*b) With Acetyl Chloride.*—As has been described in a), 1.75 g. of a neutral oil was obtained from the reaction of 1.95 g. (13 mmol.) of I with 1.02 g. (13 mmol.) of acetyl chloride in the presence of 2 mol. equivalents of sodium ethoxide in an ethanolic solution. The oil crystallized partly when allowed to stand. Filtration, followed by recrystallization from ethanol, afforded 360 mg. of VI as colorless needles (m. p. 114—115°C). The filtrate

was then evaporated, dissolved in benzene and chromatographed by passing it through a column containing 50 g. of aluminum oxide (Grade I). The evaporation of the elute with benzene-ether (5 : 1) yielded 450 mg. of an oil, which crystallized on standing. The recrystallization of the crystals from ethanol gave 250 mg. of the starting material (I) (m. p. 60—62°C) as colorless prisms. Elution with ether gave 70 mg. of orange crystals, which, on recrystallization from benzene, afforded 10 mg. of red needles (m. p. 140—170°C), mainly composed of 8, 8-dicyanoheptafulvene (identified by its infrared spectrum). The benzene filtrate was evaporated to give crystals which, on recrystallization from ethanol, afforded 25 mg. of V (m. p. 120—123°C). The evaporation of the elute with ether-methanol (1 : 1) afforded 350 mg. of crystals (m. p. 140—142°C), which, on recrystallization from ethanol, gave IV (m. p. 168—169°C).

**The Hydrolysis and Synthesis of Ethyl Ditropylcyanoacetimidate (VI).**—*a) The Hydrolysis of VI.*—A solution of 100 mg. of VI dissolved in a mixture of 1 ml. each of 2 N hydrochloric acid and ethanol was refluxed for 30 min. After neutralization with 2 N sodium hydroxide, the reaction mixture was extracted with benzene. The benzene extract was then washed with water, dried over sodium sulfate, and evaporated to give 60 mg. of an yellow oil, which crystallized on cooling. Recrystallization from ethanol gave V as pale yellow needles (m. p. 126—127°C).

*b) The Synthesis of VI.*—To a solution of sodium ethoxide prepared from 600 mg. (24 mmol.) of sodium and 20 ml. of absolute ethanol, 500 mg. (2 mmol.) of III was added; the reaction mixture was stirred at room temperature for 20 hr., during which time colorless crystals separated out. After the evaporation of the ethanol, the reaction mixture was poured into water and extracted with benzene. The extract was washed with water, dried over sodium sulfate, and evaporated to give colorless needles, which, on recrystallization from ethanol, afforded 150 mg. of VI as colorless needles (m. p. 110—111°C). The residue from the mother liquor was recrystallized from ethanol to give 153 mg. of IV (m. p. 167°C).

**The Reaction of Tropylmalononitrile (I) with Sodium Ethoxide in Ethanol.**—To a solution of sodium ethoxide prepared from 46 mg. (2 mmol.) of sodium and 4 ml. of absolute ethanol, 312 mg. (2 mmol.) of I was added under cooling with ice. After it had been stirred for 24 hr. at room temperature, the solution was poured into water and extracted with ether; the usual treatment of the ether-extract then gave 300 mg. of an oil. The oil was dissolved in benzene and chromatographed by passing it through a column containing 9 g. of aluminum oxide (Grade I). The evaporation of the benzene elute gave 73 mg. of the starting material (I) (m. p. 62°C). Elution with benzene-ether gave 20 mg. of 8, 8-dicyanoheptafulvene (VII) (m. p. 199°C), while elution with ether-methanol gave 120 mg. of tropylcyanoacetamide (m. p. 145°C).

**The Reaction of Ethyl Tropylcyanoacetate (II) with Acyl Chloride in Pyridine.**—*a) With Benzoyl Chloride.*—To a solution of 2 g. (11 mmol.) of II dissolved in 4 ml. of pyridine, 1.55 g. (11 mmol.) of benzoyl chloride was added drop by drop under cooling with ice. The mixture was stirred under cooling for 1 hr. and at room temperature for 20 hr. The solution was then poured into water and extracted with benzene. The benzene-extract was successively washed with 2 N hydrochloric acid, 2 N sodium hydroxide and water, dried over sodium sulfate, and evaporated to give 2 g. of a brown oil, which crystallized on standing. Filtration, followed by recrystallization from ethanol, gave 485 mg. of ethyl ditropylcyanoacetate (V) (m. p. 125—127°C).[8] The ethanolic filtrate was evaporated, dissolved in benzene, and chromatographed using aluminum oxide. The evaporation of the benzene elute gave 143 mg. of V (m. p. 124—126°C), and the following benzene elute gave 95 mg. of a brown oil, which was identified with the starting material (II) by a comparison of their infrared spectra.

*b) With Acetyl Chloride.*—The reaction of 2 g. (11 mmol.) of II and 0.865 g. (11 mmol.) of acetyl chloride was carried out as in a). Only 52 mg. of V was obtained as colorless crystals (m. p. 127—128°C). The acidification of the alkaline washings, followed by extraction with ether and the usual treatment of the ether-extract, gave 1.12 g. of an acidic oil which contained the starting material (II) (identified from the infrared spectrum).

**The Reaction of a Sodio Compound of Ethyl Tropylcyanoacetate (II) with Acyl Chloride in Ethanol.**—*a) With Benzoyl Chloride.*—A sodio compound of II was obtained from 253 mg. (11 mmol.) of sodium and 2 g. (11 mmol.) of II in 10 ml. of absolute ethanol. To this solution, 1.55 g. (11 mmol.) of benzoyl chloride was added under cooling with ice. After it had been stirred for 20 hr. at room temperature, the mixture was poured into water and extracted with benzene. The benzene extract was washed with water, dried over sodium sulfate, and evaporated to give 2.1 g. of an oil, which crystallized on cooling. Filtration, followed by recrystallization from ethanol, gave 510 mg. of V as colorless crystals (m. p. 124—125°C). The ethanolic filtrate was evaporated, and the residue was dissolved in benzene and chromatographed using 40 g. of aluminum oxide (Grade I). The evaporation of the benzene elute gave 380 mg. of V (m. p. 124—125°C). After the mother liquor from the benzene extract had been acidified and extracted with ether, the ether-extract was dried over sodium sulfate and evaporated to give 587 mg. of an acidic oil containing crystals of ethyl benzoylcyanoacetate (m. p. 39.5—40.0°C)[9]

*b) With Acetyl Chloride.*—When the reaction of 2 g. (11 mmol.) of II with 0.864 g. (11 mmol.) of acetyl chloride was carried out in the same way as in a), and 1.4 g. of a neutral oil was obtained; this crystallized partly. Filtration, followed by recrystallization from ethanol, afforded 605 mg. of V (m. p. 126—127°C). The filtrate was evaporated, dissolved in benzene, and chromatographed using aluminum oxide (Grade I) to give 106 mg. of V and 150 mg. of II.

9) M. Haller, *Bull. soc. chim. France* [2], **45**, 271 (1886).

**The Reaction of Ethyl Tropylcyanoacetate (II) and Acyl Chloride in Ethanol in the Presence of 2 Molar Equivalents of Sodium Ethoxide.**—*a) With Benzoyl Chloride.*—To a solution of 506 mg. (22 mmol.) of sodium dissolved in 15 ml. of absolute ethanol, 2 g. (11 mmol.) of II was added, and then 1.55 g. (11 mmol.) of benzoyl chloride was added under cooling with ice. The usual treatment of the reaction mixture afforded 1.40 g. of a neutral oil, which crystallized partly, and 1.26 g. of an acidic oil. The former was filtered and recrystallized from ethanol to give 298 mg. of V as colorless needles (m. p. 124—125°C).

*b) With Acetyl Chloride.*—As has been described in a), 2 g. (11 mmol.) of II was acetylated with 0.864 g. (11 mmol.) of acetyl chloride in the presence of 2 molar equivalents of sodium ethoxide. From the reaction mixture, 760 mg. of a neutral oil, which crystallized partly, and 690 mg. of an acidic oil were obtained. When the crystals obtained from the neutral oil by chromatography were recrystallized from ethanol, 415 mg. of V (m. p. 126—127°C) were obtained.

The authors wish to express their deep gratitude to Professor Tetsuo Nozoe for his kind guidance throughout the course of this work. They also wish to thank the Sankyo Co. for its donation of research funds to cover a part of the expenses of their work. The infrared and ultraviolet spectrophotometers used in this work were purchased with a grant-in-aid for Fundamental and Technical Research from the Toyo Rayon Co., to whom the authors are grateful.

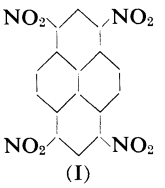
# Photoelectric Emission and Electrical Conductivity of the Cesium Complex with Pyrene Derivatives

By Kyohei OGINO, Satoshi IWASHIMA, Hiroo INOKUCHI and Yoshiya HARADA

(Received August 17, 1964)

The efficiency of the photoelectric emission of an alkali metal was promoted by the evaporation of a hydrocarbon, naphthalene or anthracene onto a sodium (or potassium) film.[1]

In the 1950's, Ubbelohde investigated the electronic properties of the solid-state complexes of polycyclic aromatics involving an alkali metal; sodium, potassium or lithium.[2]



Recently, we have found a strong photoelectric emission and a high quantum efficiency of the complexes between cesium and polycyclic aromatic compounds in the region with wavelengths shorter than 600 m$\mu$.[3]

On the basis of the charge transfer process of the complexes, the selection of the types of the two components—the electron donor and the acceptor—may help to yield a group of materials with higher conductivities. In this article, we will discuss the photoemission and the electronic conduction of the cesium complexes with pyrene derivatives in an attempt to understand better the mechanism of the charge transfer process.

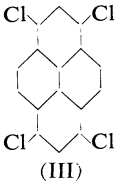
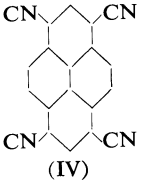
## Experimental Procedures



Though preparations of the pyrene derivatives have already been reported,[4] the descriptions are not reliable. The pyrene derivatives applied in this experiment were synthesized as follows:



(I)

(II)

(III)

(IV)

**1, 3, 6, 8-Tetranitropyrene** ($TNO_2P$) (**I**). — One hundred grams of nitric acid ($d$=1.5) was added slowly to a 300 ml. nitrobenzene solution containing 30 g. of pyrene. With the addition of nitric oxide, yellow needle crystallites were deposited.

4) H. Vollmann, H. Becker, M. Corell and H. Streeck, *Ann.*, **531**, 1 (1937).

TABLE I. THE CHANGE OF COLOUR BY THE FORMATION OF THE COMPLEXES

| Complex | | Change of colour | |
|---|---|---|---|
| Donor | Acceptor | After formation 30 min. | 1 day |
| Cs | Pyrene (white) | Pink | Blue |
| Cs | $TNO_2P$ (orange yellow) | Dark brown | Dark brown |
| Cs | TCNP (yellow) | Orange yellow | Dark violet |
| Cs | TClP (pale yellow) | Bluish brown | Bluish brown |
| Cs | TBrP (pale yellow) | Dark brown | Dark brown |

After the solution had been stirred for 4—5 hr. at 110—120°C, the crystallites were separated with a glass-filter. Through sublimation in vacuo, purified crystallites, m. p. 334—336°C, were obtained.

**1, 3, 6, 8-Tetrabromopyrene (TBrP) (II).**—Twenty grams of pyrene was dissolved in 300 ml. of nitrobenzene. Seventy grams of bromine was then stirred drop by drop into the solution. Through continuous shaking at 120—125°C, pale yellow crystallites separated from the solution as precipitates. These crystallites were filtered and washed with ethanol. The melting point of tetrabromopyrene, which was purified by sublimation under a pressure of $10^{-4}$ mmHg, was 399—404°C.

**1, 3, 6, 8-Tetrachloropyrene (TClP) (III).**—Thirty-eight grams of 1, 3, 6, 8-tetranitropyrene (I) and 150 g. of phosphorus pentachloride were dissolved in 150 ml. of trichlorobenzene and heated at around 150°C for 8—9 hr. while being continuously stirred. During the operation, a large amount of gas was removed from the solution and the colour of solution changed from pale brown to dark brown. Dark brown crystallites were separated from the solution as precipitates. Through vacuum sublimation, purified compounds, for which the melting point was 358—360°C, were pale yellow-coloured crystallites.

**1, 3, 6, 8-Tetracyanopyrene (TCNP) (IV).**—Twelve grams of tetrabromopyrene (II) and 90 g. of copper cyanide (CuCN) were dissolved in 120 ml. of benzyl cyanide ($C_6H_5CH_2CN$) which had been purified by vacuum distillation. The solution was heated at 100°C for half an hour and then at 234°C (the boiling point of benzyl cyanide) for 4 hr. while being continuously stirred. Through these reactions, the color of the solution changed from pale brown to dark brown. One hundred millilitres of ethanol was added to the solution at 80—90°C for 1—1.5 hr. with stirring continuously. The precipitates which separated from the solution were washed with 30 per cent nitric acid to eliminate the residue of copper and then repeatedly washed with ethanol. The melting point of compound, sublimed in vacuo, was 445—448°C.

**The Preparation of a Cesium Complex Photocell (Fig. 1).**—A vapour of cesium metal (8), prepared from a reaction between cesium chloride and calcium metal, was brought in contact with a thin film (3) of pyrene derivatives which had previously been deposited on the surface of a glass plate with two aluminium electrodes. By the contact between the aromatic compound and cesium vapour, an abrupt change in the colour occurred, as Table I shows.

The formation of a complex was terminated by the saturation of the cesium metal involved. All preparations of the complexes were carried out at room temperature except that of the cesium-pyrene complex. In the latter, the thin film of the hydrocarbon had to be kept at a low temperature (around 0°C) in order to decrease the vapour pressure of the compound. The ratio of the components of cesium-tetranitropyrene, $Cs/TNO_2P$, was found to be two by chemical analysis.

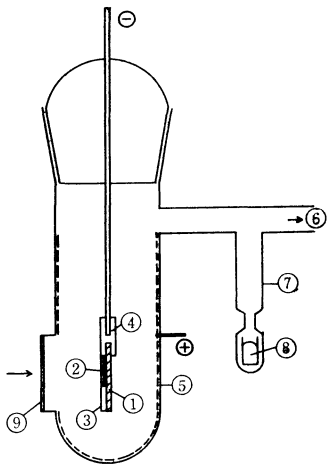


Fig. 1. The cesium complex photocell: 1, glass plate; 2, aluminium electrode; 3, organic thin film; 4, electrode connector; 5, collector (silver film); 6, to connect vacuum system, 7, annex glass for reaction; 8, CsCl+Ca mixture; 9, quartz window.

Under illumination by a visible and an ultraviolet light from a Hitachi spectrometer through a quartz window (9), a strong photoemission from the surface of the complex was found when an electric field (1—30 V.) between a specimen and a collector (5), deposited as a silver film, was applied.

**The Observation of the Quantum Yield of Photoemission.**—The quantum efficiency ($Y$) derives from the ratio between a number of incident photons ($n_p$) and a number of emissive electrons ($n_e$) observed in a photocurrent;

$$Y = \frac{n_e}{n_p} \qquad (1)$$

The photocurrent, $10^{-14}$—$10^{-6}$ amp., was observed by means of a Cary model 32 vibrating reed electrometer.*

* One ampere corresponds to $1.6\times10^{19}$ electrons/sec. in this experiment.

The incident photons ($n_p$) were measured by means of the thermoelectric power of the thermopile:

$$n_p = \frac{V\lambda}{vch} \times 10^7 \text{ photons/sec.} \quad (2)$$

where $v(\mu V./\mu W.\,cm^2)$ is the sensitivity of the thermopile, $V$ is an applied potential on the photocell, $\lambda$ is a wavelength of light, $c$ is the light velocity and $h$ is Plank's constant.

When a Nipponbunko thermopile was applied (its sensitivity was $7.0\times10^2\ \mu V./\mu W.\,cm^2$), the spectral response of the quantum efficiency of cesium-aromatics complexes in the wavelength range from 200 m$\mu$ to 900 m$\mu$ was obtained.

**The Measurement of the Electrical Resistivity of the Complexes.**—The thin organic film evaporated on a silica plate, with two aluminium electrodes as a surface-type cell, came in contact with the vapour of cesium gas in vacuo. The resistivity of the cell was measured with a Kawaguchi Denki model MMA III-13 vibrating reed electrometer.

The absorption spectra of the thin complex films were observed with a Cary recording spectrometer model 14.

## Experimental Results

A variation in the emission current as a function of the applied potential for a Cs-(TBrP) photocell under illumination by monochromatic light (550 m$\mu$), its intensity being $3.6\times10^{11}$ photons/sec., is illustrated in Fig. 2. From an irregularity in the geometrical arrangement of the photocell, as is shown in Fig. 1, the saturation potential of the photoemission was found to be around ten volts. Therefore, the observation has been carried out under an applied potential of 10 V. An ageing of the emission was found.

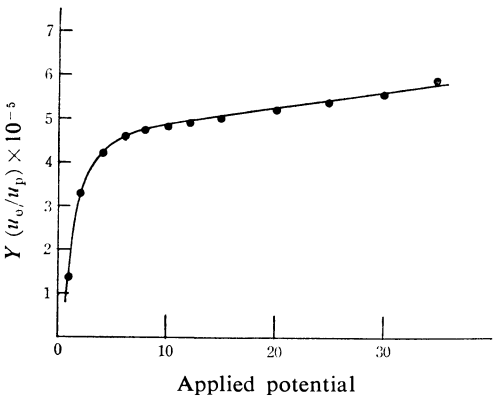

Fig. 2. The variation of photoemission as a function of applied potential for Cs-TBrP.

The spectral responses of the photo-emissive current were curves decreasing gradually from the short wavelength side to the long wavelength side as Fig. 3 shows. However, the response curves changed with time at an initial stage of the complex formation, as is shown in the figure, and converged to the stable state.

The electrical resistivity of the complexes, which was observed with a surface-type cell,[5] possessed a wide range of values, depending on the pyrene derivatives applied as acceptors. The temperature dependence of the resistivity was semiconductive in character ($\rho=\rho_0 \exp \Delta\varepsilon/2KT$), as Table II demonstrates.

Table II. The semiconductivity of pyrene-cesium complexes

| Complex | $\rho$, $\Omega$ cm. at 15°C | $\Delta\varepsilon$, eV. |
|---|---|---|
| Pyrene-Cs | $2.1\times10^4$ | 0.42 |
| TClP-Cs | 8 | 0.34 |
| TBrP-Cs | $1.6\times10^1$ | 0.35 |
| $TNO_2P$-Cs | $2\times10^6$ | 0.94 |
| TCNP-Cs | $6\times10^5$ | 0.70 |

## Discussion

The threshold values of the spectral response of the photoemission of the cesium complexes which correspond to the ionization potential are situated around $1.6\times10^4\ cm^{-1}$. The pure cesium metal has a strong response peak at around $2.5\times10^4\ cm^{-1}$. Further, the threshold value of the photoemission of pyrene was reported to be around $4.7\times10^4\ cm^{-1}$.[6] Therefore, it is reasonable to consider that the emission from a cesium-aromatics system, observed in the experiment, occurs from new compounds.

The formation of complexes demonstrated an increase in the quantum yield of photoemission from $10^{-3}$—$10^{-4}$, the values for pure cesium metal and also for pure aromatic compounds, to $10^{-1}$—$10^{-2}$, an increase shown in Fig. 3. These promotions may take place from the electron transfer from a cesium metal to a partner molecule.

The transfer charge carriers depends roughly on the energy difference between the ionization potential of metal, 1.9 eV. for cesium, and the electron affinity of the acceptor, pyrene derivatives. On the basis of organic chemistry, the order of the values of electron affinity is;

tetracyanopyrene > tetranitropyrene > tetrabromopyrene $\geqq$ tetrachloropyrene > pyrene

The velocity of complex formation followed the above relation qualitatively, and also the quantum yield of the photoemission was increased in roughly the above order. The spin

(d) Cs-TCNP: ● immediately after reaction, ⊙ 2 days, △ 10 days

concentrations of the Cs-complexes, which will be reported elsewhere,[7] were also increased in the order of the above relation.

As mentioned above, the changed in the spectral response of the photoemission occured gradually. In the case of cesium-tetracyanopyrene, the response peak, around $1.7\times10^4$—$1.8\times10^4$ $cm^{-1}$, was found during the formation of the complex, as Fig. 3 shows. This peak may be produced by cesium metal and was disappeared with time. Sometimes, the peak around $2.8\times10^4$ $cm^{-1}$ was found in the spectral response of the photoemission and was independent of the nature of the organic acceptors applied. Similar peaks, $2.87\times10^4$ $cm^{-1}$ for naphthalene-Cs and $2.87\times10^4$ $cm^{-1}$ for hydrogenated cesium, have already been observed by Suhrmann.[1] The source of the peak may be atomic cesium dispersed in the acceptors.

The absorption spectra of the Cs-aromatics complexes in th solid phase also gradually changed with time; a strong new absorption

7) K. Ohigashi, S. Iwashima and H. Inokuchi, Private Communication.

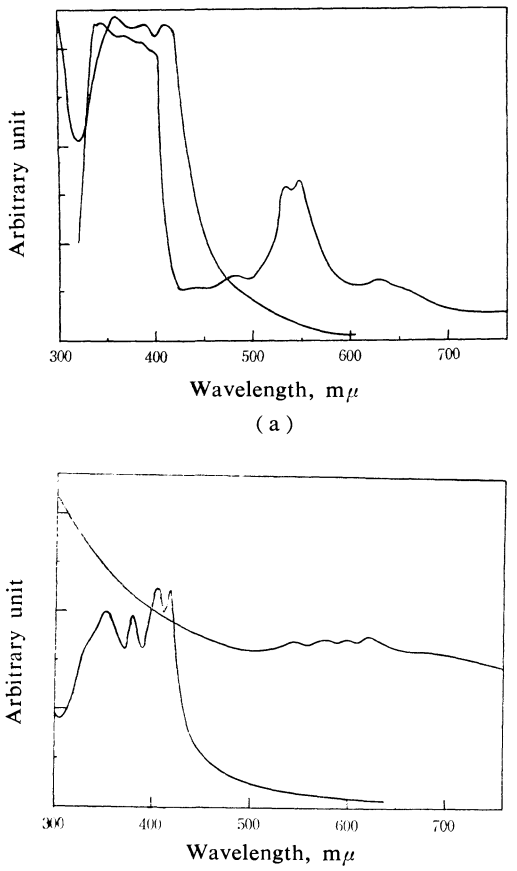

Fig. 4. The absorption spectra of the thin film of Cs-aromatics complex and its aromatic component.
(a) Cs-TCNP; curve I aromatic component and II the complex
(b) Cs-TBrP; curve I aromatic component and II the complex

peak, $1.7\times10^{4}$ cm$^{-1}$ for (TCNP) or $1.85\times10^{4}$ cm$^{-1}$ for ($TNO_2P$), was found after the complex formation had been completed. However, only a very weak peak for (TBrP) was detected or no new peak for (TClP) (Fig. 4). The behaviour is also explained by the order of the electron affinity of the organic compounds.

The charge-transfer absorption peaks resemble to that of the mono-negative pyrene ion;[8] that is, the results suggest that the components in the complex are charged as [$Cs^+$] [aromatics$^-$], as was described in our previous work.[3]

The electrical resistivity of the complexes has a fairly strange result, as is illustrated in Table II. The electrical conduction of (TBrP)-Cs or (TClP)-Cs is higher than that of ($TNO_2P$)-Cs or (TCNP)-Cs; in the case of the latter, the contribution of the dative-bond character to the interaction between donor and acceptor may be larger than the contributions of the former compounds. Because of the strong coupling between two components, it may be expected that the mobile carriers contributing to the electronic conduction will decrease.

## Summary

On the basis o the charge transfer process of the complexes, the photoemission and the electronic conduction of the complexes between cesium and pyrene derivatives, tetranitropyrene ($TNO_2P$), tetrachloropyrene (TClP), tetrabromopyrene (TBrP) and tetracyanopyrene (TCNP) have been measured. A strong increase in the quantum yield of photoemission, from $10^{-3}$—$10^{-4}$ to $10^{-1}$—$10^{-2}$, resulting from the formation of the complexes, has been found. The promotion may take place by means of an electron transfer from cesium metal to a partner molecule; [$Cs^+$] [Aromatics$^-$]. The assumption is supported by the findings concerning electron spin resonance absorption and charge-transfer spectra.

The electrical resistivity of the complexes, $\rho$ at 15°C of pyrene-Cs$=2.1\times10^{4}$ Ωcm., (TClP)-Cs$=8$Ωcm., (TBrP)-Cs$=1.6\times10^{1}$Ωcm., ($TNO_2P$)-Cs$=2\times10^{6}$ Ωcm. and (TCNP)-Cs$=6\times10^{5}$ Ωcm., is strongly affected by the contribution of the dative-bond character of the complexes.

# A Kinetic Study of the Isotopic Exchange of Thallium(III) between the Thallium(III) Ion and the Thallium *N*-2-Hydroxyethyl-ethylenediamine-*N*, *N'*, *N'*-triacetate Complex in Water

By Michiko TSUCHIMOTO

(Received August 19, 1964)

The kinetic study of isotopic exchange involving co-ordinated compounds with a $d^{10}$ structure, will in this paper be extended to thallium(III), with $^{204}Tl$ as tracer. The exchange of thallium in its *N*-2-hydroxyethyl-ethylenediamine-*N*, *N'*, *N'*-triacetate (henceforth written as EDTA-OH with the formula $H_3Z$) is very fast in strongly basic and acid solutions. The rate is measurable in the pH regions from 4 to 6 and from 7 to 10 under appropriate experimental conditions. This paper will give the results of kinetic studies of the thallium EDTA-OH complex $[TlZ\cdot OH_2]\cdot H_2O$ with thallium(III), in basic, neutral and acid media separately, and the mechanisms will be discussed.

Unlike the cases involving corresponding gallium and indium complexes, tervalent thallium is very unstable and is readily reduced to thallium(I) or precipitated as thallium(III) oxide. Hence, the exchange kinetics can be studied only in the presence of triethanolamine and chloride; their contribution to the reaction kinetics was precisely examined, as will be seen below. The thallium(III) ion will be present in a rather complicated form in the given solutions, but the state does not appear important in discussing the reaction mechanism. The rate constant is independent of the concentration of uncomplexed thallium, although it is proportional to that of the complex throughout these regions. Hence, it is written in the chemical equations in rather arbitrary forms, such as $[Tl(TEA)_x]^n$ or $[Tl(TEA)_xCl_y]^n$.

## Experimental

**The Preparation of the Complex.**—The processed radioisotope $^{204}Tl$ (half life 3.56*y*, Radio Chemical Centre, Amersham) with a specific activity about 0.15 mc./mg. was diluted to produce radioactive thallium with a specific activity of 0.4 $\mu$c./mg. Commercial univalent thallium nitrate in water (extra pure grade) was oxidized by bromine in an acid solution and precipitated with an aqueous ammonia solution as thallium(III) oxide. The precipitate was then filtered off, dried for about 2 hr. at 120°C, weighed, and dissolved in 6 N nitric acid to give a thallium(III) nitrate solution. The absence of thallium(I) was confirmed with a potassium chromate solution.

The thallium EDTA-OH complex was formed instantaneously on mixing a thallium(III) nitrate solution in nitric acid with an equivalent amount of EDTA-OH in water. The labeled complex was prepared immediately before use from a radioactive thallium(III) nitrate solution with a suitable specific activity and an equivalent amount of EDTA-OH in water. When titrated with a sodium hydroxide solution, an aqueous solution of this complex gave the titration curve shown in Fig. 1. From analogy

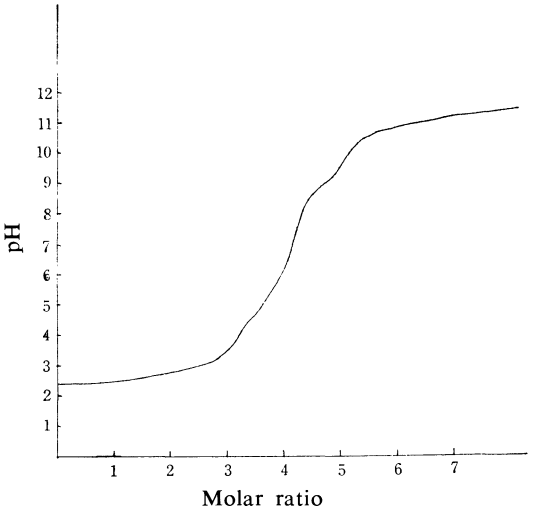

Fig. 1. Titration of $[Tl\cdot EDTA\text{-}OH\cdot OH_2]\cdot H_2O$ with sodium hydroxide.
$[TlZ\cdot OH_2]\cdot H_2O$, $1.2\times10^{-4}$ M;
$\mu=0.20$ ($KNO_3$); 25°C

to the corresponding gallium and indium homologue[2,3] and thallium(III) EDTA complex,[5] it is very probable that the [TlZ] complex contains one mole of co-ordinated water. The first rise in the curve will correspond to the neutralization of the $H^+$ liberated from $H_3Z$, and the second, to that of the $H^+$ liberated from the co-ordinated water.

5) M. Tsuchimoto and K. Saito, ibid., in press.

$$H_3Z + Tl^{3+} \text{ aq.} \rightleftarrows [TlZ\cdot OH_2] + 3H_2O$$

$$[TlZ\cdot OH_2] \rightleftarrows H^+ + [TlZ\cdot OH]^-$$

**Buffers.**—Since thallium(III) is readily reduced to the thallium(I) state, only a few varieties of buffers are useful. The tartrate and citrate used in the studies with gallium and indium are not useful. In basic media *p*-hydroxybenzoate, glycine, ammonia, and barbiturate were used, whereas in the neutral region only barbiturate was useful. In the weakly acid region acetate was used. Their participation in the kinetics was carefully examined, as will be seen in the next section.

**The Procedure for Kinetic Runs.**—An aqueous thallium(III) nitrate solution (not radioactive) was mixed with potassium nitrate (or potassium chloride and nitric acid in the acid region), triethanolamine and the buffer in order to give it an appropriate pH value and ionic strength. A radioactive thallium(III) nitrate solution was mixed with an equivalent amount of EDTA-OH, potassium hydroxide (or nitric acid), and potassium chloride, and the pH value was made approximately the same as that of the thallium(III) solution with which the isotopic exchange is studied. Both solutions were mixed in a thermostat. An aliquot was taken at selected intervals, and a part of the initially-inactive thallium(III) precipitated with 8-quinolinol in ethanol, less than the equivalent of that of the initially-inactive thallium(III), the pH being adjusted to 5—7 with diluted nitric acid (or an aqueous ammonia solution). The precipitate was swiftly filtered through a filter paper of fine texture, washed with water, and dried under an infrared lamp. The composition of the thallium(III) 8-quinolinol complex remained unchanged in the presence of an excess of thallium(III) and the thallium(III) EDTA-OH complex. The pH value of the reaction mixture was measured carefully with a glass electrode pH meter from time to time during the kinetic runs in order to confirm the maintenance of the chemical equilibrium.

**The Measurement of Radioactivity.**—The Geiger-Müller counting method was adopted. $^{204}Tl$ gives $\beta$ rays of a maximum energy, 0.764 MeV. Dried thallium(III) oxinate on the filter paper was placed about 27.5 mm. below a Geiger-Müller tube, and the counting rate was measured. It was proportional to the amount of radioactive thallium on the filter.

**The Measurement of the Thallium.**—After the measurement of the radioactivity, the precipitate on the filter paper was placed in a flask containing a few drops of 6 N hydrochloric acid and treated with 50 ml. of hot water and a known excess of a disodium EDTA solution. After the pH had been adjusted to 4—5 with an ammonium acetate solution, excessive EDTA was back-titrated with an indium nitrate solution, using xylenol orange as an indicator. The specific activity was calculated from the titrated amount of thallium(III). The direct titration of thallium(III) with disodium EDTA was not successful because of the precipitation of thallium(III) oxide and the 8-quinolinol complex.

The fractional exchange, $F$, is expressed by:

$$F = (x_i - x_0)/(x_\infty - x_0)$$

where $x_\infty$, $x_i$ and $x_0$ are the specific activities at infinite time, time $i$ and time zero respectively, the last being about 5—30 min. after the solution is mixed.

The reaction was very slow in a neutral solution at 25°C, and so the kinetics was mainly studied at 40°C.

## Results and Discussion

The rate of exchange, $R$, is expressed by McKay's[1] formula:

$$R = -2.303 \cdot \frac{a\cdot b}{a+b} \cdot \frac{\log(1-F)}{t}$$

where $a$ and $b$ are the molar concentrations of the uncomplexed thallium (initially inactive) and of the thallium EDTA-OH respectively; $t$ is the lapse of time in seconds, and $F$, the fractional exchange.

The $R$ values are independent of the concentration of uncomplexed thallium ions ($a$)

and proportional to the concentration of the thallium EDTA-OH complex (*b*), regardless of the pH value in the given range, as is shown in Table I. Hence, the rate constant, $k$, is expressed by $R/b$ and has a dimension of $t^{-1}$ under the experimental conditions.

The kinetics is very different in the acid, the neutral, and the basic regions; these regions will be discussed separately below. Tervalent thallium easily gives a precipitate of thallium(III) oxide over pH 1.5. Triethanolamine and potassium chloride were added to keep the thallium(III) and thallium EDTA-OH complexes respectively in the aqueous phase. Their participation in the exchange kinetics will be discussed in detail below.

**Isotopic Exchange in a Weakly Basic Solution.**—Figure 2 illustrates the relationship between $k$ and the $OH^-$ ion concentration, and Fig. 3, that between $k$ and the concentration of triethanolamine in various buffer solutions. In barbiturate, glycine, and ammonia buffers, the rate constant, $k$, is proportional to $[OH^-]$ and to the concentration of triethanolamine (henceforth written as TEA) :

$$R = k' \cdot b \cdot [OH^-] \cdot [TEA]$$

where [TEA] denotes the total concentration of TEA. Different ionization states of TEA do not affect the kinetic expression, because this formula is valid at various pH values, where TEA is present in different states. At a given temperature, $k$ is little influenced by the concentrations of the buffering agents, ammonia and barbiturate, and it is almost

completely independent of the ionic strength and of the concentration of chloride (Table II). The temperature dependence of $R$ is shown in Fig. 4. The Arrhenius activation energy is calculated to be 29 kcal. mol$^{-1}$ in barbiturate and ammonia solutions.

The concentration of triethanolamine contributes to the exchange rate. The thallium(III) EDTA-OH complex is most likely present in the aqueous phase in a mixed complex anion form, containing EDTA-OH and TEA in the ligand.

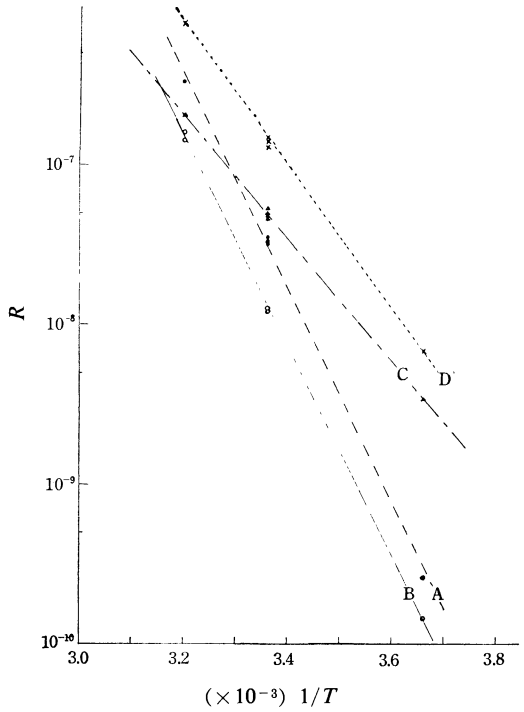

Fig. 4. Temperature dependence of the exchange constant $R$ in weakly basic media.

} pH 8.50

$$[^*TlZ\cdot OH_2]+N\equiv(-CH_2CH_2OH)_3 \rightleftarrows [^*TlZ\cdot TEA]+H_2O \qquad (1)$$

Despite their different structures, barbiturate and ammonia give the same kinetics as that mentioned above. Hence, the exchange mechanism would involve the exchange of EDTA-OH, -TEA mixed complexes, as will be shown below. Equilibrium 2 should be shifted towards the right-hand side with a rise in pH, bringing about the de-protonation of triethanolamine:

$$[^*TlZ\cdot TEA]+OH^- \rightleftarrows [^*TlZ\cdot TEA']+H_2O$$

equilibrium to form a conjugate base (2)

$$\left\{ N\equiv(CH_2CH_2OH)_3 = N=(CH_2CH_2O)^-{}_2H + H^+ \right\}$$

(TEA) (TEA')

$$^*[TlZ\cdot TEA']^- + [Tl(TEA)_x]^n \rightleftarrows [TlZ\cdot TEA']^- + [^*Tl(TEA)_x]^n \qquad (3)$$

In the case of corresponding gallium[2] and

indium[3] complexes, labile conjugate bases are formed by the de-protonation of the co-ordinated water molecule. However, the reaction mechanism does not appear to differ much. Similar values of the Arrhenius activation energies and the insignificant influence of the ionic strength (Table II) seem to support such a view. Other buffers, *p*-hydroxybenzoate and glycine seem to accelerate the exchange reaction.

In the glycine buffer, the reaction becomes more complex, and the rate constant, $k$, depends on the concentrations of both glycine and triethanolamine. It appears that glycine would replace co-ordinated triethanolamine, at least partly, in the presence of a large amount of glycine, and the exchange reaction proceeds in quite a different manner. Such a complication in the presence of glycine was also observed with indium EDTA[3] and EDTA-OH[4] and thallium EDTA[5] complexes.

In a *p*-hydroxybenzoate buffer solution, the rate of exchange, $R$, is apparently proportional to $[OH^-]^{1/2}$; therefore, the exchange reaction would involve both [TlZ·TEA] and [TlZ·TEA']$^-$.

As will be shown in the next section, the former complex undergoes a slow exchang with thallium(III) independent of the $[OH^-]$ concentration, and its contribution would be negligible in a high pH region, where the latter complex gives a greater exchange rate. However, in the presence of *p*-hydroxybenzoate, the former exchange would be accelerated so that its contribution would remain significant in a high pH region, thus giving such a complicated kinetic form.

**Isotopic Exchange in Neutral Solutions.**—In the pH region near 6—7.5, the rate constant little influenced by pH. The exchange rate constant, $k$, is proportional to the concentration of triethanolamine, and it is independent of the concentrations of barbiturate and potassium chloride and also of the ionic strength (Table II):

$$R = k'' \cdot b' \cdot [\mathrm{TEA}]$$

The temperature dependence of $k$, which is illustrated in Fig. 5, indicates that the Arrhenius activation energy is 22 kcal./mol. Thus, the exchange seems to proceed as follows:

$$[{}^*\mathrm{TlZ}\cdot\mathrm{OH_2}] + \mathrm{N}{\equiv}(\mathrm{CH_2CH_2OH})_3 \xrightleftharpoons{\text{equilibrium}} [{}^*\mathrm{TlZ}\cdot\mathrm{TEA}] + \mathrm{H_2O} \quad (4)$$

$$[{}^*\mathrm{TlZ}\cdot\mathrm{TEA}] + [\mathrm{Tl(TEA)}_x]^n \overset{\text{slow}}{\rightleftarrows} [\mathrm{TlZ}\cdot\mathrm{TEA}] + [{}^*\mathrm{Tl(TEA)}_x]^n \quad (5)$$

In this pH range, the thallium EDTA-OH complex is present mainly in the aquo complex form, as may be seen in Fig. 1, so the triethanolamine complex [*TlZ·TEA] is formed by the replacement of co-ordinated water.

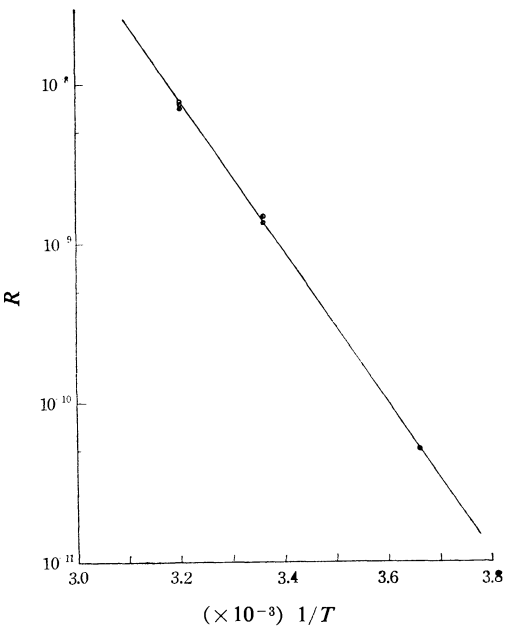

Fig. 5. Temperature dependence of the exchange constant, in neutral media.
$\mu$=0.2 ($KNO_3$); (*a*), $1.2\times10^{-3}$ M; (*b*), $1.2\times10^{-3}$ M TEA, 0.1205 M; KCl, 0.0015 M; barbiturate, 0.025 M

Ammonia and *p*-hydroxybenzoate are not useful buffers in neutral media, and glycine reduces thallium(III) to thallium(I). Hence, only barbiturate was used as a buffer.

With a rise in pH, the co-ordinated TEA liberates protons to give a de-protonated ligand, and the isotopic exchange proceeds through the conjugate base, as Eqs. 2 and 3 show. The $OH^-$ concentration that is independent of the exchange in neutral media would also promote the reaction in basic media with a pH of more than 8, but it would be overwhelmed by the faster exchange through the conjugate base, giving an apparent first-order dependence upon the hydroxide ion concentration.

**Isotopic Exchange in an Acid Solution.**—In the absence of chloride in acid solutions, a white precipitate is formed when thallium(III) nitrate and a disodium EDTA solution are mixed. When the concentration of chloride is of the same order as that of uncomplexed thallium(III), a homogeneous exchange rate is measurable near pH 3.5. However, the relationship between $R$ and $a$ and $b$ is very complicated, and the rate, $R$, is not expressed in a simple formula. This may be due to the

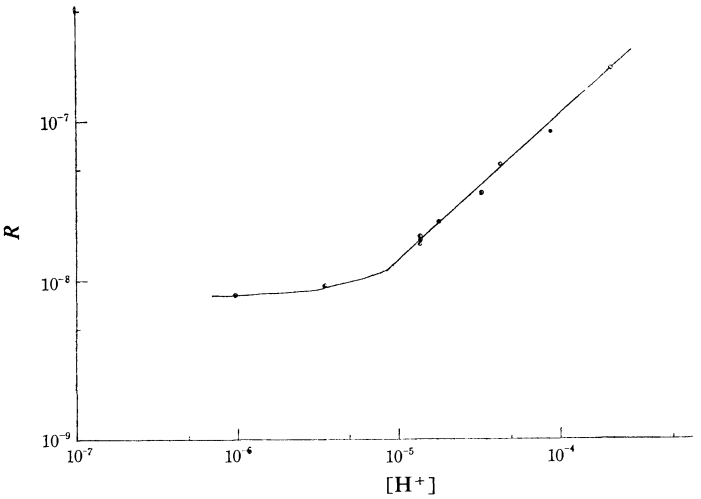

Fig. 6. Relationship between $[H^+]$ and the exchange constant in acid media.
$\mu=0.2$ (KCl); 25°C; TEA, 0.0268 M; NaOAc, 0.025 M; (*a*), $1.2\times10^{-3}$ M; (*b*), $1.2\times10^{-3}$ M

formation of chloro-complexes, such as $[TlCl_2]^+$ and $[TlCl_4]^-$,[6] with different labilities. In the presence of a large excess of chloride, the rate, $R$, is expressed by $R=k\cdot b$, and it is independent of $a$ at pH values from 4 to 6. The following discussion deals with the exchange under such conditions, the ionic strength being adjusted by potassium chloride. Figure 6 shows the relationship between $k$ and the $[H^+]$. The $k$ is proportional to $[H^+]$ and apparently to $[Cl^-]^{1.5}$, as Fig. 7 illustrates, so the rate constant, $k$, is expressed as $k=k'\cdot[H^+][Cl^-]^{1.5}$. The influence of the concentrations of triethanolamine and sodium acetate (see Experimental section) is not significant. The temperature dependence of $R$ is shown in Fig. 8, from which the Arrhenius activation energy is calculated to be 11 kcal./mol.

In the acid solution both aquo- and chloro-mixed EDTA-OH complexes could be present and participate in the exchange reaction.

TABLE III. COMPARISON OF KINETIC DATA FOR GALLIUM, INDIUM, THALLIUM COMPLEXES

| | Ga·EDTA | Ga·EDTA-OH | In·EDTA | In·EDTA-OH | Tl·EDTA | Tl·EDTA-OH |
|---|---|---|---|---|---|---|
| $K_2$ | $1.2\times10^{-6}$ | $1.5\times10^{-5}$ | $1.6\times10^{-9}$ | $1.5\times10^{-6}$ | $3.2\times10^{-7}$ | $2.5\times10^{-9}$ |
| in weakly basic media | | | | | | |
| $k$ | $k'\cdot[OH^-]$ | $k'\cdot[OH^-]$ | $k'\cdot[OH^-]^2$ | $k'\cdot[OH^-]$ | $k'\cdot\frac{[OH^-]}{[TEA]}$ | $k'\frac{[OH^-]}{[TEA]}$ |
| $k'$ | 11.3 (l./mol./sec.) | 37 (l./mol./sec.) | 52 ($l^2$/$mol^2$/sec.) | $1.1\times10^{-1}$ (l./mol./sec.) | 3.4 (l./mol./sec.) | 0.49 (ammonia) 2.7 (barbiturate) (l./mol./sec.) |
| $E_A$ (kcal.) | 25 | 27 | 25 | 25 | 22 | 29 |
| in neutral media | | | | | | |
| $k$ | | | | $k'$ | | $k'\cdot[TEA]$ |
| $k'$ | | | | $1.3\times10^{-5}$ ($sec^{-1}$) | | $9.8\times10^{-6}$ ($sec^{-1}$) |
| $E_A$ (kcal.) | | | | 19 | | 22 |
| in acid media | | | | | | |
| $k$ | $k'\cdot[H^+]^{2.4}$ | $k'\cdot[H^+]^{2.4}$ | $k'\cdot[H^+]^3$ | $k'\cdot[H^+]$ | $k'\cdot\frac{[H^+]^{1.4}}{[Cl^-]^{1.5}}$ | $k'\cdot[H^+][Cl^-]^{1.5}$ |
| $k'$ | $4.5\times10^{-3}$ ($l^{2.4}$/$mol^{2.4}$/sec.) | $1.8\times10^{-2}$ ($l^{2.4}$/$mol^{2.4}$/sec.) | $4.3\times10$ ($l^3$/$mol^3$/sec.) | $1.0\times10^{-2}$ (l./mol./sec.) | 2.7 ($l^{1.4}$/$mol^{1.4}$/sec.) | 12 (l./mol./sec.) |
| $E_A$ kcal. | 15 | 16 | 18 | 11 | 8.5 | 11 |

$$[*TlZ\cdot H_2O]+Cl^- \rightleftarrows [*TlZ\cdot Cl]^-+H_2O \quad (6)$$

$$[*TlZ\cdot Cl]^-+Cl^- \rightleftarrows [*TlZ\cdot Cl_2]^{2-} \quad (7)$$

However, when the chloride ions overwhelm the Tl-EDTA-OH complex, the $[*TlZ\cdot Cl]^-$ complex would predominate to make the relation between $R$ and $b$ simpler. The exchange reaction would proceed through the two chlorinated forms side by side:

$$[*TlZ\cdot Cl]^-+H^+ \rightleftarrows [*TlHZ\cdot Cl] \quad (8)$$

$$[*TlZ\cdot Cl_2]^{2-}+[H^+] \rightleftarrows [*TlHZ\cdot Cl_2]^- \quad (9)$$

$$[*TlHZ\cdot Cl]+[Tl\cdot Cl_x(TEA)_y]^n \rightleftarrows [TlHZ\cdot Cl]+[*Tl\cdot Cl_x(TEA)_y]^n \quad (10)$$

$$[*TlHZ\cdot Cl_2]^-+[Tl\cdot Cl_x(TEA)_y]^n \rightleftarrows [TlHZ\cdot Cl_2]^-+[*Tl\cdot Cl_x\cdot(TEA)_y]^n \quad (11)$$

At a higher pH than 4.5, the rate is too small to be measured. In the neutral region at pH near 7, the $k$ is independent of $[Cl^-]$ but dependent on [TEA]. Since TEA is present in the ammonium ion form in the pH region $<8$, its co-ordinating ability would be very small and would increase with a rise in pH. At pH values near 7, TEA in its basic form will replace co-ordinated chloride to give a rather labile mixed complex $[TlZ\cdot TEA]$ (Eq. 4).

Hence, Eq. 4 is more properly written as:

$$[TlZ\cdot Cl]^-+TEA \rightleftarrows [TlZ\cdot TEA]+Cl^- \quad (4')$$

The chloro-complexes, such as $[TlZ\cdot Cl]^-$ and $[TlZ\cdot Cl_2]^{2-}$, seem to undergo isotopic exchange only through the protonated complex as an intermediate, so the rate is very small in the pH range from 4.5 to 6.

The kinetic data of the EDTA-OH complexes are summarized in Table III. The gallium complex gives kinetics different from that of indium or thallium, but it is rather similar to the EDTA complexes of these three elements. The thallium complex gives kinetic data very similar to those of the indium complex, whereas the thallium-EDTA complex gives kinetics similar to those of the gallium-EDTA complex rather than to the indium complex. Further discussion will be given elsewhere, including the exchange data of the corresponding EDTA complexes.[7]

## Summary

1) The kinetics of the isotopic exchange of the thallium(III) EDTA-OH complex with uncomplexed thallium(III) has been studied in acid, neutral and weakly basic solutions, with $^{204}Tl$ as tracer.

7) K. Saito and M. Tsuchimoto, VIII International Conference on Co-ordination Chemistry, Vienna, 1964.

2) The exchange rate is independent of the concentration of uncomplexed thallium and proportional to that of the EDTA-OH complex, giving the relationship $R=k\cdot b$ under appropriate conditions throughout the pH range.

3) In a basic solution buffered by ammonia or barbiturate, the $k$ is proportional to $[OH^-]$ and [TEA] and is little affected by the concentration of buffers. The Arrhenius activation energy is 29 kcal./mol.

4) In a neutral solution, near pH 7, the rate is small but measurable. It is independent of the pH value but proportional to the concentration of TEA, and it is little affected by the concentration of barbiturate. The activation energy is 22 kcal./mol.

5) In an acid solution buffered by acetate, the $k$ is proportional to $[H^+]$, and $[Cl^-]^{1.5}$ and is little influenced by the concentration of acetate. The Arrhenius activation energy is 11 kcal./mol.

6) The features of the isotopic exchange of the thallium EDTA-OH complex are very similar to those of the thallium(III) EDTA complex.[5]

The author wishes to thank Dr. Kazuo Saito (Department of Chemistry, Faculty of Science, Tohoku University, Sendai) for his many helpful discussions and suggestions during this work and the Ministry of Education for its grant-in-aid.

# Adsorption of Trimethylamine, Ammonia and Pyrrole on Amorphous Silica-alumina

By Yosisato TEZUKA and Toyosaburo TAKEUCHI

(Received August 20, 1964)

It is evident from many studies[1] that the catalytic property of silica-alumina closely depends upon the nature of the acidity of its surface; the adsorption of basic gases on the catalyst has therefore been carried out to clarify the nature of the acidity from the standpoint of surface structure. The basicity of the gaseous molecule depends upon the electronegativity of the nitrogen atom of the molecule, such as trimethylamine and ammonia; the nitrogen atom of trimethylamine is regarded as being more basic than that of ammonia, since the electron cloud of three carbon atoms of the molecule concentrates more densely around the nitrogen atom than around the hydrogen atoms of ammonia. Pyrrole is considered to be neutral, because the $\pi$ electrons of the nitrogen of the compound are incorporated into the sextet and so cannot coordinate with an acid without disrupting the "aromatic sextet." Richardson and Benson[2] investigated the adsorption of trimethylamine on silica-alumina by means of a spring balance included in an adiabatic calorimeter. They presented the correlations of the acidity and the catalytic activity with the heat of the adsorption of trimethylamine. Their results, however, were ambiguous in establishing the correlation of the heat of adsorption with the coverage, a correlation which is important in determining the amount of acid point. Clark et al.[3] have obtained the heats of the adsorption of ammonia on various silica-alumina from the adsorption isotherms. It is impossible, however, to compare these results because of the differences in the preparation of these samples. The present paper will report the results of the study of the surface nature of silica-alumina by means of the adsorption of gases of different basicities, i.e., trimethylamine, ammonia and pyrrole on silica, alumina and silica-alumina.

## Experimental

The amorphous silica which was used for the column packing of the gas chromatography was furnished by the Kotaki Co. and was 120-mesh. Silica-alumina containing 2% alumina (SA-2) was

prepared in the usual way by co-precipitation from solutions of sodium silicate and sodium aluminate.

Silica-alumina containing 13% alumina (SA-13) was furnished by the Davison Chemical Co. Silica-alumina containing 26% alumina (SA-26) was furnished by the Nikki Chemical Co. It was in tablet form. Trimethylamine and pyrrole were carefully purified by means of a vacuum distillation. Ammonia was distilled by pumping it after freezing.

The apparatus used for testing trimethylamine and ammonia was the same as that described elsewhere.[4] The volume of the reaction vessel, including the McLeod gauge, was about 350 cc. An adsorption spring balance made of quartz was used for testing the pyrrole. The reaction vessel of this experiment was a modification of that used by Richardson an Benson.[2] The diameter of the reaction vessel and its length were 30 mm. and 550 mm. respectively. Helix elongation was measured by a cathetometer, giving measurements within 0.05 mm., while the sensibility $Y$ (mm.) of helix was expressed as $Y=0.220X+0.004$, where $X$ denotes the gravity (mg.) of the sample. Prior to the adsorption measurement, the sample was degassed at a constant temperature of 200 and 500°C for about 20 hr. to remove physically adsorbed water or constitutional water from the sample. After the pressure had attained the order of $10^{-6}$ mmHg, the temperature was lowered to the reaction temperature. In the cases of trimethylamine and ammonia, the gas was admitted and the decrease in pressure was followed by the McLeod gauge until the equilibrium pressure was obtained. The temperature of the reaction vessel was raised or lowered at 20-degree intervals in the range from 100 to 140°C. In the case of pyrrole, the amount of gas still remaining on the surface after the evacuation was measured using the spring balance. That is, a certain amount of pyrrole was admitted into the reaction vessel and the mixture was kept for about one hour ; then the vessel was evacuated under a constant temperature until the helix elongation indicated a constant value. The sample was changed anew for every series of adsorption studies on the sample evacuated at a certain temperature.

The BET areas were measured by means of nitrogen adsorption at −196°C. The loss of the water included in each such sample was measured by the spring balance. The titration of the acidity of silica-alumina was made in anhydrous benzene, using *p*-dimethylaminoazobenzene as an indicator in the same way as has been described by Tamele.[5]

## Results

The adsorption isotherms of trimethylamine on silica and alumina evacuated at 200 and 500°C are shown in Fig. 1. The adsorption on silica was reversible in all the regions investigated, and the Langmuir equation could be approximately adapted to the isotherms; however, it could not be adapted for the isotherms on alumina, though the adsorption occurred reversibly. Figures 2—6 show the adsorption isotherms of trimethylamine on SA-2, SA-13 and SA-26, and those of ammonia on SA-13 and SA-26, respectively. Every isotherm shows a steep rise in an initial region but then enters a region of slow rise. The dependence of the adsorption amount on the temperature in the region of steep rise was conspicuously small. The velocity of the desorption by the evacuation or by the elevation of the temperature in this region was very slow, as if the adsorption were irreversible. It was determined, however, that the adsorption of this region was reversible, because the amount of adsorption on a virgin sample was practically equal to that of the sample which had been preliminarily covered by a certain

amount of gas, if the samples were kept under the same conditions of temperature and equilibrium pressure.

The heats of the adsorption of trimethylamine on silica and alumina obtained from the isotherms by adapting the Clausius-Clapeyron equation are summarized in Fig. 7. The heat of adsorption on silica was not practically affected by the variation in the coverage and the temperature of evacuation. However, that on alumina decreased markedly with an increase in the coverage. The heats of the adsorption of trimethylamine and ammonia on silica-alumina are summarized in Figs. 8 and 9. The heats always increased

markedly with an increase in the coverage, but then decreased gradually. The coverages which gave the maximum heat varied with the samples in the order of the alumina concentration. The shift is toward the greater coverage by the elevation of the evacuation temperature. of trimethylamine and ammonia adsorbed up to the steep rise of every isotherm, and the BET areas of the samples.

## Discussion

The heat of adsorption at the region near zero coverage could not be obtained in this study because of the difficulty of accurately reading pressures of less than $10^{-4}$ mmHg. Richardson and Benson[2] have reported that the initial heats of the adsorption of trimethylamine on two kinds of silica-alumina were about 38 kcal. and 33 kcal. respectively, and that they decreased with an increase in the amount of gas adsorbed. Clark et al.[3] reported that the heat of adsorption of ammonia on silica-alumina of various compositions began at more than 40 kcal. These, and the reports published recently by other authors,[6,7] suggest that the peak of heat on silica-alumina in our study should succeed the decrease after the initial great heat. Therefore, we call the peak the "secondary peak."

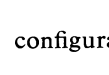

Table I indicates that the amount of gas adsorbed at the secondary peak of the heat in each silica-alumina is approximately equal to the amount of acid point measured by the titration. Such coincidence suggests that the secondary peak of the heat is caused by the complete occupation of the basic gas to both Lewis and Brønsted acid points. Beebe[8] and Rhodin[9] had found that the heat of the

6) V. Kevorkian and R. O. Steiner, *J. Phys. Chem.*, 67, 545 (1963).
7) P. Y. Hsieh, *J. Catalysis*, 2, 211 (1963).
8) R. A. Beebe and D. M. Young, *J. Phys. Chem.*, 58, 93 (1954).
9) T. N. Rhodin, *J. Am. Chem. Soc.*, 72, 5691 (1950).

physical adsorption of gas is increased by the interaction of gas near the completion of the monolayer. In our results, however, the coverage which gave the secondary peak was far less than unity. Moreover, the distance between aluminum atoms seems too large for mutual interaction due to the van der Waals force if the acid points are assumed to exist uniformly on the surface. Danforth[10] had proposed that silica-alumina is formed by the interconnecting rings of six silica tetrahedra, whose silicon atoms on the outer side are replaced by aluminum atoms keeping the distance of 5 Å. Though such a structure might be suitable for silica-alumina, the silica-alumina of our experiment should be considered to be formed by the mixture of perfect and inperfect structures, comprising the structures of pure silica and alumina. In view of the above situation, it can be proposed that the acid points, both Brønsted and Lewis acid points, exist in clusters, and that such acidic domains will be covered preferentially by basic gas at the initial stage of the adsorption. If these domains are regarded as aggregations of acidic points with different strengths, the adsorption occurs probably in an order of strength indicating a gradual decrease of heat, and the secondary peak of the heat would depend upon the mutual attraction of molecules adsorbing closely to one another.

The coverage of the secondary peak of the heat on ammonia was greater than that of trimethylamine and approached toward unity by the elevation of the evacuation temperature. These facts would reveal that ammonia is adsorbed partly on non-acid points as well as on acid points, before the completion of the monolayer on the acidic domains. Ammonia seems to adsorb more readily than trimethylamine and pyrrole on silica-alumina in virtue of the formation of a hydrogen bridge between its hydrogen atom and the lone pair electron of the oxygen of the adsorbent. Zettlemoyer and Chessick[11] proposed, as had been assumed by Young,[12] that the elevation of the evacuation temperature causes water to be removed from silica-alumina and produces surface sites of the  , where M and M* indicate silicon and aluminum atoms respectively. The increase of the oxygen on the surface would increase the amount of adsorption due to the hydrogen bridge. If the adsorption of ammonia occurs when the electron is switched to the acid point, the polarization will be accelerated by the shift of the electron of hydrogen atoms toward the nitrogen atom, and the attractive force between ammonia molecules will be strengthened; as a result, the piled-up adsorption of ammonia may be considered to occur. It is considered impossible, in view of their structure, for the hydrogen atoms of trimethylamine and pyrrole to form the hydrogen bridge.

The heat of the adsorption of trimethylamine on pure silica was approximately constant over the wide region of coverage, and it was practically the same as that of the secondary peak in silica-alumina catalysts. This fact reveals that the adsorption of trimethylamine initiated at active points, such as holes, crevices or crystal defects, as had been discussed by de Boer,[13] and spread gradually from these points to form two-dimensional layers by the van der Waals force of the adsorbing molecules. The heat of the adsorption of trimethylamine on SA-2 was approximately constant, except for the initial region of small heat. This might be explained combining the conceptions of the surface nature of silica and silica-alumina which have been proposed above. Most of the surface of SA-2 would be similar to that of silica, and the basic gas would begin the adsorption from the acid point then on the surface of the silica type, behaving in the way which has been proposed above. The correlation between the heat of trimethylamine and the coverage on alumina would reveal that the adsorption is of the chemical type, and suggests that the surface is substantially different from that of silica.

The unexpected characteristics of pyrrole in the adsorption on silica-alumina may be explained as follows. Two out of the six $\pi$ electrons in the ring of pyrrole are localized toward the nitrogen atom when it adsorbs on the acid point, and they fill one of four $sp^3$ orbitals forming a lone pair in a pyramidal configuration,  . Consequently, the nitrogen atom of pyrrole can behave like that of trimethylamine or ammonia on the surface.

## Summary

The adsorptions of trimethylamine, pyrrole and ammonia on pure silica, alumina and three silica-aluminas with (2%, 13% and 26% of alumina) have been studied. Isosteric heats have been obtained from adsorption isotherms at 100 and 120°C. A conspicuous rise, followed

by a gradual fall, was observed at an early stage of the heat curve obtained from the isotherm on silica-alumina, but not from those on silica and alumina. At the peak of the curve, the amount of the adsorption of trimethylamine agreed with that of pyrrole, both of which, again, agreed with the amount of the acid point as measured by the titration using *n*-butylamine. The amount of ammonia was twice as large as that of the acid point. The acid points of silica-alumina are assumed to exist in clusters on the surface. The rise of heat is due to the mutual interaction of the adsorbed molecules, the peak indicating the completion of the monolayer on such acid domains.

# D and $^{14}N$ Quadrupole Interaction in the Ammonium Ion of Ammonium Dihydrogen Phosphate

By Takehiko CHIBA

(Received August 25, 1964)

The deutron magnetic resonance (DMR) of $ND_4$ in a single crystal of $ND_4D_2PO_4$ (ADP) was measured in the paraelectric phase at room temperature and in the antiferroelectric phase at about $-40°C$. The $^{14}N$ resonance of ADP was also measured at room temperature. The observed quadrupole couplings are given in Table I. Lowering the temperature through the phase-transition temperature shatters a single crystal, but the fragments are held together, keeping the original crystal shape. It is known[1] that each fragment is oriented with its a or b axis parallel to the axis direction of the original high-temperature form. The spectra, therefore, correspond to a superposition of those two crystals which are oriented perpendicular to each other. It was then possible to determine $eqQ$ and the orientation of the field gradient (f. g.) tensor of the low temperature phase, except that there remains a choice of two alternatives of the a and b axes to which the f. g. tensor is referred, from the observed spectra with the help of symmetry considerations and the powder spectrum.[2]

And three other sets of f. g. direction cosines which differ from the one listed by the sign of either $a$, or $b$, or $c$ axis components.

$^{14}N$

Room temp. $eqQ/h=24.6$ kc. ($NH_4H_2PO_4$) $\eta=0$.
F. g. parallel to c axis.
$eqQ/h=27.3$ kc. ($ND_4D_2PO_4$)

* F. g. components 1, 2 and 3 are in the order of the largest absolute value.

In general, except at very low temperatures, a large part of the quadrupole coupling of the D of an $ND_4^+$ ion is cancelled because of the rapid interchanges of its four deuterons, leaving the small fraction due to the deviation from the exact tetrahedral symmetry of the ion. On some ammonium salts DMR was measured and the results compared with the calculated f. g. from the point charge approximation, assuming a net charge located at the center of $ND_4^+$. The results were not in agreement with the observed value, although the magnitude of the calculated f. g. was of the right order. In the paraelectric phase of

2) T. Chiba, *J. Chem. Phys.*, **36**, 1122 (1962).

ADP the hydrogen positions have been determined by neutron-diffraction study.[3] The point charge calculation was carried out, taking hydrogen positions into account, to see if any better result can be obtained. In the present case the f. g. at a deuteron of $ND_4^+$ is axially symmetric about the c axis, so that only the f. g. component in that direction need be considered. The calculation was made* by taking all atoms within a sphere of 46Å (6-unit-cell distance) into account, by assuming charges for $NH_4$, H (acid), and $PO_4$ of $+e$, $+e$ and $-3e$ respectively, and by assuming parameter $\alpha$ to be the fraction of $+e$ on N and $\beta$, that of $-3e$ on P ($1 \geq \alpha$, $\beta \geq 0$). For those atoms outside 25Å (3-unit-cell distance), $\alpha$ and $\beta$ are set equal to zero. The same calculation was made at a nitrogen position. For the f. g. at a hydrogen position the effect of the directly-bonded nitrogen atom was excluded. Similarly for the f. g. at a nitrogen atom, the effect of directly-bonded hydrogens was excluded. The results are given by $V_h$ and $V_{h'}$ at hydrogen and by $V_n$ at nitrogen in the following equations (in units of $e/Å^3$).

$$V_h = -0.0079 - 0.0022\alpha - 0.0903\beta \quad (1)$$

$$V_{h'} = -0.0152 + 0.0051\alpha - 0.0403\beta \quad (2)$$

$$V_n = -0.0534 - 0.0033\alpha - 0.0612\beta \quad (3)$$

$V_h$ gives the value without the contribution to f. g. from the three hydrogen atoms which are bonded to the same nitrogen atom, and $V_{h'}$, that including it. The fact that the difference between the values of the calculated f. g. for a hydrogen and for a nitrogen ($V_h$ and $V_n$) is rather large indicates the strong dependence of this quantity on the atomic coordinates. The order of magnitude of the calculated f. g. is about the same as that in the previous paper. The observed $eqQ$ of 3.4 kc. corresponds to a field gradient of ($\pm$) 0.035 if the polarization effect[2] is disregarded. This can be fitted by Eq. 1 or 2 with reasonable values of parameters $\alpha$ and $\beta$. The difficulty arises when one compares Eq. 3 with the observed values. For nitrogen, the antishielding factor is not well known. However, Kanda gave an estimate of about 47 in the state of the $NH_4^+$ ion.[4] If one assumes this value, the observed f. g. will be ($\pm$)0.0006.** Equation 3 gives far too large an f. g. with any set of $\alpha$ and $\beta$ for the experimental value to be accounted for. Point charges at the four directly-bonded hydrogen atoms make an f. g. contribution of $-0.031(1-\alpha)$ at nitrogen, which only increases the discrepancy. This means an inadequacy of the point charge approximation in the present case. The reason why it fails most likely lies in the evaluation of the contribution from the neighboring atoms. However, there might be another reason, namely, that the charge distribution is diffuse in nature, as has been noted in the crystal analysis of ammonium bifluoride,[5] so that the f. g. arising from the crystalline field is actually much smaller. Therefore, it may be more reasonable to relate the observed $eqQ$ of deuteron, simply neglecting the effect of the long-range crystalline field, as in the previous paper, to the f. g. in each N–D bond direction which deviates from that of a regular tetrahedron by 2.0° as determined by neutron diffraction. That is, $3.4\ \text{kc.} = (eq_0Q_D/h) \times 2\sqrt{2/3} \times 2.0\pi/180$, which leads to $eq_0Q_D/h = 130$ kc. Considering the facts that an N–D···O hydrogen bond is present[3] and that a hydrogen bond tends to decrease $eqQ$, this value appears reasonable. For the f. g. at nitrogen, the observed value is so small that one needs to take the f. g. contribution from the crystalline field into consideration. Then one has to assume that there is a rather accidental cancellation of this effect by that due to the electronic configuration of the $NH_4^+$ ion. This point may be cleared up if the $eqQ_N$ values of other ammonium salts are measured.

Although the displacements of atoms in the ADP crystal due to the transition from the para- to the antiferroelectric phase have been determined for heavier atoms,[6] those for the hydrogen atoms are not known. Therefore, the calculation of f. g. values for the antiferroelectric phase could not be made. However, the large quadrupole coupling seems to indicate a greater distortion of the $ND_4^+$ ion in this phase than in the paraelectric one.

# The Effect of Several Condensed Phosphates on the Dissolution of Strontium Sulfate

By Masaji MIURA and Hiromitu NAONO

(Received September 3, 1964)

The subject of the retarding action of several condensed phosphates on the crystallization of such sparingly soluble inorganic salts as strontium sulfate,[1-4] calcium carbonate[5] and calcium sulfate[6] has been investigated in our laboratory. It has been found that the retarding action is closely correlated with the adsorption of condensed phosphates on the crystal surface. In continuation of these works, we have studied the dissolution of strontium sulfate in the dilute solutions of several condensed phosphates and have found that the dissolution is considerably retarded in the presence of phosphates and inhibited almost completely under suitable conditions. Such a phenomenon as the inhibition of dissolution has not yet been investigated, however, although the retarding action of some additives on the dissolution of such crystals as lithium fluoride[7] and silver chloride[8] has been studied. In the present paper, some results will be given on the effect of condensed phosphates on the dissolution of strontium sulfate, and the mechanism of the dissolution will be discussed.

## Experimental

**Materials.**—An analytical-grade reagent of sodium dihydrogen orthophosphate was further purified by recrystallization from its aqueous solution. Sodium pyro-, tri- and trimetaphosphate were prepared and then purified by the same procedure as has been described previously.[2,5] The powder of the strontium sulfate was the same as that used in the previous work ;[2] its specific surface area was 0.29 $m^2$/g.

**Dissolution.** — The dissolution process was followed by the conductance method at 25°C. Thirty milliliters of the phosphate solution was poured into a conductivity cell and then left to reach thermal equilibrium in a thermostat ; then 1 ml. of the strontium sulfate sol was quickly added to the solution, the concentration of the sol being 1 mg. $SrSO_4$/ml. While the cell was being shaken continuously, the conductivity of the solution was measured at regular intervals.

**Adsorption.** — The adsorption of triphosphate on strontium sulfate was measured by the radio tracer method at 25°C with the aid of triphosphate labelled with $^{32}P$. A known weight of the strontium sulfate powder was then added to 30 ml. of the triphosphate solution. The rate of the adsorption was determined by measuring the decrease in the radioactivity of the solution at intervals.

## Results

The effect of ortho-, pyro-, tri- and trimetaphosphate on the dissolution of strontium sulfate is shown in Figs. 1—4, which give the increase in the specific conductance arising from the dissolution of strontium sulfate in the presence of various amounts of the phosphates. Curve A in each figure indicates the dissolution into pure water. The effect of these phosphates on the dissolution of strontium sulfate is summarized in Fig. 5, where the increase in the specific conductance after 50 min. is plotted against the phosphate concentration.

The adsorption rate of triphosphate on the surface of the strontium sulfate is shown in

## Discussion

As may be seen in Figs. 1—4, pyro- and triphosphate, even in their dilute solutions, exert a profound influence upon the dissolution of strontium sulfate, and an increase in the concentration of these phosphates brings about an increase in the retarding action until finally it practically inhibits the dissolution. Moreover, when a small amount of triphosphate is added to a system in which strontium sulfate has been dissolving in water, the dissolution of the substance is immediately and almost completely inhibited, as may be seen in Fig. 7. On the other hand, the effect of

ortho- and trimetaphosphate is not so large as that of the other phosphates.

From Fig. 5 it may be seen that the retarding action of these four phosphates increases in the order of ortho-, trimeta-, pyro- and triphosphate and that there is a great difference in the retarding action between the former two phosphates and the latter two ones. The same tendency has been observed in the retarding action of these phosphates on the crystallization of strontium sulfate.[2]

The retarding action of phosphates may be considered to be caused by the covering of the surface of particles by the phosphates adsorbed, thus preventing the escape of ions from the surface of crystal into the solution. The adsorption of phosphates on the surface of crystal seems, then, to play a predominant role in the retarding action. According to the results of the measurements of the adsorption of these phosphates on the strontium sulfate particles previously reported,[2] the adsorbed amount of tri- or pyrophosphate is much larger than that of trimeta- or orthophosphate. The results of the adsorption reveal that the retarding action on the dissolution of strontium sulfate is closely related to the adsorption of phosphates.

It is of much interest to discuss the retarding action by combining the dynamic behavior of the dissolution of strontium sulfate with the rate of the adsorption of phosphate. Let us now consider the case where 1 mg. of strontium sulfate is dissolved in 30 ml. of a solution. The initial slope of the dissolution curve in water gives the initial rate of the dissolution. From the initial rate, the increase in the concentration of strontium sulfate in the solution is calculated to be $1.9\times10^{-4}$ M per minute, where a linear relationship is assumed between the specific conductance and the concentration. On the other hand, the average area occupied per ion pair of strontium sulfate on the (001), (010) and (100) faces of its crystal was found to be 23.2 Å$^2$.[3] The suface area of 1 mg. of strontium sulfate was also found to be $2.9\times10^{-4}$ m$^2$ from its specific surface area.[2] If the outermost layer of the crystal surface dissolves into 30 ml. of the solution, it can be calculated from the above two data that the increase in the concentration of strontium sulfate is $6.9\times10^{-8}$ M. The time necessary for removing the outermost layer of the particle surface is approximately $3.6\times10^{-4}$ min., by which time the surface layer of particles is uniformly removed by the dissolution. As is shown in Fig. 6, the amount of adsorbed triphosphate increases rapidly within the first few minutes, but it needs at least more than ten minutes to reach the adsorption equilibrium.

From these results, it is clear that there is an extremely large difference between the time required to remove one layer of the crystal surface of strontium sulfate by dissolution and that required to cover the surface by a monomolecular layer of triphosphate. In spite of such a large difference between these two times, the dissolution is greatly retarded. In order to explain such facts, the following mechanism may tentatively be proposed for the dissolution of strontium sulfate.

The surface of crystal may not be uniform; the special places may play a predominant role for the dissolution. On the other hand, the fact that the adsorption isotherm of triphosphate on strontium sulfate approaches the saturation point in an extremely dilute concentration, namely, ca. $10^{-6}$ M, shows that a strong interaction exists between the surface of strontium sulfate and triphosphate. The adsorbed triphosphate may form a fairly strong bond with the strontium ions of the crystal surface, presumably forming a compound such as the surface complex. When such places as the active sites for the dissolution are covered by the adsorption of triphosphate, the dissolution may be remarkably retarded. Such places may be kinks or steps on the crystal surface, as has been presumed by Sears et al.[7] in the case of the dissolution of lithium fluoride poisoned by a trace of ferric fluoride. It may be inferred that the adsorption on the kinks or steps prefers the adsorption on the flat surface of the crystals. The probability that such places are covered increases with the increase in the concentration of triphosphate, resulting in the strong retarding action. A similar consideration may be applied to the case of pyrophosphate.

The insignificant effect of ortho- and trimetaphosphate may be attributed not only to

the small adsorption amount, but also to the weak bond between these phosphates and the crystal surface in comparison with the case of tri- or pyrophosphate.

**Summary**

The effect of ortho-, pyro-, tri- and trimetaphosphate on the dissolution of strontium sulfate has been studied. Pyro- and triphosphate remarkably retard the dissolution, even in an extremely dilute solution, while ortho- and trimetaphosphate exhibit only an insignificant effect. From the results of the measurements of the adsorption of these phosphates onto the crystal surface, it is considered that the retarding action of these phosphates is to be attributed to the adsorption. The kinetic treatments of the dissolution and adsorption lead to the conclusion that the dissolution may be controlled by the specific places on the crystal surface and that such places may be the rate-determining sites for the dissolution.

## The Synthesis of Ethyl 4-Carbethoxy-3-keto-2-tetrahydrothiophenevalerate, the Synthetic Intermediate of Biotin

By Hirozo SEGAWA and Eiji IMOTO

(Received June 15, 1964)

Biotin has previously been synthesized by Cheney and his co-workers through the diethylester of 4-carboxy-3-keto-2-tetrahydrothiophenevaleric acid[1] and by Baker and his coworkers through the corresponding dimethylester.[2] Although these synthetic intermediates were prepared by the same investigators, many steps were involved in their methods, and hence the yields were poor.

This paper will describe an improved method of synthesizing ethyl 4-carbethoxy-3-keto-2-tetrahydrothiophenevalerate, a method in which five steps are involved, as is shown in Fig. 1.

The starting compound, cyclohexanone, was first converted to 2-carbethoxycyclohexanone (II) and then to 6-bromo-2-carbethoxycyclohexanone (III) by Brenner's method.[3] Compound III condensed readily with ethyl β-mercaptopropionate in the presence of sodium ethoxide to produce 2-carbethoxy-6-(β-carbethoxyethylthio)cyclohexanone (IV), which gave an intense purple color with ferric chloride in ethanol.

The treatment of IV with a strong alkali gave a ring-opening product, 2-carboxyethyl 1,5-dicarboxyamyl sulfide (V), along with a by-product, 2-(β-carboxyethylthio)cyclohexanone (IX). The isolation and purification of V and IX were not attempted in this step, since their boiling points were too high for them to be distilled, even under reduced pressure. The esterification of a mixture of V and IX gave the corresponding esters, 2-carbethoxyethyl 1,5-dicarbethoxyamyl sulfide (VI) and 2-(β-carbethoxyethylthio)cyclohexanone (X). The by-product, X, was identified by means of a comparison of its infrared spectrum and the melting point of its 2,4-dinitrophenyhydrazone with those of an authentic sample prepared from 2-chlorocyclohexanone (VIII) and ethyl β-mercaptopropionate, as is shown in Fig. 2.

The yields of VI and X varied to some

extent in each experiment. Compound VI was obtained in a 64% yield based on IV under the reaction conditions described in the "Experimental" section.

The Dieckmann cyclization of VI was performed by Cheney's method to produce VII. The melting point of its copper chelate compound agreed satisfactorily with the literature value.[1]

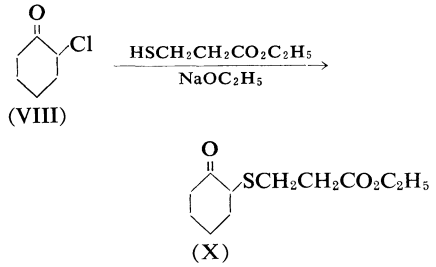

Fig. 2.

## Experimental*

**2-Carbethoxy-6-(β-carbethoxyethylthio)-cyclohexanone (IV).** — To a solution of sodium ethoxide (4.6 g. of sodium and of 70 ml. absolute ethyl alcohol), a solution of 27 g. of ethyl β-mercaptopropionate in 10 ml. of absolute ethyl alcohol was added. After this mixture had been cooled in a dry ice-acetone bath to −20°C, a solution of 50 g. of 6-bromo-2-carbethoxycyclohexanone in 20 ml. of ethyl alcohol was stirred drop by drop into the mixture under nitrogen. After the addition had been completed, stirring was continued for two hours at room temperature. During this period sodium bromide precipitated. After it had stood for fifteen hours at room temperature, the mixture was concentrated under reduced pressure to about 70 ml. The residue was poured into water, and the oily layer obtained was separated. The aqueous layer was then extracted three times with ether. The oily compound and the extracts were combined, washed with sodium bicarbonate solution, and dried over sodium sulfate. The ether was removed, and the residue was distilled to give 51 g. (84%) of IV as a colorless oil; b. p. 141—142°C/0.1 mmHg.

Found: C, 55.67; H, 7.42. Calcd. for $C_{14}H_{22}O_5S$: C, 55.61; H, 7.33%.

**2-Carbethoxyethyl 1,5-Dicarbethoxyamyl Sulfide (VI).**—In a 300 ml. three-necked flask equipped with a stirrer, a dropping funnel, a reflux condenser, a gas inlet tube and a thermometer were placed 50 g. of sodium hydroxide, 40 g. of water and 110 g. of ethyl alcohol. The stirred mixture was then heated for half an hour in a water bath at 50°C under nitrogen. A solution of 20 g. of 2-carbethoxy-6-(β-carbethoxyethylthio)cyclohexanone in 40 ml. of ethyl alcohol was then added to the mixture over a period of twenty minutes. The resulting mixture was heated further for five hours at 50°C. After this mixture had been diluted with 100 ml. of water, ethyl alcohol was removed under reduced pressure. The residue was washed with 50 ml. of ether, and the aqueous layer was made acidic to Congo red with concentrated hydrochloric acid. The mixture was continuously extracted with ether for forty hours, and the extract was dried over sodium sulfate. The ether was removed, and the residual, thick, oily compound was dissolved in 150 ml. of absolute ethyl alcohol. The solution was cooled in an ice-bath, saturated with dry hydrogen chloride, and refluxed for half an hour. Ethyl alcohol was then evaporated to about 50 ml. The residue was diluted with 200 ml. of water, and the oily compound obtained was separated. The aqueous layer was extracted with ether. The oily compound and the extracts were combined and washed with a sodium bicarbonate solution and then with water.

After the ether had been removed, the VI, distilling at 178.5—180°C/0.25 mmHg., weighed 14.8 g. (64%). The redistillation of the lower boiling

* All boiling and melting points are uncorrected.

distillate gave 1.9 g. (13%) of 2-(β-carbethoxyethylthio)cyclohexanone, b. p. 149—151°C/1 mmHg.

**2-(β-Carbethoxyethylthio)cyclohexanone (X).** — To a solution of 3.5 g. of sodium in 80 ml. of absolute ethyl alcohol, 20 g. of ethyl β-mercapto-propionate in 10 ml. of ethyl alcohol was added. To the stirred solution 20 g. of 2-chlorocyclohexanone in 40 ml. of ethyl alcohol was then added over a period of half an hour while the temperature was maintained at −20°C. After it had stood for fifteen hours at room temperature the mixture was diluted with 300 ml. of water and extracted three times with ether. The combined extract was then washed successively with aqueous sodium bicarbonate and dilute hydrochloric acid. After the ether had been removed, 31 g. (89%) of an oil was obtained; b. p. 151—152°C/1 mmHg.

Found: C, 57.48; H, 8.02. Calcd. for $C_{11}H_{18}O_3S$: C, 57.36; H, 7.88%.

The 2,4-dinitrophenylhydrazone prepared in the usual manner was separated as orange-yellow crystals from ethyl alcohol; m. p. 103—104°C.

**Ethyl 4-Carbethoxy-3-keto-2-tetrahydrothiophenevalerate (VII).** — According to the method of Cheney,[3] 3 g. of 2-carbethoxyethyl-1,5-dicarbethoxyamylsulfide (VI) in dry benzene was treated with sodium ethoxide at room temperature. The light-brown oil thus obtained gave a deep-red color when treated with ferric chloride in an alcoholic solution. The oil was converted into a copper chelate compound by treating it with a saturated cupric acetate solution. The recrystallization of the chelate compound from ether-petroleum ether yielded 2.6 g. (90.5%) of fine, light-green crystals, m. p. 120—121°C.

Found: C, 50.60; H, 6.55. Calcd. for $(C_{14}H_{22}O_4S)_2$-Cu: C, 50.32; H, 6.63%.

The authors are indebted to Mr. Noboru Matsumura for the microanalyses.

# Recalculation of the Bond Moments and the Bond Derivatives of the Dichloromethane Molecule

By Utako KANBAYASHI*1 and Kenkichi NUKADA*2

(Received August 19, 1964)

Straley[1] measured the absolute intensities of perpendicular bands of dichloromethane in vapor, expessed $\partial\mu/\partial Q_i$ (where $\mu$ is the dipole moment and $Q_i$ is the normal coordinates of the molecule) in terms of the bond moments ($\mu_{CH}$, $\mu_{CCl}$) and the bond derivatives ($(\partial\mu/\partial r)_{CH}$ and $(\partial\mu/\partial r)_{CCl}$), and calculated the values of the bond moments and the bond derivatives. (The results are given in column I of Table I.) In this case, one half of the observed intensity of the doublet centered at 2995 $cm^{-1}$, was allotted to the intensity of $\nu_6$ (the antisymmetrical stretching vibration).

Several recent studies[2-5] have shown, however, that it is reasonable to assign the doublet centered at 2995 $cm^{-1}$ to the P and R branch maxima of $\nu_1$ (the symmetrical stretching vibration) and that $\nu_6$ is not observed because of its very weak intensity in vapor. The present authors have, therefore, recalculated the bond moments and the bond derivatives by using the new assignment; the method is described below, and the results are shown in Table I.

1) The values in column II are the result of the recalculation made by following the process of Ref. 1 except that $A_6$ is set at zero. These values agree with those in column I except that the absolute value of $(\partial\mu/\partial r)_{CH}$ is smaller than that in column I.

2) When the above calculations (Ref. 1 and 1)) were made, it was assumed that the vector sum of the all bond moments obtained by infrared work was equal to the total dipole moment determined by dielectric measurements. However, this assumption is not valid, particularly if there are lone-pairs present, as Coulson indicated.[6] Therefore, the recalculation was made without using this assumption. The results are shown in column III.

3) Finally, the authors made more rigorous

TABLE I. BOND MOMENTS AND BOND DERIVATIVES OF THE DICHLOROMETHANE MOLECULE CALCULATED FROM THE PERPENDICULAR BANDS

| | I | II | III | IV |
|---|---|---|---|---|
| $A_6$ (c. p. s./cm. at NTP) | $48.0\times10^{10}$ | 0 | 0 | 0 |
| $\mu_{CH}$ ($D$) | +0.45 | +0.45 | +0.60 | +0.58 |
| $\mu_{CCl}$ ($D$) | −0.95 | −0.95 | −1.4 or −3.0 | −1.4 or −3.0 |
| $(\partial\mu/\partial r)_{CH}$ ($D/A$) | +0.3 or −0.2 | +0.06 | +0.09 or +0.24 | +0.11 or +0.23 |
| $(\partial\mu/\partial r)_{CCl}$ ($D/A$) | +3.7 | +3.7 | ±3.8 | ±4.5 |

calculations of $\partial\mu/\partial Q_i$ by using the newest data on the normal vibrations of the dichloromethane molecule[7] and so got the following relations:

$$\pm\frac{\partial\mu}{\partial Q_6} = 1.679x + 95.525x' + 7.444y \quad (3081\ \mathrm{cm}^{-1}) \quad (1)$$

$$\pm\frac{\partial\mu}{\partial Q_7} = 54.539x + 4.458x' + 14.625y \quad (901\ \mathrm{cm}^{-1}) \quad (2)$$

$$\pm\frac{\partial\mu}{\partial Q_8} = 108.708x + 2.085y + 0.496y' \quad (1264\ \mathrm{cm}^{-1}) \quad (3)$$

$$\pm\frac{\partial\mu}{\partial Q_9} = 18.602x + 6.518y + 28.182y' \quad (747\ \mathrm{cm}^{-1}) \quad (4)$$

$$\pm\frac{\partial\mu}{\partial Q_1} = 11.661x + 62.514\chi' + 3.504y + 2.637y' \quad (3019\ \mathrm{cm}^{-1}) \quad (5)$$

where $x=\mu_{CH}$ (Debye), $x'=(\partial\mu/\partial r)_{CH}$ (Debye/Å), $y=\mu_{CCl}$ (Debye), and $y'=(\partial\mu/\partial r)_{CCl}$ (Debye/Å). (The numbers in parentheses reprsent the calculated frequencies.)

After Straley's observed values of $\partial\mu/\partial Q_7$ (±11.7), $\partial\mu/\partial Q_8$ (±63.1) and $\partial\mu/\partial Q_9$ (±123.0), and zero for $\partial\mu/\partial Q_6$ had been introduced into Eqs. 1—4, the bond moments and the bond derivatives for the perpendicular bands were calculated; they are given in column IV. It is interesting that the values of column IV based on the more accurate data agree approximately with those of column III.

The value of $\partial\mu/\partial Q_1$ calculated from Eq. 5 using the values in column IV was 20—25 (if $(\partial\mu/\partial r)_{CCl}=+4.5\ D/A$) or $\partial\mu/\partial Q_1=-3--2$ (if $(\partial\mu/\partial r)_{CCl}=-4.5\ D/A$). Neither of these values coincides with the value determined from the intensity of the doublet centered at 2995 $\mathrm{cm}^{-1}$ observed by Straley[1] (±32). In this case, the values of the bond moments and the bond derivatives calculated from the perpendicular bands are different from those calculated from the parallel bands, as has previously been pointed out.[8-10]

# The Spectrophotometric Determination of Anions by Solvent Extraction with Metal Chelate Cations. VII.* A New Method for the Determination of Pentachlorophenol

By Yuroku YAMAMOTO, Keiya KOTSUJI and Sadayasu TANAKA

(Received August 21, 1964)

In the course of our study of the solvent extraction of an anion with a metal chelate cation,[1] it has been observed that not only inorganic anions, such as iodide, perchlorate and tetra-iodo-mercury(II) or cadmium, but also organic anions, such as trichloroacetate, or pentachlorophenolate (PCP), can be extracted into an organic solvent as nitrobenzene if the aqueous solution contains an excess of phenanthroline or dipyridyl iron(II) chelates cations.

This study will present a method for the determination of PCP based on solvent extraction with the tris-phenanthroline iron(II) chelate. Figure 1 shows the absorption spectra of the extracts against nitrobenzene as a reference. Curve 1 is a spectum of the extracts with PCP, while curve 2 is that of the extract when PCP is absent. It is shown that, when a small amount of PCP is present, the chelate cation is quite extractable into the organic layer. The absorbance maximum of the associated species, which may be assumed to be $[Fe(phen)_3][PCP]_2$, is found at 514 mμ. A maximum extraction is obtained in the range of pH 6.0—12.0, when the molar concentration of the chelate is kept five times that of PCP. The recommended procedure for the calibration curve is as follows.

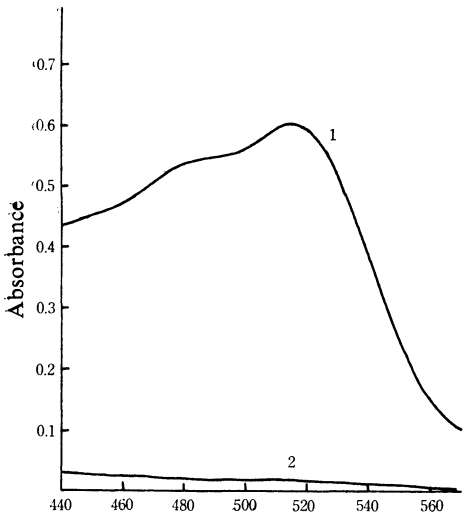

Fig. 1. Absorption spectra (reference: nitrobenzene).
Curve 1: Spectrum of organic phase extracted from the aqueous solution (25 ml.) containing $[Fe(phen)_3](2\times10^{-4}$ M), borax ($1\times10^{-2}$ M) and PCP ($4\times10^{-5}$ M), pH 10.0.
Curve 2: Spectrum of organic phase extracted from the aqueous solution (25 ml.) containing $[Fe(phen)_3](2\times10^{-4}$ M), borax ($1\times10^{-2}$ M), but PCP is absent, pH 10.0.

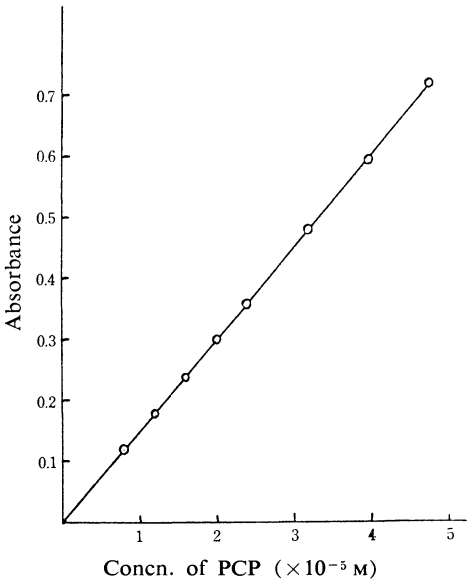

Fig. 2. Calibration curve at 514 mμ. $[Fe(phen)_3]^{2+}$ ($2\times10^{-4}$ M), borax ($1\times10^{-2}$ M), PCP ($8\times10^{-6}$—$5\times10^{-5}$ M), pH 10.0, reference: reagent blank

Mix 5 ml. of a tris-phenanthroline-iron(II) sulfate solution ($1\times10^{-3}$ M), 5 ml. of a borax buffer solution ($5\times10^{-2}$ M, pH 10.0), and varying amounts of the standard PCP solution, and then dilute to 25 ml. with distilled water. Shake the solution with 10.0 ml. of nitrobenzene (3 min.). Transfer the organic layer to a flask containing 1 g. of anhydrous sodium sulfate, and measure the absorbance at 514 mμ

* VI: K. Kotsuji, This Bulletin, 38, 402 (1965).
1) Y. Yamamoto et al., ibid., 37, 434, 594, 785 (1964).

using a reagent blank as a reference. Beer's law is followed in the range from $8\times10^{-6}$ to $5\times10^{-5}$ M. The presence of diverse ions, such as chloride, phosphate, sulfate and nitrate does not interfere with the determination, even when their amounts are about 1000 times that of PCP, but the same amount of tetrachlorophenol as that of PCP gives a slight positive error.

Although several methods,[2-4] based on the colorimetric estimation of the product obtained by the oxidation of PCP, have recently been reported, the method proposed here is based on a different mechanism of the color development and has a higher sensitivity and a better accuracy.

# The Application of Brown Reduction to an $\alpha, \beta$-Unsaturated Keto-steroid

By Hisao NAKATA

(Received August 25, 1964)

Recently Brown and Brown[1,2] have reported a simple and convenient procedure for the catalytic hydrogenation of olefins[3-5] and aromatic nitro compounds.[6] The method utilizes the new active platinum metal catalysts prepared by the in situ treatment of platinum metal salts with sodium borohydride.[3,4,7] It is of interest to examine whether or not the Brown reduction may be undergone also with olefins that have other functional groups, such as oxo or formyl groups. We now wish to report a successful application of the Brown reduction to the double bond of an $\alpha, \beta$-unsaturated keto-steroid.

The platinum metal catalyst was prepared as reported,[5] and the reaction was tested with $\Delta^{16}$-5$\alpha$-pregnene-3$\beta$-ol-20-one, using sodium borohydride and acetic acid as a hydrogen source. At room temperature, the absorption of hydrogen took place smoothly, and the expected saturated ketone, 5$\alpha$-pregnane-3$\beta$-ol-20-one, was obtained in a good yield.

The results indicate that the Brown reduction may be expected to be applicable to a wide variety of compounds that have functional groups susceptible to reduction with sodium borohydride.

## Experimental

The procedure of the reduction followed that of Brown and Brown.[5] The platinum catalyst was prepared by adding 3 ml. of a standard stabilized solution of sodium borohydride[5] to an ethanolic solution of chloroplatinic acid (0.120 g./10 ml.). After the mixture had been acidified with 5 ml. of acetic acid, the solution of 0.442 g. (1.40 mmol.) of $\Delta^{16}$-5$\alpha$-pregnene-3$\beta$-ol-20-one (m. p. 207—208°C) in 20 ml. of ethanol was added and the reduction was carried out by adding 10 ml. of a 0.203 M solution of sodium borohydride in ethanol.

After it had been stirred for two hours, the reaction mixture was filtered to remove the catalyst and then concentrated to 25 ml. under reduced pressure. The solution was diluted with 30 ml. of ether and washed with a dilute sodium hydroxide solution. The evaporation of the solvent gave 0.427 g. of a white solid. Recrystallization from aqueous methanol afforded 0.425 g. of colorless needles; m. p. 189—190°C. Yield, 96%.

In order to remove a persistent impurity, 0.272 g. of this material in benzene was chromatographed on 10 g. of Florisil (10×150 mm.-column). Fractions eluted with 2% acetone-benzene were collected, and the removal of the solvent gave 0.251 g. of the white solid. Recrystallization from aqueous methanol yielded 0.210 g. of a pure specimen of 5$\alpha$-pregnane-3$\beta$-ol-20-one as colorless needles; m.p. 193—194°C. $\nu_{max}^{CHCl_3}$ 1708 cm$^{-1}$. The reported m.p. of 5$\alpha$-pregnane-3$\beta$-ol-20-one (17-normal, i.e., 17$\alpha$-H) is 194°C.[8,9]

# ESR Studies of the Reactions of Triphenylamine with Alkali Metals

By Masamoto IWAIZUMI and Taro ISOBE

(Received August 26, 1964)

In secent years, many organic radicals have been prepared by reactions of the conjugated compounds with alkali metals in tetrahydrofuran (THF), 1, 2-dimethoxyethane (DME) and in solvents with similar properties.[1] Most of these radicals have been shown to be anion radicals formed by the transfer of an electron from the alkali metals to the conjugated compounds, and ESR studies of these radicals have yielded much interesting information about these molecules.

This work was undertaken to study the reactions of triphenylamine with alkali metals in DME and THF by ESR techniques. It has been found that the reactions are not simple one-electron reductions but that they proceed through the cleavage of C-N bonds and the subsequent recombination to yield a biphenyl anion radical as one of the reaction products.

## Experimental and Results

The reactions of triphenylamine with alkali metals (lithum, sodium and potassium) were undertaken in THF or DME as a solvent in vacuo. The reactions at $-70°C$ and at room temperature gave the same results. It was observed that, if a solution of triphenylamine in THF or DME was allowed to contact with an alkali metal, a deep green solution was obtained, a solution which exhibited an ESR absorption as is shown in Fig. 1. The measurements of ESR spectra were carried out with a Hitachi X-band ESR spectrometer, model MPU-3B, employing a field modulation at a frequency of 100 kc./s.

The spectrum can be explained by the couplings with three sets of equivalent protons, via., the coupling with two equivalent protons with the coupling constant of 5.33 gauss, four equivalent protons which have half the coupling of the former, and four equivalent protons with a smaller coupling constant, 0.43 gauss. Namely, the hyperfine structure can be interpreted as arising from the protons of two benzene rings, and no structures resulting from a nitrogen nucleus and the remaining five protons are evident. Recently, Hanna[2] has

reported that the odd-electron distribution in the triphenylphosphine anion is restricted to one benzene ring, and that the ESR spectrum can be interpreted by assuming the couplings with a phosphine nucleus and only four protons. He attributed this to the Jahn-Teller distortion. In the case of triphenylamine, because of its threefold symmetry, its anion radical was expected to be subjected to the Jahn-Teller distorsion. However, the ESR spectrum of the radical formed from triphenylamine agrees well with that of the biphenyl anion radical already reported by Carrington et al.[3]

We also observed the electronic absorption spectrum of the product formed upon the reaction of triphenylamine with potassium and that of the biphenyl anion radical obtained by the reduction with potassium using THF as a solvent. As Fig. 2 shows, the two spectra resemble each other very closely except that the spectrum of the reaction product triphenylamine exhibits an additional absorption at 430 mμ.

Gilman et al.[4] have reported that triphenylamine is cleaved by lithium at reflux in THF to yield, upon carbonation, diphenylamine in a low yield. However, from the agreement of the ESR and the electronic absorption spectra of triphenylamine with those of the biphenyl anion radical, it seems most reasonable to conclude that the radical formed on the reactions of triphenylamine with alkali metals under our experimental conditions was the biphenyl anion radical, though the mechanism of the reactions is unknown to us at the present time. The additional absorption band at 430 mμ of the reaction product of triphenylamine must be due to some other species.

Also, in the case of tri-*p*-tolylamine, the radical formed on the reactions with alkali metlas was the anion radical of the biphenyl derivative, the *p,p'*-bitolyl anion radical; its ESR spectrum, which is shown in Fig. 3, was identical with that of the *p,p'*-bitolyl anion radical previously reported by Ishizu.[5]

## SHORT COMMUNICATIONS

# Ein neues Pteridin aus *Bombyx mori lem*

Von Miki GOTO, Masaki KONISHI und Motoo TSUSUE

(Eingegangen am 3. Dezember, 1964)

Aus 400 g Epidermis von *Bombyx mori lem* konnten 2 mg eines intensiv grün fluoreszierenden neuen Pteridins (I) isoliert werden. Die Ultraviolett Spektren von I sind mit denen von 2-Amino-4-hydroxy-6-lactoyl-7, 8-dihydropteridin (Sepiapterin)[1] sehr ähnlich. Bei der Behandlung mit Natriumborhydrid und der Rückoxydation mit Luft entstehen drei fluoreszierende Stoffe II, III und IV. III ist eine Säure; beim Erhitzen (250°C, 3 Std) entsteht II. Bei der Behandlung mit $KMnO_4$ oder $KJO_4$ sowie durch Bestrahlung oder Behandlung mit Natronlauge wird die Substanz I leicht zu III oxydiert; dies wird durch Papierchromatographie, Dünnschichtchromatographie und Elektrophorese festgestellt. II sowie III sind jeweils sehr ähnlich mit 2-Amino-4-hydroxypteridin und mit 2-Amino-4-hydroxy-pteridin-6-carbonsäure, jedoch nicht identisch. Es wird hierbei zum Vergleich 2-Amino-4-hydroxy-8-methylpteridin V durch Kondensation von 2,5-Diamino-4-methylamino-6-hydroxypyrimidin und Glyoxal hergestellt. Ebenfalls wird 2-Amino-4-hydroxy-8-methyl-pteridin-6-carbonsäure (VI) durch Kondensation von 2,5-Diamino-4-methylamino-6-hydroxypyrimidin und $\beta$-Bromobrenztraubensäure synthetisiert. Es werden keine Unterschiede in den Ultraviolett Spektren (Abb. 1), $R_f$-Werten und dem elektrophoretischen Verhalten (s. unten) zwischen dem synthetischen Material und dem durch Hydrierung erhaltenen Produkt (II oder III) beobachtet. Diese Tatsachen zeigen, dass die Substanz I ein 6-Derivat des 2-Amino-4-hydroxy-8-methylpteridins ist. Beim Schütteln von I mit 5% iger Boraxlösung ergibt sich Milchsäure und ein gelb fluoreszierender Stoff VII. Die Ultraviolett Spektren von VII sind fast identisch mit denen von 7,8-Dihydroxanthopterin.[2] Die Menge der dabei entstandenen Milchsäure wird spektrophotometrisch bestimmt;[3] ein Mol Milchsäure entsteht aus 1 Mol von I (Molekulargewicht als 251 gerechnet). Aufgrund dieser Ergebnisse wird die Konstitution 2-Amino-4-hydroxy-6-lactoyl-8-methyl-7, 8-dihydropteridin für I vorgeschlagen. IV und VII sind nicht identifiziert, jedoch kommen dazu wahrscheinlich die Konstitutionen von 8-Methyl-7, 8-dihydrobiopterin und 8-Methyl-7, 8-dihydroxanthopterin.

# Chemical Effects Following the Isomeric Transition of $^{80m}Br$ in Pentamminecobalt(III) Bromides

By Nobufusa SAITO, Shizuko ITO and Takeshi TOMINAGA

(Received December 9, 1964)

In the course of an investigation of the behavior of hot radiobromine atoms produced by (n, $\gamma$) reaction in cobaltammine bromides, two of the present authors (N. S. and T. T.) found that the percentage of such energetic radiobromine atoms finally complexed with cobalt (i.e., the ligand yield) was related to the chemical or physical properties of the ligands in the target complexes.[1] In order to clarify the mechanism of such recoil reactions, it seemed worthwhile to compare chemical effects following different nuclear reactions. Therefore, they have studied the recoil reactions following the isomeric transition of $^{80m}Br$ in $^{80m}Br$-labeled cobaltammine bromides and have compared the results with those obtained with (n, $\gamma$) reaction.

TABLE I. LIGAND YIELD OF $^{80}Br$ PRODUCED IN ISOMERIC TRANSITION OF $^{80m}Br$

| No. | $^{80m}Br$-labeled complex salt | Ligand yield, % In dry ice-ethanol | Ligand yield, % In liquid nitrogen |
|---|---|---|---|
| 1 | $[Co(NH_3)_6]Br_3$ | 7.6±1.7 | 7.5±0.4 |
| 2 | $[Co(NH_3)_5NCS]Br_2$ | 6.1±0.9 | 4.9±0.9 |
| 3 | $[Co(NH_3)_5NO_2]Br_2$ | 6.1±1.3 | 7.8±0.3 |
| 4 | $[Co(NH_3)_5OH_2]Br_3$ | 10.9±2.1 | 9.5±1.0 |
| 5 | $[Co(NH_3)_5ONO]Br_2$ | 6.7±1.4 | 10.0±0.7 |

The ten kinds of pentamminecobalt bromides listed in Tabel I have been investigated.* The $^{80m}Br$-labeled bromide of each complex was precipitated from an aqueous solution by the addition of radioactive ammonium bromide irradiated in a nuclear reactor, filtered, washed

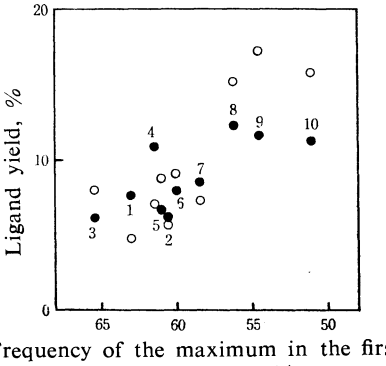

Fig. 1. The relationship between the ligand yield and the frequency of the maximum in the first absorption band.
● Isomeric transition; ○ (n, $\gamma$) reaction
Numbers in Fig. 1 correspond to those in Table I.

* Bisethylenediaminecobalt bromides, $[Co(en)_2X_2]Br_{1,3}$, have also been studied, and apparent ligand yields of about 2—10%, obtained. Unlike as in pentamminecobalt bromides, however, it appears that 2—5% of $^{80}Br$ is not complexed with cobalt but presumably bound in the ligand molecule (i.e., the ethylenediamine molecule).

and dried in air. After it had stood for 3 hr. in a mixture of dry ice and ethanol, or in liquid nitrogen, each salt was dissolved in water at 0°C, and cations (radiobromine complexed as ligands) and anions (bromide ions) were separated by means of ion-exchange resins. The radioactivities in both fractions were measured with a G-M counter, and the distribution of $^{80}Br$ was determined.

Table I shows the percentage of $^{80}Br$ complexed with cobalt (i.e., the ligand yield). For convenience of comparison, the ligand yields of radiobromine obtained in the (n, $\gamma$) reaction and the isomeric transition are plotted together in Fig. 1 against the frequency of the maximum in the first absorption band of the complex ion. The results may be summarized as follows:

1) Regarding the relationship between the ligand yield and the stability of the ligand, the ligand yield of $^{80}Br$ produced in the isomeric transition also tends to increase with the decrease in the frequency of the maximum in the first absorption band. Although this trend is very similar to that observed in the case of the (n, $\gamma$) reaction, the inclination is less pronounced for the former than for the latter.

2) Comparing ligand yields in the two reactions for the same salt, a higher ligand yield is generally obtainable in the (n, $\gamma$) reaction.

3) No remarkable difference is found between ligand yields obtained after storage in dry ice - ethanol and in liquid nitrogen.

# The Radiolysis of Cobaltammine Complexes

By Nobufusa SAITO and Takeshi TOMINAGA

(Received December 12, 1964)

It has been found that the recoil and subsequent reactions in cobaltammine complexes irradiated with thermal neutrons are greatly influenced by such chemical factors as the chemical composition and stability as ligand of the outer anion.[1] Although a systematic study of the stability with regard to the ionizing radiations of these complex is also needed for the purpose of elucidating the intricate mechanism of such reactions, very few investigations have so far been made of the radiolysis of cobalt complexes in the solid state.[2,3] Therefore, the present authors have studied the radiolysis of the 23 kinds of crystalline cobaltammine complexes listed in Table I.

The cobaltammine complexes were irradiated with Co-60 gamma rays at an ambient temperature and at a dose rate of about $1.6\times10^5$ r./hr., up to a total dose of about $2\times10^8$ r., in

TABLE I. $G(Co^{2+})$ VALUES OF COBALTAMMINE COMPLEXES

the presence of air. After irradiation, each complex was dissolved in water, and the cobalt-(II) present in the solution was determined spectrophotometrically, by means of solvent extraction into chloroform, as β-nitroso-α-naphtholato-complex. The $G(Co^{2+})$ values obtained are shown in Table I. For convenience of comparison, the $G(Co^{2+})$ values of nitroamminecobalt complexes are plotted against the number of $NO_2$ groups contained in ligands of a complex in Fig. 1, while the $G(Co^{2+})$ values of pentamminecobalt complexes are plotted against the frequency of the maximum in the first absorption band in Fig. 2.

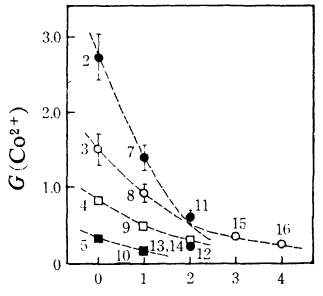

Fig. 1. The $G(Co^{2+})$ value of nitroammine complexes.
-●- Nitrates ; -○- Nitrites ;
-□- Chlorides ; -■- Bromides
(Numbers in Figs. 1 and 2 correspond to those in Table I.)

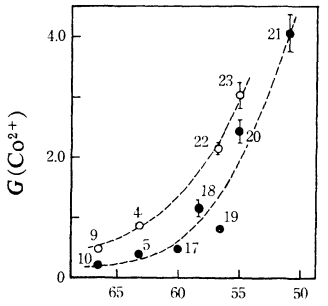

Fig. 2. The $G(Co^{2+})$ value of pentammine complexes.
-●- $[Co(NH_3)_5X]Br_{2,3}$
-○- $[Co(NH_3)_5X]Cl_{2,3}$

The following conclusions may be drawn from the experimental results:

1) For a series of nitroammine complexes which contain the same outer anion (those plotted on the curves in Fig. 1), the $G(Co^{2+})$ value decreases with the increase in the number of $NO_2$ groups in the ligands. Hence, it may be tentatively assumed that the stability of nitroammine complexes towards gamma irradiation increases with the increase in the thermodynamic stability of these complexes.[4]

2) For a series of pentammine complexes containing the same outer anion and a different acidic ligand, X ($[Co(NH_3)_5X]Br_{2,3}$ and ($[Co(NH_3)_5X]Cl_{2,3}$), the $G(Co^{2+})$ value decreases with the increase in the stability in the spectrochemical series.

3) In a group of salts composed of the same complex cation and a different outer anion, the $G(Co^{2+})$ value is greatly affected by the kind of outer anion. For hexammine complex salts, the $G(Co^{2+})$ value increases with the variation in the outer anion in the order: $I < Br < Cl < NO_2 < NO_3 < F$. For nitropentammine and other complex salts, the $G(Co^{2+})$ value increases in a similar order.

# The Reduction of Gamma-Irradiated Nickel Oxide by Hydrogen

By Toshiro YAMASHINA and Takaaki NAGAMATSUYA

(Received December 23, 1964)

In the process of reducting nickel oxide by hydrogen, it has been observed by several investigators that the reduction started after an induction period.[1-3] According to Hauffe,[1] the induction period should correspond to the period required for the nuclei formation of metallic nickel. Parravano[2] investigated the reduction process of nickel oxide from the view point of the electronic state of the semiconductor. Because the nickel oxide is a p-type semiconductor containing excess oxygen, it may be expected that the reduction process of nickel oxide could be affected by its physical properties, such as the electronic state and its non-stoichiometry. In this work, a gamma-irradiated nickel oxide will be found to behave in an unusual manner in the reduction process by hydrogen, depending upon the radiation dose.

Pure nickel oxide samples were obtained by decomposing and firing c. p. nickel nitrate in an atmosphere of air for five hours at 500°C. The reduction velocities were measured in an all-glass, closed system of a Gulbransen-type microbalance[4] with a sensitivity of $7.21\times10^{-7}$ g./div. The reaction temperature was 190°C

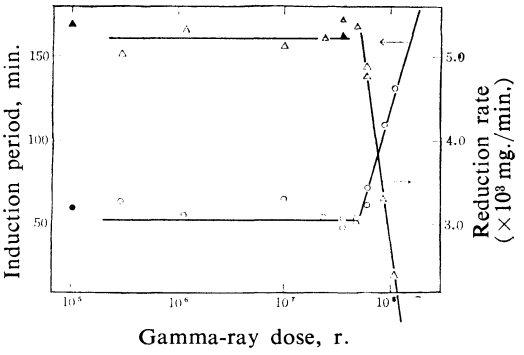

Fig. 2. Induction period and reduction rate as a function of irradiation dose.

▲, ● not irradiated

and the hydrogen pressure, 60 mmHg. The hydrogen used in these experiments was prepared by diffusing it through a palladium film. The irradiation was carried out with Co-60 gamma-rays, the intensity of which was $5.85\times10^5$ r./hr.; the total dose reached about $2\times10^8$ r.

The reduction curves of the irradiated nickel oxide are presented in Fig. 1. The reduction velocities were found to decrease with the radiation dose, being remarkable over a total dose of $5.8\times10^7$ r. The induction periods and the reduction rates are plotted as a function of the irradiation dose in Fig. 2, for which the induction periods were obtained by extraporating the curves in Fig. 1 to the time axis while the reduction rates were estimated from the slope of the linear part after the induction period. It is to be noted that both values changed abruptly at irradiation doses above $5\times10^7$ r. In order to explain the above phenomena, other measurements with a change of irradiation dose were made. The measurement of chemisorbed oxygen by means of iodometry[5,6] showed the same tendency as that in the induction periods and the reduction rates with irradiation; in other words, no change in the excess oxygen in nickel oxide was revealed up to irradiation dose of $5\times10^7$ r., while an abrupt increase of excess oxygen was

observed above $1\times10^8$ r. The excess oxygen in nickel oxide was found to be 0.04—0.05 atm. % in the case of both unirradiated and irradiated less than $5\times10^7$ r., while 0.12 atm. % in that of $2\times10^8$ r. irradiated. No differences in BET surface area were observed in any case.

On the basis of results presented above, it may be concluded that the reduction of nickel oxide by hydrogen is greatly influenced by non-stoichiometry with gamma-irradiation. Detailed observations, such as hydrogen adsorption and catalysis by the gamma-irradiated nickel oxide, are now being made.

# Proton Magnetic Resonance of Thianaphthenes. II.* The Long-range Coupling between 2- and 6-Hydrogens

By Kensuke TAKAHASHI, Tatsuo KANDA, Fusaji SHOJI and Yasuo MATSUKI

(Received December 24, 1964)

In a previous communication, we have shown the long-range coupling between 3- and 7-hydrogens in some thianaphthenes and have also suggested, from the observation of the line width, the presence of another long-range coupling connected with 2-hydrogen.[1] In this report we will clear up this point. In the spectrum of 5-bromothianaphthene in a 5 mol. % solution in acetone, the signal of the 6-hydrogen consists of eight lines, as is shown in Fig. 1a; therefore, we must consider the coupling between 6-hydrogen and one of the hydrogens in the five-membered ring. The signals of 2- and 3-hydrogens also show second-order splittings by about 0.5 and 0.75 c. p. s. respectively. We have also examined the spectrum of 3,5-dibromothianaphthene in a 1.5 mol. % solution in cyclohexane. In this spectrum, the signal of the 6-hydrogen in question is overlapped with the signal of 2-hydrogen by nearly half, but the other half of it clearly consists of four lines, as was observed in the former compound. On the other hand, the signal of 2-hydrogen is unresolved and broad. Therefore, we can conclude that the 2-hydrogen is coupled to the 6-hydrogen in thianaphthenes. Recently, Black et al. have also suggested the presence of a similar 2,6-coupling in indolizine.[2]

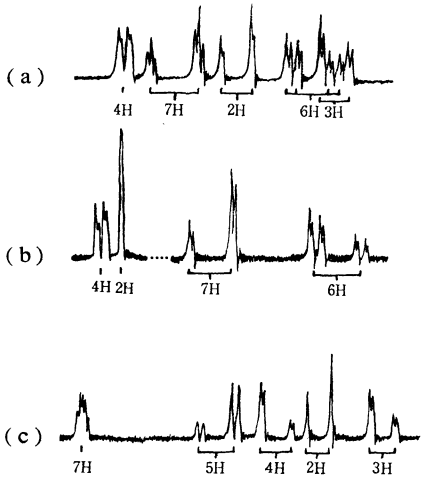

Fig. 1. The ring proton spectra of (a) 5-bromothianaphthene in a 5 mol.% solution in acetone, (b) 3-acetyl-5-bromothianaphthene in a 5 mol.% solution in acetone and (c) 6-carbomethoxythianaphthene in a 3 mol.% solution in carbon tetrachloride. Applied magnetic field increases from left to right in all figures.

It is said that there is a straight zig-zag path or some stereospecificity that gives facilities for coupling to hydrogens.[3] This 2,6- or 3,7-coupling in thianaphthenes is also a typical example in which the interacting hydrogens are located in such a straight zig-zag path as is shown in the following figure by the bold line. Although this kind of zig-zag path is found in some other aromatic compounds,

such as naphthalene, quinoline, benzofuran, etc., the coupling across the six bonds found here has not yet been reported in these compounds except in *N*-benzylthieno[3,2-b]-pyrrole.[4] The 2,5-hydrogens in thianaphthenes are also located in such a position, but no 2,5-coupling has yet been resolved, so any such coupling may be assumed to be smaller than 0.5 c. p. s. if one exists at all. The difference in condition between 2,5- and 2,6-couplings in thianaphthene is mainly due to the presence or absence of the intervening sulfur atom. The sulfur atom seems to play an important role in the transmission of this long-range coupling.

For the verification of our new finding in thianaphthenes, we have also examined some other compounds. The expected 2,6-coupling is also observed in the spectrum of 3-acetyl-5-bromothianaphthene, as Fig. 1b shows. On the other hand, the signal of 6-hydrogen in 2-acetyl-5-bromothianaphthene consists of four lines, as usual. In the spectra of 6-carbomethoxy-, 3-bromo-6-carbomethoxy- and 3-bromo-6-acetylthianaphthenes, no resolved structures were observed in the signals of 2-hydrogens. Table I lists the observed PMR data of our first-order analyses; the observed second-order splitting gives $J_{26}$ ~0.5 c. p. s. Figure 1 shows some typical spectra of these compounds. The chemical shifts were measured in solutions concentrated 0.1 g./cc. or less in carbon tetrachloride containing 0.5 wt. % cyclohexane as an internal reference.

# Temperature Dependency of the ESR Absorption of the Diphenylamine Polymer with Reference to Its Electric Conductivity*

By Keiji KUWATA, Yoichi KAGEYAMA and Kozo HIROTA

(Received January 5, 1965)

As has been reported, a deep-brownish polymeric product can be obtained by oxidizing diphenylamine with vanadium pentoxide. This polymer is semiconductive and shows a sharp ESR absorption line.[1] Its specific conductivity, $\lambda$, and the number of unpaired electrons increases by several orders of magnitude if its complexes are formed with several electron acceptors.[2] In the present note, the temperature dependence of the number of unpaired electrons in the polymer will be reported on, as well as that of its conductivity.

Since the polymer is powdery, samples for conductivity measurement were pressed at more than 80 kg./cm$^2$. The apparatus used in the measurement was kindly provided by Dr. Seiichi Kanda of our University. The molecular weight of sample A (softening pt.=ca. 150°C) was ca. 3000, while that of sample B (softening pt.=ca. 200°C) was estimated to be higher than 3000 on the basis of its low solubility in ordinary solvents. The data obtained were very reproducible, irrespective of the order of measurement. In Fig. 1, the $\log \lambda$ of both samples is plotted against the reciprocal of the measuring temperature, $T$. Since a linear relation is given over the range between 32—120°C, we can determine the constants $\lambda_0$ and $\varepsilon_0$ in Eq. 1, where $k$ is the Boltzmann constant:

$$\lambda = \lambda_0 \exp(-\varepsilon_0/2kt) \qquad (1)$$

For samples A and B, $\varepsilon_0$ is given as 1.1 and 0.7$_9$ eV. respectively. These numerals show the magnitude of $\lambda$, which corresponds to the semiconductive nature of the samples.

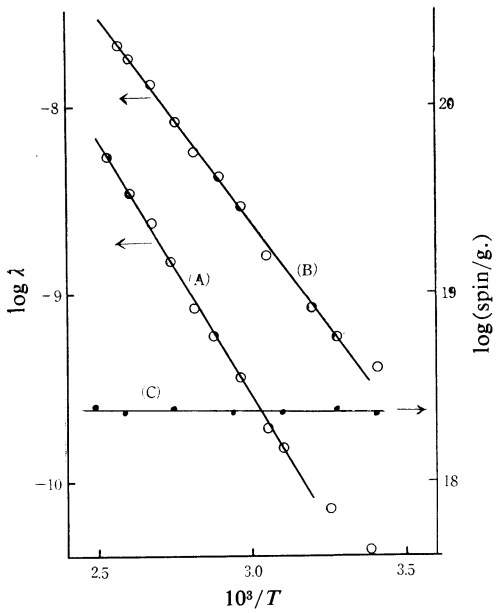

Fig. 1. Temperature variation of specific conductivity and spin concentration.
Softening pt.
(A) 150°C
(B) 200°C
(C) 220°C

The ESR measurement was the same as was hitherto adopted,[1,2] except that the rectangular cavity of the multiple mode, $H_{014}$, was used so as to determine the spin concentration with a greater reliability. The standard substance containing the free-radical, DPPH, was always inserted in the part of the cavity kept at room temperature, while the sample was placed in the part where the temperature could be varied independently of the standard. By the repeated determination of the spin concentration on sample C (sintering temp. 220°C and $\lambda = 1.83 \times 10^{-10}$ ohm$^{-1}$·cm$^{-1}$ at 24°C; $\varepsilon_0 = 1.07_6$ (24—80°C)), it was found to be constant, $2.4 \times 10^{18}$ spin/g., over the temperature range investigated (20—130°C), as Fig. 1 shows.

The results obtained above may be important, because they give us information which clarifies the conduction mechanism of organic semiconductors.

# Change in the Structure of Evaporated Aluminum Chloride by Adsorbing Several Substances

By Toshinobu IMANAKA and Kozo HIROTA

(Received January 5, 1965)

The catalytic polymerization of propylene on evaporated aluminum chloride has been studied in the absence of a solvent by spectroscopic methods and a kinetic method[1-4] in order to make clear the reaction mechanism.

During the course of these studies, it was found that the infrared spectrum of evaporated aluminum chloride is changed slowly by the adsorption of benzene derivatives, cyclohexene, and nitromethane. Therefore, infrared spectrum of crystallized aluminum chloride was measured for the sake of comparison and in order to make clear this phenomenon.

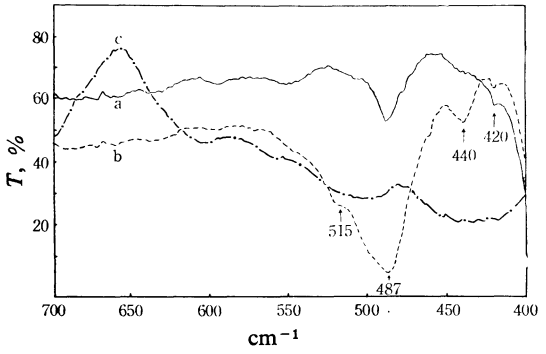

Fig. 1. Infrared absorption spectrum of evaporated aluminum chloride absorbing *p*-xylene.

a ——— Evaporated aluminum chloride alone
b ------ Evaporated aluminum chloride adsorbing *p*-xylene
c —·—· Crystallized aluminum chloride

In Fig. 1, curves a and b show a change in the infrared spectrum of evaporated aluminum chloride by adsorbing *p*-xylene. The band near 487 $cm^{-1}$ increased remarkably in intensity and in width with the lapse of time. Furthermore, new bands were observed near 520—500, 440 and 420 $cm^{-1}$. Even if this system was evacuated until the infrared bands due to *p*-xylene vanished, these bands did not change. However, these bands did disappear upon the addition of water. The same phenomenon was also observed with the adsorption of benzene, toluene, mesitylene, cyclohexene, and nitromethane. On the other hand, the phenomenon was not observed in the case of the adsorption of nitrogen or cyclohexane.

Curve c shows the infrared spectrum of crystallized aluminum chloride, which can be observed by mixing aluminum chloride with Nujol, putting the mixture between two potassium bromide plates, and painting vacuum grease around the potassium bromide plates. This spectrum shows that very broad absorption bands exist near 600, 500 and 450—420 $cm^{-1}$. Aluminum chloride was recently evaporated onto a platinum plate at −195°C by Perkampus and Baumgarten,[5] who observed its reflective absorption spectrum. By annealing the evaporated aluminum chloride, they found that the bands near 606 (very strong) and 467 $cm^{-1}$ (strong) shifted to a lower wavelength, i. e., 599 (very strong) and 440 $cm^{-1}$ (very strong), while the 508 $cm^{-1}$ band increased in intensity.

In view of this fact, the appearance of the infrared bands near 520—500 and 440 $cm^{-1}$ may be due to the crystallization of the evaporated aluminum chloride. When aluminum chloride is evaporated onto a potassium bromide plate at room temperature, the band near 487 $cm^{-1}$ increases remarkably in intensity. On the other hand, when aluminum chloride is evaporated onto the platinum plate at −196°C, the band does not even seem to exist, judging from the above data. This band was assigned by Klempeler to the dimer structure of gaseous aluminum chloride. This finding may suggest that the increase in the band near 487 $cm^{-1}$ is due to the dispersed state of the evaporated aluminum chloride.

On the basis of these data, it seems reasonable to assume that the absorbates which have such an action exist as compounds of the

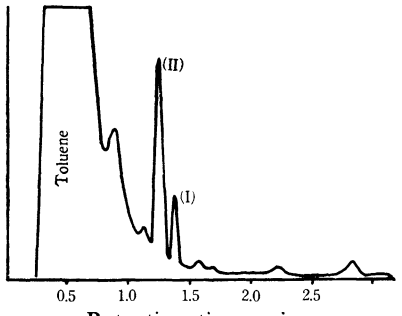
# The Catechol Group in Lignosulfonate

By Akira HAYASHI and Yoshifumi NAMURA

(Received January 5, 1965)

The catechol group was proposed by Hayashi[1] as a functional group in lignosulfonate for the gelling reaction with dichromate. This assignment was also supported by a similarity in the reactivity of lignosulfonate with catechol.[2] Recently, several authors have also suggested the catechol group in lignosulfonate or in other lignin preparation.[3] These works, however, have dealt with the catechol group only by means of indirect methods, and this group did not yet have general support.



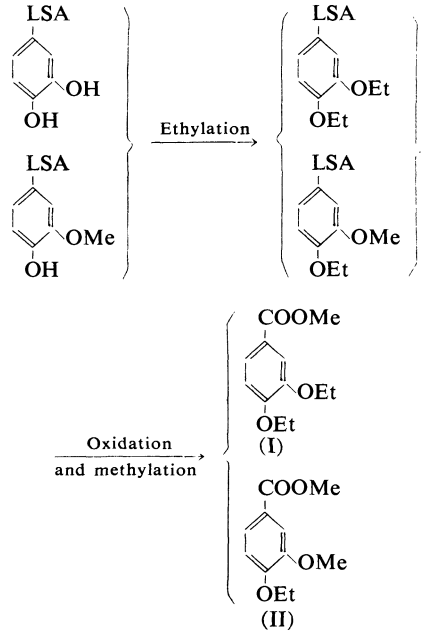


Fig. 1. Gas chromatogram of oxidation product of lignosulfonate.
Column: Apiezon Grease L 2.0 m.
Column temp.: 250°C
Carrier gas: $H_2$, 50 cc./min.

In order to establish the catechol group directly, softwood lignosulfonate was ethylated with diethyl sulfate, oxidized with potassium permanganate,[4] and methylated with methanol; then the resultant products were examined by means of gas chromatography. An Apiezon Grease L column was used at 250°C. The chromatogram obtained is given in Fig. 1.

Sufficient methyl 3,4-diethoxy-benzoate (I) was detected, along with methyl 3-methoxy-4-ethoxy-benzoate (II). Compounds I and II were derived from the pendant catechol group and the guaiacyl group in lignosulfonate respectively according to the following reaction scheme:

Thus the catechol group was directly confirmed in the lignosulfonate molecule by the formation of compound I.

Vanillyl alcohol was cooked in sulfite cooking liquor in order to ascertain the mechanism of catechol group formation. Methanol was obtained from the cooked liquor by gas chromatography, which corresponded to the 4% demethylation of the methoxyl group in vanillyl alcohol. I was also obtained from the

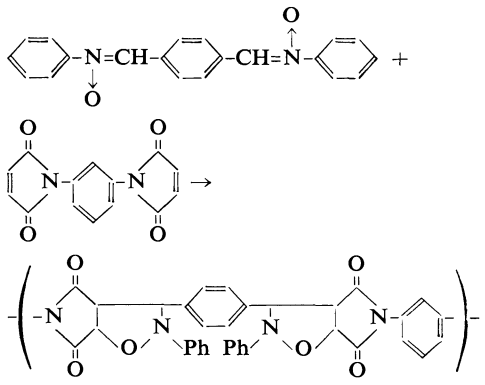
# Polymerizations by 1, 3-Dipolar Cycloaddition Reactions. II. $\alpha, \alpha'$-(*p*-Phenylene)bis(*N*-phenylnitrone)

By Yoshio IWAKURA, Masayasu AKIYAMA and Shinsaku SHIRAISHI

(Received January 12, 1965)

In a previous communication,[1] a 1, 3-dipolar cycloaddition polymerization of isophthalonitrile di-*N*-oxide with diolefins was reported. Hitherto extensive studies have been made on the chemistry of nitrones,[2-4] and some bisnitrones have been prepared for dialdehyde syntheses.[3,5] This communication will describe a new polymerization of $\alpha, \alpha'$-(*p*-phenylene)-bis(*N*-phenylnitrone) (I) with diolefins, *m*-phenylenebismaleimide and ethylene dimethacrylate, by the 1,3-dipolar cycloaddition reaction.



A new bisnitrone, I, was obtained by the reaction of terephthalaldehyde with phenylhydroxylamine[6] (yield, 66%), and recrystallized from dimethylformamide; m. p. 227—228°C (decomp.). Found: C, 75.71; H, 4.97; N, 9.11. Calcd. for $C_{20}H_{16}O_2N_2$: C, 75.93; H, 5.10; N, 8.86%.

I gave an infrared spectrum similar to that of $\alpha$, *N*-diphenylnitrone.

Two bisadducts of I were prepared as model compounds. I (0.414 g.) was refluxed in methyl methacrylate to yield 1, 4-bis(2'-phenyl-5'-methyl-5'-methoxycarbonyl-3'-isoxazolidinyl)-benzene (II) as colorless needles (0.186 g.); m. p. 188—190°C (from ethylacetate). Found: C, 69.67; H, 6.26; N, 5.38. Calcd. for $C_{30}H_{32}O_6N_2$: C, 69.75: H, 6.24; N, 5.42%.

By the addition reaction of I (0.316 g.) with *N*-phenylmaleimide (0.346 g.) in dimethylformamide at 120°C for 3 hr., 3, 3'-(*p*-phenylene)-bis(2-phenylisoxazolidine-4, 5-dicarboxyphenylimide) (III) was obtained (0.620 g.); m. p. 228—229°C (from benzene), (Found: C, 72.35; H, 4.69; N, 8.25. Calcd. for $C_{40}H_{30}O_6N_4$: C, 72.49; H, 4.56; N, 8.46%).

A typical polymerization of I with *m*-phenylenebismaleimide is as follows. 0.473 g. (0.0015 mol.) of I, 0.402 g. (0.0015 mol.) of *m*-phenylenebismaleimide, 0.005 g. of phenyl-$\beta$-naphthylamine and 8.0 ml. of dimethylformamide were placed in a glass ampule; the mixture was then sealed under an atmosphere of nitrogen, heated for 30 hr. at 95°C, and poured into diethyl ether. The polymer (IV) which separated was washed with ether, dried under vacuum (yield, 90%), and reprecipitated from dimethylformamide with ether. The inherent viscosity was 0.19 (0.5 g./100 ml. of dimethylformamide at 30°C). IV did not melt up to 300°C. Found: C, 69.88; H, 4.37; N, 9.32. Calcd. for $C_{34}H_{24}O_6N_4$: C, 69.85; H, 4.14; N, 9.59%. The infrared spectrum of IV exhibited the following absorption bands: 1790(w), 1720(s), 1600, 1490, 1450, 1365(broad), 1180-(broad), 1020(w), 755 and 688 $cm^{-1}$ (KBr disk), and showed good agreement with that of III. These data strongly suggest that the polymerization proceeds by a repetition of the 1, 3-dipolar cycloaddition reaction, as in the equation below:

1) Y. Iwakura, M. Akiyama and S. Shiraishi, This Bulletin, **38**, 335 (1965).
2) L. I. Smith, *Chem. Revs.*, **23**, 193 (1938).
3) J. Hamer and A. Macaluso, ibid., **64**, 473 (1964).

5) T. Sone, This Bulletin, **37**, 1197 (1964).
6) O. H. Wheeler and P. H. Gore, *J. Am. Chem. Soc.*, **78**, 3363 (1956).

A similar polymerization of I with ethylene dimethacrylate was carried out in hexamethylphosphoramide at 140°C for 4 hr. The yield of the polymer (V), obtained as an ether-insoluble fraction, was 11%; m. p. 100—107°C, and the inherent viscosity, 0.09. Found: C, 69.89; H, 5.76; N, 5.43. Calcd. for $C_{30}H_{30}O_6N_2$: C, 70.02; H, 5.88; N, 5.44%. The infrared spectrum of V displayed the following maxima: 2940, 2850(w), 1735(s), 1600, 1490, 1453, 1375 (w), 1280(broad), 1175(s), 1125—1095, 1030(w), 753 and 690 $cm^{-1}$ (KBr disk), and was essentially identical with that of II.

Further investigations are now in progress.

# On Glumamycin, a New Antibiotic. V.* The Steric Configuration of α, β-Diaminobutyric Acid

By Masahiko FUJINO, Michitaka INOUE, Jisaburo UEYANAGI and Akira MIYAKE

(Received October 7, 1963)

The authors[1] previously isolated α, β-diaminobutyric acid (α, β-Dab) from the acid hydrolysate of glumamycin, an acidic peptide-type antibiotic. About the same time, Martin et al.[2] reported the separation of α, β-Dab from Aspartocin, an antibiotic resembling glumamycin. Although the two products seem to have the same configuration, judging from their optical rotation, this question has so far not been studied.

In a previous paper of this series[3] it was shown that glumamycin contains two moles of α, β-Dab and that only one β-amino group of the α, β-Dab is free. These facts were then utilized to determine the steric configuration of α, β-Dab.

The configuration of the α-carbon of α, β-Dab has been studied by the conversion of the free β-amino group of glumamycin into a hydroxyl group and by subsequent hydrolysis to α-amino-β-hydroxybutyric acid, and that of the β-carbon of α, β-Dab, by the oxidation of α, β-Dab to alanine.

That is, glumamycin was treated with sodium nitrite in 80% acetic acid to convert the free amino group into hydroxyl, and then the resulting deamino-glumamycin was hydrolyzed with hydrochloric acid. The reaction mixture was developed on a column of Dowex 50 with an ammonium formate buffer (pH 3.4),[4] after which a crystalline substance was obtained from the threonine fraction. The product was found to be a mixture of threonine and allothreonine by paper chromatography with *n*-butanol - acetone - ammonia - water (50 : 6.25 : 6.25 : 37.5)[5] and by a study of its infrared spectrum (Fig. 1).

Fortunately, it is known that DNP-L-threonine and DNP-L-allothreonine exhibit the same optical rotation, $[M]_D^{25} = +305°$ (4% sodium bicarbonate).[6] The above product was converted into its DNP derivative by the method of Levy[7] and then submitted to column chromatography on Amberlite IRC-50, according to the method of Seki,[8] in order to remove the DNP-OH which was formed as a by-product. The DNP derivative showed an optical rotation of $[M]_D^{24} = -294° \pm 14$ (*c* 0.48, 4% sodium bicarbonate), and its yield was 92%. The results mentioned above show that the threonine and allothreonine obtained in the present work take the D-configuration; consequently, the α-carbon of α, β-Dab with the free β-amino group belongs to the D series. Further, as the α, β-Dab obtained from the hydrolysate of deamino-glumamycin and that obtained from the hydrolysate of glumamycin have the same optical rotation and physical properties, the two moles of α, β-Dab in glumamycin evidently have the same steric configuration.

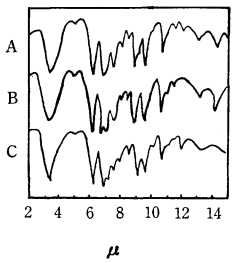

Fig. 1. Infrared-Spectra of α-amino-β-hydroxybutyric acid.
A: α-Amino-β-hydroxybutyric acid from deamino-glumamycin
B: L-Threonine
C: L-Allothreonine

Next, in order to establish the configuration at the β-carbon of α, β-Dab, it was oxidized with hydrogen peroxide according to the method of Dakin.[9] That is, the compound was allowed to react with 2 mol. of 3% hydrogen peroxide at 50°C for one hour in the presence of a small amount of ferrous sulfate. The reaction mixture was then passed

through a column of Amberlite IR-120 ($H^+$), and the adsorbed substance was eluted with N ammonia, the effluent giving D-alanine. Thus, it was found that the configuration at the $\beta$-carbon of $\alpha,\beta$-Dab belongs to the D series and that, consequently, $\alpha,\beta$-Dab takes the D-erythro-configuration.

## Experimental

**Deamino-glumamycin.**—Into a solution of 10 g. (ca. 7.7 mmol., mol. wt. taken as 1300*) of glumamycin in 100 ml. of 80% acetic acid, 1.06 g. (ca. 15.4 mmol.) of sodium nitrite and 11.6 ml. of N hydrochloric acid were stirred alternately over a period of 5 hr. at 0°C; the mixture was then left standing at room temperature for 12 hr.

The reaction mixture was concentrated to 20 ml. under reduced pressure, and water was added to separate the deamino-glumamycin. The precipitate was washed three times with water to remove the unchanged glumamycin, which is soluble in water; it was dissolved in acetone and reprecipitated by the addition of water. The product was washed twice with water and dried, giving 8 g. of deamino-glumamycin**.

**The Hydrolysis of Deamino-glumamycin with Hydrochloric Acid.** — Two grams of deamino-glumamycin was hydrolyzed by heating it with 40 ml. of 6 N hydrochloric acid at 110°C for 20 hr. in an oil bath. The hydrolysate was concentrated in vacuo, water was added to the residue, and the mixture was evaporated to dryness under reduced pressure.

**The Isolation of the Threonine Faction.**—The above residue was dissolved in 100 ml. of water, the solution was passed through a column (3×10 cm.) of Amberlite IR-4B (OH form) to remove acidic substances, and the effluent was evaporated to dryness in vacuo.

The residue was dissolved in 10 ml. of an ammonium acetate buffer (pH 5.0), and the solution was passed through a column (7×20 cm.) of Dowex-50×8 (200—400 mesh) treated beforehand with the same buffer.

The effluent was collected in 50-ml. fractions and examined by paper chromatography. All the neutral amino acids constituting deamino-glumamycin were then eluted out in 100—300 ml. of the effluent.

This portion of the effluent was evaporated to dryness under reduced pressure. The residue was dissolved in 10 ml. of an ammonium formate buffer (pH 3.4), and the solution was again passed through a column (6×60 cm.) of Dowex-50×4 (200—400 mesh) bufferized at pH 3.4. The fraction of the effluent showing the same $R_f$-value as threonine by paper chromatography with *n*-butanol - acetic acid - water (120 : 30 : 50) was collected and poured on a column of Amberlite IR-120 (H form). The adsorbed portion was eluted with N ammonia. The eluate was concentrated to give crude crystals, which were purified by recrystallization from aqueous ethanol, yielding 104 mg. of a mixture of threonine and allothreonine.

Found: C, 40.06; H, 7.81; N, 11.70. Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76%.

**The Isolation of $\alpha,\beta$-Dab.**—When the above column of Dowex-50×8 (pH 5.0) was further eluted with 0.25 N aqueous ammonia, it was found by paper chromatography that 230—300 ml. of the effluent contained $\alpha,\beta$-Dab. This fraction was evaporated under reduced pressure. The residue was dissolved in a small amount of hydrochloric acid, and the ethanol was added to the solution, giving colorless needles which were purified by recrystallization from aqueous ethanol (yield, 130 mg.).

Found: C, 31.24; H, 6.88; N, 17.96; Cl, 22.41. Calcd. for $C_4H_{10}O_2N_2 \cdot HCl$: C, 31.06; H, 6.48; N, 18.11; Cl, 22.95%. $[\alpha]_D^{23} = +20$ ($c$ 1, 6 N HCl).

The isolation of $\alpha,\beta$-Dab from the hydrolysate of glumamycin was previously reported.[3]

**The Dinitrophenylation and Optical Rotation of the DNP Derivative.** — According to Levy's method, 10.42 mg. of the mixture of threonine and allothreonine obtained above was dissolved in 5 ml. of water; 200 mg. of sodium carbonate and 0.2 ml. of 2,4-dinitrofluorobenzene were added to the solution, and the mixture was kept at 40°C for 20 min. while being vigorously stirred. The reaction mixture was diluted with 10 ml. of water, shaken three times with each half volume of ether to remove the excess 2,4-dinitrofluorobenzene, and, after being made acidic, again shaken with ether to extract DNP-threonine and DNP-allothreonine. The extract was evaporated to dryness and developed on a column (4×30 cm.) of Amberlite CG-50 (type II) with 1% hydrochloric acid-ethyl methyl ketone (75 : 25). In this case, the simultaneously-produced DNP-OH was developed half as slow as DNP-threonine and DNP-allothreonine, so the former was completely separated from the latter. The fraction containing DNP-threonine and DNP-allothreonine was evaporated under reduced pressure, and the residue (yield, 92%*) was dissolved in 2 ml. of a 4% sodium bicarbonate solution. The optical rotation of the solution is $[\alpha]_D^{24} = -102° \pm 5$, and from this the molecular rotation is calculated to be $[M]_D^{24} = -294° \pm 14$.

**Oxidation with Hydrogen Peroxide.**—To a solution of 1 g. of $\alpha,\beta$-Dab·HCl in 14.5 ml. of 3% hydrogen peroxide, about 5 mg. of ferrous sulfate was added; the mixture was then kept at 50°C for one hour with stirring. The reaction mixture was diluted with 2 vol. of water and passed through a column of Amberlite IR-120 ($H^+$ form). The column was eluted with N ammonia, the eluate was evaporated to dryness, and the residue was recrystallized from aqueous ethanol to give 120 mg. of D-alanine, $[\alpha]_D^{20} = -16°$ ($c$ 1, 6N HCl).

Found: C, 40.51; H, 7.88; N, 15.44. Calcd. for $C_3H_7O_2N$: C, 40.44; H, 7.92; N, 15.72%.

* The mol. wt. of the glumamycin determined by the method of the Vapor Pressure Osmometer is 1285 (sample, 13.400 mg.; solvent, 1 ml. of water; mole concentration, 0.01043), which is in good agreement with the min. mol. wt. (1, 300) obtained by means of amino acid analysis.[3]

** The DNP derivative was not obtained by Sanger's method.

* This yield was calculated from the ultraviolet-absorption at 360 m$\mu$.

## Summary

Glumamycin has been treated with nitrous acid to convert the free amino group into hydroxyl, and the resulting deamino-glumamycin has been hydrolyzed with hydrochloric acid. A mixture of threonine and allothreonine has then been isolated from this hydrolysate. The DNP derivative of the product shows an optical rotation $[M]_D^{24} = -294° \pm 14$ (*c* 0.48, 4% sodium bicarbonate). This fact shows that the above product is a mixture of D-threonine and D-allothreonine.

Further, as the $\alpha, \beta$-diaminobutyric acid obtained from the hydrolysate of deamino-glumamycin and that obtained from the hydrolysate of glumamycin have the same optical rotation, it may be concluded that the two moles of $\alpha, \beta$-diaminobutyric acid in glumamycin have the same steric configuration.

On the other hand, the product obtained by the oxidation of $\alpha, \beta$-diaminobutyric acid with hydrogen peroxide is in agreement with D-alanine. Thus, it has been found that the $\alpha$- and $\beta$-carbons of $\alpha, \beta$-diaminobutyric acid belong to the D series and that, consequently, $\alpha, \beta$-diaminobutyric acid takes the D-erythro-configuration.

The authors are grateful to Dr. Sueo Tatsuoka, the Director of Research Laboratories, and Drs. Satoru Kuwada, Kikichi Sato and Kuniyoshi Tanaka for their guidance and encouragement, and to Drs. Koichi Nakazawa and Motoo Shibata for their kind advice.

# On Glumamycin, a New Antibiotic. VI.*1 An Approach to the Amino Acid Sequence

By Masahiko FUJINO

(Received October 21, 1963)

In previous papers,[1-3] it was reported that glumamycin ($C_{59}H_{91}O_{20}N_{13}$, M. W. 1300[4]) was an acidic peptide consisting of 3-ITA[2] (1 mol.), L-Asp (3 mol.), L-MeAsp (1 mol.), Gly (2 mol.), L-Pro (1 mol.), L-Val (1 mol.), D-Pip (1 mol.) and $\alpha,\beta$-Dab (2 mol.), and that, of the 2 mol. of $\alpha,\beta$-Dab contained in glumamycin, the $\alpha$- and $\beta$-amino groups of one molecule take part in the peptide combination, while the $\beta$-amino group of the other is free.

