for fluoridine. The range of the temperature of the measurement was limited because of the high resistances of the samples at temperatures lower than 20°C and because of the easy sublimation at temperatures higher than 140°C. The resistance of triphenodioxazine was too high to measure in bulk.

The electrical resistivity (ρ) at an ascending temperature was identical with that at a descending temperature, and a linear relationship between $\log \rho$ and $1/T$ (reciprocal absolute temperature) was observed, as Fig. 4 shows. Thus, the resistivity of the substances as typical organic semiconductors obeyed the following equation:

$$\rho = \rho_0 \exp(\Delta\varepsilon/2kT)$$

where $\Delta\varepsilon$ is the energy gap and k, the Boltzmann constant. The values of ρ_{20} and $\Delta\varepsilon$ are shown in Table I, in which the values of pentacene are those given by Northrop and Simpson.[6]

9) H. Inoue, T. Takiuchi and E. Imoto, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **65**, 1291 (1962).

Photo-conductivities.—A tungsten lamp as the light source, and a band-pass filter which allowed the ray to pass between 350 and 700 mμ, were used for the measurement of photo-conductivities. Light intensity was measured by using a standard cadmium sulfide cell. A surface-type cell was used for the measurement, and the back face of a sample was illuminated (Fig. 2). As Fig. 5 shows, the

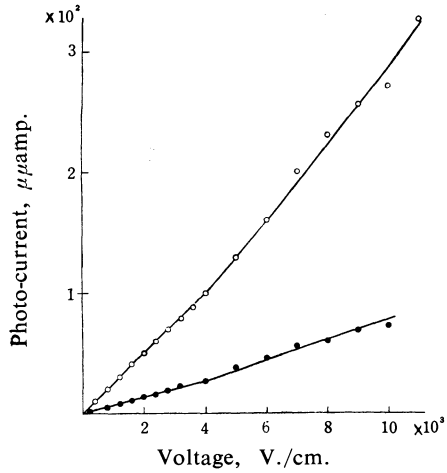

Fig. 5. The variation of the photo-current with the applied voltage: illuminated with tungsten lamp at 6000 lux.
● for fluoridine, ○ for triphenodioxazine

photo-currents of fluoridine and triphenodioxazine approximately obeyed Ohm's law up to 4×10^3 V./cm. The dependence of the steady-state photo-current on the light intensity in the absence of oxygen gas was investigated at a field strength of 2×10^3 V./cm. The rise and the decay of the photo-current of triphenodioxazine and fluoridine were comparably rapid, 5 sec. or less. The photo-current (i_{ph}) was related to the light intensity (L) by the following equation:

$$i_{ph}\propto L^{0.67}$$

Since the photo-current is nearly proportional to half the order of the light intensity, it seemed probable that the generation of a carrier is bimolecular. The ratio of the photo-current to the dark-current at a light intensity of 10^5 lux was about 39 for fluoridine, and about 8100 for triphenodioxazine. The photo-current of triphonodioxazine was about ten times larger than that of fluoridine.

The Effect of Oxygen.—The effect of oxygen on the dark- and photo-conductivity of fluoridine and triphenodioxazine was examined using a surface-type cell. After a cell of fluoridine had been degassed in vacuo, it was heated on P_2O_5 at 150~160°C in the presence of air for 2 hr., then the temperature dependence of the dark-conductivity was investigated. As is shown in Fig. 6, the resistivity and the activation energy became smaller after the air treatment, but recovered to some extent when the oxygen absorbed was pumped out in vacuo. The reason why the initial conductivity in vacuo was not recovered entirely, even after prolonged heating at 100°C, may be explained by the retention of a small amount of oxygen in the film. Moreover, the decrease in the activation energy of the dark-conductivity after the air treatment might allow it to assume the energy level of an oxygen-trapped state, similar to the case of phthalocyanine as reported by Vartanian and Karpovitch.[10] Furthermore, the air treatment of fluoridine increased its photo-current, as Fig. 7 shows, and the photo-current was proportional to the intensity (i_{ph}) of light irradiated, as given by the following equation:

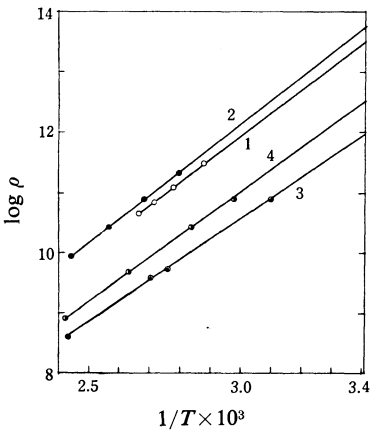

Fig. 6. The effect of oxygen on the surface dark-conductivity of fluoridine: 1, 2 in the absence of oxygen; 3 heated at 150~160°C on P_2O_5 in the presence of air for 2 hr. and measured in vacuo; 4 the oxygen absorbed was pumped out in vacuo.

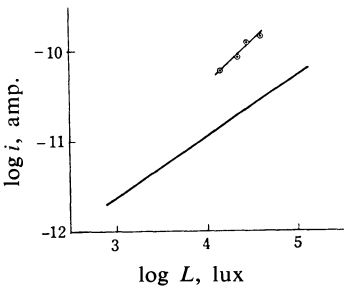

Fig. 7. The effect of oxygen on photo-current of fluoridine: —⊙— kept on P_2O_5 in the presence of oxygen for 1.5 months; — heated at 130°C in vacuo for 4 hr.

10) A. T. Vartanian and I. A. Karpovitch, *Zhur. Fiz. Khim.*, 32, 178, 274, 543 (1958).

$$i_{ph} \propto L$$

On the other hand, the air treatment of triphenodioxazine resulted in a lowering of the dark- and photo-conductivity, but the photocurrent was proportional to the light intensity, similar to the case of fluoridine.

Visible Light Absorption Spectra.—The visible light absorption spectra of fluoridine and triphenodioxazine in dimethylformamide or ethanol, and of their sublimed thin films (0.02～0.03 in thickness), are shown in Figs. 8 and 9

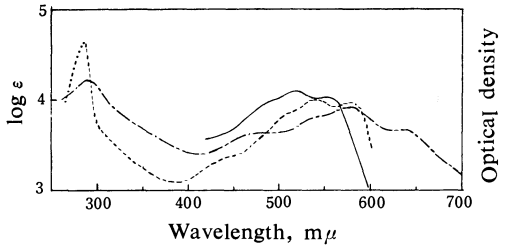

Fig. 8. Absorption spectra of fluoridine:
—— in dimethylformamide, ------ in ethanol,
—·—·— of sublimed thin film.

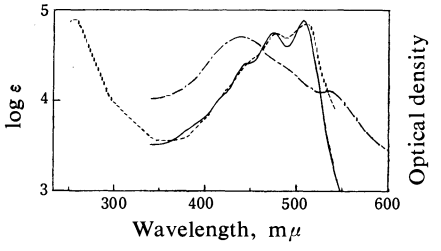

Fig. 9. Absorption spectra of triphenodioxazine:
—— in dimethylformamide, ------ in ethanol,
—·—·— of sublimed thin film

respectively. In these figures, the absorption coefficient was taken for the solution spectra, and the optical density for films. The main absorption bands of fluoridine dissolved in ethanol were in good agreement with those reported by Badger.[7] The main absorption maxima are evident in their visible regions. The absorption curves of sublimed films were broad and seemed to correspond to those in solution, although the absorption densities were altered. Namely, the absorption spectrum of a sublimed film of fluoridine showed two main absorption maxima, at 580 and 640 mμ, which shifted bathochromically from the corresponding band in the solution. On the other hand, the absorption maximum of triphenodioxazine at 479 mμ in solution was shifted to blue, while the one at 510 mμ shifted to red. Also, the spectral shifts of fluoridine were found to be larger than those of triphenodioxazine. The presence of oxygen did not change the spectral curve.

X-Ray Diffraction.—The X-ray diffraction of the transparent films sublimed on a glass was examined by using a Geiger counter X-ray diffractometer. The number of the diffraction lines in sublimed films decreased in both fluoridine and triphenodioxazine compared with that of the powder, whereas the intensity of the diffraction was very small. No remarkable change of X-ray diffraction pattern in fluoridine upon the thermal or air treatment of a sublimed film was found.

Discussion

As Table I shows, the activation energy ($\Delta\varepsilon$) obtained from the dark-conductivity of a sandwich cell was in quite good agreement with that of the surface cell for both fluoridine and triphenodioxazine. However, the resistivity of a surface-type cell was less than that of the sandwich-type cell by a factor of 10～10^2; this indicates an anisotropy of resistivity which may be caused by the mode of the arrangement of crystallites, as has already been mentioned by Akamatu and Inokuchi.[11] The ρ_0 of three compounds decreased in the following order: triphenodioxazine>fluoridine in the surface type, and fluoridine>triphenodioxazine >pentacene in the sandwich type. The ρ_0 of fluoridine along the surface of the film is the smallest in three compounds; particularly, the anisotropy in the surface and sandwich conductivity of fluoridine becomes larger than that in the case of triphenodioxazine. This probably means that the mode of the arrangement of crystallites in fluoridine may become better than that in triphenodioxazine, because of the effects of -NH- groups in fluoridine, for example, the hydrogen bond between adjacent molecules. Thus, the substitution of a heteroatom for a ring carbon atom has a large effect on ρ_0. On the other hand, the relation between the lowest singlet absorption level ($^1E_1$) in a solution and $\Delta\varepsilon$ for fluoridine and triphenodioxazine coincided with that for various aromatic hydrocarbons, as Fig. 10 shows. Thus, the $\Delta\varepsilon$ of triphenodioxazine and fluoridine depends on the $^1E_1$ of the absorption spectrum.

The property of being a charge carrier was investigated by means of the effect of oxygen on the dark- and photo-conductivity. The effects of oxygen on the electrical conductivity of many dye stuffs have been examined by Meier,[12] who has shown that the electrical conductivity of a p-type compound increases in the presence of oxygen, while that of a n-type compound decreases. If Meier's results are applied to the present case, the charge carrier must be posi-

1 anthracene, 2 pyrene, 3 perylene, 4 1,2-benzanthracene, 5 chrysene, 6 tetracene, 7 pentacene, 8 triphenodioxazine, 9 fluoridine, 10 triphenodioxazine (film), 11 fluoridine (film)

tive for fluoridine (p-type) and negative for triphenodioxazine (n-type). Moreover, it is found from the report of Vartanian[13] that the photo-current of a p-type compound containing heteroatoms is generally less than that of an n-type compound containing heteroatoms. As has been described above, the characters of the photo-current of fluoridine and triphenodioxazine coincided with Vartanian's results; that is, the photo-current of fluoridine, which is considered to be p-type, is less than that of triphenodioxazine, which is n-type. That is, the mobility of the photo-current is less than that of triphenodioxazine in spite of the large molecular interaction in fluoridine. This implies that the probability of a drift of a hole is small because of the localization of a hole on heteroatoms, as has been shown by Rosenberg[3] in the difference in photo-current in anthracene and phenazine of the p-type.

Summary

The electrical conductivities of fluoridine and triphenodioxazine have been measured, and it has been confirmed that (1) the ρ_0 of three compounds decreased in the following order: triphenodioxazine>fluoridine in the surface-type cell and fluoridine>triphenodioxazine>pentacene in the sandwich-type cell; (2) $\Delta\varepsilon$ depended on the $^1E_1$ of the absorption spectrum; (3) in the presence of oxygen, the dark- and photo-current of fluoridine increased, while those of triphenodioxazine decreased; (4) the photo-current of fluoridine was less than that of triphenodioxazine, and (5) the generation of the charge carrier in both fluoridine and triphenodioxazine was bimolecular in the absence of oxygen.

The authors wish to express their gratitude to Dr. Kosaburo Baba of the Hayakawa Electric Industry Co. for permitting the use of the experimental apparatus and for his helpful advice in this study.

The Electrical Conductivity of Heterocyclic Compounds. Molecular Complexes of Phenazine

By Hiroo INOUE, Shigeki HAYASHI and Eiji IMOTO

(Received September 12, 1963)

As a part of a series of studies of the electrical conductivity of heterocyclic compounds, some molecular complexes of phenazine (cf. Fig. 1) were prepared, and their electrical conductivities were compared with those of molecular complexes of the quinhydrone-type.

Experimental

Materials.—Phenazine, phenazinium chloride and phenazinium methosulfate were prepared according to the methods described in the literature.[1] Hydroquinone, pyrene and all other materials were of a commercial grade. All the materials were purified by repeated recrystallization and sublimation.

The Preparation of Molecular Complexes.—*Molecular Complexes of the Quinhydrone Type.*—Molecular complexes of the quinhydrone type of phenazine (abbreviated as ph) with *o*-, *m*- and *p*-hydroquinone (abbreviated as Hy), *o*-phenylenediamine (abbreviated as BNH_2), dihydrophenazine (abbreviated as phH_2) or trinitrobenzene (abbreviated

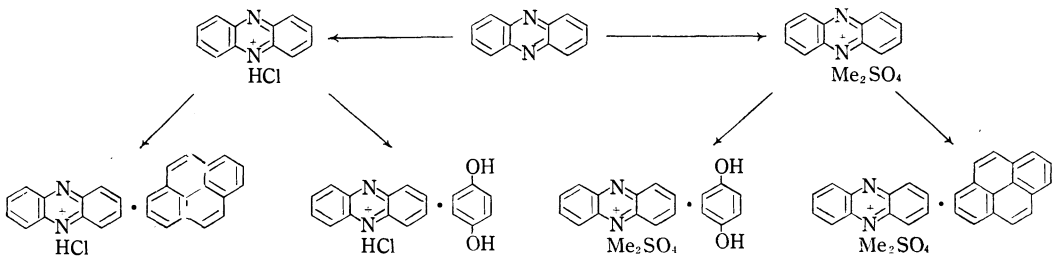

Fig. 1. Molecular complexes of salt type.

TABLE I. THE CONDITIONS OF THE PREPARATIONS FOR MOLECULAR COMPLEXES

Donor and acceptor	Solvent	Yield %	M. p. °C	Color of crystals
py, ph-HCl	HCl-ethanol	90	133 ~135	Black needle
Hy(*p*), ph-HCl	HCl	60	168.5~170	Black-brown plate
py, ph-Me_2SO_4	Ethanol	30~40	156 ~157	Black prism
Hy(*p*), ph-Me_2SO_4	Ethanol	30~40	118 ~119.5	Black prism
py, ph-HCl	Dry ether	0	—	—
Hy(*p*), ph	Ethanol	62	234 ~236	Yellow needle
Hy(*m*), ph	Ethanol	70	213 ~214	Yellow needle
Hy(*o*), ph	Ethanol	74	181 ~182	Yellow needle
BNH_2, ph	Ethanol	70	150 ~151	Red-blown plate
ph, TNB	Ethanol	85	151 ~153	Yellow needle
phH_2, ph	Acetone	50	223 ~225	Blue-violet needle

as TNB) were prepared according to the methods described in the literature,[2-4] these will be abbreviated as ph-Hy(*o*), ph-Hy(*m*), ph-Hy(*p*), ph-BNH_2, ph-phH_2 and ph-TNB in this paper. The conditions of the preparation of these molecular complexes are shown in Table I.

Molecular Complexes of the Salt Type.—a) Phenazinium Chloride and Pyrene (abbreviated as ph-HCl-py).—To a warm solution of 0.9 g. of phenazine in 70 ml. of concentrated hydrochloric acid, 1 g. of pyrene dissolved in 80 ml. of ethanol was added, and the mixture was refluxed for about half an hour. After filtering, the filtrate was left to cool, and 1.8 g. of black needle crystals were obtained. However, no molecular complex was obtained from pyrene and phenazine themselves. When hydrogen chloride was introduced into a solution of pyrene and phenazine in dry ether, no black precipitate was obtained, but red crystals of phenazinium chloride were recovered. However, when ether which had previously been saturated with water was used instead of dry ether as the solvent, black needle crystals of the molecular complex were obtained. Thus, it seems that a little water may be necessary in a reaction system to form a molecular complex of a salt type from phenazinium salt.

b) Phenazinium Chloride and p-Hydroquinone (abbreviated as ph-HCl-Hy(*p*)).—To a solution of 0.3 g. of phenazine in 30 ml. of concentrated hydrochloric acid, 1 g. of *p*-hydroquinone was added at 70~80°C, and the solution was refluxed for half an hour. After it had been treated in a manner similar to that described above, 0.3 g. of black plate crystals was obtained.

c) Phenazinium Methosulfate and Pyrene (abbreviated as ph-Me_2SO_4-py).—Into a solution of about 0.5 g. of phenazine in 25 ml. of nitrobenzene, 0.5 g. of dimethylsulfate was stirred, after which the reaction mixture was heated at 100~110°C for about 15 min. The cooling of the reaction mixture resulted in a precipitation of crystals. After filtering, the filtrate was diluted by 25 ml. of dry ether to precipitate crystals again. Both sets of crystals were recrystallized from ethanol; yield, 0.6 g. (70%); m. p. 151~153°C (decomp.). Six-tenths of a gram of ph-Me_2SO_4 and 0.4 g. of pyrene were dissolved in 4~5 ml. of ethanol and refluxed for about half an hour. About 0.3 g. of black prism crystals precipitated. After filtering, the precipitate was washed with a mixed solvent of benzene and ether and dried on P_2O_5 under the reduced pressure of 10 mmHg for about ten hours; m. p. 156~157°C.

d) Phenazinium Methosulfate and p-Hydroquinone (abbreviated as ph-Me_2SO_4-Hy(*p*)).—A solution of 0.3 g. of ph-Me_2SO_4 and 0.18 g. of *p*-hydroquinone in 1~2 ml. of ethanol was refluxed for about half an hour and then treated in a manner similar to that used in the case of ph-HCl-py. About 0.15 g. of black prism crystals was precipitated. The properties of the molecular complexes obtained above are shown in Table I.

Results

The Properties of Molecular Complexes of the Salt Type.—The constitutions of the molecular complexes obtained were analyzed. Since

ph-HCl-py and ph-HCl-Hy(p), which were dried on calcium chloride at 20°C under the reduced pressure of 10 mmHg for 5 hr., contained more than the expected amounts of excess hydrogen chloride and water, as may be seen in Figs. 2 and 3, they were dried under the same conditions for a prolonged period. During this treatment, the features of the molecular complexes changed, as Table II and Figs. 2 and 3 show.

The color changed from black to yellow, and the shape of the crystals changed from needle to fine amorphous. The melting points decreased gradually. When kept on P_2O_5 at 50~60°C under the reduced pressure of 5~10 mmHg for a long time, the melting points of the molecular complex became near to those of the simple mixture of their constituents.

The content of hydrogen chloride and water, which had been calculated from the analytical results of nitrogen and chlorine shown in Figs.

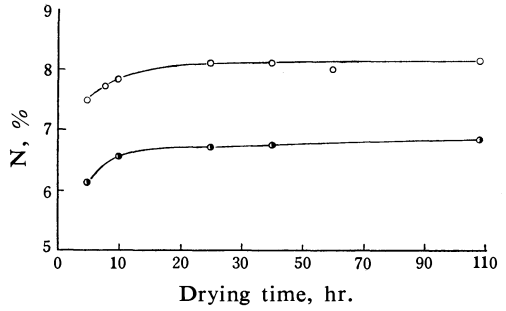

Fig. 2. The variation of nitrogen percentage to drying time: ◑ ph-HCl-py, ○ ph-HCl-Hy(p); Calcd. for ph-HCl-py: N, 6.69%, for ph-HCl-py-H_2O: N, 6.41%, for ph-HCl-Hy(p): N, 8.56%, and for ph-HCl-Hy-H_2O: N, 8.12%.

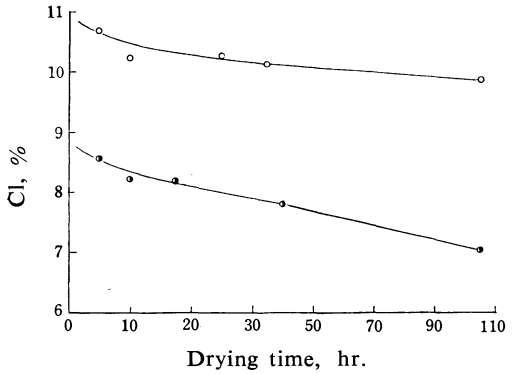

Fig. 3. The variation of chlorine percentage to drying time: ◑ ph-HCl-py, ○ ph-HCl-Hy(p); Calcd. for ph-HCl-py: Cl, 8.46%, for ph-HCl-py-H_2O: Cl, 8.11%, for ph-HCl-Hy(p): Cl, 10.86%, and for ph-HCl-Hy(p)-H_2O: Cl, 10.30%.

TABLE II. THE VARIATION OF MELTING POINT TO DRYING TIME

Melting point of the simple mixture: ph and py; 118~121°C, ph and Hy(p); 167~230°C

Drying time hr.	ph-HCl-py °C	ph-HCl-Hy(p) °C	ph-HCl °C
1	133~135	168.5~170	214~216
3	130~133.5	168 ~170	212~216
10	128~133	162 ~166	205~209
30	123~132	—	—
100	120~130	163 ~167	169~175

2 and 3, decreased gradually with the drying time. The decrease in the quantity of water during the process of drying was confirmed also by the disappearance of the infrared absorption band at 3500 cm^{-1} after the drying. Thus, the water included in the crystals of the molecular complexes may be regarded as one of the constituents of the molecular complex, because a little water in a reaction system is necessary in order to obtain the molecular complexes.

The ultraviolet absorption spectrum of an ethanolic solution of ph-HCl-py was merely the sum of the absorption spectra of ph-HCl and py in ethanol, because ph-HCl-py dissociates thoroughly into each component in ethanol. On the other hand, the ultraviolet absorption spectrum of the same compound obtained by the KBr-method showed a new band at about 620 mμ which must be a charge transfer absorption, as Fig. 4 shows. A charge

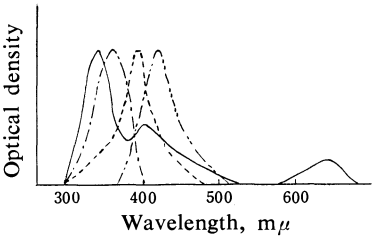

Fig. 4. Absorption spectra of ph-HCl-py, ph-HCl-Hy(p), ph-HCl and ph in KBr: —— ph-HCl-py, ------ ph-HCl-Hy(p), —··— ph-HCl and —·— ph.

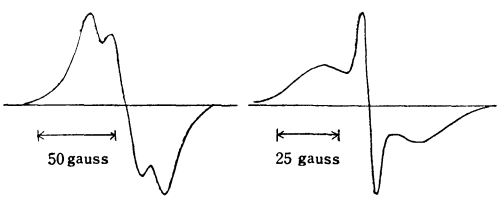
transfer absorption for ph-HCl-Hy(p) could not be confirmed by the KBr method. The infrared absorption spectra of ph-HCl-py and ph-HCl-Hy(p) showed out-of-plane deformation bands at 700~1000 cm^{-1} which shifted about 5~30 cm^{-1} to a lower wave number than those of each component. This may imply that there is some molecular interaction in the molecular complex.

The ESR spectra of ph-HCl-py and ph-HCl-Hy(p) which had been kept over calcium chloride at room temperature under the reduced pressure of 10 mmHg for three days are shown in Fig. 5. The spin concentrations and g values which were calculated from the ESR spectra were as follows:

ph-HCl-py; g value 2.0033, spin concentration 5.8×10^{20}

ph-HCl-Hy(p); g value 2.0022, spin concentration 3.9×10^{20}

Though the curves of the ESR spectra were comparably broad, they showed three fine structures. Hence, it may be considered that an unpaired electron is localized on the nitrogen atom of phenazine. Also, the infrared spectra showed that the intensities of the peaks at 1917 and 2380 cm^{-1} assigned to $=\overset{+}{N}H-$ for py-HCl-ph and ph-HCl-Hy(p) decreased as compared with those of ph-HCl. From these results, the following structural formula may be assigned to the structure of molecular complexes:



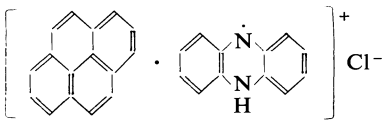


Fig. 5. ESR spectra of ph-HCl-py and ph-HCl-Hy(p).

The properties of molecular complexes of a methosulfate type were similar to those of a hydrogen-chloride type.

Electrical Conductivities.—The d.c. resistivity was measured under the pressure of 100 kg./cm^2 in vacuo according to the methods described in previous papers.[5] Since the dark current of all samples obeyed Ohm's law up to $10^3\sim10^4$ V./cm., all d.c. resistivities in this paper were measured at an applied electric field in the range of 2000$\sim$4000 V./cm.

The electrical resistivity (ρ_{20}) of ph-HCl-py, ph-HCl-Hy(p) and ph-HCl, which had been dried under the conditions shown in Figs. 2 and 3, was measured at 20°C for various periods, as is shown in Fig. 6. Each resistivity increased with the drying time, but each then became nearly constant after about 20 hr. Also, the resistivity of the compounds which had been dried for 20 hr. or more did not change when kept under the applied field of about 10^4 V./cm. for eight days. Judging from these results, it seems probable that the electrical conductivities of the compounds dried for over 20 hr. are electronic.

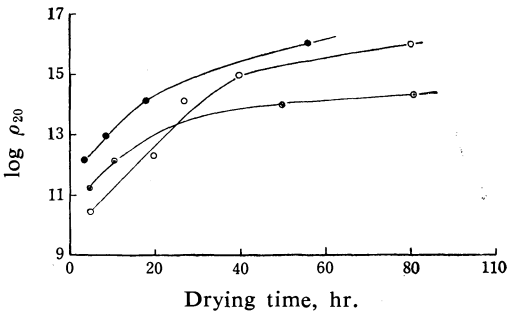

Fig. 6. The variation of log ρ_{20} of salt type compounds to drying time: ● ph-HCl, ⊙ ph-HCl-Hy(p), ○ ph-HCl-py.

The dependencies of the d.c. resistivities on the measuring temperature are shown in Fig. 7. The resistivity as an ascending temperature coincides with that at a descending temperature for all samples, except ph-phH_2, ph-HCl-Hy(p) and ph-Me_2SO_4-Hy(p), and a linear relationship between log ρ and $1/T$ was confirmed. $\Delta\varepsilon$ was calculated by the following equation:

$$\rho=\rho_0\exp(\Delta\varepsilon/2kT)$$

where $\Delta\varepsilon$ is an appearent energy gap, k is the Boltzman constant, and ρ is a specific electrical resistivity. The values of ρ_{20} and $\Delta\varepsilon$ are given in Table III.

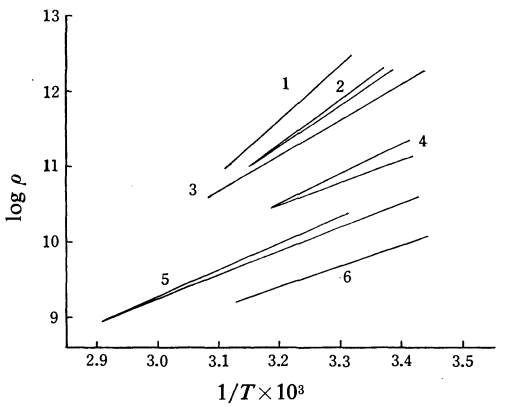

Fig. 7. The relationship between log ρ and $1/T$: 1 ph-Me_2SO_4-py, 2 ph-Me_2SO_4-Hy(p), 3 ph-HCl, 4 ph-HCl-Hy(p), 5 ph-phH_2, 6 ph-HCl-py.

ph-Hy(*m*)	1×10^{16}	—
ph-Hy(*o*)	7×10^{12}	0.5
ph-TNB	1×10^{15}	—
ph-BNH_2	3×10^{13}	—
ph-phH_2	3.7×10^{10}	1.3~1.5

* This sample was dried on P_2O_5 under the ordinary pressure at room temperature for a week.

Discussion

The ρ_{20} values of salt-like molecular complexes are smaller than those of molecular complexes of the quinhydrone type. This means that the effect of the intermolecular charge-transfer on the ρ_{20} of the former is larger than that on ρ_{20} of the latter. Also, the resistivities of molecular complexes of the methosulfate type were larger than those of molecular complexes of the hydrogen-chloride type. These results seem to show that the resistivity is affected by the compactness of molecular arrangement, because it seemed that the molecular arrangement of the methosulfate-type complex was less compact than that of the hydrogen chloride-type complex because of the steric effect of the CH_3-group.

The ρ_{20} of ph-phH_2 was the lowest among those of the molecular complexes of the quinhydrone type. This may be caused by the fact that the molecular arrangement of ph-phH_2 is more favorable than that of the others because of the good symmetry in the dimensions of the donor and acceptor molecules.

The resistivities of the salt-like molecular complexes described above possess a much higher value than those of the aromatic hydrocarbon-halogen complexes, which have been reported on by Akamatu and Inokuchi.[6] That is, it seems that these results may be attributed to the following causes; (1) the crystal of the molecular complex was contaminated with phenazine and pyrene or *p*-hydroquinone, because a part of the molecular complex dissociates to these compounds when water was removed; (2) an unpaired electron was localized on nitrogen atoms of phenazine, and (3) the molecular arrangement is incomplete, as may be presumed from the broadness of the ESR spectrum.

Summary

Some molecular complexes of the salt type have been prepared from phenazinium chloride or methosulfate and pyrene or *p*-hydroquinone. It has been confirmed that (1) the constitution, the color and the melting point of the molecular complexes varied with the drying conditions; (2) the ultraviolet absorption spectrum of ph-HCl-py by KBr shows a new band at about 620 mμ; (3) an unpaired electron is localized on the nitrogen atom of phenazine, and (4) the electrical conductivities of molecular complexes of the salt type are better than those of the quinhydrone type of phenazine.

The Reaction of Carbon Monoxide with Organometallic Compounds. VIII. The Synthesis of Aromatic Aldehydes by the Reaction of Iron Pentacarbonyl with Aryllithiums*

By Membo RYANG, Ilsong RHEE and Shigeru TSUTSUMI

(Received October 3, 1963)

In a previous paper[1] of this series, it was reported that carbon monoxide reacted with organolithium compounds in an ether solution at $-70°C$ to give the corresponding symmetrical ketones in good yields. In these reactions, it was assumed that carbon monoxide attacked organolithium compounds and abstracted the lithium as lithium carbonyl, producing symmetrical ketones (Eq. 1).

$$2\ R\text{-}Li + 3\ CO \rightarrow R\text{-}\underset{\underset{O}{\|}}{C}\text{-}R + 2\ LiCO \qquad (1)$$

On the other hand, iron pentacarbonyl reacted with organolithium compounds in an ethereal solution at $-50°C$, giving various reaction products.[2] For example, the aryllithium yielded the corresponding aromatic aldehydes, benzhydrol derivatives and benzoin derivatives by the reaction with iron pentacarbonyl, but the alkyllithium and *p*-tolyllithium yielded symmetrical ketones. The formation of aldehydes, benzhydrol derivatives and benzoin derivatives can be interpreted in terms of an ionic reaction sequence judging from the results of the reaction of carbon monoxide with organomagnesium halides[3]. Therefore, the following reaction scheme was assumed: the addition of aryllithium to the carbonyl double bond of iron pentacarbonyl resulted in the fission of the iron-carbon bond of iron pentacarbonyl, producing the unstable intermediate I (aroyllithium). (Fig. 1)

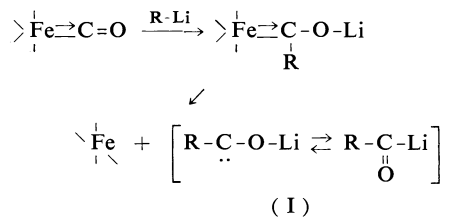

Fig. 1

This intermediate I is assumed to give aldehydes by hydrolysis (Eq. 2), benzoin derivatives by dimerization (Eq. 3), and benzhydrol derivatives by further reaction with aryllithium (Eq. 4).

$$I \xrightarrow{H^+} RCHO \qquad (2)$$

$$I + R\text{-}\underset{\underset{O}{\|}}{C}\text{-}Li \longrightarrow R\text{-}\underset{\underset{O}{\|}}{\overset{\overset{Li}{|}}{C}}\text{-}R \xrightarrow{H^+} R\text{-}\underset{\underset{O}{\|}}{\overset{\overset{H}{|}}{C}}\text{-}R \qquad (3)$$
$$\qquad\qquad\qquad

* The calculations of yields are based on the number of organic halides used.

methods: elementary analysis, mixed melting point measurements of their semicarbazone derivatives, and infrared absorption spectra measurements.

Thus various aromatic aldehydes were synthesized in a good yield, and we have found that this new method is simple and can be extended to the synthesis of other aromatic aldehydes, the preparation of which by earlier methods was not satisfactory in yield and involved complicated starting materials. Of course, the exclusive formation of aldehydes in good yields in these reactions, even though various products were obtained from the reaction in the previous report,[2] is not due only to the reaction conditions (dilution with the solvent and the rapid addition of iron pentacarbonyl). It also seemed to be connected with the structural factor of organolithium compounds; for example, *m*-tolylaldehyde was isolated as a main product from the reaction of *m*-tolyllithium with iron pentacarbonyl under the conditions described in our previous report.

Details of the studies of the mechanism of the above reactions will be published elsewhere in the near future.

Experimental

Materials. — Several bromobenzene derivatives were prepared by the Sandmeyer reaction of the corresponding aniline derivatives: 2, 6-dimethylbromobenzene (b. p. 97°C/26 mmHg, $n_D^{15.5}$ 1.5573), 2, 4-dimethylbromobenzene (b. p. 95~97°C/22 mmHg), *o*-*t*-butylbromobenzene (b. p. 115°C/22 mmHg, n_D^{15} 1.5285), and *p*-*t*-butylbromobenzene (b. p. 114°C/20 mmHg, n_D^{15} 1.5377).

p-Methoxybromobenzene.—Commercial *p*-methoxybromobenzene was purified by fractional distillation; b. p. 95°C/15 mmHg, n_D^{15} 1.5641. Bromomesitylene was prepared by the action of bromine on mesitylene:[6] b.p. 105~107°C/17 mmHg. Iron pentacarbonyl was prepared by the reaction of fine iron poweder with carbon monoxide at 200°C under 300 CO atm. and was purified by distillation; b. p. 102°C, n_D^{15} 1.5202.

n-Butyllithium.—A commercial heptane solution of *n*-butyllithium (21.4 wt.%) was used.

The Synthesis of Aromatic Aldehydes.—*2, 6-Dimethylbenzaldehyde.*—Into a 500 ml., four-necked flask equipped with a mechanical stirrer, a low temperature thermometer, a reflux condenser protected from moisture, a gas bubbler and a dropping funnel, 40 ml. of anhydrous ether (dried over sodium) were placed and, after sweeping the apparatus with dry oxygen-free nitrogen, 1.4 g. (0.2 g. atom.) of lithium in the form of small pieces of thin coil. A solution of 14.8 g. (0.08 mol.) of 2, 6-dimethylbromobenzene in 20 ml. of anhydrous ether was stirred in via the dropping funnel over a period of 2 hr., while the internal temperature was maintained at 35°C.

After the addition had been completed, the stirring was continued for a further 2 hr., after which the reaction mixture was cooled to −60°C with a dry ice-methanol bath kept at −65°C. 3.2 g. (0.016 g. atom) of iron pentacarbonyl in 40 ml. anhydrous ether were next introduced via the dropping funnel over a period of 2 min. Then, with the internal temperature maintained at −50°C, the stirring was continued for a further 2 hr. The reaction mixture was decomposed with 20 ml. of 95% ethanol and, further, with 40 ml. of 4 N hydrochloric acid. The separated organic layer was treated with three succesive 50 ml. portions of saturated aqueous potassium carbonate and then with three succesive 50 ml. portions of aqueous sodium hydroxide and divided into (1) the organic layer, (2) a potassium carbonate solution and (3) a sodium hydroxide solution. The organic layer containing neutral compounds was washed with water and dried over sodium sulfate. The brownish residual oil obtained after removal of the solvent was distilled under reduced pressure to give the following fractions: (1) b. p. 30~40°C/18 mmHg (0.8 g.), (2) b. p. 40~60°C/18 mmHg (1.1 g.), (3) b. p. 100~110°C/18 mmHg (3.9 g.), and a dark orange residue. Fraction 3 was identified as 2, 6-dimethylbenzaldehyde from the results of infrared absorption spectra measurement and a mixed melting point test of its semicarbazone (m. p. 176~177°C, recrystallized from benzene). Also, the results of gas chromatographic analysis showed that fraction 3 was mainly 2, 6-dimethylbenzaldehyde (theoretical yield: 36.4 %).

Found: C, 62.76; H, 6.92. Calcd. for $C_{10}H_{13}ON_3$: C, 62.80; H, 6.85%.

The other fractions have not yet been examined. The acidic and phenolic compounds which were involved in the potassium carbonate solution and the sodium hydroxide solution respectively were confirmed to be the same as those of a previous report.[1]

6) "Organic Syntheses," Coll. Vol. II (1948), p. 95.

2, 4-Dimethylbenzaldehde. — The procedure employed here was identical with that described above. 3.92 g. of iron pentacarbonyl were added to the ethereal solution of 2,4-dimethylphenyllithium, which had been prepared by using 18.5 g. of 2, 4-dimethylbromobenzene and 1.75 g. of lithium. The neutral part was distilled under reduced pressure to give the following fractions: (1) b. p. 110~137°C/13 mmHg (8.7 g.), and (2) b. p. 160~163°C/4 mmHg (0.3 g.). Fraction 1 gave a positive result with the Brady's reagent and was identified as 2, 4-dimethylbenzaldehyde by the elementary analysis of its semicarbazone derivative (m. p. 222°C, recrystallized from ethanol) (theoretical yield: 65.4 %).

Found: C, 62.50; H, 6.93. Calcd. for $C_{10}H_{13}ON_3$: C, 62.82; H, 6.85%.

Fraction 2 was recrystallized from petroleum ether to give yellow crystals (m. p. 137°C). The infrared spectrum of this crystal showed the presence of the conjugated carbonyl group (1650 cm^{-1}), and the elementary analysis of the above crystal is correct for $C_{18}H_{18}O_2$. From the above results, fraction 2 was confirmed to be 2, 2', 4, 4'-tetramethylbenzil.

Found: C, 81.08; H, 6.93. Calcd. for $C_{18}H_{18}O_2$: C, 81.20; H, 6.78%.

p-t-Butylbenzaldehyde.—2.5 g. of pure iron pentacarbonyl were allowed to react with *p-t*-butylphenyllithium prepared from 10.7 g. of *p-t*-butylbromobenzene and 1 g. of lithium. The neutral part was distilled under reduced pressure to give the following fractions: (1) b. p. 100~115°C/11 mmHg (2.8 g.), (2) b. p. 130~133°C/3 mmHg (0.3 g.), and (3) b. p. 160~185°C/3mmHg. (2.3 g).

The infrared spectrum of fraction 1 showed the presences of a carbonyl group conjugated with an aromatic ring (1680 cm^{-1}) and a 1, 4-disubstituted aromatic ring (820 cm^{-1}, 1210 cm^{-1}, 1090 cm^{-1} and 1070 cm^{-1}). Fraction 1 was confirmed to be *p-t*-butylbenzaldehyde from the results of the mixed melting point measurement of its semicarbazone derivative. Fraction 3 was recystallized from ethanol to give colorless crystals (m.p. 131°C). This compound was assumed to be 1, 4-disubstituted aromatic hydrocarbon from the results of the infrared spectrum and was confirmed to be *p, p'*-di-*t*-butyl-diphenyl.

Found: C, 89.50; H, 10.06. Calcd. for $C_{20}H_{26}$: C, 90.16; H, 9.84%.

o-t-Butylbenzaldehyde.—2.5 g. of iron pentacarbonyl were added to an ether solution of *o-t*-butylphenyllithium prepared by using 10.7 g. of *o*-bromo-*t*-butylbenzene and 1.0 g. of lithium. The distillation of the neutral part gave the following fractions: (1) b. p. 50~55°C/10 mmHg (0.6 g.), (2) b. p. 80~90°C/3 mmHg (4.4 g.), and (3) b. p. 100 ~160°C/3 mmHg (0.3 g.). Fraction 2 gave a positive result to Brady's reagent and was identified as *o-t*-butylbenzaldehyde by the mixed melting point measurement of its 2, 4-dinitrophenylhydrazone (m. p. 256°C, recrystallized from ethylacetate) and of its semicarbazone (m. p. 210~211°C, recrystallized from ethanol) (theoretical yield: 54.3%). The elementary analysis of semicarbazone is correct for $C_{12}H_{18}ON_3$:

Found: C, 65.68; H, 7.93. Calcd. for $C_{12}H_{18}ON_3$: C, 65.72; H, 7.81%.

p-Methoxybenzaldehyde.—A solution of 18.7 g. of *p*-bromoanisol in 40 ml. of anhydrous ether was stirred in via the dropping funnel, over a period of 2 hr., to 30 g. of a solution of *n*-butyllithium (*n*-heptane solution, 21.4 wt. %), while the internal temperature was maintained at −10°C. After the addition had been completed, the stirring was continued for a further 8 hr., after which the reaction mixture was cooled to −65°C and allowed to react with 5 g. of iron pentacarbonyl. The neutral part was distilled under reduced pressure to give the following fractions: (1) b. p. 20~27°C/22 mmHg (2.4 g.), (2) b. p. 80~118°C/15 mmHg (3.3 g.), and (3) b. p. 105~140°C/5 mmHg (1.6 g.). Fraction 2 gave a positive result to Brady's reagent and was confirmed to be *p*-methoxybenzaldehyde from the results of the elemental analysis of its semicarbazone (m. p. 211~212°C, recrystallized from ethanol) (theoretical yield: 24.2%).

Found: C, 56.19; H, 5.80. Calcd. for $C_9H_{11}O_2N_3$: C, 55.95; H, 5.69%.

Fraction 3 was recrystallized from ethanol to give colorless crystals (m. p. 185°C), which were assumed to be *p, p'*-dimethoxy-diphenyl.

2, 4, 6-Trimethylbenzaldehyde.—2.5 g. of iron pentacarbonyl were added to a solution, cooled to −65°C, of 2, 3, 6-trimethylphenyllithium prepared from 10 g. of bromomesitylene and 15 g. of a heptane solution of *n*-buthyllithinum (21.4 wt. %). The neutral part was distilled under reduced pressure to give the following: (1) b. p. ~115°C/10 mmHg (2.3 g.), (2) b. p. 105~110°C/10mmHg (5.0 g.), and (3) b. p. 160~170°C/2.5 mmHg (1.4 g.).

Fraction 2 gave a positive result to Brady's reagent and was assumed to be 2, 4, 6-trimethylbenzaldehyde (theoretical yield: 60.5%), and its 2, 4-dinitrophenylhydrazone was recrystallized from ethylacetate to give reddish-yellow crystals (m. p. 227~228°C).

Summary

The reaction of iron pentacarbonyl with aryllithiums at −50~−60°C has yielded the corresponding aromatic aldehydes in good yields. 2, 6-Dimethylbenzaldehyde (36.4%), 2, 4-dimethylbenzaldehyde (65.4%), *p-t*-butylbenzaldehyde (47.0%), *o-t*-butylbenzaldehyde (54.3%), *p*-methoxybenzaldehyde (24.2%) and 2, 4, 6-trimethylbenzaldehyde (60.5%) have been prepared by this method.

A reaction process for this reaction has been discussed.

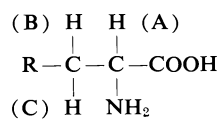
Nuclear Magnetic Resonance Spectra of Amino Acids and Their Derivatives. III



By Shizuo FUJIWARA and Yoji ARATA

(Received September 27, 1963)

The proton magnetic resonance of NH and CH groups of amino acids has been studied by a number of workers.[1-5] Takeda and Jardetzky[1] measured the resonance positions of NH protons in strongly acidic solutions and those of CH protons of such simple amino acids as alanine and glycine. O. and C. D. Jardetzky[2] published additional measurements of the chemical shifts of CH and NH groups, but they did not include any information concerning the spin coupling constants. Bovey and Tiers[3] obtained the spectra of amino acids in trifluoroacetic acid, where the NH signal is observable. They also presented the spectra with a fine structure due to spin coupling and reported the values of several spin coupling constants obtained by first order analyses.

Generally, the NH proton signal cannot be observed in aqueous solutions because of rapid proton exchange with the solvent. However, it was found that the 2, 4-dinitrophenyl (DNP) derivatives of amino acids dissolved in dry dioxane exhibit signals due to NH protons and that their resonance positions are useful for the identification of molecules.[4]

The CH protons give spectra which are more complex than those due to NH protons. For example, the spectra due to the three protons of the type:

where "R" has no protons interacting with those under investigation, were measured and analyzed. Some of these results have been previously reported.[5] In many cases the three protons, A, B, and C, are non-equivalent to each other. However, in the case of amino acids with small R groups, such as cysteine dissolved in an acid medium, H_B and H_C are equivalent.

The three non-equivalent protons show spectra of the ABC type.[6] This type of spectra has been investigated by a number of groups of workers.[7-13] Iterative methods have commonly been used for the analyses of these spectra. The method of least-squares proposed by Shimizu and the present authors[13] has been successfully applied to acrylic acid and its related compounds[13] and to amino acids.[5] This paper will present the results of the application of this method to L-cystine, L-cysteine, L-serine, L-phenylalanine, and L-aspartic acid.

A chief drawback of the iterative method is that it is always accompanied by ambiguities, whether the molecular constants (chemical shifts and spin coupling constants) obtained by analyses are unique or not. In fact, it has been found that, in analyzing the spectra of acrylic acid and ethyl acrylate, two sets of molecular constants were obtained which gave exactly the same line positions, fitting the observed data satisfactorily.[13] These ambiguities can be avoided when the relative intensities are used as a criterion. A correct set of constants may be obtained by a careful comparison of the relative intensities of the calculated spectra with those observed. The results may be further confirmed by measuring the spectra at different spectrometer frequencies; the correct molecular constants must explain the observed spectra at different frequencies.

The relative signs of spin coupling constants can also be determined conventionally by the iterative method outlined above, utilizing

various sets of spin coupling constants with different relative signs. As is well known, the determination of the relative sign can best be accomplished by using the double resonance technique.

Experimental

Materials.—The amino acids studied were L-cysteine, L-cystine, L-phenylalanine, L-aspartic acid, and L-serine, all commercial materials (Ajinomoto Co.). They were dissolved in heavy water of various acidities. The acidity was adjusted by adding concentrated hydrochloric acid or powdered sodium peroxide to heavy water. One-molar solutions were used for all measurements. Heavy water was purchased from the Showa Denko Co. and had a purity of 99.5 mol.%.

Spectrometer.—A Varian DP-60 NMR spectrometer operating at 60.00 Mc./sec. was employed for all measurements.

Calibration of the Spectra.—Measurements were performed at about 28°C. The frequency separations were determined by the usual side-band technique. Numerical data for the line positions used for the analyses were obtained by averaging the results of ten determinations. The numerical data for line positions are listed in Table I.

Numerical Calculations

Analyses were carried out through the use of the Parametron digital computer PC-2 of the Physics Department of the University of Tokyo. The flow diagram of the computation is given in Fig. 1. If molecular constants are adequately assumed, after four or five iterations, within one minute, the refined molecular constants and the corresponding spectrum are printed out.

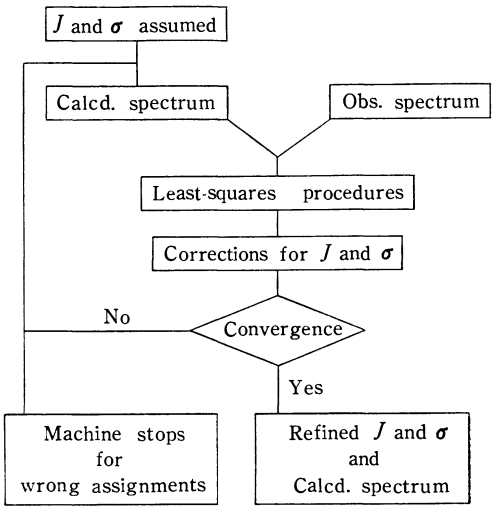

Fig. 1. The flow diagram of computation.

Results

Analyses of the Spectra and the Relative Sign of the Spin Coupling Constants.—As an

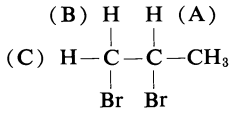
example of spectra of the ABC type, the observed spectra of phenylalanine in 2 N hydrochloric acid and 2 N sodium deuteroxide are shown in Fig. 2. The numerical data of the observed line positions and relative intensities are listed in Table I. In the table the observed data of other amino acids exhibiting spectra of the ABC type are also included.



When spin coupling constants are initially assumed to have the same relative sign, one obtains the refined constants shown in Table II, a portion of which has already been reported.[5] These results seem quite satisfactory with regard to the positions of the spectral lines. Calculated spectra obtained from these constants are compared with the observed ones in Table I and in Fig. 2, which show good coincidence. A careful comparison of the relative intensities of the observed spectra with those calculated shows that these constants are unsatisfactory. For instance, in the calculated spectra of phenylalanine the "e" and "f" lines are reversed in the ratio of intensities (in an alkaline solution) and the "e" and "j" lines

TABLE II. THE RESULTS OF ANALYSES IN C. P. S. AT 60.00 Mc./sec.

			δ_{AC}	δ_{BC}	J_{AB}	J_{BC}	J_{CA}
Phenylalanine	2 N HCl	A	68.1	4.9	5.5	−14.6	7.7
		B	67.4	3.7	3.2	14.6	10.0

	2 N NaOD	A	39.5	13.0	4.5	−13.2	7.5

are too weak to be observed (in a hydrochloric acid solution). The situation is almost the same with other amino acids.

Because of the above findings, it seemed advisable to seek another means of choosing a set of spin coupling constants with different relative signs. When J_{BC} was initially assumed to have a sign opposite J_{CA} and J_{AB}, a different set of molecular constants was obtained, which gave quite a satisfactory fit between the observed and calculated spectra with respect not only to the line positions but also to the relative intensities. The molecular constants obtained are shown in Table II, while the spectra calculated by using these constants are presented in Fig. 2. The results on the relative sign of spin coupling constants are consistent with those of Freeman and Bhacca,[14] who showed by using the double resonance technique that in 1, 2-dibromopropane,

J_{BC} has a sign opposite J_{AB} and J_{CA}.

To confirm the results obtained, spectra were measured at 40 Mc./sec. and were compared with the spectra calculated by using two sets of constants with different relative signs. For example, the observed and calculated spectra of cystine in 2 N hydrochloric acid are shown in Fig. 3. Unfortunately, as can been seen from this figure, the calculated spectra were very similar to each other. In addition to this, the signal-to-noise ratio was not satisfactory. Therefore, it was difficult to eliminate a wrong set and to determine the relative sign by this procedure.

14) R. Freeman and N. S. Bhacca, *J. Chem. Phys.*, **38**, 1088 (1963).

TABLE III. THE CHEMICAL SHIFTS AND SPIN COUPLING CONSTANTS IN C. P. S. OF L-SERINE AT 60.00 Mc./sec.

		$\nu_A - \nu_B$	J
2 N HCl		11.1	4.2
pH	2	− 5.2	4.6
	5	− 6.9	4.8
	9	−10.6	4.9

The Spectra of Serine and Their pH Dependence.—The molecular constants and, hence, the patterns of the spectra are sensitively influenced by the acidity of the solutions. An example of this is the case of L-valine, which was previously reported on.[5] Another example will now be presented. The spectra of serine in heavy water with various acidities are given in Fig. 4. The a through d spectra are of the AB_2 type[6] and can easily be analyzed to furnish the molecular constants. They are shown in Table III. Serine dissolved in a 2 N sodium deuteroxide solution gives a different type of a spectrum. At first sight it seems to be of the AB_2 type. However, it does not give a satisfactory fit to the observed spectrum when J_{AB} and J_{CA}, and δ_{AB} and δ_{CA}, are assumed to be identical. This suggests that the B and C protons are no longer equivalent.

Concluding Remarks

The values obtained above for chemical shifts and spin coupling constants are actually averages over rotational isomers. The appearance of the spectra is governed by the factors, including the relative energies of the rotational isomers, the potential barriers to internal rotation about the C–C bond, and the chemical shifts and spin coupling

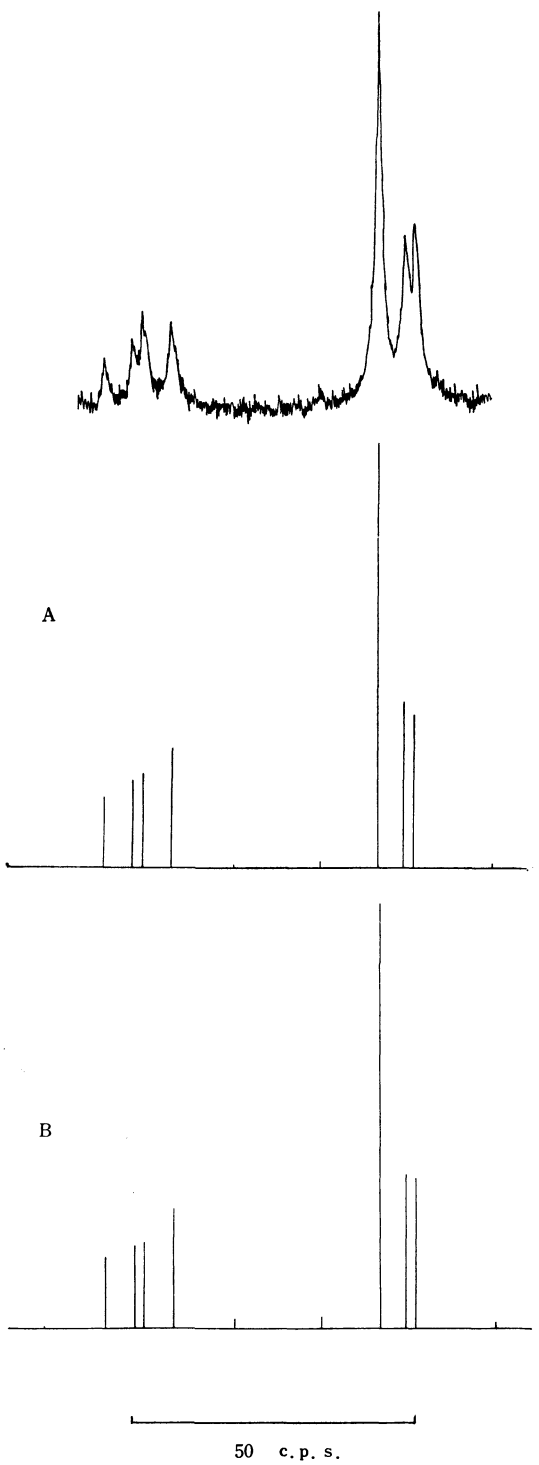

Fig. 3. The observed and calculated spectra of cystine in 2 N HCl at 40 Mc./sec.
A and B were calculated from the molecular constants given in Table II. The magnetic field increases from left to right.

constants, characteristic of each isomer.[15,16] Several groups of workers have tried to obtain these quantities by analyzing spectra at various temperatures.[17-19] Gutowsky, Belford, and McMahon[19] studied the temperature dependence of the spectra of polysubstituted ethanes and developed a method including the least-squares procedure. When the spectra of the amino acids studied here show an appreciable dependence upon the temperature, it may be possible to obtain the above quantities utilizing this method.

The Normal Vibrations of Diketopiperazine and Its N-Deuterated Compound

By Kunio FUKUSHIMA, Yoshiko IDEGUCHI and Tatsuo MIYAZAWA

(Received October 21, 1963)

The infrared absorption bands of the *trans*-CONH group have been extensively studied.[1] On the other hand, the characteristic vibrations of the *cis*-CONH group have not been established. Newman and Badger[2] and Shimanouchi et al.[3] measured the infrared dichroism of single crystals of diketopiperazine in the region above 700 cm^{-1} and assigned the observed bands to the A_1 or B_u fundamental vibrations. Miyazawa, measuring the infrared spectra of diketopiperazine and its *N*-deuterated compound, assigned that absorption bands with reference to the isotope shifts and to the normal vibration calculation for the planar cis form of *N*-methylacetamide.[4]

In the present study the normal vibrations (B_u) of diketopiperazine and its *N*-deuterated compound are treated, and the origin of the infrared bands is studied. The nature of the characteristic vibrations of the *cis*-CONH group will also be elucidated.

Normal Coordinate Treatment

According to the X-ray diffraction study by Corey,[5] the molecule of diketopiperazine is planar (except for the hydrogen atoms of the methylene groups) with the point group, C_{2h}. On the basis of this model, we have calculated the normal vibrations of diketopiperazine and its *N*-deuterated compound as a ten-body problem, treating the methylene groups as mass points. Wilson's $\boldsymbol{GF}$ matrix method[6] was used for the calculation. The internal coordinates are as shown in Table I, while the molecular parameters used are the same as those of polyglycine I.[7] The inverse kinetic energy matrix, $\boldsymbol{G}(B_u)$, for the B_u vibrations was constructed in terms of the symmetry coordinates:

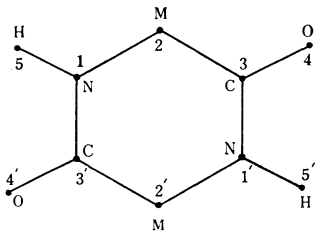

Fig. 1. Molecular conformation and indices of atoms of diketopiperazine.

$$S_j=(R_i-R_i')/2^{1/2} \quad (i=1, 2,\cdots\cdots, 10) \qquad (1)$$

The two redundant coordinates were removed by the numerical diagonalization of the $\boldsymbol{G}$ matrix. The potential energy matrix, $\boldsymbol{F}(B_u)$, was derived from the Urey-Bradley potential function,[8] and the potential constants were taken to be the same as those of polyglycine I.[7] The numerical computations were made with an NEAC 2101 electronic computer. The calculated frequencies, the diagonal terms of the potential energy distributions, and the atomic displacements are shown in Tables II and III, and Figs. 2 and 3, respectively.

Assignments

With reference to the calculated frequencies and the potential energy distributions, the observed infrared bands[4] may be assigned as shown in Table III. The present assignment agrees with the previous assignments except for the few cases described below (the abbreviations DP and DP-d represent diketopiperazine and *N*-deuterated diketopiperazine respectively). The band of DP at 806 cm^{-1} has been established as due to B_u vibrations.[2,3] In a previous study[4] this band has been assigned to the C=O in-plane bending mode. However, since the observed frequency corresponds most closely with the calculated frequency at 728 cm^{-1}, this band is now assigned to the ring deformation vibration. The dichroism of the bands at 449 cm^{-1} (DP) and at 446 cm^{-1} (DP-d) have not been determined experimentally. These bands correspond to the B_u frequency calculated at 403 cm^{-1} (DP) and at 401 cm^{-1} (DP-d) respectively, and are now assigned to the C=O in-plane bending mode as coupled slightly with the $N-CH_2$ stretching mode.

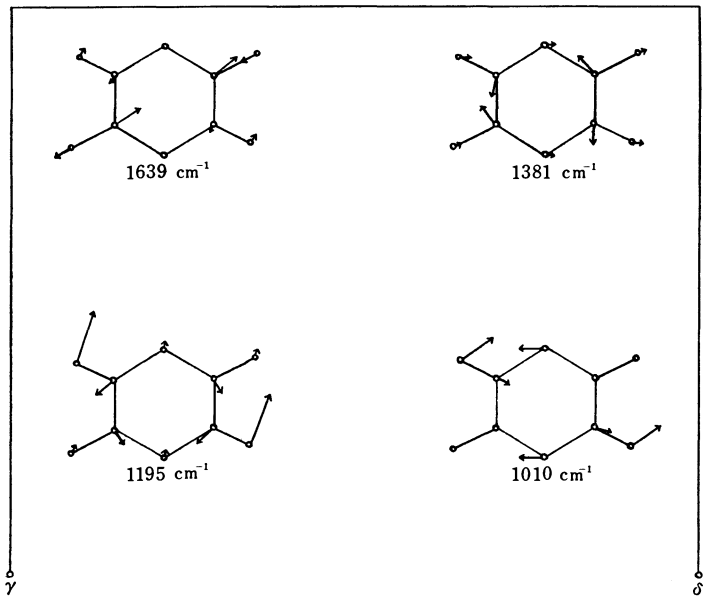

Fig. 3a.

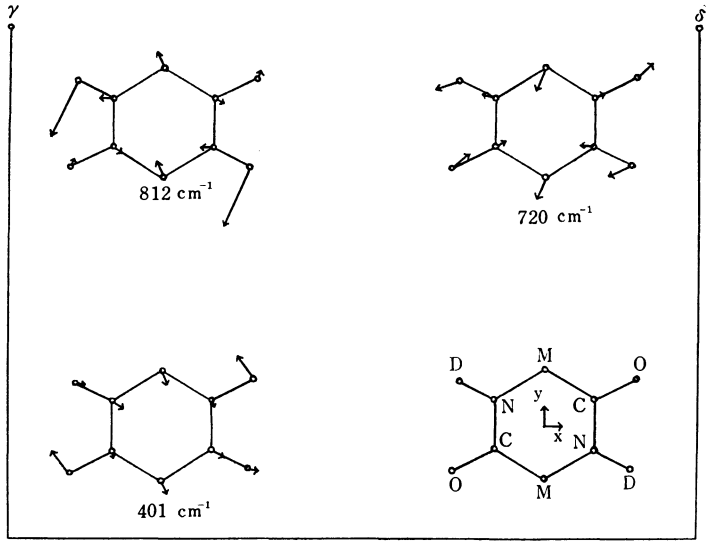

Fig. 3b.

Fig. 3. Schematic representation of the vibrational modes of *N*-deuterated diketopiperazine.

The Characteristic Vibrations of the *cis*-CONH Group

The *cis*-Amide I Band (C=O Stretching Vibration).—For this vibration at 1690 cm^{-1}, 70% of the potential energy is associated with the C=O stretching mode. However, the energy distributions at the C–N stretching (18%) and the N–H bending modes (16%) are not quite negligible.

The *cis*-Amide II Band (N–H In-plane Bending Vibration). — For this vibration at 1443 cm^{-1}, 80% of the potential energy is associated with the N–H in-plane bending mode, while 20% of the energy is associated with the C=O stretching mode.

The *cis*-Amide III Band (C–N Stretching Vibration).—For this vibration at 1340 cm^{-1}, 70% of the potential energy is associated with the C–N stretching mode, and 25% of the energy is associated with the C–CH_2 stretching mode.

The *cis*-Amide IV Band (C=O In-plane Bending Mode).—For this vibration at 449 cm^{-1}, 65% of the potential energy is associated with

the C=O in-plane bending mode, while 26% of the energy is associated with the N-CH_2-C symmetric streching mode. This vibration is not localized in the CONH group as highly as are the *cis*-amide I, II, or III vibrations.

The *N*-Deuterated *cis*-Amide Group.—On *N*-deuteration, the frequencies and the potential energy distributions of the *cis*-amide I, III, or IV vibrations do not change appreciably (Tables II and III). The *cis*-amide II vibration is shifted to a much lower frequency, and then the N–D in-plane bending mode is strongly coupled with the C–N and C–C stretching modes (see Table III for the nature of the vibrations at 1195 cm^{-1} and 812 cm^{-1}).

Summary

The normal vibrations of diketopiperazine and its *N*-deuterated compound have been calculated, with the metylene groups treated as mass points. An assignment of the infrared absorption bands has been made on the basis of the calculated frequencies and potential energy distributions, and the nature of the characteristic vibrations of the *cis*-amide group has been discussed.

*The Formation of Sulfur Compounds in the Radiolysis of a Toluene Solution of Sulfur**

By Wataru ANDO, Ken'ichi SUGIMOTO and Shigeru OAE

(Received September 9, 1963)

In a previous investigation of the radiolysis of a benzene solution of sulfur,[1] the formations of mercaptan, disulfide and a few minor products have been observed, and it has been suggested that the reaction passes through the initial formation of a phenyl radial, which eventually reacts with sulfur to give the final products.

The treatment of hydrocarbon with ionizing radiation usually results in the formation of a variety of fragmentation products.[2] These radicals attack the S–S bond of elemental sulfur, thus:

$$RH \overset{I}{\sim\!\sim\!\sim\!\sim}\!\!\rightarrow R + H$$

$$R + S_8 \rightarrow RS_8 \rightarrow RS$$

Consistent with this view, the reaction of sulfur with cyclohexane under the ionizing radiation with gamma rays has also been shown by Barzynski and Hummel[3] to proceed via the initial formation of a cyclohexyl radical which cleaves the S–S bond of sulfur in the following step.

However, in the case of toluene, the free radical that formed initially would be benzyl which is remarkably more stable than the phenyl or cyclohexyl radical, and which hence might show somewhat different reaction patterns. In fact, the formation of dimerization products is the main path for the thermal reaction of toluene with sulfur,[4] while the similar reaction of cyclohexane undergoes dehydrogenation to benzene[5] and that of benzene leads to the formation of benzenethiol and its derivatives.

Thus, the study of the radiolysis of a toluene solution of sulfur would provide further insight into the nature of the radiolysis process of hydrocarbons in the presence of sulfur.

In the radiolysis of a toluene solution of sulfur, benzyl mercaptan was found to be formed by the cleavage of the S–S bond with the benzyl radical. Hydrogen and hydrogen sulfide were observed to evolve during the runs. This paper will describe a detailed study of the mechanism of the radiation-induced reaction of toluene with sulfur.

Experimental

Reagents.—Toluene was purified by fractional distillation just before use. The sulfur used in this

work was of an exceptionally high purity, as in the previous experiment.[1]

The preparation of the samples and the techniques of irradiation by cobalt-60 gamma rays have been described in a previous paper.[1]

Product Handling and Analysis.—After irradiation, the ampoules were broken in an evacuated system. All the volatile products formed were vacuum-transferred into a trap cooled with liquid nitrogen and carefully degassed by repeated warming and cooling. Then, non-condensable gases were vacuum-transferred to another trap by pumping.

The major portion of the non-condensable gases at the temperature of liquid nitrogen, e.g., hydrogen and methane, were pumped into calibrated glass tubing with a Töpeler pump, and the pressure was measured. From this pressure measurement, *G*-values for the hydrogen gases were calculated.

The procedures for the determination of the mercaptan and hydrogen sulfide were almost identical with those described in the previous paper.[1]

Results and Discussion

Effects on Radiation on the Toluene-Sulfur System.—The irradiation of toluene with sulfur at room temperature gave benzyl mercaptan, hydrogen and hydrogen sulfide as the main products. The results of several illustrative runs are shown in Table I. In the experimental results, the following features are observed; 1) The *G*-value of the formation of the mercaptan depends on the concentration of sulfur. 2) The *G*-value for the formation of hydrogen is almost identical with that of hydrogen formation in the radiolysis of toluene alone, increasing slightly with the increase in sulfur concentration.

TABLE I. IRRADIATION OF TOLUENE WITH SULFUR

Sulur concn.	*G*-Value of product		
g./100 ml.	$C_6H_5CH_2SH$	H_2	H_2S
0.25	0.068	0.14	0.008
0.5	0.088	0.15	0.011
1.0	0.107	0.17	0.014
1.5	0.123	0.18	0.017

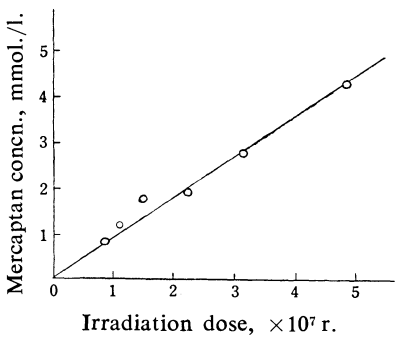

Fig. 1. Formation of benzyl mercaptan in radiolysis of toluene with sulfur (1.0 g. sulfur per 100 ml. of toluene).

Figure 1 shows that the amount of mercaptan formed increases linearly with the increase of the dose.

The increasing formation of the mercaptan appears to suggest that the reaction proceeds through the initial opening of the S_8 ring by γ-ray irradiation to form an open-chain sulfur radical which subsequently abstracts the hydrogen of the methyl group of toluene, producing the benzyl radical and the HS_x radical:

$$S_8 \overset{\gamma}{\rightsquigarrow} S_x$$

$$C_6H_5CH_3 + S_x \rightarrow C_6H_5CH_2 + HS_x$$

$$C_6H_5CH_2 + S_x \rightarrow C_6H_5CH_2S_x \rightarrow C_6H_5CH_2S$$

However, the fact that the *G*-value of the hydrogen formation in this reaction system is nearly identical with that of the radiolysis of toluene alone[6] seems to suggest that the first step of this reaction is the radiolysis of toluene, forming hydrogen and the benzyl radical, which then opens the S_8 ring to form the mercaptan.