As the glumamycin was resistant to such enzymes as pepsin, trypsin, chymotrypsin and pronase, the antibiotic was subjected to partial hydrolysis with hydrochloric acid. The present paper deals with experiments designed to determine the amino acid sequence of glumamycin.

## Experimental

**The Partial Hydrolysis of Glumamycin with N Hydrochloric Acid.** — One gram of glumamycin purified by the method reported in a previous paper[5] was heated with 10 ml. of N hydrochloric acid in an oil bath at 100°C for 4 hr. The mixture became turbid in about 2 hr., and an oily substance separated in 4 hr. The reaction mixture was then diluted with 40 ml. of water and extracted with three 30 ml.-portions of ethyl acetate and a 30 ml.-portion and two 20 ml.-portions of *n*-butanol in order to remove the oily substance. The aqueous layer (W-fraction) was lyophilized, and 100 mg. of this substance was dissolved in 2 ml. of 0.5 N acetic acid and poured on a column (2×40 cm.) Dowex-1×4 (200—400 mesh). The column was washed with 0.5 N acetic acid, and the effluent was collected in 5 ml.-portions with a fraction collector (Fig. 1).

The ethyl acetate layer was extracted three times with 20 ml. of a 2% sodium hydrogen carbonate solution, and the aqueous layer, after being adjusted to pH 2 with 2 N hydrochloric acid, was extracted again with ethyl acetate. The ethyl acetate

5) M. Shibata, T. Kanzaki, K. Nakazawa, M. Inoue, H. Hitomi, K. Mizuno, M. Fujino and A. Miyake, *J. Antibiotics* (*A*), 15, 1 (1962).

extract was evaporated to dryness, and the residue was washed with petroleum ether to give the E substance. The *n*-butanol extract was treated in the same manner to give the B substance.

**The Partial Hydrolysis of Glumamycin with 6 N Hydrochloric Acid.**—Four hundred milligrams of glumamycin was heated with 8 ml. of 6 N hydrochloric acid in a sealed tube at 100°C for 80 min.; the contents became turbid in about 40 min., and an oily substance separated in 60 min. The reaction mixture was diluted with 5 vol. of water and extracted with ethyl acetate to remove the fatty acid; after it had been diluted further with two times its volume of water, it was passed through a column (2×25 cm.) of Amberlite IR-120 (H-form) in order to adsorp the amino acids and peptides. The colum was washed with water to remove the hydrochloric acid and then eluted with 0.5 N aqueous ammonia, and the eluate was evaporated to dryness under reduced pressure at 35°C to give a sample for investigation by paper ionophoresis.

**The Partial Hydrolysis of DNP-glumamycin.**—On hundred milligrams of DNP-glumamycin obtained by Sanger's method (described in Part IV[3]) was dissolved in 2 ml. of concentrated hydrochloric acid and they hydrolyzed by being heated in a seald tube at 80°C for 2 hr. The hydrolysate was diluted with 11 volumes of water, and an oily substance was removed by extraction with ethyl acetate. The aqueous layer was poured on a talc-celite (2 : 1) column (2×20 cm.),[6] whereby all the yellow substance were adsorbed. The column was washed with N hydrochloric acid, and the washings were concentrated to yield non-DNP-peptides. The yellow zone of the column was eluted with N hydrochloric acid-ethanol (1 : 4), and the eluate was evaporated to dryness to give DNP-peptides.

**The Separation of Peptide Fragments by Paper Chromatography and Ionophoresis.**—The mixture of peptide fragements (30—40 mg.) described above was applied, in the form of a narrow band, to Toyo Roshi No. 526 (10×40 cm.) and was submitted to ionophoresis in a pyridine-acetate buffer of pH 6.5[7] (300—400 V., 2—4.5 hr.). In this manner the various peptide fragments were separated and were located by dipping narrow guide strips cut from both long edges of the paper in a 0.25% ninhydrin solution in acetone. The bands were then eluted with 5% acetic acid (0.5 ml.), and the solutions were taken to dryness in vacuo over potassium hydroxide pellets and stored at 0°C. A portion of each peptide fraction was tested for homogeneity by paper chromatograph in *n*-butanol - acetic acid - water (12 : 3 : 5, solvent A) and *n*-butanol - acetic acid - pyridine - water (15 : 10 : 3 : 12, solvent B). If more than one component was revealed in a peptide fraction by either of these solvents, it was refractionated and the additional peptide components were isolated as has been described above.

**The Characterization of Purified Peptides; Amino Acid Composition.** — The amino acid components of each peptide were determined, after hydrolysis with 6 N hydrochloric acid in a sealed tube at 105°C for 20 hr., by paper chromatography using solvent A and *n*-butanol - pyridine - water (1 : 1 : 1, solvent C), and by paper ionophoresis in 2 N acetic acid at 300—400 V. for 3 hr. Quantitative amino acid analyses of peptides were performed according to Levy's method[8] as described in a previous paper.[2] The paper chromatography of fatty acid and its related compound was carried out in *n*-butanol saturated with 2N aqueous ammonia (solvent D) and located by a pH indicator (bromophenol blue).

***N*-Terminal Analyses.**—0.3—1.0 mg. of a peptide and 2 mg. of sodium hydrogen carbonate were dissolved in 0.2 ml. of water in a small test tube, and then 0.4 ml. of a 5% ethanolic solution of DNFB was added. After 2 hr., the reaction mixture was diluted with 0.6 ml. of water, extracted with ether to remove the unreacted DNFB, and, after being adjusted to pH 2 with 4 N hydrochloric acid, extracted three times with 1 ml. of ethyl acetate. (All the DNP-peptides treated in the present work were extractable with ethyl acetate.) The ethyl acetate extract was then washed twice with 0.5 ml. of water and evaporated to dryness in a small test tube. The residue was sealed in a tube with 6 N hydrochloric acid and heated at 100°C for 6—8 hr. The hydrolysate was dried over potassium hydroxide in a desiccator to remove hydrochloric acid, dissolved in 1 ml. of water, and shaken three times with ether to extract DNP-amino acid for paper chromatographic identification. The paper chromatography of DNP-amino acids was conducted by the two-dimensional ascending method using solvent C and a 1.5 M phosphate buffer (pH 6.0).

***C*-Terminal Analyses.**—1—3 mg. of a dried peptide was heated with 0.1—0.2 ml. of anhydrous hydrazine in a sealed tube at 100°C for 4—6 hr. The reaction mixture was dried over sulfuric acid in a desiccator to remove the excess hydrazine, and the free amino acid therein was determined by paper chromatography and paper ionophoresis after the amino acid hydrazide has been removed by enanthaldehyde.

**The Hydrazinolysis of Glumamycin.**—Ten milligrams of glumamycin was dried with 65 mg. of hydrazine sulfate over phosphorus(V) oxide in a desiccator for 2 days, sealed together with 0.5 ml. of anhydrous hydrazine in a tube, and heated at 60°C for 16 hr. Another hydrazinolysis was conducted in a similar manner except that hydrazine sulfate was not added and the reaction was effected at 100°C for 10 hr. In both cases, the reaction mixture was dried over sulfuric acid in a desiccator, the residue was dinitrophenylated by Sanger's method, and the reaction mixture was extracted fractionally and subjected to paper chromatography. In all cases, no DNP-amino acid deriving from the *C*-terminus was detected. As a control, glumamycin was hydrazinolyzed in the presence of several moles of glycine per mole of glumamycin, but in this case only DNP-Gly was clearly detected.

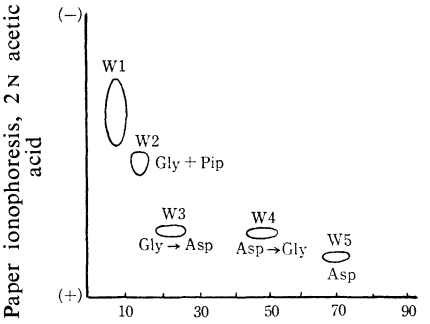
## Results and Discussion



**The Partial Hydrolysis of Glumamycin with N Hydrochloric Acid.**—The partial hydrolysate of glumamycin with N hydrochloric acid was extracted successively with ethyl acetate (E-fraction) and *n*-butanol (B-fraction). The E-fraction was negative to the biuret and ninhydrin reactions and showed a fatty acid-like property, and on its paper chromatogram using solvent system D, only a spot of an acidic substance with an $R_f$ value of 0.32 was detected. Next, the E-substance was completely hydrolyzed with hydrochloric acid and extracted with ether; it was found with the ether extract that the $R_f$ 0.32 spot disappeared, while instead a spot ($R_f$ 0.61) corresponding to 3-ITA was detected. When the aqueous layer of the ether extraction was subjected to paper chromatography using solvent systems A and B, a spot corresponding to Asp was detected. The E-substance gave no DNP-derivative by Sanger's method;[9] its hydrazinolysis by Akabori's method[10] released Asp (0.4 mol./mol., uncorrected) and in this case no di-DNP-Asp monohydrazide was detected by paper chromatography. From the facts mentioned above, the structure of E-substance was found to be 3-ITA→Asp.

The B-fraction was positive to the biuret reaction and weakly positive to the ninhydrin reaction, and its acid hydrolysis gave all the components of glumamycin. Therefore, sequence studies of the B-fraction were not carried out.

Paper ionophoresis of the aqueous fraction of the *n*-butanol extraction mentioned above (W-fraction) detected many ninhydrine positive substance assumed to be amino acids and peptides. Therefore, the fraction was developed on a column of Dowex-1×4 with 5 N acetic acid in order to separate it into a basic (W1), a neutral (W2) and three acidic fractions (W3—W5), as is shown in Fig. 1. Further, the basic fraction, W1, was fractionated by a combination of paper ionophoresis in a pyridine-acetate buffer (pH 6.5) (Fig. 2) and paper chromatography in solvent systems A and B. The chromatographically-pure peptides obtained in this way analyzed for constituent amino acids and *N*- and *C*-terminal groups. The results obtained are summarized in Table I. From the results concerning the W1 fraction, a partial structure of glumamycin could be deduced as follows:

H·Gly→$\alpha$, $\beta$-Dab→Val→Pro→$\alpha$, $\beta$-Dab(→Pip)

Effluent of Dowex-1×4 chromatography with 0.5 N acetic acid (×5 ml.)

Fig. 1. Separation of partial acid (N HCl) hydrolysate by Dowex-1×4 column (2×40 cm) chromatography.
Each fraction of the effluent was subjected to paper ionophoresis in 2 N acetic acid (400 V., 2 hr.). W2—W5 were identified by making use of their authentic samples by paper chromatography and infrared spectrum.

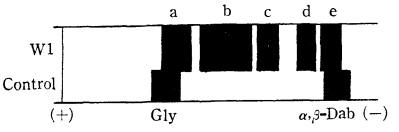

Fig. 2. Separation of W1 fraction by paper ionophoresis in pyridine-acetate buffer, pH 6.5, 300 V., 4.5 hr.

**The Partial Hydrolysis of Glumamycin with 6 N Hydrochloric Acid.**—The partial hydrolysate of glumamycin with 6 N hydrochloric acid was extracted with ethyl acetate in a manner similar to that used in the extraction of the partial hydrolysate with N hydrochloric acid. The aqueous fraction was passed through a column of Amberlite IR-120 (H-form), the absorbed substances were eluted with 0.5 N aqueous ammonia, and the eluted substances were fractionated by paper ionophoresis in a pyridine-acetate buffer (pH 6.5) (Fig. 3), followed by paper chromatography using solvent systems A and B. The components and the *N* terminal residues of the peptides thus separated were further investigated, as has been mentioned before; the results obtained are summarized in Table II.

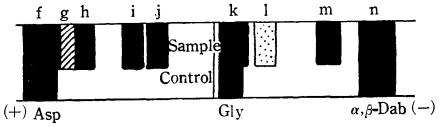

Fig. 3. Separation of partial acid (6 N HCl) hydrolysate by paper ionophresis in pyridine-acetate buffer, pH 6.5, 300 V., 5 hr.

TABLE I. AMINO ACID SEQUENCE OF PEPTIDES ISOLATED FROM PARTIAL ACID (N HCl) HYDROLYSATE OF GLUMAMYCIN

Fractions (W1 : a—e) obtained by ionophoresis at pH 6.5 (Fig. 2) were separately chromatographed in *n*-butanol - acetic acid - water (solvent A) or *n*-butanol - pyridine - acetic acid - water (solvent B). Fractions c and d were chromatographically pure, e was separated into $e_1$ and $e_2$; a and b were not identified.

| Peptide | | $R_f$ in A | $R_f$ in B | Amino acid composition* and deduced partial structure** |
|---|---|---|---|---|
| W1 : | a | | | all the amino acids constituting glumamycin were detected |
| | b | | | |
| | c | 0.36 | 0.34 | Gly·(α, β-Dab, Val)·Pro |
| | d | 0.34 | 0.28 | Gly·α, β-Dab·Val |
| | e : 1 | 0.21 | 0.21 | Gly·(α, β-Dab, Val, Pro)·α, β-Dab |
| | e : 2 | 0.41 | 0.45 | Gly·(α, β-Dab, Val, Pro, α, β-Dab, Pip) |

* Analyzed by paper chromatography and ionophoresis.
** *N*-Terminal was analyzed by Sanger's DNP-method and *C*-terminal was analyzed by hydrazinolysis.

TABLE II. PEPTIDES AND AMINO ACIDS ISOLATED FROM PARTIAL ACID (6N HCl) HYDROLYSATE OF GLUMAMYCIN

Fractions obtained by ionophoresis at pH 6.5 (Fig. 3) were separately chromatographed in *n*-butanol - acetic acid - water (solvent A) or *n*-butanol - pyridine - acetic acid - water (solvent B) and gave the additional components as shown.

| Peptide and amino acid | | $R_f$ in A | $R_f$ in B | Amino acid composition* | Deduced partial structure** |
|---|---|---|---|---|---|
| f | | 0.20 | 0.17 | Asp | — |
| g | | 0.22 | 0.25 | MeAsp, Asp | MeAsp·Asp |
| h : | 1 | 0.12 | 0.13 | Gly (1), Asp (1) | Gly·Asp |
| | 2 | 0.15 | 0.13 | Asp (1), Gly (1) | Asp·Gly |

** *N*-Terminal was analyzed by Sanger's DNP-method.

TABLE III. PEPTIDES AND AMINO ACID OBTAINED FROM PARTIAL ACID HYDROLYSATE OF DNP-GLUMAMYCIN

| DNP-peptide (Fig. 5) | | Amino acid composition* | Deduced partial structure** |
|---|---|---|---|
| DNP-C : | a | β-DNP-α, β-Dab Val, Pro | β-DNP-α, β-Dab·(Val, Pro) |
| | b | β-DNP-α, β-Dab Val, Pro, α, β-Dab | β-DNP-α, β-Dab·(Val, Pro, α, β-Dab) |
| Non-DNP - Pertide (Fig. 6) | | | |
| n : | 1 | Val, Pro, α, β-Dab, Pip | Val·(Pro, α, β-Dab, Pip) |
| | 2 | α, β-Dab | — |

* Analyzed by paper chromatography and ionophoresis.
** *N*-Terminal was analyzed by Sanger's DNP-method. Non-*N*-terminal α, β-Dab was detected as β-mono-DNP-α, β-Dab by paper chromatography in the analysis of peptides DNP-C·b and n·1 respectively.

From the results on peptides f—j summarized in Table II, and also from the results of the partial hydrolysis with N hydrochloric acid shown in Fig. 1, the presence of the H·MeAsp →Asp→Gly→Asp·OH sequence was presumed. Results on the other peptides, m and n in Table II, were in accord with the sequence deduced from the results of the partial hydrolysis with N hydrochloric acid.

**The Partial Hydrolysis of DNP-glumamycin with Concentrated Hydrochloric Acid.** — DNP-Glumamycin prepared by Sanger's method[8] was hydrolyzed partially with concentrated hydrochloric acid, and the resulting oily substance was removed with ethyl acetate. The DNP-peptides were separated from non-DNP-peptides on a column packed with a mixture of talc and celite (2 : 1) and subjected to paper chromatography to give four yellow spots, as Fig. 4 shows. All the amino acids

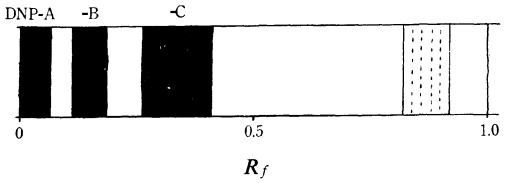

Fig. 4. Paper chromatogram of DNP-peptides obtained from partial acid hydrolysate of DNP-glumamycin.
Solvent system : *n*-butanol saturated with 2 N aqueous ammonia

constituting glumamycin were detected in the hydrolysate of DNP-A and -B and Val, Pro, α, β-Dab, β-DNP-α, β-Dab and a small amount of the other amino acids in that of DNP-C. The DNP-C was subjected to paper ionophoresis using a pyridine-acetate buffer (pH 6.5). It was separated into a neutral (DNP-C·a) and a basic (DNP-C·b) fraction, as is shown in Fig. 5. Analyses of these fractions are

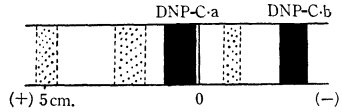

Fig. 5. Separation of DNP-C fraction by paper ionophoresis in pyridine-acetate buffer, pH 6.5, 300 V., 6 hr.

shown in Table III. From the results described above and from those of the partial hydrolysis of glumamycin, it was possible to formulate the partial sequence in the neighborhood of the free β-amino group in glumamycin as follows:

$$\rightarrow \alpha\text{-Dab} \rightarrow \text{Val} \rightarrow \text{Pro} \rightarrow \underset{\beta\text{-NH (free)}}{\alpha\text{-Dab}} \rightarrow \underset{\beta\text{-NH}}{\alpha\text{-Dab}} \leftarrow$$

Next, the non-DNP-peptide fraction from the above-mentioned talc-celite column was passed through a column of Amberlite IR-4B (OH form) in order to remove acidic amino acids and peptides. Peptides and amino acids in the effluent were adsorbed on a colum of Amberlite IR-120 (H from) and eluted with 0.5 N aqueous ammonia to give a sample for paper ionophoresis. The results are shown in Fig. 6. Analyses of the isolated substances are shown in Table III.

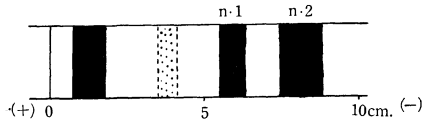

Fig. 6. Separation by paper ionophoresis of non-DNP-peptides obtained from partial acid hydrolysate of DNP-glumamycin.
Pyridine-acetate buffer, pH 6.5, 300 V., 3.5 hr.

From the results summarized in Table III, the structure of non-DNP-peptide n·1 may be as follows;

$$\text{H-Val} \rightarrow \text{Pro} \rightarrow \underset{\beta\text{-NH}_2}{\alpha\text{-Dab}} \rightarrow \text{Pip-OH}$$

**The Elucidation of the Sequence.**—The partial structure of glumamycin, inferred from the sequence of amino acids in the peptide fragments obtained by the partial hydrolysis of glumamycin and DNP-glumamycin, may be represented by 3-ITA→Asp·(OH), (H)·Gly→ $\underset{\beta\text{-NH}_2}{\alpha\text{-Dab}}\rightarrow\text{Val}\rightarrow\text{Pro}\rightarrow\underset{\beta\text{-NH}_2}{\alpha\text{-Dab}}\rightarrow$Pip·(OH) and (H)·MeAsp→Asp→Gly→Asp·(OH). All the amino acid residues constituting glumamycin are contained in the above three peptides. Glumamycin was subjected to the hydrazinolysis-DNP method of Akabori in the presence and in the absence of hydrazine sulfate, but no DNP-amino acid derived from *C*-terminal was detected in either case. Therefore, the three peptides above are presumed to be arranged in a cyclic form in glumamycin.

From these facts, the structure of glumamycin may be supposed to be one of the following two;

$$\text{(A)}\quad \text{3-ITA} \rightarrow \text{Asp} \rightarrow \text{Gly} \rightarrow \underset{\beta\text{-NH}_2}{\alpha\text{-Dab}} \rightarrow \text{Val} \rightarrow \text{Pro} \rightarrow \alpha,\beta\text{-Dab} \begin{cases} \nearrow \text{Pip} \rightarrow \text{MeAsp} \searrow \\ \nwarrow \text{Asp} \quad\rightarrow\quad \text{Gly} \swarrow \end{cases} \text{Asp}$$

$$\text{(B)}\quad \text{3-ITA} \rightarrow \text{Asp} \rightarrow \alpha,\beta\text{-Dab} \begin{cases} \nearrow \text{Pip} \rightarrow \text{MeAsp} \rightarrow \text{Asp} \rightarrow \text{Gly} \searrow \\ \nwarrow \text{Pro} \leftarrow \text{Val} \leftarrow \underset{\beta\text{-NH}_2}{\alpha\text{-Dab}} \leftarrow \text{Gly} \swarrow \end{cases} \text{Asp}$$

Fundamentally these structures of glumamycin are similar to those of the antibiotics of the polymixin series[11,12] but they are reverse in the relation of functional groups; that is, in the former, one amino group and four carboxyl groups are free, while in the latter only the amino groups are free. It is interesting to compare these points with their antibacterial spectra; glumamycin is active only to Gram-positive microorganisms, and the antibiotics of polymixin, only to Gram-negative microorganisms.

## Summary

To elucidate the amino acid sequence of glumamycin, glumamycin and DNP-glumamycin have been partially hydrolyzed with hydrochloric acid, and various peptides have been isolated by column chromatography on ion-exchange resin or talc-celite, paper chromatography and paper ionophoresis. From the structures of the peptides, two possible structures (A and B) for glumamycin have been presumed.

The author wishes to express his thanks to Dr. Sueo Tatuoka, the Director of the Research Laboratories, Dr. Satoru Kuwada and Dr. Kuniyoshi Tanaka for their guidance and encouragement, and to Drs. # The Extractional Behavior of Cerium with Acetylacetone

By Shōhachirō Ōki*

(Received December 10, 1963)

In previous papers[1,2] we have studied some details of the solvent extraction of cerium with acetylacetone—the conditions for the extraction, the interfering substances, and the application of the extraction technique to the separation of cerium-144 from the mixture of fission products.

In this paper we hope to make clear the extractional behavior of cerium in the form of the acetylacetonate. The oxidation number of cerium will be estimated, and the effects of the concentration of acetylacetone and temperature on the extraction will be studied.

## Experimental

**Reagents.**—Commercial acetylacetone was purified by washing it with dilute ammonia water and then with distilled water, followed by distillation under the reduced pressure of 47 mmHg; the 56—57°C fraction was then collected. The purity of the product was checked by gas chromatography.

The carrier-free cerium-144 was imported from Amersham, England, in the form of cerous trichloride in a hydrochloric acid solution, which was dissolved in 2 N perchloric acid and then stored.

Benzene was purified by washing it with sulfuric acid and then with distilled water; it was then distilled.

The other chemicals used are all of a guaranteed reagent grade.

**Distribution Measurements.** — The distribution ratio of acetylacetone was determined as follows: A mixture of 5 ml. of an acetylacetone benzene solution of a known concentration and 5 ml. of an aqueous solution of 0.1 M sodium perchlorate at various pH values was mechanically shaken for 30 min. in order to attain the distribution equilibrium of acetylacetone at a regulated temperature. After the phases had settled, the volumes of the two phases, the concentration of acetylacetone and the pH in the aqueous phase were measured. The distribution ratio was defined as the ratio of the concentration of acetylacetone in the organic phase to the concentration in the aqueous phase.

The concentration of acetylacetone in the aqueous phase was determined by adding a large excess of an aqueous solution of ferric sulfate at pH 0.5 to an aliquot (1 ml.) of the sample solution, while the absorption at 650 mμ was measured by a spectrophotometer. The pH measurements were carried

* Present address: Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu.

2) N. Suzuki and S. Oki, This Bulletin, ibid., 35, 273 (1962).

out within an accuracy of 0.01 pH unit with a glass electrode pH meter.

The distribution ratio of cerium was determined as follows: A mixture of 5 ml. of an acetylacetone benzene solution of a known concentration, which had extracted cerium at pH 6—7 beforehand, and 5 ml. of an aqueous solution of 0.1 M sodium perchlorate at various pH values was mechanically shaken for an hour in order to attain the distribution equilibrium at a regulated temperature. The initial concentration of cerium in the organic phase was the tracer concentration, the order of $10^{-9}$ M. After the phases had settled, an aliquot (1 ml.) was taken out from each phase into each polyethylene test tube in order to count the gamma activity of cerium-144. Measurements of the gamma activity were carried out by a well-type NaI(Tl) scintillation countor, after a period of time, for the radioactive equilibria of cerium-144 and praseodymium-144.

**Symbols and Formulae.**—The following symbols and formulae are used:

[ ]=concentration in the aqueous phase

[ ]$_o$=concentration in the organic phase

HA=acetylacetone

$D_A$=distribution ratio of acetylacetone

$$D_A=[HA]_o/\{[HA]+[A^-]+[H_2A^+]\} \quad (1)$$

$D_A^\circ$=distribution coefficient of acetylacetone

$$D_A^\circ=[HA]_o/[HA] \quad (2)$$

$K_a$=acid dissociation constant of acetylacetone

$$K_a=[H^+][A^-]/[HA] \quad (3)$$

$K_b$=base dissociation constant of acetylacetone

$$K_b=[H_2A^+]/[H^+][HA] \quad (4)$$

$D_c$=distribution ratio of cerium

$D_c^\circ$=distribution coefficient of ceric acetylacetone

$$D_c^\circ=[CeA_4]_o/[CeA_4] \quad (5)$$

$K_n$=formation constant of the chelate $CeA_n$

$$K_n=[CeA_n^{4-n}]/[Ce^{4+}][A^-]^n \quad (6)$$

$k_m$=formation constantant of the compounds $CeA_4\cdot mHA$ in the organic phase

$$K_m=[CeA_4\cdot mHA]_o/[CeA_4]_o[HA]_o^m \quad (7)$$

## Results and Discussion

**The Distribution of Acetylacetone.** — The equilibrium distribution ratio of acetylacetone varies with the pH of the aqueous phase. The variation depends on the dissociation of acetylacetone as an acid or a base. When it is assumed that ions are not extracted, the distribution ratio will be given as Eq. 1 or:

$$D_A=D_A^\circ/\{1+K_a/[H^+]+K_b[H^+]\} \quad (8)$$

Equation 8 indicates that $D_A$ has a maximum value equal to $D_A^\circ/(1+2\sqrt{K_a\cdot K_b})$ at pH$=(pK_a-pK_b)/2$.

Since the prodct $K_a\cdot K_b$ is much smaller than unity, the maximum distribution ratio is reduced to $D_A^\circ$. A plot of $D_A$ vs. pH at 25°C is given in Fig. 1. The distribution ratio is found to be almost constant in the pH range from 1.5 to 7, and $D_A^\circ$ is determined graphically by Fig. 1. The distribution coefficients at various temperatures were determined in the same way; the results are summarized in Table I.

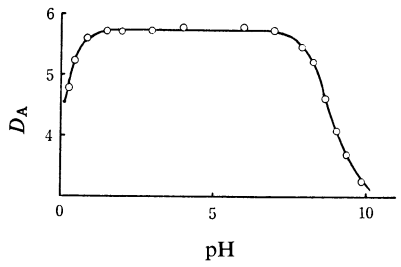

Fig. 1. Distribution curve of acetylacetone.

TABLE I. EQUILIBRIUM CONSTANTS OF ACETYLACETONE AT VARIOUS TEMPERATURES

| Temp., °C | $D_A^\circ$ | p$K_a$ |
|---|---|---|
| 10 | 5.5 | $8.9_0$ |
| 25 | 5.4 | $8.8_8$ |
| 40 | 5.3 | $8.8_6$ |

When the term of $K_b[H^+]$ is small enough to be negligible compared with $K_a/[H^+]$, Eq. 8 is rewritten as:

$$D_A=D_A^\circ/\{1+K_a/[H^+]\},$$

or

$$\log\{(D_A^\circ-D_A)/D_A\}=pH-pK_a$$

A plot of $\log\{(D_A^\circ-D_A)/D_A\}$ as ordinate against pH as abscissa is given in Fig. 2. The pH value where $D_A$ is equal to $D_A^\circ/2$ will be the p$K_a$ of acetylacetone. The dissociation constants at various temperatures were obtained in the same way and are summarized in Table I; they are in good agreement with the literature.[3,4] The decrease in the distribution ratio is observed in the pH range below 1. Acetylacetone is assumed to be present in an acid form such as $H_2A^+$ in strong acid solutions.[4] The decrease in the distribution ratio may be attributed partially to the fact that the ionic strength in the pH range below 1 was not maintained constant, but mainly to the gradual transformation of acetylacetone into an acid form or a cationic form with a decreasing pH, which is incapable of being extracted with benzene.

**The Distribution of Cerium.**—The distribution ratio of cerium increases with an increase in the concentration of acetylacetone in the

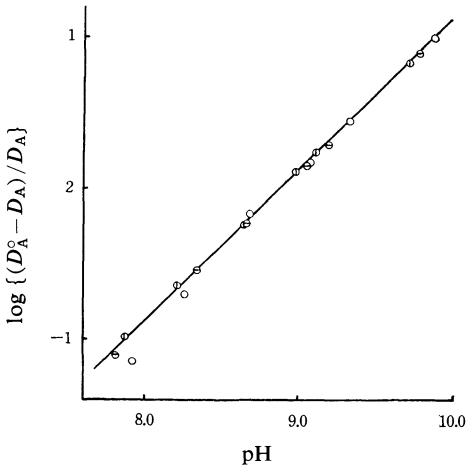

Fig. 2. Determination of p$K_a$ of acetylacetone.
⊖ 10°C ○ 25°C ⊕ 40°C

organic phase, as is shown in Fig. 9, which suggests the presence of such compounds as $CeA_N \cdot mHA$ $(m, N \geqq 0)$ in the organic phase. Accordingly, the distribution ratio of cerium may be given as:

$$D_c = \sum_{m=0} [CeA_N \cdot mHA]_o / \sum_{n=0} [CeA_n^{N-n}] \qquad (11)$$

where $N$ is the number of the acetylacetonate ligand coordinated to cerium. In Eq. 11 it is assumed that the ionic species are not extracted in the organic phase.

The distribution curves of cerium are given in Figs. 3, 4, and 5 at 10, 25, and 40°C respectively. Fortunately, the distribution ratio of acetylacetone was proved to be constant under these experimental conditions, and the concentration of acetylacetone can easily be maintained constant, while changing that of the acetylacetonate ion in the aqueous phase, by changing the pH. In either Figs. 3, 4, or 5, straight lines with fourth-power dependence of the concentration of a hydrogen ion are obtained in the lower pH region. With an increase in the pH, however, the experimental values show a discrepancy from the straight lines downwards. If the tendency were due to the hydrolysis of cerium, the discrepancy would disappear when the concentration of acetylacetone in the system was increased against the experimental results. In Figs. 6, 7, and 8 the distribution of cerium is plotted against p$A$, $-\log[A^-]$. Straight lines with fourth-power dependence of the concentration of the acetylacetonate ion in the higher p$A$ region are also given. The distribution curves are observed to give the same slopes at the

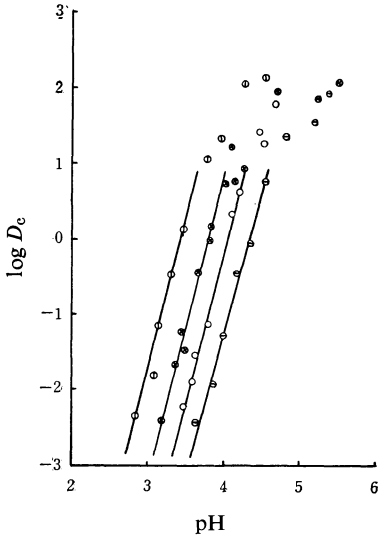

Fig. 3. Disrtibution curves of cerium as a function of pH at 25°C.

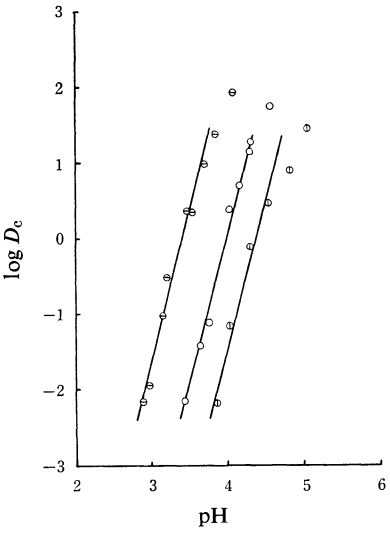

Fig. 4. Distribution curves of cerium as a function of pH at 10°C.
$[HA]_o$, M: ⊖ 0.897, ○ 0.310, ⊕ 0.167

same p$A$ value. The distribution ratio, however, increases with an increase in the concentration of acetylacetone in the organic phase. These results are adequately explained by Eq. 11, where $N$ is substituted for 4, or Eq. 12;

$$D_c = \sum_{m=0} [CeA_4 \cdot mHA]_o / \sum_{n=0} [CeA_n^{4-n}] \qquad (12)$$

Equation 12 is also supported by the early experimental results;[1] cerium(III) is not extracted, while in the presence of bromate cerium is extracted. By combining Eqs. 5, 6,

7, and 12, $D_c$ may be rewritten as:

$$D_c = D_c^\circ K_4 [A^-]^4 \{ \sum_{m=0} k_m [HA]_o^m \sum_{n=0} K_n [A^-]^n \} \quad (13)$$

When the p$A$ is high enough to make the products $K_n[A^-]$ ($n \geqq 1$) negligible compared with unity in the denominator in Eq. 13, that equation is reduced to:

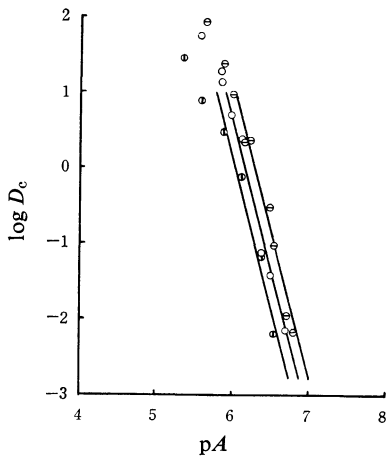

Fig. 7. Distribution curves of cerium as a function of p$A$ at 10°C.
$[HA]_o$, M: ⊖ 0.897, ○ 0.310, ⊕ 0.167

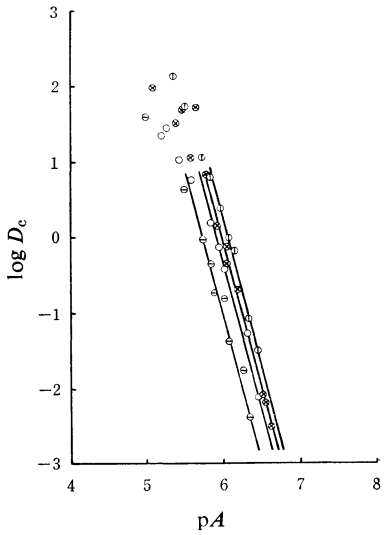

Fig. 8. Distribution curves of cerium as a function of p$A$ at 40°C.
$[HA]_o$, M: ⊕ 0.904, ⊗ 0.437, ○ 0.302
⊖ 0.155

$$D_c = D_c^\circ K_4 [A^-]^4 \sum_{m=0} k_m [HA]_o^m \quad (14)$$

Equation 14 indicates that in the higher p$A$ region the distribution ratio of cerium is proportional to the fourth power of the concentration of the acetylacetonate ion for a constant concentration of acetylacetone in the organic phase. The reason why the distribution ratio is observed to bend gradually downwards may be explained by Eq. 13 to be the result of the gradual formation of ceric acetylacetonate, $CeA_n^{4-n}$ ($n \geqq 1$), in the aqueous phase, because distribution curves at the respective

concentrations of acetylacetone seem to give the same slope at the same p$A$ values in Figs. 6, 7, and 8. The distribution data, however, were considerably scattered, and the reproducibility was somewhat poor in the higher pH region, where gradual hydrolysis may take place. Therefore, the stoichiometric treatments were not applied in the lower p$A$ regions.

The variations in the distribution ratio with the concentration of acetylacetone in the organic phase are given in Fig. 9, which was obtained by interpolating the distribution curves of Figs. 6, 7, and 8 at p$A$ 6.25. The increase in the distribution ratio of cerium with an increase in the concentration of acetylacetone in the organic phase is comprehensible as the results of the formation of the compounds, $CeA_4 \cdot mHA$ in the organic phase, which is explained by Eq. 14 (Fig. 9). Since the distribution ratio is proportional to the square of the concentration of acetylacetone below 0.5 M, it may be concluded that a molecule of cerium acetylacetonate combines

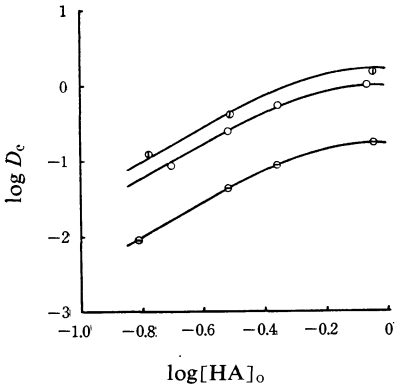

Fig. 9. Distribution curves of cerium as a function of $[HA]_o$ at p$A$ 6.25.
Temp., °C: ① 10, ○ 25, ⊖ 40

with two molecules of acetylacetone to form a compound $CeA_4 \cdot 2HA$ in the organic phase.

The effects of the temperature on the distribution ratio of cerium are given in Fig. 9. The effects of the temperature are small for reactions 1, 2, and 3. Supposing that reactions 5 and 6 are not so much influenced by the temperature as usual, reaction 7 has to be influenced by the temperature. The enthalpy change of reaction 7 was calculated to be −13 kcal. from Fig. 9 on the above assumption ($\Delta \log D_c = 1$ for $\Delta T = -30°$). If the interaction between benzene and $CeA_4$ does not amount to any appreciable amount, the enthalpy change is regarded as the binding energy between $CeA_4$ and 2HA. The magnitude of the energy needed for a molecule of acetylacetone to bind with $CeA_4$ is 6.5 kcal., which corresponds to the energy of hydrogen bond. The discrepancy from the straight line in the higher concentration regions is assumed to be the result of the saturation of hydrogen bonds for $CeA_4$ to combine with molecules of acetylacetone, or to be the result of changes in the solvent properties of benzene resulting from an increase in the concentration of acetylacetone in the organic phase.

## Summary

The extraction behavior of tracer amounts of cerium-144 with acetylacetone has been studied. The distribution ratio of acetylacetone between benzene and a 0.1 M sodium perchlorate solution is constant in the pH range 1.5−7, and the distribution coefficients have been determined to be 5.5, 5.4, and 5.3 at 10, 25, and 40°C respectively. The distribution ratio of cerium has been shown to be proportional to the fourth power of the concentration of the acetylacetonate ions and to the square of that of acetylacetone in the organic phase. From these results, it has been concluded that cerium exists as a tetravalent ion in the system and that the chemical form of cerium extracted in the organic phase is $CeA_4 \cdot 2HA$. Two molecules of acetylacetone are assumed to combine with $CeA_4$ forming hydrogen bonds.

# The Dielectric Properties of Some Alkyl Thiol

By Seiichi KONDO

(Received July 13, 1964)

As has already been studied by some authors, molecular crystals with a spherical molecular shape sometimes possess a small entropy of fusion, and such physical properties as nuclear magnetic resonance, dielectric properties, and X-ray diffraction can be well explained by the assumption of molecular rotation on the crystalline lattice site.

2-Methyl-2-propanethiol and 2-methyl-2-butanethiol also have small entropies of fusion,[1] 2.16 cal./deg. mol. and 0.86 cal./deg. mol. respectively, and the X-ray diffraction study of the plastic phase IV (the highest temperature solid phase) of 2-methyl-2-propanethiol shows a random orientation of molecules on the face-centered-cubic crystal lattice sites.[2] These facts lead us to the assumption that molecules on the lattice sites would make rotational motion as a whole, in spite of the possibility of interactions between thiol groups revealed by infrared spectroscopy of other compounds in liquid states.[3] It is of interest to compare the properties of such compounds with those of 2-methyl-2-propanol, which forms a stronger intermolecular hydrogen bond between hydroxyl groups than do thiols and which is not a plastic crystal.

Similarly, it is also interesting to compare the properties of cyclohexanethiol with those of cyclohexanol, which shows many properties characteristic of plastic crystals[2] in spite of the existence of a hydrogen bond between molecules. It is questionable whether or not cyclohexanethiol, which is supposed to have a weaker intermolecular interaction between thiol groups, is a plastic crystal. The dielectric study of these compounds has, therefore, been carried out, in both liquid and solid states, in respect to the dipole interaction of these molecules in condensed states, as one of the series of dielectric investigations of plastic crystals.

## Experimental

**Sample Preparation and Measuring Apparatus.**—2-Methyl-2-propanethiol and 2-methyl-2-butanethiol were supplied in vacuum-sealed glass ampules with breakable joints by the U. S. Bureau of Mines, through the courtesy of Dr. J. P. McCullough. These were vacuum-sublimed, dried with magnesium perchlorate, and then placed in glass dielectric cells with platinum electrodes. All these procedures were carried out in the same vacuum system without any exposure to air. The melting points of these materials after repurification are equal to those obtained by McCullough and others[1] within the range of experimental error. Cyclohexanethiol was synthesized in this laboratory from cyclohexanol and purified by the same method. However, the purity of this sample was not as high as that of the others, as may be seen in the curve near the melting point in Fig. 3, partly because of the difficulty in drying.

The measuring circuit used in this study is a low-frequency bridge with a frequency range from $10^2$ to $10^4$ c. p. s. It has been described elsewhere.[4] The dielectric constant was determined by a comparison of the electric capacity with purified organic liquids, such as benzene, ethyl ether and acetone, with accurate dielectric constant values.

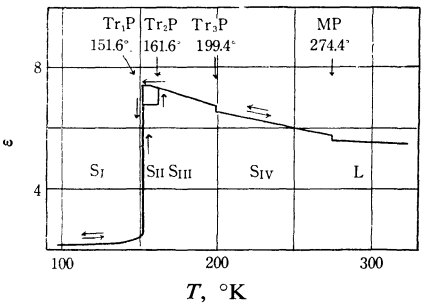

Fig. 1. The dielectric constant versus temperature curve of 2-methyl-2-propanethiol.

## Results and Discussion

**2-Methyl-2-propanethiol.**—The variation in the dielectric constant of this material with the temperature is illustrated schematically in Fig. 1. The value of the dielectric loss, tan $\delta$, was less than $10^{-3}$. This value, together with that of the dielectric constant, showed no detectable frequency effect within our temperature range. The dipole moment, $\mu$, of

4) S. Kondo and T. Oda, This Bulletin, **27**, 567 (1954).

this molecule in the liquid state at 20° C can be calculated by using the Onsager equation[5] for pure polar liquid,

$$\frac{(\varepsilon-n^2)(2\varepsilon+n^2)M}{\varepsilon(n^2+2)^2 d}=\frac{4\pi N}{3}\frac{3kT}{\mu^2}$$

With $T=293°$ K, dielectric constant $\varepsilon=5.55$, density $d=0.8002$ g./cm$^3$,[6] and refractive index $n=1.4232$, the value of $\mu$ is calculated to be 1.67 D. This is almost equal to that of ethanethiol, 1.56 D, in the gas phase,[7] suggesting that the molecular association through the intermolecular hydrogenbond is very small.

The dipole moment of the plastic Phase IV, as calculated in the same manner, is 1.6 D, equal to that of the liquid. This suggests that the degree of molecular dipole rotation in the plastic phase is almost the same as that in the liquid state, as has been seen in other plastic crystals studied elsewhere.[2] The high symmetry of this crystal phase (face-centered-cubic structure) as shown by X-ray diffraction work,[2] compared with the low molecular symmetry of this compound, can be explained by the molecular rotation.

The same order of magnitude of the dielectric constant in phases III and II indicates the existence of some kind of molecular rotation in these phases. A thermal hysteresis of phase change was observed in phase II, as may be seen in Fig. 1. Careful thermal treatment shows that this is a sort of supercooling phenomenon probably accompanied by the molecular rearrangement process in this temperature region. The dielectric constant of phase I is nearly equal to the square of the refractive index of this material, suggesting the absence of the rotation of the molecular dipole in this phase.

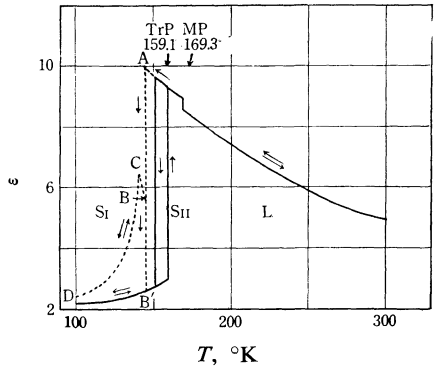

Fig. 2. The dielectric constant versus temperature curve of 2-methyl-2-butanethiol.

**2-Methyl-2-butanethiol.**—The dielectric constant versus the temperature relation is shown in Fig. 2. No anomalous dispersion has been observed in the present frequency and temperature range. As the application of the Onsager equation to the liquid and crystalline phase II of this material in the same manner as was done with 2-methyl-2-propanethiol gives, in both states, the value of 1.6 D as the dipole moment, this seems to be reasonable in comparison with those of other aliphatic thiols. This fact, and the very low entropy of fusion of this material, indicate the existence of molecular rotation in phase II. As may be seen in Fig. 2, this material shows a large thermal hysteresis on the phase transition from phase II to phase I; this hysteresis depends upon the cooling velocity. With a cooling rate smaller than 0.2 deg./min., the phase change occurs in accordance with the full line in Fig. 2. More rapid cooling gives rise to complicated behavior such is shown by the dotted line "A-B-C-D". Heating this sample from point "D" leads to the change "D-C-B-B'," and from point "B'" the system follows the full line. These facts seem to indicate the existence of a supercooled crystalline phase. McCullough and others observed a very small $\lambda$-type heat capacity anomaly at about 145°K which is likely to coincide with our point "C" in Fig. 2. The small value of the dielectric constant in phase I suggests the cessation of the rotation of the molecular dipole in this phase.

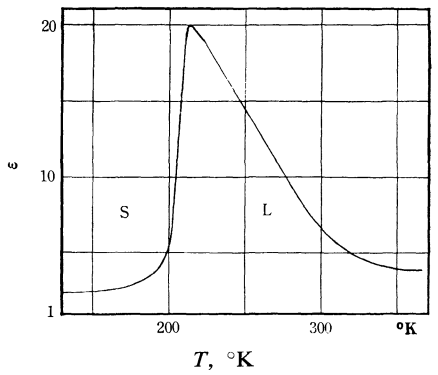

Fig. 3. The dielectric constant versus temperature curve of cyclohexanethiol.

**Cyclohexanethiol.**—In Fig. 3, the dielectric constant of this material decreases to about 2 in the solid phase upon being frozen, and no further marked change in the dielectric constant which indicates the phase change, has been observed within the present temperature and frequency range.

The curve of Fig. 3 near the melting point is somewhat ambiguous, as has been described

5) L. Onsager, *J. Am. Chem. Soc.*, **58**, 1486 (1936).
6) J. P. McCullough, *Private communication.*

in the section on sample preparation, because of the low purity of the sample. Therefore, no more detailed discussion will be made on this material beyond the suggestion that this material is not a plastic crystal.

The infrared absorption spectroscopy of this material by Kozima and Koda[8] shows the existence of a weak hydrogen bond in both the liquid and solid phases. They also concluded on the basis of an analysis of SH group vibration frequencies in these two states, that the molecule assumes both "a" and "e" forms in liquid phase but only "a" form in the solid phase. These properties of cyclohexanethiol are in marked contrast to those of cyclohexanol, which is a plastic crystal.

## Summary

It has been concluded that both 2-methyl-2-propanethiol and 2-methyl-2-butanethiol are plastic crystals and that, in their highest temperature crystalline phases, molecules perform a rotational motion on the lattice sites. The intermolecular S-H···S hydrogen-bond, which might possibly exist in these phases, seems to be too weak to hinder the molecular rotation. Cyclohexanethiol does not seem to be a plastic crystal, probably because of its low molecular symmetry in the solid phase and its intermolecular hydrogen bond.

The author wishes to express his thanks to Dr. J. P. McCullough of the U. S. Bureau of Mines for the supply of the samples of 2-methyl-2-propanethiol and 2-methyl-2-butanethiol and for his helpful discussions. Thanks are also due to Dr. Tsutomu Oda, Mr. Masaru Matsumoto and Mr. Kaoru Kawabe for their useful discussions and for their help with some of the measurements.

# The Quenching Action of Benzoic Acid and Methyl Benzoate on the Fluorescence of Naphthalene Derivatives

By Takuji MIWA and Masao KOIZUMI

(Received July 16, 1964)

In a previous paper,[1] the present authors investigated the quenching action of pyridine and quinoline on the fluorescence of naphthylamine and naphthol and their related compounds, in connection with the effect of intermolecular hydrogen bonding on the fluorescence power. A high degree of quenching was observed in the system consisting of naphthylamine or naphthol as a fluorescer and pyridine or quinoline as a quencher; this was just what had been expected from Mataga's finding[2] that a fluorescer loses its emissivity when hydrogen-bonded directly with another conjugated system. A notable result then found was that a rather large quenching was observed in the system consisting of *N*, *N*-dimethyl-2-naphthylamine or 2-naphthyl methyl ether (fluorescer) and pyridine or quinoline (quencher), where no hydrogen bonding is conceivable. These phenomena were explained by assuming an intermolecular charge transfer between the excited fluorescer and the quencher. Although analogous mechanisms of quenching have long been postulated, no confirmative evidence had been presented until recently, when Weller,[3] by means of a flash photolytic technique, succeeded in providing strong support for this mechanism holding in the perylene - amine system. However, from the standpoint of a charge-transfer mechanism, there seems to be very little work which has succeeded in correlating the quenching constants with such properties of fluorescers and quenchers as the ionization potential or electron affinity. Among recent articles, the works

of Weller[4] and Majumder et al.[5] are prominent. The former compared the quenching action of various aliphatic amines on the fluorescence of an aqueous acridine solution, while the latter investigated the fluorescence power of some condensed aromatic compounds, such as anthracene, dissolved in benzene, toluene, xylene, and mesitylene. Still fewer have been the systematic studies of various systems undertaken from this point of view.

We became interested in undertaking such a study in the expectation that it would make our proposed mechanism more concrete. In this paper, the first in a series devoted to the above study, we will describe the quenching action of benzoic acid and its methyl ester, both chosen as weak electron acceptors, on the fluorescence of naphthalene derivatives, including *N,N*-dimethylnaphthylamine and naphthyl methyl ether.

It will be shown that the benzoic acid dimer has a rather large quenching action on the above-mentioned compounds; the molecular mechanism will also be discussed.

## Experimental

**Materials.**—*Benzoic Acid.*—The standard sample for calorimetry, obtained from the Shigen Gijutsu Shikenjo (Natural Resources Institute), was recrystallized three times from benzene.

*Methyl Benzoate.* — Commercial material was treated twice with a concentrated aqueous potassium carbonate solution to remove the free acid, dehydrated over potassium carbonate (for more than a week), and finally distilled twice under reduced pressure.

*Cyclohexane and Other Materials.*—The procedure for purification was the same as that described in a previous paper.[1)]

**Apparatus and Procedure.** — The absorption spectra were measured with a Hitachi EPS or EPU spectrophotometer. The fluoresecence intensity was measured with a fluorometer made by the Narumi Shokai (the details of the apparatus were given in the previous paper[1)]) or an Aminco-Bowman spectrophotofluorometer. In the former apparatus, only the exciting light is monochromatized by a prism while the entire (not monochromatized) fluorescence or a part of it (through a filter) is caught by a photomultiplier. Intensities were measured on a photometer. In the latter apparatus both the exciting light and the fluorescence are monochromatized with a diffraction monochromator. The action spectra as well as the fluorescence spectra can be recorded automatically. The fluorescence intensity of the sample solution containing a quenching substance was compared with that of the reference solution, measurement of which was performed immediately before and after the measurement of the sample solution. All the measurements were made at room temperature without degassing. Integrated fluorescence spectra or the height of the maxima in the fluorescence spectra were used for the analysis. A suitable correction was made when necessary, for example, when the addition of a quenching substance changed the optical density at the exciting wavelength or affected the fluorescence spectra to an appreciable extent. The absorption spectra and the fluorescence spectra of the substances employed are given in Figs. 1—4. The error in wavelength is about $\pm 0.5\ m\mu$ for absorption and about $\pm 3\ m\mu$ for fluorescence spectra.

## Results

**Quenching Action of Methyl Benzoate.**—*N, N-Dimethyl-2-naphthylamine in Cyclohexane.*—Upon the addition of 0.2 M of quencher, the absorption spectra undergo a distinct red shift, which increases with the concentration of the quencher and which, at the same time, causes a broadening of all the features of the spectra. This phenomenon may be attributed to the so-called solvent effect. The fluorescence spectra show similar changes in the concentration range 0—2 M of the quencher. The fluorescence intensity decreases only a little with the addition of 0.2 M of quencher. In the region 0—2 M, the $F_0/F-1$ vs. [Q] (Q=quencher) plot does not obey the Stern-Volmer relation, but resembles the curve of the second degree, as Fig. 5 shows. The quenching constant was estimated to be $k<0.8$ from the tangent at $[Q]\rightarrow 0$.

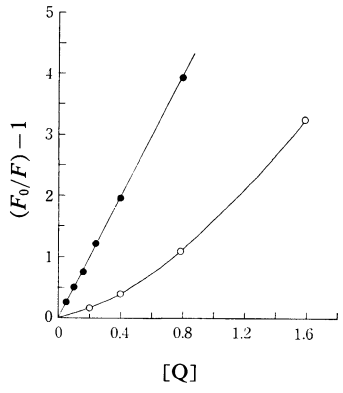

Fig. 5.

○ *N,N*-Dimethyl-2-naphthylamine ($1.00\times10^{-4}$ M/l.) - methyl benzoate in cyclohexane
● *N,N*-Dimethyl-2-naphthylamine ($1.00\times10^{-4}$ M/l.) - methyl benzoate in benzene
Q Methyl benzoate

*N, N-Dimethyl-2-naphthylamine in Benzene.* — This solution shows qualitative features similar to those of the cyclohexane solution, but the Stern-Volmer relation holds exactly in the range 0—2 M of [Q], as Fig. 5 shows. The value of the quenching constant is 5.

*2-Naphthyl Methyl Ether in Cyclohexane.*—With the addition of the quencher, the absorption spectra become a little diffused and suffer a slight red shift. The fluorescence spectra show a similar change, but the intensity is not practically affected, even by the addition of as much as 8 M of quencher (i. e., $k\approx 0$).

*2-Naphthylamine in Cyclohexane.* — With the addition of the quencher, the absorption spectra show a change characteristic of intermolecular hydrogen bonding, as Fig. 6 shows. The results can be analyzed by using the well known Eq. 1, where $K$ is the equilibrium constant, where $[Q_0]$ and $[A_0]$ denote the total concentrations of quencher and fluorescer respectively, where $d$ and $d_0$ are the optical densities at a certain wavelength in the presence and in the absence of the quencher respectively, and where $\varepsilon$ is the molar extinction coefficient of the hydrogen-bonded species at the same wavelength:

$$\frac{d-d_0}{[Q_0]}=\varepsilon K[A_0]-Kd \qquad (1)$$

The value of $K$ obtained is 0.7. Thus, the strength of the hydrogen bond is so weak that its effect on the absorption spectra may be

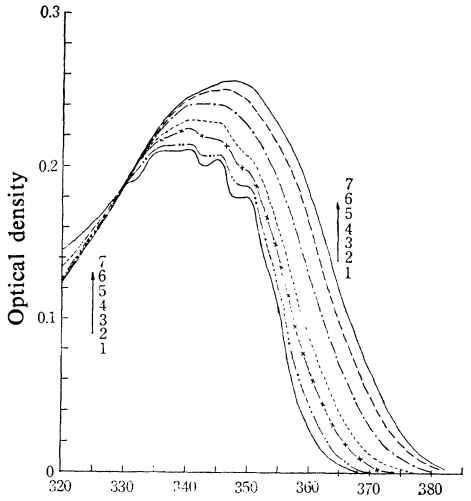

Fig. 6. Absorption spectra of 2-naphthylamine ($0.998\times10^{-4}$ M/l.) - methyl benzoate in cyclohexane. The concentrations of methyl benzoate are; 1) 0 M/l.; 2) $1.60\times10^{-1}$ M/l.; 3) $4.00\times10^{-1}$ M/l; 4) $8.01\times10^{-1}$ M/l.; 5) 2.40 M/l.; 6) 4.80 M/l.; 7) 8.00 M/l.

considered to be of the same degree as the solvent effect. In such situations, the change in the absorption spectra cannot be attributed only to hydrogen bonding, and hence, the above value may be an underestimation.

The fluorescence spectra do not change essentially with the addition of the quencher up to 0.2 M; beyond this value, they do show a slight red shift, but the intensity becomes so weak that one cannot say much about the spectral features. In any case, the hydrogen-bonded species is considered to be completely or almost completely non-fluorescent. The quenching constant obtained from the Stern-Volmer formula, which holds in this case up to $10^{-2}$ M (Fig. 7a), is 84. Beyond $1.6\times10^{-2}$ M, the $(F_0/F-1)/[Q]$ vs. [Q] plot becomes linear, as Fig. 7b shows. This indicates that the hydrogen-bonded species is non-fluorescent or negligibly fluorescent. It may be concluded that the quenching mechanism obeys the following scheme:

$$\begin{array}{ccc} & \mathrm{A^*} + \mathrm{Q} \underset{k_{-Q}}{\overset{k_Q}{\rightleftarrows}} \mathrm{A^*Q} & \\ k_f + k_d \downarrow\uparrow & & \uparrow\downarrow k_f' + k_d' \\ & \mathrm{A} + \mathrm{Q} \underset{}{\overset{K}{\rightleftarrows}} \mathrm{AQ} & \end{array} \qquad (2)$$

with $k_d' \gg k_{-Q}, k_f'$

From this scheme, the following relation can easily be derived:

$$\{(F_0/F)-1\}/[Q]=\left\{k+\left(\frac{\varepsilon'}{\varepsilon}\right)K\right\}+k\left(\frac{\varepsilon'}{\varepsilon}\right)K[Q];$$

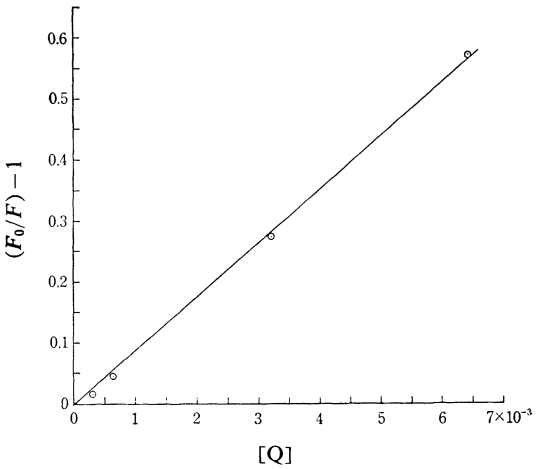

Fig. 7a. 2-Naphthylamine ($0.998\times10^{-4}$ M/l.) - methyl benzoate in cyclohexane.
Q: Methyl benzoate

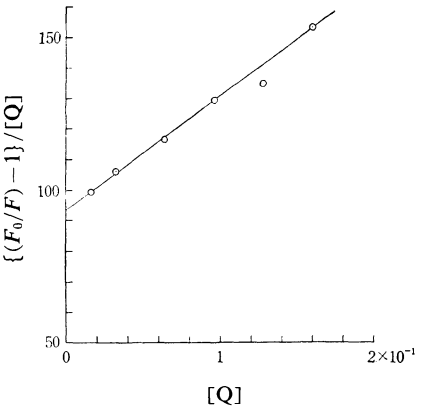

Fig. 7b. 2-Naphthylamine ($0.998\times10^{-4}$ M/l.) - methyl benzoate in cyclohexane.
Q: Methyl benzoate

$$k=\frac{k_Q}{k_f+k_d+k_Q}$$

where $\varepsilon$ and $\varepsilon'$ are, respectively, the molar extinction coefficient of the free species and of the hydrogen-bonded species at the exciting wavelength. It should be noted that actually the exciting wavelength was chosen at the position where $\varepsilon=\varepsilon'$. From the inclination and the intercept of the plot in Fig. 7b, one gets the quenching constant $k$ of 89, while the equilibrium constant $K$ for the hydrogen bonding (in the ground state) is 4. The former value agrees well with the quenching constant obtained from the inclination at $[Q]\rightarrow0$, and the latter value is consistent with the view that the hydrogen-bonding equilibrium constant obtained from the absorption spectra was underestimated.

*2-Naphthol in Cyclohexane.*—The absorption spectra show a typical change due to hydrogen bonding with isosbestic points at 315 and 330 mμ. From measurements of the optical densities at a fixed wavelength (334 mμ) of solutions of various compositions and by analyzing the data with Eq. 1, one gets the hydrogen-bonding equilibrium constant $K$ in the ground state of 11.5 (at 22.6°C).

The fluorescence spectra are scarcely affected at all by the addition of the quencher up to $5\times10^{-1}$ M, and at higher concentrations the fluorescence intensity is too weak for the spectra to be measured. By the application of the Stern-Volmer equation, which holds for quencher concentrations up to $8.0\times10^{-3}$ M, the quenching constant, $k$, was found to be 87 (Fig. 8a). At higher concentrations, the $\{(F_0/F)-1\}/[Q]$ vs. [Q] plot shows a linear relation, as may be seen in Fig. 8b. The values of $k$ and $K$ as determined from both the intercept and the slope were found to be 78 and 15 respectively. These data are quite consistent with one another, and there is no doubt that the hydrogen-bonded species is non-fluorescent or very poorly fluorescent and that the fluorescence phenomena obey Scheme 1.

In the higher concentration region the $\{(F_0/F)-1\}/[Q]$ vs. [Q] plot is linear and one gets $k=48$.

*vii) 2-Naphthol in Cyclohexane: viii) 2-Naphthol in Benzene.*—In these systems, neither the fluorescence nor the absorption spectra show any essential change. Quenching occurs and is well reproduced by the Stern-Volmer equation in both cases. The quenching constants $k$ are, respectively, 39 and 35. Some examples for v, vi, vii and viii are shown in Fig. 10.

## Discussion

A summary of the above results is given in Tables IA, IB and IC. The results in Table IA can be interpreted, for the most part, on the basis of hydrogen bonding. Thus, a remarkable difference in the magnitude of quenching between naphthylamine and naphthol, on the one hand, and their methyl derivatives, on the other, is without doubt due to the existence of intermolecular hydrogen bonding in the former case and the non-existence of it in the latter case.

The results conform quite well to Mataga's view-point, and one can say that such a compound as benzoic acid ester, which has a conjugated system of $\pi$-electrons extended to the side chain, can act as a quencher by forming a hydrogen bond with the fluorescer at the side-chain oxygen atom. The finding that a slight quenching occurs in the *N,N*-dimethyl-2-naphthylamine - benzoic acid ester system, but not in the 2-naphthyl methyl ether - benzoic acid ester system, may be interpreted by means of the charge transfer mechanism proposed in the previous paper, because naphthylamine derivatives are expected to act as stronger donors than naphthol derivatives.

Tables IB and IC contain the results for the systems in which benzoic acid is used as a quencher. They all show quenching phenomena to some extent. It is well-known that benzoic acid has a strong tendency to dimerize in non-polar solvents, and since the dimerization constant is so large,[6] practically all the molecules of benzoic acid are considered to exist as dimers under the present experimental conditions. Hence, there is no doubt that the quenching action of benzoic acid is phenomenologically to be attributed to its dimer. As for the detailed mechanism, however, no definite picture can be given at the present stage of investigation. Discussion of possible mechanisms will, however, be given below: the fluorescers being classified into two

6) For example, according to M. Ito (*J. Mol. Spectry*, 4, 144, (1960)) the value is of the order of $10^4$.

TABLE IA. QUENCHING ACTION OF METHYL BENZOATE (Q)

| Solvent | Fluorescer | Absorption spectra | | Fluorescence spectra | | |
|---|---|---|---|---|---|---|
| | | [Q] M/l. | Spectra | [Q] M/l. | Spectra | Quenching constant |
| Cy | $-NC(CH_3)_2$ | 0—8.01 | Red shift $\Delta\tilde{\nu}=630$ | 0—2 | Red shift | <0.8 |
| B | $-NC(CH_3)_2$ | 0—8.01 | Red shift $\Delta\tilde{\nu}=160$ | 0—2 | Red shift | 5 |
| Cy | $-NH_2$ | 0—8.01 | Red shift $\Delta\tilde{\nu}=680$ H.B.; $K>0.7$ | 0—8.01 | Ambiguous | 86 |
| Cy | $-OCH_3$ | 0—8.01 | Red shift $\Delta\tilde{\nu}=190$ | 0—8.01 | Red shift | ~0 |
| Cy | -OH | 0—8.01 | Red shift $\Delta\tilde{\nu}=390$ H.B.; $K=11.5$ (22.5°C) | 0—8.01 | Ambiguous | 87 |

Cy: Cyclohexane, B: Benzene, $-NC(CH_3)_2$: *N*,*N*-Dimethyl-2-naphthylamine, $-NH_2$: 2-Naphthylamine, -OCH: 2-Naphthyl methyl ether, -OH: 2-Naphthol, H.B.: Hydrogen bond formation, *K*: H.B. formation constant.

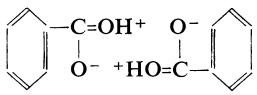
TABLE IB. QUENCHING ACTION OF BENZOIC ACID (Q)

| Solvent | Fluorescer | [Q] M/l. | Absorption spectra | Fluorescence spectra | Quenching constant |
|---|---|---|---|---|---|
| Cy | $-NC(CH_3)_2$ | $0—1.75\times10^{-2}$ | No change | No change | 36 |
| B | $-NC(CH_3)_2$ | $0—4\times10^{-1}$ | No change | No change | 50 |
| Cy | $-OCH_3$ | $0—4\times10^{-2}$ | No change | No change | 16 |
| B | $-OCH_3$ | $0—4\times10^{-1}$ | No change | No change | 22 |

Abbreviations are the same as before. Quenching constants are referred to a monomer unit.

TABLE IC. QUENCHING ACTION OF BENZOIC ACID (Q)

| Solvent | Fluorescer | [Q] M/l. | Absorption spectra | Fluorescence spectra | Quenching constant |
|---|---|---|---|---|---|
| Cy | $-NH_2$ | $0—4\times10^{-2}$ | Slight blue shift | No change | 52 |
| B | $-NH_2$ | $0—4\times10^{-1}$ | Blue shift H.B.; $K=11$ | No change | 48 |
| Cy | -OH | $0—4\times10^{-2}$ | No change | No change | 39 |
| B | -OH | $0—4\times10^{-1}$ | No change | No change | 35 |



Abbreviations are the same as before. Quenching constants referred to a monomer unit.

groups: B; the fluorescers that cannot act as hydrogen donors; and C; those that can act as hydrogen donors.

It seems plausible to attribute the quenching phenomena observed in group B entirely to a charge transfer mechanism in which the fluorescer acts as an electron donor and the benzoic acid dimer acts as an acceptor.

The reason will be given below. Firstly, the possibility of hydrogen bonding in this group is limited to the case in which a fluorescer and a quencher act, respectively, as a hydrogen acceptor and a donor. However, since a rather strong intermolecular hydrogen bonding is present in the benzoic acid dimer, the dimer itself is expected to have little or no power to act as a hydrogen donor. In fact, no significant change is observed in the absorption spectra of systems made up of this group. Moreover, the formation constant of hydrogen bonding of this type is expected to be smaller in the excited state than in the ground state. In accord with this, there is, in fact, no change in the fluorescence spectra. Hence, one may safely rule out the possibility of hydrogen bonding between the excited fluorescer and the ground-state benzoic acid dimer. Thus, the mechanism of quenching must be of another type, and a charge-transfer mechanism, with charge transfer taking place between the fluorescer and benzoic acid dimer, seems to be the most plausible alternative. If charge transfer

were to take place between the benzoic acid monomer and the fluorescer, then the quenching constants for free acid and the $CH_3$-ester should be of the same order of magnitude, since the accepting powers of these two substances are not very different. The present result, however, shows that the quenching constant for free acid is far greater than that for the methyl ester. This may be interpreted as follows. According to the general view, the effect of hydrogen bonding on the $\pi$-electronic configuration is somewhat similar, though to a lesser extent, to that of acid dissociation, which in the present case is represented as follows*:

In other words, the delocalization of $\pi$-electrons in the carboxyl group is increased to some extent in the hydrogen-bonded system. Hence, the vacant level of this group is lowered, and a dimer is expected to be a better electron acceptor than a monomer. Furthermore, the following results can be easily comprehended on the basis of the above point of view: a) The quenching constant for *N*, *N*-dimethyl-2-naphthylamine is larger than that for 2-naphthyl methyl ether. This is because the dimethyl-amino group has a larger electron-releasing power than the methoxy group. b) The fluorescence of *N*, *N*-dimethyl-2-naphthylamine and 2-naphthyl methyl ether is quenched by benzoic acid much more than by methyl benzoate. The reason for this has already been stated above.

Turning to group C, the fluorescer is now free amine or free acid. In these cases there are two types of hydrogen bonding conceivable. One is type-a, in which the fluorescer is a donor and the quencher is an acceptor, and the other is type-b, in which their roles in the hydrogen bonding are reversed.

However, if one assumes that type-b hydrogen bonding is of no importance in the quenching phenomenon, as has been established already, then only type-a remains to be considered. However, in this connection it should be noted that the absorption spectra of naphthylamine display a slight blue shift after the addition of benzoic acid and that such a blue shift is usually related to type-b hydrogen bonding. This might imply that the formation constant of the hydrogen bond between naphthylamine and benzoic acid is large enough to compete with the dimerization of the acid. However, it is still open to question whether this is really true or whether the phenomenon is due to other unknown causes. On the other hand, the fluorescence spectra still display either a red shift or no change at all, which suggests the existence of type-a hydrogen bonding in the excited state. This is consistent with the expectation that this type of hydrogen bonding will become stronger in the excited state. Thus, one may safely assume that type-b does not take part in the quenching phenommena, whereas it is plausible that the hydrogen bond of type a participates in the quenching to some extent. However, there is a question about how the hydrogen bond is formed in this case; thus it is quite unknown whether such a hydrogen bond is formed between the fluorescer and benzoic dimer as it is, or whether the hydrogen bond formation is accompanied by a partial or a complete dissociation of the dimer molecules. The view that quenching really occurs through hydrogen bonding is supported by the fact that the quenching constant for naphthylamine and naphthol is somewhat larger than that for their methyl derivatives. However, on the basis of the discussion of group B, there is no doubt that the charge transfer mechanism also takes part in the quenching. The view that both the mechanisms are taking part in this group is supported by the following findings: a) The quenching constant of benzoic acid is larger for naphthylamine than for naphthol, while the quenching constant of methyl benzoate is of the same magnitude for naphthylamine and naphthol. This can be interpreted by taking account of the charge transfer mechanism in the former case, since the hydroxyl group is a stronger hydrogen donor than the amino group, while the amino group is a stronger electron-releasing group than the hydroxyl group. b) Benzoic acid quenches the fluorescence of naphthylamine more than it does that of dimethylnaphthylamine, and that of naphthol more than that of naphthyl methyl ether. This can be interpreted as being due to hydrogen bonding in the cases of the free amine and phenol. c) Methyl benzoate is a stronger quencher than benzoic acid toward naphthylamine and naphthol. This may be due to the fact that benzoic acid is a weaker hydrogen accepter than the ester, as has already been stated. It should be noted, however, that the quenching constants of benzoic acid in Tables 7B and 7C are given in terms of the monomer unit. If they are expressed in terms of the dimer unit, the values become twice as large and the statement in c) is not so decisive.

To summarize, only the charge transfer

* The contribution of this structure is inferred from the charge-transfer mechanism of the hydrogen bonding.[7]

7) S. Nagakura and M. Gouterman, *J. Chem. Phys.*, **26**, 881 (1957).

mechanism need be considered for group B, while the charge transfer mechanism and the hydrogen-bonding mechanism simultaneously take place in group C. It is apparent, however, that more confirming evidence is necessary before the charge transfer mechanism can be fully accepted.

## Summary

1) The quenching action of benzoic acid (dimer) (BA) and methyl benzoate (MB) on the fluorescence of 2-naphthol (I), 2-naphthylamine (II), 2-naphthyl methyl ether (III) and *N*, *N*-dimethyl-2-naphthylamine (IV) in benzene and in cyclohexane has been studied.

2) MB has little or no quenching effect on the fluorescence of III and IV, whereas it shows a significant quenching action on I and II. The latter is due to the intermolecular hydrogen bonding between the fluorescer and the quencher (the H.B. mechanism).

3) BA shows quite a large quenching action on III and IV. All the results can be interpreted on the basis of a charge transfer mechanism for quenching (the C.T. mechanism).

4) The quenching action of BA is larger on I than on III, and larger on II than on IV, except for benzene solutions of II and IV, in which case the magnitudes are equal within the range of experimental error. These results has been discussed on the basis of a simultaneous occurrence of the C.T. and H.B. mechanisms.

The authors wish to express their thanks to Professor Shunji Kato for his kind advice.

# The NMR Spectra of Triethylsilane and Triethylhalogenosilane

By Osamu YAMAMOTO and Kikuko HAYAMIZU

(Received July 17, 1964)

The proton magentic resonance spectra of a number of metal ethyl compounds have been studied, and attempts have been made to correlate the internal chemical shift, $\delta$, between the methyl and the methylene protons in the ethyl group ($\nu_{CH_3}-\nu_{CH_2}$) with the electronegativity, $x$, of the metal attached to the ethyl group. Although the empirical relationship between $\delta$ and $x$ proposed by Dailey and Shoolery[1] approximately holds over a wide variety of metals, considerable deviations are observed when one of the ethyl group in the metal compounds is replaced by a halogen atom.[2,3] This is due to the magnetic anisotropy of the halogen atom or the C-X bond, where X denotes a halogen atom. Since the order of magnitude of the magnetic anisotropy effect of halogens in aliphatic compounds has been observed to increase with an increase in their atomic weight,[4] the deviation of the $\delta$ value from the simple Dailey and Shoolery relationship will increase in the order of fluorine, chlorine, bromine and iodine. Hence, when a more electronegative halogen atom substitutes on the metal, the $\delta$ value decreases in a manner contrary to that expected from the simple inductive mechanism. This trend has been observed in diethylaluminum monohalides.[3]

In connection with this, the NMR spectra of triethylsilane and triethylhalogenosilane were studied in the present work, and accurate $\delta$ and $J$ (coupling constant) values were given through a rigorous analysis of the spectra. Althought triethylchloro- and triethylbromosilane show the $A_3B_2$ spectra for their ethyl groups, which can be analyzed in the manner described in the previous paper,[3] triethylsilane and triethylfluorosilane give the $A_3B_2X$ spectra. The analysis of the $A_3B_2X$ system has been already made by Narasimhan and Rogers[5] using the model of the composite spin particles which have total spin angular momenta of 3/2, 1, and 1/2 respectively. In the present work this method is also followed, though the spin-spin coupling between A and X is also taken

into account. (This corresponds to the coupling between the methyl protons and fluorine or hydrogen directly attached to silicon.) While such a long-range coupling can be, practically speaking, extremely small in most organic compounds, it may not be negligible when such an atom as fluorine is present in the coupling system.[6]

Hereafter, in the notations $A_3B_2$ and $A_3B_2X$, A and B refer to methyl and methylene protons in an ethyl group respectively, and X to hydrogen or fluorine directly attached to silicon. Thus, for example, $J_{AB}$ means the coupling constant between the methyl and the methylene protons in the ethyl group.

## Experimental

Triethylsilane was prepared from trichlorosilane and ethylmagnesium bromide ;[7] triethylfluorosilane and triethylchlorosilane were prepared by adding the corresponding ammonium halide to hexaethyldisiloxane in concentrated sulfuric acid[8] triethylbromosilane was prepared by dropping liquid bromine into phenyltriethylsilane.[9] The purity of the samples was examined by means of their infrared absorption spectra and by gas chromatography.

The NMR spectra of the compounds were obtained by means of a Varian Associates DP-60 spectrometer at 60, 40, and 15 Mc./sec., together with a Varian HR-100 spectrometer at 100 Mc./sec. for the pure liquid samples degassed in a high-vacuum apparatus.

## Results and Discussion

The spectra for all of the compounds obtained at 60 Mc./sec. are illustrated in Fig. 1—4, together with the calculated spectral lines (shown at the bottoms of the figures). In addition, the spectra at 40 and at 100 Mc./sec. were also obtained for triethylsilane and triethylfluorosilane, which show the more complex spectra due to the $A_3B_2X$ spin system than do the other two, with the $A_3B_2$ pattern.

The analyses of the spectra as an $A_3B_2$ or $A_3B_2X$ system were accomplished with a NEAC-2101 digital computor. The procedure was the same for the $A_3B_2$ system as that described in the previous paper.[3] For the analysis of the $A_3B_2X$ system, the calculations were repeated until a good agreement in the coupling constants and the chemical shift values was obtained among 40, 60, and 100 Mc./sec. spectra by using the least-squares method.

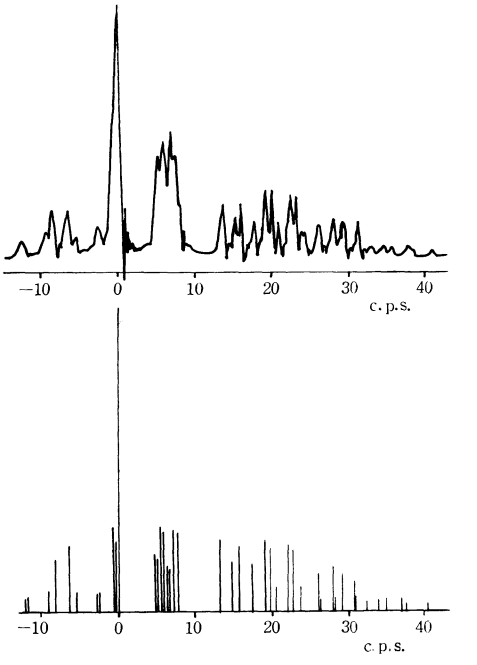

Fig. 1. The observed and the calculated spectra of $SiH(C_2H_5)_3$ at 60 Mc./sec.

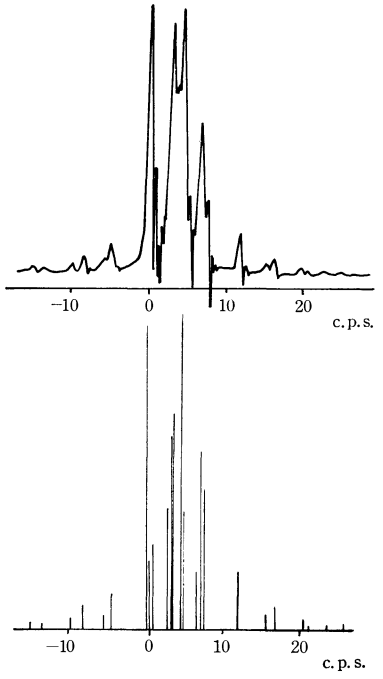

Fig. 4. The observed and the calculated spectra of $SiBr(C_2H_5)_3$ at 60 Mc./sec.

Mc./sec. are given in Tables II and III respectively. Similar good agreements between the observed and the calculated spectra were also obtained at other resonant frequencies.

The coupling constants, $J_{BX}$, can also be obtained from the X part of the $A_3B_2X$ spectra. As is shown in Table I, the observed values are in agreement with the values obtained from the $A_3B_2$ part of the spectra within the range of experimental error.

**Coupling Constants in Triethylfluorosilane.**— In triethylsilane the long-range coupling constant, $J_{AX}$, is practically zero, as is usually observed for two protons which are more than three bonds removed from each other in aliphatic compounds. In triethylfluorosilane, however, $J_{AX}$ definitely has a non-zero value, as may be seen from Table I. In fact, the calculations taking no account of $J_{AX}$ were tried at first, but in this case no overall agreement of the calculated coupling constants and chemical shift values was obtained among the spectra different in resonant frequencies.

The long-range coupling between protons and fluorines which are separated through four bonds from each other has been reported for fluorocarbon derivatives.[6] The order of magnitude of such coupling constants is from about 0.4 to 1.5 c.p.s., which is comparable with the value obtained, $J_{AX}$, for triethylfluorosilane. Further evidence for the long-range coupling is obtained from the 15 Mc./sec. spectrum of this compound. The most intense central line in the $A_3B_2$ spectrum splits into two lines of equal

intensity in the $A_3B_2X$ system due to the coupling between the A and X spins, the separation between the two lines being just equal to $J_{AX}$ (see Appendix). However, if $J_{AX}$ is too small to be resolved under the conditions of a given magnetic field, the splitting is not observed. This is the case for the resonant frequency of 40 Mc./sec. or higher. The inhomogeneity, $\Delta H$, of the field may be reduced by decreasing the static field, $H_0$, in such a manner that $\Delta H/H_0 \sim$constant.[10] Thus, at the low static field, it may be possible to ovserve the splitting of two lines which can not be resolved in the higher field. As Fig. 5 shows, the two split lines are clearly realized at 15 Mc./sec., the separation of them being

10) A. Abragam, "The Principles of Nuclear Magnetism," Oxford University Press, London (1961), p. 64.

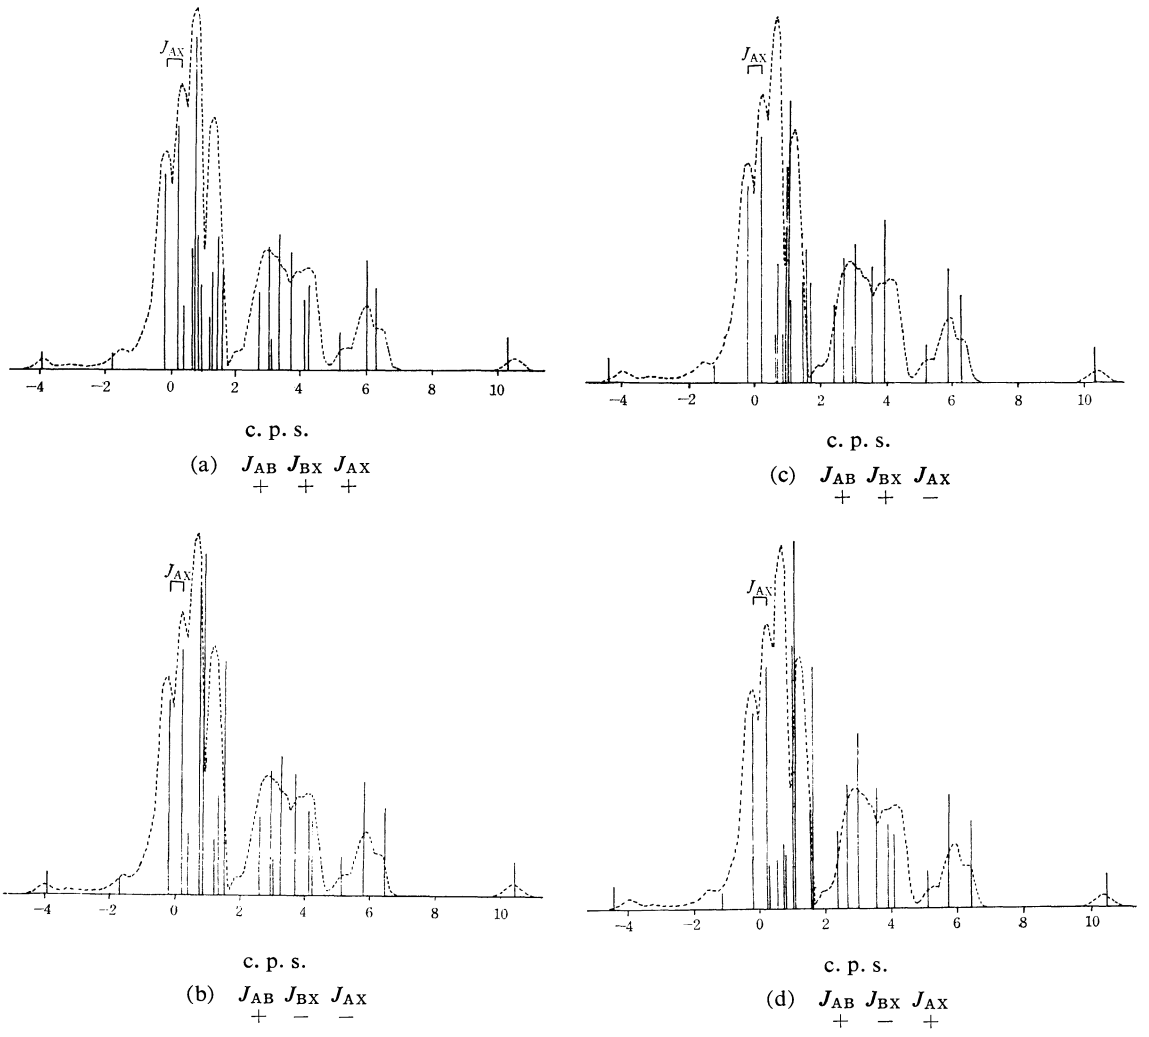

Fig. 5. The calculated spectra of $SiF(C_2H_5)_3$ at 15.085 Mc./sec. for possible four combinations of the signs of $J_{AX}$ and $J_{BX}$ with positive $J_{AB}$. The observed spectrum (dotted lines) is superposed on each calculated spectrum for comparison.

just the coupling constant, $J_{AX}$, calculated from the spectra at the higher resonant frequencies. Thus, it seems reasonable to assume the existence of the long-range coupling between the methyl protons and fluorine in this compound.

In the $A_3B_2X$ system the relative sign determination of the coupling constants is possible in principle.[5] Whether it is really possible or not, however, depends upon the relative order of magnitude between the $J$'s and $\delta$'s. Tentative calculations show that at 15 Mc./sec. the spectrum is sufficiently altered in its appearance by changing the signs of the couping constants, thus permitting an unambiguous determination of the relative signs for triethylfluorosilane, though not for triethylsilane. It can be assumed that $J_{AX}$ is positive on the basis of the theoretical considerations by Karplus[11] and by McConnell.[12] Thus, it is sufficient to consider the possible four cases with positive $J_{AB}$ values. In Fig. 5 the calculated spectra for triethylfluorosilane at 15 Mc./sec. are shown for possible combinations of the signs for $J_{BX}$ and $J_{AX}$ using the $J$'s and the $\delta_{AB}$ obtained from the spectra of other resonant frequencies. A close inspection of Figs. 5a—5d suggests that the best fit is obtained when all the signs are alike, i.e., when $J_{AB}$, $J_{BX}$, and $J_{AX}$ are all positive. To make the conclusion more unambiguous, NMR measurements on other similar compounds involving the double resonance experiment will be required. We are now planning to study further along these lines.

**The Internal Chemical Shift, $\delta$.**—The additivity for the $\delta$ value in the $Si(C_2H_5)_4-SiCl_3(C_2H_5)$ series was pointed out by Narasimhan and Rogers.[2] They derived the empirical equation:

$\delta$ for $SiCl_n(C_2H_5)_{4-n} = -0.420+0.205\,n$ (in p.p.m.)

from the observed values for $Si(C_2H_5)_4$ and its di- and trichloro-derivatives. It is interesting, as they pointed out, to compare the value predicted for triethylchlorosilane from the above equation with the observed value. The predicted value is $-0.215$ p.p.m., while the observed value obtained in this work is $-0.22$ p.p.m.; thus, a good agreement is obtained.

The effect of the number of the substituents on the $\delta$ value in this case can be interpreted on the basis of the inductive mechanism, as has been mentioned by Narasimhan and Rogers.[2] The increase in the number of the substituents causes the metal atom to withdraw more electrons and results in less shielding on the methylene protons, which in turn leads to a larger $\delta$ value (including the sign) than that of the compound with fewer substituents.

The result can also be interpreted, however, in terms of the magnetic anisotropy effect. It was pointed out by Spiesecke and Schneider[13] that the anisotropy contributions to the methyl and the methylene protons in the ethyl halides, $CH_3CH_2X$, are in the same direction and of comparable magnitude; thus, on taking the difference (the $\delta$ value), the effects are largely cancelled. In the present case, the X group is a metal, and in the halides an additional substituent, Y (i.e., a halogen atom), is further attached to the X group. In this instance, the situation is rather different. The $\alpha$ and the $\beta$ protons from the metal are now at the $\beta$- and the $\gamma$-positions respectively in relation to the Y substituent. The $\gamma$ protons will be little affected by the secondary magnetic field generated by the diamagnetic circulation of electrons at the X-Y bond; therefore, they will suffer no appreciable contribution to shift to a lower field by the Y substituent.[14] There is no proton at the $\alpha$-position relative to the Y substituent. Thus, only the $\beta$ protons are subjected to a lower field shift, the extent increasing as the number of substituents increases. Thus, the above linear relation only states that the extent of the decrease in the $\delta$ value is proportional to the number of the Y substituent. The origin of the decrease may be either the inductive or the anisotropy effect, or it may perhaps be both.

On the contrary, the present study clearly indicates that the effect of the nature of the substituents attached to the metal on the $\delta$ value results from the magnetic anisotropy of the Y substituent. As may be seen in Table I, there is also a tendency for the $\delta$ values of the compounds to increase in the descending order of the electronegativity of the Y substituents in the triethylhalogenosilane, as in the case of diethylaluminum monohalides.[3] On the basis of the inductive mechanism, it would be expected that the $\delta$ values would become larger when a halogen atom with a larger electronegativity is substituted into the metal, and the order for the $\delta$ value would be reverse to the above results. Since the magnitude of the magnetic anisotropy effect of halogens increases with an increase in their atomic weight, as has been mentioned earlier, the tendency of the $\delta$ value can be elucidated on the basis of the anisotropy effect stated above in the triethylhalogenosilanes also.

The authors express their hearty thanks to Mr. Atsuo Tokutake for his assistance in the experimental work.

## Appendix

The transitions which give the two central lines in question are shown in Table IV, in which such abbreviations for the spin functions as $A_{I_A,m_A}\cdot B_{I_B,m_B}X_{I_X,m_X}$, are used where $I_A$ and $m_A$ are the total spin and $z$-component of the angular momentum for the A nuclei respectively. The spin product functions of the states corresponding to these transitions are characterized by containing a $B_{0,0}$ term. In the $A_3B_2X$ system, $\delta_{AX}$ $(=\nu_X-\nu_A)$ is large compared with $J_{AX}$, so we have for transition 1:

$$\frac{1}{2}\delta_{AX}+J_{AX}-\frac{1}{2}\sqrt{(\delta_{AX}+J_{AX})^2+3J_{AX}^2}$$
$$=\frac{1}{2}(\nu_X-\nu_A)+J_{AX}-\frac{1}{2}(\nu_X-\nu_A+J_{AX})$$
$$\times\left\{1+\frac{3}{2}\left(\frac{J_{AX}}{\nu_X-\nu_A+J_{AX}}\right)^2+\cdots\cdots\right\}$$
$$=\nu_A+\frac{1}{2}J_{AX}$$

In a similar way, all of the first four transitions in Table IV give the frequency of $\nu_A+\frac{1}{2}J_{AX}$, and the other four $\nu_{AX}-\frac{1}{2}J_{AX}$. Thus, the transitions between these energy levels give two intense lines separated by $J_{AX}$ from each other, the center being at $\nu_A$. The relative intensities of the two lines can be shown to be equal. In the $A_3B_2$ system, however, the corresponding states, such as $A_{3/2,\,3/2}B_{0,0}$,

13) H. Spiesecke and W. G. Schneider, ibid., 35, 722 (1961).
14) J. R. Cavanaugh and B. P. Dailey, ibid., 34, 1099 (1961).

are themselves a stationary state, and all of the transitions between them give a single line at $\nu_A$, which forms the most intense central line in the $A_3B_2$ pattern.

TABLE IV. A-TRANSITION CONCERNED WITH $B_{0,0}$ SPIN STATES

| | Transition in the limit $J_{AX} \to 0$ | Frequency |

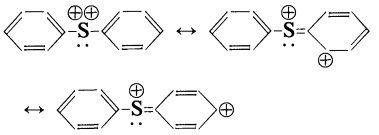
# Sulfoxides. V.[1] The Ionization of Sulfoxides in Sulfuric Acid[2]



By Shigeru Oae, Teijiro Kitao and Yoshinori Kitaoka

(Received July 18, 1964)

Some years ago, Szmant and Brost[3] investigated the cryoscopic behaviors of several organic sulfur compounds in sulfuric acid and presented, among other things, the interesting observation that diphenyl sulfoxide gave a large and reproducible freezing point depression with an *i*-factor of 4.7 with the formation of a brilliant green solution. They theorized that diphenyl sulfoxide ionizes in 100% sulfuric acid according to the following Eq. 1:

$$(C_6H_5)_2\text{-}SO + 3H_2SO_4 \rightleftarrows \underset{\text{(I)}}{(C_6H_5)_2\overset{\oplus\oplus}{S}:} + H_3\overset{\oplus}{O} + 3HSO_4^{\ominus} \quad (i=5) \tag{1}$$

The green color of the double positive species, "diphenyl sulfidonium ion," I, was assumed to result from the contribution of such resonance structures as II. They also indicated that this species, I, in the presence of water

(II)

restored the original sulfoxide according to Eq. 2:

$$(C_6H_5)_2\text{-}\overset{\oplus\oplus}{S}: + 3H_2O \rightarrow (C_6H_5)_2\text{-}SO + 2H_3\overset{\oplus}{O} \tag{2}$$

1) a) Paper I: S. Oae, T. Kitao and Y. Kitaoka, *Chem. & Ind.*, **1961** 291; b) II: S. Oae and S. Kawamura, This Bulletin, **36**, 163 (1963); c) III: S. Oae, T. Kitao, S. Kawamura and Y. Kitaoka, *Tetrahedron*, **19**, 817 (1963); b) IV: S. Oae, T. Kitao and S. Kawamura, ibid., **19**, 1783 (1963).

2) a) Preliminary Communication; see Ref 1a; d) The early part of this work was performed at the Department of Chemistry, Brookhaven National Laboratory, under the auspices of the U. S. Atomic Energy Commission, while S. O. was a visiting chemist there. We wish to thank Dr. David R. Christman for some of the $^{18}O$ analyses. Appreciation is also expressed to Mr. Motoyoshi Hatada for his generous collaborations in the mass-spectroscopic analyses.

3) H. H. Szmant and G. A. Brost, *J. Am. Chem. Soc.*, **73**, 4175 (1951).

This conclusion was later challenged,[4] and it was claimed that the *i*-factor of this green solution was 2.0, that this gradually changed to about 3 when the solution was left standing and that the original sulfoxide could not be recovered after some time when its freezing point had become approximately constant.[5]

A convenient way to test the rather attractive Szmant & Brost's hypothesis of the presence of the doubly-charged "sulfidonium ion" I in sulfuric acid is to determine the $^{18}O$ incorporation into the resulting sulfoxide recovered by quenching the green solution by $^{18}O$-enriched water. When diphenyl sulfoxide was dissolved in 97% sulfuric acid and this brilliant green solution was diluted with a large excess of $^{18}O$-enriched water (0.6 atom % $^{18}O$), the original sulfoxide was recovered in almost a quantitative yield. However, the sulfoxide recovered was found to be incorporated with no excess of $^{18}O$, contrary to what one would expect from the conclusion by the previous workers.[3]

| | |
|---|---|
| $^{18}O$ for Ph-SO-Ph | 0.208% |
| $^{18}O$ for tank $CO_2$ | 0.211% |

Since this $^{18}O$ tracer experiment clearly excludes the hypothesis of the presence of the "diphenyl sulfidonium ion" in sulfuric acid, the other alternative would be that the ionization of the sulfoxide in sulfuric acid takes place according to Eq. 3, as was suggested by Gillespie *et al.*[4] Accordingly, the cryoscopic determinations were made on diphenyl sulfoxide and

$$(C_6H_5)_2S \rightarrow O + H_2SO_4 \rightleftarrows (C_6H_5)_2\overset{\oplus}{S}\text{-}OH + \overset{\ominus}{HSO_4} \quad (i=2) \qquad (3)$$

other related sulfoxides with about 99% sulfuric acid. Although some of the sulfoxides, e. g., phenyl benzyl sulfoxide and phenyl methyl sulfoxide, gradually decomposed in sulfuric acid, others were recovered in satisfactory yields when treated within an hour. Even the unstable sulfoxides could be recovered in satisfactory yields when the solutions were treated within ten to fifteen minutes. Therefore, with these compounds, the cryoscopic determinations were carried out in such short periods. The results obtained are shown in Table I.

An inspection of the results in Table I indicates that none of the sulfoxide measured gave an *i*-factor as large as 4 or 5; all the values fall around two, within the range of experimental error, suggesting that the sulfoxide in general ionizes according to Eq. 4, possibly with only the exception of thianthrene monoxide.[6]

TABLE I. CRYOSCOPIC *i*-FACTORS AND COLORS OF VARIOUS SULFOXIDES IN 99.5% SULFURIC ACID

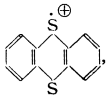
| Compound | *i*-Factor | Color of solution |
|---|---|---|
| Ph-SO-Ph | 2.15 | Deep green |
| 4-$MeC_6H_4$-SO-$C_6H_4$-$NH_2$-4′ | 2.15 | Deep green |
| Ph-SO-$CH_2$Ph | 1.95 | Red |
| Ph-SO-$CH_3$ | 2.10 | Pale orange |
| $CH_3$-SO-$CH_3$ | 1.90 | None |

$$\underset{\underset{O}{\downarrow}}{R\text{-}\ddot{S}\text{-}R} + H_2SO_4 \rightleftarrows \underset{\underset{O\text{-}H}{|}}{R\text{-}\overset{\oplus}{S}\text{-}R} + \overset{\ominus}{HSO_4} \qquad (4)$$

Although we cannot offer any satisfactory explanation for the different colors associated with different compounds in sulfuric acid, these colors are probably related to the ease of charge-transfer. The sulfoxides bearing a $\pi$-electron system of a benzene ring at the $\alpha$-position appear to give deeper colors.

Earlier, it was suggested that the *i*-factor changes in value from 2 to 3 when diphenyl sulfoxide was kept in sulfuric acid for hours. We also confirmed this. It should be mentioned here also that the recovery of diphenyl sulfoxide was better from the green solution of less concentrated sulfuric acid, while the recovery became negligible and a large amount of a gummy, brown substance was formed when the sulfoxide was dissolved in over 100% of sulfuric acid. Even with 100% sulfuric acid, however, the yield of the recoverable sulfoxide was very small.

## Experimental



**Materials.** — *Diphenyl sulfoxide* purchased from K and K Laboratories, Inc., was recrystallized from a mixture (1 : 1) of benzene and ligroin. White crystals (m. p. 70.5—71°C) were used.

*Dimethyl Sulfoxide.*—The oxidation of dimethyl sulfide was performed by the method reported by R. L. Shriner et al.,[7] using 30% hydrogen peroxide in an acetone solution. The fraction boiling at 90—91°C/26 mmHg was used.

*Benzyl Phenyl Sulfoxide.* — The oxidation of benzyl phenyl sulfide was carried out in a similar way.[7] To the sulfide (52 g., 0.26 mol.) in 250 ml. of acetone 40 g. of 30% $H_2O_2$ was added. The

4) R. J. Gillespie and J. A. Leisten, *Quart. Rev.*, **8**, 40 (1954).

5) R. J. Gillespie and R. C. Passerini, *J. Chem. Soc.*, **1956**, 3850.

6) H. J. Shine and L. Piette have reported (*J. Am. Chem. Soc.*, **84**, 1798 (1962)) that thianthrene monoxide dissociates to form an ion radical.  , in 96—97% sulfuric acid. This view seems to be favored by our preliminary $^{18}O$-tracer experiment, a full account of which will be reported shortly.

7) R. L. Shriner, H. C. Struck and W. J. Jorison, *J. Am. Chem. Soc.*, **52**, 2060 (1930).

mixture was shaken and allowed to stand at room temperature for 72 hr. After the acetone had been removed, the oil which remained immediately solidified upon cooling. The solid was recrystallized from 60% ethanol. The yield was 40 g. (70%). After repeated recrystallization, white crystals m. p. 122—123°C were used.

*Phenyl Methyl Sulfoxide.*[8]—Phenyl methyl sulfide was prepared by treating thiophenol with dimethyl sulfide under alkaline conditions. Phenyl methyl sulfoxide was obtained by an oxidation similar to that described above, and the fraction boiling at 91—92°C/12 mmHg was collected and used.

*d,l-4-Amino-4'-methyldiphenyl Sulfoxide.*[9]—A mixture of *p*-toluenesulfinic acid (1 part) and aniline (4 parts) was heated at 110—115°C for 30 hr. The excess of aniline was removed by steam distillation, and the non-volatile residue was filtered, washed with ether, and recrystallized from ethanol. Pure d, l-4-amino-4'-methyldiphenyl sulfoxide m. p. 169.5—170.5°C was obtained in a 45% yield.

**Cryoscopic Measurements.**—The apparatus used for the cryoscopic measurements was essentially the same as that reported by Newman et al.[10]

Near 100% sulfuric acid was prepared by mixing extra pure concentrated sulfuric acid and fuming sulfuric acid. The concentration of sulfuric acid was checked by measuring the freezing point, which was determined by a Beckmann-type thermometer.

The thermometer was calibrated each time by a standard thermometer. All the determinations were carried out in an air-conditioned room which was kept at around 20°C with a humidity of slightly less than 40%. In all the runs, the freezing points of the acids were in the 9.80—10.20°C range. The samples taken to lower the freezing point of the solution were about $(1.0—2.0)\times10^{-2}$ mol./l.; they were kept in very thin glass ampules. After the acid had been kept in the apparatus for a few hours, the freezing point of the solvent was determined; then the solute in the ampule was put in as rapidly as possible through one of the three necks of the apparatus, and the apparatus was closed with a glass stopper. The ampule was broken with a glass-rod stirrer, and the solute was thoroughly dissolved by stirring it at room temperature. The system was then cooled in an ice-salt bath. The temperature of the solution was read every minute, and the freezing point was graphically recorded. The calculation of the van't Hoff factor was made by the equation where $\Delta m$ is the molarity of the solute, $\Delta\theta$ is the freezing point depression, and $\theta$ is the total freezing point depression:

$$i=\frac{\Delta\theta}{\Delta m\times 6.154\ (1-0.0047\theta)}$$

The average *i*-values of three to five runs are shown in Table II.

Table II. *i*-Factors of the Sulfoxides in Sulfuric Acid

| Compound | Initial f. p. °C | $\Delta w$, g. | $\Delta m$ (mol./1.) $\times10^2$ | $\Delta\theta$ °C | *i* |

**The Oxygen Exchange Reaction of Diphenyl Sulfoxide.**—Diphenyl sulfoxide (1.0 g.; 5 mmol.) was dissolved in 10 ml. of 98.99% sulfuric acid, prepared by adding fuming sulfuric acid to c. p.-grade 93.5% sulfuric acid under ice-cooling. A brilliant blue-green color formed immediately. After this ice-cooled solution had been kept for from five to ten minutes, the solution was poured into 25 ml. of frozen $^{18}O$-enriched water (0.6 atom% $^{18}O$). The pale yellow precipitate which formed was collected on a sintered-glass filter, washed once with 5 ml. of a cold, diluted, alkaline solution of the same $^{18}O$-enriched water, washed three times with 5 ml. of the same $^{18}O$-enriched water, and then dried. The dried sample (0.95 g.), recovered in nearly a quantitative yield, was recrystallized from ethanol to give colorless crystals with a m. p. of 70—71°C; the mixed melting point with an authentic sample was 70—71°C. This sample was subjected to $^{18}O$ analysis.

**Isotopic Analysis.**—The analysis of the $^{18}O$ content of the sulfoxide was performed by an adaptation of the method of Rittenberg and Ponticorvo.[11] The compound (50 mg.) was introduced, together with a 1:1 mixture (300 mg.) of mercuric chloride and mercuric cyanide, in to an 8 mm. A-top tube (27 cm.) with a break off-seal at one end and a seal-off construction at the other. The tube was vacuum-sealed and then heated at 500°C for 3—5 hr. After it had then been cooled, the tube was opened in a vacuum line and the hydrogen chloride which had formed was removed by adding a few drops of quinoline, while the hydrogen sulfide which had formed was removed by passing the gas through a glass-wool-packed tube absorbing a small amount of lead acetate. The gases which had formed were condensed by cooling the gas with liquid nitrogen, and the non-condensable gases which had formed were pumped off. After repeated fractionations, the carbon dioxide was collected and subjected to mass-spectrometric analysis. The atom % $^{18}O$ was calculated from the peak of mass 44 and 46 according to the following equation:

$$\text{Atom \% } ^{18}O=\frac{\text{Peak 46/Peak 44}}{2+\text{Peak 46/Peak 44}}$$

## Summary

Contrary to the earlier claim that diphenyl sulfoxide ionizes in nearly 100% sulfuric acid to give a "diphenyl sulfidonium" ion, which

# Sulfoxides. VI.[1] The Oxygen Exchange Reaction of Sulfoxides in Sulfuric Acid[2]

By Shigeru OAE, Teijiro KITAO, Yoshinori KITAOKA and Shunichi KAWAMURA

(Received July 18, 1964)

Unlike those in sulfone groups, the sulfur-oxygen links in sulfoxides are known to be considerably weak. A number of reactions are known to involve the facile cleavage of the S-O bonding.[3] A typical illustration of the weaker S-O bonding in sulfoxide than that in sulfone can be seen in the following $^{35}S$-tracer experiment. Diphenyl sulfone reacts sluggishly with sulfur above 300°C to give diphenyl sulfide, with a replacement of the sulfur atom of the sulfone group involving the cleavage of the C-S bond, while diphenyl sulfoxide is reduced quantitatively to the sulfide via the cleavage of the S-O bond by heating it with sulfur at 280°C.[4]

Another marked difference between the sulfoxide group and the sulfone group is that the former still retains a lone electron pair on the sulfur atom. Because of this lone electron pair, the sulfur atom of the sulfoxide is still nucleophilic in nature in spite of the positive charge. Thus, dimethyl sulfoxide is known to react with methyl iodide to yield trimethylsulfoxonium iodide.[5]

An interesting reaction in this connection is the oxygen exchange reaction of sulfoxides in sulfuric acid;[2] this paper will present detailed accounts of this rather unusual reaction.

## Results and Discussion

It was shown in the previous paper[1] that diphenyl sulfoxide ionized in concentrated sulfuric acid in the following manner, giving a deep green solution:

$$(C_6H_5)_2\ddot{S}\rightarrow O + H_2SO_4 \rightleftarrows (C_6H_5)_2\overset{\oplus}{\ddot{S}}-OH + H\overset{\ominus}{SO_4} \quad (1)$$

When diphenyl sulfoxide was dissolved in a large excess of concentrated $^{18}O$-enriched sulfuric acid for five to ten minutes at around 0°C, and the resulting green solution was diluted with normal water and $^{18}O$-enriched water (0.6 atom% $^{18}O$), and it was found that

Table I. $^{18}O$ Concentrations of diphenyl sulfoxides recovered from the green solution with $^{18}O$-enriched $H_2SO_4$

| | |
|---|---|
| Ph-SO-Ph (Quenched with $^{18}O$-enriched water, 0.6 atom% $^{18}O$) | 0.412% |
| Ph-SO-Ph (Quenched with normal water) | 0.426% |
| $H_2SO_4$ | 0.480% |
| Natural $CO_2$ | 0.212% |

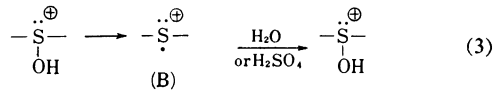
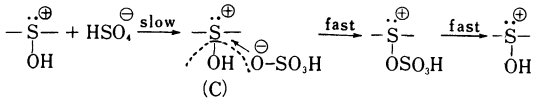
the recovered diphenyl sulfoxide was incorporated with a similar concentration of $^{18}O$. A typical run is shown in Table I.



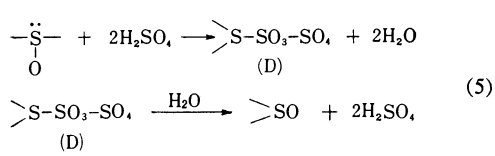
Among a number of mechanisms that could be considered, the following are a few mechanisms that are conceivable for this $^{18}O$ exchange reaction:

a) $SN_1$-Type:



(2)

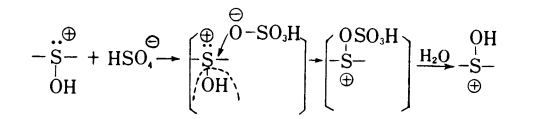
b) Free Radical Type:



(3)

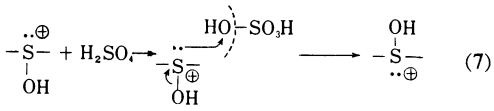
c) SNi-Type:

(4)



d) Oxidative Adduct Formation and Subsequent Hydrolysis:

(5)



e) $SN_2$-type:

*1) Nucleophilic Attack on Sulfoxide by Sulfate Ion:*

(6)

*2) Nucleophilic Attack on Sulfuric Acid by Sulfoxide:*

(7)

**$SN_1$-Type Mechanism.** — Although Szmant's hypothesis of the formation of the diphenyl sulfidonium ion in the deep green solution was excluded by the $^{18}O$ tracer experiment[1] and by the careful determination of the i-factor[1], the $SN_1$-type mechanism still remains acceptable if one assumes that the formation of the sulfidonium ion (A) is the slow, rate-determining step and that the sulfidonium ion hydrolyzes to give the sulfoxide in the subsequent fast step. Here, the facile $^{18}O$ exchange of diphenyl sulfoxide can be explained on the basis of the resonance stabilization of the incipient sulfidonium ion, just as in the case of the facile solvolysis of benzhydryl compounds. The replacement of a phenyl group by an alkyl or an aralkyl substituent would retard the $^{18}O$ exchange. However, such was not found to be the case. Especially, the facile $^{18}O$ exchange of dimethyl sulfoxide, where the formation of the corresponding sulfidonium ion would be very difficult, does not seem to favor the mechanism. (See Table II).

It is known that $SN_1$ reactivity increases if the starting substance has a steric strain and the strain is relieved in going to the transition state. Thus, 2, 4, 6-trimethyl-$\alpha$-phenethyl chloride reacts far faster (ca. 2000 fold.) than $\alpha$-phenethyl chloride in ethanolysis.[6]

A similar steric acceleration in the $SN_1$ reaction was observed in the ethanolyses of substituted benzhydryl chlorides[6].

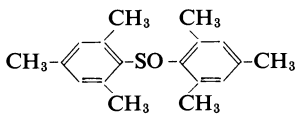


Table II. $^{18}O$-Exchange of various sulfoxides with 97% $^{18}O$-labeled sulfuric acid at 0°C for five minutes

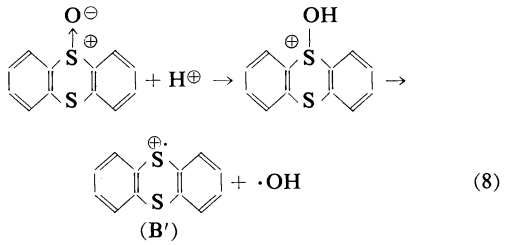
| Compound | Color of solution | $^{18}O$ Incorporation |
|---|---|---|
| $C_6H_5$-SO-$C_6H_5$ | Deep green | 0.42 |
| $C_6H_5$-SO-$CH_2C_6H_5$ | Red | 0.42 |
| $C_6H_5$-SO-$CH_3$ | Pale orange | 0.42 |
| $CH_3$-SO-$CH_3$ | Colorless | 0.45 |
| $H_2SO_4$ | | 0.48 |
| Tank $CO_2$ | | 0.21 |

Table III. Rates of $^{18}O$ exchange of diaryl sulfoxides with $^{18}O$-labeled 94.5% sulfuric acid at 0°C

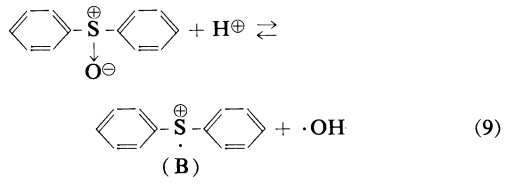
$3.4\times10^{-4}$ sec$^{-1}$



$1.0\times10^{-5}$ sec$^{-1}$

A similar comparison of rates between diphenyl sulfoxide and dimesityl sulfoxide has therefore been carried out; the results are shown in Table III. An inspection of the data clearly excludes the $SN_1$-type mechanism for this $^{18}O$ exchange, since in this case the sterically-strained dimesityl sulfoxide was found to be much less reactive than diphenyl sulfoxide this is contrary to what one would expect from the $SN_1$-type mechanism.

6) E. L. Eliel, "Substitution at Saturated Carbon Atoms," in "Steric Effects in Organic Chemistry," Ed. by M. S. Newman, John Wiley and Sons, N. Y. (1965), pp. 88—89.

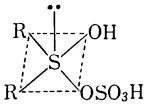


**Free Radical Mechanism.**—Hirshon, Gardner and Fraenkel[7] have reported that the sulfuric acid solutions of certain sulfur-containing aromatic compounds show electron spin resonance and contain free radicals in substantial concentrations. German workers have reported recently[8] that the sulfuric acid solutions of aryl sulfoxides are paramagnetic. Especially well-studied are the solutions of diphenyl disulfide, thianthrene and thianthrene oxides.[9,10] It has been suggested that the species present in the sulfuric acid solution of thianthrene oxide on thiantrene is the positive ion-radical (B'), as is shown below:

(8)

(B')

A similar mechanism could be adopted in this case. If the hydroxyl radical thus formed would transfer with either water or sulfuric acid to regenerate an alternative hydroxyl radical, the recombination between the positive ion-radical (B) and the hydroxyl radical will give rise to the sulfoxide in which the original oxygen atom is exchanged. However, it is unlikely that a substantial amount of radical transfer takes place between the hydroxyl radical and water or sulfuric acid, or both. If there were the following dissociation (Eq. 9),



(9)

(B)

the presence of the radical ion (B) could be detected by a conventional electron spin-resonance spectroscopy. When diphenyl sulfoxide was dissolved in 93—98% sulfuric acid at various concentrations and the solutions were subjected to ESR spectroscopic analysis, however, no noticeable signal was detected, contrary to the early claim by German workers.[11] None of the other sulfoxides, used for this $^{18}O$ exchange study, showed a noticeable ESR signal. Therefore, it is not likely that such a free radical dissociation takes place in sulfuric acid.

Another remaining possibility in the free radical mechanism is the process which involves a rate-determining dissociation of protonated diphenyl sulfoxide into the radical ion (B) and the hydroxyl radical, followed by the subsequent recombination of the two radicals. This is also rather unlikely, since the hydroxyl radical so formed would attack not only the sulsur atom but also benzenoid carbon atoms, usually giving some rearranged products,[12] if there were any radical transfer of the hydroxyl radical during the process. Moreover, the radical ion would accept an electron to be reduced back to the sulfide more easily than it would one to recombine to yield the original sulfoxide. In fact, thianthrene monoxide, which is believed to give the radical ion, B', in sulfuric acid, showing clear ESR signals, is reduced back to thianthrene chiefly when the solution is quenched with water.[10,13] Obviously, a different reaction is taking place in the case of thianthrene.

**$SN_i$-Type Mechanism Involving 3d Orbitals of Sulfur Atom.**—Since the sulfur atom can utilize its 3d orbitals for forming an extra bond, expanding its valence shell beyond the octet, especially when the central sulfur atom bears positive charge, such as in the sulfoxide or sulfonium group,[14] the formation of an incipient intermediate, (C), is possible. If the intermediate (C) has a square pyramidal structure, stereochemical considerations will predict a net retention of the original configuration:

(C)

In fact, retention was found to be the case in some of the various nucleophilic substitutions involving tetracovalent phosphorous compounds,[15] and moreover, a similar nucleophilic addition-elimination process was suggested in the reaction of sulfonium compounds with phenyllithium.[16]

This mechanism can be readily tested by using

an optically-active sulfoxide. Thus, an optically-active sulfoxide, *d*-4-methyl-4-amino-diphenyl sulfoxide,[17] $[\alpha]_D^{30}$ +105.9 ($c$=1.10, $l$=2.0) in 98% ethanol, was synthesized and subjected to the $^{18}O$-exchange. When the blue green solution of the *d*-isomer sulfoxide $^{18}O$-enriched sulfuric acid was diluted with water, the compound recovered was found to be racemized completely to the *d, l*-isomer, while there was a usual amount of $^{18}O$ incorporation in the racemized sulfoxide, as Table IV shows.

Table IV. $^{18}O$ Exchange of *d*-4-amino-4'-methyldiphenyl sulfoxide in 97% $^{18}O$-enriched sulfuric acid at 0°C for five minutes

| | |
|---|---|
| $^{18}O$ for 4-$NH_2$-$C_6H_4$-SO-$C_6H_4$-$CH_3$-4' | 0.45% |
| $^{18}O$ for $H_2SO_4$ | 0.48% |
| $^{18}O$ for tank $CO_2$ | 0.21% |

This data clearly excludes the possibility of a $SN_i$-type process involving the incipient nucleophilic adduct intermediate, C.

**The Oxidative Formation of Adduct and Subsequent Hydrolysis.**—Very recently, it has been reported by Mislow, Simmons, Melillo and Ternay that sulfoxides are readily racemized in the presence of hydrochloric acid accompanied by oxygen exchange with solvent water. The mechanism suggested for this reaction involves the initial oxidative adduct formation (Eq. 10) and the subsequent hydrolysis of the adduct (Eq. 11), as is shown below:[18]

$$R_2SO + 2HCl \rightleftarrows R_2SCl_2 + H_2O \quad (10)$$

$$R_2SCl_2 + H_2{}^{18}O \rightleftarrows R_2S^{18}O + 2HCl \quad (11)$$

The reversible formations of dibromo compounds[19] or dichloro compounds[20] from the corresponding sulfoxides by the treatment of hydrobromic acid or hydrochloric acid have been known for some time. In fact, some dibromo compounds were successfully isolated, and the subsequent treatment of the dibromo compounds with $^{18}O$-enriched water was found to give the corresponding sulfoxides labeled with $^{18}O$.[21] However, unlike hydrohalous acid, sulfuric acid is not a good nucleophile and cannot be oxidized so readily by such a weak oxidizing agent. Meanwhile, it has been suggested that concentrated sulfuric acid dissociates to form sulfur trioxide and water.[22] Sulfur trioxide is a powerful electrophile and possibly coordinates with the sulfur atom of sulfoxide, replacing oxygen, as is shown by Eq. 5, to form perhaps the incipient intermediate (D), which would immediately react with water to give the original sulfoxide. If this were the case, then sulfides, being more nucleophilic in nature, would react more readily with sulfur trioxide to form the corresponding sulfoxides, as in the case of the bromine oxidation of sulfides and their corresponding sulfoxides.[21] However, the reaction of diphenyl sulfide in concentrated sulfuric acid or in oleum is very sluggish; only when the red solution of the sulfide was kept in sulfuric acid for a long time, was the formation of a small amount of the sulfoxide observed.[23] On the other hand, the $^{18}O$ exchange reaction of the sulfoxide is very fast in concentrated sulfuric acid; it is usually completed within a few minutes at 0°C. Therefore, it is likely that the $^{18}O$ exchange reactions of sulfoxides in concentrated sulfuric acid do not follow a path — oxidative adduct formation and subsequent hydrolysis — similar to that of the reactions with hydrohalous acids.

**The Nucleophilic Attack on Sulfoxide by the Hydrogen Sulfate Ion or Water.** — Since both sulfate and hydrogen sulfate ions are known to be very weak nucleophiles, it is difficult to accept the mechanism involving the nucleophilic attack of hydrogen sulfate or sulfate ion. Recently, however, Leonard and Johnson[24] have

Table V. Rates of the $^{18}O$ exchange of diphenyl sulfoxide and dimesityl sulfoxide with $^{18}O$-labeled sulfuric acid

| | Atom% $^{18}O$ of recovered sulfoxide | | | | | |
|---|---|---|---|---|---|---|

presented a case in which the sulfur atom of a cyclic sulfoxide, 1-thiacycloocta-5-one, was presumed to be attacked by a water molecule in the presence of 2, 2-dimethoxypropane and 70% perchloric acid. When diphenyl sulfoxide was treated with 70% perchloric acid, however, it was found not to exchange with oxygen, but to be oxidized to the sulfone when it was kept at 0°C for four hours. Therefore, it appears that this nucleophilic attack of water on the sulfur atom is limited to the reactions of the particular thiacyclooctanone and possibly some related ones, and that it is not a general reaction to ordinary sulfoxides.

Moreover, if one assumes the nucleophilic attack of hydrogen sulfate or water on the sulfur atom of sulfoxides, the same nucleophilic attack may also be considered to take place on the nitrogen atom of *N*-oxides as well as on the phosphor atom of tertiary phosphine oxides, since these semipolar linkages are known to have a magnitude of force constants similar to that of diphenyl sulfoxide, $7\times10^5$ dyn./cm. Thus, phenazine *N*-oxides, whose force constant of the N-O bond is $7.0\times10^5$ dyn./cm. and triphenylphosphine oxide ($8\times10^5$ dyn./cm.) were subjected to the $^{18}O$ exchange experiment. However, neither phenazine *N*-oxide nor triphenyl phosphine oxide was found to exchange oxygen in concentrated sulfuric acid. Diphenyl sulfone, which bears a double positive charge to attract nucleophilic attack[25] but has a stronger S-O bond (force constants $9.6\times10^5$ dyn./cm.), also failed to exchange oxygen. Furthermore, a more nucleophilic hydroxide ion also failed to attack the sulfur atom of diphenyl sulfoxide to exchange oxygen in a dioxane-water solution under prolonged refluxing. Thus, the mechanism involving the nucleophilic attack of the hydrogen sulfate ion or the water molecule on the sulfur atom of the sulfoxide cannot be accepted either as likely for this $^{18}O$ exchange reaction.

**The Nucleophilic Attack on Sulfuric Acid by Sulfoxide.**—One noteworthy fact which characterizes the sulfoxide bond is that the sulfur atom still bears a lone electron pair for nucleophilic reactions, unlike the hetero atoms in phenazine *N*-oxide, triphenylphosphine oxide and sulfones. Therefore, one can safely assume that the sulfur atom would undergo a nucleophilic attack on sulfuric acid, as is shown by Eq. 7. Meanwhile, this nucleophilic attack is considered to be suppressed by bulky substituents around the neighborhood of the reaction center. In fact, it was found that the rate of the $^{18}O$ exchange of dimesityl sulfoxide was 34 times slower than that of diphenyl sulfoxide. The extremely facile $^{18}O$ exchange of other sulfoxides tested can also be explained on the basis of the nucleophilic nature of the sulfur atoms of these sulfoxides, whose lone pair electrons are less delocalized and thus more nucleophilic than that of diphenyl sulfoxide. Therefore, this appears to be the only surviving, and hence the most favorable, mechanism for the $^{18}O$ exchange reactions.

As an outcome of the stereochemical considerations of this nucleophilic mechanism, one would expect that the rate of $^{18}O$ exchange will be exactly half of that of the racemization. Unfortunately, however, the kinetic control is very difficult with the optically-active sulfoxide, namely *d*-4-amino-4-methyldiphenyl sulfoxide, and only very crude, not very reproducible results were obtained. In several runs with different concentrations of sulfuric acid, it was found that the ratio of the rate of exchange ($k_e$) vs. that of racemization ($k_r$), $k_e/k_r$, fluctuates between 1/2—1/3.5, but that it is always less than 1/2 and never comes to 1. Although the $k_e/k_r$ value lies in the right direction and is close to the 1/2 which is predicted from this mechanism, this cannot serve as foolproof evidence for this mechanism, since it was thought that a kind of acid-catalyzed racemization[26] was taking place independently. Thus, the optically-active sulfoxide was dissolved in 50% sulfuric acid and kept at 0°C for five hours and a half; however, there was no racemization in the recovered sulfoxide. In more concentrated acids in which oxygen exchange occurs, however, it seems that an independent process of racemization takes place to cause a rate of racemization twice as fast as that of $^{18}O$ exchange. More careful kinetic studies with less reactive systems are necessary for more accurate evaluations of both rates of $^{18}O$ exchange and rates of racemization.[27]

## Experimental

**Materials.**—The manners of preparing the sulfoxides were similar to those previously reported. *Phenazine N-oxide*[28] was prepared by reacting aniline and nitrobenzene in the presence of sodium hydroxide. Yellow crystals with a m. p. of 221—222°C were used. *Triphenylphosphine oxide*[29] was prepared by reacting phenyl magnesium bromide with phosphorus oxychloride. The sample was repeatedly recrystallized from ethyl acetate to obtain colorless crystals with a m. p. of 157—157.5°C.

**The Preparation of Dimesityl Sulfoxide.**—A mixture of mesitylene (155 g.) and thionyl chloride (33 g.) was cooled in an ice-salt bath. To this

26) H. F. Herbrandson and R. T. Dickerson, Jr., *J. Am. Chem. Soc.*, **81**, 4102 (1959).

27) Studies are now underway in these laboratories.

28) A. Wohl and W. Aue, *Ber.*, **34**, 2442 (1901).

29) G. M. Kosolapoff, *J. Am. Chem. Soc.*, **64**, 2984 (1942).

mixture anhydrous aluminum chloride (60 g.) was added in portions over a period of two hours. Then mesitylene (60 g.) was added and the solution refluxed until no further hydrochloric acid gas was evolved. After the mixture had been allowed to stand at room temperature for one or two hours, it was poured slowly onto 600 g. of ice. After a vigorous reaction had taken place, the white solids which had separated were collected and washed with water. Recrystallization from acetone gave 64 g. (25%) ; m. p. 153.5—154°C.

Found : C, 75.57 ; H, 7.67. Calcd. for $C_{18}H_{22}OS$: C, 75.52 ; H, 7.69.

**$^{18}O$-Enriched Sulfuric Acid.** — The apparatus shown in Fig. 1 was used for the preparation of

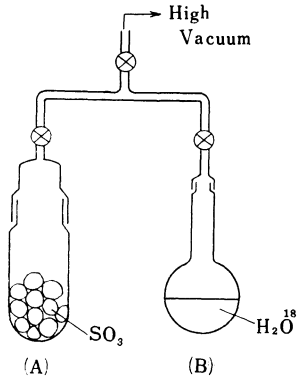

Fig. 1.

$^{18}O$-enriched sulfuric acid. An aliquot of sulfur trioxide distilled in a vacuum line was placed in one of the containers (A) and an equimolar amount of $^{18}O$-enriched water in the other (B). Both were first repeatedly frozen and degassed. Then the vessel (A) was warmed in a water bath at 50—60°C, while the other vessel (B) was cooled with dry-ice-acetone. By this procedure sulfur trioxide was introduced into the $^{18}O$-enriched water. After about twenty minutes, the introduction was stopped and the cooled trap was removed. The system was gradually warmed up to room temperature. After it had stood for a few minutes at room temperature, the vessel (A) was cooled once more and the other system (B) was warmed. By repeating this procedure, the introduction of sulfur trioxide into water was achieved. The concentration of the resulting sulfuric acid was determined by measuring the freezing point.

**The Resolution of *d, l*-4-Amino-4'-methyldiphenyl Sulfoxide**[17]. — The *d,l*-sulfoxide was prepared by reacting *p*-toluenesulfinic acid and aniline.[1] The *d,l*-sulfoxide (55 g.) was dissolved in 100 ml. of a hot water solution containing 60 g. of *d*-camphor sulfonic acid. Upon cooling, crude *d*-4-amino-4'-methyldiphenyl sulfoxide *d*-camphorsulfonate came out. After twenty recrystallizations (with 2% fresh *d*-camphor sulfonic acid added each time), the resolved salt was decomposed by ammonia and the sulfoxide obtained was recrystallized from ethanol. The *d*-isomer of the sulfoxide was thus obtained ; m. p. 150.5—151°C, with $[\alpha]_D^{30°}$ +105.9° in a 98% ethanol solution ($c$=1.10, $l$=2.0), +80.5° in a chloroform solution ($c$=1.15, $l$=2.0).

**$^{18}O$-Exchange Reactions in $^{18}O$-Enriched Sulfuric Acid.** — *Diphenyl Sulfoxide.* — Diphenyl sulfoxide (0.53 g.) was dissolved in 5.95 g. of 97% $^{18}O$-enriched sulfuric acid while the mixture was being cooled with ice, and the deep green solution was kept for fifteen minutes. From the deep green solution, about a half was quenched with 20 ml. of $^{18}O$-enriched water (ca. 0.6 atom% $^{18}O$), while the rest was quenched with 25 ml. of ordinary water. The precipitates were collected, washed with dilute alkali and water, and dried as usual. The two crude sulfoxide samples thus obtained were recrystallized from ethanol, and the samples with a m. p. of 70—71°C were subjected to $^{18}O$ analysis.

*Sulfoxides in General.*—An aliquot amount of sulfoxide was dissolved in a 10 molar equivalent of $^{18}O$-enriched sulfuric acid, and the solution was kept at the desired temperature for the desired period. Then the solution was poured into a large excess of ice-water, and the precipitate was washed with dilute alkali and then water. Solid samples were collected and recrystallized from either ethanol or benzene, while liquid samples were extracted with ether, and from the ether layer the samples were collected either by crystallization or by distillation. The samples thus collected, identified by their correct m. p.(s) or b. p.(s), were subjected to $^{18}O$-analysis.

*Phenazine N-Oxide.*—Phenazine *N*-oxide (200 mg.) was dissolved in 1.5 ml. of $^{18}O$-enriched 97% sulfuric acid (0.70 atom% $^{18}O$) ; the red solution was then allowed to stand at 0°C for 20 min. This solution was neutralized with 28% ammonia under cooling and then poured into 30 g. of ice-water. The precipitates were filtered and recrystallized from 99% ethanol, and the crystals m. p. 221—222°C were subjected to $^{18}O$ analysis.

*Triphenylphosphine Oxide.* — The oxide (1.0 g.) was dissolved in 5.0 ml. of $^{18}O$-enriched sulfuric acid (0.70 atom% $^{18}O$) and allowed to stand at 0°C for 10 minutes. The solution was then poured onto ice-water, and the resulting precipitates were collected and recrystallized repeatedly from ethyl acetate m. p. 157°C. They were used for the usual oxygen-18 analysis.

*Diphenyl Sulfone.*—Diphenyl sulfone (0.5 g.) was dissolved in 5 ml. of $^{18}O$ sulfuric acid (0.70 atom% $^{18}O$) ; the solution was kept at room temperature for 20 min. and then poured onto ice-water. The precipitate was collected and dried. Recrystallization from benzene gave colorless crystals with a m. p. of 128°C ; they were subjected to $^{18}O$-analysis.

| | | |
|---|---|---|
| Analysis : | Ph-$SO_2$-Ph | 0.209% |
| | Tank $CO_2$ | 0.211% |

**The Reaction of Diphenyl Sulfoxide With 70% Perchloric Acid.**—Diphenyl sulfoxide (0.5 g.) was dissolved in 10 ml. of 70% perchloric acid. The mixture was allowed to stand at 0°C for 4 hr. Then the mixture was poured into water, and the resulting solid was separated. Repeated recrystallizations from a mixture of benzene and ligroin gave a product the m. p. of which agreed with that of diphenyl sulfone. A mixed melting point determined with an authentic sample of diphenyl sulfone was

not depressed.

**$^{18}$O-Exchange of Diphenyl Sulfoxide in an Alkaline Solution.** — Diphenyl sulfoxide (1.01 g.) was dissolved in 60 ml. of a 70% dioxane solution, made by diluting 42 ml. of absolute dioxane with $^{18}$O-enriched water (0.61 atom% $^{18}$O) to 60 ml. of the solution. To this solution was added 0.28 g. of $^{18}$O-enriched potassium hydroxide (0.61 atom% $^{18}$O). Then the whole mixture was sealed in an ampoule and heated at 90°C for 8 hours and a half. After the ampoule had been broken and neutralized with hydrochloric acid, the solvent was distilled off. The precipitate was recrystallized from benzene, and the sample of sulfoxide m. p. 71°C was subjected to $^{18}$O-analysis.

| | | |
|---|---|---|
| Analysis: | Ph-SO-Ph | 0.214% |
| | Tank $CO_2$ | 0.212% |

**ESR Spectra.** — Sulfuric acid solutions (93.6%) containing $1.0\times10^{-2}$—$1.0\times10^{-4}$ mol./l. of the compounds, such as diphenyl sulfoxide, diphenyl sulfone, 4-amino-4'-methyldiphenyl sulfoxide and phenazine *N*-oxide, were subjected to ESR spectroscopy. However, none of the solutions of these compounds except phenazine *N*-oxide gave any sign of the presence of a free radical.

**Kinetic Studies of the Oxygen Exchange Reactions of Diphenyl Sulfoxide and Dimesityl Sulfoxide.**—To compare the rate constants of diphenyl sulfoxide and dimesityl sulfoxide, exchange reactions of both the sulfoxides were carried out under the same conditions. Both sulfoxides ($4.0\times10^{-2}$ mol.) were dissolved in 40 g. of $^{18}$O-enriched 94.5% sulfuric acid (0.57 atom% $^{18}$O) at 0°C. Aliquot portions (5.0 ml.) of the solutions were taken up after 5, 10, 30, 60 and 120 min., and each portion was quenched with ice-water. The precipitates were collected, recrystallized, and then subjected to $^{18}$O analyses. From the incorporation values of $^{18}$O in the recovered compounds, the rate constants of the oxygen exchange reactions were calculated.

**The Rate Constants of the Racemization and $^{18}$O-Exchange Reaction of *d*-4-Amino-4'-methyldiphenyl Sulfoxide in $^{18}$O-Enriched Sulfuric Acid.** —The kinetic studies of the rates of $^{18}$O exchange reaction and racemization were carried out in $^{18}$O-enriched 93% sulfuric acid (0.76 atom% $^{18}$O). The reaction conditions and the procedure of the separation were similar to those used with the diphenyl sulfoxide. However, in this case a portion of the sample was decomposed to give colored substances. In a separate experiment, it was confirmed that no change in the optical activity was observed when the *d*-isomer was treated with activated charcoal. Therefore, the recovered substance was refluxed with activated charcoal in order to purify it. The samples taken for $^{18}$O-analysis and for measuring the optical activity were repeatedly recrystallized from ethanol until the correct m. p. values were obtained. A solution containing 0.11 g. of the sample in 10 ml. of 98% ethanol was used for each measurement of the optical rotation. The same experiment was performed three times, but the rate constant of the racemization fluctuated from $2.5\times10^{-5}$ sec$^{-1}$ to $4.2\times10^{-5}$ sec$^{-1}$. Meanwhile, the $^{18}$O analyses of the same sample were done by the usual methods, and the rate constant, $k_{ex}=1.2\times10^{-5}$ sec$^{-1}$, was obtained.

Sulfoxides in general have been shown to exchange oxygen very readily in concentrated sulfuric acid. On the other hand, sulfones, *N*-oxides and phosphine oxides, with no lone electron pair, have been shown not to exchange oxygen with concentrated sulfuric acid. This oxygen exchange was accompanied by racemization and retarded by adjacent bulky substituents. All these observations seem to indicate that the oxygen exchange reaction proceeds by the nucleophilic attack of sulfoxide on sulfuric acid, as is depicted by Eq. 7.

# Particle-size Determination of Suspensions or Emulsions by Viscometry*

By Sachio MATSUMOTO

(Received July 20, 1964)

The purpose of this work is to evaluate the particle-size distribution in the subsieve range of disperse systems, either suspensions or emulsions, by determining the relation between the relative viscosity of the system ($\eta_{rel}$) and the volume fraction of the particles ($\phi$). The measuring apparatus is an assembly of a modified Maron-Belner-type capillary viscometer[1] and a sedimentation tube, which provides a means for the measurement of the viscosity change with time at a fixed position in the bulk resulting from the sedimentation or ascension of dispersed particles.

In addition, this method seems to be useful for the viscosity measurement of dispersions with either quickly-sedimenting or -ascending particles.

## Apparatus and Theoretical

**Equipment.**—Figure 1 shows a sketch of the measuring apparatus, which is composed of two glass units; one is a sedimentation tube (S), and the other is essentially a capillary viscometer, consisting of a capillary tube (C) and a manometer tube (M). The two units are connected by a rubber stopper at the end of the sedimentation tube.

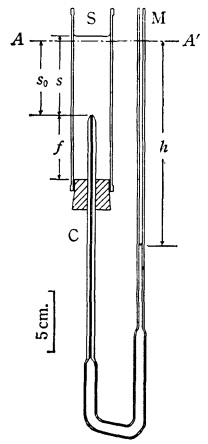

Fig. 1. Measuring apparatus.
A—·—A': Liquid level of the hydrostatic balance.

In the present study, an apparatus was employed in which the inner radii of the sedimentation tube ($R_S$), the capillary tube ($R_C$) and the manometer tube ($R_m$) were $1.47_8$ cm., $0.0249_2$ cm. and $0.304_4$ cm. respectively, while the length of the capillary tube ($L$) was 19.90 cm. The height of the capillary in the sedimentation tube, presented as $f$ in Fig. 1, can be changed from 0 to 10 cm. in accordance with the movements of the dispersed particles.

Although the dimensions of all the sections can be assembled interchangeably, the ratio $(R_C/R_m)^4$ must be kept in all instances below 0.004 in order to make negligible the resistance of flow in the manometer tube compared to that in the capillary tube.[1]

**Operation.**—The two units are joined as shown in Fig. 1 and are held vertically in place by means of a clamp. The sample is next introduced into the sedimentation tube, and the sample flows to the manometer tube through the capillary. During this flow, the times corresponding to the liquid meniscus in the manometer tube are recorded.

It may be desired that the above procedure be made in a thermostat since the viscosity changes remarkably with the temperature.

**The Theory of Measurement.**—The measuring apparatus is designed on the basis of a linear relationship between $\log \eta_{rel}$ and $\phi$ in the low dispersion concentrations.[2] Moreover, if the value of $\eta_{rel}$ is measured at a fixed position in the sedimentation tube containing the dispersion, this value will decrease with time as a result of the sedimentation or ascension of dispersed particles. The decreasing curve of $\log \eta_{rel}$ against time may correspond to the cumulative curve for the volume frequency of dispersed particles against the particle sizes.

The proper selection of suspending fluid to be used depends on various factors, as has been illustrated in the ordinary sedimentation method.[3]

Typical observations obtained by using the measuring apparatus are schematically presented

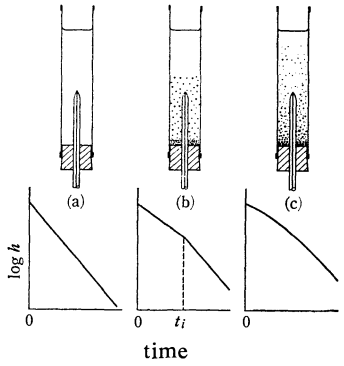

Fig. 2. Schematic curves of $\log h$ vs. time for suspending fluid (a), mono (b) and polydispersed (c) suspensions.

in Fig. 2, where $h$ denotes the difference in the meniscus of the fluid between the manometer tube and the hydrostatic balance, as is shown in Fig. 1. In the case of a suspending medium (Newtonian fluid), $\log h$ against time reveals a linear relationship, as is shown in Fig. 2(a), while the broken line at time $t_i$ in (b) is obtained with a monodispersed suspension. At time $t_i$, the boundary part between the dispersion and its suspending fluid may pass down or up to the end of the capillary tube. In the case of a polydispersed suspension, which is the most frequent case in practice, the plot of $\log h$ against time shows an upward convex curve, as may be seen in c.

In the same manner as has been established by Maron and Belner[1] for the capillary tube viscometer, the viscosity of the suspending fluid ($\eta_0$) with the present apparatus may be given by

$$\eta_0 = -\{R_c^4 \alpha / 8(2.303) L R_m^2\} \rho_0 / m_0 \qquad (1)$$

or

$$\mathrm{d}\log h/\mathrm{d}t = -m_0 = -B\rho_0/\eta_0 \qquad (2)$$

where $\rho_0$ is the density of the suspending fluid, $m_0$ is the slope of $\log h$ against time, and $\alpha$ and $B$ are the constants of the apparatus, as Eqs. 3 and 4 show:

$$\alpha = g\{1 + (R_m^2/R_s^2)\} \qquad (3)$$

$$B = R_c^4 \alpha / 8(2.303) L R_m^2 \qquad (4)$$

where $g$ is the gravitational constant, and $R_c$, $R_m$, $R_s$ and $L$ are the dimensions of the apparatus, as has been described above.

When a monodispersed suspension flows in the capillary tube, the slope of $\log h$ against time, presented as $m$, is smaller than $m_0$ and will agree with $m_0$ after time $t_i$. On the other hand, the slope of a polydispersed suspension approaches $m_0$ with time, so that the $\eta_{rel}$ value of this system will approach unity with a decrease in the dispersion concentration. If the relation of Eq. 2 is expanded for a given time, $t$, the ratio of the slope of the suspending fluid to that of the dispersion at time $t$ should be expressed as Eq. 5:

$$m_0/m = \eta\rho_0/\eta_0\rho \simeq \eta_{rel} \propto \phi \qquad (5)$$

where $\eta$ is the viscosity, $\rho$ is the density, and $\phi$ is the volume fraction of dispersed particles of the system at the end of the capillary tube at time $t$ respectively. Figure 3 shows the schematic plots of the ratio $m_0/m$ corresponding to the times for mono- and polydispersed systems.

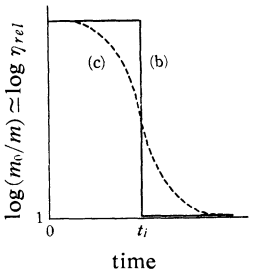

Fig. 3. Schematic curves of $m_0/m$ vs. time for mono (b) and polydispersed (c) suspensions.

In the case of a monodispersed suspension, the time $t_i$ corresponds to the dispersed particle size according to Stokes' equation:

$$t = 18x\eta_0/(\rho - \rho_0) g D^2 \qquad (6)$$

where $D$ is the particle diameter, and $x$ agrees with the distance of the sedimentation (equal to $s$ in Fig. 1) or ascension (equal to $f$ in Fig. 1) of dispersed particles. On the other hand, the size distribution of the particles of a polydispersed suspension may be reflected in the results over the entire measuring times; therefore, the decreasing curve c in Fig. 3 reminds us of a cumulative curve for the volume frequency of dispersed particles against the particle sizes, and of the possibility of obtaining the size distribution curve. The distribution function of the particle size frequency for the volume concentration is shown in Eq. 7:

$$F(D) = -4t/\mathrm{d}\cdot t/\mathrm{d}t\cdot(\phi_D/\phi) \qquad (7)$$

where $\phi_D$ is the cumulative volume fraction of a particle diameter below $D$.

When the particle sediments, the adjustment must be made for the sedimentation distance, $s$, as in Eq. 8, because $s$ decreases with an increase in the sample meniscus in the manometer tube:

$$\mathrm{d}(s - s_0)/\mathrm{d}t = -\mathrm{d}\log h/\mathrm{d}t\cdot(R_m^2/R_s^2) \qquad (8)$$

where $s_0$ is the distance from the end of the capillary tube to the sample position at a hydrostatic balance in the sedimentation tube, as is shown in Fig. 1.

## Experimental Results

**Potato Starch Granule.**—As an example of the sedimentation of dispersed particles, the potato starch granule was used, since it has such advantages as a large specific volume, a relatively spherical shape and a wide range of particle-size distribution.

The starch granule was extracted from fresh potatoes and then stored in a desiccator over calcium chloride until used. Suspensions of various concentrations were prepared with a 2 wt.% Tween 20 (polyoxyethylene sorbitan monolaurate) aqueous solution immediately before measurement.

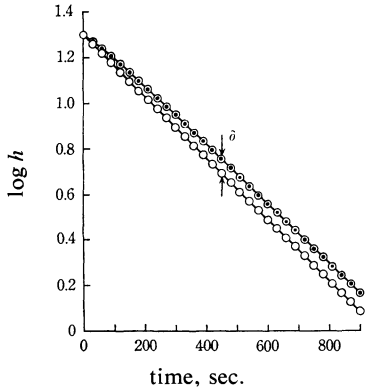

Fig. 4. Log $h$ vs. time plots for 3.91 vol. % potato starch granule suspension (⊙) and its suspending fluid (○) at 32°C.

Figure 4 shows the plots of log $h$ against time at 32°C for a 3.91 vol.% suspension and for a 2 wt.% Tween 20 aqueous solution. As may be seen in Fig. 4, these fluids do not show large differences of slopes from one another at the entire measuring times; hence, the d log $h$/d$t$ procedure may not be directly applied with accuracy. To avoid this difficulty, the so-called "$\delta$ method"[1] was employed. That is to say, a straight line of the suspending fluid was assumed as the standard line; then the differences, $\delta$, were measured between the curve of the suspension flow and the assumed line at the experimental values of $t$. When $\delta$ is plottod against $t$ and the curve is differentiated at $t$, d$\delta$/d$t$ is obtained; from this quantity, d log $h$/d$t$ is calculated.

Figure 5 gives the plots of log ($m_0/m$) against time deduced in this manner by using the data obtained from the relation between log $h$ and $t$ for a 2 wt.% Tween 20 aqueous solution and potato-starch-granule suspensions in various dispersion concentrations. Figure 6 shows the particle-size distribution of the potato starch granule, which was calculated from the decreasing curve in Fig. 5.

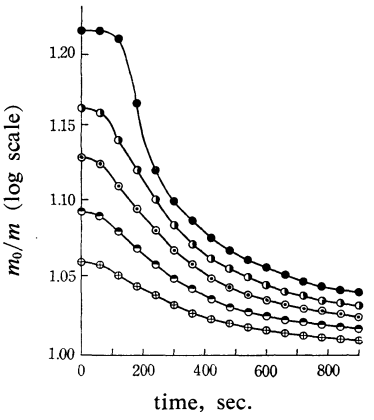

Fig. 5. $m_0/m$ vs. time plots for potato starch granule suspensions of 5.75 vol. % (●), 4.84 vol. % (◑), 3.91 vol. % (⊙), 2.96 vol. % (◓) and 1.99 vol. % (⊕) at 32°C.

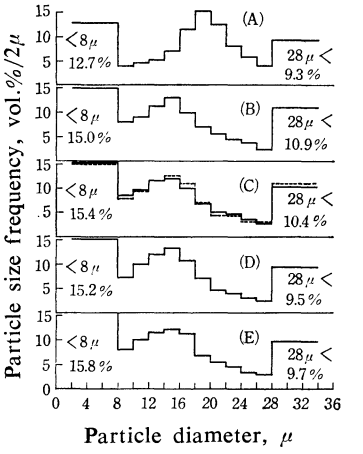

Fig. 6. Particle size distribution curves for potato starch granule suspensions of 5.75 vol. % (A), 4.84 vol.% (B), 3.91 vol.% (C), 2.96 vol.% (D) and 1.99 vol.% (E), calculated from $m_0/m$ vs. time plots in Fig. 5. Broken line represents a result by using Wiegner's tube method.

The distribution curves differ slightly from each other in the shape but they all correspond to the maximum for the frequency, except for the suspension with a 5.75 vol.% concentration. From these results, it may be understood that the upper limit of the dispersion concentration for the determination is below about 5 vol.%. On the other hand, the lower limit of the dispersion concentration for the determination depends on the accuracy of viscosity measurement.

For the suspension of a 3.91 vol.% dispersion concentration, the result obtained by this method was compared with that obtained by Wiegner's

tube method,[4] which is shown as a broken line in Fig. 6.

**Oil in Water Emulsions.**—Emulsions of 1-hexanol, benzene or *n*-hexane in water, stabilized by 1 wt.% SDS (sodium dodecyl sulfate), were used for viscosity and particle-size determinations, as in the case of ascending particles.

These emulsions were readily prepared by shaking mixtures of the 9.1 vol.% oil phase and the residual water phase; the shakings were done under similar conditions so as to give products of the same dispersion state. However, the plots of $\log h$ against $t$ for the emulsions differ according to the kind of dispersed liquids, as Fig. 7 shows. From these results, it is evident that the viscosity and the particle size of oil in a water emulsion are dependent on the nature of the dispersed substance, as Figs. 8 and 9 show. More detailed experimental results have been presented in a previous article.[5]

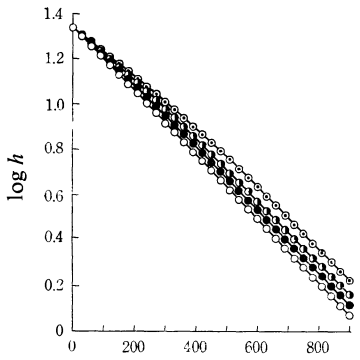

Fig. 7. Log $h$ vs. time plots for emulsions of 1-hexanol (⊙), benzene (◑) or *n*-hexane (●) in water, stabilized by sodium dodecyl sulfate, and these spending fluid (○) at 32°C; dispersion concentration are 9.1 vol.% in all the systems.

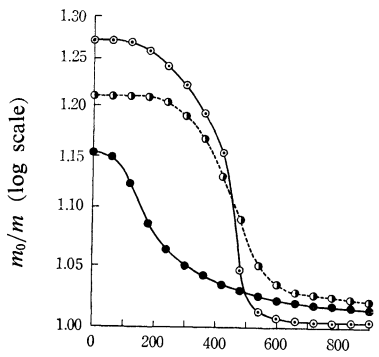

Fig. 8. $m_0/m$ vs. time plots for emulsions of 1-hexanol (⊙), benzene (◑) or *n*-hexane (●) in water at 32°C.

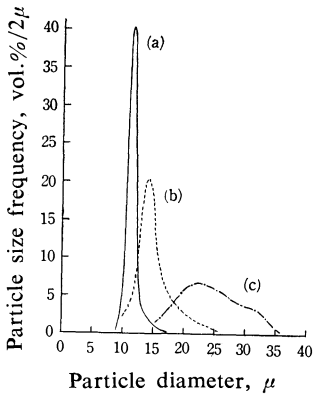

Fig. 9. Particle size distribution curves for emulsions of 1-hexanol (a), benzene (b) or *n*-hexane (c) in water.

As for the application, the advantage of this method is that it enables one to obtain the viscosity of dispersions with quickly-sedimenting or -ascending particles. The viscosity appears in the initial slope of $\log h$ against the $t$ curve where the original dispersion concentration is held.

Although independent of the particle size determination, the relation between the shearing stress and the rate of shear on the fluid may also be obtained from the measurements made during a single run,[1,6] so the apparatus can be used for the observation of the non-Newtonian flow.

## Summary

An apparatus for sedimentation analysis by the viscometric method, making possible the measurement of viscosity change with time at a fixed position in the bulk due to the sedimentation or ascension of dispersed particles, has be constructed. The new method has been examined with both a potato-starch-granule suspension and oil-in-water emulsions.

The author is very grateful to Professor Sôzaburo Ono and Dr. Takehiko Watanabe for their many helpful discussions and suggestions during this work. Thanks are also due to Professor Shû Nagayama for his continued interest and support.

# Nature of the Longest Wavelength Absorption Bands of *N*-Substituted Maleimides*

By Taku MATSUO

(Received July 29, 1964)

In spite of the considerable progress in recent years in understanding the absorption spectra of many $\pi$-electron systems, not much knowledge has been obtained as to the spectra of cyclic imides derived from anhydrides. For example, the absorption spectra of several imides have been reported in some papers without any theoretical consideration of the nature of each band.[1] The present paper will study the effects of *N*-substitution on the electronic spectra of maleimide derivatives from both the theoretical and experimental points of view.

## Experimental

The compounds used for the measurement of the absorption spectra were obtained in the same way as reported in the previous paper in which the infrared spectra of the carbonyl groups of maleimide and its *N*-substituted derivatives were discussed.[2]

The spectra were measured with a Hitachi model EPS-2U recording spectrophotometer.

## Experimental Results and Discussion

The absorption spectra of the compounds investigated are shown in Figs. 1 and 2 as measured in *n*-hexane. Since the main interest was concentrated on the longest wavelength absorption band of each compound, the highly intense bands in the shorter wavelength region are not shown in the figures. These high intensity bands are due to electronic transitions of a nature different from that discussed in this paper. The same could be said about the medium intensity band of *N*-(*p*-methoxyphenyl)-maleimide at 275 m$\mu$, which shows less solvent effect than does the lower intensity band at 350 m$\mu$, as will be discussed later. Also excluded from the present discussion are the bands with some fine structures around 260 m$\mu$

4 *N*-(*p*-Methoxyphenyl)-maleimide

in the spectra of those compounds with a phenyl group as the constituent of their substituents. Obviously the bands are due to the transitions localized at the phenyl group, not to the characteristics of cyclic imides.

The longest wavelength absorption bands in question are classified into four groups according to their intensities and the wavelengths of the absorption maxima. The corresponding *N*-substituents of the four groups are found to be as follows:

* Contribution No. 72 from the Department of Organic Synthesis, Faculty of Engineering, Kyushu University. Presented, in part, at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, (1964).

2) T. Matsuo, This Bulletin, **37**, 1844 (1964).

Group 1: hydrogen,
Group 2: ethyl, cyclohexyl and benzyl,
Group 3: phenyl, *p*-tolyl and *p*-chlorophenyl, and
Group 4: *p*-methoxyphenyl.

The groups are numbered in the order of the increasing wavelength, or of the decreasing intensity, of the absorption maximum of the band concerned.

The difference between the classes given above becomes more evident when a comparison is made in terms of their solvent effects, shown in Figs. 3, 4 and 5. The solvent effect is also summarized in Table I. A strong bathochromic shift is observed for group 1 when the measurement is made in polar solvents. The bathochromic effect is very small or almost negligible in the case of group 2. The effect of the polar solvent becomes hypsochromic in group 3, and this same effect is further pronounced in group 4.

1 Maleimide
2 *N*-Etylmaleimide
3 *N*-Cyclohexylmaleimide
4 *N*-Phenylmaleimide
5 *N*-(*p*-Methoxyphenyl)-maleimide

Attempts were made to interpret the above experimental results by means of the Hückel LCAO-MO theory. The calculations were made by assuming a $C_{2v}$ symmetry and parameters for the imide system:

$\alpha_{\dot{O}} = \alpha_C + h_{\dot{O}}\beta$
$\alpha_{\ddot{N}} = \alpha_C + h_{\ddot{N}}\beta$
$\beta_{CO} = k_{CO}\beta$
$\beta_{CN} = k_{CN}\beta$

The effect of the expansion of conjugated systems on their energy levels was first examined by using the coplanar, axial structures and parameters shown in Fig. 6. When the substituent, R, is an aryl group, a new highest-occupied $\pi$-electron level appears. The lowest unoccupied energy level, on the other hand, is not affected at all, since the orbital is localized at the carbonyl groups and at the double bond connecting them. A decrease in the energy difference between the highest-occupied and the lowest-unoccupied levels results, therefore, when an aryl group is attached to the nitrogen atom. The decrease in the separation of the two $\pi$-electron energy levels argees qualitatively with the trend observed in the behavior of the longest-wavelength absorption bands of the four groups described above. This agreement, however, is not the true answer to the present problem, as may be seen by the following arguments. First of all, the oscillator strength of the pure $\pi \rightarrow \pi^*$ transition implied by the energy diagram may be expected to be much larger

than the largest observed values (of the order of $10^{-2}$) for the longest-wavelength absorption bands of *N*-alkylmaleimides. In the case of *N*-arylmaleimides, the molecular orbital of the highest-occupied $\pi$-electron energy level is localized at the aryl group. Therefore, the transition from that level to the lowest-unoccupied energy level has a strong character of charge-transfer absorption. An appreciable bathochromic shift may be expected, then, when the absorption band is measured in polar solvents. The experimental results are just the opposite of this prediction. In short, the absorption band in question can not be explained as due to a pure $\pi\rightarrow\pi^*$ transition.

The extent of the contribution of the nitrogen atom to the conjugated system was examined explicitly in the next calculations. In the cases of *N*-substituted phthalimides, their dipole moments indicate that the hybridization of the nitrogen orbital for the N-R bond changes from $sp^3$ to $sp^2$ types as the substituent is changed from hydrogen to methyl and then to phenyl groups.[4] Correspondingly, the orbital for the lone pair electrons of the nitrogen atom changes from a $sp^3$ to a pure p orbital in the order of the substituents given above. The same situation may be expected for *N*-substituted maleimides. In the Hückel LCAO-MO method, the above change in the hybridization of atomic orbitals corresponds to a modification of the parameters to be used in the calculations. In order to minimize any further complications, only $k_{CN}$ was varied in examining the effect of the isolation of the nitrogen atom from the conjugated system. The results are summarized in Fig. 7 and Table II. It shoud be noted that the electron densities at the nitrogen and oxygen atoms decrease and increase respectively as the $k_{CN}$ value increases. The increased electron density at the oxygen atom raises the energy level, *En*, of the lone pair electrons on the atom. Therefore, an interpretation of the absorption band as being due to the $n\rightarrow\pi^*$ transition of the carbonyl groups becomes possible, even though the lowest unoccupied level is not affected for the first approximation. Assuming that the nitrogen and the four carbon atoms make a completely coplanar system and that $k_{CN}$ is linearly proportional to the overlap integral, the $k_{CN}$ value is estimated to decrease approximately by a factor of 0.7 as a change is made from pure p to $sp^3$ orbitals for the nitrogen atom. A further reduction in $k_{CN}$ is expected if the nitrogen atom rises a little above the plane made by the carbonyl groups and the double bond. A close examination of the lowest unoccupied level reveals that it is also affected by the delocalization of the electrons of the nitrogen atom, as will be shown below. The molecular orbital of this level is:

$$\phi_5=\frac{1}{\sqrt{6}}(\phi_1-\phi_2+\phi_4-\phi_5-\phi_6+\phi_7) \qquad (1)$$

and its energy is given by:

$$E_5=\int\phi H\phi d\tau=\alpha_C+\frac{1}{3}(h_O-1)\beta+\frac{2}{3}(1-k_{CO})\beta \qquad (2)$$

4) a) H. Lumbroso and R. Dabard, *Bull. soc chim. France*, **1959**, 749; b) A. Arcoria, H. Lumbroso and R. Passerini, ibid., **1959**, 754.

The delocalization of the electrons to carbonyl groups increases the contribution of an ionic structure where the oxygen atom is bonded to the carbon atom through a single bond. Therefore, $k_{CO}$ becomes less than when the contribution of the ionic structure is small. The increased electron density at the oxygen atom in the ionic structure causes a reduction in the value of $h_O$ which appears in Eq. 2. The net results of these corrections are minor, however, in comparison with the change in *En*. Therefore, the increase in $k_{CN}$, or the contribution of the ionic structures, makes the separation between *En* and $E_5$ narrower than before after all.

The results obtained above agree qualitatively with the observed shift of the wavelength of the absorption band under discussion when the before-mentioned group is advanced from 1 to 4. However, neither the difference in the solvent effects of the four groups nor the relatively large intensities of the absorptions can be explained by a simple $n\rightarrow\pi^*$ transition of the carbonyl groups. Thus, it is clear that some modification of the above discussion are required. This modification is brought about quite naturally when the interaction between the $n\rightarrow\pi^*$ and other transitions of the system is taken into consideration.

A fairly large number of $\beta,\gamma$-unsaturated ketones have been known to show extraordinarily strong $n\rightarrow\pi^*$ transitions.[5,6] According to Labhart and Wagniere, the high intensities observed for these $n\rightarrow\pi^*$ transitions are due to a perturbation of the absorptions by the $\pi\rightarrow\pi^*$ transitions through the overlap of the oxygn 2p lone-pair orbital with the $\beta$-carbon $2p_\pi$ orbital.[6] Quite similar situations may be expected for the maleimide derivatives under discussion. Using Mulliken's table[7] and the geometry assumed for maleimide as shown in Fig. 8, the overlap integral between the oxygen 2p orbital and the nitrogen $sp^3$ orbital has been calculated to be 0.013. The overlap becomes small as the nitrogen orbital approaches a pure p orbital corresponding to the presumed cases of *N*-arylmaleimides. The nitrogen orbital, on the other hand, plays an important role in the $\pi$-electronic system of the imide group. As is shown in Table III, a large contribution of the nitrogen atomic orbital, to the third energy level $\pi_3$ of the imide systems given in Fig. 7 is observed. Therefore, a considerable interaction between the two transitions, $n$-$\pi^*$ and $\pi_3\rightarrow\pi^*$, may be expected when a noticeable

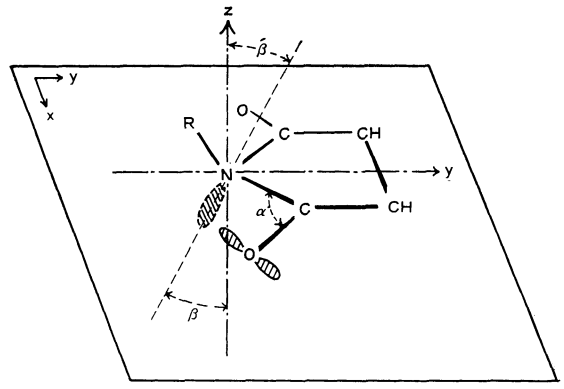

Fig. 8. Steric arrangement of atoms and the orbitals assumed for maleimide and its *N*-alkylsubstituted derivatives. The oxygen 2p orbitals are in the xy plane. The N—R bond and the nitrogen orbital as indicated by the shadowed area are directed up and down, respectively, from the xy plane. The following bond distance and bond angles were assumed in the calculation described in the text.
$r_{CN}=r_{CO}=1.25$Å, $\alpha=125°$, and $\beta=35°$

TABLE III. THE COEFFICIENTS FOR ATOMIC ORBITALS IN THE THIRD MOLECULAR ORBITAL $\pi_3$ SHOWN IN Fig. 7

| Atom | $k_{CN}=0.8$ | $k_{CN}=0.6$ | $k_{CN}=0.4$ | $k_{CN}=0.2$ |
|---|---|---|---|---|
| N | −0.709 | −0.781 | −0.863 | −0.952 |
| O | 0.346 | 0.304 | 0.242 | 0.146 |
| $C_{C=O}$ | 0.097 | 0.104 | 0.099 | 0.069 |

overlap exists between the oxygen 2p orbital and the nitrogen orbital. Unfortunately, the $\pi_3\rightarrow\pi^*$ transition could not be identified in the present experiment. The oscillator strength of the corresponding absorption band, however, is estimated theoretically to be of the order of $10^{-1}$, since it is a possible $\pi\rightarrow\pi^*$ transition. Therefore, the overlap between the oxygen 2p lone-pair orbital and the nitrogen orbital as estimated above is large enough to explain the intensification of the $n\rightarrow\pi^*$ transition of the carbonyl groups by the perturbation. Furthermore, the $\pi_3\rightarrow\pi^*$ transition has a strong charge-transfer absorption character as is obvious from an inspection of the molecular orbitals concerned. Therefore, it is quite natural that a bathochromic shift is observed for the longest-wavelength absorption band of maleimide and its *N*-alkyl substituted derivatives when the spectra are measured in polar solvents. The overlap described above decreases rapidly as the nitrogen orbital approaches a pure p orbital. A decrease in intensity and a change in solvent effect are

5) R. C. Cookson and N. S. Wariyar, *J. Chem. Soc.*, **1956**, 2302.
6) H. Labhart and G. Wagniere. *Helv. Chim. Acta*, **42**, 2219 (1959).
7) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

expected, accordingly, for the longest-wavelength absorption band of *N*-arylmaleimide.

In the case of *N*-arylmaleimide, an interaction of the oxygen 2p orbital with the $\pi$ orbital on the phenyl group must also be taken into consideration. This type of interaction is expected to have a small effect upon the longest-wavelength absorption for the following two reasons. The overlap between the oxygen lone-pair orbital and the $\pi$ orbital of the phenyl group is strongly dependent on the twisting angle, $\theta$, of the phenyl group around the $C_2$ axis, as is shown in Fig. 9. For the best situation, where $\theta$ is 90°, the overlap between the oxygen 2p orbital and the highest-occupied orbital of the phenyl group is estimated to be 0.01 or so. Actually, the phenyl group does not stay at the perpendicular position relative to the imide plane. Thus, the real or average value of the overlap integral is less than 0.01. Secondly, moment of the transition from the $\pi$ orbitals on the phenyl group to $\pi^*$ is expected to be small when $\theta$ is different from zero. Therefore, the $\pi \rightarrow \pi^*$ transition under discussion is not intensified very much by the perturbation through the interaction of the oxygen lone-pair orbital with $\pi$ orbitals of the phenyl group.

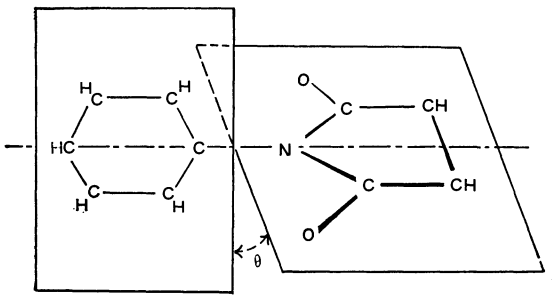

Fig. 9. Orientation of the plane of phenyl group with respect to the imide plane. The angle of twisting is indicated by $\theta$.

In conclusion, the longest-wavelength absorption bands of *N*-substituted maleimides are found to be essentially due to the $n \rightarrow \pi^*$ transition of the carbonyl group. When the hydrogen on the nitrogen atom is replaced by alkyl and aryl groups, the nitrogen lone-pair electrons delocalize more and more to the carbonyl groups and the absorption bands in question shift to longer wavelengths. In the case of maleimide, the $n \rightarrow \pi^*$ transition is perturbed strongly by the $\pi \rightarrow \pi^*$ transition of the cyclic imide system, and an appreciable intensification of the absorption band and its bathochromic shift in the polar solvents result. The perturbation decreases rapidly in the order of *N*-alkyl- and *N*-arylmaleimides, and the absorption approaches a pure $n \rightarrow \pi^*$ transition.

The author wishes to express his gratitude to Dr. Mitsuo Ito of the Department of Chemistry, Faculty of Science, Kyushu University, for his interest in this work and his continuous encouragement. He is also indebted to Miss Katsumi Mera for measuring the spectra reported in this paper.

# Quinoxaline Derivatives. V.[1] Some Reactions of 2-Cyano-3-hydroxyquinoxaline 1-Oxide

By Yusuf AHMAD, M. S. HABIB,* M. IQBAL and ZIAUDDIN

(Received July 30, 1964)

The presence of a nitrile group and an *N*-oxide function, side by side in the same molecule, confers some unusual properties on 2-cyano-3-hydroxyquinoxaline 1-oxide (Ia), as has been reported in an earlier paper.[2] It is recovered unchanged when it is refluxed with phosphorus trichloride. All atempts to deoxygenate it to 2-cyano-3-hydroxyquinoxaline (II: R=R'=H; R''=CN) by reduction with sodium dithionite in acetic acid (or aqueous ethanol), zinc and acetic acid, or by catalytic hydrogenation in the presence of Pd-C, were unsuccessful. Instead of the expected deoxygenated base (II: R=R'=H; R''=CN), the

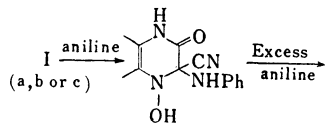
1) Part IV: Y. Ahmad, M. S. Habib, Ziauddin and N. Bashir, *Tetrahedron*, **21**, April (1965).

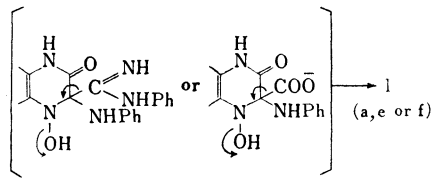
2) Part III; Y. Ahmad, M. S. Habib and Ziauddin, ibid., **20**, 1107 (1964).

product isolated in each case was 2-hydroxyquinoxaline (II: R=R'=R''=H), indicating that although deoxygenation had been achieved, it was accompanied by a simultaneous loss of the nitrile group.

During the reaction of 3-hydroxyquinoxaline-2-carboxyamide 1-oxide (III) with aniline (or *N*-methylaniline) to obtain 3-hydroxyquinoxaline-2-carboxyanilide (or *N*-methylanilide) 1-oxide (III: CONHPh or CONMePh for $CONH_2$), it was observed that if the reactants were heated together for only a few minutes the product obtained in both cases was 3-hydroxyquinoxaline-2-carboxyamide (II: R=R'=H; R''=$CONH_2$), whereas if the heating was prolonged for 24 hr., 3-hydroxyquinoxaline-2-carboxyanilide (II: R=R'=H; R''=CONHPh) and 3-hydroxyquinoxaline-2-carboxy-*N*-methylanilide (II: R=R'=H; R''=CONMePh) respectively were obtained. This indicated that these amines deoxygenated the *N*-oxide (III) and that the resulting amide reacted further to give the corresponding anilides (II: R=R'=H; R''=CONHPh or CONMePh). This observation, combined with the fact that amines are known[3] to deoxygenate heterocyclic *N*-oxides, prompted us to try the action of amines on the *N*-oxide (Ia) to obtain 2-cyano-3-hydroxyquinoxaline (II: R=R'=H; R''=CN) which was needed in connection with another investigation.



The *N*-oxide (Ia), on being heated with *N*-methylaniline, gave a product which also seemed to have lost the nitrile group (the infrared absorption peak at 2240 $cm^{-1}$ for CN was missing). Its constitution was established as 3-hydroxy-2-(*N*-methylanilino)quinoxaline (IIb) on the basis of the following evidence:



(i) Its elementary analysis agrees with $C_{15}H_{13}N_3O$.

(ii) On methylation with methyl sulphate in acetone in the presence of potassium carbonate, it was converted to 3,4-dihydro-4-methyl-2-(*N*-methylanilino)-3-oxoquinoxaline (IIc), identical (infrared spectra and mixed melting point) with an authentic sample prepared[4] by heating 2-chloro-3,4-dihydro-4-methyl-3-oxoquinoxaline and *N*-methylaniline together in methanol.

Aniline and cyclohexylamine also reacted similarly with the *N*-oxide (Ia) and yielded the corresponding amino-derivatives (IIa and d). 7-Chloro- and 7-ethoxy-derivatives (Ib and c) of 2-cyano-3-hydroxyquinoxaline 1-oxide also behaved similarly and with aniline gave anilino-derivatives (IIe and f) of the same type. The structures of these amino-derivatives (IIa and d-f) followed by analogy and on the basis of their elementary analysis. This reaction of bases on the *N*-oxides (Ia-c) can be compared to asimilar action of aqueous potassium hydroxide, described in Part III,[2] wherein the highly-developed electrophilicity of the $C_{(2)}$ of the *N*-oxide (Ia), on account of its attachment to two strong electron-withdrawing functions (i. e., CN and *N*-oxide), is considered to be responsible for the attack of the OH anion and, thereby, the displacement of the nitrile group.

The bases similarly attack the electron-deficient $C_{(2)}$. However, no free CN anions were detected in the reaction mixture, as in the case of the action of aqueous potassium hydroxide on I (a, b or c). Therefore, the amines (e. g. aniline) probably react further with the nitrile group and result in a simultaneous deoxygenation, as is shown below: **

3-Hydroxy-2-phenylquinoxaline 1-oxide[1] (Ia: Ph for CN), when heated under reflux with fuming hydrobromic acid, is quantitativly deoxygenated[5] to 3-hydroxy-2-phenylquinoxaline (II: R=R'=H; R''=Ph). This interesting transformation led us to study the effect of fuming hydrobromic acid on the *N*-oxide (Ia). On being refluxed with this reagent for two hours, Ia gave, in a 30% yield, a product which contained bromine in a non-reactive form. Its infrared spectrum resembled that of 2,3-dihydroxyquinoxaline. Elementary analysis agreed well with a monobromo-derivative of 2,3-dihydroxyquinoxaline. The position of bromine was established as follows:

(a) Its infrared spectrum was identical with that of 6-bromo-2,3-dihydroxyquinoxaline (IVa), which was synthesised by the condensation of 4-bromo-*o*-phenylenediamine with ethyl oxalate as described by Curd et al.[6]

(b) The mono-bromo compound, on methylation with methyl sulphate and aqueous alkali,

gave a dimethyl derivative, m. p. 205—207°C, which was identical (infrared spectra and mixed melting point) with an authentic sample of 6-bromo-1, 2, 3, 4-tetrahydro-1, 4-dimethyl-2, 3-dioxoquinoxaline (IVb) synthesised by the methylation of 6-bromo-2, 3-dihydroxyquinoxaline or 6-bromo-3, 4-dihydro-4-methyl-3-oxoquinoxaline (IVc). This unusual formation of 6-bromo-2, 3-dihydroxyquinoxaline from 2-cyano-3-hydroxyquinoxaline 1-oxide (Ia) probably takes place in two steps. The *N*-oxide (Ia) is first converted to 2, 3-dihydroxyquinoxaline through the sequence (cyano *N*-oxide (Ia) → amide *N*-oxide (III) → carboxylic acid *N*-oxide (III, $CO_2H$ for $CONH_2$) → decarboxylation to 3-hydroxyquinoxaline 1-oxide → rearrangement to 2, 3-dihydroxyquinoxaline) as was previously envisaged[2] in its reaction with a mixture of concentrated sulphuric acid and acetic acid. Bromination takes place later with bromine, which is either generated in situ by the consumption of a part of the *N*-oxide or by the aerial oxidation of hydrobromic acid itself. This is supported by the fact that 2, 3-dihydroxyquinoxaline (IVa: H for Br) itself gives 6-bromo-2, 3-dihydroxyquinoxaline (IVa) (a) on prolonged heating with fuming hydrobromic acid or (b), far more quickly and in a quantitative yield on the addition of an aqueous solution of potassium bromate (to generate one equivalent of bromine) to its solution in hydrobromic acid.

In contrast to this is the observation that the *N*-oxide (Ia) is recovered unchanged even after eight hours boiling with a mixture of concentrated hydrochloric acid and acetic acid.

## Experimental

Infrared spectra were measured in Nujol mull. The light petroleum used had a 60—80°C boiling range.

**2-Anilino-3-hydroxyquinoxaline (IIa).**—2-Cyano-3-hydroxyquinoxaline 1-oxide[2] (Ia) (1g.) and aniline (20 ml.) were heated together under reflux for 4 hr. The reaction mixture was allowed to cool and then diluted with light petroleum. The solid thus separated was crystallised from ethanol as pale yellow micro-needles of the anilinoquinoxaline (IIa), yield, 90%; m. p. 247—248°C (Found: C, 69.6; H, 4.4; N, 17.5. Calcd. for $C_{14}H_{11}N_3O$: C, 70.8; H, 4.6; N, 17.7%).

**3-Hydroxy-2-(*N*-methylanilino)quinoxaline (IIb).**—Similarly, the *N*-oxide (Ia) in an excess of *N*-methylaniline gave, in a 40% yield, colourless cubes (from ethanol) of the *N*-methylanilinoquinoxaline (IIb), m. p. 180—182°C (Found: N, 16.5. Calcd. for $C_{15}H_{13}N_3O$: N, 16.7%). The compound IIb (0.13 g.), on methylation with methyl sulphate (0.1 ml.) in the presence of anhydrous potassium carbonate (0.5 g.) and acetone (heated under reflux), gave, in a 50% yield, 3, 4-dihydro-4-methyl-2-(*N*-methylanilino)-3-oxoquinoxaline (IIc), m. p. 145—146°C (Found: N, 15.95. Calcd. for $C_{16}H_{15}N_3O$: N, 15.8%). Its melting point was not depressed by admixture with a sample (m. p. 143—144°C) prepared by the method of Clark-Lewis[4] by the condensation of 2-choro-3, 4-dihydro-4-methyl-3-oxoquinoxaline with *N*-methylaniline in boiling methanol.

**2-Cyclohexylamino-3-hydroxyquinoxaline (IId).**—Similarly, the *N*-oxide (Ia), on being treated with cyclohexylamine, gave, in a 90% yield, yellow needles (from ethanol) of the cyclohexylaminoquinoxaline (IId), m. p. 246°C (Found: C, 63.8; H, 7.1; N, 16.3. Calcd. for $C_{14}H_{17}N_3O \cdot H_2O$: C, 64.3; H, 7.2; N, 16.1%).

**2-Anilino-7-chloro-3-hydroxyquinoxaline (IIe).**—7-Chloro-2-cyano-3-hydroxyquinoxaline 1-oxide[2] (Ib) with aniline gave, in a good yield, yellow cubes (from glacial acetic acid) of the anilinochloroquinoxaline (IIe), m. p. 318—319°C (Found: Cl, 13.15; N, 15.3. Calcd. for $C_{14}H_{10}ClN_3O$: Cl, 13.1; N, 15.5%).

**2-Anilino-7-ethoxy-3-hydroxyquinoxaline (IIf).**—2-Cyano-7-ethoxy-3-hydroxyquinoxaline 1-oxide[2] (Ic) with aniline gave in a good yield, yellow needles (from ethanol) of the anilinoethoxyquinoxaline (IIf), m. p. 260—261°C (Found: C, 67.65; H, 5.4; N, 15.0. Calcd. for $C_{16}H_{15}N_3O$: C, 68.3; H, 5.4; N, 14.9%).

**The Reduction of 3-Hydroxyquinoxaline-2-carboxyamide (III).**—The amide *N*-oxide[2] (III), on being heated under reflux with aniline or *N*-methylaniline for 3 min., gave 3-hydroxyquinoxaline-2-carboxyamide (II: R=R′=H; R″=$CONH_2$), m. p. 308—310°C (decomp.) in a quantitative yield. Its melting point was not depressed by admixture with a sample[7] (m. p. 308—310°C) obtained by the action of concentrated ammonium hydroxide on ethyl 3-hydroxyquinoxaline-2-carboxylate. The infrared spectra of the compounds obtained by the two methods were also identical.

**6-Bromo-2, 3-dihydroxyquinoxaline (IVa).**—a) The *N*-oxide (Ia) (1 g.) or amide *N*-oxide (III) (1 g.) in fuming hydrobromic acid (30 ml.) was heated under reflux for 2 hr. The reaction mixture was then allowed to cool. On dilution with water, a yellow solid separated which crystallised from dimethylformamide-ethanol as colourless cubes of the bromoquinoxaline (IVa), m. p. >350°C, yield 30% (Found: N, 11.8. Calcd. for $C_8H_5BrN_2O_2$; N, 11.6 %). This was identical (infrared spectra) with an authentic sample of 6-bromo-2, 3-dihydroxyquinoxaline.[6] The *N*-oxide (Ia) was recovered unchanged on being heated under reflux for 8 hr. with a mixture (1 : 1) of HCl and AcOH or on being heated under reflux with acetylchloride in a sealed tube at 100°C for 72 hr. The amide *N*-oxide (III), on the other hand, gave 2, 3-dihydoxyquinoxaline on being heated with a mixture (1 : 1) of HCl and AcOH.

b) A mixture of 2, 3-dihydroxyquinoxaline (1 g.) and fuming hydrobromic acid (50 ml.) was heated under reflux for 8 hr. The solid separated during the reaction was collected and crystallised from dimethylformamide-ethanol as colourless cubes of the monobromo-2, 3-dihydroxyquinoxaline (20% yield, m.p. >350°C, identical (infrared spectra) with a sample obtained under a). Curd, Davey and Stacey[6] have reported this compound, but have not given any melting point for it.

c) The addition of a calculated amount of aqueous potassium bromate to a solution of 2, 3-dihydroxyquinoxaline in hot fuming hydrobromic acid immediately precipitated, in a quantitative yield, the monobromo-2, 3-dihydroxyquinoxaline, which was then collected and crystallised from dimethylformamide-ethanol as colourless cubes, m. p. >350°C (The infrared spectrum was identical with that of 6-bromo2, 3-dihydroxyquinoxaline.).

**6-Bromo-1, 2, 3, 4-tetrahydro-1, 4-dimethyl-2, 3-dioxoquinoxaline (IVb).**—6-Bromo-2, 3-dihydroxyquinoxaline (obtained under a, b or c; see above) (1 g.), anhydrous potassium carbonate (2 g.) and methyl sulphate (0.5 ml.) in acetone (50 ml.) were heated under reflux for 3 hr. The reaction mixture was then filtered, and the filtrate on concentration gave a solid which crystallised from ethanol as white needles of the tetrahydroquinoxaline (IVb), m. p. 205—206°C, in a good yield. It was identical (infrared spectra and mixed melting point with a synthetic sample prepared by the methylation of 6-bromo-3, 4-dihydro-2-hydroxy-4-methyl-3-oxoquinoxaline (IVc) (see below) with methyl sulphate and aqueous sodium hydroxide. Curd, Davey and Stacey[6] recorded its m. p. as 205—206°C.

**6-Bromo-3, 4-dihydroxy-2-hydroxy-4-methyl-3-oxoquinoxaline (IVc).**—Without being isolated from its ethanolic solution, 4-bromo-2-methylaminoaniline prepared by the hydrogenation of 4-bromo-2-methylamino-1-nitrobenzene (5 g.) in ethanol (60 ml.) over Pd-C was condensed with ethyl oxalate (20 g.) by heating them together under reflux for 3.5 hr. The solid which separated was collected and crystallised from acetic acid as colourless micro-needles of the bromoquinoxaline (IVc), m. p. 325—327°C (Found: Br, 31.05; N, 10.7. Calcd. for $C_9H_7BrN_2O_2$: Br, 31.4; N, 11.0%).

## Summary

2-Cyano-3-hydroxyquinoxaline 1-oxide (Ia), and its 7-chloro- or 7-ethoxy-derivatives (Ib, c), on treatment with aniline, are deoxygenated, with a simultaneous displacement of the nitrile group, resulting in the formation of 2-anilinoquinoxalines (IIa, e and f). Ia undergoes similar transformations with *N*-methylaniline and cyclohexylamine.

The *N*-oxide (Ia), on being heated with fuming hydrobromic acid, yields 6-bromo-2, 3-dihydroxyquinoxaline (IVa), the mechanism of formation of which has been outlined.

We wish to thank Dr. S. Siddiqui, F. R. S., Chairman of the Pakistan Council of Scientific and Industrial Research, for his interest and encouragement. The analyses were carried out by M/S. # The Electrokinetic Potential of Lead(II) Sulfate

By Tetsuo MORIMOTO, Yutaka HIRATA and Shigeharu KITTAKA

(Received July 30, 1964)

It was reported in a previous paper that the signs of the electrokinetic potentials of sparingly soluble salts in water generally agree with those of the excess ions used when the salts are prepared. Lead(II) sulfate, however, was observed to be an exception.[1] Samples of lead sulfate which were prepared using either excess lead or sulfate ions both had positive charges. Buchanan and Heymann[2] observed that lead sulfate possesses a positive charge in a saturated solution. In the present paper, further studies of the electrokinetic behaviors of lead sulfate have been carried out in order to determine the origin of its positive electrokinetic potential. The electrokinetic potentials have been determined by applying the streaming potential method to samples prepared by different methods and treated at various temperatures, and the surface acidities of the samples have been investigated by the dye-adsorption method.

## Experimental

**Materials.** — Two solutions containing 0.005 M lead nitrate and 0.005 M sodium sulfate were mixed at room temperature in a large flask. In mixing, one reagent was used in a 5% excess over the other. The precipitations occurred after the solutions had been vigorously mixed for one minute or less. The pH values of the supernatant liquids were in the range from 4.60 to 4.74. The precipitates formed were washed with conductivity water by decantation and filtration until the pH values and the conductivities of the supernatant liquids attained limiting values. After these procedures the final pH values were 6.10—6.20 at 25°C. Finally, the samples were dried at 110°C for three hours. Parts of each sample were treated at 300, 500 and 700°C in an electric oven for an hour each.

**Electrokinetic Measurements.** — The streaming potential method was used for the determination of the electrokinetic potentials (ζ-potentials). For the measurement of the streaming potentials, an apparatus and techniques similar to those described in previous papers[1,3] were employed. The specific conductivity of the cell packed with the powdered sample was obtained by using the conductometer made by the Toa Dempa Co. The streaming potentials produced on the electrodes placed at the ends of the diaphragm were read by a precision potentiometer and were plotted against the pressure applied on the liquids flowing through the diaphragm. The linear relation obtained between them made possible the calculation of the ζ-potentials by using the Helmholtz-Smoluchowski equation. All the measurements were carried out at 15—20°C.

**Surface Acidity.**—In order to test the surface acidities, the dye-adsorption method was employed. 0.3 g. samples of the powders were shaken with 4 cc. of an isooctane solution containing 0.01% of methyl red.[4] After the adsorption of the dye molecules, the powders were separated and dried in air. The color of the adsorbed molecules on the surface of the powders was analyzed against magnesia as a reference by means of a Shimadzu spectrophotometer.

## Results and Discussion

The ζ-potentials obtained in water are summarized, together with those of the samples used, in preliminary experiments, in Table I. These values are equilibrium values obtained after a long streaming of water.

It may be seen from Table I that all the values of the ζ-potential of lead sulfate have a positive sign, irrespective of the kinds of reagents used, of the excess ions, and of the pH values of the solutions. It was found in a previous paper that the surfaces of lead(II) chromate, barium sulfate and barium chromate have charges of the same sign as that of the excess ion used in the preparation.[1] This suggests that the lattice ions extensively occupy the lattice points on the surface and that it is very difficult to remove them by washing. However, this is not true for lead sulfate.

The ζ-potentials, obtained from measurements on the samples at intervals of about one hour, of lead sulfate, treated at different temperatures, vary slowly with time to an equilibrium value which is positive, as is shown in Figs. 1 and 2. The equilibrium ζ-potentials are plotted against the treatment temperatures in Fig. 3. The ζ-values decrease

initially to an almost constant value, irrespective of the kinds of excess ions used in the preparation of the samples.

Figure 4 shows the reflectance spectrum of lead sulfate, which adsorbed the molecules of methyl red. The yellow colors of the samples treated at higher temperatures indicate a decrease in the surface acidities with a rise in the treatment temperature. The same tendency has been seen in samples prepared from both excess lead ions and excess sulfate ions.

When the samples treated at higher temperatures were exposed to water vapor, the surfaces of the samples recovered their original acidities. It may be seen from Fig. 5 that the longer the time of exposure to water vapor, the deeper the red color of the adsorbed dye molecules, and, therefore, the stronger the acidity of the surface.

If lead sulfate is hydrolyzed in an aqueous solution, the following relations will hold in equilibrium at 25°C:

$$[Pb^{2+}]\,[SO_4^{2-}] = K_S{}^{5)} = 1.58\times10^{-8} \quad (1)$$

$$[Pb^{2+}]\,[OH^-]^2 = K_B{}^{6)} = 3\times10^{-20} \quad (2)$$

$$[H^+]\,[OH^-] = K_W = 10^{-14} \quad (3)$$

$$2[Pb^{2+}] + [H^+] = 2[SO_4^{2-}] + [OH^-] \quad (4)$$

The hydrogen ion concentration which can satisfy these four equations is $10^{-6.2}$ at 25°C. The pH value of the saturated solution of

lead sulfate should, therefore, be 6.2. The experimental pH values of the saturated solution of lead sulfate were 6.10—6.20, in good agreement with the calculated value. This suggests that the surface hydrolysis of lead sulfate leaves lead hydroxide on its surface although the saturated solution becomes acidic. From these considerations, it seems plausible that the lead sulfate produced from an aqueous phase and dried at lower temperatures has an acidic surface due to surface hydrolysis in the presence of adsorbed water. If the sample is treated at higher temperatures, the sulfuric acid will be removed, a solid surface being a basic characteristic of adsorbed dye molecules. The inversion of the surface acidity of the sample by water adsorption or by immersion in water can probably be explained by additional hydrolysis on the surface. In the measurement of the ζ-potentials on such hydrolyzed samples of lead sulfate, the solid surface may largely act like lead hydroxide.

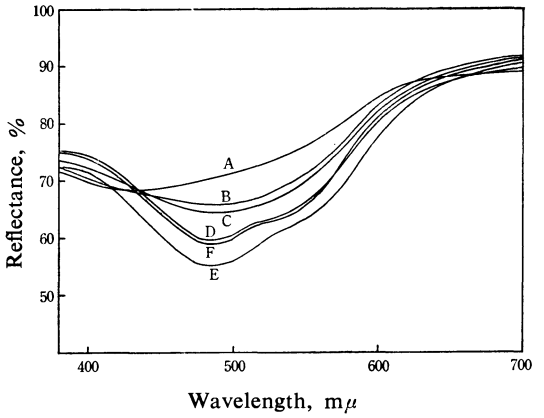

Fig. 5. Reflection spectra of methyl red adsorbed on lead sulfate treated at 700°C (A) and then exposed to saturated water vapor at 22°C for 1 hr. (B), 3 hr. (C), 24 hr. (D), 30 hr. (E). Sample F was immersed in water for 3 days and after that dried at 110°C for 1 hr.

In order to test the ζ-potential of lead hydroxide, a sample was prepared in the following way: in order to produce lead oxide pure lead oxalate was decomposed in an electric oven held at 600°C for an hour. The ζ-potential of this sample was found to be +10.1 mV. in water. Lead oxide can be hydrated to form surface hydroxyl groups in water. The fact that the surface of lead oxide has a positive charge is probably the result of the dissociation of surface hydroxyl groups thus formed:

$$-PbOH \rightarrow -Pb^{+} + OH^{-}$$

These considerations appear to indicate why the ζ-potential of lead sulfate is always positive in water. In this case, the preferential adsorption of hydrogen ions produced by surface hydrolysis may more or less contribute to the surface charge of lead sulfate. By progressive treatment at higher temperatures, the ζ-potentials decrease to a constant value, probably because the lead oxide produced by heat treatment by the condensation of surface hydroxyl groups, or by the decomposition of lead sulfate, can not be easily rehydrated on immersion in water, resulting in a decrease in the charge density on the surface.

## Summary

The ζ-potential of lead sulfate has been studied by applying the streaming potential

method to samples obtained by various preparative methods and subjected to various temperature treatments. All the ζ-potentials measured have a positive sign, irrespective of such conditions as the kinds of reagents and excess ions used in the preparation or the pH value of the reacting solution. It has been postulated that the surface of lead sulfate is hydrolysed to produce lead hydroxide, whose ζ-potential is explicit in the measurement of the streaming potential of lead sulfate. This is supported by the pH value of the saturated solution of lead sulfate. The surface behavior of lead sulfate in relation to the dye adsorption can also be explained in this way.

# Electronic Spectra of 1, 4, 9, 10-Anthradiquinone and Its Complexes with Aromatics

By Akira KUBOYAMA and Kōichi WADA*

(Received July 30, 1964)

The electronic spectra of quinones and carbonyl compounds have previously been studied by one of the present authors.[1] Moreover, Hartmann and Lorenz[2] reported on the electronic spectrum of 1, 4, 9, 10-anthradiquinone[3] in dioxane, together with the absorption spectra of many quinones. Except for these reports, however, the electronic spectrum of ADQ has never been studied. Since ADQ has four carbonyl groups in its conjugated system, as is shown below, its electronic spectrum and the charge-transfer absorption bands of ADQ complexes with aromatic compounds are of great interest to us. Accordingly, these spectra were studied. The results obtained will now be reported.

## Experimental

**Materials.**—ADQ was synthesized by the cautious oxidation of quinizarin(1,4-dihydroxy-anthraquinone) with lead tetraacetate in acetic acid, according to the method of Dimroth et al.[4] ADQ is so easily reduced to quinizarin that special caution is needed in its purification. Reddish-brown ADQ crystals dissolved in benzene at room temperature were separated from the solution by the addition of a large volume of isooctane. This procedure was repeated several times. The ADQ crystals obtained were straw-yellow needles. The melting point was consistent with that described in the literature.[5] Commercially-available, special-grade hydroquinone dimethyl ether, pyrene, and anthracene were purified by recrystallization from ethanol. The solvents were purified according to the methods described in our previous works.[1b,1d]

**Measurements.**—The absorption spectra were measured with a Cary 14M recording spectrophotometer with 1 and 5 cm.-path, fused quartz cells.

## Results

After leaving ADQ one day after synthesis, we found in the electronic spectra of ADQ solutions a slight absorption band of quinizarin near 480m$\mu$, an absorption which is characterized by a sharp vibrational structure in *n*-heptane. Therefore, each time ADQ was synthesized in the morning and the electronic spectra of its solutions were measured that afternoon. The electronic spectra of ADQ obtained in various solvents are shown in Figs. 1—4. The wavelengths ($\lambda_{max}$) and the molar absorption coefficients ($\varepsilon_{max}$) of the peaks of these spectra are shown in Table I. The wavelengths of the peaks of the charge transfer absorption bands[6] of ADQ complexes with aromatic compounds in carbon tetrachloride

## Discussion

Comparing Figs. 1—4 with the absorption spectrum reported by Hartmann and Lorenz,[2] two distinct differences between these two absorption spectra can be found. One is that, in the absorption spectrum reported by Hartmann and Lorenz, the weak absorption band near 600 m$\mu$ shown in Fig. 1 is not found. The other is that, in the absorption spectrum reported by them, an absorption band near 480 m$\mu$ ($\varepsilon_{max}\sim150$) is found, while in Fig. 2 no such absorption band is found. As has been described before, this absorption band near 480 m$\mu$ is thought to be that of quinizarin contained in ADQ.

The weak absorption band near 600 m$\mu$ in Fig. 1 may reasonably be assigned to an $n\rightarrow\pi^*$ band judging from its position and intensity. The fact that this band in carbon disulfide is found at longer wavelengths than in other solvents is characteristic of the $n\rightarrow\pi^*$ bands of the quinones, as has been studied in our previous work.[1b] From this fact, the band near 600 m$\mu$ may safely be assigned to an $n\rightarrow\pi^*$ band. The fact that this band in dioxane is found at shorter wavelengths than in other solvents may be attributed to the relatively strong charge transfer interaction between ADQ and dioxane.[1b] Indeed, as is shown in Table II, the CT bands of the ADQ complexes and of the chloranil complexes are at nearly the same position in a fixed electron-donor. Accordingly, the electron affinity of ADQ is thought to be nearly the same as that of chloranil, which is a strong electron-acceptor. The CT band of the ADQ complex with pyrene or anthracene is at almost the same position as that of the corresponding chloranil complex, while the CT band of the ADQ complex with hydroquinone dimethyl ether is at considerably longer wavelengths than that of the corresponding chloranil complex. This fact is thought to be due to the fact that the charge transfer interaction between ADQ and pyrene or anthracene is stronger than that between ADQ and hydroquinone dimethyl ether.[8] In Table II the values in parentheses which are representative of the broadness of the CT bands, in general become larger with an increase in the energies of the CT bands in a fixed electron-donor. The large values of this quantity in hydroquinone dimethyl ether in comparison with those ones in other electron-donors are thought to be related to the fact that the molecular structure of hydroquinone dimethyl ether is not so rigid because of the methoxyl groups not being fixed in this compound.

It is thought that ADQ has the four filled molecular orbitals, consisted of the lone pair orbitals of the four oxygen atoms, $((n_1+n_2)\pm(n_3+n_4)$ and $(n_1-n_2)\pm(n_3-n_4))$,[9] where $n_i$ denotes the lone pair orbital of the $i$-th oxygen atom in ADQ. Therefore, it may be expected that ADQ will show some $n\rightarrow\pi^*$ bands except for the band near 600 m$\mu$. In Fig. 2, the non-selective absorption band in the range from 550 m$\mu$ to 450 m$\mu$ is thought to contain some of these $n\rightarrow\pi^*$ bands. In Fig. 2, the spectrum of ADQ in carbon tetrachloride shows a shoulder near 425 m$\mu$. In other solvents the corresponding shoulders are masked by the absorption bands at the shorter wavelengths. Therefore, the solvent effect for this shoulder cannot be examined, and it is difficult to determine whether this shoulder should be interpreted as an $n\rightarrow\pi^*$ band or not.

In Fig. 3 a distinct peak near 350 m$\mu$ and a slight shoulder near 310 m$\mu$ are found, while in Fig. 4 a shoulder near 255 m$\mu$ and a strong peak near 230 m$\mu$ are found. In Figs. 3 and 4, all the absorption bands except for the slight shoulder near 310 m$\mu$ are assigned to $\pi\rightarrow\pi^*$ bands on the basis of their large intensities. The shoulder near 310 m$\mu$ may be assigned to an $n\rightarrow\sigma^*$ band on the basis of its weak intensity. Regarding Fig. 3, two points should be noticed about the distinct absorption band near 350 m$\mu$. First, this band in chloroform is found at far longer wavelengths than in other solvents. It is thought that this fact should be attributed mainly to the hydrogen bond formation between ADQ and chloroform. Second, the intensity of this band in dioxane is far larger than in other solvents. Since, as has been described before, ADQ is nearly as strong as chloranil as an electron-acceptor and since the CT band of the chloranil complex with dioxane is found near 330 m$\mu$,[7a] the CT band of the ADQ complex with dioxane is also expected to appear near 330 m$\mu$. Therefore, this CT band is thought to contribute much to the large intensity of the band near 350 m$\mu$ of ADQ in dioxane.

## Summary

The electronic spectrum of 1,4,9,10-anthradiquinone, and the charge transfer absorption bands of molecular complexes between

8) A. Kuboyama, *J. Am. Chem. Soc.*, **86**, 164 (1964).

9) The normalizing factor is omitted.

1, 4, 9, 10-anthradiquinone and aromatic compounds in solutions, have been studied. The weak absorption band near 600 m$\mu$ ($\varepsilon_{max}\sim 20$) of 1, 4, 9, 10-anthradiquinone has been assigned to an $n\rightarrow\pi^*$ band. The charge transfer absorption bands of the molecular complexes are found at nearly the same positions as those of the corresponding chloranil complexes. From this fact it has been concluded that the electron affinity of 1, 4, 9, 10-anthradiquinone is nearly the same as that of chloranil.

# The Mass Transfer Rate through the Liquid-Liquid Interface. I. Potential Barriers near the Interface

By Teruya SHIMBASHI and Tadao SHIBA

(Received April 10, 1964)

In the treatment of mass-transfer through phases, the two concentrations immediately next to the interface have been assumed to be in distribution-equilibrium. In recent years, however, efforts have been made to obtain the true relation between these concentrations,[1-13] and some workers reported that there is a resistance in mass-transfer through the interface, so that the two concentrations are not in equilibrium.[1,3,8,13] Sinfelt and Drickamer[8] observed a high interfacial resistance by a static experiment on the diffusion of molecular sulfur across liquid-liquid interfaces; they associated this with the hydrogen bonding of liquids. On the other hand, Ward and Brooks[4] studied the diffusion of carboxylic acids statically across the water-toluene interface by the Lamm scale method; no distinct interfacial resistance was observed, but they carefully stated that this type of experiment does not detect an activation barrier to the crossing of the interface unless it is very high. Quinn and Jeannin[13] more recently studied the diffusion of isobutanol into the laminar aqueous isobutanol-water jet and found an interfacial resistance of approximately 80 cm./sec.

One of the factors that fix the rate of mass-transfer may be the amount of adsorption as well as the two concentrations immediately next to the interface at a constant temperature, although this aspect has been rather neglected. The present work is concerned with some relations between these three quantities.

Both phases, one of which is a pure solvent and the other a solution of a surface-active transfer-material in a different solvent, and the two solvents are mutually-immiscible, are brought into contact with each other. The adsorption of the transfer-material from the solution onto the interface takes place after the contact, and, consequently, the amount of adsorption increases quickly; the concentrations immediately next to the interface vary at the same time, so that the initial uniformity is destroyed and a new distribution of concentration appears at every moment until equilibrium. This variation in local concentration is originated only by the chemical potential gap obtained by comparing the zero amount of adsorption on the interface with the concentration of the solution immediately next to the interface at the beginning, and so it spreads out from the interface to the interiors of both bulks. That is, this variation in a sufficiently small lapse of time is practically limited to the vicinity of the interface, because the diffusion in liquid is rather slow. Consequently, it can be considered to be nearly independent of the thickness and shape of the layers.

The net rate of adsorption generally decreases, and so the amount of adsorption becomes nearly constant with an increase in the time of contact. This state is usually reached in a very short time when the molecule of the transfer-material is sufficiently small. The first stage, where the net rate of adsorption is high enough, is called the "adsorption stage," while the second, where the rate is nearly zero and the amout of adsorption is nearly constant, is called the "transfer stage" hereafter. The "transfer stage" will be discussed in this work.

A curve of the time dependence of the transfer-amount extrapolated to zero time does not necessarily coincide with that of the real process when all the observations are in the "transfer stage." The imaginary process obtained from this extrapolation, which has no "adsorption stage," is now called the "ideal process" in contrast with the real one. In other words, a curve of the time dependence of the transfer-amount in the "ideal process" does not necessarily start from the point of origin, and the amount of transfer in the initial state of the "ideal process" is not necessarily zero, but rather may apparently have a finite value in contrast with that in the real process, which is undoubtedly zero. It is assumed that the initial state of the "ideal process" holds a relation in the "transfer stage" and that it is independent of the thickness and the shape of the layers. This assumption is quite valid if the "adsorption stage" ceases in a short enough time, as has been described above. We will concentrate on the initial state of the "ideal process," because we can thus not only obtain the amount of adsorption, the two concentrations immediately next to the interface, and the transfer rate in this state, as will be described later, but also it is the most appropriate method for detecting the deviation from the equilibrium relation of the concentrations because of the high transfer rate.

## Experimental

An aqueous solution of *n*-butyric acid of a certain volume and concentration was placed in a glass vessel (I), shown in Fig. 1; at the same time, carbon tetrachloride was placed in another vessel (II), which had the same shape as vessel I. The temperature of vessels I and II was kept constant at 30°C by circulating jacket-water supplied from a thermostat. After the vessels had stood for 1 hr., carbon tetrachloride equal in volume to the aqueous *n*-butyric acid solution in vessel I was quickly taken out with a syringe from vessel II and introduced into vessel I, beneath the aqueous layer, much care being taken not to disturb the upper

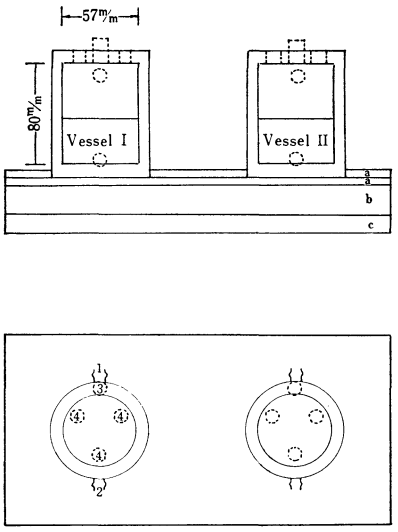

Fig. 1. Apparatus for the "layer absorption method."

4: Sample-inlets and beaker-supporter

layer. Vessel I had been mounted on a stand to which a foam-rubber cushion was attached in order to insulate it from outside vibrations. *n*-Butyric acid was allowed to transfer from its aqueous solution into the carbon tetrachloride layer. After a certain lapse of time, the carbon tetrachloride layer was thoroughly taken out with a syringe, and the amount of *n*-butyric acid transferred into the carbon tetrachloride layer was determined by titration. This operation, now referred to as the "layer absorption method," was repeated with various volumes and concentrations of the aqueous *n*-butyric acid solution at definite periods of elapsed time after the contact of the two layers.

When benzene was used in place of carbon tetrachloride, benzene was placed in vessel I and the aqueous solution of *n*-butyric acid, in vessel II, and then the latter was introduced beneath the benzene layer in vessel I. After a definite period of time, the aqueous layer was separated from the benzene layer and the titration was made on the latter.

The amount of *n*-butyric acid adsorbed at the interface was determined by the pendant drop method.[14] A drop of the denser phase was hung from a capillary tip (0.1 mm. I. D. and 3 mm. O. D.) which was attached to a syringe, and the silhouette of the drop was obtained by parallel-ray photography. This procedure was repeated with various concentrations of *n*-butyric acid at definite time intervals.

In order to recognize whether observations have

14) J. M. Andreas, E. A. Hauser and W. B. Tucker, *J. Phys. Chem.*, **42**, 1001 (1938).

been made in the "transfer stage" or not, the variation in the amount of adsorption in very early stages must be determined, strictly, but, conventionally, recognized as follows. The "adsorption stage" takes place, but the "transfer stage" does not, when a new interface is made in the pendant drop method if the two phases have been previously brought into transfer-equilibrium. Consequently, this means that the observation has been made in the "adsorption stage" when the interfacial tension in the above experiment varies with time; on the contrary, the "adsorption stage" has ceased when no variation occurs, though only an approximate relation is obtained if the result is applied in the non-equilibrium system as it is.

The partition-equilibria of *n*-butyric acid in the water - carbon tetrachloride and water - benzene systems were determined by titrating equilibrated solutions.

## Results

Examples of the amounts of *n*-butyric acid in organic solvents transferred from the aqueous phase in the "layer absorption method" are plotted against the time in Figs. 2a and 2b. All the observations were made in the "transfer stage," because its "adsorption stage" ended within 1 min., as was established by determining the variation of interfacial tension in the equilibrated system, as has been described above. Consequently, the curves in Figs. 2a and 2b indicate the "ideal process," though these are probably deformed by a disturbance.

The initial transfer rates at the extrapolated points or the initial state of the "ideal process," are plotted against the thickness of both layers in Figs. 3a and 3b. All the points in each concentration before contact nearly lie on a straight line; the straight lines in the case of carbon tetrachloride are inclined to the horizontal axis, but those in the case of benzene are parallel to the horizontal axis. According to the assumption that the initial state of the

"ideal process" is independent of the thickness of the layer, all the straight lines in Figs. 3a and 3b should be parallel to the horizontal axis. The present authors attribute the cause of this discrepancy in the case of carbon tetrachloride to a disturbance at the beginning by the injection of carbon tetrachloride beneath the aqueous solution. The larger the thickness of the layer, the longer the time of injection, and therefore the stronger the disturbance. The disturbance deforms the intrinsic curve of the time dependence of the amount of *n*-butyric acid in the carbon tetrachloride phase transferred through the interface, as is shown schematically in Fig. 4. If the determinations are done after $t_1$ in Fig. 4, the initial rate of transfer on the extrapolated line should be less than the intrinsic one, and therefore the

straight lines should incline to the horizontal axis. Consequently, the correct values of the rate are given by extrapolating the straight lines to zero layer-thickness. On the contrary, the disturbance in the case of benzene is considered to be negligible, since the injection of the aqueous solution of *n*-butyric acid beneath the benzene layer causes much disturbance in the aqueous layer, but scarcely any in the benzene layer, which is sensitive to disturbance because of its low concentration.

The layer-thickness dependence of the average concentrations of *n*-butyric acid transferred into organic solvents at zero time in the apparent "ideal process," which means that it may include the disturbance effect, is shown in Figs. 5a and 5b, which were obtained from the amount of transfer extrapolated to zero time, as in Figs. 2a and 2b, divided by the volume of the layer. However, the values at the points extrapolated to zero thickness of the layer should show no disturbance, as has been described above, while at the same time they indicate the concentrations immediately next to the interface in the organic solvent at zero time in the "ideal process," according to the assumption that the initial state of the "ideal process" is independent of the thickness of the layer.

On the other hand, those for the aqueous phase are given from the following equation:

$$m = c_{10}v - c_{1a}v$$

$$c_{1a} = (c_{10}v - m)/v = c_{10} - c_{2a}$$

Concn. in the aq. soln.: ○, zero; ●, 0.0206 N; ◑, 0.0514 N; ⊙, 0.1041 N

where $m$ is the amount of solute transferred at time $t$; $c_{10}$ is the concentration of *n*-butyric acid in the aqueous phase before contact; $c_{1a}$ and $c_{2a}$ are the average concentrations of *n*-butyric acid in an aqueous and an organic solvent respectively at time $t$, and $v$ is volume of the phase.

The results of the pendant drop experiment are shown in Figs. 6a, 6b and 6c. In the case of carbon tetrachloride, all points after about 30 min. are nearly on a straight line in every

run, and the straight lines are nearly parallel with each other. It may be seen that a rapid change of interfacial tension sets in within about 5 min. The first period, within 5 min., is considered to include the "adsorption stage," and the second period, from 5 to 30 min., the "transfer stage," while in the third period, after 30 min., a process is dominant in which carbon tetrachloride in the pendant drop dissolves in the aqueous phase outside the drop.

Therefore, the value obtained by extrapolating the interfacial tensions along the second process to zero time gives an interfacial tension of the "ideal process" at zero time nearly equal to that in the "layer absorption method," because the initial state in the "ideal process" is independent of the thickness and the shape of the layer according to the above assumption, provided that the curvature effect of the drop-surface is assumed to be negligible.

On the other hand, the value by extrapolating it along the third process to zero time gives the interfacial tension at an equilibrium state in the transfer of *n*-butyric acid and water eliminated the effect of transfer for carbon tetrachloride. The concentration in the aqueous phase outside the drop in transfer-equilibrium is approximated as equal to that before contact for a large volume ratio (1000 times) of the aqueous to the carbon tetrachloride phase.

In the case of benzene, the technique to obtain initial interfacial tensions is almost same, but those in transfer-equilibrium at various concentrations in the aqueous phase were obtained with systems previously brought into transfer-equilibrium.

Since the interfacial phases are composed of a mono-layer of *n*-butyric acid,[15] no distribution of the concentration of *n*-butyric acid in the interfacial phases along the transfer coordinate can be defined; therefore, the transfer of *n*-butyric acid in the interfacial phases in the transfer direction is regarded as in equilibrium at every moment, even in the transfer process. Therefore, the equations of state for the interfaces, which exist as a rule in equilibrium systems, must hold even in the rate process. In other words, the amount of adsorption in the rate process is determined by the surface pressure, the difference between the interfacial tension of a certain solution-system and that of the pure solvent-system, at every moment.

Table I shows the results of this experiment. In Table I the fractions of area covered by *n*-butyric acid molecules, $\theta$, are nearly equal to the corresponding fractions, $\theta_1$, calculated by assuming an equilibrium with the concentrations immediately next to the interfaces in the aqueous phase ($c_{1i}$), but the corresponding fractions, $\theta_2$, calculated by assuming an equilibrium with those in the organic phases ($c_{2i}$), are very different from $\theta$ or $\theta_1$ in some cases. ($\theta_1$ and $\theta_2$ are, so to speak, reduced concentrations of $c_{1i}$ and $c_{2i}$ respectively, calculated for comparison with $\theta$.) This indicates that a distinct resistance occurs in the process of desorption into the organic phase required in order to transfer through the interfaces.

In comparison with other formula, the following semi-empirical one was fond the best to represent the relation of factors in a simple form:

$$r=k(a_{1i}-K_0a_{2i})A/(1+b\theta) \qquad (1)$$

where $r$ is transfer rate through the interface; $k$ is the apparent rate constant transferring through the interface; $K_0$ is the distribution coefficient for an infinite dilution; $b$ is a constant determined by means of the materials and temperature; $a_{1i}$ and $a_{2i}$ are the activities of the solute immediately next to the interface for bulks 1 and 2 respectively; $\theta$ is the fraction of area covered by adsorbed molecules, and $A$ is the area of the interface. As a process of transferring through the interfaces, an adsorption-desorption mechanism is considered according to the method of Langmuir;[16] when the amount of adsorption is in equilibrium with the concentration in bulk 1 (the aqueous layer) immediately next to the interface, as is indicated in our experiments, and the interaction among adsorbed molecules is negligible, it would seem that an equation replaceing $\theta$ with the $a_{1i}$ in Eq. 1 should be derived.[17] However, a comparison applying

15) R. K. Schofield and E. K. Rideal, *Proc., Roy. Soc.*, **A109**, 57 (1925).

16) I. Langmuir, *J. Am. Chem. Soc.*, **39**, 1858 (1917).

17) S. Glasstone, K. J. Laidler and H. Eyring, "The Theory of Rate Processes," McGraw-Hill, New York (1941), p. 367.

the experimental data prefers Eq. 1. This might be due to interaction among adsorbed molecules.

From Eq. 1:

$$A(a_{1i}-K_0a_{2i})/r=1/k+b\theta/k$$

As in our experiments, $a_{1i}=c_{1i}$ ($f_1=1.000-0.985$); therefore,

$$A(c_{1i}-Kc_{2i})/r=1/k+b\theta/k \qquad (2)$$

where $c_{1i}$ and $c_{2i}$ are the concentrations immediately next to the interface for bulks 1 and 2 respectively; $f_1$ is the activity coefficient in bulk 1, and $K$ is the distribution coefficient. If Eq. 2 holds good, the value on the left-hand side of the equation must be in linear relation to $\theta$, as is shown in Figs. 7a and 7b. The point at $\theta=1.0$ in Fig. 7a is far away from the straight line which indicates the linear relation; the reason for this not distinct. Figures 7a and 7b indicate plainly that the two concentrations immediately next to the respective interfaces, $c_{1i}$ and $c_{2i}$, are not in equilibrium with each other in these cases, because if $c_{1i}=Kc_{2i}$, $A(c_{1i}-Kc_{2i})/r=0$ and all the points should fall on the horizontal axis; the facts are otherwise.

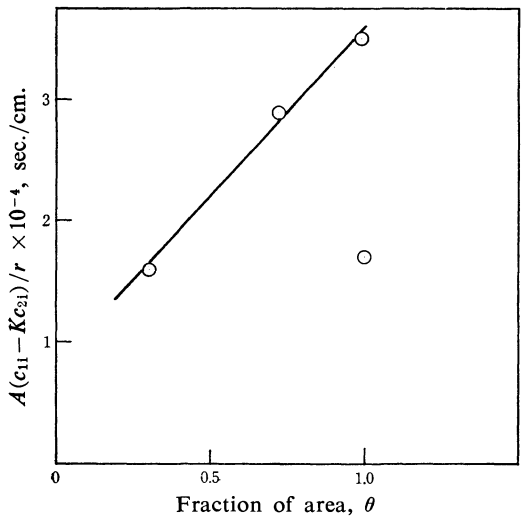

Fig. 7a. Plot of Eq. 2 for the system of an aqueous solution of *n*-butyric acid and carbon tetrachloride at 30°C.

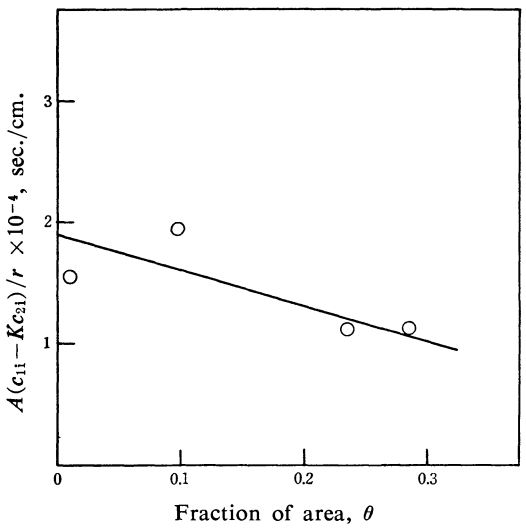

Fig. 7b. Plot of Eq. 2 for the system of an aqueous solution of *n*-butyric acid and benzene at 30°C.

## Discussion

In order to compare it with the theory, Eq. 1 is transformed as follows. If $c_{1i}=\tau'\theta$, $\tau'=\boldsymbol{F}(c_{1i}, T)$, and

$$r_0=r/A=k(\tau'\theta-Kc_{2i})/(1+b\theta)$$
$$=k\tau'\theta/(1+b\theta)-kKc_{2i}/(1+b\theta) \qquad (3)$$

where $\tau'$ is the coefficient representing the equilibrium-relation between $c_{1i}$ and $\theta$; $T$ is the absolute temperature, and $r_0$ is the transfer rate through the interface per unit of area.

A theoretical formula of the adsorption rate,[18] which has exponential factors representing the interaction among adsorbed molecules, is:

$$-r_0=k_{a2}a_{2i}(1-\theta)e^{x\theta}-k_{d2}\theta e^{-y\theta} \qquad (4)$$

where $k_{a2}$ is the rate constant of absorption from bulk 2 to the interface; $k_{d2}$ is the rate constant of desorption from the interface to bulk 2, and $x$ and $y$ are constants representing the effect of interaction among adsorbed molecules.

For an infinite dilution, $\theta\to0$, and $a_{2i}\to c_{2i}$; Eq. 4 then becomes:

$$-r_0=k_{a2}c_{2i}-k_{d2}\theta$$

At the same time, Eq. 3 becomes:

$$r_0=k\tau'_0\theta-kK_0c_{2i}$$

where $\tau'_0$ is the critical value of $\tau'$ for an infinite dilution.

$\theta$ and $c_{2i}$ are mutually independent variables, and therefore

$$k_{a2}=kK_0, \qquad k_{d2}=k\tau'_0 \qquad (5)$$

and

$$-r_0=kK_0a_{2i}/(1+b\theta)-k\tau'\theta/(1+b\theta)$$
$$=kK_0a_{2i}(1-\theta)e^{x\theta}-k\tau'_0\theta e^{-y\theta}$$

Accordingly,

$$\left.\begin{aligned} x&=-(1/\theta)\ln(1+b\theta)-(1/\theta)\ln(1-\theta)\\ y&=(1/\theta)\ln(1+b\theta)-(1/\theta)\ln(\tau'/\tau'_0)\end{aligned}\right\} \qquad (6)$$

The numerical values of $x$ and $y$ obtained from

Eq. 6 are shown in Table II, but actually $x$ and $y$ are rather affected by $\theta$ or $\tau'$.

The free energy of attractive interaction between one adsorbed molecule and its neighbors in a saturated state is calculated as follows:[19]

$$x = psV/\boldsymbol{RT}, \qquad y = (1-p)sV/\boldsymbol{RT}$$
$$\therefore \quad sV = (x+y)\boldsymbol{RT} \tag{7}$$

where $p$ is the fraction of free energy; $s$ is the coordination number of absorbed molecules in a saturated state; $V$ is the free energy of attractive interaction between two adjacent adsorbed molecules; $\boldsymbol{R}$ is the gas constant, and $T$ is the absolute temperature.

According to the activated-complex theory, specific rate constants are given by:

$$k'_{a2} = \kappa_{a2}(\boldsymbol{kT}/\boldsymbol{h})e^{-\Delta F^{\ddagger}_{a2}/\boldsymbol{RT}}$$
$$k'_{d2} = \kappa_{d2}(\boldsymbol{kT}/\boldsymbol{h})e^{-\Delta F^{\ddagger}_{d2}/\boldsymbol{RT}}$$

where $k'_{a2}$ is the specific rate constant of adsorption from bulk 2 to the interface; $k'_{d2}$ is the specific rate constant of desorption from the interface to bulk 2; $\kappa_{a2}$ and $\kappa_{d2}$ are the transmission coefficients; $\boldsymbol{k}$ is the Boltzmann constant; $\boldsymbol{h}$ is the Planck constant; $\Delta F^{\ddagger}_{a2}$ is the free energy of activation to adsorb from bulk 2 to the interface, and $\Delta F^{\ddagger}_{d2}$ is the free energy of activation to desorb from the interface to bulk 2.

From the definitions,

$$k_{a2} = k'_{a2}\lambda \quad \text{or} \quad \lambda = k_{a2}/k'_{a2} \tag{8}$$
$$k_{d2}\theta = (k_{d2}/\Gamma_\infty)\Gamma = k'_{d2}\Gamma \quad \text{or} \quad k'_{d2} = k_{d2}/\Gamma_\infty \tag{9}$$

where $\lambda$ is the length of the adsorption path from the boundary site of bulk 2 to the interface; $\Gamma$ is the amount of adsorption, and $\Gamma_\infty$ is the value of $\Gamma$ in a saturated state.

19) Ibid., pp. 363—366. In the original, $sV$ means the free energy of the repulsive interaction instead of that of the attractive interaction.

If both $\kappa_{a2}$ and $\kappa_{d2}$ are assumed to be unity:

$$k'_{a2} = (\boldsymbol{kT}/\boldsymbol{h})e^{-\Delta F^{\ddagger}_{a2}/\boldsymbol{RT}} \tag{10}$$
$$\Delta F^{\ddagger}_{d2} = \boldsymbol{RT} \ln (\boldsymbol{kT}/\boldsymbol{h}k'_{d2})$$
$$= \boldsymbol{RT} \ln (\boldsymbol{kT}\Gamma_\infty/\boldsymbol{h}k_{d2}) \tag{11}$$
$$\Delta F^{\ddagger}_{a2} = \Delta F^{\ddagger}_{d2} + \Delta F_1 - \Delta\chi \tag{12}$$

where $\Delta F_1$ is the standard free energy of adsorption from bulk 1 to the interface, and $\Delta\chi$ is the standard free energy of transference from bulk 1 to 2.

According to Ward and Tordai,[20]

$$\tau = \delta\boldsymbol{kT}e^{-\Delta F_1/\boldsymbol{RT}}, \text{ or } \Delta F_1 = \boldsymbol{RT} \ln (\delta\boldsymbol{RT}/\tau) \tag{13}$$

where $\tau$ is Traube's constant, and $\delta$ is the thickness of the interfacial phase. Thermodynamically, $\Delta\chi$ is given by:

$$\Delta\chi = \boldsymbol{RT} \ln (a_1/a_2)_e = \boldsymbol{RT} \ln K_0 \tag{14}$$

where $a_1$ and $a_2$ are activities, and e indicates equilibrium.

The values of $\Delta F^{\ddagger}_{d2}$, $\Delta F_1$ and $\Delta\chi$ are calculated according to Eqs. 11, 13 and 14 respectively, with the experimental values, $k_{d2}$, $\Gamma_\infty$, $\tau$ and $K_0$, and $\delta$, which is given as equal to the statistical length of a *n*-butyric acid molecule (9.86Å[20]), because the adsorbed molecules in these cases have been known to form monolayers.[15] Therefore, $\Delta F^{\ddagger}_{a2}$ is given by Eq. 12, considering the continuity of the standard free energy in the transfer process. Then $k'_{a2}$ is calculated by Eq. 10, and finally $\lambda$ is given by Eq. 8.

The results of calculations from the experimental data are given in Table III. The values of both $k_{a2}$ and $k_{d2}$ in one system are very different from those in the other system; nevertheless, the values of $\Delta F^{\ddagger}_{d2}$, the free energy of activation to desorb from the interface into the bulk of organic solvent, in the

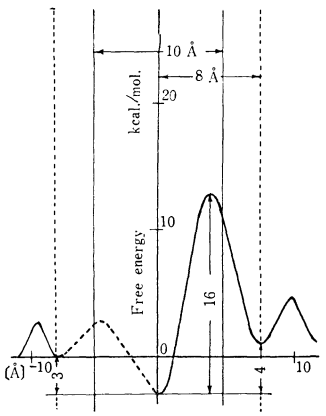
20) A. F. H. Ward and L. Tordai, *Trans. Faraday Soc.*, **42**, 415 (1946).

two systems are nearly equal (16 kcal./mol.), so it may be supposed that the desorptions in the two systems proceed via the same mechanism.



The values of $\lambda$, the length of the adsorption path from the boundary site in an organic bulk to the interface, for the two systems are also nearly equal, 8Å, and are reasonable when compared with the statistical length of an *n*-butyric acid molecule, 9.86Å.

The value of $sV$, the free energy of attraction between an adsorbed molecule and the adjacent one in a saturated state, for the water-benzene system is very small compared with the value for the other system, and both values are positive, indicating that the interactions are both attractive. These results are considered to agree with those given by Schofield and Rideal in a study of surface film.[15]

Figure 8 shows the standard free energy change for our systems in the course of mass transfer through the interface. To interpret the origin of such a potential barrier, the following hypothesis is introduced. As Fig. 9

System : Water - *n*-butyric acid - benzene

System : Water - *n*-butyric acid - $CCl_4$

Fig. 8. Potential barriers near the interfaces.

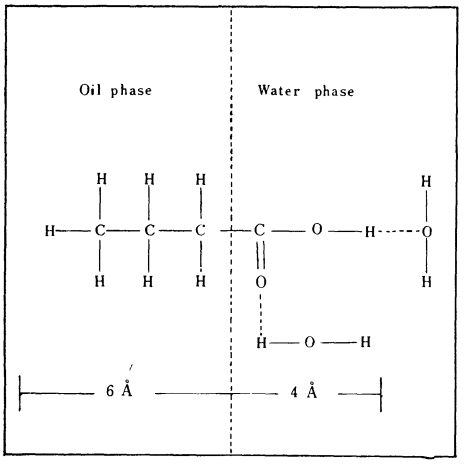


Fig. 9. Model of the adsorption state of a *n*-butyric acid molecule at the oil-water interface.

shows, it is known that two hydrogen bonds exist between two water molecules and a carboxyl radical of the *n*-butyric acid molecule in the state of adsorption at the interface;[21,22] the bonds must be split off when the molecule transfers from the interface into the organic solvent bulk. Therefore, the molecule should have a free energy higher than that required to cut off the hydrogen bonds for the desorption into the organic phase. This may be considered to be the origin of such a high potential barrier, because the energy of that

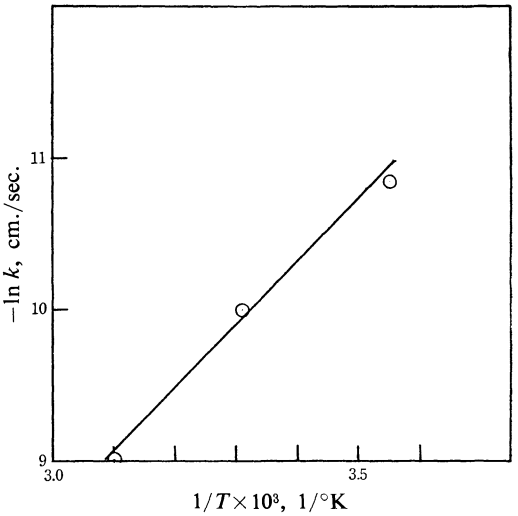

Fig. 10. Arrhenius plot for *n*-butyric acid transfer from the aqueous to the benzene phase.

21) W. J. Moore and H. Eyring, *J. Chem. Phys.*, **6**, 391 (1938).

22) G. C. Pimentel and A. L. McClellan, "The Hydrogen Bond," Freeman, San Francisco (1960), p. 352.

sort of hydrogen bond, O–H–O, is usally about 5—8 kcal./bond.

In order to separate the energy term from the free energy of activation, experiments similar to those which had been made at 30°C were made in the systems of aqueous solutions of *n*-butyric acid and benzene at the temperatures of 10°C and 50°C respectively. The activation energy of mass transfer through the interface from the aqueous to the benzene phase, $\Delta E^*_{12}$, for *n*-butyric acid was determined to be 8.15 kcal./mol. by the Arrhenius plot, as is shown in Fig. 10.

The standard free energy of adsorption from the aqueous phase to the interface, $\Delta F_1$, is determined to be $-2.39$ kcal./mol., as is shown in Table III; if the entropy term is negligible, as in the case of the system composed of an aqueous solution of *n*-butyric acid and air ($\Delta E_1 = -2.83$ kcal./mol., $\Delta F_1 = -2.54$kcal./mol.), the energy of activation for the desorption of *n*-butyric acid from the interface into the benzene bulk, $\Delta E^*_{d2}$, becomes 10.5 kcal./mol. (obtained by subtraction, $\Delta E^*_{12} - \Delta F_1$). If this value is given by the sum of energies for the two hydrogen bonds, the average bond-energy is 5.2 kcal./bond, which agrees well with the literature, 5.1 kcal./bond.[22]

The entropy of activation associated with this process, $\Delta S^*_{d2}$, is calculated as follows:

$$\Delta S^*_{d2} = (\Delta E^*_{d2} - \Delta F^*_{d2})/T = -19.2 \text{ e. u.}$$

Davies observed a large negative entropy of activation ($-20$ e. u.) in the diffusion of potassium iodide from the nitrobenzene phase into the aqueous phase.[1] It is interesting that the present result of the entropy of activation in the desorption of *n*-butyric acid from the water-benzene interface into the benzene phase has the same sign and magnitude as the above datum of Davies.

We should like to express our gratitude to Professor A. F. H. Ward, University of Manchester, for his useful suggestions regarding this work. We also wish to express our indebtedness to Professor Tominaga Keii of this Institute for his helpful discussions of this subject.

# The Mass Transfer Rate through the Liquid-Liquid Interface. II. The Boundary Condition of the Diffusion Equation at the Interface

By Teruya SHIMBASHI and Tadao SHIBA

(Received April 10, 1964)

When dealing with mass transfer through an interface which consists of either a gas phase and a liquid phase, or two liquid phases, it has been assumed that the concentration for the phase immediately next to the interface is in distribution-equilibrium with that for the other phase. However, this is only an assumption and no distinct theoretical or experimental verification has been given. Therefore, it may be equally probable *a priori* that the equilibrium relation does not hold in the process. In order to verify that the equilibrium relation does exist in the process, it is insufficient to indicate only that the experimental values are in accord with the theoretical values calculated on the basis of this equilibrium; it is also necessary to indicate that the experimental values are not in accord with the theoretical values calculated on the non-equilibrium basis. In other words, when the difference between the experimental and the theoretical values calculated on the basis of this equilibrium is smaller than the experimental error, the experimental values are apparently in accord with the theoretical values, even if the true equilibrium relation does not exist in these concentrations, as has also been described by Ward and Brooks.[1)]

The authors have previously studied a mass transfer through liquid-liquid interface; the results have been described in the preceding paper. In that study the transfer rate of *n*-butyric acid through the water-carbon tetrachloride or the water-benzene interface, both concentrations of *n*-butyric acid immediately next to the respective interfaces, and the

1) A. F. H. Ward and L. H. Brooks, *Trans. Faraday Soc.*, **48**, 1124 (1952).

amounts of adsorption at the respective interfaces were determined under particular conditions; the results of analysis indicate that Nernst's law of distribution, which exists as a rule in equilibrium systems, does not hold in the mass-transfer process between these concentrations immediately next to the interface. This paper will deal with the experimental data as has been described in the first paper, but in the method of analysis these papers differ from each other. This paper will also deal with Fick's differential equation of diffusion.

Some authors have reported mass transfer through liquid-liquid interfaces with Fick's equation of diffusion.[1-8] Crank gave the solution of the one-dimensional semi-infinite composite medium with no interfacial resistance.[9] Scott, Tung, and Drickamer gave a solution of a finite composite medium with finite interfacial resistance phenomenologically in terms of an interfacial transfer coefficient.[3] Auer and Murbach gave some solutions with or without interfacial resistance by means of a three-region model.[5] It seems to us, the present authors, that the boundary and initial conditions have been decided rather conventionally. The properties of the interface have been studied, however, by Gibbs, Langmuir, and others theoretically or experimentally.[10,11] Consequently, the present authors are now concentrating on the interfacial phase, so that a reasonable boundary condition can be derived.

## Theoretical

The nature of a surface, or an interface in general, is very different from a bulk phase, because the state of the aggregation of molecules is converted discontinuously at the interface. Adsorption and desorption, accordingly, are characteristic of the interface. Therefore, in treating a process of mass transfer through an interface, it is rational to distinguish the interfacial phase, in which adsorption and desorption govern mass transfer, from the bulk phases, in which Fick's law of diffusion governs mass transfer.

A model of the neighborhood of the interface is shown in Fig. 1. The positions of the two boundaries of the interfacial phase are appointed on the distance axis as minus-zero and plus-zero, where the activities of the solute in the bulk phase are $a_{1i}$ and $a_{2i}$ respectively; the relation between the two activities, namely, the boundary condition for Fick's law of diffusion at the zero-position, will be derived, so that we can solve the equation of diffusion in the usual manner. The distance between $x=-0$ and $x=+0$, where $x$ is the distance from the interface, has a finite value, about 16 Å, according to our experimental results, as has been indicated in the first paper, but this is to be regarded as zero compared with the thickness of the bulk phase.

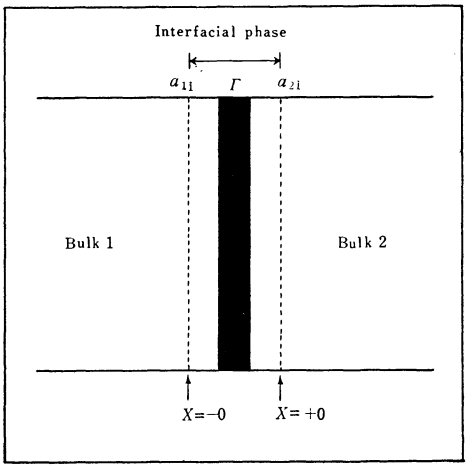

Fig. 1. A model of the neighborhood of the liquid-liquid interface.

Adsorption rate equations, taking the effect of interaction among adsorbed molecules into account,[12] are represented as:

$$\left.\begin{aligned} d\Gamma_1/dt &= k_{a1}a_{1i}(1-\theta)e^{x_1\theta} - k_{d1}\theta e^{-y_1\theta} \\ d\Gamma_2/dt &= k_{a2}a_{2i}(1-\theta)e^{x_2\theta} - k_{d2}\theta e^{-y_2\theta} \end{aligned}\right\} \quad (1)$$

where $\Gamma_1$ and $\Gamma_2$ are the net amounts of the solute adsorbed by the interface per unit of area from bulks 1 and 2 respectively; $t$ is the time; $k_{a1}$ and $k_{a2}$ are the rate constants of the adsorption to the interface from bulks 1 and 2 respectively; $k_{d1}$ and $k_{d2}$ are the rate constants of the desorption from the interface into bulks 1 and 2 respectively; $a_{1i}$ and $a_{2i}$ are the activities of the solute in bulks 1 and

2 respectively immediately next to the interface; $\theta$ is the fraction of area covered by adsorbed molecules, and $x_1$, $y_1$, $x_2$, and $y_2$ are constants representing the effect of interaction among adsorbed molecules.

It is assumed that the amount of adsorption, $\Gamma$, is constant with the lapse of time, as

$$d\Gamma/dt = d\Gamma_1/dt + d\Gamma_2/dt = 0 \tag{2}$$

From Eqs. 1 and 2,

$$a_{2i} = \alpha a_{1i} + \beta \tag{3}$$

$$\alpha \equiv -\left(\frac{k_{a1}}{k_{a2}}\right) e^{(x_1 - x_2)\theta}$$

$$\beta \equiv \left(\frac{k_{d1} e^{-y_1\theta} + k_{d2} e^{-y_2\theta}}{k_{a2} e^{x_2\theta}}\right) \frac{\theta}{1-\theta}$$

where $k_{a1}$, $k_{d1}$, $k_{a2}$ and $k_{d2}$ are positive constants determined by the material system and the temperature, and $\theta$ is a positive constant less than unity due to the definition and the assumption; consequently, in the rate process $\alpha$ is always a negative constant and $\beta$ is always a positive constant.

When a distribution-equilibrium is attained, the net amount of solute adsorbed by the interface from each bulk becomes constant:

$$d\Gamma_1/dt = k_{a1} a_{1i} (1-\theta) e^{x_1\theta} - k_{d1}\theta e^{-y_1\theta} = 0$$

$$\therefore \quad \theta/(1-\theta) = k_{a1} e^{x_1\theta} a_{1i} / k_{d1} e^{-y_1\theta} \tag{4}$$

From Eqs. 3 and 4 the distribution coefficient, $K$, is derived, since $x_1 + y_1 = x_2 + y_2 = sV/\boldsymbol{R}T$:[12]

$$\frac{a_{2i}}{a_{1i}} = \left(\frac{k_{a1}}{k_{d1}}\right) e^{(x_1+y_1)\theta} \Big/ \left(\frac{k_{a2}}{k_{d2}}\right) e^{(x_2+y_2)\theta}$$

$$= \frac{k_{a1}/k_{d1}}{k_{a2}/k_{d2}} = K$$

where $s$ is the coordination number of adsorbed molecules in the saturated state; $V$ is the free energy of attractive interaction between two adjacent adsorbed molecules; $\boldsymbol{R}$ is the gas constant, and $T$ is the absolute temperature.

When $\alpha$ and $\beta$ are defined as only unfixed constants, it becomes possible for the boundary condition derived in the rate process, $a_{2i} = \alpha a_{1i} + \beta$, to represent also the relation in the distribution-equilibrium, for the equilibrium relation is represented by specifying $\alpha = K$, and $\beta = 0$. Consequently, it is possible to distinguish whether or not the equilibrium relation holds between $a_{1i}$ and $a_{2i}$ in the rate process, because $\alpha$ should have a negative and $\beta$, a positive finite value in the case of non-equilibrium on the one hand, and on the other hand, $\alpha$ should be positive, equal to the distribution coefficient, and $\beta$, zero in the case of equilibrium.

As has been described in the first paper, the condition $\theta = \text{const.}$ does not necessarily hold in the initial state of the real process, but it can be assumed that this condition holds even in the initial state of the so-termed "ideal process" obtained by extrapolating the part of the real process where this condition actually holds. The analytical results in the preceding paper, which have been obtained on the basis of this assumption, have not indicated any serious conflict. Consequently, as far as we take the boundary condition to be $a_{2i} = \alpha a_{1i} + \beta$, derived by assuming $\theta = \text{const.}$, the "ideal process" should be studied. The concept of the "ideal process" has been described in detail in the first paper.

Now let us solve the differential equations of diffusion with a suitable initial condition and with the boundary condition obtained for the semi-infinite composite medium in one-dimensional diffusion.

Fick's second law of diffusion is represented by:

$$\left.\begin{aligned} \frac{\partial c_1}{\partial t} &= D_1 \frac{\partial^2 c_1}{\partial x^2}, \quad x<0 \\ \frac{\partial c_2}{\partial t} &= D_2 \frac{\partial^2 c_2}{\partial x^2}, \quad x>0 \end{aligned}\right\} \tag{5}$$

where $c_1$ and $c_2$ are the concentrations of the solute in bulks 1 and 2 respectively, while $D_1$ and $D_2$ are the diffusion coefficients in bulks 1 and 2 respectively.

The initial conditions are, as will be described later, assumed to be:

$$\left.\begin{aligned} c_1 &= c_{10}, \quad x<0, \quad t=0 \\ c_2 &= \xi e^{-\eta x}, \quad x>0, \quad t=0 \end{aligned}\right\} \tag{6}$$

where $c_{10}$ is the initial value of $c_1$, and $\xi$ and $\eta$ are constants independent of $x$.

The boundary conditions are given by:

$$\left.\begin{aligned} c_2 &= \alpha c_1 + \beta, \quad x=0 \\ D_1 \frac{\partial c_1}{\partial x} &= D_2 \frac{\partial c_2}{\partial x}, \quad x=0 \end{aligned}\right\} \tag{7}$$

where $\alpha$ and $\beta$ are defined as unfixed constants independent of time; the second equation represents the mass balance between the positions for the two sides immediately next to the interface, involving that the amount of adsorption is constant.

As the solution of Eqs. 5, 6, and 7, we have

$$c_1 = c_{10} - \left[\frac{\alpha c_{10} + \beta}{\alpha + (D_1/D_2)^{1/2}}\right] \operatorname{erfc}\left\{\frac{|x|}{2(D_1 t)^{1/2}}\right\}$$

$$+ \left[\frac{\xi}{\alpha + (D_1/D_2)^{1/2}}\right] \exp\left\{\eta (D_2/D_1)^{1/2} |x| + D_2 \eta^2 t\right\} \operatorname{erfc}\left\{\frac{|x|}{2(D_1 t)^{1/2}} + \eta (D_2 t)^{1/2}\right\}$$

$$c_2=\left[\frac{(D_1/D_2)^{1/2}(\alpha c_{10}+\beta)}{\alpha+(D_1/D_2)^{1/2}}\right]\mathrm{erfc}\left\{\frac{x}{2(D_2t)^{1/2}}\right\}$$
$$-\left(\frac{\xi}{2}\right)e^{D_2\eta^2t}\left\{e^{-\eta x}\cdot\mathrm{erfc}\left[\frac{x}{2(D_2t)^{1/2}}-\eta(D_2t)^{1/2}\right]+e^{\eta x}\cdot\mathrm{erfc}\left[\frac{x}{2(D_2t)^{1/2}}+\eta(D_2t)^{1/2}\right]\right\}+\xi\cdot\exp\left\{D_2\eta^2t-\eta x\right\}$$
$$+\left[\frac{\alpha\xi}{\alpha+(D_1/D_2)^{1/2}}\right]\exp\left\{\eta x+D_2\eta^2t\right\}\mathrm{erfc}\left\{\frac{x}{2(D_2t)^{1/2}}+\eta(D_2t)^{1/2}\right\} \quad (8)$$

If we assame that $\alpha=K$, $\beta=0$, $\xi=0$, and $\eta$ =finite, we obtain:

$$c_1=\frac{c_{10}}{1+(K(D_2/D_1)^{1/2}}\left[1+K(D_2/D_1)^{1/2}\mathrm{erfc}\left\{\frac{|x|}{2(D_1t)^{1/2}}\right\}\right]$$
$$c_2=\left[\frac{Kc_{10}}{1+K(D_2/D_1)^{1/2}}\right]\mathrm{erfc}\left\{\frac{x}{2(D_2t)^{1/2}}\right\}$$

which is identical with the solution by Crank.[9]

The diffusion rate immediately next to the interface in bulk 1, $r_{1i}$, is given by:

$$r_{1i}=-D_1\left(\frac{\partial c_1}{\partial x}\right)_{x=0}=(D_1/\pi t)^{1/2}[\alpha c_{10}+\beta-\xi+\xi\eta(\pi D_2t)^{1/2}e^{D_2\eta^2t}\mathrm{erfc}\{\eta(D_2t)^{1/2}\}]/[\alpha+(D_1/D_2)^{1/2}]$$

or

$$\alpha+\boldsymbol{F}_1(t)\beta=\boldsymbol{F}_2(t) \quad (9)$$
$$\boldsymbol{F}_1(t)\equiv 1/[c_{10}-r_{1i}(\pi t/D_1)^{1/2}]$$
$$\boldsymbol{F}_2(t)\equiv\{r_{1i}(\pi t/D_2)^{1/2}+\xi[1-\eta(\pi D_2t)^{1/2}\cdot e^{D_2\eta^2t}\mathrm{erfc}\{\eta(D_2t)^{1/2}\}]\}\boldsymbol{F}_1(t)$$

Consequently, it becomes possible to give $\alpha$ and $\beta$ numerically from $D_1$, $D_2$, $c_{10}$, $\xi$, $\eta$, and $r_{1i}(t)$ by means of Eq. 9.

## Results and Discussion

The experimental procedures and the basis of analysis have been described in the first paper. Examples of time dependences of the transfer rate through the interface for *n*-butyric acid from aqueous solutions to carbon tetrachloride layers are shown in Figs. 2a and 2b. The inversion on the early stages in Figs. 2a and 2b is interpreted in terms of a disturbance effect, as has been described in the first paper, resulting from the injection of carbon tetrachloride beneath the aqueous layers of an *n*-butyric acid solution, provided that the initial values are given by extrapolation. Because the two curves representing the time dependences of the transfer rate in 2.34 and 3.12 cm. layer-thicknesses coincide approximately except for the part indicating the inversion by disturbance, they are taken to approximate the case of an infinite layer-thickness. Therefore, the full curve of the

envelope in the group of dotted lines is regarded as indicating the case of a semi-infinite composite medium, including no disturbance effect of injection, provided that the initial transfer rates (in the "ideal processes") are obtained by the way described in the first paper.

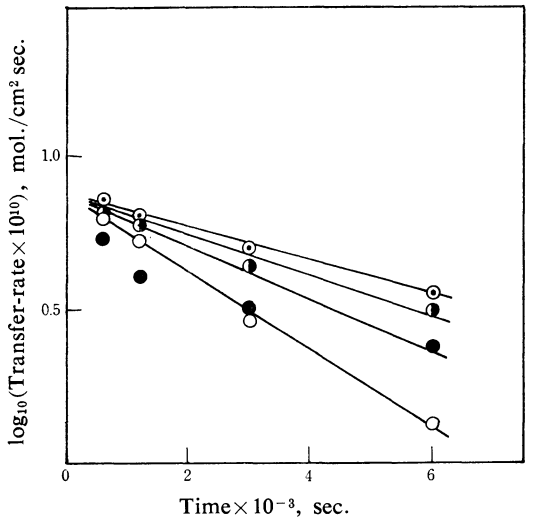

Fig. 3a. Time dependences of the apparent transfer-rate of *n*-butyric acid from the aqueous phase ($c_{10}$=0.0216 N) to the benzene phase in natural, one-dimensional diffusion at 30°C.
Layer-thickness: ○, 0.78 cm.; ●, 1.56 cm.; ◑, 2.34 cm.; ◉, 3.12 cm.

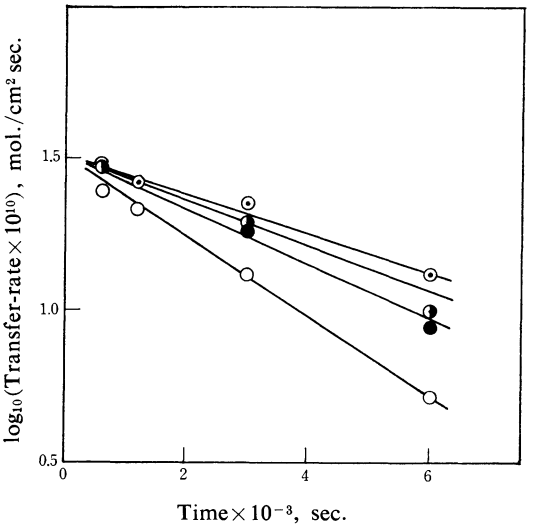

Fig. 3b. Time dependences of the apparent transfer-rate of *n*-butyric acid from the aqueous phase ($c_{10}$=0.0503 N) to the benzene phase in natural, one-dimensional diffusion at 30°C.
Layer-thickness: ○, 0.78 cm.; ●, 1.56 cm.; ◑, 2.34 cm.; ◉, 3.12 cm.

Examples of the time dependences of the apparent transfer rate through the interface for *n*-butyric acid from aqueous solutions to benzene layers are shown in Figs. 3a and 3b. Unlike the case of carbon tetrachloride, Figs.

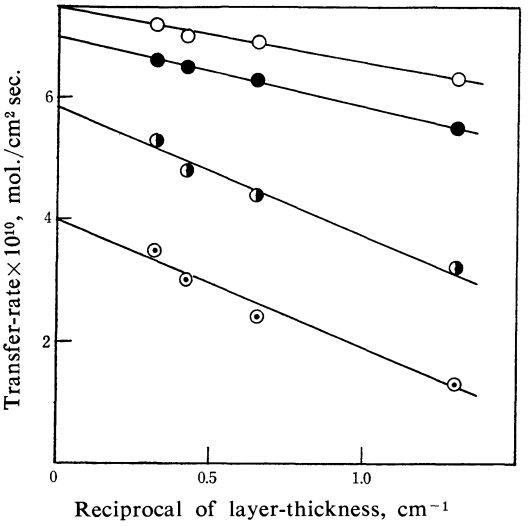

Fig. 4a. Relations between the corrected transfer-rates of *n*-butyric acid and the reciprocals of layer-thickness with the time as a parameter.
System: 0.0216 N aqueous soln. of *n*-butyric acid and benzene (30°C)
Time: ○, 0.60×10³ sec.; ●, 1.20×10³ sec.; ◑, 3.00×10³ sec.; ◉, 600×10³ sec.

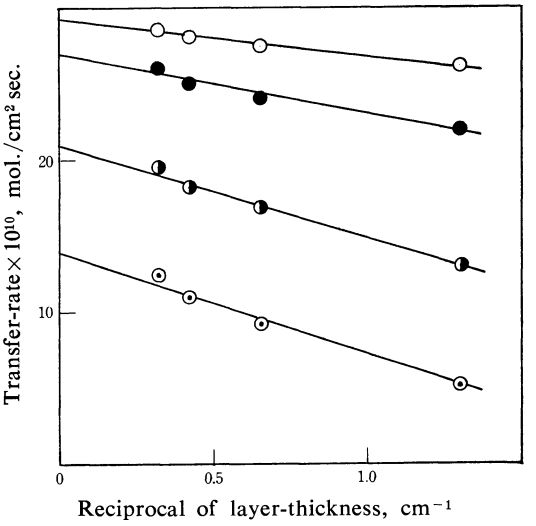

Fig. 4b. Relations between the corrected transfer-rates of *n*-butyric acid and the reciprocals of layer-thickness with the time as a parameter.
System: 0.0503 N aqueous soln. of *n*-butyric acid and benzene (30°C)
Time: ○, 0.60×10³ sec.; ●, 1.20×10³ sec.; ◑, 3.00×10³ sec.; ◉, 6.00×10³ sec.

3a and 3b show no appreciable inversion in the time dependences of the transfer rate, indicating that the disturbance effect is negligible in this case. This agrees with the interpretation of the disturbance effect in this system described in the first paper. Figures 4a and 4b show examples of the relations between the transfer rates and the reciprocals of layer-thickness; the rates extrapolated to zero of the reciprocal of layer-thickness are regarded as indicating one in a semi-infinite composite medium.

The diffusion coefficients of *n*-butyric acid were estimated from the data in the literature.[1,13] They are shown in Table I.

TABLE I. DIFFUSION COEFFICIENTS OF *n*-BUTYRIC ACID AT 30°C

| Solvent | Diffusion coefficient $\times 10^5$, cm²/sec. |
|---|---|
| Water | 1.21 |
| Carbon tetrachloride | 1.60 |
| Benzene | 1.71 |

The initial distributions of concentration in the "ideal process" required in order to obtain $\xi$ and $\eta$ in Eq. 9 were estimated as follows. The time dependences of the amount of solute transferred through the interface in the "ideal process" were obtained from the apparent dependences, correcting the parts deviated by the disturbance, which were easily distinguished in Figs. 2a and 2b, by graphical integration on the curve of the time dependence of transfer rate in the "ideal process," shown as the full curves in these figures. The layer-thicknees dependence of the initial amount of solute transferred in the "ideal process," as defined in the first paper, was obtained from this. The initial distributions of the concentration in an organic solvent in the "ideal process" were finally given from the layer-thickness dependences by graphical differentiation of the initial amount of solute transferred in the "ideal process," assuming that the initial state of the "ideal process" is independent of the layer-thickness. These are approximately represented by the second equation of Eq. 6 in the cases of both carbon tetrachloride and benzene.

The initial condition in the real process is undoubtedly represented as $c_1=c_{10}$, $x<0$ and $t=0$, and $c_2=0$, $x>0$ and $t=0$ instead of Eq. 6. However, the amount of adsorption increases relatively quickly in the early stages after these two bulks are brought into contact with each other if the solute is surface-active; then the boundary condition of Eq. 7 becomes unsuitable, because Eq. 7 holds only when $\theta$ =const. Consequently, if the solute is surface-active and the second equation of Eq. 7 is adopted, the initial condition in the real process, mentioned above, should not be adopted.

The initial distributions of the concentration in the aqueous phase in the "ideal process" could also be obtained in the same way, but the concentrations were estimated to be constant throughout the layer, because the deviation from the values before constact was kept relatively small, even near the interface, for the sake of simplification. This is considered to be the reason why the disturbance effect was negligible in the case of benzene, since the benzene layer was little disturbed, in this case, by the injection of an aqueous solution beneath the benzene layer at the

beginning (actually the benzene layer must be more or less disturbed by the so-called "Marangoni effect,"[1,7,14-17] though this effect might be small compared with the disturbance effect of the injection), whereas the aqueous layer was disturbed very much.

The constants specifying the initial distribution of concentration and the transfer rate in the "ideal process" as a function of time are shown in Table II, while the values of $\alpha$ and $\beta$ calculated statistically by the method of least squares from the data in Tables I and II by Eq. 9 are shown in Table III.

Table III. Values of $\alpha$ and $\beta$ calculated from the experimental data (30°C)

* Estimated standard error

Fairly large errors are estimated in some cases of $\xi$ and $\eta$ parameters of the initial distribution of the concentration in the "ideal process." However, the contribution of such errors in both $\xi$ and $\eta$ to that in $\alpha$ and $\beta$ factors specifying the boundary condition is not very serious. For example, the estimated contributions of the errors in the case of a $c_{10}=1.14\times10^{-5}$ g. mol./cm³ aqueous solution of *n*-butyric acid and carbon tetrachloride, are $\alpha\pm0.073$ and $\beta\pm0.053\times10^{-5}$ g. mol./cm³ (about 9 and 5% $\alpha$ and $\beta$ respectively, against 69 and 11% $\xi$ and $\eta$ respectively).

Moreover, $\alpha<0$ and $\beta>0$ do not come from adopting the initial condition of the "ideal process," since the results of adopting that of the real process, $c_1=c_{10}$ ($x<0$, $t=0$) and $c_2=0$ ($x>0$, $t=0$), are, for example, $\alpha=-0.84$ and $\beta=0.97\times10^{-5}$ g. mol./cm³ and $\alpha=-0.78$ and $\beta=4.51\times10^{-5}$ g. mol./cm³ in $c_{10}=1.14$ and $5.66\times10^{-5}$ g. mol./cm³ aqueous solutions of *n*-butyric acid and carbon tetrachloride respectively.

Table IV shows what the values of $\alpha$ and $\beta$ in Eq. 9 should be when Nernst's law of distribution holds in the two concentrations immediately next to the interface. In order to obtain the theoretical values of $\alpha$ and $\beta$ in Eq. 3 when Nernst's law does not exist generally, it is assumed for the sake of simplification that $k_{a1}=k_{a2}$, $k_{d1}=k_{d2}$, $x_1=x_2$ and $y_1=y_2$; then Eq. 3 becomes

$$\alpha=-(k_{a1}/k_{a2})e^{(x_1-x_2)\theta}=-1$$
$$\beta=[(k_{d1}e^{-y_1\theta}+k_{d2}e^{-y_2\theta})/k_{a2}e^{x_2\theta}]\theta/(1-\theta)$$
$$=2(k_{d2}/k_{a2})e^{-sV\theta/RT}\cdot\theta/(1-\theta) \quad (10)$$

Approximate values of $\alpha$ and $\beta$ obtained by Eq. 10 from the data in the first paper are shown in Table V. It may be clearly seen by comparing Tables III, IV and V with one another that Nernst's law of distribution does not hold in these two concentrations immediately next to the interface in the mass-transfer process for our experimental series.

Table IV. Values of $\alpha$ and $\beta$ in case Nernst's law holds (30°C)

| Org. solvent | $\alpha$ | $\beta$ |
|---|---|---|
| $CCl_3$ | 0.087 | 0 |
| $C_6H_6$ | 0.309 | 0 |

| Org. solvent | $c_{10}\times10^5$ g. mol./cm³ | $\alpha$ — | $\beta\times10^5$ g. mol./cm³ |
|---|---|---|---|
| $CCl_4$ | 1.14 | −1 | 0.24 |
| $CCl_4$ | 5.66 | −1 | 3.60 |
| $C_6H_6$ | 1.00 | −1 | 0.61 |
| $C_6H_6$ | 2.16 | −1 | 1.29 |
| $C_6H_6$ | 5.03 | −1 | 2.82 |
| $C_6H_6$ | 10.38 | −1 | 3.70 |

The convection effect resulting from the dependence of the local density on the concentration is, in general, considered to increase the diffusion coefficients obviously. The experiments, however, were made with samples as dilute as possible for the sake of analysis (0.01—0.10 N), so that this effect might be negligible. No such convection effect should take place in the system of an aquous solution of *n*-butyric acid and benzene, considering the variation in density with the concentration. In the case of carbon tetrachloride, however, a little such effect should take place in the aqueous phase. This may be negligible, though, because the convection in the aquenus phase should have little effect on the mass-transfer through the interface, as has been indicated above in discussing the disturbance effect.

Besides the convection arising from the difference in local density, a spontaneous interfacial turbulence resulting from the Marangoni effect, referred to above, must more or less affect the mass transfer. However, the evaluation of this effect is considered to be difficult.

# The Mass Transfer Rate through the Liquid-Liquid Interface. III. Factors Specifying Boundary Conditions

By Teruya SHIMBASHI and Tadao SHIBA

(Received April 10, 1964)

In the previous papers of this series, it was found that the resistance to the transfer of *n*-butyric acid through the interfaces of water-benzen and water - carbon tetrachloride systems were appreciably high. In these systems, no equilibrium was established during the transference process for the solute in the two concentrations immediately next to the interface. A rate-determining potential barrier was found on the interfaces of the non-aqueous side, a barrier which was attributed to the breaking of the hydrogen bonds between the carboxyl radicals and water.

In the present paper, the results of studies of carboxylic acids and amines will be summarized. These substances form hydrogen bonds with water and show similar transference resistances. The second paper of this series gave an equation, $c_{11}=\alpha c_{21}+\beta$, which holds when the amount of adsorption on the interface, $\Gamma$, is constant with respect to the time, when, that is, the fraction of coverage, $\theta$, is constant. In this equation, $c_{11}$ and $c_{21}$ are the concentrations (or, more precisely, the activities) of the solute in phases 1 and 2 respectively, next to the interface, and $\alpha$ and $\beta$ are functions of $\theta$, independent of the time at a constant temperature. When the interfacial resistance is not zero, $\alpha<0$ and $\beta>0$; $\alpha=K>0$ and $\beta=0$ otherwise, as has been described in the preceding paper. Here $K$ is Nernst's partition coefficient. It is possible to determine whether the interfacial resistance is zero or not by solving this equation numerically for $\alpha$ and $\beta$. The boundary condition of Fick's diffusion equation is specified by determining the values of $\alpha$ and $\beta$ and the problem of transference through the interface is solved by solving Fick's equation. The numerical evaluation of $\alpha$ and $\beta$ is an important problem from both theoretical and practical points of view.

## Experimental

The apparatus used is shown in Fig. 1. The experimental procedure was given in detail in the first

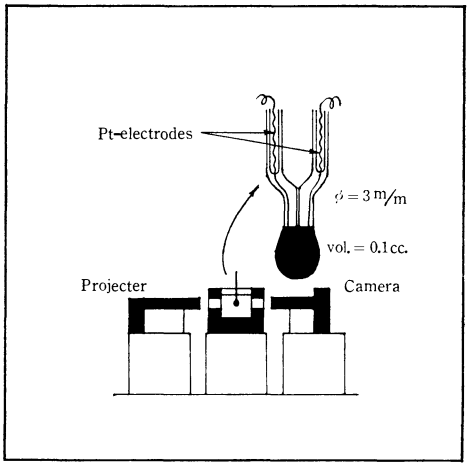

Fig. 1. Apparatus.

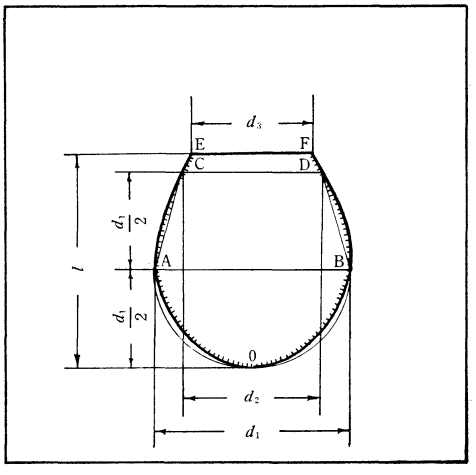

Fig. 2. Scheme of the pendant drop.

paper. As in the pendant-drop method of measuring interfacial tension, a water drop was suspended in an organic solution of a solute, and the change in the average concentration of the solute in the drop was traced conductometrically, with a pair of platinum electrodes coated with platinum black. Every result was recorded automatically. The use of the platinum black increased the sensitivity and improved the response. The average concentration was obtained approximately from the relationship between the equilibrium concentration and the conductivity calibrated beforehand. The actual concentration-distributions in the drop were, however, not uniform, and only approximate values could be estimated by this method. The interfacial tension was determined by the pendant-drop method,[1] in the same time, using photographs of the drop.

The final concentration in the drop was about 0.01—0.10 N. In the calculation of the interfacial tension, the densities of the first and second phases were given to be approximately equal to those of the pure solvents. In order to prevent the communication of the solute from the internal part of the syringe, the tip was made from a capillary tube. No transfer of the solute from the syringe to the drop of pure water hung at the tip of the capillary tube was detected by the conductometry, even when the syringe was filled with a concentrated solution.

The drop was estimated to be a sphere of the same volume. The volume and surface area of the drop were calculated from the OAB hemisphere and from the truncated cones, ABCD and CDEF, shown in Fig. 2, by using these equations:

$$V=\frac{\pi}{24}[2d_1^3+d_1(d_1^2+d_1d_2+d_2^2)+2(l-d_1)(d_2^2+d_2d_3+d_3^2)]$$

$$A=\frac{\pi}{4}[2d_1^2+(d_1+d_2)\{d_1^2+(d_1-d_2)^2\}^{1/2}+(d_2+d_3)\{4(l-d_1)^2+(d_2-d_3)^2\}^{1/2}]$$

where $V$ is the volume of liquid drop, and $A$ is the surface area of the liquid drop. The values obtained by this method were in agreement with those determined by Simpson's method of graphical integration, in which the height was divided into ten sections, with an accuracy of 5%. The radii of spheres with both the same volume and the same interfacial area show a good agreement (within 2%).

All disturbance effects, for example, the disturbance of making the pendant drop, the convection resulting from the difference in local density, and the spontaneous interfacial turbulence, due to the so-called "Marangoni effect," were disregarded.

## Theoretical

Consider a sphere of the first phase suspended in a second phase of infinite dimensions. The three-dimensional diffusion equations[2] are represented as:

$$\frac{\partial U_1}{\partial t}=D_1\frac{\partial^2 U_1}{\partial r^2},\quad 0\leqslant r<R,\ t>0 \tag{1}$$

$$\frac{\partial U_2}{\partial t}=D_2\frac{\partial^2 U_2}{\partial r^2},\quad R<r,\ t>0 \tag{2}$$

$$U_1=\alpha U_2+\beta,\quad r=R,\ t>0 \tag{3}$$

$$D_1\left(\frac{1}{r}\cdot\frac{\partial U_1}{\partial r}-\frac{U_1}{r^2}\right)=D_2\left(\frac{1}{r}\cdot\frac{\partial U_2}{\partial r}-\frac{U_2}{r^2}\right),\quad r=R,\ t>0 \tag{4}$$

$$\left.\begin{aligned}&U_1=rC_{10},\quad 0\leqslant r<R,\ t=0\\&U_2=rC_{20},\quad R<r,\ t=0\end{aligned}\right\} \tag{5}$$

$$C_1:\ \text{finite},\quad r=0 \tag{6}$$

where $U_1$ and $U_2=rC_1$ and $rC_2$ respectively; $r$ is the distance from the center of the sphere; $C_1$ and $C_2$ are the local concentrations of the solute in phases 1 and 2 respectively; $R$ is the radius of the sphere; $D_1$ and $D_2$ are the diffusion coefficients of the solute in both phases; $t$ is the time, and $C_{10}$ and $C_{20}$ are the initial concentrations of the solute in the two phases respectively. Equation 4 expresses the condition of continuity, indicating that the amount of solute flowing into the interface from the first phase in the unit of time is equal to that from the interface into the second.

The initial concentration in the drop of pure water, $C_{10}$, is zero, while $C_{20}$ is the concentration in the solution before their contact. As has been shown in the first paper, however, the amount of adsorption on the interface may be increased very rapidly in the early stage, the "adsorption stage." According to the second paper, Eq. 3 holds only when there is no time-change in the amount of adsorption. In the "adsorption stage," neither Eq. 3 nor 4 is applicable.

As may be seen in Fig. 3, the process in the early stage (in 5 min.) is quite different from that in the later stage. As was described in the second paper, the interfaces of water-benzene and water - carbon tetrachloride systems show a high resistance to the passage of *n*-butyric acid. Putting other resistances in the bulk diffusion of zero as the limiting case, we have:

$$\frac{dm}{dt}=V\frac{dC_1}{dt}=-k(C_1-KC_2)A \tag{7}$$

where $m$ is the amount of solute transferred, and $k$ is the rate constant of transferring through the interface.

Since the concentration-distribution is to be assumed even in each phase, and since the second phase is infinite in volume, we have $C_2=C_{20}$, and

$$\frac{dC_1}{dt}=-k\left(\frac{A}{V}\right)(C_1-KC_{20}) \tag{8}$$

Assuming that the radius of the sphere is

1) J. M. Andreas, E. A. Hauser and W. B. Tucker, *J. Phys. Chem.*, **42**, 1001 (1938).

2) J. Crank, "Mathematics of Diffusion," Clarendon Press, Oxford (1956).

independent of the time, we integrate Eq. 8 as:

$$\ln[(KC_{20}-C_{10})/(KC_{20}-C_1)]=ktA/V \quad (9)$$

An example of the plots of Eq. 9 is shown in Fig 3, where the measured values after about 3 min. fall on a straight line. In some cases no such liner plot was observed. This is probably due to the facts that the interfacial phase is not taken account in Eq. 7, and that the actual situation is not strictly represented by such a limiting equation as Eq. 7.

All the plots obtained consist of two sections, one for the early stage (in 5 min.) and the other for the later stage. The extrapolation of the later section meets the ordinate. The values of $C_{10}$ obtained by this extrapolation are all positive. This result is not contrary to the following interpretation. Let us denote the starting time of the later stage as $t_0$ and then shift the origin to $t_0$. When $t$ is sufficiently large, this transformation produces no error. This situation corresponds to the case where no "adsorption stage" occurs, and $C_{10}>0$. As for $C_{20}$, the values preceding the contact were used. As the magnitude of $C_{20}$ is sufficiently large, the error due to the use of this initial value is considered to be negligible.

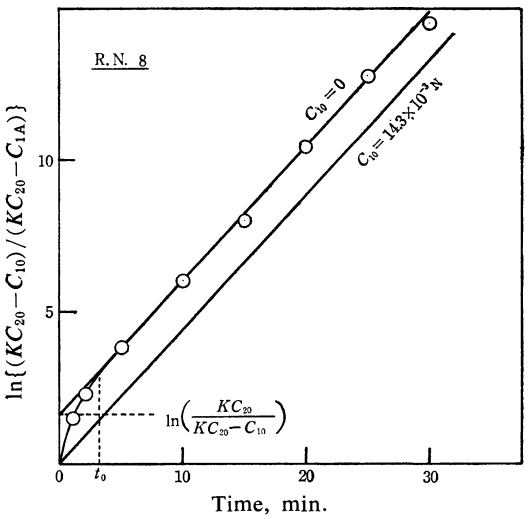

Fig. 3. An example of time dependences of the average concentration in the drop.

Solving Eqs. 1—6 (see Appendix I), we have

$$C_1\fallingdotseq C_{10}+\frac{1}{r}\sum_{n=0}^{\infty}\left\{K_1\left[\mathrm{erfc}\left\{\frac{(2n+1)R-r}{2(D_1t)^{1/2}}\right\}-\mathrm{erfc}\left\{\frac{(2n+1)R+r}{2(D_1t)^{1/2}}\right\}\right]+\frac{K_2}{h}\left[\mathrm{erfc}\left\{\frac{(2n+1)R-r}{2(D_1t)^{1/2}}\right\}-e^{h\{(2n+1)R-r\}+D_1th^2}\,\mathrm{erfc}\left\{\frac{(2n+1)R-r}{2(D_1t)^{1/2}}+h(D_1t)^{1/2}\right\}-\mathrm{erfc}\left\{\frac{(2n+1)R+r}{2(D_1t)^{1/2}}\right\}+e^{h\{(2n+1)R+r\}+D_1th^2}\,\mathrm{erfc}\left\{\frac{(2n+1)R+r}{2(D_1t)^{1/2}}+h(D_1t)^{1/2}\right\}\right]\right\} \quad (10)$$

$$C_2\fallingdotseq C_{20}+\frac{1}{r}\left\{K'_1\left[\mathrm{erfc}\left\{\frac{r-R}{2(D_2t)^{1/2}}\right\}-2\sum_{n=0}^{\infty}\mathrm{erfc}\left\{\frac{2(n+1)(D_2/D_1)^{1/2}R+(r-R)}{2(D_2t)^{1/2}}\right\}\right]+\frac{K'_2}{h'}\left[\mathrm{erfc}\left\{\frac{r-R}{2(D_2t)^{1/2}}\right\}-e^{h'(r-R)+D_2th'^2}\,\mathrm{erfc}\left\{\frac{r-R}{2(D_2t)^{1/2}}+h'(D_2t)^{1/2}\right\}\right]+\frac{K'_3}{h'}\sum_{n=0}^{\infty}\left[\mathrm{erfc}\left\{\frac{2(n+1)(D_2/D_1)^{1/2}R+(r-R)}{2(D_2t)^{1/2}}\right\}-e^{h'\{2(n+1)(D_2/D_1)^{1/2}R+(r-R)+D_2th'^2\}}\,\mathrm{erfc}\left\{\frac{2(n+1)(D_2/D_1)^{1/2}R+(r-R)}{2(D_2t)^{1/2}}+h'(D_2t)^{1/2}\right\}\right]\right\} \quad (11)$$

$$K_1\equiv\frac{R(\alpha C_{20}-C_{10})+\beta}{1+\alpha(D_1/D_2)^{1/2}}$$

$$K_2\equiv\frac{\alpha\{1+(D_1/D_2)^{1/2}\}\{R(\alpha C_{20}-C_{10})+\beta\}}{R\{1+\alpha(D_1/D_2)^{1/2}\}^2}$$

$$h\equiv\frac{1-\alpha D_1/D_2}{R(D_1/D_2)^{1/2}\{1+\alpha(D_1/D_2)^{1/2}\}}$$

$$K'_1\equiv\frac{-(D_1/D_2)^{1/2}\{R(\alpha C_{20}-C_{10})+\beta\}}{1+\alpha(D_1/D_2)^{1/2}}$$

$$K'_2\equiv\frac{(D_1/D_2)^{1/2}\{1+(D_1/D_2)^{1/2}\}\{R(\alpha C_{20}-C_{10})+\beta\}}{R\{1+\alpha(D_1/D_2)^{1/2}\}^2}$$

$$K'_3\equiv\frac{2(D_1/D_2)^{1/2}(1-\alpha D_1/D_2)\{R(\alpha C_{20}-C_{10})+\beta\}}{R\{1+\alpha(D_1/D_2)^{1/2}\}^2}$$

$$h'\equiv\frac{1-\alpha D_1/D_2}{R\{1+\alpha(D_1/D_2)^{1/2}\}}$$

The Concentrations immediately next to the interface, $C_{1i}$ and $C_{2i}$, are given from Eqs. 10 and 11, putting $r=R$, as:

$$C_{1i}\fallingdotseq C_{10}+K_1/R+(K_2/Rh)\times[1-e^{D_1th^2}\,\mathrm{erfc}\{h(D_1t)^{1/2}\}] \quad (12)$$

$$C_{2i}\fallingdotseq C_{20}+K'_1/R\left[1-2\sum_{n=0}^{\infty}\mathrm{erfc}\left\{\frac{(n+1)R}{(D_1t)^{1/2}}\right\}\right]$$

$$+(K'_2/Rh')\,[1-e^{D_2th'^2}\,\mathrm{erfc}\{h'(D_2t)^{1/2}\}]$$
$$+\frac{K'_3}{Rh'}\sum_{n=0}^{\infty}\left[\mathrm{erfc}\left\{\frac{(n+1)R}{(D_1t)^{1/2}}\right\}\right.$$
$$-e^{2(n+1)(D_2/D_1)^{1/2}Rh'+D_2th'^2}\,\mathrm{erfc}$$
$$\left.\left\{\frac{(n+1)R}{(D_1t)^{1/2}}+h'(D_2t)^{1/2}\right\}\right] \qquad (13)$$

Equations 10 and 11 exist strictly at $t\to 0$ (see Appendix I) : $\lim_{t\to 0} C_{11}=C_{10}+K_1/R$, $\lim_{t\to 0} C_{21}=C_{20}+K'_1/R$, and $\lim_{t\to 0} C_{11}=\alpha(\lim_{t\to 0} C_{21})+\beta/R$, that is in accord with Eq. 3.

The average concentration in the drop is represented as:

$$\bar{C}_{1A}=\frac{\iiint_v \bar{C}_1 r^2\sin\theta\,dr\,d\theta\,d\varphi}{\iiint_v r^2\sin\theta\,dr\,d\theta\,d\varphi}=\frac{3}{R^3}\int_0^R \bar{U}_1 r\,dr \qquad (14)$$

where $\theta$ and $\varphi$ are the angles in the solid polar coordinates.

By calculating Eq. 14 by applying Eq. 27 in Appendix I, and by inversion to the original function, we have:

$$C_{1A}\doteqdot C_{10}+[R(\alpha C_{20}-C_{10})+\beta]$$
$$\times\left\{\frac{6(D_1t/\pi)^{1/2}}{R^2}\left[\frac{1+\alpha(D_1/D_2)^{3/2}}{(1-\alpha D_1/D_2)^2}\right]\right.$$
$$-\frac{3D_1t}{R^3(1-\alpha D_1/D_2)}+3\alpha(D_1/D_2)$$
$$\times[1+(D_1/D_2)^{1/2}]^2\,[e^{D_1th^2}\,\mathrm{erfc}\{h(D_1t)^{1/2}\}$$
$$\left.-1]/R(1-\alpha D_1/D_2)^3+S_1+S_2\right\} \qquad (15)$$

$$S_1\equiv\frac{12}{R^2(1+\alpha(D_1/D_2)^{1/2})}\sum_{n=1}^{\infty}[(D_1t/\pi)^{1/2}e^{-n^2R^2/D_1t}$$
$$-nR\,\mathrm{erfc}\{nR/(D_1t)^{1/2}\}]$$
$$S_2\equiv\frac{6\alpha\{1+(D_1/D_2)^{1/2}\}(1-\alpha D_1/D_2)^2}{(D_1/D_2)R^5\{1+\alpha(D_1/D_2)^{1/2}\}^4}$$
$$\times\sum_{n=1}^{\infty}\left[2h\left(\frac{D_1t}{\pi}\right)^{1/2}e^{-n^2R^2/D_1t}\right.$$
$$-(1+2nRh)\,\mathrm{erfc}\left\{\frac{nR}{(D_1t)^{1/2}}\right\}$$
$$\left.+e^{2nRh+D_1th^2}\,\mathrm{erfc}\{nR/(D_1t)^{1/2}+h(D_1t)^{1/2}\}\right]$$

Therefore, our purpose is to determine the numerical values of $\alpha$ and $\beta$ suitable for Eq. 15 from the expermental data, $R$, $C_{10}$, $C_{20}$, $C_{1A}$, $D_1$ and $D_2$. Equation 15 is deformed as:

$$\beta=(C_{1A}-C_{10})/F(\alpha,t)-R(\alpha C_{20}-C_{10}) \qquad (16)$$
$$F(\alpha,t)\equiv\frac{6(D_1t/\pi)^{1/2}}{R^2}\left[\frac{1+\alpha(D_1/D_2)^{3/2}}{(1-\alpha D_1/D_2)^2}\right.$$
$$-\frac{3D_1t}{R^3(1-\alpha D_1D_2)}$$
$$\left.+\frac{3\alpha(D_1/D_2)\,[1+(D_1/D_2)^{1/2}]^2}{R(1-\alpha D_1/D_2)^3}\right.$$
$$\times e^{D_1th^2}\,\mathrm{erfc}\{h(D_1t)^{1/2}\}-1]+S_1+S_2 \qquad (17)$$

As $\beta$ is an explicit function of the time, $t$, it can be evaluated as the function of $t$ by specifying $\alpha$. We denote the values of $\beta$ at $t=t_1, t_2,\cdots\cdots,t_n$ as $\beta=\beta_1, \beta_2,\cdots\cdots,\beta_n$, and define $\tilde{\beta}=(\beta_1+\beta_n)/2$ and $\Delta\beta=|\beta_1-\beta_n|$ (see Appendix II). Therefore, the requisite condition of $\alpha$ and $\beta$ being the solution of Eq. 16 is $\Delta\beta=0$ in a definite value of $\alpha$, because $\alpha$ and $\beta$ are constant with the time-lapse.

An example of plots of $\tilde{\beta}$ and $\Delta\beta$ against $\alpha$ is shown in Fig. 4. In Fig. 4, points A and B satisfy the condition, $\Delta\beta=0$. Point A is,

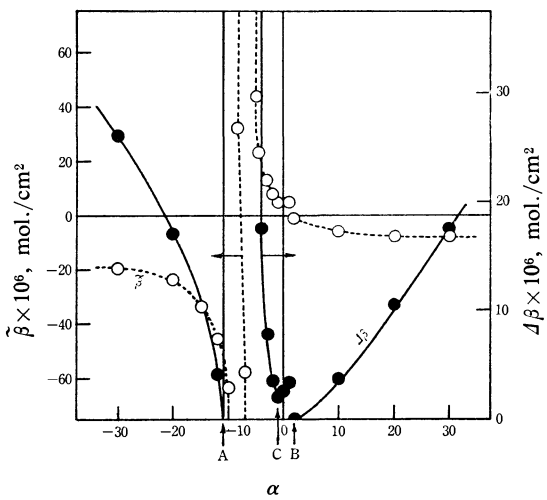

Fig. 4. An example of $\alpha$-dependences of the $\Delta\beta$ and $\tilde{\beta}$.
System: water-benzene solution of *n*-butyric acid ($C_{20}=10.41\times10^{-6}$ mol./cm³) at 30°C.

however, physically meaningless, since $C_1<0$ when $\alpha$ and $\beta<0$ and $C_2>0$ in Eq. 3. Point B has no definite value, because at B, $\alpha=D_2/D_1$, both denominater and numerator in the third term of Eq. 17 become zero; in the limiting value of the indefinite form, $\Delta\beta=0$.

From the physical point of view, one reasonable solution at least should be definitive. If we can assume that the value of point C, where $\Delta\beta$ is at its minimum, must fall on the $\alpha$ axis in spite of its actually taking some finite value because of errors, we can estimate, from the position of the minimum, the approximate value of $\alpha$, or $\alpha_0$, and the corresponding value of $\tilde{\beta}$ (the most probable value of $\beta$), or $\beta_0$, as is shown in Fig. 4. All the experimental plots behave similarly.

$C_{11}$ and $C_{21}$ were estimated by putting the numerical values of $\alpha_0$ and $\beta_0$ obtained by the above graphical method into Eqs. 12 and 13.

## Results

The results obtained are shown in Table I. These were obtained by the aid of an electronic digital computer using Eqs. 12, 13 and 16, assuming that $D_1$ and $D_2$ in these equations can be estimated by Wilke's method.[3] In Table I, no description is given for water, which is a substance common to all the systems. $C_{1i}$ is the concentration of the solute in the first (aqueous) phase immediately next to the interface. $C'_{20}$ and $C'_{2i}$ are the concentrations of the solute in the first phase in equilibrium with those in the second phase, initial ($C_{20}$) and immediately next to the interface ($C_{2i}$). $C_S$ is the concentration of the solute in the first phase in equilibrium with the surface pressure (or the difference between the interfacial tension of the pure solvents and that of the solutions). $C'_{20}$, $C'_{2i}$, and $C_S$ are, so to speak, the reduced concentrations of $C_{20}$, $C_{2i}$ and $\Gamma$ respectively, in comparison with $C_{1i}$. $C_{1i}$, $C'_{2i}$ and $C_S$ are the values at $t=2$ min. In all the results, $\alpha_0<0$ and $\beta_0>0$. No consistent relation is found between $\alpha_0$ and $C'_{20}$, while $\beta_0$ increases with the increase in $C'_{20}$. According to the second report,

$$\alpha = -(k_{a2}/k_{a1})e^{(x_2-x_1)\theta}$$

$$\beta = [(k_{d1}e^{-y_1\theta}+k_{d2}e^{-y_2\theta})/k_{a1}e^{x_1\theta}]\,[\theta/(1-\theta)]\,R$$

where $k_{a1}$ and $k_{a2}$ are the rate constants of the adsorption onto the interface from the two phases respectively; $k_{d1}$ and $k_{d2}$ are the rate constants of desorption from the interface into the two phases respectively; $x_1$, $x_2$, $y$, and $y_2$ are factors defining the mutual interaction of adsorbed molecules, and $\theta$ is the relative amount of adsorption (the fraction of coverage). When $k_{a1}$, $k_{a2}$, $k_{d1}$ and $k_{d2}$ have finite values, $\alpha<0$ and $\beta>0$. If $\theta/(1-\theta)$ has a large effect upon the variation in $\beta$, $\theta$ generally increases with the increase in $C'_{20}$, while $\theta/(1-\theta)$ increases more rapidly, resulting in the increase in $\beta$. The experimental results are not inconsistent with these speculations; this is evidence that a finite interfacial resistance exists in these cases.

In the cases of fatty acids and also in the P'C system (though $C'_{2i}$ shows unreasonable values in these cases), the value of $C_S$ approach those of $C_{1i}$, while others approach those of $C'_{2i}$. These facts may be ascribed to the existence of a rate-determining potential barrier. That is to say, in the former cases the rate-determining stage may be the adsorption from the organic solvent onto the interface, while in the latter it may be the desorption from the interface into the aqueous phase. The reason for the appearance of unreasonable values of $C'_{2i}$ in some cases is not certain, but it may be connected with the long time range, $t_1-t_n$, for the calculation of $\tilde{\beta}$ or $\Delta\beta$, because on a

3) C. R. Wilke, *Chem. Eng. Progress*, **45**, 218 (1949).

longer time range the applicability of the condition, that is, the base of Eqs. 3 and 4, $\theta=$ const., seems poor in these cases; as has been described above, when we put other resistances in a bulk diffusion of zero as a limiting case compared with the interfacial resistance, we have $C_{1i}=C_{1A}$ and $C'_{2i}=C'_{20}$. When $C_S=C_{1i}$, the condition in the cases of fatty acids and in the P'C system, $C_S=C_{1A}$ and $\theta\neq$const.; on the other hand, when $C_S=C'_{2i}$, $C_S=C'_{20}$ and $\theta=$const.

The values of $\alpha$ and $\beta$ recalculated from the data of the reverse, one-dimensional diffusion given in the second paper are as follows: $\alpha=-1.3$; $\beta=2.2\times10^{-6}$ (No. 7) and $13.0\times10^{-6}$ (No. 8) g. mol./cm$^2$. These values are in good agreement with the present results for the Bu-B system shown in Table I, considering rough approximations are included in the present results. The values of the present results, if denoted as $\alpha'$ and $\beta'$, are related to those ($\alpha$ and $\beta$) in the preceding paper as follows: $\alpha'=1/\alpha$, and $\beta'=-R\beta/\alpha$, provided that $R=0.294$ (No. 7), 0.317 (No. 8) cm.; $\alpha=0.779$, that is the average of $\alpha'$ sin $c_{10}=2.16\times10^{-5}$, $5.03\times10^{-5}$ and $10.38\times10^{-5}$ g. mol./cm$^3$ (as shown in Table III of the second paper), and $c_{1i}$, which should fix the value of $\beta$, approximates $c_{10}$. The positions of the potential barriers have been taken to be the same for both sets of results.

The time dependence of the thickness of the diffusion layer in the aqueous drop has also been calculated. As may be seen in Fig. 5,

$$dm/dt=V(dC_{1A}/dt)=D_1(\Delta C_1/l)A$$

or
$$l=D_1\Delta C_1/(V/A)(dC_{1A}/dt) \qquad (18)$$

where $l$ is the thickness of the diffusion layer of phase 1, and $\Delta C_1$ is the difference in the boundary concentrations in the diffusion layer of phase 1.

It is assumed that $C_{1i}$, on which the calculation of $\Delta C_1$ is based, is in equilibrium with the surface pressure. As $C_{1i}=C_S$, we have

$$l=D_1(C_S-C_{1A})/(V/A)(dC_{1A}/dt) \qquad (19)$$

The values of the thicknesses of the diffusion layer, $l$, calculated according to Eq. 19

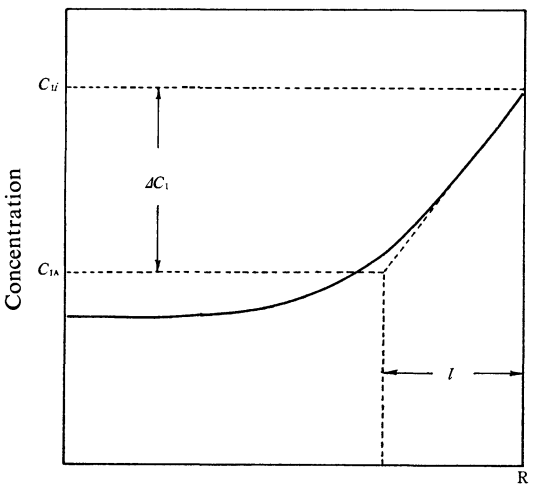

Fig. 5. Scheme of the distribution of concentration in the drop.

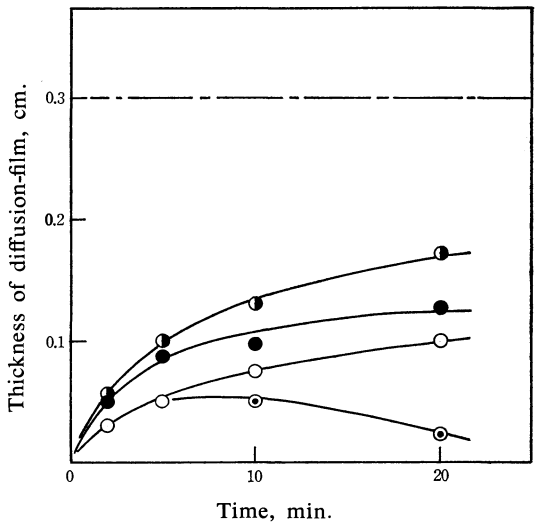

Fig. 6a. Time dependences of the thickness of the diffusion film in fatty acid series of solute (30°C).
System: ○, PB (0.0106 N); ●, BuB (0.0309 N); ◑, PC (0.0053 N); ⊙, BuC (0.0298 N)

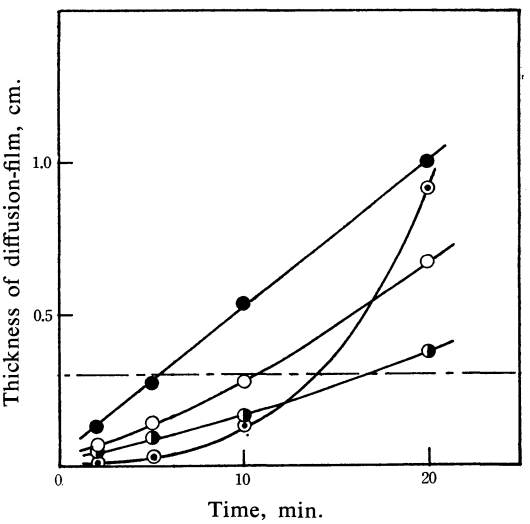

Fig. 6b. Time dependences of the thickness of the diffusion film in fatty amine series of solute (30°C).
System: ○, P'B (0.0201 N); ●, Bu'B (0.0214 N); ◑, P'C (0.0096 N); ⊙, BU'C (0.0200 N)

are shown in Figs. 6a and 6b. As may be seen in these figures, $l$ is smaller than the radius of the aqueous drop for the fatty acids used as solutes, while it becomes much larger than the radius for the fatty amines. When the various theoretical errors included are taken into account, the plots of the fatty acids are quite reasonable, while those of the amines are ununderstandable.

In the cases of fatty acids, the condition, $C_{1i}=C_S$, is satisfied, while in the amine systems except P'C, this condition is not fulfilled in Table I. It should be noted here that Eq. 19 is based on this condition. We put $C_S-C_{1i}=\phi$. Then the error in $l$, $\Delta l$, is represented as $\Delta l=D_1\phi A/V(dC_{1A}/dt)$. For the amine systems except P'C, $\phi\gg 0$. Therefore, $\Delta l>0$, and positive deviations may be anticipated. The unreasonable behavior in the plots of fatty amines is to be ascribed to the error due to the assumption that $C_{1i}=C_S$. The curious results of P'C will be discussed later.

## Discussion

In the first paper, the transference of *n*-butyric acid from the aqueous to the benzene phase was studied. The rate-determining potential barrier which the solute molecules encounter during the passage from the interface into the benzene phase was ascribed to the breaking of the two hydrogen bonds formed per solute molecule between the carboxyl radicals of *n*-butyric acid adsorbed on the interface and water molecules. The energy of the breaking of the hydrogen bonds was assumed to be equal to the activation energy of the desorption process. However, more data must be collected in order to prove the general applicability of this assumption.

In general, it may be assumed that the activation energy of the desorption of a solute from an interface made up of a polar and a non-polar medium to the non-poar sollvent is the sum of the association energies between the polar groups in the adsorbed molecule and the polar solvent (for example, the hydrogen bond), and that the activation energy of the reverse process is the sum of the interaction energies between the non-polar groups in the adsorbed molecule and the non-polar solvent. The entropy associated with the processes is taken to be constant in every case, as in the case of a gas-liquid transition, for which the law of constant entropy is known as Trouton's rule.

If the transfer of *n*-butyric acid from the interface to the benzene phase is the rate-determining step, it may be concluded from the above assumption that the activation energy of the transfer from the interface to the benzene phase is greater than that of the reverse process. Therefore, the association energy between a carboxyl radical and water may be greater than that of a *n*-propyl radical and benzene. The interaction of solute molecules among themselves can be disregarded, because the standard state of the rate process is that of infinite dilution. There is not much difference in the interacticn energies between solute and solvent for the solvents used (benzene, toluene, and cyclohexane), which have similar molecular configurations. Since the interaction energy between a non-polar solvent and the non-polar groups of the solute increases at a rate approximately equal to the increase in the carbon number in the non-polar group of a molecule, the association energy of a carboxyl radical with water may be far greater than the interaction energy between an ethyl radical and benzene. In the present results concerning the fatty acid systems, the assumption given above, on the basis of which the rate-determining step in all these systems is presumed to be the transfer of the solute from the interface into the non-polar solvent, is proved experimentally.

In the case of amine systems besides the system of *n*-propyl amine and cyclohexane, the rate-determining step, on the contrary, is taken to be the transfer from the interface into the aqueous phase. These facts may be explained by assuming that the interaction energy of an amino radical and water is slightly smaller than that of a *n*-propyl radical and benzene. In the *n*-propyl amine and cyclohexane system, if the interaction energy between a *n*-propyl radical and cyclohexane is sufficiently smaller than that with benzene, the situation may be reversed.

As has been shown above, the thickness of the diffusion layer has apparently been found by calculation to become greater than the radius of the water drop in this system. This fact may be explained as follows. The transfer of the solute from the interface into the cyclohexane phase might not be the rate-determining step because of the small difference in interaction energies between an amino radical - water and an *n*-propyl radical - cyclohexane; therefore, no equilibrium may be established between the interfacial tension and the concentration in the aqueous phase immediately next to the interface, whereas the calculation of the thickness of the diffusion layer is based on this equilibrium.

The interaction energies between a non-polar radical and a non-polar solvent are calculated as follows: according to Benson,[4] the interaction energy per mole of a non-polar solvent is represented as:

$$(E_m)_{AA}=\phi_{AA}N\sum_{i=1}^{\infty}n_i/r_i^6$$

were $r_i$ is the distance between $i$-th and the center molecule; $n_i$ is the coordinate number of the $i$-th molecules; $N$ is Avogadro's number, and $\phi_{AA}$ is the force constant between solvent molecules.