The radiolysis of toluene can be represented by the equation:

$$C_6H_5CH_3 \overset{\gamma}{\rightsquigarrow} C_6H_5CH_2 + H \qquad (1)$$

The benzyl radical thus formed can react by any one of the following paths:

$$C_6H_5CH_2 + H \rightarrow C_6H_5CH_3 \qquad (2)$$

$$2C_6H_5CH_2 \rightarrow C_6H_5CH_2CH_2C_6H_5 \qquad (3)$$

$$C_6H_5CH_2 + S_8 \rightarrow C_6H_5CH_2S_8 \rightarrow C_6H_5CH_2S \qquad (4)$$

The formation of the mercaptan can be considered to result from reaction 4, and the mercapto radical thus formed would abstract hydrogen from the methyl group of toluene:

$$C_6H_5CH_2S + C_6H_5CH_3 \rightarrow C_6H_5CH_2SH + C_6H_5CH_2 \qquad (5)$$

while the hydrogen atom formed in the initial radiolysis of toluene is expected to react as in the following scheme:

$$H + C_6H_5CH_3 \rightarrow H_2 + C_6H_5CH_2 \qquad (6)$$

$$H + S_8 \rightarrow HS_8 \rightarrow HS \qquad (7)$$

The benzyl-hydrogen atom is undoubtedly more readily abstracted than phenyl hydrogen.

As can be seen from Table I, the *G*-values of hydrogen formation are considerably larger than those of hydrogen sulfide but are not much

6) L. H. Gale, B. E. Gordon, G. Steiberg and C. D. Wagner, *J. Phys. Chem.*, 66, 1538 (1962).

larger than that of toluene alone ($G_{H_2}=0.13$). The hydrogen atom, once formed, will react either with toluene to give a hydrogen molecule or with sulfur to form hydrogen sulfide, and the results suggest that the former reaction is more favorable. The increasing G-values of hydrogen formation with the increasing sulfur concentration could be interpreted as resulting from the additional formation of hydrogen in the secondary reaction of the decomposition of mercaptan to form the disulfide and the hydrogen molecule.

The G-value of the formation of hydrogen sulfide varies remarkably when the hydrocarbon in the reaction system is changed.

The relative ratios of the G-values of hydrogen and of hydrogen sulfide for the benzene system are far less than those for the toluene system.

The Toluene-Sulfur-Carbon Disulfide System.—In order to clarify the nature of the radiolysis of toluene and sulfur, radiolysis was studied for a mixed solution of carbon disulfide and toluene, with a constant concentration of sulfur dissolved in it. In this mixture, the fate of the radical or atom formed could be altered by the presence of the other component. However, if the initial step of the reaction process is the cleavage of the sulfur ring, the formation of the sulfur biradical must depend on the irradiation dose, and the G-value of formation of mercaptan is constant when the irradiation was applied to solutions containing enough toluene and a constant concentration of sulfur, because the formation of mercaptan depends on the number of sulfur biradicals formed—toluene is merely a hydrogen donor in such a reaction process.

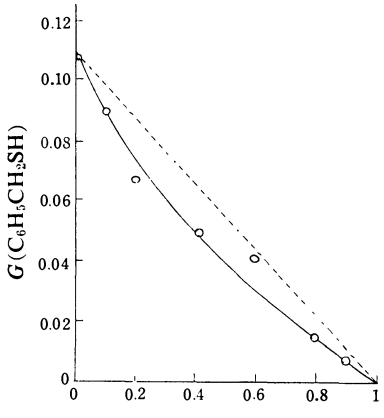

Fig. 2. Variation of G-value of mercaptan with electron fraction of carbon disulfide for toluene-carbon disulfide-sulfur system. (2.0 g. sulfur per 100 ml. of solution, irradiation dose was 4.8×10^7 r.).

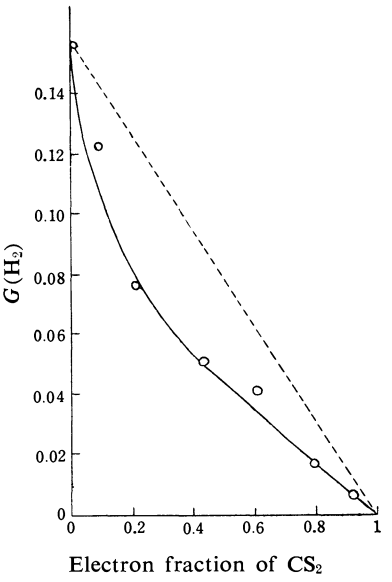

Fig. 3. Variation of G-value of hydrogen with electron fraction of carbon disulfide for toluene-carbon disulfide-sulfur system: (2.0 g. of sulfur per 100 ml. of solution, irradiation dose was 4.8×10^7).

Figures 2 and 3 give the G-values for the formation of benzyl mercaptan and hydrogen as a function of the electron fraction of a toluene-carbon disulfide mixture. The G-values of the formation of mercaptan and hydrogen are proportional to the electron fraction of toluene. The actual curves obtained show a substantial departure from the dotted lines, which represent the yields that are expected in an average absorption of energy into the system.

The results could, therefore, be explained on the basis of an energy transfer mechanism in which the initial step is the decomposition of the toluene molecule. Here again, the formation of hydrogen and mercaptan should result from the initial radiolysis of toluene.

The Interaction of Hydrogen Atom and Elemental Sulfur.—It has been shown in a previous paper[1] that the hydrogen atom formed by the radiolysis of benzene could be used for the formation of hydrogen sulfide by reacting it with sulfur and that this reaction between hydrogen and the sulfur molecule takes place more readily than the reaction between hydrogen and benzene. In the radiolysis of a toluene solution of sulfur, however, the G-value of the formation of hydrogen is higher than that of hydrogen sulfide. In order to compare the reactivity of various types of hydrocarbons, the radiolysis of a toluene-cyclohexane mixture dissolving sulfur of a definite concentration were carried out. Data on the hydrogen and

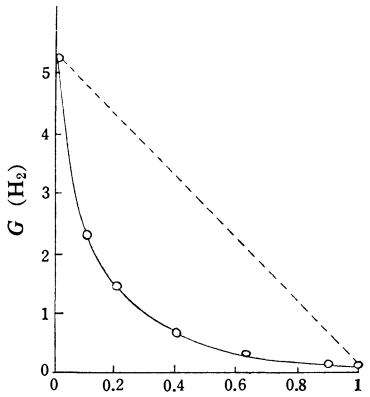

Fig. 4. Variation of G-value of hydrogen with electron fraction of toluene for cyclohexane-toluene-sulfur system (0.2 g. sulfur per 100 ml. of solution).

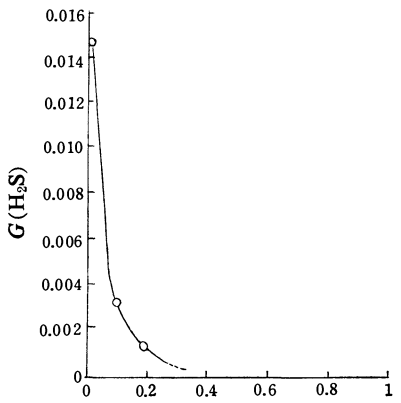

Fig. 5. Formation of hydrogen sulfide with electron fraction of mixture for toluene-cyclohexane-sulfur system (0.2 g. sulfur per 100 ml. of solution).

hydrogen sulfide yields are shown in Figs. 4 and 5.

The G-value of the formation of hydrogen sulfide which may be formed from the initial reaction of the hydrogen atom with sulfur clearly depends on the concentration of toluene. At a high concentration of cyclohexane, hydrogen is the major product, and the reaction between sulfur and the hydrogen atom is apparently of minor importance. Therefore, the hydrogen atom, once formed, seems to abstract hydrogen from cyclohexane preferentially, to form a hydrogen molecule rather than to react with sulfur.

A General Scheme for the Radiolysis of Hydrocarbon Solutions of Elemental Sulfur.—In a series of the related reactions of hydrocarbons with sulfur, the primary reaction involving C–H bond rupture may be schematically written as:

$$RH \overset{r}{\sim\!\sim\!\sim\!\longrightarrow} R + H$$

Here, the reaction undoubtedly depends on the bond energy of the C–H bond from which the hydrogen atom is cleaved in the reaction. Hydrocarbon-free radicals which escape the recombination reaction will react with sulfur to form mercapto radicals, which eventually give rise to mercaptan or disulfide.

$$R + S_8 \rightarrow RS_8 \rightarrow RS$$

In benzene or cyclohexane, the formation of orgnic sulfur compounds does not depend on the concentration of sulfur, but it does on that of toluene, probably because the benzyl radical is cosiderably stabilized by the resonance, and the reaction of sulfur with the benzyl radical apppears to be the product-determining step.

In the case of toluene and cyclohexane mixtures, the hydrogen atom probably abstracts hydrogen from the hydrocarbons a little faster than it reacts with sulfur to form hydrogen sulfide, thus lowering the yield of hydrogen sulfide. Only in benzene would the reaction of the hydrogen atom with sulfur be favored, and thus the yield of hydrogen sulfide is more than that of hydrogen molecules.

A General Examination of the Energy Transfer of the Radiolysis of the Toluene Solution System.—The formations of both the hydrogen molecule and the mercaptan are initiated by the prior decomposition of toluene. In the mixture of toluene and carbon disulfide, carbon disulfide is considered to behave only as an energy-absorbing solvent which absorbs the radiation energy of gamma rays and transfers the energy to reacting molecules to form excited molecules, since carbon disulfide does not seem to react to give the related products.

The deviation from linearity in Figs. 2 and 3 can be considered to be derived from the energy transfer from toluene to carbon disulfide. Probably the contribution of the ionization transfer mechanism is unimportant, for the ionization potential of toluene is lower than that of carbon disulfide. Consequently, the overall reaction may proceed via energy transfer only through excitation. As has been stated by Inokuti,[7] it might be that carbon disulfide has a large cross section value for the excitation of electrons, and that it is easily excited to lower excited levels. The energy stored in the lower excited levels of carbon disulfide is then transferred to toluene molecules, which eventually undergo a series of radiolysis reactions.

7) M. Inokuti, *Isotope and Radiation*, 1, 82 (1958).

The Cyclohexane-Toluene System. — As has been stated by Manion and Burton, the formation of hydrogen in Fig. 4 clearly shows that energy transfer is taking place from cyclohexane to toluene; this is consistent with the interpretation that toluene protects cyclohexane because it has both lower ionization and lower excitation potentials.

Summary

The radiolysis of a toluene solution of sulfur has been investigated. The formations of benzyl mercaptan, hydrogen, and hydrogen sulfide have been observed, and their amounts determined under various considerations. The amounts of mercaptan formed increase linearly with the concentration of sulfur, and the reactions seem to proceed through the initial decomposition of toluene to form the benzyl radical, which then opens the S_8 ring molecule to form the mercaptan. The *G*-value of hydrogen formation is considerably larger than that of hydrogen sulfide. Similar studies were made of the systems of toluene - cyclohexane - sulfur and of toluene - carbon disulfide - surfur in order to clarify the nature of the radiolysis of toluene and sulfur.

*Decomposition and Energy Transfer in the Radiolysis of Sulfur Compounds in Toluene**

By Wataru ANDO, Ken'ichi SUGIMOTO and Shigeru OAE

(Received September 9, 1963)

One of the most interesting problems in the radiation chemistry of organic compounds is that of energy transfer from excited solvent molecules to reacting solute molecules. Energy transfer has been used to explain the non-linear dependence of product yields upon the electron fraction of a two-componet system. In the typical example of the cyclohexane-benzene system,[1] the yield of the hydrogen formed was found to be always less than that to be expected from the decomposition of two components.

Much evidence on the energy transfer has been obtained recently. For example, unusually high *G*-values have been found for the nitrate decomposition in alkali halide,[2] and for the radical formation in a benzene solution of organic disulfide.[3] Gusynin and Tal'roze[4] have found that, for terphenyl in dioxane, the quenching cross section for an alcohol is proportional to the number of carbon atoms in the alcohol, suggesting that energy can be transferred readily along the $-CH_2-$ chain to the OH group. The compounds, 1, 1-dicyclohexyldodecane, 1, 1-diphenyldodecane, 1-phenyl-1-cyclohexyldodecane, cyclohexane, and benzene, were irradiated while frozen at $-120°C$, and their radical yields and ESR spectra were measured.[5] The results have suggested a possible intramolecular transfer of energy to the benzene ring. Intermolecular transfer also occurs, but with a lower efficiency.

The recent study of energy transfer in the benzene - thiophenol system[6] has shown that most of the energy of the excited benzene molecule is transferred to thiophenol. Furthermore, in the toluene - sulfur - cyclohexane or the toluene - sulfur - carbon disulfide system,[7] hydrogen formation is consistent with the interpretation that toluene is protected by carbon disulfide because the latter compound has a lower excitation, or that cyclohexane is protected by toluene because the latter has lower excitation and ionization potentials.

The present investigation was undertaken in order to obtain some direct information about the energy transfer in the free radical formation from a toluene solution of sulfur compounds under irradiation.

Experimental

Material.—Toluene was purified by the usual fractional distillation, and its purity was checked by gas chromatography. All the disulfides were purchased from Tokyo Kasei and were used after recrystallization from 96% ethanol. Purified products with a melting point range of less than 1.0 deg. were used. Diphenyl sulfide was obtained by the reaction of benzene with sulfur in the presence of aluminum chloride, and it was purified by vacuum distillation[8] (b. p. 126°C at 3 mmHg.).

Procedure.—The free radical yields in the decomposition of the sulfur compounds were determined by scavenging the radicals with diphenyl picryl hydrazyl (DPPH). The disappearance of the scavenger was followed by measuring the decrease in the optical density at 530 mμ with the absorption coefficient of 1.2×10^{4} mol^{-1} l. cm^{-1}, where the absorption of the yellow scavenged product is insignificant.

The concentration of DPPH in toluene was kept constant within the range of 1×10^{-3} and 4×10^{-4} mol./l. during the run. The observed optical densities were corrected against the relaltive background absorption of the solution of DPPH in toluene without sulfur compounds which would be formed during the irradiation. The solution of DPPH in pure toluene was irradiated under the same conditions as those used for the solution ncotaining the sulfur compound, and the differenec between the absorbances of DPPH in the two solutions was taken as the consumption of DPPH reacting with radicals derived from the sulfur compounds.

All the samples were thoroughly degassed by twice freezing and thrawing them in a vacuum. Irradiation was carried out with a 1000-curie Co-60 source at room temperature, and the dose rate was 1.6×10^{4} r.

Results and Discussion

The irradiation of the sulfur compounds in toluene at room temperature produced a significant change in the optical density of DPPH, presumably by means of the formation of radicals from the decomposition of the sulfur compounds. The overall reaction of DPPH with free radicals is complicated by secondary reactions.[9,10] However, it may safely be assumed that the free radicals formed by the decomposition of the sulfur compounds in the primary step react with two DPPH molecules to form inactive products, and that, therefore, the amount of the decomposition of a sulfur compound is just a half of that of the disappearance of DPPH.

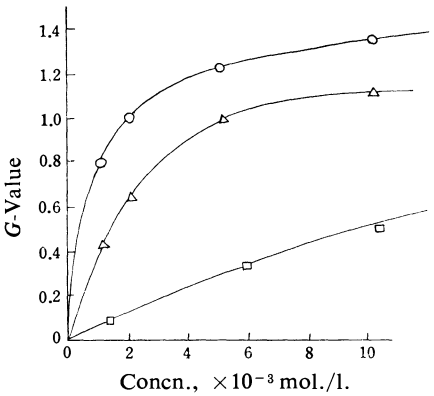

Fig. 1. Comparison of *G*-value on the decomposition of benzyl sulfur compounds in toluene solution.
○ Benzyl mercaptan
△ Benzyl disulfide
□ Benzyl sulfide

From Fig. 1, it is quite obvious that the amount of the decomposition of a sulfur compound depends on the initial concentration of the sulfur compounds. Assuming that the ionizing radiation directly effects the decomposition of the sulfur compound, the apparently higher *G*-values can be calculated on the basis of the direct effect; thus, the *G*-values are calculated to be nearly 700 for the disulfide, 200 for the sulfide, and 25000 for the mercaptan.

When one considers their bond dissociation energies, these *G*-values are much higher than the maximum *G*-values to be expected from the complete consumption of the direct energy absorbed. A better interpretation would be that the excited toluene formed by the irradiation transfers energy relatively easily to the sulfur compounds, resulting in dissociation into free radicals. Figure 2 shows the linearity of the relationship of the benzyl disulfide decomposition against the irradiation dose.

Now, let us assume that most of the energy is absorbed by toluene and that the amount of energy absorbed directly by the small amount of a sulfur compound is presumably small enough to be disregarded, since the absorption of energy is essentially independent of the nature of the component.

$$C_6H_5CH_3 \overset{I}{\sim\!\sim\!\sim\!\rightarrow} C_6H_5CH_3^* \qquad (1)$$

Therefore, excited toluene molecules in the system would usually lose their energy by the

Each sulfur compound, when sufficiently excited, produces at leasts two radicals by the decomposition. A part of the excited sulfur compound may lose its energy by collision without decomposition.

Decomposition

$$\text{Sulfur compd.}^* \xrightarrow{k_3} 2\ \text{Radicals} \quad (4)$$

Deactivation

$$\text{Sulfur compd.}^* \xrightarrow{k_4} \text{Sulfur compd.} \quad (5)$$

Recombination

$$2\ \text{Radicals} \xrightarrow{k_5} \text{Sulfur compd.} \quad (6)$$

Radicals formed according to Eq. 4 will be trapped by DPPH, which is present in a high concentration.

$$\text{Product Radical} + \text{DPPH} \xrightarrow{k_6} \text{Product} \quad (7)$$

Using the steady state equation, the G-value of the decomposition of a sulfur compound is obtained from this expression, which is based on a relatively small value of k_2:

$$G = -\frac{k_3 \cdot k_2 \cdot I \cdot C}{(k_3 + k_4)(k_1 + k_2 \cdot C)}$$

In the above equation I represents the number of molecules excited by 100 eV. of gamma rays, where C is the concentration of the sulfur compound. The above relation may be rewritten in the following convenient form, since k_3 would be much larger than k_4:

$$\frac{1}{G} = \frac{1}{I}\left(1 + \frac{k_1}{k_2 \cdot C}\right)$$

The relations of $1/G$ and $1/C$ for the benzyl sulfur compounds are shown in Fig. 3.

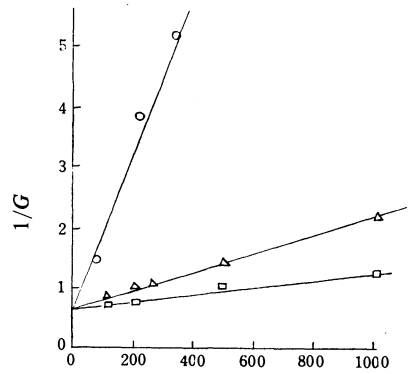

Fig. 3. Relation of $1/G$ and $1/C$ of sulfur compounds.
□ Benzyl mercaptan
△ Benzyl disulfide
○ Benzyl sulfide

The intercept of a straight line in Fig. 3 presumably gives the value of $1/I$, in which I represents the number of excited toluene molecules formed by 100 eV. of gamma rays. From the slope of the lines, one can get the relation of k_1 and k_2, which may represent the efficiency of the energy transfer from excited toluene to the sulfur compounds. Table I shows the relative energy transfer and the G-value at 5 mmol. of the sulfur compounds.

Table I. Radiolysis of sulfur compounds in toluene

Compound	I	k_2/k_1	G-Value at 5 mmol./l.
Benzyl mercaptan	1.4	1160	1.22
Benzyl disulfide	1.4	470	1.0
Benzyl sulfide	1.4	45	0.26
Diphenyl disulfide	1.4	660	1.1
p-Tolyl disulfide	1.4	660	1.1
Diphenyl sulfide	1.4	3.5	0.01
p-Tolyl sulfide	1.4	1.4	0.025

The largest energy transfer from toluene was observed in the decomposition of benzyl mercaptan. The lower value of decomposition for the disulfides shows that the disulfides can absorb energy from the excited toluene less than half as effectively as does the mercaptan.

As compared to the mercaptans or the disulfides, benzyl sulfide is less effective in energy absorption. This means that the C–S bond is relatively insensitive to radiation compared to the –S–H or –S–S– bond. However, the C–S bond in dibenzyl sulfide is relatively

more sensitive to the radiation than that in diphenyl sulfide.

In dibenzyl sulfide, not only the cleavage of C–S bond but also that of the C–H bond of methylene linkage could take place, since the latter cleavage would be facilitated by the stabilization through the following electron-sharing 3d-orbital resonance with a sulfur atom :[11,12]

$$\mathrm{Ph{-}\overset{\cdot}{\underset{\mathrm{H}}{\overset{\cdot\cdot}{\underset{|}{C}}}}{-}\overset{\cdot\cdot}{S}{-}CH_2{-}Ph} \leftrightarrow \mathrm{Ph{-}\overset{\cdot}{\underset{\mathrm{H}}{\underset{|}{C}}}{=}\overset{\cdot}{\underset{\cdot\cdot}{S}}{-}CH_2Ph}$$

Particularly important are the findings that the S–H bond is very effective in energy absorption from the solvent and that the S–S bond is similarly quite effective in energy absorption from the solvent.

An interesting implication from these data is that a similar process may be involved in the radiation protection in the biological system by such mercapto compounds as cystein or cysteamine.[13-15] Here, too, mercaptans are more effective in protecting radiation than disulfides, which in turn are better radiation-protecting compounds than sulfides.

Summary

The decomposition yields of organosulfur compounds in toluene have been studied using DPPH as a radical scavenger. The effect of the concentration of sulfur compound is quite marked, and the irradiation energy absorbed in the solution of toluene seemed to be transferred to the sulfur compound. The largest energy transfer from toluene has been observed in the decompostion of benzyl mercaptan, while the disulfide has been shown to absorb the energy from the excited toluene less than half as effectively as does the mercaptan. As compared to the mercaptan or the disulfide, benzyl sulfide is far less effective in energy absorption.

*The Radiation-induced Reaction of Benzyl Mercaptan and p-Tolyl Mercaptan in Various Organic Solvents**

By Wataru ANDO, Ken'ichi SUGIMOTO and Shigeru OAE

(Received September 9, 1963)

The radiation chemistry of hydrocarbon has been widely investigated. However, the effect of a minute amount of solute in the radiolysis of hydrocarbon has to date received very little attention.[1,2] When a solute is dissolved in a large excess of hydrocarbon, the direct effect of irradiation on the solute is rather unimportant. However, when the solute is involved in the reaction, additional effects occur; the solute is attacked by active species formed from the hydrocarbon, or excited energy is transferred to it from the hydrocarbon. Williams and Hamill[3] have previously shown that the irradiation of cyclohexane containing methyl iodide at the concentration of 1 mol.% results in a considerable dissociation of the methyl iodide. The effect has been ascribed to the dissociative capture of free electrons by methyl iodide. Furthermore, Hughes[4] has pointed out, in the radiolysis of iodine cyanide as a scavenger in liquid benzene, that energy from benzene is transferred, leading to the dissociation of the iodine cyanide, which in turn results in the production of iodine.

It has been observed in previous investigations[5,6] the radiolysis of hydrocarbon solutions of sulfur compounds that they are all appreciably reactive and that the efficiency of energy absorption from hydrocarbon is usually very high.[7,8] The effect of thiophenol in the radiolysis of benzene has already been investigated.[5]

It is the purpose of the present investigation to extend these studies to other organic solvents. It is well known that six electrons of the aromatic molecule are loosely coupled to form a π-bond and that these π-electrons are non-localized and are thus free to move around in the molecule. Therefore, a π-electron system is expected to possess many excited levels, with lower excited energies. When an electron collides with a hydrocarbon which has a π-electron system, the non-localized electrons are expected to interact with the incident electron rather strongly, either dissociating themselves to form two active species or absorbing the energy. Meanwhile, the yields of free radicals from hydrocarbons have been shown to be related to the sensitivities of the hydrocarbons to radiation.[9]

In this work, the effects of the solvents on the decomposition of benzyl mercaptn and *p*-tolyl mercaptan will be investigated using a wider variety of solvents.

The solvents are divided into radiation-sensitive and -insensitive molecules from the magnitudes of the *G*-values of the radical formations, as is shown below :[10]

RELATIVELY RADIATION-INSENSITIVE MOLECULES

Solvent	*G*-value for radical yield
Carbon disulfide	0.85
Benzene	1.8
Toluene	3.1
Nitrobenzene	4.5

RELATIVELY RADIATION-SENSITIVE MOLECULES

Solvent	*G*-value for radical yield
Hexane	7.6
Cyclohexane	14.3
Acetone	50.0
Methanol	24.0
Dioxane	20.0

This paper will also discuss the reaction mechanism on the basis of a good set of experimental data on the effect of solvents.

Experimental

Experimental details are similar to those outlined in an earlier paper.[5] All the solvents used were purified by ordinary distillations. Benzyl mercaptan and *p*-tolyl mercaptan were purchased from Tokyo Kasei and were distilled in a vacuum under a nitrogen atmosphere before use. A solution of mercaptan was made by weighing, and also the concentration was checked by potentiometric titration with silver nitrate. Each sample was composed of a 20 ml. solution and was degassed in a vacuum line by repeating a cycle of freezing, pumping and melting at least three times. The degassed samples were sealed in irradiation tubes 200 mm. long and 20 mm. in diameter and irradiated.

After irradiation the samples were placed in a beaker, and the amount of mercaptan present was determined by potentiometric titration with silver nitrate. Irradiations were carried out at room temperature with a 5000 curie Co-60 source at a dose rate of 2×10^5 r/hr. The relative values for the decompositions were expressed by the difference between the mercaptan concentrations before and after the irradiation of 100 eV. absorbed into the solution.

Results

The Decomposition of Benzyl Mercaptan in Relatively Radiation-sensitive Solvents.—The radiolysis of benzyl mercaptan in the solvents which are relatively sensitive to the irradiation leads the mercaptan to the disulfide quite readily. The results obtained in cyclohexane, dioxane, methanol, acetone and hexane solutions are shown in Table I. The results indicate that in all the runs high degrees of the decomposition of the mercaptan (over 50~80% at 9.0×10^6 r) were observed.

TABLE I. THE DECOMPOSITION OF BENZYL MERCAPTAN IN THE SOLVENTS

Solvent	% Decomposition of 0.047 mol./l. of solvent at 9.0×10^6 r
Hexane	79
Acetone	64
Methanol	63
Cyclohexane	57
Dioxane	56

Although the initial mercaptan concentration varied from about 10 to 50 mmol./l., the *G*-values apparently depend on the concentration of the mercaptan.

The kinetics of the decomposition of the mercaptan are summarized in Fig. 1.

The decomposition of the mercaptan appears to be of the first order with respect to its concentration at the beginning, but it then rapidly levels off as soon as an equilibrium is

TABLE II. THE EFFECT OF CONCENTRATION ON THE DECOMPOSITION OF BENZYL MERCAPTAN IN SOLVENTS

Solvent	Initial concentration mol./l.	*G*-Value of decomposition of mercaptan at 9.0×10^6 r
Hexane	0.047	6.1
	0.035	4.5
	0.024	3.0
	0.0096	1.0
Acetone	0.047	4.1
	0.035	2.8
	0.024	2.5
	0.0096	0.8
Methanol	0.048	4.2

attained by the reversal hydrogen-abstraction reaction of the mercapto radical from the solvents.

The Decomposition of *p*-Tolyl Mercaptan in Relatively Radiation-sensitive Solvents. — The radiolysis of *p*-tolyl mercaptan in hexane, cyclohexane, dioxane, methanol and acetone follows a course very similar to that of benzyl mercaptan in relatively radiation-sensitive solvents; the conversion of the mercaptan with radiation dose was nearly of the first order with

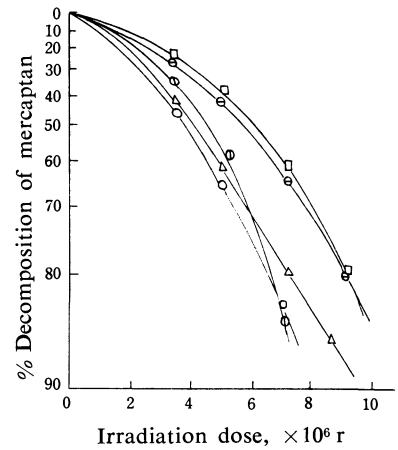

Fig. 2. The decomposition of *p*-tolyl mercaptan in various solvents at room temperature.
△ hexane ○ cyclohexane ◑ dioxane
□ acetone ⊖ methanol

respect to its concentration, but it is gradually accelerated as the decomposition of the mercaptan proceeds further. Table III and Fig. 2 show the results of these experiments.

TABLE III. THE EFFECT OF CONCENTRATION ON THE DECOMPOSITION OF *p*-TOLYL MERCAPTAN IN SOLVENTS

Solvent	*G*-Value of the decomposition of the mercaptan at 9.0×10^6 r Initial concn., mol./l.			
	0.048	0.036	0.024	0.010
Hexane	4.6	4.4	3.5	1.5
Acetone	3.7	3.2	2.5	1.2
Methanol	2.7	2.7	2.6	1.1
Cyclohexane	4.2	3.8	3.3	1.4
Dioxane	2.2	2.1	2.3	0.6

This evidence leads to the following conclusion. The mercapto radical formed in the radiolysis of the mercaptan may usually abstract hydrogen from hydrocarbon, as was discussed in the previous section. However, the mercapto radical formed by the decomposition of *p*-tolyl mercaptan would be substantially resonance-stabilized, and hydrogen abstraction by this mercapto radical is not favored. In this case, probably some radicals formed by the dissociation of solvent molecules leads the decomposition of *p*-tolyl mercaptan.

The Decomposition of Benzyl Mercaptan and *p*-Tolyl Mercaptan in Relatively Radiation-insensitive Solvents.—Carbon disulfide, benzene, toluene and nitrobenzene were investigated as solvents for the decomposition of benzyl mercaptan and *p*-tolyl mercaptan (Tables IV and V). It was found that the amount of the decomposition of the mercaptans in these

solvents was much less than that in radiation-sensitive solvents, and that the *G*-values of the decomposition of the mercaptans were of the same order of magnitude in all four cases.

TABLE IV. THE EFFECT OF THE CONCENTRATION ON THE DECOMPOSITION OF BENZYL MERCAPTAN IN RELATIVELY RADIATION-INSENSITIVE SOLVENTS

Solvent	The *G*-value of decomposed mercaptan at 9.0×10^6 r Initial concn., mol./l.			
	0.048	0.036	0.024	0.0096
Carbon disulfide	0.78	—	0.58	0.35
Benzene	1.9	1.7	1.5	0.8
Toluene	2.1	1.8	1.7	0.8
Nitrobenzene	1.3	1.1	0.9	0.36

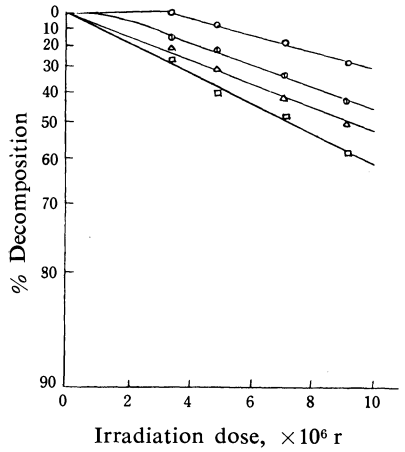

Fig. 3. The decomposition of benzyl mercaptan in aromatic hydrocarbon at room temperature.
○ carbon disulfide △ benzene □ toluene
① nitrobenzene

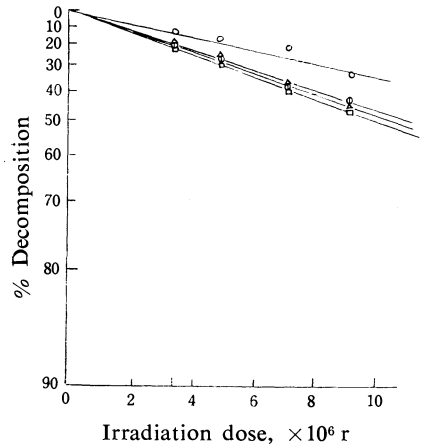

Fig. 4. The decomposition of *p*-tolyl mercaptan in aromatic hydrocarbon at room temperature.
○ carbon disulfide △ benzene ① toluene
□ nitrobenzene

TABLE V. THE EFFECT OF THE CONCENTRATION ON THE DECOMPOSITION OF *p*-TOLYL MERCAPTAN IN RELATIVELY RADIATION-INSENSITIVE SOLVENTS

Solvent	The *G*-value of Decomposition of mercaptan at 9.0×10^6 r Initial concn., mol./l.			
	0.048	0.036	0.024	0.0096
Carbon disulfide	0.96	0.76	0.65	0.33
Benzene	1.7	1.5	1.3	0.5
Toluene	1.9	1.7	1.1	0.5
Nitrobenzene	1.1	1.1	1.0	0.5

Figures 3 and 4 indicate that the decomposition of both benzyl mercaptan and *p*-tolyl mercaptan is of the first order with respect to the mercaptans and that there is no deviation from the first order kinetics, unlike in radiation-sensitive solvents.

The results indicate that either the mercapto radicals formed by the decomposition of the mercaptans do not abstract hydrogen from these solvents, or the induced decomposition of the mercaptans by the solvent radicals is much less than that in radiation-sensitive solvents.

Discussion

A General Examination of the Reaction Mechanism for the Decomposition of Mercaptan. —Our original intention was to estimate the extent of the radiation-induced decomposition of mercaptan. For this purpose it is, however, necessary to identify the liquid decomposition products. Even so, a few suggestions can be made on the basis of our previous observations and of the present findings on the decomposition of the mercaptans.

Haines, Cook and Ball,[11] in studying the photochemical decomposition of sulfur compounds, have indicated that the decomposition of mercaptan involves primarily the cleavage of RS-H linkage, as can be formulated in the following equations:

$$RSH \rightarrow RS + H \quad (1)$$

$$H + RSH \rightarrow RS + H_2 \quad (2)$$

$$2RS \rightarrow RS\text{-}SR \quad (3)$$

This mechanism can be adopted similarly for the interpretation of the observation made in the radiolytic decomposition of benzyl mercaptan. In order to get a clear picture of the decomposition of the mercaptan in the solvents, it is desirable to obtain the *G*-values of the decomposition of the mercaptan alone without solvents.

The results obtained are shown in Table VI.

11) W. E. Haines, G. L. Cook and J. S. Ball, *J. Am. Chem. Soc.*, **78**, 5213 (1956).

TABLE VI. BENZYL MERCAPTAN DECOMPOSITION UNDER GAMMA-RAY IRRADIATION

Irradiation	1.8×10^{7} r
Sample	5.290 g.
$G(H_2)$	0.95
$G(-C_6H_5CH_2SH)$	1.9, assuming $G(-SH)=2G(H_2)$

Now that the G-value of the mercaptan decomposition can be compared with those in solvents, one can draw the following conclusions concerning the general nature of the decomposition processes of mercaptan. (1) The reaction presumably proceeds through the process of transferring energy from the solvents to mercaptan. (2) The intermediate radicals from solvents are hydrogen acceptors of mercaptan.

It may be seen from the data in radiation-insensitive solvents that the concentration of mercaptan appears to effect the decomposition of mercaptan, and that the G-value of mercaptan decomposition is nearly identical with that of mercaptan alone. One can, therefore, assume that the radiation energy from the gamma rays effects the mercaptan decomposition either by a direct or an indirect process.

First the energy of irradiation is absorbed by then solvent; then it forms some radicals so formed attack the S–H bond of the mercaptan as illustrated below:

$$S \rightsquigarrow S^* \quad (4)$$

$$S^* \rightarrow S\cdot \quad (5)$$

$$S\cdot + RSH \rightarrow SH + RS\cdot \quad (6)$$

where S is the solvent.

The mercapto radicals formed will then lead to reaction 3. However, the kinetic data which follow the first order with respect to the mercaptan are not in accord with this process. The other possibility is that the radiation energy initially absorbed by the solvent is transferred very rapidly to the mercaptan. Such a direct transfer of radiation-excited energy is well known in liquid solutions.[12] It is possible that this process of energy transfer is responsible for the decomposition of mercaptan. In addition to the excitation process of the solvent in reaction 4, the energy transfer to the mercaptan can be represented by:

$$S^* + RSH \rightarrow S + RSH^* \quad (7)$$

Excited mercaptan would then be led to dissociation into two radicals according to reaction 1. The decomposition of the mercaptan can thus be correlated with the experimental observations, especially in the case of the decomposition in radiation-insensitive solvents.

However, since mercaptan is quite sensitive to radical attack, one cannot be absolutely certain that this process alone is responsible for the decomposition of mercaptan. The results obtained in this work to indicate, however, that energy can be absorbed readily into the solvent and that the process of energy transfer to the solute (reaction 7) is in competition with the process of forming their own radicals from the excited solvent molecules (reaction 5).

Evidence of Solvent-Mercaptan Interaction.—As can be seen in Figs. 1 and 2, the two different mercaptans follow different courses in the decompositions in relatively radiation-sensitive solvents. The decomposition of benzyl mercaptan initially increases linearly with the increase in the radiation dose, then it rapidly levels off from the linear relationship. This could be interpreted as being caused by the equilibration, arising from the hydrogen abstraction by the mercapto radicals in order to reverse the reaction, since the solvents are generally thought to function as hydrogen donors.[13]

$$RS\cdot + RH \rightleftarrows RSH + R\cdot \quad (8)$$

However, the results for the decomposition of the mercaptan in radiation-insensitive solvents indicate that it is difficult for the above process to occur, as can be seen in Figs. 3 and 4, since the bond energy of the C–H linkage of the radiation-insensitive solvents is much higher than that of the sensitive solvents; hence, the radiation-insensitive solvents can not be good hydrogen donors. Meanwhile, the decomposition of *p*-tolyl mercaptan in radiation-sensitive solvents initially shows a linear relationship with the dose; it is rapidly accelerated as the decomposition proceeds, thus suggesting that the reaction is promoted by some process as the decomposition of the mercaptan proceeds further.

This is not surprising, since the mercapto radical from *p*-tolyl mercaptan is substantially resonance-stabilized; thus the radicals, formed by the radiolysis of solvents, may easily abstract hydrogen from *p*-tolyl mercaptan, accelerating the decomposition of the mercaptan as the reaction proceeds.

The Solvent Effect on the Decomposition of Mercaptan.—The results of the decomposition of mercaptan in various solvents may be summarized thus. (1) The radiation-sensitive solvents are easily attacked by the benzyl mercapto

12) J. P. Manion and M. Burton, *J. Phys. Chem.*, **56**, 560 (1952).

13) C. Walling and R. Rabinowitch, *J. Am. Chem. Soc.*, **81**, 1137 (1959).

radical and function as hydrogen donors. (2) When the resulting mercapto radicals are fairly stabilized by resonance such as that of the tolyl mercapto radical obtained from tolyl mercaptan, solvent radicals from the radiolysis of solvents will abstract hydrogen from mercaptan. This will cause the additional decomposition of mercaptan which is seen in *p*-tolyl mercaptan in solvents. (3) The decomposition of the mercaptan in radiation-insensitive solvents show relatively lower *G*-values than those in radiation-sensitive solvents. When a radiation-insensitive solvent has an aromatic π-electron system, the radiation energy absorbed will be dissipated quite readily through the electronic excitation to lower levels of the solvent molecules; therefore, the proportion of energy transferred to the solute became very small, thus reducing the decomposition of the mercaptan.

Summary

The decomposition of benzyl mercaptan and *p*-tolyl mercaptan in various organic solvents has been studied, and the following conclusions have been obtained. 1) A radiation-sensitive solvent such as hexane is readily attacked by the benzyl mercapto radical. 2) When the resulting mercapto radicals are stabilized substantially by resonance, solvent radicals from the radiolysis of solvents will abstract hydrogen from the mercaptan. 3) The *G*-values of mercaptan decomposition in such solvents as hexane, cyclohexane, acetone, methanol and dioxane are relatively higher than those in carbon disulfide, benzene, toluene and nitrobenzene. The reaction presumably proceeds through the energy transfer process from solvent to mercaptan. When an aromatic π-electron system is present in any solvent, the radiation energy absorbed will be dissipated quite readily through electronic excitation to lower-energy levels of the solvent molecule.

*The Radiation-induced Addition of Hydrogen Sulfide to Propylene**

By Ken'ichi SUGIMOTO, Wataru ANDO and Shigeru OAE

(Received September 20, 1963)

The free-radical addition of thiols to olefinic compounds has been studied extensively during the past twenty-five years,[1] but the addition of hydrogen sulfide to olefinic compounds has received rather scanty attention. The photochemical addition of hydrogen sulfide to olefinic bonds has, however, at least been shown to give mixtures of the corresponding mercaptans and the sulfides.[2] This paper will present the results of a study of the gamma-ray initiated free radical addition of hydrogen sulfide to propylene.

The radiation-induced addition of hydrogen sulfide to propylene took place very readily, giving mainly *n*-propylmercaptan and di-*n*-propylsulfide, and was completed at room temperature with a relatively small radiation dose. The *G*-values of this reaction were found to be more than ten thousand. The addition followed a non-Markownikoff rule, as in the case of the change of mercaptan to olefins.[3] Apparently the reaction proceeds through a free radical chain process, where the sulfhydryl radicals formed in the initial step of the radiolysis of hydrogen sulfide undergo a radical addition to the olefin in the following chain-propagating step.

During the preparation of this paper, a report[4] on the X-ray initiated addition of hydrogen sulfide to fluoroethylenes appeared. Although the *G*-values for these reactions were somewhat smaller than those of the present work, the nature of the addition appears to be similar.

Irradiation dose rate 1.1×10^4 r/hr.

Experimental

Irradiations.—The gamma radiation was provided by a 1000 curie cobalt-60 source.[5] The dose rates were obtained by means of a Fricke ferrous sulfate dosimeter, taking G as 15.6.[6] Samples were irradiated at three fixed positions, at which the dose rates were 2.8×10^4, 1.1×10^4, and 5.7×10^3 r/hr. respectively. The G-values were calculated from the relation of the products formed and the absorption energy of the gaseous sample. The absorption energies of propylene and hydrogen sulfide were based on the absorption energy of air, 88 erg./g./r. All the irradiations were carried out at room temperature.

Reaction Vessel.—The irradiation vessel used for this gaseous reaction was a Pyrex tube 25 mm. in outside diameter and 25 cm. long, and equipped with a breakoff seal.

Materials.—Propylene was purchased from the Takachiho Chemicals Co., Tokyo, and hydrogen sulfide, from the Seitetsu Chemicals Co., Kakogawa; both were purified by vacuum distillation. The impurities in both the propylene and the hydrogen sulfide used were found to be less than 0.5% by gas-chromatographic analysis.

Analyses.—Conventional high-vacuum techniques were employed throughout the investigation. All the analyses of the irradiated samples were carried out by a combination of fractional distillation and gas-chromatographic separation. The irradiated sample was passed first through a series of dry-ice acetone-cooled traps and then through liquid nitrogen-cooled traps.

The fraction condensed in dry-ice acetone cooled traps was analyzed by gas-chromatography (Hitachi Type KGL-2A) using a 2 m. column packed with celite 545, impregnated with 30% silicon DC 550 and operated at 80°C with an H_2 carrier at 40 ml./min.; it was found to be a mixture of *n*-propylmercaptan and di-*n*-propylsulfide. The amount of *n*-propylmercaptan was also determined by potentiometric titration with silver nitrate in isopropyl alcohol;[7] the end point was found to be between approximately −200 and −50 mV. vs. SCE. On the other hand, the amount of di-*n*-propylsulfide was calculated by subtracting that of the *n*-propylmercaptan formed from the amounts of hydrogen sulfide and propylene reacted. The gas which condensed at the liquid-nitrogen temperature through a series of dry-ice acetone traps was identified as unreacted hydrogen sulfide and propylene. This portion was measured by a manometer.

Results and Discussion

Various amounts of hydrogen sulfide were mixed with propylene, and these mixtures were irradiated at several radiation doses in a static system. The results of the radiation-induced addition of hydrogen sulfide to propylene are shown in Tables I and II.

In Table I, the apparent yield of products means the amount of the final products formed against the initial amount of propylene, while the net yield is the total amount of *n*-propylmercaptan formed during the reaction, that is, the actual amount of the mercaptan plus the sulfide formed, because the *n*-propylmercaptan is gradually converted to the di-*n*-propylsulfide by the further reaction of *n*-propylmercaptan with propylene.

The Effects of the Dose Rate on the *G*-Value.—The effects of dose rate *I* on the yield are shown in Figs. 1 and 2. The *G*-values were estimated from the initial inclination of the curves in Fig. 1, while the logarithms of the *G*-values are plotted against the logarithms of *I* in Fig. 2. From these plots, it is clearly shown that *n*-propylmercaptan and di-*n*-propylsulfide are produced in proportion to the -0.52 and -0.54 powers of *I*. These values are slightly smaller than -0.50 which would be derived under the assumption of a bimolecular termination of all the propagating radicals. This finding also seems to indicate a radical chain mechanism[8] for this radiation-induced reaction.

⊙ 5.7×10^3 r/hr.
Sample C_3H_6 7.48 mmol.
H_2S 4.27 mmol.

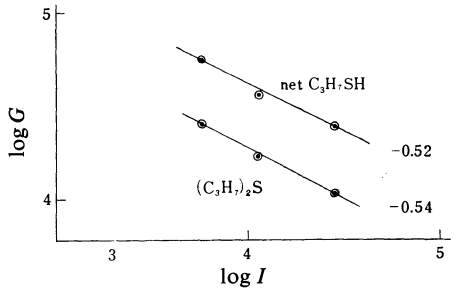

Fig. 2. The relation of log *G* and log *I*.

The Effect of the Molar Ratio of the Hydrogen Sulfide in the Sample.—It is shown in Fig. 3 that the yield increases with the increasing molar ratio of hydrogen sulfide, while the inclination of the curve gradually decreases. It would be interesting to see whether or not the yield will keep increasing at a higher molar per cent of hydrogen sulfide. Further work in this connection is in progress in our laboratory.

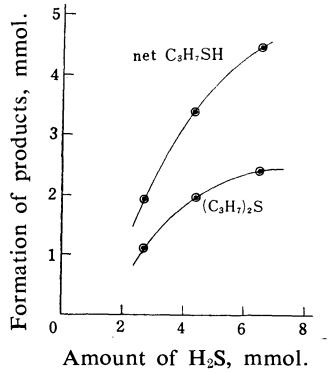

Fig. 3. Effect of molar ratio of hydrogen sulfide in the sample.
Dose rate 1.1×10^4 r/hr.
Irradiation time 48 hr.
C_3H_6 7.48 mmol.

When one makes *n*-propylmercaptan, it is desirable to employ a large molar ratio of hydrogen sulfide initially, or to separate the mercaptan at an early period of the radiation-induced reaction, as shown in Table II. When the reaction is completed, the product is found to be mainly di-*n*-propylsulfide; also, the radiolysis of propylene with a smaller amount of hydrogen sulfide preferentially leads to the formation of di-*n*-propylsulfide rather than to that of *n*-propylmercaptan. Therefore, this reaction can be used for the preparation of

8) S. Iizuka, M. Hatada and K. Hirota, This Bulletin, 36, 817 (1963).

n-propylmercaptan or of di-*n*-propylsulfide if one properly adjusts the reaction conditions.

The Reaction Mechanism. — Both *n*-propylmercaptan and di-*n*-propylsulfide were found to be produced in the irradiation of the sample. *n*-Propylmercaptan is undoubtedly the free-radical addition product of hydrogen sulfide to propylene, while di-*n*-propylsulfide is the secondary addition product of *n*-propylmercaptan to propylene.

$$CH_2{=}CH{-}CH_3 + H_2S \rightarrow HSCH_2{-}CH_2{-}CH_3 \quad (1)$$

$$CH_2{=}CH{-}CH_3 + HSCH_2{-}CH_2{-}CH_3 \rightarrow (CH_3{-}CH_2{-}CH_2)_2S \quad (2)$$

Both yields increased with an increase in the irradiation time, as is shown in Fig. 1. Besides, a small amount of hydrogen was found, probably produced by the following termination reaction.

$$H\cdot + H_2S \rightarrow H_2 + HS\cdot \quad (3)$$

The hydrogen atom in Eq. 3 might be produced by the radiolysis of hydrogen sulfide:[9]

$$H_2S \rightsquigarrow H\cdot + HS\cdot \quad (4)$$

A small amount of air was found to reduce the production of *n*-propylmercaptan and di-*n*-propylsulfide. Air apparently acts as a free radical scavenger to retard this chain reaction.

As has been discussed above, the reaction in all the cases is undoubtedly a free-radical chain reaction. The *G*-values calculated for the gamma ray-initiated experiments indicate that, in most cases, the kinetic chain is quite long.

Hydrogen sulfide is known to decompose the H atom and the HS radical.[9] These radicals can initiate a chain reaction in the following manner. As well as the reaction started by the radiolytically-generated HS radical in process 4, the HS radicals generated in the processes 6 and 3 would also lead to the chain propagation,

$$H_2S \rightsquigarrow HS\cdot + H\cdot \quad (4)$$

$$H\cdot + H_2C{=}CH{-}CH_3 \rightarrow H_3C{-}\dot{C}H{-}CH_3 \quad (5)$$

$$H_3C{-}\dot{C}H_3 + H_2S \rightarrow H_3C{-}CH_3{-}CH_3 + HS\cdot \quad (6)$$

$$H\cdot + H_2S \rightarrow H_2 + HS\cdot \quad (3)$$

$$HS\cdot + H_2C{=}CH{-}CH_3 \rightarrow HSCH_2{-}\dot{C}H{-}CH_3 \quad (7)$$

$$HSCH_2{-}\dot{C}H{-}CH_3 + H_2S \rightarrow HSCH_2{-}CH_2{-}CH_3 + HS\cdot \quad (8)$$

The reaction proceeds according to the chain mechanism shown by Eqs. 7 and 8, regenerating the sulfhydryl radical during these chain-propagating steps. Such a free radical chain mechanism is in good accord with the inhibiting effect of air. The great length of the chains precludes the ready detection of the saturated hydrocarbon or hydrogen formed in 6 and 3. Steps 7 and 8 are the chain-carrying steps, their length depending upon the processes of radical termination, which may occur either at walls or by recombination in the system.

n-Propylmercaptan, once formed, undergoes further reaction with propylene to give di-*n*-propylsulfide. The free radical addition of thiols to olefins, which has been studied extensively,[10] is considered to involve the following chain-propagating steps:

$$C_3H_7SH \rightsquigarrow H\cdot + C_3H_7S\cdot \quad (9)$$

$$C_3H_7S\cdot + CH_2{=}CH{-}CH_3 \rightarrow C_3H_7SCH_2{-}\dot{C}H{-}CH_3 \quad (10)$$

$$C_3H_7SCH_2{-}\dot{C}H{-}CH_3 + C_3H_7SH \rightarrow C_3H_7SCH_2{-}CH_2{-}CH_3 + C_3H_7S\cdot \quad (11)$$

Summary

The radiation-induced free radical addition of hydrogen sulfide to propylene to give *n*-propylmercaptan and di-*n*-propylsulfide has been studied. The direction of the addition to propylene is consistent with that of the radical addition to such olefins previously studied, suggesting that the SH is both the adding and chain-carrying species. The addition of the thiol to propylene has been found to undergo a free radical chain reaction, readily yielding di-*n*-propylsulfide in the succeeding step.

The Polymerization and Polymers of Itaconic Acid Derivatives. VI.[1] *The Polymerization and Copolymerization of Itaconic Anhydride*[2]

By Susumu NAGAI

(Received September 11, 1963)

Previous work reported in this series of papers has shown that[3] the rate constants of the polymerization of dialkyl itaconates decrease in the order of di-2-ethylhexyl> di-*n*-butyl>di-*n*-propyl≃diethyl>dimethyl, and that[4] the monomer reactivity ratios in the copolymerization with vinyl chloride are as follows: $r_1=0.053\sim0.06$ (M_1: vinyl chloride) and $r_2=5.1\sim7.0$ (M_2: dialkyl itaconates).

The purpose of the present investigation is to clarify the polymerization and copolymerization characteristics of itaconic anhydride compared with those of itaconic esters.

While many reactions of itaconic anhydride are described in the literature, its polymerization has not yet been reported* except for a few patents[5] including copolymers with styrene.

Experimental

Materials.—Itaconic anhydride (produced by the Tokyo Kasei Co.) was recrystallized from ethyl ether. M. P. 67~68°C. Dimethyl itaconate and di-2-ethylhexyl itaconate were prepared by the method described before.[4] Vinyl chloride, supplied by the Kanegafuchi Kagaku Co., was used as a comonomer. Butyl acetate and tetrahydrofuran were distilled and used as solvents in the copolymerization.

Copolymerization.—The copolymerization of itaconic anhydride with vinyl chloride was carried out, first in butyl acetate and then in tetrahydrofuran, in both cases in a sealed glass tube at 50°C. In both cases, copolymers were found to precipitate after copolymerization. The precipitates were filtered and washed with ethyl ether before being dried. The compositions of the copolymers were determined by the analysis of their chlorine contents.

The Rate of Polymerization.—The rates of the bulk polymerization of itaconic anhydride, dimethyl itaconate and di-2-ethylhexyl itaconate were measured in a dilatometer at 75°C. It is difficult to feed a monomer as crystal or powder through the capillary tubing into the bulb of the commonly-used dilatometer. In the present study a special dilatometer, shown in Fig. 1, was used. In this

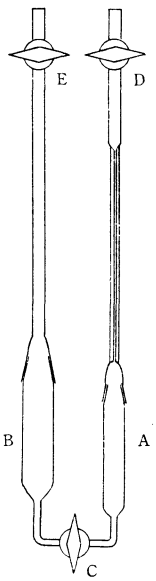

Fig. 1. The dilatometer used in the present study.

apparatus the capillary tubing and the bulb were connected by ground glass joints in order to facilitate the feeding of the monomer. The height of the meniscus of the melted monomer could be controlled by means of a movable bottom of mercury, which will be described below. There are two chambers, A and B, separated by a glass stopper, C. First, with C opened, several milliliters of clean mercury was charged into the bottoms of both A and B. Then C was closed. Monomer was charged into A on the mercury, and then the initiator was charged. Assembled with the tubings, the dilatometer was attached to the vacuum line. The content of the dilatometer was degassed and flushed with nitrogen alternatively. Then the dilatometer was immersed in a thermostat set at 75°C. As soon as the monomer melted, the dilatometer was picked up quickly and inclined, with the stopper C, and D and E opened, so that the mercury in B moved over to A, sending the liquid monomer

on the mercury up until the meniscus rose to a sufficient level of the capillary. Then, with all the stoppers closed, the dilatometer was again immersed into the bath. It took less than 7 min. from the first immersion to the final setting. The polymerization time was counted from this final setting, and the rate of the shrinkage of the monomer was measured with a cathetometer. After it had been polymerized for 1~2 hr., the dilatometer was taken off the bath and cooled. Polyitaconic anhydride was precipitated by pouring an acetone solution of the reaction mixture into a large excess of ethyl ether; it was then washed with fresh ether and dried in a vacuum oven at 40~50°C. for several hours. For polydimethyl itaconate and polydi-2-ethylhexyl itaconate, benzene was used as the solvent and methanol was used as the precipitant.

Viscosity Measurement.—The viscosity of the polymer solution was measured by a Ubbelohde-type viscometer at 30°C, using acetone as the solvent.

Hydrolysis.—Polyitaconic anhydride (54.1 mg.) was dissolved in 50 ml. of water at room temperature. After it had been stirred for 5 min., the pH of the solution showed 3.1; it changed no more, even after 24 hr.

Results and Discussion

Copolymerization.—The results of the copolymerization of itaconic anhydride and vinyl chloride are presented in Table I and Figs. 2 and 3.

From these results it can be seen that, when copolymerized with vinyl chloride, the anhydride always produced copolymers with considerably higher ratios of anhydride than in the feed. This tendency is quite analogous to the case of itaconic esters and vinyl chloride, as Fig. 2 shows.

The monomer reactivity ratios are approximately 5~10 for r_2 (M_2: ItAnh) and 0.01 for r_1. However, it is rather difficult to determine their definite values for each solvent system,

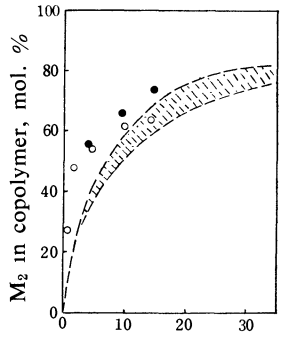

Fig. 2. Relationship between monomer compositions and copolymer compositions in the copolymerization of vinyl chloride (M_1) and itaconic derivatives (M_2).
○ M_2: ItAnh (in BuAc), ● M_2: ItAnh (in THF), dotted line zone: M_2: DMI, DEI, DiPI and DEHI (bulk)

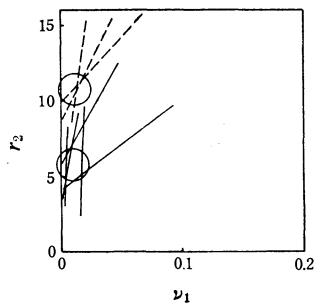

Fig. 3. Diagram of calculation for r_1 and r_2.
---- VC-ItAnh (in THF)
—— VC-ItAnh (in BuAc)

since a large difference exists between r_1 and r_2 values; on the other hand, in the case of itaconic anhydride and styrene Drougas and Guile[6] determined somewhat different values for r_1 and r_2 depending on the different solvent systems.

The Rate of Polymerization.—The copolymerization data obtained above suggest that itaconic anhydride homopolymerizes quite readily. For the preliminary test the bulk polymerization in a sealed glass tube was carried out at 75°C, using 5 wt. % benzoyl peroxide as the initiator. After the polymerization had continued for 140 min., the conversion of the monomer to the polymer was about 76%.

Detailed results of the dilatometry are shown in Figs. 4 and 5 and in Table II.

It is of interest to note that the rate constant of the polymerization (k_o) of itaconic anhydride is larger than that of dimethyl itaconate but smaller than that of di-2-ethylhexyl itaconate. As for the viscosity data, although the intrinsic viscosity of the polyitaconic anhydride

obtained was somewhat larger than that of polydimethyl itaconate, these small values of both polymers, at any rate, represent very low $\bar{P}$ values.

The above facts might be partly explained qualitatively by considering the propagation reactivity as well as the chain transfer reactivity of the anhydride in comparison with those of dialkyl itaconates.[3] It is thought that the double bond of itaconic anhydride is in the most free state from the steric effect, if any, of the adjacent carboxylate groups among the double bonds of itaconic derivatives. This advantage might serve somewhat to increase k_o. On the contrary, it is also considered that the anhydride has the most exposed active methylene among the itaconic derivatives. This might increase the anhydride's susceptibility to the chain transfer reaction and, hence, decrease k_o to some degree. Perhaps the observed rate of polymerization can be determined from a balance of these factors. Of course,

however, it is not possible at present to come to any definite conclusion.

Infrared Spectra.—Infrared absorption spectra of the monomer and polymer are presented in Fig. 6. The bands near 1665 cm^{-1} (CH_2=C< stretching), 1408 cm^{-1} (CH_2=C< in plane deformation) and 925 cm^{-1} (CH_2=C< out plane deformation) in the monomer disappeared in the polymer, while the bands near 1850 and 1760 cm^{-1} (C=O stretching) and 1220 cm^{-1} (C–O–C stretching) in the monomer remained, slightly shifting to 1860, 1775 and 1225 cm^{-1} respectively after polymerization.

Solubility Test.—Ten milligrams of itaconic anhydride did not dissolve in 4 cc. portions of petroleum ether, ligroin, *n*-hexane, cyclohexane, benzene, toluene or carbon tetrachloride at

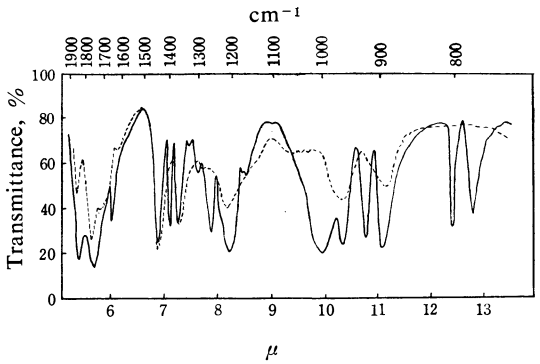

Fig. 6. Infrared spectra of monomer (——) and polymer (----). (Nujol).

room temperature. The monomer dissolved in ethyl ether and chloroform, but the polymer did not dissolve. The solvents for both the monomer and the polymer so far tested are acetone, cyclohexanone, ethyl methyl ketone, dioxane, glacial acetic acid, tetrahydrofuran and ethyl ether. Water, alcohols, dimethyl sulfoxide, dimethyl formamide, and pyridine may be classified as reactive solvents. The anhydride dissolved rapidly in methyl alcohol, but it did so slowly in ethyl and propyl alcohols. It is considered that the corresponding monoesters were partly formed. When the anhydride was dissolved in dimethyl sulfoxide, dimethyl formamide and pyridine respectively, a yellow or brownish yellow color appeared, and this became deeper with time. Perhaps some complex was formed, but this has not yet been confirmed. In the case of the polymer solution, the color was slight and did not become deeper with heating.

The Hydrolysis of the Polymer.—The hydrolysis of polyitaconic anhydride was carried out with ease, yielding polyitaconic acid or its copolymer structure with the unreacted anhydride, if any. The viscosity measurement of

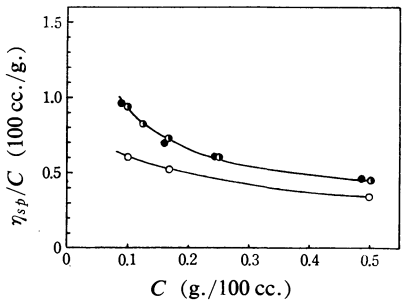

Fig. 7. Viscosity of aqueous solution of polyitaconic anhydride polymerized in bulk with [I]=2.80×10^{-2} mol./l. (◑) and [I]=5.34×10^{-2} mol./l. (○) at 75°C compared with that of polyitaconic acid obtained previously by polymerization of itaconic acid with [M]=1.5, [I]=1.0×10^{-2} mol./l. at 50°C (●).

the aqueous solution of polyitaconic anhydride showed a concentration-viscosity curve similar to that of polyitaconic acid, as Fig. 7 shows.

It is of much interest that polyitaconic acid is easily obtained (in the form of an aqueous solution) in the course of the polymerization of itaconic anhydride, followed by a simple isolation process and further hydrolysis,* while the direct polymerization of itaconic acid itself has been stated to occur only rarely in bulk, in acetone and methyl alcohol, but chiefly in water.**

Summary

The copolymerization of itaconic anhydride and vinyl chloride has yielded copolymers with itaconic anhydride much richer than that in the feed. The rate of the homopolymerization of itaconic anhydride has been compared with the rates of itaconic esters, obtaining the following order: di-2-ethylhexyl ester>anhydride>dimethyl ester. The infrared spectra and solubility character of the polymer have been shown in comparison with those of the monomer. Further, polyitaconic acid has been obtained by the hydrolysis of polyitaconic anhydride with some ease.

The author wishes to thank Dr. Keinosuke Yoshida and Dr. Taizo Uno for their direction, Dr. Kazuhiro Shimizu for his kind advice regarding infrared spectroscopy, Mr. Yoshihiro

* Although the preparation of polyitaconic acid by means of the hydrolysis of polyitaconic anhydride might easily follow from the knowledge of the reactivity of anhydride, the homopolymerization of itaconic anhydride itself had been an untouched problem before the beginning of the present study.

** It was rather tedious to isolate the polymer from the solution of the reaction mixture in this case (Ref. S. Nagai and K. Yoshida, *Chem. High Polymers, Japan*, 17, 748 (1960)).

Hidaka for his help in the dilatometry, and Mr. Yasushi Yoshinaga for his cooperation throughout this experiment.

The Preparation of Dimer Aldehydes and Dimer Alcohols in an Oxo Reactor. II. The Initial Rate of the Hydroformylation of Propylene in the Presence of Magnesium Methylate as a Modifier

By Hiroshi UCHIDA and Akio MATSUDA

(Received October 10, 1963)

The preceding paper[1] of this study reported that the addition of magnesium methylate to the starting material for propylene hydroformylation produced C-8 aldehydes in a good yield, without causing any reduction in the initial rate at 150°C. These results alone, however, were not enough to enable us to understand well the effect of magnesium methylate addition upon the initial rate. This paper will, therefore, present more accurate and comprehensive data on the initial rates in a certain range of temperatures which are prevalent in practical hydroformylation runs. The discussion of the results obtained will suggest other catalysts for hydroformylation in the presence of magnesium methylate besides that of cobalt carbonyl.

Experimental

The hydroformylation run was conducted, by use of the same 300 cc. autoclave, in essentially the same way as in the preceding paper,[1] except that the addition of dicobalt octacarbonyl was modified in such a manner that a more accurate determination of the initial rate was possible: Before the autoclave was covered up, an amount of dicobalt octacarbonyl crystals was placed in a small saucer (0.5 cc.) of stainless steel held on a wing of a stirring mechanism. Having been charged with a *n*-butyraldehyde solution of magnesium methylate besides the carbonyl in the saucer, the autoclave was flushed with a synthesis gas of 1 : 1 H_2-CO, some propylene was introduced, and then the autoclave was pressured with the synthesis gas from a pressure storage, to which the autoclave was connected by way of a needle valve, to about 140 kg./cm^2 at room temperature. The autoclave was heated to the reaction temperature, and then a small amount of the synthesis gas was added from the pressure storage to raise the total pressure to 200 kg./cm^2. The instant the stirring mechanism was started, the saucer was allowed to fall down from the wing to dissolve the dicobalt octacarbonyl in the solution, whereupon the hydroformylation reaction set in. During the run, the synthesis gas was continuously supplied through the needle valve from the pressure storage into the autoclave in order to maintain the total pressure at 200 kg./cm^2. The accompanying pressure drops in the pressure storage with time were recorded. The recorded data might serve as a measure of the initial rate provided that the data could be interpreted in terms of a reasonable evaluation of the amount of synthesis gas consumed by the hydroformylation itself.

After the reaction period of an hour, the autoclave was cooled in running water. The gaseous material was purged, metered, and analyzed for the unchanged propylene in order to obtain the propylene conversion rate. The analysis of propylene as well as that of constituents in the liquid product was made in the way described in the preceding paper.[1] The raw materials used in this study were obtained from the same sources as those in the preceding study.[1]

In order to obtain a picture of the catalyst in the simultaneous presence of cobalt carbonyl and magnesium methylate, both the ratio of combined carbon monoxide (mole) to the total cobalt (atom) (hereafter denoted by CO_c/Co) and the ratio of cobalt (atom) existing as a carbonyl anion to the total cobalt (atom) (hereafter denoted by Co_{an}/Co) were determined, together with an infrared spectrum, on the liquid samples at the earlier stages of runs with and without magnesium methylate. The runs for this purpose were made by means of another autoclave (100 cc. in volume) of the same construction but lined with titanium over the whole inner surface lest the liquid samples should be contaminated with metal carbonyls from the autoclave material. From the beginning a few samples of a small portion (ca. 5 cc.) of the liquid product were sucked at five-minute intervals into a titanium dip-tube withdrawn out of the autoclave by passing them through a stainless steel tube cooled in ice, and subjected to immediate determination. The

1) H. Uchida and A. Matsuda, This Bulletin, **36**, 1351 (1963).

combined carbon monoxide was determined according to the method of Sternberg et al.[2] who measured the volume of the carbon monoxide liberated by the addition of excess iodine, and the carbonyl anion according to the method of Iwanaga,[3] who titrated the sample with an acetic acid-toluene solution of methyleneblue. The infrared spectrum was determined by means of a rock salt prism using *n*-butyraldehyde as the reference solution.

Results and Discussion

The Rate of Hydroformylation. — In the preceding paper,[1] the initial rate constant, k, for the batchwise run of propylene hydroformylation was represented by the following formula:

$$k=(1/t)\ln(c_0/c_t)=(1/t)\ln[c_0/(c_0-V/2)] \quad (1)$$

where t (min.) was the reaction time, c_0 (mol.) was the initial amount of propylene, c_t (mol.) was the amount of propylene at reaction time t, and V (mol.) was the amount of synthesis gas introduced from the pressure storage into the autoclave at reaction time t. The formula, however, was rather a conventional one because V, as measured by the drop in pressure of the pressure storage, was simply put as equal to $2(c_0-c_t)$ (mol.). In fact, however, V consisted of two portions of the synthesis gas, one (V_r, mol.) that consumed by the hydroformylation reaction itself and the other (V_0, mol.) that necessary to compensate for the fall in propylene partial pressure as the reaction proceeded. V_r, in place of V, should have been identical with $2(c_0-c_t)$. In this connection, Eq. 1 will be improved to give a more accurate expression of k.

Under the assumption that the propylene partial pressure, p, is proportional to the total propylene content,[4] the drop in propylene partial pressure (p_0-p) is written as:

$$p_0-p=p_0(c_0-c_t)/c_0 \quad (2)$$

where p_0 is the initial propylene partial pressure under the reaction conditions. Taking Eq. 2 into consideration, V_0 is given by Eq. 3:

$$V_0=a(p_0-p)=ap_0(c_0-c_t)/c_0 \quad (3)$$

In the above equation, a is a coefficient whose value is dependent on the reaction temperature. Since $V=V_r+V_0$, V is then expressed as follows:

$$V=2(c_0-c_t)+ap_0(c_0-ct)/c_0 \quad (4)$$

The substitution of the c_t obtainable from Eq. 4 into Eq. 1 results in the following expression of k:

$$k=(1/t)\ln\{c_0/[c_0-V(2+ap_0/c_0)]\} \quad (5)$$

To calculate Eq. 5 for k, ap_0 (mol.) at the present reaction conditions should be determined first. The determination, including some experimental measurements, has resulted in the respective values of 0.140, 0.155, 0.178, and 0.191 mol. at 130, 140, 150, and 160°C, provided that the initial charges of propylene and *n*-butyraldehyde in the autoclave are 0.22 and 0.068 mole respectively and the total pressure is 200 kg./cm^2.