Now one solvent molecule (A) is replaced by one solute molecule (B). Hereby it is assumed that the relative positions of the solvent molecules are unchanged. Then the interaction energy between A and B molecules made from the above exchange may be represented as:

$$(E_m)_{AB}=(\phi_{AB}/\phi_{AA})(E_m)_{AA} \qquad (20)$$

Considering that $\phi_{AA}=(3/4)h\nu_A\alpha_A^2$, $\phi_{AB}=(3/2)\alpha_A\alpha_B h\nu_A h\nu_B/(h\nu_A+h\nu_B)$, $\alpha=3[R]/4\pi N$, and $h\nu=P$, the $\phi_{AB}/\phi_{AA}$ factor is represented as:

$$\phi_{AB}/\phi_{AA}=([R]_B/[R]_A)2P_B/(P_A+P_B) \qquad (21)$$

where $\alpha$ is the polarizability: $h$ is Planck's constant; $\nu$ is the intrinsic oscillation number of the electron system; $[R]$ is the molar refraction, and $P$ is the ionization potential. The interaction energy (the dispersion effect) between A and B molecules at an infinite dilution may then be easily calculated according to Eqs. 20 and 21 and the method of Benson.[4]

According to this method, the interaction energies between a propane-molecule and benzene and cyclohexane solvents were calculated for 9.8 and 9.3 kcal./mol. respectively at 30°C, assuming that $(P)_{benzene}=9.6$ eV.,[5] $(P)_{cyclohexane}=9.24$ eV.[6] and $(P)_{propane}=11.3$ eV[7]. If a *n*-propyl radical can be assumed to approximate a propane-molecule (considering that the contribution of a hydrogen-atom is negligible), the interaction energy between an radical and benzene should become more or less higher than that between the radical and cyclohexane; this does not contradict the above discussion.

The relation between the interaction energy of a functional radical of a transfer material with a solvent and the activation energy of the transfer process through the liquid-liquid interface (or the activation free energy) is an important subject both theoretically and experimentally.

The present theory is based on the following crude approximations, and therefore, the conclusion is not precisely quantitative. 1) The pendant drop is taken to be a sphere. 2) The difference between the values of concentration obtained by the conductometric method and the true mean concentrations is neglected. 3) The entropy of activation associated with the desorption of the solute from the interface is assumed to be constant irrespective of the direction of movement and the materials used as solvent and solute. 4) All disturbance effects are disregarded.

We are much indebted to Mr. Setsuo Mimasu of Toyo Koatsu Industries, Inc., Tokyo, for his aid in performing the calculations with an electronic computer.

## Appendix I

By the Laplace transformation, Eqs. 1—6 are reduced to the ordinary differential equations as:

$$\frac{d^2\overline{U}_2}{dr}-q_1^2\overline{U}_1=-\left(\frac{C_{10}}{D_1}\right)r,\ 0\leqslant r<R \qquad (22)$$

$$\frac{d^2\overline{U}_2}{dr^2}-q_2^2\overline{U}_2=-\left(\frac{C_{20}}{D_2}\right)r,\ R<r \qquad (23)$$

$$\overline{U}_1=\alpha\overline{U}_2+\beta/p \quad r=R \qquad (24)$$

$$D_1\left(R\frac{d\overline{U}_1}{dr}-\overline{U}_1\right)=D_2\left(R\frac{d\overline{U}_2}{dr}-\overline{U}_2\right),\ r=R \qquad (25)$$

$$\overline{C}_1:\ \text{finite},\ r=0 \qquad (26)$$

where $p$ is the conversion parameter in the Laplace transformation, and $q_1$ and $q_2=(p/D_1)^{1/2}$ and $(p/D_2)^{1/2}$ respectively.

Solving Eqs. 22, 23, and 26, we obtain:

$$\overline{U}_1=rC_{10}/D_1q_1^2+A\sinh(rq_1) \qquad (27)$$

$$\overline{U}_2=rC_{20}/D_2q_2^2+B[\cosh(rq_2)-\sinh(rq_2)] \qquad (28)$$

where $A$ and $B$ are integration constants.

Applying the boundary conditions, Eqs. 24 and 25, the constants, $A$ and $B$, in Eqs. 27 and 28 are given as Eqs. 29 and 30.

$$A=\frac{R(\alpha C_{20}-C_{10})+\beta}{p\left[\left\{1-\frac{D_1}{D_2}\left(\frac{\alpha}{1+Rq_2}\right)\right\}\sinh(Rq_1)+\frac{D_1}{D_2}\left(\frac{\alpha Rq_1}{1+Rq_2}\right)\cosh(Rq_1)\right]} \qquad (29)$$

$$B=A\left(\frac{D_1}{D_2}\right)\left\{\frac{Rq_1\cosh(Rq_1)-\sinh(Rq_1)}{(1+Rq_2)[\sinh(Rq_2)-\cosh(Rq_2)]}\right\} \qquad (30)$$

4) S. W. Benson, *J. Chem. Phys.*, **15**, 367 (1947).
5) *Int. Crit. Table*, **6**, p. 72.
6) J. D. Morrison, *J. Chem. Phys.*, **19**, 1305 (1951).
7) D. P. Stevenson and J. A. Hipple, *J. Am. Chem. Soc.*, **64**, 1588 (1942).

$$A=\frac{2[(\alpha C_{20}-C_{10})R+\beta]}{pe^{Rq_1}\left[1-\alpha\left(\frac{D_1}{D_2}\right)\left(\frac{1-Rq_1}{1+Rq_2}\right)\right]\left[1-\left\{\frac{1-\alpha\left(\frac{D_1}{D_2}\right)\left(\frac{1+Rq_1}{1+Rq_2}\right)}{1-\alpha\left(\frac{D_1}{D_2}\right)\left(\frac{1-Rq_1}{1+Rq_2}\right)}\right\}e^{-2Rq_1}\right]} \tag{31}$$

$$A\fallingdotseq\frac{2[(\alpha C_{20}-C_{10})R+\beta]}{pe^{Rq_1}[1-\alpha(D_1/D_2)(1-Rq_1)/(1-Rq_2)](1-e^{-2Rq_1})} \tag{32}$$

Converting Eq. 29 to an exponential function, we have Eq. 31.

If $0<Rq_1\ll 1$, we have Eq. 32.

Then, converted by the binomial theorem into a form in which the inversion is easy, we have:

$$A\fallingdotseq 2\sum_{n=0}^{\infty}\left[K_1\left\{\frac{e^{-(2n+1)Rq_1}}{p}\right\}+K_2\left\{\frac{e^{-(2n+1)Rq_1}}{p(q_1+h)}\right\}\right] \tag{33}$$

$$B\fallingdotseq K'_1\left[\frac{e^{Rq_2}}{p}-2\sum_{n=0}^{\infty}\frac{e^{-Rq_2\{2(n+1)(D_2/D_1)^{1/2}-1\}}}{p}\right]+K'_2\left\{\frac{e^{Rq_2}}{p(q_2+h')}\right\}+K'_3\sum_{n=0}^{\infty}\frac{e^{-Rq_2\{2(n+1)(D_2/D_1)^{1/2}-1\}}}{p(q_2+h')} \tag{34}$$

Even if Eq. 32 does not hold, Eqs. 33 and 34 are approximately true when the time, $t$, is sufficiently small.

Putting Eqs. 33 and 34 into Eqs. 27 and 28, and by inversion to the original functions,[8] we obtain Eqs. 10 and 11.

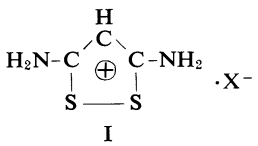
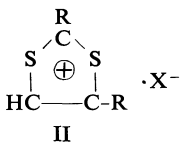
## Appendix II



The time range, $t_1$—$t_n$, on the basis of which $\tilde{\beta}$ and $\Delta\beta$ were calculated, was determined to be as follows. As has been described above, Eqs. 3 and 4 do not hold in the "adsorption stage." Therefore, the authors took $t_1$ to be greater than the $t_0$ shown in Fig. 3. Equations 10, 11, 12, 13, and 15 are applicable, on the other hand, in a range where $t$ is sufficiently small (see Apendix I). Precisely speaking, when the true exponential-type solution is composed of an infinite series, these equation hold only approximately in the range where the terms higher than the second of the true solution are negligible. The smaller the value of $t$, the better the approximation obtained generally in such an exponential-type solution. We assume that the terms higher than the second in the true solution and Eq. 17 become negligible at the same time, $t_n$, Therefore, the upper limit of $t_n$ can be estimated from experimental values, specifying $\alpha=-0.01$, $-0.10$, $-1.00$, etc. $S_1$ and $S_2$ in Eq. 17 correspond to the terms higher than the second in the infinite series, and were neglected if their sum was less than 1% of the $F(\alpha, t)$ in Eq. 17.

# Meso-ionic Compounds of the 1, 3-Dithiole Ring System[1]



By Masaki OHTA and Masatoshi SUGIYAMA

(Received June 4, 1964)

In connection with the research on the 1, 2- and 1, 3-dithiole ring systems, it has been reported that the oxidation of dithiomalonamide with hydrogen peroxide in the presence of the appropriate acid gives 3, 4-diamino-1, 2-dithiolyl salt (I)[2] and that the dehydration of phenacyl or acetonyl carbodithioate with hydrogen chloride gives 1, 3-dithiolium salts (II).[3]

I

II

In a previous paper,[4] we reported that a new type of meso-ionic compounds containing two sulfur atoms in a ring, which were referred to as dithiolone imine salts, was prepared by the action of hydrogen chloride or acyl chlorides on cyanomethyl dithiobenzoate. The object of this paper is to describe the synthesis of dithiolone, which has an exocyclic oxygen atom instead of a nitrogen atom of dithiolone imine salts, and the properties of dithiolone imine salts.

It has been reported that *N*-thiobenzoylsarcosine under goes ring closure in hot acid anhydrides to give meso-ionic compounds, $\psi$-4-acyl-3-methyl-2-phenylthiazol-5-one.[5] As the

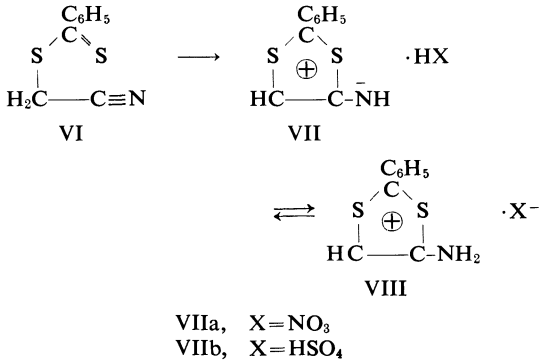
formation of a meso-ionic ring occurred between thiocarbonyl and carboxyl groups, a ring closure may be expected with carboxymethyl dithiobenzoate. Carboxymethyl dithiobenzoate was prepared by the action of chloroacetic acid upon potassium dithiobenzoate prepared from benzotrichloride and potassium sulfide by the elimination of potassium chloride.[6]



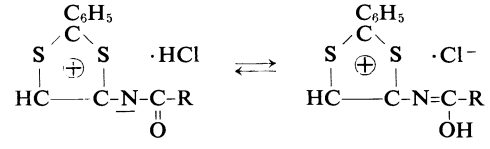
When carboxymethyl dithiobenzoate (III) was heated in acetic anhydride for several hours, a pale red substance which could not be purified was isolated. The treatment of III with acetic anhydride in the presence of triethylamine or pyridine led to tar formation.

III IV V

It is well known that acetic anhydride, in the presence of boron trifluoride, is a strong acetylating agent,[7] but the formation of a meso-ionic ring with this reagent has not been reported.

When carboxymethyl dithiobenzoate (III) was treated with acetic anhydride at 60°C in the presence of a catalytic amount of boron trifluoride etherate, a red substance with an empirical formula, $C_9H_6OS_2$, was isolated. The compound was unchanged on treatment with hot acid or cold alkali, but when treated with hot alkali it decomposed to give a substance of an unknown structure. The analytical results and the infrared spectrum of the compound suggested that it was not acetylated 2-phenyldithiolone (V), but 2-phenyldithiolone (IV). Attempts to prepare the corresponding 2-benzyl derivative were unsuccessful. The treatment of *S*-thiophenacyl thioglycolic acid with acetic anhydride, or with acetic anhydride and boron trifluoride etherate, led to tar formation. It has been expected that an increased charge distribution provided by the phenyl substituent would stabilize the dithiolone ring.

VI VII VIII



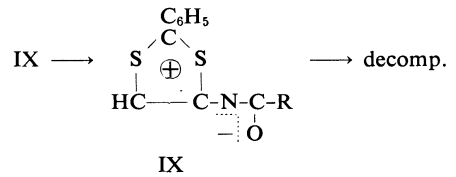
VIIa, X=$NO_3$
VIIb, X=$HSO_4$

The preparations of cyanomethyl dithiobenzoate and of 2-phenyldithiolone imine picrate, *N*-acetyl- and *N*-benzoyl-2-phenyldithiolone imine hydrochlorides were reported in a previous paper.[4]

When a benzene solution of cyanomethyl dithiobenzoate (VI) was treated with an excess of nitric acid and sulfuric acid, the nitrate (VIIa) and the hydrogen sulfate (VIIb) of 2-phenyldithiolone imine crystallized out in 50% and 60% yields respectively. The nitrate is in the form of orange plates and is slightly soluble in water, alcohol and acetone, but insoluble in benzene, ether and chloroform. Dithiolone imine salts are stable towards acids, but a trace amount of even a weak base causes its instant decomposition. An attempt to prepare the corresponding 2-benzyl derivative was unsuccessful owing to the failure to obtain cyanomethyl dithiophenylacetate.

Infrared spectra show that the cation (VII) may be considered to be an amino derivative of the pseudoaromatic ring system isosteric with the dithiolyl cation, it is probable that the phenyl substituent stabilizes the dithiolone imine salts.

By the action of acyl chlorides, e.g., propionyl chloride, (β-carbomethoxy)propionyl chloride and (δ-carbomethoxy)valerianyl chloride, upon VI, the corresponding *N*-acyl derivatives crystallized out, as in the case of benzoyl and acetyl chlorides.[4]



IX X

IXa, R=$CH_2CH_3$
IXb, R=$(CH_2)_2CO_2CH_3$
IXc, R=$(CH_2)_4CO_2CH_3$

The infrared spectrum indicates that they exist, at least in part, in the enolic forms (X).

When the *N*-acyl salts (IX) were treated with a weak base, e.g., sodium hydrogen carbonate or ammonia, free bases (XI) were formed, but when they were treated with a strong base, decomposition occurred.

* Taken on an EPI-S2 Model manufactured by Hitachi Ltd. by KBr tablets and are reported in wave numbers.
s: strong, m: middle, w: weak, br: broad

The frequencies of the infrared absorption bands of the dithiolone imine salts, related compounds and the dithiolone (IV) are shown in Table I. The spectrum of the dithiolone (IV) shows the characteristic strong bands at 1690, 1590 and 1570 $cm^{-1}$ and differs from the spectrum of carboxymethyl dithiobenzoate. The absorptions, ranging between 3000 and 2500 $cm^{-1}$, and 1710 $cm^{-1}$, due to the COOH stretching and deformation, disappear in the spectrum of the dithiolone. Bellamy suggested[8] that the C=O absorption of thiols appeared at 1680 $\pm$ 10 $cm^{-1}$ as a result of the resonance, as is shown below:

$$R\text{-}\overset{O}{\overset{\|}{C}}\text{-}S\text{-}R \longleftrightarrow R\text{-}\overset{O^-}{\overset{|}{C}}\text{=}\overset{+}{S}\text{-}R$$

Accordingly, the absorption of the dithiolone (IV) at 1690 $cm^{-1}$ may, with great certainty, be assigned to the polarized C=O band. The strong band at 1590 $cm^{-1}$ in the spectrum of carboxymethyl dithiobenzoate is assigned to a phenyl absorption. The strong band at 1570 $cm^{-1}$ may be ascribed to a vibration of the aromatic ring system which disappears in the spectrum of the dithiobenzoate (III) and is comparable with the absorption at 1520 $cm^{-1}$ in the spectra of dithiolone imine salts.

The spectra of the picrate, nitrate and hydrogen sulfate are practically identical, they all show a very strong band at ca. 1520 $cm^{-1}$. This band may be ascribed to the vibrations of the aromatic ring system and should be compared with the two strong bands of the dithiolyl cation at 1515 and 1530 $cm^{-1}$. The absorptions at 3210, 3100 and 1615—35 $cm^{-1}$ are assigned to $NH_2$ stretching and deformation frequencies, they are very similar to the absorptions of the dithiolyl salts. A characteristic feature of the spectra of *N*-acyl hydrochlorides is the appearance of broad bands at ca. 3400 $cm^{-1}$ and at 1150—75 $cm^{-1}$. These absorptions are assigned to the OH group and show that acylamino groups are present in part in the enolic form, R-C(OH)=N-. The spectra of *N*-acyl hydrochlorides also show a very strong band due to C=O stretching at 1645—75 $cm^{-1}$. The spectra of the *N*-($\beta$-carbomethoxy)propionyl and *N*-($\delta$-carbomethoxy)valerianyl hydrochlorides, show in addition, strong ester absorptions at 1725 and 1715 $cm^{-1}$ respectively.

## Experimental

**2-Phenyldithiolone (IV).**—In 100 ml. of acetic anhydride, 12.75 g. of carboxymethyl dithiobenzoate (III) was dissolved with heat; then 5 ml. of boron trifluoride etherate was added to the mixture, and the resulting mixture, was stirred for an hour below 60°C. After it had cooled, the mixture was poured onto 500 g. of ice, and the precipitate which separated out was collected, washed with water and dried. Recrystallization of the precipitate from chloroform-ether gave red needles (4.9 g., 42%), m. p. 185—186°C (decomp.).

Found: C, 55.68; H, 3.30; S, 32.73. Calcd. For $C_9H_6OS_2$: C, 55.67: H, 3.09: S, 32.91%.

**2-Phenyldithiolone Imine Nitrate (VIIa).**—The preparation of cyanomethyl dithiobenzoate was described in a previous paper.[4] Forty-eight grams of

crude cyanomethyl dithiobenzoate was dissolved in 100 ml. of benzene to a total volume of 160 ml. (solution A), and the solution was then dried over anhydrous sodium sulfate. A solution of 3.5 g. of nitric acid (65% conc.) in 10 ml. of ethanol was vigorously stirred, drop by drop, into 20 ml. of solution A while the mixture was being cooled with an ice bath, orange plates (3.9 g., 50%) crystallized out. Recrystallization from ethanol-ethyl acetate gave orange plates, m. p. 130.5°C (decomp.).

Found: C, 41.86; H, 3.18; N, 10.75. Calcd. for $C_9H_8N_2O_3S_2$: C, 42.19; H, 3.13; N, 10.94%.

**2-Phenyldithiolone Imine Hydrogen Sulfate (VIIb).**—To 20 ml. of solution A, a solution of 4.5 g. of sulfuric acid in 20 ml. of ethanol was added with vigorous shaking, the temperature of the mixture rose gradually and gave a red oil which, on cooling, gave a red precipitate. The recrystallization of the separated precipitate (5.5 g., 62%) from ethanol gave red-orange needles, m. p. 152—154°C (decomp.).

Found: C, 37.07; H, 3.52; N, 4.81. Calcd. for $C_9H_9NO_4S_3$: C, 37.11; H, 3.19; N, 4.81%.

***N*-Propionyl-2-phenyldithiolone Imine Hydrochloride (IXa).**—To 20 ml. of solution A, 4.6 g. of propionyl chloride was added drop by drop while the solution was cooled and shaken; the mixture was then kept standing for a day. The recrystallization from ethanol of the precipitate (4.7 g., 59%) gave yellow needles, m. p. 215—216°C (decomp.).

Found: C, 50.67; H, 4.28; N, 5.12. Calcd. for $C_{12}H_{12}NOS_2Cl$: C, 50.35; H, 4.20; N, 4.90%.

***N*-(β-Carbomethoxy)propionyl-2-phenyldithiolone Imine Hydrochloride (IXb).**—The treatment of 20 ml. of (β-carbomethoxy)propionyl chloride by a procedure similar to thas described above gave a yellow precipitiate (4.6 g., 49%). The recrystallization of the precipitate from ethanol gave yellow needles, m. p. 186°C (decomp.).

Found: C, 48.83; H, 4.97; N, 3.98. Calcd. for $C_{14}H_{14}NOS_2Cl$: C, 48.84; H, 4.07; N, 4.07%.

***N*-(δ-Carbomethoxy)valerianyl-2-phenyldithiolone Imine Hydrochloride (IXc).**—The recrystallization from ethanol of the yellow precipitate (3.7 g., 36%) obtained from the treatment of 20 ml. of solution A with 6.5 g. of (δ-carbomethoxy)valerianyl chloride in a procedure similar to that used in the experiment with IXa, gave yellow needles, m. p. 196°C (decomp.).

Found: C, 51.27; H, 4.84; N, 4.05. Calcd. for $C_{16}H_{18}NO_3S_2Cl$: C, 51.61; H, 4.84; N, 3.76%.

The preparations of 2-phenyldithiolone imine picrate, *N*-acetyl-2-phenyldithiolone imine and *N*-benzoyl-2-phenyldithiolone imine hydrochlorides were reported in a previous paper.[4]

# The Ionization and Dissociation of Methyl Butyl Ketones under Electron Impact.* I. Methyl *n*-Butyl Ketone and Methyl Isobutyl Ketone

By Motoyoshi HATADA and Kozo HIROTA

(Received June 26, 1964)

The method of equivalent orbitals has been applied by Hall and Lennard-Jones[1,2] to the calculation of the ionization potentials of normal paraffins; Fueki and Hirota[3] applied it to the predictions of the scission probability of each bond of normal paraffin positive ions, calculating the distribution of the positive charge over the molecular ion in the lowest ionized state. However, the order of the secular determinant which has to be solved in this method is too high for larger molecules to be solved without a computer. In the calculation of ionization potentials, Franklin[4] has simplified this problem by assuming that the molecular orbital can be set up from the united atom molecular orbitals, i.e., group orbitals, each of which represents a group of the molecule.

In the present research, calculations have been carried out in an attempt to predict the ionization potentials and the bond scission probabilities of methyl butyl ketones by assuming a wave function for each bond between the groups of the molecule. The results of the calculations have also been compared with those obtained from the mass spectra.

* A part of this paper was presented by M. Hatada and K. Hirota at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

## Experimental

**Materials.**—Two types of methyl butyl ketone and their deuterated compounds, methyl isobutyl ketone (MIBK-$d_0$) and methyl *n*-butyl ketone (MNBK-$d_0$), were obtained from the Tokyo Kasei Co. and used after drying with drierite. Methyl isobutyl ketone-1,1,1,3,3-$d_5$ (MIBK-$d_5$) and methyl *n*-butyl ketone-1,1,1,3,3-$d_5$ (MNBK-$d_5$) were prepared from the ketones by repeated exchange with deuterium oxide, followed drying with drierite and distillation. Impurities of ca. 5% were found in the samples by gas chromatographic analysis. The isotopic impurities ($d_4$) of MIBK-$d_5$ and MNBK-$d_5$ were ca. 3 and 10% respectively.

(MIBK-$d_5$)

(MNBK-$d_5$)

**The Measurement of Ionization Potentials and Mass Spectra.**—The ionization potentials as well as the mass spectra of these compounds were obtained by the use of a Hitachi RMU-5 type mass spectrometer modified for the present purpose. The mass spectrometer is a 90° sector instrument. The accelerating potential was 1500 V., and magnetic scanning was employed. The ionization potentials were determined by the linear extrapolation method, calibrated with the first ionization potential of argon (15.75 eV.). The mass spectra were obtained using bombarding electrons of 90 eV.

## Calculation

The secular equation for a molecule is:

$$|e_{ij}-\delta_{ij}E|=0$$

where $i$ and $j$ refer to various bonds between groups in the molecule, $e_{ij}$ is the matrix element which shows the interaction between the group bond orbitals, $\phi_i$ and $\phi_j$, and $E$ is the energy of the molecular orbitals, the highest of which corresponds to the lowest ionization potential of the molecule. All interactions except those of adjacent group bonds are assumed to be zero. The secular determinant for methyl-isobutyl ketone is illustrated below:

$$\begin{vmatrix} e-E & b & b & 0 & 0 & 0 \\ b & e-E & b & 0 & 0 & 0 \\ b & b & e-E & b & 0 & 0 \\ 0 & 0 & b & e-E & b & c \\ 0 & 0 & 0 & b & e-E & c \\ 0 & 0 & 0 & c & c & f-E \end{vmatrix} = 0$$

The elements in the determinant are shown in Table I. The $e$ and $b$ elements were taken to be −13.75 eV. and −1.80 eV. respectively from the values obtained by Fueki[5] for saturated hydrocarbons. The elements $c$ and $f$ were calculated from the secular equations for acetone and methyl ethyl ketone using the measured ionization potentials of these two compounds. The values of $c$ and $f$ obtained in this way are −2.626 eV. and −12.37 eV. respectively.

TABLE I

| | $C\overset{i}{-}C$ | $C\overset{i+1}{-}C$ | C-O |
|---|---|---|---|
| $C\overset{i}{-}C$ | $e$ | $b$ | $c$ |
| $C\overset{i+1}{-}C$ | $b$ | $e$ | $c$ |
| C-O | $c$ | $c$ | $f$ |

## Results and Discussion

The calculated ionization potentials of MIBK and MNBK are shown in Table II, along with the measured ones. The square of the coefficient of the group bond orbital in the highest-occupied molecular orbital is shown in Table III as an indication of the distribution of the positive charge when an electron is removed from the molecule.

TABLE II

a) J. D. Morrison and A. J. C. Nicholson, *J. Chem. Phys.*, **20**, 1021 (1952).
b) This work.

The mass spectra of MIBK, MNBK and their deuterated compounds are shown in Fig. 1. The peaks which appear in the mass spectra of MIBK can be classified into ($C_1$), ($C_2$, CO), ($C_2O$, $C_3$), ($C_4$), ($C_3O$), ($C_5O$) and ($C_6O$) groups. The sum of the relative intensities of the peaks in each group in the mass spectra of the $d_0$ compound was nearly equal to the corresponding one, as they were in those of $d_5$.

The peak of $d_0$, at $m/e=43$ which was the highest, shifted to 46 in the mass spectrum of $d_5$. Thus, this ion has been assigned to $\underline{CH_3}CO^+$, which is formed by the scission of bond 4.* Since the peak of $d_0$ at $m/e=57$ shifted to $m/e=59$, this ion is probably $(CH_3)_2CH\text{-}\underline{CH_2}^+$. The peak of $d_0$ at $m/e=58$ shifted to $m/e=63$ upon deuteration. This

ion is interpreted as $CH_3COCH_2H^+$ formed by the following hydrogen transfer reaction:

$$CH_3CH(CH_3)-CH_2-COCH_3 \longrightarrow CH_3COCH_2H^+ + CH_3CH=CH_2 + e$$

This reaction was also found by Ausloos[6] in the ionization and dissociation of methyl-*n*-propylketone-1, 1, 1, 3, 3-$d_5$. Since the peak of $d_0$ at $m/e=85$ splits into peaks of $m/e=87$ and 90 upon deuteration, this peak is interpreted as consisting of two ions which have the same mass, $\overset{+}{C}O-CH_2-CH(CH_3)_2$. and $CH_3CO-\overset{+}{C}H_2-CH(CH_3)-CH_3$. Similar results are also obtained in the cases of MNBK-$d_0$ and -$d_5$.

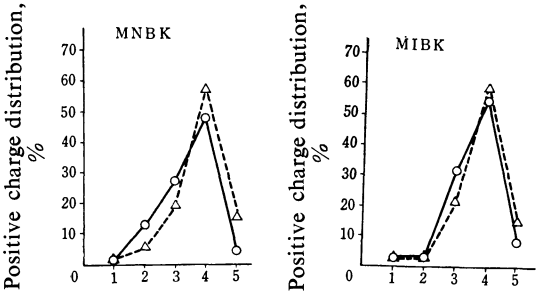

Fig. 2. Bond scission probability and positive charge distribution in MNBK and MIBK.
—○— Experimental: probability of bond scission
--△-- Theoretical: positive charge distribution

Figure 2 shows the relation between the bond scission probability and the position at which the bond scission occurs. The scission at bond 6 was excluded from the calculations, because the removal of an electron from the C=O bond was considered not to cause the scission of this bond and, actually, no scission at this bond was found in the mass spectra. Figure 2 illustrates that a close correlation exists between the measured and calculated values for MIBK and MNBK.

This paper has not described anything about the C-H bond scission, which seems to be related to the $CH_3COCH_2H^+$ formation which involves the hydrogen transfer reaction. This is a problem which will require further study.

Th authors wish to express their deep thanks to Dr. Kenji Fueki of Nagoya University for his helpful discussions concerning this research.

# A Phase Study of Sodium Soap - Sodium Silicate - Water Systems

By Yasushi KIMURA, Terunosuke SHIMO and Hitoshi SEKIGUCHI

(Received July 22, 1964)

Since it was established by McBain and his collaborators that the ordinary phase rule applies strictly to the phase diagrams of soap, various phase diagrams of soap - water or soap - alkaline electrolyte - water systems have been determined by McBain and by others.[1-3] However, the number of soap systems is so large, and the field to be covered is so extensive, that only minor portions of a few typical systems have as yet received quantitative study.[4] One of the practical industrial applications of these works is to predict the amounts of various builders which will dissolve in soaps at crutching temperatures.[3]

In the soap industry, particularly that concerned with the manufacture of commercial soaps, soap-silicate-water systems are important. However, although the amounts of silicates which can suitably be added to the soap at crutching temperatures have been known empirically for various soaps with different fatty acid compositions, these amounts have been determined incompletely from the phase-rule point of view.

Merrill,[5] using a typical commercial mixed soap and some industrially important silicates or other salts, measured the salting-out power of these salts at the arbitrarily chosen soap concentration of 24%, on the assumption that the relative efficiency is the same for different soap concentrations. However, no one has yet determined the phase behavior of the soap-silicate-water systems using a silicate and soaps with various structures and compositions.

For the purpose of supplying some date on the correlation of the suitable amounts of sodium silicate with the composition of sodium soaps, a phase study of some sodium soap - sodium silicate - water systems has been made using a silicate with a $SiO_2/Na_2O$ weight ratio of 2.1, and six single soaps or their mixtures. This report will describe the $T_c$ temperature in the systems with a 24% soap concentration, at which hydrated crystals or curd fibers change completely to liquid crystals, isotropic solutions, or both upon heating, as determined by the synthetic method.[5] The single sodium soaps used were laurate, palmitate, stearate, oleate, elaidate, and isoöleate (L). The data cover the silicate concentrations to 10 or 15%, and the temperatures to 80°C.

## Experimental

**Materials.**—*Single Soaps.*—Table I gives the properties and compositions of the methyl esters which are the raw materials of these six soaps.

Methyl laurate, palmitate, and stearate were prepared by methanolysis and subsequent fractional distillation from the corresponding reagent grade fatty acids. Methyl oleate was prepared from commercial-grade rice oil by methanolysis and fractional distillation to isolate the C-18 fraction, followed by two low-temperature crystallizations from 15 volumes of acetone at −70°C and one distillation.[6] Methyl elaidate was prepared by the elaidinization[7] of the oleate with potassium nitrite and nitric acid at 30—35°C and four low-temperature crystallizations of the reaction mixture from 10 volumes of acetone at −40°C.

Figure 1 shows the infrared spectra of methyl oleate and methyl elaidate. Methyl elaidate has a strong absorption at 10.36$\mu$, arising from a trans C=C bond ;[8] the melting point of elaidic acid prepared from methyl elaidate was found to be 43.9°C, which is in agreement with the published value of Swern.[9] Therefore, the methyl elaidate used is considered to be pure.

For the purpose of obtaining the position isomers of elaidic acid, which have a double bond in $\Delta^{11:12}$ or $\Delta^{12:13}$ and different melting points,[10] the isoöleates (S) and (L) were prepared from caster oil containing ricinoleic acid by the following procedure: the oil was hydrogenated, using methanol as the solvent and 5% of a Raney nickel catalyst at 57°C and 44 atm. The hydrogenated product, after the solvent and the catalyst, had been removed, was dehydrated with 2% of sodium bisulfate at 200°C and 100 mmHg ; the product was then separated by low-temperature fractional crystallization from the acetone solution into two fractions, one from

** Determined by gas chromatography

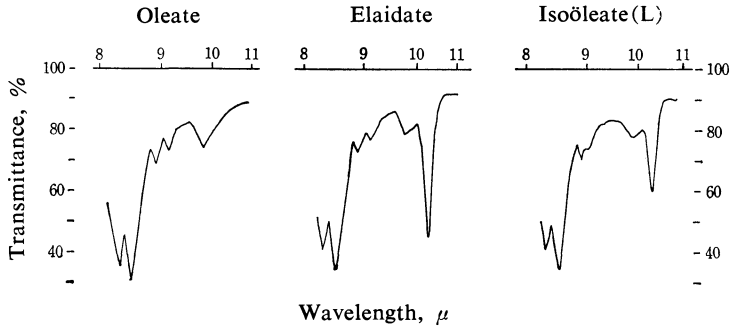

Fig. 1. Infrared absorption spectra of methyl esters of unsaturated fatty acids.

10 volumes of acetone at −30°C and the other from 15 volumes of acetone at −70°C. The solvent was removed, and, by the fractional distillation of the residues, the isoöleates (S) and (L), respectively, were obtained. However, the results of gas chromatography showed that the isoöleate (S) contains about 10% saturated ester. Therefore, this isoöleate was discarded.

Moreover, in the results of the paper chromatography of the mono-basic acids obtained by the periodate-permanganate oxidation of the isoöleate (L), contrary to expectations, it was seen that the isoöleate (L) consists of some position-isomers, $\Delta^{13:14}$ 24.4, $\Delta^{12:13}$ 18.0, $\Delta^{11:12}$ 35.9, $\Delta^{10:11}$ 14.1, and $\Delta^{9:10}$ 5.1, and the saturated 2.5%.

As Fig. 1 shows, furthermore, the isoöleate (L) has a rather weaker absorption intensity at 10.36 μ than that of elaidate; therefore, it is considered that some cis-geometrical isomers are also included.

Partially-hydrogenated commercial oils contain various isoöleates, owing to selective addition or isomerization during the hydrogenation of such elements as the isomers included in the isoöleate (L), and they are used in the manufacture of commercial soaps; therefore, this isoöleate (L) was used as one of raw materials of the soaps for the determination.

All of the single soaps were prepared by the neutralization of the fatty acids obtained from the corresponding methyl esters by saponification and subsequent acidification, and the free alkali of these soaps was adjusted to have a slight excess (less than 0.05%). The isoöleate soap, prepared from the methyl isoöleate (L) by the same procedure, is also described for the sake of convenience as a single soap in spite of its complex composition.

In the following figures, sodium soaps of laurate, palmitate, stearate, oleate, elaidate, and the isoöleate (L) are abbreviated as NaL, NaP, NaOl, NaEl, and Na*i*Ol (L) respectively.

*Two-Single Soaps and Commercial Type Soap.*—Equimolar mixtures of two-single soaps, with such combinations as saturated - saturated soaps and saturated - unsaturated soaps, were prepared from the corresponding single soaps.

A mixed soaps with almost the same composition as that of typical commercial laundry soap was prepared from sodium laurate, palmitate, oleate, and stearate in the ratio of 6.1, 32.6, 42.6, and 18.5% respectively. Hereafter, this mixed soap will simply be described as "commercial soap."

*Sodium Silicate.*—The sodium silicate of the JIS No. 1 grade of the Nihon Chemical Industry, Ltd., was used; the composition as determined by the JIS analytical method (K-1408) was 38.2% $SiO_2$ and 18.2% $Na_2O$; i.e., the $SiO_2/Na_2O$ weight ratio was 2.10.

**Procedure.**—*The Preparation of Materials.*—All date were obtained by the synthetic method,[5] consisting of observing the temperature at which phase changes occur in systems of known compositions. To facilitate the visual observation for the soap phases, the determination was made at the relatively low soap concentration of 24%.

The calculated quantities (total weight 1.65 g.) of soap, silicate, and distilled water were weighed into a 2.35-ml. stainless steel micro-autoclave in the order named. In order to transform the contents into a

single homogeneous solution, the autoclave was then heated in an electric muffle-furnace at about 210°C for a quarter hour and then quenched into ice water to settle the contents in an unseparated state. A part of the solid soap obtained, about 0.5 to 0.6 g., was taken into a 0.75-ml. glass micro-cell (inside diameter, 11 mm.; height, 8 mm.); this cell was covered with a slide glass and then sealed by epoxy adhesives (Bond-E7, Konishi Gisuke Co.).

*The Determination of the $T_c$ Temperature.*—The determination was made by using an electric oven of the hot-plate type, Model MHS-3 (Union Optical Co.), with quartz-glass windows and jackets.

The micro-cell was heated slowly in order to allow adequate time for the soap system to acquire the successive temperature, and then the determination was made of the temperature, $T_c$, at which all traces of the opaque white solid disappeared to complete the formation of an isotropic liquid, an anisotropic liquid crystalline phase, or a mixture of the two. The curve of $T_c$ values is, therefore, a solubility curve.[4] The identification of the phases in a state of equilibrium at the $T_c$ temperature was made by crossed polaroid disks.[11]

The heating rate was rather quick, about 1°C/10 min., until 2—3°C below the $T_c$ temperature; then the system was allowed to reach equilibrium, for which it took more than two hr.[11] Stirring was effected by rotating the oven as a whole slowly and frequently. When the $T_c$ temperature of the materials was lower than 30°C, the cell was dipped in ice-salt solution prior to the determination in order to transform the contents into a completely rigid solid. Moreover, the oven was kept 5°C below the $T_c$ temperature by pumping cold water or a cold salt solution through the jackets, and then the determination was started.

The $T_c$ values are reproducible to within 1°C; the values which were determined in single soap-water binary systems agreed closely with those reported by McBain and Lee,[12] who used the vapor pressure method (Table II). Temperatures were measured with a calibrated thermometer.

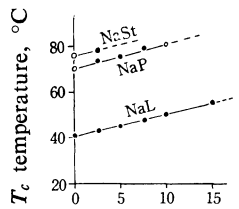

TABLE II. THE $T_c$ TEMPERATURE OF A SINGLE SOAP-WATER BINARY SYSTEM IN °C

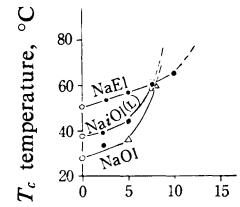
| | NaL | NaP | NaSt | NaOl |
|---|---|---|---|---|
| McBain and Lee[12] | 41.5 | 70.0 | 77.5 | 29.0 |
| The present authors | 41.0 | 72.0 | 77.0 | 28.5 |



## Results and Discussion

Figure 2 shows the effect of the silicate on the transition temperatures of these six single soaps. The effects on the equimolarly mixed soaps and on the commercial soap are shown in Figs. 3 and 4 respectively.

In the $T_c$ values for single-soap systems, there is a characteristic tendency arising from the structure of the fatty acids of the soaps. Within the range determined, the $T_c$ values for the saturated soaps are raised in proportion to the amounts of the silicate and their $T_c$ value curves are parallel. While the amount of the

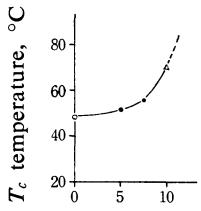

Fig. 4. The $T_c$ curve of commercial soap - silicate - water system.

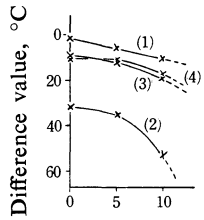
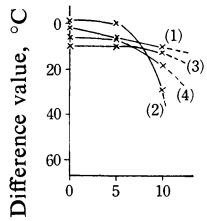


silicate in the system is small, the $T_c$ value of oleate soap is lower than any of the former, but it is elevated steeply when the concentrations of the silicate increase to more than 5%. These results agree with those of McBain et al.,[4] who found that oleate soap is salted out more easily (by sodium chloride) than are saturated fatty acid soaps.

As elaidic acid has a trans structure and its molecular form is similar to that of saturated acid, it may be assumed that the behavior of its soap, which has not yet been determined in any system, resembles that of the saturated soaps.[13] However, the $T_c$ value curve obtained was in the middle of the oleate and palmitate soaps, and that of isoöleate (L) soap, though not pure, resembles that of the oleate. It seems that the influence of the tendency to salt out of cis unsaturated soap present in small amounts is very great.

In the systems of the two-single soaps, also there is a characteristic tendency arising from three main combinations; laurate soap - palmitate soap, the said saturated soap - oleste soap, and the said saturated soap - elaidate soap. The $T_c$ value for the saturated - saturated soap systems is raised in proportion to the amounts of the silicate, as is the case with single-saturated-soap systems. The $T_c$ values for the saturated soap - oleate soap systems are raised rather steeply as the silicate contents become relatively large. In the case of the combination with laurate soap, the $T_c$ shows extremely low values with small amounts of the silicate. The $T_c$ curves for saturated soap - elaidate soap systems are similar to the curves for the saturated - saturated soaps. However, the $T_c$ curves for the saturated soap - isoöleate soap systems do not show any consistent behavior in the combinations with palmitate and with laurate.



As a rule, the $T_c$ values which have been determined in the present experiment are lower than those estimated on a molecular basis from the $T_c$ values for the ingredient soaps on the assumption that the $T_c$ value has an additive

property. The same is true also on a weight basis. These differences between determined and estimated values are shown in Fig. 5 as "difference values." It seems likely, as has been suggested previously,[2] that a less soluble soap can be prevented from separating as "curd" simply by adding it to the system of a soap with a shorter chain length. Mixed micelles of a smaller size, less orientation, and greater solubility must be produced by the presence of the shorter laurate molecules among the longer homologs, which is an example of mutual solubilization.[2] In other words, the solubility of sodium palmitate is effectively raised to near that of laurate soap by the addition of laurate soap to the system. The difference in the oleate soap - saturated soap system increases steeply when the silicate contents increase to more than 5%. This phenomenon shows that the tendency of oleate soap to salt out is substantially prevented by the saturated soap. In the commercial soap system, the $T_c$ value determined is also lower than the estimated value. This difference is shown in Fig. 6.

In the manufacture of soap, the temperature at which silicates are mixed into soaps, i.e., the crutching temperature, is about 70—80°C. In this case, for the silicate to be mixed in homogeneously the $T_c$ temperature of these systems must be lower than the crutching temperature.[3] However the $T_c$ temperature increases with the amounts of the silicates added. Therefore, the amounts of the silicates which can be added are restricted. From the findings

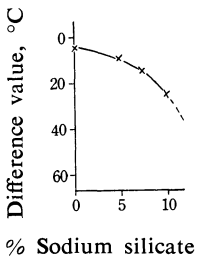

Fig. 6. The difference value curve of the commercial soap - silicate - water system.

concerning two-single soap systems, it may be concluded that, in order to increase the amounts of sodium silicate which can be added to the soap of higher saturated fatty acid, the combination with the lower saturated soap is suitable, because of the effect of lowering the $T_c$ values through the higher concentrations of the silicate (Fig. 3).

Together with the combination of soaps, the mixing ratio of the two-single-soaps also influences the $T_c$ value of two-single-soap systems greatly. This influence was determined for the ternary system of laurate roap - oleate soap - water. As Fig. 7 shows, when the substances are mixed with each other the $T_c$ value is lowered, and at an equimolar ratio the value reaches a minimum, at which it is lower than that of a single-oleate-soap system with a low $T_c$ value. This phenomenon is also due to the multiplicity of mutual effects.

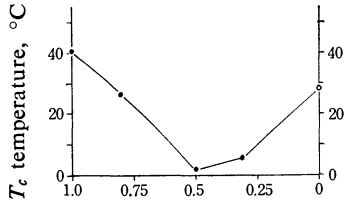

Fig. 7. Molar fraction and the $T_c$ temperature in sodium laurate - sodium oleate - water ternary system.

**Summary**

The $T_c$ temperatures of sodium soap - sodium silicate - water systems, which are important but are usually neglected, have been determined using a silicate with an $SiO_2/Na_2O$ weight ratio of 2.1, and six single soaps or their mixtures.

It has been found that there is a characteristic tendency arising from the structure of the fatty acids of the soaps, saturated (higher or lower) and unsaturated (cis or trans). The $T_c$ values of the saturated - fatty acid soap systems increase linearly in proportion to the silicate in the system. The $T_c$ value curves of the unsaturated soaps are rather complicated. Their $T_c$ values, while the contents of the silicate in the system are small, are relatively lower than those for the former, but when the silicate concentrations increase to relatively large amounts, the $T_c$ values are elevated rapidly. This inclination is more remarkable for cis unsaturated soap than for the trans isomer.

In the system of the mixed soaps, there is a complex mutual effect. By the combination with a lower saturated-soap, the solubility of the higher saturated-soap is increased, and by the combination with a saturated soap, the tendency of unsaturated soap to salt out is substantially prevented. Consequently, the rising of the $T_c$ curve for unsaturated soap becomes mild.

As a rule, the $T_c$ values determined, therefore, are lower than those estimated from the $T_c$ values for the ingredient soaps. It seems that, in order to increase the amount of builder which can be added to the soap of higher saturated-fatty acid, combination with a lower saturated-soap is suitable.

Moreover, in the case of the sodium laurate - sodium oleate - water system, it has been shown that the mixing ratio of the two-single soaps influences the $T_c$ value greatly.

# Über das Waschvermögen und die Hygroskopizität von Natriumdodecylbenzolsulfonat-Natriumsulfat-Systemen

Von Yasushi KIMURA, Syûhei TANIMORI und Terunosuke SHIMO

(Eingegangen am 11. August, 1964)

Natriumdodecylbenzolsulfonat ist als Waschmittel sowohl im Haushalt als auch in der Industrie am weitesten in Gebrauch. Die oberflächenaktiven Eigenschaften von Natriumdodecylbenzolsulfonaten werden zum grossen Teil durch die Zusammenhänge ihrer Strukturen bestimmt. Auch über die Beeinflussung des Waschvermögens durch die verschiedenen Strukturen ist bereits einiges ermittelt worden.

Alle diese Bestimmungen des Vermögens sind jedoch ausnahmslos an Baumwollgeweben mit künstlicher Beschmutzung durch Russ durchgeführt worden. Auch ist als Waschlösung, verschieden von der Praxis, im allgemeinen destilliertes Wasser gebraucht worden. Über den Tellerwaschversuch im harten Wasser durch Natriumdodecylbenzolsulfonate mit verschiedenen Strukturen konnte man noch keine Veröffentlichung finden. Ginn[1] hat von kurzem festgestellt, dass die von dem Waschvermögen stark abhängende Solubilisieraktivität wesentlich von der Wasserhärte und Builder beeinflusst worden ist. Es liess sich also erwarten, dass das Tellerwaschvermögen mit dieser Solubilisieraktivität in besonders engem Zusammenhang stehen.[1,2]

Anderseits sind die Hygroskopizität und Agglomerativität des Waschmittels auf der praktischen Anwendung der Proben sehr wichtig. Die Beeinflussung dieser beiden Eigenschaften durch die verschiedenen Strukturen der Dodecylbenzolsulfonate ist jedoch nur wenig untersucht worden, oder wenn das der Fall war, noch nicht quantitativ versucht worden.[3,4]

So hat man aus praktischen Gesichtspunkten über Natriumdodecylbenzolsulfonate mit verschiedenen Strukturen Solubilisieraktivität und Waschvermögen (im Zusammenhang mit der Härte und Buildereffekt) gearbeitet. Daneben wurden auch die Hygroskopizität und Agglomerativität von Natriumdodecylbenzolsulfonat-Natriumsulfat-Systemen untersucht.

## Materialien

**Natriumdodecylbenzolsulfonate (DBSNa)**: Es sind folgende sieben Typen davon in Gebrauch genommen;

*n-Dodecylbenzolsulfonate* (*n-DBSNa*), dargestellt vornehmlich nach Gray.[5] Reinheit von mehr als 99.8%.

*Dodecyl-6-benzolsulfonat* (*6-DBSNa*), dargestellt ebenso vornehmlich nach Gray.[5] Reinheit von mehr als 99.8%.

*sek-Dodecylbenzolsulfonat* (*Sek-DBSNa*), dargestellt durch Alkylierung von *n*-Dodecen-1 und Benzol.[6] Die Isomerenzusammensetzung: 2-, 31.9%; 3-, 19.9%; 4-, 16.2%; 5,6-, 31.8% (Die mit dem Bindungsstrich versehene Ziffer stellt die Stellung vom Benzolkern dar.).

*Dobane-JN Sulfonat* (*JN-DBSNa*), Sulfoniertensubstanz des Dodecylbenzols von linearem Typ (Dobane-JN von der Firma Shell Öl Co.).

*Alkane-56 Sulfonat* (*56-DBSNa*), Sulfoniertensubstanz des Dodecylbenzols von tetramerem Typ (Alkane-56 von der Firma Oronite Chem. Co.).

*Die zerlegten DBSNa.*[7] Das Blei Alkane-56 Sulfonat wurde durch fraktionierte Kristallisation in zwei Portionen (löslich und unlöslich) zerlegt, um die reinen Stellungsisomeren zu gewinnen. Diese Zerlegung erfolgte bei 9°C in 10 Teilen von 95%-igem Äthanol. Wobei die bei wiederholten Zerlegungen entstandenen Verhältnisse von löslich und unlöslich DBSNa 0.1 bzw 0.7 gegenüber der ursprünglichen Substanz wurden.

Aber die Bestimmungsergebnisse durch Messung ihrer Dipolmomente* und Infrarot-Spektra zeigen, dass das lösliche DBSNa ein wenig *p*-Stellungsisomer enthält.

Von hier an abbreviiert man die löslichen und unlöslichen DBSNa als FF- bzw CC-DBSNa.

**Natriumsulfat ($Na_2SO_4$).** — Natriumsulfat wurde als Reagenz gebraucht.

**Natriumtripolyphosphat (NaTPP).** — Natriumtripolyphosphat von hoher Reinheit (hergestellt von der Firma Nippon Kagaku Co., $P_2O_5$ im Gehalt von 58%), wurde gebraucht.

**Orange-OT.**—Es wurde durch Rekristallisierung von Orange-OT für spezielles Reagenz, (hergestellt von der Firma Tokyo Kasei Co.), aus 99%igem Äthanol und durch Austrocknung unter vermindertem Druck bei 50°C hergestellt.

6) A. C. Olson, *Ind. Eng. Chem.*, **52**, 833 (1960).
7) Y. Kimura, K. Ōba und M. Tobari, *Yukagaku*, **11**, 36 (1962).
* 5.20 und 5.42 $\mu$ [D] für bzw. löslich und unlöslich DBSNa in Dioxan-Lösung bei 25°C.

## Messergebnisse und Diskussionen

**Solubilisieraktivität.**—Das wurde vornehmlich nach Ginn[1] mit Orange-OT als Solubilizat bestimmt.

*Solubilisieraktivität von DBSNa in dest. Wasser.* —Zusammenhang zwischen den Konzentraten und den solubilisierten Mengen von Orange-OT durch DBSNa in 0.20%igem Natriumsulfatlösungen bei 25°C ist in Abb. 1 aufgetragen. Die solubilisierten Mengen von Orange-OT durch linearen DBSNa waren grösser als jene durch tetrameren. Die Löslichkeit von *n*-DBSNa ist sehr gering (löslich bei 25°C nur unter 0.03%). Dadurch ist die Solubilisieraktivität auch schwach, obwohl es sich um einen linearen Typ handelt.

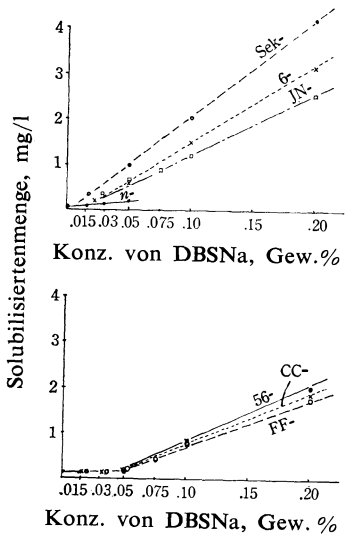

Abb. 1. Solubilisieraktivität der DBSNa für Orange-OT in 0.20%-Natriumsulfatlösung bei 25°C.
Bestimmung durch Extinktionsgrad in 498 mμ

Die kritischen Mizellbildungskonzentrationen (KMK) sind auf der Tabelle I aufgetragen. Die Erniedrigung von KMK durch Natriumsulfat, scheint bei linearem Typ grösser als bei anderen zu sein.

TABELLE I. KRITISCHE MIZELLBILDUNGSKONZENTRATION DER DBSNa
(Konzentration in Gew.%)
Bestimmung durch Solubilisierenverfahren von Orange-OT bei 25°C

| DBSNa | Dest. Wasser | 0.20% $Na_2SO_4$ Lösung |
|---|---|---|
| 6- | 0.06 | 0.01 |
| Sek- | 0.04 | 0.005 |
| JN- | 0.04 | 0.01 |
| 56- | 0.08 | 0.04 |
| CC- | 0.09 | 0.04 |
| FF- | 0.10 | 0.05 |

*Härte und Solubilisieraktivität.* — Die Solubilisieraktivität wurde in einem Bereich von 0 bis 30°dH bestimmt. Die Härte der Lösung wurde durch Kalziumchlorid eingestellt.

Die Menge von solubilisierten Orange-OT in einer Lösung mit dem Gehalt von 0.05% DBSNa und 0.20% $Na_2SO_4$ sind in Abb. 2 dargestellt. Aus diesen Diagrammen ist recht deutlich zu ersehen, dass *n*-DBSNa schwach

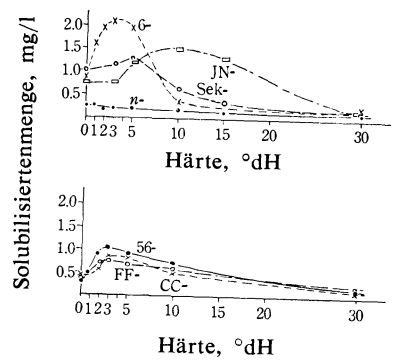

Abb. 2. Solubilisieraktivität der DBSNa bei verschiedener Wasserhärte.
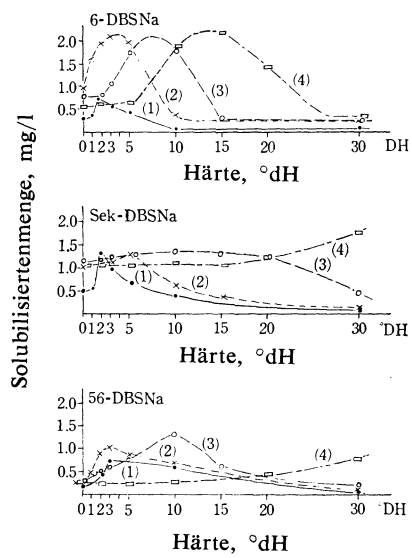
Bestimmung bei 25°C und 0—30°dH in 0.05%-DBSNa Lösungen unter Zusatz von 0.2% $Na_2SO_4$



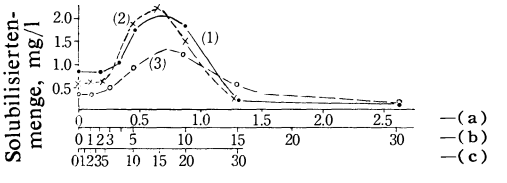


Abb. 3. Effekte von $Na_2SO_4$ und NaTPP auf Solubilisieraktivität von 6-, Sek-, und 56-DBSNa in verschiedener Wasserhärte.
(1) Nicht Builder
(2) 0.20% $Na_2SO_4$
(3) 0.03% NaTPP und 0.19% $Na_2SO_4$
(4) 0.06% NaTPP und 0.16% $Na_2SO_4$
Bestimmung bei 25°C und 0—30°dH in 0.05%-DBSNa Lösungen

löslich ist, die Solubilisieraktivität jedes einzelnen DBSNa stieg höher mit der Zunahme von Härte. Bei einer geeigneten Härte erreicht sie das Maximum und bei weit höherer Härte näherte sie sich dem Nullpunkt.

Abbildung 3 zeigt den Effekt von Natriumsulfat und NaTPP auf die Solubilisieraktivität von 6-, Sek- und 56-DBSNa. Wie aus der Abbildung ersichtlich war, falls kein Builder zugegeben wurde, lag die Solubilisiertenmenge im allgemeinen ganz niedrig. Die Menge erreichte das Maximum bei schwacher Härte und näherte sich bei weiter starker Härte schnell dem Nullpunkt. Wenn Natriumsulfat zugegeben wurde, stieg die Solubilisieraktivität bei relativ schwacher Härte an. Wenn NaTPP, das gegen Kalzium weichmachend wirkt, zugegeben wurde, ging das Maximum nach der höheren Härte über. Diese Tendenz verstärkte sich, wenn noch ein Teil des Natriumsulfat durch NaTPP ersetzt wurde. 6-DBSNa zeigt dieses Übergangsphänomen sehr deutlich. Trägt man in einem Diagramm die Solubilisieraktivität von 6-DBSNa als Ordinate gegen das Äquivalentverhältnis von Ca : NaTPP als Abszisse auf, dann ergibt sich das in Abb. 4 dargestellte Bild. Wie aus der Abb. ersichtlich ist, ist das Maximum der Solubilisieraktivität unabhängig von der Konzentration von NaTPP und DBSNa und liegt bei Äquivalentverhältnis von 0.6 bis 0.7 (Ca/NaTPP).

(a) äqui. Verh. von Ca/NaTPP
(b) °dH (NaTPP 0.03%)
(c) °dH (NaTPP 0.06%)

Abb. 4. Abhängigkeit der Solubilisieraktivität von der Äquivalentverhältnis von Ca : NaTPP, hinsichtlich 6-DBSNa.

| | DBSNa | NaTPP | $Na_2SO_4$ |
|---|---|---|---|
| (1) | 0.05% | 0.03% | 0.19% |
| (2) | 0.05 | 0.06 | 0.16 |
| (3) | 0.03 | 0.03 | 0.19 |

Bestimmung bei 25°C und 0—30°dH

Es lässt sich für diese Phänomene annehmen, dass der Mizellenaufbau sich bei der Umwandlung eines Teils von DBSNa zum Kalziumsalz verändert. Der Solubilisierungstyp von Orange-OT verändert sich auch hierbei und die solubilisierte Menge vermehrt sich.

**Härte und Waschvermögen.**—Der Waschversuch wurde an einer Glasplatte (2.5×7.5 cm) mit künstlicher Anschmutzung eines Gleichmengengemisches von Rindertalg und Sojabohnenöl in der Scrub-O-Meter-Waschmaschine bei 25°C fünf Minuten lang durchgeführt. Aus dem Wegschaffeverhätnis von Schmutz wurde das Waschvermögen bestimmt.

Die Waschlösungen enthielten 0.03% von DBSNa und 0.22% von Builder. Die Härte der Lösungen wurde durch Kalziumchlorid eingestellt. Die Ergebnisse der Bestimmungen zeigt Abb. 5. Abgesehen von *n*-DBSNa mit schwacher Löslichkeit konnte man ersehen, dass das Waschvermögen im allgemeinen in einem bestimmten Härtebereich sich vermehren liess.

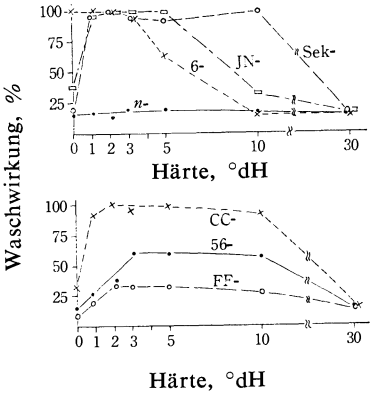

Abb. 5. Waschvermögen der DBSNa bei verschiedener Wasserhärte (I).
Bestimmung durch Glasplattenmethode nach Scrub-O-Meter bei 25°C und 0—30°dH in 0.03%-DBSNa Lösungen unter Zusatz von 0.2% $Na_2SO_4$

Wenn ein Teil von Natriumsulfat durch NaTPP ersetzt wird, so geht der verstärkte Waschvermögensbereich nach der höheren Härte über ; das Waschvermögen aber verringert

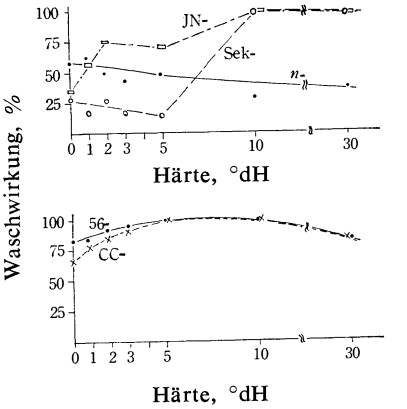

Abb. 6. Waschvermögen der DBSNa bei verschiedener Wasserhärte (II).
Bestimmung bei 25°C und 0—30°dH in 0.03%-DBSNa Lösungen unter Zusatz von 0.03% NaTPP und 0.19% $Na_2SO_4$.

sich auch nicht in der höheren Härte (Abb. 6). Daß das Waschvermögen in jedem Falle in einem bestimmten Härtebereich verbessert wird, beruht auf der Tatsache, dass die mit diesem Vermögen zusammenhängenden Faktoren,[2,8] wie Solubilisieraktivität und Suspendierbarkeit, durch die Bildung der Gemischmizelle von Natrium- und Kalziumsalz stark beeinflusst werden können. In diesem Falle wurde angenommen, dass eine optimale Grenze über die Verhältnisse zwischen diesen beiden Salzen vorhanden ist.[1] So kann man sich vorstellen, dass die Verbesserung des Waschvermögens im höheren Härtebereich durch Zugabe von NaTPP sich auf die Überführung des optimalen Härtebereich nach höherer Seite wegen der weichmachenden Wirkung von NaTPP auf hartes Wasser zurückführen lässt.

**Hygroskopizität und Agglomerativität.** — *Hygroskopizität.*—Ein Teil vom jeder der obengenannten sieben DBSNa wurde mit vier Teilen des Natriumsulfat eingemischt. Dieser wurde in einer Versuchsanlage von Scheibentyp mit Durchmesser von 1.4 m nach parallelströmenden Verfahren bei der Einlassluft-temperatur von 220 bis 230°C sprühgetrocknet.

Die Feuchtigkeit und Freifalldichte der sprühgetrockneten Proben sind auf der Tabelle II und die Teilchenverteilung auf der Tabelle III aufgetragen. In dem folgenden Hygroskopizitätsversuch wurden die Proben während einer Std. bei 110°C getrocknet.

TABELLE II. FEUCHTIGKEIT UND FREIFALLDICHTE DER SPRÜHGETROCKNETEN DBSNa

| DBSNa | Feuchtigkeit | Freifalldichte |
|---|---|---|
| *n*- | 1.6 | 0.19 |
| 6- | 3.7 | 0.24 |
| Sek- | 4.7 | 0.12 |
| JN- | | 0.20 |
| 56- | 7.4 | 0.19 |
| CC- | 3.3 | 0.22 |
| FF- | 1.6 | 0.22 |
| $Na_2SO_4$ (100%ig) | 1.2 | 0.35 |

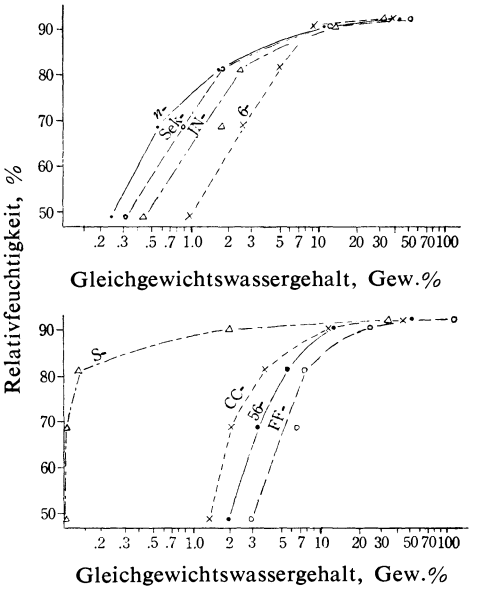

TABELLE III. TEILCHENVERTEILUNG DER SPRÜHGETROCKNETEN DBSNa (Gew.%)

| | "Mesh" | | | | |
|---|---|---|---|---|---|
| DBSNa | <28 | 28—35 | 35—60 | 60—100 | >100 |
| *n*- | 1 | 2 | 83 | 10 | 4 |
| 6- | 50 | 27 | 18 | 3 | 2 |
| Sek- | 1 | 63 | 28 | 6 | 4 |
| JN- | 6 | 39 | 45 | 6 | 4 |
| 56- | 1 | 43 | 47 | 7 | 2 |
| CC- | 7 | 40 | 44 | 6 | 3 |
| FF- | 1 | 1 | 68 | 15 | 15 |
| $Na_2SO_4$ (100%ig) | 1 | 41 | 42 | 7 | 9 |

8) A. M. Mankowich, *Ind. Eng. Chem.*, **44**, 1151 (1952).

In Reagensröhren gleicher Grösse (1.5×10 cm) wurden von jeder Proben 1.0 g eingewogen. Die Röhren wurden in jeden Exsikkatoren gestellt, in dem bei 35°C und 48.5—92% relative Luftfeuchtigkeit vorhanden war (erreicht durch 44.5—15.5 Gew.%iger Schwefelsäure). Die Gewichtszunahme wurde während zweier Monate festgestellt.

Abbildung 7 zeigt die Relativfeuchtigkeit-Gleichgewichtswassergehalt-Diagramm nach zwei Monaten.

Fbb. 7. Abhängigkeit der Relativfeuchtigkeit von der Gleichgewichtswassergehalt von DBSNa - $Na_2SO_4$-Systeme nach 2 Monat. Bestimmung bei 35°C und 48.5—92% relativer Luftfeuchtigkeit.

Es lässt sich feststellen, dass die Hygroskopizität der Proben bei 80% relative Luftfeuchtigkeit von ihren Strukturen stark beeinflusst wird. Je mehr die Alkylkette sich linear gestaltet, je ferner nach dem Kettenende der Benzolkern anhaftet, desto geringer wird das Gleichgewichtswassergehalt; d. h., *n*-DBSNa ist sehr schwach hygroskopisch und die Hygroskopizität vermehrt sich in der Folge von *n*- → Sek- → 6-DBSNa. Ebenso ist die Hygroskopizität von JN-DBSNa von mehr linearem Typ schwächer als die von 56-DBSNa von tetramerem Typ mit mehreren Verzweigästen. Wie es auch aus dem Unterschied von Löslichkeiten verstanden werden kann, ist CC-DBSNa weniger hygroskopisch als 56-DBSNa, dagegen FF-DBSNa mehr hygroskopisch.

*Agglomerativität.* — Diese wurde mit einem neuen Apparat,[9] der die Erniedrigung der Höhe des Fluidiertetbett von Waschmittelteilchen durch Agglomerieren anwendet, bestimmt. Der Apparat ist schematisch auf der Abb. 8 aufgezeichnet. Wenn die Waschmittelteilchen sich mit der feuchten Luft berühren und Wasser aufnehmen, so fangen sie an durch Adhäsion zu agglomerieren. Dadurch wachsen die Korngrössen der Teilchen, ihre Schwimmkraft dagegen verringert sich. So kann die Agglomerativität durch die Zeitabschnitte, die das Fluidierbett von Teilchen braucht bis 25% von der Initialhöhe zuerniedrigen, bestimmt werden.

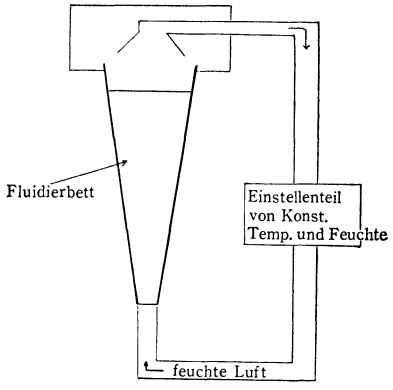

Abb. 8. Der Apparat für Bestimmung von Agglomerativität.

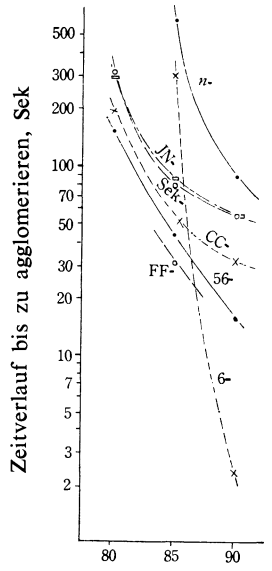

Abb. 9. Agglomerativität der sprühgetrockneten DBSNa.
Bestimmung bei 35°C und 80—90% relativer Luftfeuchtigkeit

Die Ergebnisse der Bestimmung sind in Abb. 9 aufgetragen. Da die Teilchenverteilung und Feuchtigkeit der Proben meist ungleich sind, war ein exakter Vergleich schwer durchzuführen. Da jedoch die Struktur und Zusammensetzung weit grösseren Einfluss ausgeübt haben, konnte man die Unterschiede zwischen einzelnen DBSNa deutlich beobachten.

Wie in Abb. 9 ersichtlich ist, je ferner der Benzolkern nach dem Alkylkettenende liegt, je weniger die Alkylkette einen Verzweigungsgrad hat, desto schwächer ist die Agglomerativität.

Das Bestimmungsergebnis von 6-DBSNa war fraglich, aber wegen des Materialmangels war die Wiederbestimmung nicht durchführbar.

## Zusammenfassung

Es wurde Solubilisieraktivität, Waschvermögen, Hygroskopizität und Agglomerativität von DBSNa-$Na_2SO_4$-Systemen in Abhängigkeit von der Struktur und Zusammensetzung der DBSNa untersucht.

**Solubilisieraktivität und Waschvermögen.**— Linearer Typ hat eine grössere Aktivität für Solubilisierung von Orange-OT in destilliertem Wasser als tetramerer Typ.

Kalzium übt einen starken Einfluss die Solubilisieraktivität und das Waschvermögen von allen DBSNa abgesehen von *n*-DBSNa aus. In einem geeigneten Härtebereich erreichen sie Maxima. Wenn ein Teil von Natriumsulfat durch NaTPP, welches gegen hartes Wasser weichmachend wirkt, ersetzt wird, so wird entweder das Maximum noch weiter nach höherer Härte übergeführt, oder keine Erniedrigung von Solubilisieraktivität und Waschvermögen sogar in weit höherer Härte beobachtet.

**Hygroskopizität und Agglomerativität.**—Diese beide sind ganz verschieden durch die Struktur und Zusammensetzungen des DBSNa.

Je nachdem die Stellung des Benzolkerns von dem Alkylkettenende aus sich nach der Mitte zu bewegt und je nachdem die Alkylkette mehrere Verzweigäste hat, wird die Hygroskopizität verstärkert.

Die mit einem neuen Apparat bestimmte Agglomerativität hat die gleiche Tendenz und zeigt eine deutliche Verschiedenheit durch die Struktur und Zusammensetzung von DBSNa.

Diese Abhandlung wurde aus Beiträgen[9,10] zusammengefasst.

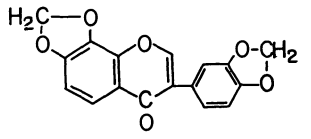
# Synthetic Studies of Sesamol Derivatives. VI.* The Synthesis of 6, 7 : 3′, 4′-Bismethylenedioxyisoflavone, an Isomer of the Maxima Substance A** and Related Compounds

By Kenji FUKUI and Takashi MATSUMOTO



(Received July 24, 1964)

The maxima substance A was isolated from the root of *Tephrosia maxima Aers.* by Rangaswami and Sastry.[1] Their degradative experiments showed it to be 6, 7 : 3′, 4′-bismethylenedioxyisoflavone (I).[2] Up to now it has been the only known naturally-occurring isoflavone containing two methylenedioxy groups in the molecule. On the basis of further experiments, Kukla and Seshadri[3] proposed the revised formula of 7, 8 : 3′, 4′-bismethylenedioxyisoflavone (II) and confirmed its structure by synthesis. However, the isoflavone I has attracted increasing attention as it belongs to the same bismethylenedioxy skeleton. The present report will describe the synthesis of I and some related isoflavones.

The Hoesch condensation of sesamol with 3, 4-methylenedioxybenzyl cyanide (III) yielded 2-hydroxy-4,5-methylenedioxyphenyl 3,4-methylenedioxybenzyl ketone (IV). By a similar Hoesch reaction employing hydroxyhydroquinone, III was converted into 2, 4, 5-trihydroxyphenyl 3, 4-methylenedioxybenzyl ketone (V). The ketone IV was also obtained by the methylenation of V with methylene sulfate. The ketone V was partially methylated with diazomethane to 2, 5-dihydroxy-4-methoxyphenyl 3, 4-methylenedioxybenzyl ketone (VI), and with dimethyl sulfate to 2-hydroxy-4, 5-dimethoxyphenyl 3, 4-methylenedioxybenzyl ketone (VII). On cyclization with ethyl orthoformate, IV afforded 6, 7 : 3′, 4′-bismethylenedioxyisoflavone (I), the melting point, of which 254—255°C, differed from the reported one, 227—229°C,[1,3] of the natural maxima substance A.

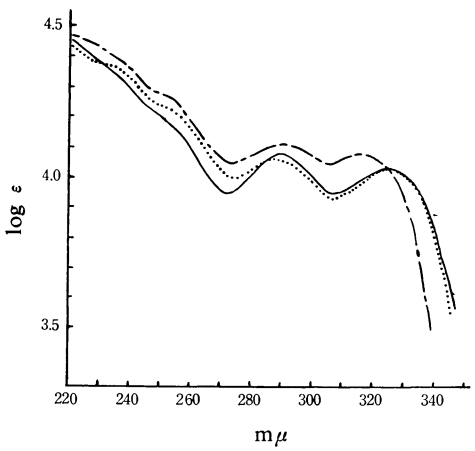

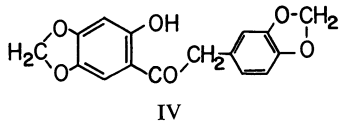

Fig. 3. Ultraviolet spectra of XIII(—), XV(···) and XVI(--) in ethanol.

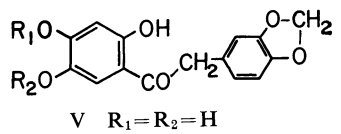

By a similar reaction, the ketones V, VI and VII were converted into 6,7-dihydroxy- (VIII), 6-hydroxy-7-methoxy- (IX) and 6,7-dimethoxy-3',4'-methylenedioxyisoflavone (X) respectively. X was also obtained by the methylation of VIII or IX with dimethyl sulfate.

The reaction of the ketone IV with acetic anhydride in the presence of sodium acetate[4] gave a 2-methyl derivative (XI) of the isoflavone I. 2-Methylisoflavone XI was also obtained from V by the following process. The reaction of V with acetic anhydride gave a cyclized diacetate XII which could easily be

hydrolyzed to 6, 7-dihydroxy-3', 4'-methylenedioxy-2-methylisoflavone (XIII) under mild conditions. The methylenation of XIII with methylene sulfate afforded XI. A similar acetylation of VI gave a cyclized acetate XIV which could be converted into 6-hydroxy-7-methoxy-3', 4'-methylenedioxy-2-methylisoflavone (XV) by alkaline hydrolysis. XIII and XV were methylated with dimethyl sulfate to 6, 7-dimethoxy-3', 4'-methylenedioxy-2-methylisoflavone (XVI), which was then changed to the ketone VII by the alkaline hydrolysis.

The ultraviolet absorption spectra of these synthetic isoflavones are recorded in Figs. 1—3 and Table I.

In most cases there are three characteristic peaks, at ca. 265 (band I), ca. 295 (band II) and ca. 325 m$\mu$ (band III). The methylation of the 6-position (IX—X and XV—XVI) or the and 6-7-positions (VIII—X and XIII—XVI) has little effect on bands I and II, but it causes a hypsochromic shift of 8—9 m$\mu$ in band III, as has been reported previously.[5] A similar shift (6 m$\mu$) in band III is also observed by the methylenation of two vicinal hydroxy groups (VIII—I and XIII—XI). The replacement of the 2-position with a methyl unit causes a displacement (4—5 m$\mu$) of bands II and III towards a shorter wave length.

## Experimental***

**2, 4, 5-Trihydroxyphenyl 3, 4-Methylenedioxybenzyl Ketone (V).**—A mixture of hydroxyhydroquinone (50 g.), 3, 4-methylenedioxybenzyl cyanide (6.5 g.) and anhydrous zinc chloride (3.0 g.) in dry ether (5.0 ml.) was saturated with dried hydrogen chloride in an ice bath and allowed to stand overnight. The ether solution was then decanted from the ketimine hydrochloride which had separated. The residue was heated on a steam bath in water (30 ml.) for 1 hr. The precipitates were collected, washed with water, and recrystallized from aqueous methanol to give V; m. p. 206—208°C (yellow needles); yield, 4.9 g. It gave a dark green color with an alcoholic ferric chloride solution and was soluble in an aqueous potassium carbonate solution. UV $\lambda_{max}^{EtOH}$ m$\mu$ (log $\varepsilon$): 241 (4.13), 287 (4.13), 354 (3.89).

Found: C, 62.29; H, 4.31. Calcd. for $C_{15}H_{12}O_6$: C, 62.50; H, 4.20%.

**2-Hydroxy-4, 5-methylenedioxyphenyl 3, 4-Methylenedioxybenzyl Ketone (IV).**—*From Sesamol.*—A mixture of sesamol (11.0 g.), 3, 4-methylenedioxybenzyl cyanide (13.0 g.) and anhydrous zinc chloride (6.0 g.) in dry ether (150 ml.) was treated with a method similar to that used for V. The product was recrystallized from acetone to give IV; m. p. 172—173°C (yellow needles); yield, 3.0 g. It gave a green color with an alcoholic ferric chloride solution. IR: 1636 (C=O), 1031 (=C-O-C), 916 cm$^{-1}$ (O-$CH_2$-O). UV $\lambda_{max}^{EtOH}$ m$\mu$ (log $\varepsilon$): 240 (4.24), 281 (3.98), 353 (3.96).

Found: C, 64.08; H, 4.15. Calcd. for $C_{16}H_{12}O_6$: C, 64.00; H, 4.03%.

*From V.*—Into a mixture of the ketone V (1.1 g.), ethanol (10 ml.) and potassium hydroxide (1.4 g.) in water (10 ml.), air being excluded by a current of nitrogen, methylene sulfate (0.9 g.) in acetone (15 ml.) was stirred at 45—50°C. After the stirring had been continued another 70 min., the solvent was removed in vacuo. After the residue had been dissolved in water, the solution was saturated with carbon dioxide. The brown precipitates were collected, washed with water, and recrystallized from aqueous acetone to give IV; m. p. 172—173°C (yellow needles); yield, 100 mg. This substance was identified with the above sample by a mixed fusion and a comparison of the infrared spectra.

**6, 7 : 3', 4'-Bismethylenedioxyisoflavone (I).** — A mixture of the ketone IV (1.5 g.), freshly-distilled ethyl orthoformate (5.0 ml.), dry pyridine (6.0 ml.) and piperidine (1.0 ml.) was refluxed for 8 hr. The crystals which separated on cooling were recrystallized from acetic acid to give I; m. p. 254—255°C (colorless needles); yield, 1.1 g. This substance was soluble in concentrated sulfuric acid to a green solution. IR: 1641 (C=O), 1037 (=C-O-C), 931 cm$^{-1}$ (O-$CH_2$-O).

Found: C, 65.90; H, 3.50. Calcd. for $C_{17}H_{10}O_6$: C, 65.81; H, 3.25%.

**2, 5-Dihydroxy-4-methoxyphenyl 3, 4-Methylenedioxybenzyl Ketone (VI).** — To a solution of the ketone V (1.0 g.) in acetone (30 ml.) was added an ethereal diazomethane solution; the mixture was then allowed to stand overnight at room temperature. After the excess diazomethane had been destroyed with acetic acid, the solvent was evaporated and the residue was recrystallized from methanol to give VI; m. p. 194—196°C (pale yellow needles); yield, 0.8 g.. It gave a green color with an alcoholic ferric chloride solution. UV $\lambda_{max}^{EtOH}$ m$\mu$ (log $\varepsilon$): 240 (4.17), 283.5 (4.10), 355 (3.77).

Found: C, 63.39; H, 4.86. Calcd. for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67%.

**2-Hydroxy-4, 5-dimethoxyphenyl 3, 4-Methylenedioxybenzyl Ketone (VII).** — A mixture of the ketone V (230 mg.), anhydrous potassium carbonate (3.0 g.) and dimethyl sulfate (0.2 ml.) in anhydrous acetone (40 ml.) was refluxed for 6 hr. The reaction mixture was then treated in a usual manner. Recrystallization from aqueous acetone give VII in the form of colorless plates; m. p. 153—154°C; yield, 100 mg. It gave a green color with an alcoholic ferric chloride solution. IR: 1625 (C=O), 1033 (=C-O-C), 920 cm$^{-1}$ (O-$CH_2$-O). UV $\lambda_{max}^{EtOH}$ m$\mu$ (log $\varepsilon$): 237.5 (4.24), 280 (4.12), 346 (3.92).

Found: C, 65.41; H, 4.94. Calcd. for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10%.

**6, 7-Dihydroxy-3', 4'-methylenedioxyisoflavone (VIII).** — A mixture of the ketone V (800 mg.), ethyl orthoformate (2.0 ml.), dry pyridine (2.0 ml.) and piperidine (0.3 ml.) was refluxed for 4 hr.

5) K. Fukui and T. Matsumoto, *J. Sci. Hiroshima Univ., Ser. A-II*, **28**, 47 (1964).

*** All melting points are uncorrected. The infrared spectra were measured in Nujol.

The reaction mixture was then poured into dilute hydrochloric acid. The precipitates were collected, washed with water, and recrystallized from aqueous pyridine to give VIII; m. p. 308—310°C (decomp.) (colorless needles); yield, 380 mg. It gave a green color with an alcoholic ferric chloride solution and was soluble in concentrated sulfuric acid to a green solution and in an aqueous sodium carbonate solution to a yellow solution.

Found: C, 64.55; H, 3.55. Calcd. for $C_{16}H_{10}O_6$: C, 64.43; H, 3.38%.

The diacetate was prepared by the pyridine-acetic anhydride method; m. p. 190.5—191.5°C (colorless needles). UV: $\lambda_{max}^{EtOH}$ mμ (log ε): 263 (4.31), 293 (4.14).

Found: C, 63.01; H, 3.88. Calcd. for $C_{20}H_{14}O_8$: C, 62.83; H, 3.69%.

**6-Hydroxy-7-methoxy-3′, 4′-methylenedioxyisoflavone (IX).** — From the ketone VI (1.2 g.), ethyl orthoformate (3.0 ml.), dry pyridine (4.0 ml.) and piperidine (1.0 ml.), synthesis was carried out by a method similar to that used for I. Recrystallization from aqueous pyridine yielded IX; m. p. 250—252°C (colorless needles); yield, 0.5 g. It gave a negative color with an alcoholic ferric chloride solution and was soluble in concentrated sulfuric acid to a green solution.

Found: C, 65.05; H, 3.88. Calcd. for $C_{17}H_{12}O_6$: C, 65.38; H, 3.87%.

**6, 7-Dimethoxy-3′, 4′-methylenedioxyisoflavone (X).**—*From IX.* — A mixture of the isoflavone IX (200 mg.), anhydrous potassium carbonate (5.0 g.) and dimethyl sulfate (0.2 ml.) in dry acetone (100 ml.) was refluxed for 20 hr. The product was recrystallized from aqueous acetic acid to give X; m. p. 237—238°C (colorless needles); yield, 170 mg. It was soluble in concentrated sulfuric acid to a green solution. IR: 1644 (C=O), 1033 (=C-O-C), 926 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 66.34; H, 4.60. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

*From VIII.* — A mixture of the isoflavone VIII (100 mg.), anhydrous potassium carbonate (5.0 g.) and dimethyl sulfate (0.2 ml.) in dry acetone (100 ml.) was treated in a method similar to that used above. Recrystallization from aqueous acetic acid yielded X; m. p. 236—237°C (colorless needles). This substance was identified with the above sample by mixed fusion and a comparison of the infrared spectra.

*From VII.*—A mixture of the ketone VII (0.9 g.), ethyl orthoformate (3.0 ml.), pyridine (4.0 ml.) and piperidine (0.5 ml.) was treated in a method similar to that used for I. Recrystallization from acetone yielded X; m. p. 237—238°C (colorless needles); yield, 0.3 g. This was identical with the above sample.

**6, 7-Diacetoxy-3′, 4′-methylenedioxy-2-methylisoflavone (XII).** — A mixture of the ketone V (4.0 g.) and anhydrous sodium acetate (7.0 g.) in acetic anhydride (70 ml.) was refluxed for 16 hr., and then the excess acetic anhydride was removed in vacuo. The residue was washed with water and recrystallized from methanol to give XII; m. p. 146—147°C (colorless needles); yield, 4.2 g..

Found: C, 63.77; H, 4.27. Calcd. for $C_{21}H_{16}O_8$: C, 63.63; H, 4.07%.

**6,7-Dihydroxy-3′,4′-methylenedioxy-2-methylisoflavone (XIII).**—A mixture of the diacetate XII (3.8 g.), sodium hydroxide (1.2 g.), water (5.0 ml.) and methanol (80 ml.) was refluxed for 30 min.

After the solvent had been distilled off in vacuo, the residue was dissolved into water and the solution was acidified. The precipitates were collected, washed with water, and then recrystallized from ethanol to give XIII; m. p. 293—294°C (colorless needles); yield, 2.8 g. It gave a green color with an alcoholic ferric chloride solution and was soluble in aqueous sodium carbonate to a yellow solution.

Found: C, 65.14; H, 4.07. Calcd. for $C_{17}H_{12}O_6$: C, 65.38; H, 3.87%.

**6,7 : 3′,4′-Bismethylenedioxy-2-methylisoflavone (XI).**—*From IV.*—From a mixture of the ketone IV (600 mg.) and anhydrous sodium acetate (0.8 g.) in acetic anhydride (10 ml.), synthesis was carried out by a method similar to that used for XII. Recrystallization from aqueous acetic acid gave XI; m. p. 219—220°C (colorless needles); yield, 450 mg.. It was soluble in concentrated sulfuric acid to a green solution. IR: 1637(C=O), 1037 (=C-O-C), 934 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 66.59; H, 3.70. Calcd. for $C_{18}H_{12}O_6$: C, 66.67; H, 3.73%.

*From XIII.* — From a mixture of the isoflavone XIII (1.0 g.), potassium hydroxide (680 mg.), ethanol (10 ml.), water (10 ml.) and methylene sulfate (650 mg.) in acetone (15 ml.), synthesis was carried out by a method similar to that used for IV. The product was recrystallized from aqueous acetic acid to give XI; m. p. 218—219°C (colorless needles); yield, 160 mg. It was identified with the above sample by mixed fusion and a comparison of the infrared spectra.

**6-Acetoxy-7-methoxy-3′, 4′-methylenedioxy-2-methylisoflavone (XIV).** — From the ketone VI (1.8 g.), anhydrous sodium acetate (5.0 g.) and acetic anhydride (50 ml.), synthesis was carried out by a method similar to that used for XII. Recrystallization from aqueous acetone gave XIV; m. p. 217—218°C (colorless needles); yield, 1.6 g.

Found: C, 65.17; H, 4.36. Calcd. for $C_{20}H_{16}O_7$: C, 65.21; H, 4.38%.

**6-Hydroxy-7-methoxy-3′,4′-methylenedioxy-2-methylisoflavone (XV).**—From the isoflavone XIV (1.1 g.), sodium hydroxide (0.5 g.), water (5.0 ml.) and ethanol (100 ml.), reaction was carried out by a method similar to that used for XIII. Recrystallization from aqueous pyridine gave XV; m. p. 244—245°C (colorless prisms); yield, 0.9 g. It was soluble in concentrated sulfuric acid to a green solution.

Found: C, 66.10; H, 4.39. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

**6,7-Dimethoxy-3′,4′-methylenedioxy-2-methylisoflavone (XVI).**—*From XIII.*—A mixture of the isoflavone XIII (2.0 g.), anhydrous potassium carbonate (15.0 g.), dimethyl sulfate (4.0 ml.) and dry acetone (190 ml.) was treated by a method similar to that used for VII. Recrystallization from ethanol gave XVI; m. p. 214.5—215°C (colorless microneedles); yield, 2.1 g. IR: 1639

(C=O), 1026 (=C-O-C), 921 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 67.02; H, 4.51. Calcd. for $C_{19}H_{16}O_6$: C, 67.05; H, 4.75%.

*From XV.* — The methylation of isoflavone XV (470 mg.) was carried out by the same procedure; yield, 430 mg.

A mixture of the isoflavone XVI (1.5 g.), sodium hydroxide (1.5 g.), water (10 ml.) and ethanol (150 ml.) was refluxed for 2 hr. under the stream of nitrogen. After the solvent had been removed in vacuo, the residue was dissolved in water and the solution was acidified. The precipitates were collected, washed with water, and recrystallized from aqueous acetone to give colorless plates; m. p. 153—154°C; yield, 1.3 g. This substance was identified with VII by mixed fusion and a comparison of the infrared spectra.

# Gamma-ray Spectrometry in Radioactivation Analysis with 14 MeV. Neutrons

By Yuzuru KUSAKA, Haruo TSUJI, Isao FUJII, Haruo MUTO and Katsuhiko MIYOSHI

(Received July 25, 1964)

A commercial small-type neutron generator producing 14 MeV. neutrons is becoming popular as a neutron source for the radioactivation analysis of various elements.[1-4] For the practical application of such a neutron generator, however, it is important to determine the analytical sensitivities of various elements under definite experimental conditions. Kusaka et al. reported some experimental results on analytical sensitivities obtained by a gross gamma-ray counting method for the induced radioactivities.[5]

This paper will describe the experimental results concerning the sensitivity obtained by gamma ray spectrometry and will show the gamma ray spectra of 37 elements. All the data are normalized to definite experimental conditions so that they can be compared with each other.

## Experimental

**Neutron Source.** — Monochromatic 14 MeV. neutrons were produced by T-d reaction in a Toshiba Neutron Generator, Model NT-20, in which a thin tritiated titanium target (4 curies; Isotope Div., Harwell, England) was bombarded with a deuteron beam of about 100 $\mu$amp. and 150 to 200 KeV. A target assembly with a sample station for neutron irradiation, similar to that described by Fujii et al.,[3] was used.

The neutron output during the irradiation of a sample was kept constant as far as possible by regulating the accelerating or extraction voltage in the generator. The output was continuously recorded by a plastic neutron scintillator which was set at a definite position below the drift tube of the generator and which was then connected to a counting-rate meter set near the operator. The absolute value of the neutron flux at the irradiation position was determined by the method of activating copper foil, the beta activity of which was measured by a $4\pi$ gas-flow counter using Q gas.

**The Sample Transfer System and Neutron Irradiation.** — Samples were packed tightly in cylindrical polyethylene containers (4.5 cm. long, 1.3 cm. i. d., 0.1 cm. thick). These "bunny" capsules were then transferred through a pneumatic tube system, operated by a vacuum cleaner blower (500 W.), between the irradiation position and the radioactivity detector. At the end of 10.0 min. of irradiation, the sample transfer system was turned on to bring the sample capsule back to the well of the scintillation detector. The average travel time of the capsule was 3.0 sec.

**Radioactivity Measurement.** — The radioactivity of the sample was measured by a shielded well-type sodium iodide scintillation detector (Harshow; 4.45

cm. diameter, 5.08 cm. height, well: 1.91 cm. diameter, 3.81 cm. deep) mounted on a photomultiplier tube (Toshiba-7696) and connected in turn to a Toshiba 128 channel pulse-height analyzer. The resolution of the detector for 0.662 MeV. $^{137}Cs$ gammas was about 12%.

The countings were started 5.0 sec. after irradiation and were stored for 1.0 min. However, the samples containing oxygen were started after 1.0 min., it being necessary to eliminate the influence of the $^{16}N$ produced by the (n, p) reaction on oxygen.

Using the mean value of neutron flux observed during the irradiation, the counting data obtained were normalized to a standard neutron flux of $1.0 \times 10^7$ neutrons per $cm^2$ per sec.

**Irradiation Sample.**—Inside the "bunny" capsule definite amounts of the sample powder mixed with pure carbon powder were packed in a definite volume (1.3 cm. diameter, 2.0 cm. long).

The chemical forms of the samples were as follows: the elements of silver, aluminum, gold, calcium, cadmium, cobalt, chromium, copper, iron, germanium, hafnium, indium, lead, magnesium, manganese, molybdenum, nickel, phosphorus, sulfur, antimony, selenium, silicon, tantalum, tin, titanium, tungsten, zinc and zirconium; the oxides of arsenic, cerium, dysprosium, gallium, gadolinium, erbium, holmium, mercury, lanthanum, praseodymium, samarium, vanadium, yttrium and ytterbium; the carbonates of potassium, sodium and rubidium; the acetates of barium and strontium; fluorine as polytetrafluoroethylene; bromine as dibromobenzene; chlorine as benzene hexachloride; nitrogen as ammonium nitrate, and oxygen as oxalic acid.

## Results

**The Gamma-ray Spectra of the Radioactive Nuclides Produced by 14 MeV. Neutron Reaction.**—The spectra obtained for each element were compared under normalized conditions; weight of sample: 1.0 g. as element; irradiation time: 10.0 min.; neutron flux: $1.0 \times 10^7$ neutrons per $cm^2$ per sec.; counting time: 1.0 min. from the end of irradiation. The results are shown in Figs. 1—38, in which the photopeaks available for the activation analysis are marked with the energies and the nuclides produced. The figures are arranged in the order of the magnitude of the photopeak area, that is, of the sensitivity of the activation analysis.

In the cases of sulfur, chlorine, calcium, titanium, indium, tin, lanthanum, gadolinium, dysprosium, holmium, erbium, ytterbium, and tantalum, no photopeaks usable for the effective activation analysis appeared in the experiments.

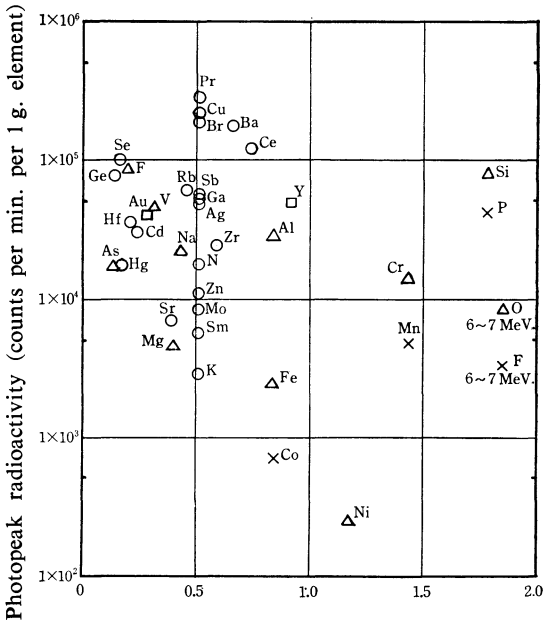

Fig. 39. Sensitivity of gamma-ray spectrometry in 14 MeV. neutron activation analysis.
○: $(n, 2n)$ reaction ×: $(n, \alpha)$ reaction
△: $(n, p)$ reaction □: $(n, n')$ reaction

**The Sensitivity of Gamma-Ray Spectrometry.** —The sensitivity of the analysis can be expressed with the photopeak radioactivity strength, which is obtained by drawing a straight line across the bottom of the peak in the spectrum and by summing up the counts above the line. The values for each element have been summarized in a graphic form and are shown in Fig. 39, in which the photopeak activity is marked with the target element and the kind of the nuclear reaction is plotted against the gamma-ray energy.

It may be possible to improve the sensitivities by using such things as more sensitive detectors, but these plots can give a general impression of the relative sensitivities in the 14 MeV. neutron activation analysis.

The authors wish to thank Dr. Kazunori Yuasa, Mr. Bunzaburo Saeki and Mr. Yoshinao Fujiwara of the Department of Physics, Konan University, for their kind and valuable advice through this study.

# The Spectrophotometric Determination of Gallium(III) with Xylenol Orange[1]

By Makoto Otomo*

(Received October 21, 1964)

The color reaction between gallium(III) and xylenol orange [bis-di(carboxymethyl)-aminomethyl-*o*-cresolsulfonephthalein] was first studied by Přibil and Kopanica,[2] who used the reagent for the detection of traces of gallium in the presence of ammonium fluoride and triethanolamine, which served as masking agents for other metal cations. The quantitative determination of gallium based on this reaction has not yet, however, been reported by any workers. It has only been disclosed that, depending on the pH value of the solution, gallium(III) reacts with xylenol orange to form two complexes, with metal-ligand ratios of 1 to 1 and 1 to 2. These reactions are applicable to the spectrophotometric determination of up to 60 $\mu$g. of gallium in 25 ml.

## Experimental

**Reagents.**—*Standard Gallium Solution.*—A standard gallium(III) solution was prepared by dissolving 0.6980 g. of pure gallium metal (99.999% pure) in dilute sulfuric acid and then diluting it with water to 1 l. The concentration of sulfuric acid in this solution was about 0.05 M. Working solutions of gallium were prepared by diluting the standard solution with water.

*Xylenol Orange Solution.*—A $1 \times 10^{-3}$ M xylenol orange solution was prepared by dissolving the Dotite XO reagent (disodium salt), which was used without further purification, in distilled water.

Nitric acid or a mixture of 0.5 M acetic acid and a 0.5 M sodium acetate solution was used for the regulation of the pH value. The former was used for pH values below 2, and the latter for pH values above 2.5. Solutions of diverse ions were prepared by dissolving the respective compounds (all reagent-grade chemicals) in distilled water in appropriate concentrations.

**Apparatus.**—A Hitachi spectrophotometer, model EPV-2, was employed, with 1 cm. cells, for all the absorbance measurements. A Shimadzu glass-electrode pH meter, model GU-1, was employed for all the pH determinations.

**The Standard Procedure for the Determination.**—To a sample solution containing gallium in a 50-ml. Erlenmeyer flask, a desired amount of nitric acid or 5 ml. of the acetate buffer, a given amount of the xylenol orange solution and a small amount of water were added to make the solution about 20 ml. when the sample solution contained aluminum(III), thorium(IV) or zirconium(IV), about 60 $\mu$mol. of potassium fluoride was added before the addition of the xylenol orange solution. The solution was heated in a boiling water bath for a few minutes, cooled with running water, transferred

to a 25 ml. volumetric flask and diluted with water to the mark. The resulting solution was kept for about 30 min. in a thermostat at 25 ± 0.5°C. The absorbance of the solution was then measured at the given wavelengths.

## Results and Discussion

**Absorption Curves.**—The visual absorption curves of the gallium - xylenol orange mixture at different pH values are shown in Figs. 1 and 2. These curves were obtained by measuring the absorbance of the colored solutions containing 34.9 μg. of gallium against a reagent blank containing the same amount of xylenol orange. Between pH 0.9 and 1.4, the solutions give identical absorption curves, with one absorption maximum at 530 mμ. Above pH 2, the position of the maximum absorption shifts toward shorter wavelengths with an increase in the pH value. The curves obtained at pH 2.0 and 2.5 have a shoulder at about 545 mμ. Between pH 3.0 and 5.5, however, the solutions again give identical absorption curves, with one absorption maximum at 502 mμ. The slight blue shift in the position of the absorption maximum which was observed at pH 6.1 seems to be caused by the contribution of the absorption by the reagent blank, which absorbs strongly in the wavelength range from 510 to 600 mμ and which decreases its absorbance at shorter wavelengths over pH 6.0. Therefore, it may be concluded that, in the presence of an excess of xylenol orange, two complexes are formed between gallium and xylenol orange.

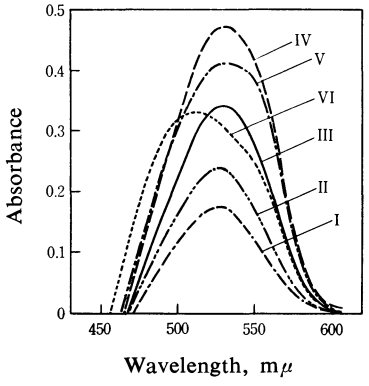

Fig. 1. Absorption curves of Ga-XO in the pH value range from 0.9 to 2.5.

**The Effect of pH.**—The effect of pH on the absorbance of the solution was examined by measuring, at two wavelengths, 530 and 502 mμ, the absorbance of a solution containing 34.9 μg. of gallium and 4 ml. of a $1\times10^{-3}$ M solution of xylenol orange. From the curves shown in Fig. 3, it was found that the maximum absorbance is obtained in the pH value range from 1.2 to 1.7 when measured at 530 mμ and from 4.5 to 5.5 when measured at 502 mμ.

Ga: 34.9 μg., XO: $1.57\times10^{-4}$ M
Reference: a reagent blank
I: at 530 mμ, II: at 502 mμ

**The Effect of the Amount of Xylenol Orange.**—The effect of the reagent concentration was studied with solutions containing a given amount of gallium and varying amounts of a

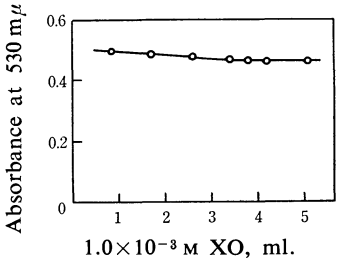

Fig. 4. Effect of amount of XO.
Ga: 34.9 μg., pH: 1.5
Reference: a reagent blank

$1 \times 10^{-3}$ M solution of xylenol orange. The pH values of the solutions were kept constant at 1.5, and the absorbance measurements were carried out at 530 mμ. The results are shown in Fig. 4. A constant absorbance is obtained when 3.5 to 5 ml. of the reagent solution is used. Therefore, 4 ml. of the reagent solution was used in further experiments.

**The Stability of the Color.**—The color formation does not occur instantaneously at room temperature. However, it is greatly accerelated by heating; the maximum color development is attained within only a few minutes when the mixture is heated in a boiling water bath. The absorbance remains almost constant for at least 6 hr. after preparation at pH 1.5 and for about 1.5 hr. when prepared at pH 5.5.

**Calibration Curves for the Gallium Determination.**—The calibration curves for the gallium determination were prepared in the manner described above with solutions containing no fluoride or 60 μmol. of fluoride. In all three curves shown in Fig. 5, linear relationships between absorbance and concentration are found to hold up to 60 μg. of gallium in 25 ml.

The apparent molar extinction coefficients of the two complexes, which were calculated from curves I and III, were found to be 22900 and 16300 respectively. According to Sandell's notation,[3] the sensitivities of the reactions are 0.003 μg. of gallium per $cm^2$ at 530 mμ and 0.004 μg. of gallium per $cm^2$ at 502 mμ.

**The Effect of Diverse Ions.**—The effect of diverse ions on the determination of gallium was then examined with the complex formed at pH 1.5, and the tolerance limit was calculated in each case. The tolerance limit was tentatively defined as the concentration of the foreign ion which affects the absorbance of the system by less than ± 3%. The results are summarized in Table I, from which it may be seen that bismuth(III), iron(III), thorium(IV) and ethylenediaminetetraacetic acid(EDTA)

interfere in even the smallest concentrations examined, but that some interfering cations, including aluminum(III), thorium(IV) and zirconium(IV), are partly masked by adding 60 $\mu$mol. of potassium fluoride. The interference of iron(III), palladium(II) and thallium(III) can be eliminated by the addition of such a reducing agent as ascorbic acid or sodium sulfite.

**Comparison with Other Methods.**—Some sensitive reagents, including rhodamine B,[4] 5,7-dichloro-8-oxine,[5] 2-(2-hydroxy-3-chloro-5-nitrophenylazo)-1-hydroxy-8-aminonaphthalene-3,6-disulfonic acid,[6] rhodamine 6G,[7] 3,4-dihydroxybenzene-4-arsonic acid (stilbazo),[8] 2,2',4'-trihydroxy-5-chloroazobenzene-3-sulfonic acid (luminogallion IREA),[9] quercetin[10] and 1-(2-pyridylazo)-2-naphthol[11] (PAN) have been used for the determination of gallium. These reagents, except stilbazo and PAN, have been used as spectrofluorometric reagents for gallium. Of the reagents which react with gallium to form water-soluble complexes, stilbazo is found to be the most sensitive to gallium. The present method using xylenol orange is very sensitive and is comparable with the stilbazo or the luminogallion IREA method in sensitivity.

**The Compositions of the Complexes.**—The compositions of the two complexes were determined by the following two methods. The method developed by Frank and Oswalt[12] and by Furman and Garner[13] was employed for determining the composition of the complex with an absorption maximum at 530 m$\mu$, and the competing equilibrium method was employed for determining that with an absorption maximum at 502 m$\mu$.

**The Complex with Its Absorption Maximum at 530 m$\mu$.**—An attempt to discover the composition was made with solutions with a given molar concentration of gallium at a given pH value, but with varying xylenol orange concentrations. If only a 1 to 1 complex is formed under certain conditions, and the absorbance, $D$, is measured against a reagent blank, the following relationship may be derived:

$$ab/D=(a+b)/(\varepsilon_C-\varepsilon_{XO})+1/K'_1(\varepsilon_C-\varepsilon_{XO}) \quad (1)$$

where $a$ and $b$ represent the total molar concentrations of gallium and xylenol orang respectively; $\varepsilon_{XO}$ and $\varepsilon_C$, the molar extinction coefficients of xylenol orange and the complex respectively, and $K'_1$, the apparent formation constant of the complex at the given pH value.

In Fig. 6 $ab/D$ is plotted against $(a+b)$ at five wavelengths between 500 and 540 m$\mu$. In these solutions, the concentration of gallium was $2.0\times10^{-5}$ M, while the concentration of xylenol orange varied from $0.8\times10^{-4}$ to $8\times10^{-4}$ M; the pH value of these solutions was held constant at 1.0. The very good linearity of the curves in Fig. 6 supports the assumptions inherent in Eq. 1, indicating that only a 1 to 1 complex is formed under the conditions investigated.

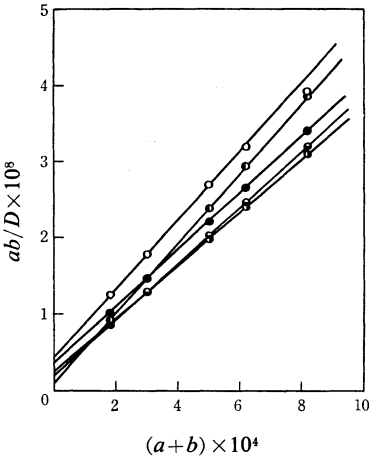

Fig. 6. Plots of $ab/D$ vs. $(a+q)$ at various wavelengths.
—○—: 500 m$\mu$, —●—: 510 m$\mu$,
—◑—: 520 m$\mu$, —◒—: 530 m$\mu$,
—◐—: 540 mu, pH: 1.0

**The Complex with Its Absorption Maximum at 502 m$\mu$.**—A substitution reaction between the complex and EDTA was used to ascertain the result obtained by the mole ratio method, which showed the presence of a 1 to 2 complex in the metal-ligand ratio. This is based on the fact that, at pH 5.5, EDTA can form a far more stable complex with gallium than does xylenol orange, and that, therefore, the xylenol orange in the gallium complex may be replaced by EDTA. A preliminary test showed that nitrilotriacetic acid (NTA) can also form a stable complex with gallium in a slightly acid medium, but it cannot extinguish the color of the gallium-xylenol orange complex at all. Therefore, it may be assumed that, in the presence of an excess of xylenol orange, the

13) S. C. Furman and C. S. Garner, *J. Am. Chem. Soc.*, **73**, 4528 (1951).

contribution of the absorbance caused by the dissociation of the gallium-xylenol orange complex is almost negligible. When the absorbance is measured against a solution containing the same amounts of gallium and xylenol orange, Eq. 2 may be written for the substitution reaction as:

$$\{(D-D_O)+x\varepsilon_C\}/\varepsilon_{XO}=nx \qquad (2)$$

where

$$D=(a-x)\varepsilon_C+(b-na+nx)\varepsilon_{XO} \qquad (2')$$

$$D_O=a\varepsilon_C+(b-na)\varepsilon_{XO} \qquad (2'')$$

In these solutions, $a$ and $b$ are the initial concentrations of the gallium-xylenol orange complex and xylenol orange respectively, $x$ is the molar concentration of EDTA added, and $\varepsilon_C$ and $\varepsilon_{XO}$ are the molar extinction coefficients of the complex and xylenol orange respectively. If $\{(D-D_O)+x\varepsilon_C\}/\varepsilon_{XO}$ is plotted against $x$, a straight line with the slope $n$ should be yielded.

In this substitution method, the absorbances were measured by adding various amounts of a $1\times10^{-4}$ M EDTA solution to known amounts of gallium ($2.0\times10^{-5}$ M) and xylenol orange ($1.0\times10^{-4}$ M), using a blank solution containing the same amounts of gallium and xylenol orange. The pH value was held constant at 5.5. The absorbances were measured at three wavelengths, 400, 410 and 420 m$\mu$, because the difference in absorbance between xylenol orange and the reference solution was the greatest at about 410 m$\mu$. Figure 7 shows the absorption curves of xylenol orange and its gallium complex at pH 5.5 in the wavelength range from 350 to 570 m$\mu$. Curve IV in Fig. 7 is the absorption curve of the complex which is partly shown by curve IV in Fig. 2. The values of $\varepsilon_C$ were evaluated at the three wavelengths by assuming a 1 to 2 complex, employing the method described by Klotz and LohMing.[14] All the curves are good straight lines with a slope of 2. As a representative result, the values of $\{(D-D_O)+x\varepsilon_C\}/\varepsilon_{XO}$ are plotted in Fig. 8, from which it may be easily understood that a 1 to 2 complex is formed between gallium and xylenol orange.

## Summary

The reaction between gallium(III) and xylenol orange has been studied spectrophotometrically in order to establish the optimum conditions for determining traces of gallium. Depending on the pH value of a solution, gallium(III) reacts with xylenol orange to form two complexes. The 1 to 1 complex which gives a maximum absorbance in the pH range from 1.2 to 1.7 has an absorption maximum at 530 m$\mu$ when measured against a reagent blank. The 1 to 2 complex which gives the maximum absorbance in the pH range from 4.5 to 5.5 has an absorption maximum at 502 m$\mu$. Either with 1 to 1 and 1 to 2 complexes, Beer's law is obeyed up to 60 m$\mu$. of gallium. The apparent molar extinction coefficients of the 1 to 1 and the 1 to 2 complexes have been calculated to be 22900 and 16300 respectively. The present method is comparable in sensitivity with the stilbazo or the luminogallion

14) I. M. Klotz and W.-C. LohMing, ibid., 75, 4159 (1953).

IREA method. The addition of a small amount of fluoride is effective in eliminating some interfering cations, including aluminum(III), thorium(IV) and zirconium(IV).

The author wishes to express his hearty thanks to Professor Kôichi Tonosaki for his kind guidance and encouragement throughout the course of this study.

# The Behavior of Manganese, Titanium and Phosphorus in Fumarolic Gas at the Mihara Volcano, Japan

By Hiroshi KAMIYA

(Received August 1, 1964)

As was described in a previous paper,[1] the low volatile components present in rocks have really been transported in fumarolic gases, although in small amounts. Because magmatic gas cannot be collected directly, however, the behavior of the low volatile components there must be surmised from observations and analyses of minerals in ore deposits and of gases and sublimates evolved from lava and fumaroles, as well as from laboratory experiments at a high temperature and a high pressure.

From thermodynamic data, Krauskopf[2] showed that magmatic gas at 600°C is, with a few exceptions, capable of transporting the common heavy metals, such as volatile chlorides, to form an ore deposit. Morey[3,4] and Kennedy[5,6] demonstrated the strong solvent action of water vapor on the relatively low volatile components with a sufficient temperature and pressure. As has been suggested by Krauskopf, the low volatile components may be transported mechanically as solid particles in gas as well as vapor.

Matsuo[7] pointed out that many reactions in fumarolic gas are quenched to a certain extent at the orifices of fumaroles. The extent of their quenching, however, will depend on the kinds of reactions and on the temperature and pressure gradients in the fumarole.

Whatever factor plays the most important part in transporting the low volatile components, it is certain that the results stated in the previous paper will correspond to the features of their behavior in the fumarolic gas.

In this paper the writer will describe the behavior in the fumarolic gas of manganese, titanium and phosphorus, which are less familiar but are yet widely distributed in rocks.

## Experimental

The investigation of the behavior of manganese, titanium and phosphorus was made in the same way as that in the previous paper, i. e., by the collection and analysis of the condensed waters from a fumarole at the Mihara Volcano. The components in the condensed water were concentrated by evaporation or separated by coprecipitation, because their contents were too low to be determined directly.

**Sample.**—An equivolume mixture of three condensed waters collected in September, 1959, i. e., in the final period of the sample collection in that year, was used as the sample for 1959. Fifty condensed waters collected in 1961 were divided into five groups according to the iron concentrations. The numbers of the condensed waters included in each group are given in the first column of Table I. The samples in each group were then mixed in the same proportions by volume and used as the samples for 1961.

**Analytical Method.**—First 1000 or 1500 ml. of the combined sample was heated, gently to expel the hydrochloric acid and then strongly until no more sulfuric acid fumes were evolved. The evaporate was then dissolved in 3 ml. of concentrated sulfuric acid and made up to 50 ml. of the final volume by adding distilled water. An aliquot of 25 ml. was used for the determination of manganese, 20 ml., for titanium, and 1 ml., for iron and for aluminum. For the determination of phosphorus, 500 ml. of the raw combined sample was used.

*Manganese.*—Manganese was determined through the photometric measurement of the violet color

developed by the periodate oxidation of manganese to permanganate, in the presence of orthophosphoric acid to eliminate interference.[8]

*Titanium.* — The determination of titanium was made colorimetrically by comparing the yellow color formed with hydrogen peroxide in a 1 : 9 sulfuric acid solution with the standard color.[9]

*Phosphorus.*—Phosphorus was separated by coprecipitation with aluminum hydroxide and determined by the molybdenum blue method.[10]

*Aluminum and Iron.*—The determination of aluminum and iron was carried out by the method described in the previous paper.

## Results and Discussion

**The Concentrations of Iron, Aluminum Manganese, Titanium and Phosphorus in Condensed Water Collected in 1959 and 1961.**—The average concentrations of iron, aluminum, manganese, titanium and phosphorus in the combined samples in both 1959 and 1961 are given in Table I. The 1959 sample was a mixture of only three condensed waters. The average concentrations in 1961 were calculated from the concentrations of the components in the five classified groups.

The titanium concentration increased and those of manganese and phosphorus decreased in 1961, as compared with their concentrations in 1959. While the increase in titanium and the decrease in phosphorus were in the same order of magnitude, the manganese concentration in 1961 was almost two orders of magnitude lower than that in 1959; i. e., the decrease in the manganese concentration in 1961 was quite remarkable.

In view of the fact that the average concentration of iron, 0.047 mmol./l., in 1959 given in the previous paper differs from that, 0.060 mmol./l., for the same year in Table I, despite the identity in aluminum concentration, it cannot be said that the fumarolic gas in 1959 described in the previous paper had the same quality as the gas from which the three condensed waters in this experiment were obtained.

**The Correlation of Aluminum, Manganese, Titanium and Phosphorus with Iron.**—In order to find the relationship between aluminum, manganese, titanium, phosphorus and iron, the fifty condensed waters collected in 1961 were classified into five groups. As may be seen in Fig. 1, when the concentrations of aluminum, manganese, titanium and phosphorus are plotted against that of iron in the five groups

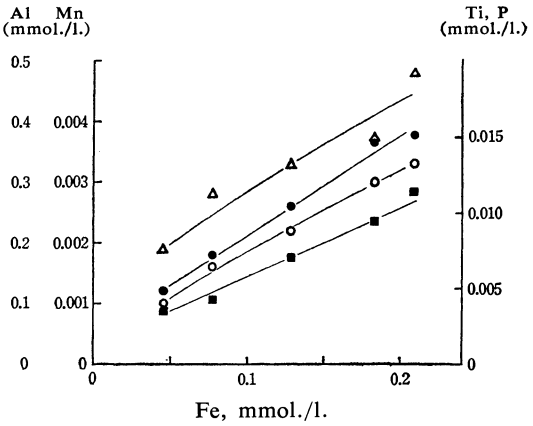

Fig. 1. Correlation of Al, Mn, Ti and P with Fe.

△ Al, ● Ti, ○ Mn, ■ P

of samples in 1961, they tend to increase simultaneously with the iron concentrations. Manganese and titanium show a nearly linear relation with iron, but the same kind of correlation between aluminum and iron is not clear. A linear increase in the concentration of phosphorus with an increasing concentration of iron is noticed.

The behavior of manganese, titanium, phosphorus, etc., in the fumarolic gas of 1959 may not be fully displayed, inasmuch as the concentrations in 1959 given in Table I are the average values from only three condensed waters. However, if the concentrations of aluminum, titanium and phosphorus are plotted against that of iron in 1959, the points fall not so far from the lines in Fig. 1 which represent the relations of aluminum, titanium and phosphorus to iron in 1961. In contrast to the above components, the unusually high concentration of manganese in the combined sample of 1959, when compared with that of iron, is quite noticeable.

**The Transport of Manganese, Titanium and Phosphorus in Gas in Comparison with the Other Major Components.** — The ratios between the mole percentages of the twelve components, including chlorine, sulfur, manganese, titanium and phosphorus, in the condensed water and those in the lava were calculated from the average concentrations of the components in the condensed waters in 1959 and in 1961 and from their contents in the lava (1951) reported by Tsuya et al.[11] and Iwasaki et al.[12] Due to the lack of data on the analysis of sulfur in the lava of 1951, the sulfur content in the lava of

Table III. Order of ratio for 12 components

| | |
|---|---|
| In 1959 | Cl > S > Mn > Na > K > P > Si > Al > (Ti, Fe) > Ca > Mg |
| In 1961 | Cl > S > P > Na > (Ca, Mn) > K > Al > Mg > (Si, Fe) > Ti |

the central cone as measured by Iwasaki[13] was employed. The results are given in Table II. Moreover, the order of the ratio for the components is shown in Table III. As was stated in the previous paper, it may be considered that the ratio denotes the measure of ease with which the components are transported in gas or the degree of concentration in gas relative to that in lava.

The low volatile components abundant in rocks probably originate from magma and/or wall rock. On the other hand, chlorine may originate from another source, as has been suggested by Matsuo.[7] Wherever they may originate, however, the general tendency of the transport of the components in gas is illustrated by the ratios.

Chlorine and sulfur, excluding the most dominant water vapor in gas, are the largest mobile elements, unless there is the possibility of the secondary addition of these components into gases. In other words, they are concentrated into gas, as they cannot enter the crystal lattice of common rock-forming minerals; in general, chlorine is incorporated in the glassy part rather than in minerals,[12] and the minor sulfur content is due to the sulfur compounds in rocks. As may be seen in Table II, chlorine and sulfur made up over 95% of the whole in 1959 and 99% in 1961.

Manganese was much more mobile than alkali metals, and the component with the largest ratio, except for such highly volatile components as chlorine and sulfur, in 1959. As has been stated previously, although the concentration of manganese became much lower in 1961 than in 1959, still it belongs to the metallic components with a relatively large ratio. Titanium had a ratio comparable to iron in the fumarolic gas of a higher temperature in 1959, but it became less mobile at a lower temperature in 1961. Phosphorus had a smaller ratio than alkali metals in 1959, and it became more mobile than any metals, with a decrease in the ratio of metallic components, in 1961.

As has been stated above, there is a marked difference in the nature of the fumarolic gases between those of 1959 and those of 1961, based

13) I. Iwasaki, ibid., 56, 1518 (1935).

on the chemical analysis of condensed waters. We are led, then, to inquire what factors govern the transport of these components, what kinds of compounds of these components are really transpired and, especially, why the fumarolic gas in 1959 had a particular ability to transport manganese. In order to answer these questions, further experiments at high temperatures and high pressures are needed.

The writer wishes to express his indebtedness to Professor Kimio Noguchi for having been good enough to read this manuscript, and also to Mr. Minoru Yamamoto for help with regard to the analyses.

# The Determination of the Heat of Adsorption by the Gas Chromatographic Method. I*

By Kimiko ARITA, Yoshio KUGE and Yozaburo YOSHIKAWA

(Received August 13, 1964)

The determination of the heat of adsorption by the gas chromatographic method has been carried out by Greene and Pust.[1] In our laboratories, the heats of adsorption of some low-boiling-point hydrocarbons and inorganic gases on active charcoal, alumina, silica gel and synthetic zeolite have also been estimated by the gas chromatographic method by using several carrier gases, such as helium, hydrogen and nitrogen.[2-4]

The purpose of this series is to establish the method of the gas chromatographic determination of the heat of adsorption and to compare the results with those obtained by usual static methods.

The heat of adsorption of an eluted gas on an adsorbent is calculated by Eq. 1[5,6]:

$$\frac{R}{R'}=\frac{1}{K_a+1}=\frac{L\cdot A}{F\cdot t_m} \tag{1}$$

where $R$, is the linear velocity of the sample gas; $R'$, the linear velocity of the carrier gas; $K_a$, the equilibrium constant for adsorption; $L$, the packed length of adsorption; $t_m$, the retention time of the sample gas; $A$, the interstitial area of the column, and $F$, the flow rate of the carrier gas.

Then, the equilibrium constant of adsorption ($K_a$) is expressed by Eq. 2, since $\Delta G=\boldsymbol{R}T_c\ln K_a$:

$$K_a=e^{-\Delta G/\boldsymbol{R}T_c}=e^{-\Delta H_a/\boldsymbol{R}T_c}\cdot e^{\Delta S/\boldsymbol{R}} \tag{2}$$

where $T_c$, is the column temperature (the gas-solid equilibrium temperature); $H_a$, the molar differential heat of adsorption; $\Delta G$, the free energy change of adsorption, and $\Delta S$, the entropy change of adsorption.

As $\Delta S$ is assumed to be constant when the temperature range is small and when the adsorbent and the adsorbate are the same substance, Eq. 2 is rewritten as Eq. 3:

$$K_a=Be^{-\Delta H_a/\boldsymbol{R}T_c} \tag{3}$$

where $B$ indicates a constant.

Moreover, the apparent retention time ($t_m'$) is expressed by Eq. 4.[7]

$$t_m'=t_m-\frac{L\cdot A}{F} \tag{4}$$

Then we have Eq. 5 from the relations of 1, 3 and 4.

$$Ft_m'=LABe^{-\Delta H_a/\boldsymbol{R}T_c} \tag{5}$$

When $\log Ft'_m$ is plotted against $T_c$, the heats of adsorption ($\Delta H_a$) can be estimated from the slope of the ($\log Ft'_m$, $1/T_c$) line according to Eq. 5. In practice, however, a slight pressure drop occurs across the column and the velocity of the sample and carrier gases might change slightly through the column. Therefore, the retention volume ($V_m$) is usually corrected in such a way that the pressure drop comes to zero, and the flow rate of the

carrier gas measured at room temperature is also converted into that at 0°C.

The corrected retention volume ($V_o$) is expressed by Eq. 6.[8,9]

$$V_o = Ft'_m \cdot \frac{273}{T} \cdot \frac{3}{2} \cdot \frac{(P_i/P_o)^2-1}{(P_i/P_o)^3-1} \qquad (6)$$

where $P_i$, is the column inlet pressure; $P_o$, the column outlet pressure, and $T_m$, the room temperature.

Practically, however, $V_m$ is observed as a function of the column temperature only:

$$V_m = Ft'_m \cdot \frac{273}{T_m} \qquad (7)$$

Therefore, we have Eq. 8 by putting Eq. 5 into Eq. 7:

$$V_m = Ce^{-\Delta H_a/RT_c} \qquad (8)$$

where $C$ is a constant.

Therefore, the heat of adsorption may be estimated by plotting $V_m$, in place of $V_o$, against $T_c$ according to Eq. 8.

## Experimental

A Yanagimoto gas chromatograph, GCG-2, was employed.

The column is made of a stainless steel U-shaped tube 5 mm. in inner diameter. The length of the column used is 1 m. in the cases of activated charcoal, molecular sieve 5A and a molecular sieve 13X, and 2 m. in the cases of alumina and silica gel. The adsorbents were supplied mostly by Nishio Industry Co., Ltd., and the size of their particles ranged from 40 to 60 mesh, while alumina was supplied by the Wako Chemical Co., Ltd., in sizes from 28 to 48 mesh.

All the sample gases were synthesized except methane, ethane, acetylene and isobutane, and all the gases used were purified.

After the column had been filled with an adsorbent, the adsorbent was activated by heating it up to 200°C and by sweeping with carrier gas with a flow rate of about 50 cc. per minute, the flow rates of the gases being measured by a soap-film flow meter. To avoid error in the determination of the retention time, the experiments were carried out under conditions which would give a symmetrical shape for any peak.

## Results

In the case of ethane, the corrected retention volume ($V_m$) was estimated for five kinds of adsorbents by using nitrogen as the carrier gas. The logarithmic plots of $V_m$ against $1/T_c$ are found to be quite linear, as Fig. 1 shows.

In the adsorption of other sample gases on active charcoal, hydrogen was employed as the carrier gas. In this case, no hydrogenation of

unsaturated hydrocarbons was recognized over the temperature range covered experimentally.

The correlation of $V_m$ with $1/T_c$ is shown in Fig. 2.

On the basis of these data, the differential heats of adsorption on sample gases were calculated. The results are listed in Table I.

The values of the heats of adsorption obtained are in almost the same sequence as those found for the van der Waals constant ($a$) of the sample gases.

The difference between the values obtained when helium, hydrogen and nitrogen were used as the carrier gases was found to be rather small. The reason for this will be discussed after the experiments using argon as the carrier gas have been carried out.

Next the relation between the order of peak appearance and the free energy change was investigated.

The relation between the retention time ($t'_m$) and the free energy change ($\Delta G$) has been obtained by Cremer[10] as follows:

$$\Delta G = G_1 - G_2 = \boldsymbol{R}T \ \mathrm{lnt'}_m(1)/t'_m(2) \qquad (9)$$

The numbers in parentheses ((1),(2)) show the kind of adsorbate.

Since the apparent retention volume ($V_m$) can be written as $V_m = Ft'_m$, $\Delta G$ is expressed as Eq. 10:

$$\Delta G = \boldsymbol{R}T \ \ln \frac{V_m(1)}{V_m(2)} \qquad (10)$$

The free energy change of the adsorption of several sample gases on the same adsorbent was calculated according to Eq. 10. The results obtained are listed in Table II, where the values are converted into those at 25°C. As is shown in Table II, the smaller the value of

10) E. Cremer, *Z. anal. Chem.*, **170**, 219 (1959).

the free energy change of adsorption ($-\Delta G$), the greater the velocity of the adsorption of sample gases.

The discussion of the results will appear in the next report.

The authors wish to express their sincere thanks to Dr. Ken-ichiro Yamasaki for his kind guidance throughout the course of this work.

# The Reaction of Carbon Monoxide with Organometallic Compounds.* X. The Reaction of Carbon Monoxide with Phenyl Derivatives of Transition Metals**

By Membo RYANG, Kunihisa YOSHIDA, Hidejiro YOKOO and Shigeru TSUTSUMI

(Received August 22, 1964)

In a previous communication[1] it was reported that the phenylcobalt compound prepared from the reaction between phenylmagnesium bromide and cobalt(II) chloride in diethyl ether reacted with carbon monoxide at a low temperature (−35——10°C) and 1 CO atm., giving benzophenone (22%) and benzoin (12.5%) at −25°C, and benzoin (35%) at −35°C. The formation of benzophenone was explained as resulting from the reaction of carbon monoxide with the phenyl radical which was formed from a homolytic fission of the carbon-cobalt bond in the phenylcobalt compound, while benzoin was assumed to be produced by the dimerization, followed by the hydrolysis, of the benzoylcobalt compound.

This reaction had a few curious and suggestive points for carbon monoxide-insertion reactions. Furthermore, since many transition metal compounds have been used in the synthetic application of carbon monoxide as catalysts and since sometimes the formation of organic derivatives of transition metals as the reaction intermediates were supposed,[2] it was felt desirable to clarify the reaction of carbon monoxide with organic derivatives of transition metals as a unit reaction in some detail, and also to discuss the effects of the variation of transition metals on the reactivities of the organic derivatives of transition metals with carbon monoxide.

This report will deal with the reaction of carbon monoxide with phenyl derivatives of transition metals and also with the relation between various transition metals and their behavior in carbon monoxide-insertion reactions. Moreover, the assumption on benzophenone formation, proposed in the previous communication, will be further discussed. The metals used in this work were divided into two groups: A: chromium, nickel and cobalt, which can form metal carbonyls by the action of carbon monoxide, and B: copper and cadmium, the carbonyls of which have not yet been isolated.

## Results and Discussion

The phenyl derivatives of transition metals were prepared by the reaction between metal halides and phenylmagnesium bromide. Although most transition metal halides react with alkyl and aryl Grignard or organolithium compounds under ordinary conditions, isolable organometallic compounds are frequently not obtained. Moreover, the major successes in the preparation of sigma-bonded transition metal alkyls and aryls have mostly resulted from close attention to experimental conditions (e.g., low temperature reactions) or, more commonly, from the use of the coordination of donor solvents or ligands.[3-5]

Therefore, the preparation of the phenyl

* In addition to these products, benzoic acid and other carbonyl compounds were obtained, for example, diphenylbenzoylmethane was obtained in 10% yield from a and in 14% yield from b.
** The calculations of yields are based on the amounts of bromobenzene used to prepare phenylmagnesium bromide.
*** Phenyllithium was used to prepare phenylcopper.

derivatives of transition metals and the reaction with carbon monoxide were carried out at a low temperature in proper solvents (tetrahydrofuran or diethyl ether), and the isolation and identification of the reaction products were carried out by the ordinary methods.[6] The results of the reaction of carbon monoxide with various phenyl derivatives of transition metals are summarized in Table I. Since the reaction of phenylmagnesium bromide with carbon monoxide at −10°C in diethyl ether (for 5 hr.) gave only small amounts of diphenylcarbinol (2%) and triphenylmethane (1%), and since benzene was obtained in about a 90% yield, the carbon monoxide-inserted products in Table I were assumed to be produced from the reaction between carbon monoxide and the phenyl derivatives of transition metals. Also, the hydrolysis of the reaction mixtures obtained from the reaction of phenylmagnesium bromide with transition metal halides in the absence of carbon monoxide gave biphneyl in yields analogous to the yields of biphenyl in the presence of carbon monoxide. (Table II)

TABLE II. THE YIELDS OF BIPHENYL FROM THE REACTION IN THE ABSENCE OF CARBON MONOXIDE

| Metal | Temp. °C | Time hr. | Solvent | Yield % |
|---|---|---|---|---|
| Co | −25 | 4 | $Et_2O$ | 55 |
| Ni | 0 | 4 | THF | 20 |
| Cu | 32 | 4 | $Et_2O$ | 35 |
| Cd | 15 | 4 | THF | 10 |

As may be seen in Table I, the phenyl derivatives of transition metals known to form metal carbonyls, including chromium, nickel and cobalt, reacted with carbon monoxide at a low temperature under 1 CO atm. to give the reaction products derived from carbon monoxide insertion, while diphenylcadmium and phenylcopper were unreactive to carbon monoxide under several reaction conditions and no products derived from carbon monoxide insertion were obtained in isolable amounts. On the basis of the above results, the coordination of carbon monoxide to metals may be considered to be the first step in these reactions; then alkyl-acyl rearrangement[7] occurs to form benzoyl derivatives of transition metals, which decompose to give benzophenone or dimerize to give benzoin.

In the previous communication, the formation of benzophenone was explained as resulting from the reaction of carbon monoxide with the phenyl radical. However, benzophenone was not isolated from the reaction between carbon monoxide and phenylcopper even at a somewhat higher reaction temperature and a more elevated carbon monoxide pressure, although biphenyl was formed in a good yield and the formation of phenyl radical was certain.

On the basis of these results, it may be considered improper to explain the mechanism of benzophenone formation by a simple radical mechanism. Therefore, benzophenone should

7) T. H. Coffield, J. Kozikowski and R. D. Closson, *J. Org. Chem.*, 22, 598 (1957).

be thought to be produced from the decomposition of thermally-unstable benzoyl derivatives of transition metal,[8] which are dimerized and then hydrolyzed, to give benzoin at a lower reaction temperature.

The mechanical aspects of the ketone formation reaction and the studies of the factors which determine the course of benzophenone formation or benzoin formation will be presented in detail in a forthcoming paper.

## Experimental

**Materials.**—*Bromobenzene.*—Commercial bromobenzene was purified by fractional distillation; b. p. 155°C, $n_D^{20}$ 1.5602.

*Metal Halides.*—Commercial anhydrous metal halides (chromium(III) chloride, nickel chloride, cobalt(II) chloride, cuprous iodide and cadmium chloride) were dried by heating under reduced pressure.

**Reactions.**—*The Reaction of Carbon Monoxide with Diphenylnickel.*[9]—The apparatus and procedure employed here were identical with those described in the previous paper.[6] Twenty-six grams (0.2 mol.) of nickel chloride was added to a ethereal solution of phenylmagnesium bromide which had been prepared by using 31.4 g. (0.2 mol.) of bromobenzene, 5.4 g. (0.22 g. atm.) of magnesium and 150 ml. of anhydrous diethyl ether; carbon monoxide was then introduced into the solution at 12°C for 4 hr. The organic layer, separated after the hydrolysis of the reaction mixture, was divided into a neutral part, an acidic part and a phenolic part by means of the ordinary method. The neutral part was distilled under reduced pressure to give the following fractions: (1) b. p. 90—140°C/20 mmHg 2.6 g., (2) b. p. 105—150°C/1 mmHg 4.9 g., (3) b. p. 150—160°C/1 mmHg 1.0 g. and (4) b. p. 190—200°C/1 mmHg 0.4 g. Fraction 1 was identified as biphenyl by its mixed melting point measurement (m. p. 70°C, recrystallized from ethanol). Fraction 2 was recrystallized from ligroin to give white crystals, m. p. 133—134°C, and was identified as benzoin from the results of a mixed melting point measurement, infrared-spectra measurements and an elemental analysis.

Found: C, 79.43; H, 5.56. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

Fraction 3 solidified on standing and was recrystallized from benzene-ligroin to give white crystals, m. p. 161—162°C, which were identified as triphenylcarbinol by a mixed melting point measurement with an authentic sample.

When tetrahydrofuran was used as a solvent, benzophenone (11.5%) was isolated in addition to the above products, and its structure was determined by the results of infrared spectra measurements and a mixed melting point measurement of its oxime (m. p. 140—141°C, recrystallized from ligroin). Furthermore, benzoic acid was obtained from the acidic part and phenol from the phenolic part.

*The Reaction of Carbon Monoxide with Triphenylchromium.*[5]—4.5 g. of chromium trichloride was added at −30°C to a tetrahydrofuran solution of phenylmagnesium bromide which had been prepared by using 15.1 g. of bromobenzene, 2.3 g. of magnesium and 133 ml. of anhydrous tetrahydrofuran, and then the stirring was continued for a further 8 hr. at −25°C. Then dry, pure carbon monoxide was bubbled into the solution at −25°C for 5 hr. The reaction mixture was hydrolized by ethanol-2 N hydrochloric acid and divided into a neutral part, an acidic part and a phenolic part. The neutral part was distilled under reduced pressure to give the following fractions: (1) b. p. ~90°C/12 mmHg 1.1 g., (2) b. p. 105—130°C/1 mmHg 3.3 g. and (3) b. p. 130—190°C/1 mmHg 0.9 g. Fraction 1 was identified as biphenyl by mixed melting point measurements. The infrared spectrum of fraction 2 showed the presence of a carbonyl group (1655 $cm^{-1}$), and fraction 2 was confirmed to be benzophenone from the results of a mixed melting point measurement of its 2,4-dinitrophenylhydrazone (m. p. 236—237°C, recrystallized from ethyl acetate).

Found: C, 62.98; H, 3.96. Calcd. for $C_{19}H_{14}O_4N_4$: C, 62.98; H, 3.89%.

Fraction 3 was recrystallized from ligroin to give white crystals (m. p. 136—138°C); the infrared spectrum of these crystals showed the presence of a carbonyl group (1675 $cm^{-1}$).

Found: C, 87.77; H, 6.16. Calcd. for $C_{20}H_{16}O$: C, 88.20; H, 5.92%.

These crystals were identified as diphenylbenzoylmethane by a mixed melting point measurement with an authentic sample. Small amounts of benzoic acid and phenol were isolated from the acidic part and the phenolic part respectively. When the reaction in diethyl ether was carried out under similar conditions, the products in Table I were isolated.

*The Reaction of Carbon Monoxide with Phenylcopper.*[10]—Phenylcopper was prepared by the reaction of cuprous iodide (19 g., 0.1 mol.) with phenylmagnesium bromide in a diethyl ether solution (0.1 mol.) or with phenyllithium in diethyl ether (0.1 mol.) at −15—−5°C. The reaction with carbon monoxide was carried out under several conditions (Table I). As a reaction product, biphenyl was obtained in a good yield, but no carbonyl compounds were obtained in isolable amounts.

*The Reaction of Carbon Monoxide with Diphenylcadmium.*[11]—To a tetrahydrofuran solution of phenylmagnesium bromide (0.1 mol.), 9.2 g. (0.05 mol.) of anhydrous cadmium chloride was added at −30°C; the reaction mixture was then kept at

# Photolysis of Acetaldehyde in the Presence of Deuterium Sulfide. Deuterium Atom Abstraction from Deuterium Sulfide Molecules by Methyl Radicals

By Naomi IMAI, Takaaki DOHMARU and Osamu TOYAMA

(Received September 3, 1964)

Previous studies of the catalytic effect of hydrogen sulfide on the photolysis[1] and pyrolysis[2] of acetaldehyde, as well as on the pyrolysis of dimethyl ether,[3] have shown that hydrogen atom abstraction from hydrogen sulfide molecules by methyl radicals:

$$CH_3 + H_2S \rightarrow CH_4 + HS \qquad (6')$$

plays an important role in these reactions. The rate constant of this metathetical reaction has been determined by photolyzing acetone[4] and acetaldehyde[1] in the presence of hydrogen sulfide, with the result that the reaction is much faster than ordinary hydrogen abstractions by methyl radicals.

In order to establish further the mechanism of the hydrogen sulfide catalysis, the study of the deuterium sulfide-catalyzed pyrolysis of acetaldehyde is now in progress. Here, in place of reaction 6', the following reaction:

$$CH_3 + D_2S \rightarrow CH_3D + DS \qquad (6)$$

is expected to play a similar role. In this work a mixture of deuterium sulfide and acetaldehyde was photolyzed, and the relative rate of reaction 6 was determined against that of reaction 5:

$$CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO \qquad (5)$$

which competes with reaction 6.

## Experimental

**Materials.** — Acetaldehyde was supplied commercially, dried by potassium chloride, and purified by repeated bulb-to-bulb distillations. Deuterium sulfide was prepared by dropping deuterium oxide (99.8 mol.%) on aluminum sulfide in an evacuated vessel, dried by passing it through a trap at −78°C, and purified by bulb-to-bulb distillations.

**Apparatus.**—The apparatus used was similar to that described previously.[1] The photolysis was carried out in a cylindrical quartz vessel with a capacity of about 110 cc. A medium-pressure mercury arc was used as the light source, and the light of the wavelength region shorter than 2800 Å was cut off in front of the vessel by a thin glass plate in order to avoid absorption by deuterium sulfide. The light intensity was kept constant by the use of a voltage stabilizer.

**Procedure.** — Required quantities of deuterium sulfide and acetaldehyde were admitted to the reaction vessel. After the gases had been allowed to mix thoroughly for a few minutes, light was admitted into the vessel. After irradiation for a certain time, the reaction mixture was led into a trap at the temperature of liquid air; the non-condensable fraction was then collected and measured by a Toepler gauge. In some runs, this fraction was analyzed by a gas chromatograph and by a mass spectrometer. No peaks at $(m/e)=19$ and 20 corresponding to methane-$d_3$ and -$d_4$ were found by mass spectrometry. The methane-$d_0$ : -$d_1$ : -$d_2$ ratio was determined from the intensities of the peaks at $(m/e)=16$, 17 and 18. Since the three components contribute to these peaks, the quantity of each component was calculated by means of simultaneous equations. The mass spectra of methane-$d_1$ and -$d_2$ were constructed from the measured mass spectrum of pure methane by the method of Schissler, Thompson and Turkevich;[5] the validity of the construction was confirmed by the close agreement between measured and calculated values for the peak at $(m/e)=15$.

## Results and Discussion

It was found by gas chromatographic analysis of the non-condensable products of the photolysis in the presence of deuterium sulfide that

1) N. Imai and O. Toyama, This Bulletin, **33**, 1120 (1960).
2) N. Imai, Y. Yoshida and O. Toyama, ibid., **35**, 752, 758 (1962).
3) N. Imai and O. Toyama, ibid., **34**, 328 (1961).
4) N. Imai and O. Toyama, ibid., **33**, 652 (1960).
5) D. O. Shissler, S. O. Thompson and J. Turkevich, *Discussions Faraday Soc.*, **10**, 46 (1951).

the fraction consists merely of methane and carbon monoxide in equal amounts within the range of experimental error. This fact indicates that acetaldehyde decomposes stoichiometrically to methane and carbon monoxide, as was observed in non-catalyzed[6] and hydrogen sulfide-catalyzed[1] photolyses. Consequently, the rate of decomposition was determined by measuring the amount of the non-condensable fraction of the products.

By analogy with the hydrogen sulfide catalysis, the photolysis of acetaldehyde in the presence of a small amount of deuterium sulfide can be explained by the following mechanism:

$$CH_3CHO + h\nu \rightarrow CH_3 + CHO \quad (1)$$

$$CHO \rightarrow CO + H \quad (2)$$

$$H + CH_3CHO \rightarrow H_2 + CH_3CO \quad (3)$$

$$H + D_2S \rightarrow HD + DS \quad (4)$$

$$CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO \quad (5)$$

$$CH_3 + D_2S \rightarrow CH_3D + DS \quad (6)$$

$$DS + CH_3CHO \rightarrow HDS + CH_3CO \quad (7)$$

$$CH_3CO \rightarrow CH_3 + CO \quad (8)$$

$$CH_3 + CH_3 \rightarrow C_2H_6[7] \quad (9)$$

Figure 1 shows the progress of decomposition with time. In the photolysis of 300 mm. of acetaldehyde with 10 mm. of deuterium sulfide (run B), the decomposition curve shows, though slightly, autocatalytic behavior in the initial stage. Such behavior is probably to be attributed to the replacement of reaction 6 by the faster reactions 6'' and 6':

$$CH_3 + HDS \rightarrow CH_4 + DS \quad (6'')$$

$$CH_3 + H_2S \rightarrow CH_4 + HS \quad (6')$$

as a result of the conversion of hydrogen sulfide-$d_2$ to -$d_1$ or -$d_0$ by reaction 7 or 7':

$$HS + CH_3CHO \rightarrow H_2S + CH_3CO \quad (7')$$

No autocatalytic behavior can be recognized unless the ratio of deuterium sulfide to acetaldehyde is sufficiently low, as in run B. In the experiments with small amounts of deuterium sulfide, consequently, care was taken to determine the initial decomposition rate by short-time irradiation.

In Fig. 2 the initial decomposition rate is

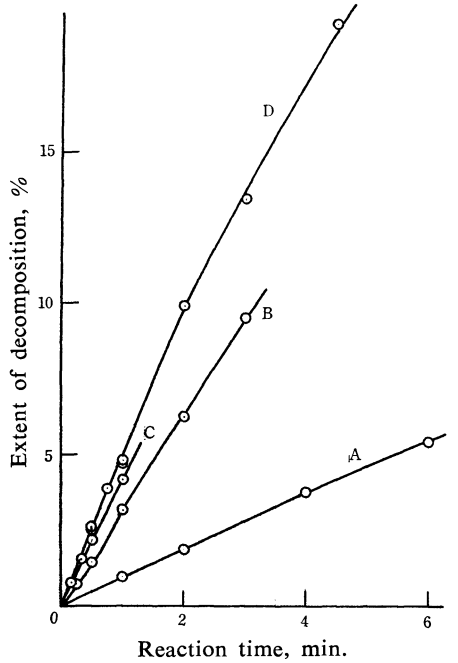

Fig. 1. Photolysis of acetaldehyde in the absence and presence of hydrogen sulfide and deuterium sulfide at 300°C.
A $D_2S$ : 0, $CH_3CHO$ : 100 mmHg
B $D_2S$ : 10 mmHg, $CH_3CHO$ : 300 mmHg
C $D_2S$ : 13.5 mmHg, $CH_3CHO$ : 100 mmHg
D $H_2S$ : 10 mmHg, $CH_3CHO$ : 300 mmHg

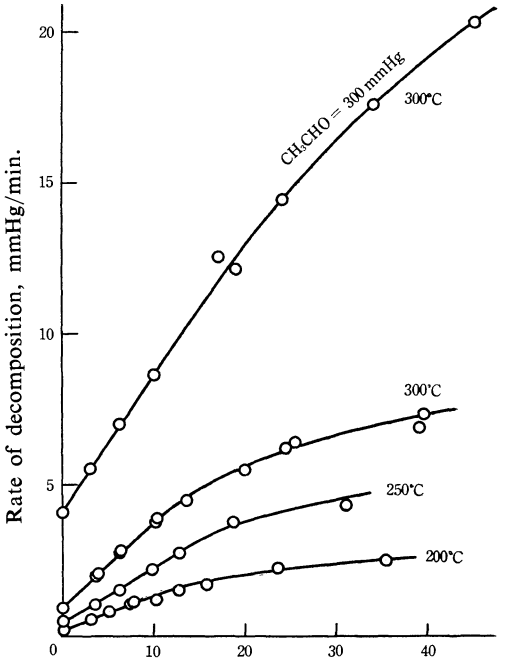

Fig. 2. Dependence of the rate of decomposition in the presence of deuterium sulfide on its pressure.
$CH_3CHO$ : 100 mmHg unless otherwise described.