Meanwhile, let us explain the procedure for calculating ap_0. The Benedict-Webb-Rubin equation of state[5] can give p_0 if the initial propylene density, d_0, in the autoclave at the reaction conditions is known. To obtain d_0, the initial propylene mole fraction, s_0, in the gas phase at the reaction conditions has only to be determined experimentally, since d_0 (g. mol./l.) is expressed by the formula:

$$d_0=n_0/V=s_0P/zRT \quad (6)$$

where n_0 is the initial propylene content (g. mol.) in the gas phase under the reaction conditions, V (l.) is the volume of the gas phase in the autoclave, P (atm.) is the total pressure, and z is the compressibility factor of the gaseous mixture under the reaction conditions. The determination of s_0 was made on four samples withdrawn from the gas phase at the temperatures of 130, 140, 150, and 160°C in the autoclave; the initial charges of the samples were 0.22 mol. propylene and 0.068 mol. *n*-butyraldehyde, with neither cobalt carbonyl nor magnesium methylate, and they were subsequently added with the synthesis gas to 200 kg./cm^2. Once s_0 is obtained, z is evaluated as ca. 1.02 at 200 kg./cm^2 over the 130 to 160°C temperature range; consequently, d_0 is determined by the aid of Eq. 6. The substitution of the values of d_0 into the Benedict-Webb-Rubin equation results in the corresponding values of p_0, which are 18.7, 21.2, 25.0 and 27.5 atm. at 130, 140, 150 and 160°C respectively. The determination of ap_0 is then possible by a simple calculation.

Findings on the initial rates of hydroformylation over a temperature range from 130 to 160°C are exemplified in Figs. 1 and 2 as plots of $\ln[c_0/\{c_0-V/(2+ap_0/c_0)\}]$ vs. t. Throughout the runs, the initial charges of *n*-butyraldehyde,

propylene, and dicobalt octacarbonyl were kept constant at the respective amounts of 0.068, 0.22 mol., and 0.4 mmol., but magnesium methylate was varied in amount at 0.8 mmol. intervals between 0 and 3.2 mmol. In each run the plot is linear, and the initial rate constant, k, is readily evaluated from the slope of the plot. For each series of runs with a fixed amount of magnesium methylate, an Arrhenius plot is drawn, as shown in Fig. 3. In the figure the plots intersect with one another at A, where $1/T$ is 423°K. This plainly indicates that the initial rate constant, and thus the initial rate at 150°C, remains unchanged, independent of the amounts of magnesium methylate added, but that within the amount of about 2.4 mmol. the initial rates at the reaction temperatures below 150°C

increase more markedly as the amount of magnesium methylate is increased, whereas the situation is reversed above 150°C.

On the basis of the plots in Fig. 3, the activation energies, E, as well as the frequency factors, A, of hydroformylation reactions with varying amounts of magnesium methylate can be calculated. A plot of E vs. Mg/Co (atom ratio) in the raw material, as illustrated in Fig. 4, indicates that E diminishes with Mg/Co at first, passes through a minimum at Mg/Co=3 and then rises. Moreover, a plot of $\ln A$ against E appears to be linear, as is shown in Fig. 5. The linear relationship is represented by the following equation:

$$\ln A = E/R\Theta + \ln A' \qquad (7)$$

where Θ is a constant of the proportionality with the dimension of temperature and A' is another constant, their respective values being calculated as 423°K (150°C) and 0.074 min^{-1}. This relationship indicates that a compensation effect appears in a particular manner that obeys the "Theta Rule."[8]

The compensation effect has been reported in a number of liquid-phase reactions, such as hydrolysis and esterification in the presence of inorganic acid, where a series of differently substituted compounds or of different kinds of solvents was used (cf. 9) and 10)). Nevertheless, no paper, so far as we are aware, has ever dealt with the compensation effect taking place in a series of liquid-phase reactions with different catalyst compositions. On the other hand, there are many examples of gas-solid heterogeneous catalysis where the compensation effect appears as the catalyst compositions are changed. According to Cremer[11] the effect on the heterogeneous catalysis can be ascribed to the simultaneous presence of two or more kinds of active sites participating in the reaction, with different activation energies and frequency factors. Extending the view of Cremer to the present liquid-phase reaction, the compensation effect can be interpreted as coming from the presence of two kinds of catalysts, presumably one being the carbonyl of cobalt and the other being the compound into which the carbonyl and magnesium methylate have been combined. At first sight, one may be apt to consider the latter catalyst as consisting of three moles of magnesium methylate and one mole of the carbonyl (cf. Fig. 4), but a detailed examination of the chemistry of the catalyst itself reveals that this is not necessarily the case, as will be mentioned in the next section.

Catalysts in the Presence of Magnesium Methylate.—The CO_c/Co and Co_{an}/Co ratios were determined for the samples at earlier stages of the runs using 0.136 mol. of *n*-butyraldehyde, 0.1 mol. of propylene, and 0.6 mmol. of dicobalt octacarbonyl, either without or with 3.6 mmol. of magnesium methylate (Mg/Co=3). The runs were conducted at 150°C at 200 kg./cm^2. The results are cited in Table I. In accordance with the results of

a) Magnesium methylate was added in the amount corresponding to Mg/Co (atom ratio) of 3.

Heck and Breslow,[12] the value of CO_c/Co is always about three, independent of whether magnesium methylate was added or not. In constrast to this, Co_{an}/Co is zero or an extremely low value in the absence of magnesium methylate, while in its presence it attains to such higher values as 0.2 to 0.34. The carbonyl anion, as is well known,[13] would not be detected in the reaction medium at the earlier stage of the usual hydroformylation where a considerable amount of olefin remains. Accordingly, the carbonyl anion thus detectable in the present runs can be ascribed to that of a mixed metal carbonyl of $[Co(CO)_4]_2Mg$ produced in a way similar to that in which the carbonyl of $[Co(CO)_4]_2Zn$[14] is produced. The mixed metal carbonyl $[Co(CO)_4]_2Mg$, as well as $[Co(CO_4]_2Zn$, can act as the catalyst for aldehyde dimerization, but it can not be the catalyst for hydroformylation. Moreover, it should be emphasized that only one-third to one-fifth of the cobalt, not all of the cobalt, participates in producing the mixed metal carbonyl, even though magnesium methylate is added in the great excess of Mg/Co=3. This may be the reason why magnesium methylate produced dimer aldehydes in a good yield, without exercising an

unfavorable effect on the initial rate of hydroformylation.

So far as the afore-mentioned results are concerned, it remains undetermined whether the remaining portions of cobalt carbonyl and of magnesium methylate exist separately or as a complex compound into which they have combined. In this connection, a possible interpretation of the compensation effect has suggested a kind of catalyst for hydroformylation besides cobalt carbonyl. The suggestion is supported by the following results on the infrared spectrum measurement: The infrared spectrum of the reaction product (e. g., the product at 10 min. interval from beginning)

Figs. 6 and 7. Infrared spectra of reaction products starting with raw materials (A) without and (B) with magnesium methylate respectively.

without magnesium methylate is similar to, though not identical with, that of dicobalt octacarbonyl (cf. 15)), but the spectrum of the reaction product with magnesium methylate differs markedly from that described just (compare Fig. 6 with Fig. 7[16]). The latter spectrum contains characteristic peaks at 1991 and 1974 cm^{-1} and a band at 1891 cm^{-1} which is assignable to the carbonyl anion of the mixed metal carbonyl,[17] besides a band at 2030 cm^{-1} which also appears in the former spectrum but is much reduced in intensity. The marked difference thus observed between the two spectra indicates a bonding taking place between cobalt carbonyl and magnesium methylate. However, nothing more decisive can be said about the composition of the compound, or of the catalyst, because the data on the equilibrium, such as $1/2 \cdot Co_2(CO)_6 + xMg(OCH_3)_2 \rightleftarrows [Co(CO)_3]^{-\delta}[Mg(OCH_3)_2]_x^{+\delta}$, are not yet available.

Propylene Conversion and Product Composition.—Table II summarizes the propylene conversion and the product composition after an hour's reaction period. The rate of conversion tends to lower with Mg/Co, and this tendency appears more clearly at the lower reaction temperatures, where the content of unsaturated C-8 aldehyde is larger. It is to be expected that the conversion should be low

a) C-8 alcohol(1) and C-8 alcohol(2) stand for 2-ethyl-4-methylpentanol and 2-ethylhexanol respectively.

in the presence of the unsaturated aldehyde because cobalt carbonyl and the unsaturated aldehyde combine into a catalytically inactive compound. This was confirmed with an experimental run starting with a raw material containing a some considerable amount of 2-ethyl-hexenal (0.05 mol.). The results, as shown by the dotted line in Fig. 1, reveal that the unsaturated aldehyde not only lowers the propylene conversion but also retards the initial rate of hydroformylation. However, it should be noticed that the retarding effect on the initial rate need not be considered with respect to the present data, since the amount of unsaturated aldehyde at the earlier stage might be too small to have any effect on the initial rate. In fact, the effect in the low temperature range is of a kind opposite to what one might expect.

Within the Mg/Co range of the present study, the dimer aldehydes content increases with the ratio. The residue in the table stands for the sum of the matter not identified as yet; it may mainly consist of compounds whose distillation temperatures are above those of C-8 aldehydes. Table III gives the compositions of some final products after the hydrogenation of the products in Table II in the usual manner, using a Raney cobalt catalyst.

Summary

The effect of magnesium methylate addition upon the initial rate of propylene hydroformylation has been explained in terms of Arrhenius plots of the initial rate constants, and in terms of the activation energy as a function of Mg/Co. Moreover, the plot of the logarithm of the frequency factor vs. the activation energy appears to be linear, which indicates that a compensation takes place with respect to the initial rate in the presence of magnesium methylate. The extension of Cremer's view about the compensation effect in heterogeneous catalysis into this kind of liquid-phase reaction leads one to expect another catalyst besides that of cobalt carbonyl.

The determination of the cobalt carbonyl anion in the reaction product obtained from raw material either with no or with a large excess of magnesium methylate (Mg/Co=3) indicates that in the former product scarcely no cobalt is detectable as the carbonyl anion, whereas in the latter product a part of the cobalt exists as such. The anion is to be ascribed to that of a mixed metal carbonyl of $[Co(CO)_4]_2Mg$, which facilitates the production of dimer aldehydes. Further, the infrared spectrum of the latter product differs markedly from that of the former product. This may afford evidence for the other catalyst expected.

In addition, this paper has presented data on the propylene conversion and the compositions of reaction products before and after hydrogenation, data obtained with raw materials containing varying amounts of magnesium methylate.

The Oxo Reaction of Unconjugated α, ω-Diolefin

By Masanobu MORIKAWA

(Received October 15, 1963)

The reaction of olefin with carbon monoxide and hydrogen to form aldehyde is well known as the oxo reaction or hydroformylation.[1] In this reaction, it is not only desirable but also interesting to study whether it is possible to prepare dialdehyde from diolefin.

It has, however, been reported that a conjugated diolefin, such as butadiene and 1, 3-pentadiene, yields not dialdehyde, but saturated monoaldehyde under oxo conditions.[2] Also, it has been reported that an unconjugated cyclic diolefin, such as 4-vinylcyclohexene and dicyclopentadiene, gives a mixture of mono- and dialdehydes in a low selectivity.[3] On the other hand, the reaction of an unconjugated α, ω-diolefin has not been thoroughly studied. From this standpoint, we have been interested in the reaction with 1, 4-pentadiene and 1, 5-hexadiene in order to synthesize dialdehydes and have found that the dialdehydes can be obtained as a main product from the unconjugated α, ω-diolefins under suitable conditions.

It was found essential to carry out the reaction at a lower temperature (below 100°C), in a dilute alcoholic solution and in the presence of a rhodium catalyst instead of the cobalt catalyst usually used in the oxo reaction. The use of a cobalt catalyst or of other solvents resulted in a lower yield of dialdehyde.

After the reaction had been carried out under the conditions cited above, the reaction mixture was catalytically hydrogenated, because it is easier to isolate the reaction products as saturated aldehydes when unsaturated ones are also present. Then the reaction products were identified by converting them into 2, 4-dinitrophenylhydrazones and other derivatives of the corresponding saturated aldehydes.

From 1, 4-pentadiene pimelaldehyde was obtained as a main product in addition to monoaldehydes and other aldehydes in the presence of a rhodium oxide catalyst, but cyclohexanecarboxaldehyde was obtained in the presence of a rhodium chloride catalyst, which generates hydrogen chloride in the course of the reaction. Cyclohexanecarboxaldehyde is formed by an intramolecular aldol condensation of the dialdehyde. As supporting evidence, cyclohexene-1-carboxaldehyde was isolated as the hydrazone in another run. Pimelaldehyde was converted by reduction with lithium aluminum hydride to 1, 7-heptanediol, which was identified as diacetate by comparing the NMR- and infrared-spectra and retention time of its gas chromatograph with those of an authentic sample.

2-Methylheptanedial was obtained from 1, 5-hexadiene as a main product. The dialdehyde was converted by permanganate oxidation to the corresponding diacid and was identified as its dimethylester.

Interestingly, it has already been reported that monoölefin forms mainly branched-chain aldehyde,[4] but in our experiments pimelaldehyde and 2-methylheptanedial were obtained from 1, 4-pentadiene and 1, 5-hexadiene respectively. This suggests that these diolefins form the complexes with the rhodium carbonyl suitable for the 1, 5-insertion of carbon monoxide and that the migration of the double bond[1] into the conjugated position does not take place.

Even under these conditions, butadiene and 1, 3-pentadiene did not give dialdehyde, but only monoaldehyde.

Experimental[5]

The Reaction of 1, 4-Pentadiene.—1, 4-Pentadiene (1.36 g.) prepared from 1, 5-pentanediol diacetate by pyrolysis,[6] rhodium oxide (0.5 g.) and ethanol (50 ml.) were charged in a 200 ml. stainless steel pressure reactor. Air was removed, and a carbon monoxide-hydrogen mixture (1 : 1) was introduced up to the pressure of 150 kg./cm^2. The reaction was carried out at 60~100°C for 15 min., during which time a pressure drop of 15 kg./cm^2 was observed. The gas mixture was released, the carbonyl catalyst was decomposed, and the reaction mixture was hydrogenated at room temperature

under atmospheric pressure over a platinum catalyst. Then, the reaction mixture was treated with 2, 4-dinitrophenylhydrazine in an acidic ethanol solution, giving 5 g. of a hydrazone mixture.

The portion of the hydrazone more soluble in benzene was separated and purified by neutral alumina column chromatography and was recrystallized from ethanol, giving 0.7 g. of yellow crystals, a mixture of the hydrazones of monoaldehydes (m. p. 95~98°C).

Found: C, 51.54; H, 5.71. Calcd. for $C_{12}H_{16}N_4O_4$; C, 51.42; H, 5.75%.

The portion less soluble in benzene was the hydrazone of cyclohexanecarboxaldehyde (0.5 g., m. p. 169~170°C), and no depression of melting point was observed with an authentic sample prepared by the hydroformylation of cyclohexene.

Found: C, 53.28; H, 5.49. Calcd. for $C_{13}H_{16}N_4O_4$: C, 53.42; H, 5.52%.

When rhodium chloride was used as a catalyst instead of rhodium oxide, cyclohexanecarboxaldehyde was a main product and the hydrazone of 1-cyclohexene-1-carboxaldehyde was isolated on treating the reaction mixture with 2, 4-dinitrophenylhydrazine without hydrogenation (red crystals of m. p. 214°C decomp., (lit.[7] 215°C decomp.)).

Found: C, 53.56; H, 4.87. Calcd. for $C_{13}H_{14}N_4O_4$: C, 53.79; H, 4.86%.

The portion insoluble in benzene was further fractionated by recrystallization from dimethylformamide. The portion less soluble was considered to be the hydrazone of branched-chain dialdehyde (0.8 g., m. p. 214~216°C).

Found: C, 47.20; H, 4.16. Calcd. for $C_{19}H_{20}N_8O_8$: C, 46.72; H, 4.13%.

The portion more soluble was a main product identified with the hydrazone of pimelaldehyde (1.6 g., m. p. 177~179°C (lit.[8] 180~181°C), and no depression of melting point was observed with an authentic sample prepared by the Rosenmund reduction of pimeloyl chloride.

Found: C, 46.81; H, 4.10. Calcd. for $C_{19}H_{20}N_8O_8$: C, 46.72; H, 4.13%.

In another run, the reaction mixture was poured into water and extracted with ether. The ether layer was dried, the extact was reduced with lithium aluminum hydride, and the dialcohol boiling between 140 and 150°C at 8 mmHg was collected (0.5 g. from 1.36 g. of diolefine). The dialcohol was converted into the diacetate and purified by "Megachrom." The identity of the product with an authentic sample of 1, 7-heptanediol diacetate was confirmed by comparing the retention time of their gas chromatographs and the NMR- and infrared-spectra. NMR-spectra: CH_2O, 6.10 τ and 6.58 τ; CH_3CO, 8.07 τ; CH_2, 8.62 τ.

An authentic sample of 2, 4-dinitrophenylhydrazone of pimelaldehyde was synthesized in the following way. Pimelic acid (8 g.) was converted into acyl chloride by treatment with oxalyl chloride in benzene. The acyl chloride was reduced in xylene (35 ml.) in the presence of 5% palladium on barium sulfate (1 g.) and "Quinoline-S" (0.1 ml.) at 150~160°C by bulbbling a hydrogen stream until no more hydrogen chloride was evolved. The catalyst was then removed, and the reaction mixture was treated with 2, 4-dinitrophenylhydrazine. The hydrazones obtained (1.2 g.) were separated into the red hydrazone of cyclohexene-1-carboxaldehyde (0.6 g., m. p. 218°C (decomp.)) and the yellow hydrazone of pimelaldehyde (0.5 g., m. p. 177~178°C).

The Reaction of 1, 5-Hexadiene.—The reaction of 1, 5-hexadiene (1.65 g.) prepared from allyl magnesium bromide[9] was carried out for 20 min. at 60~100°C in the same way as with 1, 4-pentadiene. The reaction mixture was hydrogenated and treated with 2, 4-dinitrophenylhydrazine. 3.6 g. of hydrazones were obtained. The hydrazones were fractionated and recrystallized to give the following products; the hydrazones of monoaldehydes (0.8 g.; m. p. 96~100°C. Found: C, 53.20; H, 5.98. Calcd. for $C_{13}H_{18}N_4O_4$: C, 53.05; H, 6.16%), the hydrazone of suberaldehyde (0.6 g., melting point and mixed melting point with an authentic sample prepared by ozonolysis of cyclooctene 177°C (lit. 175°C,[10] 167~169°C[8]). Found: C, 47.30; H, 4.46. Calcd. for $C_{20}H_{22}N_8O_8$: C, 47.77; H, 4.41%), and the hydrazone of 2-methylheptanedial (1.3 g. obtained at a main product; m. p. 185°C (unreported). Found: C, 47.81; H, 4.38. Calcd. for $C_{20}H_{22}N_8O_8$: C, 47.77; H, 4.41%).

In another run, the reaction mixture was poured into water and extracted with ether, and then the ether was replaced by acetone. The acetone solution was oxidized with an aqueous permanganate solution to give the dicarboxylic acid. After esterification, 0.6 g. of pure dimethyl 2-methylheptanediate (b. p. 90~92°C/5 mmHg) was obtained from 1.67 g. of diene and was identified by comparing the infrared- and NMR-spectra and the retention time in its gas chromatography with those of an authentic sample, which had in turn been prepared from dimethyl pimelate and methyl iodide in the presence of sodium alcoholate.[11] The NMR-spectra ($CHCl_3$); OCH_2, 6.34 τ; CH_2CO and CHCO, 7.75 τ; CH_3, 8.50 τ; CH_3, 8.85 τ.

Summary

Pimelaldehyde and 2-methylheptanedial have been obtained from 1, 4-pentadiene and 1, 5-hexadiene respectively by carrying out the oxo reaction in alcohol at a lower temperature (below 100°C) using a rhodium catalyst.

The Complex Formation of Boron Fluoride with Lower Olefins at Low Temperatures. II. Isotope Effects and Absorption Spectra of Boron Fluoride-Butene Systems

By Ryohei NAKANE, Tsunao WATANABE and Toshiyuki ŌYAMA

(Received July 5, 1963)

By measuring the isotope effects and absorption spectra of boron fluoride-ethylene and -propyrene systems, the authors predicted in a preceding paper[1] that only polar mono-olefins would form σ-complexes with boron fluoride at low temperatures. In the present report similar measurements for boron fluoride-1-butene, -*cis*-2-butene and -*trans*-2-butene systems will be reported and the prediction confirmed. The relation between the values of the equilibrium constant of isotopic exchange and the catalytic ability of boron fluoride complexes will also be discussed.

Experimental

Except for a low temperature bath prepared by the use of the melting point of $-95°C$ of toluene, the experimental methods were exactly the same as those used in the preceding work.

Results and Discussion

Isotope Effects. — Findings concerning the isotope effect are shown in Table I. The values

TABLE I. EQUILIBRIUM CONSTANT OF BORON ISOTOPE EXCHANGE FOR BORON FLUORIDE-BUTENE SYSTEMS AT LOW TEMPERATURE

System	Equilibrium constant $[^{10}B/^{11}B]_{liq}/[^{10}B/^{11}B]_{gas}$	
	$-95°C$	$-112°C$
BF_3-1-C_4H_8	1.012 ± 0.002	1.017 ± 0.002
BF_3-*cis*-2-C_4H_8	1.015 ± 0.002	1.020 ± 0.002
BF_3-*trans*-2-C_4H_8	1.006 ± 0.002	1.011 ± 0.002

of the equilibrium constants of isotopic exchange with polar mono-olefins, 1-butene and *cis*-2-butene, were found to be appreciably larger than 1.011 while that with a non-polar *trans*-2-butene was 1.011 at $-112°C$.

These findings indicate again that boron fluoride can form σ-complexes with polar mono-olefins at low temperatures, but not with non-polar mono-olefins. Thus, the conclusion drawn in the preceding work was confirmed to be correct.

The values of the equilibrium constants of isotopic exchange between boron fluoride gas and many liquid boron fluoride complexes at various temperatures are summarized in Table II, and the values for very strong complexes with an *n*-donor, such as methyl ether, are compared with the values for weak complexes found by us. The equilibrium constants for systems of boron fluoride-*n*-donor complexes or of tetrafluoborate ions are the largest, while those for systems of liquid boron fluoride or of solutions of boron fluoride in non-polar mono-olefins are the smallest. The equilibrium constant for the system of tetrafluoborate ions, the structure of which is completely tetrahedral, is 1.028 ± 0.008 at temperatures from 20 to 30°C.[2] The equilibrium constant for the boron fluoride-methyl ether complex system is also 1.028 ± 0.002 at 25°C,[3] and the value calculated from the experimental equation given by Palko et al.[3] is 1.082 at $-112°C$. In the boron fluoride-methyl ether complex, every boron atom is situated at the top of the pyramidal structure.[4] On the other hand, the equilibrium constant for the system of liquid boron fluoride, the molecule of which has a structure of a planar form, is 1.011 ± 0.002 at $-112°C$.[1] The methyl fluoride-boron fluoride complex has been considered to be a weak complex, $^{\delta+}CH_3\cdot F \rightarrow {}^{\delta-}BF_3$, for its conductivity is poor.[5] The equilibrium constant for the methyl fluoride-boron fluoride complex system is 1.020 ± 0.002 at $-95°C$,[6] appreciably smaller than that for the boron fluoride-methyl ether complex system and larger than that for the liquid boron fluoride system. Though the boron fluoride-sulfur dioxide complex has been considered to be a weak complex because of the shape of its

a) solid; b) calculated from experimental equation; c) measured newly; d) estimated

fusion curve,[7] its equilibrium constant is nearly equal to that for the boron fluoride-methyl chloride complex system.[8] These results show that the value of the equilibrium constant is proportional to the stability of the complex.

Now, when the following isotopic exchange occurs betwen gaseous boron fluoride and the liquid boron fluoride complex which is formed with the donor molecule YA,

$$^{10}BF_{3(gas)} + {}^{11}BF_3\cdot YA_{(liq)} \overset{k}{\rightleftharpoons} {}^{11}BF_{3(gas)} + {}^{10}BF_3\cdot YA_{(liq)} \quad (1)$$

the equilibrium constant is given by

$$K=\frac{[Q_{^{10}BF_3\cdot YA\,(liq)}]}{[Q_{^{11}BF_3\cdot YA\,(liq)}]}\Big/\frac{[Q_{^{10}BF_3\,(gas)}]}{[Q_{^{11}BF_3\,(gas)}]} \quad (2)$$

Here, the ratio between the partition functions of isotopic molecules is

$$\frac{Q_2}{Q_1}=\frac{\sigma_1}{\sigma_2}\prod_i \frac{u_{2i}\exp(-u_{2i}/2)\,[1-\exp(-u_{1i})]}{u_{1i}\exp(-u_{1i}/2)\,[1-\exp(-u_{2i})]} \quad (3)$$

where 1 and 2 refer to the different isotopic molecules, σ_1 and σ_2 are the symmetric numbers, $u_i=hc\omega_i/kT$, and ω_i is the ith normal vibrational frequency.[9] Thus, when the normal vibrational frequencies of gaseous boronfluoride and liquid boron fluoride complexes are obtained, the equilibrium constants can be calculated from Eqs. 2 and 3.

In the isotopic exchange between boron fluoride gas and the boron fluoride-methyl ether complex, Palko et al.[3] compared the observed equilibrium constants with the values calculated by Eqs. 2 and 3 from infra and Raman spectra data and found that, when the transformation of boron fluoride from planar to pyramidal resulted in an increase in the B—F distance and a weakening of the B—F force constant, the isotope effect caused by the B—F bond was so marked that it overbalanced the formation of the B—O bond, which had the opposite effect upon the partition function ratio. This suggests the possibility that the equilibrium constants of the isotopic exchange between gaseous boron fluoride and all boron fluoride complexes may depend mostly on the B—F force contants and scarcely at all on the force constant of the bond formed between boron and donor atoms. This possibility is supported by the observation of many strong boron fluoride complexes other than the boron fluoride-methyl ether complex, for example, boron fluoride-anisole,[10] -thioether,[10] -phenole,[10] -triethyl amine[11] and -furan[11] complexes. That is, the equilibrium constants between gaseous boron fluoride and these complexes, in which every boron atom will be situated at the top of the pyramidal structure and the vacant orbital of the boron atom will

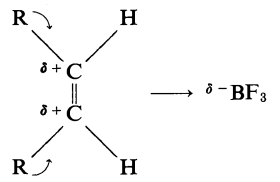
be completely filled with electrons from donor atoms, as in the cases of the boron fluoride-methyl ether complex and tetra-fluoborate ions, are also approximately 1.03 at room temperature, as is shown in Table II.

Therefore, the equilibrium constants for these strong complex systems may always be expected to be approximately 1.08 at $-112°C$, for the value calculated for the boron fluoride-methyl ether system is 1.082 at $-112°C$.

Liquid boron fluoride, the equilibrium constant of which is 1.011 at $-112°C$, has the planar structure and vacant orbitals of the boron atom. The weak complexes which have intermediate values between 1.011 and 1.08 at $-112°C$ have slightly-dissociated polar covalent bonds such as are found in $^{\delta+}CH_3 \cdot F \rightarrow {}^{\delta-}BF_3$, but the boron fluoride in these complexes has not yet been completely transformed to a pyramidal structure and only small parts of the electrons from donor atoms may be located on the vacant orbitals of boron atoms.

Thus, it seems very likely that the equilibrium constants of isotopic exchange for boron fluoride complex systems depend mostly on the density of electrons coming from donor atoms and locating on the vacant orbitals of boron atoms, or on the B—F force constant, which becomes weaker in proportion to the transformation of boron fluoride from planar to pyramadial; the equilibrium constants seem to depend scarcely at all on the force constant of the bond formed between boron and donor atoms. Accordingly, they indicate the possibility of complex formation and the degree of the transformation of boron fluoride. Therefore, the larger the equilibrium constant, the larger the degree of deformation, and, hence, the more stable the complex.



If, in the complex, the pyramidal form is the dative structure and the planar form is the no-bond structure, the equilibrium constant of isotopic exchange may be assumed to represent the abundance ratio of both structures in the complex, as does the dipole moment.

When the structure of complex is completely dative, the equilibrium constant will be approximately 1.08 at $-112°C$, as in the case of the boron fluoride-methyl ether complex system, while when it is completely no-bond, the constant will be 1.011 at $-112°C$, as in the case of the liquid boron fluoride system. In a complex in which the constant has intermediate values, the ratio of dative to no-bond structures will have values between one and zero.

Thus, it seems certain, from the observed values of the equilibrium constants, that boron fluoride can form weak σ-complexes with polar mono-olefins only at low temperatures, but that boron fluoride dissolved in liquid non-polar mono-olefins has the same planar structure as liquid boron fluoride molecule and that, therefore, no σ-bond can be formed between boron and carbon atoms, even at low temperatures.

In boron fluoride-polar mono-olefin-σ-complexes, the dative structure may be ($R-{}^{+}CH-CH_2-{}^{-}BF_3$), in which π-electrons of the double bond are transferred completely to vacant orbitals of the boron atoms and the boron fluoride molecule becomes deformed completely to the pyramidal structure, while the no-bond structure remains ($R-CH=CH_2$, BF_3). The ratio of dative to no-bond structures may be far smaller than one, for the equilibrium constants observed at $-112°C$ are far smaller than 1.08. Hence, it seems clear that σ-complexes have not the ultimate structure of $R-{}^{+}CH-CH_2-{}^{-}BF_3$, as was formerly believed of intermediate products in the polymerization of olefins by a boron fluoride catalyst.[12]

As has been shown in the preceding work and as will also be shown in the next section, V←N absorption bands, indicating the presence of a double bond, were still observed in the measurements of the absorption spectra of boron fluoride-mono-olefin complexes. Therefore, it seems very likely that the σ-complexes are $R-{}^{\delta+}CH=CH_2 \rightarrow {}^{\delta-}BF_3$ or

It is also interesting to consider the relation between the equilibrium constants and the dipole moments of mono-olefins. The following values of the dipole moments of gaseous mono-olefins are known: 0.35 D,[13] 0.37 D[14] or 0.35 ± 0.01 D[15] for propylene; 0.30 D[16] or 0.37 D[17] for 1-butene; 0.00 D[16] for *trans*-2-butene, and 0.33 D[18] for *cis*-2-butene. The values for liquid mono-olefins at low temperatures are not known, but they may not be very different from the above values.

16) H. Watson and K. Ramaswamy, *Proc. Roy. Soc.*, **A156**, 142 (1936).
17) C. Smith and C. Zahn, *J. Am. Chem. Soc.*, **47**, 2501 (1925).
18) J. Boggs, C. Crain and J. Whiteford, *J. Phys. Chem.*, **61**, 482 (1957).

Propylene and 1-butene are both mono-substituted terminal mono-olefins, although their electron-releasing substituents are different. *cis*-2-Butene is a di-substituted internal mono-olefin. Now, mono-olefin must polarize in order to form σ-complexes with boron fluoride. When polar, the larger the dipole moment of mono-olefin, the larger the deformation of boron fluoride, and therefore, the larger will the equilibrium constant be expected to become. To infer from the values of the dipole moments of gaseous propylene and 1-butene, liquid propylene and 1-butene may be expected to have nearly the same dipole moment value. Therefore, it is no wonder that boron fluoride-propylene and boron fluoride-1-butene systems have nearly the same equilibrium constant of the isotope. However exchange the equilibrium constant for boron fluoride-*cis*-2-butene system is larger than that for the boron fluoride-propylene and -1-butene systems even though the value of the dipole moment of liquid *cis*-2-butene is supposed to be nearly the same or a little smaller than that of propylene or 1-butene. This may be attributed to the fact that there are two electron-releasing groups in one molecule of *cis*-2-butene, while there is only one electron-releasing group in one molecule of propylene or 1-butene. Thus, it seems certain that equilibrium constant relates not only to the dipole moment but also to the steric structure of mono-olefin or the number of electron-releasing groups existing in a molecule of mono-olefin.

The boron fluoride-methyl ether complex is a very active catalyst. The methyl fluoride-boron fluoride complex, which is a less reactive catalyst, can alkylate benzene readily, since alkylation needs the presence of only such incipient carbonium as is found in the $^{\delta+}CH_3 \cdot F \rightarrow {}^{\delta-}BF_3$ complex, for example; such free carbonium ions as CH_3^+ are not required.[19] Polar mono-olefin-boron fluoride complexes do exist at low temperatures, but they do not partake in the polymerization of mono-olefin, and methyl chloride or mono-chlorodifluoro methane-boron fluoride complexes have no catalytic ability. Therefore, there should also be the following relation between the equilibrium constant and the catalytic ability of a Friedel-Crafts catalyst: the larger the former, the more active will the latter become.

Absorption Spectra.—No $T_R \leftarrow N$ absorption band of 1-butene, *cis*- and *trans*-2-butenes could be observed at the temperatures of their melting points, for the band was obscured by the long-wavelength tail of strong $V \leftarrow N$ absorption bands. Therefore, the effects of boron fluoride upon the $T_R \leftarrow N$ bands of 1-butene, *cis*- and *trans*-2-butene have been left unexamined.

In the present work, the effects of boron fluoride upon the fine structure of the long-wavelength tail of $V \leftarrow N$ bands have been examined, because the band peaks that lie in the region of wavelengths shorter than 190 mμ could not be traced by the Type 14 M Cary recording spectrophotometer used. The fine structure of the $V \leftarrow N$ bands of 1-butene dissolved in a large amount of methane at a temperature near the freezing point of the solution (approximately -170°C) is shown in Fig. 1. Since the fine structure of the V←N bands of *trans*-2-butene was indistinct, a measurement similar to the above was made on ethylene instead; the results are shown in Fig. 2.

19) H. Brown, H. Pearsall, L. Eddy, W. Wallace, M. Grayson and K. Nelson, *Ind. Eng. Chem.*, 45, 1462 (1953).

Similar measurements were also made on the absorption spectra of 1-butene and ethylene in large amounts of boron fluoride at temperatures near the freezing points of the solutions (approximately $-130°C$); these results are also shown in Figs. 1 and 2. Although the $V \leftarrow N$ bands were still observed in both cases, two points are noticeable. First, in order to obtain the same values of intensity for $V \leftarrow N$ bands at the same wavelengths, the concentration of mono-olefin must be larger in a boron fluoride solution than in a methane solution. Second, the fine structures of $V \leftarrow N$ bands, which were observed in a methane solution, disappeared in a boron fluoride solution. As for the first point, it cannot yet be determined whether the intensity of $V \leftarrow N$ bands really decreases or whether the peaks of these bands shift towards shorter wavelengths, for these peaks were not measured. At any rate, the fact is that boron fluoride influenced. the intensity or the wave number of $V \leftarrow N$ bands. As for the second point, it must be remembered that the fine structures of the absorption bands in benzene at 267 mμ disappeared when benzene formed a π-complex with hydrogen fluoride.[20] Therefore, the above two points seem to suggest the complex formation of boron fluoride with 1-butene and ethylene.

However, in the preceding work, experiments on isotope effects showed that ethylene cannot form a σ-complex with boron fluoride. Hence, the complex formed with ethylene is concluded to be an unstable π-complex:

trans-2-Butene may also form a π-complex:

On the other hand, 1-butene, and perhaps propylene and *cis*-2-butene too, may form both σ-complexes and π-complexes.

In the polymerization isomerization and other reaction of olefins by boron fluoride catalysts, the σ-complexes found by us are not the intermediate products, and the σ-complex formation proceeds parallel with these reactions, as has been explained in the preceding work. No doubt these reactions occur through the actual transfer of protons to mono-olefins to form such ions as $R-{}^{+}CH-CH_3$, and the rates of the reactions are proportional to the stability of the ion. No doubt, it can be taken for granted that these reactions proceed through π-complexes, yet needless to say, the rate-determining step in these reactions does not involve the initial formation of π-complexes as is in the case of aromatic substitution.[21]

Summary

The equilibrium constants of isotopic exchange between boron fluoride gas and boron fluoride in 1-butene and *cis*-2-butene solutions have been found to be 1.017 ± 0.002 and 1.020 ± 0.002 at $-112°C$, and 1.012 ± 0.002 and 1.015 ± 0.002 at $-95°C$. In boron fluoride-*trans*-2-butene system, the equilibrium constant is 1.011 ± 0.002 at $-112°C$ and 1.006 ± 0.002 at $-95°C$.

When 1-butene and ethylene are dissolved in liquid boron fluoride, the intensity or the wave number of the $V \leftarrow N$ absorption bands in mono-olefins is changed and the fine structure of these bands disappear.

Thus, the following conclusion, more decisive than that of the preceding work, has been obtained:

Boron fluoride can form liquid σ-complexes with polar mono-olefins with electron-releasing substituents. On the other hand, with non-polar mono-olefins it cannot form σ-complexes but only unstable π-complexes. Although σ-complexes are not the intermediate products in reactions by boron fluoride catalysts, it is possible that these reactions proceed through π-complexs. However, the rate-determining step does not involve the initial formation of π-complexes.

It has also been suggeted that the equilibrium constant may be proportional to the ratio of dative to no-bond structure in the complex, and it has been found that the larger the equilibrium constant, the higher become the stability and the catalytic activity of the complexes.

The Electrokinetic Potential of Sparingly Soluble Salts

By Tetsuo MORIMOTO

(Received August 16, 1963)

Investigations concerning the dispersion of particles have been made in this laboratory by measuring the sedimentation volume of sparingly soluble salts in electrolyte solutions.[1] Actually the sedimentation volume of precipitated salts changes widely upon the addition of ions to water in which the particles are suspended. This fact suggests that the preferential adsorption of ions on the solid-liquid interface may result in the variation of charge density on it. The electrical charge on solid particles is the only cause of the repulsive force between them,[2] having been also the essential factor for interpreting the stability of hydrophobic colloids. The origin of the surface charge is, however, still obscure. In order to clarify, therefore, the surface charge or the electrokinetic potential and the origin of ionogenic substances, the present work has been carried out for barium sulfate, barium chromate, lead sulfate and lead chromate. For these purposes, two different samples of each salt were prepared, in each of which one of the two component ions of the precipitated salts were used in excess.

Also, the effects of the lattice ions and some non-lattice ions on the electrokinetic potential of the precipitated salts have been examined. Experiments have been carried out along lines analogous to this study by Reyerson et al.[3] and Buchanan and Heymann,[4] who investigated principally the charge of barium sulfate. Reyerson et al. report a negative charge on barium sulfate in water, while the result of Buchanan and Heymann is the reverse. It is, however, found in the present work that most of the precipitated salts tested may represent either a positive or negative charge in water according to the method of preparing the sample. Furthermore, a few measurements were carried out on the electrokinetic potential of the crystal surfaces in a solution containing two electrolytes, giving some information about the preferential adsorption of ions. It is also noticeable that some phosphates have a serious effect on the charge of the solid surface, as a citrate does.

Experimental

Materials.—All the materials used in this experiment were prepared by means of precipitation reaction; e. g., barium sulfate was prepared by allowing 1M barium chloride and 1M sodium sulfate to mix while being vigorously stirred in water heated at 80°C. The other materials were precipitated in the same manner except for different temperatures: barium chromate was prepared from barium chloride and potassium chromate at 60°C, lead sulfate from lead nitrate and sodium sulfate at 30°C, and lead chromate from lead nitrate and potassium chromate at 30°C. The precipitated salts were washed with water by repeating the decantation and filtration for a few months, until the electrical conductivity of the supernatant liquid attained a lower limiting value. Finally, the salts were washed with pure ethanol and dried at 110°C for several hours. Two different samples of each salt were provided in which either component ion was used in a 5% excess over the other when the salts were prepared.

Electrokinetic Measurements.—To determine the electrokinetic potential, the streaming potential method was used. The cells for the streaming potential measurement were almost the same as those described by Gortner[5] and by Reyerson et al.[3] In order to prevent the polarization of electrodes, the perforated platinum electrodes were substituted for by a reversible electrode, Ag-AgCl.[6] This device made it possible to develop the stable streaming potential between the electrodes. The precipitates were packed directly between the electrodes.

To develop a streaming potential, the solution was forced to flow through the diaphragm under a given pressure from one reservoir to the other. The nitrogen was used to maintain the pressure needed for the streaming potential measurement. The streaming potentials developed were measured by the vacuum-tube potentiometer with a highly sensitive galvanometer attached. Besides the measurement of the streaming potential, it was necessary to measure the specific conductance of the solution in the pores of the diaphragm. A sensitive conductance bridge was used satisfactorily for this purpose, and the cell constant was determined in each packed diaphragm by using a 0.01M

potassium chloride solution. From the measurement of the streaming potential developed, the specific conductance of the liquid in the diaphragm, and the pressure applied to force the liquid to flow, it was possible to calculate the electrokinetic potential (ζ-potential) from Helmholtz-Smoluchowski's equation:

$$\zeta=\frac{4\pi\eta\kappa E}{DP} \quad (1)$$

where E is the streaming potential; κ, the specific conductance of a liquid in the diaphragm; P, the pressure driving the liquid; η, the viscosity of the streaming liquid, and D, the dielectric constant of the liquid. In any given run the linear relationship between E and P was checked, because the leakage of precipitated substances from a diaphragm might cause a deviation from linearity. Practically, the gradient of the straight line obtained by plotting E against P, was used for calculating the electrokinetic potential. It is shown by Eq. 1 that the greater the specific conductance of a solution, the less the streaming potential develops and, accordingly, the greater the experimental error, in a system consisting of one solid and one liquid. At a higher concentration of an electrolyte, therefore, the streaming potential measurement is difficult. In the present work the upper limit of the electrolyte concentration capable of the measurement was about 0.02N.

Results and Discussion

Electrokinetic Potentials in Water.—The ζ-potentials obtained on sparingly soluble salts in water are presented in Table I. Most samples studied have a charge of the same sign as that of the lattice ions used in excess when the sample was prepared; e. g., the ζ-potential of barium sulfate prepared from excess barium ions is 11.2 mV., while that of the sample prepared from excess sulfate ions is −6.10 mV. It is often described how the ζ-potential of such ionogenic substances as silver iodide is greatly affected by the adsorption of ions, especially that of lattice ions.[7] Accordingly, it is plausible that, if the one component ions of the substance are present in excess when the substance is formed, the surface lattice points occupied by the ions will be increased in number compared to those occupied by the other component ions. The present results not only prove the above statement to be valid, but also establish the great persistence of the ions against washing. Therefore, we may generally conclude that the surface of an ionogenic substance has a charge of the same sign as that of the ions used in excess on its preparation.

Table I. ζ-Potentials of sparingly soluble salts in water

Substance	Reactant used in excess	mV.
$BaSO_4$	$BaCl_2$	+11.2
	Na_2SO_4	− 6.10
$BaCrO_4$	$BaCl_2$	+10.2
	K_2CrO_4	− 7.75
$PbSO_4$	$Pb(NO_3)_2$	+16.0
	Na_2SO_4	+ 7.00
$PbCrO_4$	$Pb(NO_3)_2$	+25.7
	K_2CrO_4	−15.1

Lead sulfate is an exception. In the case of lead sulfate, the two samples have a positive charge irrespective of the method of preparing them; the ζ-potential is 16.0 mV. on the sample prepared from excess lead ions and 7.00 mV. on the sample prepared from excess sulfate ions. According to the experiments carried out in more detail in our laboratory,[8] the charge of lead sulfate appears to be always positive in water, regardless of such conditions of preparation as the kind of reagents and the pH value of the reacting solutions.

In Table II the solubilities of all the samples studied in this experiment are presented.[9] The solubility of lead sulfate is the greatest of those of the four salts, while that of lead chromate is the least. Because of this relatively larger solubility of lead sulfate and the extremely small solubility of lead hydroxide,[10] it is conceivable that the surface of lead sulfate crystals is hydrolyzed partially in water to produce lead hydroxide. Considering the fact that most metal hydroxides have a positive charge in water,[11] one can understand the fact that the surface of lead sulfate crystals has a positive charge. This, however, does not occur on the surface of a lead salt with so small a solubility as lead chromate.

Table II. Solubilities of sparingly soluble salts in water (25°C)[9]

Substance	$BaSO_4$	$BaCrO_4$	$PbSO_4$	$PbCrO_4$*
Solubility (mol./l.)	1.25×10^{-5}	1.64×10^{-5}	14.8×10^{-5}	0.053×10^{-5}

* The value obtained at 20°C.

The Electrokinetic Potential in an Electrolyte Solution.—As has been described above, it is seen that the lattice component ions which were used in excess on preparation have a pronounced effect on the surface of ionogenic

substances. Similarly, it is expected that when the lattice ions are added to the water with which the surface of the salt crystals comes in contact, they will have a great influence on the surface charge. In the preliminary experiments, by using samples charged both positively and negatively in water, the effect of barium ions on the ζ-potential of barium sulfate was tested. It was thus found that the ζ-potential curves were nearly parallel to each other, independently of their initial ζ-values. This was the case also with the effect of sulfate ions. Hence, in this series of experiments, one kind of sample for each material was chosen. The results obtained are shown in Figs. 1—4. As expected, it is seen that the lattice ions have a great effect on the surface charge of the precipitated salts. The barium ions, even at an extremely small concentration, charge barium sulfate, which originally has a negative charge, positively. After that the ζ-value increases with the increasing concentration of barium nitrate to a limiting value of 45 mV. Sodium sulfate increases the negative charge of barium sulfate, but the change in ζ-potential caused by sulfate ions is much less than that caused by barium ions.

The results obtained in this work agree well with those of Reyerson et al.[3] and Buchanan and Heymann[4] in that barium ions affect barium sulfate more pronouncedly than sulfate ions, irrespective of the ζ-value in water. Furthermore, Reyerson et al. concluded that barium ions act peptizingly and sulfate ions coagulatingly on barium sulfate. In our laboratory it has been found that the sedimentation volume of barium sulfate decreased steeply in the presence of barium ions, whereas no great changes occurred in the solution of sulfate ions.[1] These phenomena may be explained in terms of the change in ζ-potential.

The behaviors of barium ions and chromate ions for barium chromate are quite similar to those of barium ions and sulfate ions respectively for barium sulfate. On lead sulfate, however, both lead ions and sulfate ions have a very weak effect compared to that of barium ions on barium sulfate. It is, therefore, characteristic that the initial part of ζ-potential curves increases or decreases slowly. Also, the limiting ζ-values are only +20 mV. and −20 mV. respectively. On the contrary, the change in the ζ-potential of lead chromate by lead ions and chromate ions is very large; the ζ-value increases from −15 mV. to +25 mV. in the presence of lead ions and decreases from −15 mV. to −70 mV. in the presence of chromate ions. In this case, the effect of chromate ions is nearly equal to or slightly greater than that of lead ions. The only previous finding concerning the ζ-potential of lead chromate, obtained by Reyerson et al.,[3] shows fairly good agreement with the present finding. Certainly the fact that the sedimentation volume of lead chromate is more decreased in the presence of chromate ions than in the presence of lead ions, must be related closely to the ζ-potential change.

It is strange that, on barium sulfate and barium chromate, the lattice cations, barium ions, have a more serious effect than the anions, while on lead chromate the lattice anions, chromate ions, have the more serious effect. Generally, the adsorbability of ions on a polar solid surface from a solution depends largely upon their hydrating tendency

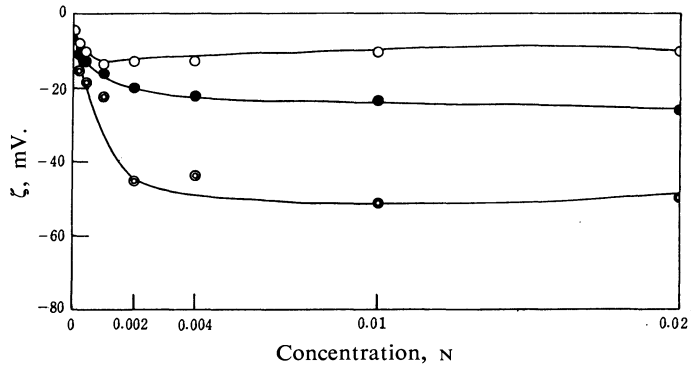

Fig. 5. ζ-Potentials of $BaSO_4$ in Solutions of phosphates and KOH.
○ KOH ● Na_2HPO_4 ◎ $Na_5P_3O_{10}$

○ KOH ● Na_2HPO_4 ◎ $Na_5P_3O_{10}$

and on their valency; the stronger the tendency, the less the adsorbability. However, the solids have also their own problems. As is shown in Table II, there are large differences in solubility among the materials used. The solubility decreases in the order: lead sulfate > barium chromate, barium sulfate > lead chromate. The variation of the potential is, however, just the reverse. Buchanan and Heymann[4] reported a similar tendency when strontium sulfate, lead sulfate and barium sulfate are used. Thus we may conclude that the smaller the solubility of the ionic crystal, the greater the effect of lattice ions on its surface. Really the variation in the ζ-potentials of lead chromate upon the addition of lead or chromate ions amounts to 50 mV., whereas that of lead sulfate upon the addition of lead or sulfate ions is only 20 mV.

At the surface of a crystal having a smaller solubility, the electrical double layer is possibly constructed more definitely than at the surface of a crystal having a larger solubility. When the solubility of a solid is large, the lattice ions will be diffused in large quantities across the electrical double layer, bringing about the agitation of the double layer; therefore, the fixation of ions on the "fixed layer" occurs only with difficulty. Of course, on such a solid surface the adsorption of indifferent ions also becomes difficult.

The interactions of a salt with its lattice ions, should be considered to cause partially the incorporation of the ions with the solid surface simultaneously with their adsorption on the fixed layer. Lead chromate shows well-defined prism-shaped crystals under an electron microscope.[1] The surface of well-defined crystals will be favorable for producing the streaming potential corresponding to the charge in the diffused layer of an electrical double layer as compared with an irregular surface, because little turbulences occur. The large change in the ζ-value of lead chromate may be partially due to this reason.

The Effect of Foreign Ions.—Sodium citrate has a remarkable effect on the ζ-potential of barium sulfate and lead chromate, as Figs. 1 and 4 show, in accordance with the results of Reyerson et al.[3] Apparently, on barium sulfate the effect of sodium citrate is much greater than that of sodium sulfate, whereas

on lead chromate it is less than that of potassium chromate. Because of the possibility of forming a complex of citrate ions with barium ions,[12] citrate ions will be adsorbed strongly onto the surface of barium sulfate.

By using sodium citrate and the lattice ions of barium sulfate, the effect of mixed electrolytes on the ζ-potential of barium sulfate was investigated, as is shown in Fig. 1. In these cases, the concentration indicated in abscissa should be read as that of each electrolyte present, so that the equal equivalents of the two electrolytes were dissolved in a solution. The ζ-potential curves of barium sulfate in these two solutions represent an almost identical development over all the range of concentration examined. As has been described above, the effect of sodium citrate on the ζ-potential of the barium sulfate crystal is greater than that of sodium sulfate. In the solution containing these two electrolytes together, the ζ-potential curve of barium sulfate initially goes parallel with the curve obtained in the presence of sodium citrate only, arriving at a limiting value. After that it rises, differing substantially from the effect of sodium citrate only. This means that, because of the stronger adsorption of citrate ions, it excels the adsorption of sulfate ions at smaller concentrations, but at increased concentrations sulfate ions also take part in the adsorption on the fixed layer, together with citrate ions, causing a considerable decrease in the negative ζ-potential of barium sulfate. Even when we use barium nitrate and sodium citrate as mixed electrolytes, the results are almost the same. The resultant ζ-potential rises more steeply after the attainment of the minimum than in the former case, but it does not exceed the isoelectric point. In any case, it is characteristic of the adsorption of ions from a mixed electrolyte solution that the preferential adsorption of the ion affecting more strongly occurs at lower concentrations. The sedimentation volume of barium sulfate measured in these mixed electrolyte solutions decreases initially, attains a minimum, and then rises, corresponding to the change in the ζ-potential.[13] In a solution of sodium citrate only, however, the sedimentation volume of barium sulfate remains almost constant after attaining a limiting value, corresponding to the change in the ζ-potential. This fact is positive evidence that the ζ-potential is responsible for the change in the sedimentation volume of powders. Although one can expect a similar conclusion concerning the ζ-potential of lead chromate in mixed electrolyte solutions, it was impossible to observe this because the extremely small solubility of lead citrate does not permit both lead ions and citrate ions to coexist at the concentrations used here.

Recently studies of the properties of various phosphates which differ in degree of polymerization have been carried out. If they are used on surface phenomena, it may be expected that they will behave as polyelectrolytes. In the present work, phosphates of a lower degree of polymerization were used, along with potassium hydroxide, to investigate the effect on the surface charge of barium sulfate and lead chromate. As shown in Fig. 6, triphosphate, orthophosphate and hydroxyl ions all seriously decrease the ζ-potential of lead chromate. It is peculiar that hydroxyl ions have a large effect in this case, probably because of their greater adsorbability arising from the extremely small solubility of lead hydroxide. For barium sulfate, three kinds of ions affect it differently: the effect of triphosphate is the greatest, as it is for lead chromate, while that of orthophosphate is moderate and that of hydroxyl ions, very small as is shown in Fig. 5. It appears that there are differences between the adsorbabilities of various phosphates corresponding to their polymerization degrees, and that the higher the polymerization degree, the stronger the adsorbability. The detailed observation of the effect of such a series of phosphates on surface properties is a problem for future study.

Summary

1) The ζ-potentials of such sparingly soluble salts as barium sulfate, barium chromate, lead(II) sulfate and lead(II) chromate have been measured in water by means of the streaming potential method. Most samples prepared by using either lattice ion in excess have a charge of the same sign as that of the ion. This suggests that the lattice ions occupy many more lattice points on the surface than do other ones, and that it is difficult to remove them by washing. One exception is lead(II) sulfate, in which the ζ-potentials of the two samples are positive. This seems to depend on the surface hydrolysis of lead(II) sulfate.

2) The ζ-potentials vary widely also when the lattice ions are added to water. The effect of both lattice ions are the greatest on lead(II) chromate and the least on lead(II) sulfate.

12) J. Schubert and J. W. Richter, *J. Am. Chem. Soc.*, **70**, 4259 (1948).

13) T. Morimoto, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **81**, 74 (1960).

14) The solubility of lead citrate is 0.05344 g./100g. (25°C), cf. Ref. 9.

The solubility of the solids is an important factor affecting the variation of ζ-potentials when the lattice ions are added.

3) In order to investigate the effect of the mixed electrolyte solution on the ζ-potential of barium sulfate, sodium citrate, which has a remarkable effect by itself, has been mixed with sodium sulfate or barium nitrate. The resultant ζ-potential curves show a definite minimum, which demonstrates that, although the adsorption of citrate ions excels that of sulfate or barium ions at smaller concentrations, the latter become comparable to the former at larger concentrations.

4) The surface chemical action of triphosphate and orthophosphate ions has been tested. As expected, the higher the polymerization degree of phosphates, the larger the effect on the charge of solid surfaces.

The author wishes to express his deep appreciation to Professor Masaji Miura of Hiroshima University for his valuable advice and encouragement, and to Mr. Masashi Sakamoto for his assistance in this work.

The Heat of Immersion of Aluminum Oxide in Water

By Tetsuo MORIMOTO, Koichi SHIOMI and Hiroshi TANAKA

(Received December 6, 1963)

It has been reported by several authors[1-4] that various silicas show a maximum in the temperature range of 200 to 300°C in the curve of the heat of immersion in water vs. the outgassing temperature. Two theories have been proposed to explain this phenomenon. According to one theory, the hydroxyl groups on the surface of silica samples form hydrogen bonds with water molecules upon immersion. Most of the heat evolved upon immersion is thus due to the hydrogen bonding energy; the highest concentration of surface hydroxyl groups brings the maximum in the heat of immersion. At temperatures higher than 300°C condensation of the surface hydroxyl groups occurs, converting silanol groups to siloxanes, which are not rehydrated easily on immersion in water; consequently, the heat of immersion decreases. On the other hand, at lower temperatures the surface hydroxyl groups are partly covered by some amount of water molecules adsorbed physically, so that the heat becomes less.[1,2]

According to another theory, the condensation of surface hydroxyl groups proceeds with heat treatment, forming a siloxane surface which, on immersion in water, reproduces the hydroxyl groups by a reverse reaction. The immersion heat increases as the dehydration proceeds with the heat treatment. When the temperature of the treatment rises further, the siloxane surface formed is stabilized and becomes difficult to be rehydrated; therefore, the heat of immersion decreases.[3,4]

In these two explanations it may be seen that the existence and behavior of surface hydroxyl groups play an important role. Also, from the viewpoint of catalytic action, the behavior of the surface hydroxyl groups on metal oxide is important. The present investigation will deal with the behavior of the surface hydroxyl groups on alumina by measuring the heat of immersion in order to compare it with that of those groups on silica samples and to test the validity of the two explanations mentioned above in the case of alumina samples.

Experimental

Samples.—The samples studied were α- and γ-alumina. The former, made by the Showa Denko Co., was washed with 4 N hydrochloric acid and then with water until the value of the electrical conductance of the mother liquor became that of water, while the latter was prepared by calcining, at 550°C in air, gibbsite, which was supplied by

the Showa Denko Co., and then washing it with water in a way similar to that used for the former. X-Ray investigations showed that the latter is amorphous, while the former gives the α-form. Just prior to the immersion measurement, the sample was outgassed in a glass ampoule for 4 hr. at a given temperature in a vacuum of 10^{-4} mmHg, and then sealed off. When the pretreatment was carried out above 500°C, silica ampoules were used.

Immersion Measurement. — The heat evolved upon the immersion of the sample in water was measured by a precision calorimeter equipped with a thermistor as a temperature-sensing element.[5,6] The galvanometer reading was calibrated by supplying a given electrical energy through a constantan wire of about 50 Ω. In the course of the measurements of the immersion heat, the slow heat evolution described by Guderjahn et al.[7] has never been detected; rather, the evolution of heat was extinguished in just a few minutes. All the measurements were carried out at 25±0.01°C.

Surface Area Measurement.—The B. E. T. surface areas were measured by nitrogen adsorption. The surface area of α-alumina was constant (1.91 m^2/g.), independent of the outgassing temperatures employed here, while the area of γ-alumina was almost constant to 600°C and then decreased with the further rise in the outgassing temperature above 600°C, as Fig. 1 shows.

Water Content. — The water content of the samples was determined as follows: the water vapor generated by the heat treatment of the

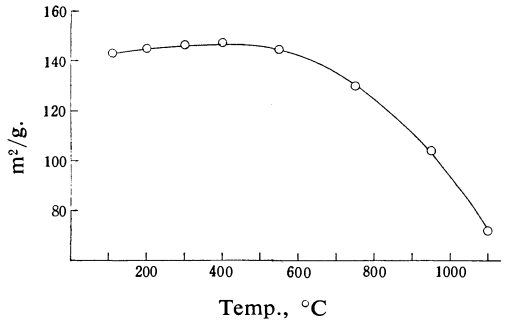

Fig. 1. Temperature variation of the specific area of γ-Al_2O_3.

samples in an evacuated apparatus was gathered in a trap cooled at the boiling point of nitrogen, and then the volume of the vapor reevaporated at room temperature was measured volumetrically. In order to raise the sensitivity of the pressure reading, an oil manometer was used. The measurements were carried out at 100°C temperature intervals from 300 to 1100°C, keeping the sample at each temperature for 4 hr.

Results and Discussion

The findings on the immersion heat of alumina in water are shown in Fig. 2. The heat of immersion of α-alumina, like that

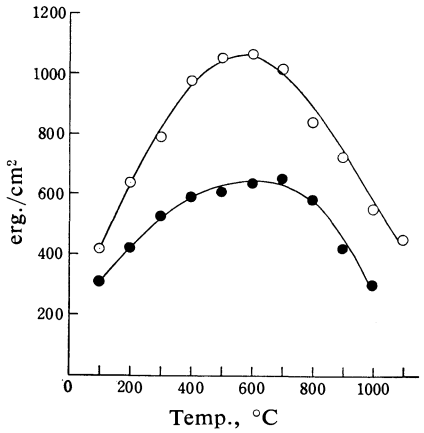

Fig. 2. Immersion heat vs. outgassing temperature curve of Al_2O_3.
○ α-Al_2O_3 ● γ-Al_2O_3

of γ-alumina, increases to a maximum value and then decreases as the outgassing temperature is raised. This phenomenon was also found in the case of silica, as has been mentioned above. It may be seen, however, that there are two remarkable differences between the immersion heat curve of silica and that of alumina. First, the absolute values of the heat of alumina are much greater than those

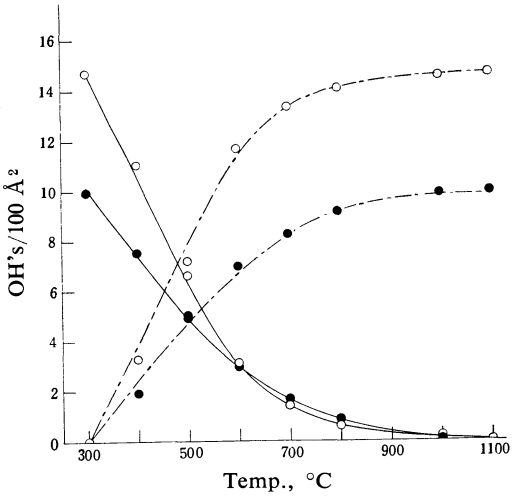

Fig. 3. Temperature variation of the dehydration amount and the water content of Al_2O_3.
○ α-Al_2O_3 ● γ-Al_2O_3
------ dehydration amount
—— water content

of silica, and, second, the outgassing temperature at which the heat of immersion of alumina showed a maximum is 600 to 650°C, much higher than that (200~300°C) in the case of silica. This latter fact suggests that the bonding energy of aluminol is remarkably large. Wade and Hackerman[8] could not find such a maximum on alumina since they treated alumina only to 450°C.

The amounts of dehydration and the water contents of alumina are given in Fig. 3. Since the degassed amounts of both α- and γ-alumina from 1000 to 1100°C were negligible, the water contents at various temperatures were calculated by assuming the value at 1100°C to be zero. Furthermore, assuming that the dehydrated water arises from the condensation of surface hydroxyl groups, the numerical value of these amounts was expressed in OH's/100Å^2. It may be seen from these curves that the water contents of alumina decrease steeply from 300 to 600°C, followed by a slow dehydration up to 1100°C.

Crystallographic data show that the surface layer of α-alumina consisting of the closest packing of oxygen ions contains 19 O^{2-}/100Å^2, as was calculated by Wade and Hackerman.[8] If all the oxide ions are hydrated normally, the same number of hydroxyl groups will be formed; this can be compared to 8 OH's/100Å^2 for the silica surface.[9] All the figures obtained as the water contents of alumina above 300°C are less than this value. Moreover, it is known that physically-adsorbed water molecules on solid surfaces can be removed by heating them up to 200~250°C.[1,10] In view of these circumstances, it is plausible to consider that the water vapor which was generated above 300°C had been bound chemically on the surface, forming surface hydroxyl groups. The water content of samples decreases linearly from 300 to 600°C, while, on the other hand, the immersion heat of the same samples increases linearly in the same temperature range. It may be considered from these observations that, on the samples treated in such a temperature range, the rehydration of dehydrated sites on the surface occurs easily on immersion in water, accompanied by the evolution of hydration energy. The appropriateness of this consideration seems to be supported by the following fact: in such a temperature range the increase in the immersion heat of α-alumina, in which the decrease in water content is more marked, is steeper than in the case of γ-alumina, in which the decrease in water content is less. In this range of outgassing temperature, surface hydroxyl groups, aluminoles, will be regenerated reversibly from dehydrated sites on immersion in water. Therefore, one can calculate the heat of hydration from the amount of dehydration and the immersion heat. Figure 4 shows the relation between the immersion heat and water

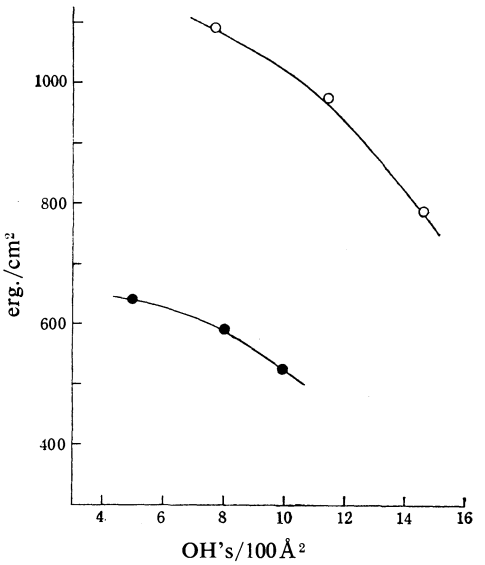

Fig. 4. Immersion heat vs. water content curve of Al_2O_3.
○ α-Al_2O_3 ● γ-Al_2O_3

contents in this temperature range. Regarding each of these curves as straight near the end, the heats of hydration on the surfaces of α- and γ-alumina can be calculated as 15.8 and 9.60 kcal./mol. water respectively. These values are several times greater than those obtained on the surface of silica samples[4] and are a little greater than the values known as the energy of hydrogen bonds.

When the outgassing temperature exceeds 600°C, the immersion heat begins to decrease, probably because of the stabilization of the dehydrated product, aluminoxane, produced on the surface. It may be seen from these discussions that the immersion phenomenon of alumina in water can be explained by the theory of rehydration, which is the second one of the two mentioned above. However, it is surprising that the immersion heats of the samples treated at 1100°C, on the surface of which the water contents are regarded as zero, are fairly large compared with those on silica samples.[1-4]

This fact seems to suggest that the wetting

8) W. H. Wade and N. Hackerman, *J. Phys. Chem.*, **64**, 1196 (1960).
9) R. K. Iler, "The Colloid Chemistry of Silica and Silicates," Clornell University Press, Ithaca, N. Y. (1955).
10) W. H. Wade and N. Hackerman, *J. Phys. Chem.*, **63**, 1639 (1959).

of the surface of aluminoxane should be considered significant. In order to solve the problem of the wetting degree of the aluminoxane surface or, in other words, the problem whether or not the rehydration of the aluminoxane surface is significant in the sample treated at 1100°C, the kinetic study of the hydration is needed for alumina samples. The heats of immersion of α-alumina are considerably greater than those of γ-alumina. Some authors have pointed out that the immersion heats of the amorphous silica in water are less than those of crystalline silica.[1,11] The reason for this phenomenon remains unclear. The strength of the bonding force of surface radicals with water molecules is, however, probably an important factor, in addition to the concentration of the surface radicals.

Summary

1) The surface properties of two kinds of alumina have been studied by measuring the immersion heats and the water contents. The heat of immersion of alumina showed a maximum at about 600~650°C, which is considerably higher than the 200~300°C of silica, and the heat values were much greater than those of silica.

2) It has been concluded that the rehydration process of dehydrated sites plays an important role in the case of the immersion of alumina in water. The heats of hydration calculated from the immersion heats of α- and γ-alumina were 15.8 and 9.60 kcal./mol. water respectively.

The Diamagnetic Study of the Nature of Association in Acetic Acid

By S. Sriraman and V. Shanmugasundaram

(Received September 25, 1963)

A great deal of work has been done on the magnetic study of liquid mixtures, but comparatively very little work has been done on the influence of the hydrogen bond on the diamagnetism. The earliest report on this subject was by Angus and Hill,[1] who studied substances capable of forming a hydrogen bond in order to ascertain whether the formation of such bonds could be detected by magnetic methods. They confined their investigations to very dilute solutions. Their results showed that the formation of hydrogen bonds involving a ring closure decreases the susceptibility value. Ananthakrishnan and Varadachari,[2] on the basis of a critical analysis of the results on the subject, concluded that the formation of hydrogen bonds in certain cases where multiple linkages are involved should increase the susceptibility value. When Venkataramiah[3] studied the susceptibility of alcohohols in various solvents, his results indicated an increase in diamagnetism when the hydrogen bond is ruptured. However, the investigations of some organic compounds by Rumpf and Seguin[4] seem to show that no appreciable change occurs in the formation of hydrogen bonds. Later Venkateswarlu and Sriraman[5] studied the changes of susceptibility when benzoic, cinnamic, salicylic, and acetic acids are dissolved in a number of solvents with widely different proton-coordinating powers. Their results are in accordance with those of Angus and Hill.[1] Recently Deshpande and Pathki[6] studied magnetically acetic acid dissolved in pyridine at different concentrations. From their results they concluded that the maximum departures from the additive value at certain concentrations are due to the formation of complexes at those concentrations and that the formation or rupture of a hydrogen

bond does not by itself appreciably affect the susceptibility value. In view of these divergent conclusions by different workers, it was considered desirable to study in detail some compounds in which the hydrogen bond is known to exist predominantly. Acetic acid, one such typical substance, has been chosen for study in the pure and dissolved states.

Experimental

The purification of the acid and the solvents was generally based upon the methods given by Vogel[7] and was continued until the acid and the solvents gave physical constants in good agreement with previously recorded values.

The susceptibility measurements were made by the Gouy method, using a large Pye magnet. The field strength had a range from 12 to 14 k. gauss for the different field currents used. For every measurement, observations were made with two experimental tubes of different cross-sections for the three field currents. Assuming the influence of the vapour to be negligible, the susceptibility values have been corrected for residual air in the space above the liquid by the manner described by Rao and Narayanaswami.[8] The densities of the liquids were found with a special type of stoppered, specific-gravity bottle assuming the density of water to be 0.9951 g. cm^{-3} at 32°C.

Results

The specific susceptibility values of the pure liquids and mixtures studied at different concentrations are given in the table with an experimental accuracy of ±0.5%. For mixtures, the χ values, calculated on the basis of the additive law, are also given. The values of χ are plotted against the weight fraction in Fig. 1. If χ_1 and χ_1' are the specific susceptibility values of the acetic acid in its pure and dissolved states respectively, and w_1, its weight fraction, then, according to Angus and Tilston ;[9]

$$\chi_1' - \chi_1 = \frac{\chi_{(observed)} - \chi_{(additive)}}{w_1} = \frac{\Delta\chi}{w_1}$$

These values are calculated and plotted against the mole fraction in Fig. 2.

Discussion

It has been generally assumed by earlier workers[5,10] that acetic acid in the pure liquid state exists in a cyclic hydrogen-bonded dimer. However, the existence of a non-zero dipolemoment indicates that a portion of the dimeric units should be non-cyclic. Pohl et al.,[11] on the basis of their studies of electric polarisation, concluded that chains of molecules are also present. Recent studies relating to the mechanism of association in acetic acid by the Raman effect,[12] the dipole moment,[13] and proton magnetic resonance[14] reveal that the

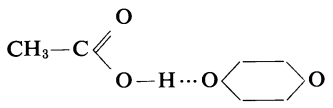
* All the susceptibility values in this paper are expressed in 10^{-6} c.g.s. units.

association is a mixture of non-polar dimer association and polar chain association.

When acetic acid is diluted with non-interacting solvents, such as benzene, toluene, cyclohexane, and carbon tetrachloride, there is no possibility of the formation of hydrogen bonds between the solute and solvent molecules; any deviation from the additive law should arise only from the change in the mechanism of association of the acetic acid molecules. The results obtained for these mixtures in Fig. 1 show that the χ values of



mixtures are strictly additive up to nearly equimolecular proportions; then a regular diminution of χ values occurs on further dilution.

The formation of hydrogen bonds between the hydrogen and carbonyl groups can be considered to be due to an electrostatic force, and the presence of such a force can be considered as equivalent to an electric field between the two groups and its contribution to the diamagnetism, to be paramagnetic. Therefore, the rupture of the hydrogen bond should give an increased χ value of the molecule. It is clear that the monomeric form of the acetic acid molecule should have a higher susceptibility value than the associated form.

The decrease in $\Delta\chi/w_1$ values at dilutions beyond equimolecular proportions can be explained in terms of polymer-dimer equilibria. The hydrogen bonds in the polar chain polymers are weaker than those in closed dimers. The effect of dilution is to break the polymers into monomers. The monomers are strongly polar and could not have stability as such. Hence, they probably combine to form closed dimers. The progressive diminution of $\Delta\chi/w_1$ in Fig. 2 at a higher dilution evidently indicates the progressive formation of ring dimers since such a formation of closed rings should result in a decrease in χ value.[1,5,15] The studies of the dilution shift of the proton resonance signal of the -OH group of acetic acid by Reeves and Schneider[14] indicate a shift to the low field up to a 0.1 mol. fraction of the acid and explains it as arising from the formation of dimers. The higher value of χ obtained by Deshpande and Pathki[6] for all the concentrations in an acetic acid-pyridine mixture has been explained as arising from the stabilization of monomers, even at a higher concentration. However, our results indicate positively that monomerization does not take place, even up to a 0.1 mol. fraction in solutions of non-interacting solvents.

Dioxan and ethyl acetate, both with powerful anionoid centres, are capable of breaking down the molecular aggregates of acetic acid.[5,10] When acetic acid is diluted with these solvents, there is a marked increase in χ at the initial dilutions but a regular decrease (Fig. 1) on further dilution. In these solutions the competition of the solvent molecule as a hydrogen-bonding base causes the dissociation of acetic acid dimers also. Therefore, even at a very low dilution the formation of a strong hydrogen bond of the hetero-molecular type is highly probable. This breaking of the non-polar dimeric units of acetic acid by donor solvents like acetone has been suggested by Huggins et al.[16] from the proton magnetic resonance study of these mixtures. The replacement of the -OH doublet of the cyclic dimer by a diffuse band in the Raman spectra of an acetic acid-dioxan mixture has been explained by Batuev[12] as being due to the breaking of ring dimers and to the formation of hydrogen-bonded chain complexes between acetic acid and dioxan. The contribution of this type of complex formation to the magnetic susceptibility may be in two forms: (1) an increased diamagnetism brought about by the release of constraints upon the breaking of the dimers, or (2) a paramagnetic contribution arising from the formation of a strong hydrogen bond with the solvent molecule. The observed increased value of χ on the initial dilution of the acid by dioxan and ethyl acetate may be the net effect of these two contributions.

The $\Delta\chi/w_1$ value of these mixtures at a high dilution causes a negative deviation (Fig. 2). The results are best explained in these cases with the predominant occurrence of a strong hydrogen-bonded addition compound of donor solvents with a monomeric acid molecule, as is shown below:

Batuev's report[17] of the complete disappearance of the lines at 1668 and 1710 cm^{-1} characteristic of C=O in ring dimers and coordinated C=O respectively, lines which appeared in the Raman spectrum of pure acid, and of the exclusive appearance of the line (1740 cm^{-1}), which is characteristic of the C=O free from a hydrogen bond, with an increased intensity in weak dioxan solutions lends support to the above argument.

Summary

The magnetic susceptibilities of acetic acid in the pure and dissolved states have been investigated, and the results obtained have been attributed to the changes that take place in the association of acetic acid molecules.

Electron Microscopic Study of the Dehydration of Brucite and the Recrystallization of Periclase upon Further Heating

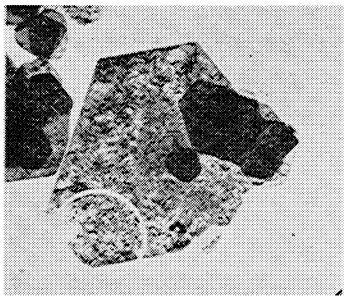
By Goro YAMAGUCHI and Toshio TOKUDA

(Received August 2, 1963)

A number of investigators have studied the transformation of brucite to periclase through dehydration. Büssem and Köberich[1] showed that the periclase crystallites produced from brucite by dehydration were oriented in such a way that (111) of the periclase is parallel with (0001) of the brucite. Goodman[2] investigated the transformation process with an electron microscope. He decomposed the brucite crystals by electron bombardment and took sets of an electron micrograph and a corresponding diffraction photograph at various stages of the bombardment. He concluded that, in the decomposition process, the small shrinkage in the basal plane of the brucite took place first, and then the collapse of the planes downward to the original [0001]. Ball and Taylor[3] proposed the existence of a spinel-like intermediate phase, $Mg_3(OH)_2O_2$, between brucite and periclase after an X-ray analysis of natural brucite. In order to explain the spinel-formation process, he suggested an inhomogeneous dehydration, instead of a homogeneous dehydration. Recently Anderson and Horlock[4] investigated the dehydration process of natural brucite and found that the dehydration proceeded from the edge of the crystal toward the center, that no spinel-like intermediate was found, and that similar lattices of magnesium hydroxide and magnesium oxide-like intermediate, with only slightly different sizes, could be recognized.

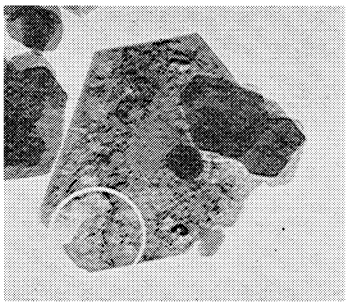
In the present work the brucite crystals obtained by the hydrothermal treatment of chemically-pure magnesium hydroxide will be used to get rid of as much effect of impurities as possible.

Experimental



The Preparation of the Brucite Crystals. — In order to take an electron diffraction photograph of a single crystal, the brucite crystals must be thin enough to transmit electrons but be at least 0.5 μ across so as to be separated from one another. Brucite crystals satisfying the requirements and still free from impurities were obtained by the following procedures. Chemically-pure magnesium hydroxide was put in an autoclave with water and kept at an appropriate temperature (with reference to the magnesium oxide water phase equilibrium[5]) for several hours. Different amounts of water and of magnesium hydroxide and various treating temperatures and heating periods were employed. Properly-crystallized brucite was obtained by treating 2 g. of chemically-pure magnesium hydroxide in a 30 cc. autoclave with 15 cc. water at 350°C for 24 hr.

Heating and Examination Methods.—The brucite crystals were heated in the following two different methods and were examined with an electron microscope operated at 80 kV.



Heating in the Electron Microscope with a Specimen-heating Attachment.—The crystals were first laid on a Pt-mesh and heated at the heating rate of about 10°C per min. up to 400°C with a heating attachment in the electron microscope. Choosing one crystal, a series of electron micrographs and corresponding diffraction photographs were taken at various stages of heating in order to pursue the crystal transformation through the dehydration. Next the crystals were heated further at a heating rate of about 30°C per min. up to 900°C, and the graphs were also taken at various stages of heating in order to observe any change after the dehydration. More than ten crystals were examined by these procedures.

Heating by Electron Bombardment. — The crystals were heated by electron bombardment in the electron microscope. The beam intensity was gradually increased, and at successive stages of bombardment, pairs of electron micrographs and corresponding diffraction photographs were taken. The maximum temperature rise as a result of the extensive electron bombardment was checked by the behavior of metal powder particles of various kinds (aluminum, copper, manganese, nickel, iron and chromium) in the bombardment. Only chromium particles remained undecomposed. From the standpoint of the melting points, the maximum temperature was estimated to be somewhere between 1453°C and 1535°C. In a high vacuum condition, however, the evaporation of metals cannot be disregarded so the temperature might be lower.

4	Random orientation		rarely	B	10b

Heating methods: A, heating attachment B, electron bombardment

Results

Crystal Changes upon Dehydration. — The brucite crystals were laid flat on carbon film, which was put on a Pt-mesh by spattering, since (0001) was perpendicular to the electron beam. Like the natural brucite crystals used by Goodman, the present ones had complex patches on the surface (Fig. 1a) which might come from the internal-disordered structures, as Goodman suggested. The changes in the diffraction patterns through the dehydration were the same in the two different ways of heating. The crystals were heated in a heating attachment at the heating rate of about 10°C per min., and electron micrographs and corresponding diffraction photographs of one crystal of each of them were taken at 250°C, 270°C, 290°C, 310°C and 330°C. These graphs are shown in Figs. 1a, 1b, 2a, 2b, 3a, 3b, 4a, 4b, 5a, 5b, 6a and 6b. The original reflections of the brucite first diffused outward, and then the reflections of the periclase appeared. In Figs. 2b and 3b, it can be observed that the original reflections have diffused outward. In the dehydrating stage, a_0 of the brucite is calculated to cover a range from 3.11 Å to 3.03 Å in Fig. 2b, and from 3.11 Å to 3.01 Å in Fig. 3b, while the a_0 of the original brucite is 3.11 Å. In Fig. 4b reflections from the periclase have appeared distinctly apart from the diffused ones. In Fig. 5b, all the reflections belong to the periclase except the six patterns nearest the center. These six reflections belong to a hexagonal lattice. Other corresponding reflections cannot be detected, perhaps because they are too vague and too near those of the periclase. From these six reflections, a_0 is calculated to be 2.99 Å. This fact shows that a_0 of the brucite shrinks to 2.99 Å through the dehydration. In Fig. 6b the dehydration has been completed. Figure 6b shows that (111) of the periclase is parallel with (0001) of the original brucite and that (220) of the periclase is parallel with (11$\bar{2}$0) of the original brucite.

Crystal Changes upon Further Heating after Complete Dehydration.—The changes in diffraction patterns caused by further heating after complete dehydration were also almost identical in the two methods of heating. Upon further heating, the patterns of many crystals remained as they were. In a few crystals, however, the patterns were changed into several other types, as Table I shows; type 1 was sometimes mixed slightly into the other types.

Discussion

Dehydration Process. — Although Goodman has observed only one intermediate shrinked lattice (a_0=2.99 Å), the results in the present work show that the brucite lattice shrinks gradually as the water molecules are expelled. No information could be obtained about the dimension of the C-axis. Judging from the crystal structure of the brucite, however, the shrinkage will be more extensive in the C direction. Each region where the shrinkage takes place is supposed to be 40~50 Å across, because the periclase crystallites produced from the brucite at 300°C are known to be about this size.[6] Water molecules possibly escape at the sites where defects exist and then through the cracks caused by the lattice shrinkage. Through the shrinkage, slight slips between oxygen layers are required to produce the periclase, because oxygens are hexagonal-closed packing in the brucite, whereas in the periclase they are cubic-closed packing. Thus the dehydration seems to take place in two steps. The gradual shrinkages of the lattice

6) W. R. Eubank, *J. Am. Cer. Soc.*, **34**, 225 (1951).

with the escape of the water molecules first take place, and then the slips between oxygen layers or the crystallizations take place.

The Changes in the Diffraction Patterns Caused by Further Heating After Complete Dehydration.—Goodman noticed a change in the diffraction patterns after the complete dehydration by extensive bombardment. The patterns partially became rings, which shows random orientation. He referred this to a bulk movement of the solids under the influence of the thermal stress. In the present work, the changes in the orientation upon further heating took place in the several ways shown in Table I. It seems that the structure immediately after complete dehydration is so defective that the recrystallization upon further heating sometimes takes place with a slight movement of the orienting direction, and also in rare cases with an extensive movement of the structure, which causes the random orientation. A strict interpretation of the mechanism of this phenomenon, however, has not yet been established.

Summary

1) The hexagonal plate crystals of the brucite, about 1 μ across, have been obtained by the hydrothermal treatment of chemically-pure magnesium hydroxide.

2) The brucite crystals transformed themselves upon dehydration into aggregates of the minute periclase crystallites oriented in such a way that (111) is parallel with (0001) of the original brucite crystal and (220) is parallel with $(11\bar{2}0)$.

3) The dehydration seems to take place in two steps. The escape of water molecules and the gradual shrinkage of the lattice take place at the first step of the dehydration. The slip of the oxygen layers and the crystallization take place at the second step.

4) Upon further heating after complete dehydration, the orientation of the crystallites remained unchanged in many crystals. In a few crystals, however, the orientation changed in the several ways shown in Table I. This phenomenon is a kind of sintering in the grain.

The Viscometric Properties of Polyesters. II. Viscosity in the Range of Low Temperatures near the Glass Transition Point

By Ryuzo NAKATSUKA

(Received July 9, 1963)

The glass transition temperature (T_g) is one of the most important properties of liquid state polymers.[1-3]

Although T_g values vary with individual polymers, the properties at a given temperature share common features; that is, (1) the apparent activation energy for viscous flow[1] ($E^{\ddagger}$), (2) the free volume fraction[1] (f), (3) the viscosity[2] (η), and (4) the thermal expansion coefficient of the free volume fraction[6,7] (α_f) show similar values irrespective of the nature of the polymers.

Hirai et al.[6] derived a theoretical expression on viscosity near the glass transition point from such empirical formulas as the WLF type,[7] the Fox-Flory type[8] and the Tobolsky-Catsiff type[10] equations, by means of the free volume theory for viscous flow.[5]

The object of the present paper is (1) to represent the viscometric property in the aspect of free volume, (2) to obtain more exact information about the "transition area" for the

C. E. D.: Cohesive energy density calculated by Kawai's method[4]

viscous flow mentioned in Part I, and (3) to consider how the viscosity is affected by the difference of a few degrees in chemical structure.

The actual observation of viscosity indicates that (1) linear relationships are obtained in curves of f vs. T, (2) the "transition area" for viscous flow is an intermediate region between the WLF and the Andrade liquid, and (3) some viscometric properties are proportional to the intermolecular force within polyesters of the same glycol series.

Experimental

The Preparation of the Polyesters.—*The Reaction of Long-chain Polyesters* (cf. Part I).

The Fractionation of Polyesters. — Samples were treated at 130°C to remove volatile contaminants and were fractionated under high vacuum (ca. 10^{-4} mmHg) by being distillated two or three times. The distillates at 160°C contained a crystalline substance, while the distillates at 200°C did not.

The Measurement of Viscosity.—A Brookfield-type rotational viscometer was used for the range of 10^{-1}∼10^{3} poises, while a Couette-type viscometer was used for the higher range (10∼10^{6} poises).

Rotational viscometer (Couette-type):

Range 1×10∼5×10^{6} poise (accuracy ±2%)

Number of revolutions 0.8∼83 r. p. m. (14-stage change)

Rate of shear 63∼0.06 sec^{-1}

Radius of outer cylinder 1.4 cm.

Radii of inner cylinders 1.2, 1.1, and 0.6 cm.

Length of inner cylinders 5.5 cm.

The sample was put in a dry ice-methanol bath and kept for 35∼40 min. until the temperature equilibrium was attained. The viscosity was measured at temperature intervals of 3∼5°C in the ragne from −60 to 30°C.

11) J. D. Ferry, "Die Physik der Hoch Polymeren," Ed. by H. A. Stuart, Springer-Verlag, Berlin, Bd 4 (1956), p. 392.

On the basis of this measurement of viscosity, every sample could be regarded as a Newtonian liquid over the whole range of viscosity as had been expected,[8,12] but over 10^3 poises it was difficult to measure the viscocity at a constant temperature except in the case of an extremely low shear rate, because of the great generation of heat by friction during the measurement, and it was also difficult to ascertain the effect of the shear rate on the viscosity.

Results and Discussion

The Temperature Dependence of the Viscosity near the Glass Transition Point. — The amorphous polyesters used in this experiment are listed in Table I. As has been stated in Part I, diethylene azelate, diethylene sebacate and triethylene sebacate were all crystalline, and therefore, their viscosities could not be measured at a low temperature.

In any case, the experimental values fit the WLF equation only within the range of 10^2~10^8 poises; the difference between the experimental and the calculated values becomes evident from the viscosity of 10~10^2 poises.

$$\log \eta/\eta_s = -8.86(T-T_s)/(101.6+T-T_s) \qquad \text{WLF eq.}$$

The "transition area" mentioned in Part I corresponds to the range of viscosity where experimental results begin to deviate from the WLF equation.

By applying the experimental values to the WLF equation, the corresponding T_s and η_s are obtained as shown in Table I.

The Temperature Dependence of the Apparent Activation Energy for Viscous Flow (E^*) in the WLF Liquid State. — The relations of $\log \eta$ vs. $1/T$ and E^* vs. $1/T$ are shown in Figs. 1 and 2. From these relations, it can be observed that the temperature dependence of E^* behaves peculiarly; over a viscosity range higher than 10^2 poises and within the region of −30~5°C, most polyesters have a region in which the apparent activation energy for viscous flow becomes nearly constant. In the case of the succinic acid polyester series, however, this region deviates a little towards the high temperature side. The average value of activation energy in this region (E_c^*) is shown in Fig. 2 and Table I.

For the purpose of elucidating this phenomenon, the same investigation was carried out on several samples of triethylene adipate with different molecular weights (690~3600), as is shown in Figs. 3 and 4.

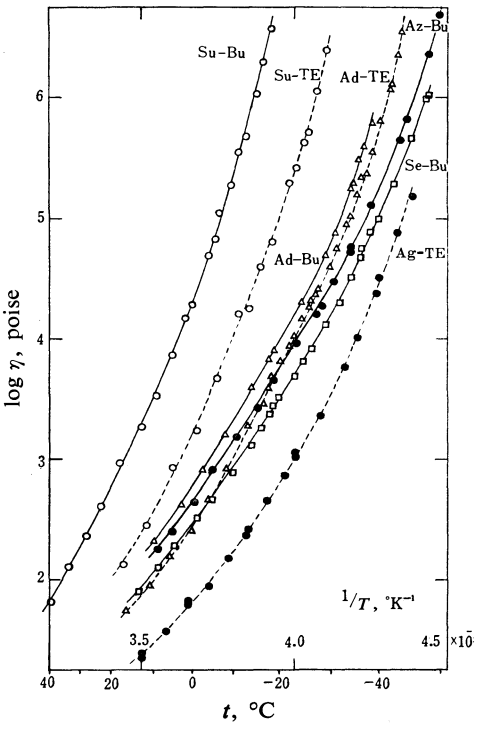

Fig. 1. Relationship between viscosity and temperature.
(1,3-Butanediol series and triethylene glycol series)
—— Bu series, ····· TE series

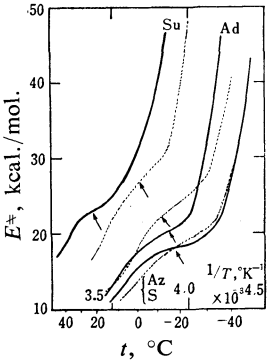

Fig. 2. Apparent activation energy for viscous flow.
(1,3-Butanediol series and triethylene glycol series)
—— Bu series, ····· TE series, ↑ E_c^*

Samples 1—3 and 4 were obtained by the conventional method and by molecular distillation at 200°C respectively.

Although polyesters have considerably different molecular weights, they show a similar tendency regarding this peculiarity of E^*: the region where E^* is considered to be constant is observed in the range of −30~5°C

12) M. Takayanagi and S. Kuriyama, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kōgyō Kagaku Zassi*), 57, 873 (1954); ibid., 57, 876 (1954); ibid., 59, 49 (1956).

for all samples, and yet the average values of $E^{\ddagger}$ in this region are equal except for sample 4.

Generally such a special type of curve for the temperature dependence of $E^{\ddagger}$ has not been observed[8,12] except in the example of a rubber-like polymer.[11]

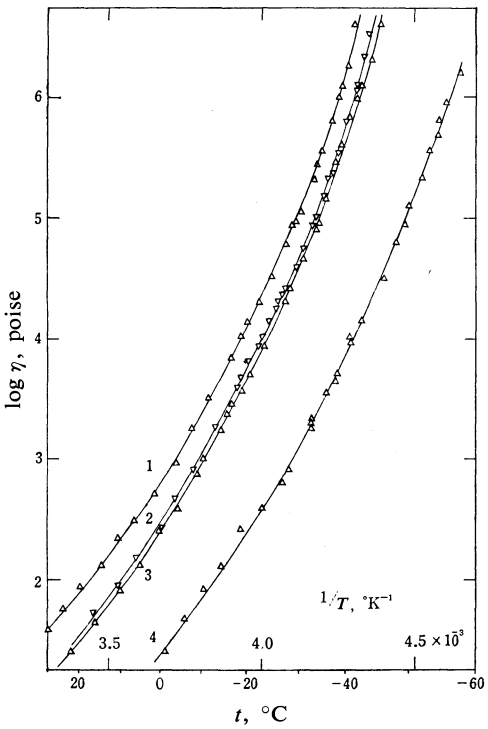

Fig. 3. Effect of molecular weight. (Triethylene adipate)

Sample	$\overline{M}_n$	Sample	$\overline{M}_n$
1	3600	2	1900
3	1200	4	680

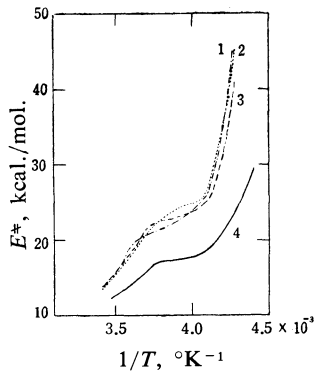

Fig. 4. Effect of molecular weight on activation energy. (Triethylene adipate)

Sample	$\overline{M}_n$	Sample	$\overline{M}_n$
1	3600	2	1900
3	1200	4	680

Even in this region each polyester behaves not as a non-Newtonian body but as a Newtonian liquid, and its molecular weight is too small to cause the so-called intermolecular entanglement; the general properties of the polyesters used in this experiment are very different from those of a rubber-like polymer.

Though it is impossible at present to explain this special phenomenon regarding the temperature dependence of $E^{\ddagger}$, the author wishes to point out two problems. One is the question whether this is one of the phenomena corresponding to the discontinuous change in the temperature dependence of the thermal expansion coefficient of the free volume fraction of the polyester, and the other is the question whether this depends on the time scale of measurement, for it takes a great deal of time to reach the equilibrium liquid state near the glass transition point. For the moment it can only be said with certainty that this phenomenon has something to do with the "transition area" for viscous flow.

Estimation of the Free Volume Fraction. — The Doolittle equation is generally applicable to the actual liquid, especially in the non-Andrade liquid state:

$$\ln \eta/\eta_g = B(1/f - 1/f_g) \tag{1}$$

The relationship between the free volume fraction (f) and the temperature (T) can be calculated from the results of the temperature dependence of the viscosity:

$$f = B/(\ln \eta/\eta_g + B/f_g) \tag{2}$$

The WLF equation and its function of the free volume fraction, $f(T)$, are deduced[7] from Eq. 1.

$$\ln \eta/\eta_g = [(T - T_g)/f_g]/[T - T_g + f_g/\alpha_{fg}] \tag{3}$$

$$f(T)_{\mathrm{WLF}} = f_g + \alpha_{fg}(T - T_g) \tag{4}$$

The functions of $f(T)_A$ and $E_A^{\ddagger}$ in the Andrade equation have been shown to be as follows by Hirai et al.:[6]

$$\ln \eta/\eta_g = (E_A^{\ddagger}/R)(1/T - 1/T_g) \tag{5}$$

$$f(T)_A = \alpha_l T \tag{6}$$

$$E_A^{\ddagger} = BR/\alpha_l \tag{7}$$

$$E_A^{\ddagger} = RT(\ln \eta/\eta_g + 1/f_g) \tag{8}$$

Equations for calculating the free volume fraction, $f(\eta)_{\mathrm{cal}}$ and $E_{A\,\mathrm{cal}}^{\ddagger}$ are obtained by substituting the following empirical values in Eqs. 2 and 8; a correction term δ is also added at the same time in order to assure the validity of this mathematical treatment.

$$f(\eta)_{\mathrm{cal}} = 1/(2.3 \log \eta + 10.1 + \delta) \tag{2'}$$

$$E_{A\,\mathrm{cal}}^{\ddagger} = 2.0T(2.3 \log \eta + 10.1 + \delta) \tag{8'}$$

In Eq. 1—8, the constants are termed as follows:

R: gas constant 1.987 cal./mol. deg.
η_g: viscosity at glass transition point (T_g) about 10^{13} poises[2]
B: a constant about 1[5,6]
f_g: Doolittle's free volume fraction at T_g about 0.025[7]
α_{fg}: thermal expansion coefficient of f at T_g about 4.8×10^{-4} ($°K^{-1}$)[7]
α_l: thermal expansion coefficient of f in Andrade liquid
E_A^*: activation energy for viscous flow in Andrade liquid

The correction term δ can be obtained from Eq. 8' by comparing the calculated value of the activation energy with the observed value, because the latter value for every polyester is almost constant (about 7.3 kcal./mol.) in the range between 370 and 420°K, as has already been shown in Part I.

The correction term δ is listed in Table I; this value depends on the molecular weight and the chemical structure of the polyester. In this table, all the δ values of the diethylene or triethylene glycol polyester series are zero.

In this manner, it is possible to discuss the temperature dependence of the f of amorphous polyesters as shown in Figs. 5—6.

The curve virtually consists of three straight-line part.

A typical pattern of the relation between f and T is represented in Fig. 7. We can divide the viscous flow state into three parts; (1) the Andrade liquid state ($T_1<T$; $f_1<f$), (2) the "transition area" for viscous flow ($T_2<T<T_1$; $f_2<f<f_1$), and (3) the WLF liquid state ($T_g<T<T_2$; $f_g<f<f_2$).

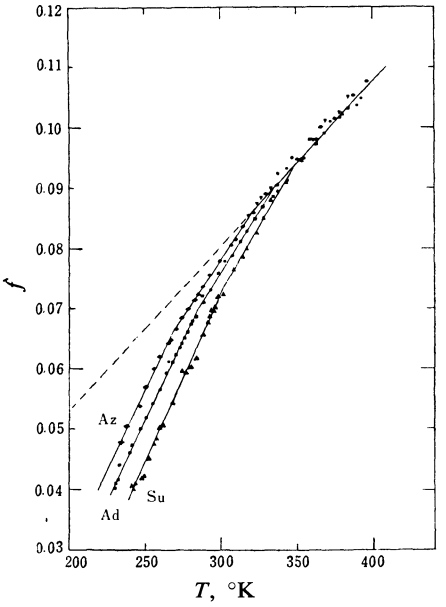

Fig. 5. Relationship between free volume fraction and temperature.
(Triethylene glycol series)

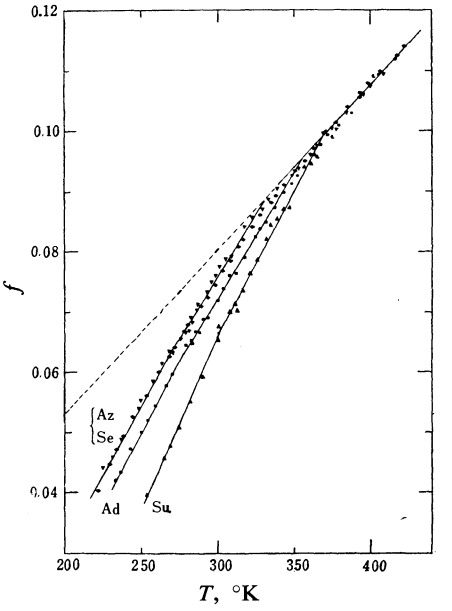

Fig. 6. Relationship between free volume fraction and temperature.
(1,3-Butanediol series)

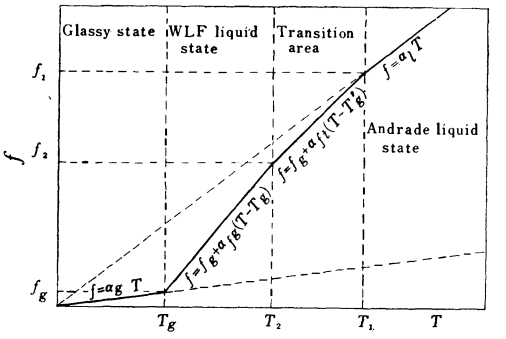

Fig. 7. Relationship between free volume fraction and viscous flow state.
(Schematic)

In the Andrade and the WLF liquid states, the values of f estimated from η are in good agreement with Eqs. 6 and 4 respectively, and the constants of these equations can be estimated for every polyester (cf. Table II).

The experimental values of f_1, f_2, α_l and α_g are approximately 0.10, 0.07, 2.69×10^{-4} and 4.8×10^{-4} respectively, independent of the type of polyester.

In the "transition area" ($0.10>f>0.07$), the relationship between f and T can be represented by Eq. 4', the form of which is similar to Eq. 4:

TABLE II. RELATIONSHIP BETWEEN CHEMICAL STRUCTURE AND TEMPERATURE DEPENDENCE OF FREE VOLUME FRACTION

Note

T_g, α_{fg}: Constants in the WLF liquid state
$f(\eta)_{cal}=f_g+\alpha_{fg}(T-T_g)$

T_g', α_{fg}: Constants in the "transition area"
$f(\eta)_{cal}=f_g+\alpha_{ft}(T-T_g')$

T_1, f_1: Boundary between the Andrade liquid state and the "transition area"

T_2, f_2: Boundary between the WLF liquid state and the "transition area"

$$f=f_g+\alpha_{ft}(T-T'_g) \qquad (4')$$

This shows that the WLF-type equation is also applicable to the "transition area," but that the estimated value of the glass transition point in this area is different from that in the WLF liquid state.

Nevertheless, even in crystalline polyesters with structures similar to those of amorphous polyesters, f at the melting point exists in the range of about 0.07~0.10 and this range of f corresponds to the "transition area" for viscous flow in amorphous polyesters.

The range corresponding to the "transition area" for viscous flow has been observed near the respective melting points of several *n*-paraffines by Miller.[13]

Moreover, even though the estimated value of f only in the range of high temperature changes considerably as a result of a little change in α_l or E_A^*, the relation between f and T would not be significantly changed.

Influences of Chemical Structure on Viscometric Properties.—The influences of chemical structure can be elucidated more clearly by comparing the cohesive energy density,[4] calculated from the structural unit of polyesters, with such viscometric properties as f, E_c^* or T_g.

It follows from these results that there is a linear relation between the cohesive energy density and the viscometric properties in a certain kind of glycol polyester series; i.e., the plots of these straight lines are those

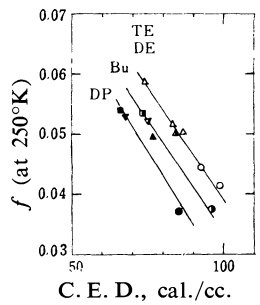

Fig. 8. Relationship between cohesive energy density and free volume fraction.

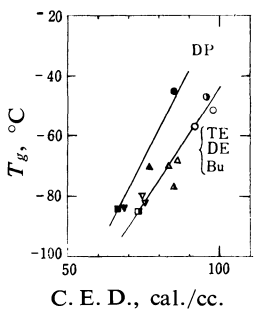

Fig. 9. Relationship between cohesive energy density and glass transition temperature.

13) A. A. Miller, *J. Chem. Phys.*, **67**, 1031 (1963).

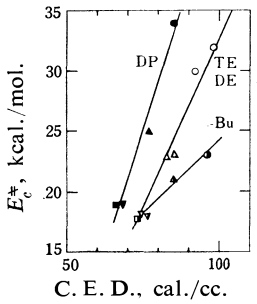

Fig. 10. Relationship between cohesive energy density and average activation energy for viscous flow (cf. Fig. 2).

from the following series respectively;

(1) Ether-type polyesters without side chains (TE and DE series)

(2) Ether-type polyesters with side chains (DP series)

(3) Ordinary-type polyesters with side chains (Bu series).

It seems probable that the viscometric properties are not perfectly represented by only the intermolecular forces because these tendencies are different according to the kinds of gylcol; a similar relation for many polymers has been obtained by Kawai.[4]

It is observed that, with an increasing intermolecular force, the free volume fraction (f) decreases, while the activation energy for viscous flow (E_c^*) in a peculiar region (cf. Fig. 2) and the glass transition point (T_g) increase.

As Figs. 8—10 show, in the series of dipropylene glycol (with the side chains) the above tendencies between the cohesive energy density and the viscometric properties are more strongly recognized than the expected tendencies from the series of diethylene- and triethylene glycols (without side chains); therefore, this shows that the intramolecular rotation in the liquid state was remarkably disturbed by the existence of side chains. In contrast with the dipropylene glycol series, the 1,3-butanediol polyester series (without ether bond) show a different pattern of viscometric properties.

Since the tendencies of the 1,3-butanediol polyester series are too complex to be explained clearly, at present it can be said with certainty only that the ether- and the methylene-bond in the main chain of polyesters behave remarkably differently in terms of viscosity.

Summary

The viscosities of amorphous long-chain polyesters have been measured in the range of $10\sim10^6$ poises and between -60 and 30°C, and the following results have been obtained (cf. also Part I).

(1) Within the limit of $10^2\sim10^6$ poises, all the polyesters are consistent with the WLF equation. At the "transition area" which was described in Part I, the observed viscosity begins to deviate from the WLF equation.

(2) The apparent activation energy for the viscous flow (E^*) is nearly constant within the range of $-30\sim5$°C, and over the range of viscosity beyond 10^2 poises for all the polyesters.

(3) The estimated curve of the temperature dependence of the free volume fraction (f) can be divided into three straight-line parts, corresponding to the WLF liquid state, the "transition area" for viscous flow, and the Andrade liquid state respectively.

(4) The relationship between the chemical structure and the viscosity can be represented in connection with intermolecular force, intramolecular rotation and so on.

The author is indebted to Professor Hiromu Murata of Faculty of Science of Hiroshima University for his helpful discussion and encouragement throughout the work, and to Dr. Keiji Oshima, Director of the Osaka Municipal Technical Institute, for his advice and encouragement. He also wishes to express his gratitude to Mr. Tadao Nakao, Senior Managing Director of Sumitomo Bakelite Co., Ltd., and Director of the Central Research Laboratory of the company, for permission to publish this paper, and to Mr. Kyosuke Miki and Mr. Shozo Yoshizumi of this Laboratory for their valuable assistance.

The Electrolytic Formation of an Oxide Layer on Platinum in a Sulfuric Acid Solution

By Shigeo SHIBATA

(Received October 7, 1963)

Although the electrolytic formation of oxide films on the surface of platinum electrodes has been extensively studied,[1-28] there are still remain quite a few questions concerning the actual electrode reaction and its mechanism.

Wakkad and Emara[9] found two plateaus in the oxygen region of a slow anodic charging curve (the variation of potential with the passage of electricity) and suggested that these were to be attributed to definite oxides of platinum(II) oxide and platinum(IV) oxide, on the basis of the fact that the potential of these plateaus were equal to the thermodynamic standard potentials of the platinum-platinum(II) oxide and platinum-platinum(IV) oxide couples respectively.

The construction of the oxide formed on the platinum surface was estimated by chemical analysis[16] to be a mixture of platinum(II) oxide and platinum(IV) oxide in a molar ratio close to 6:1. Laitinen[23] pointed out that one must be certain that during the chemical attack in this analysis the oxidation state of the platinum has not been changed. Giner[20] has examined the question of whether or not the definite oxides are formed on platinum by anodic polarization and has concluded that definite oxides don't exist, only chemisorbed oxygen.

A comparison of the anodic and the cathodic charging curves also shows that more electricity is used to form the oxide than to remove it. Vetter and Berndt[19] attributed the difference in the amounts of electricity to the possibility that some of the oxide or oxygen layer is reduced to hydrogen peroxide, which requires less electricity than the formation of the layer. Laitinen and Enke[23] stressed another possibility, that on the loss of oxygen atoms from the surface oxygen tends to diffuse into the grain boundaries of the platinum.

This study was undertaken in order to obtain further information on the behavior of deposited oxygen and on the oxide-film formation on smooth platinum electrodes by measuring the potential behavior, the electrode capacity and the attack on the electrode surface by the alternating anodic and cathodic polarizations.

The results of the present investigation indicate that the anodic film formation reaction proceeds through two steps: an adsorption step of deposited oxygen, and a step of the formation of a definite oxide film.

Experimental

The electrolyte used was a 1 N sulfuric acid solution. Sulfuric acid was distilled twice under reduced pressure, and laboratory-distilled water was further purified by redistillation with alkaline permanganate, followed by double distillations in a quartz still. The electrolyte was pre-electrolyzed with a current of 100 mamp. for at least 23 hr. using platinum electrodes. Unless otherwise stated, the solution was continuously swept with purified nitrogen gas in order to keep it free from dissolved

oxygen and hydrogen. The presence of oxygen or hydrogen is undesirable; oxygen acts as a depolarizer when the electrode is treated cathodically, while hydrogen reacts chemically with the oxygen on the platinum electrode surface and acts as a depolarizer for anodic electrode treatment.

The test electrodes were cleaned by treating them successively with hot concentrated hydrochloric acid, hot concentrated nitric acid and hot chromic acid, and finally by washing them with distilled water.

As the reference electrode, a saturated calomel electrode was used throughout. The values of the potentials described in this paper are on the standard hydrogen scale. All measurements were made at a constant temperature of 25 ± 0.1°C.

The Charging Curves.—Both the test electrode and the counter electrode were smooth platinum plates 2.0 cm^2 in apparent area, counting both sides. The electrolytic cell was constructed entirely of Pyrex glass, with the two compartments of the test electrode and of the counter electrode separated from one another by a sintered glass disk; each was equipped with a gas inlet tube. The compartment of the test electrode was fitted with a water jacket, through which water regulated at 25°C was circulated.

The circuit for the measurement was of the usual type, equipped with two large B-type batteries of 67.5 V. in series to power the electrolysis circuit. A potentiometer recorder with a high impedance input pre-amplifier (50 MΩ) was used to record the charging curves.

Electrode Capacity. — The test electrode was formed of wire 0.5 mm. in diameter and 5 mm. long; the end of the electrode was covered with a small glass ball to prevent an edge effect of the discharge. The counter electrode of platinum gauze in the shape of a cylinder 20 mm. high and 25 mm. in diameter was placed around the test electrode. The set of these electrodes was placed in a double walled glass vessel, between which two walls there flowed water of a constant temperature. This cell was also used for the measurement of the square-wave alternating-current electrolysis to be described in the next section.

The behavior of the differential capacity of the electrical double layer during forced anodic polarization with a constant current was measured by a fast single-current pulse method. This technique is nearly the same as that described by Schmid and Hackerman.[29] The method consists of calculating the capacity from the initial slope of the potential-time curve produced by the pulse under the assumption that the slope of the potential-time curve just before the onset of the pulse is zero. Though this is not true in a strict sense, the slope before the onset of the pulse, not exceeding the order of 10^{-2} V./sec., can be ignored in comparison with the slope produced by the pulse of the order of 10^2 V./sec.

A block diagram of the electronic apparatus is given in Fig. 1. The potential of the electrode

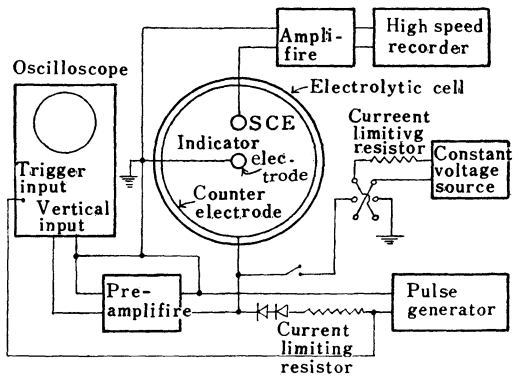

Fig. 1. Circuit diagram.

was measured against the reference electrode through a Luggin capillary by feeding the output of this cell into the recorder. In addition to the steady current, the cathodic pulses were delivered from a generator at the regular rate of 1 pulse every 2.0 sec. The pulses from the generator were passed first through a current-limiting resistor and then through a series of two diodes in order to eliminate a residual direct current from the genarator. The pulse-rise time was 0.2 μsec., and the duration was 8 μsec. The ratio of the current to the slope of the potential-time curve, $\Delta E/\Delta t$, gives the double-layer capacity. In practice, the current was so adjusted that ΔE was 1~4 mV. at a Δt of 8 μsec. Since Presbery and Schuldiner[30] showed that practically all of the applied current goes to the charging of the double layer in the first 10 μsec., the Faradaic effect is probably negligible. The potential changes of the test electrode caused by these pulses were photographed from the screen of a carefully calibrated cathode-ray oscilloscope (Iwasaki synchroscope, Model SS-5151) equipped with an input pre-amplifier (1 mV./cm.). The beam of the oscilloscope was triggered by the pulse itself, and the curves of the potential change caused by the pulse were successively photographed by means of winding a roll film a little every pulse, the shutter of the camera being kept open.

Square-wave Alternating-current Electrolysis.—This experiment was undertaken to study the effect of the repeated alternate anodic formation and cathodic dissolution of the oxide film on the electrode surface.

The test electrodes for this experiment were platinum wire 0.5 mm. in diameter and 6~4 mm. long; a new one was used for every run of the measurement. The frequency of the square wave was 78 or 40 c. p. s., the rise time was 1 μsec., and the voltage, 100 V.

The electrolysis was carried out in a hydrogen-saturated solution for a given time under the conditions of a constant shape and a constant amplitude of a charging curve resulting from the square-wave current electrolysis. When any change was found on the curve during the electrolysis, which was watched closely with the oscilloscope,

29) G. M. Schmid and N. Hackerman, *J. Electrochem. Soc.*, **109**, 1096 (1962).

30) C. H. Presbery and S. Schuldiner, ibid., **108**, 985 (1961).

the current was increased or decreased slightly so as to restore the curve to its original state. The degree of the attack of the surface may be estimated by measuring the increase in true area per apparent unit area, i. e., the increase in roughness factor, because the surface is coarsened by the electrolytic attack ; the increase in the true surface area can be approximated to the degree of the attack, unless the surface suffers too much corrosion. Since the value of the electricity Q_a (coulombs/apparent unit area) required to form the oxide film, which can be measured from the anodic charging curve, is proportionate to the true area of the electrode, the degree of the attack is estimated by the ratio of the Q_a' for the electrode already electrolyzed to the Q_a for that not yet electrolyzed. For this purpose, the charging curves were photographed with the oscilloscope.

Results and Discussion

The Possibility of the Existence of Adsorbed Hydrogen Which is Removed in the Oxygen-deposition Region.—Typical charging curves for an oxygen-hydrogen-free solution with a small current density are shown in Fig. 2. The initial rise of the potential (region α_a) is attributed to the ionization of adsorbed hydrogen. The second rapid linear rise (region β_a) is ascribed to the charging of the double layer, and a final slow linear change (region γ_a), to the deposition of oxygen, which forms a monolayer of oxygen atoms on the surface

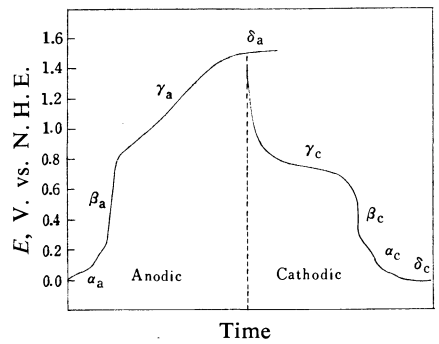

Fig. 2. Charging curves with small current density.

prior to the evolution of gas (region δ_a). When the current is reversed and the anodized electrode is made cathodic, the potential falls very rapidly to a plateau (region γ_c) which corresponds to the reduction of the oxide film formed during the γ_a region of the anodization. When all of the oxide has been reduced, the potential falls again through β_c and the hydrogen deposition (region α_c) prior to the final evolution of gas (region δ_c).

One of possible presumptions we can make as to the cause of the fact that the quantity of the electricity, Q_c, required to remove the oxide is smaller than that, Q_a, required to form the same substance would be that, in the anodic polarization, some of hydrogen atoms not removed in the α_a region are oxidized at the initial stage of γ_a.[31] If this is the case, Q_a, the sum of the quantity of electricity consumed to remove the hydrogen and to form the oxide film, should be larger than Q_c, the quantity required only to remove the oxide, and there should be a difference in the shape of the charging curve for the γ_a stage or in the quantity of electricity consumed for this stage in the anodic polarization between the bare electrode and that one covered with adsorbed hydrogen. The BCDEF curve in Fig. 3 is for the electrode polarized

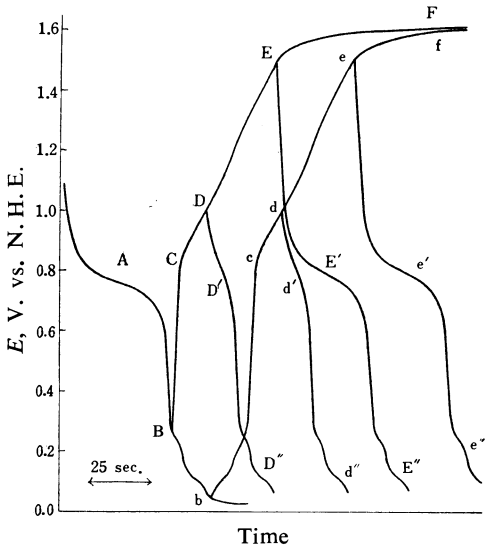

Fig. 3. Anodic and cathodic curves from various initial potentials.
$i_a = i_k = 20$ μamp./cm^2

from the potential B, where its surface is bare, while the bcdef curve is for the one polarized from the potential b, where its surface is completely covered with adsorbed hydrogen atoms. Between these curves no difference can be found. Moreover, it should be expected that the transition time of γ_c for the DD'D'' curve obtained when the current is reversed immediately at the D potential on the ABCD curve is larger than that for the dd'd'' curve reversed at the d potential on the abcd curve, but in practice these two curves, like also EE'E'' and ee'e'', were identical. For these reasons, we cannot accept the above assumption under the conditions of the experiment carried out in this work.

31) T. C. Franklin and S. L. Cooke, ibid., **107**, 556 (1960).

The Detection of Hydrogen Peroxide.—If the presumption of Vetter and Berndt[19] is true as to the cause of inequality between Q_a and Q_c, it should be possible to detect hydrogen peroxide near the electrode during cathodization.

A differential spectrophotometric method using 1,10-phenanthroline[32] was used for the determination of a trace of hydrogen peroxide. This method enables us to detect 0.1 to 2.5 p. p. m. of hydrogen peroxide with satisfactory precision and accuracy.

As the test electrode, a platinum wire 0.1 mm. in diameter and 10 m. long wound on a glass frame was used. According to the above presumption, 0.203×10^{-6} mol. hydrogen peroxide must be produced in the electrolyte during cathodization, because the value of Q_c for this electrode was measured as 4.032×10^{-2} coulombs. Since the volume of the electrolyte used for the measurement was 15 cc., the concentration of the hydrogen peroxide is expected to be 0.474 p. p. m.

Although the analysis was carried out very cautiously several times, the hydrogen peroxide could not be detected in a stationary solution, in an agitated solution, or on a rotated electrode. Consequently, the suggestion of Vetter and Berndt must be rejected.

The Loss of the Oxygen Deposited on the Surface.—In order to study the behavior of the oxygen deposited on the platinum electrode, the anodic and cathodic charging curves were taken under various conditions.

When the anodic current was reversed immediately at a potential, E_a, during the γ_a process, the charging curves shown in Fig. 4 were obtained. The ratios of q_a, the quantity of electricity required for the process from the initial potential of γ_a to E_a on the anodic curve, to q_c, that used for the plateau of γ_c on the cathodic curve taken subsequently, were plotted against E_a, as is shown by curve A in Fig. 5. For E_a exceeding 1.20 V. ($=E_a^\circ$), the ratio, q_c/q_a, has a constant value, but it decreases below this value.

32) R. Bailey and D. F. Boltz, *Anal. Chem.*, 31, 117 (1959).

When the solution was agitated vigorously by passing bubbling nitrogen gas through, the value of Q_a increases to 1.4 times that obtained under the stationary solution, whereas the value of Q_c suffers little effect from the agitation. For this reason, it may be presumed that a part of the oxygen deposited in the process of γ_a is very unstable and may be easily removed from the surface. After it is polarized to a given potential, E_a, of the γ_a region with a constant anodic current, the electrode was allowed to remain at an open circuit for 2 min.; then it is polarized cathodically with the same current density. The variation of the ratio, q_c/q_a, thus obtained against E_a is shown by curve B in Fig. 5. If the solution was agitated while the electrode was allowed to stand in this experiment, curve C in Fig. 5 was obtained. When the solution was continuously agitated throughout the anodic polarization and the standing, the curves shown in Fig. 6 were obtained. The plateau, γ_c, of the cathodic curve for the electrode anodized to the potential E_a below 1.05 V. vanished completely, and the potential fell rapidly and immediately reached the hydrogen deposition region.

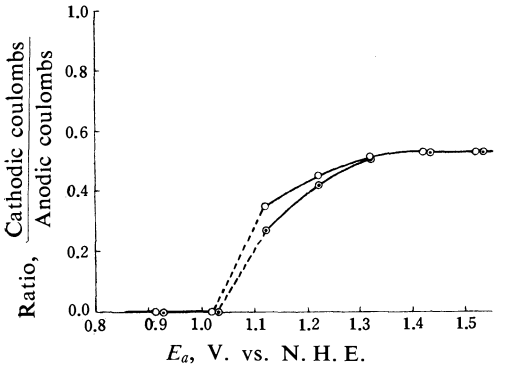

Fig. 7. Cathodic to anodic coulomb ratio as a function of anodically polarized potential, E_a.
$i_a = i_k = 20$ μamp./cm^2
-○- for anodic process in agitated solution and cathodic process in stationary solution after standing for 2 min. in stationary solution.
-⊙- for anodic process in agitated solution and cathodic process in stationary solution after standing for 2 min. in agitated solution.

The data shown in Figs. 5 and 7 suggest strongly that oxygen deposited in the first half of the γ_a region is attached loosely on the surface and is easily removed spontaneously during the standing or by the agitation of the solution.

The inequality between Q_a and Q_c may be caused by such a loss of the deposited oxygen from the surface in the initial stage of γ_a.

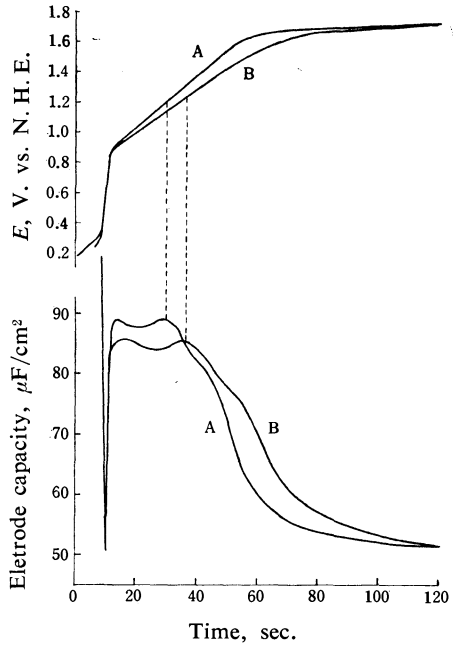

Fig. 8. Electrode potential and double layer capacitance during anodization at 25 μamp./cm^2 as a function of time.
A in stationary solution

The Capacity Change in the Course of the Anodic Process.—The potential-time and the capacity-time curves were measured simultaneously during the anodic polarization in the stationary solution, the results being shown in Fig. 8. The capacity-time curve may be divided into three portions: (a) the first portion, which starts with the oxygen deposition potential, where the capacity has a maximum value of approximately 90 μF/cm^2; (b) the second portion, characterized by a fall of the double layer capacity with time, beginning from 1.15 V. ($=E_w^\circ$), and (c) the third portion, with a stationary capacity value of 50 μF/cm^2, which is very close to the value found by Laitinen and Enke[23] for an oxidized surface. The result obtained with an agitated solution is shown by curve B in Fig. 8. The maximum value of the capacity is 4~5 μF/cm^2, which is smaller than that for the stationary solution, but the potential at which the capacity value begins to fall coincides with that for the stationary solution.

According to Llopis and Colum,[33] the increase of the electrode capacity of a

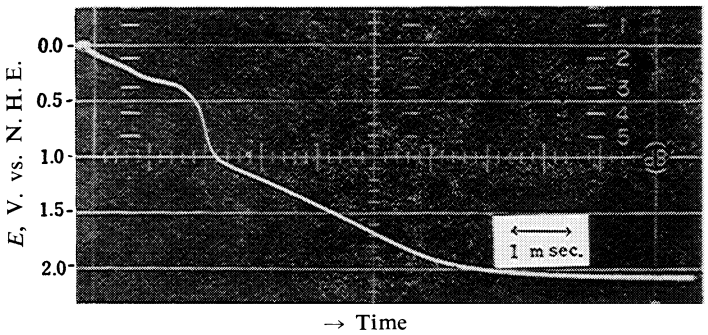

Fig. 10. Typical oscilloscope trace of anodic charging curve. i_a=190 mamp./cm²

platinum electrode at the beginning of the surface oxide formation is due to the presence of a dipole such as Pt···O at the electrode-solution interface. On the basis of this explanation, it is possible to account for the capacity vs. surface charge curve. Highly polar groups, which might be represented by $Pt^+\cdots O^-$, $Pt^+\cdots OH^-$ or $Pt\cdots OH_2$, may exist at the metal-solution interface on which the initial stage of oxygen deposition is proceeding. These dipoles replace the water molecules and ions which had formed the electrical double layer at the reduced electrode surface. The decrease in electrode capacity that was observed at the potential above E_w° may be caused by the decrease in the number of highly polar groups, or by their conversion to non-polar ones, probably to definite oxide molecules.

The Attack by Square-wave Alternating-current Electrolysis.—The mechanism of the change in the structure of a platinum electrode surface caused by repeated alternate anodic and cathodic polarizations calls for our intensive attention. The oscillogram of Fig. 9 shows the charging curves of the test electrode observed when the square-wave current of various current densities were passed through the cell containing a hydrogen-saturated solution. The amplitude of its oscillation increased with the increase in current density. A square-wave current was so adjusted that the maximum value of the oscillating potential was the desired value, E_s; the lowest potential, on the other hand, was equal to the hydrogen-evolution potential, which should be slightly increased by the hydrogen overpotential when the current density increases. The oscillogram shown in Fig. 10 is typical of the anodic charging curves photographed in order to determine the increase in true surface area caused by the electrolysis. The degree of the attack resulting from the electrolysis is shown in Fig. 11. It may be found from this figure that the surface of the electrode was not attacked at all as long as the potential did not exceed 1.15 V. ($=E_s^\circ$), regardless of the electrolysing duration or the frequency, whereas if the potential exceeded E_s°, the ratio Q_a'/Q_a rose rapidly, the bright surface becoming cloudy. The rate of the attack is faster at a frequency of 78 c. p. s. than at one of 40 c. p. s. and the surface is attacked more deeply when the electrolysis is prolonged at a given fre-

quency. As has been pointed out in previous papers[34,35] on the sine-wave alternating-current electrolysis, it is clear that the attack of the electrode is not due to the alternate anodic dissolution and cathodic redeposition of platinum itself. Rather, the attack may be attributed to the repetition of the alternate formation and reduction of the oxide film, in which an oxygen atom forms a chemical bond with a surface platinum atom so that the bonds between the oxidized platinum atom and atoms adjoining it are either weakened or ruptured, according to the circumstances. The accumulation of these bond changes due to the repetition of the formation and reduction of the oxide rearranges the platinum atoms to make a recrystallization of platinum on the surface. The fact that surface did not suffer any attack at all the potential below E_s° suggests that the oxygen atoms deposited on the surface under that condition are only at a state of the adsorption in which they are not able to effect a serious change in the Pt–Pt bonds.

During the electrolysis at a potential below E_s° with a constant current density, the shape of the charging curve did not change for a long time. The activity of the electrode, however, was lost gradually as the electrolysis was prolonged. At a potential above E_s°, the current density had to be increased slowly with time in order to hold the wave shape invariable, because the roughness factor of the surface was increased by the beginning of the attack. In this case, the activity suffered no decay at all for the long period of the electrolysis.

The activation of the platinum surface by the pretreatment of anodic and subsequent cathodic polarization may be attributed to the light platinization due to the formation and reduction of oxide films.[36] On the other hand, the loss of the activity with time may be attributed to the settling down of the active platinum atoms on the surface into a stable state[37,38] as well as to poisoning by the impurities. Consequently, whether or not the activity decays during the alternating-current electrolysis should depend on whether the deposited oxygen is only adsorbed on the surface or whether it forms the oxide with platinum.

When platinum electrodes which have been aged in a hydrogen atmosphere for a long period of time are anodically polarized with a small constant current in a solution containing hydrogen, periodic oscillations of the electrode potential are often observed.[39,40] This potential-time curve for an acidic solutions shows a transition to a potential ca. +1.0 V., at which the deactivated electrode is reactivated, and then it sweeps down to near the reversible hydrogen potential. The noteworthy fact is found in this experiment that the electrode is not activated at the starting potential of the oxygen deposition process, γ_a, but at the potential nearly, corresponding to E_s°. This behavior of the electrode may also be interpreted reasonably by the mechanism described above.

Conclusion

The process of the deposition of the oxygen at the anodization has been observed only as a monotonous increase in the potential on the charging curve. However, it has been found that the γ_a region may properly be divided into two portions at the potential 1.15 V.

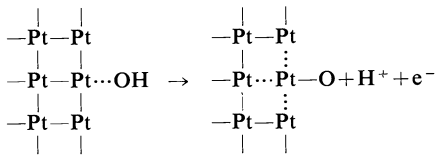
($=E_a^\circ=E_w^\circ=E_s^\circ$), the reaction taking place in different ways in the respective portions.

According to the observed anodic behavior of the electrode, the mechanism of the surface oxidation may be proposed as follows, partly in identical terms with the proposal of Laitinen and Enke.[23]

On the first half portion of γ_a,



$$Pt + H_2O \rightarrow Pt\cdots OH + H^+ + e^- \quad (1a)$$

some of the $\cdots$OH intermediates thus adsorbed weakly on surface platinum atoms can further behave in either of two ways. First, they may be desorbed naturally from the surface, and, secondly, an oxygen evolution reaction may remove the surface hydroxyl, forming a bare platinum site as follows:

$$Pt\cdots OH + H_2O \rightarrow Pt\cdots OOH + 2H^+ + 2e^- \quad (1b)$$

$$Pt\cdots OOH \rightarrow Pt + O_2 + H^+ + e^- \quad (1c)$$

On the latter half of γ_a, the surface hydroxyl is converted to a surface oxygen atom which is so firmly bound, producing the definite oxide of platinum, that the bond between the oxidized platinum atom and atoms adjoining it is weakened.

Vacuum Ultraviolet Absorption Spectra of Saturated Organic Compounds with Non-bonding Electrons

By Hiroshi TSUBOMURA,* Katsumi KIMURA,* Koji KAYA, Jiro TANAKA and Saburo NAGAKURA

(Received November 7, 1963)

The electronic spectra of aliphatic compounds have received relatively little attention from organic chemists because they lie mostly in the vacuum ultraviolet region. Saturated compounds containing non-bonding electron pairs like alcohols, ethers, amines, and halides show characteristic absorption bands in the region between 1600 and 2000 Å, the investigation of which seems to be important for a theoretical understanding of the electronic structures of these compounds. These bands may be important also for the chemical analysis of these compounds.

Most of the spectral measurements in the vacuum ultraviolet region have been made with the photographic method. About ten years ago, Klevens and Platt[1] measured the spectra of various aliphatic and aromatic compounds in the vacuum ultraviolet region up to 1750 Å. A group at Mount Holyoke College has also measured the vacuum ultraviolet absorption spectra of many aliphatic compounds, including olefins, aliphatic amines and alcohols.[2,3]

Photoelectric measurements of the vacuum ultraviolet spectra have been carried out by Watanabe and others.[4] Most of their work, however, has been on very simple molecules. Recently, some automatic recording spectrophotometers have become commercially available with which the measurements can be extended down to 1850 or even 1750 Å. Kaye[5] has done work by a commercially-available instrument on some alcohols and has found that their spectra shift to the blue as a result of the hydrogen bonding. Under these circumstances, the present authors undertook to construct a recording spectrophotometer suitable

for the accurate measurement of absorption intensity in the vacuum ultraviolet region from 1450 to 2200 Å, and to measure the vacuum ultraviolet absorption spectra of some saturated organic compounds with non-bonding electrons, such as alcohols, ether, amines and chlorides.

Mulliken was the first to give a theoretical explanation of the spectra of aliphatic alcohols, amines and halides. In his early-published paper,[6a] he explained that the near vacuum ultraviolet absorption bands of these compounds may be attributed to the Rydberg-type transition from the lone pair np atomic orbital to the vacant $(n+1)$s atomic orbital. Later, he pointed out that these bands are more likely to be of the $n \rightarrow \sigma^*$ type, because of the transition from the non-bonding atomic orbital (abbreviated hereafter to AO) to the vacant σ-antibonding molecular orbital (abbreviated hereafter to MO), although the possibility of the Rydberg nature of these bands can not be entirely excluded.[6b] The present authors intend to give a more detailed theoretical interpretation of the nature of these bands.

Experimental

The near ultraviolet absorption spectra ($\lambda > 1900$ Å) were measured with a Cary model 14M spectrophotometer, while the spectra in the region of wavelengths shorter than 2200 Å were measured by a vacuum ultraviolet spectrophotometer constructed in our laboratory. The instrument, shown diagramatically in Fig. 1, is more or less similar to the one constructed by Watanabe and Inn.[7]

The spectrophotometer uses a Bausch & Lomb concave grating (catalog No. 33-52-25-41; concave radius 995.4 mm., ruled area 56 mm. × 96 mm., 600 grooves/mm., blazed at 1500 Å, blaze angle 2°35′). The center of the grating and the two slits S_1 and S_2 are on the Rowland circle (with the diameter equal to the concave radius), so the light from the entrance slit, S_1, is always focused at the exit slit, S_2. The grating holder is fixed on a steel ball at the center of the circle and has two small rollers under the grating. It also has a vertical lever which is pushed by a micrometer head for scanning. The micrometer has a pitch of 0.5 mm. and is rotated by a synchronous motor through a gear set at speeds of 2, 4 and 8 rotations per minutes. The wavelength changes by about 45 Å per each rotation.

Hydrogen-discharge lamps from Hitachi, Ltd. and the Asahidenko Co. were used as light sources. They are hot-cathode type lamps with working voltages of 60 to 100 V. and a current of about 1 amp. Each of these lamps has a specially-designed power supply; further, a voltage stabilizer was used. The lamp has an optically-flat fused silica window which is pushed against the lithium fluoride window (also optically-flat) in front of the entrance slit of the monochrometer so as to minimize the air gap between them.

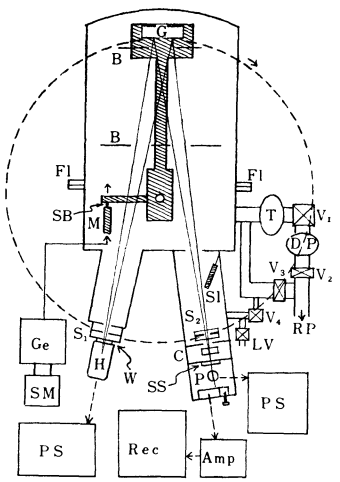

Fig. 1. Block diagram of the vacuum ultraviolet spectrophotometer. G, Grating; B, Baffle; Fl, Flange; SB, Steel ball; M, Micrometer; Sl, Shutter; S_1, S_2, Slits; H, Hydrogen disharge lamp; W, Lithium fluoride window; C, Cell; SS, A glass plate coated with sodium salicylate; P, Photomultiplier; Z, Zero adjuster; PS, Power supply; Amp, Amplifier; Rec, Recorder; SM, Synchronous motor; Ge, Gear set; LV, Leak valve; V_1, $\sim V_4$, Valves; T, Cold trap; Dp, Diffusion pump; RP, Rotary pump

The shutter designated by Sl in Fig. 1 can be operated from outside and serves both as a light shutter and a vacuum valve to insulate the cell compartment from the main body of the monochrometer. Each of the cells is cemented with Araldite to the cover plate, which is fixed in position at the flange of the cell compartment when it is in use (see Fig. 2). Such cell assemblies can be exchanged for various purposes after filling the cell compartment with air by operating the shutter, Sl, the valves LV, and other parts.

The light passing through the cell finally hits a glass window cemented on the outer surface of the cell compartment. The inner surface of the glass is covered with a thin layer of sodium salicylate, and the fluorescence caused by the vacuum ultraviolet light is received by a RCA 1P28 photomultiplier tube. The output is amplified by a DC micromicroammeter of the Ohkura Electric Co. and recorded by a Brown recorder. A zero adjuster consisting of a battery and a variable resistance is also connected.

The monochrometer tank consists of two parts, which are joined together with volts and nuts at the flanges. The rear part of the tank has rollers under it and can be moved along the rail when service is needed for the inside of the monochrometer.

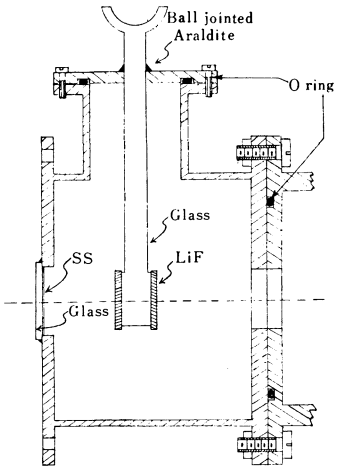

Fig. 2. The cell compartment and the vapor cell.

Figure 2 shows one of the cells for vapor measurement; they are made of glass and have two lithium fluoride windows cemented with Araldite. The inner thickness of the cell ranges from 7 to 30 mm. Each of the cells is connected with a vacuum line with a ball joint and is evacuated. The hydrogen lamp emission intensity is recorded under these conditions for use as reference. The sample vapor is then introduced, and the pressure is measured with a mercury manometer with an inner diameter of 20 mm. The mercury level is read with a measuring microscope. The sensitivity of the pressure reading is about 0.01 mm. The emission intensity is recorded for the sample. In Fig. 3, the measured curve for ethanol is given as a typical example of vapor measurements. Curve A is for the reference, curve B for the sample, and curve C for the molar extinction calculated from the two former curves. The short vertical lines on curves A and B are wavelength marker, given by the short-circuiting of the recorder input voltage at each rotation of the wavelength-drive micrometer. This is actually done by a microswitch in contact with the micrometer drum, which has a small cut at the periphery. The calibration of the wavelength has been done by comparing the marker readings recorded on the chart and the peak wavelengths of the absorption spectra of a certain number of compounds, for instance, acetone, whose peak wavelengths have been given in an earlier work.