6) F. E. Blacet and D. Volman, *J. Am. Chem. Soc.*, **60**, 1243 (1938); F. E. Blacet and W. J. Blaedel, ibid., **62**, 3374 (1940); R. E. Dodd and J. D. Waldron, *Nature*, **167**, 655 (1951).

7) In the pyrolysis of acetaldehyde reaction 9 was suggested to be third order (N. Imai, T. Fujii and O. Toyama, This Bulletin, **38**, 410 (1965).) but it is supposed to be second order at lower temperature.

plotted against the deuterium sulfide pressure. At a constant acetaldehyde pressure and light intensity, the rate increases linearly with deuterium sulfide pressure in its low pressure range, but it tends to saturation in its higher pressure range. These phenomena are similar to those found in hydrogen sulfide catalysis and can similarly be explained.

The reaction scheme for the photolysis of acetaldehyde alone[8] (reactions 1, 2, 3, 5, 8 and 9) leads to Rate Eq. I ($I_a$[9] denotes the rate of the absorption of light quanta):

$$-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k_5 k_9^{-1/2} I_a^{1/2} [CH_3CHO] \quad (I)$$

while that in the presence of deuterium sulfide (reactions 1—9) leads to Rate Eq. II:

$$-\mathrm{d}[CH_3CHO]/\mathrm{d}t = k_5 k_9^{-1/2} I_a^{1/2} [CH_3CHO] + k_6 k_9^{-1/2} I_a^{1/2} [D_2S] \quad (II)$$

Equation II explains the linear relation between the rate and deuterium sulfide pressure, while Eqs. I and II explain the coincidence of the intercepts of the linear curves with the rates in the absence of deuterium sulfide, as may be seen in Fig. 2. At higher deuterium sulfide pressures, the concentration of DS radicals increases in relation to that of methyl radicals, and the contribution of DS radicals to chain termination has now to be taken into account. Thus the rate should be lower than that expected from Eq. II, as may be seen in Fig. 2.

From the slopes and intercepts of the linear portions in Fig. 2, the values for $k_6/k_5$ were determined; they are listed in Table I. At 300°C the values for 100 and 300 mm. of acetaldehyde approximately agree with each other.

Table I. Values of $k_6/k_5$ and $k_6'/k_5$

| Temp., °C | $k_6/k_5$ | $k_6'/k_5$ |
|---|---|---|
| 200 | 51[a] | 121 |
| 250 | 35[a] | 80 |
| 300 | 29.2[a] 30.3[b] 28.2[c] | 56 |

a) Obtained from Fig. 2 for 100 mm. acetaldehyde.
b) Obtained from Fig. 2 for 300 mm. acetaldehyde.
c) Obtained from Fig. 3.

The distribution of deuterium in methane was determined mass spectrometrically for the photolysis of 10 mm. deuterium sulfide and 300 mm. acetaldehyde mixtures with varied irradiation times at 300°C. The only methanes detected in appreciable amounts by the mass spectrometer are methane-$d_0$ and -$d_1$. The amount of methane-$d_2$ was negligible. The ratio of methane-$d_1$ to methane-$d_0$ is plotted against the time in Fig. 3, in which the ratio falls off with the progress of the reaction. This falling off in the ratio may, again, be attributed to the conversion of hydrogen sulfide-$d_2$ to -$d_1$ and -$d_0$ by reactions 7 and 7',

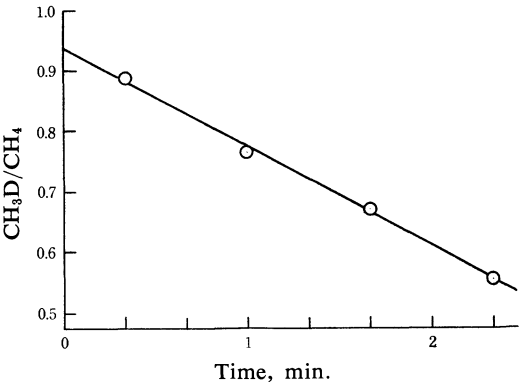

Fig. 3. Dependence of $CH_3D/CH_4$ ratio on reaction time at 300°C.
$CH_3CHO$: 300 mmHg; $D_2S$: 10 mmHg

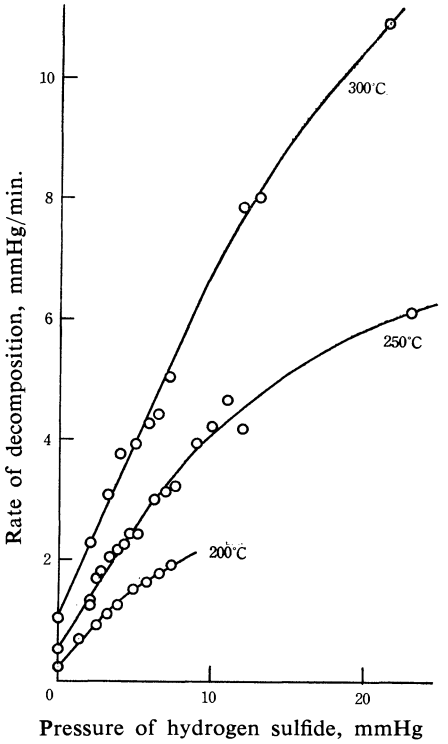

Fig. 4. Dependence of the rate of decomposition in the presence of hydrogen sulfide on its pressure. $CH_3CHO$: 100 mmHg.

if the methane-$d_1$ is not subsequently converted to methane-$d_0$.

Provided that methane-$d_0$ is formed only by reaction 5 and methane-$d_1$, by reaction 6 in the initial stage of the photolysis, the extrapolation of the linear plot in Fig. 3 gives the ratio of the rate of reaction 6 against that of reaction 5 and, consequently, the $k_6/k_5$ ratio shown in Eq. III:

$$\frac{R_{CH_3D}}{R_{CH_4}}=\frac{k_6[CH_3][D_2S]}{k_5[CH_3][CH_3CHO]}=\frac{k_6[D_2S]}{k_5[CH_3CHO]} \quad \text{(III)}$$

The value for $k_6/k_5$ thus obtained shows, as may be seen in Table I, a good agreement with those obtained from Fig. 2.

The values of $k_6/k_5$ in Table I give the Arrhenius expression:

$$k_6/k_5=2.0\exp(3000/\boldsymbol{RT}) \quad \text{(IV)}$$

In this work, the photolysis of acetaldehyde in the presence of hydrogen sulfide was investigated and the results are shown in Fig. 4, which corresponds to Fig. 2. The values of $k_6'/k_5$ obtained from this figure are also listed in Table I. They yield the expression:

$$k_6'/k_5=1.5\exp(4150/\boldsymbol{RT}) \quad \text{(V)}$$

which is in excellent agreement with $k_6'/k_5=1.7\exp(4000/\boldsymbol{RT})$, a value previously obtained by the method of total pressure measurement.[1)]

By dividing Eq. V by Eq. IV, we obtain:

$$k_6'/k_6=0.75\exp(1150/\boldsymbol{RT}) \quad \text{(VI)}$$

The ratio here obtained is fully comparable with that for hydrogen and deuterium atom abstraction from HD molecules by methyl radicals, but it is considerably lower than those for other abstraction reactions by methyl radicals as is shown in Table II.

By combining Eqs. IV and V with the $k_5=10^{11.3}\exp(-6800/\boldsymbol{RT})$ $mol^{-1}$ cc. $sec^{-1}$ reported by Ausloos and Steacie,[14)] we obtain:

$$k_6=10^{11.6}\exp(-3800/\boldsymbol{RT})\ mol^{-1}\ cc.\ sec^{-1} \quad \text{(VII)}$$

and

$$k_6'=10^{11.5}\exp(-2650/\boldsymbol{RT})\ mol^{-1}\ cc.\ sec^{-1} \quad \text{(VIII)}$$

The latter expression is almost identical with

the $k_6' = 10^{11.4} \exp(-2600/RT)$ $mol^{-1}$ cc. $sec^{-1}$ obtained in the photolysis of acetone in the presence of hydrogen sulfide.[4]

## Summary

The photolysis of acetaldehyde in the presence of deuterium sulfide has been investigated over the temperature range from 200 to 300°C, in order to determine the rate constant for the deuterium atom abstraction from deuterium sulfide molecules by methyl radicals. The effect of deuterium sulfide addition is similar to that of the addition of hydrogen sulfide previously studied. The results obtained with low concentrations of deuterium sulfide can be explained by the following reaction scheme: $CH_3CHO + h\nu \rightarrow CH_3 + CHO$ (1), $CHO \rightarrow CO + H$ (2), $H + CH_3CHO \rightarrow H_2 + CH_3CO$ (3), $H + D_2S \rightarrow HD + DS$ (4), $CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO$ (5), $CH_3 + D_2S \rightarrow CH_3D + DS$ (6), $DS + CH_3CHO \rightarrow HDS + CH_3CO$ (7), $CH_3CO \rightarrow CH_3 + CO$ (8), and $CH_3 + CH_3 \rightarrow C_2H_6$ (9). The rate equation derived from the scheme, $-d[CH_3CHO]/dt = k_5 k_9^{-1/2} I_a^{1/2} [CH_3CHO] + k_6 k_9^{-1/2} I_a^{1/2} [D_2S]$, is in agreement with the results. The application of this rate equation leads to $k_6/k_5 = 2.0 \exp(3000/RT)$, and to $k_6 = 10^{11.6} \exp(-3800/RT)$ $mol^{-1}$ cc. $sec^{-1}$, if $k_5 = 10^{11.3} \exp(-6800/RT)$ $mol^{-1}$ cc. $sec^{-1}$, as has been reported by Ausloos and Steacie. On reinvestigating the effect of hydrogen sulfide addition, it was found that $k_6'/k_5 = 1.5 \exp(4150/RT)$, where $k_6'$ refers to the $CH_3 + H_2S \rightarrow CH_4 + HS$ (6') reaction. We thus obtain $k'_6/k_6 = = 0.75 \exp(1150/RT)$.

# Amylose-Iodine Complex. IV. The Complex in Dimethyl Sulfoxide - Water Mixtures

By Sôzaburo ONO, Takehiko WATANABE, Kozo OGAWA and Nobuhiko OKAZAKI

(Received September 19, 1964)

In a previous report[1] the failure of amylose to form an iodide-free iodine complex in solution has been reported. Judging from the physicochemical properties, Kuge and Ono[2] have suggested a deformed helix conformation, similar to the one proposed by Holló and Szejtli,[3] of amylose in neutral aqueous solutions. However, the dependence of the formation of blue amylose-iodine complex on both the iodide ion and the dissolved state of aqueous uncoupled amylose has not yet been perfectly demonstrated.

In the present work, in order to obtain further knowledge on the conditions of amylose-iodine complex formation, colorimetric, spectrophotometric and viscometric studies have been made of the complex in dimethyl sulfoxide - water mixtures.

## Experimental

**Materials.** — Amylose was obtained from potato starch as follows.[4] Potato starch dispersed in a small quantity of water was poured into 1 N sodium hydroxide and dissolved by stirring them with a magnetic stirrer under nitrogen. After the starch had dissolved, the pH of the solution was adjusted to 5.4—5.6 with 2 N hydrochloric acid. The temperature of the solution was then raised to 70—80°C, and the solution was saturated with an excess of *n*-butanol while being stirred constantly, after which it was continually stirred for one day. After centrifugation of the amylose-butanol complex, the complex was recrystallized three times from hot water (about 90°C) in the presence of excess butanol. The recrystallized complex was washed thrice with absolute methanol and then once with absolute ethanol to remove butanol and water, and then dried in a vacuum over anhydrous calcium chloride.

The fractionation of amylose was carried out at

4) H. Azumi and T. Nakajima, *Sci. Rep. Tohoku Univ. Ser. I*, **36**, 278 (1952).

room temperature. The amylose was dissolved in dimethyl sulfoxide (DMSO) and fractionated by the addition of appropriate amounts of absolute ethanol, as described by Everett and Foster.[5] Seven subfractions of amylose were prepared.

The amylose subfraction whose number average molecular weight, as determined by osmotic pressure measurements, was $6\times10^5$ in DMSO at 35°C was principally used in this experiment.

As DMSO, commercially-available DMSO was distilled in a closed system under reduced pressure over Drierite.[6] This procedure gave a distillate whose density and viscosity agreed well with those reported in the literature.[6]

The water used was thrice distilled by using a glass apparatus.

**Sample Solution.**—The amylose DMSO solution was prepared as follows. Amylose was dissolved in DMSO by stirring them with a magnetic stirrer in a glass-stoppered flask for several hours and then allowing the mixture to stand for one night in a desiccator over calcium chloride in order to complete the dissolution.

Iodine purified by sublimation was dissolved in DMSO or potassium iodide aqueous solutions.

Amylose iodine DMSO solutions were prepared by mixing both the amylose and the iodine DMSO solutions.

**Colorimetry.** — The blue-colored amylose-iodine complex DMSO-$H_2O$ solutions were prepared in glass-stoppered test tubes. The test tubes were immersed in a water bath whose temperature was raised at the rate of one degree per minute. Then the colored solution in the test tube changed its color from blue through green to yellow (or red brown*1) with the rising temperature. The temperature at which the greenish color of the solution completely faded ($T_f$) was determined. After the above procedure, the temperature of the bath was reversely allowed to fall slowly and the temperature was determined at which the solution perfectly developed a blue color ($T_d$). Generally, the values of both $T_f$ and $T_d$ obtained were accurate within ±2°C.

**Spectrophotometry.** — The spectrophotometric measurements were carried out by using a Hitachi-type EPU-2A photo-electric spectrophotometer with silica cells 1.00 cm. thick.

**Viscometry.** — Viscosity was determined in suspended-level dilution viscometers modelled after FitzSimons' modification of the Ubbelohde viscometer with one capillary tube. The dimensions were as follows: capillary diameter, 0.6 mm.; capillary length, 110 mm.; volume of efflux bulb, 5 ml.; volume of dilution bulb, 150 ml. The procedure used for determining the change in the viscosity of solutions with dilution by DMSO or by the addition of water to a given amylose DMSO solution, was as follows. Twenty milliliters of a given amylose DMSO solution was pipetted into the dilution bulb of the viscometer in a thermostat at a given temperature and then allowed to stand for 20 min. in order to establish the temperature equilibrium. The efflux time was determined with a stopwatch to the nearest 0.1 sec. The dilution of the solution by DMSO was made up by the repeated dilution of the charged solution in the dilution bulb. The addition of water to the DMSO solution was also made up by the repeated addition of water to the charged solution in the dilution bulb. Dilution by DMSO or the addition of water was done volumetrically. In the case of DMSO-$H_2O$ mixtures, the specific viscosities were obtained by comparing the viscosities of the solutions with those of the corresponding DMSO-$H_2O$ mixtures.

## Results and Discussion

The formation of blue amylose-iodine complex can not be observed in an amylose iodine DMSO solution, but it is sharply observed when the concentration of water in an amylose iodine DMSO-$H_2O$ solution reaches a critical value, as has been reported by Peticolas.[7] Figure 1 shows the dependences of $T_f$ and $T_d$ on the concentration of water in DMSO-$H_2O$ mixtures. The critical concentration of water for the formation of the blue complex could not be reduced below 28 mol./l., irrespective of both the amylose and iodine concentrations. Above the critical water concentration, both $T_f$ and $T_d$ rise with the increase in water concentration. $T_f$ and $T_d$ also rise with the increase in iodine concentration, as is shown in Fig. 2. Figure 3 shows the dependence of $T_f$ on the amylose concentration and also the results with amyloses, whose number average molecular weights were $4\times10^5$ *2 and $4\times10^4$ *3

respectively. The results illustrated in Figs. 1, 2 and 3 show that the influence of amylose concentration and its molecular weight on $T_f$ values is slight compared with that of the water or iodine concentration. This fact, together with the fact that no purple or reddish color was observed at temperatures ranging from $T_d$ to $T_f$, may indicate that in this range of temperature the amylose-iodine complex has a fixed length of iodine chain and that the formation of the complex proceeds in all fashions or in none, irrespective of the concentrations and the molecular weights of amylose.

of a given amylose concentration is shown in Table I. A regular relationship has been found only between $T_f$ values and triiodide ion concentrations (Fig. 4). The iodine, iodide ion and triiodide ion concentrations were calculated with the equilibrium constants[8] of the ($I_3^- \rightleftarrows I_2+I^-$) reaction at the temperature of $T_f$. In these experiments $T_d$ values could not be determined accurately because of the pale blue color development. The results shown in Fig. 4 indicate that the triiodide ion contributes to the thermal stability of the amylose-iodine complex.

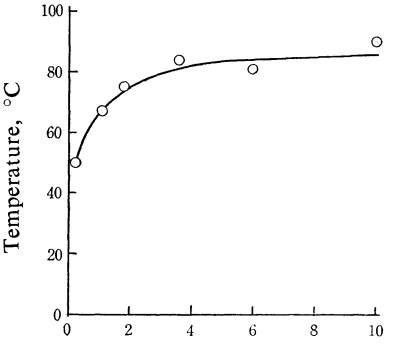

Fig. 4. Plot of $T_f$ against triiodide ion concn. in amylose (0.1 g./l.) potassium iodide-iodine aqueous solution.

The color of the iodine DMSO solution is similar to that of the iodine-iodide aqueous solution. The iodine DMSO solution possesses two absorption peaks (at 295 and 365 mμ), similar to those of the iodine-iodide aqueous solution (at 288 and 350 mμ). When water is added to the iodine DMSO solution, the two peaks shift towards the shorter wavelengths. The addition of amylose to the iodine DMSO solution causes no change in the ultraviolet absorption spectrum of the solution. When

8) M. Davies and E. Gwynne, *J. Am. Chem. Soc.*, **74**, 2748 (1952).

water is added to the amylose iodine DMSO solution, the ultraviolet and visible spectra of this amylose iodine DMSO-$H_2O$ solution show no change in nature compared with those of the corresponding iodine DMSO-$H_2O$ solution, as Fig. 5 shows, unless the blue coloration of the amylose iodine solution has been developed. When the concentration of water has exceeded a critical value, the blue amylose-iodine complex is produced in solution and the suppression of the peak at about 290 m$\mu$ and an increase in the height of the peak at about 355 m$\mu$ are observed, contrasting to the peaks of the corresponding iodine DMSO-$H_2O$ solution (Fig. 6). A similar change in the height of both the peaks in the ultraviolet spectrum

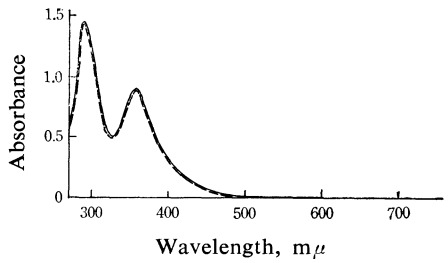

Fig. 5. Absorption spectra of 0.04 g./l. iodine in DMSO : $H_2O$=2 : 3 (v/v) mixture with 0.6 g./l. amylose (solid line) and without amylose (dashed line) at 24°C.

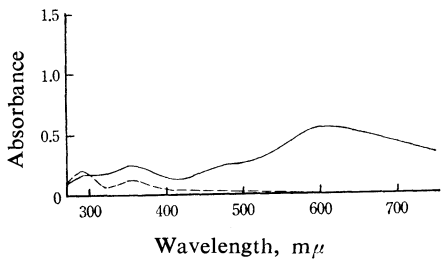

Fig. 6. Absorption spectra of 0.02 g./l. iodine in DMSO : $H_2O$=1 : 4 (v/v) mixture with 0.3 g./l. amylose (solid line) and without amylose (dashed line) at 24°C.

is observed with the amylose iodine-iodide aqueous solution (Fig. 7), as reported by Bebbington et al.[9] and Mould.[10]

These spectrophotometric results show that the nature of the amylose-iodine complex in DMSO-$H_2O$ mixtures is essentially the same as that of the complex in water. Both the peaks observed at the ultraviolet spectrum with a potassium iodide-iodine solution have been attributed to the triiodide ion by Awtrey and Connick.[11] The peaks observed with an iodine DMSO-$H_2O$ solution might also be attributed to the triiodide ion or the chemical species with an electron configuration similar to that of the triiodide ion, i. e., the polyiodide ion. Moreover, the rise in the values of $T_f$ and $T_d$ with the increase in iodine concentration (Fig. 2) seems to be explainable in terms of the increase in the triiodide (polyiodide) ion concentration.

Further spectrophotometric investigation of iodine DMSO-$H_2O$ solutions with or without amylose is in progress.

Figure 8 shows the viscometric results. Curve A shows the relationship between the amounts of water added to the 20 ml. of a 1% amylose DMSO solution and the specific viscosity of

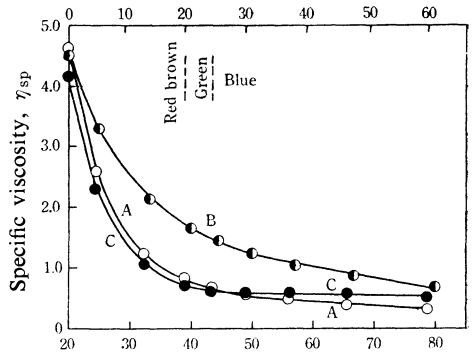

Fig. 8. The change in specific viscosity of the amylose solutions (with and without iodine) observed in the following experiments at 35°C.

Curve A 1% amylose DMSO solution (20 ml.) + water

Curve B 1% amylose DMSO solution (20 ml.) + DMSO

Curve C 1% amylose, 0.15% iodine DMSO solution (20 ml.) + water (in this case blue color development of the solution occurs at the water content shown in figure)

11) A. D. Awtrey and R. E. Connick, *J. Am. Chem. Soc.*, **73**, 1842 (1951).

the solution. Curve B shows the change in the specific viscosity of the amylose DMSO solution in the case of dilution with DMSO. The change in the specific viscosity with the increase in the amount of water (curve A) is very sharp compared to that in the case of simple dilution with DMSO (curve B). Curve C*[4] shows the relationship between the specific viscosity of the amylose iodine solution and the amounts of water added to the 20 ml. of a 1% amylose and 0.15% iodine solution. In this case the color of the solution changes from red brown through green to blue at the water content level where the sharp decrease in the specific viscosity terminates with the addition of water. The viscosity of DMSO-$H_2O$ mixtures shows no appreciable change with the dissolution of iodine. Therefore, the character of curve C may be determined primarily by the dissolved state of amylose in solution. No appreciable discontinuity in the change of the curvature of curve C has been observed at the range of water content where the blue amylose-iodine complex formation proceeds. This fact suggests that the formation of the complex does not accompany any appreciable conformational change of the amylose molecule. With the iodine complex, the molecular chain of amylose takes a helical conformation; therefore, the uncoupled amylose molecule in the corresponding DMSO-$H_2O$ mixture must take a conformation which may easily be transformed into the well-ordered helix accompanying the complex formation, i. e., the deformed helix.[2,3] The critical water concentration for blue amylose-iodine complex formation, as observed by colorimetric studies, agrees with the water content level of the amylose DMSO-$H_2O$ solution at which the sharp decrease in specific viscosity terminates. This fact suggests that the molecular chain of amylose must exist primarily as a deformed helix prior to the formation of the iodine complex.

An experiment similar to that of curve A has been made using 0.05 M iodic acid instead of water. In this case, the production of the triiodide (polyiodide) ion was repressed by the iodic acid,*[5] and no blue-colored complex was formed. The curve obtained was similar to curve A and lay parallel to and somewhat downward from it. This character of the curve shows that the amylose exists as a deformed helix at a high water content, as in the case of curve A. This result suggests that the amylose molecule existing as a deformed helix alone could not form the amylose-iodine complex without the presence of an amount of triiodide (polyiodide) ions sufficient to form the complex in solution.

The fact that the specific viscosity of the amylose-iodine complex solution is higher than that of the amylose solution at a high concentration of water in DMSO-$H_2O$ mixture may be attributed to the rigid nature of the structure of the complex compared to that of the uncoupled amylose.

Everett and Foster[12] have demonstrated that amylose exists as a coil in DMSO. Cowie,[13] on the other hand, has suggested that the existence of a helical structure could be expected of the amylose molecule dissolved in both DMSO and DMSO-$H_2O$ mixtures. Taking these authors' results into account, the present experimental results may be explained as follows. The amylose molecule may exist as a coil in DMSO; however, it can not be expected to exist as a completely extended linear chain because of the $\alpha$-1, 4-glucosidic linkages that impose steric limitations on the molecular chain. When water is added to the amylose DMSO solution, the degree of extension of the molecular chain may decrease, and the chain tends to draw itself into a somewhat helical conformation (the deformed helix[2,3]). This change in molecular chain extension seems to reveal itself as the initial sharp decrease in specific viscosity with the addition of water shown in curve A of Fig. 8. Spectrophotometric studies show that there is no interaction between the amylose and iodine unless the blue complex has been formed. The initial sharp decrease in the specific viscosity observed with curve C of Fig. 8 may be expected to be brought about by the same conformational change in the amylose chain as in the case of curve A.

The deformed helix may be regarded as a chain conformation in which the thermal fluctuations in the conformation of the molecular chain occur between the helically-wound chain conformation and the linear-extended one in a single molecule; the helical conformation is superior to the linear. Probably the

*[4] The amylose DMSO solution shows no change in viscosity after standing for one month after preparation. On the contrary, in the amylose iodine DMSO solution, amylose is degraded by the action of iodine, and the viscosity of the solution slowly decreases. Therefore, the specific viscosity of the amylose DMSO solution (without the addition of water) of curve A (without iodine) does not coincide with that of curve C (with iodine).

*[5] In the present case, the production of the triiodide (polyiodide) ion was not completely repressed. For example, the absorbance at 355 m$\mu$ of the iodine solution in DMSO: 0.05 M iodic acid = 1 : 3 (v/v) decreases by an order of magnitude of $10^{-2}$ compared to that of iodine in DMSO: $H_2O$ = 1 : 3 (v/v); the former solution with amylose could not develop the blue color at 35°C, but it slowly developed a somewhat purple color when the solution was cooled below 20°C.

12) W. W. Everett and J. F. Foster, *J. Am. Chem. Soc.*, **81**, 3464 (1959).

13) J. M. G. Cowie, *Makromol.*, **42**, 230 (1961); **59**, 189 (1963).

formation of the amylose-iodine complex proceeds by holding the iodine molecules inside the helically-wound chain parts of the amylose molecule. Therefore, the number of iodine molecules concerned in the complex formation may be determined by the length of the helically-wound parts of the deformed helical amylose molecule. However, a stable iodine complex may be expected to be formed against the thermal fluctuations of the conformation when the length of the helically-wound parts of the amylose molecule has exceeded a certain value. Therefore, the minimum number of iodine molecules necessary for the stable amylose-iodine complex formation may be determined mainly by the conformation of the amylose molecule. As for the stable iodine complex formation, the concentration of water in a DMSO-$H_2O$ mixture may be the primary factor in determining the amylose conformation, and the concentration of triiodide (polyiodide) ions would be a subsidiary factor contributing to the thermal stability of the iodine molecules in the helix. In these circumstances, the iodine complex with fewer iodine molecules than necessary can not exist stably but will release the combined iodine instantly. This prerequisite to the iodine complex formation reveals itself as an all or nothing feature of the complex formation. The increase in water concentration in the DMSO-$H_2O$ mixture beyond the critical value necessary for the complex formation would cause an increase in the superiority of the helical conformation and also a rise in both $T_a$ and $T_f$ values. With the rise in temperature, the deformed helical amylose molecules would change their conformation to a somewhat extended one as the result of the decrease in the superiority of the helical conformation, and they would become unable to combine with the iodine molecules to form the stable iodine complex because of their deficiency in the conformational prerequisite to the holding of the minimum necessary number of iodine molecules inside the helically-wound parts of the amylose molecule.

Further physicochemical studies of the deformed helical conformation of amylose are in progress.

As for the iodine, its contribution to the formation of the complex may be made through two chemical species, i. e., the iodine molecule and the triiodide (polyiodide) ion. The existence of the triiodide (polyiodide) ion is indispensable for the formation of the complex; the minimum concentration of this ion necessary for complex formation is determined by the water concentration in the DMSO-$H_2O$ mixture at a given temperature and increases with the rise in temperature in a given water concentration. The spectrophotometric results show that no interaction between iodine or the triiodide (polyiodide) ion and the amylose molecule occurs unless the blue complex has been formed in the solution. Therefore, both the chemical species may be said to make a co-operative contribution to the complex formation. In these circumstances, the triiodide (polyiodide) ion may be supposed not only to assist the entrance of the iodine molecules into the helically-wound chain of amylose but also to act as a stabilizer for the fixation of the iodine within the helix. Thus, the resonating iodine chain in the amylose helix may be expected to be stabilized against thermal disturbance by the triiodide (polyiodide) ions adsorbed at both ends of the iodine chain, and the amylose-iodine complex may be expected to become more rigid in nature compared to that of the uncoupled amylose molecule.

## Summary

The temperature at which the blue color due to the formation of amylose-iodine complex fades completely has been determined with a system of amylose and iodine dissolved in dimethyl sulfoxide-water mixtures. This temperature rises with the increase in the concentration of iodine in mixtures, and also with the increasing concentration of water in the mixed solvents.

The spectrophotometric results show that the nature of the amylose-iodine complex in a dimethyl sulfoxide-water mixture is similar to that of one in water, and that the triiodide ion or a chemical species similar to the ion, i. e., the polyiodide ion, contributes to the formation of the complex.

The viscometric studies show that the amylose molecule takes a deformed helix conformation prior to the formation of the blue iodine complex and that this conformational prerequisite to the complex formation is fulfilled when the water concentration in a dimethyl sulfoxide-water mixture exceeds a critical value.

These results stated above may indicate that the triiodide (polyiodide) ion plays the part of "stabilizer" for the fixation of iodine molecules within the helically-wound chain of the amylose molecule when the amylose exists primarily as a deformed helix in solution.

# The Electrooxidation of Absolute Methanol

By Kazuo SASAKI and Shigeo NAGAURA

(Received September 25, 1964)

Tsutsumi and his collaborators[1] first reported that several hydrocarbons give the corresponding methyl ethers upon the electrolysis of their methanolic solutions. They stated that the reaction proceeds through the formation of a methoxy-free radical.

As is well known,[2] alkoxy-free radicals can generally be produced by neither irradiation nor thermal decomposition from their parent alcohol. Electrolysis, therefore, seems to be a quite specific method for producing alkoxy-free radicals.

In this paper, the electrolytic behavior of absolute methanol containing sodium methylate or certain inorganic salts as supporting electrolytes will be described. The reactions of several hydrocarbons in the methanolic media will be reported on successively.

## Experimental Procedures and Results

**General Description of the Experiment.**— Special grade methanol obtained from the Wako Pure Chemicals company was distilled once and dehydrated by the usual method before use. Smooth or platinized platinum was used for both the anode and the cathode electrode throughout the present investigation. The size of the electrode was changed with each experiment. The electrode potential was measured with reference to a saturated calomel electrode (SCE). Besides sodium methylate, some inorganic salts were examined as supporting electrolytes. Unless otherwise stated, the concentration of the electrolyte was kept at 0.1 mol./l. The solution was deaerated by nitrogen before each experiment.

**The Static Potential of the Platinum Electrode (Fig. 1).**—The electrode potential at a no-current flow was measured as a function of the sodium methylate concentration and of the hydrogen partial pressure, which was varied by mixing hydrogen with dry nitrogen. Both smooth and platinized platinum electrode were examined, but the data concerning the smooth platinum electrode were discarded because of their poor regularity.

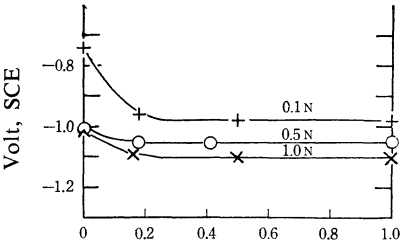

Fig. 1. Static electrode potential of Pt-Pt electrode in absolute methanol.
+ : 0.1 N Sodium methylate
○ : 0.5 N Sodium methylate
× : 1.0 N Sodium methylate

Although no quantitative conclusion can be obtained from this measurement, it is evident that the electrode potential is affected by the methylate concentration. The proportionality coefficient between the potential and the logarithm of concentration can roughly be estimated to be $2RT/F$.

**The Constant-current Polarization in the Stirred Solution.** — The current-potential and potential-time curves under the constant-current conditions were measured for sodium methylate solutions using a smooth platinum electrode with an apparent area of 30 $cm^2$. During the experiment nitrogen was bubbled into the solution.

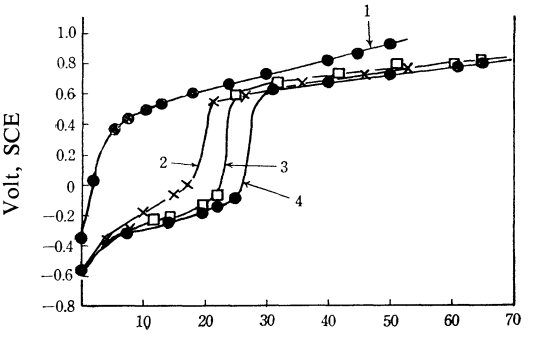

Fig. 2. Current-potential curves for various methylate concentrations.
Curve 1, 0.24 mol./l.; 3, 1.9 mol./l.;
2, 0.96 mol./l.; 4, 2.2 mol./l.

1) T. Inoue, K. Koyama, T. Matsuoka, K. Matsuoka and S. Tsutsumi, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **66**, 1659 (1963).
2) P. Gray and A. Williams, *Chem. Revs.*, **59**, 239 (1959).

Figure 2 shows the *i-E* curve obtained for solutions with different salt concentrations. It is significant that the *i-E* curves show a sudden rise in potential at a certain current value. The current value at which the potential rises suddenly is shifted regularly to a lower value with a decrease in the methylate concentration. A similar shape of the polarization curve has often been reported in the case of Kolbe electrosynthesis.[3-5]

In the latter case, it has been explained that the accumulation of carboxyl radicals, formed by the discharge of the carboxylate anion, on the electrode surface, causes the potential jump. In any case, it is clear, in the present experiment, that during the discharge of the methylate anion the electrode potential is kept at a lower value.

The potential-time curve obtained by constant current electrolysis is shown in Fig. 3. In this case, the concentration of methylate is kept constant. The figure shows that the time required for the potential rise is lengthened by the decrease in the current applied.

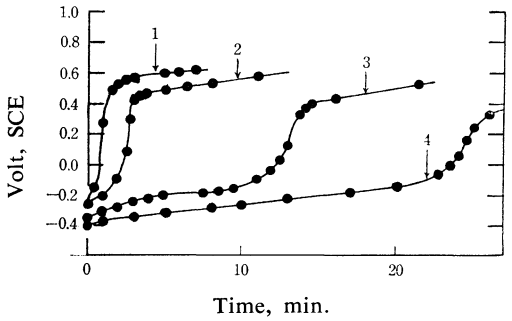

Fig. 3. Potential-time curves in the stirred solution.

**Constant-current Polarization under Unstirred Conditions (Chronopotentiometry).** — Another from of potential-time relationship was obtained under unstirred conditions. A schematic diagram of the cell for this measurement is shown in Fig. 4a. The *E-t* curves were obtained by an automatic pen-recorder. Platinized platinum (0.5 mm. in diameter and 5 mm. long) was used as the working electrode.

The most striking feature observed in this experiment is that the shape of the chrono-

potentiogram is determined solely by the kind of supporting electrolyte used (Figs. 5a—c).

When sodium methylate was examined as a supporting electrolyte, the normal potential arrest (the chronopotentiometric "transition time") was observed in the process of anodic polarization. Upon the immediate reversal of the direction of the current flow, the potential decreased steeply without any characteristic change (Fig. 5a). The potential arrest observed in the anodic process satisfied approximately the requirement of the constancy of $i\tau^{1/2}$. This is illustrated in Fig. 6, which depicts the

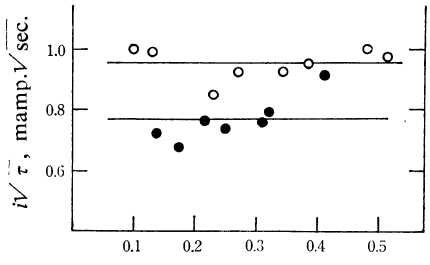

Fig. 6. Relation between $i\tau^{1/2}$ and current for methylate solution obtained from two separate runs; apparent area of Pt-Pt electrode is 0.08 cm$^2$.

results obtained from two separate runs.*

The anodic chronopotentiogram for sodium perchlorate, on the other hand, showed no characteristic potential arrest and reached the final plateau gradually. In this case, however, a definite potential arrest appeared in the cathodic half cycle (Fig. 5b). It is interesting that the potential arrest, $T_c$, is affected by the duration of the current rupture, $T_r$, between the anodic and cathodic half-cycles. Notations are illustrated in Fig. 5d.

As Fig. 7 shows, the cathodic arrest time decreases proportionally with the square root

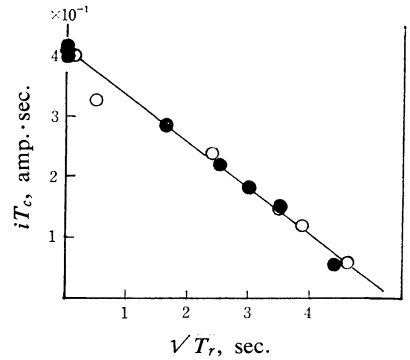

Fig. 7. The effect of the current rupture on the cathodic transition time in the perchlorate system.
Full and empty circles represent the results obtained by polarizing current of 330 and 770 $\mu$amp., respectively.

of the time of the current rupture. Although no active materials in this cathodic potential arrest are known, it is clear that such materials are produced during the anodic half-cycle but disappear from the electrode surface according to some simple kinetic rule.

By EPR measurement, Maki and Geske[8] observed the perchlorate-free radical formed electrolytically in an acetonitrile solution. Their results were confirmed in our laboratory, although no EPR signal was detected in the methanolic media.[9]

Although the shape of the chronopotentiogram of the ammonium chloride solution (Fig. 5c) is not simple enough for us to say more, it is at least clear that no potential arrest is observed in the anodic half-cycle.

The three types of chronopotentiograms obtained above suggest that methanol, as it is, can be oxidized electrochemically only with difficulty. In other works, the primary electroactive species in the electrooxidation of absolute methanol are the supporting electrolytes, not methanol itself or anythingelse which is derived from methanol.

The fact that the final values of the anodic potential for three kinds of electrolytes differ from each other may be a support for this statement.

**Potentiostatic Polarization.** — Potentiostatic measurements were also made using sodium

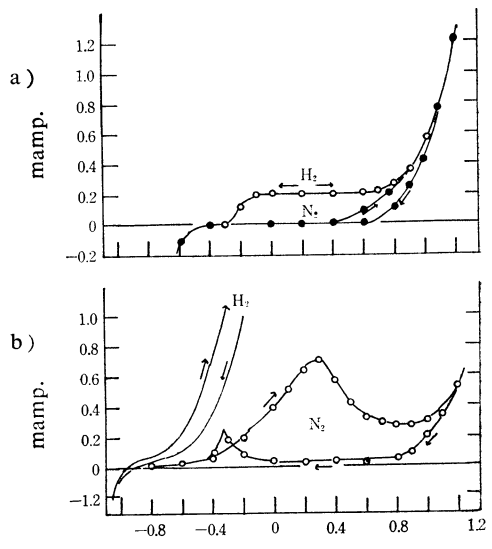

Fig. 8. Potentiostatic $i$-$E$ curves for sodium perchlorate (Fig. 8a) and sodium methylate solution (Fig. 8b).

* By using the mean value of these two experiments, and by evaluating the apparent surface area of the electrode, the concentration of methylate can be estimated as 0.3 mol./cc. If the true area of the platinized platinum electrode is 2000 times greater than the apparent one,[6] the figure calculated above agrees roughly with the real one. This treatment, however, seems to be too arbitrary. In the rigorous sense of the terminology, this case must be treated as the solution containing no supporting (indifferent) electrolyte. Accordingly, the chronopotentiometric transition time will be affected by the electric migration.[7]

methylate and sodium perchlorate as the supporting electrolytes. The platinized platinum electrode used in the chronopotentiometry was used again in this experiment. The rate of voltage scanning was 0.05 V./min. The electrolysis cell is shown in Fig. 4b. During the experiment, nitrogen or hydrogen gas was bubbled in order to agitate the solution.

In accordance with the results of the chronopotentiometry, the potentiostatic *i-E* curve was greatly affected by a change in the kind of electrolyte used. Figure 8a represents the results with a perchlorate solution. If the solution was under the nitrogen atmosphere, the *i-E* curve was quite simple and the anodic and cathodic scan curves were on almost the same line. When the solution was saturated with hydrogen, however, a definite diffusion limiting current was observed. The reverse scan curve coincided with the curve of forward scan. The fact that the anodic and cathodic scan curves are on the same line suggests that the complication of the surface change of platinum electrode encountered in the aqueous phase experiment[10] can be ignored in the methanolic media, at least if the scan speed is not exceptionally large.

Figure 8b presents the results concerning the methylate solution. In this case, the shape of the *i-E* curve is quite similar to that obtained in the aqueous solution of methanol. For instance, the anodic current shows a peak in the moderate potential range.

Furthermore, the potential at which the anodic current peak appears in the course of the cathodic scan is shifted to a less positive potential than in the case of the foregoing scan. In addition, the peak value of the anodic current is successively decreased when the scan is multiplicated. In this case the accumulation of electrolytically-inert material may be significant.

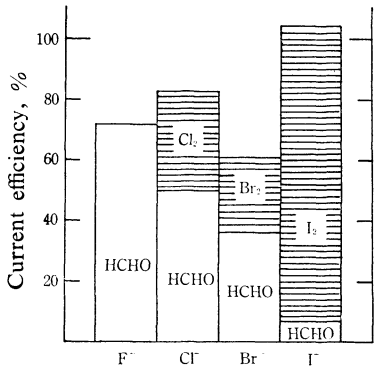

Fig. 9. Current efficiencies for the formation of formaldehyde (empty area) and free halogen (shaded area) with respect to four ammonium halides.

**Product Analysis.**—Methanol in an aqueous solution, especially in an acidic medium, is oxidized anodically to carbon dioxide, but the final product in absolute methanol is carbon monoxide. This was confirmed by mass spectrometric analysis.[11] In the present experiment, the products in the liquid phase was analyzed. One hundred cubic centimeters of absolute methanol containing either one of four ammonium halides or sodium methylate was electrolyzed for two hours at 100 mamp. The electrolysis cell was then cooled by ice-water mixiure in order to minimize the evaporation. The results of the analysis of free halogen and formaldehyde as determined by iodometric titration are shown in Fig. 9. In this figure, the product yield is expressed in terms of current efficiency. It can be seen that the formation of both formaldehyde and free halogen molecules is affected by the change in the supporting electrolyte.

As for ammonium iodide, the current is consumed almost completely in the liberation of the free iodine molecule. No free fluorine was detected, perhaps because of the immediate formation of hydrogen fluoride. It is interesting to notice that the formation of free halogen increased and formaldehyde decreased in the following order of supporting electrolytes: $F^-$, $Cl^-$, $Br^-$ and $I^-$.

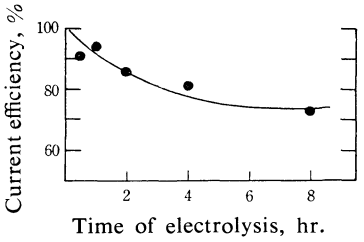

Fig. 10. The current efficiency of the formation of formaldehyde and the duration of the electrolysis. Supporting electrolyte is sodium methylate.

Except the case of iodide, the total current efficiency for the formation of free halogen and formaldehyde differed greatly from 100%. This is also ture when sodium methylate is used as the electrolyte. In the latter case, the current efficiency for the aldehyde formation is reduced by the duration of electrolysis (Fig. 10). The remainder of the current is consumed by the further oxidation of the

11) K. Sasaki and S. Nagaura, This Bulletin, **37**, 1086 (1964).

aldehyde, yielding carbon monoxide. In addition, since the present analysis does not cover the vapor phase, the evaporation of the products may be another reason for this discrepancy.

## Summary

From the several experiments described above, it can be concluded that the electroactive species in the anodic reaction of methanol in the moderate potential range is the methylate anion only.

The evidence for this conclusion will be summarized below.

The static potential of the platinized platinum electrode in absolute methanol is affected by the methylate concentration.

It is confirmed that a definite transition time in an anodic chronopotentiogram is observed only for the case of the methylate ion. The results from the potentiostatic experiments also support this conclusion.

Although this is the case, methanol is still electrolyzed to form formaldehyde at a higher potential range. Product analysis shows that the yield of formaldehyde is affected appreciably by the kind of supporting electrolyte. Except fluorine, an appreciable number of free halogen molecules is detected in the solution after electrolysis. Even in the case of an iodine/iodide couple, the thermodynamic potential is far more positive than that of methanol. It may be understood from this fact that the electrooxidation of neutral methanol is strongly irreversible. Furthermore, it seems quite plausible that some part of the methanol is decomposed by the attack of the free radicals (or atoms) formed by the discharge of salt anion. The reaction scheme can be formulated as follows:

$$X^- \rightarrow X + e$$

$$X + CH_3OH \rightarrow HX + CH_3O \text{ (or } CH_2OH)$$

$$2CH_3O \text{ (or } CH_2OH) \rightarrow CH_3OH + HCHO$$

Coinciding with this hypothesis, the current efficiencies of formaldehyde formation are increased in the order of the hydrogen-abstracting power of the four halogen atoms examined, i.e., $I < Br < Cl < F$ (see Fig. 9).

The mechanism of the electrolytic oxidation of methanol in aqueous solution has been studied by many authors, but no mechanism has yet been accepted without any ambiguity.

The static electrode potential observed in an aqueous methanol solution rests near the thermodynamic redox couple:

$$CH_3OH = HCHO + 2H^+ + 2e \quad 0.23 \text{ V. NHE}$$

It is evident, however, that the real process does not proceed through such a simple reversible path.

Another mechanism proposed is the catalytic dehydrogenation:

$$CH_3OH = HCHO + 2H(Ads)$$

$$2H(Ads) \rightarrow 2H^+ + 2e$$

This mechanism seems somewhat plausible, and some indirect evidence for it has been pointed out by the present authors.[12]

Although it is difficult to state a definite conclusion about the reaction mechanism in the aqueous solution, the present conclusion, emphasizing the importance of the methylate ion, seems applicable in the case of the aqueous phase reaction. The fact that the performance of the methanol fuel cell in the alkaline medium is superior to that in the acidic one can thus be understood if the following reaction is taken into account:

$$CH_3OH + OH^- = CH_3O^- + H_2O$$

# The Rotatory Dispersion of Cobalt(III) Ammine Complexes Containing Amino Acid as a Unidentate Ligand

By Junnosuke FUJITA*, Takaji YASUI and Yoichi SHIMURA

(Received October 13, 1964)

Although several studies[1-4] have been made of the rotatory dispersion of metallic complexes in which the asymmetric center is not around the metal ion but is only at the atom in the coordinated ligand, most of these studies have been made on planar-type complexes such as copper(II) alaninate. For octahedral complexes, Jaeger[5] has prepared the molecular complex $[Co(NO_2)_3NH_3(d\text{-chxn})]$** and shown that this complex exhibits an anomalous dispersion in the region of the first absorption band. A similar study has been reported by Mathieu[6] on a similar complex, $[Co(NO_2)_3NH_3(d\text{-pn})]$. Recently, Shimura[7] has prepared the complex $[Co(NH_3)_4(\text{L-leuc})]^{2+}$, which has a much simpler structure than those of the above type, and has observed an anomalous dispersion which consists of two inversive dispersions in the vicinity of its first absorption band. Through these experiments, the existence of the so-called "vicinal effect"[1,2] between the central metal ion and the asymmetric atom in the ligand has been proved.

It should be noted, however, that the previous investigations were made with complexes containing an optically active reagent as a chelate ligand. The chelate ligand sometimes takes the gauche form upon coordination, which may result in another optically active structure. In order to study the vicinal effect in more detail, it would be desirable to measure the rotatory dispersion of the complex coordinating with a unidentate optically active ligand. Unfortunately, no complexes of such type are known. It was decided at first, therefore, to prepare cobalt(III) complexes in which amino acid is coordinated as a unidentate ligand.

In the present paper, the preparation and the absorption studies of a large number of pentammine and tetrammine cobalt(III) complexes containing both optically active and inactive amino acids will be described. The rotatory dispersion and the circular dichroism of the optically active complexes will also be measured, and the results will be discussed from the standpoint of the structure of these complexes.

## Experimental

**Preparation.** — *Pentammineglycinecobalt(III) Perchlorate Monohydrate: $[Co(NH_3)_5(glyH)](ClO_4)_3\cdot H_2O$.* — An aqueous solution containing 5 g. of aquopentamminecobalt(III) perchlorate[8] and 2 g. (excess) of glycine in 50 ml. of water was gradually evaporated on a water bath at 75—80°C to a volume of about 20 cc. The dark red solution obtained was kept in a refrigerator overnight. The orange-pink crystals formed were filtered and washed with a water-ethanol (1 : 1) mixture and then with absolute ethanol. This was recrystallized by dissolving it in warm water and then cooling it in a refrigerator. Recrystallization from a cold aqueous solution was also effected by the addition of 30% perchloric acid.

*Pentamminecobalt(III) Perchlorates of β-Alanine, DL-α-Alanine, L-α-Alanine and γ-Aminobutylic Acid: $[Co(NH_3)_5(\beta\text{-alaH})](ClO_4)_3$, $[Co(NH_3)_5(\text{DL-}\alpha\text{-alaH})](ClO_4)_3\cdot H_2O$, $[Co(NH_3)_5(\text{L-}\alpha\text{-alaH})](ClO_4)_3\cdot 2H_2O$ and $[Co(NH_3)_5(\gamma\text{-ambutH})](ClO_4)_3$.* — These complexes were prepared by the same method as the glycine complex described above, using β-alanine, DL-α-alanine, L-α-alanine and γ-aminobutylic acid respectively. These complexes are more soluble in water than is the glycine complex.

*Pentammine-L-phenylalanine-cobalt(III) Perchlorate Monohydrate: $[Co(NH_3)_5(\text{L-phalaH})](ClO_4)_3\cdot H_2O$.* — To 50 ml. of an aqueous solution containing 5 g. of aquopentamminecobalt(III) perchlorate 2 g. (a slight excess) of L-phenylalanine was added. The mixture was warmed on a water bath at 80°C until the amino acid was dissolved. The dark red solution

obtained was then evaporated on a water bath at 75—80°C to a volume of about 20 cc. and cooled in ice. The red crystals obtained were filtered and washed with a water-ethanol (1 : 1) mixture and then with absolute ethanol. Fine crystalline needles were obtained from a cold aqueous solution by adding 30% perchloric acid.

*Glycinatopentamminecobalt(III) Perchlorate: [Co-gly($NH_3$)$_5$]($ClO_4$)$_2$.* — Three grams of pentammineglycinecobalt(III) perchlorate monohydrate was dissolved in 20 ml. of 30% aqueous ammonia. To the dark red solution obtained ethanol was then added. Upon cooling in ice, the dark red crystals formed were filtered and washed with a water-ethanol (1 : 1) mixture and then with absolute ethanol. This complex was recrystallized from 3% aqueous ammonia by adding ethanol.

*DL-α-Alaninato-pentamminecobalt(III) Perchlorate Monohydrate: [Co(DL-α-ala)($NH_3$)$_5$]($ClO_4$)$_2$·$H_2O$.* — The dark red crystals of this complex were obtained by the method described above for the glycinato complex, but using [Co($NH_3$)$_5$(DL-α-alaH)]($ClO_4$)$_3$·$H_2O$ instead of [Co($NH_3$)$_5$(glyH)]($ClO_4$)$_3$·$H_2O$.

*Tetrammine-bis(glycine)cobalt(III) Perchlorate: [Co($NH_3$)$_4$(glyH)$_2$]($ClO_4$)$_3$.* — To 30 ml. of an aqueous solution containing 5 g. of diaquotetramminecobalt(III) perchlorate[9] a slight excess of glycine (1.8 g.) was added. The resulting solution was gradually evaporated on a water bath at 75—80°C to a volume of about 10 ml. After cooling, the drop-by-drop addition of absolute ethanol to this solution resulted in the formation of purple crude crystals, which were then filtered and washed with ethanol. These crystals were recrystallized by dissolving them in the minimum amount of water and then adding ethanol and a few drops of concentrated perchloric acid. Purple crystals were obtained after the solution had been kept in a refrigerator overnight.

*Tetrammine-bis(DL-α-alanine)-, and Tetrammine-bis(L-α-alanine)cobalt(III) Perchlorates: [Co($NH_3$)$_4$-(DL-α-alaH)$_2$]($ClO_4$)$_3$ and [Co($NH_3$)$_4$(L-α-alaH)$_2$]-($ClO_4$)$_3$·$2H_2O$.*—Purple crystals of these complexes were prepared by the same method as the bis(glycine) complex described above, but using 2 g. of DL-α-alanine and L-α-alanine respectively instead of glycine.

*Aquotetrammineglycinecobalt(III) Perchlorate Monohydrate: [Co($OH_2$)($NH_3$)$_4$(glyH)]($ClO_4$)$_3$·$H_2O$.* — To an aqueous solution of 5 g. of diaquotetramminecobalt(III) perchlorate in 50 ml. of water 1 g. of glycine was added. The purple red solution obtained was warmed on a water bath at 80°C for 15 min. and cooled in ice. Pink-colored crystals were precipitated by adding concentrated perchloric acid; the crystals were then filtered and washed with ethanol. This complex was recrystallized from a cold aqueous solution by adding concentrated perchloric acid.

*Aquotetrammine-DL-α-alanine- and Aquotetrammine-L-α-alaninecobalt(III) Perchlorates: [Co($OH_2$)($NH_3$)$_4$-(DL-α-alaH)]($ClO_4$)$_3$·$H_2O$ and [Co($OH_2$)($NH_3$)$_4$(L-α-alaH)]($ClO_4$)$_3$·$H_2O$.* — These complexes were prepared and recrystallized by the method which has been described above for the aquo-glycine complex, but using 1.2 g. of DL-α-alanine and L-α-alanine respectively instead of glycine. These complexes were more soluble in water than the corresponding

glycine complex.

*Tetrammineglycine-L-α-alaninecobalt(III) Perchlorate Dihydrate: $[Co(NH_3)_4(glyH)(L\text{-}\alpha\text{-}alaH)](ClO_4)_3\cdot 2H_2O$.* — To an aqueous solution containing 5 g. of aquotetrammineglycinecobalt(III) perchlorate dissolved in the minimum amount of water 0.9 g. of L-α-alanine was added. The reddish-violet solution obtained was warmed on a water bath at 80°C for 15 min. After it had cooled as a clear, dark violet solution, ethanol was added, resulting in the slow formation of purple crystals. These were filtered and washed with ethanol. Recrystallization from a concentrated aqueous solution was effected by the addition of ethanol and of a few drops of concentrated perchloric acid. Purple crystals were obtained after the solution had been kept in a refrigerator overnight.

*Pentamminebetaine- and Tetrammine-bis(betaine)-cobalt(III) Perchlorates: $[Co(NH_3)_5bet](ClO_4)_3$ and $[Co(NH_3)_4(bet)_2](ClO_4)_3$.*—These betaine complexes were prepared by the method described in the literature[10] and were recrystallized several times from the aqueous solutions.

*L-α-Alaninato-tetramminecobalt(III) Sulfate: $[Co(L\text{-}\alpha\text{-}ala)(NH_3)_4]SO_4$.*—This complex was prepared by the method given by Shimura[11] for the preparation of DL-α-alaninato-tetramminecobalt(III) sulfate. The corresponding D-α-alaninato complex was also prepared by this method.

The results of the chemical analysis for all the complexes prepared are given in Table I.

**Spectral Measurements.**—Visible and ultraviolet absorption spectra were obtained by using a Shimadzu QR-50 spectrophotometer in the 30 to $150\times 10^{13}$ $sec^{-1}$ range. Infrared spectra were obtained with a Hitachi EPI-2G infrared spectrophotometer. The rotatory dispersion measurements were made by a Rudolph photoelectric spectropolarimeter, Model 200S-80. A Roussel-Jouan dichrograph in University of Pittsburgh, U. S. A., was used to obtain the circular dichroism spectra. All the measurements were made in aqueous solutions and at room temperature.

## Results

Table II lists the numerical data for the A, the first and the second absorption bands obtained in the present measurements. The data for the complexes which contain DL-α-alanine are not listed in this table, because they are exactly identical with those of the corresponding L-α-alanine complexes. Some typical absorption curves of the spectra are shown in Figs. 1 and 2. Figures 3—9 show the rotatory dispersion, the circular dichroism and the absorption curves of different complexes.

## Discussion

**Amino Acid in Unidentate Coordination.** — It has been well known that an amino acid usually coordinates to a metal as a chelate ligand with its amino and carboxyl groups. In some particular complexes, however, the ligand amino acid is considered to act as a

unidentate ligand,[12-15] although no such complexes of cobalt(III) have been isolated. In the present study, the analytical values of the complexes prepared clearly indicate that the amino acids in these complexes coordinate to the cobalt(III) ion as a unidentate ligand. With respect to the amino acids concerned, there are two possible ways of bonding to the cobalt ion as a unidentate ligand. One is to be coordinated to the cobalt with the oxygen atom of the carboxyl group, and the other, with the nitrogen atom of the amino group. In the present case, the results of the absorption measurements suggest that the coordination of amino acid corresponds to the former way. The maximum frequencies and intensities of the first and the second bands of the unidentate amino acid complexes are almost the same as those of the betaine complexes in which the ligand betaine undoubtedly coordinates to the cobalt(III) ion with its carboxyl group (see Table II). Other evidence of the cobalt-oxygen linkage in the unidentate amino acid complexes lies in their infrared spectra. All the unidentate amino acid complexes except for the $[Co\,gly(NH_3)_5](ClO_4)_2$ and $[Co(DL\text{-}\alpha\text{-ala})(NH_3)_5](ClO_4)_2\cdot H_2O$ complexes show the C-O stretching band of the coordinated carboxyl group at about 1650 $cm^{-1}$.[10,16] and the deformation band of $-NH_3^+$ group at about 1500 $cm^{-1}$.[17] The $[Co\,gly(NH_3)_5](ClO_4)_2$ and $[Co(DL\text{-}\alpha\text{-ala})(NH_3)_5](ClO_4)_2\cdot H_2O$ complexes, which are prepared in alkaline media, do not show the $-NH_3^+$ deformation band. This indicates that the structure of the amino group is the $-NH_2$ form caused by the neutralization with alkali. All these facts lead to the conclusion that the carboxyl group is more favored than the amino group in the unidentate coordination to the cobalt(III) ion.

An attempt to prepare a complex in which the unidentate amino acid is coordinated to the cobalt(III) ion with its amino group was not successful. In the reaction of aquopentamminecobalt(III) perchlorate with amino acid, the treatment above 85°C or the addition of activated charcoal always produced complexes containing amino acid as a chelate ligand, with the evolution of ammonia gas.

In the tetrammine-bis(amino-acid)cobalt(III) ion two geometrical isomers, cis and trans, are possible, but only one species for each tetrammine complex has been obtained in the present preparation. As Figs. 1 and 2 show, the first bands of all the tetrammine complexes exhibit no splittings. The tetrammine complex with two oxygen atoms in trans positions may be expected to show distinct splittings of the first absorption band.[18] Thus, it has been concluded that all the tetrammine complexes prepared here correspond to the cis isomers. The first band of the bis(acetato)tetramminecobalt(III) complex, which has a structure similar to that of the unidentate amino acid complexes, shows a remarkable splitting in the trans isomer, but no splitting in the cis isomer.[19]

The first and the second absorption bands of the pentammine(amino-acid)cobalt(III) complexes shifted to a longer wavelength than

those of the aquopentamminecobalt(III) complex.[20] As Fig. 1 shows, the same relation may be seen to result from the replacement of the water molecule by amino acid in a series of complexes, $[Co(NH_3)_4(glyH)_2]^{3+}$, $[Co(NH_3)_4(OH_2)(glyH)]^{3+}$ and $[Co(NH_3)_4$-

20) Y. Shimura and R. Tsuchida, This Bulletin, 29, 311 (1956).

$(OH_2)_2]^{3+}$. The first and the second bands of the last complex have been observed at 59.4 and $84.6\times10^{13}$ sec$^{-1}$ respectively.[20] From these spectral results, it has been concluded that the position of the unidentate amino acid in the spectrochemical series[20,21] is behind $OH_2$, but higher than $CH_3COO^-$ or $CO_3^{2-}$.

**Rotatory Dispersion and Circular Dichroism.** —As has been mentioned above, Shimura[7] measured the rotatory dispersion of the complex, $[Co(L\text{-leuc})(NH_3)_4]^{2+}$ which contains only one optically active chelate ligand. The shape and the magnitude of the anomalous dispersion of this complex in the region of its first absorption band are very similar to those of $[Co(L\text{-}\alpha\text{-ala})(NH_3)_4]^{2+}$, which has been measured in the present study in order to compare with the dispersion of the unidentate amino acid complexes. Shimura has also shown, by curve analysis, that the first band of $[Co(L\text{-leuc})(NH_3)_4]^{2+}$ exhibits two inversive dispersions, one of which shows a positive Cotton effect and the other, a negative Cotton effect. A similar result is obtained by the analysis of the rotatory dispersion curve of $[Co(L\text{-}\alpha\text{-ala})(NH_3)_4]^{2+}$. The circular dichroism of $[Co(L\text{-}\alpha\text{-ala})(NH_3)_4]^{2+}$, on the other hand, indicates that the first band should have another weak, negative Cotton effect on the longer wavelength side adjacent to the above-mentioned two strong Cotton effects and, moreover, one negative Cotton effect in the region of the second absorption band (see Fig. 3). In the rotatory dispersion curve of $[Co(L\text{-}\alpha\text{-ala})(NH_3)_4]^{2+}$, some indications of the inversive dispersion are seen at 55 and $87\times10^{13}$ sec$^{-1}$. In order to establish these small anomalous dispersions, the rotatory dispersion of $[Co(D\text{-}\alpha\text{-ala})(NH_3)_4]^{2+}$ has been measured. As may be seen in Fig. 4, the dispersion curve of this complex is almost antipodal to that of the corresponding L-$\alpha$-alaninato complex. It may be concluded, therefore, that the first absorption band of the $[Co(L\text{-}\alpha\text{-ala})(NH_3)_4]^{2+}$ complex shows three inversive dispersions and the second band, one or more additional inversive dispersions.

The rotatory dispersion curve of the unidentate amino acid complex $[Co(NH_3)_5(L\text{-}\alpha\text{-alaH})]^{3+}$, on the other hand, shows a very weak anomalous dispersion in its first band compared with that of the chelate complex (see Fig. 5). The magnitude of the partial molar rotation of the former is about 1/10 that of the latter. The circular dichroism of $[Co(NH_3)_5(L\text{-}\alpha\text{-alaH})]^{3+}$ is also so weak that quantitative measurement was impossible. The circular dichroism curve given in Fig. 5 is only qualitative. In the rotatory dispersion curve of $[Co(NH_3)_5(L\text{-phalaH})]^{3+}$ (Fig. 6), a more distinct anomalous dispersion than that of the corresponding L-$\alpha$-alanine complex is observed in the region of the first band, although the magnitude of this dispersion is still very weak compared with those of the chelate amino acid complexes. The difference in the magnitude of anomalous dispersion between the unidentate and the chelate amino acid complexes might be caused by: 1) the difference in the distance from the asymmetric carbon atom to the cobalt ion, Co-O-C-C*- for the unidentate complex, but Co-O-C-C*- and Co-N-C*- for the chelate complex; 2) the conformational difference (that is, the conformation of the amino acid in the chelate complex is fixed by the formation of the chelate ring, but in the unidentate complex the amino acid can rotate about the Co-O bond axis), or 3) the difference in the electronic states of the complex ions caused by the coordination of the different atoms or by the different structures.

In order to study the points above-mentioned in more detail, the rotatory dispersion of three tetrammine complexes of $[Co\,N_4O_2]$ type have been measured. As Fig. 7 shows, the anomalous dispersion of *cis*-$[Co(NH_3)_4(L\text{-}\alpha\text{-alaH})_2]^{3+}$ in its first band is rather remarkable compared with that of $[Co(NH_3)_5(L\text{-}\alpha\text{-alaH})]^{3+}$. The

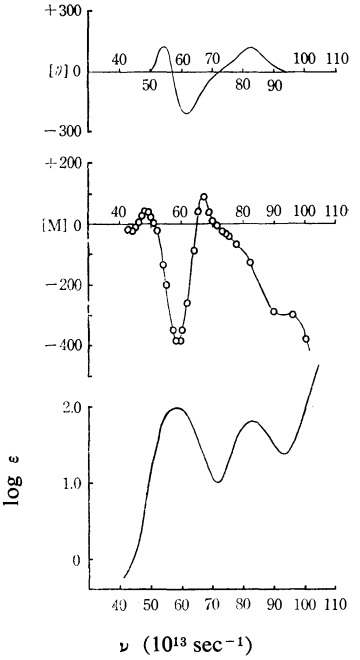

Fig. 7. Circular dichroism, rotatory dispersion and absorption of *cis*-$[Co(NH_3)_4(L\text{-}\alpha\text{-alaH})_2](ClO_4)_3\cdot2H_2O$.

21) R. Tsuchida, ibid., 13, 388, 436 (1938).

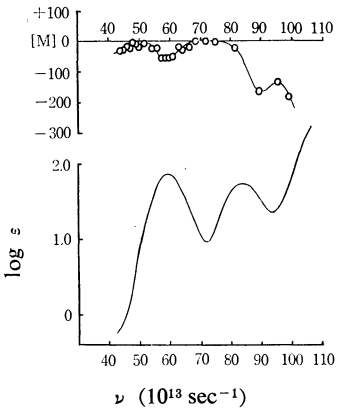

Fig. 8. Rotatory dispersion and absorption of *cis*-$[Co(OH_2)(NH_3)_4(L\text{-}\alpha\text{-alaH})](ClO_4)_3 \cdot H_2O$.

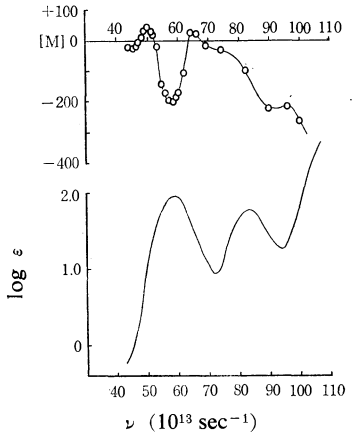

Fig. 9. Rotatory dispersion and absorption of *cis*-$[Co(NH_3)_4(glyH)(L\text{-}\alpha\text{-alaH})](ClO_4)_3 \cdot 2H_2O$.

magnitude of the inversive dispersion in the former is estimated to be almost four times larger than that in the latter. This fact seems to suggest that the magnitude of the anomalous dispersion is not proportional to the number of the optically active ligands. This might be caused by the difference in the conformational mobility of the coordinated amino acid. The difference in the types of the complexes ([Co $N_5O$] and [Co $N_4O_2$]) does not seem to be important in this case. In *cis*-$[Co(NH_3)_4(L\text{-}\alpha\text{-alaH})_2]^{3+}$, two amino acids in the cis positions should take a conformation somewhat restricted by the mutual interaction, in contrast with the fact that the amino acid in $[Co(NH_3)_5(L\text{-}\alpha\text{-alaH})]^{3+}$ should be rather free from the interaction with the coordinated ammonia molecules. The anomalous dispersion of *cis*-$[Co(OH_2)(NH_3)_4(L\text{-}\alpha\text{-alaH})]^{3+}$, in which the conformational mobility of the amino acid is similar to that of $[Co(NH_3)_5(L\text{-}\alpha\text{-alaH})]^{3+}$, is as weak as that of $[Co(NH_3)_5(L\text{-}\alpha\text{-alaH})]^{3+}$. The anomalous dispersion of *cis*-$[Co(NH_3)_4(glyH)(L\text{-}\alpha\text{-alaH})]^{3+}$, on the other hand, shows a shape very similar to that of *cis*-$[Co(NH_3)_4(L\text{-}\alpha\text{-alaH})_2]^{3+}$, but its magnitude is almost half that of the latter (see Figs. 7 and 9). This fact indicates that the L-$\alpha$-alanine *cis*-$[Co(NH_3)_4(glyH)(L\text{-}\alpha\text{-alaH})]^{3+}$ is in the same conformational state as those in *cis*-$[Co(NH_3)_4(L\text{-}\alpha\text{-alaH})_2]^{3+}$ as a result of the effect of the glycine coordinated in the adjacent cis position. Therefore, the proportionality of the magnitudes of the anomalous dispersions to the number of optically active ligands holds in this case.

From all these observations, including the fact that the first band of the chelate complex $[Co(L\text{-}\alpha\text{-ala})(NH_3)_4]^{2+}$ exhibits a strong anomalous dispersion, it may be concluded that the magnitude of the anomalous dispersion of the optically active $\alpha$-amino acid complex in its first absorption band depends mainly on the conformational mobility of the optically active ligand.

As a further investigation, the measurement of the rotatory dispersion for *trans*-$[Co(NH_3)_4(L\text{-}\alpha\text{-alaH})_2]^{3+}$ will be an interesting subject, since the steric condition in the trans complex will be quite different from those in the cis isomers. Several attempts to prepare the trans complex, however, have been unsuccessful.

## Summary

Fifteen new cobalt(III) ammine complexes containing amino acids as unidentate ligands have been prepared. The infrared, visible and ultraviolet absorption spectra of these complexes indicate that the oxygen of the carboxyl group acts as a donor atom. The circular dichroism and the rotatory dispersion of the unidentate complexes of the optically active $\alpha$-amino acids and such chelate amino acid complexes as $[Co(L\text{-}\alpha\text{-ala})(NH_3)_4]^{2+}$ have been measured. The results suggest that the magnitude of the anomalous dispersion of the $\alpha$-amino acid complex in the region of its first absorption band seems to depend mainly on the conformational mobility of the optically active ligand in the coordination sphere.

The authors wish to express their sincere thanks to Professor B. E. Douglas and Dr. J. Hidaka for their aid in obtaining the circular dichroism spectra.

# Electrochemical Syntheses. III. The Homolytic Methoxylation of Some Arylated Olefins by the Anodic Oxidation of Methanol

By Tadao Inoue and Shigeru Tsutsumi

(Received July 29, 1964)

A method for the electrochemical methoxylation of furans has been developed.[1-3] Recently, Belleau and Weinberg[4] have reported the anodic methoxylation of dimethoxybenzenes and the ring fission of 1, 2-dimethoxybenzenes.

In the previous papers in this series,[5,6] we have described how the anodic oxidation of methanol in the presence of alkylated aromatic hydrocarbons produces $\alpha$-methoxy derivatives, which are formed by the reaction of the methoxy radical generated by the electrolysis of methanol as an intermediate.

The present investigation was undertaken in order to study the addition of the methoxy radical to olefinic double bonds. Thus, styrene, $\alpha$-methylstyrene and 1, 1-diphenylethylene were chosen as the starting olefins.

## Results and Discussion

**The Addition of the Methoxy Radical to Styrene.**—According to the procedure described earlier,[5-6] the electrolysis of a methanol solution containing sodium methoxide was carried out in the presence of styrene (I) at 34°C; styrene glycol dimethyl ether (II) was obtained as a main proudct (current yield, 16—22%). The formation of $\alpha$-methoxyethylbenzene (III) and $\beta$-methoxyethylbenzene (IV) as by-products was observed; *meso*-1, 4-dimethoxy-2, 3-diphenylbutane (V) was also isolated from the higher boiling fractions, and in addition a small amount of formaldehyde was isolated as its 2, 4-dinitrophenylhydrazone. The results obtained under various conditions are summarized in Table I, where the yield is calculated from the results of gas chromatographic analysis.

Since the methoxy radical may be initially produced as an intermediate in these reaction systems, it was expected that the reaction of methoxy radicals with styrene might take place in the first step of the reaction. The formation of *meso*-1, 4-dimethoxy-2,3-diphenylbutane (V) may be due to the coupling of an unstable intermediate radical (VI), which may be produced by the attack of the methoxy radical, formed by the anodic oxidation of methoxide ion, upon styrene, as is shown below:

$$CH_3O^- \xrightarrow[\text{anode}]{-e} CH_3O\cdot \qquad (1)$$

$$\underset{\text{(I)}}{C_6H_5CH=CH_2} \xrightarrow{\cdot OCH_3} \underset{\text{(VI)}}{C_6H_5CH(\cdot)-CH_2OCH_3} \qquad (2)$$

$$\text{VI} \xrightarrow{\text{dimerization}} \underset{\text{(V)}}{C_6H_5CHCH_2OCH_3 \\ | \\ C_6H_5CHCH_2OCH_3} \ (meso\text{-}) \qquad (3)$$

For the formation of styrene glycol dimethyl ether (II), two reaction paths are possible: In the first, the benzylic intermediate radical (VI) reacts with another methoxy radical to give the dimethyl ether (II), since the environment around the electrode might have a particularly high concentration of the methoxy radical (Eq. 4):

$$\text{VI} \xrightarrow{\cdot OCH_3} \underset{\text{(II)}}{C_6H_5CH(OCH_3)-CH_2OCH_3} \qquad (4)$$

In the second, the intermediate radical (VI) may be oxidized to the carbonium ion (VII) to give the solvolysis product (II) (Eq. 5):

$$\text{VI} \xrightarrow[\text{anode}]{-e} \underset{\text{(VII)}}{C_6H_5\overset{+}{C}H-CH_2OCH_3} \xrightarrow{^-OCH_3} \text{II} \qquad (5)$$

Recently, Bonner and Mango[7] reported that electrolytically-generated benzyl radicals in the Kolbe elctrolysis are oxidized to carbonium ions with greater ease. Such a possibility can not be excluded in the present case.

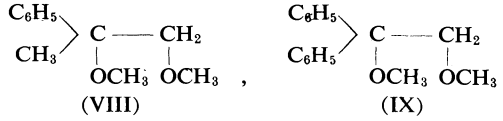
* The temperature was kept at 34±1°C.

reported that the bromine which is formed during the electrolysis reacts immediately with furan-compounds and methanol to give the methoxylated products and hydrogen bromide. On the other hand, in the present system, the anodic methoxylation of these olefins would proceed in the radical mechanisms, as has been mentioned above. This is also supported by the recent observation that the anodic oxidation of methanol in the presence of 1,2-dimethoxybenzene gives 5,5,6,6-tetramethoxy-1,3-cyclohexadiene under modified conditions.[4]

β-Methoxyethylbenzene (IV) might be produced by the hydrogen abstraction of the intermediate radical (VI) from the solvent:

$$\text{VI} \xrightarrow{CH_3OH} \underset{\text{(IV)}}{C_6H_5CH_2CH_2OCH_3} \quad (6)$$

One possible rationalization for the formation of α-methoxyethylbenzene (III) in this system involves, in the first step, the addition of adsorbed hydrogen, which may be produced by the anodic oxidation of methoxide ions, as has been reported by Buck and Griffith,[8] to styrene; then methanolysis of the subsequent benzylic cation may furnish the methoxylated product (III), as is shown in Eqs. 7—9;



$$CH_3O^- \rightarrow CH_2O^-_{adsorbed} + H_{adsorbed} \quad (7)$$

$$C_6H_5CH=CH_2 + H_{adsorbed} \rightarrow C_6H_5\overset{+}{C}HCH_3 + e \quad (8)$$

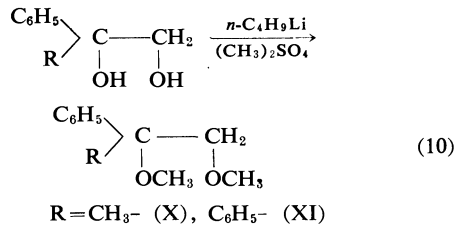
$$C_6H_5\overset{+}{C}HCH_3 + CH_3O^- \rightarrow \underset{\text{(III)}}{C_6H_5CH(OCH_3)CH_3} \quad (9)$$

We have little experimental evidence, however, bearing on the validity of this suggestion.

**The Addition of the Methoxy Radical to α-Methylstyrene and 1,1-Diphenylethylene.**—When α-methylstyrene or 1,1-diphenylethylene was used instead of styrene, 1-methyl-1-phenylethylene glycol dimethyl ether (VIII) (current yield, 15%) or 1,1-diphenylethylene glycol dimethyl ether (IX) (current yield, 23%) was obtained as the main product in each case.

(VIII)

(IX)



The structure of these products was confirmed by the synthetic route. α-Methylstyrene glycol (X), which had been prepared by hydroxylation with a Milas-reagent,[9] and 1,1-diphenylethylene glycol (XI), prepared by the reaction of benzoylcarbinol with phenylmagnesium bromide,[10] were treated with *n*-butyl lithium and dimethyl sulfate successively in dry benzene to give the corresponding dimethyl ethers, which showed infrared absorptions and melting points identical

with those of the electrochemical methoxylated products.

(10)

R=$CH_3$- (X), $C_6H_5$- (XI)

The results obtained are summarized in Table II. In these electrolyses, small amounts of the respective mono-ethers were also detected; white crystals which might be formed by the dimerization of an unstable intermediate radical were also isolated, as has been observed above. In the case of α-methylstyrene, in addition, a small amount of acetophenone was isolated as its 2, 4-dinitrophenylhydrazone.[11]

The current yields of these main products increased in the order $CH_3-<H-<C_6H_5-$ in the α-substituent group of styrene, as is shown in Table II.

It is of interest to note that the dimethyl ether derivatives (II, VIII and IX) are easily produced in fairly high yields by the anodic oxidation of methanol in the presence of the respective arylated olefins.

## Experimental

Melting points and boiling points are uncorrected. Electrolyses were carried out by using three platinum-foil electrodes with the apparatus previously described.[5]

**Materials.**—Styrene and α-methylstyrene were commercial materials, carefully purified in the usual manner,[12] distilled before use, and stored in an ice-box. 1, 1-Diphenylethylene was obtained by the dehydration of the alcohol formed by the action of phenylmagnesium bromide and ethyl acetate;[13] b. p. 97—97.5°C/0.5 mmHg, $n_D^{15}=1.6098$. Methanol was purified in a manner described earlier.[5] These materials were confirmed to be pure by gas chromatography.

**The Anodic Oxidation of Methanol in the Presence of Styrene.**—The reaction conditions and the yields of the products are summarized in Table I.

R-4 is exemplified as follows: Metallic sodium (1.0 g., 0.043 mol.) was dissolved in 80 g. of absolute methanol (2.5 mol.), and then 52 g. of freshly-distilled styrene (0.5 mol.) was added to the mixture. After dry nitrogen had been bubbled through the mixture for about 1 hr., the mixture was electrolyzed at 34±1°C for 26.8 hr., during which time a current was maintained at neary 1.0 amp. (current density, 8.3 amp./$dm^2$). The electrolyzed solution turned slightly yellowish-brown. The reaction mixture was then distilled at room temperature under 25—30 mmHg pressure (water-aspirator). From this distillate, trapped by the receiver in a bath containing dry-ice and acetone, a small amount of formaldehyde was identified as its 2, 4-dinitrophenylhydrazone; m. p. 161—162°C; a mixed melting point with an authentic sample showed no depression.

Found: C, 40.22; H, 3.12; N, 26.80. Calcd. for $C_7H_6N_4O_4$: C, 40.00; H, 2.87; N, 26.62%.

The residue was poured into water (50 ml.), neutralized with 3 N hydrochloric acid, and extracted with ether; the extract was dried over magnesium sulfate. After the ether had been removed, the oily residue (49.5 g.) was distilled under diminished pressure to give the following fractions;

| Fraction | B. p. | Weight, g. |
|---|---|---|
| 1 | ~ 51°C/25 mmHg | 18.3 |
| 2 | 30— 90°C/2—3 mmHg | 21.1 |
| 3 | 90—103°C/2—3 mmHg | 3.6 |
| 4 | ~143°C/0.8—0.9 mmHg | 4.0 |
| 5 | Residue | 1.5 |

By gas chromatographic analysis (conditions: column, polyethylene glycol (P. E. G.) 1500, 2 m. and polyester D A (P. E. DA), 3 m.; column temperature, 153°C; carrier gas, $H_2$), it was shown that fractions 1, 2 and 3 were mixtures of unreacted styrene, α-methoxyethylbenzene, β-methoxyethylbenzene and styrene glycol dimethyl ether, and that the total amounts of these products were as follows: unreacted styrene, 23.0 g.; α-methoxyethylbenzen, 1.3 g.; β-methoxyethyl benzene, trace; styrene glycol dimethyl ether, 16.8 g.

Fraction 2 was chromatogroaphed over active alumina (2.5×58 cm.). Elution with benzene led to the isolation of styrene glycol dimethyl ether; b. p. 75—76°C/2 mmHg, $n_D^{20}=1.4948$ (lit.,[14] $n_D^{20}=1.4948$).

Found: C, 72.49; H, 8.79. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

The infrared spectrum of this product showed the characteristic absorption band at 1105 $cm^{-1}$ (C-O-C of aliphatic ether.) and was identical with that of an authentic sample prepared as will be described below.

α-Methoxyethylbenzene and β-methoxyethylbenzene were identified by gas chromatographic analysis.

Fraction 4 was cooled below 0°C to give a white crystal (0.6 g.) of *meso*-1, 4-dimethoxy-2, 3-diphenylbutane (m. p. 128.5-130°C) from methanol; a mixed melting point with the sample prepared as will be described below showed no depression.

Found: C, 80.07; H, 8.19. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%.

The infrared spectrum of this compound showed the characteristic absorption band at 1112 $cm^{-1}$ (C-O-C). The mother liquid filtered from fraction 4 was chromatographed over active alumina (2.5×30 cm.) and, from the eluate with benzene, 0.2 g. of *meso*-1, 4-dimethoxy-2, 3-diphenylbutane and oily compounds were separated. The latter oily compounds consisted of miscellaneous products, which

11) For the formation of this ketone, further studies are now being undertaken.

13) "Organic Syntheses," Coll. Vol. I, 226 (1956).
14) C. R. Ganellin and R. Pettit, *J. Chem. Soc.*, 1958, 576.

showed the infrared absorption band at 1110 $cm^{-1}$ (C-O-C); b. p. 130—170°C/2—3 mmHg.

**The Synthesis of Styrene Glycol Dimethyl Ether.**—Styrene diacetate was prepared by the reaction of styrene dibromide with fused lead acetate in glacial acetic acid, according to the procedure of Evans and Morgan;[15] b. p. 126—128°C/4—5 mmHg. Styrene glycol was prepared by the hydrolysis of styrene diacetate[14] and was methylated with methyl sulfate as has been described for glucose;[16] b. p. 72—73°C/1.5 mmHg, $n_D^{20}=1.4948$.

**The Synthesis of α- and β-Methoxyethylbenzene.**—α-Methoxyethylbenzene was prepared by the reaction of styrene with methanol according to the procedure of Stanley and was then purified by preparative gas chromatography;[5] b. p. 74—75°C/30—32 mmHg, $n_D^{22}=1.4900$. β-Methoxyethylbenzene was prepared by the reaction of phenethyl alcohol with metallic sodium and methyl iodide; b. p. 46—47°C/3—4 mmHg.

**The Synthesis of *meso*-1, 4-Dimethoxy-2, 3-diphenylbutane.**—*meso*-2, 3-Diphenyl-1, 4-butanediol[17] was prepared by the reduction, with lithium aluminum hydride, of *meso*-diethyl α, α'-diphenylsuccinate,[18] which had been synthesized by the coupling of ethyl phenylacetate[19] with sodium ethoxide and iodine; m. p. 143—144°C (lit., m. p. 143—144°C). *meso*-1, 4-Dimethoxy-2, 3-diphenylbutane was prepared by the following procedure: *meso*-2,3-diphenyl-1, 4-butanediol (1.5 g., 0.006 mol.) was dissolved in 60 ml. of dry benzene, and then the solution was further dried by the distillation of 10 ml. of benzene. To the solution at room temperature, 6 ml. of *n*-butyl lithium in *n*-heptane (21% solution, 0.015 mol.) was added, and then the solution was stirred at 60°C for 1.5 hr. Dimethyl sulfate (3.78 g., 0.03 mol.) in 20 ml. of dry benzene was then added, and the solution was heated at 80°C for 8 hr., cooled in ice, transferred to an amber separatory funnel, and washed successively with a cold solution of 0.5 N sulfuric acid (100 ml.), N ammonium hydroxide (twice) and water (three times). The solution was dried over anhydrous sodium sulfate, filtered, concentrated at 40°C under reduced pressure, and cooled to give crystals (1.4 g., 85% yield) of *meso*-1, 4-dimethoxy-2, 3-diphenylbutane; m. p. 128.5—130°C, from methanol.

**The Anodic Oxidation of Methanol in the Presence of α-Methylstyrene.**—Metallic sodium (1.0 g., 0.043 mol.) was dissolved in 80 g. of absolute methanol (2.5 mol.). and then 59 g. of freshly-distilled α-methylstyrene (0.5 mol.) was added to the mixture. After dry nitrogen had been bubbled through the mixture, the mixture was electrolyzed at 34±1°C, for 26.6 hr. during which time the current was maintained at 1.0 amp. The reaction mixture was then worked up in a manner similar to the procedure described above. After the ether had been removed, the oily residue was distilled under reduced pressure to give the following fractions;

| Fraction | B. p. | Weight, g. |
|---|---|---|
| 1 | ~ 40°C/2—3 mmHg | 20.6 |
| 2 | 40— 55°C/2—3 mmHg | 8.8 |
| 3 | 55—105°C/2—3 mmHg | 22.3 |
| 4 | Residue | 5.3 |

Gas chromatographic analysis (conditions: column, polyester DA, 3 m. and polyethylene glycol 6000, 3 m.; column temperature, 173°C; carrier gas, $H_2$) showed that fractions 1, 2 and 3 were mixtures of unreacted α-methylstyrene, α-methoxyisopropylbenzene, acetophenone, β-methoxyisopropylbenzene and 1-methyl-1-phenylethylene glycol dimethyl ether, and that the total amounts of these products were as follows: unreacted α-methylstyrene, 33.7 g.; α-methoxyisopropylbenzene, 2.2 g.; acetophenone, 3.2 g; β-methoxyisopropylbenzene, trace; 1-methyl-1-phenylethylene glycol dimethyl ether, 13.7 g.

When fraction 3 was distilled through a five-foot vacuum-jacketed column packed with glass helices, 1-methyl-1-phenylethylene glycol dimethyl ether was isolated; b. p. 68—69°C/1.5 mmHg, $n_D^{14}=1.5022$.

Found: C, 73.59; H, 9.20. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95%.

The infrared spectrum of this dimethyl ether showed the characteristic absorption bands at 1110 $cm^{-1}$ and 1128 $cm^{-1}$ (C-O-C) and was identical with that of an authentic sample prepared as will be described below. From the lower boiling fraction, acetophenone was identified as its 2, 4-dinitrophenylhydrazone derivative; m. p. 237—238°C; a mixed melting point with an authentic sample was not depressed.

Found: C, 56.17; H, 3.93. Calcd. for $C_{14}H_{12}N_4O_4$: C, 56.00; H, 4.03%.

α-Methoxyisopropylbenzene and β-methoxyisopropylbenzene were identified by gas chromatographic analysis (conditions; described above). When fraction 4, the residue, was chromatographed over active alumina (2.5×45 cm.) and eluted with benzene, a white crystal (0.1 g. with m. p. 95—96.5°C, from methanol), was isolated from oily miscellaneous products.

Found: C, 80.36; H, 8.89. Calcd. for $C_{20}H_{26}O_2$: C, 80.49; H, 8.78%.

The infrared spectrum of this compound showed the characteristic absorption bands at 1088 $cm^{-1}$ and 1098 $cm^{-1}$ (C-O-C).

**The Synthesis of 1-Methyl-1-phenylethylene Glycol Dimethyl Ether.**—1-Methyl-1-phenylethylene glycol was prepared by the action of Milas reagents on α-methylstyrene[9] and methylated in a good yield with *n*-butyl lithium and dimethyl sulfate in dry benzene in a manner similar to the procedure described above. The product had a b. p. of 66°C/1 mmHg, $n_D^{14}=1.5022$.

**The Synthesis of α- and β-Methoxyisopropylbenzene.**—α-Methoxyisopropylbenzene was synthesized in a manner described earlier;[5] b. p. 77—78°C/12—13 mmHg, $n_D^{20}=1.4911$. β-Methoxyisopropylbenzene was synthesized by the *O*-methylation of β-phenylpropyl alcohol with *n*-butyl lithium and dimethyl sulfate in a manner similar to the

procedure as described above; b. p. 85—86°C/14 mmHg. β-Phenylpropyl alcohol was prepared by the reduction of β-phenylpropionaldehyde, which was prepared by the dehydration of 1-methyl-1-phenylethylene glycol with 20% sulfuric acid,[20] with zinc and acetic acid[21]; b. p. 99—102°C/7—8 mmHg.

**The Anodic Oxidation of Methanol in the Presence of 1, 1-Diphenylethylene.**—Metallic sodium (0.5 g., 0.022 mol.) was dissolved in 40 g. of methanol (1.25 mol.), and then 45 g. of freshly-distilled 1,1-diphenylethylene (0.25 mol.) was added to the mixture. After dry nitrogen had been bubbled through the cell, the mixture was electrolyzed at 34±1°C, for 13.8 hr., during which time the current was maintained at 1.0 amp. The electrolyzed solution was worked up in a manner similar to the procedure described above, and the oily residue (50.0 g.) was distiiled under reduced pressure to give the following fractions;

| Fraction | B. p. | Weight, g. |
|---|---|---|
| 1 | 90— 99°C/1.0 mmHg | 22.5 |
| 2 | 99—125°C/1.0 mmHg | 23.5 |
| 3 | Residue | 3.0 |

These fractions were chromatographed over active alumina (2.5×26 cm.). Elution with benzene led to the isolation of unreacted 1, 1-diphenylethylene (31.4 g.), 1, 1-diphenylethylene glycol dimethyl ether (13.8 g.), miscellaneous oily products (4.5 g.) and a white crystal (0.4 g.) with a m. p. of 228—230°C, from benzene.

1, 1-Diphenylethylene glycol dimethyl ether was melted at 65.5—66.5°C from ligroin; a mixed melting point with the sample prepared as will be described below showed no depression.

Found: C, 79.06; H, 7.25. Calcd. for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%.

The infrared spectrum of this dimethyl ether showed the characteristic absorption bands at 1108 $cm^{-1}$ and 1138 $cm^{-1}$ (C-O-C) and was identical with that of the sample prepared as will be described below. The infrared spectrum of a white crystal with a m. p. of 228.5—230°C also showed the characteristic absorption band at 1072 $cm^{-1}$ (C-O-C).

Found: C, 85.53; H, 7.41. Calcd. for $C_{30}H_{30}O_2$: C, 85.27; H, 7.16%.

**The Synthesis of 1, 1-Diphenylethylene Glycol Dimethyl Ether.** — Benzoylcarbinol[22] was prepared by the hydrolysis of benzolycarbinol acetate prepared by the reaction of ω-bromoacetophenone with potassium acetate;[22] m. p. 80—82°C. 1, 1-Diphenylethylene glycol was prepared by the treatment of benzoylcarbinol with phenylmagnesium bromide;[10] m. p. 119—120.5°C (lit.,[10] m. p. 121°C), and methylated in a good yield with *n*-butyl lithium and dimethyl sulfate in dry benzene in a manner similar to the procedure described above. The product was purified by column chromatography (active alumina, 2.5×26 cm.; eluted with benzene); m. p. 65.5—66.5°C, from ligroin.

# The Thermal Isomerization of Alkoxycycloheptatrienes and Some Reactions of Its Products[1]

By Tetsuo Nozoe and Kazuko Takahashi

(Received September 3, 1964)

The tropylium ion (I), which is formed from 1, 3, 5-cycloheptatriene by a hydride abstraction, exhibits a highly electrophilic character and can thus readily give rise to compounds (general formula II) in which the cycloheptatriene group is bonded to an oxygen, sulfur, nitrogen, or carbon atom.[2] This cation, in aqueous solutions at a suitable pH, undergoes disproportionation to cycloheptatriene and tropone.[3] Ditropyl ether (III), which is easily obtained by the action of the base on I, also gives rise to cycloheptatriene and tropone in the presence of a trace of tropylium ion or an acid.[4] Thus, the above reactions would

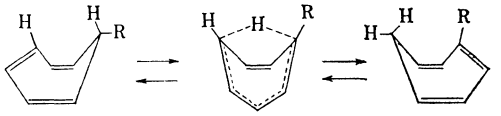
provide a very convenient route for the synthesis of troponoids and azulenoids, via the corresponding substituted tropones which



(I) (II) (III) (IV)

should be obtainable from the corresponding tropylium ion (IV) formed from cycloheptatriene derivatives (II), by a similar hydride abstraction.[5] However, *O*-, *S*- and *N*-tropyl compounds are in general labile in acidic media,[2] and some *C*-tropyl compounds undergo fragmentation during treatment with strong acid.[2,6] For this reason, the direct formation of troponoids or azulenoids from cycloheptatriene derivatives is not generally feasible. In the presence of concentrated acids, alkoxycycloheptatrienes (alkyl tropyl ethers) (Va and Vb) and ditropyl ether (III) dissociate quantitatively to the cation (I). Furthermore, these are very effective tropylating reagents since they are quite soluble in most organic solvents and tend to react with phenols, tropolones, and compounds with an active methylene group, giving the corresponding cycloheptatriene derivatives.[7]

During the last few years, the reactions of alkoxycycloheptatrienes and ditropyl ethers have been extensively investigated in our laboratory, with the aim of devising a synthesis of tropones and various derivatives of cycloheptatriene along the lines discussed above. In the course of this study, however, it was noticed that yields varied from time to time and that some reactions led to unexpected products. In order to clarify these ambiguities, we commenced extensive studies of the thermal reactions as well as of the effects of acids and alkalis on these alkoxycycloheptatrienes (Va and Vb).

Ethoxycycloheptatriene, on being mixed with phenols or tropolones, forms 7-substituted cycloheptatrienes, and, as has been previously noted, the heating of these products cases a migration of the double bonds.

The present authors obtained interesting results by following the thermal isomerization of alkoxycycloheptatrienes with the NMR technique. After we had started this work, a detailed study of the thermal isomerization of 7-substituted cycloheptatrienes was published by ter Borg et al.,[8] who examined changes in the NMR and mass spectra of 7-*D*-cycloheptatriene (II; R=D) at 100—140°C and in the NMR and ultraviolet spectra of 7-phenylcycloheptatriene (II; R=ph). They found that successive 1—5 transannular hydrogen shifts were taking place. From the kinetic study of this reaction, they concluded that the transition state had the symmetrical structure A shown below:

(A)

After the completion of our present study, Weth and Dreiding[9] published a short communication on the thermal isomerization of 7-methoxycycloheptatriene (Va); their results seem to be in substantial agreement with ours. The photoisomerization of Va and Vb in the vapor phase has also been noted by Chapman and Borden.[10]

In this paper we will report the results of a study of the thermal isomerization of

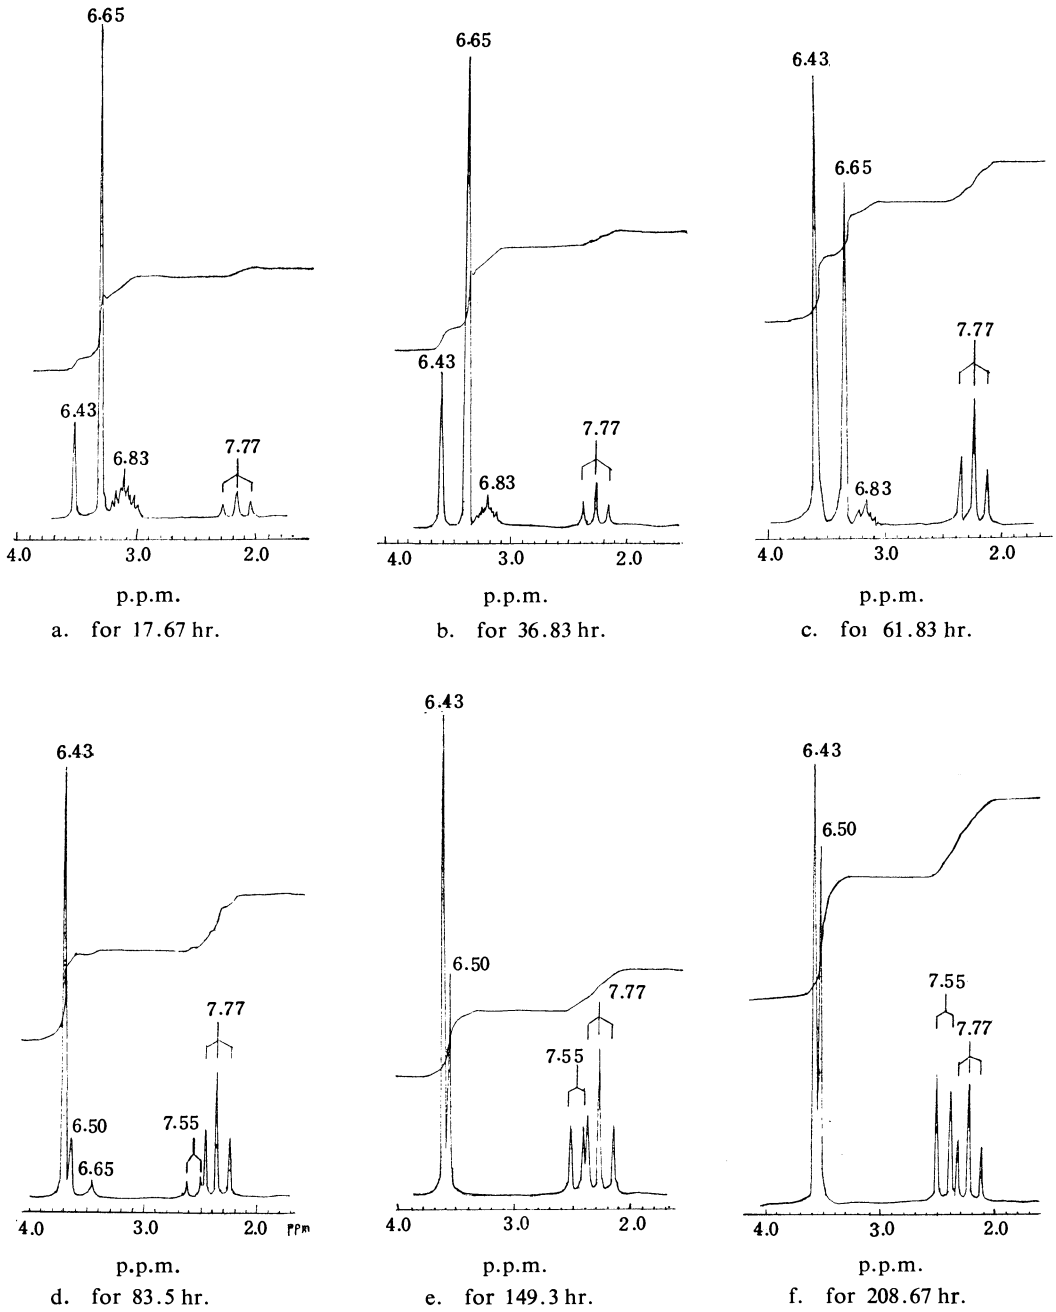

Fig. 2. NMR spectra of 7-methoxycycloheptatriene heated at 103° for various lengths of time.

methoxy- and ethoxy-cycloheptatriene; the reactions of the alkoxycycloheptatriene, obtained as the products of the above isomerization, will also be discussed.

**7-Alkoxycycloheptatriene.**—The 7-substituted cycloheptatrienyl structure can plausibly be assigned to the alkoxycycloheptatrienes (Va and Vb)[11] which are readily obtained by the addition of sodium hydrogen carbonate to a solution of tropylium ions in aqueous alcohols (see Fig. 1). As can be seen from Fig. 1a, the NMR spectrum of Va exhibits methyl signal at 6.65$\tau$ and a signal at 6.83$\tau$ resulting from the methine proton at the 7-position. By analogy with cycloheptatriene,[12] the signals

11) K. Conrow, *J. Am. Chem. Soc.*, **83**, 2347 (1961).

12) a) G. Frankel, R. E. Carter, A. Mc Lachlan and J. H. Richards, ibid., **82**, 5846 (1960); b) R. Barton, L. Pratt and G. Wilkinson, ibid., **83**, 594 (1961).

at 4.46$\tau$, 3.96$\tau$ and 3.59$\tau$ are assigned to the protons at the 1, 6-, 2, 5- and 3, 4-positions respectively. Usually the protons at the 7-position of cycloheptatrienes appears as a triplet. However, this is not the case with 7-methoxycycloheptatriene and 7-ethoxycycloheptatriene (Fig. 1b), as these exhibit symmetrical multiplets, centered at 6.83$\tau$ and 6.76$\tau$ respectively, which are attributed to the existence of a long-range coupling between the 7-proton and the two protons $\beta$ to it (H-2 and H-5), since the signals at 3.96$\tau$ and 3.97$\tau$, due to the protons at positions 2 and 5 in methoxy- and ethoxy-cycloheptatriene, (Va and Vb), are more complicated than the corresponding signals in the spectrum of cycloheptatriene itself (Fig. 1c). The NMR spectrum of 7-ethoxycycloheptatriene (Vb) is quite similar to that of 7-methoxycycloheptatriene, except that in the former additional signals due to the ethyl group appear at 8.79$\tau$ and 6.43$\tau$.

**The Thermal Isomerization of Alkoxycycloheptatrienes.**—The NMR spectrum of neat 7-methoxycycloheptatriene (Va), which had been heated for a short time in a sealed tube was measured in order to obtain information about the process of isomerization occurring in alkoxycycloheptatrienes heated in the 75—220°C temperature range. As an example, the NMR spectrum of a sapmle of 7-methoxycycloheptatriene which had been heated at 103°C for various lengths of time is shown in Fig. 2.

As can be clearly seen in Fig. 2, the signals at 6.65$\tau$ (methyl proton) and 6.83$\tau$ (H-7) decrease with time, and simultaneously two new signals, one a singlet at 6.43$\tau$, 13.1 c./s. lower than the methyl signal of the starting material, and the other a triplet at 7.77$\tau$ ($J$=6.6 c./s.), gradually apppear (curve a) and increase in intensity. Continued heating causes the appearance of two new sets of signals, a singlet at 6.50$\tau$ and a doublet at 7.55$\tau$ ($J$=7.1 c./s.). These results are attributed to the occurrence of consecutive reactions, the second of which occurs after a period of 62 hr. at 103°C, 2.5 hr. at 120°C, or 1.5 hr. at 130°C (curve d). The signal at 6.65$\tau$, due to Va, almost entirely disappears on prolonged heatings, e. g., 100 hr. at 150°C, and does not reappear again. It has, therefore, been concluded that the reverse reaction, VIa or VIb to Va or Vb, does not occur. The doublet signal at 7.55$\tau$ increases with time, and simultaneously the triplet signal at 7.77$\tau$ gradually decreases. At equilibrium new signals appear at 7.83$\tau$ (triplet; $J$=6.0 c./s.) and 6.58$\tau$ as a result of the corresponding methyl group (Fig. 3). It is now clear that the equilibrium mixture is characterized by the appearance of three signals, 6.43$\tau$, 6.50$\tau$ and 6.58$\tau$, in the ratio of 13.6 : 80.5 : 6.0. These signals, appearing on the heating of 7-methoxycycloheptatriene, are summarized in Table I.

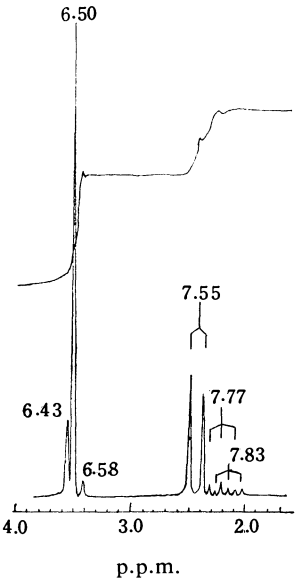

Fig. 3. NMR spectrum of 7-methoxycycloheptatriene which had been heated at 150°C for 100 hr.

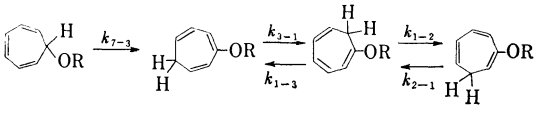
Similar results were also obtained for 7-ethoxycycloheptatriene (Vb); these are shown in Table II. The signal due to the hydrogen at the 7-position is observed to undergo changes in the sequence of multiplet → triplet → doublet → triplet. The rate of isomerization seems to be of the same order as that for Va. The same sequence for the appearance of the signals is found at different temperatures for methoxy- and ethoxy-cycloheptatriene. This

TABLE I. THE CHANGES OCCURRING ON HEATING OF 7-METHOXYCYCLOHEPTATRIENE



| The sequence of the appearance of the signals | The type of signals | Chemical shift of H-7 $\tau$ | Coupling constant c./s. | Chemical shift of $CH_3$ $\tau$ | Substituted position of $OCH_3$ |
|---|---|---|---|---|---|
| 1 | Multiplet | 6.83 | ca. 4.2 | 6.65 | 7 |
| 2 | Triplet | 7.77 | 6.6 | 6.43 | 3 |
| 3 | Doublet | 7.55 | 7.1 | 6.50 | 1 |
| 4 | Triplet | 7.83 | 6.0 | 6.58 | 2 |

Table II. The changes occurring on heating of 7-ethoxycycloheptatriene

| The sequence for the appearance of the signals | The type of signals | Chemical shit of H-7, $\tau$ | Coupling constant c./s. | Substituted position of OEt |
|---|---|---|---|---|
| 1 | Multiplet | 6.76 | ca. 4.2 | 7 |
| 2 | Triplet | 7.79 | 6.8 | 3 |
| 3 | Doublet | 7.54 | 7.2 | 1 |
| 4 | Triplet | 7.87 | 6.6 | 2 |

means that successive migrations of hydrogen are taking place and that the same 1—5 transannular hydrogen shift observed by ter Borg et al.[8] for 7-*D*- and 7-phenyl-cycloheptatriene is operating in the case of alkoxycycloheptatrienes. As is shown in Tables I and II, all these chemical shifts can be assigned to the revelant isomer from which they originate.

**Kinetic Study.**—The ultraviolet spectrum of 7-methoxycycloheptatriene (Va) exhibits an absorption maximum at 255 m$\mu$ ($\log \varepsilon = 3.61$), and the ultraviolet spectrum of 3-methoxycycloheptatriene (VIa) shows a peaks at 261 m$\mu$ ($\log \varepsilon = 3.60$). Therefore, the ultraviolet spectrophotometric method could not conveniently be applied to a study of the rate of

Va : R=Me Vb : R=Et VIa : R=Me VIb : R=Et VIIa : R=Me VIIb : R=Et VIIIa : R=Me VIIIb : R=Et

thermal isomerization, Va → VIa, as was done in the case of phenylcycloheptatriene. As was mentioned in the preceding section, methyl signals appear at different fields, e.g., at 6.65$\tau$ for Va and 6.43$\tau$ for VIa. The area of these two signals can be separately measured by NMR an integrator technique thus provides a useful method for studying the kinetics.

In Fig. 4, a plot of the area proportion to the total area against time is made for each methyl signal. The straight line indicates that

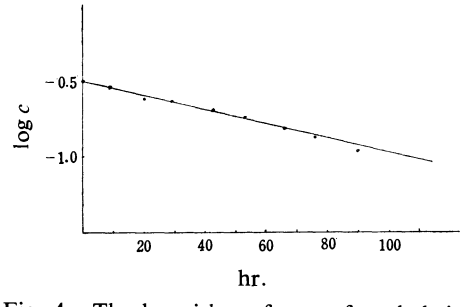


Fig. 4. The logarithm of area of methyl signal proportional to total area ($\log c$) as a function of time at 99.0°C.

Table III. Rate constants of isomerization of 7-methoxycycloheptatriene

| Temp., °C | $K_{7-3}$ |
|---|---|
| 116.3 | $1.76\times10^{-5}$ |
| 99.0 | $3.04\times10^{-6}$ |
| 76.1 | $3.36\times10^{-7}$ |

the isomerization of Va to VIa is of the first order and that the rate constant, $k_{7-3}$, for the conversion of 7-methoxycycloheptatriene (Va) to the first isomer 3-methoxycycloheptatriene (VIa) can be obtained from the slope of the line. This rate constant at different temperatures is given in Table III. These figures were derived from the NMR spectra of aliquots taken at special time intervals. However, it was found necessary to purify the aliquots by vacuum distillation in order to remove a small amount of a high boiling product before measuring the spectra. The yield of a high boiling product became progressively larger as the heating period and temperature were increased, but it did not go beyond 10% under the conditions used.

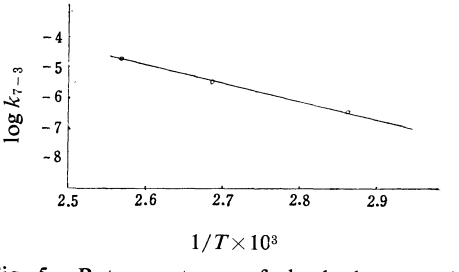

Fig. 5. Rate constants of the hydrogen shifts as a function of temperature.

In Fig. 5, a linear relationship between $\log k_{7-3}$ and $1/T$ is demonstrated. By the method of least squares, Eq. 1 was obtained for the straight line in Fig. 5:

$$\log k_{7-3} = 10.04 - 5.774\times10^3\, T^{-1} \qquad (1)$$

From this relationship, $\log A$ and the experimental activation energy, $\Delta E$, are found to be 10.04 and 26.407 kcal. mol$^{-1}$ respectively. Thus, from the absolute rate theory, the following figures are calculated by assuming the transmission coefficient to be unity: enthalpy

Table IV. Rate constants of the isomerization of cycloheptatriene and 7-methoxycycloheptatriene

| Temp. °C | Cycloheptatriene | 7-Methoxycycloheptatriene |
|---|---|---|
| 98 | $3.8\times10^{-8}$ | $3.07\times10^{-6}$ |
| 121 | $6.0\times10^{-7}$ | $2.48\times10^{-5}$ |
| 140 | $3.2\times10^{-6}$ | $1.17\times10^{-4}$ |

Table V. Rate constants of the isomerization of 7-phenylcycloheptatriene and 7-methoxycycloheptatriene

| Temp. °C | 7-Phenylcycloheptatriene | 7-Methoxycycloheptatriene |
|---|---|---|
| 80.4 | $6.83\times10^{-7}$ | $5.15\times10^{-7}$ |
| 99.9 | $4.76\times10^{-6}$ | $3.68\times10^{-6}$ |
| 120.2 | $3.60\times10^{-5}$ | $2.31\times10^{-5}$ |

of activation: $\Delta H^{\ddagger}=25.7$ kcal. mol$^{-1}$ and entropy of activation: $\Delta S^{\ddagger}=-15.0$ cal. mol$^{-1}$·deg$^{-1}$.

For comparison, Tables IV and V list values of the rate constant, $k_{7-3}$, at different temperatures for the thermal isomerization of cycloheptatriene itself, for that of 7-phenylcycloheptatriene to 3-phenylcycloheptatriene, and for 7-methoxycycloheptatriene, the values for the last compound being calculated from Eq. 1. 7-Methoxycycloheptatriene is seen to undergo isomerization about 100 times faster than cycloheptatriene; $k_{7-3}$ is almost identical in the cases of phenylcycloheptatriene and of methoxycycloheptatriene.

Although a quantitative analysis could not be made of ethoxycycloheptatriene, it seems that its rate of isomerization is not markedly different from that of methoxycycloheptatriene at the initial stage. However, the NMR spectra of the pyrolysates obtained by heating 7-methoxycycloheptatriene and 7-ethoxycycloheptatriene at 195°C for 2 hr., indicate that the former consists of a mixture of 3-methoxy-, 1-methoxy- and 2-methoxy-cycloheptatriene in a ratio of 18.5, 77.0, and 4.63, whereas the latter contains only 3-ethoxy-, and 1-ethoxycycloheptatriene in a ratio of 15.2 and 84.8. It is interesting to note that the formation of 2-ethoxycycloheptatriene is not detected in the isomerization of 7-ethoxycycloheptatriene. This may imply that there is some difference in the ratio of $k_{2-1}$ to $k_{1-2}$ for methoxy- and ethoxycycloheptatriene.

The negative sign of $\Delta S^{\ddagger}$ indicates that this reaction may proceed through a transition state such as that shown by A. The value, $-15.0$ cal. mol$^{-1}$ deg$^{-1}$, seems to be reasonable when compared with the corresponding value, $-8.2$ cal. mol$^{-1}$ deg$^{-1}$, for cycloheptatriene. The fact that this value ($-15.0$ cal. mol$^{-1}$ deg$^{-1}$) is even lower than that ($-11.7$ cal. mol$^{-1}$ deg$^{-1}$) for phenylcycloheptatriene may be ascribed to some contribution of the lone pair of electrons to the rigidity of the transition state. However, before drawing any final conclusion it is necessary to carry out further investigations.

**Chemical Reactions of Alkoxycycloheptatrienes.** — As has been seen above, a simple method is now available for the preparation of cycloheptatriene derivatives in which the alkoxy group is present at positions other than the 7-position. This makes it possible to compare the 7-alkoxycycloheptatrienes with their isomers with regard to their reactivity towards acids, alkalis and dehydrogenating reagents.

When a 7-alkoxycycloheptatriene was shaken with a 6 N hydrochloric acid, tropylium ion (I) was formed in a quantitative yield. The similar treatment of a 7-alkoxycycloheptatriene with a dilute aqueous hydrogen chloride solution at pH 2 for 30 min. gave rise to a 65% yield of the cation I as well as to the formation of some tropone and cycloheptatriene by a disproportionation; however, no traces of the starting material, Va and Vb, were recovered. When a 10% aqueous solution of tropylium bromide (pH=2) was shaken, tropone was slowly formed; this is attributed to a disproportionation of the tropylium ions and tropylalcohol.

On the other hand, the treatment of a mixture of a 3-alkoxycycloheptatriene (VIa and VIb) and a 1-alkoxycycloheptatriene (VIIa and VIIb) with 6 N hydrochloric acid did not result in the formation of tropylium ions to any detectable extent. Similarly, a 95% recovery of the starting materials (as determined by NMR spectral analysis) was obtained when 3-ethoxycycloheptatriene (VIb) and 1-ethoxycycloheptatriene (VIIb) were shaken for 30 min. with 1 N hydrochloric acid at 0°C. When 0.5 N hydrochloric acid was used, 98% of the starting materials was again recovered. These experiments show that, in contrast to 7-alkoxycycloheptatrienes, the isomerization products, 1- and 3-alkoxycycloheptatrienes, are stable in dilute aqueous acid.

When 7-methoxycycloheptatriene was heated at 103°C for 55—60 hr. and when the reaction was then stopped at a point before the doublet signal due to 1-methoxycycloheptatriene (VIIa) appeared in the NMR spectrum, a mixture of Va and VIa was obtained. If this mixture was then shaken with cold 0.5 N hydrochloric acid, Va was transferred to the aqueous phase as tropylium ions, it was thus possible to isolate pure 3-methoxycycloheptatriene (VIa). Pure 3-ethoxycycloheptatriene (VIb) could be obtained by a similar procedure. Fractional distillation could also be used to separate

a mixture of 7-ethoxycycloheptatriene (b. p. 71—76°C/20 mmHg) and 3-ethoxycycloheptatriene (81—82°C/20 mmHg). The NMR spectra of 3-methoxycycloheptatriene and 3-ethoxycycloheptatriene are shown in Figs. 6 and 7.

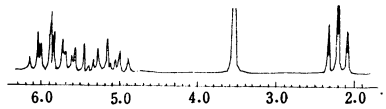

Fig. 6. NMR spectrum of 3-methoxycycloheptatriene and some reaction of its products.

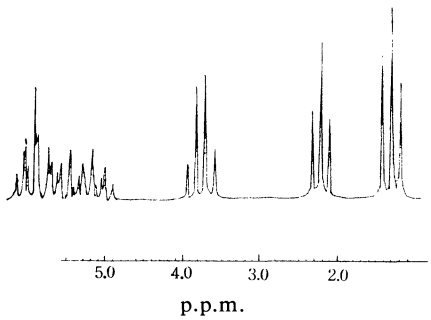

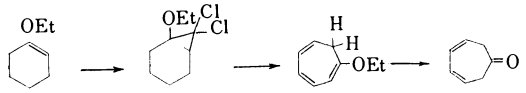

Fig. 7. NMR spectrum of 3-ethoxycycloheptatriene.

Parham et al.[13] have reported that 1-ethoxycycloheptatriene (VIIb) was obtained by heating 1-ethoxy-7, 7-dichlorocarane (X) in quinoline, the X having been prepared from 1-ethoxycyclohexene (IX) and dichlorocarbene.

(IX) (X) (VIIb) (XI)

Parham et al. have also obtained a good yield (95%) of 2, 7-dihydrotropone (XI)[14] through the action of a small amount of acid on a methanol solution of 1-ethoxycycloheptatriene. When 7-ethoxycycloheptatriene was kept at 195°C for 2 hr., it afforded a mixture of 84.8% 1-ethoxycycloheptatriene (VIIb) and 15.19% 3-ethoxycycloheptatriene (VIb), which, after hydrolysis and purification by distillation, afforded a liquid in a 69% yield. The NMR spectrum (see Fig. 8) of this liquid shows a sharp doublet at 7.01$\tau$ ($J$=5.7 c./s.) and the presence of vinylic protons and ethylenic protons whose signals have intensities in the ratio

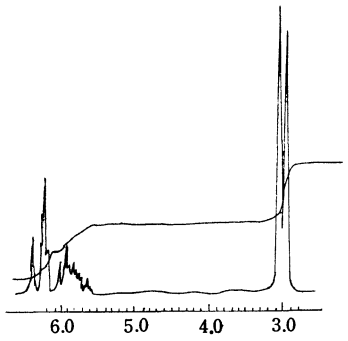

Fig. 8. NMR spectrum of 2,7-dihydrotropone.

of 1 : 1, strongly indicating that the liquid may be 2, 7-dihydrotropone (XI). Since no signals are observed above 7.01$\tau$, the formation of 2, 5-dihydrotropone could not be confirmed.

As has already been noted, the isomerization products, VIa and VIb, VIIa and VIIb, and VIIIa and VIIIb, are stable in dilute aqueous acid. However, the treatment of them with 6 N hydrochloric acid gave cycloheptadienone (XI or its isomer) and also XII as a liquid, b. p. 40—45°C/7 mmHg, and its dimer (XIII) (b. p. 115°C/1 mmHg). The former XII is considered to be hydroxycycloheptenone and the latter XIII, a dimer of XII on the basis of the elementary analyses of their 2, 4-dinitrophenylhydrazones. However, the structure of the latter is not clear.

7-Alkoxycycloheptatriene was found to be stable in alkali at room temperature.

The reaction of 7-alkoxycycloheptatriene with such dehydrogenating reagents as phosphorus pentachloride (Volpin's method[15]) does not give rise to a dehydrogenated product but instead, forms tropylium ions through the elimination of the alkoxy group. However, the treatment of a mixture of 1- and 3-alkoxycycloheptatriene in carbon tetrachloride with 2 molar equivalents of phosphorus pentachloride does not yield tropylium ions but instead produces an alkoxytropylium ions (IV: R= OMe or OEt) in more than a 50% yield. Alkoxytropylium ions separated as a double salt with phosphorous pentachloride from carbon tetrachloride; when this salt was treated with chloroplatinic acid in acetonitrile, the chloroplatinate of IV (R=OMe or OEt) was precipitated as prisms. When the aqueous solution of the double salt was heated, tropone was formed in a quantitative yield.

An unsuccessful attempt was made to prepare

ethoxytropopylium bromide by allowing a mixture of 1- and 3-ethoxycycloheptatriene in carbon tetrachloride to react with bromine, and then attempting a dehydrobromination under reduced pressure; however, tropone was obtained. This may be explained by assuming that alkoxytropoylium bromide, a reaction intermediate, was hydrolyzed to tropone during the reaction.

It was hoped that the oxidation of a 3-alkoxycycloheptatriene would yield a 4-alkoxytropone. However, when 3-ethoxycycloheptatriene in dry dioxane was oxidized with selenium dioxide, it unexpectively gave only tropone. Although doubt still remains, this may be attributed to the fact that 3-alkoxycycloheptatrienes (VI) are initially oxidized to an alkoxytropylium salt (IV), which subsequently hydrolyzed to tropone.

The present study has made it clear that 7-alkoxycycloheptatrienes can be converted to alkoxytropylium ions by dehydrogenation after the thermal isomerization. It is also apparent that tropones can be obtained from the dihydrotropones (XI) which are the hydrolysis products of the above isomers of 7-alkoxycycloheptatrienes.

The 7-alkoxycycloheptatrienes gave cation I by the action of acid, and they also reacted with compounds with active hydrogens or with nucleophilic substances,[7] the presence of a trace of acid being sometime necessary. It has thus been established that 7-alkoxycycloheptatrienes may be used effectively as tropylating reagents. As has been mentioned above, one of the advantages of the alkoxycycloheptatrienes (Va and Vb) is that they are readily soluble in organic solvents. In contrast to cation I, alkoxycycloheptatrienes alone do not show any dehydrogenating or oxidizing character. We have also studied the thermal isomerization of alkylmercapto- and amino-cycloheptatrienes, the results of which study will be shortly reported in this Bulletin.

## Experimental

**Reaction Rate Measurements.** — Alkoxycycloheptatrienes (Va and Vb) were sealed in tubes (8 mm. in outer diameter and 40 mm. long) and hung in the vapor of refluxing carbon tetrachloride (76.1°C), water (99.0°C) and acetic acid (116.3°C) respectively. The temperature was uniform over the whole length of the tubes. At regular intervals the tube was taken out and the contents were separated by distillation into alkoxycycloheptatriene and a high boiling product. The NMR spectrum (60 Mc./s. : A-60 Varian spectrometer) was recorded and electrically integrated.

The high-boiling product was found to form more readily from methoxycycloheptatriene than from ethoxycycloheptatriene. When 7-methoxycycloheptatriene (Va) and 7-ethoxycycloheptatriene (Vb) were kept under the same conditions, at 195°C for 2 hr. (these conditions were far more drastic than those applied to the determination of the rate constant $k_{7-3}$), Vb gave a high boiling product in 13.35%, whereas Va gave it in 18.15%.

**7-Ethoxycycloheptatriene (Vb).**—7-Ethoxycycloheptatriene was prepared by a slight modification of the method described by Conrow.[11] A mixture of 6 l. of dry carbon tetrachloride and 1 kg. of phosphorus pentachloride was shaken for 30 min., and then 320 g. of cycloheptatriene was added. The reaction mixture was shaken for 5—6 hr. and allowed to stand overnight. The separated precipitates were collected and poured into 2.6 kg. of ice. After the addition of 260 ml. of ethanol, the solution was neutralized by sodium hydrogencarbonate and extracted by ether (or benzene). The extract was dried over sodium carbonate, and the solvent was evaporated. The residue was then distilled under reduced pressure, giving 173 g. of a colorless liquid, 7-ethoxycycloheptatriene, b. p. 72—73°C/25 mmHg.

**The Action of 6 N Hydrochloric Acid on 7-Alkoxycycloheptatrienes (Va and Vb).**—A mixture of 300 mg. of Vb and 1 ml. of 6 N hydrochloric acid was shaken for 0.5 hr. To the resulting mixture a 30% aqueous solution of $H_2PtCl_6 \cdot 6H_2O$ was added, giving 596 mg. (90.6%) of pale yellow crystals. Its infrared spectrum was identical with that of tropylium chloroplatinate.

Under identical conditions but starting from 300 mg. of Va, 644 mg. (89%) of tropylium chloroplatinate was obtained.

**The Action of 1 N Hydrochloric Acid on 7-Methoxycycloheptatriene (Va).**—A mixture of 3 g. (0.025 mol.) of Va and 23.58 ml. of 1 N hydrochloric acid was adjusted to pH 2 by the addition of some water and shaken for 5 hr. at room temperature. The reaction mixture was then extracted with chloroform. The extract was dried over sodium sulfate, and the solvent was evaporated to give 666 mg. of a liquid. Infrared and ultraviolet spectral analyses showed that the liquid contained 408 mg. (theoretical yield ; 31.4%) of tropone. The aqueous layer was saturated with sodium perchlorate to separate 3.03 g. (64.8%) of colorless needles, the infrared spectrum of which was identical with that of tropylium perchlorate.

**The Action of Water on Tropylium Bromide.**—Tropylium bromide (2.205 g.) was dissolved in about 20 ml. of water, and the pH of the solution was adjusted to ca. 2. by the addition of water. This solution was then shaken vigorously for 5 hr. at room temperature. The reaction mixture was allowed to stand overnight and was extracted with chloroform. After it had dried over sodium sulfate, the solvent was evaporated, giving 212 mg. of a liquid. Ultraviolet spectral analysis showed that the liquid contained 145.5 mg. (theoretical yield ; 21.2%) of tropone. The aqueous layer was saturated with sodium perchlorate to separate 1.92 g. (78.8%) of tropylium perchlorate.

**The Action of 6 N Hydrochloric Acid on Thermally-Isomerized Methoxycycloheptatriene.**—7-Methoxycycloheptatriene (Va) was heated for 2 hr. at 195°C and distilled to remove the high boiling

product. The distillate was a mixture of 3-methoxycycloheptatriene (VIa), 1-methoxycycloheptatriene (VIIa) and 2-methoxycycloheptatriene (VIIIa) in the ratio of 18.5 : 7.70 : 4.63, judging from the analysis of MNR spectrum. The above-obtained mixture (400 mg.) and 1 ml. of 6 N hydrochloric acid were shaken for 30 min. When the reaction mixture was extracted with chloroform, 263 mg. of a brown liquid was afforded by the evaporation of the solvent. Infrared spectrum of the liquid was virtually identical with that of a mixture of XII and the XIII dimer. From the aqueous layer, no precipitates appeared upon the addition of a 30% aqueous solution of $H_2PtCl_6 \cdot 6H_2O$.

**The Action of 1 N Hydrochloric Acid on Thermally-Isomerized Ethoxycycloheptatriene.** — When 7-ethoxycycloheptatriene was heated for 2 hr. at 195°C, it gave a liquid which contained 3-ethoxycycloheptatriene (VIb) and 1-ethoxycycloheptatriene (VIIb) in the ratio of 15.19 : 84.8. To 4 g. of this liquid, 33 ml. (1.1 mol. eq.) of 1 N hydrochloric acid was added. After it had been shaken for 30 min. at 0°C, the reaction mixture was extracted with chloroform. The extract was dried over sodium sulfate, and the solvent was evaporated in vacuo, affording a yellow liquid. Its NMR spectrum showed that this liquid contained 3.87 g. (96.7%) of the starting material.

**The Action of 0.5 N Hydrochloric Acid on Thermally-Isomerized Ethoxycycloheptatriene.**—To 4 g. of the thermally-isomerized ethoxycycloheptatriene, which comprises 15.19% of VIb and 84.8% of VIIb, 66 ml. of 0.5 N hydrochloric acid was added. When this mixture was treated in the same manner as described above, it afforded 3.90 g. (97.5%) of the starting material.

**3-Methoxycycloheptatriene (VIa).** — 7-Methoxycycloheptatriene (Va) was heated for 55—60 hr. at 106°C, affording a liquid which was found to be a mixture of 40% of Va and 60% of VIa by a comparison of its NMR spectrum with those of Va and VIa. To 300 ml. of 0.5 N hydrochloric acid, 34.8 g. of this mixture was added at 0°C. This mixed solution was shaken for 30 min. at 0—5°C and then extracted with chloroform. The extract was washed with a saturated aqueous solution of sodium hydrogen carbonate and dried over sodium sulfate. After the evaporation of the solvent, the residue was distilled under reduced pressure to give 17.10 g. of 3-methoxycycloheptatriene (VIa), b. p. 74—75°C/15 mmHg, 716 mg. of substance A b. p. 60—100°C/0.5 mmHg, and 527 mg. of B b. p. 100—125°C/0.5 mmHg. The NMR spectra showed A to be a mixture of VIa and B, and B to be a mixture of XII and XIII. An undistilled residue (6.76 g.) remained.

**3-Ethoxycycloheptatriene (VIb).**—a) Under the same conditions as with 3-methoxycycloheptatriene, 34.0 g. of a mixture of Vb and VIb afforded 20.29 g. of 3-ethoxycycloheptatriene, b. p. 76 — 80°C/15 mmHg and 294 mg. of a yellow oil, b. p. 125—130°C/0.5 mmHg. The NMR spectrum of the latter is identical with that of above B. An undistilled residue (2.77 g.) remained.

b) After 19 g. of 7-ethoxycycloheptatriene had been heated for 2.5 hr. at 130°C, the thermally-isomerized product was distilled fractionally through a column which was 25 mm. in diameter and 30 cm. long. A colorless liquid, 9.24 g. of A, b. p. 71—76°C/20 mmHg, 3.08 g. of B, b. p. 76—81°C/20 mmHg, and 2.71 g. of C, b. p. 81—82°C/20 mmHg were obtained. From the NMR spectral comparison, it was clarified that A and C were identical with Vb and VIb respectively, and that B was a mixture of the two. An undistilled residue (3.20 g.) remained.

**2, 7-Dihydrotropone (XI).** — 7-Ethoxycycloheptatriene was heated for 2 hr. at 195°C and distilled under reduced pressure to give a liquid which contained 84.8% of VIIb and 15.19% of VIb. A mixture of 80 ml. of methanol, 11 ml. of water and 10 ml. of concentrated hydrochloric acid was then added. After this mixture had been stirred for 2 hr. at 15—20°C, cold water was added to dilute the reaction mixture to a volume of 200 ml. The resulting solution was extracted with 100 ml. of chloroform. After the extract had been washed with a saturated aqueous solution of sodium hydrogen carbonate, the solvent was evaporated to give 4.25 g. of a liquid. By the vacuum distillation of the liquid, 3.28 g. (68.87%) of XI, b. p. 71—74°C/20 mmHg was obtained.

**The Action of 6 N Hydrochloric Acid on Thermally - Isomerized Ethoxycycloheptatriene.** — 7-Ethoxycycloheptatriene (Vb) was heated for 1 hr. at 200°C and distilled to afford a clear liquid which was more than 80% 1-ethoxycycloheptatriene (VIIb). A mixture of 15 g. of this liquid and 51 ml. of 6 N hydrochloric acid was shaken vigorously at room temperature for 5 hr. The reaction mixture was then extracted with 100 ml. of chloroform, and the extract was washed with a saturated aqueous solution of sodium hydrogen carbonate. After the evaporation of the solvent, 13.09 g. of a brown oil was obtained; 4 g. of it was distilled in vacuo to give 314 mg. of a colorless liquid (XII), b. p. 40—55°C/7 mmHg and 1.86 g. of a pale yellow oil (XIII), b. p. 115°C/1 mmHg.

**2, 4-Dinitrophenylhydrazone of XII.**—A mixture of 180 mg. of XII, 10 ml. of ethanol and 825 mg. of 2,4-dinitrophenylhydrazine was refluxed for 1 hr.; then the excess 2,4-dinitrophenylhydrazine was removed by hot filtration. The filtrate was cooled in ice and the resulting crystals recrystallized from ethanol to give red plates, m. p. 175—181°C.

Found: C, 51.67; H, 4.42; N, 17.96. Calcd. for $C_{13}H_{14}O_5N_4$: C, 50.98; H, 4.61; N, 18.29%.

**2, 4-Dinitrophenylhydrazone of XIII.**—A mixture of 300 mg. of XIII, 10 ml. of ethanol and 800 mg. of 2,4-dinitrophenylhydrazine was refluxed for 1 hr.; then the resulting crystals were fractionally recrystallized from ethanol, giving red crystals from the easily soluble part and yellow crystals from the sparingly soluble part. Although the former was difficult to purify, the latter was purified by repeated recrystallization, giving yellow needles, m. p. 161—162°C.

Found: C, 60.64; H, 4.99; N, 13.70. Calcd. for $C_{20}H_{20}O_5N_4$: C, 60.60; H, 5.09; N, 14.14%.

**The Action of Phosphorus Pentachloride on Alkoxycycloheptatriene (Va and Vb).**—A mixture of 3.98 g. (2.6 mol. eq.) of phosphorus pentachloride and 35 ml. of anhydrous carbon tetrachloride

was stirred for 30 min., and then a solution of 1 g. of Vb in 1 ml. of carbon tetrachloride was stirred in. Immediately colorless precipitates were separated out. Stirring was then continued for a further 5 hr. at 15—20°C. The reaction mixture was allowed to stand overnight and poured onto 5 g. of ice. Sodium perchlorate was added to the aqueous layer, giving 1.13 g. (81%) of tropylium perchlorate. Under identical conditions but starting with 1 g. of Va, 1.34 g. (85.8%) of tropylium perchlorate was obtained.

**Methoxytropylium Ions (IV; R=OMe).** — To a mixture of 2.15 g. (2 mol. eq.) of phosphorus pentachloride and 30 ml. of anhydrous carbon tetrachloride, a solution of 1 g. of thermally-isomerized methoxycycloheptatriene (a mixture of 18.5% of VIa, 77.0% of VIIa, and 4.63% of VIIIa) in 1 ml. of carbon tetrachloride was added. After 6 hr. stirring, the reaction mixture was allowed to stand overnight. The resulting colorless precipitates were separated by filtration under dry air; after the precipitates had been dried under the vacuo, they were poured into 2 ml. of anhydrous acetonitrile. The resulting solution was filtered to remove insoluble substances, and then to the filtrate was added, drop by drop, a 30% solution of $H_2PtCl_6 \cdot 6H_2O$ in acetonitrile to give 152 mg. yellow prisms, m. p. 180°C (decomp.)

Found: C, 29.52; H, 2.78; Pt, 29.79. Calcd. for $C_8H_9O_{1/2}PtCl_6$: C, 29.55; H, 2.79; Pt, 30.01%.

The filtrate was then concentrated, giving further 531 mg. of crystals (Total yield: 683 mg.). An infrared spectrum of the crystals differs from that of the chloroplatinate of tropone.

**Ethoxytropylium Ions (IV; R=OEt).** — Under the same conditions with methoxytropylium ions, 600 mg. of thermally-isomerized ethoxycycloheptatriene (a mixture of 15.19% of VIb and 84.81% of VIIb) gave 669 mg. of pale orange prisms, m. p. 164—165°C (decomp.).

Found: C, 32.15; H, 3.25; Pt, 28.55. Calcd. for $C_{18}H_{22}O_2PtCl_6$: C, 31.89; H, 3.27; Pt, 28.76%.

When absolute alcohol was used instead of anhydrous acetonitrile, 1 g. of thermally-isomerized ethoxycycloheptatriene also gave 194 mg. of chloroplatinate of IV; R=EtO.

**The Action of Bromine on Thermally-Isomerized Ethoxycycloheptatriene.**—To a cold solution of 4 g. of thermally-isomerized ethoxycycloheptatriene (a mixture of 15% of VIb and 85% of VIIb) in 35 ml. of carbon tetrachloride, a solution of 4.7 g. of bromine in 13 ml. of carbon tetrachloride was stirred in drop by drop. Stirring was then continued for a further 5 hr. at 15°C, after which the solvent was evaporated at 40—50°C under reduced pressure. The residue was allowed to stand for 3 days at 50°C under 100 mmHg. At the end of this period, 4.68 g. of strongly hydroscopic black precipitates were obtained. These precipitates (1.42 g.) were added to 2 ml. of acetonitrile, and the insoluble substance was removed by filtration. A solution of $H_2PtCl_6 \cdot 6H_2O$ (1 g.) in 2 ml. of acetonitrile was added to the filtrate, giving 139 mg. of orange needles. Their infrared spectrum was identical with that of the chloroplatinate of tropone.

**Tropone from Ethoxytropylium Ions.**—Starting from 3 g. of thermally-isomerized ethoxycycloheptatriene, 11.24 g. of phosphorus pentachloride and 120 ml. of carbon tetrachloride, ethoxytropylium ions were obtained as 7.02 g. of double salt with phosphorus pentachloride. This salt was dissolved in water, and the solution was warmed on a water bath and neutralized by the addition of sodium hydrogen carbonate. The reaction product was extracted with chloroform, giving 1.23 g. of an oil. Its infrared spectrum was identical with that of tropone, and by the action of picric acid, this oil afforded 3.5 g. of topone picrate.

**The Action of Selenium Oxide on 3-Ethoxycycloheptatriene (VIb).**—Into a solution of 5 g. of VIb in 100 ml. of dry dioxane, 8.15 g. (2 mol. eq.) of selenium oxide under a nitrogen atmosphere was stirred. The mixture was heated at 120—125°C for 3 hr. under stirring and allowed to stand overnight. The selenium with separated was removed by filtration, and the solvent was evaporated under reduced pressure. Ether was added to the residue, and 2.15 g. of an oil was obtained by the evaporation of the solvent. Its infrared spectrum was identical with that of tropone, and by the action of hydrazine hydrate, the oil afforded 1.59 g. of 2-aminotropone.[16]

The authors wish to express their sincere gratitude to the Sankyo Co., Ltd., which defrayed a part of the expenses for the present work. Thanks are also due to the Toyo Rayon Co., Ltd., for supplying infrared spectrophotometer which was used for these experiments. The authors are also grateful to Mr. Fujio Masuko for his measurement of the reaction rate.

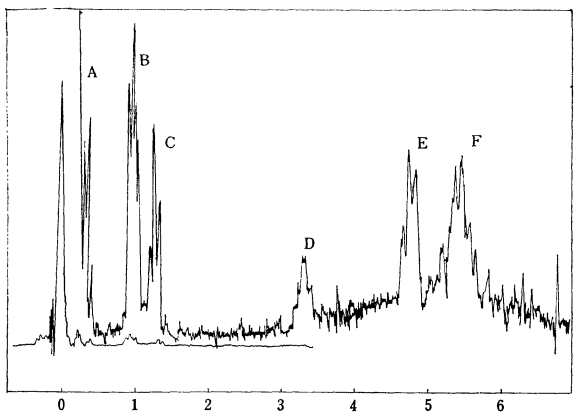
# NOTES

## The Thermal Dimerization of 2-Vinylfuran*

By Chuji Aso, Toyoki KUNITAKE and Yoshinari TANAKA

(Received August 31, 1964)



2-Vinylfuran was found to undergo a rather facile thermal polymerization[1] during the course of the study of its free radical polymerization.[2]

Since the thermal dimerization of styrene has been studied in connection with the elucidation of the initiation mechanism of thermal polymerization,[3] similar experiments were carried out for 2-vinylfuran.

### Results

The monomer prepared in a manner described previously[2] was dissolved in purified toluene or bromobenzene (molar ratio 1 : 10) in an ampule. After it had been sealed under reduced nitrogen pressure, the ampule was allowed to stand at 130°C for 300 hr. After the insoluble fraction in methanol had been removed and the solvents had been evaporated at a reduced pressure, viscous oil was obtained. The gas chromatogram of the distillable portion of the oil (ca. 100°C/4 mmHg) consisted of one major peak, and its yield was 10 to 20% with a toluene solvent and 30 to 50% in bromobenzene. Elementary analysis: Found: C, 75.65; H, 6.40. Calcd. for $C_6H_6O$: C, 76.57; H, 6.43%. The molecular weight determination (Vapor Pressure Osmometer, Model 301A, Mechrolab. Inc.) showed the portion to be a dimer (Found: 175, 198. Calcd. for dimer: 188). The residues of the distillation had molecular weights from that of a trimer to that of a hexamer, depending on the solvent used. Thus, the distillate was concluded to be a dimer of 2-vinylfuran. Subsequent measurements of infrared, ultraviolet and NMR spectra gave the following results:

a) IR data. Characteristic bands for furans[4] observed at 3150, 1595, 1500, 1006, 881 and

Up-field shift from benzene, p. p. m.

Fig. 1. NMR spectrum of the dimer.

The dimer may be formed either by a Diels-Alder type reaction, followed by isomerization, or by a coupling of biradicals. Although it is not clear whether this compound can be related with the thermal initiation of polymerization, the contrast should be interesting between this compound and the cyclobutane derivative obtained thermally from styrene.[3]

We wish to express our thanks to Professor Taku Matsuo of our department for his helpful discussions.

# The Removal of Copper from the Copper Complex of ω-Acylamino Acid with EDTA*

By Shigeru KUWATA and Hiroshi WATANABE

(Received September 14, 1964)

ω-Acyl derivatives of basic amino acids can be synthesized most conveniently by the acylation of the copper complexes of the amino acid, followed by the removal of copper by hydrogen sulfide. This method is, however, rather troublesome for the synthesis of lysine or ornithine derivatives (e. g. ε-carbobenzoxy-lysine or δ-carbobenzoxy-ornithine) when water is used as a solvent, because their final products are only slightly soluble in water or are strongly adsorbed on cupric sulfide. This difficulty can be avoided by using such a solvent as boiling 70—80% acetic acid[1] or dilute hydrochloric acid[2], which dissolves the product. However, it might be desirable to avoid the hydrogen sulfide process for the benefit of subsequent catalytic reduction. For this reason, Zahn[3] has used potassium cyanide in 20% acetic acid to remove copper from the copper complex of ε-lysine peptide. Although we applied this method to the preparation of ε-carbobenzoxy-lysine, we could not obtain any successful results because of the low solubility of the product in this solvent. In principle, a reagent which has a stronger affinity to copper than that of amino acid, may also be useful. Therefore, we intended to use EDTA (ethylenediaminetetraacetic acid), which is well known to form a water-soluble copper chelate, as a copper-removing reagent.

Thus, we were successful in obtaining a ω-acyl derivative, e. g., γ-carbobenzoxy-L-α, γ-diaminobutyric acid or ε-tosyl-L-lysine, from its copper complex by merely boiling it with EDTA in water or aqueous ethanol, from which the product separated as white precipitates in the cold. A ω-acyl derivative, such as ε-carbobenzoxy-L-lysine, which is very slightly soluble even in hot water, was also easily prepared by boiling the aqueous suspension of a copper derivative with EDTA, followed by the recrystallization of the raw product from 50% acetic

acid containing some EDTA, thus removing the trace of copper.

The yields are comparable to those obtained by the hydrogen sulfide method, as is shown in Table I.

## Experimental

The copper complexes of the ω-acyl amino acids were prepared by acylating the copper complexes of the amino acids by the usual method.

EDTA was used as the disodium salt.**

**ε-Tosyl-L-lysine.**—The copper complex of ε-tosyl-L-lysine was suspended in water or 50% ethanol containing EDTA, the mixture was then boiled until the complex had dissolved completely. When the resulting blue colored solution had cooled, colorless needles were separated from it. The crystals were washed with water and recrystallized from 50% ethanol. For further purification, they were dissolved in dilute hydrochloric acid, decolorized, and neutralized with alkali, and the resulting white precipitates were recrystallized from 50% ethanol.

**γ-Carbobenzoxy-L-α,γ-diaminobutyric Acid.** — The copper complex was treated as above.

**ε-Carbobenzoxy-L-lysine.**—The copper complex of ε-carbobenzoxy-L-lysine was suspended in an aqueous EDTA solution and boiled until the violet color of the complex had almost disappeared. After the mixture had cooled, a white product was filtered off, washed thoroughly with water, and recrystallized from 50% acetic acid containing some EDTA in order to remove the trace of unreacted copper. The product was then recrystallized from the same solvent. For further purification, it was treated as above.

The results are summarized in Table I in comparison with those obtained by the hydrogen sulfide method.***

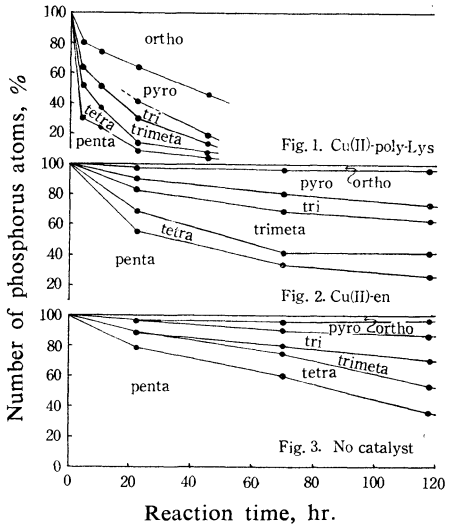
** Clewat AM (technical grade, kindly supplied by the Teikoku Chem. Ind., Ltd.) or Dotite 2Na (analytical grade, purchased from Wako Pure Chemical Ind., Ltd.) was used. The grade of reagent had no influence on the results.

*** According to the private communication from S. Sakakibara, Institute for Protein Research, Osaka University, this method was also applied successfully in the case of ornithine.