As shown in the figure, the intensity of the emission of the hydrogen lamp decreases gradually in the vacuum ultraviolet region, reaching a minimum at about 1700 Å. Then it rises because of the atomic emission, falls very steeply because of the absorption of fused silica, and becomes almost flat below 1500 Å. In the flat region the intensity of the monochromatized light must be zero; hence, it gives the intensity of the stray light. We therefore call it the stray level. The final falling of the curve corresponds to the shutting off of the shutter, Sl. From the flatness of the stray level below 1500 Å, one may assume that the intensity of the

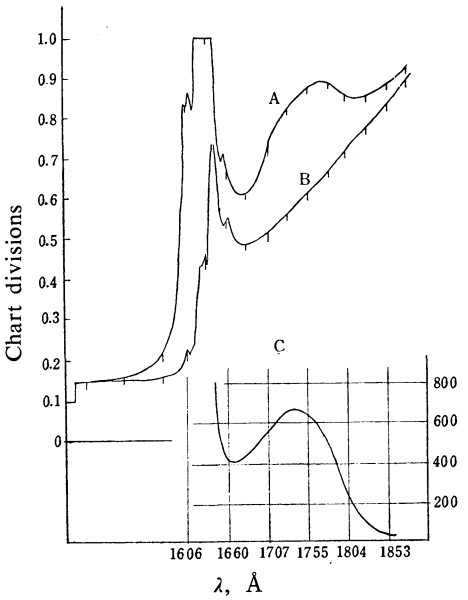

Fig. 3. Recorded curves for ethanol. A, Reference recording; B, Sample recording; C, The curve calculated from A and B (See text).

stray light is nearly constant in the wavelength range we are interested in. Therefore, by taking the "stray level" appearing in the curve to be the zero line, we can calculate the absorbance, $\log_{10}(I_0/I)$, from the curves for the reference and the sample. The effect of stray light can thus be reduced to less than a few percent. The extinction coefficients at about 2000 Å measured with this instrument agree well with those measured with the Cary 14 M spectrophotometer, the differences being in most cases less than 10%.

For solution measurements, fused silica cells, an example of which is depicted in Fig. 4, (made by the Nihon Sekiei Co.) were used. The inner thickness is about 0.1 mm. This seems to be the technically available lower limit for the precise

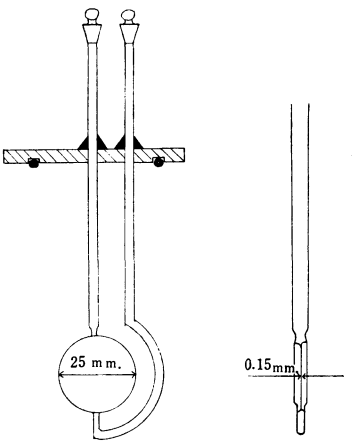

Fig. 4. The solution cell.

TABLE I. THE OBSERVED CHARACTERISTICS OF THE ULTRAVIOLET BANDS

Compound	λ_{max}, Å	ε_{max}, l./mol. cm.	$\Delta\nu_{1/2}$, cm^{-1}	f
a) Oxygen compound				
Water	1670	2120	9100	0.084
Methanol	1742	356	3400	0.0052
Ethanol	1740	670	4400	0.013
Ethyl ether	1885	2820	3400	0.041
b) Amine				
Triethylamine	2120	6100	8400	0.22
c) Chloride				
Methyl chloride	1690	370	6500	0.010
Dichloromethane	1790	510	—	—
Chloroform	1755	950	6400	0.026
Carbon tetrachloride	1740	2370	6200	0.063

construction of such cells. The thickness was calibrated by measurements of the absorption spectrum of a *n*-heptane solution of chlorobenzene with the Cary spectrophotometer. Even with such thin cells, the absorption by the solvents is enormous, and purified *n*-heptane has turned out to be the only solvent which can be used in this range, though some other homologues can probably be so used also.

Results and Discussion

Water, Alcohol and Ether.—Figures 5 and 6 and Table Ia give the results for the spectra of water, alcohols and ether. The spectral shapes obtained are in good agreement with those of Harrison et al.[8,9] and with those of Watanabe and Zelikoff,[10] although our molar extinction values are 1.5 times to twice as large as theirs. The reason for this discrepancy is not clear.

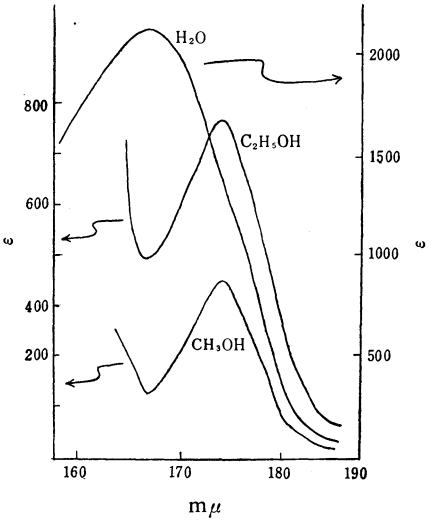

Fig. 5. The absorption spectra for water, methanol and ethanol.

The experimental results seem to be explained reasonably by the following assumption (see Fig. 7): 1) These bands are essentially of the $n\rightarrow\sigma^*$ type, where n means the 2p AO of the oxygen atom directed along the line perpendicular to the molecular plane; 2) the σ^* orbital for the C-O bond, σ^*(CO), has an orbital energy appreciably lower than that for the σ^*(OH) orbital (the reason for this will be given later), and 3) the matrix elements of the Hamiltonian between two σ^* orbitals in a molecule are small (see the Appendix). Therefore, the two upper configurations, $n\rightarrow\sigma^*$(OH) and $n\rightarrow\sigma^*$(CO), in alcohols interact slightly, while the two $n\rightarrow\sigma^*$ configurations of water and ether interact strongly with each other, because they are degenerate. If the

* It may be expected that the electron affinity of a molecule generally gets larger as the molecule becomes larger, because the extra charge is more or less stabilized by the polarization of other electrons in the molecules. Therefore, the transition energy may conceivably be affected by the electron affinity, too, but its effect may be smaller than the effect of the ionization potential.

energy levels of the molecular states are approximated by the relevant orbital energies, the lower levels shown in Fig. 7 correspond to the orbital energies of the oxygen non-bonding orbitals, which are taken to be equal to the ionization potentials for these molecules (with the sign reversed). The upper levels correspond to the orbital energies of the σ^* (antibonding) molecular orbitals. The differences in energies between the two levels are taken to be equal to the observed transition energies.

From Fig. 7 it may be seen that the transition energy increases in the order of $(C_2H_5)_2O < C_2H_5OH < H_2O$. The transition energy corresponds roughly to $(I-A-Q)$, where I is the ionization potential of the molecule, A is the electron affinity associated with the σ^* orbital, and Q is the electrostatic energy due to the charge unbalance in the upper state. Moreover, the ionization potential value undoubtedly increases in the following order; $(C_2H_5)_2O<C_2H_5OH<H_2O$. Thus, we can explain the fact the $n\rightarrow\sigma^*$ band shifts toward shorter wavelengths in the order of ether, alcohol and water.* The reason why ether absorbs at longer wavelengths than alcohol may be partly attributed to the splitting of the antibonding σ^* orbital in the former.

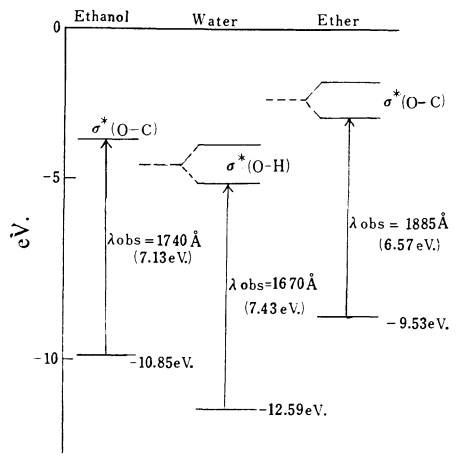

Fig. 7. The energy levels of ethanol, water and ether.

The oscillator strength of a transition, f, is related to the transition moment, μ (in Debye units), by the following equation;

$$f=8\pi^2\nu_{max}\boldsymbol{m}\mu^2/3\boldsymbol{he}^2=4.704\times10^{-7}\nu_{max}\mu^2 \quad (1)$$

where ν_{max} (in cm^{-1}) is the wave number at the maximum, $\boldsymbol{m}$ and $\boldsymbol{e}$ are the mass and the charge of an electron, and $\boldsymbol{h}$ is Planck's constant. The transition moment for the $n\rightarrow\sigma^*$ (CO) transition can be expressed by the present scheme as follows:

$$\mu=\int\psi(n)(\boldsymbol{ex})\psi^*(\sigma)dv=\int\psi_{2px_0}\times(\boldsymbol{ex})(a\psi_{2pz_0}-b\psi_c)dv=b\int\psi_{2px_0}(\boldsymbol{ex})\psi_c dv \quad (2)$$

where a and b are normalized coefficients for the σ^* MO, z is directed along the bond, and x is vertical to the molecular plane. ψ_c is an sp^3-hybridized AO directing the bond. Calculation by the use of the Slater AO's leads to $\mu=0.74b$ in Debye units. If one assumes that $a=b$, f is calculated to be of the order of 0.011, a value which is in good agreement with the experimental value for alcohols. On the other hand, if the upper MO is assumed to be $\sigma^*(OH)=a'\psi_{2pz_0}-b'\psi_{1s_H}$, the transition moment is given by $\mu'=b'\int\psi_{2px_0}(\boldsymbol{ex})\psi_{1s_H}dv$. The result is $\mu=3.0$ D and $f=0.24$. The f value obtained is 20 times larger than the observed f values for alcohols. Therefore, it can be concluded that the upper MO for the case of alcohols is more likely to be σ^*(CO).

In the water and ether molecules, the two σ^* orbitals interact with each other, resulting in two MO's;

$$\psi_1=2^{-1/2}\{\sigma^*(OX_1)+\sigma^*(OX_2)\}$$
$$\psi_2=2^{-1/2}\{\sigma^*(OX_1)-\sigma^*(OX_2)\} \quad (3)$$

The symmetric combination ψ_1 will have the lower energy. By inspection one can easily see that ψ_1 is equivalent to the first vacant SCF MO of water as calculated by Ellison Shull.[11] The transition moment in this case is then given by

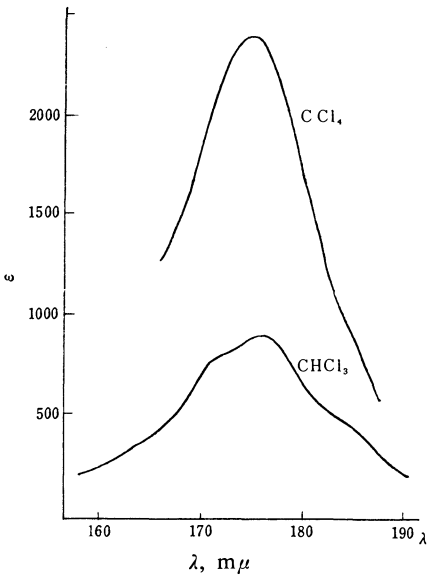
$$\mu_{n\psi_1}=2^{-1/2}\left\{\int\psi(n)(\boldsymbol{ex})\sigma^*(OX_1)dv+\int\psi(n)(\boldsymbol{ex})\sigma^*(OX_2)dv\right\} \quad (4)$$

The two terms in the brackets have directions parallel to each other, and their magnitudes are same. Hence,

$$\mu_{n\psi_1}=2^{1/2}\int\psi(n)(\boldsymbol{ex})\sigma^*(OX_1)dv \quad (5)$$

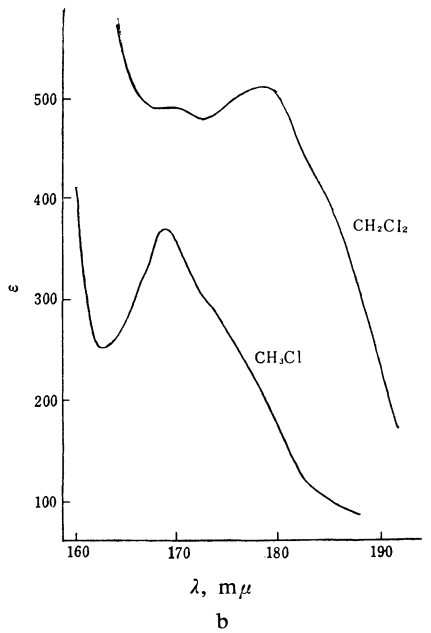
Therefore, the $n\rightarrow\psi_1$ transition has a probability twice as large as that of the $n\rightarrow\sigma^*$ transition in alcohols, and that of $n\rightarrow\psi_2$ is impossible.

In this way we can explain the experimental result that the symmetric molecule (ether) has stronger absorption bands than asymmetric molecules (alcohols). Also, the larger calculated f value for the $n\rightarrow\sigma^*$(OH) transition may explain the experimental f value for water larger than that for ether. Thus, it can be seen that the transition scheme prosposed above explains the qualitative characteristics of observed bands, although a more quantitative agreement between theory and observed



results can not be expected from such a simple treatment.

According to the above treatment, $\mu_{n\psi_2}$ becomes zero. The second absorption band of ether observed by us and also by Harrison and Price at about 1700Å has an intensity larger than that of the first band. It is, therefore, concluded to be due to another transition, and the $n\rightarrow\psi_2$ band may be hidden in it.



Amine.—The lone pair AO of the nitrogen atom in alkyl amines and ammonia is thought to be the (s, p)-hybridized AO, directed along the symmetry axis or pseudo-symmetry axis of the pyramidal molecules. Therefore, it can easily be seen that the $n\rightarrow\sigma^*$ transition has a fairly strong intensity, since the transition moment integral contains not only the two center terms, such as appear in Eq. 2, but also the one center terms, like

$\int \psi_{2p_xN}(ex)\psi_{2sN}dv$, which is quite large.

Our experimental result on the vapor spectrum of triethylamine has shown that its f value is indeed of an order of magnitude higher than that for alcohols (see Table I).

a

b

Fig. 8. Spectra for the chlorides of methane.

Chlorides.—Figure 8 and Table Ic show the experimental results obtained for the four chlorides of methane. The ε and f values for methyl chloride are of an order of magnitude equal to those for alcohols, and to those for bromides and iodides measured by Kimura and Nagakura.[12] Hence, it seems reasonable to assume that the transition is $n\rightarrow\sigma^*$, where n is the 3px AO of chlorine and σ^* is the antibonding MO for the C–Cl bond.

In polychlorides, there are a number of n and σ^* orbitals. Theoretically, these orbitals should not interact strongly with each other. Hence, the absorption intensities, or f values, for polychlorides must be approximately proportional to the number of chlorine atoms when the axes of the n AO's of the Cl atoms are assumed to be all parallel. The experimental results show that the f values increase approximately at the predicted rate.

The observed spectra of polychlorides show rather complicated features, suggesting that these spectra consist of a certain number of divided bands, as was observed in the case of bromides and iodides.[12] However, the splitting in the present case appears to be much smaller, indicating that the interactions between orbitals belonging to different C–X bonds are smaller in this case.

Comment on the Rydberg Nature of the Transitions. — It is clear that the vacuum ultraviolet bands discussed above are more or less of a *molecular* nature, because they are rather sensitive to the atoms or groups of atoms to which the central atom is bonded. In this sense, it is definitely errorneous to conclude simply that these bands are due to transitions from AO's np to $(n+1)$s, with the energies of these AO's independent of the other components of the molecules.

Kimura and Nagakura[12] calculated the

11) F. O. Ellison and H. Shull, *J. Chem. Phys.*, **23**, 2348 (1955).

oscillator strengths of the $np \rightarrow (n+1)s$ transitions for bromides and iodides and showed that the calculated values were much higher than the observed values. For this reason the bands were concluded to be of the $n \rightarrow \sigma^*$ nature.

The calculated oscillator strength for the $np \rightarrow (n+1)s$ transition generally gets smaller as n becomes smaller. For the $2p \rightarrow 3s$ transition of the oxygen atom, the calculation leads to $f=0.01$, which coincides with the observed value for ethanol. Therefore, we can not apply the same reasoning for the determination of nature of the transition in the present case.

It has been suggested by Mulliken that the σ^* MO of these molecules (especially those of a higher symmetry, for emample, NH_3 or H_2O) may resemble very closely the 3s AO of the central atom, and that they are both appropriate orbitals for describing the first molecular Rydberg states.[13] It also seems probable that the two orbitals will interact with each other and form a mixed MO. The electronic transition to this MO will perhaps describe these upper states the most correctly insofar as the one-electron approximation is concerned. In fact, the $(n+1)s$ AO is so large that it must interact very strongly with the AO's of other atoms in the same molecules. What we want to point out in this paper is that the various charateristics of these bands can be explained well, at least in part, by the $n \rightarrow \sigma^*$ type transition.

Appendix

For molecules of the X_1OX_2 type, the σ^* orbitals for the OX_1 bond and the OX_2 bond are given by the following LCAO MO:

$$\sigma^*(OX_1) = a\psi_{\sigma_1} + b\psi_{X_1}$$

$$\sigma^*(OX_2) = a\psi_{\sigma_2} - b\psi_{X_2}$$

where ψ_{σ_1} and and ψ_{σ_2} are the valence AO's directed along the two bonds and where ψ_{X_1} and ψ_{X_2} are the two valence AO's of X_1 and X_2. The interaction between these two orbitals depends on the difference between their orbital energies and the interaction matrix element;

$$\beta = (\sigma^*(OX_1) \mid H \mid \sigma^*(OX_2)).$$

Inserting the explicit form, we have:

$$\beta = a^2 H_{\sigma_1\sigma_2} - b^2 H_{X_1X_2} - ab(H_{\sigma_1X_2} - H_{\sigma_2X_1})$$

All the terms contained in the equation except for $H_{\sigma_1\sigma_2}$ are between the AO's of atoms long distances apart and, hence, small. $H_{\sigma_1\sigma_2}$ is between AO's which belong to the same atom but which are orthogonal to each other with respect to the core potential. Therefore, we can see that all the terms in this equation must be small in absolute magnitude.

NOTES

The Radiolysis of Squalane ($C_{30}H_{62}$) from −196°C to 350°C

By Kiyoshi FURUKAWA,* Shigeyoshi ARAI, Hideo YAMAZAKI** and Shoji SHIDA

(Received July 30, 1963)

The radiolysis of squalane at room temperature has been already studied by Yamazaki and Shida.[1] The present note will describe a study of the influence of the temperature on the γ-radiolysis of squalane. This substance is favorable for studying the effect of the temperature on radiolysis because of its characteristic nature of being liquid over a sufficiently wide range of temperature, i. e., −78.5 to 350°C or more. It was irradiated in vacuo at 350, 300, 250, 200, 150, 100, 0, −78.5 and −196°C by γ-rays with the total doses of 1.5×10^7 and 2.13×10^7 r.

Non-condensable gases at the temperature of liquid nitrogen, hydrogen plus methane, were collected in a micro gas burette mounted directly above a toepler pump until the sample tube was evacuated to 10^{-3} mmHg. The total volume of non-condensable gases was next measured, after which hydrogen was removed by a liquid nitrogen trap through a tube of cupric oxide heated to 270°C, at which temperature no methane was decomposed. The mass-spectrometric analysis of the residual non-condensable gas on several occasions showed it to consist of almost pure methane. The condensable gases were analyzed by gas chromatography. Each product was identified by using a mass-spectrometer. The *G*-values*[1] obtained are given in Table I. In this table, it may be seen that the *G*-values of hydrogen production are nearly constant at 3.8 from −196°C to 100°C, but that they increase to 7.0 at 350°C. For the other products of hydrocarbon, the increases in *G*-values in the region from 150°C to 300°C are larger than those at lower temperatures.

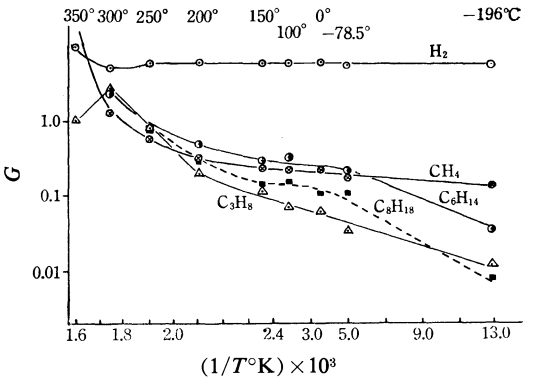

Fig. 1. Plots of log *G* against $1/T$°K.

The skeleton of squalane is as follows:

In this figure, the relation between the logarithmic *G*-values and $1/T$°K is plotted. It appears preferable to divide the temperature range into two parts, below and above 150°C.

Below 150°C.—In this region of temperature, the viscosity of squalane is so high that the molecular motion may be reduced, and the so-called cage effect seems to take place. The diffusion of radicals produced by γ-irradiation, therefore, must be greatly diminished. Under these circumstances, the radical reactions, which are expected to be abstraction, recombination and disproportionation, will be very much affected. Radicals that have diffused out of the cage are converted into products by abstracting hydrogen atoms from squalane molecules. On the other hand, those held in cages may react with each other, undergoing recombination and disproportionation to form original molecules and products consisting of aliphatic

350	7.0	12.0	1.0	—	0.7	2.4	—	—	—

or olefin. Therefore, the reactions in cages are thought to proceed in a relatively short time, before radicals diffuse out of the cages, i. e., to occur in a spur.[2] The products due to this instantaneous disproportionation reaction may be formed as soon as the C–C bonds are separated by γ-irradation. It should be, therefore, interpreted that a reaction like the so-called molecular detachment takes place in a liquid of high viscosity at a low temperature.[3] In this figure, it may be seen that the curve becomes steeper with the increasing molecular weight of the product. This may be due to the fact that the activation energy for diffusion becomes larger with the increasing molecular weight of the fragment. It may also be noted that near 150°C the slopes tend to be flat. These inflexion points of the curve may indicate some difference between the liquid states below and above 150°C. The pursuit of the discontinuity of this curve will be one of the objects of our later work.

Above 150°C.—Since no thermal cracking of free radicals takes place about 150°C,[4] the activation energies for each product were obtained from the curve above 150°C; they were estimated to be 15±1 kcal./mol. Large radicals, such as that of squalane, presumably, need lower activation energies for thermal cracking.

The rapid increase observed in this region may come simply from the cracking of free radicals produced by the γ-irradiation. It is necessary also to mention that the rupture of the C–C bonds of a radical by thermal cracking occurs at the β-position of free valence.[5] Since the *G*-values of hydrogen production are the largest of all, a lot of squalane radicals may be produded. Among them, the tertiary radicals will be predominant, and the products of their thermal cracking are expected to be C_4, C_5 and C_9. Actually the C_4 and C_5 were produced abundantly. Contrary to the expectation, however, the C_9 product was not observed. It seems, therefore, that the inner C–H bonds of a long molecule have less reactivity. This observation suggests that the "*intramolecular energy transfer*"[6] may take place in a long molecule. Thus, prior to the rupture of C–H bonds, the energy absorbed in a molecule is transferred to the end parts of the molecule and makes their reactivity large enough to separate the hydrogen atoms from the original molecule.

This experiment owes much to Dr. Hirofumi Danno, who offered us a ^{60}Co-γ source in the Japan Atomic Energy Research Institute.

Spectrophotometric Determination of the Acid Dissociation Constants of Plasmocorinth B

By Haruo MIYATA

(Received Septemper 12, 1963)

Plasmocorinth B (2-(1-hydroxy-4-chloro-2-phenylazo)-1, 8-dihydroxynaphthalene-3, 6-disulfonic acid disodium salt) was proposed as a colorimetric reagent for calcium in serum by Yanagisawa,[1] and it was studied then by Brush;[2] more recently this reagent has been utilized as an indicator of the chelometric titration[3] of calcium in the presence of magnesium.

This paper will report on a more detailed study of the absorption spectra and the acid dissociation constants of this reagent by the spectrophotometric method.

Experimental

Reagents.—A reagent obtained from the Sumitomo Dye Co. (SPB*) and the Dôjin Pharmaceutical Co. (DPB**), with the trade name Plasmocorinth B, was used for the studies without any further purification. It was dried at 60°C in a vacuum, cooled in a phosphorus pentoxide desiccator, and weighed. A solution (3×10^{-4} mol./l.) was prepared and stored in the dark.

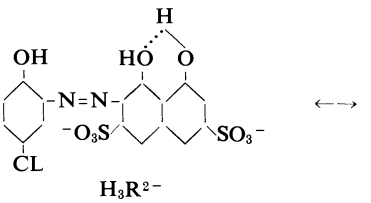
Buffer Solution and Sodium Perchlorate Solution.—The method of preparation has been described earlier.[4]

Procedure and Apparatus.—The measurements of the absorption spectra at various pH values were made as follows: Five milliliters of a 3×10^{-4} mol./l. reagent solution was placed in a 50 ml. volumetric flask, and an adequate volume of 1 M perchloric acid, 1 M sodium hydroxide or a buffer solution (acetic acid-sodium acetate, ammonium acetate-ammonia or ammonia-ammonium chloride) was added in order to adjust the pH value. 0.1 ml. of a 0.01 M EDTA solution was added to mask trace amouts of calcium or magnesium contained in sodium hydroxide or ammonia, because the definite isosbestic points can not be obtained in the absence of EDTA, especially at a higher pH. Then, a 1 M sodium perchlorate solution was added to maintain the ionic strength at 0.1, and the volume was made up to 50 ml. with water. The absorbance was then measured with a Shimadzu spectrophotometer QR-50 type, and a Hitachi automatic recording spectrophotometer EPS-2 type, with 1 cm. cells, using water as a reference, while the pH value was measured with a Tôa-Denpa glass electrode pH meter, Model HM-8A.

All the measurements were made at 25°C.

Results and Discussion

Spectral Properties of the Reagent. — The absorption spectra of the reagent solution (3×10^{-5} M) are shown in Fig. 1 over various pH values.



Below pH 4, the reagent gives an absorption spectrum with one absorption maximum at 530 mμ; when the pH of the solution is increased to 8.8, the maximum shifts to 610 mμ. Between pH 1 and 8.8, four isosbestic points exist, at 367, 413, 456 and 573 mμ.

Above pH 9.3, an absorption maximum appears at 576 mμ, and between pH 9.3 and 13, the two isosbestic points are at 467 and 612 mμ.

Between pH 8.8 and 9.3, there are no isosbestic points, so that the curves pass neither the point at 573 mμ nor that at 612 mμ.

Since the reagent faded gradually at a higher pH, the effect of *l*-ascorbic acid and hydroxylamine on the absorbance at the maxium (576 mμ) was studied at pH 13.0. The effect of neither reagent is good, but in the presence of 1.5×10^{-6} M *l*-ascorbic acid the absorbance is constant for ten minutes.

The Acid Dissociation Constant of the Reagent. —Judging from the presence of the isosbestic point, the structures H_3R^{2-} and H_2R^{3-} between pH 1 and 8.8 and the structures H_2R^{3-} and HR^{4-} between pH 9.3 and 13.0 are expected:

H_3R^{2-}

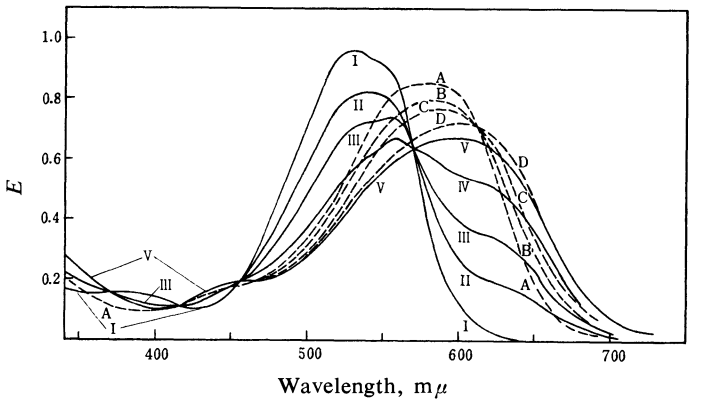
4) H. Miyata, This Bulletin, **36**, 382, 386 (1963).



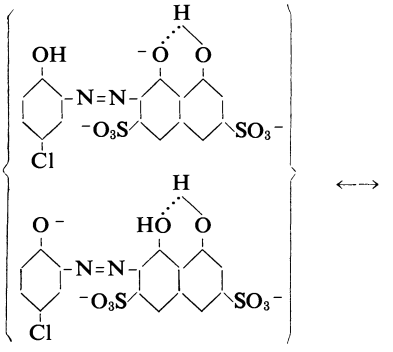


Fig. 1. Absorption spectra of Plasmocorinth B (SPB).
I, pH ~3.86; II, pH 6.64; III, pH 7.25; IV, pH 7.73; V, pH 8.47.
A, pH 13.01; B, pH 10.93; C, pH 10.52; D, pH 9.33

The dissociation constants, K_1 and K_2, can be calculated by the following equations:

$$H_3R \rightleftarrows H_2R + H \quad (1)$$

$$K_1 = [H]\,(E_{H_3R} - E)/(E - E_{H_2R}) \quad (2)$$

$$H_2R \rightleftarrows HR + H \quad (3)$$

$$K_2 = [H]\,(E'_{H_2R} - E')/(E' - E'_{HR}) \quad (4)$$

where E_{H_3R}*, E_{H_2R} and E represent, respectively, the absorbances of H_3R, H_2R and the mixture of H_3R and H_2R at 600 mμ, and E'_{H_2R}, E'_{HR}** and E' represent, respectively, the absorbances of H_2R, HR and their mixture at 640 mμ.

E_{H_3R}* and E'_{HR}** are equal to the absorbances at pH 1~4 and pH 12.4~13 respectively; E_{H_2R} and E'_{H_2R} are, however, not obtainable directly from the experimental absorbances, because the difference between pK_1 and pK_2 is small and the species H_2R always exists together with H_3R or HR, even under the most favorable conditions. Thus, at pH 8.8~9.3 the absorption curves have no isosbestic points, although H_2R is predominant.

Consequently, E_{H_2R} and E'_{H_2R} must be calculated by the following equations reported by Yoshioka et al.:[5]

$$E_{H_2R} = (a_1E_2 - a_2E_1)/(a_1 - a_2)$$

$$a_1 = [H_1]\,(E_{H_2R} - E_1)$$

$$a_2 = [H_2]\,(E_{H_3R} - E_2)$$

$$E'_{H_2R} = (b_1E'_1 - b_2E'_2)/(b_1 - b_2)$$

$$b_1 = [H'_1]/(E'_1 - E'_{HR})$$

$$b_2 = [H'_2]/(E'_2 - E'_{HR})$$

In the equations, E_1 (or E'_1) and E_2 (or E'_2) represent the absorbances at the hydrogen ion concentrations $[H_1]$ (or $[H'_1]$) and $[H_2]$ (or $[H'_2]$) respectively.

On the basis of these calculations, the acid dissociation constants of the reagent have been estimated and compared with the values of Brush:[2]

		pK_1	pK_2	pK_3
Brush[2]		8.0	10.5	11.9
The author	SPB	7.1_5	10.4_8	—
	DPB	7.1_6	10.4_8	—

The value of pK_3 could not be found from the absoption spectra of highly alkaline solutions; however, judging from the pK_2 values of chromotropic acid (15.6)[6] and

* E_{H_3R} = 0.090 for SPB; 0.075 for DPB.
** E'_{HR} = 0.250; 0.223.

Anomalies in the Temperature Dependences of the ESR Absorption and Electrical Conductivity of an Anion Radical Salt, $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$

By Yôichi IIDA, Minoru KINOSHITA, Mizuka SANO and Hideo AKAMATU

(Received October 9, 1963)

In recent years the anion radical salts of tetracyanoquinodimethane (TCNQ) have aroused much interest because of their prominent electronic properties. In particular, the magnetic property of the salts at low temperature range has been explained in full by Chesnut et al.[1,2] in terms of the singlet-triplet equilibrium resulting from the spin correlation between two anion radicals of TCNQ. Chesnut et al. have referred to the existence of a discontinuity in the magnetic susceptibility of the TCNQ salt of methyltriphenylphosphonium, $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, at 315°K.[1,3] In this report we will present the temperature dependences of the ESR absorption and electrical conductivity of the salt in the temperature range including 315°K.

Single crystals of the phosphonium salt were prepared in the manner described by Melby et al.,[4] and all the measurements were performed with these single crystals. The crystal showed the same ESR fine structures at about 130°K arising from the magnetic dipole interaction as has been examined by Chesnut and Phillips.[1] At a higher temperature range, where the fine structures coalesced, the ESR absorption intensity and the line width varied with the temperature, as shown in Figs. 1 and 2, respectively.

The intensity increased with the rising temperature until about 310°K, in accordance with the following equation:

$$\text{Intensity} \propto [kT(3+e^{J/kT})]^{-1} \quad (J=0.08\text{eV.}) \quad (1)$$

A discontinuity in the intensity occurred at 310~315°K, and then the intensity seemed to obey Curie's law above 315°K. This means

that the reduction of J in Eq. 1 should take place in the higher temperature range. The line width became slightly sharper above 315°K. These changes were found to be reversible. It is worthwhile noting that a similar anomaly has been found in the magnetic susceptibility of Würster's blue perchlorate at 186°K.[5]

A similar discontinuity was found in the electrical conductivity, which was measured by the d. c. method. This is shown in Fig. 3. The crystal was a rectangular prism about 2×1×0.5 mm. The conductivity was measured in three directions, which were chosen arbitrarily so that (a) was along the long axis, (b) was normal to the largest plane, and (c) was perpendicular to (a) and (b). In all directions the conductivity varied abruptly by a factor of about 3.5 at about 310°K, and this change was reversible. The current varied with the applied voltage in good acordance with Ohm's law below the electric field of 100 V./cm., and it was found to be constant with time. Hence, the electronic conduction mechanism must be plausible for this salt. although in some salts, for example, $Li^+(TCNQ)^-$, the current was found to change with time; this may be attributable to a partial contribution from the ionic conduction. The activation energy E in the equation $\sigma=\sigma_0 \exp(-E/kT)$ was found to be almost isotropic, and its magnitude changed at the temperature where the anomaly occurred. These values were (a) 0.32 eV., (b)

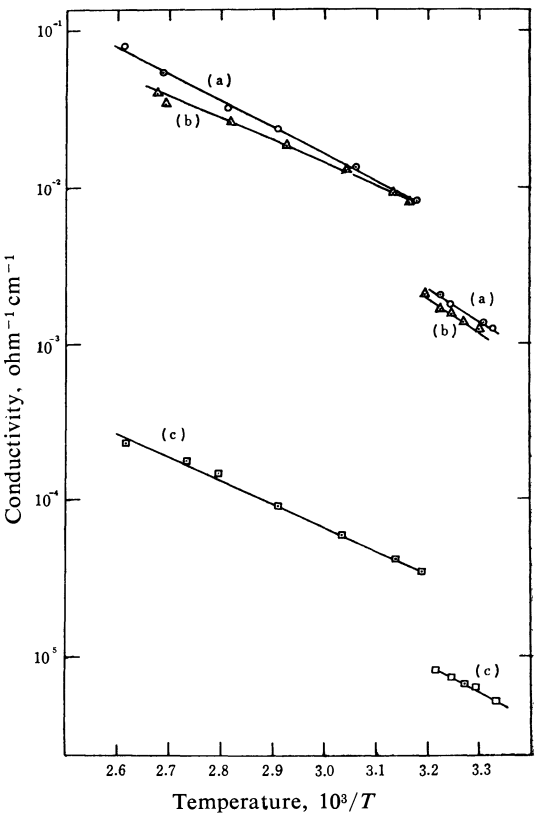

Fig. 3. The temperature dependence of the electrical conductivity of the single crystal of $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, for three directions arbitrarily chosen (a), (b) and (c).

0.29 eV. and (c) 0.30 eV. above 310°K, but a 0.42 eV., (b) 0.42 eV. and (c) 0.38 eV. below 310°K. On the other hand, the conductivity was not isotropic. This might be ascribed to anisotropy in the mobility of the charge carriers.

The reproducibility of our magnetical and electrical observations is good within the range of experimental error, and the values obtained did not depend on the specimens used. Hence, the discontinuity observed for the $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$ crystal might be attributed to a phase transition, which is of the same type as has been suggested by McConnell and Lynden-Bell[6] for the case of the Würster's blue perchlorate crystal. Preliminary investigation by the X-ray diffraction method showed that there was a slight, but clear difference in the crystal lattices between those observed at temperatures below and above 310°K.

The Effect of Thiols on the Oxo Reaction

By Masanobu MORIKAWA

(Received October 15, 1963)

The reaction of olefins with carbon monoxide and hydrogen to form saturated aldehydes is well known as the oxo reaction or hydroformylation.[1] In general, this reaction is carried out at an elevated temperature and under a high pressure in the presence of the salts or oxides of cobalt. In this case the reaction products are composed of a mixture of isomeric aldehydes, accompanied by other by-products formed by the secondary reaction of the aldehydes.

In this sense, a high selectivity of the reaction is very desirable. For this purpose, the reaction is carried out at a relatively low temperature. In addition, aliphatic acids,[2] organic bases[3] or noble metals[4] have been proposed as promoters of the lower temperature reaction.

In the course of our studies of the effect of organic ligands co-ordinating with cobalt on the oxo reaction products and conditions, we have found that the reaction is most accelerated by the addition of a small amount of an organic sulfur-compound such as thiol, because of the weak ability of such compounds to co-ordinate.

This accelerating effect of thiols has been investigated; the results of the experiments with cyclohexene are shown in Table I. The results clearly indicate that the reaction can proceed at a lower temperature with a short induction period and with a rapid reaction rate in the presence of a limited amount of thiol. The activation energy of the reaction of cyclohexene was found to be reduced, by the addition of thiophenol, to 13 kcal./mol. from the about 30 kcal./mol. reported without the addition.[5]

The lower temperature-reaction of propylene upon the addition of thiophenol resulted in the selective formation of a straight chain aldehyde. Thus, *n*-butyraldehyde was obtained in a 83% yield at 120°C, as compared to 57% at 160°C without the addition.

It seems likely that thiol has an accelerating effect not only on the reaction catalyzed by the salts or oxides of cobalt, but also on the reaction catalyzed by cobalt calbonyl. Although the raction usually takes place at a lower temperature in the presence of cobalt carbonyl, it has a lengthy induction period under a pressure lower than 110 kg./cm^2. Upon the additon of thiol, the reaction proceeds with a short induction period, as is shown in Table II.

Experimental[6]

The experimental results listed in the tables were obtained in the following way.

In a 100 ml. stainless steel perssure reactor, 0.05 mol. of olefin and 20 ml. of toluene were charged with a cobalt catalyst and additives in the amounts specified in the tables. The air was purged, and a carbon monoxide-hydrogen mixture (1 : 1) was

introduced up to the pressure of 200 kg./cm^2. As soon as the reactor was heated to a specified reaction temperature, agitation was started.

The induction period of the reaction was defined as the time taken for the reaction to start after the beginning of agitation.

The reaction rate deteremined by the rate of gas absorption, while the rate constant was calculated on the basis of the linear relationship between the rate and the olefin concentration.[5]

The reaction was continued until no further pressure drop was observed. The yield of aldehydes and the ratio of the straight chain aldehyde to the branched aldehyde were determined by gas chromatography using an internal standard carried out with a 2 m. "Silicone DC-550" column operated at 120°C or 180°C and with the flow rate of 50 ml./min. of helium gas.

The products was identified by comparing the retention time of the gas chromatograph, the infrared spectra and the melting points of the 2, 4-dinitrophenylhydrazones of the aldehydes with those of authentic samples.

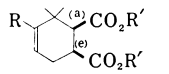
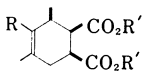
SHORT COMMUNICATIONS

Stereochemistry Related to the Diels-Alder Adducts of 4-Methyl-1, 3-pentadienes[1]



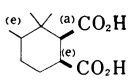
By Iwao ICHIKIZAKI and Atsuaki ARAI

(Received November 6, 1963)



It has been obscure why the conclusions reported by several authors about the behaviour of 3, 4-dimethyl-1, 3-pentadiene (I)[2-4] and 4-methyl-1, 3-pentadiene (II)[5-8] in the Diels-Alder reaction did not agree with each other. We can, however, now reasonably surmise that, during the course of the Diels-Alder reaction with less reactive dienophiles, these dienes are mostly isomerized to more stable ones,[3] while with more reactive dienophiles the reaction smoothly proceeds to give the normal adducts.[8] A recent publication[9] discussing the formation of the normal adducts in the reaction of the dienes I and II with maleic anhydride has prompted us to report our independent studies of the formation and structure of the same adducts and some derivatives.

The diene I reacted easily with maleic anhydride in benzene at a temperature range of 70~120°C in a nitrogen atmosphere to afford an inhomogeneous adduct which gave, on hydrolysis with boiling water, a high yield of the diacid (IIIa) as colorless needles (m.p. 153~153.5°C (lit. m. p. 150~151°C[9]) ; dimethyl ester (IIIb), b. p. 106~107°C/0.4 mmHg, n_D^{15} 1.4781 (lit. b. p. 90~92°C/0.05 mmHg, n_D^{25} 1.4742[9]), ν_{max}^{film} 1735 cm^{-1}, NMR (in CCl_4) : 8.98, 8.86 (gem-Me_2), 8.34 (Me at $C_{(4)}$), 6.45, 6.37 (ester Me) and 4.66 τ (olefinic H)), and the diacid (Va) (m. p. 173~174°C (lit. m. p. 167°C[2]) ; dimethyl ester (Vb), b.p. 149°C/0.7 mmHg, n_D^{15} 1.4816, ν_{max}^{film} 1735 cm^{-1}). It should be emphasized here that the formation of the adduct corresponding to Va tends to be promoted when air remains in the reaction vessel.



The diacid IIIa was hydrogenated over an Adams catalyst in ethanol or ethyl acetate to afford the saturated diacid (VIIa) (89%), (m.p. 191~192°C, ν_{max}^{KBr} 1706 cm^{-1}). When heated at 220~230°C with concentrated hydrochloric acid, the diacid gave the epimer (VIIb) (80%) (m. p. 202~202.5°C, ν_{max}^{KBr} 1706 cm^{-1}), which returned, after refluxing with acetic anhydride and succeeding hydrolysis, to the starting diacid VIIa. The diacid IIIa was readily lactonized, in the presence of a catalytic amount of hydrochloric acid, to a γ-lactonic acid (VIIIa) (90%) (m. p. 196~197°C, ν_{max}^{KBr} 1772, 1704 cm^{-1}; methyl ester (VIIIb), m.p. 112°C, ν_{max}^{KBr} 1775, 1741 cm^{-1}, NMR (in $CDCl_3$) : 8.89 (gem-Me_2), 8.71 (Me–C(–O)–) and 6.27 τ (ester Me)). Considering the facile formation of VIIIa in addition to the non-bonded 1, 3-diaxial interaction, the present authors confirmed the conformation for the normal product as IIIa.

different $\nu_{C=O}$ bands and a considerably intense band at 1625 cm^{-1} assignable to $\nu_{C=O}$, while that in a solution ($CHCl_3$) showed only a single absorption, due to $\nu_{C=O}$, at 1709 cm^{-1}. Such spectral characteristics were also observed in a diacid (IVa) described below, but not in several other Δ^4-cyclohexene-1, 2-diacids, including 3, 3, 5-trimethyl-4-cyclohexene-1, *cis*-2-dicarboxylic acid (IX). The lactonization of IX gave δ-lactonic acid, 1, 8, 8-trimethyl-3-oxo-2-oxabicyclo [2, 2, 2]octane-exo-5-carboxylic acid (m.p. 166°C, ν_{max}^{KBr} 1741, 1706 cm^{-1}; methyl ester, (b.p. 131~132°C/0.8 mmHg, n_D^{20} 1.4755, ν_{max}^{film} ~1750 cm^{-1} (broad)).

The diene II produced the diacid IVa as colorless needles (m. p. 172~173°C (lit. m. p. 172~173°C[9]), ν_{max}^{KBr} 1730, 1709 (sh), 1624, 705 cm^{-1}), along with the diacid (VIa) (m. p. 154°C (lit. m. p. 154°C[5])) and *cis*-3, 5-dimethyl-5(a)-hydroxycyclohexane-1, *cis*-2-dicarboxylic acid (m. p. 208~209°C, ν_{max}^{KBr} 3400, 1707, 1698 (sh), 1112 cm^{-1}); the latter two were converted into 1, 8-dimethyl-3-oxo-2-oxabicyclo [2, 2, 2] octane-exo-5-carboxylic acid (m. p. 147~148°C, ν_{max}^{KBr} 1748, 1709 cm^{-1}; methyl ester, b.p. 147~148°C/1.8 mmHg, $n_D^{18.5}$ 1.4752, ν_{max}^{film} ~1743 cm^{-1} (broad)).

Satisfactory analyses were obtained for all compounds.

A New Method for the Protection of the Sulfhydryl Group during Peptide Synthesis

By Shiro AKABORI, Shumpei SAKAKIBARA, Yasutsugu SHIMONISHI and Yoshifumi NOBUHARA

(Received November 27, 1963)

The protection of the thiol group in the cysteine residue is of great importance in the field of peptide synthesis. Glutathione, oxytocin and vasopressin have been synthesized by many investigators, and the *S*-benzyl group has generally been used to protect the thiol during the procedures. Recently, however, in connection with the synthesis of insulin, several new *S*-protecting groups have been developed. Some of them, however, were too stable to be split from the final products without causing partial destruction of the peptide, and some of them were too labile to allow preparation of the peptide in a good yield.

In the present investigation, the *p*-methoxybenzyl (anisyl) group was found to be valuable for masking the thiol; that is, the *S*-*p*-methoxybenzyl group was easily cleaved by treatment with boiling trifluoroacetic acid, although it was not affected by hydrogen bromide, as is shown below. Moreover, the synthesis of *S*-*p*-methoxybenzyl-L-cysteine (I) was as easy as that of the *S*-benzyl derivative. Freshly-prepared L-cysteine was treated with *p*-methoxybenzyl chloride in liquid ammonia to form I, which was recrystallized from water; colorless plates were obtained in a 78% yield; m. p. 198~199°C (decomp.), $[\alpha]_D^{25}$ +22.6° (*c* 1.02, N NaOH). Found: C, 54.50; H, 6.33; N, 5.89; S, 13.05. Calcd. for $C_{11}H_{15}O_3NS$: C, 54.75; H, 6.26; N, 5.81; S, 13.29%. After the treatment of I with anhydrous trifluoroacetic acid containing phenol or anisol, followed by oxidation with iodine solution, L-cystine was recovered in a 84% yield; it had the same optical activity as the starting L-cystine. Compound I was submitted to reaction with carbobenzoxy chloride in a basic condition to give *N*-carbobenzoxy-*S*-*p*-methoxybenzyl-L-cysteine (II), which was recrystallized from toluene as colorless needles; yield, 76%; m.p. 66~67°C, $[\alpha]_D^{24}$ −42.1° (*c* 2.0, acetone). Found: C, 60.73; H, 5.80; N, 3.55, S, 8.46. Calcd. for $C_{19}H_{21}O_5NS$: C, 60.78; H, 5.64; N, 3.73; S, 8.54%. The dicyclohexylamine salt of II was recrystallized from ethanolether as fine colorless needles; m. p. 148~149°C, $[\alpha]_D^{27}$ −8.4° (*c* 2.22, EtOH). Found: C, 66.85; H, 7.90; N, 4.94; S, 5.60. Calcd. for $C_{31}H_{44}O_5N_2S$: C, 66.87; H, 7.97; N, 5.03; S, 5.76%. When II was treated with hydrogen bromide in acetic acid, *S*-*p*-methoxybenzyl-L-cysteine was recovered in a 77% yield; this had the same melting point as I and gave one spot on a paper chromatogram.

Compound II was coupled with glycine ethyl ester in the presence of dicyclohexylcarbodiimide in anhydrous acetonirile. Carbobenzoxy-*S*-*p*-methoxybenzyl-L-cysteinyl-glycine

ethyl ester (III) was obtained as fine colorless needles after recrystallization from ethyl acetate-petroleum benzine (81%); m.p. 87.5~89.5°C, $[\alpha]_D^{27}$ −31.1° (*c* 3.15, EtOH). Found: C, 59.89; H, 6.20; N, 5.95; S, 7.07. Calcd. for $C_{23}H_{28}O_6N_2S$: C, 59.98; H, 6.13; N, 6.08; S, 6.96%. Substance III was hydrolyzed in dioxane, using N sodium hydroxide, to give carbobenzoxy-*S*-*p*-methoxybenzyl-L-cysteinyl-glycine (IV), which was recrystallized from ethyl acetate-petroleum benzine as fine colorless needles (69%); m. p. 132~133.5°C, $[\alpha]_D^{24}$ −35.0° (*c* 3.14, EtOH). Found: C, 58.57; H, 5.42; N, 6.34; S, 7.35. Calcd. for $C_{21}H_{24}O_6N_2S$: C, 58.32; H, 5.59; N, 6.48; S, 7.41%. The treatment of IV with hydrogen bromide, followed by neutralization with aqueous sodium acetate, gave *S*-*p*-methoxybenzyl-L-cysteinyl-glycine (V) in a 83% yield; m.p. 164~164.5°C, (decomp.), $[\alpha]_D^{25}$ +29.3° (*c* 2.00, N NaOH). Found: C, 52.52; H, 6.02; N, 9.35; S, 10.47. Calcd. for $C_{13}H_{18}O_4N_2S$: C, 52.33; H, 6.08; N, 9.39; S, 10.75%. Compound V was refluxed with anhydrous trifluoroacetic acid containing phenol. The cysteinyl-glycine thus formed was oxidized by an iodine solution to L-cystinyl-diglycine (VI), which was purified by the procedure descrived by Weygand.[1] Yield, 48%; $[\alpha]_D^{28}$ −68.9° (*c* 0.944, water), reported[2] $[\alpha]_D^{27}$ −67.5° (*c* 1, water). Found: C, 33.91; H, 5.37; N, 16.10; S, 17.59. Calcd. for $C_{10}H_{18}O_6N_4S_2$: C, 33.89; H, 5.12; N, 15.81; S, 18.10%. Detailed results and the application of the procedure will be published elsewhere.

A New Colorimetric Determination of Iodide Ions by Solvent Extraction with the 1, 10-Phenanthroline-Iron(II) Complex

By Yuroku YAMAMOTO and Seiichiro KINUWAKI

(Received December 7, 1963)

This study presents a new method for the determination of iodide ions by solvent extraction. We have found that a colored 1, 10-phenanthroline-iron(II) chelate cation was extractable into nitrobenzene from aqueous solution when a small amount of iodide was present. Figure 1 shows the absorption spectra of the extracts against nitrobenzene used as a reference. The extractions were carried out from aqueous solutions containing the phenanthroline-iron(II) complex in an acetate buffer (pH 4.5). Curve 1 is a spectrum of the extract with iodide ions, while curve 2 is that of the extract when iodide is absent. It is shown that when the concentration of acetate ion is quite high, the chelate cation is also extractable into nitrobenzene, but when a small amount of iodide is present, the chelate cation is much more extractable into the organic layer. The results suggest that it is possible to determine the quantity of iodide ions by solvent extraction with the chelate cation, using the reagent blank solution as a reference.

① Extracts by nitrobenzene with iodide ion.
② Extracts by nitrobenzene without iodide ion.
Reference: Nitrobenzene

The absorbance maximum of the chelate cation in the organic layer is 516 mμ. The maximum of the chelate cation in an aqueous solution is 510 mμ, which coincides with the

value of the literature.[1] This red shift of the spectrum in the organic layer may be due to the effect of the association between the chelate cations and iodide ions in such a polar solvent as nitobenzene.

The percentage of the extraction of iodide ions was about 90%. This was determined by the radiochemical technique using radioisotope I-131 (NaI) as a tracer. From the above findings, it may be presumed that the chemical form of the extracted species is $[Fe(phen)_3]^{2+} \cdot (I^-)_2$.

Besides nitrobenzene, various organic solvents, such as chloroform, 1, 2-dichloroethane, cyclohexanone, chlorobenzene, and benzene, were tested for the extraction. However, the associated species between the phenanthroline-iron(II) complex and iodide ions was not extractable into such a solvent.

	I^-	$3.4\times10^{-6}\times x$
	pH	4.5
	Reference	Reagent blank

To obtain an optimum conditions for the determination of iodide ions, various factors were studied: the effects of the concentration of iron(II) ions (as ferrous ammonium sulfate), phenanthroline, the pH of the solution, the stability of the color, the shaking time, and the presence of diverse ions. The recommended procedure for the calibration curve (Fig. 2) is as follows:

Two milliliters of the 1, 10-phenanthroline solution (1×10^{-2}M), 1.0 ml. of the ferrous ammonium sulfate solution (5×10^{-3}M), 2 ml. of the sodium acetate buffer solution (3M, pH 4.5) and varying amounts of the standard sodium iodide solution (8.5×10^{-5}M; 0.5~5.0 ml.) are mixed and diluted to 25 ml. with distilled water. Then 10.0 ml. of purified nitrobenzene is added. After the mixture has been shaken for 20 min., and after the organic layer has been transferred to a glass flask containing 1 g. of anhydrous sodium sulfate, the transparent solution is transferred into a 10.0 mm. cell through folded filter paper. The absorbance of the solution is measured at 516 mμ using the reagent blank solution as a reference. As is shown in Fig. 2, Beer's law is followed in the range of 1×10^{-6} ~5×10^{-5} M of iodide ions.

When a considerable amount of chloride (about 100 times that of iodide) is present, the determination of iodide is not interfered with, but the presence of the same amounts of perchlorate or thiocyanate as iodide gives a considerable positive error.

The Condensation of 9-Ethylacridine and p-Nitosodimethylaniline[1]

By Otohiko TSUGE, Minoru NISHINOHARA and Kunio SADANO

(Received December 24, 1963)

It has previously been reported[2] that the condensation of the 9-methylacridine derivative and the aromatic nitroso compound in the presence of a catalytic amount of hydrochloric acid affords the condensation products, an anil and a nitrone, in a fairly good yield compared with the yield when a basic catalyst is used.

From this result, it may be concluded that hydrochloric acid can noticeably activate the active methyl group at the 9-position of the acridine ring in the reaction with the aromatic nitroso compound.

Accordingly, it appeared of interest to investigate whether 9-ethylacridine (I) can be condensed with the aromatic nitroso compound in the presence of hydrochloric acid.

The reaction of I with *p*-nitrosodimethylaniline (II) did not take place in the presence of potassium carbonate, and *p,p'*-bis(dimethylamino)azoxybenzene (III) (m. p. 240~241°C (reported, 241~242°C[3])) was formed in only a small amount. In the presence of hydrochloric acid, however, I reacted with II to give the condensation products. For example, when a solution of 1.0 g. of I, 1.4 g. of II and 0.20 ml. of concentrated hydrochloric acid in 25 ml. of ethanol was refluxed for 5 hrs., 1.29 g. of reddish brown crystals (IV) (m. p. 261~263°C (decomp.)) was obtained. Found: C, 77.51, 77.74; H, 6.04, 6.10; N, 14.11, 14.36%.

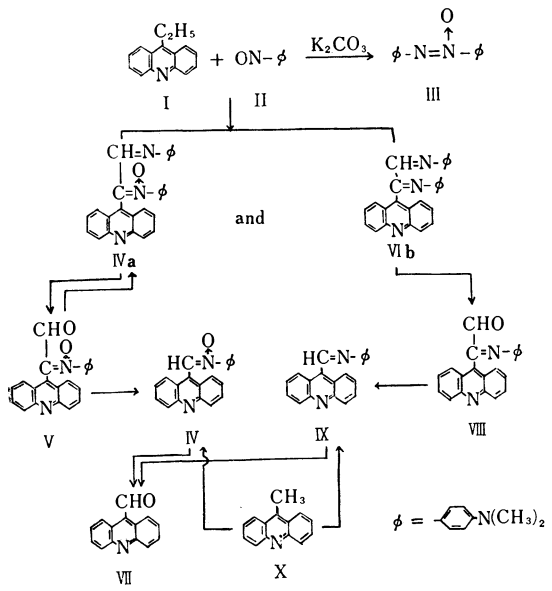

Chart 1.

The hydrolysis of 1.0 g. of IV with 10 ml. of 12% aqueous hydrochloric acid afforded 0.30 g. of acridine-9-carboxaldehyde (VII) (m.p. 147°C (reported, 147°C[4])). The treatment of 0.5 g. of IV with 10 ml. of cold 10% aqueous sulfuric acid gave the α-nitrone-β-formyl compound (V) as orange prisms (m. p. 208°C (decomp.)). Found: C, 74.85; H, 5.18; N, 11.13. Calcd. for $C_{23}H_{19}O_2N_3$: C, 74.78; H, 5.18; N, 11.37%. IR (Nujol): 1662 cm^{-1} (C=O).

From the condensation of V and *p*-aminodimethylaniline, the α-nitrone-β-anil compound (IVa) was obtained as reddish brown prisms (m. p. 265°C (decomp.)). Found: C, 76.67; H, 6.24; N, 14.10. Calcd. for $C_{31}H_{29}ON_5$: C, 76.36; H, 6.00; N, 14.36%. The infrared spectrum of IVa showed the characteristic bands at 1212, 1119, 818 and 758 cm^{-1}. Furthermore, 0.26 g. of V was oxidized with silver oxide to give 0.10 g. of the nitrone (VI), which was prepared by the condensation of 9-methylacridine (X) and II and which was easily hydrolyzed to VII. V was also easily hydrolyzed with dilute hydrochloric acid to afford VII.

On the other hand, the dianil compound (IVb) was obtained as red prisms (m.p. 283°C (decomp.)) by several fractional recrystallizations of IV from pyridine. Found: C, 78.87; H, 6.19; N, 14.65. Calcd. for $C_{31}H_{29}N_5$: C, 78.95; H, 6.20; N, 14.85%. Its infrared spectrum exhibited the distinctive bands at 1228, 1158, 819 and 742 cm^{-1}.

From the results of the infrared spectrum of IV, which revealed all the distinctive bands of IVa and IVb, and from the results of the elemental analysis, IV seems to be a mixture of the two compounds. However, the ratio of these two compounds in IV has not been established.

4) L. Chardonnens and P. Heinrich, *Helv. Chim. Acta*, 32, 635 (1949).

The compounds VIII and IX could not be separated, but it seems most reasonable to conclude from the above results that the hydrolysis of IV to VII proceeds successively through the course depicted in Chart 1.

Further investigation is in progress; details of this work will be published in the near future.

The Crystal Structure of Spermine Phosphate Hexahydrate

By Yōichi IITAKA and Yukiko HUSE

(Received January 9, 1964)

Recently, many interesting findings have been reported concerning the effect of spermine on various enzyme activities and on the relationship of this amine to nucleic acids and to problems of membrane stability.[1] Much of the evidence is indirect, but the data definitely indicate that spermine and nucleic acids have a strong affinity for each other.[2-4] The analysis of the crystal structure of spermine phosphate hexahydrate was, therefore, undertaken to provide information on the binding relation of this amine to phosphoric acid and water.

The unit cell dimensions were found to be: $a=7.95_5$, $b=23.21_6$, $c=6.87_0$ Å, and $\beta=113°39'$. The space group is $P2_1/a$. Density measurements indicated that two units of $C_{10}H_{26}N_4 \cdot 2H_3PO_4 \cdot 6H_2O$ are contained in a cell. The structure was solved by analysis of a three-dimensional sharpened Patterson function and was refined by the Fourier and least-squares methods. The final reliability factor for the 1747 non zero (*hkl*) data was 0.127.

From a consideration of the arrangement of hydrogen bonds and the bond lengths of the phosphate group, it has been concluded that the chemical formula of this compound can be written as $NH_3^+(CH_2)_3NH_2^+(CH_2)_4NH_2^+ \cdot (CH_2)_3NH_3^+ \cdot 2HPO_4^{2-} \cdot 6H_2O$. Two views of the structure, along the b- and c-axes, are shown in Figs. 1 and 2 respectively. The structure consists of parallel sheets of spermine molecules separated by a sheet of phosphate ions and water molecules. These two kinds of sheets are stacked alternatively parallel to the (001) plane and are held together by N–H···O hydrogen bonds. The latter sheet has the composition $HPO_4^{2-} \cdot 3H_2O$, containing hydrogen-bonded chains of phosphate ions, $\cdots O_2\text{–}P\text{–}O_4\text{–}H\cdots O_2\text{–}P\text{–}O_4\text{–}H\cdots$, running along the a-axis. As Fig. 2 shows, adjoining chains in the sheet are arranged antiparallel and are sparated by the distance $b/2=11.6$ Å. The water molecules form a hexagonal network of hydrogen bonds and fill up the spaces between the chains. In the molecular sheets of spermine, the molecules are tilted at about 33° from the a-axis and are arranged in parallel, keeping van der Waals distances, with adjacent molecules in the a-direction. Adjacent molecules in the b-direction are oppositely inclined and form a planar herring-bone arrangement with the spermine molecules. Along the backbones run the phosphate chains. Because of this tilting, the amino and imino nitrogen atoms on one side of a molecule are linked to the same phosphate chain. It is to be noted that of the ten such N–H···O hydrogen bonds, only two are those to the water molecules. All of the rest link the molecule strongly to the phosphate ions.

As for the arrangement of phosphate groups, we noticed a certain similarity between that found in crystalline DNA and that in spermine phosphate. Langridge et al.[5] have shown the arrangement of phosphate groups along the polynucleotide helices in the B-form of LiDNA (Figs. 13 and 14 in their paper). In this structure, two oxygen atoms O2 and O3 of a phosphate group which share one negative formal charge turned outwards and are readily available for interaction with proteins, water, etc. The distance between the O3 oxygen atoms of the successive phosphate groups along the helix is about 7.3 Å, which may be compared

with the a-translation period of 7.96 Å along the phosphate chains in spermine phosphate. The perpendicular distance between two nucleotide chains (chains A and B of the same molecule, measured across the shallow) in LiDNA is about 13 Å, while in the latter structure the separation of the phosphate chains within the same sheet is found to be about 11.6 Å.

The Isolation, Structure and Properties of a New π-Diene-Iron Tricarbonyl Complex Formed from Methyl Linolate and Iron Pentacarbonyl

By Ikuei OGATA and Akira MISONO

(Received January 10, 1964)

A π-diene-iron tricarbonyl complex, the formation of which in the process of the hydrogenation of cotton seed oil with the iron pentacarbonyl catalyst was reported on in a previous paper,[1] has now been prepared for the first time and isolated by the following procedure: A mixture of fatty acid methyl ester of dehydrated castor oil (30 g.) and iron pentacarbonyl (13.7 ml.) was heated repeatedly under nitrogen at 180°C in a stainless-steel bomb until the evolution of carbon monoxide ceased. The ether solution of the reaction mixture was then washed with aqueous hydrochloric acid (1 : 1) and with water. After the solvent had been removed, a few drops of low-boiling materials were distilled off at 0.1 mmHg below 205°C, the temperature of the bath. The remaining liquid was distilled in a magnetic-stirred pot-type molecular distillation still; as a last fraction, about 8 g. of a yellow-orange oil was obtained. B. p. 79~90°C/10^{-4} mmHg; d_4^{28} 1.092; n_D^{26} 1.5158; mol. wt. (ebullioscopic in MEK), 414; Found: C, 62.2; H, 8.1; Fe, 12.8. Calcd. for $C_{22}H_{34}O_5Fe$: C, 60.8; H, 7.9; Fe, 12.9%.

An attempt to isolate the compound by chromatography over alumina (Woelm, grade II.) with petroleum benzine was unsuccessful.

The infrared spectrum taken in carbon disulfide shows characteristic M–C≡O bands at 2045 and 1975 cm^{-1} ($E_{cm}^{\%}=93$ at $I/I_0=0.5$), and these bands agree closely with those of cyclo-

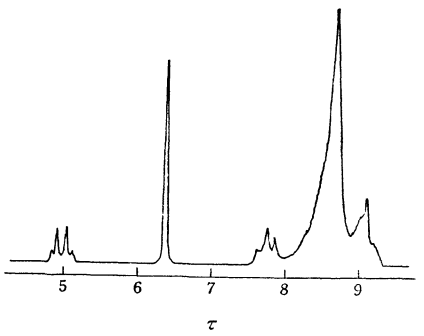

Fig. 1.

octadiene-iron tricarbonyl.[2]

The ultraviolet spectrum taken in cyclohexane shows an absorption maximum at 210(?)~220 mμ (log ε=4.37). The value reported in the literature[3] for butadiene-iron tricarbonyl is 211 mμ (log ε=4.36).

The high resolution NMR-spectrum (Fig. 1) taken in carbon tetrachloride at 60 Mc. indicates the following signals (range in τ-value, relative intensity, structure and/or assignment): 4.8~5.2, 2, double-triplet, coordinated olefinic protons; 6.3~6.5, 3, $-OCH_3$; 7.5~7.9, 2, $-CH_2-CO-$; 7.9~9.4, 27, two overlapped, unsymmetrical bands, aliphatic protons. By analogy from the spectra of the iron tricarbonyl complexes of butadiene, 1, 3-cyclohexadiene, and

1, 3-cycloheptadiene,[4] the lowest-field band may be assigned to the "central" protons of a coordinated conjugate system.

Ligand-exchange reaction with triphenylphosphine in liquid paraffin in a tube at 150°C for 24 hr. afforded yellow crystals, the infrared spectrum of which is identical with that of bis(triphenylphosphine)-iron tricarbonyl.[5] From the infrared spectrum and from the gas-liquid chromatography, the remaining liquid proved mainly to be one of the stereoisomers of methyl-C_{18}-conjugated-diene-carboxylate.

These results indicate that this compound is the iron tricarbonyl complex of methyl-C_{18}-conjugated-diene-carboxylate formed from methyl linolate by isomerization reaction.

The complex is reasonably stable in the condensed state, but it is readily decomposed in solution, even under nitrogen in a dark, cold place, and gives brown or black precipitates. When treated above its decomposition temperature (ca. 225°C), a mixture of this complex and diene-carboxylic acid ester polymerized mainly to the dimer of the acid ester. By hydrocracking at 200°C (100 atm. in a stainless-steel bomb), the complex was converted mainly to methyl stearate.

The Reduction of Zinc Oxide by Hydrogen. III. The Effect of Nitrogen on the Reduction

By Tatsuya IMOTO, Yoshio HARANO, Yasuhide NISHI and Satoru MASUDA

(Received May 16, 1963)

The following results were obtained in the previous study of the reduction of zinc oxide by hydrogen.[1,2] The reaction proceeds independently of the hydrogen pressure. Additionally, in the presence of a large amount of zinc oxide (case 1), the reduction is not affected by the amount of zinc oxide, and the relationship between the pressure and the reaction time is linear. In the presence of a small amount (case 2), however, the relation is not linear. In the latter case, the data well satisfied Eq. 1, deduced from the assumption that the reaction rate is proportional to the surface area.

$$(p_0-p_\infty)^{1/3}-(p-p_\infty)^{1/3}=k_2(t-t_0) \qquad (1)$$

Here p_0 and p_∞ are the hydrogen pressures when the reaction starts to obey Eq. 1 and when zinc oxide is completely used up respectively. As a result, the reduction of zinc oxide was suggested to be not a surface reaction, but a consecutive one consisting of two processes, the sublimation-decomposition of zinc oxide to zinc vapor and oxygen and the subsequent reaction of oxygen and hydrogen. Further, the former process is the rate-determining step in case 2.

The thermal decomposition of zinc oxide has been known to be influenced by the third gas, i.e., nitrogen or zinc vapor.[3,4] Hence, one can expect the variation of the reaction modes, in case 2, in the presence of these gases. With this expectation the present work was carried out, using nitrogen as the third gas.

Experimental

The apparatus used for this work was the same as that used in the previous paper.[1,5] Just before the reaction started, the reaction tube was evacuated for five minutes, and then nitrogen and, finally, hydrogen were admitted at a given pressure and composition. The rate of the reduction was measured in the temperature range 690~738°C, with the amount of zinc oxide, 40.0 mg., and the pressure range of nitrogen, 0~2 cmHg. The analysis of data was made by applying Eq. 1 as in the previous work.[2] The initial pressure of hydrogen was 6.0~6.4 cmHg. Nitrogen was prepared by purifying the commercial gas in a bomb by passing it through the reduced copper heated at 500°C, through concentrated sulfuric acid and finally through magnesium perchlorate.

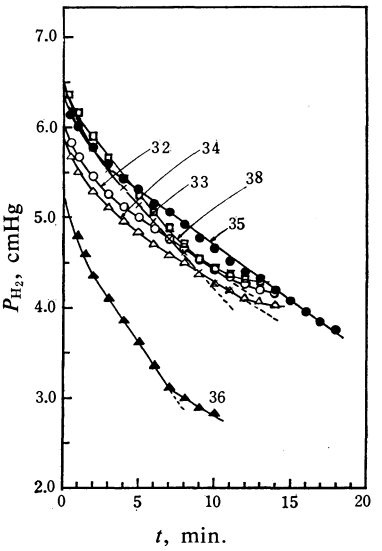

Fig. 1. The relation between residual H_2 and reaction time. Runs are shown in Table I.

Results and Discussion

The results obtained at 670°C are shown in Fig. 1. The initial amount of zinc oxide in all experiments was 40.0 mg., except for the 300 mg. in No. 35, which was done under the same conditions as No. 32. As has been mentioned above, when a large amount of zinc oxide is present, only the linear part appears in the relation between the hydrogen pressure and the reaction time.[1,2] Hence, the slope of a straight line in No. 32 can be estimated by comparing No. 32 with No. 35. From Fig. 1 and by applying Eq. 1, the specific reaction rates, k_1 and k_2, are as shown in Table I; k_1

34	1.470	40.0	0.105	0.029

and k_2 correspond to the reactions revealed as a straight line and a curve respectively in Fig. 1 (see also Fig. 2 in the previous report[2]). No. 38 at the zero nitrogen pressure obtained in the previous work[2] was also tabulated for the sake of comparison.

As may be seen in Table I, both k_1 and k_2 decrease with the nitrogen pressure. Moore et al.,[4] who studied the thermal decomposition of zinc oxide, found that the amount of zinc oxide decomposed in the stream of nitrogen is smaller than that in oxygen, and that it is, moreover, much smaller than would be expected from the thermodynamics by 10^{-2}. They made no reference to the reason for this. Assume that some substance retarding the sublimation-decomposition of zinc oxide is produced in the presence of nitrogen, and that the surface area of zinc oxide poisoned by the retarding substance is θ, by taking $\theta=0$ for the surface in the absence of nitrogen. Since k_2 is the specific decomposition rate of zinc oxide per unit surface area, θ at various nitrogen pressures will be given Eq. 2:

$$\theta = 1 - \frac{(k_2)_{P_{N_2}}}{(k_2)_{P_{N_2}=0}} \qquad (2)$$

Let us assume additionally that the retarding substance is produced on the whole surface with the same probability by molecular nitrogen. Thus, at equilibrium, θ will expressed by a form similar to the Langmuir-type adsorption isotherm,[6] Eq. 3:

$$\theta = \frac{aP_{N_2}}{1+aP_{N_2}} \qquad (3)$$

$$\frac{1}{\theta} = 1 + \frac{1}{aP_{N_2}} \qquad (4)$$

TABLE II. THE RELATION BETWEEN P_{N_2} AND θ

No.	P_{N_2} cmHg	$1/P_{N_2}$ cmHg^{-1}	$\frac{(k_2)_{P_{N_2}}}{(k_2)_{P_{N_2}=0}}$	θ

6) I. Langmuir, *J. Am. Chem. Soc.*, **40**, 1361 (1918).

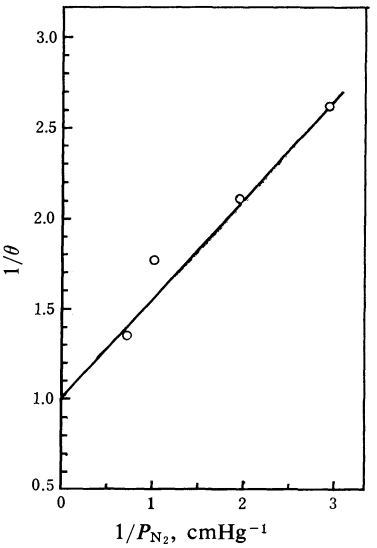

Fig. 2. $1/\theta \sim 1/P_{N_2}$ at 690°C.

θ values calculated from k_2 in Table I according to Eq. 2 are shown in Table II.

In Fig. 2, $1/\theta$ is plotted against $1/P_{N_2}$. Figure 2 shows that every value gives a good straight line, and that Eqs. 2—4, based on the above assumptions, are satisfied. $1/a$ is estimated to be 1.73 from the slope of the line in Fig. 2.

As a result, it is considered that the effect of the nitrogen molecule can be evaluated by the magnitude of a. There is another method of estimating a, even when no data of $(k_2)_{P_{N_2}=0}$ is obtained. As $(k_2)_{P_{N_2}=0}$ will be constant at a constant temperature and a constant state of the surface, the following relations are obtained from Eqs. 2 and 3:

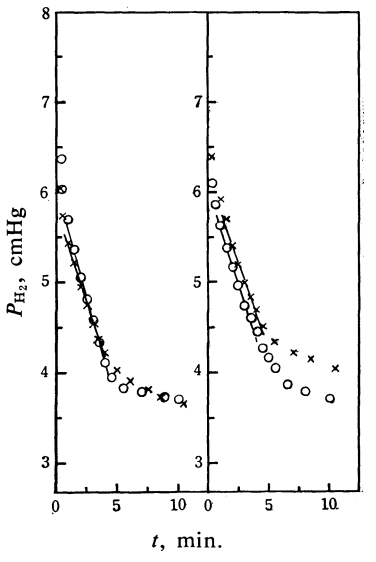

Fig. 3. $P_{H_2} \sim t$, at 714°C; P_{N_2} (cmHg) left: ○ 0.538, × 0.916; right ○ 1.480, × 1.974

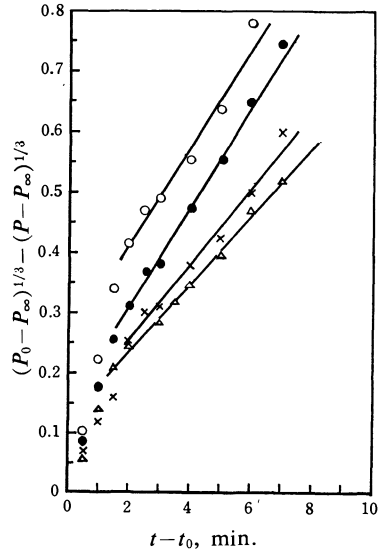

Fig. 4. Plots according to Eq. 1, at 714°C. P_{N_2} (cmHg) ○ 0.538, ● 0.916, × 1.480, △ 1.968

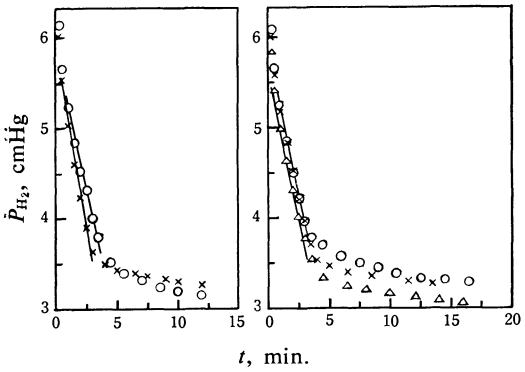

Fig. 5. $P_{H_2}\sim t$, at 738°C.

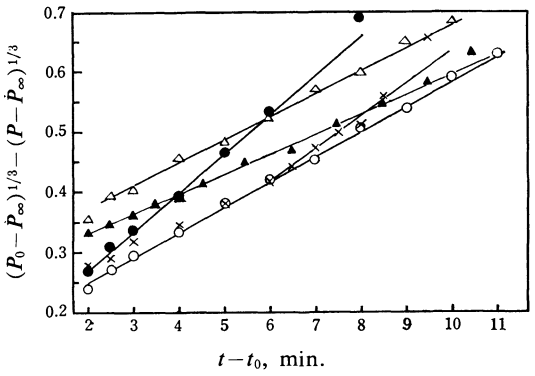

Fig. 6. Plots according to Eq. 1, at 738°C. P_{N_2} (cmHg) ● 0.000, × 0.512, ○ 1.000, △ 1.500, ▲ 2.000

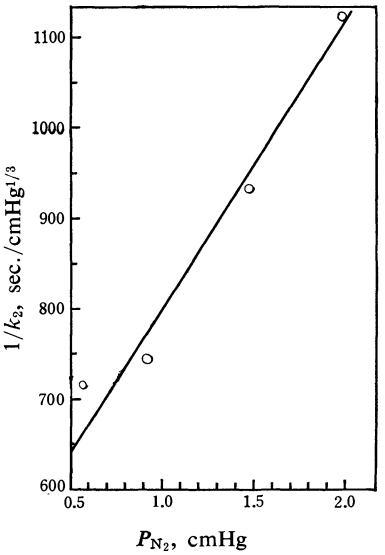

Fig. 7. Plot according to Eq. 4', at 714°C.

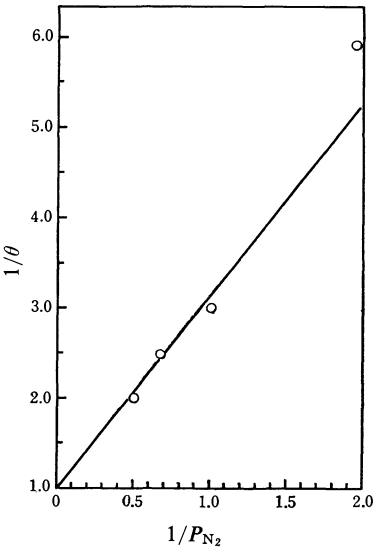

Fig. 8. Plots according Eq. 4, at 738°C.

$$1-\frac{(k_2)_{P_{N_2}}}{A}=1-\frac{1}{1+aP_{N_2}}$$

$$\frac{1}{(k_2)_{P_{N_2}}}=\frac{1}{A}-\frac{a}{A}P_{N_2} \qquad (4')$$

where A is $(k_2)_{P_{N_2}=0}$.

According to Eq. 4', a can also be determined from the linear relation between $1/(K_2)_{P_{N_2}}$.

Results at 714 and 738°C are shown in Figs. 3—8 and Tables III and IV. Figure 7 shows the plotting according to Eq. 4', and Fig. 8, according to Eq. 4. All values give good straight lines; from them a at 714°C and 738°C are evaluated to be 0.500 and 0.400 respectively.

TABLE III. RESULTS AT 714°C

1.500	0.038	0.41	0.67	
2.000	0.032	0.50	0.50	

As has been mentioned above, it was found that a indicates the degree of the influence of nitrogen, and that a decreases with the temperature. It is comprehensible from the deriving principle of Eq. 3 that a corresponds to an equilibrium constant of the attraction between the substance retarding the decomposition of zinc oxide and the nitrogen in the gas phase. Therefore, the relation between $1/a$ and $1/T$ (°K^{-1}) was obtaining as shown in Fig. 9. The linearity in Fig. 9 supports the above considerations. The slope of the line gives the enthalpy of the reaction, which produces retarding substances by interaction between the surface of zinc oxide and the nitrogen molecule, as -11.5 kcal./mol.

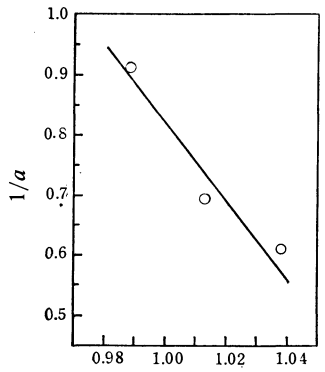

Fig. 9. $1/a$ vs. $1/T$.

As a result, it was found that nitrogen retards the reaction, the rate of which is proportional to the surface area of zinc oxide, and that the degree of the influence of nitrogen is evaluated by means of the constant, a in Eq. 3, which may be considered to reveal the equilibrium constant if the above presumption is valid. It has been reported that zinc nitride is produced by exposing the heated zinc powder in a stream of nitrogen.[7] The most probable retarding factor is the Langmuir-type chemisorption on the surface of zinc oxide —in this case, 11.5 kcal./mol. will represent the heat of chemisorption. The chemisorption of nitrogen, however, occurs only with difficulty on the normal surface of zinc oxide. The effect of nitrogen on the reduction will, however, require further studies from the point of view of the chemisortion and the surface compounds, because, as is well known,[3,4] the surface of zinc oxide submerged in the reducing gas at a high temperature has an excess of zinc, and hence its thermodynamical behavior is abnormal.

It was found that k_1 also decreases with the increase in the pressure of nitrogen (cf. from Table I). Since k_1 is the specific rate of the reaction of hydrogen and oxygen, the depressing effect of such an inert gas as nitrogen is unlikely. As has been previously reported, however, the reduction of zinc oxide is a consecutive reaction involving the decomposition of zinc oxide and the reaction of hydrogen with oxygen. Consequently, the equilibrium constant k is expected to be involved in observable k_1 generally. At present, the authors have not obtained the true rates of the reaction between hydrogen and oxygen and of the formation of zinc oxide from zinc vapor and oxygen (the specific rates are k_1° and k_{-2} respectively) under these experimental conditions; hence, the quantitative relation between k_1 and K $(=k_2/k_{-2})$ is known. At any rate, k_1 may be expressed by a function, $f(k, k_1^\circ)=f(k_2/k_{-2}, k_1^\circ)$. Therefore, k_1 would be affected by nitrogen, since k_2 is affected by nitrogen, as has been mentioned already.

Adsorption of Congo Red and Fuchsine Base by Hydrous Beryllium Oxide Aged for Different Periods

By Rup DUTTA

(Received July 4, 1963)

It is well known that hydrous oxides like those of iron, chromium and aluminum are well known to possess a high adsorptive capacity. Mokuskin and Esin, White, Gorden and Porter studied the association of several dyes[1] by these hydrous oxides. Weiser[2] and Sen[3] also made a comparative study of adsorption capacity of the hydrous oxides of chromium, aluminum and iron for different inorganic ions. They are of the opinion that the adsorption process depends on valency of ion, pH of the medium, chemical activity and reactivity of the adsorbent, etc. The aging of hydrated oxides of aluminum, iron, nickel and cobalt has been studied by Lottermoser[4] who performed sedimentation experiments and X-ray studies, and ascribed the changes to be due to (a) the rate of growth of the secondary particles and (b) the rate of orientation of the structural units of the secondary particles. Similar observations were also made by Tewari, Dey and Ghosh[5] who discussed the mechanism of aging of the hydrous oxides of iron, aluminum and chromium.

It has been shown from these laboratories that aging of hydrous oxide has a marked effect on the role of adsorption. But, it can clearly be mentioned here that very little work appears to have been done on the subject, specially on the adsorption of dyes and ions on hydrous beryllium oxide of different characters, aged for different lengths of periods. Hence, in this paper the adsorption of Congo red and fuchsine base by hydrous beryllium oxide aged for different lengths of periods, have been studied and the results are represented in the following tables.

Experimental

Three samples of hydrous beryllium oxide were prepared by adding different quantities of 0.2 N sodium hydroxide solution to a fixed volume of 0.2 N beryllium sulfate solution as follows:

Sample A: precipitated with equivalent sodium hydroxide

Sample B: precipitated with 10% deficient sodium hydroxide

Sample C: precipitated with 10% excess sodium hydroxide.

These samples were then washed thoroughly with distilled water by decantation and allowed to age progressively by standing as a suspension at 30°C.

Adsorption Experiment.—In several 25 ml. jena flasks, containing 5 ml. of 0.001 g. of beryllium oxide and 5 ml. of (0.55 M : 0.1 M) boric acid-borax buffer solution of pH 8.5, varying amounts of the prepared dye solutions of known concentrations were added and the volume of the solutions was raised upto the mark in each case. The dyes used for adsorption were all B. D. H. AnalaR grade and purity was 98% and above. Each sample of the aged hydrous oxid was then kept in contact with the dye solution for 24 hr. at 30°C to attain equilibrium. An aliquot portion was then centrifuged and a measured volume was diluted as required for the estimation.

The residual concentration of the dye solution in the supernatant liquid was estimated by using Klett-Summerson photo-electric colorimeter. Filter number 54 (transmission 520~580 mμ) was found to be suitable for the dye. Before using colorimeter the applicability of Beer's law was tested in the range of pH maintained by the buffer. It was observed that Beer's law only holds good in low concentrations of the dye solution as far as 1×10^{-6}. Therefore, for the purpose of estimation, the dye solution present in the supernatant liquid was diluted to the requisite concentration, where Beer's law holds good, for its estimation.

The concentration of the residual dye solution was calculated by comparing with that of the same concentration, so that:

$$\text{Concn. of unknown dye soln.} = \frac{\left(\begin{array}{c}\text{Colorimetric}\\ \text{reading of}\\ \text{unknown dye}\\ \text{solution}\end{array}\right)\times\left(\begin{array}{c}\text{Concn. of}\\ \text{standard dye}\\ \text{solution}\end{array}\right)}{\text{Colorimetric reading of standard dye solution}}$$

In the following tables the results are recorded in gram moles of the dye adsorbed by the different samples, containing the same hydrous oxide in the system, where x is the amount of adsorbed dye in gram mole, and m is the amount of adsorbent in gram.

beryllium oxide are given in Tables I and II, and the amounts adsorbed have been plotted (not shown here) against the end concentrations of the adsorbate. It would be seen that most of the curves are convex to the concentration axis as in the case of Freundlich's adsorption isotherm and, therefore, similar to those obtained for the adsorption of bromine (at 79°C) or iodine by a silica gel.

The adsorption data for different dye-stuffs reveal that the three samples possess different adsorptive capacities. Thus, for the adsorption of Congo red it is maximum for the sample B but in the case of fuchsine base it is maximum for sample C, obtained by adding excess of an alkali for precipitation. These results are quite in good agreement with the view of Ghosh and co-workers. According to them the hydrous oxides, specially of amphoteric nature, should develop a large adsorptive capacity for anions, when precipitated with deficient quantity of an alkali and the adsoption of cation should be more marked for the precipitate obtained by the addition of an excess of an alkali.

It will be further seen that the same sample of hydrous beryllium oxide, aged for different period, have decreasing adsorptive capacity for dye-stuffs. The decrease in the adsorptive capacity with aging, may be due to the following two reasons.

(i) Hydrous beryllium oxide when freshly prepared, shows a high adsorptive capacity for ions and dye-stuffs from the solution due to the size of the particles of the hydrous oxide, which on aging tend to grow larger in size, causing a diminution in the total surface area of the particles and consequently the adsorptive capacity is decreased.

(ii) Adsorptive capacity also decreases, with aging, due to the formation of an inert substance, produced by the internal neutralization of the acidic and basic character of the amphoteric hydroxide, as given below:

$$Be(OH)_2 \rightleftarrows Be(OH)^+ + OH^-$$

$$Be(OH)_2 \rightleftarrows Be\cdot O\cdot (OH)^- + H^+$$

$$Be\cdot O\cdot (OH)^- \cdot Be(OH)^+ \rightarrow 2BeO + H_2O$$

$$H^+ + OH^- \rightarrow H_2O$$

Summary

Three samples of hydrous beryllium oxide, of different character, were prepared by adding different quantities of an alkali to a fixed volume of beryllium sulfate solution for precipitation. These samples were allowed to age progressively and there adsorptive capacities for dye-stuffs were studied. It has been found that the adsorptive capacity of the samples decreases with aging of the hydroxide and the adsorption data dye-stuffs reveal that the three samples possess different adsorptive capacities.

The author is deeply grateful to Professor S. Ghosh and Dr. A. K. Dey for their painstaking and critical review of the work. The author also wish to thank to Council of Scientific and Industrial Research to have had the financial support during this investigation.

*Kinetic and Spectrophotometric Studies of the Homogeneous Catalytic Activity of Iron(III) Complexes upon the Decomposition of Hydrogen Peroxide in Aqueous Solution**

By Goro WADA, Tadayoshi NAKAMURA, Kunio TERAUCHI and Toru NAKAI

(Received September 9, 1963)

The mechanism of the homogeneous catalytic decomposition of hydrogen peroxide by ferric or ferrous ions was first presented by Haber and Weiss,[1] who described how the reaction proceeds through a chain mechanism, with the HO_2 radical or the HO_2^- ion as chain carriers and accompanied by repeated redox cycles, Fe(III) $\rightleftarrows$ Fe(II), at the same time. This idea was examined carefully by Barb and others.[2-4] The existence of the free HO_2 radical as an intermediate was confirmed chemically employing 2, 6-di-*t*-butyl-4-methyl phenol in the reaction system[5] and also physically from the ESR spectrum in the case of the cerric ion catalyst.[6] After all, Wang and Jarnagin[7-9] and Kremer and Stein[10,11] proposed a transient occurrence of complex ions between the catalytic ions and the reaction intermediates. Wang and Jarnagin investigated the influence of ligands which occupy coordination sites other than those occupied by HO_2 in a ferric complex ion and found that triethylenetetramineiron(III) ions are most catalytically active in the decomposition of hydrogen peroxide in an alkaline solution, because this ligand is tetradentate and HO_2 is probably bidentate.[9] The study was ultimately intended for the elucidation of the reaction mechanism of catalase, a large coordination compound of the ferric ion, which exhibits the greatest catalytic ability for the decomposition of hydrogen peroxide.[7,12]

In the present paper, it will be made clear how the varieties and the numbers of the coordinating ligands affect, in connection with the energy of coordinate bonds, the catalytic activity of the ferric ion.

Experimental

Materials.—The pure hydrogen peroxide used was obtained by the vacuum distillation of 30% commercial hydrogen peroxide at 30 mmHg, after removing the contained stabilizers by means of adsorption on stannic acid. The concentration of hydrogen peroxide was determined by titration with potassium permanganate. Iron(III) and iron(II) salts were recrystallized from sulfuric acid solutions of $Fe_2(SO_4)_3 \cdot 9H_2O$ and $FeSO_4 \cdot 7H_2O$ respectively. The ligands employed as complexing reagents were monoethylamine (ea), ethylenediamine (en), diethylenetriamine (dien), triethylenetetramine (trien), tetraethylenepentamine (tetraen), *o*-phenanthroline (phen) and α, α'-dipyridyl (dip), which were used without further purification. Iron(III) complexes were prepared by merely mixing the two solutions of the Fe^{3+} ion and a ligand in an appropriate proportion. The pH of the solution was adjusted by adding perchloric acid and was assayed by a pH-meter. The effect of the ionic strength was negligible in every case, because the concentrations of all ionic components in the solution were extremely low.

Kinetic Measurements.—The reaction was regarded as starting at the moment when a solution of the iron(III) complex ion was quickly poured into a reaction vessel containing a hydrogen peroxide solution in a thermostat. The rate of the reaction was determined by measuring the volume of evolved oxygen with a gas buret.

The Determination of Stability Constants.—The stability constants of several iron(III)-complex ions were measured by the pH method, using a Hitachi-Horiba pH-Meter Model P, with an accuracy of pH ± 0.01. Bjerrum's formation function, $\bar{n}$, is thereby defined as follows:

$$\bar{n}=\frac{\sum_{i=1}^{m} iK_1K_2\cdots K_i[L^*]^i}{1+\sum_{i=1}^{m} K_1K_2\cdots K_i[L^*]^i} \quad (1)$$

$$=\frac{C_L-(C_H-[H^+])/p^+}{C_M} \quad (2)$$

where K_i is the i-th stepwise stability constant; [L*] and [H$^+$], the concentrations of the free ligand (coordinating with neither the metal ion nor the hydrogen ion) and of the hydrogen ion respectively; m, the coordination number of the central metal ion; C_M, C_L and C_H, the total concentrations of the Fe^{3+} ion, the ligand and perchloric acid respectively added to the solution, and $\bar{p}$, the ratio between the number of ionizable hydrogen atoms attached to the ligand and the total number of ligand molecules which are not coordinated with the metal ion; namely,

$$\bar{p}=\frac{\sum_{i=1}^{p} \frac{i[H^+]^i}{K_{HL^+}\cdot K_{H_2L^{2+}}\cdots K_{H_iL^{i+}}}}{1+\sum_{i=1}^{p} \frac{[H^+]^i}{K_{HL^+}\cdot K_{H_2L^{2+}}\cdots K_{H_iL^{i+}}}}$$

where $K_{H_iL^{i+}}$ indicates the acid dissociation constant of H_iL^{i+}. By putting this relation into Eq. 2, $\bar{n}$ can be calculated, if the $K_{H_iL^{i+}}$'s are known. According to the difinition, [L*] is also expressed as

$$[L^*]=\frac{C_H-[H^+]}{\sum_{i=1}^{p} \frac{i[H^+]^i}{K_{HL^+}\cdot K_{H_2L^{2+}}\cdots K_{H_iL^{i+}}}}$$

Therefore, by means of titrating a mixed solution of the Fe^{3+} ion and the ligand with perchloric acid and by measuring its pH, one can plot the relation between $\bar{n}$ and $-\log[L^*]$, from which the stability constants are obtained, as is clear from Eq. 1. K_i's are known at the value $\bar{n}=i-0.5$ according to Bjerrum's approximation.

Spectrophotometry.—The individual absorption spectra of aqueous solutions of the Fe^{3+} ion, the Fe^{2+} ion and their complex ions and hydrogen peroxide were observed separately in advance. Then the variations of the spectra of the solution under reaction with the lapse of time were observed as the catalytically-working state of complex ions. For the observation, a Hitachi recording spectrophotometer type EPS-2 was used at the 220~900 mμ wevelength range. A tungsten lamp and a hydrogen discharge tube were employed as light sources for the visible and the ultraviolet regions respectively. The cell was one made of quartz and had an optical length of 1 cm.

Results and Discussion

Velocity Curves and Their pH Dependence.—The reaction rates of hydrogen peroxide decomposition catalyzed by the Fe-aq^{3+} ion are generally of the S-type, as Fig. 1 shows. The reaction proceeds nearly linearly, something like a zeroth-order reaction, after the continuance of some induction period, and then

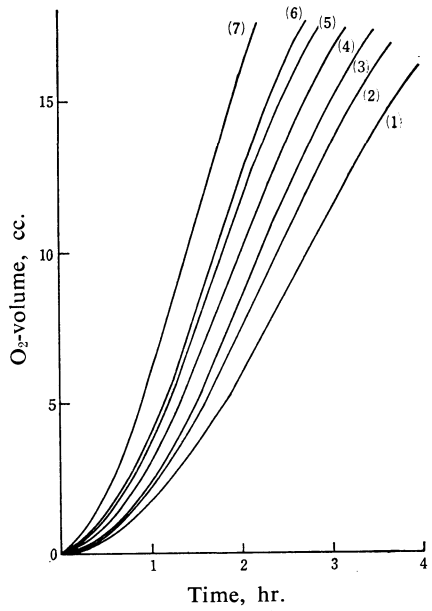

Fig. 1. The pH dependence of the reaction rate at 45°C.
[Fe-aq^{3+}]$=1.013\times10^{-4}$ mol./l., [H_2O_2]$_0=1.010\times10^{-2}$ mol./l. (1) pH 2.65; (2) 2.80; (3) 2.90; (4) 3.01; (5) 3.10; (6) 3.20; (7) 3.40

it falls off gradually.*1

On the average, it takes as long as a few minutes for an Fe^{3+} ion to decompose only one hydrogen peroxide molecule, judging from the slope of the linear part of the reaction in such cases as in Fig. 1. Considering this fact, together with the stability constant of Fe^{3+}-HO_2^-, $\log K_1=9.31$,[13] the rate of the reaction may probably be controlled either by an activated collision between the Fe^{3+} ion and HO_2^- (or HO_2) or by the self-decomposition of the complex. For this reason, the reaction appears as of the zeroth-order. Hereafter, the rate constant, k, will be expressed by the slope of the linear part of the reaction in mol.-H_2O_2/l. hr. The values of k are dependent on the pH of the solution, as is shown in Table I, where the reaction is found to be accelerated as the pH value is raised. However, on account of the restriction arising from the solubility of the iron-complex salts, the pH of the solutions will be generally fixed at

*1 As soon as hydrogen peroxide is supplemented up to a concentration equal to that of the initial state when the reaction has almost completely finished, the reaction comes back immediately to the linear part at the same velocity as that of the previous time, without exhibiting the induction phenomenon again.

13) "Stability Constants of Metal-ion Complexes," Part II, Compiled by J. Bjerrum et al., Chem. Soc., London (1958), p. 68; M. G. Evans, P. George and N. Uri, *Trans. Faraday Soc.*, **45**, 230 (1949).

3.00 in the following sections, unless otherwise specified.

Variations in the Reaction Rate with Concentration and Temperature.—Table II shows the variations in the reaction rate with the concentrations of the Fe^{3+} ion, hydrogen peroxide and the ligand and with the temperature of the reaction system. The ratios of the concentration of the ligand to that of Fe^{3+} in solutions are expressed by $[L]/[Fe^{3+}]$. The apparent activation energies, E_a, are also obtained from the relation between $\log k$ and $1/T$. It can easily be seen from the table that k diminishes with an increase in $[L]/[Fe^{3+}]$ as long as both $[Fe^{3+}]$ and $[H_2O_2]_0$ are kept constant and that k increases approximately in proportion to $[Fe^{3+}]$ and to the 1.5th power of $[H_2O_2]_0$.

Only when phen is employed as a ligand, is the reaction not of the S-type but appears

a) pH 3.1
b) pH 2.9

as a first-order reaction with respect to the concentration of hydrogen peroxide, since $\ln[(a-x)/a]$ is linear against time, where x and a are the volumes of oxygen evolved at t and the infinite time respectively, as is pictured in Fig. 2. The rate constants at various temperatures and the apparent activation energies are listed in Table III.

Inspection of Tables II and III reveals that the catalytic activities of iron(III) complexes depend upon the sort of ligands, decreasing in the order:

$$\text{en} > \text{dien} \sim (H_2O) \sim \text{ea} > \text{trien} > \text{tetraen} \sim \text{dip} \sim \text{phen} \quad (3)$$

where H_2O indicates the simple iron(III)-aquo ion without any other ligand in the solution.

On the other hand, the apparent activation energies, E_a, of the reaction catalyzed by various complexes generally show peaks near the concentration ratio of $[L]/[Fe^{3+}]=1$, except for the cases of trien and phen, where the former increases and the latter decreases monotonously with the increasing concentration ratio, as is pictured in Fig. 3. Therefore, the order of E_a with respect to ligands is as follows at their low concentration:

$$\text{dien} \sim \text{trien} > \text{tetraen} > \text{en} > \text{ea} > (H_2O) > \text{phen} \quad (4)$$

All the ligands except phen make E_a larger than that for the case of the simple Fe-aq^{3+}, so long as their concentration is low. Wang[9] said that trien showed the highest catalytic activity in an alkaline solution because of the steric advantage arising from its tetradentate nature. We, however, have found this ligand to be merely a poor catalyst at pH 3, contradictory to Wang's description. In the case of en and dien, since their complexes are more active than Fe-aq^{3+} in spite of the larger E_a, they must make the reaction much easier sterically, overcoming the energetic disadvantage.

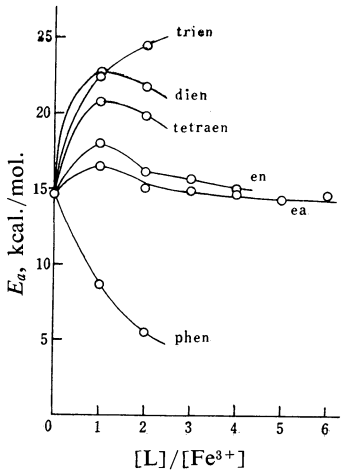

Fig. 3. The variations of the apparent activation energies, E_a, with $[L]/[Fe^{3+}]$ at pH 3. $[Fe^{3+}]=1.013\times10^{-4}$ mol./l., $[H_2O_2]_0=1.010\times10^{-2}$ mol./l.

The Stability Constants of Several Complexes.—The stability constants of iron(III) complexes with ea, en, dien and trien at 30 and 45°C are listed in Table IV. Using the data of the stability constants, the percentages of the coordinated iron in the total iron at $[Fe^{3+}] = 1.013 \times 10^{-4}$ mol./l. are calculated as α, shown in the last column of the table.

The various values of k and E_a as shown in Table II are, of course, those which are averaged with respect to the hydrated iron(III) (non-coordinated by ligands, Fe-aq^{3+}) and the coordinated iron (III) (FeL_i^{3+}) in accordance with their percentages of occurrence. The true values, purely due to the catalytic activity of the coordinated complexes calibrated by α, are shown in Table V. Since K_1 does not vary with the temperature in comparison with the experimental errors, α's at 30°C were used withought alteration in the calculation for other temperatures. In the case of $[L]/[Fe^{3+}] = 1$, $[FeL_2^{3+}]$ and higher complexes are negligibly rare.

According to Table V, the true activation energies, E, are generally greater than E_a, with the exception of the case of ea. Hence, the activation entropy increments putting the activation entropy of the aquo ion as the standard, $\Delta(\Delta S)$, have been calculated and been found to be positive in the cases of en, dien and trien and negative in the case of ea. The parallelism between E and $\Delta(\Delta S)$ is fairly good (the compensation effect). Judging from the large positiveness of $\Delta(\Delta S)$ in the cases of several iron(III)-*N*-multidentate complexes, the activated states of these complexes are supposed to be looser than the pre-activated states; they may be less coordinated than six. This supposition will be proved later.

The Absorption Spectra of Catalytically-Active Complexes in the Working State.—Table VI shows the positions of the peaks, λ_{max}, and the extinction coefficients, ε, in the absorption spectra of phen, hydrogen peroxide, Fe-aq^{3+}, Fe-aq^{2+}, Fe-phen$_3^{3+}$ and Fe-phen$_3^{2+}$ in aqueous solutions. Hydrogen peroxide, Fe-aq^{3+} and Fe-aq^{2+} exhibit no remarkable characteristic absorptions except their end absorption in the region of very short wavelengths. The observed values of λ_{max} and ε of iron-phen complexes agree with the values in the literature rather well.[14] The reason why the phen-complexes are used here is merely the convenience of the spectrophotometric observation, even though they have a disadvantage that the phen molecules themselves are liable to decompose during the reaction.

The visible spectra of Fe-phen$_3^{2+}$ in the catalytically-working state during the decomposition of hydrogen peroxide are shown in Fig. 4, where the absorption at 515 mμ characteristic of Fe-phen$_3^{2+}$ decreases with time, while that at 350 mμ characteristic of Fe-phen$_3^{3+}$ increases. This means that the iron(II)→iron(III) oxidation is occurring. However, with a longer lapse of time, the absorption at 350 mμ begins to decrease after attaining a maximum, while the absorption band at 515 mμ is never recovered again; the solution becomes almost colorless, and at last the spectrum coincides with that of Fe-aq^{2+}. This is due to the consecutive reduction, iron(III)→iron(II), after the preceding oxidation,[15] as well as to the simultaneous decomposition of phen itself. A similar conclusion can be derived from the observed results in the ultraviolet region.

In the same way, the visible absorption curves of the reaction system containing Fe-phen$_3^{3+}$ and hydrogen peroxide show that, although the height of the comparatively low peak at 350 mμ hardly varies at all, another new peak appears at 515 mμ, changing the color of the solution from yellow to reddish. This indicates the occurrence of the iron(III)→iron(II) reduction. However, after more than three hours, the peak at 515 mμ disappears and the solution again becomes yellow, indicating a recovery of iron(II)→iron(III). After that, the curve gradually approaches the characteristic weak curve of Fe-aq^{3+} on account of the decomposition of phen, just as in the case of Fe-phen$_3^{2+}$.

Figures 5 and 6 show the time variations of the ultraviolet absorption spectra in reaction systems containing Fe-phen$_3^{2+}$ and hydrogen peroxide, and Fe-phen$_3^{3+}$ and hydrogen peroxide respectively. Since Fe-phen$_3^{2+}$, Fe-phen$_3^{3+}$ and phen exhibit their individual peaks at 265~267 mμ with nearly the same extinction coefficients, the fact that the absorption at this wavelength region diminishes monotonously with time indicates that the decomposition of phen has begun even at the initial stage of the reaction. In the 300~320 mμ region, on the other hand, the absorption grows stronger with time in Fig. 5, while it does not vary so much in Fig. 6*[2] because of the difference in ε between Fe-phen$_3^{2+}$ and Fe-phen$_3^{3+}$ in this wavelength region. The electron transfer between iron(II) and iron(III) is, therefore,

proved.*3

Considering that the absorbance of hydrogen peroxide gradually increases towards shorter wavelengths, as Fig. 5 shows, the characteristic peaks of Fe-phen$_3^{2+}$ at 267 mμ and Fe-phen$_3^{3+}$ at 266 mμ should shift in appearence towards shorter wavelength because of a simple overlapping with hydrogen peroxide, if these complexes do not interact with hydrogen peroxide. In fact, however, according to Figs. 5 and 6, they clearly shift towards rather longer wavelengths as far as 1~4 mμ. This indicates changes in the strength of chemical bondings in both complexes, probably due to the formation of the coordination of HO_2 to iron. Generally speaking, the absorption bands of any complex are determined by the total influence of all the coordinated ligands, and their wavelengths shift continuously with the exchange of the ligands with others one by one. A red shift means the loosening of the coordinate bondings as the resut of the substitution for one ligand of another. HO_2 may be a ligand that makes the coordinate bonds slightly looser.

The Relation Between the Reaction Mechanisms and the Stabilization Energies of the Ligand Fields.—Concerning the central metal ions with the coordination number of six, the order of the ligand field stabilization energy

*3 The rate constant of the Fe-phen$_3^{2+}$→Fe-phen$_3^{3+}$ electron transfer was found to be $k>1\times10^5$ mol^{-1}·sec^{-1} by the N. M. R. method. M. W. Dietrich and A. C. Wahl, *J. Chem. Phys.*, **38**, 1591 (1963).

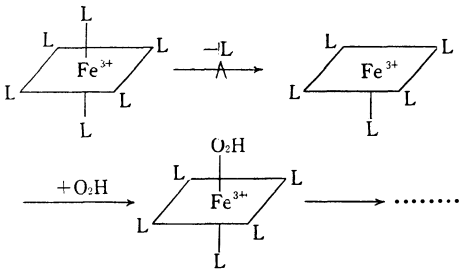
	Weak	4.00	2.72	1.28	4.57	−0.57	5.28	−1.28

* Among the strong field complexes of ions having d^5 or d^6 electrons, those with the configuration of pentagonal bipyramid are theoretically impossible, because the inner d-orbitals can be completely occupied only by four electrons.

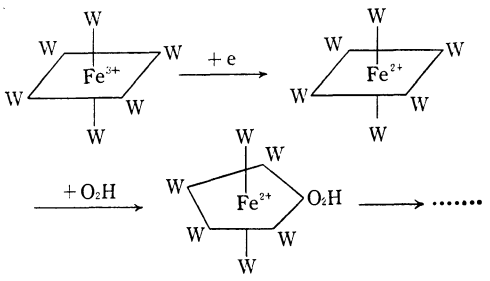
decided from the absorption spectra is known as Fajans-Tsuchida's spectrochemical series:[16]

$$CN^- > phen > dip > trien \sim dien \sim en > NH_3 \sim py > H_2O > OH^- \quad (5)$$



Although this series is not absolutely applicable for iron(III),[17] one can easily find, by comparing the two series, 4 and 5, that the first ligand of the 4 series, dien, is in the middle of the 5 series and that the succeeding ones in the 4 series are situated before and behind dien in the 5 series, regularly going farther away from the middle.

Since the 5 series generally indicates the order of the strength of the coordinate bonds between the central metal ion and the ligand, the following theory seems reasonable. The stability of iron complexes coordinated by HO_2 is quite decisive on the reaction rate, and their stability depends upon the ligand molecules occupying sites other than that occupied by HO_2. Dien, therefore, is the most suitable ligand for the reaction in this point. Ligands of neither higher nor lower ranking positions than dien in the 5 reries are favorable for the reaction, on account of their too strong or too weak coordinate bondings.



Iron(III) and iron(II) ions have the electron configurations of d^5 and d^6 respectively and ordinarily form complexes with a coordination number of six. According to whether the reaction proceeds through an S_N1 mechanism or through an S_N2 mechanism, there appears an intermediate complex with a coordination number of five or seven respectively. As a complex with the coordination number of five, we must take into account a complex of a trigonal bipyramid with a dsp^3 hybridization orbital and that of a square pyramid with a d^2sp^2 hybridization orbital, and as a complex with the coordination number of seven, that of a pentagonal bipyramid with a d^3sp^3 hybridization orbital. On the basis of the ligand field theory, the energy levels of these d-orbitals can be calculated as shown in Table VII.[18] Accordingly, the ligand field stabilization energies of these complexes and the energy losses, ΔE, of ligand field stabilization on the occasion of the transition from an octahedron to one of other intermediate structures are listed in Table VIII. Since a larger ΔE corresponds to a more difficult transition, the S_N1 mechanism via a square pyramid at the iron(III) state is the most probable in the strong ligand field and the S_N2 mechanism via a pentagonal bipyramid at the iron(II) state in the weak field. Judging from the values of the activation energies and the activation entropies in Table V, the ligands can be divided into two groups: (a) water and ea, which are monodentate ligands with low E and $\Delta(\Delta S)$, and (b) en, dien and trien, which are multidentate ligands with comparatively high E and $\Delta(\Delta S)$. The group a may form weak field complexes with the iron(III) ion (in the case of the Fe-aq^{3+} ion, this is already known from the magnetic and optical data) and make the reaction proceed through the S_N2 mechanism after the complex ion has undergone the acceptance of an electron from the surroundings, while the group b may form strong field complexes, driving the reaction through the S_N1 mechanism. These considerations can be justified as quite plausible from miscellaneous aspects of the activation energies, the activation entropies, the spectrochemical series, the molecular shapes and structures of ligands (whether they are monodentate or multidentate), the ligand field theory, and so forth. The paths of the S_N1 and S_N2 mechanisms may be shown schematically as follows:

S_N1 mechanism (strong field) :

S_N2 mechanism (weak field) :*4

It is especially noteworthy that, since the CN^- ion stands first in the 5 series, the reaction was somewhat suppressed by its stronger coordinate bonding and, therefore, by its greater stabilization in the case of $[Fe^{3+}]$: [en] : $[CN^-] = 1:1:1$,*5 with the result that the reaction rate was lowered as much as 10% and the apparent activation energy was raised as high as 2 kcal./mol. This fact is also consistent with the above explanation. The well-known retardation by the CN^- ions of the coordination of oxygen to hemoglobin in blood might occur in a similar way.

Summary

Hydrogen peroxide is catalytically decomposed by the Fe^{3+} ion, the activity of which is remarkably affected by the kind and the number of ligands coordinated to it. In this paper, the effects of ligands have been kinetically and spectrophotometrically determined and discussed from the view-point of the ligand field theory.

(1) The reaction generally proceeds linearly with time after a certain induction period, and the rate depends upon the pH of the solution.

(2) The reaction rate varies with the kind of the ligand and with its concentration. When $[L]/[Fe^{3+}]$ is equal to unity, the rate decreases in the order: en>dien~(H_2O)~ea >trien>tetraen~dip~phen.

(3) The apparent activation energy of the reaction exhibits a maximum, except in the cases of trien and phen, at the concentration ratio $[L]/[Fe^{3+}] = 1$, and the values of the activation energy at this concentration ratio are in the order: dien~trien>tetraen>en>ea >(H_2O)>phen.

(4) The true activation energy of the reaction catalyzed by the pure iron-complex is calculated from the observation of the stability constants to be in the order: dien>trien>en >(H_2O)>ea, which completely coincides with the order of the activation entropy.

(5) The visible and ultraviolet absorption spectra of Fe-$phen_3^{2+}$ and Fe-$phen_3^{3+}$ as catalysts in the working state were observed, and it was found that there takes place a redox cycle, $Fe^{3+} \rightleftarrows Fe^{2+}$, during the reaction and that phen molecules are gradually decomposed at the same time.

(6) In the course of the reaction, the peaks of the ultraviolet absorption of Fe-$phen_3^{2+}$ and Fe-$phen_3^{3+}$ bring about a slight red shift, which is caused by the coordination of HO_2 to the iron ion.

(7) Judging from a comparison between the activation energy of the reaction and the spectrochemical series of ligands and from the calculation of the stabilization energy due to the ligand field theory, the reaction proceeds through an S_N1 mechanism under the iron(III) oxidation state in the case of strong field complexes and through an S_N2 mechanism under the iron(II) state in the case of weak field complexes.

(8) The reaction is retarded and the activation energy is raised by the addition of the CN^- ion, which strongly coordinates with iron and forms a very strong field complex.

The authors wish to thank President Taro Kaneko and Professor Kiyoshi Tsukida of Kobe Women's College of Pharmacy for allowing them to use a recording spectrophotometer.

Studies on the Polymerization of Bifunctional Monomers. IV.[*1] *The Intramolecular-Intermolecular Polymerization of 3-Substituted Glutaraldehydes*[*2]

By Chuji Aso and Yuzo AITO

(Received September 17, 1963)

Previously, the present authors found that the concept of intramolecular-intermolecular polymerization, which had been proposed in the polymerization of non-conjugated divinyl compounds,[1] might be applied to the addition polymerization of glutaraldehyde.[2,3]

The polymerization of glutaraldehyde[*3] was also studied by Overberger et al.,[4] Meyersen et al.,[5] and Moyer et al.[6] at almost the same time as by the present authors. These workers, as well as the authors, came to the conclusion that the polymer contained a tetrahydropyran ring as a main structure, although there were a few differences in the polymerization conditions, etc.

Meyersen et al. also described how 3-methylglutaraldehyde and 3-phenylglutaraldehyde were polymerized without a catalyst.[5] However, the catalytic polymerization of these dialdehydes was not reported. The present authors, independently, studied the polymerization of these 3-substituted glutaraldehydes in the absence of a catalyst. Moreover, 3-methyl- and 3-phenylglutaraldehyde were polymerized with a catalytic system of triethylaluminum-water, in order to clarify whether these dialdehydes would yield polymers containing a ring structure similar to that of poly(glutaraldehyde). The influences of substituents and of several additives to the reaction rate were also investigated.

Experimental

3-Methylglutaraldehyde and 3-phenylglutaraldehyde were prepared by hydrolysis of the corresponding 4-substituted 2-ethoxy-3, 4-dihydropyrans.[8] 3-Methylglutaraldehyde: b. p. 87.0 ~ 88.0°C/21.0 mmHg, n_D^{25}, 1.4365. Found: C, 62.51; H, 8.84. Calcd. for $C_6H_{10}O_2$: C, 63.13; H, 8.83%. 3-Phenylglutaraldehyde: b. p. 129.0~131.5°C/4.5 mmHg, n_D^{14}, 1.5355. Found: C, 74.48; H, 7.19. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.87%.

The catalyst, solvents and polymerization procedures have been previously described.[3] The viscosities of the soluble polymers were determined in benzene at 30°C, using a modified Ubbelohde viscometer. Molecular weights were measured by Rast's method (solvent: camphene), and the infrared spectra, with a Nippon Koken model 301 spectrophotometer.

The pendant aldehyde content in the polymers was determined by the aid of infrared spectroscopy at the 1730 cm^{-1} band, which is characteristic of the carbonyl group.[3]

Results and Discussion

3-Substituted glutaraldehyde was polymerized at a low temperature to a white solid by using a triethylaluminum-water system as the catalyst. Some of these results are listed in Table I. Polymers in general consist of soluble as well as of insoluble fractions in benzene. The properties of the soluble polymers are shown in Table II.

The infrared spectra of the soluble and the insoluble fractions of poly(3-substituted glutaraldehydes) were quite similar. The infrared spectra of the soluble fraction of 3-methyl- and 3-phenylglutaraldehyde polymers are shown in Figs. 1 and 2 respectively. A very weak band was still observed at 1730 cm^{-1} (C=O band). However, quantitative comparison of the carbonyl bands of these soluble polymers with those of monomers and some monoaldehydes suggests that the pendant aldehyde content of the polymers is very low. Moreover, the absorption bands of these polymers in the

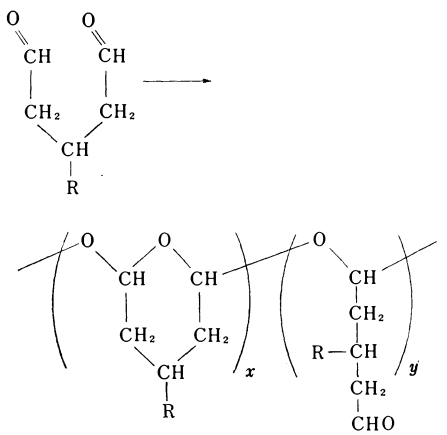
M-1a	35～ 44	—	11.0	1900～2500
M-2a	35～ 40	—	15.8	1000～1200
M-24a	115～120	0.18	18.3	—
Ph-12a	93～ 97	0.07	6.1	—
Ph-13a	87～ 96	0.06	23.3	—

a) η_{sp}/C (C=0.150 g./dl. in benzene, 30°C)
b) Pendant aldehyde content determined by the infrared spectroscopy.

1000～800 cm^{-1} region resemble those of the 4-substituted 2-ethoxytetrahydropyrans chosen as model compounds. These facts suggest that the polymer formed by the triethylaluminum-water catalyst consists also of recurring tetrahydropyran rings, as Meyersen et al. indicated in the case of spontaneous polymerization.[5]



3-Substituted glutaraldehydes changed spontaneously to glassy materials at room temperature or in an ice-box. After repeated reprecipitations, white, solid polymers were obtained. Some properties of these polymers are shown in Table III.

TABLE III. SOME PROPERTIES OF SPONTANEOUS POLYMERS OF 3-METHYLGLUTARALDEHYDE AND 3-PHENYLGLUTARALDEHYDE

No.	M. p. °C	$[\eta]$ dl./g.	[CHO] %	Molecular weight
M-4	56～67	—	8.7	700～800
M-5	62～67	0.03	8.1	—
Ph-2	83～86	—	16.3	～700
Ph-3	79～82	0.03	17.6	—

Since the infrared spectra of the polymers obtained spontaneously are almost in accordance with those of the polymers obtained with a catalyst, the structure of the former is considered to be substantially the same as that of the latter.

As mentioned above, the solubility, the fusibility, the low pendant aldehyde group content and the resemblance of the infrared spectrum of the polymer to those of the model compounds suggest that the ring formation occurs in the course of the polymerization of 3-substituted glutaraldehyde and that the polymer mainly consists of the tetrahydropyran ring. Therefore, polyglutaraldehydes obtained by the polymerization, with or without a catalyst, are probably polyethers with the following structures:

where R is H, CH_3, or C_6H_5. As the content of the ring unit in the polymer is high, the polymerization is considered to proceed mainly through alternative intramolecular cyclization and intermolecular propagation reactions. Succinaldehyde seems also to polymerize through this mechanism.[9]

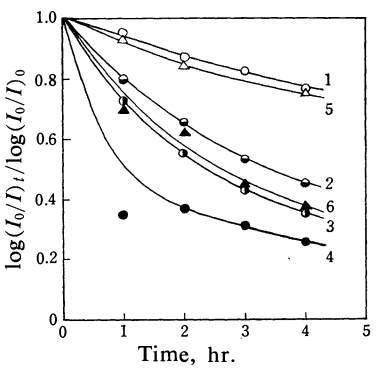


Fig. 3. Influence of additives in polymerization system.
1: Glutaraldehyde (non-additives)
2: Glutaraldehyde (5% of phenol was added)
3: Glutaraldehyde (5% of benzyl alcohol was added)
4: Glutaraldehyde (10% of water was added)
5: 3-Methylglutaraldehyde (non-additives)
6: 3-Methylglutaraldehyde (5% of ethanol was added)

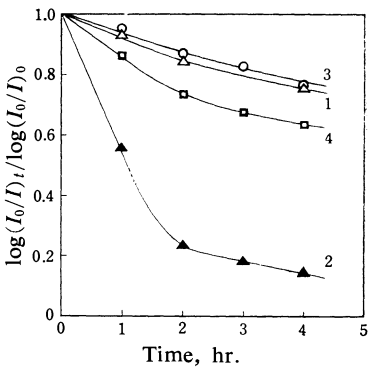

Fig. 4. Influence of polymerization temperature and substituents.
1: 3-Methylglutaraldehyde, at 25°C
2: 3-Methylglutaraldehyde, at 59°C
3: Glutaraldehyde, at 25°C
4: 3-Phenylglutaraldehyde, at 25°C

The infrared absorption intensity due to the carbonyl group of aldehyde was measured during the spontaneous polymerization under given conditions. The ratio of the intensity at time t to that at $t=0$ was plotted against the time.

The rate of consumption of the aldehyde group was markedly accelerated by the addition of a small quantity of water, ethanol or benzyl alcohol, as shown in Fig. 3. The infrared spectrum of the polymer formed spontaneously in the presence of benzyl alcohol shows the presence of a benzyl group in the polymer chain. Thus, these added substances seem to influence the initiation of the polymerization. The polymerization temperature and the substituent at the β-position to the aldehyde group also influenced the rate of aldehyde consumption (Fig. 4). The polymerization mechanism, however, is now being investigated; the details will be reported in the future.

The authors wish to express their gratitude to the Asahi Glass Technical Aid Association for providing the funds for this investigation and also to the Mitsui Petrochemicals Co., Ltd., for the supply of triethylaluminum.

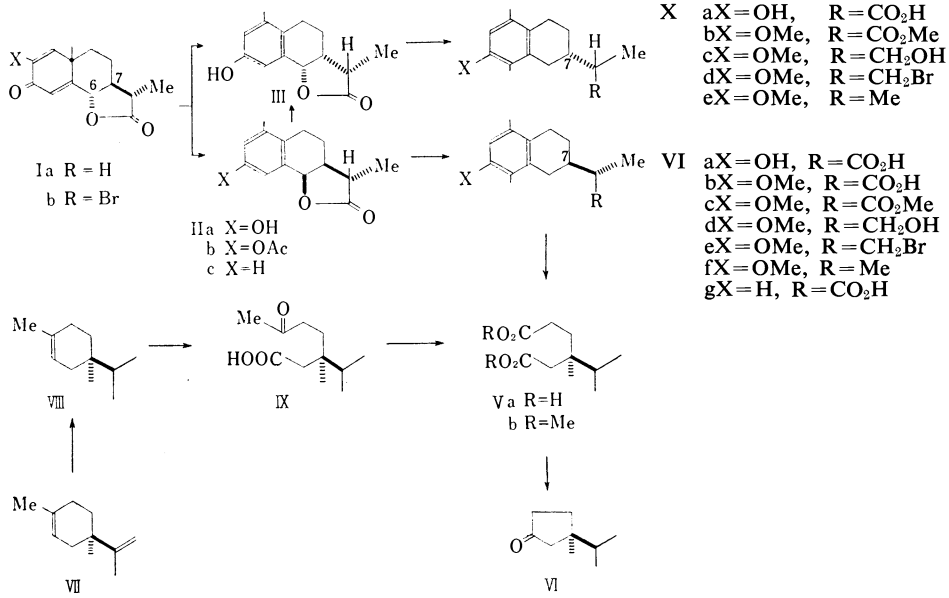
The Absolute Configuration at C_7 of α- and β-Desmotroposantonin[1]



By Masao NAKAZAKI and Kiyoshi IKEMATSU

(Received September 21, 1963)

Although the bulk of evidence,[2] mainly deduced from the stereochemistry of α- (IIa) and β-desmotroposantonin (III), strongly favors the (R)-configuration at position 11 of (−)-α-santonin (Ia), recent publications[3,4] have confirmed Abe's assignment[5] of the (s)-configuration at this center.

Not only to settle this discrepancy, but also in order fully to understand the mechanism of the well-known peculiar cycle of rearrangements in the desmotroposantonin series,[6] the determination of the absolute configuration of α- and β-desmotroposantonin, which have not been established on a firm ground, seems imperative.

Acetyl (−)-α-desmotroposantonin (IIb) prepared from (−)-α-santonin following Huang-Minlon's procedure[7] was first hydrolyzed to (−)-α-desmotroposantonin (IIa), which was then reduced with zinc powder in acetic acid to afford (+)-α-desmotroposantonous acid (IVa).[8] After methylation with dimethyl sulfate, the methyl ether IVb which resulted was esterified with diazomethane to the methyl ester IVc. The methyl ester of (+)-α-desmotroposantonous acid methyl ether was reduced with lithium aluminum hydride to the alcohol IVd, which was converted with phosphorus tribromide/pyridine to the bromide IVe. The bromide was refluxed with lithium aluminum hydride to afford the methyl ether IVf; b. p. 145~155°C/3 mmHg, n_D^{29} 1.5328, $[\alpha]_D^{25}$ +60.0° (in ethanol). Exhaustive ozonolysis of the methyl ether IVf, followed by

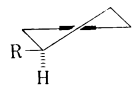
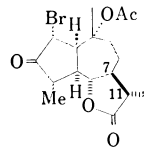
peracetic acid oxidation, gave crude β-isopropyladipic acid (Va),[9] which was purified via dimethyl ester Vb. Heating the acid with barium hydroxide at 280~300°C following the procedure of Burger and Macbeth[10] gave 3-isopropylcyclopentan-1-one (VI), which was directly converted into the semicarbazone; m. p. 181~183°C, $[\alpha]_D^{31}$ +43.8° (in ethanol). Its identity with (R)-(+)-3-isopropylcyclopentan-1-one semicarbazone (m. p. 186~187°C, $[\alpha]_D^{26}$ +65.2° (in ethanol)) prepared from (R)-(+)-limonene (VII)[11] (via (+)-dihydrolimonene (VIII) and (+)-3-isopropylheptan-6-onic acid (IX)) was established by a mixed melting point comparison (181~183°C) and by a comparison of their infrared absorption spectra (in chloroform).



This correlation established the (R)-configuration at position 7. The fact that (+)-β-desmotroposantonin (III) has the opposite configuration from (−)-α-desmotroposantonin (IIa) at C_7 was confirmed by the conversion of the former, through the same sequence of conversions described in the α-series, into the enantiomer Xe (b. p. 110~120°C/0.1 mmHg, n_D^{29} 1.5322, $[\alpha]_D^{28}$ −65.2° (in ethanol)), which showed an infrared spectrum superimposable on that of the methyl ether IVf from (−)-α-desmotroposantonin (IIa).

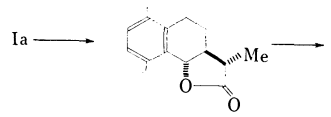
It is of interest to note here that the compounds derived from (+)-α-desmotroposantonous acid (IVa) as well as from hyposantonous acid (IVg) and occidol (XII),[15] all of which have the same (R)-configuration at C_7, show dextrorotation, whereas the compounds Xa, Xb, Xc, Xd and Xe from the (−)-β-desmotroposantonous acid series all exhibit the opposite rotation (see the Experimental section).

Mill's rule[12] and Brewster's[13] model of optical activity extended to endocyclic compounds show that the cyclohexene derivative with a configuration similar to that of (+)-limonene (VII) exhibits dextrorotation. It is apparent from our experimental results that their rules can be extended to the tetralin series: *2-(R) substituted tetralin XII is dextrorotatory provided that the optical rotatory power of the conformational asymmetry XII is not exceeded by that of the side chain.*

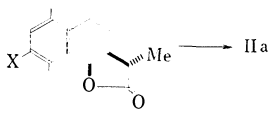


XI

XII



Thus having had established the absolute configuration of the C_7 asymmetric centers of α- and β-desmotroposantonin, our attention was next directed to correlating these centers of asymmetry with that of C_7 of (−)-α-santonin. The C_7 asymmetric center in (−)-α-santonin has been assigned the (R)-configuration[2] by correlating it with (+)-dihydrocarvon via carrison through a long series of degradations and synthetic works involving at least 20 compounds, among them artemisin, ψ-santonin, β-selinene, α- and β-eudesmol and costol. Since these natural compounds related to (−)-α-santonin are important relay substances in the stereochemistry of eudesmane-type sesquiterpene, it seems not superfluous to add other evidence to support the (R)-configuration at the asymmetric center C_7 of (−)-α-santonin. Especially is this so when it is reflected that the absolute configuration of C_{11} of bromoiso-α-photosantonic lactone acetate (XIII)[14] (and consequently that of santonin) has been assigned by X-ray crystal analysis with reference to this C_7 asymmetric center.



XIII

Hyposantonin (XIV)[15] derived from (−)-α-santonin under very mild conditions, which possesses the original asymmetric configurations of C_6, C_7 and C_{11} of santonin intact, appears a convenient intermediate with which to link (−)-α-santonin and α-desmotroposantonin. During the course of their study of hyposantonylquinol, Asahina and Momose[16] nitrated hyposantonin to obtain a mononitro derivative which they named 2-nitrohyposantonin. Since the same compound could be prepared from isohyposantonin (XVa), which has a cis lactone ring, it is evident that the epimerization at C_6, reminiscent of the process from santonin to α-desmotroposantonin, intervenes during the nitration, implying that the proper name should be 2-nitroisohyposantonin (XVb). The diazotization of 2-amino-isohyposantonin (XVc) prepared from the nitro compound XVb afforded (−)-α-desmotroposantonin (IIa). Thus, this sequence of reactions seems to provide evidence that (−)-α-desmotroposantonin (IIa) and isohyposantonin (XVa) have the same absolute configuration at C_7 and C_{11}.

XIV

XVa R=H
b R=NO_2
c R=NH_2

However, since Asahina and Momose used rather severe conditions (concentrated nitric acid and concentrated sulfuric acid in acetic acid) in the nitration reaction, during the nitration a rearrangement similar to (−)-α-desmotroposantonin (IIa)→(+)-β-desmotroposantonin (III) may intervene simultaneously. To clarify this point, 2-aminoisohyposantonin (XVc) was diazotized; the deamination of the diazonium compound with hypophosphorous acid[17] gave back the starting compound, isohyposantonin (XVa) implying that no such inversion occured. Thus, the configuration of (−)-α-santonin at C_7 can be related with that of (−)-α-desmotroposantonin; this (R)-configuration at C_7 of (−)-α-santonin is completely in accord with the results obtained from the X-ray crystal analysis of 2-bromosantonin (Ib) by the Glasgow group.[18]

Experimental*

A) The α-Desmotroposantonin Series

Acetyl (−)-α-Desmotroposantonin (IIb).[7]—Twenty grams of (−)-α-santonin was slowly stirred into a mixture of 120 cc. of acetic anhydride and 2 cc. of concentrated sulfuric acid at room temperature. After the solution had been kept at room temperature overnight, the crystals which precipitated were filtered and washed with water. The mother liquor was added to 500 cc. of ice water, and the crystals which deposited were filtered and washed with water. Recrystallization of the combined crystals from ethanol gave 20 g. of IIb (m. p. 155～156°C (lit.[7] m. p. 156～157°C)).

(−)-α-Desmotroposantonin (IIa).[7]—To 20 g. of acetyl-(−)-α-desmotroposantonin (IIb), a mixture of 20 g. of potassium hydroxide, 50 cc. of water and 200 cc. of methanol was added. The mixture was refluxed for 5 hr, and the methanl was distilled off. The residue was dissolved in 200 cc. of water, and the solution was made acidic with concentrated hydrochloric acid. After the crystals had been filtered and washed with water, they were recrystallized from ethanol to give 12 g. of IIa (m. p. 190～192°C). The mother liquor was concentrated to yield the second crop of crystals (m. p. 186～190°C (lit.[7] m. p. 194°C)).

(+)-α-Desmotroposantonous Acid (IVa).[19]—Into a mixture of 50 g. of (−)-α-desmotroposantonin (IIa), 1.2 l. of acetic acid and 100 cc. of water, 300 g. of zinc powder were vigorously stirred (Vibro-Mischer). After the solution had been refluxed and stirred for 16 hr., the excess zinc powder was filtered, and the zinc power was washed with hot acetic acid on a Buchner funnel. The combined filtrate and washing were concentrated under reduced pressure. The crystals which were precipitated by adding water to the residue were collected and washed with water. Recrystallization from ethanol yielded 44 g. of (+)-α-desmotroposantonous acid (IVa) (m. p. 176～178°C). Further recrystallization from 75% acetic acid yielded needles (39 g.) melting at 177～179°C; $[\alpha]_D^{25}$+77.6° (*c* 1.81 in ethanol), (lit.[8] m. p. 182～183°C, $[\alpha]_D$+75° (in ethanol)).

(+)-α-Desmotroposantonous Acid Methyl Ether (IVb).—In an atmosphere of nitrogen, 21 g. of (+)-desmotroposantonous acid (IVa) was dissolved in 127 cc. of 6.5% aqueous sodium hydroxide. When 3.4 g. of dimethyl sulfate was added to the stirred solution, a solid deposited which was then dissolved by adding 70 cc. of water and heating the solution at 50°C. In a period of 1 hr., 10.2 g. of dimethyl sulfate was added; the reaction mixture was then stirred at 80°C for 2 hr. After 20 cc. of 6.5% of aqueous sodium hydroxide was added, the reaction mixture was made acidic with concentrated hydrochloric acid and kept in a refrigerator overnight. The crystals which were deposited were filtered and washed with water. The product weighed 22 g. and melted at 114～117°C after recrystallization from 70% acetic acid; $[\alpha]_D^{25}$+69.5° (*c* 1.21 in ethanol) (lit.[8] m. p. 116～117°C, $[\alpha]_D^{26}$+72.2° (in ethanol)).

Methyl Ester of (+)-α-Desmotroposantonous Acid Methyl Ether (IVc).—A solution of 34 g. of (+)-α-desmotroposantonous acid methyl ether in 60 cc. of methanol was added into a chilled solution of diazomethane in ether prepared from 42 g. of nitrosomethylurea, and the mixture was kept in a refrigerator overnight. The excess diazomethane was decomposed with a small amount of acetic acid. After the reaction mixture had been washed with saturated aqueous sodium chloride to remove the methanol, it was dried over calcium chloride and freed from the solvent. The residue was distilled to yield 33.5 g. of an oil, b. p. 128～140°C/10^{-2} mmHg, n_D^{27} 1.5293, $[\alpha]_D^{27}$+82.0° (*c* 1.82 in ethanol).

Found; C, 73.62; H, 8.82. Calcd. for $C_{17}H_{24}O_3$: C, 73.88; H, 8.75%.

The Alcohol IVd.—In a stream of nitrogen, a solution of 33.5 g. of methyl ester IVc in 40 cc. of ether was stirred into suspension of 3.7 g. of lithium aluminum hydride in 350 cc. of anhydrous ether at room temperature. After the reaction mixture had been gently refluxed for 1.5 hr., the excess lithium

* All melting and boiling points are uncorrected. The analyses were performed in the Microanalytical Laboratory of the Shionogi Pharm. Co. through the courtesy of Dr. Kenichi Takeda, which is gratefully acknowledged.

19) Following the procedure of G. R. Clemo, *J. Chem. Soc.*, **1934**, 1343.

aluminum hydride was decomposed with 5 cc. of ethyl acetate. Water was added until the aluminum hydroxide deposite in an easily filterable state (about 50 cc. of water was required). The aluminum hydroxide was then filtered and washed with ether thrice. The combined ether solution was washed with saturated aqueous sodium chloride, dried over anhydrous magnesium sulfate, and freed from the solvent. When the residue was distilled, 28.1 g. of a viscous colorless liquid (b. p. 160~180°C/10^{-2} mmHg) was collected in a 94% yield. $[\alpha]_D^{27}$+60.8° (*c* 2.90 in ethanol).

Found; C, 77.0; H, 9.7. Calcd. for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74%.

Phenylurethane. — The recrystallization of the phenylurethane, prepared by the usual method, from ethanol gave prismatic crystals; m. p. 125~126°C, $[\alpha]_D^{27}$+47.3° (*c* 0.65 in ethanol).

Found: C, 75.2; H, 8.2. Calcd. for $C_{23}H_{29}O_3N$: C, 75.17; H, 7.95%.

The Bromide IVe.—Into a chilled (−5~10°C) mixture of 12.0 g. of phosphorus tribromide, 1.7 g. of pyridine and 8 cc. of benzene, a mixture of 28.1 g. of the alcohol IVd, 30 cc. of benzene and 0.6 g. of pyridine was stirred over 4 hr., during which time the temperature was kept constant. After being stirred at this temperature for 2 hr., the reaction mixture was warmed on a water bath (40~50°C) for 2 hr. and then poured on 200 g. of crashed ice and extracted with ether. The ether extract was washed with aqueous sodium hydrogen carbonate, water and saturated sodium chloride solution successively, and then dried over calcium chloride. Removal of the solvent gave a residue which was distilled to yield 18.4 g. (51% yield) of a liquid (b. p. 150~160°C/10^{-2} mmHg, n_D^{29} 1.5638, $[\alpha]_D^{28}$+66.4° (*c* 2.24 in ethanol)).

Found: Br, 22.8. Calcd. for $C_{16}H_{23}OBr$: Br, 22.49%.

The Methyl Ether IVf.—Into a slurry of 2.9 g. of lithium aluminum hydride in 30 cc. of anhydrous tetrahydrofuran, a solution of 18 g. of the bromide in 20 cc. of tetrahydrofuran was stirred over a 1/2 hr. period. The exothermic reaction was observed, and the reaction mixture was gently refluxed for another 2 hr. The cold mixture was diluted with 180 cc. of ether, and the excess reducing reagent was decomposed with a small amount of ethyl acetate. The mixture was decomposed by a dropwise addition of water until aluminum hydroxide was deposited in an easily filterable state. The ether solution was filtered, and the collected aluminum hydroxide was washed with ether three times. The ether filtrate and washings were combined and washed with water and with a saturated sodium chloride solution. After being dried over calcium chloride, the solution was concentrated to afford the residue, which was distilled to give 12.0 g. of a liquid (92.4% yield) (b. p. 145~155°C/3 mmHg, n_D^{29} 1.5328, $[\alpha]_D^{25}$+60.0° (*c* 2.52 in ethanol)).

Found: C, 83.0; H, 10.4. Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.41%.