## SHORT COMMUNICATIONS

# The Selective Hydrolysis of Pentaphosphate by Copper Chelate Catalysts*

By Yoshiki MORIGUCHI and Masaji MIURA

(Received December 26, 1964)

Although several studies of the hydrolytic degradation of substances using chelates as the catalyst have recently been made,[1] these have dealt almost exclusively with kinetic problems; little attention has been paid to the selective action of the chelates. We have, therefore, attempted to study the selective hydrolysis of polyphosphates by chelate catalysts and have obtained some interesting results on the hydrolysis of pentaphosphate.

Hydrolytic degradation of pentaphosphate in the presence of copper chelate catalysts at 45°C and pH 8.

Pentaphosphate was prepared by the method which has been reported previously.[2] The decomposition products were identified and determined quantitatively by ion-exchange chromatography, using $^{32}P$ as a tracer.[3]

As may be seen in Table I, the chelates used remarkably accelerate the decomposition rate of pentaphosphate. The main decomposition product is orthophosphate in the presence of copper(II)-polylysine (Fig. 1), while the product is trimetaphosphate in the presence of copper(II)-ethylenediamine (Fig.

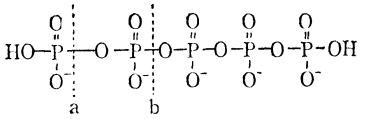


Fig. 4

2). These results lead us to the conclusion that these two kinds of chelates act in different ways in the hydrolytic degradation of pentaphosphate; that is, the former accelerates the terminal chain attack (Fig. 4a), whereas the latter promotes the intermediate chain attack (Fig. 4b).

Similar studies of various polyphosphates and chelates are in progress.

# The Synthesis and Biological Activities of a Hexadecapeptide Corresponding to a Modified Sequence in the Corticotropin Structure

By Hideo OTSUKA, Ken INOUYE, Makoto KANAYAMA and Fusako SHINOZAKI

(Received December 28, 1964)

The syntheses of adrenocorticotropically active peptides, which have chain lengths of less than a half of the 39-amino acid chain in the corticotropin (ACTH) structure, have been reported by several investigators,[1-7] We wish to describe herein the synthesis of a hexadecapeptide with a modified sequence of the first octadecapeptide portion of the ACTH molecule, in which the *N*-terminal serine is replaced by a glycine and the lysyl-lysyl sequence at positions 15—16 is removed; this substance is, namely, glycyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-arginyl-arginine (I),*1 which may be designated as $\alpha^{1-14,17-18}$-Gly$^{1}$-ACTH. This synthetic peptide has been shown to have a very low but a consistently reproducible adrenal steroidogenic activity of 0.134 U.S.P. unit per mg., as estimated by the in vitro method;[8] it has also brought about a plasma corticosterone elevation in a hypophysectomized rat.*2 The results may partially validate the finding of Lebovitz and Engel that the hydroxymethyl group of the *N*-terminal serine is not necessary for the ACTH activity.[9] The peptide has been also found to exhibit a high lipolytic potency[10] of the minimal effective doses, 0.00093 $\mu$g. in rabbit adipose tissue and 0.031 $\mu$g. in the rat,*2 values which were of the same order of magnitude as those reported for the heptadecapeptide, $\alpha^{1-17}$-ACTH.[3,10]

$N^{\alpha}$-Cbz-$N^{\varepsilon}$-BOC-lysyl-prolyl-valyl-glycyl-nitroarginyl-nitroarginine benzyl ester (II) (m. p. 114—115°C, $[\alpha]_D^{25}$ −49.4° (*c* 2.0, methanol). Found: C, 52.54; H, 6.49; N, 18.52. Calcd.: C, 52.48; H, 6.78; N, 18.36%) was obtained by the DCCI-mediated condensation of $N^{\alpha}$-Cbz-$N^{\varepsilon}$-BOC-lysyl-prolyl-valyl-glycine[11] with nitroarginyl-nitroarginine benzyl ester, which had been derived by trifluoroacetic acid treatment from the BOC-nitroarginyl-nitroarginine benzyl ester ($[\alpha]_D^{25}$ −18.1° (*c* 2.5, methanol). Found: C, 47.68; H, 6.78; N, 21.42. Calcd.: C, 47.21; H, 6.27; N, 22.94%). Compound II was hydrogenolyzed to give $N^{\varepsilon}$-BOC-lysyl-prolyl-valyl-glycyl-arginyl-arginine diacetate (III) ($[\alpha]_D^{26.5}$ −50.1° (*c* 1.6, 50% acetic acid). Found: N, 19.51; $CH_3CO$, 9.68. Calcd.: N, 19.54; $CH_3CO$, 9.24%), which was then converted into the trihydrochloride (IV) (Found: Cl, 12.05.

Calcd.: Cl, 11.54%).

BOC-glycine was coupled with tyrosine methyl ester (m. p. 134—135°C, $[\alpha]_D^{23.5}$ +26.9° (*c* 2.4, methanol); lit.[12] m. p. 135°C) by DCCI to give the acyldipeptide ester, which was then converted into the BOC-glycyl-tyrosine hydrazide (V) (m. p. 189—190°C, $[\alpha]_D^{26.5}$ +0.5° (*c* 2.0, dimethylformamide). Found: C, 54.56; H, 6.79; N, 15.93. Calcd.: C, 54.53; H, 6.87; N, 15.90%). The BOC-seryl-methionine methyl ester (VI) (m. p. 66—67.5°C, $[\alpha]_D^{25.5}$ −29.5° (*c* 2.0, methanol). Found: C, 48.06; H, 7.61; N, 8.20; S, 9.34. Calcd.: C, 47.98; H, 7.48; N, 7.99; S, 9.15%) was prepared by the DCCI-induced coupling of the methionine methyl ester with the crystalline BOC-serine monohydrate (m. p. 45—47°C, $[\alpha]_D^{25}$ −7.6° (*c* 2.6, water), $[\alpha]_D^{26}$ −3.0° (*c* 2.3, acetic acid). Found: C, 43.25; H, 7.88; N, 6.52; $H_2O$, 7.19. Calcd.: C, 43.04; H, 7.68; N, 6.28; $H_2O$, 8.07%). The azide prepared from V was allowed to react with the dipeptide ester, which had beed derived from VI by HCl/ethyl acetate treatment, to obtain the protected tetrapeptide BOC-glycyl-tyrosyl-seryl-methionine methyl ester (VII) (m. p. 183—185°C, $[\alpha]_D^{24}$ −16.5° (*c* 1.15, methanol). Found: C, 52.44; H, 7.01; N, 9.98; S, 5.70. Calcd.: C, 52.62; H, 6.71; N, 9.82; S, 5.62%). Compound VII was treated with hydrazine to give the corresponding hydrazide hemihydrate (VIII) (m. p. 201—203°C decomp., $[\alpha]_D^{27}$ −19.4° (*c* 1.2, 50% acetic acid). Found: C, 50.07; H, 6.93; N, 14.24; S, 5.48. Calcd.: C, 49.73; H, 6.78; N, 14.50; S, 5.53%).

γ-*t*-Butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine[13] and the azide, which had been derived from VIII, were coupled together to give the decapeptide derivative BOC-glycyl-tyrosyl-seryl-methionyl-γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine dihydrate (IX) (m. p. 212—218°C (decomp.), $[\alpha]_D^{26.5}$ −15.5° (*c* 1.7, dimethylformamide). Found: C, 55.17; H, 6.84; N, 15.03; S, 2.14. Calcd.: C, 55.05; H, 6.62; N, 15.33; S, 2.19%). The hydrochloride of IX was then converted into the *N*-hydroxysuccinimide ester,[14] and this active ester was allowed to react with IV in an aqueous pyridine solution to give the hexadecapeptide derivative BOC-glycyl-tyrosyl-seryl-methionyl-γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-$N^{\epsilon}$-BOC-lysyl-prolyl-valyl-glycyl-arginyl-arginine (X), which was then partially purified on a CMC column. Compound X was treated with 90% trifluoroacetic acid to yield the free hexadecapeptide I, which was then purified by CMC column chromatography. The purified material was found to be homogeneous in paper electrophoresis and in paper chromatography. $\lambda_{max}^{0.1N\ HCl}$ = 278 mμ (ε = 5990), $\lambda_{shoulder}^{0.1N\ HCl}$ = 288 mμ (ε = 4490); $\lambda_{max}^{0.1N\ NaOH}$ = 281 mμ (ε = 6950), $\lambda_{max}^{0.1N\ NaOH}$ = 288 mμ (ε = 6840). $[\alpha]_D^{52}$ −54.3° (*c* 0.5, 0.1N acetic acid). Amino acid ratios in the acid hydrolysate:[15] Gly 2.84, Tyr 1.01, Ser 1.05, Met 1.05, Glu 1.00, His 1.12, Phe 1.00, Arg 2.89, Lys 0.97, Pro 1.04, Val 0.94 (average recovery 92.5%).*3 The intact hexadecapeptide was determined spectrophotometrically to contain tyrosine and tryptophan in a molar ratio of 1.00 : 0.95.[16]

# A Mössbauer Resonance Absorption Study of the Photolysis and Radiolysis of Ferric Oxalate*1

By Nobufusa SAITO, Hirotoshi SANO, Takeshi TOMINAGA and Fumitoshi AMBE

(Received January 22, 1965)

The technique of the Mössbauer resonance absorption of $\gamma$ rays has recently been applied to the study of the valence state, structure and nature of the chemical bond of various compounds. Because of the favorable properties of $^{57}Fe$ for the observation of the resonance absorption spectra, a number of iron compounds have been investigated. However, the Mössbauer resonance absorption technique has not so far been used to investigate the chemical change induced by ionizing radiation or light in iron compounds.[1] Therefore, the present authors have applied this technique to the study of the photolysis and radiolysis of ferric oxalate.

Ferric oxalate, $Fe_2(C_2O_4)_3 \cdot nH_2O$,*2 was irradiated with $^{60}Co$ $\gamma$ rays at an ambient temperature in the presence of air. The total dose was $2\times10^8$ r. In case of photolysis, the same salt was exposed to the light from a mercury lamp. The resonance absorption of 14.4 KeV. $\gamma$ rays in irradiated and non-irradiated iron oxalates (as absorbers) was measured with a source of $^{57}Co$ diffused into copper foil. The source was moved linearly at a constant velocity by means of a mechanical drive. No remarkable change was observed between the spectra obtained with the same absorber at 22°C and at the temperature of liquid nitrogen. Their Mössbauer spectra are shown in Figs. la-lc.

As may be seen in Fig. la, the spectrum of non-irradiated ferric oxalate consists of two lines, at 0.27 and 0.70 mm./sec. (vs. stainless steel). After irradiation with $\gamma$ rays, the height of both lines is decreased, and new lines appear at about 0.5 and 2.3 mm./sec. (Fig. lb). Since the positions of these new lines nearly correspond to those in the spectrum of non-irradiated ferrous oxalate (Fig. lc), it may be concluded that the electron configuration around the iron atom in ferric oxalate irradiated with $\gamma$ rays

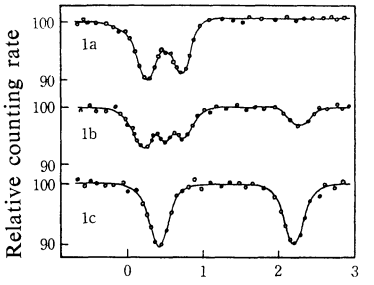

Fig. la-lc. Mössbauer resonance absorption spectra (at 22°C).
la : Non-irradiated ferric oxalate
lb : Irradiated ferric oxalate
lc : Non-irradiated ferrous oxalate

becomes very similar to that in ferrous oxalate (and that, therefore, $Fe^{3+}$ is reduced to $Fe^{2+}$ as the result of radiolysis). The Mössbauer spectrum obtained with ferric oxalate which has undergone photolysis is almost identical in shape with that of $\gamma$ ray-irradiated sample.*3

The above conclusion may be confirmed by the investigation of their infrared spectra shown in Figs. 2a-2c. The infrared spectra of irradiated and non-irradiated iron oxalates were measured as a KBr disk by using a Hitachi EPI-510 spectrophotometer. By examining the 750-850 $cm^{-1}$ (O-C-O bending) and 1250-1350 $cm^{-1}$ (C-O

*1 Presented at the 8th Symposium on Radiochemistry, November, 1964, Osaka.

1) The effect of $\gamma$ rays on the shape of Mössbauer spectra has been reported only on some tin compounds: A. Y. Aleksandrov et al., *Soviet Physics JETP*, **16**, 1467 (1963).

*2 $n$=nearly 5.

*3 It is well known that ferric oxalate is decomposed by light to yield ferrous oxalate.

stretching) regions, it may be concluded that the spectrum of irradiated ferric oxalate (Fig. 2b) is obtainable by the superimposition of the spectrum of non-irradiated ferrous oxalate (Fig. 2c) on that of non-irradiated ferric oxalate (Fig. 2a) in adequate proportions.

Further study is now in progress to investigate the possibility of the semiquantitative determination of the $Fe^{2+}$ formed in ferric oxalate in the course of $\gamma$ radiolysis using the Mössbauer technique.

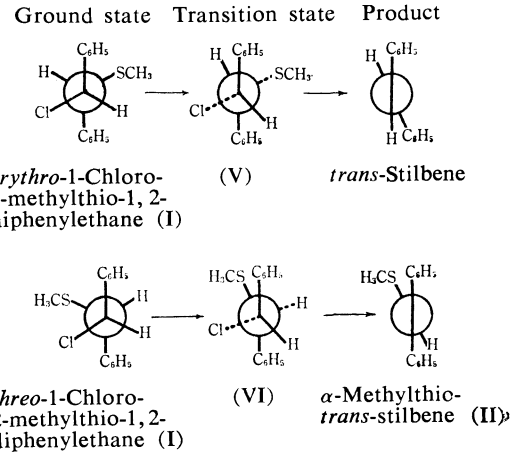
# The Reactions of Isomeric 1-Chloro-2-methylthio-1, 2-diphenylethanes with the Base

By Michinori Ōki and Atsuko Kimura



(Received February 8, 1965)

In the course of other study the authors encountered a striking difference in the reactivities of *erythro*- and *threo*-isomers. When isomers of 1-chloro-2-methylthio-1, 2-diphenylethane (I) were treated with potassium *t*-butoxide, the former gave *trans*-stilbene and the other, possibly α-methylthio-*trans*-stilbene (II). The results may be attributed to the different stabilities of the transition states, as will be described below.

*trans*-Stilbene oxide was treated with sodium methylmercaptide in ethanol to produce *erythro*-2-methylthio-1, 2-diphenyl-1-ethanol (III), m. p. 74°C (Found: C, 74.02; H, 6.66. Calcd. for $C_{15}H_{16}OS$: C, 73.75; H, 6.60%), which was converted into *erythro*-I, m. p. 123°C (Found: C, 68.59; H, 5.73. Calcd. for $C_{15}H_{15}ClS$: C, 68.40; H, 5.74%), by treating it with thionyl chloride in chloroform. Similarly, *threo*-III, which was characterized as acetate, m. p. 71.5—72°C (Found: C, 71.49; H, 6.27. Calcd. for $C_{17}H_{18}O_2S$: C, 71.30; H, 6.34%), and *threo*-I, m. p. 52.5°C (Found: C, 68.52; H, 5.76%), were prepared from *cis*-stilbene oxide.

The stereochemistry of these compounds was established by the mode of preparation, since the ring opening of an epoxide proceeds in the trans fashion and the chlorination of an alcohol with thionyl chloride proceeds with the retention of the configuration.[1] The results were further confirmed by the NMR spectra, in which *threo*-I shows a coupling constant of benzylic hydrogens of 7.5 c. p. s., whereas *erythro*-I shows one of 9.5—9.9 c. p. s.

The refluxing of a *t*-butyl alcohol solution of *erythro*-I with ca. 1 N potassium *t*-butoxide for 12 hr. yielded *trans*-stilbene as the sole product. Thus it is apparent that the elimination of methanesulfenyl chloride took place during this treatment. On the other hand, *threo*-I, upon similar treatment, gave II (NMR; $\tau$ 2.3—2.9 (multiplet), $\tau$ 8.05 (singlet), $\tau$ 3.23 (singlet): $\lambda_{max}$ 308 mμ, ε 15000), which was then oxidized with peroxyacetic acid to α-methylsulfonyl-*trans*-stilbene (IV), m. p. 118—119°C (Found: C, 69.48; H, 5.61. Calcd. for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46%). Thus, the elimination of hydrogen chloride took place wih *threo*-I. The configuration of IV has not been firmly established, but from the mode of elimination, which will be discussed below, the trans configuration seems most probable.

*erythro*-1-Chloro-2-methylthio-1, 2-diphenylethane (I) — *trans*-Stilbene

*threo*-1-Chloro-2-methylthio-1, 2-diphenylethane (I) — α-Methylthio-*trans*-stilbene (II)

1) E. L. Eliel, "Steric Effects in Organic Chemistry," Ed. by M. S. Newman, John Wiley & Sons, Inc., New York (1956), Chap. 2.

One possible explanation* of these results is that an $E_2$-type elimination occurs during this treatment. If so, the results could be interpreted as follows. *threo*-I, taking its most stable conformation, as is shown in the figure, will give II, in accord with expectations, through the transition state VI. *threo*-I must assume a transition state of high energy if it reacts to give *cis*-stilbene. On the other hand, a transition state which gives rise to the elimination of hydrogen chloride from *erythro*-I will be of too high an energy to be a major contribution, because the two bulky phenyl groups are opposed. It may be expected that the transition state V will be formed much more easily. Thus, instead of hydrogen chloride, methanesulfenyl chloride is eliminated from the *erythro* isomer, as is shown in the figure.

In this respect, it is very interesting that Helmkamp and Pettitt reported[2] recently that methanesulfenyl bromide was eliminated when two isomers of 2-bromo-3-methylthiobutane were treated with iodine, irrespective of their configurations.

The isomers of I also behave differently toward pyridine. The effect of the bulkiness of the substituent and/or base on the elimination and the effect of the acidities of $\alpha$-hydrogens are now under investigation.

*Hongo, Tokyo*

* An alternative explanation will be an anchimeric assistance of a methylthio group to form a bridged cation as a transition state. However, this mechanism is less likely, because no sulfur-containining compound is isolated inspite of an expected competitive abstraction of $CH_3S^+$ or $H^+$.

# A Novel Five-co-ordinate Complex of Cobalt(II)

By Shoichiro YAMADA and Hiroaki NISHIKAWA

(Received February 12, 1965)

Most cobalt(II) complexes are known to be four- or six-co-ordinate; very few five-co-ordinate complexes have so far been characterized.[1] The present communication deals with the successful preparation of a new cobalt(II) complex of a Schiff base, which is now believed to be five-co-ordinate.

The compound prepared (A) is a pyridine adduct of bis-(*N*-*o*, *o*'-xylidyl-salicylideneiminato)cobalt(II), which is abbreviated as Co-(Sal·N·*o*,*o*'-xyl)$_2$·Py. This pyridine adduct has been obtained as green crystals by cooling a hot solution of the red-coloured parent cobalt-(II) complex in pyridine or in pyridine-petroleum ether. Elemental analysis agreed quite well with the above formula with one pyridine molecule, but not with the formula with two pyridine molecules.

The spectrum of compound A in the solid state is quite different from any of the typical spectra[2] of the tetrahedral, the square-planar and the octahedral cobalt(II) complexes, as well as from the spectrum of the parent complex in the solid state or in solution (Fig. 1).

All these findings indicate that the pyridine adduct A in the solid state is most likely to be a five-co-ordinate complex, one in which the pyridine molecule is bound with the cobalt(II) ion.

On the contrary, the use of a similar procedure with the *N*-monosubstituted phenyl complexes of cobalt(II) yielded adducts B, Co-(Sal·N·R)$_2$·2Py, which has been concluded, from electronic spectra and elemental analysis, to be six-co-ordinate. The difference in the structure of the pyridine adduct between the parent complexes of A and B is regarded as due to the much more marked steric hindrance in A, which prevents the complex from taking the otherwise favourable six-co-ordination.[3]

1) G. A. Barclay and R. S. Nyholm, *Chem. & Ind.*, **1953**, 378; R. S. Nyholm and M. L. Tobe, "Essays in Co-ordination Chemistry," Ed. by W. Schneider, G. Anderegg and R. Gut, Birkhäuser Verlag, Basel (1964), p. 112.

2) H. Nishikawa and S. Yamada, This Bulletin, **35**, 1430 (1962); ibid., **37**, 8 (1964); L. Sacconi, M. Ciampolini, F. Maggio and F. P. Cavasino, *J. Am. Chem. Soc.*, **84**, 3246 (1962); L. Sacconi, P. L. Orioli, P. Paoletti and M. Ciampolini, ibid., **85**, 411 (1963), and references therein.

3) Recently Sacconi and Ciampolini (private communication) studied the equilibrium between bis(salicylaldehyde)-*N*, *N*-disubstituted polymethylenediiminato-cobalt-(II) complexes and their pyridine adducts in solution; they concluded the existence in solution of the adduct of the cobalt(II) complex with one pyridine molecule.

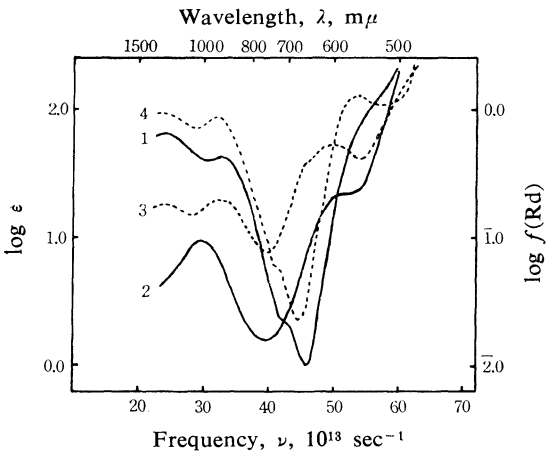

Fig. 1. Electronic spectra of: 1, [Co(Sal·N·*o*,*o*'-xylidyl)$_2$] in chloroform (tetrahedral) ; 2, [Co(Sal·N·*o*-tolyl)$_2$] in pyridine (octahedral); 3, [Co(Sal·N·*o*,*o*'-xylidyl)$_2$·Py] in the solid state by reflectance (five-co-ordinate) ; 4, [Co-(Sal·N·cyclohexyl)$_2$]·lPiperidine in the solid state by reflectance (tetrahedral).

The conclusion of the five-co-ordination in A is also supported by the magnetic moment of A (4.53 B.M.), which is definitely different from the moment of the parent complex (4.35 B. M.). Thus, A is of a high-spin type and differs from the previously-reported five-co-ordinate cobalt(II) complexes, which are of a low-spin type.[1] As has been discussed by Nyholm and others on the basis of the current theory of directed valence,[4] the magnetic moment indicates that, in compound A, $4s4p^34d$ hybridized orditals may most probably be used for bonding, a trigonal-bipyramidal configuration being predicted; a tetragonal pyramid on the basis of $4s4p^24d^2$ hybridization may not be completely eliminated.

It should be noted that the solid spectra of Co(Sal·N·cyclohexyl)$_2$·Py and Co(Sal·N·cyclohexyl)$_2$(Piperidine) are nearly identical with the spectrum of the parent cobalt(II) complex of a tetrahedral configuration.

# The Fe-57 Mössbauer Effect in Ferrocyanide Derivatives

By Hirotoshi SANO and Fukiko HASHIMOTO

(Received February 23, 1964)

The measurement of the nuclear gamma-ray resonance absorption, the so-called Mössbauer effect, has been applied to the study of the electronic environment in various compounds, because the position and structure of resonance lines depend on the state of the chemical bonding of the atom. It has been reported in potassium ferrocyanide that the cyano groups are combined with the central iron atom by $\sigma$ and $\pi$ bonding.[1] The purpose of the present work is to study the effect of outer sphere ions or groups on the Mössbauer spectrum in the ferrocyanide derivatives, and to explain the lower value of the isomer shift of the ferrocyanide ion in Prussian blue and Turnbull's blue than that in potassium ferrocyanide.

Four ferrocyanide derivatives, $H_4[Fe(CN)_6]$,[2] $H_4[Fe(CN)_6](C_2H_5)_2O$,[2] $[Fe(CN)_2(CNCH_3)_4]$[3] and $[Fe(CNCH_3)_6](HSO_4)_2 3H_2O$[4], were prepared by conventional methods. The resonance absorption spectra of 14.4 keV. gamma rays in these compounds and potassium ferrocyanide, Prussian blue and Turnbull's blue were measured at room temperature with a source of cobalt-57 diffused into copper foil. The sample was moved at a constant velocity by means of a mechanical drive. Both the isomer shift and the quadrupole splitting were determined from the gamma ray resonance spectrum. The infrared absorption spectra in the KBr disk of these compounds were also measured.

Table I shows that the isomer shifts of $[Fe(CNCH_3)_6](HSO_4)_2 3H_2O$, $[Fe(CN)_2(CNCH_3)_4]$,

TABLE I. RESULTS FROM THE MÖSSBAUER SPECTRA AND INFRARED SPECTRA

| Compound | Isomer shift relative to stainless steel mm./sec. | Quadrupole splitting mm./sec. | Wave number $cm^{-1}$ |
|---|---|---|---|
| $K_4[Fe(CN)_6]3H_2O$ | $+0.03\pm0.01$ | $0.00\pm0.01$ | 2050 |
| $H_4[Fe(CN)_6]$ | $-0.01\pm0.01$ | $0.00\pm0.01$ | 2090<br>2110 |
| $H_4[Fe(CN)_6](C_2H_5)_2O$ | $-0.01\pm0.01$ | $0.00\pm0.01$ | 2090<br>2110 |
| $[Fe(CN)_2(CNCH_3)_4]$ | $-0.08\pm0.01$ | $0.00\pm0.01$ | 2090<br>2200 |
| $[Fe(CNCH_3)_6[(HSO_4)_23H_2O$ | $-0.08\pm0.01$ | $0.00\pm0.01$ | 2230 |
| Prussian blue and Turnbull's blue | $-0.05\pm0.03$<br>$+0.55\pm0.03$ | $0.00\pm0.02$<br>$0.50\pm0.03$ | 2075 |

$H_4[Fe(CN_6]$ and $H_4[Fe(CN)_6](C_2H_5)_2O$ are lower than that of $K_4[Fe(CN)_6]3H_2O$, and that the wave numbers of the C-N stretching vibration increase in accordance with the decrease in the isomer shift. The results suggest that the $d\varepsilon$ electrons of the iron atom are attracted through the cyano group by the methyl groups, and that then the total $s$ electron density on the iron nucleus increases. The fact that the isomer shifts of the spin-paired iron atom in Prussian blue and Turnbull's blue are lower than that in potassium ferrocyanide may be explained by assuming some co-ordination bonding between nitrogen atoms and spin-free iron(III) ions.

# The Mechanism of the Piezochromism of Hexaphenyl-biimidazolyl

By Taro HAYASHI and Koko MAEDA

(Received March 1, 1965)

We have found that 2,2',4,4',5,5'-hexaphenyl-1,1'-biimidazolyl and its derivatives, which exhibit both photochromism and thermochromism,[1] which have been ascribed to a radical dissociation of the N-N bond,[2] exhibit also piezochromism and that the mechanism of this is a radical dissociation of the N-N bond brought about mechanically on grinding or pressing. This piezochromism is probably the first case in which the mechanism has been elucidated.

When pale yellow fine crystals of hexaphenyl-biimidazolyl which had been recrystallized from benzene, m. p. 198—199°C, were ground in an agate mortar or pressed at a pressure of about 10—50 kg./cm$^2$ at room temperature in the dark, they turned reddish-purple. The reddish-purple crystals reverted to the original pale yellow crystals when kept at about 50°C in the dark or when subjected to liquid or to the vapor of ether, ethanol, acetone or benzene.

This piezochromism is not the thermochromism ascribed to a rise in temperature upon grinding or pressing, because the reddish-purple color due to the thermochromism began to appear at about 170°C, which was unlikely to occur upon grinding or pressing, and the piezochromic color hardly faded at room temperatures, whereas the thermochromic color disappeared immediately upon the crystals being cooled to room temperature. The pale yellow solid exhibited no ESR, whereas the reddish-purple solid obtained by grinding or pressing exhibited an ESR of a single peak ($g=2.003$), as in the cases of the photochromism and the thermochromism in a solid state. The spin concentration in the reddish-purple solid which has been obtained by grinding for 5 min. was about $10^{16}$—$10^{17}$ spins/g. This fact indicates the formation of a free radical on grinding or pressing.

The reddish-purple solid, obtained by grinding for 5 min. in the dark or by pressing at a pressure of 30 kg./cm$^2$ for 5 min. at room temperature, showed an absorption maximum at 563 m$\mu$ ; the maximum was measured by the

1) T. Hayashi and K. Maeda, This Bulletin, 33, 566 (1960).
2) T. Hayashi and K. Maeda, ibid., 37, 1564 (1964); 37, 1717 (1964).

opal-glass transmission method and the potassium bromide disk method respectively. A benzene solution of the reddish-purple solid showed an absorption maximum at 554 mμ, a value which agreed with the 554 mμ assigned to the triphenylimidazolyl produced in a benzene solution of hexaphenyl-biimidazolyl on irradiation.

These results indicate that the free radical produced in the piezochromism of hexaphenyl-biimidazolyl is triphenylimidazolyl and that the piezochromism of hexaphenyl-biimidazolyl may be ascribed to the dissociation of the N-N bond to triphenylimidazolyl which is mechanically brought about on grinding or pressing. It seems probable that this conclusion is correct, since the heat of the dissociation of hexaphenyl-biimidazolyl to triphenylimidazolyl by the homolytic rupture of the N-N bond, $\Delta H$, was found to be 26 kcal./mol.[2] in a benzene solution.

2, 2', 4, 4', 5, 5'-Hexa-*p*-tolyl-1, 1'-biimidazolyl, fine, pale greenish-yellow crystals, m. p. 194—195°C, hexa-*p*-chlorophenyl-biimidazolyl, fine, yellow crystals, m. p. 213—214°C and 2, 2'-di-*p*-chlorophenyl-4, 4', 5, 5'-tetraphenyl-1, 1'-biimidazolyl, fine, almost colorless crystals, m. p. 219—220°C which exhibited[2] both photochromism and thermochromism in a solution and in the solid state, were found to exhibit the piezochromism, the color changing from pale greenish-yellow to pale bluish-violet (absorption maximum 589 mμ in the solid state), from yellow to pale bluish-violet (absorption maximum 586 mμ) and from colorless to pale violet (absorption maximum 578 mμ) respectively. The mechanism of the piezochromism in these cases was found to be the same as that of hexaphenyl-biimidazolyl.

The decay rate of ESR due to the piezochromism of hexaphenyl-biimidazolyl was measured by the decrease in the signal intensity $h$ (the vertical distance betweeen two peaks of a signal[2]) and found to obey the following formula; $1/2(1/h^2-1/h_0^2)=kt$, which was obtained by the substitution of $h$ for the concentration in the rate expression of the third order reaction. The values of $k$ were $2.0\times10^{-5}$ at 48.0°C and $8.9\times10^{-5}$($cm^{-2}$, $min^{-1}$) at 51.5°C. Since the line widths of the signals were almost constant during the measurement, $h$ can be assumed to be approximately proportinal to the concentration of triphenylimidazolyl. Hence, the rate of the recombination of triphenylimidazolyl in the fading process of the piezochromism appears to be of the third order, and hence different from the second order of the rate of the recombination of triphenylimidazolyl in the photochromism in a solution.[2] This result seems to suggest that the recombination of triphenylimidazolyl in the piezochromism takes place through a diffusion process which is the rate-determining step of the third order with respect to triphenylimidazolyl.

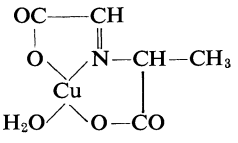
# The Copper(II) Complex of the Schiff Base Derived from Glyoxylic Acid and α-Alanine



By Yasuo NAKAO, Ken-ichi SAKURAI and Akitsugu NAKAHARA

(Received March 17, 1965)

A number of investigations[1] of non-enzymatic transamination reactions catalyzed by metal ions has resulted in the discovery of the importance of the coordination of metal ions with the Schiff bases produced from aldehydes and amino acids or from keto acids and amines. Comparatively few papers[2] have, however, been published to report on the isolation of metal Schiff-base chelates as the intermediate compounds in the mechanism of these transamination reactions. We have recently prepared a pair of copper(II) Schiff-base complexes, which are considered to be fairly important in any consideration of the mechanism of the transamination reactions in the metal-pyruvate-glycinate and the metal-glyoxylate-alaninate systems; we therefore investigated their properties and correlations. They are the copper(II) complexes of Schiff bases derived from pyruvic acid and glycine,[3] A, and glyoxylic acid and α-alanine. The latter was believed to have the structure B, in the light of many results obtained by other, similar preparations. However, the complex isolated in the crystalline state from the copper-(II)-glyoxylate-alaninate system has been proved to be the pyruvideneglycinatoaquocopper(II) (A) instead of glyoxylidenealaninatoaquocopper(II) (B). This finding is understandable only in connection with some kind of rearrangement—a part of the process of the transamination reaction. Although the transaminations of this kind and of the glyoxylate-pyridoxamine system in the presence of metal ions have already been reported,[4] the previous conclusions were drawn only from the equilibrium studies of solutions; the intermediate complexes were not isolated. The present paper will report on a quite effective transamination based on an investigation of the isolated intermediate complex. It is also of interest to note that only a chelate of glycine with pyruvate and copper(II), not one of alanine with glyoxylate and copper(II), is isolated.

(A)

(B)

The method of the preparation of B employed in this work was the same as that of A which has already been reported in a previous paper.[3] Found: C, 23.03; H, 4.27; N, 5.29; $H_2O$, 20.31. Calcd. for $CuC_5H_5NO_4 \cdot 3H_2O$: C, 23.00; H, 4.21; N, 5.36; $H_2O$, 20.65%.

The complex began to decompose at 192°C, coinciding precisely with the decomposition temperature of A. A microscopic observation of the two crystals, A and B, revealed that there was no difference in their colors, shapes and habits.

No difference was observed either in their solubilities in water, ethanol and dimethylsulfoxide. The infrared studies and the X-ray powder measurements of the two crystals also verified their identity.

However, an additional decisive proof for the identity of the two compounds and the elimination of the possibility of the structure B was given by a cleavage reaction of the Schiff-base >C=N– double bond of the respective complex. The aqueous solutions of the two complexes were separately treated with hydrogen sulfide in order to give the precipitate of copper sulfide from each solution. The two filtrates were then examined for the amino acids they contained by means of paper chromatography. Both solutions exhibited only one spot corresponding to glycine in the presence of pyruvic acid. No other spots, not even that of alanine were detected on the whole strip. If the real structure of the complex produced from copper(II)-glyoxylate-alaninate system were B, alanine would have been detected instead of glycine. This may

# Studies of Ion Exchange Membranes. XXII. Semicontinuous Preparation of Ion Exchange Membranes by the "Paste Method"[1]

By Yukio MIZUTANI, Reiichi YAMANE and Hirozi MOTOMURA

(Rcecived August 10, 1964)

Previous work in this series[2] has presented a method for the preparation of ion exchange membranes called the "paste method," in which paste I, composed of styrene (St), divinylbenzene (DVB), and poly(vinyl chloride) fine powder (PVC), or paste II, composed of St, DVB, 2-methyl-5-vinylpyridine (MVP), and PVC, was coated onto the cloth or the net of the synthetic resin and then heated in order to prepare the polymer film backed with a reinforcing material (Base Membrane), to which the ion exchange group was then introduced by appropriate after-treatments.

The preparative method previously described was excellent in terms of its ease and the mechanical and electrochemical properties of the products, but it was unsuited as a continuous preparative process.

The present investigation was, therefore, undertaken to develop the paste method into a continuous process. In the first stage the continuous preparation of the base membrane was attempted.

The roll coating system being employed, the process of the coating could be carried out continuously, thus obtaining a base membrane 1 m. wide and 50 m. long with a good uniformity. The preparative methods of the base membrane and the ion exchange membrane will be described, and the properties of the products will be discussed in relation to the preparative conditions.

## Experimental

**The Preparation of the Paste.** — Table I shows some typical compositions of the pastes. The components of the paste were mixed to disperse PVC homogeneously, and then the paste was kept for 16 hr. at 20°C (paste I) or 10°C (paste II) in order to stabilize its properties. Prior to coating, the paste was filtered through a 50-mesh polyethylene screen.

**Coating.**—Figure 1 shows the roll coating system. The wind-up roll 3 was the only driven roll; the others were idler rolls. The reinforcing material reserved to roll 1 was tensioned in its length by the application of the brake on roll 1, expanded in its width by the expander roll 5, and then dipped in the paste in the paste reservoir 4. The covering material which was fed from roll 2 was tensioned and expaned in the same ways as the reinforcing material. The reinforcing material coated with the paste was wound up on roll 3 with the covering material in layers. The pressure which was placed on roll 3 by roll 6 adjusted the quantity of the paste coated onto the reinforcing material. The reinforcing material, 1 m. wide and 50 m. long, was coated once.

**Heating.** — After the coating process, roll 3 was dismantled, cramped with iron shackles at the hems of the wound reinforcing material, thus preventing the reinforcing material from shrinking

TABLE I. TYPICAL COMPOSITIONS OF THE PASTES

| Component | Paste I | Paste II |
|---|---|---|
| PVC*1 | 1.00 | 1 |
| St | 2.3 | 0.22 |

in width during heating, and then heated at 80—120°C for an hour under high nitrogen pressure (5 kg./cm²) and then at 80°C for 4 hr. The poly(vinyl chloride) was fused to the continuous film, the monomers were polymerized for the first heating, and the polymerization was completed for the second heating. By being unwound from the roll and torn off from the covering material, the base membrane was obtained.

**The Introduction of the Ion Exchange Group to the Base Membrane.**—The ion exchange group was introduced to the base membrane by the after treatments described earlier.[2] Typical conditions of the after-treatments are shown in Table II.

TABLE II. TYPICAL CONDITIONS OF THE AFTER-TREATMENTS

| Active group | Paste | After-treatment |
|---|---|---|
| Cation exchange | I | Sulfonation with sulfuric acid (98%) at 60°C for 12 hr. |
| Anion exchange | II | Quanternization with petroleum ether solution of methyl iodide (methyl iodide/petroleum ether=1/4 by vol.) at 25°C for 24 hr. |

**Measurements.** — *Mechanical Strength.* — Mullen test—burst strength was measured. In the case of the ion exchange membrane, measurement was carried out on a test piece equilibrated with a 0.5 N aqueous solution of sodium chloride.

*Expansion by the After-treatment.* — Expansion was shown as a ratio of the length of the ion exchange membrane, equilibrated with a 0.5 N aqueous solution of sodium chloride, to that of the base membrane before the after-treatment. Measurement was carried out in the direction of the width of reinforcing material.

*Electrochemical Properties.* — The water content, ion exchange capacity, electric resistance, and transport number were measured at 25°C according to the procedures described before.[2] Electric resistance was measured on a membrane dipped in a 0.5 N aqueous solution of sodium chloride. The transport number was calculated by Nernst's equation from the membrane potential of a concentration cell composed of 0.5 N and 2.5 N aqueous solutions of sodium chloride, separated from each other by the ion exchange membrane under consideration.

## Results and Discussion

In relation to the continuous preparation of the base membrane by the roll coating system, the composition of a paste, the choice of a reinforcing material, the choice of a covering material, the conditions of the coating, and the conditions of the heating were investigated.

**The Composition of a Paste.** — The composition of a paste, which was decided mainly on the basis of the electrochemical properties of the ion exchange membrane,[2] also affected its viscosity, which was a main factor in the coating process, and the mechanical properties of the ion exchange membrane.

Table III shows the mechanical and electrochemical properties of the base membrane and the cation exchange membrane in relation to the composition of paste I.

The burst strength of the base membrane did not appreciably change with a weight ratio of either R/PVC or DVB/R, where R was St+DVB or St+DVB+MVP, while that of the ion exchange membrane decreased with an increasing R/PVC. This may be attributed to the brittleness of the sulfonated styrene-divinylbenzene copolymer. The expansion by sulfonation increased with an increasing R/PVC because of the swelling of the styrene-divinylbenzene copolymer through sulfonation.

**Reinforcing Material.** — To provide the ion exchange membrane with mechanical strength and dimensional stability, the following characteristics are required in the reinforcing material: dimensional stability, adhesiveness with the ion exchange resin, and chemical stability in the processes of the preparation and the application.

TABLE III. COMPOSITIONS OF THE PASTES—PROPERTIES OF THE BASE MEMBRANES AND THE ION EXCHANGE MEMBRANES

| Paste | | I | | | | | |

TABLE V. THE RESIN RATIOS—ELECTROCHEMICAL PROPERTIES OF THE ION EXCHANGE MEMBRANES

| | Paste | Reinforcing material | Resin ratio g./g. | Ion exchange membrane: Thickness mm. | Electric resistance Ω·cm² | Transport number |
|---|---|---|---|---|---|---|
| Cation exchange membrane | I | Teviron-A | 1.09 | 0.180 | 4.7 | 0.87 |
| | | | 1.26 | 0.190 | 4.6 | 0.87 |
| | | | 1.44 | 0.210 | 4.5 | 0.88 |
| | | | 1.58 | 0.230 | 4.5 | 0.88 |
| | | | 1.79 | 0.235 | 4.7 | 0.87 |
| Anion exchange membrane | II | Teviron-B | 1.46 | 0.190 | 3.0 | 0.91 |
| | | | 1.35 | 0.185 | 3.3 | 0.92 |
| | | | 1.26 | 0.185 | 3.1 | 0.92 |
| | | | 1.17 | 0.180 | 3.4 | 0.91 |
| | | | 1.12 | 0.180 | 3.2 | 0.92 |

Composition of the paste I: R/PVC=2.5, DVB/R=0.10, DOP/PVC=0.15, BPO/R=0.005.
Composition of the paste II: R/PVC=1.8, MVP/R=0.80, DVB/R=0.04, DOP/PVC=0.30, BPO/R=0.01.

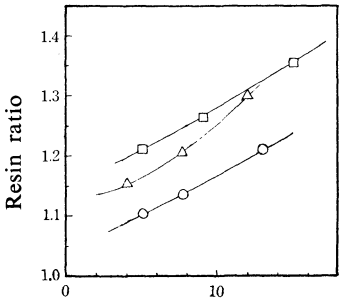

Table IV shows the properties of the reinforcing materials under consideration. It was apparent that the poly(vinyl chlroide) cloth was advisable for a cation exchange membrane, and the poly(vinyl chloride) cloth, the polypropylene cloth, and the poly(ethylene terephthalate) cloth, for an anion exchange membrane. Subsequent experiments were, therefore, carried out with the poly(vinyl chloride) cloth, Teviron-A 0.13 mm. thick and Teviron-B 0.09 mm. thick, from the Teijin Co., Ltd.

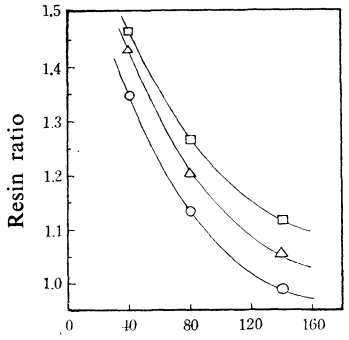
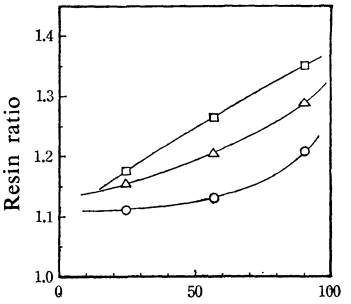
**Covering Material.**—With a view of separating the layers of the paste coated onto the reinforcing material, the covering material was wound up simultaneously in layers.

A poly(vinyl alcohol) film (Kurarebiniron film from the Kurashiki Rayon Co., Ltd.) was adopted on the basis of its mechanical strength, flexibility, and lesser adhesiveness with the paste.



**The Conditions of the Coating.** — It was required that the paste should be coated uniformly in thickness and in composition, without a pinhole. The weight ratio of the paste to the reinforcing material (Resin ratio) was

found to be closely connected with the requirements described above. When the resin ratio was too high (type H), the base membrane was likely to lack uniformity and the ion exchange membrane was apt to be uneven in its plane and the resinous part was apt to come off from the reinforcing material during the after-treatments. When the resin ratio was too low (type L), the ion exchange membrane was likely to have pinholes.



Viscosity of the paste, poise

○ Paste I, Teviron-A, Viscosity of the paste is 7 poise
△ Paste I, Teviron-B, Viscosity of the paste is 7 poise
□ Paste II, Teviron-B, Viscosity of the paste is 9 poise
Pressure of the press roll is 80 kg. per a meter of the roll. Tension offered to the reinforcing material in length is 57 kg. per a meter of the reinforcing material in width.

Table V shows, however, that, as far as this study could ascertain, a resin ratio does not affect the electrochemical properties of the ion exchange membrane.

Judging from the mechanical properties and the appearance of the ion exchange membrane, the resin ratios of 1.12—1.17 for Teviron-A and 1.20—1.25 for Teviron-B were found to be most desirable (type M).

Figures 2—5 show the relations between the

resin ratios and the conditions of the coating, i. e., the viscosity of the paste, the pressure of the press roll, the tension of the reinforcing material, and the rate of the coating.

With a paste with a high viscosity, the product is likely to be type H, and vice versa (Fig. 2).

When the pressure of the press roll is too high or low, the base membrane is apt to be type L or H (Fig. 3).

When increasing tension is offered to the reinforcing material, the resin ratio of the base membrane is increased (Fig. 4).

The rate of the coating did not affect the resin ratio, as is shown in Fig. 5, but when it was too high, the base membrane was apt to lack uniformity in its thickness. Considering the balances among the factors described above, the conditions of Table VI are recommended for the coating process.

Table VI. Optimum conditions of the coating process

| Paste | I | II |
|---|---|---|
| Reinforcing material | Teviron-A or B | Teviron-A or B |
| Viscosity of the paste, poise | 8 | 10 |
| Temperature of the paste at the coating, °C | 20 | 20 |
| Pressure of the press roll (kg./m. of roll) | 80 | 80 |
| Tension offered to the reinforcing material in length (kg./m. of the reinforcing material in width) | 50 | 50 |
| Rate of the coating, m./min. | 2 | 2 |

**The Conditions of the Heating.**—When the paste was heated, fine particles of poly(vinyl chloride) were fused to form a continuous film, in which the monomers were polymerized simultaneously, and part of the monomers were immersed and polymerized in the reinforcing material.

Because the fine particles of the poly(vinyl chloride) were swollen with the monomers, its fusion was carried out at comparatively low temperatures; i. e., the heating of paste I at 90°C and of paste II at 70°C were found to be sufficient to obtain a continuous film.

The temperature of the first heating, as well as the concentration of the catalyst in the paste, affected the characteristics of the products.

Table VII shows the effects of the temperature of the first heating. With a rising temperature the strengths of the base membrane and of the ion exchange membrane were decreased, and the expansion by the after-treatment was increased. These effects may be attributed to the fact that the more a monomer is immersed and polymerized in the reinforcing material with a rising temperature, the more the mechanical strength and the dimensional stability of the reinforcing material is decreased because of the polymer composed in it.

The effects of an increasing concentration of the catalyst were the reverse of those of a rising temperature, as Table VIII shows. This is accounted for by the fact that the increasing rate of the polymerization of the monomer, accompanied by the increasing concentration of the catalyst, may exceed the immersion rate of the monomers into the reinforcing material and so lead to a decrease in the polymer content in the reinforcing material; therefore, the strength of the reinforcing material does not decrease very much.

**The Characteristics of Typical Ion Exchange Membranes.**—The characteristics of typical ion exchange membranes obtained by the paste

*3 Measured by electrophoresis with 0.5 N sodium chloride aqueous solution, current density: 10(mamp./cm²), at 25°C.

method using the roll-coating system are shown in Table IX.

The CL and CH types are cation exchange membranes, and the AV and AVS types are anion exchange membranes; the AVS type especially has much less permselectivity for $SO_4^{2-}$ than $Cl^-$.[3] The transport numbers in the ninth column were measured by the electrophoresis described in a previous paper.[4]

According to the results obtained by the electrophoretic concentration of sea water over a long period,[3] the ion exchange membranes obtained by the paste method were proved to have a good durability.

**Summary**

A method for the preparation of ion exchange membranes called the "paste method" has been developed into a semicontinuous preparation.

The roll-coating system being employed, a base membrane 1 m. wide and 50 m. long is prepared continuously; the ion exchange group is then introduced to it.

The ion exchange membranes thus prepared have been proved to have excellent electrochemical and mechanical properties as well as an excellent appearance.

# The Separation of Rare Earths by Paper Electromigration and Focusing Chromatography

By Yoshiyuki KISO,* Itsuko YAMADA, Yuroku YAMAMOTO and Mutsuaki SHINAGAWA**

(Received February 21, 1964)

Paper electromigration has been used for the separation of rare earths by Maki,[1] Sato et al.,[2] Pučar and Jakovac,[3] Kawamura,[4] and Shvedov and Stepanov.[5] Moreover, Schumacher and Friedli[6] separated rare earths successfully by a new technique, "electorophoretic ion-focusing," i. e., focusing chromatography. However, comparatively little attention has been paid to the theoretical study. In a previous paper[7] one of the present authors has derived a theory of the migration of soluble metal complexes. The present experiment was carried out to examine its applicability to the separation of rare earths by the two procedures of ordinary paper electromigration[7] and focusing chromatography.[8]

## The Theory of Separation by Electromigration

In the paper electromigration, the zone mobility in a complexing agent-background electrolyte solution is given by the following equation[7]:

$$U=1/2\cdot U_M\{(1+(m-n)/m\cdot r_{MA}/r_M)+(1-(m-n)/m\cdot r_{MA}/r_M)\cdot \tanh\,[2.303/2\cdot(pK_{MA}-pC_{H_nA}+p\beta)]\} \quad (1)$$

$$p\beta=1/(1+(H)/K_n+(H)^2/k_nk_{n-1}+\cdots+(H)^n/K_nK_{n-1}\cdots K_1)$$

where $U$ is the zone mobility; $U_{MA}$, the mobility of the complex species MA; $m$, the charge of the single metal ion; $n$, the all over number of hydrogen ions dissociated from the ligand donor, $H_nA$; $r_M$ and $r_{MA}$, the ionic radii of the single and complex species; $K_{MA}$, the stability constant of the complex species; $C_{H_nA}$, the concentration of the complexing agent, and $K_1-K_n$, the consecutive dissociation constants of the complexing agent.

On moist paper, the zone mobility of ions is less than the mobility in a free solution because of the more tortuous path of the ions through the networks of fiber forming the paper or possibly because of other factors related to the affinity of the ion with the medium.[9] This relation is given by:

$$U_Z=\rho U_F \qquad \rho<1 \quad (2)$$

where $U_Z$ is the zone mobility; $\rho$, the obstructive factor and $U_F$, the mobility in a free solution. The zone mobility, $U$, in Eq. 1 corresponds to $U_Z$ in Eq. 2. In the case of EDTA complexes of rare earth elements, Eq. 1 turns into a simpler form, since $m=3$, $n=4$ and $r_{MA}\approx r_M$ for rare earth.[7]

$$U_{RE}\approx U_M\{1/3+2/3\cdot[\tanh\,(2.303/2\cdot(pK_{MA}+pC_{H_4A}+p\beta)]\} \quad (3)$$

with

$$p\beta=1/(1+(H)/K_4+(H)^2/K_4K_3+(H)^3/K_4K_3K_2+(H)^4/K_4K_3K_2K_1) \quad (4)$$

The mobility-pH ($U$-pH) curves in Fig. 1 were obtained by putting the values of $K_{MA}$ for rare earths,[10] the $K_i$ ($i=1$—4) values and $pC_{H_4A}=2.3$ ($C_{H_4A}=5\times10^{-3}$ M) into Eq. 3.

The differences between zone mobilities for two kinds of rare earths reach a maximum at the mean value of their p$S$'s, which represent the pH values at the points of inflection of the $U$-pH curves.

The p$S$ values for EDTA complexes of various rare earths vary with the concentration of EDTA. From the relations in Figs. 1 and 2, it can be predicted that, in one fixed pH of a background solution, one can separate only a few kinds of rare earths. However, all 15 different kinds of rare earths can probably be

## Experimental

**Apparatus.**—This apparatus was formed of a high d. c. power supplier, a migration cell, and 20 multi-compartment cells.[7] These were all hand made. The power supplier can give a continuously variable output voltage up to 1000 V. against the multi-compartment cells. By using a large migration cell ($4\times30\times7$ cm$^3$) containing carbon tetrachloride and a water-flowing jacket, the temperature in the migration cell was kept constant; thus the evaporation of water from the paper was also prevented.

**Radioactive Tracers.** — Radioactive isotopes, lanthanum-140, cerium-144 and yttrium-90 were imported, while praseodymium-142 and samarium-135 were produced by the JRR-1 at the Japan Atomic Energy Institute. Each 10-mg. portion of those rare earth oxides was irradiated at a flux of $3\times10^{11}$ n/cm$^2$/sec. for 1—5 hr. The specific activities thus obtained were about 6 mc./g. for samarium-153 and 4 mc./g. for praseodymium-142. Each oxide irradiated was dissolved in hydrochloric acid. The concentration was in the $10^{-3}$—$10^{-4}$ M range. The mixed solution was prepared to have a uniform activity of each species.

**Background Electrolytes.**—The concentration of the EDTA used as the complexing agent was $5\times10^{-3}$—$10^{-4}$ M. In order to keep constant the ionic strength of the solution (mostly $\mu=0.1$), sodium chloride was added supplementarily. The adsorption of migrant rare earth by the paper was minimized at this ionic strength in a manner shown in a previous report.[7] The pH of the background electrolyte was adjusted by the addition of sodium hydroxide or hydrochloric acid.

**Procedure.** — *Ordinary Paper Electromigration.*— First, the paper (Toyo Roshi No. 5, $2\times40$ cm$^2$) was cut in half in the long direction. Each sheet of the paper was then uniformly dipped in the background electrolyte solution, and the excess solution on the paper was removed by using other filter paper. Then about 0.005 ml. of the radioactive migrant solution was placed with a glass capillary on a pencil line on the moist paper. The width of the solution placed on the paper was about 1—2 mm. After twenty sheets of paper had been set into the migration cell, the stabilized voltage ranging from 300 to 500 V. was applied for 20—50 min. The water-cooling jacket and carbon tetrachloride in the migration cell were useful in maintaining the initial temperature of the paper during the migration. Even in the more highly-conducting background electrolytes, such as pH 1.0—1.5, no heating was observed during the migration. After the fixed migration time, all the strips were taken out from the cell and dried as fast as possible by an infrared lamp in order to prevent the diffusion of the separated zone.

*Focusing Chromatography.* — First, a 3-cm.-wide space in the middle of the paper was moistened with the sample solution to be separated; then all the anodic space beside this middle space was moistened with a hydrochloric acid solution adjusted to some selected pH, and finally the rest of the space was moistened with a EDTA solution. In this procedure, particular care was taken to avoid the confusion of the border between the sample and the solution in cathodic or anodic solutions respectively. The other procedure was the same as that used for the ordinary electromigration.

*The Detection and Identification of the Migration Zone.*—The detection of the radioactive migrant on paper was carried out by the autoradiographic or $\beta$-ray counting technique. The identification of radioactive nuclides on paper was carried out by the measurement of the half-life and $\gamma$-ray energy.

## Results and Discussion

**The Effects of the Concentration of the Migrant Ion and the Complexing Agent on the Mobility-pH Curve.**—Figure 3 shows the effect of the EDTA concentration on the $U$-pH curve obtained by a "carrier-free" (yttrium-90)

yttrium-EDTA system. In the concentration of $5\times10^{-3}$—$10^{-3}$ M EDTA, the shift of the *U*-pH curves of yttrium-EDTA toward the higher pH axis was in agreement with the calculated value, as is shown in Fig. 2. In the range below $5\times10^{-4}$ M EDTA, the shift was more pronounced than was the theoretical shift, and the *U*-pH curve in the end was close to that of yttrium-hydroxide complex (Y-OH). Using the EDTA concentration higher than $10^{-3}$ M, the *U*-pH curve for the yttrium-EDTA complex was the same in the concentration range of the carrier-free $\sim10^{-3}$ M of yttrium. Accordingly, in the later experiment, a comparatively high EDTA concentration of $5\times10^{-3}$ M was used in order to make the theoretical analysis and practical use easy.

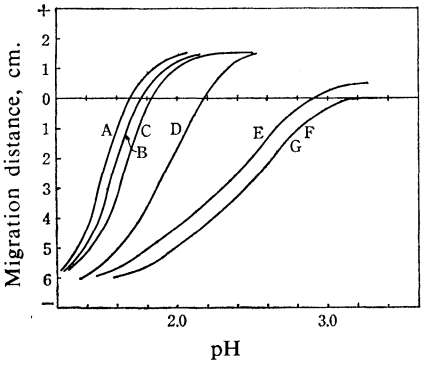

Fig. 3. *U*-pH curve of yttrium at different EDTA concentration.

Intensity of electric field: 300 V./30 cm., migration time: 33 min., temp: 28±1°C, background electrolyte; EDTA concentration A: $5\times10^{-3}$ M, B: $2\times10^{-3}$ M, C: $10^{-3}$ M, D: $5\times10^{-4}$ M, E: $2\times10^{-4}$ M, F: $10^{-4}$ M, G: absent, ionic strength: 0.1 $\mu$, migrant: carrier-free yttrium.

**The Separation of Rare Earths by Ordinary Paper Electromigration.** — From the results shown in Fig. 2, one can evaluate the optimum pH range, 1.7—1.9, for the separation of light rare earths in $5\times10^{-3}$M EDTA. The autoradiogram trace in Fig. 4 shows the separated patterns under the conditions mentioned above and under other pH conditions close to the former. The separation was unsatisfactory in the pH range higher than 2, but the width of each zone was comparatively narrow. Below pH 1.5, the separated zones of lanthanum, cerium and praseodymium were brought close to those of strontium and barium. The separated pattern of each in Fig. 4 was in good agreement with the expected pattern.

**The Separation of Rare Earths by Focusing Chromatography, pH Adjustment in Anodic and Cathodic Sides.**—From the theoretical and experimental results in the ordinary electromigration, one can predict that the pH of a background electrolyte solution mixed with a sample (the rare earth to be separated) will also lie between or be close to the respective p*S* value of rare earths-EDTA in the focusing chromatography process as well as in the ordinary electromigration process. In order to obtain the desired pH condition, one must arrange the initial pHs of the solution on the cathodic and anodic sides. Figure 5 shows the results of the attempt to find a suitable pH arrangement on

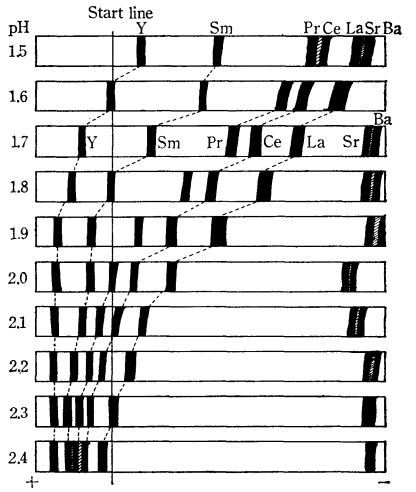

Fig. 4. Separation of RE using ordinary electromigration at different pH for background electrolyte.

Intensity of electric field: 300 V./30 cm., migration time: 50 min., temp.: 25±2°C, background electrolyte: anodic side: pH 1.9—2.1, cathodic side: pH 2.7—4.7 EDTA $5\times10^{-3}$ M, width placed by sample: 3 cm.

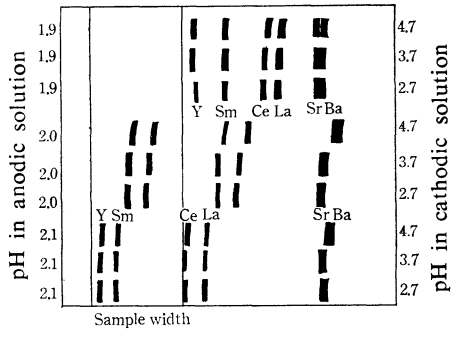

Fig. 5. Focusing chromatographic separation at differant pH gradient.

Intensity of electric field: 800 V./30 cm., migration time: 16 min., temp.: 26±2°C, background electrolyte: anodic side: pH 1.9—2.1, cathodic side: pH 2.7—4.7 ($5\times10^{-3}$ M EDTA, width dipped by sample solution: 3 cm.

each side. In Fig. 5, the selected pHs on the anodic side were 1.9, 2.0 and 2.1. These pH values were the same as the suitable ones of a EDTA background solution for the separation of rare earths by the ordinary electromigration method. On the other hand, the pHs of a EDTA solution on the cathodic side were the same as those on the anodic side (which data are not presented in Fig. 5) and higher than those on the anodic side, i.e., 2.7—4.7.

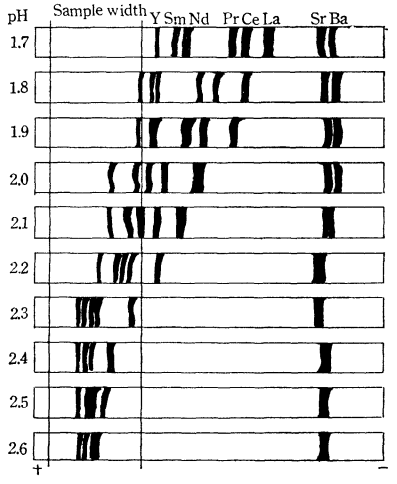

Fig. 6. Focusing chromatogram of RE at different pH in anodic side.

Intensity of electric field: 800 V./30 cm., migration time: 15 min., anodic side: hydrochloric acid, cathodic side: $3\times10^{-3}$ M EDTA, pH 4.7.

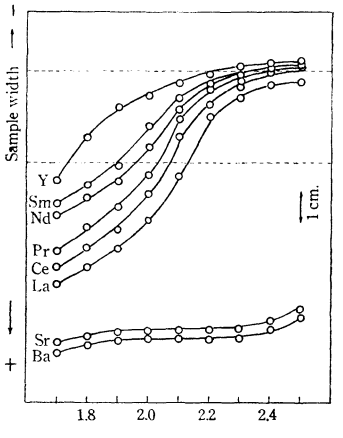

Fig. 7. *U*-pH curves of RE obtained by focusing chromatography.

Intensity of electric field: 800 V./30 cm., migration time: 15 min., temp.: 21—28°C., cathodic side: $3\times10^{-3}$ M EDTA, pH 4.7.

From the results shown in Fig. 5, it may be concluded that one should be careful to adjust the initial pH on the anodic side since the effect of pH on a resolution and the shift of the relative position for the separated bands are much more intensive than those on the cathodic side, and the pH range to be selective on the anodic side is equal to the optimum one obtained by ordinary electromigration. Figure 6 gives autoradiograms showing the separated pattern of rare earths at different pH arrangements between the anodic and cathodic solutions. The pHs in the anodic solution were selected so that they could be compared with the results shown in Fig. 4. The *U*-pH curves shown in Fig. 7 were drawn by plotting the separated bands obtained under the same conditions as that of Fig. 6 except for the pH value of the initial sample solution of rare earths. That is, the pH of the sample solution was about 1.2 in Fig. 6 and 1.5 in Fig. 7. The difference between two separated patterns in both Figs. 6 and 7 was probably caused by the different pH values of the sample solution. If the pH of the sample is the same as that of hydrochloric acid on the anodic side, the separated bands will be close to that obtained by ordinary electromigration.

## Summary

The optimum pH value and concentration of EDTA for separating rare earths (lanthanum, cerium, praseodymium, neodymium, samarium and yttrium) by the technique of paper electromigration have been evaluated on the basis of the migration theory. The validity of the theory has then been justified experimentally. The best condition for separating was at the range of pH 1.7 — 2.1 of $5\times10^{-3}$ M EDTA. Also, the applicability for focusing chromatographic separation has been examined with several pH arrangements between hydrochloric acid on the anodic side and a EDTA complexing agent solution on the cathodic side. Summarizing the above results, it has been concluded that the initial optimum pH of an anodic solution for separation may be obtained by selecting the pH range close to the expected one for the ordinary electromigration, while the effect of pH in a cathodic solution was not as severe as the former.

# Monolayer Studies of the Interactions between Histidyl Polypeptides and Metal Ions. II. The Effects of Copper, Zinc, Cobalt and Calcium Ions on the Monolayer Properties of Poly-1-benzyl-L-histidine

By Takuya YAMASHITA* and Toshizo ISEMURA

(Received May 19, 1964)

The reactivity of the imidazole group of the histidyl residue in protein has a great importance in the understanding of interactions between proteins and several metal ions.[1] In the preceding paper,[2] the interactions of the cupric ion with poly-1-benzyl-L-histidine and with copoly-2 : 2 : 2 : 1-(glycine, *O*-benzyl-DL-serine, β-benzyl-L-aspartate, 1-benzyl-L-histidine) have been studied by using monolayer techniques at the air/water interface. It was found that the cupric ion has a strong interaction with the poly-1-benzyl-L-histidine monolayer at pH 5.6, while it interacts with the copolypeptide only with difficulty. For the present study, the effects of copper, zinc, cobalt and calcium ions on the film properties of poly-benzyl-1-L-histidine were investigated at the air/water interface when the pH of the subsolution was varied and at the oil/water interface at pH 5.6.

## Experimental

Poly-1-benzyl-L-histidine was spread from a solution in 0.05 N hydrochloric acid containing 20% of isopropyl alcohol, as in the previous study.[2] The desired pH value of the subsolution was obtained with a 0.1 M acetate buffer (acetic acid + sodium acetate) in the range of 4.8—6.2, and with a 0.1 M citrate buffer (sodium citrate + sodium hydroxide) at 6.7. The pH was measured with a Horiba M-3 glass electrode pH-meter.

The surface pressure, the surface viscosity and the surface potential at the air/water interface were measured by the methods described in the preceding paper.[2] The surface moment was calculated from the surface potential by utilizing the Helmholtz formula. The compression of the film was started 20 min. after the polypeptide had been spread.

At the oil/water interface, the interfacial pressure was measured by the ring method. The diameter of the ring used was 2.77 cm. Petroleum ether (boiling point, 85—115°C) was used as an oil phase. The interfacial concentration of the polypeptide was changed by successive injections with an Agla micrometer syringe, and corrected by the Thomas theoretical correction formula.[3-5] The measurement of the interfacial pressure was carried out five minutes after each injection.

All the experiments were performed at room temperature, but the change in temperature never exceeded one degree during the course of an experiment.

## Results

Figures 1, 2, 3 and 4 illustrate, at various pH values, the surface viscosity-area ($\eta_s$-$A$) curves of poly-1-benzyl-L-histidine on subsolutions containing cupric sulfate (0.01 M), zinc sulfate (0.01 M, 0.05 M), cobaltous sulfate (0.01 M, 0.05 M) and calcium chloride (0.05 M) respectively. Figure 5 shows the areas per residue at 0.05 surface poise in the presence and absence of these divalent metal ions against the pH. As can be seen in these figures, the cupric ion has a remarkable effect on the $\eta_s$-$A$ relation of this polypeptide over a wide pH range, while the effects of the zinc, cobaltous and

calcium ions are much less than that of the cupric ion.

The surface pressure-area (*Π-A*) curves of poly-1-benzyl-L-histidine on subsolutions at various concentrations of zinc sulfate are shown in Fig. 6 at pH 5.6. The presence of 0.001 M zinc sulfate does not practically affect the shape of the *Π-A* curve, while the values of 0.01 M and 0.05 M are high enough to cause the disappearance of the plateau of the *Π-A* curve found on the control subsolution.

Figure 7 shows the surface potential-area (*ΔV-A*) and the surface moment-area (*μ-A*) curves of poly-1-benzyl-L-histidine at pH 5.6 in the presence and absence of the zinc ion. In the presence of 0.01 M zinc sulfate, the surface potential and the surface moment are higher by ca. 50 mV. throughout the measured areas, and higher by 52 mD in the linear portion of the *μ-A* curve than on the control subsolution.

subsolution. On the other hand, 0.05 M calcium chloride resulted in film condensation. The film was unstable over areas smaller than 19 Å² per residue.

The interfacial pressure-area ($\Pi_i$-$A$) curves of poly-1-benzyl-L-histidine at the interfaces between oil and water when various salts were dissolved are shown in Fig. 9. The $\Pi_i$-$A$ curves were nearly identical with one another on the 0.1 M potassium chloride subsolution and on the acetate buffer subsolutions at pH 5.6 with and without 0.01 M zinc or cobaltous sulfate. The cupric ion had a remarkable effect as well as at the air/water interface.[2]

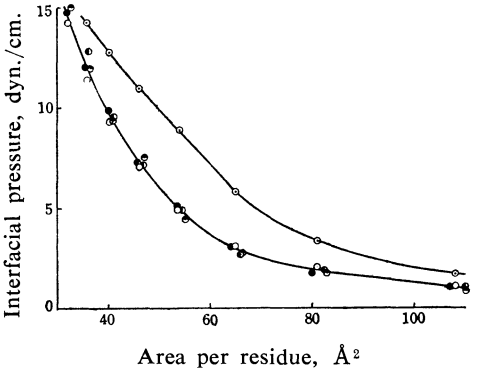

Fig. 9. Monolayers of poly-1-benzyl-L-histidine at the oil/water interface at 21°C : ○, 0.1 M KCl ; ●, 0.1 M Acetate buffer (pH 5.6) ; ⊙, 0.01 M $CuSO_4$ ; ◐, 0.01 M $ZnSO_4$ ; ◓, 0.01 M $CoSO_4$ (the last three salts were dissolved in 0.1 M acetate buffer, pH 5.6).

## Discussion

**Air/Water Interface.** — *The Effect of the Cupric Ion.*—It has been found that the various metal ions form complexes with imidazole,[6,7] 4-methylimidazole,[8] and poly-L-histidine[9] as model substances of the histidyl residue in protein. In the preceding work,[2] a strong interaction of the cupric ion with the poly-1-benzyl-L-histidine monolayer has been found at pH 5.6 at the air/water interface. In the presence of the cupric ion in the subsolution, the surface pressure increased remarkably throughout the measured areas, and the $\eta_s$-$A$ curve shifted to a much larger area than on the control subsolution, the surface pressure being quite low at the area where the surface viscosity began to rise. This finding was interpreted in terms of the cross-linkage formation

between molecules at the surface through the complex formation of copper with the side chains of poly-l-benzyl-L-histidine.

In the present study, the effect of the cupric ion on the $\eta_s$-$A$ relation of poly-l-benzyl-L-histidine was investigated in the 4.8—6.7 pH range. As Fig. 1 shows, in the presence of the cupric ion, the $\eta_s$-$A$ curves shift to much larger areas than on the control subsolutions at the pH's studied. The effect of the cupric ion is remarkaly large compared with those of zinc, cobaltous and calcium ions, as Fig. 5 shows. The cross-linked structure should be formed between poly-peptide molecules at the surface in these pH range as a result of complex formation between the cupric ions and the side chains. The optimum pH for the copper-monolayer interaction is in the 5.1—6.2 range.

*The Effect of the Zinc Ion.*—As Figs. 2 and 5 show, the zinc ion interacts considerably with the monolayer of poly-l-benzyl-L-histidine in the pH range of 5.1—6.2, where the areas per residue at the 0.05 surface poise are higher by 8—10 Å$^2$ than on the control subsolutions. This value is much less than in the case of the cupric ion. The cupric ion causes the increment of 26—34 Å$^2$ in the optimum pH range. At pH 5.6, which seems to be an optimum pH for the zinc-monolayer interaction, the plateau of the $\Pi$-$A$ curve found on the control subsolution disappears in the presence of 0.01 M and 0.05 M zinc sulfate. This might be caused by the cross-linkage formation in the monolayer. Such a cross-linked structure has also been found with tanned protein monolayers.[10-12]

The rise in the surface potential or surface moment in the presence of the zinc ion might be caused by the increment in the net positive charge of the film as a result of the combination of zinc ions with the interacting sites of the side chains of polypeptide, as in the case of copper ions,[2] and so may be another evidence of the complex formation. A similar increase in the surface potential has been reported for a gelatin monolayer tanned with basic chromium sulfate.[11]

*The Effect of the Cobaltous Ion.*—The effect of the cobaltous ion on the $\eta_s$-$A$ relation of poly-l-benzyl-L-histidine was investigated in the 5.1—6.7 pH range. The optimum pH for the cobalt-monolayer interaction is found to be in the 5.6—6.2 range, and the cobalt ion does not interact practically at the 5.1 and 6.7 pH's, as Figs. 3 and 5 show. The interaction of the cobalt ion with the monolayer is somewhat weaker than that of the zinc ion in the pH range studied. Such a weaker interaction of the cobalt ion than those of the zinc and copper ions has also been found in bulk with bacterial-$\alpha$-amylase,[13] the interacting sites of which are histidyl groups, and with imidazole.[3]

The effect of the cobaltous ion on the $\Pi$-$A$ relation of poly-l-benzyl-L-histidine was investigated at a pH in the optimum pH range. At pH 5.6, in the presence of the cobaltous ion, the film expanded more than on the control subsolution. However, even 0.05 M cobaltous sulfate does not cause the disappearance of the plateau of the $\Pi$-$A$ curve observed on the control subsolution unlike zinc ion. This fact may indicate that the cross-linked structure caused by the cobalt ion is somewhat looser than that caused by the zinc ion because of its weaker interaction, even though such a structure is formed.

*The Effect of the Calcium Ion.*—The effect of the calcium ion on the $\eta_s$-$A$ relation of poly-l-benzyl-L-histidene is quite small. Even a 0.05 M calcium chloride subsolution causes merely an increase of 2—3 Å$^2$ in areas per residue at a 0.05 surface poise in the 5.6—6.7 pH range. At pH 5.6, the calcium ion reduces the surface pressure more than on the control subsolution, unlike copper,[2] zinc and cobalt ions. This finding resembles the facts found concerning the metal-stearic acid monolayer interactions;[14] it might be caused by the difference in modes of interactions between the alkaline earth metals and the copper, zinc and cobalt ions. The calcium ion might form the cross-linked stucture in the monolayer only with difficulty.

*The Estimation of the Extent of Metal-Monolayer Interactions.*—On the basis of the preceding[2] and the present works, we conclude that the cupric ion interacts especially strongly with the monolayer of poly-l-benzyl-L-histidine, and

that the decreasing order of the metal-monolayer interactions is $Cu^{2+}$, $Zn^{2+}$, $Co^{2+}$, $Ca^{2+}$. As Table I shows, this order corresponds to the first association constants of imidazole or 4-methylimidazole, which are measures of the extent of interaction.

**The Oil/Water Interface.**—At the oil/water interface, the poly-1-benzyl-L-histidine monolayer expands much more than at the air/water interface as a result of the release of van der Waals force between side chains. The extent of the expansion is considerably larger than the film of poly-DL-phenylalanine which has benzyl groups directly attached to the backbone carbon atoms. The areas occupied by poly-1-benzyl-L-histidine film are compared with those by poly-DL-phenylalanine under various interfacial pressures in Table II. Such a large expansion of the former film suggests that the imidazole groups, which are hydrophilic to some extent because of the effect of nitrogen atoms, lie at the interface.

Unlike at the air/water interface, no appreciable effects of zinc and cobalt ions on the monolayer of poly-1-benzyl-L-histidine are found at the concentrations of 0.01 M at pH 5.6. This fact might be caused by the restriction of the accessibility of these metal ions to the interacting sites by the oil. On the other hand, the effect of the cupric ion is quite large, as at the air/water interface.[2] Accordingly, complexes of cupric ions with poly-1-benzyl-L-histidine should be formed even at the oil/water interface.

Interestingly, the plateau of the *II-A* curve found on the 0.1 M acetate buffer subsolution at pH 5.6 disappears at the oil/water interface. The $\Pi_i$-*A* curve practically agrees with that at the oil/0.1 M potassium chloride interface. At the oil/water interface, the lateral cohesion between side chains is released by the intervening of oil between them. This may be the cause of the lack of a difference between the $\Pi_i$-*A* curves at the interfaces between oil and the 0.1 M potassium chloride solution and between oil and the 0.1 M acetate buffer.

## Summary

The effects of metal ions on the monolayer properties of poly-1-benzyl-L-histidine, a model substance of the histidyl residue in protein, have been investigated at the air/water interface when the subphase pH is varied, and at the oil/water interface at pH 5.6.

At the air/water interface, it was found from the measurements of the surface viscosity that the cupric ion interacts especially strongly with the monolayer of poly-1-benzyl-L-histidine over a wide pH range and that the interaction of the calcium ion is quite weak. The decreasing order of metal-monolayer interactions is $Cu^{2+}$, $Zn^{2+}$, $Co^{2+}$, $Ca^{2+}$. The surface pressure-area isotherms suggest that the cobalt ion forms a somewhat looser cross-linked structure in the monolayer than does the zinc ion because of its weaker interaction.

At the oil/water interface, the film expands remarkably because of the release of van der Waals force between side chains. No appreciable effects on the interfacial pressure-area relation were observed with the zinc and cobaltous ions, because the accessibility of these ions to the interacting sites of side chains would have been restricted by the oil. The cupric ion had a considerable effect here as well as at the air/water interface.

The authors wish to express their hearty thanks to Professor Junzo Noguchi of Hokkaido University for supplying a valuable sample to them.

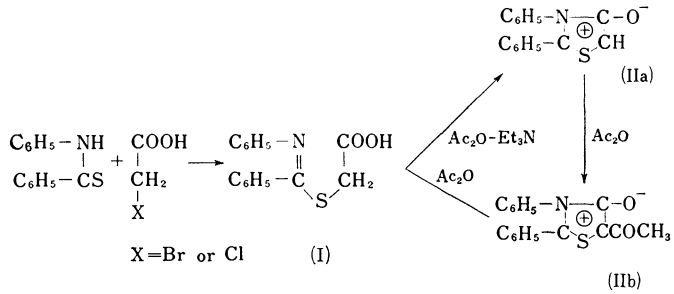
# The Syntheses and Properties of 5-Thiazones[1]

By Masaki OHTA and Chung-gi SHIN



(Received June 10, 1964)

In a previous paper of this series,[2] it was reported that the treatment of *S*-carboxymethylisothiobenzanilide (I) with acetic anhydride in the presence or absence of triethylamine yielded new meso-ionic compounds, which we named 2, 3-diphenyl-4-thiazone (IIa) and 5-acetyl-2, 3-diphenyl-4-thiazone (IIb) respectively:

Syntheses of 5-thiazone derivatives by the ring-closure of *N*-substituted-*N*-thiobenzoylglycine with acetic anhydride or benzoyl chloride have already been reported by Lawson et al., but all of the compounds thus obtained have an acyl substituent in the 4-position which can not be removed by hydrolysis.[3,4]

The present paper will describe the syntheses and properties of 5-thiazones with neither acetyl nor benzoyl group in the 4-position. It has now been found that, as in the case of 4-thiazone, 2, 3-diphenyl- and 3-methyl-2-phenyl-5-thiazone (IV) can be readily obtained by treating *N*-thiobenzoylsarcosine (IIIa) or *N*-thiobenzoyl-*N*-phenylglycine (IIIb) with an acetic anhydride-triethylamine mixture at room temperature. When pyridine is used in place of triethylamine in these cyclization, only a small quantity of 4-acyl derivative (V) is obtained instead of IV. These new meso-ionic compounds, IVa and IVb, are readily soluble in such polar solvents as ethanol, but they are insoluble in such nonpolar solvents as ether. IVa is insoluble in 10% aqueous sodium hydroxide, and IVb is easily hydrolyzed by 10% aqueous hydrochloric acid to the corresponding parent acid. IVb is soluble in hot aqueous sodium hydroxide and insoluble in 10% aqueous hydrochloric acid. The structure of these new meso-ionic compounds is supported by elementary analysis and by their infrared spectra. The infrared spectra of IVa and IVb, in comparison with those of the parent acid, have a strong new absorption at 1620—1630 $cm^{-1}$ and the band near 1700 $cm^{-1}$ disappears as a result of the carbonyl vibration of the carboxy group. This characteristic change of the spectra due to the formation of a meso-ionic ring from III has been observed also in infrared spectra of meso-ionic compounds derived from 2-(carboxymethylmercapto)-pyridine,[5] and from azoles with a carboxymethylmercapto group.[6] Since the 5-thiazone derivatives obtained above should have an aromatic character because their structures are like sydnones, we examined several reactions of IV as in the case of sydnones.

The acetylation of IV with acetic anhydride gave V, which is identical with the *C*-acetyl derivatives prepared directly by the reaction of III with acetic anhydride. On the treatment of IVa with benzoyl chloride in the presence of pyridine, a benzoyl derivative was obtained; it is identical with the *C*-benzoyl derivative obtained by Lawson et al.[3,4] In order to prepare the halogen derivatives substituted at the 4-position, halogenation was carried out under several conditions; the hydrobromide

(IX) was obtained in the presence of acetic anhydride. The corresponding free base, however, could not be obtained, even when IX was treated with a weak base, this fact might indicate its instability. Similar properties have been observed also in the case of 4-thiazone.[2] In a procedure similar to that used on sydnones,[7] IV reacted immediately with mercuric chloride in 50% methanol to give chloromercuri derivatives quantitatively, while only IVa reacted with mercuric acetate in methanol to give an acetoxymercuri derivative. These mercuri derivatives are insoluble in almost all organic solvents except ethanol and methanol. Though VIIIa and VIIIb are very stable, VII is unstable in the air and turned into a black material. When the chloromercuri derivative (VIIIb) was treated with iodine in methanol, an iodo derivative was obtained in a good yield ; this derivative was considered from elementary analysis to be X. Attempts to prepare the analogous iodo derivative from VIIIa and bromo derivatives from VIIIa and VIIIb were unsuccessful. These results make it seen likely that the reactivity at the 4-position of 5-thiazone with a phenyl group in the 3-position decreases as a result of the stabilization of the ring and that the halogen at the 4-position becomes reactive, as in the case of usual aromatic compounds.

## Experimental

**3-Methyl-2-phenyl-5-thiazone (IVa).** — *N*-Thiobenzoylsarcosine (1 g.) was dissolved in a mixture of acetic anhydride and triethylamine (volume ratio 1 : 2) (3 ml.) at room temperature. The solution immediately turned brown, and after a few minutes yellowish prisms were crystallized out. After 2 hr. in an ice box, the crystals were filtered off and washed with ether. Recrystallization from acetone gave yellow needles, (m. p. 144—145°C (decomp.)). Yield, 0.8 g. $\lambda_{max}^{EtOH}$ 362 m$\mu$ ($\varepsilon$, 10191)

Found: C, 63.91; H, 4.51; N, 7.43. Calcd. for $C_{10}H_9NOS$: C, 62.83; H, 4.71; N, 7.33%.

IVa is easily soluble in methanol and ethanol, soluble in hot benzene, ethyl acetate and acetone, and almost insoluble in ether, petroleum ether and 10% aqueous sodium hydroxide. When treated with 10% aqueous hydrochloric acid at room temperature, IVa was hydrolyzed to give the starting material, *N*-thiobenzoylsarcosine (IIIa).

**2,3-Diphenyl-5-thiazone (IVb).**—*N*-Thiobenzoyl-*N*-phenylglycine (1 g.) was dissolved in a mixture of acetic anhydride and triethylamine (volume ratio 1 : 1) (4 ml.) at room temperature. The solution immediately turned brown, and after a few minutes yellow crystals were crystallized out. After the solution had stood overnight in an ice box, the crystals were filtered off and washed with ether. Recrystallization from ethyl acetate gave yellow needles, (m. p. 130—131°C (decomp.)). Yield, 0.8 g. $\lambda_{max}^{EtOH}$ 382 m$\mu$ ($\varepsilon$, 10170).

Found: C, 70.90; H, 4.38; N, 5.61. Calcd. for $C_{15}H_{11}NOS$: C, 71.15; H, 4.35; N, 5.53%.

IVb is soluble in methanol, ethanol, acetone and hot 10% aqueous sodium hydroxide, and almost insoluble in ether and 10% aqueous hydrochloric acid.

**4-Acetyl-3-methyl-2-phenyl-5-thiazone (Va).**—IVa (0.5 g.) was heated with acetic anhydride at 100°C on a steam bath for 2 hr. The solution slowly darkened, and then the acetic anhydride was removed by evaporation under reduced pressure and by two subsequent evaporations with xylene. The recrystallization of the residual semi-solid from ethyl acetate-petroleum ether gave yellow needles, (m. p. 133—134°C (decomp.)). Yield, 0.6 g.

In the same manner as in the case of Va, the acetyl derivative (Vb) was obtained from IVb (0.5 g.) and recrystallized from benzene-petroleum ether as yellow needles, (m. p. 192—193°C (decomp.)). Yield, 0.4 g. Lawson et al., however, reported the melting point as 170—172°C.

Va and Vb showed no depression on admixture with the compounds by the ring-closure of IIIa and IIIb respectively.

**4-Benzoyl-3-methyl-2-phenyl-5-thiazone (VI).**—Into a solution of IVa (0.8 g.) in pyridine (5 ml.) benzoyl chloride (0.6 g.) was stirred at room temperature. The resultant brown mixture was warmed at 50°C on a water bath for 10 min.; then pyridine was evaporated under reduced pressure, and the green residual oil was washed twice with 10% aqueous hydrochloric acid and water. Recrystallization from benzene gave yellow needles, (m. p. 219—220°C (decomp.)). This compound showed no depression on admixture with an authentic specimen prepared by the ring-closure of IIIa with benzoyl chloride.

**4-Chloromercuri-3-methyl-2-phenyl-5-thiazone (VIIIa).**—A solution of mercuric chloride (1.2 g.) in 50% aqueous methanol (60 ml.) was stirred into a solution of IVa (0.7 g.) and sodium acetate (1.2 g.) in the same solvent at room temperature. Yellow precipitates were immediately separated, collected by filtration, and washed successively with ether, acetone and methanol. This compound did not melt below 300°C. Yield, 1.4 g.

Found: N, 3.41. Calcd. for $C_{10}H_8NOSHgCl$: N, 3.32%.

VIIIa is insoluble in usual organic solvents. In the same manner as in the case of VIIIa, the chloromercuri derivative (VIIIb) was obtained from IVb (0.5 g.) and recrystallized from 50% aqueous ethanol to give yellow needles, (m. p. 187—189°C (decomp.)). Yield, 0.85 g.

Found: N, 2.90. Calcd. for $C_{15}H_8NOSHgCl$: N, 2.89%.

VIIIa is soluble in methanol and ethanol, insoluble in benzene and ether.

**4-Acetomercuri-3-methyl-2-phenyl-5-thiazone (VII).**—A solution of mercuric acetate (0.9 g.) in methanol (30 ml.) was stirred into a solution of IVa (0.5 g) in methanol (10 ml.) at room temperature. The solution immediately turned yellow, and after a few minutes yellow precipitates separated. Recrystallization from ethanol gave small yellow needles, (m. p. 158—159°C (decomp.)). Yield, 1.1 g.

When this compound was kept standing for several days in the air at room temperature, it turned black.

Found: N, 3.12. Calcd. for $C_{12}H_{11}NO_3SHg$: N, 3.11%.

VIIIa is soluble in hot ethanol, and insoluble in methanol, chloroform, ethyl acetate and ether.

**4-Bromo-2, 3-diphenyl-5-thiazone Hydrobromide (IX).**—When a solution of bromine (0.3 g.) in acetic anhydride (3 ml.) was stirred, portion by portion, into a solution of IVb (0.5 g.) in acetic anhydride (5 ml.) below 0°C, orange precipitates were gradually separated. After the solution had stood overnight in an ice box, the precipitates were collected by filtration and washed with ether. Recrystallization from acetone gave pale yellow small needles, (m. p. 163—164°C (decomp.)) Yield, 0.4 g. These crystals are deliquescent.

Found: C, 42.89; H, 3.46; N, 3.24. Calcd. for $C_{15}H_{11}NOSBr$: C, 43.58; H, 2.66; N, 3.39%.

IX is easily soluble in water and methanol, soluble in hot ethanol and acetone, and almost insoluble in ether and benzene.

**2, 3-Diphenyl-4-iodo-5-thiazone (X).**—A solution of iodine (0.42 g.) in methanol (30 ml.) was stirred, portion by portion, into a solution of VIIIb (0.8 g.) in methanol (40 ml.) below 0°C over a 10 min. The color of the iodine immediately disappeared, and yellow precipitates were gradually separated. After the solution had stood overnight in an ice box, the precipitates were collected by filtration and recrystallized from ethanol as yellow needles, (m. p. 168—169°C (decomp.)) Yield, 0.4 g. $\lambda_{max}^{EtOH}$ 405 mμ ($\varepsilon$, 38596).

Found: C, 47.45; H, 2.66; N, 3.72. Calcd. for $C_{15}H_{10}NOSI$: C, 47.49; H, 2.64; N, 3.70%.

X is soluble in hot ethanol, methanol and benzene, but almost insoluble in acetone, ether and ethyl acetate.

The authors are indebted to Miss Toshiko Aoyagi for her elementary analysis and Mr. Eiji Saito for his ultraviolet spectral data.

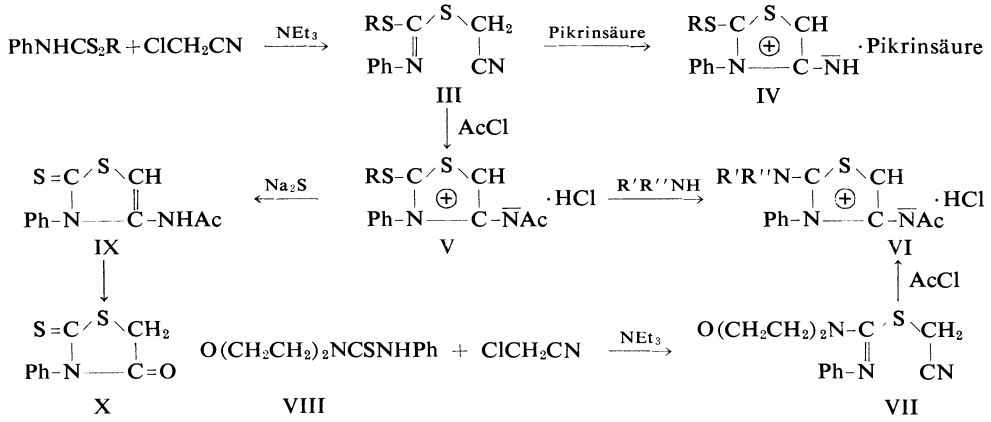
# Über die Reaktion zwischen *N*-Substituierten Dithiocarbamidsäureestern und α-Chlornitrilen*

Von Kunihiro ICHIMURA und Masaki OHTA

(Eingegangen am 4. September, 1964)

Kürzlich beschrieben wir, dass *S*-Cyanmethyl-isothiobenzanilid (I) durch die Einwirkung von sauren Mitteln oder Acylchloriden unter Ringschluss zum "sydnonimin" ähnlichen Heterocyclus von Formel II überführt wird,[1] das wir bequemlichkeitshalber "2, 3-Diphenyl-thiazonimin-Salz" genannt hatten.[2] In dieser Arbeit haben wir statt Isothioamid Dithiokohlensäure-diesterimid und Isothioharnstoff gewählt, die das analoge Kettensystem $-N{=}C-S-CH_2CN$ wie beim Isothioamid haben.

I II (R=H, R'CO)



*N*-Phenyldithiocarbamidsäureester wird mit Chloracetonitril in der Gegenwart von Triäthylamin zu *N*-Phenyldithiokohlensäure-diesterimid (III) kondensiert.

Setzt man III mit Pikrinsäure in einer benzolischen Lösung um, so ist unter dem Ringschluss erwartetes 2-Alkylmerkapto-3-phenyl-thiazonimin-pikrat (IV) erhältlich, auf dessen Struktur es aus der Elementaranalyse und dem Infrarot-Spektrum (Abwesenheit des Nitrilbandes) geschlossen wird, während bei der Einwirkung von Chlorwasserstoff auf III eine unbeständige, in reiner Form nicht isolierte Verbindung entsteht.

Bei der Reaktion von III mit Acetylchlorid erfolgt glatt der analoge Ringschluss unter der Bildung von *N*-Acetyl-2-alkylmerkaptothiazonimin-hydrochlorid (V), den Strukturbeweis dafür liefern die Analysenwerte und Infrarot-Spektren.

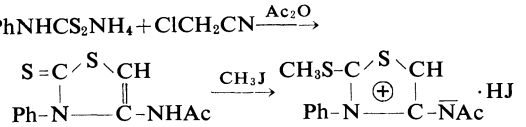
Die Äthylmerkapto-Gruppe von V wird glatt durch Morpholin substituiert. Die so erhaltene 2-Morpholino-Verbindung (VI; $R'R''N{=}O(CH_2CH_2)_2N$) wird für Vergleichszweck durch ein anderes Verfahren synthesiert; trisubstituierter Thioharnstoff (VIII) liefert mit Chloracetonitril in der Gegenwart von Triäthylamin *S*-Cyanmethylisothioharnstoff (VII). Bei der Einwirkung von Acetylchlorid erlaubt VII in geringer Ausbeute die Darstellung von 2-Morpholino-Verbindung. Diese geringe Ausbeute hat wohl die grössere Basizität des Isothioharnstoffs zur Folge, weshalb es bevorzugter mit Acetylchlorid quarternisiert, als zum Ringschluss gebracht wird.

Mit den anderen aliphatischen Aminen kann 2-Äthylmerkapto-Verbindung gleicherweise in entsprechende 2-Amino-Derivate (VI) überführt werden, aber mit Anilin reagiert sie erst beim Erhitzen unter dem Austritt des Merkaptans zu einer unbekannten Verbindung, deren

* 22. Mitteilung der Untersuchungen über Mesoionische Verbindungen.

1) H. Chosho, K. Ichimura und M. Ohta. Dieses Bulletin, 37, 1670 (1964).

2) Siehe die Fussnote in der 20. Mitteilung (Ref. 1). In dieser Mitteilung nehmen wir auch den Namen "Thiazonimin" für das Ringsystem von II.



Analysenwert mit dem der 2-Anilino-Verbindung nicht im Einklang steht.

Mit Natriumhydrogencarbonat wird 2-Äthylmerkapto-Verbindung unter Merkaptanentwicklung zu zersetzlichen Kristallen übergeführt.

Bei der Umsetzung mit Natriumsulfid liefert sie 3-Phenyl-4-acetamido-4-thiazolin-2-thion (IX), dessen Strukturbeweis auf dem Analysenwert sowie dem Infrarot-Spektrum, schliesslich auf der Hydrolyse in 3-Phenylrhodanin (X) beruht. Diese Überführung von V in bekanntes X über IX stützt sich intensiv auf die Ringstruktur von V.

3-Phenyl-4-acetamido-4-thiazolin-2-thion (IX) ist auch beim Behandeln des Reaktionsgemisches zwischen dem *N*-phenyl-dithiocarbamidsäuren Ammoniumsalz und Chloracetonitril mit Acetanhydrid erhältlich, wahrscheinlich über 3-Phenyl-4-thiazolin-2-thion, das Davies u. a.[3] bei der Umsetzung der beiden Komponenten jedoch erfolglos zu isolieren versucht hatten.

Methyljodid führt IX in 2-Methylmerkapto-Derivat (XI) über. Seine Struktur wird ausser der Ähnlichkeit seines Infrarot-Spektrums mit denen von 2-Äthyl- und 2-Benzyl-Verdindungen intensiv von dem Austritt des Merkaptans bei der Einwirkung von Benzylamin unterstützt.

## Beschreibung der Versuche

***N*-Phenyldithiokohlensäurediester-imid (II).**—Zur Lösung von 10 g *N*-Phenyldithiocarbamidsäureäthylester und 5.0 g Chloracetonitril in 75 ml Benzol gibt man 21 ml Triäthylamin und erhitzt bei 80°C 2 Std. Nach dem Stehenlassen über Nacht macht man die Lösung von Triäthylamin-hydrochlorid frei, dampft darauf in Vakuum zum Trocknen ein und löst den kristallinen Rückstand aus Methanol um. Man erhält 7.1 g Dithiokohlensäurediester-imid als farblose Kristalle vom Schmp. 59°C.

Gef.: C, 55.85; H, 4.97; N, 11.98. Ber. für $C_{11}H_{12}N_2S_2$: C, 55.93; H, 5.08; N, 11.86%.

**2-Äthylmerkapto-3-phenylthiazonimin-pikrat (IV).**—Man setzt zur Lösung von Dithiokohlensäurediesterimid (III) (0.5 g) in Benzol Pikrinsäure in Äther zu. Beim Stehenlassen scheiden sich gelbe Nadeln aus. Durch Umlösen aus Methanol erhält man 1.25 g reines Pikrat vom Schmp. 158—159°C (Zers.).

Gef.: C, 43.97; H, 3.46; N, 15.10. Ber. für $C_{17}H_{15}N_5S_2O_7$: C, 43.85; H, 3.25; N, 15.04%.

***N*-Acetyl-2-äthylmerkaptothiazonimin-hydrochlorid (V: R=$C_2H_5$).**—Man gibt Acetylchlorid (3.0 ml) zur Lösung von 6.0 g Dithiokohlensäureimid (III) in Benzol zu und lässt das Reaktionsgemisch bei Zimmertemperatur stehen. In einigen Tagen bilden sich farblose Kristalle, und sie werden abgenutscht und getrocknet. Durch Umfällung aus der methanolischen Lösung mit Äther erhält man 5.1 g Hydrochlorid vom Schmp. 170°C (Zers.).

Gef.: C, 49.75; H, 4.81; N, 9.04. Ber. für $C_{13}H_{15}N_2S_2OCl$: C, 49.58; H, 4.80; N, 8.90%.

***N*-Acetyl-2-benzylmerkapto-3-phenylthiazoniminhydrochlorid (V: R=$CH_2Ph$).**—Zur Lösung von 4.80 g Phenyldithiocarbamidsäure-benzylester und 1.50 g Chloracetonitril in 30 ml Benzol versetzt man 8.0 ml Triäthylamin und rührt während einer Stunde bei 60°C. Nach dem Abfiltrieren des Triäthylaminhydrochlorides dampft man das Filtrat im Vakuum zum Trocknen ein, löst den öligen Rückstand wieder in Benzol, setzt darauf 2.0 g Acetylchlorid zu, dabei fällt etwas Harz aus, das durch Filtration entfernt wird. Nach dem Stehenlassen über Nacht nutscht man 2.45 g gebildete Kristalle ab, löst sie in Methanol auf und fällt mit Äther. Farblose Nädelchen vom Schmp. 120°C (Zers.).

Gef.: C, 56.93; H, 4.58; N, 7.69. Ber. für $C_{18}H_{17}N_2S_2OCl$: C, 57.37; H, 4.52; N, 7.44%.

**Überführung von 2-Äthylmerkapto-Verbindung (V: R=$C_2H_5$) in 2-Amino-Verbindung (VI).**—*Mit Morpholin.*—Man löst 0.4 g 2-Äthylmerkapto-Verbindung in 6 ml Äthanol und setzt darauf mit 0.12 g Morpholin um. Unter Merkaptanaustritt lässt man die Lösung bei Raumtemperatur 2 Std. stehen und bei Zusatz von Äther scheiden sich farblose Kristalle aus, die abgenutscht und aus Methanol/Äther umkristallisiert werden; 0.2 g *N*-Acetyl-2-morpholino-3-phenylthiazonimin-hydrochlorid (VI: R'R''N=O($CH_2CH_2CH_2$)$_2$N) als farblose Nädelchen vom Schmp. etwa 260°C (Zers.).

Gef.: C, 53.15; H, 5.66; N, 12.40. Ber. für $C_{15}H_{18}N_3O_2SCl$: C, 53.00; H, 5.32; N, 12.37%.

*Mit Benzylamin.*—Zur Lösung von 0.40 g. 2-Äthylmerkapto-Verbindung in Methanol (2 ml) setzt man 0.14 g Benzylamin zu, wobei es gleich nach Merkaptan riecht, erwärmt um 50°C während einer Stunde und lässt über Nacht stehen. Nach tropfenweisem Zusatz von Äther fällt zuerst etwas von Benzylaminhydrochlorid aus, das sofort abfiltriert wird, dann tropft man in das Filtrat weiter Äther ein und nutscht 0.1 g *N*-Acetyl-2-benzylamino-3-phenylthiazonimin-hydrochlorid (VI: R'=$PhCH_2$, R''=H) als gelbliche Kristalle ab, die aus Methanol/Äther umkristallisiert werden und um 190°C unter Zersetzung schmelzen.

Gef.: C, 60.07; H, 5.23; N, 11.72. Ber. für $C_{13}H_{18}N_3OSCl$: C, 60.08; H, 5.03; N, 11.68%.

*Mit Cyclohexylamin.*—Gleicherweise erhält man aus 0.68 g 2-Äthylmerkapto-Verbindung und 0.22 g Cyclohexylamin in 10 ml Methanol 0.1 g *N*-Acetyl-2-cyclohexylamino-3-phenylthiazonimin-hydrochlorid (VI: R'=H, R''=CH($CH_2$)$_5$) vom Schmp. etwa 218°C (Zers.).

Gef.: C, 58.04; H, 6.35; N, 11.98. Ber. für $C_{17}H_{22}N_3OSCl$: C, 58.05; H, 6.31; N, 11.94%.

**Umsetzung von 2-Äthylmerkapto-Verbindung (V: R=$C_2H_5$) mit Anilin.**—Der Merkaptanaustritt bei der Umsetzung von 0.40 g 2-Äthylmerkapto-Verbindung mit 0.12 g Anilin in Methanol geschieht erst unter Rückfluss und 0.15 g gelbliche, halogen-haltige, in Wasser lösliche Nädelchen vom Schmp. 85°C werden bei Zusatz von Äther niedergeschlagen.

3) W. Davies J. A. Maclaren und L. R. Wilkinson, *J. Chem. Soc.*, **1950**, 3491.

Gef.: C, 45.75; H, 5.60; N, 8.19%.

**Cyanmethyl *N*-Phenylthiolmorpholinimidat (VII).**—In trocknem Dioxan (50 ml) löst man 2.7 g Chloracetonitril und 7.5 g Morpholin-4-thiokohlensäureanilid (VIII), das beim Gemisch von Morpholin und Phenylisothiocyanat in Aceton unter Kühlung glatt hergestellt wird, setzt darauf Triäthylamin (14 ml) zu und erhitzt 3 Std bei 70°C unter Rühren. Nach dem Stehenlassen über Nacht und dem Abfiltrieren von ausgeschiedenem Triäthylamin-hydrochlorid dampft man das Filtrat im Vakuum ein und erhält als Rückstand 5.57 g Kristalle vom Schmp. 78—90°C. Durch dreimaliges Umkristallisieren aus Methanol ergeben sich reiner Isothioharnstoff (VII) vom Schmp. 85—88°C als farblose Säulen, die während langem Stehenlassen in der Luft verbraunt sind.

Gef.: C, 59.64; H, 5.84; N, 16.23. Ber für $C_{13}H_{15}N_3OS$: C, 59.76; H, 5.79; N, 16.08%.

***N*-Acetyl-2-morpholino-3-phenylthiazoniminhydrochlorid (VI: $R'R''N=O(CH_2CH_2)_2N$).**—Wenn man zur Lösung von 1.0 g *S*-Cyanmethylisothioharnstoff (VII) in trocknem Benzol (15 ml) 0.5 g Acetylchlorid zusetzt, wird die Lösung trübe und bald scheiden sich farblose Kristalle aus. Nach dem Stehenlassen über Nacht nutscht man sie ab, versetzt in wenig Methanol, filtriert die in Methanol unlösliche Verbindung ab, setzt dem Filtrat Äther tropfenweise zu und erhält 0.1 g farblose Nädelchen vom Schmp. etwa 260°C (Zers.). So erhaltenes *N*-Acetyl-2-morpholino-3-phenylthiazonimin-hydrochlorid hat keine Schmp.-Depression mit oben erhaltenem ergeben; Infrarot-Spektren sind praktisch identisch.

**Reaktion von 2-Äthylmerkapto-Verbindung (V: $R=C_2H_5$) mit Natriumhydrogencarbonat.**—Man rührt die wässrige Lösung von 0.5 g 2-Äthylmerkapto-Verbindung und 0.20 g Natriumhydrogencarbonat 2 Std bei Raumtemperatur, extrahiert mehrmals mit Chloroform, trocknet die Auszüge und dampft ein. Man erhält 0.35 g kristallinen Rückstand, der in Methanol gelöst und mit Petroläther in reiner Form niedergeschlagen wird. Diese orangen, halogenfreien, strukturunbekannten Kristalle sind in der Luft verfärbt, schmelzen unter Zersetzung bei etwa 140°C und zeigen den folgenden Analysenwert; C, 55.81; H, 6.06; N, 9.94%.

**Reaktion von 2-Äthylmerkapto-Verbindug (V: $R=C_2H_5$) mit Natriumsulfid.**—Zur wässrigen Lösung von 0.45 g 2-Äthylmerkapto-Verbindung setzt man eine Lösung von 0.35 g Natriumsulfidnonahydrat zu, rührt darauf während einer Stunde bei Raumtemperatur (Geruch nach Merkaptan), und filtriert 0.20 g ausgefallene Kristalle. Aus dem Filtrat extrahiert man dieselben (0.1 g) mit Chloroform. Durch Umkristallisieren aus Chloroform/Petroläther wird 3-Phenyl-4-acetamido-4-thiazolin-2-thion (IX) gereinigt, das bei 182—183°C schmilzt.

Gef.: C, 52.82; H, 4.25; N, 11.41. Ber. für $C_{11}H_{10}N_2S_2O$: C, 52.80; H, 4.04; N, 11.20%.

Infrarot-Spektrum: 3220 (NH), 1680 (CO), 1608 (C=C) $cm^{-1}$.

**3-Phenyl-4-acetamido-4-thiazolin-2-thion (IX).**—Setzt man zur Suspension von 5.00 g Ammoniumsalz der *N*-Phenyldithiocarbamidsäure in Chloroform 2.03 g Chloracetonitril unter Kühlung zu, so tritt die Reaktion alsbald unter Erwärmung ein, man lässt darauf eine Stunde stehen, setzt nach dem Freisetzen vom Ammoniumchlorid die dunkel verbraunte Lösung mit Acetanhydrid um und lässt zwei Tage stehen. Nach dem Zusatz von Petroläther nutscht man ausgefallene Kristalle ab: 2.6 g gelbliche Blättchen, die aus Choroform/Petroläther gereinigt werden, bei 182—183°C schmelzen und gemäss Misch-Schmp. und Infrarot-Spektrum mit oben erhaltenem 3-Phenyl-4-acetamido-4-thiazolin-2-thion (IX) identisch sind.

**Säure Hydrolyse von 3-Phenyl-4-acetamido-4-thiazolin-2-thion (IX).**—Eine Suspension von 0.10 g 3-Phenyl-4-acetamid-4-thiazolin-2-thion in 2N Salzsäure kocht man 2 Std unter Rückfluss und nutscht dann ab: 0.07 g gelbliche Kristalle (aus Chloroform/Petroläther), deren Identifizierung mit 3-Phenylrhodanin (X) das Infrarot-Spektrum zugrunde liegt.

**Überführung von 3-Phenyl-4-acetamido-4-thiazolin-2-thion (IX) in 2-Methylmerkapto-3-phenylthiazonimin-hydrojodid (XI).**—Man kocht 0.55 g 3-Phenyl-4-acetamido-4-thiazolin-2-thion und 0.70 g Methyljodid in 5 ml Methanol 15 Minuten unter Rückfluss, setzt Äther nach Kühlung tropfenweise zu und nutscht 0.65 g ausgeschiedene gelbe Nadeln ab, die hygroskopisch sind und bei 100—120°C schmelzen. # The Hydroesterification of Propylene with Carbon Monoxide and Methanol in the Presence of Dicobalt Octacarbonyl

By Akio MATSUDA and Hiroshi UCHIDA

(Received June 24, 1964)

The syntheses of esters from olefins, alcohols, and carbon monoxide in the presence of dicobalt octacarbonyl, that is, the hydroesterification of olefins,[1] have been investigated by Natta and his co-workers.[2,3] This reaction is of a considerable interest from the industrial point of view, however, its application to industry has not yet been realized. This may have been due to the fact that this reaction proceeds at a rate much slower than the hydroformylation reaction. Starting with propylene and methanol, the authors of this paper have succeeded in increasing the reaction rate of hydroesterification to such a high level as to be comparable with that of hydroformylation. The details of the rate and the yields of products will be reported in this paper.

## Experimental

The hydroesterification reactions were carried out by using the same 300-cc. stainless-steel autoclave as was used in the hydroformylation reaction of propylene.[4] The procedure was essentially the same as the one previously used except that in most of the runs a small amount of hydrogen was added to the autoclave from a 30-cc. hydrogen-pressure storage before carbon monoxide was introduced from another 500-cc. carbon monoxide pressure storage. The amount of hydrogen introduced was calculated from the pressure drop in the former pressure storage. After the temperature and pressure had been adjusted to definite levels, the stirrer was started. The dicobalt octacarbonyl in a stainless saucer held on a wing of the stirrer was allowed to drop into the liquid phase, and the reaction began. During the reaction period, carbon monoxide was continuously introduced from the pressure storage through a needle valve in order to maintain the autoclave pressure at a constant level of 190 kg./cm$^2$. The pressure in the pressure storage tended to drop as the reaction proceeded, but a simple recording of the pressure drops with time could not always serve as a measurement of the initial rate of hydroesterification, because the hydroesterification and the hydroformylation occurred simultaneously. As it was, the initial rate of the two reactions was determined independently by analyses of the product; samples of a small portion of the liquid product were withdrawn from the autoclave at time intervals during the reaction and were analyzed for methyl butyrate and butyraldehyde dimethylacetal. The former is the product of the hydroesterification of propylene, while the latter is the product formed by the combination of the butyraldehyde formed by the hydroformylation and methanol. The samples were analyzed by means of gas chromatography using a 4 m. column of triethanolamine on cellite at 80°C.[5] Ethylbenzene was used as an internal reference. The gaseous product was analyzed in the same way as has been described previously.[4]

Commercially-available propylene, methanol, and pyridine were used. Propylene was 93% pure and contained 6.5% propane and 0.5% ethane. Methanol and pyridine were distilled before use. The procedure for the preparation of dicobalt octacarbonyl, $Co_2(CO)_8$, was quite the same as has been mentioned previously.[4] Carbon monoxide was prepared by decomposing commercial formic acid with sulfuric acid and was more than 97% pure, containing less than 0.5% hydrogen.

## Results and Discussion

The hydroesterification of propylene using carbon monoxide of a high purity usually proceeds at a much slower rate than the hydroformylation with the $1H_2$-1CO synthesis gas. It has now been found that the addition of even a small amount of hydrogen into the autoclave results in a considerable increase in the rate of propylene conversion, and that some amounts of butyraldehyde dimethylacetal are also produced as a result of the hydroformylation of propylene.

In this connection, attention should be called to the finding of Wender et al.,[6] who stated that the rate of the hydroformylation of cyclohexane is increased by the addition of very small amounts of organic bases and decreased when larger amounts of these bases are present.

| 6 | Pyridine | 0.04 | 85 | 0.62 | 0.17 | 0.03 | 0.01 |
| 7 | Pyridine | 0.06 | 92 | 0.67 | 0.19 | 0.02 | 0.01 |
| 8 | *N*,*N*-Dimethylaniline | 0.04 | 42 | 0.28 | 0.08 | 0.02 | 0.01 |
| 9 | Quinoline | 0.04 | 54 | 0.39 | 0.11 | 0.02 | 0.01 |
| 10 | α-Picoline | 0.04 | 45 | 0.32 | 0.09 | 0.02 | 0.01 |
| 11 | Triethylamine | 0.004 | 40 | — | — | — | — |
| 12 | Triethylamine | 0.02 | 0 | 0.26 | 0.08 | 0.02 | 0.01 |
| 13 | Piperidine | 0.004 | 37 | — | — | — | — |
| 14 | Piperidine | 0.02 | 0 | — | — | — | — |
| 15 | Benzylamine | 0.02 | 0 | — | — | — | — |
| (16 | Zinc acetate | 0.008 | 0 | — | — | — | —) |

The raw material consisted of 0.5±0.01 mol. $C_3H_6$, 2 mol. $CH_3OH$, and was added with 4 mmol. $Co_2(CO)_8$. A small amount of hydrogen (0.02 mol.) was introduced before the autoclave was pressured with CO. Every run was conducted at the total pressure of 190 kg./cm² at 160°C.

This finding suggests that the addition of an appropriate amount of organic bases might serve to improve the selectivity for hydroesterification, even though it might retard the rate of propylene conversion to some extent. A few preliminary experiments made along this line have surprisingly proved that the addition of such a large amount of pyridine as 0.03/0.004 in terms of moles of pyridine/moles of $Co_2(CO)_8$ ratio not only improves the selectivity for hydroesterification, but also increases the rate of propylene conversion (cf. Table I). Accordingly, the effect of a variety of organic bases on the yield of the hydroesterification product will have to be examined more closely.

**The Effect of Bases on the Yield of Hydroesterification Product.** — Table II summarizes data obtained on the hydroesterifications in the presence of different amounts of various organic bases. Among the bases studied, pyridine has been found to be most effective in the production of methylbutyrate, and the yield increases with the amount of pyridine in the range under investigation; by the use of 0.06 mol. pyridine, the yield of the reaction for 1 hr. attains as high a level as 0.86 mol. from 1 mol. propylene. In contrast to this base, such strong bases as triethylamine, piperidine, and benzylamine inhibit the hydroesterification completely, even in the relatively small amount of 0.02 mol. The effects of *N*,*N*-dimethylaniline, quinoline, and α-picoline on the yield are very small.[7] Further investigation, therefore, will be directed to the problem of the presence of pyridine.

Figures 1, 2 and 3 illustrate plots of the amounts of methyl butyrate and of butyraldehyde dimethylacetal produced vs. the reaction time at the reaction temperatures of 160, 170 and 180°C respectively. The runs were conducted by using the same amounts of raw materials, of hydrogen, and of $Co_2(CO)_8$, as in the runs of Table II, but pyridine was varied

7) The hydroesterification does not take place at all in the presence of a very small amount of zinc acetate, which reacts readily with $Co_2(CO)_8$ to form the mixed metal carbonyl.

in amount at 0.03 mol. intervals between 0 and 0.12 mol. The figures show that, throughout every series of runs at the different reaction temperatures, the amount of methyl butyrate produced after a 20 min. reaction increases with the amount of pyridine, reaches a maximum, and then decreases. The optimum amount of pyridine is increased as the reaction temperature is raised.

As is evident from the formula of $C_3H_6+CO+H_2 \rightarrow C_3H_7CHO$ for the hydroformylation, the

hydrogen in an autoclave tends to diminish as the hydroformylation proceeds, and the amount of butyraldehyde or its dimethylacetal in the products can not exceed 0.02 mol., which is equivalent to the initial hydrogen content in the autoclave. In fact, the acetal remains about 0.018 mol. at the most. These facts make it difficult to estimate the selectivity for hydroesterification from a simple comparison of the experimental rate of hydroesterification with that of hydroformylation, unless a certain attention is paid to the amount of hydrogen existing in the autoclave. In connection with this, a more reasonable measure of the selectivity may be given by means of the ratio of the initial rate at the zero-conversion of propylene for hydroesterification (hereafter denoted by $r_{oe}$) to the corresponding rate for hydroformylation (hereafter denoted by $r_{of}$); at this stage, the amount of hydrogen is 0.02 mol. The values of $r_{oe}$ and $r_{of}$ are obtained from slopes of the tangents drawn along the plots at the origin.

**The Effect of Pyridine on the Initial Rates of Hydroesterification and Hydroformylation at Zero-conversion.**—Figure 4 illustrates the plots of $r_{oe}$ vs. the amount of pyridine for series of runs at 160, 170, and 180°C. Every plot first rises with the amount of pyridine, and in each the rise at the higher temperature is more rapid than that at the lower temperature. At 160 and 170°C, the maximum of the curve appears at the pyridine amount of 0.06 mol., whereas at 180°C the $r_{oe}$ is maintained essentially constant over the range from 0.06 to 0.12 mol. of pyridine.

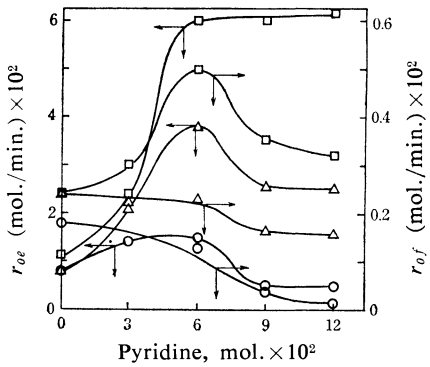

Fig. 4. Initial rates at zero-conversion of propylene for hydroesterification ($r_{oe}$) and hydroformylation ($r_{of}$) as function of pyridine amount.
React. temp.: ○ 160°C, △ 170°C, □ 180°C

Figure 4 includes the same plots with respect to $r_{of}$. The situation is different from that of $r_{oe}$; the plots of $r_{of}$ at 160 and 170°C continue to be lowered slowly with the amount of pyridine, but the plot at 180°C shows a slight maximum at 0.06 mol. The retarding effect of pyridine on the initial hydroformylation rate becomes so remarkable at lower reaction temperatures that the reaction at 160°C is almost completely inhibited by the addition of 0.12 mol. of pyridine.

Figure 5A presents selectivity data for hydroesterification at 160, 170, and 180°C. The curve at 180°C shows an approximately linear increase over the whole range of pyridine amount studied, whereas the curves at 160 and 170°C show the increase only in the range below 0.06 mol. Beyond that amount of pyridine, the ratios stay on the same level, about 12. It should be noted that the molar ratio, $C_3H_7CHO/C_3H_7CH(OCH_3)_2$, after the reaction of 1 hr. is much higher than the $r_{oe}/r_{of}$ ratio; e. g., the former ratio from run No. 7 in Table II is twice as large as the latter ratio of run No. 29. The ratio of $r_{oe}/r_{of}$ thus can not directly relate the yield ratio after a prolonged duration of a batchwise reaction, where the initial hydrogen is allowed to diminish as the reaction proceeds.

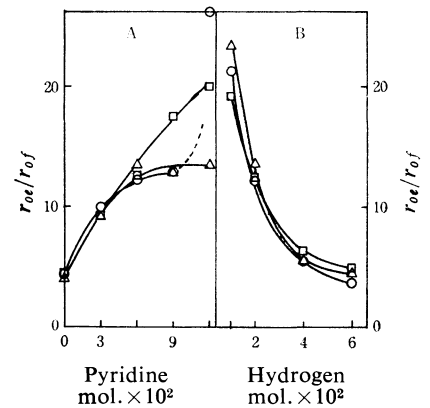

Fig. 5A and 5B. Ratio $r_{oe}/r_{of}$ as function of amount of pyridine (A) and of hydrogen (B).
React. temp.: ○ 160°C, △ 170°C, □ 180°C

**The Effect of Hydrogen on the Initial Rates of Hydroesterification and Hydroformylation at Zero-conversion.**—The $r_{oe}$ and $r_{of}$ values in the presence of various amounts of hydrogen in an initial charge of autoclave were determined by the above-described method. The runs for this purpose were always conducted with the same amounts of raw materials, while the pyridine amount was fixed at 0.06 mol. The hydrogen amount was varied at intervals from 0 to 0.06 mol. Figure 6 illustrates plots of $r_{oe}$ vs. the initial hydrogen amount in the autoclave at 160, 170, and 180°C. Every curve first rises with the amount of hydrogen, reaches a maximum, and then decreases slowly. The rise of the curve at the high temperature is more rapid than that at the lower temperature; at 180°C, the $r_{oe}$ in the presence of 0.02 mol. hydrogen can be five times as fast as the $r_{oe}$ in its absence. It is natural that the $r_{of}$ should increase with the hydrogen amount, as is shown in Fig. 6.[8]

As is shown in Fig. 5B, three plots at 160, 170, and 180°C of $r_{oe}/r_{of}$ vs. the initial amount of hydrogen similarly decrease with the amount of hydrogen. The initial hydrogen amount in an autoclave should be less than 0.01 mol. in order to have such a high selectivity for the hydroesterification as 15 in terms of the $r_{oe}/r_{of}$ ratio. This initial hydrogen content in the

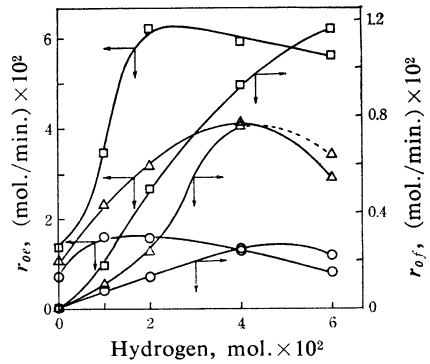

Fig. 6. Dependency of $r_{oe}$ and $r_{of}$ on hydrogen amount.

| | Expt. No. | React. temp. |

8) Figure 6 indicates falls in both the $r_{oe}$ and $r_{of}$ by the addition of 0.06 mol. hydrogen at the lower reaction temperatures. There is, as yet, no probable explanation of this finding.

autoclave at the reaction conditions is equivalent to 0.013 in terms of the $H_2/CO$ molar ratio.

**The Initial Rate of Hydroesterification as a Function of the Propylene Concentration.**—Although Ercoli et al.[3] have pointed out the zero-order reaction of the hydroesterification of olefins, such as 1-hexene, cyclohexene, and 2-ethyl-1-hexene, with respect to the olefin concentration, the data presented here on this reaction of propylene, as shown in Figs. 1—3, are rather suggestive of another order, presumably of the first order. However, the experimental runs in the figures were conducted in such a manner that the hydrogen in an initial charge of the autoclave was allowed to decrease with the progress of a simultaneous side-reaction, hydroformylation; hence, the data are not sufficient for us to draw a conclusion from them. An alternative run, therefore, was attempted, in which the hydrogen content was kept at a constant level during the run. The autoclave was charged with the raw material consisting of 0.51 mol. of $C_3H_6$, 2 mol. of $CH_3OH$, 0.06 mol. of pyridine, and 1 mmol. of $Co_2(CO)_8$ placed in a stainless steel saucer; then carbon monoxide containing 2.7% hydrogen was introduced. The initial hydrogen in the gas phase under the reaction conditions amounted to 1.9 mol.%. During the run, the synthesis gas (composed of 91.9% CO, 6.3% $H_2$, and 1.8% $N_2$) was continuously introduced from the pressure storage in order to maintain the total pressure at 190 kg./cm$^2$ at 180°C, and pressure drops in the storage with the reaction time were recorded, from which values the amounts of the gas supplied, $V_s$ (mol.), could be calculated.

When the run was finished, after 1 hr., $V_s$ amounted to 0.526 mol., and propylene was reduced to 0.05 mol. from 0.51 mol., corresponding to a 90% conversion of propylene. The hydrogen was found to be 1.7 mol. %, almost the same as the initial content. The products were 0.32, 0.09, 0.02, and 0.01 mol. for methyl esters of *n*- and isobutyric acids and for dimethylacetals of *n*- and isobutyraldehydes respectively. The sum of products was 0.44 mol. No products other than ethyl acetate[9] (less than 0.005 mol.) were detected. On the basis of these data, the percentage conversion of propylene was calculated to be 86%; this rate is close to, but not identical with, the value obtained from the data of propylene consumption.[11]

In a previous paper[4] dealing with the hydroformylation of propylene, it was described how the amount of synthesis gas supplied stands for the sum of two portions, one consumed by the hydroformylation itself and the other, that necessary to compensate for the fall in partial propylene pressure as the reaction proceed, and that the amount of gas supplied for a hydroformylation run, $V_{sf}$ (mol.), is expressed by:

$$\left.\begin{aligned} & V_{sf}=2(c_0-c)+ap_0(c_0-c)/c_0 \\ \text{or} \quad & V_{sf}=(2+ap_0/c_0)(c_0-c) \end{aligned}\right\} \quad (1)$$

where $c_0$ (mol.) is the initial propylene concentration; $c$ (mol.) is the concentration at the reaction time $t$, $p_0$ is the initial partial propylene pressure, and $a$ is a coefficient whose value is dependent on the reaction temperature. Similarly, the amount of gas supplied for a run of hydroesterification, $V_{se}$ (mol.), is expressed by:

$$V_{se}=(1+ap_0/c_0)(c_0-c) \quad (2)$$

In the present run, in which both of the reactions occur, the amount of gas supplied, $V_s$ (mol.), is, hence, given by Eq. 3, if it may be assumed that the (moles of gas consumed by hydroestrification)/(moles of gas consumed by hydroformylation) ratio remains invariable during the run.

$$V_s=\alpha(c_0-c) \quad (3)$$

where $\alpha$ is a coefficient whose value lies in a range between $(2+ap_0/c_0)$ and $(1+ap_0/c_0)$.

The substitution of the experimental data of $V_s$ at $t=60$ min. (0.526 mol.), $c_0$ (0.51 mol.), and $c$ at $t=60$ min. (0.05 mol.) into Eq. 3 results in the evaluation of $\alpha$ as 1.14.[12] Once $\alpha$ is evaluated, $c$ at any $t$ can, in turn, be calculated by the aid of Eq. 3.

As is shown in Fig. 7, a plot of $(c_0-c)$ vs. $t$ is not linear, whereas a plot of $\ln(c_0/c)$ is linear. This finding leads to the following expression of the over-all initial rate of propylene consumption, $r$ (mol./min.):

$$r=-dc/dt=kc \quad (4)$$

In the present run, the over-all initial rate is the sum of two initial rates, the initial rate of propylene consumption by hydroesterification, $r_e$, and the initial rate by hydroformylation, $r_f$:

$$r=r_e+r_f=kc \quad (5)$$

On the other hand, it has already been shown that the $r_f$ is of the first-order with respect to propylene concentration, namely, $r_f=k'c'$, hence,

9) Ethylacetate can be a product of acetaldehyde, which is produced from methanol under the reaction conditions of oxo synthesis (cf. Ref. 10).

10) G. Natta and R. Ercoli, "Catalysis," II, Reinhold Publishing, N. Y. (1957), p. 171.

11) The disagreement may perhaps be due to an inaccuracy in the determinations of propylene and its products.

12) This value of $\alpha$ is applicable only to the data of the present run.

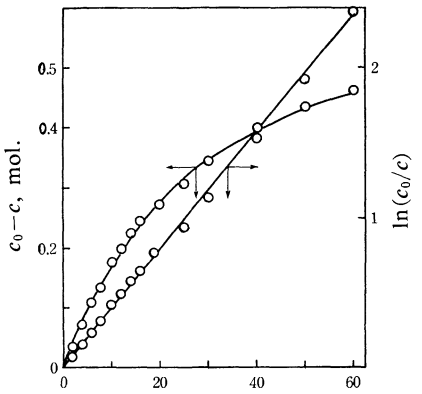

Fig. 7. Amount of propylene consumed under high pressure of carbon monoxide containing hydrogen at 180°C plotted against reaction time (Expt. No. 44).

$$r_e+k'c=kc \quad \text{or} \quad r=(k-k')c \qquad (6)$$

Equation 6 plainly indicates that the initial rate of hydroesterification is first-order with respect to propylene concentration, provided that the run is conducted in the presence of excess pyridine and with carbon monoxide containing a small amount of hydrogen.

Runs (No. 45—47) were conducted with pure carbon monoxide[13] in order to compare them with run No. 44. In these runs, the same amounts of propylene and methanol as in run No. 44 were used with no pyridine, while $Co_2(CO)_8$ was varied in amount over a range from 1 to 4 mmol. The data are presented as plots of $(c_0-c)$ vs. $t$. The plots are linear, showing that the hydroesterification is zero-order with respect to propylene concentration, in accordance with the result of Ercoli et al.[3] Moreover, an approximately linear relationship is found between the initial rate and the amount of $Co_2(CO)_8$. It should also be noted that the initial rate, as conventionally expressed by $(c_0-c)/t$ (mol./min.), where $(c_0-c)=0.1$ mol., of run No. 44 in Fig. 7 is about 30 times as high as the rate of run No. 45 in Fig. 8 with the same amount of $Co_2(CO)_8$ (1 mmol.).

Ercoli et al.[3] stated that cobalt hydrocarbonyl can be the real catalyst for the hydroesterification of olefins. Therefore, it is likely that the addition of hydrogen results in an increase in the initial rate, for the addition considerably facilitates the formation of the hydrocarbonyl. However, in the presence of excess pyridine and methanol, other salts, which contain $[Co(CO)_4]^-$ as an anionic constituent, can be formed. These salts may be, for instance, $[Co(CH_3OH)_6][Co(CO)_4]_2$, $[Co(Pyr)_6][Co(CO)_4]_2$, and $[PyrH][Co(CO)_4]$, and they presumably participate in the reaction as catalysts, either positive or negative. However, no satisfactory interpretation of the effects of hydrogen and pyridine on the initial rate of this reaction can be expected until sufficient knowledge of the catalyst materials and their catalytic behaviors are available.

13) The carbon monoxide contained 0.3% hydrogen.

## Summary

Propylene can be hydroesterified to methyl butyrate in a good yield and with an initial rate as high as the initial rate of the hydroformylation of propylene, provided a small amount of hydrogen and excess pyridine are present. Detailed data on the initial rates at the zero-conversion of propylene for both the hydroesterification and hydroformylation and the ratio between the two initial rates have been presented as a function of the amount of pyridine and hydrogen, together with data on the products obtained from the respective reactions.

The initial rate of hydroesterification in this study has proved to be first-order with respect to the propylene concentration. This result is different from that of Ercoli et al., who carried out hydroesterification runs of olefins with pure carbon monoxide.

The authors wish to thank Mr. Teiichi Ikeda for his participation in a part of this work.

# Effect of Density in the Radiolysis of *n*-Butane

By Tetsuo MIYAZAKI and Shoji SHIDA

(Received June 26, 1964)

The radiolysis of *n*-butane has been studied by several investigators. We reported in a previous paper[1] on the difference between the gas-phase and the condensed-phase radiolyses of *n*-butane and concluded that the fragmentation of the butane ion is important in the gas-phase radiolysis, while that of the butane molecule is predominant in the liquid-phase radiolysis. In order to obtain further information on the different mechanisms involved in the two phases, we have now undertaken a study of the radiolysis of *n*-butane near the critical state. Toi et al.[2] reported on the effect of the density in the radiolysis of ammonia at the critical temperature and found sharp decreases in $G(H_2)$ and $G(N_2)$ in the density region from 0.05 to 0.15 g. $cc^{-1}$. Hotta[3] reported the radiolysis of ethane at high pressures and found a decrease in $G(H_2)$ in the density region from 0.08 to 0.14 g. $cc^{-1}$. Recently Ausloos et al.[4] reported the effect of pressure from 0.05 atm. to 180 atm. in the radiolysis of methane.

In the present work the yields of propane and methane have been found to decrease sharply in the 0—0.1 g. $cc^{-1}$ density region. The results are interpreted in terms of the deactivation of excited ions.

## Experimental

The sample and the analytical procedure are similar to those described before.[1] The critical temperature, pressure and density of *n*-butane are 152°C, 37.5 atm. and 0.228 g. $cc^{-1}$ respectively. The samples were irradiated at 170°C with $\gamma$-rays from cobalt-60 of 16000 c.

Stainless-steel autoclaves have usually been used in high-pressure experiments, but they have some drawbacks, such as the condensation of *n*-butane in the needle valve, contamination by air during the sampling procedure, etc. Therefore, it is useful to use a glass reaction cell, even in a high-pressure experiment. The authors found that a glass cell with a small diameter can bear a pressure of 40 atm. After pure *n*-butane had been sealed off in a glass cell (0.5 cm. external diameter, 0.3 cm. inner diameter and 6 cm. long), the cell was placed in a stainless steel autoclave (30 cc.; 2 cm. inner diameter); the latter was then surrounded by a heated jacket which permitted the temperature to be controlled within ±2°C at 170°C.

The energy absorbed in *n*-butane was calculated from Fricke dosimetry without using any correction factor,[2] on the assumption that the energy input is simply proportional to the electron density. The energy absorbed in the low density is due almost entirely to secondary electrons produced by $\gamma$-ray absorption in the glass vessel wall. If the stopping power per electron in *n*-butane is assumed to be the same as that in the wall, the energy absorbed in *n*-butane of a low density can be determined directly from Fricke dosimetry,[5] as in the liquid. In the intermediate density region, however, it might be necessary to use some correction factor in calculating the energy absorbed.

## Results and Discussion

The variation in the major products of the radiolysis of *n*-butane in the density region from the gas phase of 3.8 atm. to the liquid phase is shown in Table I and Fig. 1. The

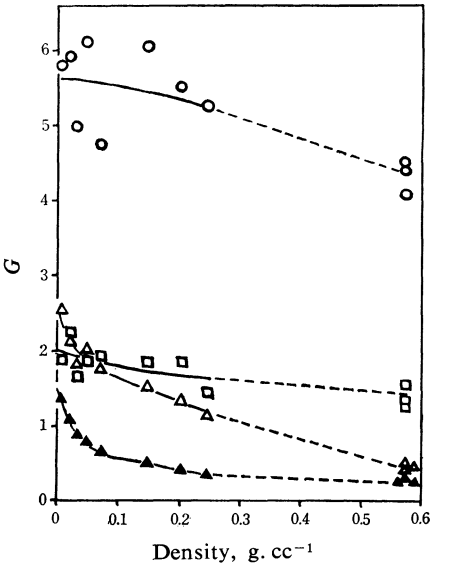

Fig. 1. Variation in $G(H_2)$ (○), $G(C_2H_6)$ (□), $G(CH_4)$ (△) and $G(C_3H_8)$ (▲) with density in the radiolysis of *n*-butane.

a) Total dose is about $1.9\times10^{21}$ eV. g$^{-1}$ and dose rate is $1.9\times10^{19}$ eV. g$^{-1}$ hr$^{-1}$.
b) Liquid at room temperature.
c) Pressure of the gas is 3.8 atm.

most striking feature of the data is the marked decrease in $G(C_3H_8)$ and $G(CH_4)$ in the density region from 0 to 0.1 g. cc$^{-1}$. $G(H_2)$ and $G(C_2H_6)$ seem, however, to be practically independent of the variation in density. The yields near the critical density except for $G(CH_4)$ are similar to those of the liquid phase.

It seems impossible to explain the marked decrease in $G(C_3H_8)$ in the density region 0—0.1 g. cc$^{-1}$ by means of the cage effect, which has been thought to be one of the most important causes of the difference between the radiolysis of the gas phase and that of the liquid phase.[6)] In the fragmentation of a molecule to radicals, the probability ($\alpha$) of the recombination of fragments was estimated by Franck and Rabinowitsch[7)] as follows:

| Pressure | 1 | 10 | 100 atm. |
|---|---|---|---|
| $\alpha$ | $10^{-9}$ | $10^{-6}$ | $10^{-3}$ |

It is clear that there exists no cage effect in the density of 0.1 g. cc$^{-1}$ (i. e., about 20 atm.). Therefore, the steep decrease must be attributed to some other effects.

It is reasonable, on the basis of a previous study by the present authors[1)] and of a study by Ausloos et al.,[8)] to expect that the butane ion plays an important role in the radiolysis of the gas phase. Since the ion may be formed in highly-excited states, it is probable that the deactivation of an excited ion occurs in the density region from 0 to 0.1 g. cc$^{-1}$; that is,

$$M \xrightarrow{I} M^{+*} + e \qquad (1)$$

$$M^{+*} \begin{cases} \xrightarrow{k_2} P \\ \xrightarrow{k_3} Q \end{cases} \qquad (2), (3)$$

$$M^{+*} + M \xrightarrow{k_4} M^{+} + M \qquad (4)$$

where M: *n*-butane molecule
$M^{+*}$: excited butane ion
$M^{+}$: stable butane ion (or perhaps the ion cluster proposed by Funabashi et al.[9)])
P: product
Q: products except P
*I*: rate of reaction 1
*k*: rate constant

The steady-state treatment leads to Eq. i:

$$G(P)=\frac{Ik_2}{k_2+k_3+k_4[M]} \qquad (i)$$

The decrease in the products with an increase in the density, or an increase in [M], could be explained by Eq. i. However, the constant yield of ethane over the whole density region and that of propane in the high density region cannot be explained by this equation only. Therefore, the production of P by the neutralization of $M^{+}$ should be considered in addition to 1—4.

$$M^{+} + e \xrightarrow{k_5} M^{*} \qquad (5)$$

$$M^{*} \begin{cases} \xrightarrow{k_6} P \\ \xrightarrow{k_7} R \end{cases} \qquad (6), (7)$$

where $M^{*}$: excited butane molecule
R: products except P

Then,

$$G(P)=\frac{Ik_2}{k_2+k_3+k_4[M]}+\frac{Ik_4k_6[M]}{(k_6+k_7)(k_2+k_3+k_4[M])} \qquad (ii)$$

6) L. Kevan and W. F. Libby, *J. Chem. Phys.*, **39**, 1288 (1963).
7) J. Franck and E. Rabinowitsch, *Trans. Faraday Soc.*, **30**, 120 (1934).
8) R. P. Borkowski and P. J. Ausloos, *J. Chem. Phys.*, **39**, 818 (1963).
9) J. L. Magee and K. Funabashi, *Radiation Research*, **10**, 622 (1959).

The first term in Eq. ii represents the production of P by ionic fragmentation, while the second term represents that by neutralization. The constant yield of $C_3H_8$ in the high density region can be explained by Eq. ii. Suppose the yield of P from the excited butane ion to be the same as that from the excited butane molecule; that is, if $k_2/(k_2+k_3)=k_6/(k_6+k_7)$, $G(P)$ is $G(P)=Ik_2/(k_2+k_3)$ and independent of [M]. The constant yield of $C_2H_6$ might be due to this effect.

**The Formation of Propane.**—Since the decomposition of neutral excited *n*-butane produced by electron bombardment in a mass spectrometer[10] yields mainly ethane and ethylene:

$$C_4H_{10}^* \rightarrow C_2H_4 + C_2H_6 \qquad (8)$$

the formation of propane at 0.00604 g. $cc^{-1}$ (i.e., 3.8 atm.) may be due to the ionic process. From the mass spectrometric study, the main fragmentation processes of butane ion are found to be as follows:[11]

$$C_4H_{10}^{+*} \xrightarrow{e_0} \begin{cases} \xrightarrow{k_9} C_2H_5^+ + C_2H_5 & 30 \text{ kcal./mol.} \quad (9) \\ \xrightarrow{k_{10}} C_2H_4^+ + C_2H_6 & 17 \text{ kcal./mol.} \quad (10) \\ \xrightarrow{k_{11}} C_3H_7^+ + CH_3 & 4 \text{ kcal./mol.} \quad (11) \\ \xrightarrow{k_3} Q & (3) \end{cases}$$

where $e_0$ denotes the heat of the reaction of ionic fragmentation. The propyl ion in reaction 11 reacts very rapidly with *n*-butane to produce propane:

$$C_3H_7^+ + n\text{-}C_4H_{10} \rightarrow C_3H_8 + C_4H_9^+ \qquad (12)$$

Propane might also be formed by the combination of the methyl and ethyl radicals produced in reactions 9 and 11, but $G(C_3H_8)=1.37$ at 170°C at 0.00604 g. $cc^{-1}$ is consistent with $G(CH_3\cdot)=1.54$[1] and with the molecular yield, $G_M(C_3H_8)=1.43$,[8] in the gaseous radiolysis of *n*-butane at ordinary pressure. Therefore, it is reasonable to consider that at 0.00604 g. $cc^{-1}$ propane is formed by the ionic process of Reaction 11, followed by 12. Since the constant yield of propane at a high density is relatively low compared with that at 0.00604 g. $cc^{-1}$, Eq. i may be used for an analytically convenient treatment in the low density region, neglecting the formation by the neutralization of butane ion. From reactions 1, 9, 11, 3, 12 and 4, we get:

$$\frac{1}{G(C_3H_8)}=\frac{k_9+k_{10}+k_{11}+k_3}{Ik_{11}}+\frac{k_4}{Ik_{11}}[C_4H_{10}] \qquad (iii)$$

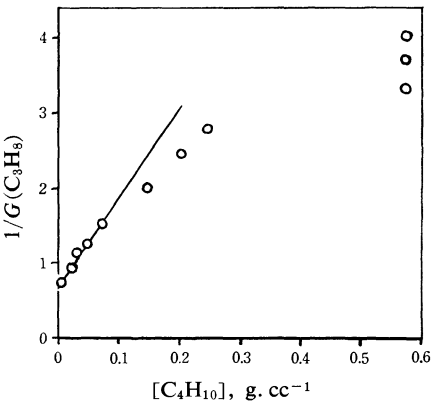

Fig. 2. Relationship between reciprocal of $G(C_3H_8)$ and density of *n*-butane.

Thus, there must be a linear relationship between $1/G(C_3H_8)$ and $[C_4H_{10}]$. As may be seen in Fig. 2, a satisfactory straight line is obtained in the low density region. The discrepancy from the straight line in the high density region may be due to the neglect of the formation by the neutralization of the butane ion. The slope-to-intercept ratio gives: $(k_9+k_{10}+k_{11}+k_3)/k_4=5.7\times10^{20}$ $cc^{-1}$ molecules. Taking $k_4=10^{-9}$ cc. molecules$^{-1}$ $sec^{-1}$ [12], $(k_9+k_{10}+k_{11}+k_3)$ is $5.7\times10^{11}$ $sec^{-1}$. Since this value is the total rate constant of the fragmentation of the excited butane ion, we have tried to estimate $k_{11}$ and $k_9$ separately. From the mass spectral pattern of *n*-butane, the ratios of the processes forming $C_3H_7^+$ and $C_2H_5^+$ to the total ionic fragmentation are 0.48 and 0.28 respectively. Therefore, we get $k_{11}=2.7\times10^{11}$ $sec^{-1}$ and $k_9=1.6\times10^{11}$ $sec^{-1}$.

**The Calculation of the Rate Constant.**—Rosenstock et al.[13] proposed the quasi-equilibrium rate theory for the fragmentation of polyatomic ions. According to the simplified treatment[14] of this theory, the rate constant of the dissociation of the molecule ion of an excitation energy of $e$ is given by $k(e)$:

$$k(e)=P\nu\left(1-\frac{e_0}{e}\right)^{S-1} \qquad (iv)$$

where $P$ is the steric factor in the range from 1 to $10^{-3}$; $\nu$ is the reaction frequency; $S=3N-6$ is the number of degrees of the vibrational freedom of the $N$-atomic molecule ion, and $e_0$ is the dissociation energy of the ion. $P\nu$ is taken as $10^{14}$ $sec^{-1}$ for a simple bond dissociation process and as $10^{12}$ $sec^{-1}$ for a four-center disproportionation process. The molecule ions produced by electron impact have

14) D. P. Stevenson, *Radiation Research*, 10, 610 (1959).

different excitation energies. If $D(e)$ is the characteristic distribution function of the excitation energy, the total rate constant is as follows:

$$k=\int_0^{e_{max}} D(e)k(e)de \qquad (v)$$

where $D(e)$ is normalized to the range $0\leq e\leq e_{max}$ and where $e_{max}$ is the maximum excitation energy of the molecule ion.

We try to calculate $k_{11}$ and $k_9$ using Eq. v.

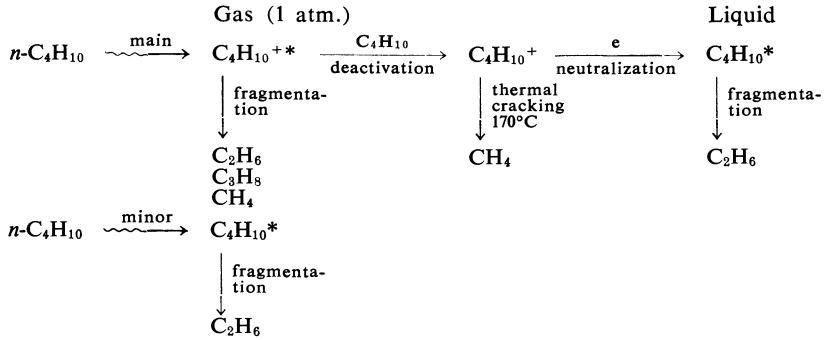
$$C_4H_{10}{}^{+*} \xrightarrow{k_{11}} s\text{-}C_3H_7{}^+ + CH_3 \qquad (11)$$

Since the propyl ion produced in reaction 11 is exclusively a secondary ion,[8] this reaction cannot occur by a simple bond dissociation process, but rather only by the dissociation process following rearrangement. Therefore, we take $P\nu=10^{12}$ sec$^{-1}$. The maximum excitation energy is assumed to be:

$$e_{max}=2\bar{e} \qquad (vi)$$

where $e$ is the average excitation energy of the ion. We take the $\bar{e}$ of the propane ion, i.e., 144.3 kcal./mol., as that of the butane ion also. An analytically-convenient distribution function that has been used in the interpretation of the mass spectra of propane[13] is:

$$D(e)=\frac{1}{e_{max}} \qquad (vii)$$



Using $S-1=35$ and $e_0=4$ kcal./mol., we get from Eq. v $k_{11}=3.2\times10^{11}$ sec$^{-1}$. In a similar fashion, we get $k_9=3.3\times10^{11}$ sec$^{-1}$ by using $e_0=30$ kcal./mol. and $P\nu=10^{14}$ sec$^{-1}$ for a simple bond dissociation. The agreement between the observed values and the calculated values is satisfactory in spite of the simplified calculation.