The Exhaustive Ozonolysis of the Methyl Ether IVf.—A stream of ozone (about 2%) was passed into a solution of 6.0 g. of the methyl ether IVf in 70 cc. of acetic acid for 30 hr. at room temperature (28~29°C). To this reaction mixture, 5 cc. of 30% hydrogen peroxide was added, and the mixture was allowed to stand at room temperature overnight. After the mixture had been warmed on a water bath for 2 hr., a small amount of palladium on a carbon catalyst was added to decompose the excess peracetic acid. The mixture was heated on a water bath for 2 hr. and freed from the catalyst. Concentration under reduced pressure gave a sirup which was dissolved in 50 cc. of water and again concentrated at reduced pressure. This process of evaporation was repeated twice in order to remove the acetic acid. The brown, viscous sirup was dissolved in 30 cc. of methanol and treated with 150 cc. of a cold ether solution of diazomethane prepared from 13 g. of nitrosomethylurea. After being kept in a refrigerator overnight, the solution was washed with water and a saturated aqueous calcium chloride solution and dried over calcium chloride. Removal of the solvent gave a viscous brown liquid which was distilled to afford 1.9 g. of the ester Vb (b. p. 100~105°C/5 mmHg (bath temp. 140~150°C), n_D^{30} 1.4493). The ester Vb was saponified by heating it with 2 g. of potassium hydroxide in 20 cc. of methanol containing 0.5 cc. of water for 3 hr. After the methanl had been removed, water was added and the mixture was made strongly acidic with concentrated hydrochloric acid. The solution was saturated with sodium chloride and continuously extracted with ether for 10 hr. When the solvent was removed and the residue was heated with 0.1 g. of barium hydroxide (at 160~180°C for 1 hr., at 180~280°C for 2 hr. and at 280~300°C for 1 hr.), 0.8 g. of a pale yellow liquid with a pleasant smell was obtained. To this oil was added a mixture of 0.7 g. of semicarbazide hydrochloride and 0.8 g. of sodium acetate with a small amount of water; drops of alcohol were also added to remove any turbidity. The crystalline product which separated was recrystallized from ethanol twice and finally from water to give 0.05 g. of fine needles (m. p. 181~183°C, $[\alpha]_D^{31}$+43.8° (*c* 0.48 in ethanol)). A mixed melting point determination with (R)-(+)-3-isopropylcyclopentan-1-one semicarbazone (m. p. 186~187°C, $[\alpha]_D^{26}$+65.2° prepared from (R)-(+)-limonene (vide infra)) was 181~183°C. The infrared spectra of the two compounds in chloroform were indistinguishable.

Found: C, 59.2; H, 8.9; N, 22.7. Calcd. for $C_8H_{17}ON_3$: C, 58.98; H, 9.35; N, 22.93%.

B) β-Desmotroposantonin Series

(+)-β-Desmotroposantonin (III).[20]—A solution of 30 g. of (−)-α-santonin in 180 cc. of fuming concentrated hydrochloric acid, prepared by saturating concentrated hydrochloric acid with dried hydrogen chloride gas at 0~5°C, was sealed in a pressure bottle and kept at 36°C for 2 days, during which time a crystalline solid was deposited. After 1 l. of water had been added to the reaction mixture, the cream-colored crystalline solid was broken up, washed with water, and dried. The product, which weighed 29 g., was recrystallized from about 1 l. of ethanol to yield 20 g. crystals (m. p. 237°C (decomp.)).

20) Following the procedure of G. R. Clemo, *J. Chem. Soc.*, **1930**, 1110, 1114.

Concentration of the mother liquor gave 1.1 g. of the second crop (m. p. 230°C (decomp.), $[\alpha]_D^{26}$ +108° (*c* 0.39 in ethanol)). (lit.[8] decomp. p. 260°C, $[\alpha]_D$ +112.1°)).

(−)-β-Desmotroposantonous Acid (Xa).—Into a refluxing mixture of 31 g. of (+)-β-desmotroposantonin (III) in 950 cc. of acetic acid and 60 cc. of water, 190 g. of zinc powder was vigorously stirred with a Vibro-Mischer. Following the procedure described for the prepartion of IVa, 23 g. of needles (m. p. 174~175°C) were obtained after recrystallization from 70% acetic acid. Concentration of the mother liquor gave the second crop; 2.3 g., m. p. 170~174°C. $[\alpha]_D^{25}$ −56.9° (*c* 1.87 in ethanol) (lit.[21] m. p. 175°C, $[\alpha]_D$ −53.3° (in ethanol)).

Methyl Ester Xb of (−)-β-Desmotroposantonous Acid Methyl Ether.—Twenty grams of sodium hydroxide was dissolved in 400 cc. of water, 280 cc. of which was then added to 25 g. of (−)-β-desmotroposantonous acid (Xa) in an atomosphere of nitrogen. Twenty grams of dimethyl sulfate was stirred into the solution over a 1~1/4 hr. period at room temperature, and the reaction mixture was heated at 70~80°C on a water bath for 2 hr. After the rest of the sodium hydroxide solution had been added, the reaction mixture was refluxed for 1 hr. After it had been acidified with concentrated hydrochloric acid, the viscous semisolid product which deposited was collected and dissolved in ether. The ether solution was washed with water and saturated sodium chloride solution, and dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous oil which was dissolved in 20 cc. of methanol and treated with 300 cc. of an ether solution of diazomethane prepared from 31 g. of nitrosomethylurea. After being allowed to stand in a refrigerator 1 for 2 days, the excess diazomethane was decomposed with 1 cc. of acetic acid. The solution was washed with saturated aqueous calcium chloride, and dried over calcium chloride. The ether was removed and the residue distilled to give 21.0 g. of a liquid (b. p. 128~135°C/10^{-2} mmHg, n_D^{27} 1.5319, $[\alpha]_D^{27}$ −37.2° (*c* 2.13 in ethanol)).

Found: C, 73.6; H, 8.6. Calcd. for $C_{17}H_{24}O_3$: C, 73.88; H, 8.75%.

The Alcohol Xc.—The reduction of 21.0 g. of the methyl ester Xb with 2.4 g. of lithium aluminum hydride, as described in the preparation of the alcohol IVd, yielded 18 g. (95% yield) of the alcohol Xc (b. p. 160~180°C/10^{-2} mmHg, $[\alpha]_D^{27}$ −74.4° (*c* 3.12 in ethanol)).

Found: C, 76.8; H, 9.7. Calcd. for $C_{16}H_{24}O_2$: C, 77.37; H, 9.74%.

Phenylurethane.—The phenylurethane prepared following the usual method was recrystallized from ethanol to give silky needles (m. p. 106~108°C, $[\alpha]_D^{28}$ −60.2° (*c* 0.93 in ethanol)).

Found: C, 74.9; H, 8.0. Calcd. for $C_{23}H_{29}O_3N$: C, 75.17; H, 7.95%.

The Bromide Xd.—Following the procedure described for the preparation of the bromide IVe, 17 g. of the alcohol Xc was converted into the bromide Xd (12.4 g., 57% yield) (b. p. 197~200°C/3 mmHg, n_D^{27} 1.5640, $[\alpha]_D^{27}$ −41.3° (*c* 1.58 in ethanol)).

Found; Br, 23.42. Calcd. for $C_{16}H_{23}OBr$: Br, 22.49%.

The Methy Ether Xe.—The reaction of 12.0 g. of the bromide Xd with 1.7 g. of lithium aluminum hydride in tetrahydrofuran, as described for the preparation of the methyl ether IVf, gave 8.0 g. of the methyl ether Xe, a colorless liquid (93% yield) (b. p. 110~119°C/0.1 mmHg, n_D^{29} 1.5322, $[\alpha]_D^{28}$ −65.1° (*c* 1.51 in etanol)). The infrared absorption spectra of the methyl ether IVf of the α-desmotroposantonin series and the methyl ether Xe of the β-desmotroposantonin series were indistinguishable.

Found: C, 82.6; H, 10.2. Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.4%.

Isohyposantonin (XVa)[22].—To a solution of 3 g. of barium hedroxide hydrate in 30 cc. of water 0.5 g. of hyposantonin XIV was added; the mixture was warmed on a water bath to gave a clear solution. The solution was made acidic with concentrated hydrochloric acid to precipitate isohyposantonin. The crystalline isohyposantonin which separated was recrystallized from ethanol to yield prismatic crystals (m. p. 168~171°C, $[\alpha]_D^{32}$ −76.6° (*c* 0.51 in benene) (lit.[22] m. p. 167.5~168.5°C, $[\alpha]_D$ −73.7° (in benzene)).

2-Nitroisohyposantoin (XVb).[16]—The nitration of 1.5 g. of hyposantonin in 5 cc. of acetic acid with a mixture of 6 g. of concentrated sulfuric acid and 3 g. of concentrated nitric acid at 20~30°C gave 0.85 g. of needles after recystallization from ethanol (m. p. 174~176°C (lit.[16] m. p. 183°C)).

2-Aminoisohyposantonin (XVc).[16]—The reduction of XVb (0.85 g.) with 5 g. of zinc powder and 0.6 g. of ammonium chloride in ethanol afforded 0.7 g. of crystals after washing and drying. Recrystallization from benzene yielded 0.65 g. of a pale yellow powderlike crystalline material (m. p. 188~191°C, $[\alpha]_D^{31}$ −168° (*c* 0.60 in benzene) (lit.[16] m. p. 193°C, $[\alpha]_D^{24}$ −165.7° (in chloroform)).

The Deamination of 2-Aminoisohyposantonin (XVc) to Isohyposantonin (XVa).—Into a chilled solution of 0.40 g. of 2-aminoisohyposantonin (XVc) in 15 cc. of 1 N hydrochloric acid, a solution of 0.12 g. of sodium nitrite in 2 cc. water was stirred. The reaction mixture was chilled at −5~0°C, and 8 cc. of 40% hypophosphorous acid was added over a 1 hr. period. After the solution had been allowed to stand in a refrigerator for 24 hr., the crystalline product was filtered, washed with water, and dried. Recrystallization from ethanol gave 0.20 g. of crystals (m. p. 168~169°C). A mixed melting point with isohyposantonin (m. p. 168~171°C) was 168~170°C. The infrared spectra in chloroform of the product and isohyposantonin were indistinguishable. $[\alpha]_D^{31}$ −73.6° (*c* 0.65 in benzene).

Found: C, 77.9; H, 7.8. Calcd. for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

(+)-3-Isopropylheptan-6-onic Acid (IX).—A stream of ozone (2%) was passed into a mixture of 80 cc. of acetic acid and 19.0 g. of (+)-dihydrolimonene (VIII) (b. p. 64~65°C/20 mmHg. $n_D^{21.5}$ 1.4555, $[\alpha]_D^{21.5}$ +100.8° (neat)) for 4 hr. at room temperature. The reaction mixture was diluted

22) Ref. 8, p. 3458.

with 10 cc. of water and oxidized by dropwise addition of a solution of 33 g. potassium permanganate in 500 cc. of water at 70°C with stirring. The oxidation mixture was filtered, and the manganese dioxide was washed with hot water. The washing was combined with the fiiltrate and was made acidic with concentrated hydrochloric acid and then extracted with ether. The ether extract was freed of the solvent and the residue was distilled to give 95 g. of a liquid (b. p. 132~137°C/0.8 mmHg, n_D^{22} 1.4557).

(+)-**3-Isopropylcyclopentan-1-one (VI) Semicarbazone.**[10]—A solution of 2.0 g. of the ketocarboxylic acid IX in 20 cc. of 5% sodium hydroxide was added to a chilled hypobromite solution prepared from 9 g. of bromine, 6 g. of sodium hydroxide and 100 cc. of water. After having been stirred for 4 hr., the reaction mixture was washed with ether and was then made acidic with concentrated hydrochloric acid. The mixture was continuously extracted with ether for 30 hr., and the extract was dried over anhydrous sodium sulfate. Removal of the solvent gave an oil which was distilled to give 0.4 g. of a liquid (b. p. 162~175°C/0.6 mmHg). A mixture of this crude β-isopropyladipic acid (Va) and 0.05 g. of barium hydroxide hydrate was heated in a salt bath. When the mixture was heated at 200~260°C for 1/2 hr. and then at 260~300°C for 2 hr., a pale yellow liquid was collected which was directly converted into the semicarbazone with 0.24 g. of semicarbazide hydrochloride, 0.29 g. of sodium acetate and a small amount of water. The crystals which deposited were collected and recrystallized from ethanol to give fine needles (m. p. 186~187°C, $[\alpha]_D^{26}$ +65.2° (*c* 0.62 in ethanol)).

Found: C, 58.8; H, 9.2; N, 22.8. Calcd. for $C_9H_{17}ON$: C, 58.98; H, 9.35; N, 22.93%.

The authors are very grateful to Mr. Eiichi Togashi, Shiono Koryo Kaisha, for his generous gift of (+)-limonene, and to the Nitto Kasei Co. for its financial support.

This work was partilally supported by a grant-in-aid for fundamental scientific research from the Ministry of Education, to which the authors' thanks are due.

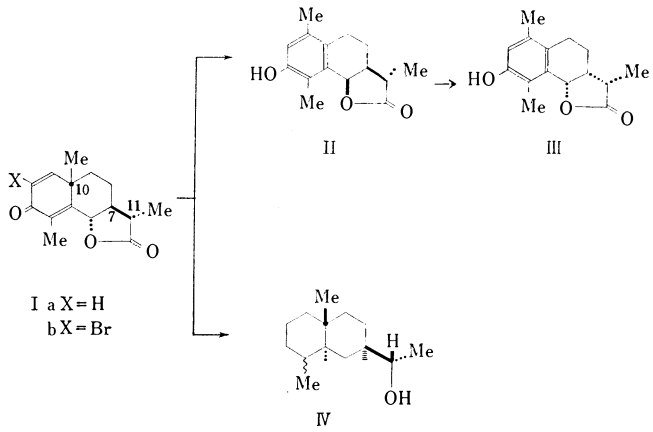
The Absolute Configuration at C_{11} of Santonin[1]



By Masao NAKAZAKI and Hisao ARAKAWA

(Received September 21, 1963)

Although the syntheses of (−)-α-santonin (Ia) and all its possible stereoisomer have been accomplished[2] and although the absolute configurations of the asymmetric centers of C_{10}[3] and C_7[4] have been established unambiguously, that of C_{11} is still in dispute.[4] Deducing mainly from the relative stability of epimeric α- (II) and β-desmotroposantonin (III),[5] Woodward and Yates,[6] Corey[7] and Cocker et al.[4] assigned the (R)-configuration to the C_{11} asymmetric center. The same conclusion was reached by Mitsuhashi[8] after a consideration of the molecular models of santonin and its derivatives as well as of their relative rates of hydrolyses.

Assuming that the stereochemistry of the lactone ring of santonin and the D ring of steroid are isosteric, Miki[9] reached the opposite conclusion, that in santonin the methyl group at C_{11} must have a quasi-equatorial conformation (i.e., the (R)-configuration) and the less stable β-santonin (the C_{11} epimer of Ia) the (S)-configuration. Prelog's atrolactic acid method[10] applied to the alcohol IV derived from santonin added conclusive evidence to support this view.[11] However, the opinions[4] of Cocker et al. have appeared to tend to favor the (R)-configuration at this asymmetic

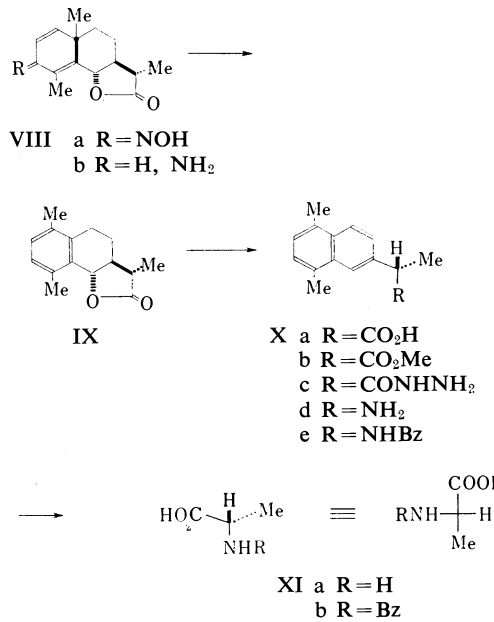
II III IV

center. Moreover, Bose and Chatterjee,[12] formulating a generalized rule permitting the prediction of the absolute configuration of an asymmetric center, have shown that the lactones of the santonin series possess the configuration assigned previously on the basis of thermodynamical studies.



The crystal structure of acetylbromogeigerin (V) determined by the Glasgow group[13] also point to this (R)-configuration when their results are combined with the chemical correlation (via anhydrogeigerin (VI)) between acetylbromogeigerin and artemisin (VII), the relative configuration of which to santonin has been elegantly established by Sumi.[11]

V VI VII

In this communication we will report findings which prove the (s)-configration around this center.

Hyposantonin (IX),[14,15] prepared from santonin oxime (VIIIa) through the dienamine VIIIb by dienamine-benzene rearrangement, was refluxed with iodine in an acetic acid solution for 3 hr., giving santinic acid (Xa),[16] which, after chromatography on silica gel, had an m.p. of 125~127°C ($[\alpha]_D$ +57.3° (in ethanol)).

(retention of configuration)[17] was directly benzoylated to the amide Xe (m. p. 172~174°C, $[\alpha]_D$ −12.7° (in chloroform)), which was dissolved in chloroform and exhaustively ozonized for 9 hr. Acetic acid (90%) was added to the remaining solution, and ozonolysis was continued for an additional 12 hr. After oxidation with peracetic acid and concentration, the reaction mixture was hydrolyzed by hot 20% hydrochloric acid and the chloride ion was removed by Amberite IR-4B resin, giving a solution which showed the presence of alanine (XIa) on paper chromatography. The alanine was then converted into (+)-benzoyl-L-alanine (XIb), which showed, after recrystallization from benzene, an m. p. of 148~151°C ($[\alpha]_D$ +7.4° (±4°) (in N potassium hydroxide)) and an infrared spectrum (in dioxane) superimposable on that of an authentic sample.

These facts show that (+)-α-santinic acid (Xa) has the (s)-configuration. Further, since, from a mechanistic standpoint, epimerization at position 11 is inconceivable during the conversion of santonin into the acid, (−)-α-santonin must also have the (s)-configuration at this center, thus confirming the assignment made by Abe et al.[11]

It is of interest to note that during their studies of the stereochemistry of pinacolic deamination, Bernstein and Whitmore[18] converted (+)-hydratropic acid[19] (XII), a phenyl analog of stantinic acid, into (−)-benzoyl-α-phenyl-α-phenylethylamine (XIII), the absolute configration of which was established by the conversion into (+)-benzoyl-L-alanine (XIb) through a sequence of degradations.[20] Eventually, the (s)-configuration was given to (+)-hydratropic acid by this correlation, and the

XII XIII

XIV

observed parallel shift of the optical rotations between these two series of compounds (Xa→Xe and XII→XIII) also confirms the (s)-configuration of santinic acid.[21] The X-ray crystal analysis of bromodihydroiso-α-photosantonic lactone acetate (XIV) by Asher and Sim[22] demonstrated that (−)-α-santonin has the stereo-chemistry Ia with reference to that of the asymmetric carbon atom 7, the absolute configuration of which has been established by a long series of inter-correlations.[4]

The seemingly inconsistent result of Barton et al.[13] (vide supra) could be interpreted by assuming the feasible inversion at C_{11} demonstrated clearly in their synthetic studies of deoxygerin from 8-epiartemisin.[23]

Finally the whole problem was settled by the X-ray analysis of 2-bromo-α-santonin[24] (Ib), which defined its constitution and relative stereochemistry as Ib. Since the absolute configuration at the asymmetric center C_{10} has been firmly established,[3] this result indicates that (−)-α-santonin has the (s)-configuration at C_{11}, confirming the results obtained by chemical methods.[1,11]

Experimental*

(+)-Santinic Acid (Xa).—A solution of 3 g. of hyposantonin (IX)[14,15] and 6 g. of iodine in 55 cc. of acetic acid was refluxed for 3 hr. After 50 cc. of water had been added, the reaction mixture was concentrated under reduced pressure to remove the excess iodine; this process was repeated twice. The residue was dissolved in 200 cc. of ether and washed with water, aqueous sodium thiosulfate and saturated aqueous sodium chloride, and then dried over anhydrous magnesium sulfate. The removal of the solvent gave a viscous oil, which was sublimed at 3 mmHg. The sublimate began to condense at 160°C (bath temperature), and the main fraction came over at 180~220°C. The condensate (2.6 g.) was dissolved in chloroform and chromatographed on a column of 70 g. of silica gel. Elution with chloroform and the removal of the solvent gave 1.5 g. of crystals (m. p. 120~125°C). Recrystallization from aqueous ethanol raised the m. p. to 125~127°C $[\alpha]_D^{20}$ +57.3° (*c* 1.22 in ethanol). (Lit.[16]: m. p. 132~132.5°C, $[\alpha]_D^{16}$ +64.37° (in ethanol)).

(+) Methyl Santinate (Xb).—To an ether solution of diazomethane prepared from 25 g. of nitrosomethylurea, 6.1 g. of (+)-santinic acid were added, and the reaction mixture was allowed to stand overnight. The usual work-up gave 6.1 g. of

methyl santinate (b. p. 155~157°C/2 mmHg, $[\alpha]_D^{20}$ +70.1° (*c* 1.49 in ethanol)).

Found: C, 78.9; H, 7.6. Calcd. for $C_{16}H_{18}O_2$: C, 79.39; H, 7.49%

The Hydrazide (Xc) of (+)-Santinic Acid.—Six grams of the methyl santinate was stirred into 2.5 g. of hydrazine hydrate (b. p. 117~119°C) at 80°C over a period of 1/2 hr. After a mixture of absolute ethanol and 2 cc. of hydrazine had been added, the reaction mixture was allowed to stand in a refrigerator overnight. The crystals which deposited were filtered and washed with ethanol to yield 1.8 g. of the hydrazide Xc. The filtrate and washing were combined and were refluxed on a water bath for 6 hr. Upon the mixture had cooled in an ice-salt bath, 3.2 g. of crystals were obtained. Recrystallization of the combined crude products from ethanol afforded 4.0 g. of partiallly-racemized hydrazide, which melted at 136°C after sintering at 127~130°C. $[\alpha]_D^{18}$ +25.5° (*c* 1.45 in 95% ethanol).

Found: C, 74.4; H, 7.5; N, 11.8. Calcd. for $C_{15}H_{18}ON_2$: C, 74.35; H, 7.49; N, 11.56%.

Concentration of the mother liquor gave the second crop which was seemingly optically pure and which weighed 0.4 g. (m. p. 151~152°C, $[\alpha]_D^{18}$ +73.2° (*c* 1.01 in ethanol)).

Found: C, 74.4; H, 7.5; N, 11.7. Calcd. for $C_{15}H_{18}ON_2$: C, 74.35; H, 7.49; N, 11.56%.

(−)-*N*-Benzoyl-α-(5, 8-dimethyl-2-naphthyl)ethylamine (Xe).—A mixture of 3.5 g. of the hydrazide Xc ($[\alpha]_D^{18}$ +25.5°), 25 cc. of acetic acid and 50 cc. of benzene was chilled (2~4°C) in an ice bath, and then a solution of 1.2 g. of sodium nitrite in 15 cc. of water was stirred in over a 10 min. period. After water was added, the benzene layer was separated and the aqueous layer was extracted with benzene. The combined benzene extracts were washed with water, aqueous sodium hydrogen carbonate and water successively. After drying over calcium chloride, the benzene solution was heated on a water bath to decompose the acyl azide. Nitrogen was observed to begin to evolve at 50°C, and a vigorous reaction occurred at 60~75°C. After the mixture was refluxed for 15 min., 18 cc. of concentrated hydrochloric acid was added and the mixture was refluxed for 2.5 hr. The crystalline product which deposited was filtered, washed with water and ether, and dried to give 2.1 g. of the hydrochloride of the amine Xd. The hydrochloride of the amine (2.1 g.) was benzoylated with 40 cc. of 10% aqueous sodium hydroxide and 5 cc. of benzoyl chloride. The crude crystalline product was recrystallized from ethanol to afford 2.3 g. of crystals (m. p. 166~172°C). A portion of the benzoyl derivative, after recrystallization from 95% ethanol, melted at 172~174°C, $[\alpha]_D^{19}$ −12.7° (*c* 1.02 in chloroform).

Found: C, 83.0; H, 7.2; N, 4.9. Calcd. for $C_{21}H_{21}ON$: C, 83.13; H, 6.98; N, 4.62%.

The Exhaustive Ozonolysis of the Benzoyl Derivative (Xe).—A stream of ozone was passed into a solution of 2.5 g. of the benzoyl derivative Xe in 60 cc. of chloroform at room temperature. After 9 hr., the solvent evaporated, leaving a residue which was dissolved in 50 cc. of 90% acetic acid; the ozonolysis was then resumed for 13 hr. To the mixture was added 8 cc. of 30% hydrogen peroxide, and the solution was allowed to stand at room temperature for 20 hr. After 50 cc. of water was added, the excess hydrogen peroxide was decomposed by heating it with a small amount of palladium on a carbon catalyst on a water bath for 4.5 hr. After the catalyst had been filtered, the filtrate was freed from the solvent under reduced pressure. The syrup was dissolved in 50 cc. of water and concentrated under reduced pressure; this process was repeated four times. The syrup was dissolved in 20 cc. of water, and an insoluble, brown, viscous material was filtered off. The filtrate was concentrated again under reduced pressure to give a viscous residue which was then dried in a vacuum dessicator over concentrated sulfuric acid overnight. The residue (2.0 g.) was dissolved in 10 cc. of 20% hydrochloric acid and refluxed for 5 hr. The solution was filtered through a layer of Hyflo super cell and treated with Norit. The filtrate was freed from chloride ions with Amberite IR-4B until its pH became about 7. Upon concentration under reduced pressure, a crystalline material deposited which was dissolved in 15 cc. of water and filtered through a layer of Hyflo super cell. A paper chromatogram (acetic acid: butanol: water) exhibited only a single spot corresponding to alanine. After 5 g. of sodium hydrogen carbonate had been added to the aqueous solution, 3.2 g. of benzoyl chloride was added drop by drop over 2 hr. with vigorous shaking at room temperature The turbid reaction mixture was filtered through a layer of Hyflo super cell and made acidic with concentrated hydrochloric acid, and then the mixture was continuously extracted with ether. The removal of the solvent gave a crystalline solid which was dried in a vacuum dessicator. The solid was extracted with four portions of 5 cc. of boiling ligroin to remove the benzoic acid. The insoluble material left in the flask was dissolved in 12 cc. of benzene. Cooling and scratching induced crystallization to afford 10 mg. of (+)-benzoyl-L-alanine (m. p. 148~151°C, $[\alpha]_D^{24}$ +7.4° (±4°) (*c* 0.597 in N potassium hydroxide)). The infrared spectra of this compound and an authentic (+) benzoyl-L-alanine[25] (m. p. 144~146°C, $[\alpha]_D^{15}$ +23.2° (*c* 1.01 in N potassium hydroxide) (Lit.:[25] m. p. 146~148°C, $[\alpha]_D^{20}$ +33.0° (in N potassium hydroxide))) were indistinguishable.

Found: C, 61.9; H, 6.0; N, 7.3. Calcd. for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25%.

The authors wish to thanks Drs. Kenichi Takeda and Kaoru Kuriyama, Shinogi Pharm. Co., for their measurement of optical rotation on a Rudolph spectropolarimeter model 200. This work was partially supported by a grant-in-aid for fundamental scientific research from the Ministry of Education, to which the authors' thanks are due.

Studies on Amino-hexoses. VII. The N-Deacetylation of Methyl N-Acetyl α-D-Glucosaminide

By Mamoru FUJINAGA and Yoshio MATSUSHIMA

(Received September 30, 1963)

One of the present authors previously presented a method which might be of use for elucidating aminopolysaccharide structures.[1] The method consisted basically of two procedures, the deacetylation of the *N*-acetyl group in *N*-acetyl aminosugar components and the deamination by nitrous acid of the free amino group thus formed. Anhydrous hydrazine, when used as a deacetylating reagent, had a minimum influence on glycosidic linkages but gave not very satisfactory results. As was shown in the original report,[1] hydrazine treatment of chondroitin sulfate caused considerable degradation of the molecule, and only about 10% of the starting material was recovered as a 90% *N*-deacetylated non-dialysable specimen. Wolfrom and Juliano[2] reported the recovery of a 59~68% *N*-deacetylated specimen in about a 50% yield. Yosizawa and Sato[3-5] observed the formation of 2, 5-anhydrohexose and pentose beside the extensive degradation of the molecule in the hydrazine treatment of the blood group aminopolysaccharide.

The above-mentioned results, obtained in several laboratories, show that more fundamental research into a method is desirable; the present authors chose methyl *N*-acetyl α-D-glucosaminide as the simplest model compound. This compound was treated both with anhydrous and hydrated hydrazine. The deacetylation yield was assayed by Van Slyke nitrogen determination, and the starting compound which remained was assayed by isolation. The results are shown in Table I.

The resultant methyl α-D-glucosaminide showed a marked stability against these reagents in the thin layer chromatography of the reaction mixture, which revealed no spots other than those of the starting compound and the deacetylated product. Refluxing with barium hydroxide for several hours did not give even a trace of any colored substance, though it did give crystalline methyl α-D-glucosaminide in a good yield. Since a convenient method for separating methyl *N*-acetyl-D-glucosaminide anomers has been established,[6] these deacetylation methods afford a conveniet

way to obtain anomerically-pure methyl D-glucosaminides.

Experimental

Hydrazine Treatment and Assay of the Reaction Mixture.—About 500 mg. of methyl *N*-acetyl α-D-glucosaminide and 1.5 ml. of hydrazine were kept in a sealed tube at 100°C for 10 or 20 hr. The reaction mixture was then evaporated in vacuo, and the residue was dissolved in 25 ml. of methanol. In order to remove the acethydrazide which had formed, 8 ml. of benzaldehyde was added and the mixture was refluxed for 15 min. and evaporated in vacuo. Twenty milliliters of water was added to the residue, and the mixture was, after having been washed twice each with petroleum ether and ethyl ether, subjected to Van Slyke nitrogen determination.

The hydrazine treated specimen was, after the removal of the excess hydrazine described above, dissolved in water and passed through a column of Dowex 50 (2×10 cm., H^+ form) and a column of Dowex 1 (2×5 cm., OH^- form). About 200 ml. of the solution thus obtained was evaporated in vacuo to dryness. The crystalline residue was weighed. The methyl *N*-acetyl α-D-glucosaminide thus recovered was identified by melting point determination, specific rotation measurement and thin layer chromatography. The results are shown in Table I and in Fig. 1. A thin layer chromatogram of the recovered substance gave only one spot identical with that of a standard sample of methyl *N*-acetyl α-D-glucosaminide in every run.

The Preparation of Methyl α-D-Glucosaminide and Its Hydrochloride.—*With Hydrazine Hydrate.*—One gram of methyl *N*-acetyl-α-D-glucosaminide and 3 ml. of hydrazine hydrate (90%) were kept in a sealed tube at 100°C for 10 hr. After hydrazine had been removed in vacuo, and after a large amount of chloroform had been added to the residue, the mixture was refluxed for an hour. The chloroform solution was concentrated to a small volume in vacuo and kept in a refrigerator. The jelly product thus obtained was filtered and dried in a desiccator. The yield was 0.54 g. (65.9%). The colorless crystals obtained from absolute ethanol melted at 154~160°C $[\alpha]_D^{30}$ +158.5° (*c* 1.06, in water).

Found: C, 43.69; H, 7.96; N, 7.20. Calcd. for $C_7H_{15}O_5N$: C, 43.51; H, 7.83; N, 7.25%.

The compound was dissolved in water, and the pH of the solution was adjusted to 4.4 with 1 N hydrochloric acid. Evaporation in vacuo gave the hydrochloride as a colorless crystalline powder $[\alpha]_D^{29}$ +131.6° (*c* 1.14, in water).

Found: C, 37.56; H, 6.96; N, 6.88; Cl, 13.97. Calcd. for $C_7H_{16}O_5NCl$: C, 36.61; H, 7.02; N, 6.10; Cl, 15.44%.

With Barium Hydroxide.—The mixture of methyl *N*-acetyl-α-D-glucosaminide (1.0 g.), barium hydroxide (2.5 g., octahydrate) and 18 ml. of water was refluxed for an hour. The mixture was then filtered and saturated with carbon dioxide. After filtration from barium carbonate, the pH of the filtrate was adjusted to 4 by 1 N sulfuric acid. The filtrate free from barium sulfate was passed through a column of Dowex 1 (OH^- form) and the solution was concentrated to dryness in vacuo. The crystalline residue was dissolved in a small volume of hot ethanol and then kept in a refrigerator. The colorless crystals obtained melted at 155~157°C ($[\alpha]_D^{22}$ +157.5°; (*c* 0.838, in water).

Found: C, 43.94; H, 7.98; N, 7.17 (6.94 (Van Slyke)). Calcd. for $C_7H_{15}O_5N$: C, 43.51; H, 7.83; N, 7.25%.

Colorless crystalline hydrochloride ($[\alpha]_{30}^{D}$ +129.2°) (*c* 1.32, in water) was obtained.

Found: C, 36.51; H, 6.99; N, 6.28; Cl, 15.37. Calcd. for $C_7H_{16}O_5NCl$: C, 36.61; H, 7.02; N, 6.10; Cl, 15.44%.

The Identification of the Hydrazinolyzed Product.—As has been described above, the hydrochloride of the deacetylated product gave optical rotation data which were in good agreement with the results obtained by Neuberger and Rivers,[7] who prepared the compound via *N*-carbobenzyloxy-D-glucosamine and gave $[\alpha]_D$ +127°. The melting

point determination of our hydrochloride was difficult because of its hygroscopic nature. While thin layer chromatography (Fig. 1) identified our compounds well, a crystalline *N*-carbobenzyloxy derivative was prepared and compared with an authentic specimen synthesized by the Neuberger and Rivers method.

The syrup obtained by treating methyl *N*-acetyl α-D-glucosaminide with hydrazine hydrate was washed repeatedly with hot chloroform until free from acethydrazide. 0.36 g. of the syrup was then dissolved in 15 ml. of water. 0.5 ml. of carbobenzyloxy chloride and 0.36 g. of sodium bicarbonate were mechanically stirred into the solution, and the stirring was then continued for an hour. After having passed through a column of Dowex 50 (H^+ form), the solution was dried up and the residue was crystallized from water as colorless needles which melted at 159~161°C alone or at 157~160°C when mixed with an authentic specimen. The yield was 0.22 g. (36.1%) $[\alpha]_D^{28}$ +100.0° (*c* 0.84, in pyridine).

Found: C, 54.62; H, 6.60; N, 4.23. Calcd. for $C_{16}H_{21}O_7N$; C, 55.04; H, 6.47; N, 4.28%.

Summary

Methyl *N*-acetyl-α-D-glucosaminide has been found to be well *N*-deacetylated by hydrazine treatment. The methyl α-D-glucosaminide thus produced shows so much stability with regarded to hydrazine and to barium hydroxide that these reagents provide a convenient means of preparing anomerically-pure methyl D-glucosaminide and its hydrochloride. The free base of methyl α-D-glucosaminide has been obtained crystalline for the first time.

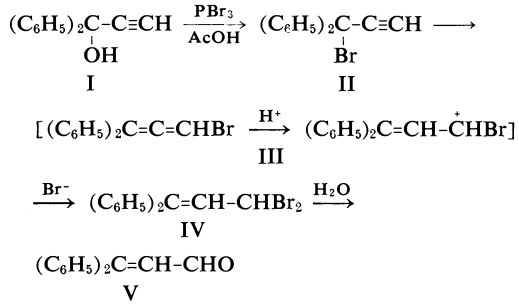
Reactions of Tertiary Acetylenic Alcohols with Phosphorus Tribromide in Acetic Acid

By Hisaya TANI and Fumio TODA

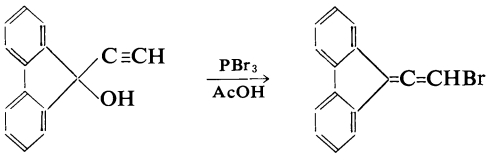


(Received October 3, 1963)

It has been well known that the reaction of acetylenic alcohols with phosphorus tribromide in the presence of pyridine gives corresponding tertiary acetylenic bromides. Some unexpected reactions, however, have been found during the course of studies of the bromination of acetylenic alcohols with phosphorus tribromide in acidic media. The present paper deals with the reaction of some aromatic tertiary acetylenic alcohols, I, VIII, and XII, with phosphorus tribromide in acetic acid.

1, 1-Diphenylprop-2-yn-1-ol (I) reacted with phosphorus tribromide in acetic acid to give 1, 1-diphenyl-3, 3-dibromoprop-1-ene (IV) in a yield of 45%. The structure of the *gem*-bromide IV was determined by the experiments to be described below in addition to elementary analysis and a study of the infrared spectrum. The ultraviolet spectrum of IV shows the presence of a conjugated system corresponding to 1, 1-diphenylethylene, and the NMR spectrum shows the presence of three kinds of hydrogen, i. e., aromatic, vinyl and aliphatic.

The behavior of IV as a representative *gem*-dihalide gave further evidence for the structure.[1] For example, the heating of II in water afforded 1, 1-diphenylprop-1-en-3-al (V) quantitatively; this was also obtained by the treatment of IV with acid, base, or silver nitrate.



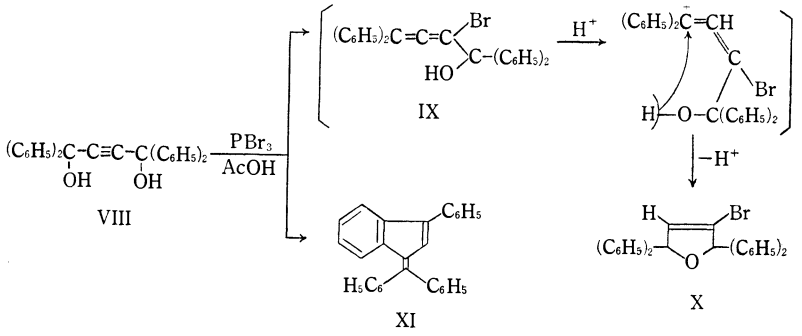
Scheme 1

1) H. Tani and F. Toda, *Chem. & Ind.*, **1963**, 1083.

The reaction can be explained by the successive addition of a proton and a bromide anion to the bromoallene intermediate III produced by the Meyer-Schuster rearrangement of the tertiary acetylenic bromide II initially produced, as is shown in Scheme 1. A proof for the initial production of the tertiary acetylenic bromide II in this reaction was given by the experimental evidence that the action of phosphorus tribromide or hydrogen bromide on the bromide II, prepared by the usual method,[2] in acetic acid yielded the *gem*-dibromide IV in a good yield.

The assumption that the above reaction proceeds through a bromoallene intermediate III was indirectly proved by the reaction of 9-ethynylfluoren-9-ol (VI) under the same conditions as those employed for I.

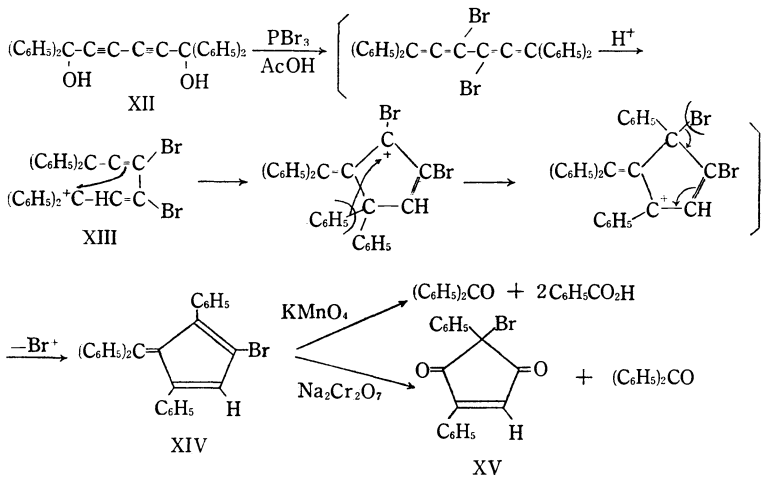
VI VII



In this case, 9-(bromovinylidene)fluorene (VII) was isolated in a 75% yield as stable yellow leaflets, the structure of which was confirmed by the presence of allenic bands at 1950 and 1915 cm^{-1} in the infrared region and by comparing its ultraviolet spectrum with that of 9-(chlorovinylidene)fluorene.[3] The stability of the allenic bromide VII is attributable to the resonance stabilization arising from the planarity of the fluorene ring. After this investigation had been completed, Landor and Landor[4] reported that the reaction of 1, 1, 3-triphenylprop-2-yn-1-ol with thionyl chloride proceeds through a chloroallene intermediate corresponding to III or VII, resulting in 1, 1, 3-triphenylprop-1-en-3-one and a cyclic dimer.

In contrast with the reaction of terminal acetylenic alcohols, disubstituted acetylenic alcohols reacted with phosphorus tribromide in acetic acid to yield cyclic compounds.

The treatment of 1, 1, 4, 4-tetraphenylprop-2-yne-1, 4-diol (VIII) with phosphorus tribromide in acetic acid gave 1, 10, 10-triphenylbenzofulvene (XI)[5] and 2, 2, 5, 5-tetraphenyl-3-bromodihydrofuran (X) in yields of 30 and 16% respectively.



The structure of the dihydrofuran (X) was confirmed by a study of its ultraviolet spectrum, which showed an absence of conjugation between the benzene ring and the double bond, and by a study of its infrared spectrum, which showed the presence of trisubstituted ethylene, vinyl ether and monosubstituted benzene groups. The formation of X may be explained by the protonation and then the cyclization of the allenic intermediate IX produced by the Meyer-Schuster rearrangement of the monobromide of VIII, as is shown in Scheme 2. On the other hand, the formation of the benzofulvene XI may well be explained by the acid-catalyzed reaction of X through the transitory formation of tetraphenylbutatriene, because it has been reported[5] that the action of hydrogen iodide on an iodo-analog of X gives the benzofulvene XI.

The action of phosphorus tribromide on 1, 1, 6, 6-tetraphenylbuta-2, 4-diyne-1, 6-diol (XII) resulted in reddish brown needles. The structure of this compound, $C_{30}H_{21}Br$, was confirmed to be 2, 5, 6, 6-tetraphenyl-3-bromofulvene (XIV) on the basis of the following data: (i) the NMR spectrum of XIV showed the presence of one vinyl hydrogen and twenty aromatic hydrogens. (ii) The bromine atom of XIV reacted with neither sodium ethoxide nor with sodium amide in liquid ammonia. (iii) XIV

Scheme 3

gave a characteristic fulvene absorption spectrum in the visible region. (iv) The oxidation of XIV by potassium permanganate in acetone gave one part of benzophenone and two parts of benzoic acid. (v) The sodium bichromate oxidation of XIV in acetic acid gave 2, 5-diphenyl-2-bromocyclopent-4-ene-1, 3-dione (XV) and benzophenone, in addition to a small amount of benzoic acid, which was supposed to be produced by the further degradation of the former XV.

The structure of the cyclopentenedione XV was confirmed by elementary analysis and by a study of its infrared, ultraviolet and NMR spectra; the last named indicated the presence of one vinyl hydrogen against ten aromatic hydrogens.

Additional evidence for the structure of the fulvene XIV was given by its infrared spectrum. Two bands of the fulvene XIV appeared at 1310 (weak) and 1265 (strong) cm^{-1}, corresponding to those of 6, 6-diphenyl-2, 3, 4, 5-tetrabromofulvene which appeared at 1315 (medium) and 1230 (strong) cm^{-1}.[6] Moreover, the presence of one nuclear ring hydrogen of the fulvene (XIV) was established by the absorption at 820 cm^{-1}.

The reaction may be interpreted in terms of the cyclization and the phenyl migration of the dibromo cation intermediate XIII produced by the Meyer-Schuster rearrangement and then the protonation of the dibromide of XII, as is shown in Scheme 3.

Experimental*

1, 1-Diphenyl-3, 3-dibromoprop-1-ene (IV).—Into an ice-chilled solution of 1, 1-diphenylprop-2-yn-1-ol (I, 10.5 g., 0.050 mol.) in acetic acid (25 ml.)-carbon tetrachloride (5 ml.), phosphorus tribromide (7.3 g., 0.027 mol.) was stirred drop by drop over a period of 15 min. under a nitrogen atmosphere; the stirring was then continued for an additional hour. The crude crystals which formed were collected by filtration and washed with cold methanol (20 ml.), resulting in IV in the form of colorless rhombic plates (8.5 g. (45%); m. p. 82°C (decomp.)); this was pure enough without further purification to carry out the following experiments. Two recrystallizations of the crystals from petroleum ether (b. p. 60~70°C) did not raise the melting point. IR: KBr disk, 882 (trisubstituted ethylene) and 768, 700 cm^{-1} (monosubstituted benzene). UV: $\lambda_{max}^{Dioxane}$, 242 mμ (ε, 10200), 266 (14700), 273 (16500). NMR: in carbon tetrachloride, 2.75 τ (singlet, aromatic), 3.60 τ (quartet, vinyl) and 7.90 τ (siglet, aliphatic).

Found: C, 51.22; H, 3.41; Br, 45.45. Calcd. for $C_{15}H_{12}Br_2$: C, 51.14; H, 3.41; Br, 45.65%.

The Formation of the *gem*-Bromide (IV) from 1, 1-Diphenyl-1-bromoprop-1-yne (II).—When phosphorus tribromide (or gaseous hydrogen bromide) was added to a solution of II in acetic acid under cooling with ice, colorless rhombic plates IV (m. p. 82°C (decomp.)) were formed almost quantitatively; these did not show any depression of the melting point when mixed with the authentic sample described above.

1, 1-Diphenylprop-1-en-3-al (V).—A solution of 1, 1-diphenyl-3, 3-dibromoprop-1-ene (IV, 1.0 g., 0.0028 mol.) in alcoholic potassium hydroxide (prepared from 30 ml. of ethanol and 0.5 g. of potassium hydroxide) was refluxed for 1 hr. After cooling, the reaction mixture was poured into water and extracted with ether. The crude crystals obtained by the evaporation of the solvent were

6) J. C. Wood, R. M. Elofson and D. M. Saunders, *Anal. Chem.*, 30, 1339 (1958).

* All melting points are uncorrected. The NMR spectra were obtained in a carbon tetrachloride solution with a Varian model A-60 spectrometer, using tetramethylsilane as an internal standard. The molecular weight was determined in a benzene solution using a Mechrolab vapor pressure osmometer model 301 A.

recrystallized from petroleum ether (b. p. 40～50°C) to give colorless needles (m. p. 43°C, 0.5 g. (90%) (lit.,[7] m. p. 44.5～45.5°C)). For this aldehyde, consistent infrared and ultraviolet spectra were obtained. The 2, 4-dinitrophenylhydrazone of the aldehyde melted at 195°C (lit.,[7] m. p. 198°C).

By treating the *gem*-bromide IV with water, aqueous acid or alcoholic silver nitrate in the manner described above, the aldehyde IV was also obtained quantitatively.

9-(Bromovinylidene)fluorene (VII).—To a stirred solution of 9-ethynylfluoren-9-ol (VI, 6.2 g., 0.03 mol.) in acetic acid (20 ml.), phosphorus tribromide (4.4 g., 0.017 mol.) was added under cooling with ice over a period of 30 min. The crude crystals which formed were collected by filtration and washed with methanol, water and methanol successively. The dried crystals were recrystallized from ethyl acetate ethanol to give yellow plates (VII) (6.0 g. (75%); m. p. 220°C (decomp.)). IR: in chloroform, 1950 and 1915 cm^{-1} (allene). UV: $\lambda_{max}^{Dioxane}$, 266 mμ (ε, 23400), 274(25700), 380 (16400).

2, 2, 5, 5-Tetraphenyl-3-bromodehydrofuran (X) and 1, 10, 10-Triphenylbenzofulvene (XI).—To a stirred solution of 1, 1, 4, 4-tetraphenylbut-2-yne-1, 4-diol (VIII, 0.7 g., 0.002 mol.) in a mixture of acetic acid (10 ml.) and carbon tetrachloride (20 ml.), phosphorus tribromide (1.35 g., 0.005 mol.) was added in one portion under cooling with ice; the reaction mixture was then stirred for a further 30 min. After it had been kept standing at room temperature for 1 hr., the reaction mixture was poured into ice-water. The carbon tetrachloride layer was separated, washed with water and dried over sodium sulfate. The evaporation of the solvent yielded a mixture of two kinds of crystals (yellow and colorless), which were then separated mechanically. The recrystallization of the yellow crystals from ethyl acetate resulted in pure bright yellow prisms (XI) (200 mg. (30%); m. p. 204°C (decomp.) (lit.,[5] m. p. 204～205°C)). UV: $\lambda_{max}^{Dioxane}$ 235 mμ (ε, 34200), 254 (32300), 297 (12500), 350 (15900), 410 (shoulder) (5200). NMR: in carbon tetrachloride, 2.62 τ (doublet, aromatic) and 3.35 τ (singlet, fulvene).

Found: C, 93.91; H, 5.69. Calcd. for $C_{25}H_{20}$: C, 94.34; H, 5.66%.

The recrystallization of the colorless crystals from ethyl acetate resulted in colorless prisms (X) (150 mg. (16%); m. p. 175°C). IR: KBr disk, 1657 (double bond), 1013 (ether), 833, 807 (trisubstituted ethylene) and 753, 700 cm^{-1} (monosubstituted benzene). UV: $\lambda_{max}^{Dioxane}$: 233 mμ (ε, 700), 247 (800), 252 (800), 259 (760).

Found: C, 74.21; H, 4.69; Br, 17.82. Calcd. for $C_{25}H_{21}BrO$: C, 74.17; H, 4.63; Br, 17.66%.

2, 5, 6, 6-Tetraphenyl-3-bromofulvene (XIV).—Phosphorus tribromide (2.2 g., 0.008 mol.) was stirred into an ice-cooled solution of 1, 1, 6, 6-tetraphenylbut-2, 4-diyne-1, 6-diol (XII, 4.2 g., 0.01 mol.) in acetic acid (30 ml.) over a period of 5 min. After stirring had been continued for a further 30 min. the crystals which had formed were filtered and washed with water and a small amount of methanol successively. Two recrystallizations of the dried crystals from ethyl acetate afforded reddish brown needles (2.1 g. (43%); m. p. 215°C (decomp.)). IR: KBr disk, 1310, 1265 (fulvene), 805 (hydrogen of fulvene ring) and 770, 723, 695 cm^{-1} (monosubstituted benzene). UV: $\lambda_{max}^{Dioxane}$, 254 mμ (ε, 21300), 358 (23200), 490 (shoulder) (500). NMR: in carbon tetrachloride, 2.63, 2.90, 3.13 and 3.36 τ (aromatic, all the areas are almost equal), 3.62 τ (hydrogen on fulvene ring).

Found: C, 77.81; H, 4.55; Br, 16.95. Mol. wt. 464 (vapor pressure osmometer*). Calcd. for $C_{30}H_{21}Br$: C, 78.10; H, 4.56; Br, 17.34%. Mol. wt. 461.

The Oxidation of XIV by Potassium Permanganate.—To a stirred solution of XIV (0.3 g., 0.00065 mol.) in acetone (20 ml.), potassium permanganate (1.0 g., 0.0063 mol.) was added; the mixture was then stirred at 30～40°C for 2 hr. After the mixture had been kept standing overnight at room temperature, the excess potassium permanganate in the reaction mixture was decomposed with a small amount of ethanol. The acetone solution obtained by the removal of the manganese dioxide by filtration was evaporated to dryness. The residue was mixed with water and extracted with ether. The ether extract was washed with aqueous sodium bicarbonate. The alkaline solution was acidified and then saturated with ammonium chloride. The crude crystals thus obtained were recrystallized from petroleum ether (b. p. 60～70°C), resulting in benzoic acid in the form of colorless plates (100 mg. (60%); m. p. 121°C), which did not show any depression of the melting point when mixed with an authentic sample (m. p. 121°C).

The recrystallization of the crude crystals obtained by the removal of the solvent from the dried ether layer from petroleum ether (b. p. 40～50°C) afforded benzophenone (60 mg. (50%); m. p. 47～48°C), which was identified by a mixed melting point determination with an authentic specimen and by a study of its infrared spectrum.

The Oxidation of XIV by Sodium Bichromate.—A mixture of XIV (0.5 g., 0.001 mol.), sodium bichromate dihydrate (1.5 g., 0.005 mol.) and acetic acid (30 ml.) was refluxed for 1.5 hr. After it had cooled, the reaction mixture was poured into dilute hydrochloric acid and extracted with ether. The ether layer was washed with aqueous potassium carbonate. From the acidified alkaline solution, a small amount of benzoic acid was isolated in the form of colorless plates. The evaporation of the solvent from the dried ether layer yielded a mixture of yellow needles and an oily material. After the mixture had been washed with methanol (5 ml.), insoluble crystals were recrystallized from ethyl acetate to give XV in the form of pale yellow needles (0.1 g. (30%); m. p. 205～206°C). IR: KBr disk, 1670, 1665 (carbonyl) and 830 cm^{-1} (trisubstituted ethylene). UV: $\lambda_{max}^{Dioxane}$, 237 mμ (ε, 19800), 248 (17800), 298 (shoulder) (7300), 332 (3900). NMR: in carbon tetrachloride, 2.10, 2.55, 2.90 τ (aromatic) and 3.53 τ (vinyl).

Found: C, 62.78; H, 3.53; Br, 27.41. Calcd. for $C_{17}H_{11}BrO_2$: C, 62.38; H, 3.36; Br, 24.46%.

7) H. Lorenz and R. Wizinger, *Helv. Chim. Acta*, **28**, 600 (1945).

The recrystallization from petroleum ether (b. p. 40~50°C) of the crude crystals obtained by the removal of the solvent from the methanol layer yielded benzophenone in the form of colorless needles (90 mg. (50%) ; m. p. 48°C), the identification of which was made by a mixed melting point determination with an authentic sample and by a study of its infrared spectrum.

The authors wish to express their thanks to Professor Yasuhide Yukawa of the Institute for Scientific and Industrial Research, Osaka University, for his helpful discussions. They also indebted to Mr. Masakazu Okumiya for the microanalyses.

Sesquiterpene Constituents of the Essential Oil of Hinoki (Chamaecyparis Obtusa (Sieb. et Zucc.) Endl.)

By Schûichi HAYASHI, Katsumi YANO and Tamon MATSUURA

(Received October 7, 1963)

The sesquiterpene constituents of the essential oil of Hinoki (*Chamaecyparis Obtusa* (Sieb. et Zucc.) Endl.) have been investigated by several workers,[1-3] and two compounds, *l*-[1] or *d*-cadinene[2-3] and cadinol,[3] have been reported. Recently, β-, γ-, δ- and ε-cadinene[4] were identified as isomeric members of cadinene, and α- and δ-cadinol[5] as isomers of cadinol. The present work, along with a forthcoming investigation of the monoterpene constituents[6], was undertaken to clarify the sesquiterpene constituents.

Results

The essential oil from the leaves and twigs of the Hinoki (*Chamaecyparis Obtusa* (Sieb. et Zucc.) Endl.) growing in Kôchi Prefecture, Japan, was investigated. The residual oil, from which the monoterpene fractions were distilled off, was repeatedly fractionated through a packing distillation column to divide it into several sesquiterpene fractions. The physical properties of the fractions are illustrated in Fig. 1.

In the present work, *d*-longifolene and calamenene were newly identified, and cadinene and cadinol, which had formerly been reported, were confirmed to be *d*-γ-cadinene and *l*-α-cadinol respectively. On the basis of the results of both fractionation and gas chromatography, it was assumed that the sesquiterpene fractions of Hinoki oil consisted of approximately 72% *d*-longifolene, 19% *d*-γ-cadinene, 1% calamenene and 8% *l*-α-cadinol. The sesquiterpene fraction amounted to 43.2% of the total essential oil.

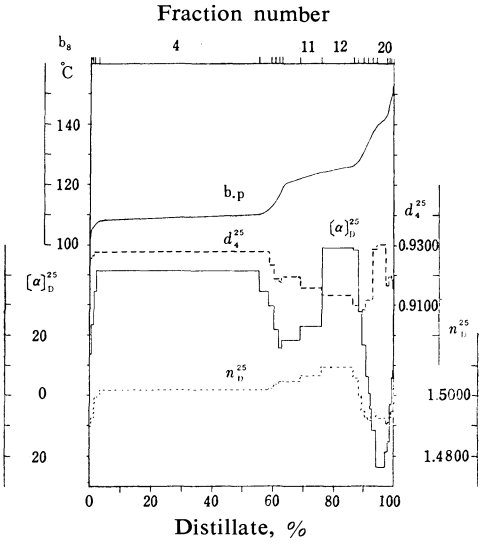

Fig. 1. Fractional distillation of sesquiterpene oil.

***d*-Longifolene.**—Fraction 4 gave a gas chromatogram which mainly showed one peak (retention time; 15.5 min.), and an infrared spectrum (1763, 1661, 1474, 1454, 1376, 1364,

1) R. Kondô, *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*), **29**, 1297 (1909).
2) S. Uchida, *J. Soc. Chem. Ind. Japan* (*Kôgyô Kwagaku Zasshi*), **28**, 1440 (1925); **31**, 650 (1928).
3) N. Hirao, *J. Chem. Soc. Japan* (*Nippon Kwagaku Kwaishi*), **58**, 222 (1937).
4) V. Herout and V. Sýkora, *Tetrahedron*, **4**, 246 (1958).
5) O. Motl, V. Sýkora, V. Herout and F. Šorm, *Collection Czechoslov. Chem. Commun.*, **23**, 1297 (1958).
6) To be published in this Bulletin.

1207, 1175, 873 cm^{-1}) which coincided entirely with that of longifolene.[7]

From this fraction longifolene hydrochloride (m. p. 59~60°C[8]) was prepared. Also, a nuclear magnetic resonance spectrum (τ; 9.116, 9.072, 9.049, 8.475, 8.000, 7.500, 5.630, 5.375) of this fraction agreed with that of longifolene.[9] Accordingly, it is confirmed that longifolene is a main component of fraction 4.

***d*-γ-Cadinene.** — From fraction 12 cadinene dihydrochloride (m. p. 116~117°C[10]) was prepared. However, a gas chromatogram of this fraction contained some weak peaks, together with the main peak (retention time; 30.4 min.), and so this fraction was eluted through a silica gel column, using petroleum ether to divide it into some fractions. The main fraction from the chromatography showed an infrared absorption spectrum (1649, 1454, 1389, 1369, 883, 835 cm^{-1}) which agreed with that of γ-cadinene.[11]

Calamenene.—Another small fraction from the above elution chromatography of fraction 12 gave a gas chromatogram which showed only one peak (retention time; 40.2 min.) and an infrared absorption spectrum (1642, 1613, 1550, 1500, 1464, 1385, 1369, 881, 815 cm^{-1}) which agreed with that of calamenene.[12] The ultraviolet absorption spectrum of this small fraction is shown in Fig. 2, for the ultraviolet spectrum of calamenene seems not to be found in the literature.

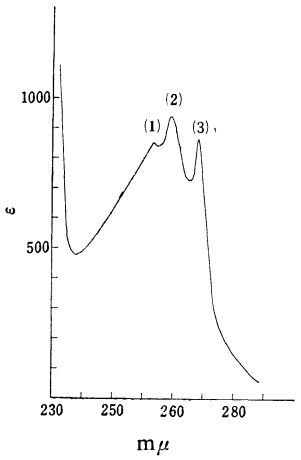

Fig. 2. The ultraviolet absorption spectrum of calamenene.
(1) λ_{max}^{EtOH} 263 mμ (ε 850)
(2) λ_{max}^{EtOH} 269 mμ (ε 940)
(3) λ_{max}^{EtOH} 278 mμ (ε 860)

In addition to *d*-γ-cadinene and calamenene, fraction 12 contained a component which showed an absorption band of λ_{max}^{EtOH} 246 mμ ($E_{1cm}^{1\%}$ 65.2) in its ultraviolet spectrum. This band suggests the presence of the isocadinene named by Gillam.[13] Thus, it is certain that fraction 12 consists of large quantity of *d*-γ-cadinene and small quantities of calamenene and other elements.

***l*-α-Cadinol.** — Cadinene dihydrochloride[5] (m. p. 115.0~116.5°C) and α-cadinol *p*-nitrobenzoate[5,14] (m. p. 134~135°C) were prepared from fraction 20. After being purified by elution chromatography on alumina (activity IV[15]) using petroleum ether, fraction 20 ($[\alpha]_D^{25}$ −32.3°, 0.1066 g./cc., ethanol) gave an infrared absorption spectrum (1656, 1450, 1380, 1370, 1119, 815 cm^{-1}) which agreed with that of α-cadinol.[5] Accordingly, it is certain that fraction 20 consists mainly of *l*-α-cadinol.

Experimental

In the present work, the residual oil (b. p. above 126°C/20 mmHg, 7.14 kg.) from which the monoterpene fractions were distilled off as described in the forthcoming work,[6] was used.

***d*-Longifolene.** — One-half gram of fraction 4 (Found: C, 88.32; H, 11.63%) was dissolved in ether and saturated with dry hydrogen chloride under cooling at −15°C. After the reaction mixture had stood for two hours, needle crystals (0.31 g.) were obtained; these, after being recrystallized from petroleum ether, melted at 59~60°C ($[\alpha]_D^{25}$ +7.5°, 0.2221 g./cc., chloroform). This melting point agrees with that of longifolene hydrochloride.[8]

***d*-γ-Cadinene.**—Seven hundred and twenty milligrams of fraction 12 was treated with dry hydrogen chloride as in the case of longifolene to give needle crystals (0.24 g.) which, after being recrystallized from ethanol, melted at 116~117°C ($[\alpha]_D^{25}$ −36.2°, 0.0486 g./cc. chloroform). This melting point agrees with that of cadinene dihydrochloride.[10] For further purification, 1.46 g. of fraction 12 was chromatographed on silica gel (100~200 mesh, 150 g.) which had been packed in a glass tube (inside diameter, 1.8 cm.) using petroleum ether. The eluate was divided into several fractions by testing its refractive index.

***l*-α-Cadinol.**—When one-half gram. of fraction 20 was treated with dry hydrogen chloride, needle crystals (0.04 g.) were obtained. The needles, after being recrystallized from ethanol, showed a melting

point of 115.0~116.5°C ($[\alpha]_D^{25}$ −35.15°, 0.0382 g./cc., chloroform), which was confirmed by admixture with cadinene dihydrochloride (m. p. 116~117°C). One gram of fraction 20 was acylated with *p*-nitrobenzoyl chloride, and the crystalline mass (0.03 g.) was prepared. The mass, after being recrystallized from ethanol, showed a melting point of 134~135°C, which agrees with that of *p*-nitrobenzoate of α-cadinol.[5,14]

Gas Chromatography.—A gas chromatogram was made by a Shimadzu GC-2 apparatus equipped with a thermal conductivity cell using a copper spiral column (inside diameter, 4 mm.; length, 3 m.). For hydrocarbon analysis, Shimalite (24~48 mesh) coated with polyethylene glycol-6000 (20%) was used at 140°C, while for oxygen-containing compound analysis, quartz powder (150~200 mesh) coated with Thermol-1 (5%) was used at 170°C.

Summary

d-Longifolene and calamenene have been newly identified from the essential oil of Hinoki. Cadinene and cadinol, which had been formerly reported, have been confirmed to be *d*-γ-cadinene and *l*-α-cadinol respectively.

Stability Constants of Palladium, Copper, Nickel, Zinc and Manganese Complexes of 3-Hydroxy-3-phenyl-1-p-chlorophenyltriazene

BY D. N. PUROHIT and N. C. SOGANI

(Received October 8, 1963)

In recent years Sogani et al.[1-5] have reported hydroxytriazenes as a very useful class of chelating reagents. They possess common functional grouping -N(OH)-N=N-. The parent compoud of the series, 3-hydroxy-1, 3-diphenyltriazene, is a highly selective reagent for palladium[1] and copper[2]. Substitution of different groups at different positions of the aryl nuclei of the present compound influenced the stabilities of resulting metal chelates. The present investigation deals with determination of stabilities of bivalent metal chelates of para chloro substituted hydroxytriazene, namely, 3-hydroxy-3-phenyl-1-*p*-chlorophenyltriazene, in 70% v/v dioxan-water mixture, by employing Bjerrum-Calvin pH titration technique.[6] Titrations were carried out in duplicate using 40 : 1 ratio of chelating agent to metal ion concentration.

Experimental

Chelating Agent Solution.—3-Hydroxy-3-phenyl-1-*p*-chlorophenyltriazene was prepared by employing the method given by Sogani et al.[3] Weighed amount of this compound was dissolved in 70% v/v dioxan-water mixture and diluted to give 0.04 M solution.

Standard Palladium, Copper, Nickel, Zinc, and Manganese Solutions.—Analytical grade reagents of palladium chloride, copper chloride, nickel sulphate, zinc oxide, and manganese sulphate were used for preparing standard solutions. After standardizing these solutions by usual classical methods, these were diluted to 0.002 M solution.

Sodium Hydroxide. — Approximately 0.1 M carbonate free sodium hydroxide was prepared and standardized with analytical grade potassium hydrogen phthalate. It was diluted to give 0.02 M solution.

Dioxan. — The B.D.H. dioxan was purified by Weissberger's method.[7]

Potentiometric Titrations.—The pH-titrations of the chelating agents with standard alkali solution in absence and in the presence of different metal ions were carried out by using Cambridge bench-type pH-meter which gave values accurate to 0.01 pH unit. The pH-meter was standardized before, and checked after, each titration with buffer solutions of pH 4.0 and 9.2. Electrode system consisted of glass electrode (pH range 1~13) and saturated calomel-electrode as reference.

Ten milliliters of 0.04 M chelating agent solution in 70% v/v dioxan-water mixture was pipetted in a titration vessel. Sufficient amount of 0.02 M nitric acid was added to it to lower the pH to about

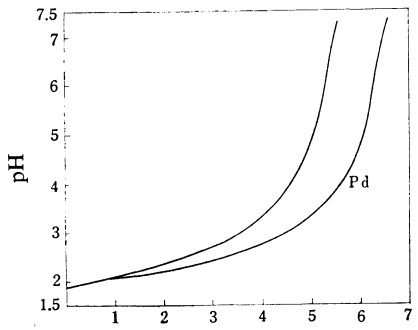
2. Final ionic concentration was maintained at 0.1 M by adding 2.5 ml. of 2 M potassium chloride. When titrating in presence of metal ions, 5 ml. of 2×10^{-3} M metal solution were added at this stage. The total volume of the contents was made to 50 ml. by adding varying amounts of dioxan and distilled water in such proportions that it finally became 70% v/v dioxane-water mixture. It was titrated against 0.02 M sodium hydroxide. The temperature of the solution throughout the titration was maintained at 25±0.5°C. The pH-meter readings obtained at a given alkali addition in duplicate titrations were reproducible with a maximum variation of ±0.01 pH unit. The titration curves are given in Figs. 1 and 2.



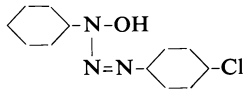


Fig. 1. Titration curve for

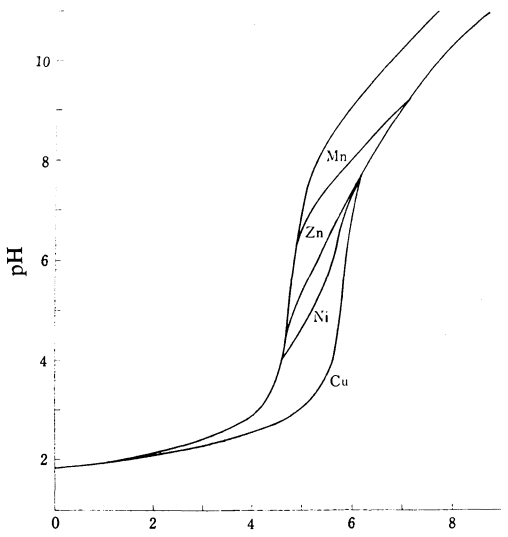

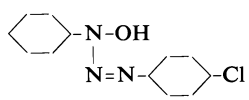

Fig. 2. Titration curve for

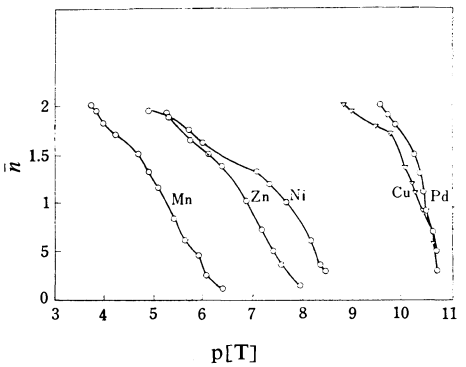
Calculations. — The horizontal distance between the reference titration curve and the curve obtained in presence of a metal ion gives the concentration of metal bound chelating agent. This value divided by the total concentration of metal ion gives the value for $\bar{n}$. In this way the values of $\bar{n}$ at different pH values were calculated.

At any pH, the value of free chelating ion concentration, $[T^-]$, was calculated from the total concentration of the chelation agent, and its dissociation quotient. This is based on the assumption that the amount of chelating agent over metal ion is so great that the removal of HT by chelation does not cause any significant change in the equilibrium: $HT \rightleftarrows H^+ + T^-$. The pK_a value of 3-hydroxy-3-phenyl-1-*p*-chlorophenyltriazene has been determined spectrophotometricaly[8] as 10.72.