Since the total specific rate of the fragmentation of the ion is $5.7\times10^{11}$ sec$^{-1}$ and since the frequency of successive collisions of a molecule in the liquid phase is of the order of $10^{-13}$ sec$^{-1}$, the excited ion produced in the liquid-phase radiolysis may be exclusively deactivated before its fragmentation, and, therefore, C–C bond rupture from butane ion may be strongly suppressed. This supports the conclusion of the previous paper by the present authors.[1]

**The Formation of Methane.**—The material balance between $CH_4$ and $C_3$-products does not hold in the radiolysis at 170°C (Table I). Methane is partly formed from the methyl radical produced in reaction 11; the yields of methane due to other processes ($G(CH_4)-G(C_3H_8)$) are shown in the last column of Table I. Though $G(CH_4)-G(C_3H_8)$ at 20°C is small, that at 170°C, near the critical state, is about unity, independent of the variation in density. These results seem to be the effect of temperature. No fragmentation products could be observed by the heating of *n*-butane without radiation at 200°C for 80 hr. Since methane is not formed by the thermal cracking of the butyl radical at 170°C,[15] the discrepancy of the material balance might be due to some characteristic reaction near the critical state. The heat of reaction[11] for the formation of methane from the butane ion is very low.

$$C_4H_{10}{}^+ \rightarrow C_3H_6{}^+ + CH_4 \quad e_0=4 \text{ kcal./mol.} \qquad (13)$$

In the fragmentation of the slightly-excited butane ion,[16] a considerable amount of $C_3H_6{}^+$ is formed, though only a small amount is formed in the fragmentation of the highly-excited butane ion. In the radiolysis of neopentane,[17] the inbalance between products has been also observed; i.e., $G(CH_4)\gg G(C_4)$. The abundance of methane might be due to following reactions, as has been suggested by Williams[18]:

Scheme 1

15) A. W. Hay and C. A. Winkler, *Can. J. Res.*, **21B**, 149 (1943).
16) B. Steiner, C. F. Giese and M. G. Inghram, *J. Chem. Phys.*, **34**, 189 (1961).
17) W. H. Taylor, S. Mori and M. Burton, *J. Am. Chem. Soc.*, **82**, 5817 (1960).
18) T. F. Williams, *Trans. Faraday Soc.*, **57**, 755 (1961).

$$neo\text{-}C_5H_{12}^+ \rightarrow \begin{matrix} C_4H_8^+ + CH_4 \quad e_0 = -4 \text{ kcal./mol.} \\ \searrow \\ \text{higher products} \end{matrix} \qquad (14)$$

Therefore, it is probable that in the radiolysis of *n*-butane near the critical state a part of the methane is formed by reaction 13, while $C_3H_6^+$ forms higher products.

From the above results and discussions, the following conclusions may be drawn. It appears difficult to consider the ionic C–C rupture in the liquid-phase radiolysis of *n*-butane at room temperature. It seems proper to consider that the suppression of the ionic C–C rupture in the liquid phase is due to the deactivation of the excited butane ion. The main C–C rupture reactions in the radiolysis of *n*-butane may be depicted as Scheme 1.

## Summary

A study has been made of the effect of density on the radiolysis of *n*-butane at 170°C over the density region 0.006—0.575 g. $cc^{-1}$. While $G(H_2)$ and $G(C_2H_6)$ are not affected by the density change, $G(CH_4)$ and $G(C_3H_8)$ decrease sharply in the density region from 0 to 0.1 g. $cc^{-1}$. The latter facts may be interpreted in terms of the collisional deactivation of the excited ion. The rate constant of the fragmentation of the butane ion has been estimated from the deactivation-fragmentation competition scheme and compared with the rate constant calculated from the quasi-equilibrium theory. Agreement is satisfactory. The formation of methane by ionic fragmentation near the critical state has also been considered.

We wish to express our appreciation to Dr. Shin Sato, Mr. Tomoyoshi Kudo and Mr. Nobuyoshi Sakai for their fruitful discussions. We appreciate also the help of the Japan Atomic Energy Institute in performing the irradiation. This research was supported, in part, by the Watanabe Memorial Foundation for Scientific Research Promotion, to which the authors are grateful.

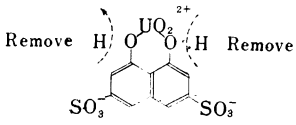
# Chelate Formation between Chromate Ions and Disodium-1, 8-dihydroxy Naphthalene-3, 6-disulphonate

By Samir K. BANERJI and Said-ul-Zafar QURESHI*

(Received July 22, 1964)



Disodium-1, 8-dihydroxy naphthalene-3, 6-disulphonate, commonly known as chromotropic acid (sodium salt), has found application in colorimetric analysis.[1] It has been reported to yield coloured complexes with vanadium, titanium, mercury, silver, uranium and ferric ions. It has also been found to yield coloured reactions with various other metals.[2,3] More detailed work on the application of this reagent in the estimation of titanium has been done by Sommer and his co-workers. Sommer and Okâć[4] discussed the functional analytical groups for titanium. The spectrophotometric determination of titanium using this reagent has been described by Sommer,[5] and Sommer and Benisêk[6] made a polarographic study of the reaction between titanium and chromotropic acid. Sommer[7,8] then extended the work, working out the details of the reaction and determining the composition and the stability constant. He also discussed the structure. The titanium-chromotropic acid system was also described by Shnaiderman[9] and Babko[10].

Heller and Schwarzenbach[11] studied the chelate formed between trivalent iron and chromotropic acid. They were of the opinion that a six-membered ring is formed and that iron is chelated between the two phenolic oxygens. The formation of manganese(II),

lead and copper chelates has also been described.[12] Mathur and Dey[2] had earlier reported the formation of a red-coloured chelate between uranium and chromotropic acid. Also, Ware[13] had earlier suggested the use of chromotropic acid for the colorimetric determination of uranium, but no details have been recorded. Mukerji and Dey[14,15] have, however, described in detail the colorimetric determination of uranium with this reagent and studied the interference of foreign ions. They also determined the composition of the chelate by conductometric methods and found it to be 1 : 1. Banerji and Dey[16] studied the uranium - chromotropic acid chelate and determined the composition, the stability, the formation constant and the free energy of formation of the chelate. This work confirmed the earlier views that a 1 : 1 chelate is formed; therefore, the following structure for the chelate was proposed:

Uranium - Chromotropic acid chelate

The chelation involved the phenolic oxygens, as had been suggested by the earlier workers.

In the course of these investigations, a detailed study was made of the reaction of chromotropic acid with different metal ions. Details of this are presented in Table I. It may be observed therein that the chromate ion develops a very beautiful red colour with chromotropic acid; this chelate was, therefore, investigated with regard to its composition, stability, formation constant and free energy of formation by the spectrophotometric method. The composition, as investigated by the conductometric method, has also been described.

## Experimental

**Materials.**—Potassium chromate of BDH Analar quality was dissolved in distilled water. A concentrated stock solution of 0.01 M was then prepared. Acid was added to prevent any possible hydrolysis. Standard solutions were prepared from this solution by dilution.

BDH reagent-grade disodium-1, 8-dihydroxy naphthalene-3, 6-disulphonate, commonly known as chromotropic acid (abbreviated as CAD), was used. A 0.01 M stock solution was prepared. Suitable standard solutions were prepared from this solution by dilution.

In all cases freshly-prepared solutions were used. Extremely dilute solutions were used for these studies so that the contraction in volume, if any, would be negligible.

The absorbance measurements were made on a Hilger Uvispek spectrophotometer using glass cells one centimeter thick. The individual solutions and mixtures were kept for 30 min. before absorbance measurements were made in order for them to attain equilibrium. All observations were made in the 2—3 pH range on a Phillips pH meter (GM 4494).

The composition of the chromate - chromotropic acid obtained from absorbance studies has also been investigated by adopting the conductometric method; the results thus obtained support those obtained by spectrophotometric methods. The electrical conductivity studies were made on a Serfass conductivity bridge.

**Optimum Conditions.**—The optimum conditions for the formation of the chelate were determined, and then these conditions were maintained throughout the studies.

**The Order of the Addition of Reagents.**—Studies were made of the addition of the chelating agent to the metal solution and vice versa. It was found that there was no change, whether the metal was added to the reagent and vice versa. To maintain uniformity, however, the chelating agent was added to the metal solution.

**The Effects of Time.**—Time effects were also studied; it was found that the chelate maintained its stability for more than twenty-four hours and, as such, was in keeping with the investigations here.

**Acid Added to Prevent Hydrolysis.**—Acid was added wherever neccessary to prevent hydrolysis.

**Colour Formation with Inorganic Ions.**—For studying the colorimetric reactions with various metal ions, a 0.05 M solution of chromotropic acid was prepared in distilled water. Solutions of various metallic salts using analytical-grade reagents was made of a 0.1 M concentration in distilled water, acid being added in several cases to prevent hydrolysis.

In several test tubes 1 ml. of solutions were placed; then two drops of the reagent solution were added to each and the colour noted visually. This colour was then compared with an equal amount of the reagent diluted to the same extent. The results have been recorded in Table I.

**The Nature of the Complexes Formed.**—The method described by Vosburg and Cooper[17] was employed to determine the nature of the complexes formed in solution. Mixtures containing different proportions of chromium - chromotropic acid (1 : 1, 1 : 2, 1 : 3, and 1 : 4) were prepared, and the absorbances of the solutions at different wavelenghts were measured. The exact compositions have been tabulated in Table II.

at 530 mμ, which also indicates that only one complex is formed under the conditions of study.

**The Stoichiometry of the Compounds.**—Job's[18] method of continuous variation has been adopted for the determination of the composition of the coloured complex formed. The total volume in each case was kept at 50 ml. The pH values of the solutions were kept between 2 and 3. The absorption spectra of the $Cr_2O_7$-chelating agent and the mixtures were measured at two different wavelengths, 500 and 530 mμ. Measurements using equimolecular and non-equimolecular solutions, in large numbers, were taken. The results obtained have been represented in Figs. 2—5.

The figures indicate the difference between the absorbance of the mixture and that which would

be shown by the metal and the chelating agent if no chelation took place. This difference is plotted against the composition of the mixtures.

**The Influence of pH on the Stability of the Chelate.**—A detailed study was made of the effect of pH on the absorption maxima of the chelate to find out its stability; it was observed that the chelate is stable in the pH range 1—6. The observations were, therefore, made between pH 2 and 3, in which range the chelate is stable. It was also ascertained beforehand that the reagent did not change colour in this range of pH.

**Conductivity Studies.**—Electric conductivity studies were made at six different equimolecular and non-equimolecular concentrations. The solutions used were always freshly prepared. The results have been graphically represented in Figs. 6 and 7.

## Conclusions

The composition of the chelate has been found to be 1 of the metal and 1 of the chelating agent, as may be seen from Table III, compiled from an examination of Figs. 2—5. The chelate can, therefore, be represented as Cr(CAD).

The results obtained from absorption measurement studies also receive confirmation from conductivity studies, as may be seen from Table IV.

For the purpose of determining the stability, calculations have been made of the formation constant from optical density data according to the method of calculation suggested by Dey[15] and worked out by Banerji and Dey[19-25] in several of their investigations. The method suggested by Dey has an advantage over the earlier method of Anderson et al.[26] wherein one of the reactants may be coloured.

By the above method the value of $\log K$ in the chromate-disodium-1,8-dihydroxy naphthalene-3,6-disulphonate systerm is $8.21 \pm 0.02$ at 25°C.

The free energy of the formation, $\Delta F^\circ$, of the chelate has been calculated with the help of the relation:

$$\Delta F^\circ = -RT\ln K$$

where $R$ is the gas constant, $T$ is the absolute temperature, and $K$ is the formation constant. The free energy of the chelate investigated here is:

$$-5.42\pm0.11 \text{ kcal. at } 25^\circ\text{C}$$

Judging from the results described here, the composition of the chelate corresponds to Cr(CAD).

## Summary

The formation of a coloured chelate with a $\lambda_{max}$ at 530 m$\mu$ between chromate ion and chromotropic acid (sodium salt)-disodium-1, 8-dihydroxy naphthalene-3, 6-disulphonate has been reported. The composition of the chelate has been studied by the method of continuous variation, using absorption spectra measurements, with a Hilger Uvispek spectrophotometer; it has been found to be Cr(CAD), (Disodium-1, 8-dihydroxy naphthalene-3, 6-disulphonate). The chelate has been found to be stable in the pH range 2—5 and so the investigations have been carried out in this range of pH. The chelate formed is deep red in colour and is very sensitive, being formed even at great dilutions.

The stability has been calculated by a method described earlier; the value of $\log K$ is $8.21\pm0.02$, and the value of the free energy of formation, $\Delta F^\circ$, has been found to be $-5.42\pm0.11$ at 25°C.

# Absorption Spectra of Dyes. IX.[1] Electronic Spectra of a 1 : 1 and a 1 : 2 Complex, and CT-Bands*

By Toshihiko Hoshi, Yoshié Tanizaki and Noboru Ando

(Received July 27, 1964)

Electronic absorption spectra are generally sensitive to the environment of the sample. In particular, the molecular complex formation brings about remarkable changes in the electronic absorption spectra of the component molecules. By applying the theory of charge transfer as developed by Mulliken[2] to electron donor and acceptor molecules, the authors have found that an intermolecular charge transfer spectrum is obtained from Chlorazol Sky Blue FF and Chrysophenine G in a complex state.[3] Moreover, by analogy with the known theoretical results, they have determined how the molecular orbitals of Chlorazol Sky Blue FF and Chrysophenine G are altered in the formation of a 1 : 1 and a 1 : 2 complex respectively. They have also assigned the actual electronic spectra of these dye complexes to empirical MO patterns, but they have not, however, discussed the relative configurations of the respective MO's in detail.

The purpose of the present investigation is to determine the absorption spectra of 1 : 1 and 1 : 2 complexes and, moreover, to explain the correlation between these electronic bands in terms of the more refined MO pattern derived from the complexes' spectra.

## Experimental and Results

The samples were the same as those used in a previous investigation.[1] The procedure already described[1] was followed in carrying out the experiments. A Shimadzu recording spectrophotometer SV-50A and, when necessary, a Shimadzu QR-50 spectrophotometer were employed in the determination of the absorption spectra at room temperature (about 20°C). The absorption cells used were 10 mm. and 2 mm. long, and the wavelength region observed was 220—700 mμ. Mixed solutions of two different concentrations were prepared, one containing $1\times10^{-5}$ mol./l. of a partner dye

(abbreviated as P) with an equal concentration of G (Chrysophenine G), and the other with the same concentration of P, together with from two to nine times the concentration of G.

The absorption spectra of the PG and the $PG_2$ species were determined by calculation, by applying, respectively, the equilibrium constants, $K_1$ and $K_2$ previously obtained[1] at 20°C, to the absorption spectra measured here. The results are illustrated in Figs. 1 and 2 respectively. In Fig. 1, the solid and the dotted

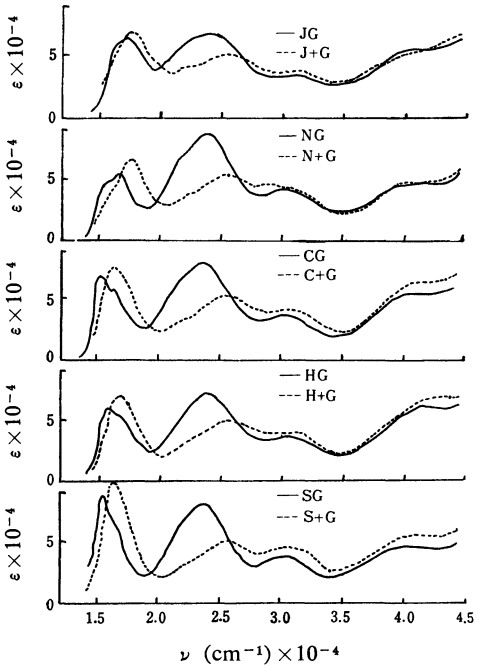

Fig. 1. Absorption spectra of a PG complex (solid lines) and the resultant ones of P and G (dotted lines).

lines indicate, respectively, the absorption curve of a 1 : 1 complex (PG) and the combined absorptions of P and G determined separately at an equimolar concentration. Similarly, the solid line in Fig. 2 indicates the absorption spectrum of a 1 : 2 complex ($PG_2$), while the dotted line represents the additive spectrum of the P curve and two times the height of the G curve.*

First of all, the following points may be noticed in Figs. 1 and 2. In the 16—18 kK (kK = 1000 $cm^{-1}$) region, the first band shifts progressively to the lower wave number,

* The absorption curves concerning $JG_2$ are not illustrated in Fig. 2. This is due to the fact that the quantity of a 1 : 2 complex ($JG_2$) could not be calculated with reliable presision at wave numbers higher than the second band on account of the smaller equilibrium constant ($K_2$).

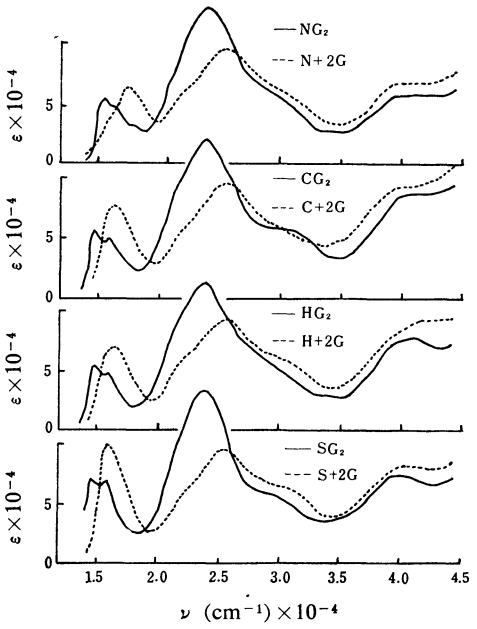

Fig. 2. Absorption spectra of a $PG_2$ complex (solid lines) and resultant ones of P and twice of G (dotted lines).

together with the decrease in intensity, with the formation of a 1 : 1 and a 1 : 2 complex, and, as the case may be, the main band is split into two bands. On the other hand, the second band (22.5 kK) is markedly intensifies by the formation of complexes. Moreover, the maximum point shift toward a much lower side with the 1 : 1 complex formation and then moves in the opposite direction to the higher side with the 1 : 2 complex formation (cf. Fig. 3). In the wave number-region higher than about 30 kK, the complex and the resultant spectrum are nearly the same in shape, but the intensities are somewhat smaller in the former than in the latter in most cases.

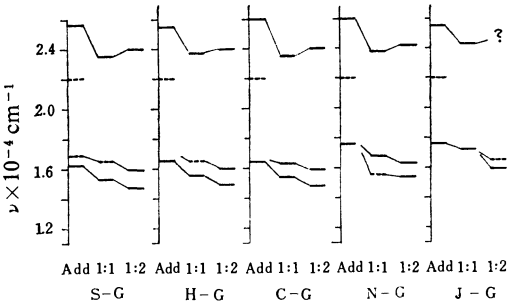

Fig. 3. Correlation of the transition energies (wave number) in the order of the additive (Add.), a PG (1 : 1) and a $PG_2$ complex (1 : 2) spectrum in the P-G system.

The most important fact in the above results is that the first and the second band behave differently. The transition energies (wave numbers) of those parts are illustrated in Fig. 3 in the order of the results of P and G, the PG complex and the $PG_2$ complex spectrum. The figure makes it apparent that in every combination the absorptions at about 16 kK shift down progressively to the low-wave number side as a result of the formation of complexes, while the absorption at about 25 kK shifts up after once falling down. Since the absorption at about 16 kK of the additive spectrum is the first band of P itself and since the 25.5 kK absorption is that of G alone, it may be considered that the variety of complex formations revealed by Fig. 3 has been brought about by interaction between the orbital states of the components in a complex.

## Discussion

The G molecule has two sulfonic groups at positions adjacent to the ethylene bond (see Fig. 4). The groups are so bulky that they may hinder the two monoazo dyes from the conjugation through the ethylene bond.[4] Therefore, the MO pattern which is responsible for the first band of G may be considered to be produced from the interaction (the weak coupling) between the MO's of the half structures (HS in Fig. 4) on the right side and on the left side of the ethylene bond. That is to say, the analogy with Platt's theory[5] leads to the relation shown in Fig. 4. Two pairs of HS levels in the same figure indicate the highest occupied ($\pi$) and the lowest unoccupied molecular orbitals ($\pi^*$). Applying the concept of the simple MO approximation, it can be said that the degenerate orbitals will split as a result of the interaction between two HS's, and that, in consequence the MO levels of FS (full structure) in Fig. 4 will be obtained; FS (i.e. the G molecule) can produce the electronic transitions $(\pi-\pi)\rightarrow(\pi^*+\pi^*)$ and $(\pi-\pi)\rightarrow(\pi^*-\pi^*)$. The actual first band of G is at 25.5 kK and is accompanied by a weak shoulder at about 22 kK.* Therefore, the main band of G may be assigned to the $(\pi-\pi)\rightarrow(\pi^*-\pi^*)$ transition and the shoulder to the $(\pi-\pi)\rightarrow(\pi^*+\pi^*)$. As most of the atoms constituting the conjugate system under consideration are carbon atoms, the location of the individual MO's may be determined without any large error by taking the Coulomb integral, Q, of the $\pi$ electron on the carbon atom as a standardized zero level. In the approximation, the $\pi^*$ and the $\pi$ levels, and also the $(\pi^*+\pi^*)$ and the $(\pi-\pi)$ levels, are arranged at equal distances above and below the Q line, as Fig. 4 shows.

For the sake of convenience, let $\pi_G$ and $\pi_G^*$ stand, respectively, for the $(\pi-\pi)$ and $(\pi^*-\pi^*)$ orbitals of G. The arrangement of $\pi_G$ and $\pi_G^*$ can be determined with respect to the Q line by utilizing the absorption data of G alone, because Q lies at the middle point between $\pi_G$ and $(\pi^*+\pi^*)$.

If the MO's of P could be determined for the Q level, the relative configuration of MO's of P and G could be decided. No such a situation as that in the case of G could, however, be found between the first band of P (disazo dye) and that of its half structure (monoazo dye). That is, for meta-Benzopurpurine, for example, the relation between the absorption specta of the half and the full structure is nearly the same as in the case of G, whereas in the case of ortho-Benzopurpurine, corresponding to P, the situation is quite different; here the first and the second band of the half structure change into an absorption delocalized over the full structure.[6] For that reason, let us suppose that the first

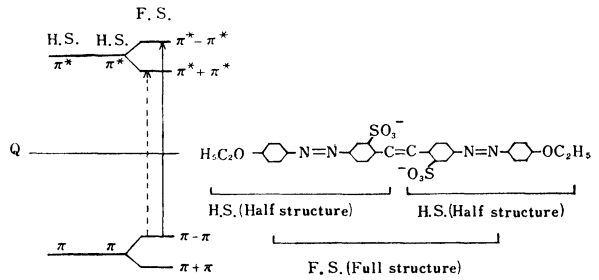

Fig. 4. Schematic MO pattern of the half (HS) and the full structure (FS) of Chrysophenine G.

4) Cf. T. Kobayashi, Y. Tanizaki and N. Ando, This Bulletin, 33, 913 (1960).
5) J. R. Platt, *J. Chem. Phys.*, 19, 101 (1951).

* This shoulder is indicated by the dotted line at 22kK in Fig. 3.
6) H. A. Standing and M. Stein, *J. Textile Inst.*, 44, T224 (1953).

band of P may be attributed to the transition between MO's which are uniformly delocalized, and let us further assume that the occupied and unoccupied MO's of P are arranged symmetrically about the same Q level as G, assuming that P has at least one symmetry species, as is seen in Fig. 1 of Part VIII.[1] Then the relative configuration of MO's concerning the first absorption bands of P and G can be decided by standardizing the Q level. Adopting S for P, the MO pattern labeled by G and S shown in the left part of Fig. 5 is obtained. Here, the Q line of S has been estimated from the maximum point of the first band corresponding to the $\pi_S \rightarrow \pi_S^*$ transition. As will be seen later, the first absorption of S (in general P) consists of two bands. One corresponds to the transition from the $\pi$-type orbital of the functional groups to the $\pi^*$ orbital, while the other corresponds to the $\pi \rightarrow \pi^*$ transition in the usual sense. In Fig. 5 the two MO's responsible for these transitions are both indicated by $\pi_S$.

According to Fig. 3, the wave number of the $\pi_S \rightarrow \pi_S^*$ transition of S (Fig. 5) shifts

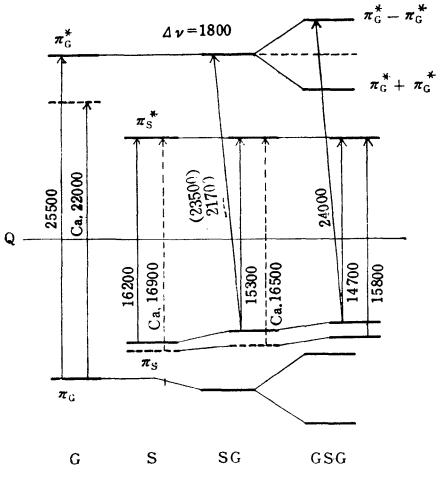

Fig. 5. Change in MO levels of S and G due to complex formations in the S-G system.

downward with the formation of a 1 : 1 complex. This implies that the complex formation has induced some interactions between MO's of G and S. In this case, the interaction should be strongest between $\pi_G$ and $\pi_S$ because the locations of $\pi_G^*$ and $\pi_S^*$ are so far apart that they cannot interact with each other. The interaction between $(\pi^* + \pi^*)$ and $\pi_S^*$ will be also neglected, because it is difficult to suppose any strong interaction between the transition vectors of $\pi_G^* \rightarrow (\pi^* + \pi^*)$ and $\pi_S \rightarrow \pi_S^*$, for the transition intensity of the former is much weaker than that of the latter. Consequently, the main interaction must be considered to be between $\pi_G$ and $\pi_S$, which are the nearest neighbors.

According to the assumption that the repulsive interaction is induced only between $\pi_G$ and $\pi_S$, the SG pattern will be obtained as shown in Fig. 5, in which the upper level of $\pi_S$ is adjusted so as to match the observed and the $\pi_S \rightarrow \pi_S^*$ distance. Figure 3 shows that the second band of the SG complex shifts also to the lower side in the same way as does the first band. However, we could not find any transition distance corresponding to the second band (23.5 kK) from the MO's of G in the SG pattern (Fig. 5). However, the distance between $\pi_S$ and $\pi_G^*$ is 21.7 kK, which corresponds well to the observed one, with a difference of only 1.8 kK. This means that a intermolecular charge transfer occurs from S to G.*

Quite similar correlation diagrams have been obtained for all other P's. The relation of the wave numbers of the $\pi_P \rightarrow \pi_G^*$ transition, as estimated by the same procedure as above, to those of the experiment is summarized in Table I. In all cases, the experimental values are larger than the estimated ones. This may be due to the assumption that the repulsion acts only between $\pi_G$ and $\pi_S$. If, for example, a small interaction between $\pi_G^*$ and $\pi_S^*$ is taken into account, the value to be estimated will become larger in some degree. At any rate, the results shown in Table I support the concept of the charge transfer.

Table I. Comparison of observed and estimated value of the P→G CT-band

| P | Charge transfer band | | |
|---|---|---|---|
| | $\nu_{obs}$ kK | $\nu_{est}$ kK | $\nu_{obs} - \nu_{est}$ |
| S | 23.5 | 21.7 | 1.8 |
| H | 23.7 | 21.7 | 2.0 |
| C | 23.5 | 21.7 | 1.8 |
| N | 23.8 | 21.2 | 2.6 |
| J | 24.3 | 22.9 | 1.4 |

(kK = 1000 $cm^{-1}$)

**Electronic Spectra of the $PG_2$ Complex.**—As may be seen in the explanation of Fig. 3, the first band of a $PG_2$ complex shifts further to the lower side than that of a PG complex, whereas the second band of the former moves in the opposite direction, to the higher wave number than that of the latter. A detailed interpretation of the behavior of the second band will be omitted at this time because the authors' previous explanation[3] can be applied here without any modification.

* According to Ref. 3, the charge transfer takes place from S (electron donor) to G (acceptor).

There is, however, one more subject to be noticed. As has been described in a preceding paper,[1] it is considered that all the partner dyes (P) take a similar sterical configuration in the complex state. If this is true, the degree of interaction between the two G molecules in the GPG (1 : 2) complex state should be constant, regardless of P. That is to say, the distance between the levels of ($\pi_G - \pi_G^*$) and ($\pi_G + \pi_G^*$) in Fig. 5 must be equal in all cases. The estimation* provides 5.8 kK for the cases when P is S, H and C, and 6.2 kK when P is N. The expectation, therefore, may be said to be satisfied.

**First Absorption Bands of Benzidine Disazo Dyes.**—It has been well known as a general tendency that the first band of a benzidine disazo dye reveals one shoulder or other in the dyed state, even when it has a single band with a simple shape in an aqueous solution. A similar tendency appears for the variation in solvent polarity. The constitution of the first absorption band has been described in a preceding paragraph. One is the electronic transition between the molecular orbitals delocalized over the two terminal naphthalene rings, while the other appears on account of the transition of a $\pi$-type lone-paired electron.[7] This is a kind of $n \rightarrow \pi^*$ transition and is called the $l \rightarrow \pi^*$ transition.[8]

The electron which transfers from P to G is the lone-paired electron of the $\pi$-type on the functional groups.[3] Therefore, the transition probability of this electron within the P molecule in the complex state should be decreased, that is, the absorption intensity of the $l \rightarrow \pi_S^*$ transition should be decreased. Indeed, the $l \rightarrow \pi^*$ intensities of C, CG and $CG_2$, for example, decrease in this order (see Figs. 1 and 2). A similar tendency is found in all other cases but the N, NG and $NG_2$ series, which is considered at present to be an exceptional case. In this case, the locations of the two sub-bands to be split may be in a reverse order relative to the other cases. The fact just mentioned makes necessary a consideration of the charge transfer. Consequently, the low wave number band can be assigned to the $l \rightarrow \pi^*$ transition, and the high one, to the $\pi \rightarrow \pi^*$ transition.

## Summary

1) The absorption spectra of binary mixtures of Chrysophenine G (notation: G) and disazo dyes (P), which were the same as those used in a preceding study,[1] have been measured at room temperature (ca. 20°C), and the characteristic spectra of the complexes have been determined by using the equilibrium constants, $K_1$ and $K_2$, previously obtained (at 20°C)[1] for the 1 : 1 (PG) and 1 : 2 ($PG_2$) complex formation.

2) The absorption spectra of the PG and $PG_2$ complex have been compared with the respective corresponding additive spectra (P+G and P+2G), and the correlations among these spectra have been discussed in detail.

3) The MO pattern of the G molecule has been decided empirically by applying Platt's theory; similarly, that of the P molecule has been decided by assuming that there is at least one symmetry species; then the spectral change caused by the complex formation could be explained in relation to the MO's of the component molecules.

4) It has been confirmed that there exists an intermolecular charge transfer from P as an electron donor to G as an acceptor. It has also been shown that the first band of a disazo dye (P) consists of two electronic transitions; one is a $\pi \rightarrow \pi^*$ (shorter wavelength) and the other an $l \rightarrow \pi^*$ transition (longer wavelength).

# A Spectrophotometric Study of Xylenol Orange as a Color Reagent for Beryllium

By Makoto OTOMO*

(Received August 1, 1964)

Xylenol orange reacts with many metal cations in a weakly or a slightly acid medium to form red or reddish-violet complexes, and it has widely been used as a metal indicator in complexometric titrations. This dye also reacts with beryllium ions to give a red coloration. The reaction is applied to the spectrophotometric determination of trace amounts of beryllium. The purpose of this study is to find the optimum conditions under which up to 6 $\mu$g. of beryllium can be determined, to ascertain the effect of diverse ions on the determination, and to determine the composition of the complexes formed. It will also be found that xylenol orange is a better color reagent for beryllium than eriochrome cyanine R[1] and 2-phenoxyquinizarin3, 4-disulfonic acid[2].

## Experimental

**Standard Beryllium Solution.** — A solution of beryllium perchlorate was prepared by dissolving the beryllium hydroxide, freshly precipitated from a beryllium sulfate solution in the presence of ethylenediaminetetraacetic acid (EDTA), which served as a masking agent for contaminating metal ions, in perchlorc acid (0.2 N in excess). The beryllium content was determined gravimetrically as oxide.

**Buffer Solution.**—A hexamethylenetetramine - perchloric acid mixture was prepared by dissolving about 4 g. of hexamethylenetetramine in 100 ml. of water and by adding a perchloric acid solution in order to bring the pH to a desired value.

The other reagents and apparatus used were the same as those reported on previously.[3] All experiments were carried out at 25±0.5°C.

**Standard Procedure for the Beryllium Determination.**—An aliquot of the standard beryllium solution was introduced into a 25 ml. volumetric flask. Ten milliliters of a pH 5.8 buffer, 2.5 ml. of a $1\times10^{-3}$ M xylenol orange solution and then a small amount of water were added to adjust the volume. After having been mixed, the solution was allowed to stand for about 30 min. The absorbance of the solution was measured against a reagent blank treated in a similar manner.

## Results

**Absorption Curves.**—When a buffered, aqueous solution of beryllium is mixed with a xylenol orange solution, a red complex is immediately formed. Figure 1 shows the absorption curves of xylenol orange and its beryllium

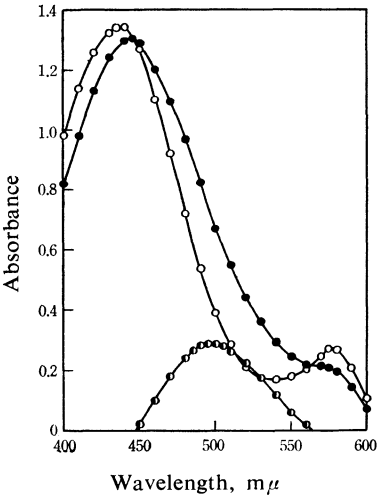

Fig. 1. Absorption curves of xylenol orange and its beryllium complex at pH 5.8.

—●— Be-XO + XO vs. water
—◐— Be-XO + XO vs. a reagent blank

complex. The absorption curve of the beryllium complex obtained with a reagent blank as reference has an absorption maximum at about 495 m$\mu$.

**The Effect of pH and Choice of Buffer.** — The pH is very important because the reagent functions as an acid-base indicator. The effect of pH on the color development of the complex was investigated by measuring the absorbance of mixtures containing 4.5 $\mu$g. (0.5 $\mu$mol.) of beryllium and 2.5 $\mu$mol. of the reagent at different pH values; the results are shown in Fig. 2, from which it can be seen that the optimum pH range for analytical purposes lies between 5.6 and 6.2. The buffer system, hexamethylenetetramine - perchloric acid, has a great

buffering capacity in the pH range from 4 to 7. The amount of the buffer had no effect on the color intensity of the complex provided that more than 3 ml. of the said solution was used. For the sake of comparison, an acetate buffer was also used, but the observed absorbance was always lower than that obtained with the hexamethylenetetramine - perchloric acid buffer.

**The Effect of the Amount of Xylenol Orange.**—Two series of colored solutions were prepared; one contained 4.5 μg. of beryllium, and the other, 9.0 μg. of beryllium. The results are shown in Fig. 3. For both series, about

a 4-fold excess of the reagent over the beryllium concentration is necessary in order to obtain the maximum color intensity. As a compromise between sensitivity and absorbance by the blank solution, 2.5 ml. of a $1\times10^{-3}$ M reagent solution was employed.

**The Color Stability.**—The red color of the complex develops immediately at room temperature, and its intensity is independent of the temperature, at least up to 80°C. The complex is very stable, and there was no change in absorbance over a period of 24 hr.

**Adherence to Beer's Law.**—The color system obeys Beer's law over the concentration range up to 0.63 μmol. (about 6 μg.) of beryllium.

**Sensitivity.**—The sensitivity of the reaction as expressed by Sandell's notation[4] is 0.0006 μg. of beryllium per $cm^2$.

**The Effect of Anions and Complexing Agents.**—The influence of various anions and some complexing agents was examined. These materials were added individually to solution containing 4.5 μg. of beryllium. The results are summarized in Table I. Chloride, nitrate and sulfate ions do not interfere, even at a high concentration. Phosphate and oxalate ions at lower concentration have no effect, either; however, these ions give negative errors at higher concentrations. Fluoride and citrate ions bleach the color of the complex, even when less than 1 μmol. is present. Nitrilotriacetic acid (NTA) and EDTA, which form stable complexes with many other metal ions to decompose the corresponding xylenol orange complexes, have almost no influence on the complex formation between beryllium and xylenol orange unless large amounts are added.

4) E. B. Sandell, "The Colorimetric Determination of Traces of Metals," Interscience Publishers, New York (1950), p. 49.

Therefore, NTA and EDTA can serve as excellent masking agents to prevent the interference of other heavy metals. The latter has been used as a masking agent in several methods of beryllium determination,[5-8] and recently Owens and Yoe[2] used the Calcium-EDTA complex as a sequestering agent in the spectrophotometric determination of beryllium.

**The Effect of Cations.**—Xylenol orange is a selective reagent for certain cations when it is used in a relatively strong acid medium. However, in a slightly acid or a neutral medium it reacts with many metal cations to give red or reddish-violet complexes, indicating that a suitable masking agent must be used to increase the selectivity. Disodium salt of EDTA was chosen for this reason. Most common bivalent metal cations except cobalt can be effectively masked by EDTA, as Table II shows. Many ter- and quadrivalent cations, including aluminum, bismuth, thorium and zirconium, however, disturb the estimation.

## Complex Formation

First, attempts were made to characterize the beryllium - xylenol orange complex by two methods, the method of continuous variations and the mole ratio method. These attempts were performed at various pH values between 5.0 and 7.0, while the absorbance measurements were made at seven wavelengths between 440 and 520 m$\mu$. Both methods revealed that beryllium forms chiefly a 1 to 1 complex with xylenol orange at a pH below 5.0; it gives, however, a mixture of 1 to 1 and 1 to 2 complexes at higher pH values. The results were further supported by the following experiments.

**The Formation of the 1 to 1 Complex.**—A method which had been described by Newman and Hume[9] was applied to the complex formed at relatively lower pH values. If $Be_n(XO)$ is the only beryllium complex in a detectable concentration in solutions containing beryllium and xylenol orange, the apparent formation constant at a given pH value, $(K_1')_H$, may be defined as:

$$(K_1')_H=[Be_n(XO)]/[Be]^n[XO] \quad (1)$$

where [XO] represents the molar concentration of the free xylenol orange at equilibrium. The absorbance of a solution containing the complex and the free xylenol orange is:

$$D=[Be_n(XO)]\varepsilon_{C_1}+([XO]_t-[Be_n(XO)])(\varepsilon_{XO})_H \quad (2)$$

where $\varepsilon_{C_1}$ is the molar extinction coefficient of the complex; $(\varepsilon_{XO})_H$ is the apparent molar extiction coefficient of xylenol orange at a given pH value, and $[XO]_t$ is the total molar concentration of xylenol orange. The concentration of the complex, beryllium and xylenol orange at equilibrium are expressed, respectively, as:

$$[Be_n(XO)]=(D-[XO]_t(\varepsilon_{XO})_H)/(\varepsilon_{C_1}-(\varepsilon_{XO})_H) \quad (3)$$

$$[Be]=[Be]_t-n(D-[XO]_t(\varepsilon_{XO})_H)/(\varepsilon_{C_1}-(\varepsilon_{XO})_H) \quad (4)$$

and

$$[XO]=[XO]_t-(D-[XO]_t(\varepsilon_{XO})_H)/(\varepsilon_{C_1}-(\varepsilon_{XO})_H) \quad (5)$$

By introducing Eqs. 3, 4 and 5 into Eq. 1 and by taking logarithms, Eq. 6 is derived:

$$\log\{(D-D_{XO})/(D_C-D)\}=\log(K_1')_H+n\log\{[Be]_t-n(D-D_{XO})/(\varepsilon_{C_1}-(\varepsilon_{XO})_H)\} \quad (6)$$

where $D_{XO}$ is the absorbance of the total xylenol orange and $D_C$ is the absorbance of a solution containing a large excess of beryllium ions and the given amount of xylenol orange.

The experimental values of $\log\{(D-D_{XO})/(D_C-D)\}$ are plotted against the values of $\log\{[Be]_t-n(D-D_{XO})/(\varepsilon_{C_1}-(\varepsilon_{XO})_H)\}$ at pH 4.5 for five wavelengths between 480 and 510 m$\mu$. When the value of $n$ was assumed to be unity, the plots gave straight lines with a slope of 1.08 (on the average), as may be seen from Fig. 4. When other values, e. g., one-half, two,

8) P. W. West and P. R. Mohilner, ibid., **34**, 558 (1962).
9) L. Newman and D. N. Hume, *J. Am. Chem. Soc.*, **79**, 4571 (1957).

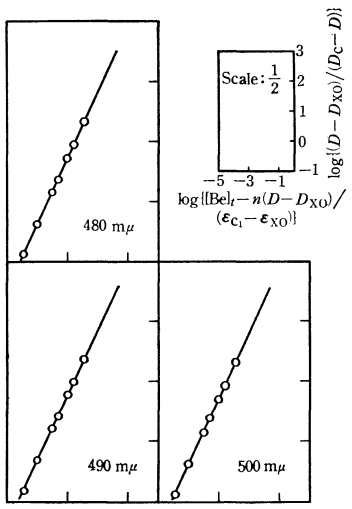

Fig. 4. Plots of $\log\{(D-D_{XO})/(D_C-D)\}$ vs. $\log\{[Be]_t-n(D-D_{XO})/(\varepsilon_{C_1}-\varepsilon_{XO})\}$.
$[XO]_t$: $4.0\times10^{-5}$ M, pH: 4.5
$\mu$: 0.10($NaClO_4$), Reference: water

etc., were assumed for $n$, however, no straight lines with slopes of the assumed values were obtained. Therefore, it may be concluded that the beryllium - xylenol orange complex formed at the investigated pH value has a molar ratio of 1 to 1. As is shown by Eq. 6, the intercept of the straight line should give the value of $\log(K_1')_H$ at pH 4.5. The values of $\varepsilon_{C_1}$, $n$ and $\log(K_1')_H$ obtained are summarized in Table III.

TABLE III. VALUES OF $\varepsilon_{C_1}$, $n$ AND $\log(K_1')_H$ AT pH 4.5

| | Wavelength, mμ | | |
|---|---|---|---|
| | 480 | 490 | 500 |
| $\varepsilon_{C_1}$ | 12550 | 12050 | 11130 |
| $n$ | 1.10 | 1.06 | 1.08 |
| $\log(K_1')_H$ | 4.00 | 3.91 | 3.92 |

**The Formation of a Mixture of 1 to 1 and 1 to 2 Complexes.**—To determine the composition of the complex formed in a higher pH region, the presence of a mixture of 1 to 1 and 1 to 2 complexes was assumed and a method described by McConnell and Davidson[10] was applied. If the total concentration of xylenol orange is high enough compared with that of beryllium and if the pH value of the solution is kept constant, the successive apparent formation constants at given pH values, $(K_1')_H$ and $(K_2')_H$, may be written, respectively, as:

$$(K_1')_H=[Be(XO)]/([Be]_t-[Be(XO)_n])[XO]_t \quad (7)$$

$$(K_2')_H=[Be(XO)_n]/[Be(XO)][XO]_t^{n-1} \quad (8)$$

If the absorbance of the solution is measured against a solution containing the same amount of free xylenol orange as that added to beryllium, it may be given by:

$$D=[Be(XO)](\varepsilon_{C_1}-(\varepsilon_{XO})_H)+[Be(XO)_n](\varepsilon_{C_2}-n(\varepsilon_{XO})_H) \quad (9)$$

where $\varepsilon_{C_1}$ and $\varepsilon_{C_2}$ are the molar extinction coefficient of Be(XO) and $Be(XO)_n$ respectively, and where $(\varepsilon_{XO})_H$ is the apparent molar extinction coefficient of xylenol orange at a given pH value. From Eqs. 7, 8 and 9, the following relationship may be derived:

$$[Be]_t/D=1/(\varepsilon_{C_2}-n(\varepsilon_{XO})_H)+F/(\varepsilon_{C_2}-n(\varepsilon_{XO})_H)(K_1')_H(K_2')_H[XO]_t^n \quad (10)$$

$$F=1+(K_1')_H[XO]_t-(K_1')_H[Be]_t[XO]_t(\varepsilon_{C_1}-(\varepsilon_{XO})_H)/D$$

The experiments were carried out in the concentration range, $[XO]_t=0.89\times10^{-4}$—$3.57\times10^{-4}$ M, the pH value being held constant at 5.30 and the ionic strength being held constant at 0.1. Although the total concentration of xylenol orange was not sufficiently large compared with that of beryllium ($1.996\times10^{-5}$ M), it is assumed, for the first approximation, that the equilibrium concentration of xylenol orange nearly equals the total concentration. The graphical analysis was done at three wavelengths, 480, 490 and 500 mμ, using the value of $(K_1')_H$ at pH 5.30 ($1.60\times10^6$), a value which was obtained according to the method described by Buděšinský,[11] and the calculated values of $(\varepsilon_{C_1}-(\varepsilon_{XO})_H)$. Although good straight lines were not obtained, the values of $(K_2')_H$ at pH 5.30 at the three wavelengths were estimated from the slopes as $7.3\times10^3$, $5.6\times10^3$ and $5.5\times10^3$ respectively. Therefore, for the second approximation to the solution of Eq. 10, the deviation between the total concentration of xylenol orange was calculated using the first approximation for $(K_2')_H$. The correction is small at relatively higher concentrations of xylenol orange, but a large correction (about 30%) was required at the lowest concentration of xylenol orange. The corrected values of the total concentration of xylenol orange were then used, and the linear character of the plots of $[Be]_t/D$ vs. $F/[XO]_t^n$ was examined. Figure 5 shows the results obtained when the value of $n$ equals two, indicating that the plots are good straight lines within the range of experimental error. The third approximation was further applied. However, it was

10) H. McConnell and N. Davidson, ibid., 72, 3164 (1950).

11) B. Buděšinský, *Collection Czechoslov. Chem. Commun.*, 27, 226 (1962).

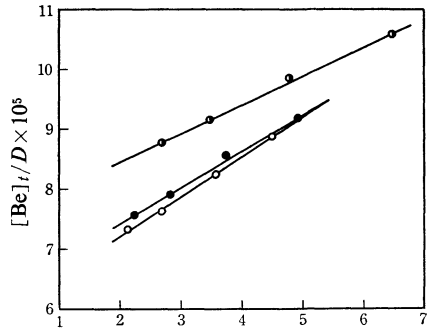

Fig. 5. Plots of $[Be]_t/D$ vs. $F/([XO]_t-[Be(XO)]-2[Be(XO)_2])^2$.

$[Be]_t$: $1.966\times10^{-5}$ M, pH: 5.3

Wavelength: —◑— 480 m$\mu$, —●— 490 m$\mu$
—○— 500 m$\mu$

found that there is little difference between the second and third approximations.

Finally, the concentrations of the 1 to 1 and the 1 to 2 complexes were calculated at pH 5.8 and at varying concentrations of xylenol orange, using the following relationships, which can easily be obtained by solving Eqs. 7 and 8:

$$[Be(XO)]=(K_1')_H[Be]_t[XO]_t/(1+(K_1')_H[XO]_t+(K_1')_H(K_2')_H[XO]_t^2) \quad (11)$$

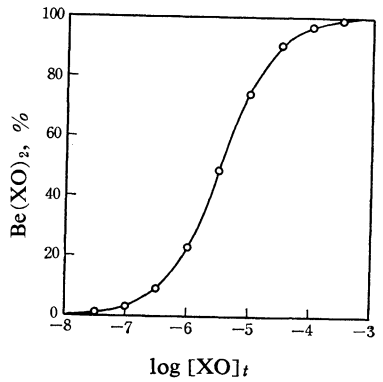

Fig. 6. Percentage occupied by $Be(XO)_2$ in a mixture of Be(XO) and $Be(XO)_2$ at pH 5.8.

Be: $2.0\times10^{-5}$ M

$$[Be(XO)_2]=(K_1')_H(K_2')_H[Be]_t[XO]_t^2/(1+(K_1')_H[XO]_t^2+(K_1')_H(K_2')_H[XO]_t^2) \quad (12)$$

The percentage occupied by the 1 to 2 complex in a mixture of the 1 to 1 and 1 to 2 complexes was calculated as a function of the concentration of xylenol orange. The curve in Fig. 6 was obtained when the total molar concentration of beryllium was constant as $2.0\times10^{-5}$ M. The reciprocal of the value of log $[XO]_t$ at the intercept of the 50% line with the curve should give the value of log $(K_2')_H$ at pH 5.8. The pH value of 5.8 was chosen because the determination of beryllium was performed at this pH value.

## Summary

The red color produced by adding a xylenol orange solution in excess to a beryllium solution has been studied spectrophotometrically in order to ascertain the optimum conditions for the determination of beryllium. The absorption curve of the colored system shows an absorption maximum at 495 m$\mu$ when measured against a reagent solution of pH 5.8. Beer's law is obeyed over the range up to 6 $\mu$g. of beryllium. The composition and the apparent formation constant of the two different complexes have then been obtained by applying some spectrophotometric techniques. Beryllium forms a 1 to 1 complex with xylenol orange below pH 5; it gives, however, mixture of 1 to 1 and 1 to 2 complexes at higher pH values.

The author wishes to thank Professor Kôichi Tonosaki for his kind guidance and encouragement throughout the course of this study and Mr. Hiroshi Osanai for his assistance. Thanks are also due to Professor Yoshinaga Oka of the Faculty of Science, Tohoku University, for his valuable advice.

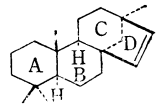
# The Structure of Hibaene[1]

By Yoshio KITAHARA and Akira YOSHIKOSHI



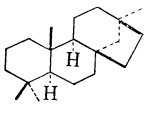
(Received August 3, 1964)

Dolabradiene, a diterpene isolated from the essential oil of the leaves of Hiba (*Thujopsis dolabrata* Sieb. et Zucc.) has been shown[2] by the present authors to have structure I.

A purification by gas liquid chromatography of the fraction of the above oil with a b. p. of 162—167° C/7 mmHg gave a new crystalline diterpene named hibaene. On the basis of the experimental data which will be described below, we could determine the absolute configuration of hibaene to be II.

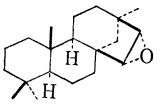
I

II



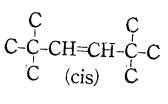
Hibaene is a crystalline compound with a melting point of 30°C; $[\alpha]_D^{23}$ −49.9°; the mass spectrum[3] of hibaene showed a molecular weight of 272. The relative abundance of the parent peak (P) and the (P+1) peak indicated the molecular formula $C_{20}H_{32}$, which was also supported by its elemental analysis.

The infrared absorption spectrum of hibaene indicated the presence of a geminal dimethyl group (1385, 1363 $cm^{-1}$) and *cis*-1,2-disubstituted ethylene (750 $cm^{-1}$). When hibaene was hydrogenated catalytically, it absorbed one molar equivalent of hydrogen, thus yielding a saturated hydrocarbon, dihydrohibaene (III). Oxidation of hibaene by peracid afforded monoepoxide (IV). From these facts, it was assumed that hibaene possesses one double bond; therefore, it must be a tetracyclic diterpene. The nuclear magnetic resonance spectrum of hibaene displays the signals (9.27, 9.19, 9.15, 9.03 $\tau$, all singlet)[4] of four methyl groups bonded on quarternary carbon atoms and the typical AB type signals of olefinic protons (4.39, 4.64 $\tau$, $J$=6 c.p.s., two protons). Accordingly, the double bond was attached to carbon which bears no proton, and the partial sturcture V was deduced.

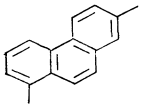


Since these physical constants were different from those of the diterpenes reported hitherto, hibaene was supposed to be a new diterpene.

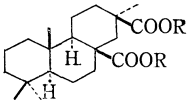
The dehydrogenation of hibaene by selenium gave pimanthrene (VI), and the oxidation of hibaene using permanganate yielded a dicarboxylic acid (VII) without loss of the carbons. VI was also obtained by the dehydrogenation of VII using selenium. The above facts indicate that three rings out of the four rings of hibaene form a perhydrophenanthrene ring system and that the double bond is contained in the remaining ring (ring D).



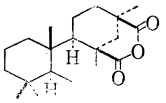
When VII was heated above 220°C or was treated with acetic anhydride, an anhydride (IX) was easily obtained. From the infrared absorption spectrum of IX, this was assumed to be a strainless cyclic anhydride (of the glutaric anhydride type). IX was stable when heated at 300°C and was recovered. The dimethyl ester (VIII) of VII did not undergo hydrolysis with diluted potassium hydroxide; therefore, both of the ester groups are considered to be linked with quarternary carbon. This fact also supports the partial structure V deduced from the nuclear magnetic resonance spectrum of hibaene mentioned before.



III



IV



V

VI

VII R=H
VIII R=Me

IX

In view of the experimental facts described so far and from a consideration of the biogenesis[5] of hibaene (Scheme 1), the structure of hibaene is presumed to be II (or its enantiomer).

As was reported earlier, the shifts of methyl group signals observed between II and III in the nuclear magnetic resonance spectra, and those observed between isophyllocladene (X)

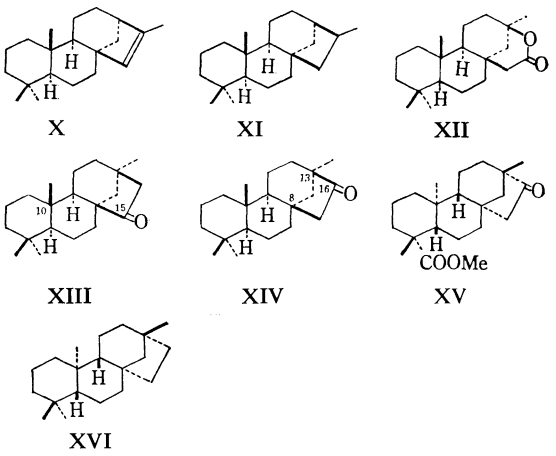
Scheme 1

and phyllocladane (XI), are parallel.[4] This also supports the theory that hibaene has structure II or its enantiomer.

Further proof for the stereochemistry was obtained as follows.

The hydroboration of II, followed by oxidation with dichromate and chromatographical separation on alumina, gave two isomeric ketones. The infrared adsorption spectrum of the polar ketone showed a band (1736 $cm^{-}$) which can be assigned to a five-membered-ring ketone. The ketone reacted with carbonyl reagents to give the corresponding derivatives and underwent oxidation by perbenzoic acid to afford a lactone (XII). On the other hand, the carbonyl band of the less polar ketone shifts to a longer wavelength region (1727 $cm^{-1}$) compared with that of the former ketone. The less polar ketone did not react with carbonyl reagents or perbenzoic acid, and the starting material was recovered.

The abnormality of the carbonyl group of the less polar ketone is considered to be due to the steric interference. Consideration using the molecular model of hibaene gave us the following information. Supposing that hibaene is a *trans-anit-trans* perhydrophenanthrene derivative, the methyl group at C-10 is cis to the D ring. Besides, when the carbonyl group is present at C-15, the carbonyl group is considerably hindered by the methyl group at C-10. Accordingly, it is assumed that the less polar ketone and the polar one are XIII and XIV respectively, or their enantiomers.



Because the optical rotatory dispersion curve of XIV shows a positive Cotton effect and is antiopodal with that of isosteviol[6] (XV), the absolute configuration of the D ring of XIV is $\beta$ (Fig. 1).

From the afore-mentioned results, out of the five asymmetric centers of hibaene the absolute configurations of C-13 and C-8 became clear; the others were proved as follows.

If the absolute configuration of hibaene is shown by II, dihydrohibaene (III) must be an enantiomer of isostevane[7] (XVI). The infrared absorption spectra of the two compounds, III and XVI, are superimposable, but a mixed melting point determination showed an apparent depression. The optical rotatory dispersion curves of both compounds show plane curves with a value of almost 0°.[8]

On the basis of the various results described hitherto, the absolute configuration of hibaene was definitely proved to be II.

Recently, the fact that hibaene is identical with cupressene[9] and enantiomeric with stachene[10] has been established.[11]

*dolabrata*) by steam distillation was washed with a diluted sodium hydroxide aqueous solution, dried over anhydrous magnesium sulfate, and fractionally distilled using a spinning band column, the theoretical plate of which was around sixty. The fraction with a b. p. of 162—167°C/7mmHg was obtained in a yield of approximately 5% of the original oil. The gas liquid chromatography (20% DC Silicon oil-Hitachi Carrier. 3 m.; column temperature 235 °C; flowing rate of helium gas 50 ml./min.) of the above fraction indicated that the oil contained a small amount of dolabradiene besides hibaene (retention time 12 min.). By the purification using preparative gas liquid chromatography under the same conditions as the above preliminary chromatography, hibaene was crystallized.

The hibaene fraction obtained from the fractional distillation was cooled to around −50°C; then the crystalline hibaene was added. Most of the liquid hibaene became a crystalline mass, which was then filtered under cooling, recrystallized from ethyl acetate at around −60°C, and further recrystallized from ethanol, thus affording hibaene (II), m. p. 29.5—30.5°C, $[\alpha]_D^{23}$ −49.9° (*c* 0.1, chloroform), molecular weight 272 (mass spectrum).

Found: C, 88.45; H, 11.89. Calcd. for $C_{20}H_{32}$: C, 88.16; H, 11.84%.

IR (KBr disk): 1385, 1363 (*gem.* dimethyl), 750 $cm^{-1}$ (*cis* 1, 2-disubstituted ethylene). NMR (10% carbon tetrachloride solution): 9.27, 9.19, 9.15, 9.03 (singlets, 3 protons each), 4.39, 4.64 $\tau$ (quartet, $J$=6 c.p.s., 2 protons).

**Dihydrohibaene (III).**—When a solution of 0.54 g. of II in 10 ml. of ethyl acetate was submitted to catalytic hydrogenation in the presence of 50 mg. of 10% palladium-charcoal under atomospheric pressure and at room temperature, 0.98 molar equivalent of hydrogen was rapidly absorbed. After the catalyst and the solvent had been removed, the residue was recrystallized from ethanol, yielding colorless plates, m. p. 41.5—42.5°C.

Found: C, 87.83; H, 12.53. Calcd. for $C_{20}H_{34}$: C, 87.51; H, 12.49%.

$[\alpha]_{300-700m\mu}=0°$ (*c* 0.6, dioxane).[13] IR (carbon disulfide solution) was entirely superimposable on that of isostevane, but the melting point of III was depressed below room temperature on admixture with isostevane.

**Monoepoxide (IV) of Hibaene.**—A solution of 0.5 g. of hibaene in 3.6 ml. of chloroform containing 0.28 g. of perbenzoic acid was allowed to stand at 0°C for one day. After ether had been added to the solution, it was washed with a 2% sodium hydroxide aqueous solution and then with water, and dried over anhydrous magnesium sulfate. The removal of the solvent gave a semisolid substance, which was purified by submitting it to alumina column chromatography using 20 g. of alumina and benzene - petroleum ether (1 : 1) as eluting solvent; thus 0.53 g. of crystals, m. p. 63—70°C, were afforded. Recrystallization from acetone gave colorless prisms, m. p. 70—71°C.

12) All melting points are uncorrected. The authors wish to express their thanks to Misses Yoko Endo and Yukiko Endo of this Institute for their microanalyses.

13) Isostevane, m. p. 41.5—43.5°C; $[\alpha]_{300-700m\mu}=0°$ (*c* 0.6, dioxane).

Found: C, 83.46; H, 10.85. Calcd. for $C_{20}H_{32}$: C, 83.27; H, 11.18%.

**The Dehydrogenation of Hibaene by Selenium.**—A mixture of 1.5 g. of hibaene and 3.0 g. of selenium was heated at 320—340°C for 43 hr. The reaction mixture was extracted with ether, and the extract was washed with a 10% potassium hydroxide aqueous solution and then with water, and dried over magnesium sulfate. The removal of the ether yielded 1.38 g. of oil, which was chromatographed on alumina (40 g. of alumina was used). From a petroluem ether - benzene (1 : 1) effluent, 0.45 g. of crystals were obtained; they were recrystallized from ethanol to give colorless leaflets, m. p. 83—84°C. This compound was proved to be pimanthrene[14] by mixed melting point determination and from a comparison of their infrared absorption spectra.

**Dicarboxylic Acid (VII).**—To a solution of 4.9 g. of hibaene in 100 ml. of acetone, 7.5 g. of powdered potassium permanganate was added in portions over a period of 70 min. while the solution was maintained at 30—35°C. After the mixture had been stirred for an additional 90 min. at the same temperature, 30 ml. of water was added. The manganese dioxide formed was reduced by sulfur dioxide gas. The acetone was removed under reduced pressure, and the residue was acidified with diluted hydrochloric acid and extracted with ether. The ether solution was then extracted with a sodium carbonate aqueous solution. The acidification of the sodium carbonate extract yielded 4.17 g. of crystalline dicarboxylic acid, m. p. 240—250°C. Recrystallization from aqueous ethanol gave colorless needles, m. p. 251—253°C (dehydrated around 220°C and thus converted to anhydride).

Found: C, 71.57; H, 9.60. Calcd. for $C_{20}H_{32}O_4$: C, 71.39; H, 9.59%.

IR (KBr disk): ~2600, 1710 $cm^{-1}$ (broad) (carboxyl).

**The Dehydrogenation of Dicarboxylic Acid (VII) by Selenium.**—A mixture of 2.0 g. of dicarboxylic acid and 4.0 g. of selenium was heated at 320—340 °C for 40 hr. The reaction mixture was extracted with ether, and the extract was washed with a 10% potassium hydroxide aqueous solution and water, dried over anhydrous magnesium sulfate, and distilled to yield 1.29 g. of a semisolid sudstance. This was purified by alumina column chromatography using 50 g. of alumina and petroleum ether - benzene (1 : 1) as the solvent, to give 0.41 g. of crystals. Recrystallization from ethanol gave colorless leaflets, m. p. 83—84°C, which were proved to be pimanthrene[14] by a mixed melting point determination and a comparison of their infrared absorption spectra.

**Anhydride (IX).**—After a mixture of 0.56 g. of dicarboxylic acid (VII) and 4 ml. of acetic anhydride had been refluxed for 1 hr., the excess acetic anhydride and acetic acid was distilled off under reduced pressure to yield 0.55 g. of a crystalline compound, m. p. 250—252°C. This was recrystallized from acetone to afford colorless needles, m. p. 253—254°C.

14) R. D. Haworth, B. M. Letsky and C. R. Mavin, *J. Chem. Soc.*, **1932**, 1789.

Found: C, 75.66; H, 9.71. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50%.

IR (KBr disk): 1790, 1758 $cm^{-1}$ (anhydride).

This anhydride was recovered after the mixture had been heated at 300°C for 10 min. without any product being formed.

**Dicarboxylic Dimethyl Ester (VIII).**—A solution of 1.50 g. of dicarboxylic acid (VII) in 40 ml. of ether was methylated with a slight excess of a diazomethane etherial solution. When the reaction mixture was treated by the usual method, 1.58 g. of crude dimethyl ester, m. p. 141.5—143.5°C, was obtained. Recrystallization from aqueous ethanol gave colorless plates, m. p. 144—145°C.

Found: C, 72.42; H, 10.09. Calcd. for $C_{22}H_{36}O_4$: C, 72.49; H, 9.96%.

IR (KBr disk): 1736, 1716 $cm^{-1}$ (ester group).

After a solution of 0.73 g. of the dimethyl ester had been refluxed in 30 ml. of a 0.1 N potassium hydroxide methanolic solution for 2 hr., the reaction mixture was concentrated under reduced pressure, diluted with water, and extracted with ether. The acidification of the water layer with diluted hydrochloric acid did not give any substance. From the ether extract, 0.73 g. of a crystalline compound, m. p. 143—144.5°C, was obtained. Recrystallization from diluted ethanol raised the melting point of the compound to 144—145°C; no depression of melting point was observed on admixture with VIII.

**Ketones (XIII and XIV).**—An excess of diborane was passed to a solution of 7.15 g. of hibaene in 70 ml. of anhydrous tetrahydrofuran under cooling with ice water and under a dry nitrogen atomosphere. After the solution had been allowed to stand at room temperature for 1 hr., the solvent was removed under reduced pressure and the residue was dissolved in 40 ml. of ether. To this solution was added a solution of 11.6 g. of sodium bichromate dissolved in a mixture of 30 ml. of water and 6.0 ml. of sulfuric acid; then the solution was refluxed gently while being stirred at around 40°C for 7 hr. After cooling, the water layer which separated from the ether layer was extracted with ether. The combined ether solution was washed with water and dried over anhydrous magnesium sulfate. The removal of the ether afforded 8.0 g. of a semisolid substance, which was purified by alumina chromatography (200 g. of alumina was used). From the petroleum ether effluent and the successive benzene effluent, 1.98 g. of an oil and 4.75 g. of a crystalline compound respectively were obtained. The crystalline compound was sublimed under reduced pressure (2 mmHg, bath temperature below 120°C) to yield 3.87 g. of crystalline sublimate. This sublimate was further purified using an alumina column containing 200 g. alumina. The results obtained were as follows: i) 0.34 g. of crystals (m. p. 73—84°C) from the petroleum ether - benzene (7 : 3) effluent; ii) 1.66 g. of crystals (m. p. 80—84°C) from the petroleum ether - benzene (5 : 5) effluent; iii) 1.01 g. of crystals (m. p. 66—88°C) from the same solvent as ii; iv) 0.95 g. of crystals (m. p. 95—102°C) from the same solvent as ii, followed by benzene.

Fractions i and ii were combined and recrystallized from methanol to give colorless prisms (XIII), m. p. 88—89°C.

Found: C, 83.19; H, 10.89. Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.18%.

IR (KBr disk): 1725 $cm^{-1}$; (carbon tetrachloride solution): 1727 $cm^{-1}$ (carbonyl group). RD (methanol solution $c$ 0.1): $[\alpha]_{700}$ −56°, $[\alpha]_{589}$ −81°, $[\alpha]_{323}$ −2040°, $[\alpha]_{285}$ +2010°.

XIII did not react with 2, 4-dinitrophenylhydrazine or perbenzoic acid under conditions similar to those in the formation of lactone (X), and only the starting material was recovered.

The recrystallization of the crystals from fraction iv from methanol gave colorless prisms (XIV), m. p. 102—103°C.

Found: C, 83.22; H, 10.86. Calcd. for $C_{20}H_{32}O$: C, 83.27; H, 11.18%.

IR (KBr disk): 1733 $cm^{-1}$; (carbon tetrachloride solution): 1736 $cm^{-1}$ (carbonyl group). RD (methanol solution $c$ 0.1): $[\alpha]_{700}$ +30°, $[\alpha]_{589}$ +48°, $[\alpha]_{318}$ +1528°, $[\alpha]_{278}$ −1720°.

2, 4 - Dinitrophenylhydrazone; Recrystallization from ethanol-ethyl acetate gave orange needles, m. p. 231—231.5°C.

Found: N. 12.05. Calcd. for $C_{26}H_{34}O_4N_4$: N, 12.01%.

**Lactone (XII).**—A solution of 3.86 g. of XIV, 39 ml. of chloroform containing 2.42 g. of perbenzoic acid, 40 ml. of acetic acid and 0.45 ml. of sulfuric acid was allowed to stand at 10—20°C for 5 days. The reaction mixture was then poured into water, and the water layer was extracted with ether. The chloroform solution, combined with the ether extract, was washed with a 2% sodium hydroxide aqueous solution and water, and dried over anhydrous magnesium sulfate. The removal of the solvent gave a crystalline residue, which was purified by a neutral alumina column (100 g. of alumina was used). The crystals from the benzene and benzene-ether (1 : 1) effluents, 3.10 g., m. p. 100—110°C, were recrystallized from *n*-hexane, affording colorless needles, m. p. 111—112°C.

Found: C, 78.82; H, 10.49. Calcd. for $C_{20}H_{32}O_2$: C, 78.89; H, 10.59%.

IR (KBr disk): 1713 $cm^{-1}$ (lactone).

## Summary

The structure and absolute configuration of hibaene, a new diterpene isolated from the essential oil of the leaves of hiba (*Thujopsis dolabrata* Sieb. et Zucc.), have been presented.

The authors are indebted to Dr. Yoshio Sato, National Institute of Health, for donating a sample of isostevane and also to the Ogawa Perfumery Co., Ltd., for supplying the original essential oil for this research.

# Absorption and Fluorescence Spectra of Anthracene-*s*-Trinitrobenzene Complex Crystal*[1]

By Jiro TANAKA*[2] and Keitaro YOSHIHARA*[3]

(Received August 10, 1964)

The electronic spectra of a crystal of a charge-transfer type molecular complex is of particular interest since the mechanism of the electronic interaction between the electron donor and the acceptor can be elucidated by the aid of polarization measurements. Nakamoto[1] measured the polarized absorption spectra of charge-transfer complexes such as quinhydrone and showed that the charge transfer absorption is stronger along the direction out of the plane of the benzene ring. The absorption spectra of the crystal formed between anthracene and 1, 3, 5-trinitrobenzene (TNB) was also studied by Lawer, Hochstrasser and Reid,[2] and the fluorescence and phosphorescence of this system was investigated by Czekalla et al.[3] and McGlynn and his co-workers.[4] According to these studies, the fluorescence is to be ascribed to a reverse process of charge transfer absorption, since a linear relationship was found between the absorption and the fluorescence for various systems having TNB as an electron acceptor. The theoretical analysis of the charge resonance interaction is facilitated by crystal studies, and the structure of the crystal has been recently determined by Wallwork and his co-workers.[5]

In this paper a polarization measurement of the absorption and fluorescence spectra of the crystal will be reported with the view of obtaining detailed information on the electronic interaction between the electron donor and the acceptor. The electric conductivity of the crystal has already been reported on by Kuroda, Yoshihara and Akamatu.[6]

## Experimental

Anthracene was purified by recrystallization from a xylene solution, followed by chromatography and sublimation in vacuo. TNB was obtained after recrystallization from an ethanol solution. The crystal for the measurement of the fluorescence of the complex was grown from a carbon tetrachloride solution. The thin flakes of single crystals obtained by sublimation were used for the absorption measurement. The crystal elongates along the c-axis.

The absorption spectrum shown in Fig. 1 was measured by using the light polarized parallel to and perpendicular to the c-axis and by using the ultraviolet microspectrophotometer described in a previous paper.[7] The measurement was made at room temperature.

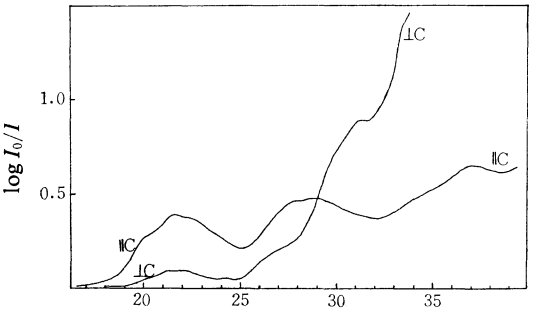

Fig. 1. Absorption spectrum of anthracene-TNB complex.

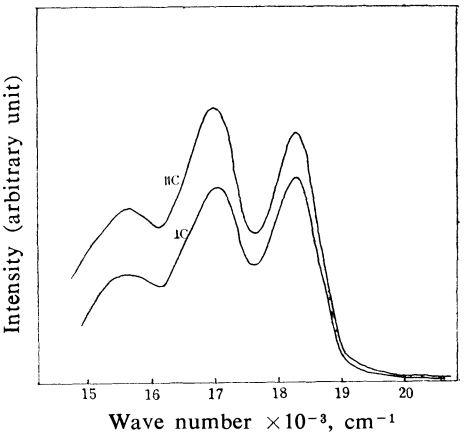
The Hückel molecular orbital of trinitrobenzene has been calculated using the parameters as The numbering of atoms is shown in Fig. 4.



The fluorescence spectrum was measured by a recording spectrofluorometer.* The crystal was excited by a high pressure mercury lamp combined with a Toshiba UVD2 filter in order to obtain the 3650Å radiation. A calcite Glan-Thompson type polarizer of the Olympus Optical Co. was used for the polarization measurement. The spectrofluorometer consists of a Kipp double monochrometer, a RCA 1P22 photomultiplier, and an amplifier in series. The slit width was kept constant at 0.2 mm. during all measurements. The characteristic sensitivity and polarization properties of the instrument were calibrated using a standard light source. The fluorescence spectra at room temperature and at the temperature of liquid helium, and of liquid nitrogen are shown in Fig. 2, and all results are summarized in Table I.

(a) room temperature

(b) liquid nitrogen temperature

(c) liquid helium temperature

Fig. 2. Fluorescence spectrum of anthracene-TNB complex.

* The authors wish to express their sincere thanks to Professor Shoji Makishima and Mr. Masao Hirata for their kind help with the spectrofluorometer.

## Results and Discussion

**(1) Theoretical Consideration.**—The charge transfer resonance interaction between the highest occupied orbital of anthracene and the lower vacant orbitals of TNB is considered. The LCAO MO calculation of TNB has been made, and it has been found that the three lowest vacant orbitals are nearly degenerate. The results of calculation are shown in Table II, where it may be seen that the lower vacant orbitals are composed mainly of nitro groups. The nitro groups have a three-fold symmetry, and the vacant orbitals of these groups are split by mutual interactions into one orbital of the lowest energy of the totally symmetric and two orbitals of a slightly higher energy of E'' symmetry. According to these calculations, the lowest symmetric vacant orbital may have a larger electron affinity than the other two orbitals, about $0.05\beta$, where $\beta$ is the exchange integral ($-2$——$3$ eV.).* However, under the influence of an electron donor or foreign ions on one particular nitro group, the lowest charge transfer state will occur when an electron is transferred into an E'' orbital where the charge density is concentrated on particular nitro groups. For instance, the ESR spectra of the TNB negative ion produced by metallic and photo-reduction shows that the excess electron is accommodated into the E''(s) orbital.[8]

The crystal structure analysis data shows that one nitro group is placed close to anthracene (Fig. 3). The electrostatic energies between partial charges on TNB and positive holes on anthracene have been calculated for molecular separations from 2.8 to 4.0 Å, whereby the geometrical planar configuration is unchanged, as in Fig. 3. The charge density of TNB is taken as those of $A_2''$, E''(s) and E''(a) orbitals, and three different orientations are considered for the calculation with E'' orbitals since the energy is dependent on the local charge densities on particular atoms (cf. Table III). The results are given in Table III, where it is found that E''(s2), E''(a1) and E''(s3) states are most stabilized by an electrostatic force. Other states are higher in energy by about 0.1—0.2 eV.

The theoretical foundation of the charge-transfer type molecular complex was given by Mulliken,[9] and the wave functions for the ground state and the charge transfer state may be given as follows:

$$\Phi_G=\varphi(D\cdot A)+\lambda_1\varphi(D^+\cdot A^-)$$
$$\Phi_C=\varphi(D^+\cdot A^-)+\delta_1\varphi(D\cdot A)+\delta_2\varphi(D^*\cdot A) \quad (1)$$

* Fischer and McDowell (private communication) have made a similar calculation of the Hückel MO of TNB using different parameters. They found a different sequence of energy levels as regards the lowest vacant A and E orbitals, where the $A_2''$ is slightly more unstable than E''. Therefore, these three levels are considered to be nearly degenerate, since the simple Hückel MO result is greatly dependent on the choice of parameters.

8) Although Ward had observed the characteristic of the E'' orbital in accommodating an excess electron, Fischer and McDowell (private communication) have found that by the electrolytic reduction a symmetric anion is formed on which an electron is put in the totally symmetric orbital. See R. L. Ward, *J. Am. Chem. Soc.*, **83**, 1296 (1961); *J. Chem. Phys.*, **38**, 2588 (1963).

where $\varphi(D\cdot A)$, $\varphi(D^+\cdot A^-)$ and $\varphi(D^*\cdot A)$ represent wave functions of a no-bond structure, the charge transfer structure and the local excited state of the donor. The perturbation coefficients are given by:

$$\lambda_1 = \frac{\int \varphi^*(D^+\cdot A^-)\mathbf{H}\varphi(D\cdot A)d\tau}{E_{CT}-E_G} \qquad (2)$$

$$\delta_1 \simeq -\lambda_1$$

$$\delta_2 = \frac{\int \varphi^*(D^*\cdot A)\mathbf{H}\varphi(D^+\cdot A^-)d\tau}{E_{D^*\cdot A}-E_{CT}} \qquad (3)$$

The integrals in Eqs. 2 and 3 might be proportional to the overlap integrals between them, so the overlap integrals have been evaluated

between the highest occupied and the lowest vacant orbitals of anthracene with the lower vacant orbitals of TNB, using a common orbital exponent for all atoms at $\xi = Z/n = 1.4$[10] and taking into account the overlap between direct-opposite and next-neighbor atoms. The results are shown in Table IV, where it is shown that $E''$(s2) is the most favorable orbital and configuration since the overlap has the same sign for both ground and excited states and since it increases at a shorter molecular separation. This means that both ground and

* Highest occupied orbital of anthracene is denoted by 1 and the lowest vacant orbital by 2.

excited states are stabilized by charge resonance interaction, particularly at a shorter molecular separation. The molecular separation of 3.28 Å found by X-ray analysis is apparently shorter than the normal van der Waals radii, and the charge transfer resonance force might be responsible for the shortening of the molecular distance. The stabilization of the excited state is demonstrated by a shift of the fluorescence band (loc. cit.).

Since we are concerned with the lowest charge transfer state, we will pay particular attention to a state in which an electron is transferred into the E''(s) orbital. Other states are less convenient from the points of view of electrostatic energy and electron overlap; for instance, the charge transfer state into the E''(a2) orbital is 0.2 eV. higher in electrostatic energy and 1/10 smaller in electron overlap effect.

The energy of the charge transfer state, $E_{CT}$, is estimated by Eq. 4:

$$E_{CT} = I_p - E_A - \sum_{i,j} q_i q_j / R_{ij} \qquad (4)$$

where $I_p$ is the ionization potential of anthracene, $E_A$ is the electron affinity of TNB, and the last term is the electrostatic energy at 3.28 Å separation, where $q_i$ and $q_j$ indicate partial charges on $i$-th and $j$-th atoms. Using values of $I_p = 7.4$ eV.[11] and $E_A = 1.86$ eV.[12] and electrostatic energy for the E''(s2) orbital, $E_{CT}$ is estimated as 2.54 eV. The local excited state of anthracene is the lowest singlet excited state of $^1L_a$ at 3.40 eV. Although it is very difficult to estimate the numerical value of the integrals quantitatively, we will tentatively assign −0.10 eV. for the integral in Eq. 2 and −0.40 eV. for Eq. 3. The perturbation coefficient is estimated as $\lambda_1 = 0.04$.

For the excited state, the perturbation treatment is not accurate enough because the $E_{CT}$ and $E_{D^*\cdot A}$ are close to each other; hence, we have solved a secular equation and found two energies and wave functions as follows:

$$\begin{aligned} &2.39\,\text{eV.}: \ 0.94\,\varphi(D^+\cdot A^-) + 0.33\,\varphi(D^*\cdot A) \\ &3.55\,\text{eV.}: \ 0.33\,\varphi(D^+\cdot A^-) - 0.94\,\varphi(D^*\cdot A) \end{aligned} \qquad (5)$$

The stabilization of the ground state is 0.004 eV. Although this figure is too small to explain the stability of the complex, a much larger energy will arise from charge-transfer interactions of other filled orbitals. Those results will be discussed in a later section.

**(2) Absorption Spectrum.**—The general feature of the spectrum coincides with the findings of Lawer et al.[2] on the longer wavelength side, but the present results show more bands in the shorter ultraviolet region. Three bands are observed along the c-axis, as Fig. 1 shows. This axis is the direction out of the benzene rings, and the charge transfer resonance interaction might occur along this axis since the electron overlap between molecules is larger for this direction (cf. Fig. 3). Three bands, at about 20000 $cm^{-1}$, 28000 $cm^{-1}$ and 37000 $cm^{-1}$, are assigned to the intermolecular charge transfer from anthracene to TNB. The energy of the first band (2.48 eV.) is nearly in agreement with the calculated value (2.39 eV.).

The transitions to $A_2''$ and E''(a2) orbitals might occur in the same energy region, but their intensities will be rather smaller than to E''(s2) since the interaction matrix is smaller. The second and the third charge transfer bands might be ascribed to transitions from the second or third occupied orbital of anthracene to TNB, since the same sort of second and third charge transfer bands were observed in the case of anthracene-tetracyanoethylene complex.[13] The energy difference between the first and second band is 8000 $cm^{-1}$ in both cases. Of course, the possibility cannot be excluded that the second and third bands arise from transitions to higher vacant orbitals of the acceptor. The band at 26500 $cm^{-1}$ observed in the direction perpendicular to the c-axis might be ascribed to the same origin of the transition to the state observed at 27500 $cm^{-1}$ along the c-axis, since the intensity is weaker in the direction perpendicular to the c-axis. It is remarkable that these extra charge transfer bands, which are difficult to see in a

solution's spectra, appear distinctly in the crystal spectrum since the polarization is different from the $\pi-\pi^*$ transition of the parent molecules. Three vibrational progressions are observed even at room temperature for the 20000 $cm^{-1}$ system, and they are in perfect agreement with the values of Lawer et al.[2]

The electronic transitions of parent molecules will be weaker in the direction parallel to the c-axis, because the transition moment of the $\pi-\pi^*$ transition is in the plane of the benzene ring. The bands at 29800 $cm^{-1}$ and 31300 $cm^{-1}$ are considered to be the $^1L_a$ bands of anthracene shifted by the interaction with TNB. They appear at 26730 $cm^{-1}$ in a solution and at 25400 $cm^{-1}$ in a crystal. The calculated value mentioned in the previous section is 28500 $cm^{-1}$ (3.55 eV.), so it explains the blue shift of the $^1L_a$ band.

The intensity of the charge transfer transition has been discussed by Murrell[14] in pointing out the important contribution of the donor's local excited configuration. The transition moment integral which is proportional to the coefficients, $\lambda_1$ and $\delta_2$, is given by Eq. 6 by neglecting the electron overlap between A and D and the ground state dipole:

$$\mu=\int \Phi^*_{CT}\mathbf{r}\Phi_G d\tau$$
$$=\lambda_1\langle D^+\cdot A^-|\mathbf{r}|D^+\cdot A^-\rangle+\delta_2\langle D\cdot A|\mathbf{r}|D^*\cdot A\rangle \quad (6)$$

The first bracket is approximately given by a vector connecting the point charge placed on the center of the E''(s2) orbital of TNB and a point-positive charge placed on the center of anthracene. The vector has components about 1 Å along the [110] and 3.3 Å along the [001] directions. The second bracket denotes the transition moment of the $^1L_a$ state of anthracene directed along the short axis of anthracene, in a direction opposite to that of the $\mathbf{r}(D^+A^-)$ vector.

The intensity of the first charge transfer band has been determined by McGlynn et al. as $\varepsilon_{max}=1600$. Using the width of the half-intensity of about 4700 $cm^{-1}$, the oscillator strength, $f$, is obtained as 0.032.* By the use of this value, the magnitude of the transition moment is determined to be 0.36 Å.

The dichroic ratio observed in Fig. 1 is $D_{C\parallel}:D_{C\perp}=5:1$; this value may be related to the vector components in Eq. 6 as follows:

$$\frac{D_{C\parallel}}{D_{C\perp}}=\frac{(\lambda_1\langle D^+\cdot A^-|\mathbf{r}|D^+\cdot A^-\rangle_{C\parallel})^2}{(\delta_2\langle D\cdot A|\mathbf{r}|D^*\cdot A\rangle+\lambda_1\langle D^+\cdot A|\mathbf{r}|D^+\cdot A^-\rangle_{C\perp})^2} \quad (7)$$

If we use values of $\lambda_1=0.09$—$0.10$ and $\lambda_2=0.33$, then the calculated value is in agreement with the observed values. The value of $\lambda_1$ determined from these results is nearly twice as large as the value estimated in the previous section; this discrepancy might be ascribed to uncertainity in the estimation of the integral in Eq. 2, to the point charge approximation for the $\mathbf{r}(D^+\cdot A^-)$ vector, and to the deviation of the intensity from the oriented gas model of the crystal.

**(3) The Fluorescence Spectrum.**—The fluorescence spectrum of the TNB-anthracene system has been ascribed to the reverse process of the charge transfer absorption.[3,4] The shift of the 0-0 band from absorption to emission (Franck-Condon gap) is 1700 $cm^{-1}$ in this experiment, while a value of 7000 $cm^{-1}$ was given by McGlynn et al.[4] The 0-0 emission band may clearly be seen at the temperature of liquid helium.

The fluorescence spectrum shown in Fig. 2 exhibits some unusual characteristics in that the shape of the bands changes markedly with a change in temperature and in that the dichroic ratio is reduced from that of the absorption. The change in the dichroic ratio cannot be understood unless we have assumed a change in the fluorescence state or configuration from that of the absorption. The big change in emission shape caused by the change in temperature will be due to a frequent thermal motion in a shallow potential, which will lead to the reduction of the vibrational overlap integral for the 0-0 transition in the Franck-Condon integral.

The relatively larger shift of the fluorescence of 1700 $cm^{-1}$ will be ascribed to the shortening of the molecular separation after the excitation, since the potential for the excited state is lower in energy at a shorter distance. However, if we ascribe the shift solely to an increase in electrostatic stabilization caused by closing, it will require an unreasonably larger value of the shortening of 0.43 Å to explain the 1700 $cm^{-1}$ shift. Therefore, it is most reasonable that the interaction term in Eq. 3 increases rapidly when the molecular separation is closed. In fact, the overlap integral increases for the excited state from $-0.025$ to $-0.035$ by a shortening of 0.20 Å, and this may correspond to an increase in the integral from $-0.40$ eV. to $-0.56$ eV. by assuming a proportionality of the energy to the overlap

14) J. N. Murrell, *J. Am. Chem. Soc.*, **81**, 5037 (1959).

* This value is smaller than the value suggested by Briegleb. We have used as a formula for oscillator strength:

$$f=4.32\times10^{-9}\int\varepsilon_\nu d_\nu$$

integral. By the use of the electrostatic energy at 3.1 Å of 3.09 eV., the excited state wave functions are given as follows:

$$\begin{aligned} &2.19\,\text{eV.}: \ 0.905\varphi(D^+\cdot A^-)+0.42\varphi(D^*\cdot A) \\ &3.67\,\text{eV.}: \ 0.42\varphi(D^+\cdot A^-)-0.905\varphi(D^*\cdot A) \end{aligned} \quad (8)$$

The excited state is stabilized about 1600 $cm^{-1}$ by this interaction. Of course, the repulsive potential in the ground state might be responsible for some part of the shift of the fluorescence.

Equation 8 involves a larger contribution of the $\varphi(D^*\cdot A)$ state. The dichroic ratio for this emission is calculated, by using Eq. 7 as:

$$D_{C\parallel} : D_{C\perp} = 1.5 : 1.0$$

The observed value is 1.2 : 1.0 at the temperature of liquid nitrogen, and 1.4 : 1.0 at the temperature of liquid helium. The calculated value is nearly in agreement with the observed values.

Therefore, the molecules in the complex are considered to be displaced to a closer position by about 0.2 Å after the excitation, the 0-0 state is stabilized about 1700 $cm^{-1}$, and the dichroic ratio is changed from 5 : 1 in absorption to 1.4 : 1 in fluorescence by an increase of the component of the locally-excited $^1L_a$ state of anthracene. The shallow intermolecular potential for this molecular motion is reflected in the emission spectrum at room temperature, where the 0-0 band decreases in intensity. The vibrational progression of 1300 $cm^{-1}$ might be due to a skeletal vibration of TNB coupled with intermolecular vibration.

**Summary**

The electronic absorption and fluorescence spectra of the single crystal of the anthracene-*s*-trinitrobenzene complex have been measured, and the polarization property of electronic transitions has been discussed in terms of interaction between the no-bond structure, the charge transfer and the locally-excited state of anthracene.

It has been shown that molecules in a pair are displaced to a closer position after the excitation, whereby the mixing of the donor-excited level occurs more than in the ground state (Frank-Condon state), and the fluorescence involves a larger contribution from the in-plane transition of anthracene.

The authors wish to express their sincere thanks to Professors Hideo Akamatu and Saburo Nagakura for their helpful discussions. They would also like to thank Drs. S. C. Wallwork, C. A. McDowell, P. H. H. Fischer and S. K. Lawer for their helpful communications of their unpublished results.

# Radiotracer Studies of Metal-Detergent Interaction by Means of a Dip Counter with an Evaporated Metal Film Window*

By Tsutomu SEIMIYA

(Received August 19, 1964)

The properties of metal-solution interfaces under equilibrium state have long been studied from various points of view,[1-5] studies which have offered useful information for the treatment of metals in water. However, for practical systems, the situations are fairly complicated, since several phenomena occur simultaneously and they are often not in equilibrium. Here, the factors affecting the equilibrium are not necessarily important for the kinetic properties of the interface. As for the kinetic nature of metallic interfaces, studies have also been

reported by many authors of, for instance, the coulometric, chronopotentiometric or differential double-layer capacity measurement of surfaces.[6,7] However, the so-called reactive metals usually involve an irreversible process which renders difficult the analysis of the data obtained except for some special cases. Therefore, it may be desirable to trace directly the surface reaction itself, both chemically and electro-chemically, using radioisotopes.

The present paper will describe radiotracer studies upon the interfacial reaction between vacuum-evaporated metal films and an aqueous solution of sodium dodecyl sulfate (SDS). In the usual practice of the measurement of such a reaction or adsorption, solid samples are dipped in a solution containing a radioactive solute and the radioactivity measurements are made for the surface after withdrawing the solid. However, the counting rate due to a merely adhering solution inevitably obscures the counting rate due to the adsorption or chemical reaction, which is generally small compared with that due to the adhering liquid.[8,9] The rinsing of the solid surface often adopted[10] is, therefore, not desirable, since it ensures neither a complete removal of the adhering liquid nor a complete retention of the substance adsorbed. To avoid these difficulties, it is desirable to measure the counting rate directly in the state of immersion, as in the Aniansson's soft beta ray method[11,12] or as in Winkler's hard radiation method[13,14]. Here we adopted the Aniansson's method but somewhat modified it. The rate of the uptake of $^{35}S$-labeled SDS from an aqueous solution by vacuum-deposited metals on a thin Tetoron window of the GM-tube was measured, and the surface nature of several metals was studied under the influence of air.

## Experimental

**Materials and Apparatus.**—Radioactive and non-radioactive SDS were synthesized according to the usual method.[15] The radioisotope $^{35}S$ used in this experiment was obtained from CEA Saclay, France, in the form of a dilute aqueous solution of sulfuric acid. The solution was concentrated, the required amount of non-radioactive sulfuric acid was added, and the mixture was used for the sulfonation of dodecyl alcohol. In the course of the purification of SDS, non-radioactive sodium sulfate was added to remove radioactive sodium sulfate impurities of a high sepecific activity considered to be present and likely to cause an error in the measurement of the counting rate. The radioactive SDS thus prepared had the specific activity of 30 curies per mol. Copper, silver, gold, lead and iron, all of a commercially pure grade, were chosen as the sample metals. These metals were vacuum-deposited on a thin Tetoron film of the Mitsubishi Chemical Industries, Limited (polyethylene terephthalate, Diafoil Type S, No. 12, 1.3 mg./cm$^2$ thick) which had been previously degreased by ether. The apparatus used in this experiment is shown in Fig. 1, where G is the gas flow Geiger-Müller counting tube (Japan Radio Corporation, Aloka FC-16; effective aperture, 34 mm.) equipped with a tambour ring, T, for the exchange of the sample window film and, H, the housing to which the counting tube is fixed. The screw stage, LL', adjusts the height of the adsorption cell, C, containing 8 cc. of a radioactive solution. The microscope, M, equipped with a calibrated scale measures the distance between the solution surface and the window of the GM tube.

**Procedures.**—The sample metal was deposited from vapor on the thin Tetoron film at the pressure of $10^{-6}$ mmHg under the specified conditions of electric current and evaporation time. The rates of deposition for copper, silver, gold, lead and iron samples were 3.83, 1.57, 4.67, 1.83 and 1.30 $\mu$g./cm$^2$sec. respectively. In each case, deposition was made for 30 sec., with the rejection of the initial portion by a magnetically-operated shutter in order

to avoid the contamination of the film by metal oxide. To the opposite side of the window film, copper was deposited; this acted as a part of the cathode of counting tube. The thickness of the vacuum-deposited metal films was directly calculated from their weight, as measured in a special weighing tube in order to avoid errors caused by the electrostatic charge of the film. The measurement of the adsorption was made by directly immersing the window of the counting tube in a radioactive sample solution and by measuring the increase in the counting rate due to the accumulation of the solute on the metal film. This increase in the counting rate was multiplied by the calibration factor $r$ which expresses the ratio of the actual amount of solute on the window to the counting rate resulting from it, which was determined by the separate measurement below. A known amount of radioactive solute was evenly placed in about 100 spots on an Acrylite disk of the same shape and area as those of GM-tube window. (The spots should be small enough to be free from self-absorption.) Then its activity was measured at varying distances, up to 3 mm., between the sample and the window. On the basis of this experiment, the counting rate at the distance zero was calculated by extrapolation. The amount of the sample, divided by this counting rate, gives the factor $r$ in mol./ c. p. m. Since the factor $r$ was determined for each sample film, solute and specific activity, the product of the observed counting rate and $r$ gives the actual amount of solute as corrected for the decay of isotope and the absorption of radiation by the window. The correction for the dead time of 300 $\mu$ sec. of the GM tube was also made.

The counting rate due to the bulk of the solution was measured as follows. The surface count over the aqueous solution of surface-inactive but radioactive sodium sulfate of a known concentration was measured at varying distances in a manner similar to that used in the measurement of $r$. The value thus obtained was extrapolated to the counting rate at zero distance and was used for the evaluation of the counting due to the bulk of each SDS solution. It was also attempted to estimate the radiation from the bulk of the solution by measuring the surface counting rate of an alcoholic solution of radioactive SDS, which showed no surface tension change with concentration and may, therefore, be considered to be free from surface adsorption;[16] however, the measurement was not successful due to the evaporation, creeping and condensation of alcohol on the window of the counting tube.

## Results and Discussion

**Uptakes of Sodium Sulfate and Sodium Dodecyl Sulfate on the Tetoron Surface and Apparent Adsorption on the Aqueous Surface.**—The counting rate before and after the dipping of the Tetoron film in an aqueous solution of sodium sulfate and a SDS solution were measured first as a function of the time; they are shown in Figs. 2 and 3 respectively. In each figure, the points show the total sum of the counting rate (left ordinate) due to the solute taken up by the Tetoron film and the solute in the bulk of the solution. The broken line indicates the counting rate due to the solute in the bulk of the solution. Therefore, the portion of the ordinate above the broken line in Figs. 2 and 3 represents the counting rate proportional to the excess amount of solute (right ordinate) on the Tetoron-solution interface. The points on the vertical axis in these figures indicate, for comparison, a counting rate referring to the counting rate of the aqueous surface. We can see in Fig. 2 that the apparent amount of the adsorption of sodium sulfate at the air-water interface is about the same as the adsorption on Tetoron except for the early period of the contact of Tetoron with water; this anomaly is probably due to the agitation of the surface by the immersion. In the case of SDS, the adsorption on the aqueous surface decreases when the air is replaced by Tetoron.

Counting rate and amount of adsorption of sodium dodecyl sulfate on Tetoron surface (○), aqueous surface (⊙), and bulk of the solution (— —).

16) T. Seimiya and T. Sasaki, Unpublished data.

Here it should be emphasized that, since we cannot expect any actual adsorption of sodium sulfate on the water surface, the excess counting rate mentioned above is evidently an apparent one exclusively due to the inevitable evaporation of water from the aqueous surface, although the experiment was conducted in a closed vessel. Detailed experiments on an aqueous surface, which will be reported on precisely in a following paper, also revealed that the mere exposure of the aqueous surface to an atmosphere with 40% humidity at 21°C without a special air current resulted in an apparent increase in the 3% surface concentration for a sodium sulfate solution.

Considering this, an evaporation effect may also be responsible to some extent for the apparent adsorption of SDS on an aqueous surface shown in Fig. 3. As will be mentioned in the following paper, this apparent adsorption gradually decreases as the space above the aqueous surface becomes saturated with water vapor. Therefore, it should at least be remarked that such an evaporation effect would introduce in some cases a serious error in the adsorption measurement on the aqueous surface. Throughout the main experiment which follows, we took special care to avoid evaporation, as is illustrated in Figs. 2 and 3, and to confirm the equilibrium count rate of the radiation from the bulk of the solution on he basis of its steady value.

**Uptake of SDS on Various Metals.**—The uptakes of SDS from its aqueous solution onto the surfaces of lead, copper, silver and gold are plotted against the time at pH from 6 to 9 in Fig. 4. From these curves it is possible to classify the metals employed as reactive or non-reactive, as has usually been done. With reactive metals like copper and lead, we can observe the dissolution of metals, as is seen from the change of pH shown in Fig. 4, and the growth of the surface film composed of the reaction product between the metal and SDS, as can be confirmed by the remarkable increase in the counting rate shown in the same figure. In this experiment, iron behaved as a non-reactive metal, like electrochemically-noble gold and silver, instead of as a usual reactive metal. This is probably due to the passivation of iron in the present experimental conditions of exposing its surface to an oxygen atmosphere.

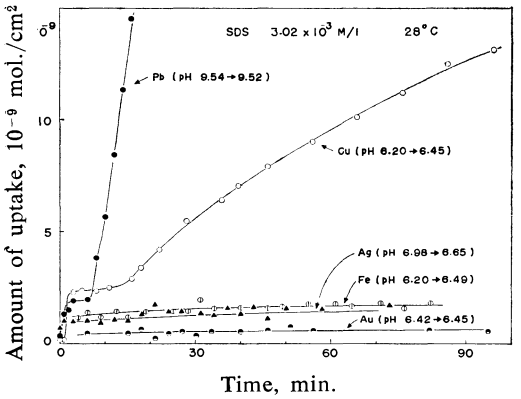

Fig. 4. Uptake of sodium dodecyl sulfate on various metals.

For non-reactive metals, a fluctuation in the counting rate exceeding the statistically probable errors of counting was observed for one and the same surface, whereas the fluctuation was very little for reactive-metal surfaces. It can be observed in Fig. 4 that the plateau appears in an early stage of the uptake curve for lead and copper at the pH listed for each case where the solution does not suffer from the change in pH in the course of SDS uptake, while in other pH regions such a plateau did not appear and the curves of uptake simply and gradually increased, though no diagrams are shown. Such a plateau and succeeding rapid increase in SDS uptake may reasonably be explained by taking account of two processes: rapid physical adsorption, resulting in a monolayer on the metal which is completed in a short time after the immersion of the metal in solution, and the slow formation of a surface film by a certain chemical reaction with the aid of oxygen, such as

$$O+Cu+2RSO_4H \rightarrow Cu(RSO_4)_2+H_2O$$

or $$Cu+O+RSO_4H \rightarrow Cu(OH)SO_4R$$

both processes being independent of the change in pH. Here R indicates the $C_{12}$ hydrocarbon chain.

**The Estimation of the Surface Roughness.**—The roughness factor, namely, the ratio of the actual area to the apparent area of the solid surface, can be obtained by calculating the

Table I. Surface roughness of various metals

| Surface | pH | Uptake of dodecyl sulfate mol./cm² ×10⁻⁹ | Weight of metal film mg./cm² | Roughness factor |
|---|---|---|---|---|
| Cu | 5.60 | 1.68 | 0.290 | 3.64 |
| | 6.20 | 1.53 | 0.071 | 3.32 |
| | 6.55 | 1.76 | 0.102 | 3.82 |
| | 6.65 | 1.71 | 0.116 | 3.71 |
| | 7.40 | 1.86 | 0.127 | 4.04 |
| | 6.20 | 2.40 | 0.497 | 5.21 |
| Pb | 9.54 | 1.92 | 0.055 | 4.17 |
| Fe | 6.20 | 2.00 | 0.039 | 4.34 |
| Ag | 6.98 | 1.70 | 0.047 | 3.69 |
| Au | 6.42 | 0.90 | 0.140 | 1.74 |

actual area, assuming the completion of monolayers at the plateau region in Fig. 4 and an area of 36 Å$^2$ per molecule for SDS.[17] The results for copper, lead, silver, gold and iron are shown in Table I. Table I indicates that copper films of a similar weight show almost the same roughness, independent of the pH used for the measurement.

**The Rate of Surface-film Growth.**—It has already been mentioned that lead and copper reacted with SDS to form a surface film of metallic soap and that these reaction products increased with time beyond the initial plateau region. The rate of uptake is considerably larger for lead than for copper. In both cases, however, the rate tends to decrease gradually with time (Fig. 4). This is considered to be due to the presence of the surface film, which acts to retard further reaction because of the slow diffusion of ions through the film. We can reasonably assume the reaction of surface film formation to take place at the film solution interface[18,19] and consider that, during the film growth, the concentration of metallic ions at a film-solution interface is almost zero, while at a film-metal interface it is large and constant. Since the diffusion rate of metallic ions and, hence, the rate of film growth is proportional to its concentration gradient in the film, the rate of film growth is considered to be proportional to the reciprocal of the film thickness, $m$, as follows:

$$\frac{dm}{dt}=\frac{k}{m} \qquad (1)$$

where $k$ is the proportionality constant. The integration of Eq. 1 gives the following parabolic rate equation, where $c$ is the integration constant:

$$\frac{1}{2}m^2=kt+c \qquad (2)$$

Equation 2 was checked by using the data for copper and lead already shown in Fig. 4. Figure 5 shows the square of the amount of the uptake of dodecyl sulfate plotted against the time for both copper and lead. A linear relation for copper, can be seen 30 min. after the immersion and after 20 min., for lead, which proves the validity of Eq. 2 as a whole. Further, it may be presumed from Fig. 5 that a film of a tight structure grows on copper, whereas a loose film grows on lead.

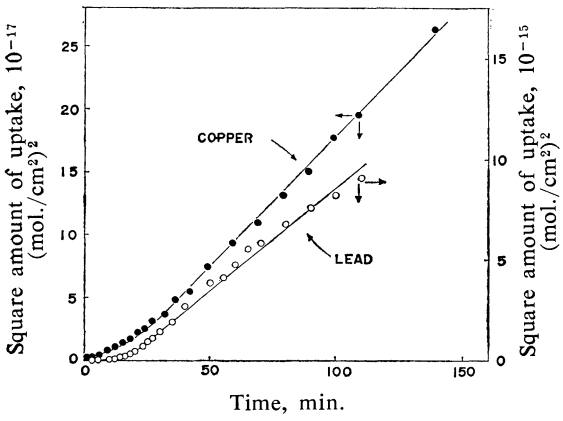

Fig. 5. Film growth on copper and lead in aqueous solution of SDS.

**The Effect of pH on the Rate of Uptake.**—The effect of the initial pH on the uptake of dodecyl sulfate was measured at various pH values for both copper and lead surfaces. The measurement of the final pH of the solution after one hour's immersion of metals was also made. Figures 6 and 7 show the results for copper and lead respectively. The tail of the arrow in these figures shows the initial pH of the solution, while the head shows the final pH measured after one hour's immersion of the metal (abscissa) and the amount of the uptake of dodecyl sulfate (ordinate). The rate of the uptake of dodecyl sulfate shows a maximum at pH 7 and decreases towards both the acid and alkaline sides. The pH increases in the acid region and decreases in the alkaline

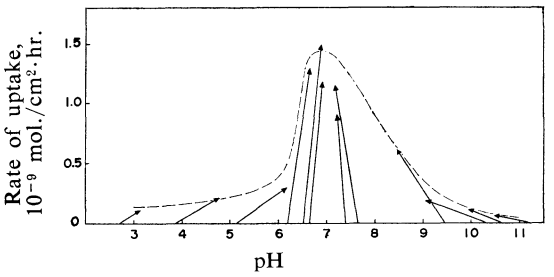

Fig. 6. Effect of pH on the rate of uptake of dodecyl sulfate on copper.

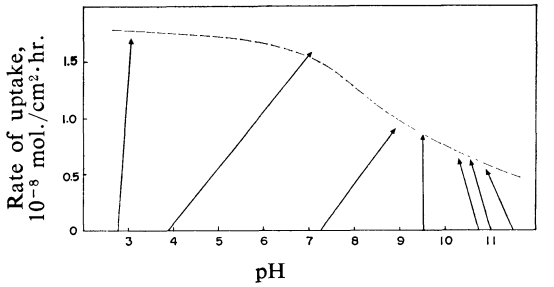

Fig. 7. Effect of pH on the rate of uptake of dodecyl sulfate on lead.

region in the course of metal dipping, but it changes little at pH 7, where the rate of uptake is at a maximum. For the lead surface, the rate of uptake is larger in the acid region and it gradually decreases toward the alkaline region. The point of no change in pH appears at pH 9; this point, however, does not correspond to the maximum rate of uptake for copper. Though the exact mechanism of these pH effects is not clear at present, a tentative explanation may be made as follows. Two fundamental types of reactions,

$$\left.\begin{aligned} &RSO_4H \rightleftharpoons RSO_4^- + H^+ \\ &RSO_4^- + H_2O \rightarrow ROH + H^+ + SO_4^{2-} \end{aligned}\right\} \quad (A)$$

$$\left.\begin{aligned} &Cu + O + 2H^+ + 2RSO_4^- \rightleftharpoons \\ &\quad Cu(RSO_4)_2 + 2H_2O \\ &Cu + O + H^+ + RSO_4^- \rightleftharpoons Cu(OH)SO_4R \\ &Cu + O + 2H^+ \rightleftharpoons Cu^{2+} + H_2O \end{aligned}\right\} \quad (B)$$

can be considered to play roles in the change in pH during metal immersion. The hydrolysis reaction of A[20] is slow and $H^+$-producing, while reaction B is $H^+$-consuming. In the acid region reaction B may be dominant, while in the alkaline region reaction A may be considered to affect the pH; in an intermediate pH, the two reactions will be balanced and the pH of the solution is unchanged during the film growth, as has been mentioned above.

However, the matter is not as clear as far as the phenomena in the alkaline region are concerned, since the error introduced during the pH measurement by the inevitable absorption of carbon dioxide obscures the results obtained.

It is interesting to repeat that the characteristic appearance of a plateau in the uptake curves is only observable at the point of no change in pH, that is, pH 7 for copper and pH 9 for lead.

## Summary

The accumulation of solute on metal surfaces has been studied using a radiotracer technique. A dip GM-counter with an end window covered with an evaporated metal film was immersed in an aqueous solution of $^{35}S$-labeled sodium dodecyl sulfate, and the change in counting rate due to the accumulation of solute on the metal surface was traced with time for various metals and pH values of the solution. The accumulation curves obtained turned out to be composed of an initial plateau, representing the region of the physical adsorption of the detergent onto the the metal surface, and/or a rising portion of the accumulation curve, indicative of chemisorption. Assuming the closely packed adsorption of solute, the roughness factors of various metal surfaces have been calculated from these plateau characteristics. The rising portion of the curve corresponds to the formation of a thick metallic soap film. The rate of film growth is controlled by the migration of the detergent or metal ions through the film, and this rate decreases as the thickness of the surface film increases. This leads to the parabolic formula for the surface film growth, which is in good agreement with the experimental results. The effect of the pH of the solution on the rate of the uptake of dodecyl sulfate has also been measured for both copper and lead surfaces. For copper surfaces the rate of the uptake of a detergent shows a maximum at pH 7 and decreases in both acid and alkaline regions. For lead surfaces, the rate is large in the acid region and gradually decreases twoards the alkaline region.

The author wishes to express his hearty thanks to Professor Tsunetaka Sasaki for his helpful guidance throughout this experiment. The cost of this research has been defrayed by a Scientific Research Grant of the Ministry of Education given to Professor Sasaki.

# Surface Chemical Properties in Aqueous Solutions of Glucosyl Alkylbenzenes

By Fumikatsu Tokiwa

(Received August 28, 1964)

For aqueous solutions of fatty acids and alcohols the surface chemical relationships between surface tension and concentration are now well understood.[1-3] However, investigations to extend the concept of the adsorption of solutes at an air/water interface, derived from the above relationships, to surface active non-ionic compounds have scarcely been made, probably because of the difficulties in obtaining pure materials. Thus, in the case of polyoxyethylated non-ionic compounds there is a considerable difficulty either in the synthesis of sharply defined compounds or in the purification of commercial materials.[4]

In the present experiment the author has investigated the surface tension vs. concentration relationship of aqueous solutions of a series of glucosyl alkylbenzenes obtained in a pure state, from which the free energy of adsorption and the attraction between hydrophobic portions in the surface layer were discussed. Glucosyl alkylbenzenes have the structure

where R is an alkyl group. These compounds are also interesting in the sense that they have a benzene ring in the hydrophobic portion. The lower members of glucosyl alkylbenzenes are surface-active but non-micellar in aqueous solution, while higher members are both surface-active and micellar.[5]

## Experimental

**Materials.**—Glucosyl alkylbenzenes were synthesized[6] and purified by Hutchinson et al.[5] The synthesis and purification will be reported in a separate publication. The glucosyl alkylbenzenes studied in this work include *p*-(β-D-glucosyl)methylbenzene, *p*-(β-D-glucosyl)ethylbenzene, *p*-(β-D-glucosyl)propylbenzene and *p*-(β-D-glucosyl)butylbenzene.

**Surface Tension.**—Surface tension measurements on aqueous solutions of these compounds were carried out by the drop-volume method, to which the corrections of Harkins et al.[7] were applied. The drops were formed slowly on a tip 0.408 cm. in diameter, attached to a micrometer syringe, in a thermostat at 25°C. Using drop forming times of five minutes or longer no evidence of aging was found.

## Results and Discussion

Results[5] for the surface tension of aqueous solutions of glucosyl alkylbenzenes at 25°C are shown in Fig. 1* in which the surface tension, $\gamma$, is plotted against the logarithm of the concentration, $c$.

Gibbs' adsorption isotherm for the adsorption of a soluble substance at an interface is written in the following form, if the solution is sufficiently dilute to replace the activity with the concentration.

$$\Gamma = -(c/\boldsymbol{R}T)(\mathrm{d}\gamma/\mathrm{d}c) \qquad (1)$$

where $\Gamma$ is the surface excess of the solute, $T$ is the absolute temperature, and $\boldsymbol{R}$ is the gas constant. On the other hand, the adsorption isotherm developed by Langmuir is written in the form

$$q = k_1 k_2 c/(1+k_2 c) \qquad (2)$$

where $q$ is the amount of the solute adsorbed per unit area of the surface, and $k_1$ and $k_2$ are constants. Here, let us assume that one can put $\Gamma = q$ when the solute molecules are adsorbed in the surface layer.

Combining Eqs. 1 and 2 we obtain

$$\gamma = \gamma_0 - \boldsymbol{R}Tk_1 \ln(1+k_2 c) \qquad (3)$$

* Micellization is generally reflected in a fairly abrupt change in the slope of the surface tension vs. logarithm of concentration curve. By this criterion micelle formation is absent in the case of glucosyl methylbenzene and glucosyl ethylbenzene. No evidence for micelle formation with these two compounds was provided by other measurements[5] as well.

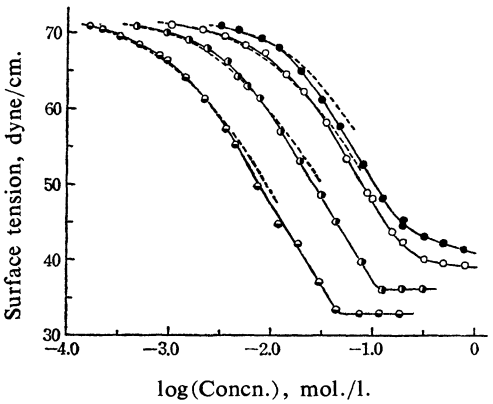

Fig. 1. Surface tension vs. log concentration curves of aqueous solutions of glucosyl alkylbenzenes at 25°C : ●, glucosyl methylbenzene ; ○, glucosyl ethylbenzene ; ◑, glucosyl propylbenzene ; ◒, glucosyl butylbenzene. (Broken lines indicate theoretical curves by Eq. 3, which are in accord with observed curves in the region of relatively low concentrations.)

where $\gamma_0$ is the surface tension of pure water. Equation 3 is consistent with Szyszkowski's empirical equation generally accepted for a series of fatty acids.[1] For concentrated solutions where $k_2c$ is large compared to unity, Eq. 3 reduces to

$$-d\gamma/d\ln c = RTk_1 \quad (4)$$

Thus the value of $k_1$ was estimated from the slope in the region of the $\gamma$-log $c$ curve where $k_2c$ is large compared to unity. The reciprocal of this value gives us the area covered by each molecule, when the surface is saturated. On the other hand, for very dilute solutions where $k_2c$ becomes small compared to unity $-d\gamma/dc$ becomes constant and

$$-d\gamma/dc = RTk_1k_2 \quad (5)$$

Thus the value of $k_2$ was also estimated from the initial slope of the $\gamma$-$c$ curve and $k_1$ according to Eq. 5. The values of $k_1$ and $k_2$ for each glucosyl alkylbenzene are listed in Table I; $k_1$ is nearly independent of the alkyl chain-length. In Fig. 1 the curves thus obtained from Eq. 3 are compared with the observed curves.

TABLE I. VALUES $k_1$ AND $k_2$, AND FREE ENERGY OF ADSORPTION FOR GLUCOSYL ALKYLBENZENES

| Compound | $k_1$ $\times 10^{10}$ | $k_2$ $\times 10^{-2}$ | $-\Delta G^\circ$ kcal./mol. |
|---|---|---|---|
| Glucosyl methylbenzene | 3.65 | 0.52 | 3.53 |
| Glucosyl ethylbenzene | 3.61 | 1.00 | 3.91 |
| Glucosyl propylbenzene | 3.66 | 2.98 | 4.56 |
| Glucosyl butylbenzene | 3.77 | 9.80 | 5.26 |

The standard free energy of adsorption, $\Delta G^\circ$, can be calculated from the equilibrium between surface and solution. Provided that both regions are sufficiently dilute for concentration to replace activity then[2]

$$\Delta G^\circ = -RT\ln(c_s/c) \quad (6)$$

where $c_s$ is the concentration in the surface region. The amount of solute $\Gamma$ adsorbed in the surface layer per square centimeter may be roughly taken to be

$$\Gamma = \tau(c_s - c)/1000 \quad (7)$$

where $\tau$ is the thickness of the surface layer in which adsorption takes place. Combining Gibbs' equation 1 with Eq. 5 we obtain

$$\Gamma = k_1k_2c \quad (8)$$

Eliminating $\Gamma$ from Eqs. 7 and 8 and combining with Eq. 6 gives for dilute solutions

$$\Delta G^\circ = -RT\ln\{1 + (1000k_1k_2/\tau)\} \quad (9)$$

Assuming a reasonable value for $\tau$ (5A), the values of $\Delta G^\circ$ given in Table I were calculated from Eq. 9.

If $\Delta G^\circ_n$ and $\Delta G^\circ_{n-1}$ are the free energies of adsorption for members with $n$ and $n-1$ carbon atoms in the alkyl chain, then

$$\Delta G^\circ_n - \Delta G^\circ_{n-1} = -RT\ln\left\{\frac{1 + (1000k_{1,n}k_{2,n}/\tau)}{1 + (1000k_{1,n-1}k_{2,n-1}/\tau)}\right\} \quad (10)$$

Here $k_{1,n}$ is nearly equal to $k_{1,n-1}$ and $(1000\, k_1k_2/\tau)$ is large compared to unity, therefore Eq. 10 reduces to

$$\Delta G^\circ_n - \Delta G^\circ_{n-1} = -RT\ln(k_{2,n}/k_{2,n-1}) \quad (11)$$

The free energy, $-\Delta G^\circ$, increases by 650—700 cal. for each additional $CH_2$ group, except for the increase in $-\Delta G^\circ$ in going from glucosyl methylbenzene to glucosyl ethylbenzene. (In the above exceptional case the increase in $-\Delta G^\circ$ is 380 cal. Probably, this could be attributed to the effect of the benzene ring on the hydrophobicity of the methyl group attached to the ring.)

The results shown above are comparable with the results obtained by Langmuir for compounds having a straight alkyl chain as a hydrophobic portion, such as fatty acids and alcohols,[1] and also indicate that Traube's rule can be applied to the non-ionic surface active compounds having a benzene ring in their hydrophobic portion.

The surface pressure-area ($\Pi$-$A$) relation for the adsorbed monolayer can be found by the use of Gibbs' equation and identifying the surface excess with an adsorbed monolayer. The result shown in Fig. 2 is plotted in the form $\Pi A/kT$ against $\Pi$, where $k$ is the Boltzmann constant. At low pressures the ideal

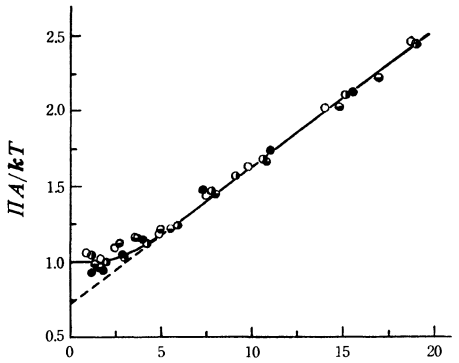

Fig. 2. $\Pi A/kT$-$\Pi$ curves for glucosyl alkylbenzenes: ●, glucosyl methylbenzene; ○, glucosyl ethylbenzene; ◑, glucosyl propylbenzene; ◒, glucosyl butylbenzene.

two-dimensional gas equation $\Pi A = kT$ is approached; at higher pressures an equation of the Amagat type

$$\Pi(A - A_0) = xkT \qquad (12)$$

is followed.

As expected, $A_0$, termed the "co-area," is independent of alkyl chain-length ($A_0 = 37.4$ Å$^2$). It is generally accepted that the deviation of $x$ from unity is a measure of attractive force between hydrophobic portions.[2] Therefore, it was expected, as in the case of a series of fatty acids,[2] that the value of $x$ decreases as the alkyl chain-length increases. However, contrary to expectation, the value of $x$ seems to be nearly independent of the chain-length, as is seen in Fig. 2 ($x = 0.72$). The following explanation may be possible for this. The attraction between the hydrophobic portions, which is responsible for the deviation of $x$ from unity, occurs predominantly between the benzene rings in the hydrophobic portion. This will reduce the effect of the alkyl chain attached to the benzene ring on the attraction, in other words, the attraction between the alkyl chains will be overwhelmed by the attraction between the benzene rings. Thus, the chain-length is not reflected in the change in $x$. The benzene ring seems to play an important role in the attraction between the hydrophobic portions.

## Summary

The surface tension in aqueous solutions of glucosyl alkylbenzenes having various alkyl chain-lengths has been measured. The surface tension vs. concentration relation of these compounds obeys Szyszkowski's equation in a relatively wide range of concentrations. For these compounds the free energy, $\Delta G°$, of adsorption was calculated; $\Delta G°$ changes by 650—700 cal./mol. for each $CH_2$ added to the alkyl chain, except in the case of going from glucosyl methylbenzene to glucosyl ethylbenzene. The adsorbed monolayer obeys an equation of state of the form $\Pi(A - A_0) = xkT$ at relatively high pressures, where $A_0$ is independent of alkyl chain-length in the present experiment. Contrary to expectation, the value of $x$, which is governed by the attractive force between hydrophobic portions, is not influenced by the alkyl chainlengths; the benzene ring in the hydrophobic portion seems to play an important role in this attraction between the hydrophobic portions.

# Aminocyclitols. V. A New Synthesis of 2-Amino-1, 3-cyclohexanediol*

By Tetsuo SUAMI, Frieder W. LICHTENTHALER and Seiichiro OGAWA

(Received September 5, 1964)

In the previous paper,[1] it has been described how the mesyloxy group of di-*O*-mesyl-*trans*-2-acetamido-1, 3-cyclohexanediol can be displaced by an azide group in an anchimeric reaction to DL-2-acetamido-3-azidocyclohexanol. In the present paper, the displacement of the mesyloxy group of 1, 3-di-*O*-acetyl-2-*O*-mesyl-cyclohexanetriol by a highly nucleophilic azide ion is the main subject.

As a starting material, 2, 6-diacetoxycyclohexanone (I)[2] is used, because its configuration has been shown to be cis by Cavill and Solomon.[2] The cis-configuration of I is, furthermore, confirmed by the NMR spectrum, which reveals one sharp signal at 7.79 $\tau$ for the methyl protons of the two acetoxy groups. Subsequently, they must be conformationally equivalent.[3]

When I is hydrogenated in a hydrogen stream with platinum oxide, a mixture of 1, 3-di-*O*-acetyl-*cis*-cyclohexanetriol (II) and 1, 3-di-*O*-acetyl-*trans*-cyclohexanetriol (IV) is obtained. Fractional crystallizations of the mixture from ethanol give only II as crystals in 40% yield. The configuration of II is confirmed by converting it to *cis*-1, 2, 3-cyclohexanetriol.[4] Several attempts have been made to obtain IV as crystals, but no satisfactory result has been achieved.

The deacetylation of the crude oily product of IV gives *trans*-1, 2, 3-cyclohexanetriol[4] (V) in 50% yield; this fact indicates that the oily product consists mainly of the trans-derivative.

Therefore, the above-mentioned, intact mixture is treated with methanesulfonyl chloride and pyridine to yield a mixture of mesyl derivatives VI and IX. When this mixture is then fractionated from ethanol, both VI and IX are obtained in pure crystalline states in 50 and 17% yields respectively. Also, VI is obtained almost quantitatively from II by treating it with methanesulfonyl chloride and pyridine, while IX is prepared from crude IV in 73% yield.

The configurations of VI and IX are substantiated by means of their proton magnetic resonance spectra. The NMR spectrum of VI, as shown in Fig. 1-A, shows signals for the two equatorial acetoxy groups at 7.93 $\tau$, and for the axial mesyloxy group at 6.92 $\tau$. The two axial ring protons show the signal at around 5.20$\tau$, while the equatorial proton (C-2) reveals a 1 : 2 : 1-triplet at 4.90 $\tau$ of $J_{ab}$ 2.5 c.p.s.,[5] proving the cis-configuration. The

* A part of this paper was presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

2) G. W. K. Cavill and D. H. Solomon, *J. Chem. Soc.*, **1955**, 4427.

3) In inositol derivatives, axial acetoxy groups usually absorb within the range of 7.78—7.87 $\tau$ [F. W. Lichtenthaler, *Chem. Ber.*, **96**, 2047 (1963)]. In view of the signal obtained (7.79 $\tau$), this might indicate a diaxial orientation of the acetoxy groups in I. However, there are not sufficient NMR-data available for us to exclude an diequatorial orientation, for the shift to a lower field might also be caused by the neighboring carbonyl group. Thus, the configuration of I can be unequivocally deduced from the NMR spectrum, but not the exact orientation of the acetoxy groups.

4) T. Posternak and F. Ravenna, *Helv. Chim. Acta*, **80** 441 (1947).

5) S. Brownstein and R. Miller, *J. Org. Chem.*, **24**, 1886 (1959).

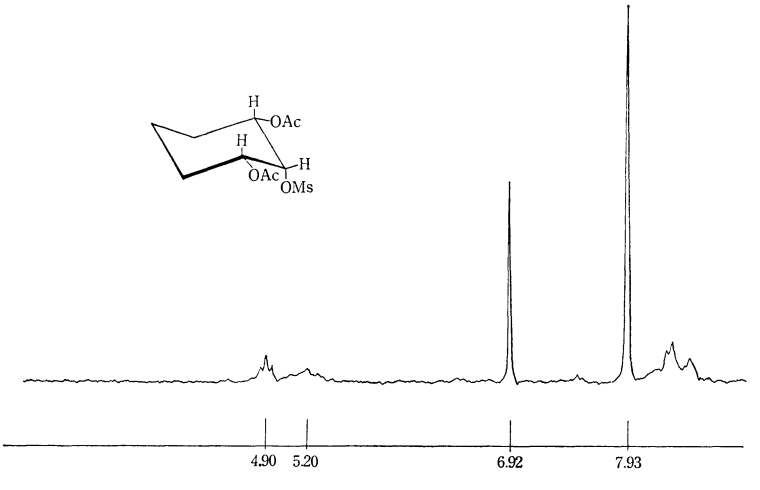

Fig. 1-A

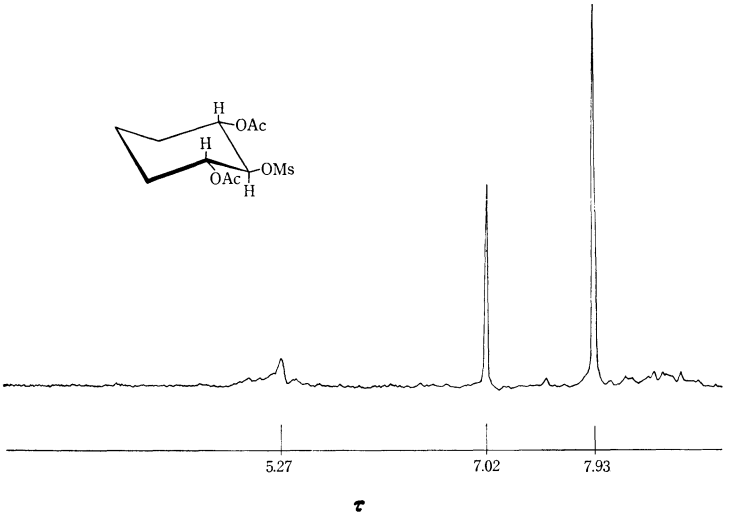

Fig. 1-B

NMR spectrum of IX, as shown in Fig. 1-B, gives signals at 7.93 $\tau$, corresponding to the two equatorial acetoxy groups, and at 7.02 $\tau$, corresponding to the equatorial mesyloxy group. The three axial ring protons are centered around 5.27 $\tau$ as an unresolved broad peaks.

This is the first interesting example of how the protons of mesyloxy groups appear at quite a different field from these of acetoxy groups; and the expected 0.1 p.p.m. difference is obtained between an axial and an equatorial mesyloxy group. Thus, the configuration of VI is established to be 1,3-di-*O*-acetyl-2-*O*-mesyl-*cis*-1,2,3-cyclohexanetriol. The configuration of the other mesylate obtained is probably that of 1,3-di-*O*-acetyl-2-*O*-mesyl-*trans*-1,2,3-cyclohexanetriol (IX). Since no acyl migration has been observed during the course of the reactions in the cis-isomer, there is more certainly no acyl migration[6] in the case of the trans-isomer.

The treatment of VI with sodium azide in boiling aqueous 2-methoxyethanol or in boiling aqueous dimethylformamide yields an oily product (VII), which shows a strong characteristic azide absorption at 2090 $cm^{-1}$.[7] The reduction of VII with a catalyst in a hydrogen stream and subsequent acetylation with acetic anhydride and pyridine give *trans*-2-acetamido-1,3-cyclohexanediol diacetate (VIII)[8,9] in 41% yield.

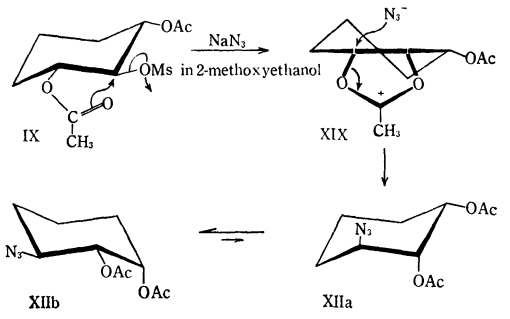
9) T. Suami and S. Ogawa, This Bulletin, **37**, 194 (1964).



When a cyclohexane ring containing vicinal sulfonyloxy and acetoxy groups in the trans position is treated with sodium acetate in an appropriate solvent, the replacement of the sulfonate group takes place with Walden inversion through an intermediary acetoxonium ion, giving *cis*-acetate alcohol.[10] When they are in the cis position, the replacement occurs at a considerably slower rate,[11] because of an anchimerically-unassisted conformation.[12] A mechanism analogous to that of the reaction with sodium azide has been proposed.[1,13]

In the present experiment, the mesyloxy group of VI is located in the cis orientation to the vicinal acetoxy group; the fact that the *trans*-2-amino-1, 3-cyclohexanediol derivative is obtained as a main product indicates that the introduction of an azide group is operated predominantly by an $S_N2$ mechanism.

The demesylation of the *trans*-mesylate, IX, by an azide ion in boiling aqueous dimethylformamide is also dominated by a direct $S_N2$ reaction, since, upon the catalytic hydrogenation of the azido derivative (X) and the subsequent acetylation, the *cis*-triacetyl derivative (XI)[9] is obtained in 43% yield.

The same reaction, however, proceeds via quite a different stereochemical course when carried out in 2-methoxyethanol. Upon hydrogenation and acetylation *cis*-2-acetamido-1, 3-cyclohexanediol diacetate is obtained in only a 3% yield, whereas DL-3$\beta$-acetamido-1$\alpha$, 2$\alpha$-cyclohexanediol diacetate (XIII)[14,15] can be isolated in 25% yield.

The formation of XIII from IX can only be rationalized by assuming neighboring-group participation from the acetoxy group in the course of the reaction; the mesyloxy group is eliminated with the formation of an acetoxonium ion intermediate (XIX), in which the nucleophilic attack occurs predominantly at the quasi-equatorial C-O bond. Thus the diaxial product (XIIa) is primarily obtained, which product then switches over to the other more stable chair conformation (XIIb). This stereochemical course of the reaction has analogies in the opening of the acetoxonium ring by the acetate ion[12] and also in the nucleophilic oxirane-ring fission.[16,17]

The solvent-dependence of the (IX → XIII) reaction—mainly a direct $S_N2$ reaction in dimethylformamide, and predominantly an anchimeric reaction in 2-methoxyethanol—can be explained by saying that the relative strengths of the two competing nucleophiles—an azide ion and an anchimeric acetoxy group respectively—are different in their solvents. Similar effects have been discussed in the demesylation of hexitol derivatives.[18]

## Experimental

All melting points were measured on a Mitamura-Riken micro hot stage. The NMR spectra were determined at a frequency of 60 Mc.p.s. with Varian Associates A-60 and Japan Electron Optics JNM-C-60 spectrometers in deuteriochloroform. Tetramethylsilane was used as an internal reference. Peak positions were given in $\tau$-values. The infrared spectra were recorded in potassium bromide pellets.

**1, 3-Di-*O*-acetyl-*cis*-1,2,3-cyclohexanetriol (II).**—The starting material, *cis*-2,6-diacetoxycyclohexanone (I), was prepared by the method of Cavill and Solomon.[2] A mixture of 5.0 g. of I and 150 ml. of ethanol was hydrogenated with 0.3 g. of platinum oxide in Parr shaker-type apparatus at 40°C for 23 hr. under 50 p.s.i.g. of an initial pressure of hydrogen. After the catalyst had been removed by filtration, the filtrate was evaporated under reduced pressure to yield 5.0 g. of a colorless semicrystalline residue. The residue was purified by crystallization from ethyl acetate to give 2.2 g. (44%) of needles melting at 103—104°C.

Found: C, 55.71; H, 7.55. Calcd. for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46%.

A solution of 81 mg. of II in 30 ml. of methanol previously saturated with ammonia was allowed to stand at room temperature overnight. The solution was then evaporated in vacuo to yield a crystalline residue, which was recrystallized from ethyl acetate to give 37 mg. of analytically-pure *cis*-1,2,3-cyclohexanetriol (III) melting at 146.5—147.5°C (lit.[3] m. p. 147—148°C). (Found: C, 54.52; H, 8.96%).

18) B. R. Baker and H. S. Sachdev, *J. Org. Chem.*, **28**, 2132 (1963).

The remaining oily product (450 mg.), obtained by evaporating the mother liquor of II, was treated in the manner which has been described for III to yield 200 mg. of crude *trans*-1,2,3-cyclohexanetriol (V). Recrystallization from ethyl acetate gave 135 mg. of analytically-pure V melting at 107—108°C (lit.[8] m. p. 108°C). (Found: C, 54.67; H, 9.15%).

**1,3-Di-*O*-acetyl-2-*O*-mesyl-*cis*-1,2,3-cyclohexanetriol (VI).**—A 0.6 ml. portion of methanesulfonyl chloride was added to a mixture of 1.0 g. of II and 15 ml. of pyridine under ice cooling, and the mixture was allowed to stand overnight in a refrigerator. Then the mixture was poured into ice-water. The precipitate was collected by filtration, washed with cold water, and dried to yield 1.3 g. (95%) of the crude product melting at 150—151°C. When recrystallized from ethanol, it melted at 152—152.5°C.

Found: C, 45.18; H, 6.23; S, 10.67. Calcd. for $C_{11}H_{18}O_7S$: C, 44.89; H, 6.16; S, 10.90%.

**1,3-Di-*O*-acetyl-2-*O*-mesyl-*trans*-1,2,3-cyclohexanetriol (IX).**—The crude oily product of IV (220 mg.) was treated in the manner described for VI. The reaction mixture was poured into ice water, and the solution was evaporated in vacuo to a half volume to yield the crude product. Recrystallization from ethanol gave 210 mg. (73%) of needles melting at 136—137°C.

Found: C, 45.33; H, 6.12; S, 10.37. Calcd. for $C_{11}H_{18}O_7S$: C, 44.89; H, 6.16; S, 10.90%.

**The Mesylation of the Mixture of II and IV.**—A 3.8 g. portion of the mixture of II and IV obtained by the hydrogenation of 5 g. of I was treated overnight with 3.0 ml. of methanesulfonyl chloride and 50 ml. of pyridine. The mixture was then treated in the manner described for IX to yield 4.2 g. (82%) of a mixture of VI and IX melting at 124—150°C. The mixture was fractionally recrystallized from ethanol to give 2.56 g. (50%) of VI melting at 150—152°C and 0.88 g. (17%) of IX melting at 136—137°C.

***trans*-2-Acetamido-1,3-cyclohexanediol Diacetate (VIII).**—a) A mixture of 0.50 g. of VI, 0.60 g. of sodium azide, and 20 ml. of 85% aqueous 2-methoxyethanol was refluxed for 14 hr. The solvent was then removed by evaporation in vacuo. The residue was repeatedly extracted with hot acetone, and the combined extracts were evaporated to give 480 mg. of a brown oil, showing a strong infrared absorption of an azide group at 2090 $cm^{-1}$. The crude VII dissolved in 8 ml. of ethanol was hydrogenated in an initial hydrogen pressure of 50 p.s.i.g. with Raney nickel. After the catalyst had been removed by filtration, the filtrate was evaporated to yield 415 mg. of an oil. This was acetylated overnight with 10 ml. of acetic anhydride and 10 ml. of pyridine. The mixture was then evaporated in vacuo to dryness, and the residue was triturated with ether to give 180 mg. (41%) of a product which, after recrystallization from ethanol-ether, gave crystals melting at 150—152°C. The melting point showed no depression upon admixture with an authentic sample.[9] b) When the same reaction was carried out in aqueous dimethylformamide, the same results as in a) was obtained.

**DL-3$\beta$-Acetamido-1$\alpha$,2$\alpha$-cyclohexanediol Diacetate (XIII).**—A mixture of 1.4 g. of IX, 1.5 g. of sodium azide, and 60 ml. of 85% aqueous 2-methoxyethanol was refluxed for 30 hr. Then the mixture was treated in a manner similar to that described for VIII to give 0.30 g. (25%) of a product melting at 146.5—147°C. The product was recrystallized from benzene to yield plates melting at 147—148.5°C (lit.[9] m. p. 148—149.5°C). (Found: C, 56.17; H, 7.40; N, 5.48%).

The infrared spectrum was superimposable on that of an authentic sample.[15]

The mother liquor of XIII was kept in a refrigerator for a long time to give 0.04 g. (3%) of crystals melting at 175°C. The crystals were recrystallized from benzene to give needles melting at 175—178°C. The product was identified as *cis*-2-acetamido-1,3-cyclohexanediol diacetate[9] on the basis of a mixed melting point determination and its infrared spectrum.

***cis*-2-Acetamido-1,3-cyclohexanediol Diacetate (XI).**—A mixture of 502 mg. of IX, 550 mg. of sodium azide, and 20 ml. of 85% aqueous dimethylformamide was refluxed for 14 hr. The mixture was treated in a manner similar to that described above to give 190 mg. (43%) of the product melting at 175.5—177°C. The product was recrystallized from ethanol-ether to give needles melting at 175—176°C. A mixed melting point determination with an authentic sample[9] was undepressed.

The authors are indebted to Professor Sumio Umezawa for his helpful advice, to Mr. Saburo Nakada for his microanalysis, to Mr. Masahiko Kitajima and Mr. Yasumasa Ishida for their assistance in the analytical experiments, and to Miss Sunao Ohata for the measurement of the infrared spectra. # Aminocyclitols. VI.* The Synthesis and Configurational Analysis of *trans*-2, 3-Diaminocyclohexanol

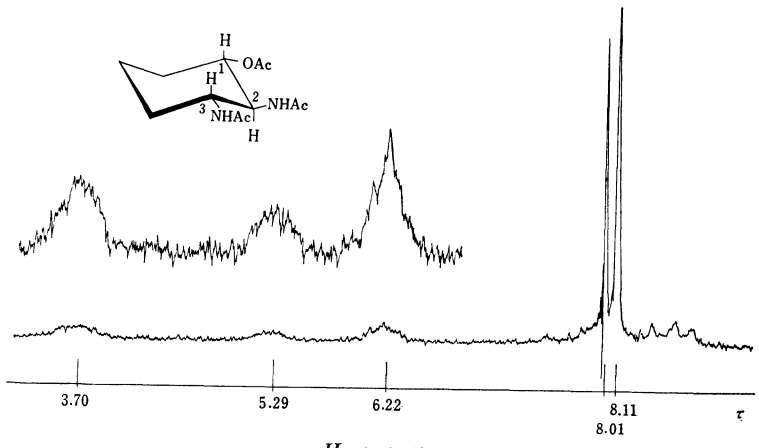
By Tetsuo SUAMI and Seiichiro OGAWA

(Received September 22, 1964)



In connection with the previous papers of this series,[1] the synthesis of DL-*trans*-2, 3-diaminocyclohexanol and a study of its structure by means of the proton magnetic resonance spectrum of the acetyl derivative will be described in the present paper.

Starting from 1-*O*-acetyl-DL-2$\alpha$-acetamido-1$\beta$, 3$\alpha$-cyclohexanediol (I),[2] 1-*O*-acetyl-3-*O*-mesyl-DL-2$\alpha$-acetamido-1$\beta$, 3$\alpha$-cyclohexanediol (II) is obtained in 58% yield by treating I with methanesulfonyl chloride in pyridine.

Compound II is treated with sodium azide in boiling 90% aqueous 2-methoxyethanol to give DL-2$\alpha$-acetamido-3$\beta$-azido-1$\beta$-cyclohexanol (III) as colorless crystals in 73% yield. Then III is hydrogenated with a platinum catalyst in a hydrogen stream to give DL-2$\alpha$-acetamido-3$\beta$-amino-1$\beta$-cyclohexanol (IV) in 87% yield. On acetylating IV with acetic anhydride and pyridine, the triacetyl derivative (V) is obtained in 83% yield. When V is refluxed with 6 N hydrochloric acid, deacetylation takes place, giving the dihydrochloride (VII) in 92% yield. By an ordinary method, di-*N*-carbobenzyloxy derivative (VIII) is prepared in 96% yield. By deacetylating V with ammonia in methanol, diacetamidocyclohexanol (VI) is prepared in 89% yield.

The mesyloxy group is located in a cis position to the vicinal acetamido group in II; therefore, the replacement of the mesyloxy group by an azide ion should take place through a direct $S_N2$ mechanism.[3] As a result, the inversion of the configuration at C-3 must occur, and the product should be DL-2$\alpha$-acetamido-3$\beta$-azido-1$\beta$-cyclohexanol. This configuration is also supported by the NMR spectrum of V; as is shown in Fig. 1, the spectrum

*H*, p. p. m.

Fig. 1

1) * Part IV: T. Suami and S. Ogawa, This Bulletin, **37**, 733 (1964).

2) T. Suami and S. Ogawa, ibid., **37**, 194 (1964)

3) T. Suami, F. W. Lichtenthaler and S. Ogawa, ibid., **38**, 754 (1965).

reveals two sharp signals of a 1 : 2 relative intensity, as is to be expected from one equatorial acetoxy group (of 8.01 $\tau$) and two equatorial acetamido groups (of 8.11 $\tau$).[2,4] The two axial ring protons on C-2 and C-3 show the broad signal (peak width : 25 c. p. s.) at 6.22 $\tau$, while the one axial ring proton on C-1 reveals an unresolved broad signal (peak width : 27 c. p. s.) at 5.29 $\tau$. Since the vicinal spin-spin coupling constant is greater between two axial protons than between axial-equatorial protons or two equatorial protons,[5] the broad peak widths of the ring protons correspond to the assigned configuration.

The protons on the nitrogen atoms in amide groups show the signal at 3.70 $\tau$.[6]

## Experimental

All the melting points have been corrected. The NMR spectrum was determined at a frequency of 60 Mc. p. s. with a Japan Electron Optics JNM-C-60 spectrometer in deuteriochloroform. Tetramethylsilane was used as an internal reference in the sample. Peak positions are given in $\tau$-values.

**1-*O*-Acetyl-3-*O*-mesyl-DL-2$\alpha$-acetamido-1$\beta$, 3$\alpha$-cyclohexanediol (II).** — To a mixture of 3.5 g. of 1-*O*-acetyl-DL-2-acetamido-1,3-cyclohexanediol[2,7] and 40 ml. of pyridine, 2.4 g. of methanesulfonyl chloride was added drop by drop under ice cooling with agitation. After it had stood overnight in a refrigerator, the reaction mixture was poured into ice and water. The mixture was then evaporated under reduced pressure until a precipitate appeared; this was collected by filtration and washed with cold water. The crude product (2.75 g.) melted at 159—163°C. The analytical sample was recrystallized from ethanol and melted at 161.5—162°C.

Found: C, 45.00; H, 6.42; N, 4.94; S, 10.70. Calcd. for $C_{11}H_{19}NO_6S$: C, 45.04; H, 6.53; N, 4.78; S, 10.93%.

**DL-2$\alpha$-Acetamido-3$\beta$-azido-1$\beta$-cyclohexanol (III).** —A mixture of 2.2 g. of II, 1.5 g. of sodium azide and 65 ml. of 90% aqueous 2-methoxyethanol was refluxed for 20 hr. The reaction mixture was then evaporated under reduced pressure to dryness, and the residue was extracted repeatedly with boiling acetone. The combined acetone extract was evaporated to yield 1.4 g. of the crystalline residue. The residue was recrystallized from acetone-ether to give 1.09 g. of crystals (73%) melting at 134—137°C. Recrystallization from the same mixed solvent raised the melting point to 137—139°C.

Found: C, 48.57; H, 7.07; N, 28.15. Calcd. for $C_8H_{14}N_4O_2$: C, 48.47; H, 7.12; N, 28.27%.

IR: 3350 (-OH), 2110 ($-N_3$), 3280, 1650, 1628 and 1555 $cm^{-1}$ (amide).

**DL-2$\alpha$-Acetamido-3$\beta$-amino-1$\beta$-cyclohexanol (IV).** —A 1.05 g. portion of III was hydrogenated in 60 ml. of ethanol over 0.2 g. of platinum oxide at room temperature for 10 hr. The catalyst was then removed by filtration, and the filtrate was evaporated to give the crystalline residue. The residue was recrystallized from ethanol-ether to give 0.8 g. of the product (87%) melting at 176—177°C. The analytical sample was recrystallized from ethanol-ether and melted at 180—181°C after having sintered at 178°C.

Found: C, 55.38; H, 9.12; N, 16.02. Calcd. for $C_8H_{16}N_2O_2$: C, 55.79; H, 9.36; N, 16.27%.

**DL-2$\alpha$, 3$\beta$-Diacetamido-1$\beta$-cyclohexanol Acetate (V).**—A mixture of 156 mg. of IV, 5 ml. of acetic anhydride and 5 ml. of pyridine was allowed to stand overnight at room temperature; then it was evaporated under reduced pressure to yield a crystalline residue. The residue was recrystallized from ethanol-ether to give 102 mg. (83%) of needles melting at 223.5—224.5°C. Further recrystallizations did not raise its melting point.

Found: C, 56.38; H, 7.68; N, 10.86. Calcd. for $C_{12}H_{20}N_2O_4$: C, 56.23; H, 7.87; N, 10.93%.

**DL-2$\alpha$, 3$\beta$-Diamino-1$\beta$-cyclohexanol Dihydrochloride (VII).**—A mixture of 455 mg. of IV and 25 ml. of 6 N hydrochloric acid was refluxed for 3 hr. and then evaporated to dryness in vacuo. The residue was recrystallized from ethanol, giving 491 mg. (92%) of crystals which melted at 263°C with decomposition, after having turned brown at 250°C. Further recrystallization from methanol-ether did not raise the melting point.

Found: C, 35.66; H, 8.02; N, 13.40; Cl, 34.65. Calcd. for $C_6H_{14}N_2O \cdot 2HCl$: C, 35.48; H, 7.94; N, 13.79; Cl, 34.91%.

**Paper Chromatography.**—An ethyl acetate - pyridine - acetic acid - water (5 : 5 : 3 : 1) system[12] gave a single spot of $R_f/R_f$glucosamine: 1.14 in ascending development at 24°C with Toyo filter paper No. 51. An upper layer of 1-butanol - acetic acid - water (4 : 1 : 5) gave a single spot of $R_f$ 0.19 at 23°C ($R_f$ of glucosamine hydrochloride: 0.19).

**DL-2$\alpha$, 3$\beta$-Diacetamido-1$\beta$-cyclohexanol (VI).**—A 136 mg. portion of V was added to 20 ml. of methanol which had previously been saturated with ammonia, and the mixture was allowed to stand overnight at room temperature. Then the mixture was evaporated in vacuo. The residue was recrystallized from ethanol-ether to give 101 mg. (89%) of crystals melting at 240—241°C with decomposition.