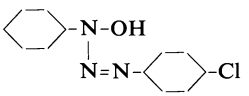


Fig. 3. Formation curves for metal chelates of

In calculating the values for $\bar{n}$ and $[T^-]$, the concentrations were corrected for changes in volume, produced by addition of alkali during titrations. In this way, a series of values for $\bar{n}$ and $[T^-]$, corresponding to different pH values, was obtained. The formation curves for metal chelates of 3-hydroxy-3-phenyl-1-*p*-chlorophenyltriazene are shown in Fig. 3. The values for stepwise stability constants and average stability constant i.e., $\log k_1$, $\log k_2$, and $\log K_{av}$ $(1/2\log K)$ for different metal chelates were

TABLE I. STABILITY CONSTANTS OF METAL CHELATE OF 3-HYDROXY-3-PHENYL-1-*p*-CHLOROPHENYL-TRIAZENE

Metal ion	$\log k_1$	$\log k_2$	$\log K_{av}$	$\log k_1k_2$
Palladium	10.70	10.25	10.47	20.95
Copper	10.67	9.98	10.35	20.65
Nickel	8.25	6.33	7.66	14.58
Zinc	7.41	6.12	6.84	13.53
Manganese	5.83	4.67	5.25	10.50

8) D. N. Purohit, Ph. D. Thesis, University of Rajasthan, Jaipur (India), 1963.

read directly from the formation curves and are given in Table I. K is the overall stability constant.

Discussion

The consumption of alkali during the course of titration may be due to the chelating agent, the hydrolysis of metal ion, and the protons of the chelating agent liberated in complex formation.

The chelating agent under study is a very weak acid ($pK_a = 10.72$) Thus, the proton of the chelating agent as such is not in a titrable form. Hydrolyses of these metal ions have been studied in 70% v/v dioxan-water mixture.[8] The pH for $\bar{n} = 1.5$ in all the cases is lower than the pH at which the hydrolysis of these metal ions start. Hence, hydrolyses of these metal ions do not interfere in the stability measurements. Moreover, there was no precipitation during chelation titrations, ruling out the possibility of appreciable hydrolyses of these metal ions in the presence of large excess of the chelating agent.

Thus, the consumption of an excess of alkali in chelation titration over the simple chelating agent titration is due to protons of the chelating agent liberated during the complex formation. This may be represented as:

$$M^{2+} + HT + OH^- \rightleftharpoons MT^+ + H_2O \quad (1)$$

$$MT^+ + HT + OH^- \rightleftharpoons MT_2 + H_2O \quad (2)$$

The order of stability of hydroxytriazene metal chelates has been found as palladium > copper > nickel > zinc > manganese.

Summary

Stabilities of palladium, copper, nickel, zinc, and manganese chelates of 3-hydroxy-3-phenyl-1-*p*-chlorophenyltriazene have been determined in 70% v/v dioxan-water mixturre by employing Bjerrum-Calvin pH titration technique. The titration medium was maintained at a constant ionic strength (0.1 M, potassium chloride) and at a temperature, 25±0.5°C. Log K, palladium 20.95, copper 20.65, nickel 14.58, zinc 13.53, and manganese 10.50.

The authors express their gratitude to Professor R. C. Mehrotra for providing facilities in the department. They are also grateful to the University Grants Commission for granting a research scholarship to one of them (D. N. Purohit).

*The Radiolysis of Biphenyl by Gamma-rays**

By Hiroaki KŌYAMA,** Gen-ichi TSUCHIHASHI and Akibumi DANNO

(Received October 21, 1963)

Polyphenyls are the most promising materials for use as organic moderators and coolants. Studies have been developed on the radiolytic and pyrolytic decomposition of these materials. Most of the papers published have, however, concerned the determination of the amount of gaseous products and of the residue with a high boiling point, or gross changes in the physical properties of such materials from engineering points of view.[1-3] Little work has been done on the mechanism of the radiolytic decomposition of polyphenyls.

For the radiolysis of benzene, Patrick and Burton[4] reported that the $G(C_6H_6 \rightarrow \text{polymer})$ value equals 0.75 and that the average polymer contains five molecules of a benzene ring. Gordon et al.[5] studied the reaction further; they identified biphenyl and several types of its partially hydrogenated compounds from the products by means of vapor phase chromatography and mass-spectrometric analysis.

For the identification of radiolytic products of biphenyl, Hellman et al.[6] and West[7]

* Presented partly at the 4th Japan Conference on Radioisotopes, Kyoto, October, 1962 and partly at the 1st Annual Meeting of the Atomic Energy Society of Japan, Tokyo, April 1963.

adopted a technique of liquid chromatography, while Boxter and Keen[8] developed high temperature gas chromatography. Hall and Elder[9] and Keen et al.[10] determined mass-spectrometrically the yields of the products with a high molecular weight from the radiolysis of biphenyl, which include terphenyl, quaterphenyl, hexaphenyl and quinquephenyl. Meanwhile, Burr and Scarborough[11] and Rayroux and Baertschi[12] investigated the isotope effect on the radiolysis of biphenyl by using deuterated biphenyl.

From these previous investigations, it is clear that the non-volatile products from the radiolytic decomposition mainly consist of polyphenyls, partially-hydrogenated polyphenyls and condensed polynuclear aromatic compounds. Among these polyphenyls appear to be the major products, but few papers have been published on accurate *G*-values for them. Therefore, the present work will aim to obtain precise information concerning the radiolytic mechanism for biphenyl by determining the *G*-values of the non-volatile products. Here, reverse isotope dilution analysis by using a ^{14}C-labeled compound was applied to determine the isomer yields of the terphenyls and quaterphenyls produced by the radiolysis of biphenyl.

On the basis of the results, the mechanism for the present reaction will be discussed.

An abstract was published previously.[13]

Experimental

Preparation of Materials. — *Biphenyl and Terphenyls.*—Commercial products were recrystallized several times from alcohol or benzene until they reached the melting point indicated in the literature.[14]

o, o'-Quaterphenyl.—This substance was synthesized, starting from *o*-aminobiphenyl, by successive diazotization, Sandmeyer decomposition and Ullmann condensation. To improve the yields, slightly modified procedures were employed.

A sodium nitrite (9 g.) solution was vigorously stirred into a mixture of *o*-aminobiphenyl (22 g.) and 6.5% aqueous hydrochloric acid solution in an ice-bath. Then a potassium iodide (50 g.) solution was added to the mixture, the temperature being kept below 10°C. The reaction product was extracted with ether (150 ml.). The ether extract was washed with water and then with a 10% sodium bisulfite solution, and dried over calcium chloride. After the removal of the solvent, 2-iodobiphenyl (46.0 g.) was distilled at 177~178°C under 18 mmHg. Found: C, 51.35; H, 3.53; I, 45.34. Calcd. for $C_{12}H_9I$: C, 51.45; H, 3.24; I, 45.31%.

In a small test tube, 2-iodobiphenyl was mixed with copper powder and placed in an oil-bath at 260°C for 20 min. The reaction mixture was extracted with benzene. Removal of the benzene, chromatography of the residue on activated aluminia with petroleum ether, and three recrystallizations from ethanol gave *o, o'*-quaterphenyl (3.9 g., 17.5% yield, m. p. 119.1~119.6°C). Found: C, 93.96; H, 5.89. Calcd. for $C_{24}H_{18}$: C, 94.08; H, 5.92%.

m, m'-Quaterphenyl.—The product was obtained, starting from *m*-aminobiphenyl, by a procedure similar to that used for *o, o'*-quaterphenyl (4.3 g., 16.3% yield, m. p. 86.6~87.2°C). Found: C, 94.25; H, 6.08. Calcd. for $C_{24}H_{18}$: C, 94.08; H, 5.92%.

p, p'-Quaterphenyl. — A product of the Pilot Chemical Co. Inc. was recrystallized, first from anisole and then from benzene (m. p. 320.0°C).

Triphenylene.—A product of the Aldrich Chemical Co. Inc. was recrystallized from ethanol (m. p. 200.4°C).

Biphenyl-(phenyl-^{14}C). — The synthesis has been described in previous papers.[15,16]

Procedure. — *Irradiation.* — Biphenyl-(phenyl-^{14}C) (33.2 mc./mol., 30~50 mg.) was placed in an irradiation tube of Hario glass (Fig. 1a) and degassed under 10^{-4}~10^{-5} mmHg in a dry ice-ethanol bath. After the sealing of the tube at the position of the dotted line (Fig. 1a), the glass tube, protected with an aluminum capsule, was heated with an electric furnace, the temperature being kept at 100±5°C. The irradiation was carried out by a Co-60 gamma-facility installed at the Japan Atomic

* Absorbent is activated alumina.

Energy Research Institute.[17] The absorbed dose was measured by means of a Fricke dosimeter using a *G*-value of 15.5.

Isolation. — After the irradiation, the radiolytic product to be determined was isolated according to the process diagrammed in Fig. 2. The technique employed here has been described in a previous report.[18] The composition of the eluting solvent in chromatography on activated alumina was gradually varied from petrolum ether to a benzene-rich solvent (Table I). For the isolation of *p,p'*-quaterphenyl, high-temperature chromatography was adopted. Namely, the column was equipped with a jacket and heated by circulating hot water. The recrystallization of the product was repeated to reach a constant specific activity. The radioactivities of all samples except *p,p'*-quaterphenyl were determined by using a Tri-Carb liquid scintillation spectrometer with a correction for the quenching effect. In the case of *p,p'*-quaterphenyl, the sample was oxidized to carbon dioxide by the Van Slyke-Folch method,[19] and the resulting carbon dioxide was charged into an ionization chamber (Applied Physics Co.). Then the radioactivity was determined by the rate-of-charge method[20] with a vibrating-reed electrometer (Cary Model 31).

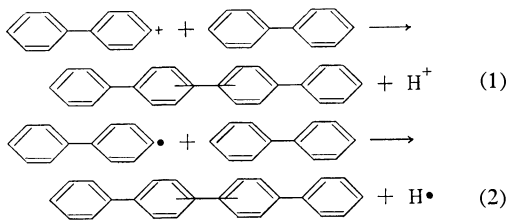
Results and Discussion

***G*-Values.**—Figures 3 and 4 show the isolation of the radiolytic products of biphenyl by liquid chromatography. The *G*-values of these products are tabulated in Table II. Table III illustrates the *G*-values for the *o,o'*-quaterphenyl produced from the radiolysis of biphenyl under various conditions. The following conclusions may be drawn from Table III; (1) the pyrolysis of biphenyl does not take place under such conditions (2) different reaction patterns were observed between the liquid and solid states, and (3) *G*-values are independent of the total absorbed dose in the range of our experiments.



Free Radical Substitution. — The primary process of radiation chemistry is conceived of as the ionization and excitation of molecules. In radiation chemistry of the liquid phase, the reactive entities which bring about most chemical changes are possibly free radicals, since the neutralization of the ions produced by the impact of secondary electrons will often enough to make very probable the production of highly-excited molecules.[21]

Deuterium isotope effects are reported from two different groups.[11,12] Rayroux and Baertschi studied the pile-irradiation of biphenyl and concluded that the deuterated

21) A. J. Swallow, "Radiation Chemistry of Organic Compounds," Pergamon Press, Oxford (1960), p. 15.

compound decomposes more slowly than the ordinary biphenyl by a factor of two. Burr and Scarborough studied the mechanism of hydrogen gas formation in the radiolysis of biphenyl by gamma-rays. They found an isotope effect of 3.00 in the formation of radiolytic hydrogen and deuterium from the ordinary and from the deuterated biphenyls. These large isotope effects clearly indicate that the cleavage of the C–H bond in biphenyl plays an important role in the radiation decomposition, since the probability for the ionization or excitation of ordinary biphenyl should not differ greatly from that of deuterated biphenyl, according to the Frank-Condon principle.[22] Accordingly, the observed isotope effects must be for those of the fragmentation of the ion or the excited molecule. The isotope effect on the fragmentation reaction may be satisfactorily explained in terms of the Frank-Condon principle.[23] The explanation for the isotope effect should be applicable to the molecules which possess large π-electron systems, for example, benzene or biphenyl. For ionization or excitation, the structure change in these molecules will be little, since the promotion of an electron from the π-electron system will have little effect on the whole electronic structure. Therefore, the internuclear distance for the potential minimum point of the upper state will be close to that of the ground state.

Now, on the basis of the isotope-effect studies, the rupture of the C–H bond should take place at the first step in the radiolysis of biphenyl. The intermediate formed as a result may be a biphenylyl cation or radical and a hydrogen atom. The former two species are capable of reacting with a biphenyl molecule to produce the quaterphenyls which are identified as major products in the present work.

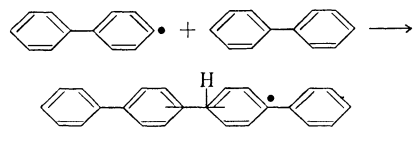
(1)

(2)

Equation 1 is a nucleophilic substitution, and Eq. 2 is a so-called homolytic aromatic substitution. The distribution of quaterphenyl isomers should be quite different in the two mechanisms. In order to establish the orientation of the reaction, it is necessary to determine the amount of all the isomers of quaterphenyls. However, it is impossible to derive the origin of quaterphenyls from these yields. For example, from the *G*-value of *o*, *p*'-quaterphenyl, it is impossible to know whether a *o*-biphenylyl radical is substituting the para-position of the biphenyl molecule or whether a *p*-biphenylyl radical is substituting the ortho-position of the biphenyl molecule.

If we assume (1) that the chemical selectivity for the cleavage of the C–H bond by radiation is so small that *o*-, *m*- and *p*-biphenylyl radicals will be produced with equal probability and (2) that the reactivities of the attacking radical are nearly equal, the product ratio for symmetrical quaterphenyls will represent the orientation of the substitution reaction. From our observed values, the ratio of the partial rate factors for ortho-, meta- and para-substitution reactions in the radiolysis of biphenyl are reduced to 1.0 : 1.0 : 8.4.

The partial rate factors for a typical nucleophilic reaction, nitration, were reported by Simamura and Mizuno as 41 and 38 for the ortho- and para-positions respectively.[24] Other types of nucleophilic substitution reactions, such as bromination, chlorination or detritiation reactions, have been tabulated in a reviewing article.[25] These experimental results indicate that biphenyl is a strongly ortho-, para-orienting substrate with relation to nucleophilic substitutions. Our present reaction seems to be different from the nucleophilic substitution mechanism, since the yield for the meta-isomer is rather larger.



As an alternative mechanism, the possibility of free radical substitution remains. Hey and his co-workers published the ratio of *o*-, *m*- and *p*-terphenyls from the free radical phenylation of biphenyl as 48.5 : 23.0 : 28.5.[26] (The ratio of partial rate factors is 2.1 : 1.0 : 2.5.) Although there remains some doubt about the mechanism of homolytic aromatic substitution by the decomposition of benzoyl peroxide,[27] the above value could be used to indicate the characteristic behavior of biphenyl toward radical substitution reactions. In Hey's experiment, phenyl is the attacking radical, whereas in the present work, the biphenylyl radical is proposed as the substituting entity. The formation of *o*, *o*'-quaterphenyl is the result of the ortho-substitution of the

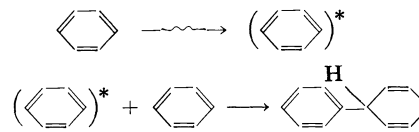
o-biphenylyl radical; hence, considerable steric hindrance of the substitution is to be expected. If the differences in the reactivities of substituting radicals by the steric hindrance are taken into account, we may conclude that the orientation of the reaction roughly agrees with that of the free radical mechanism.

The same examination for the product ratio of terphenyls leads to the conclusion that the phenyl cation should not be the intermediate, but the phenyl radical is likely to give terphenyl by substituting biphenyl molecule.

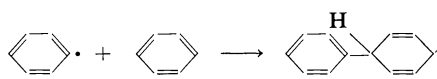
The formation of polyphenyls by the free radical mechanism probably proceeds according to DeTar's mechanism.[27]



(3)

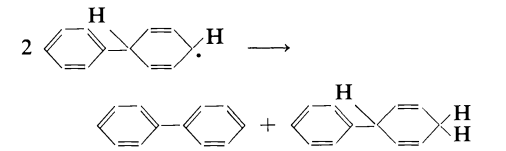
(4)

Equation 4 is a disproportionation reaction of radicals. The plausibility of this mechanism has been discussed in the summary by Walling, together with other possible mechanisms.[28] DeTar and Long actually obtained 1, 4-dihydrobiphenyl from the reaction of the phenyl radical with benzene; the amount nearly equals that of biphenyl.



Gordon, Van Dyken and Doumani carried out the gamma-irradiation of benzene and found a mixture of phenyl cyclohexene and phenyl cyclohexadiene in the C_{12} fraction, together with biphenyl.[5] They proposed a molecular-mechanism to account for the formation of these partially-hydrogenated biphenyls:

(5)



(6)

However, the formation of phenylhexadiene is alternatively explained by the free radical mechanism:

(8)

A Comparison of the Formation of Terphenyls and Quaterphenyls.—The production of phenyl and biphenylyl radicals as the intermediates which bring about the formation of polyphenyls may be presented by the following equations:

(9)

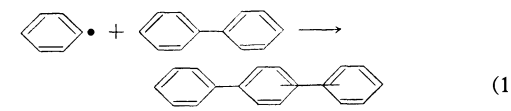
(10)

(11)

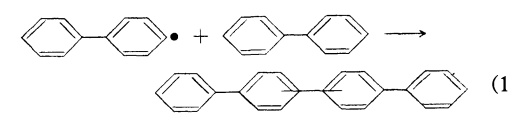
(12)

(13)

(14)



(15)



(16)

where $\left(\text{C}_6\text{H}_5\text{-C}_6\text{H}_5\right)^*$ and $\left(\text{C}_6\text{H}_5\text{-C}_6\text{H}_5\right)^+$ represent an excited biphenyl molecule and a biphenyl cation. $\text{C}_6\text{H}_5\text{-C}_6\text{H}_5\cdot$ and $\text{C}_6\text{H}_5\text{-C}_6\text{H}_5^+$ are, respectively, one of three isomeric biphenylyl radicals and cations.

(17)

(18)

Each molecule of terphenyl or quaterphenyl is presumed to be formed by the attack of a phenyl radical or a biphenylyl radical respectively on the biphenyl molecule, while radicals are undoubtedly produced directly in the primary process of the irradiation. Although we did not determine *G*-values for the formation of the three remaining unsymmetrical

quaterphenyls, they would probably be of the same magnitude as those for the symmetrical quaterphenyls. Therefore, the G-value of the unsymmetrical quaterphenyl could be calculated as an arithmetical average of the symmetrical ones; for example, the G-value of m,p'-quaterphenyl is 0.0078. The sums of the G-values for terphenyls and quaterphenyls are 0.0083 and 0.041 respectively; the latter is about five times as large as the former. This relation is different from Hall's report.[9]

The authors are grateful to Dr. Tsutomu Watanabe, the University of Tokyo, for his valuable discussions. They also wish to express their thanks to Dr. Yoshihiko Kashida of the National Institute of Radiological Science for permitting the use of a liquid scintillation spectrometer.

Fundamental Conditions and Reaction Mechanisms in Formation of Phosphomolybdenum Blue

By Hiroshi NAMIKI

(Received September 9, 1963)

Fundamental studies of the color development of phosphomolybdenum blue are essential for establishing the method for determining micro amounts of phosphate. Strickland[1] has extensively studied the condition of the formation and reduction of silicomolybdate, which is similar to phosphomolybdate. Only a few studies, however, have been made of the reduction mechanism of phosphomolybdate. Bolz et al.[2] tried a polarographic study and found two reduction stages in the reduction process of phosphomolybdate, but the half-wave potential for each stage was not clearly given.

The studies described in this paper were undertaken in order to establish the optimum conditions for the determination of phosphate and to explain the mechanism of phosphomolybdenum blue formation.

The effect of acidity and the concentration of molybdate, which affect the formation of phosphomolybdate remarkably, have been extensively studied; the results obtained will be graphically shown. Many photometric methods proposed for the determination of phosphate by the formation of phosphomolybdate are explained by the graph obtained.

The reduction products obtained in the process of phosphomolybdenum blue development have been studied photometrically by measurements of its absorption spectra. Useful information concerning the chemical properties of the development of phosphomolybdenum blue has thus been obtained.

Conditions for the Formation of Phosphomolybdenum Blue

Acidity and Molybdate Concentration. — The acidity and concentration of molybdate, which remarkably affect the formation of phosphomolybdenum blue, were examined in detail. To a solution containing 50 μg. of phosphate, different amounts of 10 N sulfuric acid and a 2.5% ammonium molybdate solution were added. After the solution had been diluted to about 40 ml., 0.25 ml. of a 2% stannous chloride solution in hydrochloric acid (1+9) was added, and then the solution adjusted to 50 ml. with water. The absorbance of the solution was measured at 10 min. after the addition of the reagents. The measurement was made by use of a Kotaki, AKA-type photoelectric photometer, with a 10-mm. cell and a 660 mμ filter. The temperature of the solution was kept at 25°C throughout the experiment. The results are given in Fig. 1.

The effect of the acidity, with reference to curves 4 and 4' in Fig. 1, for example, the final concentration of 0.15% ammonium molybdate, may be summarized as follows:

(1) When the acidity is lower than 0.5 N, the excess molybdate reagent is also reduced to form a blue color.

(2) With acidity from 0.5 to 0.8 N, a nearly identical intensity of the blue color is always obtained.

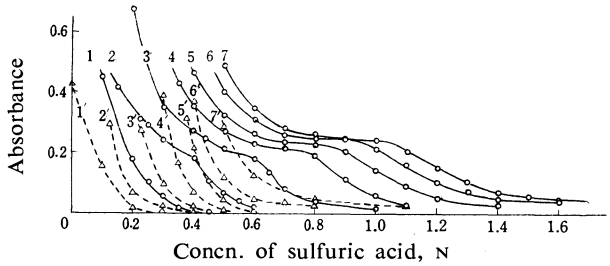

Fig. 1. Effect of concentration of sulfuric acid and ammonium molybdate
PO_4 (1)—(7), 1.0 p.p.m.; (1')—(7'), 0
Ammonium molybdate
1,1'; 0.025% 2,2'; 0.05% 3,3'; 0.10% 4,4'; 0.15% 5,5'; 0.20% 6,6'; 0.25% 7,7'; 0.30%

(3) With acidity more than 0.8, but lower than 1.1 N, the intensity of the blue color is affected by a slight change in acidity.

(4) When the acidity is higher than 1.1 N, no blue color is develops.

Therefore, the suitable acidity for the determination is considered to be in a range of 0.5 to 0.8 N, with 0.15% of ammonium molybdate.

With another concentration of ammonium molybdate, the effect of acidity upon color formation on the curves in Fig. 1 was also examined. Figure 2 indicates the relationship, showing domains, divided by curves, which the author calls "phosphomolybdenum blue color fields." The conditions shown by field 1 in Fig. 2 have been further investigated in order to establish the optimum conditions, and 0.65 N sulfuric acid and 0.15% ammonium molybdate were selected. A mixed solution of sulfuric acid (6.5 N)-ammonium molybdate (1.5%) was then prepared for practical use.[3]

An Interpretation of the Phosphomolybdenum Blue Color Field.—When blue color is developed under the conditions given by fields 1 and 2 in Fig. 2, approximately the same absorbance values, after correction for blank values, are obtained. This fact indicates that under these conditions all the phosphate is converted to phosphomolybdate and all of the latter is reduced to phosphomolybdenum blue. Therefore, phosphomolybdenum blue color fields may be explained as follows.

Fields 1 and 2: All the phosphate is converted to phosphomolybdate and then reduced to phosphomolybdenum blue. Under the conditions given by field 2, however, molybdate added in excess is also reduced to a blue color.

Field 3: A part of the phosphate is converted to phosphomolybdate, which is reduced to phosphomolybdenum blue.

Field 4: No phosphomolybdate is formed.

These fields are obtained in 10 min. of reaction time at 25°C. The acceleration of the reaction at an elevated temperature would probably result in the complete formation of phosphomolybdate and then phosphomolybdenum blue, even in field 3.

An Examination of Methods for the Photometric Determination of Phosphate by the Formation of Phosphomolybdate.—The photometric determination of phosphate by the formation of phosphomolybdate is carried out by the following different methods:

1) Phosphate in an aqueous solution is converted to phosphomolybdate.

2) The color of phosphomolybdenum blue is developed in an aqueous solution.

3) Phosphomolybdate is extracted by some organic solvents and, after the extraction, the color of phosphomolybdenum blue is developed.

4) Phosphomolybdenum blue is extracted by

3) F. Kawamura and H. Namiki, *Japan Analyst (Bunseki Kagaku)*, **7**, 238 (1958).

some organic solvents.

The acidity and ammonium molybdate concentrations proposed by many authors[4-21] for these procedures are plotted in a phosphomolybdenum blue color field in Fig. 4. Other molybdate is calculated to an equivalent amount of ammonium molybdate. Many conditions have been proposed, as may be seen in Fig. 3; however, a reasonable interrelation between the concentrations of acid and ammonium molybdate in the above methods can easily be obtained from the interpretation of the phosphomolybdenum blue color field.

The Phosphomolybdate Method, The Phosphomolybdate Extraction Method and The Method of Reducing Extracted Phosphomolybdate to a Blue Color.—All these methods depend on the complete conversion of phosphate to phosphomolybdate. The condition given by fields 1 and 2 in Fig. 3 are, therefore, suitable. Under the conditions given by field 1, however, standing for 10 min. or warming is required in order to complete the reaction. No. 18 in Fig. 3 corresponds to field 1. In this case extraction is made after accelerating the reaction by warming the solution. The conditions reported by many authors correspond to field 2, however. Extensive work by Ishibashi and Tabushi[16] on the extraction of phosphomolybdate also show a good agreement with this explanation.

The Phosphomolybdenum Blue Method and Its Extraction Method.—As has been discussed field 1 is suitable for these methods when the reactions take place at room temperature. If the color is developed by heating, the conditions shown by field 3 are also applicable. The conditions plotted in Fig. 3 show good agreement with this explanation.

The Reducing Agent.—In old works, various reducing agents were proposed in an attempt to effect the selective reduction of phosphomolybdate only. However, the control of acidity and of the concentration of molybdate is more important for this purpose. When these concentrations meet field 1 conditions, an excess of the molybdate reagent does not form a blue complex. (The details will be given in the next section.) The use of weak reducing agent sometimes limits the reduction of the molybdate reagent, even under the conditions in field 2.[4,5,8] Nevertheless, in this case only a part of the phosphomolybdate formed is often reduced to a blue color. The intensity of the resultant color, therefore, is liable to be affected by time and by temperature.

There is a procedure using weak reducing agents for determining more than 10 p.p.m. of phosphate by the phosphomolybdenum blue method.[8,23] With this procedure, only a part of the phosphate may be converted to phosphomolybdenum blue; therefore, the results are considered to be affected by the time, the temperature and other factors. The stannous chloride solution used as the reducing agent

for the procedure recommended by the author is superior in that even considerable deviations from the specified amount do not affect the color intensity and in that it can be used for a long time.

The Reaction Mechanism for the Development of Phosphomolybdenum Blue

The Valency of Molybdenum in a Phosphomolybdenum Blue Complex.—Phosphate solutions containing 1, 2, 3, 4 and 6 p. p. m. (0.105×10^{-4}, 0.211×10^{-4}, 0.316×10^{-4}, 0.421×10^{-4} and 0.632×10^{-4} M respectively) were reduced to molybdenum blue by the use of various amounts of a diluted stannous chloride solution, in the optimum concentration of sulfuric acid and ammonium molybdate as described in a previous section. The absorbance of a colored solution at 700 mμ was measured with a Shimadzu photoelectric spectrophotometer, type QB-50, using a 10-mm. cell and water as a reference. The results obtained are shown in Fig. 4. Each of the five curves shows good linearity and has a sharp deflection point, indicating the quantitative reaction of phosphomolybdate with stannous chloride under such conditions. The equivalent mole of stannous

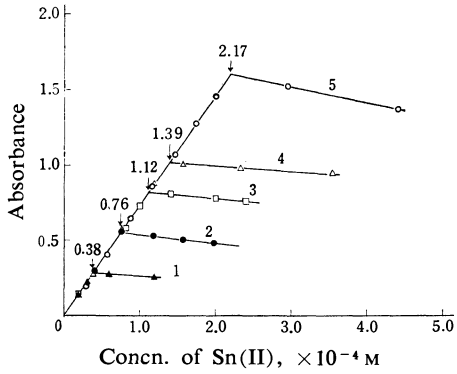

Fig. 4. Intensity of phosphomolybdenum blue vs. Sn(II) concentration.

chloride can be found by each deflection point to be 3.62, 3.60, 3.18, 3.30 and 3.43 mol. for each curve, to 1 mol. of phosphate. It has already been reported that, under these conditions, the total amount of phosphate in the solution is completely converted to phosphomolybdate. It is also generally known[24,25] that one molecule of phosphomolybdate contains one atom of phosphorus and 12 atoms of molybdenum. Therefore, according to the reaction ratio described above, it is presumed that in this first step of the reduction seven of the molybdenum atoms in phosphomolybdate are reduced from molybdenum(VI) to molybdenum(V).

The Reduction by Stannous Chloride in Excess Amounts.—A phosphate solution of 2 p. p. m. was reduced to blue with varying amounts of stannous chloride solution in excess. The absorbance of the colored solutions at 700 mμ is given in Fig. 5, while the absorption spectra of these solutions are shown in Figs. 6 and 7. The curve in Fig. 5 shows a horizontal line between the concentration of stannous chloride from 0.74×10^{-4} M (equivalent mole to phosphate) to 3×10^{-4} M. It seems that the same blue product of the first stage of the reduction of phosphomolybdate is always formed in this range of stannous chloride concentration. The blue product obtained within this concentration

range of stannous chloride is hereafter called "normal phosphomolybdenum blue" in this paper. The absorption spectra of the normal phosphomolybdenum blue are given by curves 1 and 2 in Fig. 6 and also by curve 1 in Fig. 7, the characteristics of all of which show good agreement.

To return to Fig. 5, the absorbance falls slightly and sharply between the concentration of stannous chloride of 3×10^{-4} M and that of 4×10^{-4} M. This seems to indicate the occurrence of a second-step reduction. More exact research is required into this interesting phenomenon; the present author has not studied it further since the decrease in absorbance is slight and does not seriously affect his studies in analytical chemistry. The absorption spectra of the blue solution obtained with 5×10^{-4} M of stannous chloride closely resemble that obtained for normal phosphomolybdenum blue, shown by curve 2 in Fig. 7. Therefore, it is also thought to be normal phosphomolybdenum blue in this paper.

The absorbance at 700 mμ decreases gradually with very high concentrations of stannous chloride. This phenomenon is considered to indicate that the third step of the reduction takes place slowly in these solutions and that a part of normal phosphomolybdenum blue is reduced further to a lower valency. Curves 3—5 in Fig. 7 indicate the absorption spectra of these solutions; these spectra differ considerably from the curve for normal phosphomolybdenum blue. Such solutions usually appear green.

The absorbance decrease at 700 mμ is regarded as due to the third step of the reduction; however, the absorbance increase at 400 mμ is not considered due to the same reason. The quantity of phosphomolybdate at the third step of the reduction is considered too small to cause the large change in the absorbanc at 400 mμ shown by curves 3—5 in Fig. 7. The absorbance increase at 400 mμ is regarded by the author as being caused by a reduction of the molybdate reagent added in excess. This consideration is confirmed by the experiments described below.

Examination by the Extraction of Phosphomolybdenum Blue. — It has been generally known[26] that in an acid solution molybdenum is reduced from molybdenum(VI) to molybdenum(V) at the first step of the reduction and from molybdenum(V) to molybdenum(III) at the second step. Some observers think that only a few of the molybdenum atoms constituting the molybdate ion are reduced to molybdenum(V) at the first step of the reduction. The two solutions containing molybdenum(V) and molybdenum(III) are said to show blue and reddish brown, respectively. As was seen in the previous section, the reduction of the molybdate reagent with a blue color development has been observed at low acidity or at a high molybdate concentration. This phenomenon can be prevented when the concentration of reagents is adjusted to proper values. In the presence of strong reducing agents or a large amount of stannous chloride, the molybdate solution is reduced directly to a final reddish-brown solution, showing no intermediate blue stage. Figure 8 gives the absorption spectra of two solutions, containing 0 and 2 p. p. m. phosphate respectively, reduced by shaking them with a 2% zinc-mercury amalgam for a proper length of time. In this case a part of the molybdate reagent has been reduced. The same operation is applicable to the volumetric determination of molybdenum, and molybdenum is known to be reduced to

b) Sn(II) equivalent to 0.211×10^{-4}M of phosphate is 0.74×10^{-4} M.

molybdenum(III) in this process. The author has studied these reduction process by the use of various amounts of stannous chloride in excess. The blue color complex obtained was extracted by shaking it with an equal volume of *n*-butyl alcohol for 5 to 10 sec.* The absorption spectra of the solvent and aqueous phase, and also of the original solution are given in Figs. 9 and 10.

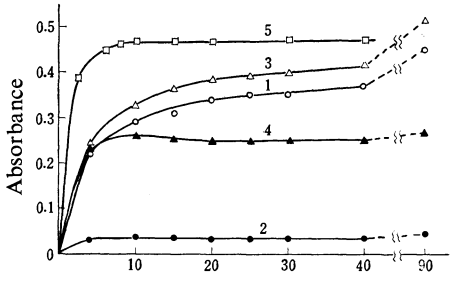
PO_4: 0, Sn(II): 40×10^{-4} M
1: Original solution
2: *n*-Butyl alcohol phase
3: Aqueous phase

* Prolonged shaking resulted in a blank color development, and also in an alteration of the absorption spectra.

The accurate comparison of the absorption curves in these figures was difficult because of the slight volume change which took place in the course of the extraction, the incomplete extraction, and the effect of the solvent on the absorption spectra. Nevertheless, curve 3 in both Figs. 9 and 10 is similiar to that in Fig. 8 at a shorter wavelength range. It is also notable that curve 2 in Fig. 9 is similar to that for normal phosphomolybdenum blue. Therefore, it has been concluded that the complex remaining in the aqueous phase consists of molybdenum reduced to a lower valency, probably molybdenum(III), and that the complex extracted with *n*-butyl alcohol is phosphomolybdenum blue. The appearance of a green color in a solution reduced with a large amount of stannous chloride is considered to be due to the co-existence of these two complexes.

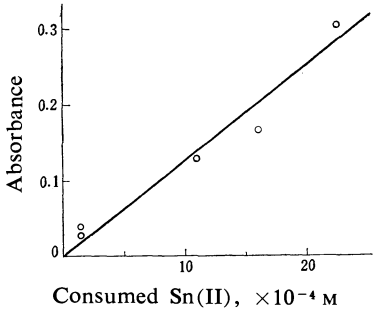
Examination by the Titration of the Stannous Chloride Remaining Unreacted.—The amounts of stannous chloride remaining unreacted in the aqueous phase after the solvent extraction described above can be determined iodometrically with starch as an indicator, and this titration can be carried out without being affected by molybdenum of a lower valency. The data of determination are given in Table I. The top line in Table I is a blank test conducted without the addition of molybdate reagent. It is confirmed that stannous chloride is not lost during this operation, either with air oxidation or with dissolution into the solvent.



The amounts of stannous chloride consumed by reduction to low valency molybdenum are calculated from the amounts of stannous chloride initially added and equivalent to the existing phosphate. As Table I shows, considerable amounts of stannous chloride, approximately half of the amounts originally

added, are consumed in the formation of low valency molybdenum. In other words, a very large amount of low valency molybdenum is formed. In spite of the fact described above, the fading of the blue color is not as prominent as in Fig. 7. This indicates that the reduction of molybdate reagent to form a low valency of molybdenum takes place more easily than the reduction of normal phosphomolybdenum blue to color fading. Earlier in this paper, it was described that reduction with stannous chloride in an amount less than a mole equivalent to phosphate results in the reduction of phosphomolybdate only.

In the presence of excess stannous chloride, therefore, reduction takes place in the following order:



(1) Phosphomolybdate → Normal phosphomolybdenum blue
(2) Molybdate reagent → Low valency of molybdenum
(3) Normal phosphomolybdenum blue→Low valency of phosphomolybdenum blue

The reactions do not always proceed in this sequence, however. With an excess of stannous chloride, reaction 3 proceeds partially via reactions 1 and 2, resulting in a decrease in the intensity of blue. However, with a slight excess of stannous chloride, reaction 3 is negligible because excess stannous chloride is quickly diminished by reaction 2.

Time after addition of reagents, min.

Fig. 12. Absorbance of low valency molybdenum compound v.s. Sn(II) consumed (Measured 10 min. after addition of reagents).

This view will be explained further by the following experiments. Figure 11 shows changes in the absorbance with time at 400 mμ and 700 mμ measured on solutions, containing 0 and 2 p. p. m. of phosphate; these solutions were treated in the same way as in the experiments for Figs. 9 and 10. Figure 12 shows the relation between the absorbance at 400 mμ of low valency molybdenum and the amounts of stannous chloride consumed for its formation. The relation was obtained from data in Table I and Figs. 6, 7, 9 and 10. The consumption of stannous chloride with time shown in Fig. 11 is obtained from the absorbance at 400 mμ and Fig. 12. The amounts of unreacted stannous chloride can be obtained by subtracting the amount consumed from the amounts added initially. For example, by means of curves 1 and 3 in Fig. 11* the amounts of unreacted stannous chloride are found to be 20×10^{-4}, 17×10^{-4}, 16×10^{-4} and 10×10^{-4} M after 5, 7.5, 15 and 30 min. respectively. Stannous chloride in an amount less than $10\sim15\times10^{-4}$ M does not cause the remarkable fading of phosphomolybdenum blue shown in Fig. 5. Thus, the reaction which takes place in Fig. 11 is explained as follows: Through the range of reaction, in the first 10 min. after the addition of the reagent, reactions 1, 2 and 3 progress simultaneously. All the phosphomolybdate is reduced in this period, and then some part of it is further reduced to that of a lower valency with less color intensity than normal phosphomolybdenum blue. After 10 min., the amount of stannous chloride decreases to approximately 16×10^{-4} M, where reaction 3 ceases and the blue color becomes stable.

Summary

The effects of acidity and molybdate concentration on the development of phosphomolybdenum blue have been studied in detail and the relationships among these three factors shown by a graph, called a "phosphomolybdenum blue color field" by the author. A further investigation was undertaken in order to explain the mechanisms of color development and the fundamental properties of reaction products under the optimum conditions established by the author for the determination

* The difference between curves 1 and 3 is due to the absorbance of phosphomolybdenum blue at 400 mμ.

of phosphate. The acidity and molybdate concentration in the graph was divided into 4 fields, the fields denoting the concentration conditions given below.

Field 1: All phosphate forms phosphomolybdate, and then forms phosphomolybdenum blue. No blue color due to the reagent blank is obtained. This field is suitable for the phosphomolybdenum blue method.

Field 2: All phosphate forms phosphomolybdate, and then forms phosphomolybdenum blue. However, the reagent blank also becomes blue. This field is suitable for the phosphomolybdate method.

Field 3: Only a part of the phosphate forms phosphomolybdate and then phosphomolybdenum blue. Heating promotes the reaction, making it suitable for the phosphomolybdenum blue method.

Field 4: No phosphomolybdate is formed. This field is not applicable for determinations.

When the reaction of phosphomolybdenum blue development is carried out in a solution containing 0.65 N sulfuric acid and 0.15% ammonium molybdate, which is optimum for the determination of phosphate, phosphate is completely converted to phosphomolybdate, which in turn is quantitatively reduced by stannous chloride to form phosphomolybdenum blue. At the first stage of the reduction, one phosphomolybdenum blue molecule is regarded as possessing seven molybdenum atoms that have been reduced to molybdenum(V). Reduction by the use of excess amounts of stannous chloride proceeds in the following order:

(1) Phosphomolybdate → Phosphomolybdenum blue
(2) Molybdate reagent → Molybdenum of low valency
(3) Phosphomolybdenum blue → Phosphomolybdenum blue of a low valency

The reduction product in reaction 2 is probably a molybdenum(III) compound. A large excess of stannous chloride fades the blue color of the solution by means of reaction 3. Reaction 3 is negligible compared with reactions 1 and 2 in solutions containing a slight excess of stannous chloride. Under the conditions established by the author for color development, no blue product is formed as a results of the reduction of the molybdate reagent. Molybdate is considered to have been reduced directly to reddish brown molybdenum(III).

The knowledge obtained from these experiments is thought to be enough for the performance of the phosphomolybdenum blue method, although it is still insufficient for a complete explanation of the properties of the reactions and the reaction products.

The author is much indebted to Professor Iwaji Iwasaki of the Tokyo Institute of Technology, Professor Isao Kayama of Hokkaido University of Liberal Arts, and Professor Fumikazu Kawamura of Yokohama National University for their invaluable advice and discussions throughout his work.

Flash Photolysis of Methylene Blue. I. Reversible Photolysis in the Absence of a Reducing Agent and in the Presence of Certain Kinds of Reducing Agents

By Shiro MATSUMOTO

(Received September 19, 1963)

It was shown in a previous paper[1] on the photoreduction of methylene blue by *N*-phenylglycines that kinetic data and some other properties of the system indicate a mechanism via a long-lived excited state (presumably the lowest triplet state) of the dye. As it was desired to detect such an intermediate in a more direct way and, simultaneously, to get more information on the mechanism of the photoreduction, a flash photolytic investigation was undertaken. Parker[2] has applied this method to methylene blue in an acid medium

1) S. Matsumoto, This Bulletin, 35, 1860, 1866 (1962).

2) C. A. Parker, *J. Phys. Chem.*, 63, 26 (1959).

with ferrous ions as reductants. He observed two transients of different lifetimes and assigned them to the triplet state and to the semiquinone of the dye. He investigated the reaction, however, only in a 0.1 N sulfuric acid solution. Details of the absorption curves were not given.

For the present work the flash photolysis of methylene blue was carried out in solvents of various pH values, both in the absence and in the presence of a reductant. In Part I, only those cases are treated in which the solution recovers its original absorption and little or no permanent spectral change is observed after a flash illumination. In this case, ferrous sulfate, *p*-phenylenediamine or benzohydroquinone is used as the reductant. When *N*-phenylglycines were used as reductants, or when organic solvents were used, flash photolysis resulted in a more or less apparent permanent spectral change of the solution. Such cases will be treated in Part II of this paper.

Experimental

The exciting flash lamp was made of a quartz tube (1 cm. in external diameter) wound in a helix (3.4 cm. in inner diameter and 6 cm. long). It was filled with xenon to 150 mmHg. To recored the transient absorption spectra, an argon-filled (200 mmHg) linear flash lamp was used. The condensers for these lamps were 20 and 10 μF respectively, and they were charged up to 4000 V. in most cases. The reaction cell was also made of quartz (2.2 cm. in external diameter and 7 cm. long). It was covered with an ordinary-glass tube (wall thickness, 1 mm.), which served as a filter for the short-wavelength part of the exciting flash. The interval between the firings of the two flashes could be varied, by means of an electronic delay circuit, from 3 to 5000 μsec. The spectra were photographed with a Shimadzu Quartz spectrograph QF-60. In ordinary cases, a "Fuji Processpan Plate for Spectrograph" was used, but in some cases a "Fuji Neopan Plate" or a "Fuji Neopan Sheet Film SSS" was preferable. Near-infrared spectra were recorded on a "Fuji Infrared Plate 820" or on "Kodak Infrared Sheet Film." The densities on the plates were traced with a Nalumi recording microphotometer NLM-VII. For a preliminary study of tracing the change in absorption at certain wavelengths, the spectro-flash lamp was replaced by a 40 W./12 V. incandiscent lamp operated by a floating-charged battery. The light was made parallel by a lens, went through the reaction cell and an interference filter, and fell on the photo-cathode of a photomultiplier. Ordinary precautions to minimize the effect of scattered light, namely the use of baffles[3] and the use of a compensating circuit,[4] were adopted, but the relatively long duration of the exciting flash interfered with a detailed kinetic study of the early stage of the photoreaction. Such kinetic study requires a much improved exciting lamp.[3]

Oxygen was removed from solutions by flushing them with pure nitrogen as in previous studies.[1] Although this method of deaeration is imperfect for the complete removal of oxygen, the results were reasonably reproducible and may be compared with the results of the previous experiments[1] performed under the same conditions.

The methylene blue was a G. R. reagent from the Koso Chem. Co.; $\varepsilon_{max}=8.15\times10^4$. The other reagents were also of G. R. grade from the same company and were used without further purification.

Results

Flash Photolysis in the Absence of a Reductant.—*A Transient in an Acid Medium.*—The transient spectrum which appears in a 0.1 N sulfuric acid solution is shown in Fig. 1. It may be seen that in this case the reaction is simple and that only one transient is formed. It has an absorption peak near 375 mμ and decays, in agreement with Parker's statement, almost in parallel with the exciting flash. This must be the triplet state of the dye. A weak second peak is present near 280 mμ. The spectrum is the same in 1 N sulfuric acid. In a more concentrated acid, the region of the absorption seems to remain the same, but its shape is obscured by an increase in the absorption of the ground state of the dye in this region.

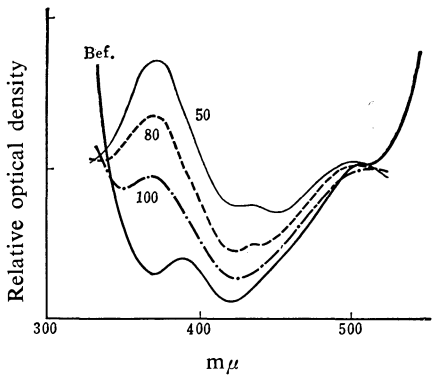

Fig. 1. Transient spectra in 0.1 N H_2SO_4 in the absence of reductant. M. B. 10^{-5} M. Figures beside curves indicate delay time Δt in μsec.

A Transient in Plain Water.—In this case, the transient spectrum is quite distinct from that in an acid medium (Figs. 2, 3 Plate 3). The absorption persists longer and shows peaks near 282 mμ, 420 mμ, and 520 mμ. It also extends to near-infrared region, where no absorption is observed in an acid medium.

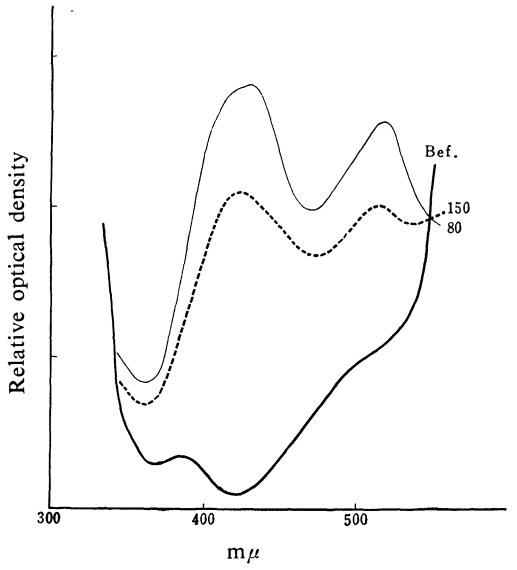

Fig. 2. Transient spectra in water in the absence of reductant. M. B. 10^{-5} M

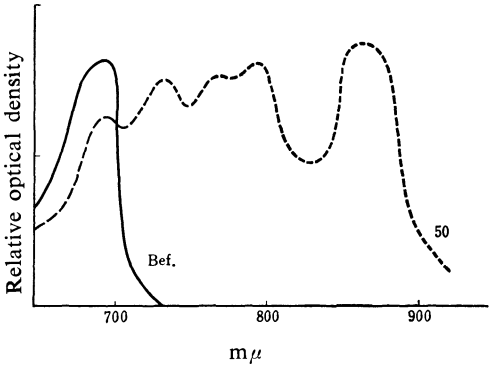

Fig. 3. The same as in Fig. 2. Near-infrared region.

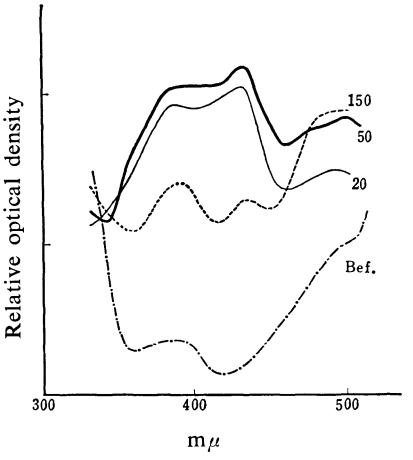

Fig. 4. Transient spectra in the absence of reductant. Solv.: buff. pH 6.8; M. B. 10^{-5} M

Another difference and complication is that the absorption around 520 mμ grows a little more slowly than that in the other region of the spectrum (Plate 1). This shows the superposition of at least two transient spectra, but their separation is difficult at present because the duration of the flash is not sufficiently short compared with the transient lifetimes. Preliminary experimentation shows the decay at 414 mμ to be unimolecular with a half-life of about 130 μsec.

A Transient in Buffer Solutions of Different pH Values.—The spectra at earlier stages of photolysis (e. g. when $\Delta t = 20$ μ sec., Δt is the time interval between the firings of the exciting flash and the spectro-flash) vary regularly according to the pH value of the solvent. Below a pH value of 6.0, only the one found in 0.1 N sulfuric acid (acid form) appears, while above 7.4 only the one found in water (neutral form) appears. At intermediate pH values the two forms appear superposed, and at a pH value near 6.8 both forms seem to appear in equal amounts (Fig. 4). It seems, therefore, that the spectrum which appears initially in the photolysis of methylene blue in water[5] corresponds to the same species as that appearing in an acid medium, only with different protonation. Its pK_A value is approximately 6.8. No other protonation type of the species is found in the pH range from 1 to 12. It may also be seen from Fig. 4 that the increase in the absorption around 500 mμ at the later stage of the flash photolysis is much more pronounced in buffer solutions than in plain water.

A Transient in Dilute Acid Solutions.—When the photolysis was carried out in dilute sulfuric acid solutions, a queer result was obtained. The spectrum in 5×10^{-5} N sulfuric acid resembles that in a buffer solution of pH 6.8 rather than that in pH 4.3. The use of hydrochloric acid in place of sulfuric acid gives the same result. In accord with these results, near-infrared absorption appears in the photolysis in sulfuric or hydrochloric acid when the acid is more dilute than about 10^{-4} N, whereas it appears in buffer solutions only when the pH value is higher than about 6.2. This descrepancy may be explained most simply by the assumption that the neutral form of the triplet is first formed in the course of the photolysis and that in a very dilute acid solution the speed of the protonation producing the acid form of the triplet is so slow that the equilibrium between the two forms is not attained during the short lifetimes of the

5) The transient spectrum in a buffer solution of pH 7.0 contains some acid form. This discrepancy may be related to the facts described in the next sub-section.

transients. In buffer solutions, rather concentrated buffer agents may catalyze the acid-base equilibrium of the triplet. It was found that, in a dilute acid solution, the ratio of the absorption at 370 mμ to that at 420 mμ somewhat increases when $\Delta t = 20 \sim 80$ μ sec.

Flash Photolysis in the Presence of Reductants.—*A Transient in an Acid Medium in the Presene of Ferrous Ions.* — The photolysis in 0.1 N sulfuric acid has been investigated by Parker[2]; in agreement with his result, the transient spectrum in the presence of this reductant is very similar to the triplet spectrum in this medium, only with a much longer lifetime. The broad band has a maximum around 375 mμ (Fig. 5). An experiment at this wavelength shows the disappearance to be roughly bimolecular (Fig. 6). This transient must be the semiquinone of methylene blue, as stated by Parker. The semiquinone also shows absorption from ca. 450 mμ down to the near-infrared region, just as with the transient observed in water in the absence of a reductant, whereas in an acid medium no absorption is observed in the absence of a reductant. Plate 2 shows that at a certain period of the photolysis the absorption in the visible region is weak, although in time the absorption of the original dye is restored. This suggests that some part of the methylene blue is trapped in a rather stable form, with no absorption in the visible region. This may be the leuco form of the dye. This supposition is supported by the appearance of an absorption around 255 mμ[6] (Plate 4). Figure 5 shows that the peak of the semiquinone absorption is displaced towards 390 mμ in media of pH > 3. Here, a less protonated form of the semiquinone must be present. No further change is observed in buffer solutions with pH values lower than 5.3 where the ferrous salt could be used without the trouble of hydrolysis. In 10 N or more concentrated sulfuric acid, a second change in the transient spectrum is observed. The peak of the absorption seems to be moved a little to a longer wavelength (ca. 390 mμ), and the absorption at wavelengths longer than 500 mμ observed in 0.1 N sulfuric acid is lacking. Another feature is that the the absorption appears delayed after the flash and persists much longer than in a 0.1 N acid solution. In an intermediate acid solution, e. g., in 3 N sulfuric acid, an intermediary situation is observed.

Transients in the Presence of p-Phenylenediamine or Benzohydroquinone. — The photolysis in the presence of *p*-phenylenediamine is simple. The spectrum and its change with time in a buffer solution of pH 7.0 is shown in Plate 7. This general apperance does not change in the pH range from 5 to 8. It shows peaks at 390 mμ and 460 mμ and one below 330 mμ. The first coincides with that of the semiquinone of methylene blue, while the latter two probably belong to the semiquinone of the diamine.[7] Absortion also appears in the near-infrared region. As the pH of the solvent is lowered below 5, the transient becomes progressively faint and appears somewhat delayed after the appearance of an absorption due to the triplet. This result is in harmony with the facts that the diamine shows acid-base equilibria[8] of pK_A 6.0 and 2.5 and that only the neutral diamine molecule seems to have a strong deactivating effect on the dye triplet.[9] The absorption near 280 mμ given in Plate 5 shows a close resemblance to that of the triplet, but

no definite distinction is possible. In Plate 5 it may also be seen that, in this case, the recovery of the ground state of the dye occurs directly from the semiquinone and that little leuco dye is formed, in contrast to the case with ferrous ions and the case with hydroquinones described below. In media with pH values higher than 8.8, the transient spectrum is different (Fig. 7). The absorption maximum at 390 mμ is displaced to a wavelength near 430 mμ, and the absorption at wavelengths longer than 500 mμ is stronger than in solvents with lower pH values.

The result is more complex when hydroquinone is used as the reductant. Figure 8 shows a transient increase in absorption around 490 mμ and at wavelengths longer than 530 mμ preceding the growth of a strong and persistent absortion around 430 mμ in a buffer solution of pH 7.4. The latter may be mainly due to

the semiquinone produced from hydroquinone,[10] probably superposed by the absorption of methylene blue semiquinone. In the earliest stage, the peak at 400 mμ is more marked than that at 430 mμ. The order is upset at later stages. This may indicate the more rapid deformation of the dye semiquinone than that of the benzosemiquinone. The reaction may be a dismutation of the semiquinone or its reduction by other molecules of hydroquinone. Probably the latter predominates, as will be seen below (Plate 6b). At some stage the absorption in the region of methylene blue absorption reaches its minimum and then increases. This stage is analogous to a later stage of the photolysis with ferrous ions, when semiquinone has been converted into leuco methylene blue (cf. Plates 2 and 8a). The general pattern is the same in the pH range 5~8. Figure 9 shows transient spectra at various pH values. The difference between the spectra at pH 6.5 and 9.2 is remarkable (cf. also Plates 8a and 8b). The spectral shift is similar to the case with *p*-phenylenediamine, but the increase in absorption at wavelengths longer than 500 mμ is more pronounced at an early period than in the latter case. It is also seen that, at pH 9.2, there is no period when methylene blue and its semiquinone disappear simultaneously. At pH values higher than 9.2, the general features of the spectrum and its change with time remain the same, but in an extremely alkaline solution, e. g., a 0.01 N sodium hydroxide solution, an irreversible bleaching of the dye becomes noticeable. In acid media (pH< 5), transient spectra and their change with time

are quite similar to those observed when ferrous ions were used, except for an absorption around 400 mμ due to benzosemiquinone. The spectrum at pH 3.2 is red-shifted compared with that at pH 1, parallel with the results obtained in the case of ferrous ions. In view of the results obtained in the cases of ferrous ions and *p*-phenylenediamine, the changes observed at other pH values must be due to the characteristics of the hydroquinone component. In a buffer solution of pH 3.8, the semiquinone of benzoquinone seems to have an absorption around 400 mμ, one which is shifted to 430 mμ in a buffer solution of pH 5.3. Plates 6a—6c show the transient spectra in the wavelength region from 220 mμ to 320 mμ at various pH values. It may be seen that, below a pH value of 8.4, leuco methylene blue is formed in a process of reversible photoreaction. At a pH value of 9.2, however, the recovery of the original dye occurs without the formation of leuco methylene blue. At a pH value of 8.4, an intermediary situation is observed. This pH dependence parallels that of the spectrum of methylene blue semiquinone at longer wavelengths. It may also be seen that, although at pH values higher than 9 little formation of leuco methylene blue is observed, the formation of

an intermediate (presumably the semiquinone of the dye) is a clear-cut process and the yield of the intermediate is good. On the contrary, the conversion in an acid medium seems to be less perfect.

Discussion

The results just described seem to be related to the fact that the quantum yield of the photoreduction of methylene blue by *N*-phenylglycines reaches a maximum at a pH near 7.8. As was seen above, the transient spectrum that appears after a flash illumination of methylene blue in a neutral or alkaline medium persists longer than the spectrum in an acid medium. Whether this means a longer lifetime of the neutral form triplet itself compared with that of the acid form, or whether it can be accounted for solely by a superposition of another intermediate with a long life, it can not be decided at present. Evidently the delayed increase in the absorption around 530 mμ indicates such a second transient, but the clear-cut separation of the spectra is difficult because of the long duration of the exciting flash. This requires a detailed kinetic study with an improved flash apparatus. At

any rate, the neutral-form triplet must have a different (probably an increased) reactivity or reaction probability towards reductants compared with that of the acid form. For this reason, the velocity of photoreduction increases with the pH value in the range below about 7.8. At still higher pH values, the semiquinone of methylene blue loses a proton to change into its conjugate base. The latter has a very slight tendency to be reduced further and returns smoothly to the original dye cation (Plate 6c). This would explain the sharp decrease in the rate of photoreduction at the higher side of the pH region. If the methylene blue cation is denoted by D^+, the neutral and acid forms of the triplet may be denoted by D^{+t} and DH^{++t} respectively. In the same way, various forms of semiquinone, which appears in solvents of different acidities, may be designated D, DH^+, DH_2^{2+}, and DH_3^{3+}. Only DH^+ and DH_2^{2+} were seen to be reduced or to dismutate rapidly to form the leuco dye, and D would have to be protonated before it is reduced further if it were the first reduction product.

The assignment of the absorption at 520 mμ (in plain water), of those at 490 mμ and at longer wavelengths than 530 mμ (Fig. 8), and of that one at longer wavelengths than 500 mμ (Plate 8b) can be only speculative at present. The first may be assigned to a labile complex between a pair of half-oxidized and half-reduced methylene blue ions produced by a redox-reaction between an excited ion and a normal one stabilized by some negative ions,[11] or to a sort of charge-transfer complex between an excited dye ion and a normal one. The second and the third absorption may also be assigned to the same species or to a similar charge-transfer type of complexes between excited dye ions and reductant molecules.

Summary

Transient spectra which appear in the flash photolysis of methylene blue in aqueous solvents of various pH values have been surveyed both in the absence and in the presence of a reductant. In the absence of a reductant, the triplet state of the dye has been observed to appear in two forms, with different degrees of protonation. The form found in neutral water seems to be formed directly from the excited singlet state of the dye. The pK_A value of the acid-base equilibrium has been found to be approximately 6.8. A second transient has been found to be produced in water and in buffer solutions of a moderate pH value at a later stage of the photolysis. Its formation is more marked in buffer solutions, and it may be supposed to be a sort of charge-transfer complex between an excited dye ion and another dye component. The photolysis in the presence of ferrous ions, *p*-phenylenediamine or benzohydroquinone is nearly reversible, and the absorption of the original dye is restored after the illumination except in an extremely alkaline solution. The transitory formation of leuco methylene blue has been observed when ferrous sulfate or hydroquinone was used as the reductant below a pH value of 8.4, while that was not the case with *p*-phenylenediamine. The formation of leuco methylene blue from semiquinone has been found to be a bimolecular dismutation process in an acid medium when ferrous ions are the reductant, but when hydroquinone is used as the reductant at moderate pH values, it also reduces the methylene blue semiquinone. When hydroquinone is used as the reductant in a neutral or alkaline solvent, an increase in absorption is often observed at some longer wavelengths; this has tentatively been attributed to a complex between excited dye ions and reductant molecules. A comparison of the transient spectra obtained in various conditions has shown that the semiquinone of methylene blue exists in variously protonated forms in the following ranges: pH>9, pH=3~8, in 0.1~1 N sulfuric acid, and in very concentrated sulfuric acid. The pH dependence of the quantum yield of the photoreduction obtained earlier has been tentatively related to the change in the degree of protonation of the triplet state and the semiquinone.

The author is indebted to Professor Noboru Ando and Professor Ikuzo Tanaka of the Tokyo Institute of Tehcnology for their permission to use the laboratory facilities that made this work possible and also for their helpful suggestions. Thanks are also due to Professor Masao Koizumi of Tohoku University and Dr. Yuji Mori of the Tokyo Institute of Technology for their valuable discussions.

Flash Photolysis of Methylene Blue. II. Photolysis in an Aqueous Solvent in the Presence of N-Phenylglycines and Photolysis in Organic Solvents

By Shiro MATSUMOTO

(Received September 19, 1963)

In Part I[1] of this paper the flash-photolytic reduction of methylene blue in aqueous solvents in the presence of several reducing agents was surveyed. Now it is desirable to investigate in this connection the reaction in the presence of *N*-phenylglycines, and to compare the results with those obtained by continuous illumination.[2] In this case an irreversible bleaching of the dye remains after flash illumination. This requires renewed preparation of a degassed solution after every flash to get a series of spectra corresponding to various delay times.

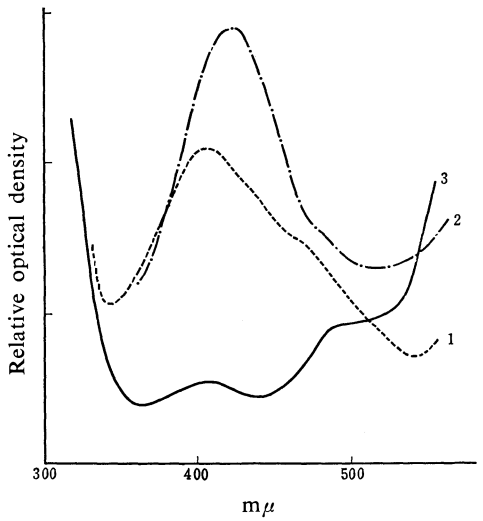
Photolysis in common organic solvents was also found to result in an irreversible bleaching. Preliminary results of photolysis in these solvents will be given also.

Experimental

The apparatus and procedure are the same as those described in Part I. The preparation of *N*-phenylglycines has been described in an earlier paper.[2] The organic solvents were G. R. reagents from the Koso Chem. Co., and were used without further purification.

Results and Discussion

Photolysis in Aqueous Solvents in the Presence of *N*-Phenylglycines.—*1) Resemblance to the Reversible Photolysis.*—Plates 1a and 1b give spectra in which the concentration of the reductant (*N*-*p*-chlorophenylglycine) is varied. It is seen that the spectrum changes from the type observed in pure water to the one observed when *p*-phenylenediamine[1] is used as the reductant. The absorption shows a peak around 410 mμ at the earliest stage of photolysis and somewhat blue-shifts later. This absorption may be mainly that of methylene blue semiquinone superposed by that of the triplet dye. This assumption is substantiated by the fact that the absorption red-shifts to 425 mμ at a pH value where the same change was observed with *p*-phenylenediamine[1] (Fig. 1).



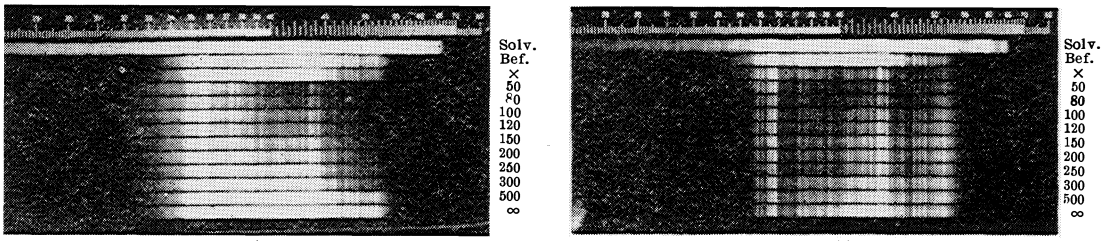


Fig. 1. Shift in transient absorption at a pH near 8, *p*-Cl-ϕ·G being added as reductant, 10^{-4} M. M. B. 10^{-5} M; delay time Δt=50 μsec. Curve 1: pH 7.4; Curve 2: pH 9.2. Curve 3 shows spectrum before flash exctn.

In this case the absorption corresponding to the oxidation product of the reductant is uncertain. The spectrum in the 220~320 mμ region resembles the spectra in the reversible reduction in Part I. The spectrum obtained with *N*-phenylglycine (Plate 2) has features intermediate between those with *p*-phenylenediamine and those with benzohydroquinone (cf. Plates 5 and 6b in Part I). Some part of the semiquinone is going to leuco methylene blue, while the other part is coming back to the original form of the dye. The spectrum with *N*-*p*-methoxyphenylglycine (Plate 3a) resembles that with *p*-phenylenediamine. In this case the photolysis is reversible, in accordance with the results described in a previous paper,[2] where the resemblance of the two reductants was stressed.

2) Relations between the Transient Spectra and the Structure of the Reductant.—Plates 3b—3g show the spectra obtained with typical derivatives of *N*-phenylglycine. The spectrum with *N*-phenylglycine is similar to that with

N-*p*-chlorophenylglycine. In the case of *N*-*p*-bromophenylglycine, the transient absorption is faint. This must be due to the strong deactivating influence of the heavy atom-containing reductant on the triplet state of the dye. In the case *N*-*m*-bromophenylglycine, the formation of methylene blue semiquinone is more apparent, but the yield is still not as good as in the case of *N*-phenylglycine, to judge from the degree of the disappearance of methylene blue absorption. The situation is similar in the case of *N*-*p*-acetylphenylglycine.

The result with α-methyl-*N*-phenylalanine is characteristic. It is seen that the dye ion is converted into its colorless form almost invariably once it is excited by the flash. The relatively faint transient absorption in this case may indicate a low stationary concentration of the intermediate that is brought about by a strong reactivity of the reductant with the intermediate semiquinone. The absorption near 330 mμ may be due to the leuco methylene blue.[3] The spectrum in the 220~320 mμ range (Plate 4) is in accord with these results. The above results, together with the results with *N*-*p*-methoxyphenylglycine described in section 1), support the general idea obtained earlier[2] about the reactivity of various derivatives of *N*-phenylglycine. One point to be modified concerns the mechanism of the deactivation of excited dye ions by some reductant. The excited state seems to be deactivated almost catalytically by *N*-phenylglycines containing heavy atoms at the ortho- or para-position of the benzene ring, while with *N*-phenylglycine having a methoxy substituent in either of these positions, a relatively long-lived intermediate (presumably the semiquinone of the dye) is formed which, in this case, is converted effectively into the ground state of the dye. The net result is an effective deactivation of the excited state. The mechanism of the strong inhibitory action of *p*-phenylenediamine also belongs to the latter category. This difference may, however, be superficial. Dye ions in their excited state may form a sort of charge-transfer complex, however short-lived, with reductant molecules before they are deactivated, as suggested by the effect of the substituent position.[2] In the case of *N*-phenyl-β-alanine, the disappearance of the methylene blue absorption and the increase in the semiquinone absorption is remarkable at first, but the recovery of the original absorption is rapid and complete compared with *N*-phenylglycine; the net quantum yield of the reduction of methylene blue is poor, in accordance with the previous results.[2] This observation stimulates a speculation as to the good quantum yield of photoreduction by *N*-phenylglycines. The half-oxidized form of *N*-phenylglycine may, for some reason, be liable to irreversible decomposition and may so become unable to reoxidize the semiquinone or the leuco base of dye, whereas the half-oxidized *N*-phenyl-β-alanine, with one more methylene unit between the amino- and the carboxyl-groups, may have a different stability and may remain efficient enough to reoxidize the semiquinone.

Photolysis in Organic Solvents.—The solvents used were methanol, ethanol, 1-propanol, 2-propanol, glycerol, acetone, pyridine and

3) A. T. Vartanyan, *Zhr. Fiz. Khimi.*, **29**, 1304 (1955).

acetic acid. The solubility of the dye is slight in 1, 1-dimethylethanol and in less polar solvents. In these solvents flash illumination resulted in a more or less irreversible fading of the dye. The degree of fading observed visually after a same number of flashes was approximately in the order: 2-propanol < 1-propanol < acetic acid, glycerol < ethanol < methanol, pyridine <acetone. There seems to be no relation between the ease with which the solvent molecule is dehydrogenated by an ordinary oxidant and the above series. Probably the net quantum yield of photoreduction depends also on the succeeding reactions, by which the first oxidation product of the solvent is removed from the reacting system;