Found: C, 55.81; H, 8.48; N, 12.72. Calcd. for $C_{10}H_{18}N_2O_3$: C, 56.05; H, 8.47; N, 13.08%.

**Di-*N*-carbobenzyloxy-DL-2$\alpha$,3$\beta$-diamino-1$\beta$-cyclohexanol (VIII).**—To a mixture of 100 mg. of VII, 336 mg. of sodium bicarbonate and 3 ml. of water, 0.3 ml. of carbobenzyloxy chloride (a 85% toluene solution) was added under agitation. After the mixture had been allowed to stand overnight, the precipitate was collected by filtration and washed with cold water and toluene, giving 188 mg. (96%) of the product. The crude product was recrystallized from ethanol to give needles melting at 157—159°C.

Found: C, 66.59; H, 6.45; N, 7.01. Calcd. for $C_{22}H_{26}N_2O_5$: C, 66.31; H, 6.58; N, 7.03%.

# Organic Photochemical Reactions. I. The Synthesis of Substituted Oxetanes by the Photoaddition of Aldehydes to Furans[1]

By Susumu TOKI, Kensuke SHIMA and Hiroshi SAKURAI

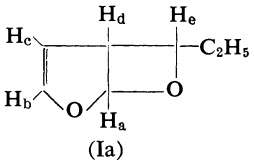
(Received September 9, 1964)

Photochemical reactions of carbonyl compounds with olefins have been studied by many workers in recent years.[2] On the photoaddition of aldehydes to olefins, acyl addition affording ketones, direct addition yielding oxetanes, and allylic addition giving unsaturated carbinols have been observed. However, little attention has been paid to the addition of aldehydes to conjugated olefins. In the present work, furan and 2-methylfuran were chosen as the conjugated olefins without an activated allylic hydrogen atom. It seemed that it would be interesting to investigate what type of reaction occurs between aldehydes (propionaldehyde and benzaldehyde) and furans on irradiation.

In this experiment, an ultraviolet light from a 350 W. high pressure mercury lamp was used. A mixture of aldehyde and furan (mole ratio: ca. 1 : 4) was irradiated in a nitrogen atmosphere at 5—10°C for 6 hr., and then the reaction product was isolated by distillation under reduced pressure.

The reaction conditions and the yields of the product are summarized in Table I.

The distilled fraction in each case was identified as an oxetane from the following observations. In the photochemical reaction of propionaldehyde and furan, a fraction with a b. p. of 74—75°C (30 mmHg) was obtained. This fraction was decomposed into its starting materials (mole ratio: 1 : 1) when passed through a Dinonyl Phthalate and Silicone DC 550 column at 80°C. This fraction was confirmed to be a 1 : 1 adduct on the basis of the above finding, elementary analysis and molecular weight determination. The infrared spectrum showed the presence of a vinyl ether group[3] and a trimethylene oxide ring,[3] but the absorptions of a carbonyl group and a hydroxy group were not observed. The structure of this photoadduct, therefore, is either Ia or Ib.



This was determined by means of the NMR spectrum. NMR spectral data are compiled

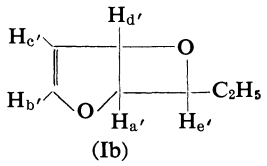


TABLE I. THE REACTION CONDITIONS AND YIELD OF THE PRODUCTS

| Furan g. | Aldehyde g. | Oxetane g. | Residue g. | Yield[a] % | Ultimate yield[b] % |
|---|---|---|---|---|---|
| $C_4H_4O$ 126 | $C_2H_5CHO$ 28 | 10 | 2.5 | 17 | 80 |
| $C_4H_4O$ 112 | $C_6H_5CHO$ 42.5 | 24.5 | 3.5 | 35 | 88 |
| $CH_3$-$C_4H_3O$ 125 | $C_2H_5CHO$ 23.2 | 9.5 | 3.5 | 17 | 73 |
| $CH_3$-$C_4H_3O$ 120 | $C_6H_5CHO$ 38.5 | 22 | 3.4 | 32 | 87 |

a) Yield of products based on aldehyde used.
b) Yield of products based on aldehyde consumed.

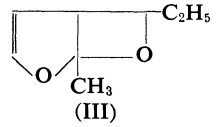
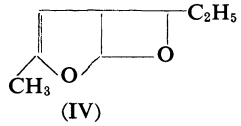
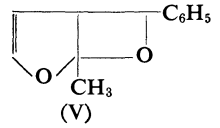
(Ia)



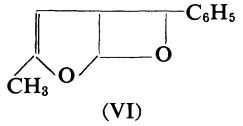
(Ib)



in Table II. Supposing that it is Ib, as all protons except for ethyl protons are adjacent to oxygen or are vinylic, it may be expected that the $\tau$-value of each proton will be less than 5.5. However, a proton with a $\tau$-value of 6.58 was observed. Moreover, although a proton a' would be a triplet and a proton d' would be a sextet or octet in the structure Ib, a doublet and a complex multiplet were actually observed. The structure, therefore, was identified as 6-ethyl-2, 7-dioxa-bicyclo-[3, 2, 0]-$\Delta^3$-heptene (Ia). The infrared spectrum of the residue showed strong bands of the carbonyl and hydroxy groups. The ratio of the residue to Ia increased with the irradiation time. Ia was rather stable in a sealed tube. When Ia was exposed to air, however, its infrared spectrum gradually became similar to that of the residue. The residue, therefore, seems to consist of the products formed from Ia by further reaction by, for instance, light or oxygen.



In the photochemical reaction of benzaldehyde and furan, the photoadduct was similarly identified as 6-phenyl-2, 7-dioxa-bicyclo-[3, 2, 0]-$\Delta^3$-heptene (II).



In the case of propionaldehyde (or benzaldehyde) and 2-methylfuran, mixtures of III (or V) and IV (or VI) were obtained.

with furan probably proceeds by the following path.

The intermediate (VII) has the structure which is to be expected from the principle of the maximum resonance stabilization of the intermediate diradical. VII is also expected from the simple LCAO-MO. Since the excited benzaldehyde has a free radical character[4] at

4) G. S. Hammond and P. A. Leermakers, *J. Am. Chem. Soc.*, **84**, 207 (1962).

the oxygen atom, as is to be expected from an excitation of the $n$-$\pi^*$ type, the oxygen atom with a free radical character will attack the site of higher free valence or a more frontier electron density[5] of the furan ring to yield VII.

## Experimental[6]

**Materials.**—Propionaldehyde was purified by distillation; b. p. 50°C, $n_D^{20}$ 1.3689. Benzaldehyde was also purified by distillation; b. p. 36.5°C (2 mmHg), $n_D^{20}$ 1.5444. Furan[7] was prepared by the decarboxylation of 2-furancarboxylic acid, formed by the Cannizzaro reaction of furfural, and purified by fractional distillation over calcium chloride; b. p. 31.5°C. 2-Methylfuran[8] was prepared by the following method. A mixture of 270 g. of furfural and 300 g. of a 30—40% aqueous hydrazine solution was added drop by drop to 50 g. of potassium hydroxide in a 1-l. Claisen flask, which was then placed in an oil bath heated at 150—160°C. The distillate was collected, and the upper layer was separated, dried over potassium hydroxide and distilled; b. p. 63°C. These materials were gas chromatographically pure and were redistilled before use.

**6-Ethyl-2,7-dioxa-bicyclo-[3,2,0]-$\Delta^3$-heptene (Ia).**—A mixture of 126 g. (1.85 mol.) of furan and 28 g. (0.48 mol.) of propionaldehyde was placed in a 180 ml. reaction vessel and irradiated at 5—10°C in a nitrogen atmosphere for 6 hr.[9] The unreacted materials were then distilled off, and the portion boiling at 70—75°C (30 mmHg) was collected; yield, 10 g. (17%). This fraction was redistilled at 30 mmHg (b. p. 74—75°C); $n_D^{20}$ 1.4567. Principal infrared bands: 3075, 2945, 1605, 1460, 1213, 1198, 1130, 1043, 1013, 985, 950, 887, 850 and 715 $cm^{-1}$.

Found: C, 66.29; H, 8.29; mol. wt., 127. Calcd. for $C_7H_{10}O_2$: C, 66.64; H, 7.99%; mol. wt., 126.

**6-Phenyl-2, 7-dioxa-bicyclo-[3, 2, 0]-$\Delta^3$-heptene (II).**—A mixture of 112 g. (1.65 mol.) of furan and 42.5 g. (0.40 mol.) of benzaldehyde was irradiated at 5—10°C for 6 hr. and then treated in the same manner as has been discribed above. A 100—115°C (2 mmHg) fraction was then collected; yield, 24.5 g. (35%). This fraction was redistilled at 1.2 mmHg (b.p. 104—105°C); m.p. 49—50°C. Principal infrared bands: 3080, 2940, 1608, 1458, 1380, 1198, 1130, 1040, 940 and 708 $cm^{-1}$.

Found: C, 76.12; H, 6.02; mol. wt., 175. Calcd. for $C_{11}H_{10}O_2$: C, 75.84; H, 5.79%; mol. wt., 174.

**1-Methyl-6-ethyl-2, 7-dioxa-bicyclo-[3, 2, 0]-$\Delta^3$-heptene (III) and 3-Methyl-6-ethyl-2, 7-dioxa-bicyclo-[3, 2, 0]-$\Delta^3$-heptene (IV).**—A mixture of 125 g. (1.52 mol.) of 2-methylfuran and 23.2 g. (0.40 mol.) of propionaldehyde was irradiated and then treated in the same manner as has been described above. A 60—90°C (17 mmHg) fraction was collected; yield, 9.5 g. (17%). This fraction was redistilled at 15 mmHg (b. p. 65—68°C), $n_D^{20}$ 1.4473. Principal infrared bands: 3060, 2910, 1668, 1605, 1460, 1382, 1222, 1167, 1125, 1050, 1010, 980, 955, 890, 850 and 720 $cm^{-1}$.

Found: C, 68.45; H, 8.65; mol. wt., 146. Calcd. for $C_8H_{12}O_2$: C, 68.54; H, 8.63%; mol. wt., 140.

This fraction was identified by NMR spectra as being composed of III and IV.

**1-Methyl-6-phenyl-2, 7-dioxa-bicyclo-[3, 2, 0]-$\Delta^3$-heptene (V) and 3-Methyl-6-phenyl-2, 7-dioxa-bicyclo-[3, 2, 0]-$\Delta^3$-heptene (VI).**—A mixture of 120 g. (1.46 mol.) of 2-methylfuran and 38.5 g. (0.36 mol.) of benzaldehyde was irradiated and treated in the same manner as has been described above. A 90—110°C (1 mmHg) fraction was collected; yield, 22 g. (32%). This fraction was redistilled at 1 mmHg (b. p. 100—110°C), $n_D^{20}$ 1.5380. Principal infrared bands: 3000, 2945, 1665, 1605, 1490, 1383, 1350, 1224, 1162, 1103, 1040, 950, 890, 750 and 698 $cm^{-1}$.

Found: C, 76.60; H, 6.63; mol. wt., 186. Calcd. for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%; mol. wt., 188.

This fraction was identified by NMR spectra as being composed of V and VI.

## Summary

The photochemical reaction of aldehydes (propionaldehyde and benzaldehyde) and furan have been studied in the liquid phase; two new compounds, oxetanes I and II have easily been produced with a high purity by this photo-reaction.

In the case of 2-methylfuran and propionaldehyde (or benzaldehyde), a mixture of oxetanes III and IV (or V and VI) has also been obtained.

The authors are indebted to the Shionogi Research Laboratory (Shionogi & Co., Ltd.) for the measurement of the NMR spectra.

# Studies of Chemical Kinetics by Means of the Velocity of Sound. II. The Condensation of Acetaldehyde to Aldol

By Tatsuya YASUNAGA, Nobuhide TATSUMOTO and Masaji MIURA

(Received September 10, 1964)

Bell[1,2] and Matsuyama[3] have investigated the kinetics of the condensation of acetaldehyde to aldol. In his earlier work Bell concluded, from his dilatometric study, that this reaction is of the first order with respect to acetaldehyde concentration and that the reaction velocity is proportional to the concentration of the $OH^-$ catalyst. A major drawback in his experimental setup was that the scale of the dilatometer was not corrected for the increase in temperature in the reaction system at the initial state of this reaction. In his report in 1960, on the other hand, he concluded, from the ultraviolet absorption study, that the reaction is of the second order. With his method it is difficult to measure the time and to control the temperature accurately without disturbing the reaction system, because a part of the solution has to be removed. Matsuyama has also studied the same reaction system with a calorimetric method and has concluded that it is of the second order and that the relation between the velocity constant and the concentration of $OH^-$ is linear. It is objectionable, however, to use, as in his study, a Beckmann thermometer with such a large heat capacity in order to measure the change in temperature in the reaction system. As has been described in a previous paper,[4] we measured the velocity of sound by means of a sing-around velocimeter in order to study the change in the chemical reaction with time. In this work we will attempt to study the condensation of acetaldehyde to aldol by the same method as has been used previously.

## Theoretical

It is highly likely that the change in the velocity of sound is in proportion to the concentration of acetaldehyde, provided that the change in the concentration is comparatively small. Therefore,

$$C_1-C_\infty=\alpha(f_1-f_\infty) \quad (1)$$

$$C_i-C_\infty=\alpha(f_i-f_\infty) \quad (2)$$

where $C_1$, $C_i$, $C_\infty$, $f_1$, $f_i$, and $f_\infty$ are the concentrations of acetaldehyde and the pulse repetition frequencies at times $t_1$, $t_i$ and $t_\infty$, respectively, $t_1$ being the starting time for the measurement, and where $\alpha$ is a proportionality constant. By subtraction,

$$C_1-C_i=\alpha(f_1-f_i) \quad (3)$$

If this reaction is of the second order with respect to the acetaldehyde concentration and if no product reacts consecutively during the measurement, the reaction may be expressed by:

$$1/(a-x)=kt+1/a \quad (4)$$

where $a$ is the initial concentration of acetaldehyde; $x$, the decrease in the concentration of acetaldehyde after the lapse of time, $t$, and $k$, the velocity constant. Equation 4 can be expressed with $C$ in place of $a$ and $x$:

$$1/(C_i-C_\infty)=k\Delta t_i+1/(C_1-C_\infty) \quad (5)$$

Thus:

$$(C_1-C_i)/\{(C_1-C_\infty)(C_i-C_\infty)\Delta t_i\}=k \quad (6)$$

or

$$(C_1-C'_i)/\{(C_1-C_\infty)(C'_i-C_\infty)\Delta t'_i\}=k \quad (7)$$

where $\Delta t_i=t_i-t_1$, $\Delta t'_i=t'_i-t_1$, and $C'_i$ is the concentration of acetaldehyde at $t=t'_i$. From Eqs. 6 and 7,

$$(C_1-C_i)/\{(C_1-C_\infty)(C_i-C_\infty)\Delta t_i\} = (C_1-C'_i)/\{(C_1-C_\infty)(C'_i-C_\infty)\Delta t'_i\} \quad (8)$$

From Eqs. 1, 2, 3 and 8,

$$f_1-f_\infty=\{(f_1-f_i)(f_1-f'_i)(\Delta t'_i-\Delta t_i)\}/\{(f_1-f_i)\Delta t'_i-(f_1-f'_i)\Delta t_i\} \quad (9)$$

where $f'_i$ is the pulse repetition frequency at $t=t'_i$. Equation 5 may also be rewritten as follows:

$$1/(f-f_\infty)=1/\{(f_1-f_\infty)-(f_1-f)\}= \alpha k\Delta t+1/(f_1-f_\infty) \quad (10)$$

Therefore, if a plot of $1/(f-f_\infty)$ obtained from Eqs. 9 and 10 against $\Delta t$ is linear, the reaction must be of the second order. On the other hand, if this reaction is of the first order, the reaction is given as follows:

$$\ln(f-f_\infty)=\ln\{(f_1-f_\infty)-(f_1-f)\}= -k\Delta t+\ln(f_1-f_\infty) \quad (11)$$

1) R. P. Bell, *J. Chem. Soc.*, **1937**, 1636.
2) R. P. Bell and P. T. McTigue, ibid., **1960**, 2983.
3) H. Matsuyama, *Proc. Japan Acad.*, **27**, 552 (1951).
4) T. Yasunaga, N. Tatsumoto and M. Miura, This Bulletin, **37**, 1655 (1964).

Therefore, $f_1-f_\infty$ is given in Eq. 12 under the condition that $2\Delta t_i=\Delta t'_i$:

$$f_1-f_\infty=(f_1-f_i)^2/(f_1+f'_i-2f_i) \qquad (12)$$

If the experimental values of $\ln(f-f_\infty)$ plotted against $\Delta t$ satisfy Eq. 11, giving a linear curve, then the reaction is probably of the first order.

## Experimental

The condensation of acetaldehyde to aldol has been investigated in a dilute aqueous solution of sodium hydroxide (0.0050—0.0145 M). The reagent was extra pure grade acetaldehyde in an ampoule and used without further purification. The acetaldehyde was diluted with air-free water in order to prepare about 0.57 mol./l. of an aqueous solution. The concentration of acetic acid contained in this solution was found to be 0.002 mol./l. by titration.

The sample and the catalyst solution were then mixed in a flask and transferred from it into a cell. Before each measurement, air was replaced with nitrogen. The measurements were carried out in a water bath at 25°C. The temperature was observed in the water bath with a Beckmann thermometer and inside the cell with a thermistor thermometer. (A detailed description of our sing-around velocimeter was given in the previous paper.[4]) As a result of the mixing of the sample solution with the catalyst, the temperature in the reacting system began to rise in seven to ten minutes and reached an equilibrium with the bath temperature, 25°C, in thirty minutes. The correction for the velocity of sound, therefore, should be made for the temperature rise in the initial stage of the reaction. Measurement over a long period is not desirable in this study, for subsequent reactions would probably occur in this system.

## Results

The changes in the velocity of sound, corrected for the temperature change with time, are shown in Fig. 1 for a dilute aqueous solution of sodium hydroxide (0.0050—0.0145 M). The changes in the values for $1/(f-f_\infty)$ and $\ln(f-f_\infty)$ with time are plotted in Figs. 2 and 3 respectively. A comparison of the two curves shows that the results from the former give a better linearity than those from the latter. That is, all of the curves for the former are linear, but those for the latter deviate from the linear line, passing through three points, $\log(f_1-f_\infty)$, $\log(f_i-f_\infty)$ and $\log(f'_i-f_\infty)$. Hence, this reaction is probably of the second order within the period studied here.

## Discussion

The above experimental results can be explained on the basis of a reaction scheme[5] of

5) A. Frost and R. G. Pearson, "Kinetics and Mechanism," John Wiley & Sons Inc., New York, London (1961), p. 335.

the following condensation of acetaldehyde:

$$HCOCH_3 + B \underset{k_2}{\overset{k_1}{\rightleftarrows}} HCOCH_2^- + BH^+ \quad (13)$$

$$HCOCH_2^- + HCOCH_3 \underset{k_4}{\overset{k_3}{\rightleftarrows}} HCOCH_2\text{-}\underset{CH_3}{\underset{|}{CHO}}^- \quad (14)$$

$$HCOCH_2\text{-}\underset{CH_3}{\underset{|}{CHO}}^- + BH^+ \underset{k_6}{\overset{k_5}{\rightleftarrows}} HCOCH_2\text{-}\underset{CH_3}{\underset{|}{CHOH}} + B \quad (15)$$

where B is a base and $k$ is the velocity constant. The last step being very fast, the above scheme can be reduced to:

$$HCOCH_3 + B \underset{k_2}{\overset{k_1}{\rightleftarrows}} HCOCH_2^- + BH^+ \quad (16)$$

$$HCOCH_2^- + HCOCH_3 \overset{k_3}{\rightarrow} \text{Product} \quad (17)$$

Thus,

$$[HCOCH_2^-] = \{k_1[HCOCH_3][B]\}/\{k_3[HCOCH_3] + k_2[BH^+]\} \quad (18)$$

$$d[\text{product}]/dt = \{k_1k_3[HCOCH_3]^2[B]\}/\{k_3[HCOCH_3] + k_2[BH^+]\} \quad (19)$$

Two limiting cases, in which $k_3[HCOCH_3]$ is much greater or much smaller than $k_2[BH^+]$, are of interest. The first case leads to:

$$\text{rate} = k_1[HCOCH_3][B] \quad (20)$$

and the second to:

$$\text{rate} = k_1k_3[HCOCH_3]^2[B]/k_2[BH^+] = k_1k_3[HCOCH_3]^2[S^-]/k_2K_B \quad (21)$$

where $K_B$ is the ionization constant of the base and $S^-$ is the anion of the solvent, SH. If $k_3[HCOCH_3]$ is greater than $k_2[BH^+]$, the reaction is of the first order. As $[HCOCH_3]$ approaches zero, the rate must become second order with respect to the concentration of acetaldehyde. The concentration of acetaldehyde is so dilute in this study that these reactions would be second order.

The above consideration leads to the conclusion that the measurement of the velocity of sound is a useful method for the study of the chemical kinetics of simple reactions as in our present and previous papers. Further, considering the advantageous characteristics of the sing-around velocimeter, we expect that this method can be extended to the study of the kinetics of the fast reaction, which is difficult to measure with other methods.

# Acid and Basic Hydrolyses of *p*-Nitrophenyl Benzenesulfonate*

By Shigeru OAE and Reiko KIRITANI

(Received September 11, 1964)

In previous papers we have reported on studies of both the acid[1] and alkaline[2] hydrolyses of phenyl benzenesulfonate, and have suggested that these reactions proceed through the $S_N2$-type process, in which a nucleophilic attack of either water or the hydroxide ion takes place on the sulfur atom. It was also shown that there was no oxygen exchange in the ester during the hydrolyses, unlike the cases of the esters of carboxylic acid.[3] There was an incorporation of only one equivalent amount of $^{18}O$ in the benzenesulfonic acid isolated from reaction products. In the case of the acid hydrolysis, however, it was found that the phenol isolated from the hydrolysis of the ester with $^{18}O$-enriched water was incorporated with the excess $^{18}O$.

Although the reaction proceeded via the acyl-oxygen cleavage, the phenol formed was found to exchange gradually its oxygen with that of the medium water during the acid hydrolysis.

During the course of our study of the oxygen exchange between phenols and water in both acid and alkaline media, *p*-nitrophenol was found to undergo the oxygen exchange more readily than the other substituted phenols studied.[4] Since the substitution of the nitro group on the benzene ring of an

aromatic compound usually causes a strong activation of the ortho- and para-positions of the benzene ring, and hence makes a nucleophilic attack at these positions easier, it is not surprising to expect an aryl-oxygen cleavage, especially in the alkaline hydrolysis of the titled compound. Therefore, one may expect that the substitution of a nitro group at the para-position, namely in the titled compound, will change the course of the hydrolyses.

Recently, Bunnett and Bassett, Jr.[5] have shown through their kinetic study that a number of mono- and dinitro phenol esters of *p*-toluenesulfonic acid are found to undergo both sulfur-oxygen and carbon-oxygen scissions in the reactions with a few such strong nucleophilic reagents as thiophenolate ions, piperidine and methoxide ions.

Meanwhile, Vizgert et al.[6] have also found that the nitro group at either ortho- or para-positions of the phenolic portion of substituted phenyl benzenesulfonates showed a marked accelerating effect in the alkaline hydrolysis of substituted phenyl benzenesulfonates.

The present research was designed to investigate further the mechanisms of both acid and alkaline hydrolyses of the titled compound by means of both the $^{18}O$ tracer technique and a kinetic study of the hydrolyses.

## Results and Discussion

**Acid Hydrolysis.** — The acid hydrolysis of the titled compound was very sluggish and was found to take place only above 160°C in a sealed tube using 10 N hydrochloric acid, much as in the case of phenyl benzenesulfonate. The ester and 10 N hydrochloric acid, made by dissolving hydrogen chloride gas into $^{18}O$-enriched water, were sealed in a tube; the tube was then heated at 180°C for 6 hr. The reaction was stopped before completion in order to see if the hydrolysis reaction proceeds through a reversible addition intermediate; thereby unhydrolyzed ester was recovered, together with the hydrolysis products, i.e., *p*-nitrophenol and benzenesulfonic acid.

Meanwhile, the same reactants were also heated in sealed tubes at 180°C for 24 hr., the ester was completely hydrolyzed, and the products were isolated. In order to see the effects of acid concentration on the hydrolysis, the hydrolysis was also carried out using 3.5 N hydrochloric acid prepared with $^{18}O$-enriched water. When the mixtures of the ester and the 3.5 N hydrochloric acid were also heated at 180°C for 6 hr., 12 hr., and 24 hr. in sealed tubes, it was found that the hydrolysis was half completed after the mixtures had been heated for 24 hr. The reaction products obtained in nearly quantitative yields after the complete hydrolysis were purified in the following ways: *p*-nitrophenol was sublimed, while benzenesulfonic acid was treated with *S*-benzylthiuronium chloride to give the *S*-benzylthiuronium sulfonate. The recovered ester was recrystallized from ethanol, and all these samples were subjected to $^{18}O$ analysis by the usual method.[7] The results are shown in Table I.

In all cases, the $^{18}O$ content of the recovered ester was found to be 0.20 atom% $^{18}O$. As this value represents the natural $^{18}O$ atom%, it illustrates that there is no exchange of $^{18}O$ in the ester during this reaction process, as in the case of phenyl benzenesulfonate. This observation clearly excludes any reversible prior addition of water molecules or hydronium ions during the hydrolysis of the titled compound and suggests that the overall reaction is irreversible. The observation also seems to suggest that the reaction is a $S_N2$-type synchronous one-step process initiated by the attack of water oxygen on the sulfur atom, which bears a formal double-positive charge as in the case of the hydrolysis of phenyl benzenesulfonate. Two alternative mechanistic

schemes are also conceivable for this reaction; one involves the nucleophilic attack of water on the aromatic ring carbon para to the nitro group, and the other is a $S_N1$-type process involving a slow cleavage of a sulfur-oxygen or carbon-oxygen bond, followed by rapid solvolysis, to form sulfonic acid and *p*-nitrophenol. However, the aromatic $S_N2$-type mechanism cannot be accepted, since the benzenesulfonic acid isolated was found to be incorporated with one atom equivalent amount of $^{18}O$ of $^{18}O$-enriched water (0.66 atom%); this cannot be reconciled with the aromatic $S_N2$-type mechanism involving the carbon-oxygen cleavage.

The $S_N1$-type mechanism involving the cleavage of the carbon-oxygen linkage is not plausible. The $S_N1$ process of this type did not take place in the acid hydrolysis of phenyl benzenesulfonate. The substitution of a strong electron-withdrawing group, such as a nitro group, at the para-position will suppress even more the $S_N1$-type C–O bond cleavage. On the other hand, the $S_N1$-type cleavage of a S–O bond is also very difficult, since it will leave an additional positive charge on the sulfur atom, which already bears double formal positive charges, and the cleavage would require an enormous energy.

The remaining and the most probable pathway is the $S_N2$-type process initiated by the attack of the water molecule on the sulfur atom. If the reaction proceeds through this process, the benzenesulfonic acid will be incorporated with one equivalent amount of $^{18}O$ and the *p*-nitrophenol will remain natural. While benzenesulfonic acid was incorporated with $^{18}O$ just as much as is required from this process, *p*-nitrophenol was always incorporated with an excess of $^{18}O$ above the natural concentration, and the amount of $^{18}O$ incorporation appeared to increase with prolonged heating, as is shown by Table I.

In separate experiments we have carried out the oxygen exchange reactions of *p*-nitrophenol, phenol, benzenesulfonic acid and

Table II. Oxygen exchange reaction of some compounds in the acidic solution

| Compound | Reaction time, hr. | $^{18}O$ Atom % of aq. HCl soln. | $^{18}O$ Atom % of products |
|---|---|---|---|
| *p*-Nitrophenol | 6 | 1.58 | 0.40 (0.80)* |
| | 24 | 1.58 | 0.37 (0.72) |
| Nitrobenzene | 24 | 1.58 | 0.20 |
| Phenol | 5 | 0.8 | 0.37 |
| | 24 | 0.77 | 0.73 |
| Benzenesulfonic acid | 5 | 0.8 | 0.23 |
| | 24 | 0.8 | 0.24 |

* See footnote in Table I.

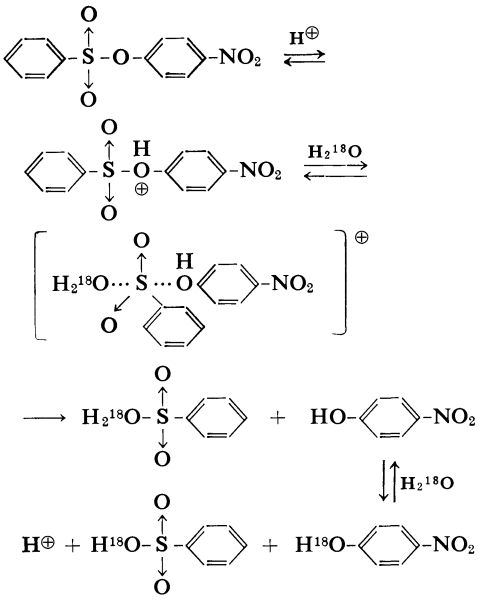

Fig. 1

nitrobenzene in the same acidic (10 N) solutions. The results are shown in Table II.

There was no apparent oxygen exchange in the nitro group; however, *p*-nitrophenol was found to undergo a more facile oxygen exchange than phenol in 6 hours of treatment. This observation also indicates that the *p*-nitrophenol formed during the acid hydrolysis of the ester gradually changed its phenolic oxygen atom with a solvent of $^{18}O$-enriched water. Thus, the overall reaction scheme of this acid-catalyzed hydrolysis of the ester is considered to be the $S_N2$ process, in which the water molecule attacks the sulfur atom, shown by Fig. 1, giving benzenesulfonic acid and *p*-nitrophenol, which then undergoes further phenolic oxygen exchange with the solvent water.

**Alkaline Hydrolysis.**—The titled ester was dissolved in $^{18}O$-enriched water containing 1% potassium hydroxide, and the solution was refluxed for 8 hr. Since the reaction was partially completed, some recovered esters were obtained, together with the reaction products, benzenesulfonic acid and *p*-nitrophenol. Similarly, the ester was hydrolyzed with $^{18}O$-enriched water containing 10% potassium hydroxide and refluxed for 8 hr. In this way the reaction was completed, and benzenesulfonic acid and *p*-nitrophenol were obtained in nearly quantitative yields. All the products and the recovered ester thus obtained were subjected to the usual $^{18}O$ analysis; the results are shown in Table III.

Here again, the $^{18}O$ content of the recovered ester was not increased more than the natural $^{18}O$ content during this partial hydrolysis

TABLE III. DISTRIBUTION OF THE $^{18}O$ LABEL IN ALKALINE HYDROLYSIS PRODUCTS

| Run | Reaction time, hr. | $^{18}O$ Atom% of aq. KOH soln. | $^{18}O$ Atom% of products | | |
|---|---|---|---|---|---|

* See footnote in Table I.

process. The overall reaction was irreversible, and obviously there was no reversible prior addition of hydroxyl ions to the sulfur atom. However, there were a few significant differences between the acid and alkaline hydrolysis of this compound. While the benzenesulfonic acid obtained in the acid hydrolysis was always incorporated with one equivalent amount of the $^{18}O$ (0.66 atom%) resulting from the $^{18}O$-enriched water used, the alkaline hydrolysis yielded benzenesulfonic acid, whose $^{18}O$ incorporation was somewhat lower (0.54, 0.57 atom%) than that of the $^{18}O$-enriched water used. *p*-Nitrophenol was also incorporated with $^{18}O$; its $^{18}O$ incorporation was apparently larger when the potassium hydroxide solution used was more concentrated.

In separate experiments the oxygen exchange reactions were carried out in aqueous potassium hydroxide under the same conditions in order to test the oxygen exchange of these products with solvent water. The results are shown in Table IV.

It is interesting to note that the $^{18}O$ exchange was negligible when the concentration of potassium hydroxide was small (1%), but that it became substantial when the alkaline concentration was increased to 10%. On the other hand, the hydrolysis in the 1% potassium hydroxide solution gave *p*-nitrophenol noticeably enriched with $^{18}O$ and benzenesulfonic acid, the $^{18}O$ concentration of which was apparently lower than what was to be expected from a straight-forward $S_N2$ process involving the nucleophilic attack of the hydroxyl ion on the sulfur atom, as is shown in Fig. 2.

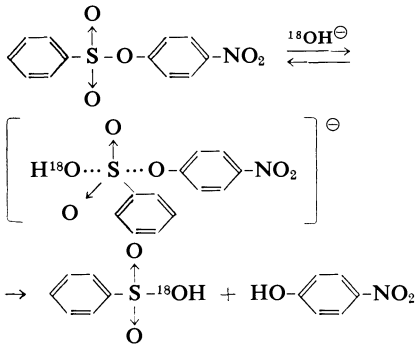

Fig. 2

The small increase in the $^{18}O$ in the *p*-nitrophenol and the decrease in $^{18}O$ in the sulfonic acid can be accounted for if one assumes that a portion of the reaction proceeded via an aromatic $S_N2$ process involving the C–O bond cleavage, as is shown in Fig. 3.

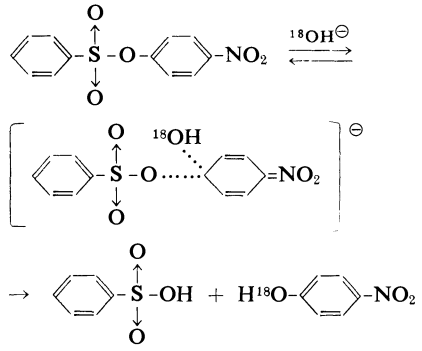

Fig. 3

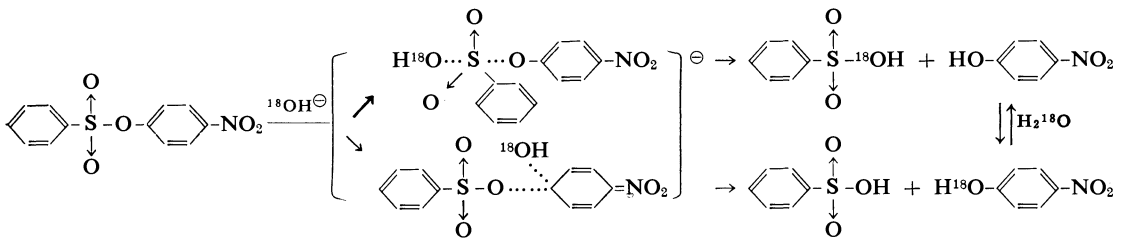
Therefore, at least in the alkaline hydrolysis with a 1% potassium hydroxide solution, the two reactions appears to compete, though the $S_N2$ process involving the nucleophilic attack on the sulfur atom is by far the predominant path (about 78—80%). In the concentrated alkaline solution (10% potassium hydroxide), the oxygen-exchange was found to take place substantially for *p*-nitrophenol. This somewhat obscures the mechanistic diagnosis with the $^{18}O$ data of the hydrolysis products. One can see, however, that the concentration of



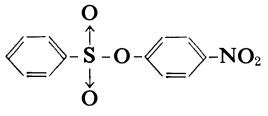


Fig. 4

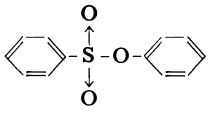

$^{18}O$ in the nitrophenol after 8 hr. of $^{18}O$ exchange was markedly higher (0.58) than that in the same compound obtained in the hydrolysis (0.48). Moreover, the $^{18}O$ concentration of the *p*-nitrophenol obtained by the hydrolysis was far smaller than that of the water used. From these results, it is clear that the major portion of the reaction proceeded via the usual $S_N2$ process involving a nucleophilic attack on the sulfur atom (Fig. 2), much as in the earlier findings with other strong nucleophiles.[5] In contrast to the marked increase in $^{18}O$ in the nitrophenol in the hydrolysis in a 10% alkaline solution, no reduction of $^{18}O$ concentration in benzenesulfonic acid resulted from the change of alkalinity from 1% to 10%. Instead, there was only a slight increase, if any. This may mean that in the concentrated alkaline solution a small portion of the reaction also proceeds via an aromatic $S_N2$ process involving C–O bond cleavage and that the resulting nitrophenol undergoes subsequent $^{18}O$ exchange. Thus, the overall reaction scheme can be represented by the two competing process shown by Figs. 2 and 3; however, the ordinary $S_N2$ process involving the attack of the hydroxyl ion on the sulfur atom is the predominant path. A schematic illustration is shown in Fig. 4.

The rates of the alkaline hydrolyses of two esters, *p*-nitrophenyl benzenesulfonate, and phenyl benzenesulfonate, have been investigated at 49.5±0.05°C in alkaline aqueous 50% dioxane. An inspection of the data reveals that the rate of the former is substantially higher than that of the latter, as Russian workers have shown previously.[7]

$k_2 = 78.6 \times 10^{-3}$ sec$^{-1}$ mol./l. for

$k_2 = 0.416 \times 10^{-3}$ sec$^{-1}$ mol./l. for

This means that the substitution of a nitro group at a para-position markedly facilitates the nucleophilic attack of the hydroxide ion on phenyl benzenesulfonate. At first it was thought that the rate-acceleration due to the *p*-nitro group is related to the facile nucleophilic attack of the hydroxide ion on the aromatic carbon atom via an aromatic $S_N2$ process; however, the $^{18}O$ data do not support this idea. The presence of a *p*-nitro group apparently reduces the electron density around not only the aromatic $C_1$ atom, but also the sulfonyl sulfur atom, thereby causing a large acceleration of the nucleophilic attack of the hydroxide ion on both positions.

## Experimental

***p*-Nitrophenyl Benzenesulfonate.**—*p*-Nitrophenol (28 g., 0.2 mol.) was dissolved in 160 ml. of pyridine. The mixture was cooled in ice water, and an equimolar amount of benzenesulfonyl chloride (35 g.) was stirred into it drop by drop and then allowed to stand at 0°C overnight. The reaction mixture was then poured in ice water. After filtering, the precipitate was repeatedly washed with water and aqueous sodium bicarbonate to remove the pyridinium hydrogen chloride completely and then recrystallized from ethanol. Ninety grams of a colorless plate, *p*-nitrophenyl benzenesulfonate, were obtained (89% purified yield); m. p. 88—89°C.

**Hydrolysis in an Acidic Solution.**—*p*-Nitrophenyl benzenesulfonate (1 g.) was dissolved in 5 ml. of 10 N hydrochloric acid containing 1.58 atom % of $^{18}O$. The mixture was kept for 24 hr. at 180°C in a sealed tube. Then the sealed tube was broken, and all the contents were extracted with ether. The aqueous layer was then evaporated down to 2 ml. To this solution a few drops of hyrochloric acid and *S*-benzylthiuronium chloride (0.7 g.) were added, and 1.3 g. of *S*-benzylthiuronium salt of benzenesulfonic acid (white plate) was obtained, m. p. 148.5°C. This corresponds to 0.55 g. of benzenesulfonic acid (97% yield). The ether extract was dissolved in aqueous sodium carbonate and extracted with ether to remove the unhydrolyzed ester (though none of the ester was extracted). The alkaline layer was then neutralized with weak hydrochloric acid and extracted with ether again. From the combined ether extract, the ether was removed and the residual mass was sublimated

twice to obtain 0.46 g. of pure *p*-nitrophenol, m. p. 113°C (92.4% yield).

**Partial Hydrolysis in an Acidic Solution.**—The same reaction mixture used for the complete acid hydrolysis was made and then heated in a sealed tube for 6 hr. at 180°C. When the products were treated as described above, the unhydrolyzed ester (0.8 g.) and *p*-nitrophenol (0.08 g.) were obtained from the ether layer, while benzenesulfonic acid (0.1 g.) was isolated from the aqueous layer as the *S*-benzylthiuronium sulfonate. Some more experiments on the partial hydrolyses were carried out using the ester and 3.5 N hydrochloric acid containing 1.58 atom% $^{18}O$ at 180°C for 6 hr., 12 hr. and 24 hr. The products were also treated as has been described above.

**Hydrolysis in an Alkaline Solution.** — When potassium hydroxide (1.9 g., 0.034 mol.) was dissolved in 15 ml. of water containing 1.58 atom% $^{18}O$, the $^{18}O$ content of this solution was found to decrease to 1.55 atom% $^{18}O$. The ester (1.2 g., 0.0042 mol.) was dissolved in this solution (10%) and refluxed for 8 hr. The products were extracted with ether (though none of the ether layer was obtained from the ether layer). The alkaline layer was treated as described above, and 0.5 g. of *p*-nitrophenol and 0.6 g. of benzenesulfonic acid were isolated.

**Partial Hydrolysis in an Alkaline Solution.**—The ester (1.2 g.) was dissolved in the solution of 30 ml. of water-$^{18}O$ and 0.38 g. (0.0068 mol.) of potassium hydroxide; this solution, containing 1.58 atom% $^{18}O$, was then refluxed for 8 hr. The recovered ester and the reaction products, *p*-nitrophenol and benzenesulfonic acid, were obtained as has been described above. The ester (1.2 g.) was dissolved in a solution of 60 ml. of 50% dioxane-water-$^{18}O$ containing 0.38 g. of potassium hydroxide, and the solution was kept 50°C for 1 hr. After evaporation, the residue was treated as has been described above. The results were the same as those obtained in a heterogeneous system of aqueous solutions.

**The Kinetic Determination of the Alkaline Hydrolyses of *p*-Nitrophenyl Benzenesulfonate and Phenyl Benzenesulfonate.** — Solutions of *p*-nitrophenyl benzenesulfonate (3.5529 g., 0.0127 mol.) in 100 ml. dioxane and 100 ml. of aqueous potassium hydroxide (0.0382 mol./100 ml.) were separately immersed in a water thermostat set at 49.5±0.05°C for at least 30 min. before mixing. The hydrolyses were then started by mixing the two solutions by means of vigorous shaking. The rates were followed by pippetting out an aliquot portion of the mixture from time to time, then quenching it with an excess of standard hydrochloric acid, and finally back-titrating with standard potassium hydroxide using a pH-meter (the endpoint was PH 4.5).

In a separated experiment, a solution of phenyl benzenesulfonate (2.9769 g., 0.0127 mol.) in 100 ml. dioxane was hydrolyzed in the way which has been described above.

In both hydrolyses, the initial concentrations of the two components, the ester and the hydroxide ion, were made in a 1 : 3 mol. ratio; therefore, one mole equivalent of the hydroxide ion should be left in the solution at the end of the reaction, because every one mole of ester is considered to consume two moles of hydroxide ions in the reaction.

Therefore, the rates were calculated following the second-order rate kinetic equation shown below.

$$kt=\frac{1}{b-2a}\ln\frac{a(b-2x)}{b(a-x)}$$

$a$: Initial hydroxide ion concentration
$b$: Initial ester ion concentration
$x$: Concentration reacted
$t$: Time

A plot of $\ln\frac{a(b-2x)}{b(a-x)}$ versus $t$ gave straight lines in both cases, as is shown by Fig. 5.

**Isotopic Analysis.**—The $^{18}O$ analysis was performed as in a previous experiment.[7]

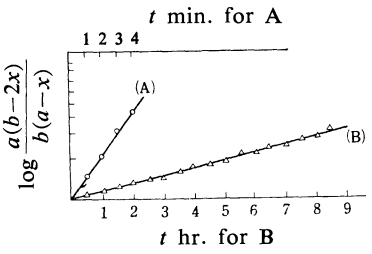

Fig. 5
(A) *p*-Nitrophenyl benzenesulfonate
(B) Phenyl benzenesulfonate

## Summary

The mechanisms of both the acid- and the alkaline-catalyzed hydrolyses of *p*-nitrophenyl benzenesulfonate have been investigated by means of the $^{18}O$-tracer technique. The acid-catalyzed hydrolysis apparently proceeds via a $S_N2$-type process involving the nucleophilic attack of water on the sulfur atom, with a S–O bond cleavage. Much as with the earlier findings concerning other nucleophiles, the major portion of the alkaline hydrolysis was also found to proceed through a $S_N2$ process which involves the nucleophilic attack of the hydroxide ion on the sulfur atom, with a S–O bond fission; only a small portion of the reaction appeared to proceed via an aromatic $S_N2$-type process.

# The Stability Constants of Ethylenediaminetetraacetato, Trimethylenediaminetetraacetato and Propylenediaminetetraacetato Complexes of Some Divalent Metal Ions

By Hiroshi OGINO

(Received September 14, 1964)

The equilibrium constants of substitution reactions involving ethylenediaminetetraacetato[1,2] and propylenediaminetetraacetato complexes[3] have been reported previously. Although Smith has reported the stability constants of propylenediaminetetraacetato complexes,[4] the values seem to be somewhat questionable.[3] Schwarzenbach et al. obtained the stability constants of trimethylenediaminetetraacetato complexes,[5,6] with which the ethylenediaminetetraacetato complexes are closely related. However, their study was restricted to alkaline earth metal, cadmium(II) and mercury(II) ions. Therefore, it seems worthwhile to clarify the relationships between the stability constants of ethylenediaminetetraacetato, trimethylenediaminetetraacetato and propylenediaminetetraacetato complexes of some divalent metal ions containing transition metal ions.

In this paper, these stability constants are determined by two methods. One is a new method which is based on the polarographic measurement of the concentration of an uncomplexed ligand in a solution containing two kinds of ligands and an appropriate metal ion. The other, a modification of the method described in the previous paper,[1] is used for the determination of the relative stability constants of trimethylenediaminetetraacetato complexes.

## Theoretical

**The Determination of the Relative Stability Constants of the Complexes with Different Ligands.**—Let us consider an equilibrated solution which contains a metal ($M^{m+}$) ion and two kinds of ligands (anions of $H_4Y$ and $H_4Z$).*

There exist the following equilibria:

$$MY^{(m-4)+} + Z^{4-} \rightleftarrows MZ^{(m-4)+} + Y^{4-} \quad (1)$$

$$Y^{4-} + nH^+ \rightleftarrows H_nY^{(4-n)-} \quad (2)$$

$$Z^{4-} + n'H^+ \rightleftarrows H_{n'}Z^{(4-n')-} \quad (3)$$

The overall reaction, therefore, may be expressed as:

$$MY^{(m-4)+} + \left\{\begin{array}{c} H_4Z \\ \uparrow\downarrow \\ H_3Z^- \\ \uparrow\downarrow \\ \vdots \\ \uparrow\downarrow \\ Z^{4-} \end{array}\right\} \rightleftarrows MZ^{(m-4)+} + \left\{\begin{array}{c} H_4Y \\ \uparrow\downarrow \\ H_3Y^- \\ \uparrow\downarrow \\ \vdots \\ \uparrow\downarrow \\ Y^{4-} \end{array}\right\} \quad (4)$$

When $[M]_t < [Y]_t + [Z]_t$, the total concentrations of metal and ligands, $[M]_t$, $[Y]_t$ and $[Z]_t$, in the solution are given as,

$$[M]_t = [MY^{(m-4)+}] + [MZ^{(m-4)+}] \quad (5)$$

$$[Y]_t = [MY^{(m-4)+}] + [Y]_f \quad (6)$$

$$[Z]_t = [MZ^{(m-4)+}] + [Z]_f \quad (7)$$

where

$$[Y]_f = \sum_0^4 [H_iY^{(4-i)-}]$$

$$[Z]_f = \sum_0^4 [H_jZ^{(4-j)-}]$$

The equilibrium constant of Eq. 4,

$$K^Y_{Z,app} = \frac{[Z]_f[MY^{(m-4)+}]}{[Y]_f[MZ^{(m-4)+}]} \quad (8)$$

can be calculated by means of the relations given by Eqs. 5 to 7, provided that the value of one term on the right-hand sides of Eqs. 5 to 7 is known. In this study, the values of $K^Y_{Z,app}$ were determined from the polarographic measurements of the concentrations of uncomplexed ethylenediaminetetraacetate or propylenediaminetetraacetate.

Equation 8 is rewritten as,

$$K^Y_{Z,app} = K^Y_Z \frac{\alpha_Z}{\alpha_Y} \quad (9)$$

where

1) N. Tanaka and K. Kato, This Bulletin, **33**, 417 (1960).
2) N. Tanaka, M. Kamada, H. Osawa and G. Satô, ibid., **33**, 1412 (1960).
3) N. Tanaka and H. Ogino, ibid., **38**, 439 (1965).
4) R. L. Smith, "The Sequestration of Metals," Chapman and Hall, London (1959).
5) G. Schwarzenbach and H. Ackermann, *Helv. Chim. Acta*, **31**, 1029 (1948).
6) G. Schwarzenbach, H, Senn and G. Anderegg, ibid., **40**, 1886 (1957).

* Although $H_4Y$ and $H_4Z$ represent alkylenediaminetetraacetic acids, they may be replaced by other appropriate ligands.

$$\alpha_Y = 1 + \frac{[H^+]}{K_{HY}} + \frac{[H^+]^2}{K_{H_2Y}K_{HY}} + \frac{[H^+]^3}{K_{H_3Y}K_{H_2Y}K_{HY}} + \frac{[H^+]^4}{K_{H_4Y}K_{H_3Y}K_{H_2Y}K_{HY}}$$

$$\alpha_Z = 1 + \frac{[H^+]}{K_{HZ}} + \frac{[H^+]^2}{K_{H_2Z}K_{HZ}} + \frac{[H^+]^3}{K_{H_3Z}K_{H_2Z}K_{HZ}} + \frac{[H^+]^4}{K_{H_4Z}K_{H_3Z}K_{H_2Z}K_{HZ}}$$

$$K_Z^Y = \frac{[Z^{4-}][MY^{(m-4)+}]}{[Y^{4-}][MZ^{(m-4)+}]} = \frac{K_{MY}}{K_{MZ}} \qquad (10)$$

$K_{H_4Y}$, $K_{H_3Y}$, $K_{H_2Y}$ and $K_{HY}$ represent, respectively, the first, the second, the third and the fourth dissociation constant of $H_4Y$, and $K_{H_4Z}$, $K_{H_3Z}$, $K_{H_2Z}$ and $K_{HZ}$, those of $H_4Z$, respectively.

Therefore, $K_Z^Y$, which is the ratio of the stability constant of $MY^{(m-4)+}$ to that of $MZ^{(m-4)+}$, can be determined from the value of $K_{Z,app}^Y$ by the use of the dissociation constants of $H_4Y$ and $H_4Z$.

**The Determination of the Relative Stability Constants of Trimethylenediaminetetraacetato Complexes.***—In the course of this study, it was found that the trimethylenediaminetetraacetatocobaltate(II) complex gives a polarographic one-electron oxidation wave.[7] In order to determine the relative stability constants of trimethylenediaminetetraacetato complexes, this anodic wave was utilized.

In an acetate buffer solution which contains cobalt(II) ions, other appropriate metal ions, and trimethylenediaminetetraacetate ions, there exist the following equilibria:**

$$\left\{\begin{matrix} Co^{2+} \\ \downarrow\uparrow \\ CoOAc^+ \end{matrix}\right\} + Mtrdta^{(m-4)+} \rightleftarrows Cotrdta^{2-} + \left\{\begin{matrix} M^{m+} \\ \uparrow\downarrow \\ M(OAc)_n^{(m-n)+} \end{matrix}\right\} \qquad (11)$$

where $trdta^{4-}$ denotes the quadrivalent trimethylenediaminetetraacetate anion.

The total concentrations of metals and TRDTA, $[Co]_t$, $[M]_t$ and $[TRDTA]_t$, in the solution are given as follows:

$$[Co]_t = [Co^{2+}]_{app} + [Cotrdta^{2-}] \qquad (12)$$

$$[M]_t = [M^{m+}]_{app} + [Mtrdta^{(m-4)+}] \qquad (13)$$

$$[TRDTA]_t = [TRDTA]_f + [Cotrdta^{2-}] + [Mtrdta^{(m-4)+}] \qquad (14)$$

where

$$[Co^{2+}]_{app} = [Co^{2+}] + [CoOAc^+]$$

$$[M^{m+}]_{app} = [M^{m+}] + \sum_1^n [M(OAc)_n^{(m-n)+}]$$

When $[Co]_t + [M]_t > [TRDTA]_t$, $[TRDTA]_f$ is negligibly small compared with the concentrations of other species present in the solution.

From the polarographic measurement of $[Cotrdta^{2-}]$, the equilibrium constant of Eq. 11

$$K_{Co,app}^M = \frac{[Co^{2+}]_{app}[Mtrdta^{(m-4)+}]}{[M^{m+}]_{app}[Cotrdta^{2-}]} \qquad (15)$$

is obtained with the relations given by Eqs. 12 to 14.

Equation 15 is rewritten as,

$$K_{Co,app}^M = K_{Co}^M \times \frac{1 + K_{CoOAc}[OAc^-]}{1 + \sum_1^n K_{M(OAc)_n}[OAc^-]^n} \qquad (16)$$

where

$$K_{Co}^M = \frac{[Co^{2+}][Mtrdta^{(m-4)+}]}{[M^{m+}][Cotrdta^{2-}]} \qquad (17)$$

Equation 17 means that $K_{Co}^M$ is equal to the ratio of the stability constant of the $M^{m+}$-TRDTA complex to that of the $Co^{2+}$-TRDTA complex:

$$K_{Co}^M = \frac{K_{MY}}{K_{CoY}} \qquad (18)$$

The values of $K_{Co}^M$ can be calculated from Eq. 16 using the values of $K_{Co,app}^M$ and the formation constants of the acetato complexes.[1,2,8]

## Experimental

**Reagents.** — Standard solutions of metal(II) nitrate, disodium dihydrogen ethylenediaminetetraacetate ($Na_2H_2edta$) and disodium dihydrogen propylenediaminetetraacetate ($Na_2H_2pdta$) were obtained by procedures reported previously.[1-3,9]

Trimethylenediaminetetraacetic acid ($H_4trdta$) was prepared according to the method described in the previous paper.[10] A stock solution of $Na_2H_2trdta$ was prepared from equimolar quantities of $H_4trdta$ and sodium carbonate. The concentration of TRDTA was determined by amperometric titration with standard solutions of copper(II) nitrate, cobalt(II) nitrate and nickel(II) nitrate in acetate buffer solutions of pH 5.4, and that of cadmium(II) nitrate, in ammonia-ammonium nitrate buffer solutions of pH 8.7. The values thus obtained were consistent with each other within the range of experimental error and were in good agreement with the value expected from the weight of $H_4trdta$.

All the other chemicals used were of analytical reagent grade.

**Apparatus and Procedure.** — The polarograph used was the same as that described in the previous paper.[3] The dropping mercury electrode had an $m$ value of $2.13_7$ mg./sec. and a drop time, $t_d$, of

7) The details will be published elsewhere.

* Trimethylenediaminetetraacetate may be replaced by other, appropriate ligands.

** It is known that cobalt(II) forms only a monoacetato complex in a solution containing acetate up to 0.2 M in concentration at ionic strength 0.2.[2]

8) N. Tanaka and K. Kato, This Bulletin, 32, 516 (1959).

9) N. Tanaka and H. Ogino, ibid., 36, 175 (1963).

10) N. Tanaka and H. Ogino, ibid., 37, 877 (1964).

3.96 sec., as measured in an air-free 0.2 M potassium nitrate solution containing 0.01% gelatin at 25°C. The pH of the solution was measured, after the polarographic measurement, with a Hitachi Horiba Model P pH meter.

In order to determine the relative stability constants of ethylenediaminetetraacetatocuprate(II), propylenediaminetetraacetatocuprate(II) and trimethylenediaminetetraacetatocuprate(II) complexes, measurements of the diffusion currents of ethylenediaminetetraacetate or propylenediaminetetraacetate in acetate buffer solutions were carried out with the following two reaction mixtures at 25°C:

(a) copper(II)-EDTA-TRDTA

(b) copper(II)-PDTA-TRDTA

The ionic strength was adjusted to be 0.2 with sodium perchlorate. Gelatin was added as a maximum suppressor by 0.01% in concentration. It was found in the preliminary experiments that the equilibria of systems a and b were attained within 30 min.

In order to determine the relative stability constants of trimethylenediaminetetraacetato complexes, measurements of the diffusion currents of the trimethylenediaminetetraacetatocobaltate(II) complex in the acetate buffer solutions were carried out with the following five reaction mixtures at 25°C:

(c) cobalt(II)-nickel(II)-TRDTA

(d) cobalt(II)-copper(II)-TRDTA

(e) cobalt(II)-zinc(II)-TRDTA

(f) cobalt(II)-cadmium(II)-TRDTA

(g) cobalt(II)-lead(II)-TRDTA

The ionic strength was adjusted to be 0.2 with potassium nitrate. Gelatin was added as a maximum suppressor by 0.005% in concentration. Since it was found that the substitution reactions between cobalt(II) ions and various kinds of metal(II)-TRDTA complexes were attained within 40 hr., measurements were made with solutions which had been kept in a thermostat for 2 days after preparation.

## Results

**The Determination of the Relative Stability Constants of Ethylenediaminetetraacetatocuprate(II), Propylenediaminetetraacetatocuprate(II) and Trimethylenediaminetetraacetatocuprate(II) Complexes.**—It is well known that EDTA gives a polarographic anodic wave[11] as a result of the following electrode reaction:

$$Hg + H_nY^{(4-n)-} \rightleftarrows HgY^{2-} + nH^+ + 2e$$

In the course of this study, it was found that PDTA gave a similar anodic wave and that its half-wave potential was slightly more negative than that of EDTA. TRDTA, on the other hand, was found to produce an ill-defined wave at a more positive potential than EDTA. These facts suggested that the concentrations of free EDTA and PDTA can be determined in systems a and b respectively. In Fig. 1 typical examples are given.

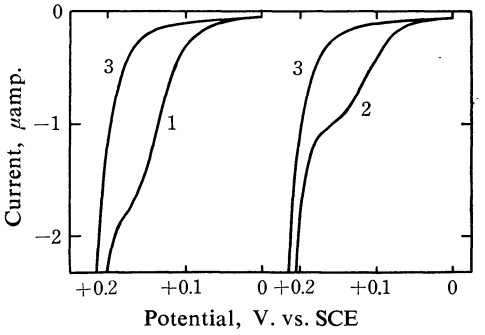

Fig. 1. Polarograms of systems a and b in the acetate buffer solutions of pH 5.38 at 25°C. Total concentrations are: 2.00 mM copper(II), 1.98$_8$ mM EDTA, 4.09$_6$ mM TRDTA (curve 1); 2.00 mM copper(II), 1.98$_8$ mM PDTA, 4.09$_6$ mM TRDTA (curve 2); 4.09$_6$ mM TRDTA (curve 3).

The diffusion current constants of EDTA and PDTA were determined by measuring the diffusion currents at various pH's. The values of $[EDTA]_f$ and $[PDTA]_f$ were calculated, with the aid of these diffusion current constants, from the diffusion currents obtained with the reaction mixtures of systems a and b respectively. Then, the equilibrium constants, $K^Y_{Z,app}$, given by Eq. 8 were calculated. The results obtained for systems a and b are given in Table I.

The reported values of the acid dissociation constants (p$K$) of EDTA, TRDTA and PDTA are summarized in Table II. The relative stability constants of the copper(II)-EDTA complex to the copper(II)-TRDTA complex, $K^{EDTA}_{TRDTA}$, were calculated from the $K^{EDTA}_{TRDTA,app}$ given in Table I and from the p$K$ values of EDTA and TRDTA reported by Schwarzenbach et al.[6] The resulting values at various pH's are presented in Table III.

It seems not appropriate to calculate the values of $K^{PDTA}_{TRDTA}$ from the observed values of $K^{PDTA}_{TRDTA,app}$ with the reported p$K$ values of TRDTA and PDTA, because these p$K$ values have not all been determined under the same conditions. However, a $K^{PDTA}_{TRDTA,app}$ value at a given pH can be converted to a $K^{PDTA}_{EDTA,app}$ value with the aid of a $K^{EDTA}_{TRDTA,app}$ value obtained at the same pH according to the equation,

$$K^{PDTA}_{EDTA,app} = K^{PDTA}_{TRDTA,app} / K^{EDTA}_{TRDTA,app} \quad (19)$$

From the $K^{PDTA}_{EDTA,app}$ thus obtained and the p$K$

values of EDTA and PDTA reported by Grimes et al.,[12] the $K^{PDTA}_{EDTA}$ values were determined; they are given in Table IV.

The hydrogen ion concentration used in this calculation was obtained from the observed pH and the activity coefficient of the hydrogen ion, which was assumed to be 0.80 at ionic strength 0.2.

12) J. H. Grimes, A. J. Huggard and S. P. Wilford, *J. Inorg. Nucl. Chem.*, **25**, 1225 (1963).

**The Determination of the Relative Stability Constants of Trimethylenediaminetetraacetato Complexes.**—Cobalt(II)-TRDTA complex gave a reversible anodic wave with the half-wave potential of about +0.05 V. vs. SCE in the acetate media, independent of pH from 4.7 to 5.5. The limiting current of the wave was found to be diffusion-controlled.

The diffusion current constants of the cobalt(II)-TRDTA complex were determined by measuring the diffusion current under various acetate concentrations and pH's. The values of $[Cotrdta^{2-}]$ were calculated, with the aid of these diffusion current constants, from the diffusion currents obtained with systems c to g. Then, the values of $K^{M}_{Co,app}$ given by Eq. 15 and those of $K^{M}_{Co}$ were calculated according to the procedures described above.

The results obtained for systems c to g are summarized in Table V.

Although the measurements were carried out for the cobalt(II)-manganese(II)-TRDTA system, no detectable decrease in the wave height of the cobalt(II)-TRDTA complex was observed. The value of $K^{Mn}_{Co}$, therefore, was calculated to be less than $2\times10^{-4}$ from the experimental errors and from the total concentrations of cobalt(II), manganese(II) and trimethylenediaminetetraacetate ions.

## Discussion

The reported values of the acid dissociation constants of EDTA, TRDTA and PDTA[6,12] ($\mu=0.1$, 20°C or 30°C) were used without correction when $K^{Y}_{Z}$ was calculated from $K^{Y}_{Z,app}$.

* The concentration of uncomplexed acetate in the solution was calculated by successive approximation.

This procedure, however, does not seem to introduce any appreciable error into the values of $K^{Y}_{Z}$ thus obtained, because the predominant species of uncomplexed ligands are always $H_2Y^{2-}$ for EDTA, TRDTA and PDTA under the present experimental conditions, and their abundances are more than 88%. From this fact, we may approximately express $\alpha_Z/\alpha_Y$ in Eq. 9 by the equation:

$$\frac{\alpha_Z}{\alpha_Y}=\frac{K_{H_2Y}K_{HY}}{K_{H_2Z}K_{HZ}} \qquad (20)$$

indicating that the values of $\alpha_Z/\alpha_Y$ are mainly dependent on the values of the third and fourth dissociation constants of ligands. According to the Debye-Hückel equation, at a given temperature and ionic strength the activity coefficients of the ions with the same charge are determined only by ion-size parameters. Since EDTA, TRDTA and PDTA are closely related compounds, the changes in the activity coefficients of the corresponding ionic species of these compounds with the changes in temperature and ionic strength are considered to be almost identical. Therefore, the values of $\alpha_Z/\alpha_Y$ would not be affected appreciably by the changes in temperature and ionic strength, as long as the acid dissociation constants are determined under the same conditions.

If $MHY^{(m-3)+}$ and $MHZ^{(m-3)+}$ are formed, the equation corresponding to Eq. 9 is given as follows:

$$K^{Y}_{Z,app}=K^{Y}_{Z}\times\frac{\alpha_Z\alpha_{MHY(H)}}{\alpha_Y\alpha_{MHZ(H)}} \qquad (21)$$

where

$$\alpha_{MHY(H)}=1+K^{H}_{MHY}[H^+]$$

$$\alpha_{MHZ(H)}=1+K^{H}_{MHZ}[H^+]$$

$K^{H}_{MHY}$ and $K^{H}_{MHZ}$ represent the formation constants of $MHY^-$ and $MHZ^-$ respectively. Schwarzenbach et al.[13] have reported that $\log K^{H}_{CuHedta}$ was 3.0 at 20°C and ionic strength 0.1. This value indicates that no appreciable amount of $CuHedta^-$ is present in systems a and b. The values of neither $K^{EDTA}_{TRDTA}$ nor $K^{PDTA}_{EDTA}$ are dependent on pH, as is shown in Table III and Table IV respectively. These also suggest that no appreciable amounts of

13) G. Schwarzenbach, R. Gut and G. Anderegg, *Helv. Chim. Acta*, **37**, 937 (1954).

$CuHtrdta^-$ and $CuHpdta^-$ are present under the experimental conditions.

The stability constants of the copper(II)-TRDTA complex and the copper(II)-PDTA complex were calculated by using the $K^{EDTA}_{TRDTA}$ value in Table III, the $K^{PDTA}_{EDTA}$ value in Table IV and the value of $K_{Cuedta}$, which was evaluated with a procedure which has been described previously.[14] The stability constants of the trimethylenediaminetetraacetato complexes of some divalent metal ions were calculated from the $K_{Cutrdta}$ value thus obtained and from the $K^{M}_{Co}$ values of TRDTA in Table V. The $K^{M}_{M'}$ values of EDTA and PDTA complexes determined previously[1-3] were used for the determination of the stability constants of ethylenediaminetetraacetato and propylenediaminetetraacetato complexes. The scheme for the determination of the stability constants is given in Fig. 2. The results obtained are shown in Table VI and Fig. 3.

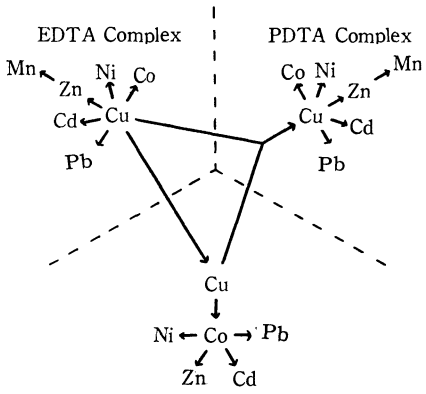

Fig. 2. Scheme for the determination of the stability constants of EDTA, TRDTA and PDTA complexes.

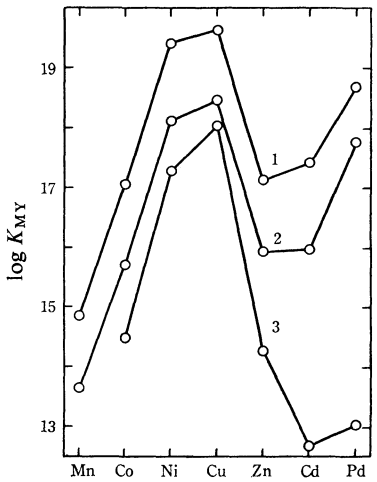

Fig. 3. The logarithmic stability constants of PDTA (1), EDTA (2) and TRDTA (3) complexes at 25°C and ionic strength 0.2.

TABLE VI. THE LOGARITHMIC STABILITY CONSTANTS OF EDTA, PDTA AND TRDTA COMPLEXES AT 25°C AND IONIC STRENGTH 0.2[15]

| Metal ion | EDTA complex | PDTA complex | TRDTA complex |
|---|---|---|---|
| Manganese(II) | 13.64* | 14.85* | <10.8 |
| Cobalt(II) | 15.71 | 17.07 | 14.48 |
| Nickel(II) | 18.12 | 19.42 | 17.29 |
| Copper(II) | 18.46** | 19.64 | 18.04 |
| Zinc(II) | 15.94 | 17.14 | 14.26 |
| Cadmium(II) | 15.98 | 17.43 | 12.69 |
| Lead(II) | 17.76 | 18.69 | 13.04 |

* These values were calculated from unpublished results.

** This value was evaluated with the same procedure as described previously.[14]

The stability constants of EDTA complexes and the cadmium(II)-TRDTA complex obtained in this study seem to be in satisfactory agreement with those reported by Schwarzenbach et al.,[6,13] provided that the differences in temperature and ionic strength between the two sets of results are considered.

For the sake of comparison, the calculations shown in Table VII were carried out. The differences between the logarithmic stability constants of PDTA and EDTA complexes, which are expressed with $\log K^{PDTA}_{EDTA}$ in Table VII, indicate that the stability constants of PDTA complexes are larger than those of

TABLE VII. COMPARISON OF THE STABILITY CONSTANTS OF EDTA, PDTA AND TRDTA COMPLEXES AT 25°C AND IONIC STRENGTH 0.2

| | Mn | Co | Ni | Cu | Zn | Cd | Pb |
|---|---|---|---|---|---|---|---|
| $\log K^{PDTA}_{EDTA}$ | 1.21 | 1.36 | 1.30 | 1.18 | 1.20 | 1.45 | 0.93 |
| $\log K^{EDTA}_{TRDTA}$ | >2.8 | 1.23 | 0.83 | 0.42 | 1.68 | 3.29 | 4.72 |

15) Note added in proof: Recently, stability constants of PDTA complexes[a] and TRDTA complexes[b-d] were reported. They seem to be in good agreement with the values obtained in this study, when the differences in the experimental conditions and in the values of acid dissociation constants used in the calculation are taken into consideration. Irving and Conesa[a] determined $K^{Pb}_{Cu}$ and $K^{Cd}_{Pb}$ of PDTA complexes in acetate media, but they did not consider the effects of acetate ions on the equilibria. The better agreement can be obtained between their values and those obtained in this study by considering the formation of acetato complexes of copper, cadmium and lead.

a) H. M. N. H. Irving and J. P. Conesa, *J. Inorg. Nucl. Chem.*, **26**, 1945 (1964); b) G. Anderegg and F. L'Eplattenier, *Chimia*, **18**, 186 (1964); c) F. L'Eplattenier and G. Anderegg, *Helv. Chim. Acta*, **47**, 1792 (1964); d) G. Anderegg, ibid., **47**, 1801 (1964).

EDTA complexes by about 1.2 $\log K$ unit, without regard to the kind of metal ions. It was found that the fourth dissociation constant of PDTA is higher than that of EDTA, and that the stability constants of alkaline earth chelates of PDTA are larger than those of EDTA.[12] Grimes et al. concluded that these results are attributable to the inductive effect of the methyl group in PDTA.[12] Therefore, the values of $\log K_{EDTA}^{PDTA}$ indicate that the increase in the basicity of the ligand has almost the same effect on the stability constants of the PDTA complexes compared with the EDTA complexes. On the other hand, the values of $\log K_{TRDTA}^{EDTA}$ are considerably dependent on the kind of metal ions. It may be considered that the values of $\log K_{TRDTA}^{EDTA}$ are affected by two factors. The first one is that the increase in basicity due to the third dissociation constant of TRDTA being higher than that of EDTA[5,6] causes the stabilization of TRDTA complexes. The second factor is that the TRDTA complexes are instabilized by the presence of a six-membered chelate ring involving two nitrogen atoms. The first factor may have almost the same effect on the $\log K_{TRDTA}^{EDTA}$ values of various metal ions, as is true in the case of $\log K_{EDTA}^{PDTA}$ values. Therefore, the orders of the instabilization by the presence of a six-membered ring may be given as:

$$Cu < Ni < Co < Zn < Mn\,;\ Zn < Cd < Pb$$

These orders agree with the order of the ionic (crystal) radii[16] of metal ions. This fact indicates that the decrease in the size of metal ions is favorable for the formation of TRDTA complex.

**Summary**

Two methods are presented for the determination of the stability constants of ethylenediaminetetraacetato, trimethylenediaminetetraacetato and propylenediaminetetraacetato complexes of some divalent metal ions. One is a new method which is based on the polarographic measurement of the concentration of an uncomplexed ligand in a solution containing two kinds of ligands and an appropriate metal ion. The other is a modification of the method described in the previous paper.[1] From the results obtained by these methods and those obtained previously,[1-3] the individual stability constants have been calculated. The values of the logarithmic stability constants of complexes at 25°C and ionic strength 0.2 are: Mn 13.64, Co 15.71, Ni 18.12, Cu 18.46, Zn 15.94, Cd 15.98 and Pb 17.76 for ethylenediaminetetraacetato complexes; Mn <10.8, Co 14.48, Ni 17.29, Cu 18.04, Zn 14.26, Cd 12.69 and Pb 13.04 for trimethylenediaminetetraacetato complexes, and Mn 14.85, Co 17.07, Ni 19.42, Cu 19.64, Zn 17.14, Cd 17.43 and Pb 18.69 for propylenediaminetetraacetato complexes.

The author wishes to thank Professor Nobuyuki Tanaka for his kind guidance and encouragement.

# The Nitration and Sulfonation of 2, 4, 6-Triphenyl-1, 3, 5-triazine[1]

By Yoshiro OGATA, Yasuji IZAWA and Yuji KAWASHIMA

(Received September 15, 1964)

There are many examples of the preparation of cyaphenine, including the trimerization of benzonitrile with acidic,[2,3] basic[4,5] or organometallic catalysts[6,7], or by the high pressure technique.[8,9] It has also been reported that the formation of cyaphenine is possible by way of such condensations as the reaction of benzoyl

chloride with potassium cyanate,[10] benzaldehyde with tetrasulfur tetranitride,[11] benzonitrile with benzoyl chloride,[12] benzene with cyanogen chloride,[13] ethyl benzimidate with its hydrochloride,[14] 4, 6-diphenyl-1,2,3,5-oxathiodiazine-2-dioxide with benzamidine,[15] and benzamide with phosphorous pentasulfide.[16] It has also been reported that methyl *m*- or *p*-nitrobenzimidate derived from the corresponding nitrobenzonitrile may be converted to 2, 4, 6-tris(*m*- or *p*-nitrophenyl)-1, 3, 5-triazine by an acid catalyst.[17] However, very little information is available on the electrophilic substitutions of cyaphenine.

The present paper will describe our data on the nitration and sulfonation of cyaphenine. The structure of the products was confirmed by infrared spectroscopy and chemical analysis, i. e., by estimations of the nitrogen content in the nitrated cyaphenine and of the sulfonyl group in the cyapheninesulfonic acid.

## Experimental

**Materials.**—Cyaphenine was prepared according to the Cook-Jones procedure.[2] The product was purified by two recrystallizations from toluene (yield, 68.4%), m. p. 233.0—234.0°C (lit.[2] m. p. 232°C). The wave numbers ($cm^{-1}$) of the characteristic infrared absorption bands of cyaphenine (KBr disk) were 1590, 1530, 1450, 1370, 840, 740 and 680 $cm^{-1}$. Cyaphenine had an ultraviolet absorption band ($\lambda_{max}$) at 272 m$\mu$ ($\log \varepsilon = 4.22$) in 95% aqueous ethanol.

**The Nitration of Cyaphenine.**—A mixed acid, that is, a mixture of aqueous nitric acid (sp. wt. of 1.42, 0.09—0.63 mol.) and concentrated sulfuric acid (sp. wt. of 1.84, 0.09 mol.), was added, drop by drop and at 0°C, to a solution of cyaphenine (0.02 mol., 6.18 g.) in 95% sulfuric acid (29 ml.). The reaction mixture was then continuously stirred under the conditions listed in Table I. The crystals separated after the completion of reaction were washed with cold water and recrystallized from nitrobenzene. The number of nitiro groups per molecule of the resulting nitrocyaphenine ($n_{NO_2}$) was determined by infrared spectrophotometry (the concentration of nitrocyaphenine in the KBr disk: 0.25%); it was then calculated by means of the following equation:

$$n_{NO_2} = 0.89 \frac{T_{1350} - T_{1420}}{T_{1370} - T_{1420}}$$

where the $T$'s are the transmittances (%) at the subscripted wave numbers and where the coefficient of "0.89" is a correction factor obtained from standard nitrated cyaphenine, for which the $n_{NO_2}$ value was calculated by the estimation of the nitrogen content according to the Dumas method.

**The Sulfonation of Cyaphenine.**—A mixture of 50% oleum (7 g.) and cyaphenine (1.5 g.) was reacted while being stirred under the conditions listed in Table III. The resulting yellow viscous liquid was then poured into a mixture of ice and water and neutralized with sodium carbonate. The slurry, obtained on the evaporation of water, had 95% ethanol added, until the concentration of ethanol became 50%. The separated sodium sulfate was then filtered off, the filtrate being evaporated to dryness. The residue was extracted with 50% aqueous ethanol. The extract was then evaporated to dryness and extracted again with 70% aqueous ethanol. The extract was condensed, and a considerable amount of 95% aqueous ethanol was added. The precipitate of a colorless crystaline product, sodium cyapheninesulfonate, was collected by filtration, washed with ethanol, and dried. For the determination of sulfonyl groups in the resulting sodium cyapheninesulfonate, the isolated sulfonate was converted into the acid with cation exchange resin, Amberlite IR 120 ($H^+$); the sulfonic acid solution thus obtained was titrated with a standard aqueous solution of sodium hydroxide.

## Results and Discussion

**The Nitration of Cyaphenine.**—Cyaphenine which had been prepared from benzonitrile according to the Cook-Jones method[2] was nitrated with a mixture of sulfuric and nitric acids. The nitrations under various conditions (i. e., reaction time, temperature, and concentrations of reactants) are listed in Table I. It is obvious that the nitration of cyaphenine is rather difficult because of the electron-attracting

nature of triazine, yielding a product with no more than two nitro groups. Trinitrocyaphenine is not obtained because of the deactivation of a residual phenyl group by the presence of two nitro groups as well as the triazine ring.

The nitrated cyaphenine shows new infrared absorptions (KBr disk), at 1350 (s), 820 (w), and 800 (s) $cm^{-1}$, not found in the spectrum of original cyaphenine. The absorption bands at 800 and 820 $cm^{-1}$ correspond to meta- and para-substituted benzenes respectively; the band at 1350 $cm^{-1}$ is assigned to the nitro group. Since the band at 820 $cm^{-1}$ (para) is weak, the *p*-nitrocyaphenine content in the product should be much lower than that of the *m*-isomer.

**The Decomposition of Cyaphenine and Nitrocyaphenine with Hydrochloric Acid.**—Frankland and Evans reported, without a detailed description, the conversion of cyaphenine to benzoic acid and ammonia[6] by heating cyaphenine with concentrated hydrochloric acid in a sealed tube to 250°C. Our experiment to confirm this decomposition gave benzoic acid in a 93.2% yield under suitable conditions, as is indicated in Table II. However, cyaphenine was not converted to benzoic acid when heated in an acidic aqueous solution (2.9% sulfuric acid), even in the presence of potassium permanganate at 100°C for 24 hr.

Table II. Decomposition of cyaphenine with aqueous hydrochloric acid in a sealed tube at 250°C for 6 hr.

| Cyaphenine g. | 35%HCl ml. | Yield of $PhCO_2H$ g. | Conversion % |
|---|---|---|---|
| 0.31 | 1 | 0.201 | 55.0 |
| 0.16 | 1 | 0.157 | 85.3 |
| 0.51 | 1 | 0.170 | 93.2 |

In the case of nitrocyaphenine, a similar decomposition was unsuccessful; green or brown solid materials of an unknown structure were obtained, but no nitrobenzoic acid was isolable.

**The Sulfonation of Cyaphenine.**—The sulfonation of cyaphenine with oleum under varying conditions are listed in Table III. Cyaphenine-trisulfonic acid was obtained by heating it at 100°C for 0.5 hr. However, a part of the introduced sulfonyl groups may be eliminated when the reaction mixture is kept standing after the completion of the reaction.

Absorption bands at 790 (s), 1040 (s), and 1100 (s) $cm^{-1}$ in the infrared spectrum (KBr disk) of sodium cyaphenine-trisulfonate may be assigned to the meta-substituted phenyl group. In addition, the lack of absorption at 800—820 $cm^{-1}$ shows the absence of the para-substituted phenyl group. Therefore, the sulfonation of cyaphenine is different from the nitration in that there is no para-substitution.

Table III. Sulfonation of cyaphenine with oleum (50% $SO_3$)

| Temp. °C | Time hr. | Yield g. | Number of $SO_3H$[a] |
|---|---|---|---|
| 40 | 6 | 1.7 | 2.6 |
| 60 | 6 | 2.7 | 2.6 |
| 100 | 6 | 2.4 | 2.3 |
| 100 | 0.35 | 2.0 | 2.7 |
| 100 | 0.5 | 2.0 | 3.0 |
| 100 | 1.2 | 2.2 | 2.8 |
| 100 | 2 | 2.1 | 2.8 |
| 100 | 4 | 2.4 | 2.7 |

a) The number of sulfonyl group per molecule of product.

## Summary

The nitration of cyaphenine (2, 4, 6-triphenyl-1, 3, 5-triazine) with a mixture of nitric and sulfuric acids has been found to give products with mostly meta- and partly para-substituted benzene rings. The composition of products varies with the varying reaction conditions. *m, m'*-Dinitrocyaphenine is the product of the highest number of nitro groups. The sulfonation of cyaphenine with oleum gives trisulfonated cyaphenine at meta-positions of benzene rings; it suffers desulfonation when left standing in the reaction mixture for a long time.

The authors are grateful to Professors T. Takeuchi and K. Fukuzumi for their aid in the measurement of infrared spectra.

# Nuclear Magnetic Resonance Studies of Fulvenes*1

By Yoshio KITAHARA,*2 Ichiro MURATA,*2 Kunikatsu SHIRAHATA,*2 Shigeyoshi KATAGIRI and Hiroshi AZUMI

(Received September 16, 1964)

Fulvene, a cross-conjugated non-alternant hydrocarbon, is of particular interest because of the relation of its properties to those of its isomer, benzene. Since 1900, when Thiele[1] reported the first synthesis of some simple fulvene derivatives, fulvene has been the subject of much research in both theoretical and experimental organic chemistry.[2,3] Some studies of the nuclear magnetic resonance spectra of fulvene derivatives described in the literature have dealt with 6-ethylfulvene,[4] 6-vinylfulvene,[5] 6-hydroxy-6-methyl-1-phenylazofulvene,[6] methylvinylfulvenes,[7] and fulvene itself.[8] A very recent paper on the nuclear magnetic resonance studies of some fulvene derivatives by Smith and Shoulders[9] has prompted us to report our own independent studies on the same subject.

In this paper, we will describe the proton magnetic resonance spectra of some fulvene derivatives, and we will discuss the magnetic constants, electron density, and especially the theoretical calculation of the ring current effect of the fulvene ring.

## Experimental

The proton magnetic resonance spectra were taken with a Varian A-60 spectrometer on 10% (w./v.) solutions of the samples in carbon disulfide, containing tetramethylsilane as an internal standard at 60 Mc. p. s., and at room temperature. The chemical shifts are expressed as p. p. m. from tetramethylsilane.

All samples were synthesized according to the known procedures[2] and purified by vacuum distillation under a nitrogen atmosphere (6,6-dimethylfulvene, 6-ethyl-6-methylfulvene, 6,6-pentamethylenefulvene) or by recrystallization (6,6-diphenylfulvene, 1,2,3,4-tetraphenylfulvene).

## Results and Discussion

**The Analysis of the NMR Spectrum of 6,6-Diphenylfulvene.**—The protons in the five-membered ring of 6,6-diphenylfulvene appear as a perfectly symmetrical twenty-line AA'BB' type[10-13] spectrum with chemical shifts of $\delta_A=\delta_{A'}=6.390$ and $\delta_B=\delta_{B'}=6.105$ p. p. m. The spectrum calculated from the magnetic parameters $\delta_A-\delta_B=0.285$ p. p. m., $J_{AB}=5.3_7$, $J_{AB'}=1.5_2$, $J_{AA'}=2.0_0$ and $J_{BB'}=2.2_8$ c. p. s., is in quite good agreement with the observed spectrum, as can be seen from Table I and Fig. 1.

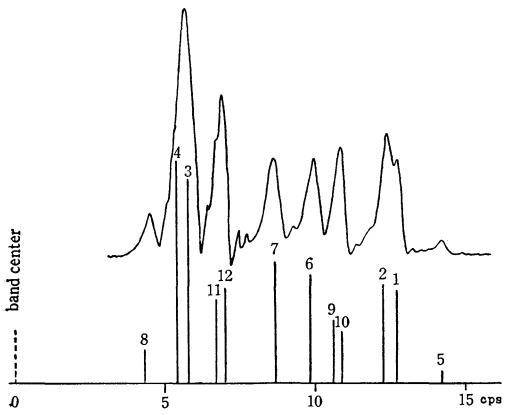

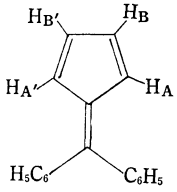

Fig. 1. The observed and calculated spectra of the ring proton of 6,6-diphenylfulvene (upfield portion).

**The Electron Density of Fulvene.**—The signals of the ring protons in 6,6-dimethylfulvene (6.27 p. p. m.), 6-ethyl-6-methylfulvene (6.28 p. p. m.), and 6,6-pentamethylenefulvene (6.31 p. p. m.) are different from those of 6,6-diphenylfulvene, and they are shifted to higher fields where they appear as singlets at almost the same position in each case. The proton at the 6-position of 1,2,3,4-tetraphenylfulvene appears as a singlet at 5.90 p. p. m. The signals arising from the fulvene ring protons show a shift from the olefinic protons of cyclopentadiene, (6.35 p. p. m.), while the 6-proton shows a shift from the olefinic protons of the methylenecycloalkanes [4.68±0.15 p. p. m.[14]]; these shifts are regarded as being due to the increased charge density on the fulvene nucleus and were calculated according to Schneider's equation.[15,16] In the case of the phenyl derivatives, Pople's simple dipole approximation[17] was used to calculate the effect of the diamagnetic shift caused by the ring current of the phenyl group. These diamagnetic shifts of the protons at the 1- or 4-position and at the 2- or 3-position in the 6,6-diphenylfulvene are 0.91 p. p.m. and 0.21 p. p.m. respectively. The shift of the proton at the 6-position of the 1,2,3,4-tetraphenylfulvene is 0.93 p. p. m. However, in the above calculations, the entire molecule was assumed to be coplanar, and the ring current of the fulvene ring was assumed to be small and was neglected. The validity of this assumption about the ring current effect of the fulvene ring was revealed by the theoretical calculations of the LCAO MO method (vide infra). The charge densities obtained were compared with the theoretical values calculated by the MO method and are shown in Table II.

It is clear from Table II that the charge densities obtained from the chemical shifts are in good agreement with those calculated by the MO method. In the case of the diphenylfulvene, however, the observed charge densities are rather high. If the non-planarity of the phenyl groups is allowed for, better results would be obtained. Charge migration from the phenyl group is thought to be responsible for the larger charge density at $C_{(1)}$ than at $C_{(2)}$.

TABLE III. RING CURRENT SHIELDING IN FULVENE

| $k$ | Relative to benzene[a] | | | Calculated shielding constants (p. p. m.)[b] | | |
|---|---|---|---|---|---|---|
| | $\bar{\sigma}_{F(1)}/\bar{\sigma}_B$ | $\bar{\sigma}_{F(2)}/\bar{\sigma}_B$ | $\bar{\sigma}_{F(6)}/\bar{\sigma}_B$ | $\bar{\sigma}_{F(1)}$ | $\bar{\sigma}_{F(2)}$ | $\bar{\sigma}_{F(6)}$ |
| 1.0 | 0.118 | 0.116 | 0.041 | 0.206 | 0.202 | 0.072 |
| 0.8 | 0.047 | 0.046 | 0.016 | 0.082 | 0.081 | 0.028 |
| 0.6 | 0.011 | 0.010 | 0.004 | 0.020 | 0.019 | 0.007 |

a) $\bar{\sigma}_B$ and $\bar{\sigma}_F$ are the shielding constants for benzene and fulvene respectively. The position of each proton in fulvene is shown in parentheses.
b) Based on an experimental estimate of 1.75 p. p. m. for the ring current shift in benzene.[20]

**The Ring Current Effect in Fulvene.** — The ring current effect of the fulvene ring was not considered in the previous calculations of the charge density. It is important, however, to decide whether the ring current effect, which depends on the aromaticity of fulvene, can, in fact, be neglected. The chemical shift of each proton in fulvene was calculated by the use of the LCAO MO theory of McWeeny.[18] In this case, electron diffraction data[19] for dimethylfulvene were used to obtain the following dimensions for the fulvene nucleus; $C_{(1)}—C_{(2)}=C_{(3)}—C_{(4)}=C_{(5)}—C_{(6)}=1.382$ Å, $C_{(1)}—C_{(5)}=C_{(4)}—C_{(5)}=C_{(2)}—C_{(3)}=1.496$ Å, $\angle C_{(1)}C_{(2)}C_{(3)}=109°$, $\angle C_{(5)}C_{(1)}C_{(2)}=107°46'$, and $\angle C_{(1)}C_{(5)}C_{(4)}=106°20'$. The fulvene nucleus in diphenylfulvene is non-benzenoid; therefore, one needs to allow for bond alternation by using the bond-alternation parameters $k=\beta_{single}/\beta_{double}$ (no magnetic field) of 1.0, 0.8 and 0.6 respectively. The results are shown in Table III.

The theoretical ratio, $\bar{\sigma}_F/\bar{\sigma}_B$, when $k=1$, is about 0.1; when $k=0.6$, it decreases to a very small value. The chemical shift of each proton in fulvene was calculated by using the estimated ring current shift of benzene. Nakajima and Katagiri[21] have proposed $k=0.57$ as a reasonable value for fulvene. Therefore, as can be seen from Table III, the chemical shift induced by the $\pi$-electron ring current in fulvene is very small and can be neglected. Although the difference is small, the chemical shift of the $C_{(1)}$ proton is larger than that of the $C_{(2)}$ proton. However, the opposite might be expected from a consideration of the charge densities. The fact that the ring protons in 6, 6-dialkylfulvene appear as a singlet may be ascribed to the above opposing effects.

The calculations were made on a NEAC-2230 computer at the Tohoku University Computing Center. Some of the NMR spectra were measured at the Research Institute of the Shionogi Pharmaceutical Company, to which company we express our gratitude.

# Ultraviolet and Visible Absorption Spectra of the Solid States of Aromatic Amine Complexes with Iodine*

By Hideaki KUSAKAWA and Shun-ichiro NISHIZAKI

(Received September 21, 1964)

It is well known that, from the interaction with an iodine molecule, a molecule of an amine forms a charge transfer complex which possesses optical absorption bands in addition to those observed for either component alone. Although many papers have been published on amine-iodine complexes in solution,[1-5] there have been few works on the electronic spectra of amine-iodine complexes in the solid state.

Blomgren and Kommandeur[6] reported that aromatic hydrocarbons become positive ions in aromatic hydrocarbon - antimony pentachloride complexes. If an aromatic amine - iodine complex is a strong charge transfer complex, its ground state is a dative state ($D^+ \cdot A^-$). It has been observed by numerous investigators that the spectrum of the aniline ions is very similar to that of benzene. Recently, Gallagher[7] has shown that the spectra of three mono-protonated isomeric phenylenediamine ions resemble that of aniline, and that the spectra of their divalent ions are similar to that of benzene. Their contention is that the addition of a proton to the lone electron pair on the nitrogen atom quenches the original effect of the amino groups upon the absorption spectrum. As an n-electron of nitrogen atom goes into the $\sigma_u(5P_z)$ antibonding molecular orbit of iodine, it is interesting to see how the electronic state in the aromatic amine changes. We have measured the ultraviolet and visible absorption spectra of the iodine complexes of five aromatic amines: aniline (ANI), *p*-phenylenediamine (*p*-PDA), 1,5-naphthylenediamine (NDA), benzidine (BEN), *o*-tolidine (TOL) and *p,p'*-diaminodiphenylmethane (APM). The spectra of the solid states were measured by means of the KBr disk method.

## Experimental

**Materials.**—The ANI-iodine complex does not precipitate from a non-polar solvent, so this complex was obtained by mixing ANI and iodine at a iodine/ANI mole ratio of 0.50 and 1.00. When the two components are blended, the temperature of the mixture was raised because of the heat of the complex formation. As the mixture is cooled, it becomes a solid which is apparently crystalline. These specimens were used as ANI-iodine complex systems. APM-iodine systems were also prepared in a similar way, and their iodine contents were varied from 0.75 to 1.50.[8]

The preparations of *p*-PDA, NDA, BEN and TOL complexes have been described in previous papers.[8,9]

**The Ultraviolet and Visible Spectra in the Solid State.**—The ultraviolet and visible spectra of these solid complexes were measured by means of the KBr disk method or with a squashed powder between quartz plates in the 222—2000 m$\mu$ wavelength region. The spectra were measured by using a Shimadzu SV50A recording spectrophotometer.

## Results and Discussion

**A. The Ultraviolet Spectra of ANI Complexes and Other Similar Compounds.** — The ultraviolet spectra of ANI hydrochloride and ANI-iodine systems are shown in Fig. 1. The spectrum of the ANI-iodine complex has an extra maximum at 370 m$\mu$ which can not be found in the absorption spectra of either component alone. It seems that this extra band is a charge transfer band. It has been reported that the absorption spectrum of a mixture of ANI and iodine in a chloroform solution has a characteristic charge transfer band at 349 m$\mu$.[5] It seems reasonable to presume that the 349 m$\mu$ band in solution is shifted to 370 m$\mu$ in a solid.

By putting the observed energy of the charge transfer transition of the ANI-iodine complex, $hc/\lambda_{CT}$ ($\lambda_{CT}$=374 m$\mu$), into the following equation,[10] the ionization potential, $I_D$, of ANI is estimated to be 7.9 eV.:

9) S. Nishizaki and H. Kusakawa, ibid., **36**, 1681 (1963).
10) G. Briegleb and J. Czekalla, *Angew. Chem.*, **72**, 401 (1960).

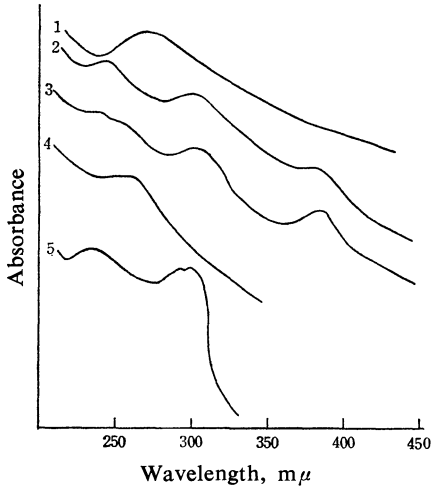

Fig. 1. Ultraviolet spectra of ANI complexes, other similar compounds and iodine in KBr disk.
1 Iodine 2 ANI-$I_2$ (1 : 0.50)
3 ANI-$I_2$ (1 : 100) 4 $C_6H_5NH_3^+Cl^-$
5 ANI (liquid membrane between quartz plates)

$$hc/\lambda_{CT}=I_D-C_1+C_2/(I_D-C_1) \qquad (1)$$

This value is in agreement with the findings of Briegleb and Czekalla,[11] but slightly larger than that of Watanabe's[12] determination with photoionization. In Eq. 1, $C_1$ and $C_2$ are constants; they are 5.20 and 1.5 eV. respectively for iodine complexes.

The 1 : 1 ANI-iodine complex possesses another new absorption band at 255 mμ, which coincides with the position of an absorption band of ANI hydrochloride. Considering this, in the 1 : 1 ANI-iodine complex one part of ANI must be in an electronic state, like the anilinium ion. The following equilibrium may represent standing in a solid state as well as in solution:

$$C_6H_5NH_2\cdot I_2 \rightleftarrows C_6H_5NH_2^+\cdot I_2^- \qquad (2)$$

The lone electron pair of the nitrogen atom is localized on the iodine molecule, and the $n$-$\pi$ resonance within the ANI molecule disappears; therefore, it is reasonable to presume that one part of ANI in the iodine complex shows an absorption spectrum like that of benzene.

**B. The Ultraviolet and Visible Spectra of Aromatic Diamine - Iodine Complexes.** — The ultraviolet spectra of amine crystals and the spectra of iodine complexes are shown in Fig. 2 and Fig. 3 respectively. The wavelength of the spectral maxima of aromatic diamine complexes with iodine in the solid state and other similar compounds are summarized in Tables I to V.

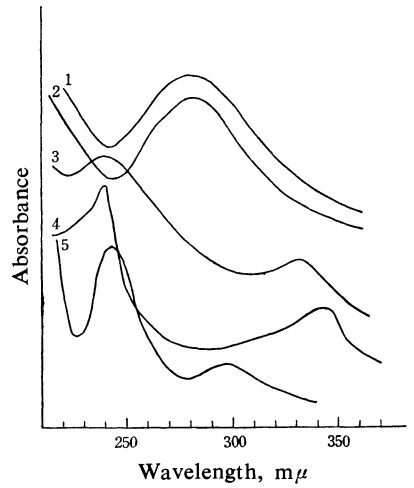

Fig. 2. Ultraviolet spectra of aromatic diamines in KBr disk.
1 BEN, 2 TOL, 3 $p$-PDA, 4 NDA, 5 APM

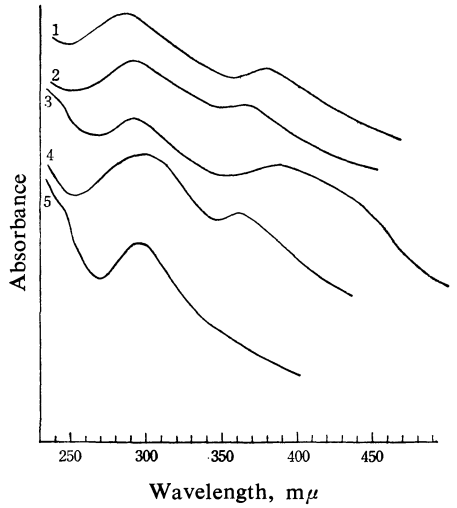

Fig. 3. Ultraviolet spectra of iodine complexes.
1 BEN, 2 TOL, 3 NDA, 4 $p$-PDA, 5 APM

It can be seen from these tables that, in the absorption spectrum of the 0.1 N hydrochloric acid solution, each aromatic diamine, including $p$-PDA,[7] has an absorption band which coincides with that of the aromatic hydrocarbon corresponding to its aromatic skeleton. Judging from those facts, it can be deduced that the spectrum of each mono-protonated diamine is similar to that of the mono-amino substituted derivative of the aromatic hydrocarbons.

In the iodine complexes of $p$-PDA and NDA, the positions of the absorption bands maxima change from 303 mμ to 285 mμ, and from 342 mμ to 296 mμ. From a comparison of these wave-

lengths, 285 mμ and 296 mμ, with those of the absorption bands of aniline and α-naphthylamine, it can be presumed that *p*-PDA and NDA become mono-positive ions in solid iodine complexes. The ground states of *p*-PDA-iodine and NDA-iodine complexes are dative states:

$$p\text{-PDA}^+\cdot I_2^- \quad \text{and} \quad \text{NDA}^+\cdot I_2^- \qquad (3)$$

In *p*-PDA-iodine and NDA-iodine complexes, an iodine molecule exists in the visinity of an amino group and localizes the lone electron pair of the nitrogen atom as in the ANI-iodine complex.

On the other hand, in the case of the BEN-iodine complex, a bathochromic shift is found. The maximum of the absorption band at 281 mμ shifts to 294 mμ. Of course, it does not correspond to that of *p*-phenylaniline[13] at 278 mμ. A similar phenomenon is found on the TOL-iodine complex, where the band maximum at 283 mμ shifts to 298 mμ. At the present time we can not explain why the bathochromic shift occurs in the case of a polyphenylene-diamine-iodine complex system.

When APM, a non-conjugated aromatic diamine, is used as the donor, there is no conspicuous change in the ultraviolet spectra of this complex system. The shoulder at 255 mμ probably arises from the reaction of the anilino group with iodine.

Excepting the APM-iodine system, the color of aromatic diamine complexes with iodine is blue at a low iodine content; it becomes black with an increase in the iodine content. As these specimens were dissolved in such polar solvents as alcohols or ketones, the color of the solution was green at first, but it changed brown with the lapse of time.

**C. The Change Transfer Bands of Semiconductive Complexes and the Ionization Potentials of Aromatic Diamines.**—The visible and near infrared absorption bands, which are assumed to be the charge transfer bands of aromatic diamine-iodine complexes, are shown in Fig. 4. In order to estimate the ionization potential of these aromatic diamines, the observed wavelength of the charge transfer band was placed into Eq. 1. However, it was not possible to calculate the ionization potential by this equation because the observed values of the energy of the charge transfer transition are so small that Eq. 1 does not give a real number. Therefore, instead of Eq. 1, the following equation are used[14] to estimate the ionization potential:

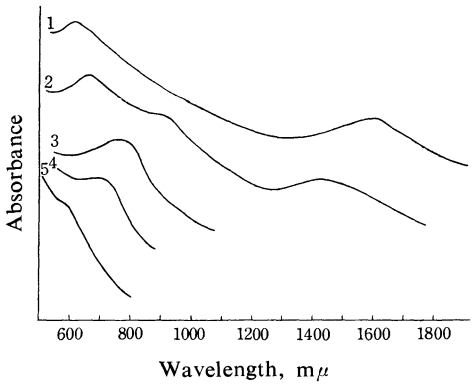

Fig. 4. The spectra of iodine complexes.
1 BEN, 2 TOL, 3 *p*-PDA, 4 NDA, 5 APM

TABLE VI. IONIZATION POTENTIAL ENERGIES ESTIMATED FROM EQS. 4 AND 5 OF AROMATIC AMINES (eV.)

| Donor | From Eq. 4 | From Eq. 5 | Corresponding methyl substituted amine |
|---|---|---|---|
| ANI | 7.9 | 7.9 | 7.2[6] |
| *p*-PDA | 6.1 | 7.2 | 6.7[6] |
| NDA | 6.1 | 7.2 | — |
| BEN | 5.1 | 6.8 | 6.7[7] |
| TOL | 5.2 | 6.8 | — |
| APM | 6.5 | 7.4 | 7.1[6] |

$$hc/\lambda_{CT}=0.87I_D-3.6 \qquad (4)$$

The values obtained are shown in Table VI. In comparison with *N*, *N*, *N'*, *N'*-tetramethyl-*p*-phenylenediamine (TMPD) or *N*, *N*, *N'*, *N'*-tetramethyl-*p*, *p'*-diaminodiphenylmethane,[15] it seems that these values are underestimated. Similar results may be obtained from an emprical linear relation between the ionization potential $I_D$ and the wave number of the charge transfer band, $\tilde{\nu}_{CT}$.[15] Such a relationship have been determined for the complexes of donors of a reliably know ionization potential (namely, 7.9 eV. for ANI[11] and 7.2 eV. for *p*-PDA[11]). This is:

$$I_D=6.5+5.19\times10^{-4}\tilde{\nu}_{CT} \qquad (5)$$

for aromatic amine - iodine complexes in solid states. From measurements of the wave numbers of charge transfer bands of specimens, the ionization potential may be evaluated. The results are quoted in the second column of Table VI. However, Foster and Thomson reported that the *N*, *N*, *N'*, *N'*-tetramethylbenzidine is as strong as TMPD as an electron donor for chloranil.[16]

The results of this investigation imply that

the charge transfer bands of aromatic diamine-iodine complexes, above all, of the polyphenylenediamine-iodine system, unusually appear in the very long wavelength region, and that the order of the energies of the charge transfer transition is in agreement with that of the electrical resistivities of these specimens.[8,9]

## Summary

The ultraviolet and visible spectra of aromatic amine complexes with iodine in the crystalline state have been investigated by means of the KBr disk method or with a squashed powder between quartz plates.

Part of the aniline (ANI) ions in the ANI-iodine system become positive, and the maximum of the spectrum band appears at 255 m$\mu$. *p*-Phenylenediamine (*p*-PDA) and 1,5-naphthylenediamine (NDA) complexes with iodine possess the band maxima at the same position as those of ANI and $\alpha$-naphthylamine. The ground states of these complexes seem to be dative states.

In benzidine (BEN) and *o*-tolidine (TOL) from polyphenylenediamines, and iodine complex systems bathochromic shifts are observed.

By estimating the ionization potential $I_D$ of these aromatic amines from the energies of the charge transfer transition, low values of $I_D$, except for ANI, are obtained.

The electrical resistivities of these specimens are in the order BEN$<$TOL$<$NDA$\approx$*p*-PDA, which is in agreement with that of the energies of the charge transfer transition.

# Studies of the Organic Reactions of Metal Carbonyls. VI.* The Isomerization of Acylcobalt Carbonyls—The Effects of Solvents and of the Structure of the Acyl Group

By Yoshinobu TAKEGAMI, Chikao YOKOKAWA, Yoshihisa WATANABE, Hiromitsu MASADA and Yasukazu OKUDA

(Received September 22, 1964)

The previous works in this laboratory have demonstrated that alkyl- and acylcobalt carbonyls readily isomerize and that this isomerization has a significant effect on the distribution of the products which are given by the reaction of olefin with cobalt hydrocarbonyl.[1,2] Heck and Breslow[3] have also observed that a similar isomerization occurs in the reaction of 1-chlorooctane with sodium cobalt carbonylate. Lately, Wakamatsu[4] has reported that this type of isomerization also occurs in the reduction of acylcobalt carbonyl with synthesis gas under Oxo conditions.

In the present program, the isomerization of acylcobalt carbonyls has been studied in detail by examining the effects of solvent, atmosphere, temperature and the structure of the acyl group on this reaction. The data obtained indicate that the solvents as well as the reaction temperature and the atmosphere have a considerable effect on the isomerization reaction, the rate and the equilibrium, and that the isomerization of $\alpha$-ethylbutyrylcobalt carbonyl to *n*-caproylcobalt carbonyl occurs.

## Experimental

**The Reaction of Acyl Halides with Potassium Cobalt Carbonylate.**—A 100 ml. four-necked flask, fitted with a 50 ml. dropping funnel, a stirrer, and a rubber stopple, was connected with a gas buret and then flushed with carbon monoxide or nitrogen. By the use of a syringe, 50 ml. of 0.09 M cobalt hydrocarbonyl in a toluene solution was put into the flask and then titrated with a 1/2 N ethanol solution of potassium hydroxide in the presence of phenolphthalein. The potassium cobalt carbonylate solution thus obtained was evaporated under a vacuum, and then 50 ml. of various solvents were

added. To the solution of potassium cobalt carbonylate, 4.5 mmol. of acyl halide was added; the mixture was then agitated vigorously for several hours at 0 or 25°C. After a desired reaction time, 30 ml. of a saturated solution of iodine in benzene and 4 ml. of alcohol were stirred into the reaction mixture; the agitation was continued until gas ceased to evolve. By this treatment, acylcobalt carbonyl was converted into the corresponding ester of carboxylic acid.[5] The solution of this ester was concentrated and then gas chromatographed.

**Materials.**—Cobalt hydrocarbonyl was prepared according to the method described in a previous paper.[1] *n*-Butyryl chloride, isobutyryl bromide and *n*-caproyl chloride were obtained commercially. α-Ethylbutyryl chloride was prepared by the chlorination of α-ethylbutyric acid with thionyl chloride.[6] These acyl halides were transformed to the corresponding esters and were proved to be sufficiently pure by gas chromatography. Diethyl ether, ethyl acetate, dioxane, benzene and hexane were dried by the usual methods.

## Results and Discussion

**The Reaction of Butyryl Halides with Potassium Cobalt Carbonylate.** — The results of the reactions of isobutyryl bromide and *n*-butyryl chloride are summarized in Tables I and II respectively. It has been known[1] that the isomerization of butyrylcobalt carbonyls is affected by the reaction conditions (temperature, atmosphere and solvent). In tetrahydrofuran, isobutyrylcobalt carbonyl readily isomerizes to *n*-butyrylcobalt carbonyl, but *n*-butyrylcobalt carbonyl seems to be difficult to isomerize. In isopropyl ether, isobutyrylcobalt carbonyl also isomerizes, but the isomerization proceeds more slowly than in tetrahydrofuran.

In this program, the reactions are carried out in various solvents, such as diethyl ether, ethyl acetate, dioxane, benzene, hexane and some mixtures of two kinds of them, in order to study the effect of the solvent in detail.

All of these reactions were carried out at 25°C, since it is relatively difficult for the isomerization reaction of acylcobalt carbonyl to occur at 0°C.[1] The percentages in the last columns of the tables indicate the degree of the isomerization, the proportion of isomerized iso- or *n*-butyrylcobalt carbonyl.

In diethyl ether under a carbon monoxide atmosphere, isobutyrylcobalt carbonyl isomerized readily to give a large amount of *n*-butyrate (Exps. 1—5). The degrees of the isomerization were 12, 29 and 41% after one

*** (Isobutyrate/(*n*-Butyrate+Isobutyrate))×100

hour, 7.5 hr. and 20 hr. of reaction time respectively. Thus, the degree of the isomerization increased with an increase in the reaction time. However, with an increase in the reaction time from 12 to 20 hr., the degree of the isomerization increased from 37 to 41% (Exps. 4, 5), suggesting that the velocity of this isomerization is small near this proportion. On the other hand, *n*-butyrylcobalt carbonyl similarly isomerized to give isobutyrate, and the degree of the isomerization increased with an increase in the reaction time (Exps. 21—28); under a carbon monoxide atmosphere, *n*-butyrylcobalt carbonyl gave 12, 31 and 44% of isobutyrate after 2, 5 and 15 hr. of reaction time respectively, but under nitrogen, it gave 31 and 44% of isobutyrate after 1.5 and 7 hr., indicating that the isomerization proceeded faster under nitrogen than under carbon monoxide. Thus, both *n*- and isobutyrylcobalt carbonyls relatively readily isomerized to give an almost equimolar mixture of two isomers. This seems to indicate that there is the following equilibrium between the isomers:

$$\begin{array}{l} \mathrm{C\text{-}C\text{-}C} \\ \quad | \\ \quad \mathrm{COCo(CO)_{3,4}} \end{array} \xrightleftharpoons{\text{in diethyl ether}} \mathrm{C\text{-}C\text{-}C\text{-}COCo(CO)_{3,4}}$$

The equilibrium proportion of two isomers under the conditions used may be about 50 and 50% respectively. The reaction atmosphere had a great effect on the rate of the isomerization, but it seemed to have no effect on the equilibrium.

Similarly, in ethyl acetate the degree of the isomerization increased with a prolonging of the reaction time. Isobutyrylcobalt carbonyl gave 13% of the isomerized product after 2 hr. and about 70% after 28 hr., but *n*-butyrylcobalt carbonyl gave less than 20% of the isomerized product even after 28 hr. This seems to indicate that it is relatively difficult to isomerize *n*-butyrylcobalt carbonyl in this solvent. Thus, in ethyl acetate, the equilibrium proportion of *n*- and isobutyrylcobalt carbonyl seemed to be about 70 and 30% respectively; ethyl acetate evidently removed this equilibrium toward *n*-butyrylcobalt carbonyl more than diethyl ether did. Moreover, in dioxane, isobutyrylcobalt carbonyl easily isomerized (Exps. 15, 16), but *n*-butyrylcobalt carbonyl did not seem to isomerize under the conditions used (Exp. 34), suggesting that this equilibrium is almost completely favorable to *n*-butyrylcobalt carbonyl.

The relation between the reaction time and the proportion of the isobutyrate included in the products is illustrated in Fig. 1. These isomerization curves evidently show that the rate and the equilibrium of the isomerization are remarkably affected by the solvents, as has been described above.

On the other hand, in nonpolar solvents, benzene and hexane, it seemed difficult for the isomerization of both *n*- and isobutyrylcobalt carbonyl to occur (Exps. 12—14, 35—38).

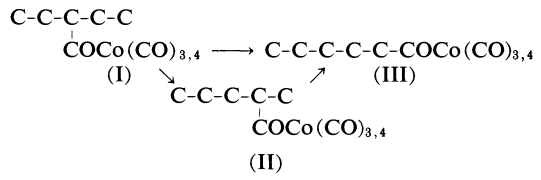
- ○ In diethyl ether under carbon monoxide
- ● In diethyl ether under nitrogen
- □ In ethyl acetate under carbon monoxide
- △ In dioxane under carbon monoxide

Potassium cobalt carbonylate relatively readily dissolves in the above-mentioned polar solvents, but it seems difficult for it to dissolve in these nonpolar solvents. However, the expected reaction, the formation of butyrylcobalt carbonyls, was proved to occur even in these solvents.** Thus, the above results with the nonpolar solvents are not due to the insolubility of the potassium cobalt carbonylate in these solvents.

The yields of the expected products, *n*- and isobutyrate, are relatively poor in the reactions in dioxane, benzene and hexane. This may be partly attributed to an instability of intermediates, i. e., *n*- and isobutyrylcobalt carbonyl, in these solvents.

In mixtures of polar and nonpolar solvents, the velocity of the isomerization of isobutyrylcobalt carbonyl was small, as compared with the case using only a polar solvent (Exps. 17—20). Especially in a benzene-dioxane solvent, a relatively small amount of benzene (20%) remarkably decreased the velocity of the isomerization (cf. Exp. 16 and 19).



As has been mentioned above, it is evident that solvents have a great effect on the isomerization of butyrylcobalt carbonyls. The reason for these phenomena can not be definitely established, but these effects may be partly attributed to the coordination of solvents with cobalt carbonyl complex, potassium and organocobalt carbonyls. This consideration seems to be supported by the facts that polar solvents have a great effect on the isomerization and that the sodium cobalt carbonylate forms a coordination compound with diethyl ether.[7]

**The Reaction of α-Ethylbutyryl Chloride with Potassium Cobalt Carbonylate.**—The isomerization of α-ethylbutyryl cobalt carbonyl (I) was also investigated. The results of this reaction are summarized in Table III. As is shown in the table, I gave an ester with a straight-chain structure, ethyl *n*-caproate (Exps. 39—44), indicating that I isomerized to *n*-caproylcobalt carbonyl (III); at 0°C, I gave only 2% of the isomerized product after 8 hr. under carbon monoxide and nitrogen atmospheres (Exps. 39, 42), but at 25°C under a carbon monoxide atmosphere, I relatively readily isomerized to give 14 and 35% of the isomerized product after 5 and 27 hr. and, under nitrogen, 21 and 26% after 3 and 5 hr. respectively. Thus, nitrogen atmosphere apparently also accelerated this isomerization. The isomerization of I seemed to proceed more slowly than that of butyrylcobalt carbonyl (cf. Exp. 2, 5 and 40).

As the course of this isomerization, two ways are possible: in the first course, I directly isomerizes to III, while in the second

** In the reactions of butyryl halides with potassium cobalt carbonylate in benzene, butyrylcobalt carbonyls were actually formed, since butyrates were given with the gas evolution when the liquid phase of the reaction mixture was treated with iodine and alcohol. The amount of butyrates increased with an increase in the reaction time, suggesting that insoluble potassium cobalt carbonylate could be transformed into soluble butyrylcobalt carbonyls, even in nonpolar solvents.

7) W. Hieber, O. Vohler and G. Braun, *Z. Naturforsch.*, 13b, 192 (1958).

course I isomerizes to III via $\alpha$-methylvaleryl-cobalt carbonyl (II). In the present case, however, it is impossible to discriminate by gas chromatography between the esters corresponding to I and II. Therefore, it can not be decided which course is taken in this type of isomerization.

The reaction of *n*-caproyl chloride was also carried out in order to check the reverse isomerization from III to I (Exp. 45). The result obtained shows that the isomerization of III to I and/or II occurred. However, it was not decided whether I or II was obtained or whether a mixture of I and II was obtained.

## Summary

The reactions of *n*-butyryl chloride, isobutyryl bromide, $\alpha$-ethylbutyryl chloride and *n*-caproyl chloride with potassium cobalt carbonylate have been studied. The results of this investigation are as follows.

(1) It has been observed that solvents have great effects on the isomerization of butyryl-cobalt carbonyls, as do the reaction temperature and the atmosphere. The rate and the equilibrium of this isomerization are remarkably affected by the solvents; in polar solvents, the equilibrium proportion of products (iso/normal) is almost zero in dioxane, 1/3 in ethyl acetate, and 1 in diethyl ether. This isomerization proceeds more rapidly under nitrogen atmosphere than under carbon monoxide. On the other hand, in nonpolar solvents such as benzene this isomerization apparently does not occur.

(2) $\alpha$-Ethylbutyrylcobalt carbonyl relatively readily isomerizes to *n*-caproylcobalt carbonyl. This isomerization is also accelerated under nitrogen atmosphere.

# The Radiolysis of Mono-, Di- and Trimethylamine in the Gas Phase

By Setsuo TAKAMUKU and Hiroshi SAKURAI

(Received September 24, 1964)

The photolysis of methylamine has been extensively studied during the past twenty years.[1-5] Although the mechanism whereby methylamine decomposes is not completely understood, the most recent study[5] has shown that the primary process is the formation of hydrogen atoms; there may also be a small degree of molecular detachment of hydrogen, which is well known in the fields of the vacuum ultraviolet photochemistry and radiation chemistry of hydrocarbons, as well as a dissociation to methyl and amine radicals.

On the other hand, the radiolysis of aliphatic amines in the gas phase has received little attention.[6,7] Hydrogen and *N*, *N'*-tetramethylethylenediamine were observed as the main products in the radiolysis of trimethylamine by Schindler and Krivak.[7] However, much, has been unknown with regard to the primary process.

We, therefore, hoped to clarify the mechanism of the radiolysis of amines and compare the results with those of the photolysis. The present study was undertaken in order to obtain information on the primary process in the radiolysis of methylamines in the gas phase. The methylamines used were mono-, di-, and trimethylamines; the radical scavenger technique was employed to estimate the mechanism of hydrogen formation.

## Experimental

**Materials.** — Methylamine was prepared from hydrochloride which had been purified by recrystallization several times with water and dried in a vacuum desiccator. The hydrochloride was treated with a nearly-saturated solution of potassium hydroxide at atmospheric pressure. The methylamine evolved was dried by passing it through a column of potassium hydroxide and then collected in a trap in liquid nitrogen, attached to a convenient vacuum line. The amine was kept in a storage bulb after trap-to-trap distillation. The infrared analysis of the sample showed that ammonia was not present as an impurity. The preparation of di- and trimethylamine was similar to that of methylamine mentioned above.

Propane was obtained from the Takachiho Chemicals Co., Tokyo, and was purified by treatment with concentrated sulfuric acid in order to remove olefins and by several trap-to-trap distillations.

**Irradiation Procedure.**—$\gamma$-Irradiation was carried out in a 500 ml. cylindrical reaction vessel fitted with graphite-coated electrodes, a guard ring and a breakable seal. This reaction vessel was similar to that described by Back.[8] The vessel was thoroughly baked in a vacuum before each experiment and filled with sample by conventional vacuum techniques. Irradiations were carried out at room temperature with a 1600 curie cobalt-60 source, applying absolute dosimetry.[8] An electric field, up to 2 kV., was applied to the central anode in order to measure the saturation ion current during irradiation. Saturation ion currents were usually measured at the beginning and the end of the irradiation; the time for the measurements was negligible compared to the total time of irradiation. Several runs were also carried out with pure propane in order to compare the results of amines with those of hydrocarbon.

**Analysis.**—After irradiation the reaction vessel was attached to a convenient vacuum line, a breakable seal was broken, and the contents of the cell were transferred to the analytical system, which consisted of the following parts: a mercury cut-off, four liquid nitrogen traps (−196°C), a mercury diffusion pump, and a Toepler pump-gas burette. The non-condensable gas collected contained hydrogen and a small amount of methane, the hydrogen in which was removed by diffusion through a palladium thimble heated at 300°C; the amount of the residual methane was then measured.

Their ion pair yields (M/N) were obtained by relating the product yields to the saturation ion currents measured in the radiolysis

## Results and Discussion

**Saturation Ion Current.**—The ion currents are plotted against the field strength for mono-, di-, and trimethylamine at different pressures in Fig. 1. Good saturation curves were

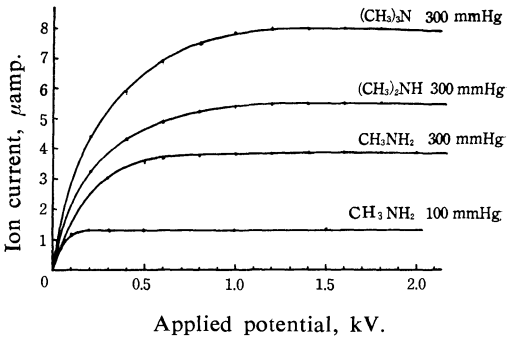

Fig. 1. Ion currents in the $\gamma$-radiolysis of amines.

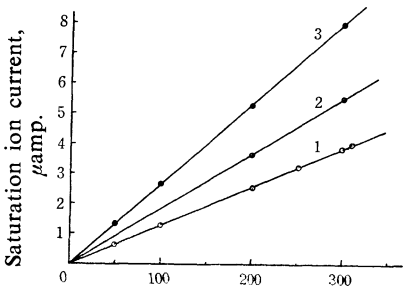

Fig. 2. Saturation ion current as a function of amine pressure.
1: Methylamine, 2: Dimethylamine
3: Trimethylamine

observed with these amines, and the saturation ion currents thus obtained were proportional to the gas pressure, up to 300 mmHg, as is shown in Fig. 2. From these results it is clear that the ions produced by $\gamma$-irradiation were quantitatively collected at the electrode under these experimental conditions and that the saturation ion current were satisfactory for calculating the ion-pair yields of the products. The differences in the saturation ion currents of these amines were due to the difference in their electron densities. After a suitable correction of their electron densities, almost the same saturation ion currents were observed.

**The Radiolysis of Pure Amine.**—The results of the radiolysis of amines at 300 mmHg are shown in Table I. The major volatile products are hydrogen, methane and ammonia. The conversion of amines shown in Table I is based on the yield of hydrogen ($2\times H_2$/amine). Hydrogen was the main product, and the yield was relatively high for methylamine, while it decreased for di- and trimethylamine. On the other hand, the yield of methane was very low for methylamine, and increased about four times for di- and trimethylamine.

On the basis of the mechanism elucidated

8) R. A. Back, T. W. Woodward and K. A. McLauchlan, *Can. J. Chem.*, **40**, 1380 (1962).

TABLE I. γ-RADIOLYSIS OF AMINES AND PROPANE
(Gas pressure, 300 mmHg)

| Compound | $CH_3NH_2$ | $(CH_3)_2NH$ | $(CH_3)_3N$ | $C_3H_8$ |
|---|---|---|---|---|
| Saturation ion current (μamp.) | 3.70 | 5.50 | 7.90 | 6.07 |
| Conversion (%) | 0.09 | 0.14 | 0.13 | 0.08 |
| $(M/N)_{H_2}$ | 3.10 | 2.78 | 1.78 | 1.55 |
| $(M/N)_{CH_4}$ | 0.10 | 0.45 | 0.41 | 0.26 |

for the photolysis of methylamine, the following possible primary dissociations of methylamine may be considered:

$$CH_3NH_2 \xrightarrow{\sim\sim} H + CH_3NH\cdot \quad (1)$$

$$\xrightarrow{\sim\sim} H + \cdot CH_2NH_2 \quad (2)$$

$$\xrightarrow{\sim\sim} \cdot CH_3 + \cdot NH_2 \quad (3)$$

$$\xrightarrow{\sim\sim} CNH_3 + H_2 \quad (4)$$

These primary reactions are followed by the secondary reactions:

$$H + CH_3NH_2 \rightarrow H_2 + CNH_4 \quad (5)$$

$$\cdot CH_3 + CH_3NH_2 \rightarrow CH_4 + CNH_4 \quad (6)$$

$$2\,CNH_4 \rightarrow NH_3 + C_2NH_5 \quad (7)$$

Since methane and ethane formations were very little, reaction 3, which should give methane by secondary reaction 6 and ethane by the recombination of the methyl radicals, seemed to be unimportant. The ammonia formation, therefore, may not be due to the hydrogen abstraction of the $NH_2$ radical produced by reaction 3 but to secondary reaction 7, involving two radicals of the empirical formula $CNH_4$, which was proposed in the photolysis of methylamine.[5]

Hydrogen-forming reactions, for which several mechanisms are possible, must be the principal primary processes. The decision between 1 and 2 must be based on the results with isotopic compounds $CH_3ND_2$ and $CD_3NH_2$, while the processes combining reaction 1 with 2, which are called radical process for hydrogen formation, may be elucidated by a radical scavenger technique, as will be described later. The importance of the amino-hydrogen atom may be pronounced, because the hydrogen yield decreased as the hydrogen atom was replaced with the methyl group, as Table I shows.

Ion-pair yields of hydrogen and methane were measured as a function of the amine pressure, as is shown in Fig. 3. They were independent of the pressure within the range of experimental error, but there was a slight decrease in hydrogen yield at pressures less than 100 mmHg in mono- and trimethylamine. This effect could be due to the wall effect. The neutralization of ions produced by primary processes may occur in the gas phase leading

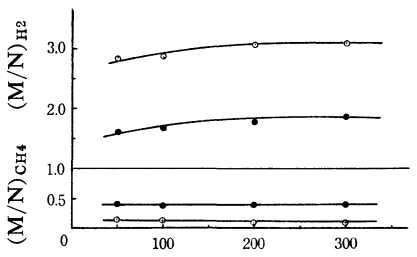

Fig. 3. Ion pair yields of hydrogen and methane as a function of amine pressure.
○ : Methylamine, • : Trimethylamine

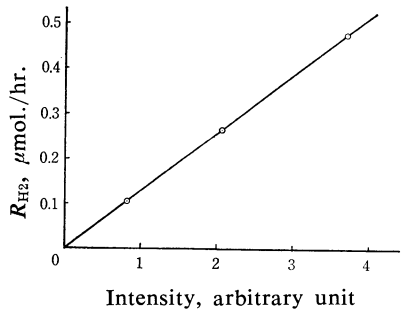

Fig. 4. Hydrogen yields as a function of intensity. (Methylamine 300 mmHg)

to dissociation, or at the surface of the vessel with deactivation. Low pressure should favor the latter and so lower the hydrogen yield.

In Fig. 4, the hydrogen yield is plotted against the irradiation intensity for the radiolysis of methylamine. A linear function was observed. This may be simply interpreted as indicating that the hydrogen atom produced in reactions 1 and 2 reacted with methylamine by reaction 5, and that the back reactions of 1 and 2, and the recombination reaction 8 of the hydrogen atom were not important in these experimental conditions:

$$H + H + M \rightarrow H_2 + M \quad (8)$$

**The Effect of the Radical Scavenger.** — In order to determine the contribution of the

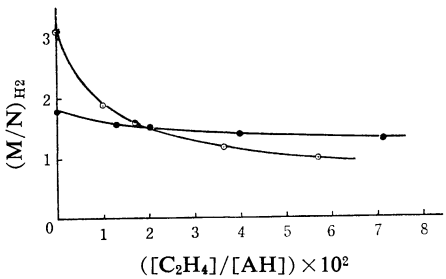

Fig. 5. The effect of added ethylene on the hydrogen yield. (Amine pressure, 300 mmHg)
○ : Methylamine, • : Trimethylamine

radical process to hydrogen formation, a radical scavenger technique, first developed by Back[9] and Hardwick[10] for hydrocarbons, was employed. The presence of a radical scavenger such as ethylene in the radiolysis of amines reduced the hydrogen yield, shown in Fig. 5, by the following reaction:

$$AH \rightsquigarrow H_2 + \text{Residue} \quad (9)$$

$$\rightsquigarrow H + \text{Residue} \quad (10)$$

$$H + AH \rightarrow H_2 + \text{Residue} \quad (11)$$

$$H + C_2H_4 \rightarrow C_2H_5\cdot \quad (12)$$

where AH shows the amine. When AH is methylamine, reaction 9 corresponds to reaction 4; reaction 10, to reactions 1 and/or 2, and reaction 11, to reaction 5. If a steady-state kinetic treatment of hydrogen atom production is made for the amine system with and without ethylene present, the following expression is obtained:

$$\frac{1}{\Delta(M/N)_{H_2}} = \frac{1}{(M/N)_{H_2(10)}} \times \frac{k_{11}[AH]}{k_{12}[C_2H_4]} + \frac{1}{(M/N)_{H_2(10)}} \quad (I)$$

where $\Delta(M/N)_{H_2}$ is the difference in the ion-pair yield of hydrogen, without and with ethylene, and $(M/N)_{H_2(10)}$ is the ion-pair yield of hydrogen by reaction 10. In Fig. 6, the values of the left-hand side of Eq. I are plotted against $[AH]/[C_2H_4]$. From these straight lines, $(M/N)_{H_2(10)}$ and $k_{11}/k_{12}$ were calculated; they are summarized in Table II.

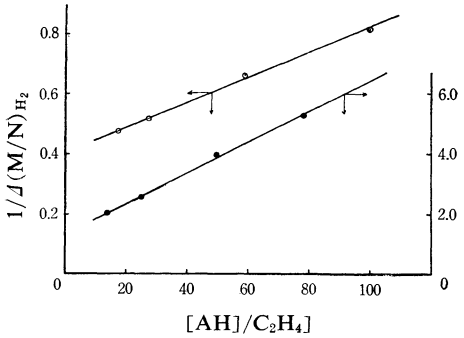

Fig. 6. Kinetic plot of the data from experiments with added ethylene.

TABLE II. HYDROGEN YIELD BY RADICAL PROCESS AND $k_{11}/k_{12}$

| Compound | $CH_3NH_2$ | $(CH_3)_3N$ | $C_3H_8$ |
|---|---|---|---|
| $(M/N)_{H_2(10)}$ | 2.50 | 0.73 | 1.12 |
| Radical (%) | 81 | 41 | 72 (75)[9] |
| Molecular (%) | 19 | 59 | 28 (25)[9] |
| $(k_{11}/k_{12}) \times 10^2$ | 1.05 | 3.56 | 0.13 |

9) R. A. Back, *J. Phys. Chem.*, **64**, 124 (1960).
10) T. J. Hardwick, ibid., **65**, 101 (1961).

These results showed that 81% of the hydrogen produced in the radiolysis of methylamine was scavengable by ethylene, indicating that the non-radical process (19%) were more important than in the photolysis. The hydrogen formed by the latter process was estimated to be less than 10% in the photolysis of methylamine, although the kinetic treatment was not carried out.[5] In the case of trimethylamine, which has no amino-hydrogen atoms, the radical process (41%) became inferior to the non-radical process. Reaction 1. therefore, seemed to be very important for the thermal hydrogen atom formation in the radiolysis, as was pointed out by Michael and Noyes[5] in the photolysis of methylamine. However, it is hoped that, by experiments with the isotopic compounds $CH_3ND_2$ and $CD_3NH_2$, it will be possible to clarify these primary processes with more certainty. At this stage of experiment, it can not be decided whether the non-radical process is a molecular process or a process involving hot hydrogen atoms.

Relatively high $k_{11}/k_{12}$ values were observed with these amines compared with that of propane, showing that the rate of the abstraction of the hydrogen atom from the amine may be estimated to be faster than that from propane.

## Summary

The $\gamma$-radiolysis of methylamines in the gas phase has been investigated, applying the absolute dosimetry involving the measurement of saturation ion currents in the gases during irradiation. The major volatile products are hydrogen, methane and ammonia. Ion-pair yields of hydrogen for mono-, di- and trimethylamine are 3.10, 2.78 and 1.78 respectively. Those of methane are 0.10, 0.45 and 0.41 respectively. The yields of hydrogen and methane are independent of the pressure up to 300 mmHg, but at pressures less than 100 mmHg there are slight decreases in hydrogen yields. The rate of hydrogen formation from methylamine is proportional to the radiation intensity, and the yield decreases in the presence of a small amount of ethylene. By kinetic analyses of the results with an added scavenger, it has been observed that 81% of the hydrogen formed from methylamine is caused by a radical process, while the value is 41% for trimethylamine.

# A Microcell for Differential Thermal Analysis*

By Satohiro TANAKA

(Received August 31, 1964)

In the differential thermal analysis of materials, it is often necessary to use only a small amount of a sample. When the amount of sample is less than 50 mg. in weight, the following methods have been used: (i) The heating rate has been increased in order to obtain a sharper peak. (ii) The sample has been diluted with a large volume of the reference inert material.[1,2] (iii) The sample has been sandwiched between two layers of the reference inert material.[2] (iv) A melting-point capillary tube has been used as a sample cell.[3]

However, each of these methods has some disadvantages. Method i is defective in the drifting of the peak temperature and base line as the heating rate is increased. Methods ii and iii usually involve a troublesome preparation of the sample, such as the homogeneous mixing of sample and reference material. Moreover, relatively large amounts of the sample, more than 10 mg. in weight are needed. In method iv a thermocouple must be inserted directly into the sample, so that the perfect cleaning of the thermocouple before and after measurement is necessary, and care must be taken to position the thermocouple centrally in the tube.

In this work, in order to carry out the differential thermal analysis (DTA) conveniently using a small amount of a sample, simple microcells were used, and the effects on the DTA peak of the amount of sample, the heating rate, the heat capacity of the cell, and the heat transfer coefficient between the cell and the metal block were investigated. The present study has been confined to the melting of benzoic acid.

## Experimental

**Benzoic Acid.** — Benzoic acid, as a standard sample for combustion calorimetry, was obtained from the Resources Research Institute, Japan, and was used without further purification.

**Microcells.**—The microcell body was a 3 mm.$\phi$× 9 mm. platinum rod with two holes, 2 mm.$\phi$×3mm. and 2 mm.$\phi$×5 mm., on the top and the bottom of the body respectively. The top hole was used as a sample hole, and the bottom hole, as a thermocouple hole. The caps, obtained from the Ishifuku Metal Co., were also made of platinum. The microcell body and the cap are shown in Fig. 1.

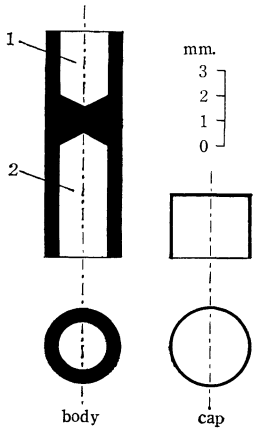

Fig. 1. Microcell.
1, Sample hole; 2, Thermocouple hole

**Metal Block.**—The metal block body and the lid, shown in Fig. 2, were made of aluminum. The body was a 27 mm.$\phi$×27 mm. cylinder with three 6 mm.$\phi$×15 mm. holes, and the lid was a 27 mm.$\phi$ ×5 mm. disk. The microcells and the metal block shown in Fig. 2 were so assembled that the microcells were supported only by the thermocouple and were not in contact with the wall of the metal block.

**Apparatus.**—A Rigakudenki Co. Automatic Recording Differential Thermal Analyzer and Adiabatic Calorimeter was used. The differential temperatures were measured by a two-junction alumel-chromel thermocouple 0.3 mm.$\phi$ in diameter.

**Differential Thermal Analysis.**—Samples, about 1—2 mg. in weight, were placed in the sample hole of a microcell and covered with the cap. The microcells were then laid on the junction of the thermocouple, as is shown in Fig. 2, and heated enough to melt the benzoic acid sample once; after the microcells had then cooled to room temperature, measurements were carried out in air. The weights of the samples were measured before and after every measurement; no appreciable weight loss of sample could be found after such measurements. The reference microcell was used without any reference materials.

## Results and Discussion

**The Shape of the DTA Curves.**—A typical finding concerning DTA curves for the melting of a benzoic acid sample is shown in Fig. 3. If the amount of sample was less than 1.5 mg. in weight, a normal thermogram (curve a) could be obtained; but when the amount of the sample was more than 1.5 mg. in weight, an abnormal thermogram was obtained (curve b).

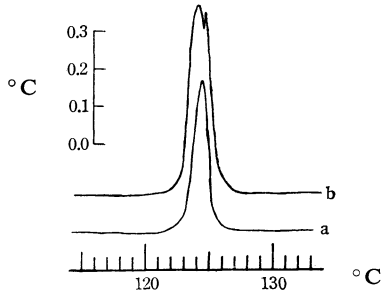

Fig. 3. Differential thermogram of benzoic acid at a heating rate of 1.0°C/min.
a, 1.4 mg. in weight; b, 4.0 mg. in weight

This abnormal curve was probably due to the fact that, as heat is transferred from the bottom to the top of the cylindrical cell, the sample first begins to melt at the bottom; then, a small part of sample stuck on the wall of the cell melts and drops into the molten sample at the bottom.

**Effect of the Sample Amount.**—DTA's were carried out in order to examine the effect of the sample amount on thermograms at a heating rate of 1.0°C/min. As Fig. 4 shows, the peak area is proportional to the sample amount over all the range. However, the peak height is proportional to the sample amount up to 1.5 mg. in weight and is not reproducible above that amount.

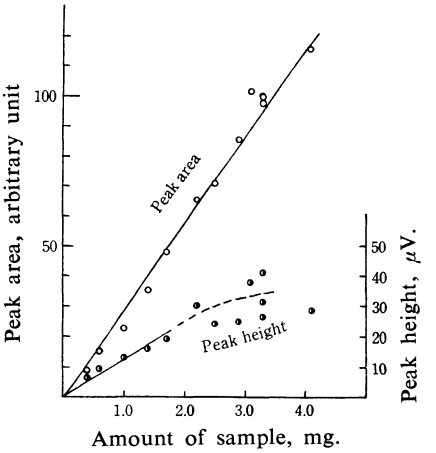

Fig. 4. Effect of sample amount on peak area and peak height at a heating rate of 1.0°C/min.

**Effect of the Heating Rate.**—The effect of the heating rate is shown in Fig. 5 and Fig. 6 using a 1.4 mg. sample. Figure 5 shows that the peak height increases with the heating rate, while the peak area is almost constant with the heating rate. Figure 6 shows that the peak beginning temperature, which is defined on the thermogram as the intersection point of the extrapolated straight-line portion of the low temperature side of the peak and the base line, and the peak temperature, which

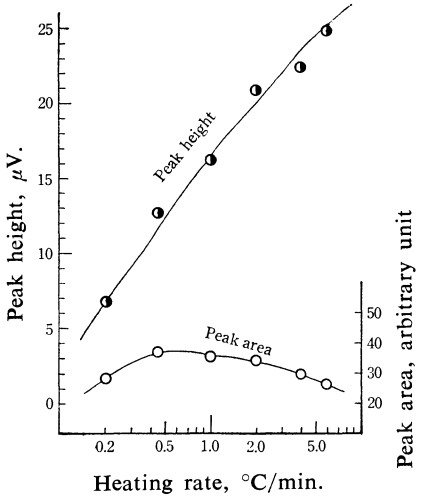

Fig. 5. Effect of heating rate on peak area and peak height using a 1.4 mg. sample.

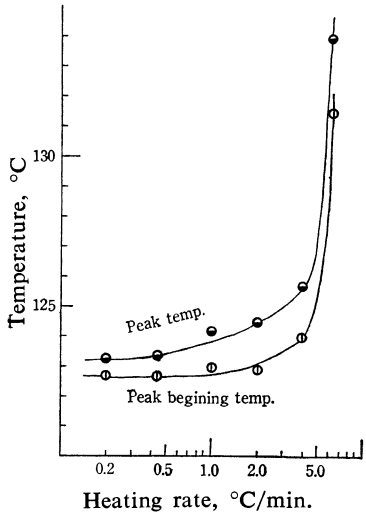

Fig. 6. Effect of heating rate on peak beginning temperature and peak temperature using a 1.4 mg. sample.

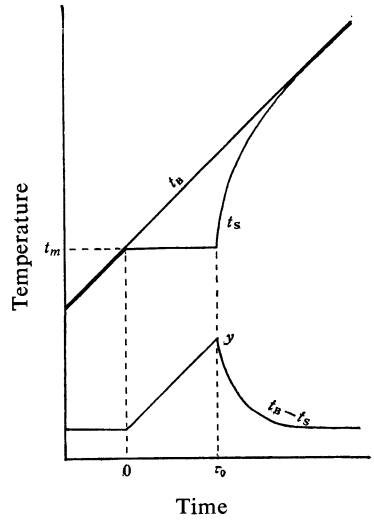

Fig. 7. Illustration of hypothetical thermal process.

is the extrapolated peak temperature, increase with the heating rate; however, if the heating rate is less than 2°C/min., the peak temperature is identical with the melting point within ±1°C.

**A Consideration of the Quality of the Microcell.**—It is necessary to investigate factors which affect the quality of the microcell in order to make further improvements of the microcell. For this purpose, two hypothetical thermal processes which take place in the microcell were considered.

*Process i.* — If the cell may be considered to be thermally isolated, a thermal transformation causes a change in the temperature, $Y$, given by:[4]

$$Y=\frac{Q}{C} \tag{1}$$

where $Q$=the heat of transformation
$C$=the mean specific heat capacity of the cell and sample.

In this work, the cell weighed about 1 g., while the samples weighed about 1—5 mg., therefore, $C$ is almost equal to the specific heat capacity of the microcell.

*Process ii.*—The temperature of the metal block, $t_B$, is equal to that of the reference cell, $t_r$, the sample cell, $t_c$, and the sample, $t_s$, and increases at a constant heating rate, $r$, at first. Then, at time $\tau=0$, the sample begins to melt at a constant temperature, $t_m$, until it finishes melting at time $\tau=\tau_0$. This process is illustrated in Fig. 7; the following equation is obtained:

$$h(t_B-t_s)d\tau=Cdt_s+dQ \tag{2}$$

with the following boundary conditions:

$$\tau=0,\ t_B=t_r=t_c=t_s=t_m$$
$$0\leqq\tau\leqq\tau_0,$$
$$t_c=t_s=t_m=\text{constant melting temperature}$$
$$t_B=t_r=t_m+r\tau$$

where $h$=the heat transfer coefficient between the cell and the wall of the metal block.

The integration of Eq. 2 gives:

$$\int_0^{\tau_0}h(t_B-t_s)d\tau=\int_0^{\tau_0}Cdt_s+\int_0^{\tau_0}dQ$$
$$hr\tau_0^2/2=Q \tag{3}$$

The maximum temperature difference, $Y$, between the temperature of the sample and that of the reference cell or block is:

$$Y=(t_B-t_s)_{\tau=\tau_0}=r\tau_0 \tag{4}$$

From Eqs. 3 and 4, one obtains:

$$Y=\sqrt{2rQ/h} \tag{5}$$

Although Eqs. 1 and 5 represent DTA peak heights in hypothetical thermal processes, some factors relating to the quality of the microcell can be interpreted on the basis of these equations. To increase the peak heights or the sensitivity of microcells, the following methods may be recommended on the basis of Eqs. 1 and 5:

(i) The specific heat of the cell, $C$, should be decreased.

(ii) The heating rate, $r$, should be increased.

4) W. J. Smother and Y. Chiang, "Differential Thermal Analysis," Chem. Publishing Co., N. Y. (1958), p. 79.

(iii) The heat transfer coefficient, $h$, between the microcell and the wall of metal block should be deceased.

Of these, method ii, as has been mentioned earlier, is not useful because of the drifting of base line and peak as the heating rate increases. Methods i and iii have already been applied to the microcells in this work; that is, these microcells are made light in weight [method i] and are supported only by the thermocouple, not coming in contact with the wall of the metal block [method iii]. Therefore, further experiments were made to check upon the efficiency of these methods.

**Experiments to Check on Methods i and iii.** —Three microcells differing in weight were made in order to investigate the effect of the heat capacity of the microcell on peak heights and areas. These microcells differ from each other only in the radius of the sample hole; their surfaces are similar in shape, as is shown in Fig. 8. Therefore, the heat transfer coefficients between each microcell and the wall of the metal block are equal. The results obtained using these cells are shown in Fig. 9 and Fig. 10.

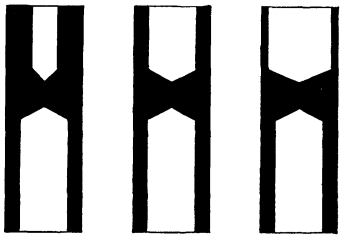

Fig. 8. Three microcells different in weights.

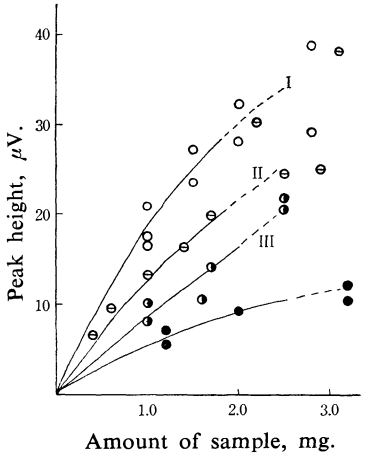

Fig. 9. Comparison of peak heights.
◑, Cell I ○, Cell III
⊖, Cell II ●, in alumina powder

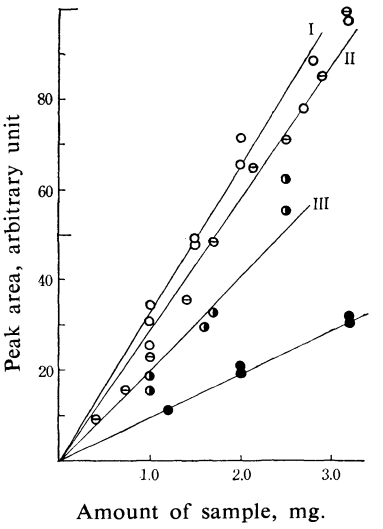

Fig. 10. Comparison of peak area.
◑, Cell I; ○, Cell III;
⊖, Cell II; ●, in alumina pouder.

Further experiments were carried out in order to investigate the effect of the heat transfer between the microcell and the wall of the metal block. The heat transfer coefficient was increased by filling the Hole Space 4 shown in Fig. 2 with alumina powder; that is, air in the space between the microcell and the wall of the metal block was replaced by alumina powder. The results are also shown in Fig. 9 and Fig. 10.

As we anticipated previously from Eqs. 1 and 5, Figs. 9 and 10 show that peak heights or areas increase as the heat capacity of the microcell and the heat transfer coefficient between the microcell and the wall of the metal block decrease. As a conclusion, as a means of improving the quality of the microcell, a smaller cell and finer leads of thermocouple in order to decrease the heat transfer coefficient are recommended.

## Summary

Microcells to carry out differential thermal analysis using a small amount of a sample have been described. The features of these cells are that they are small and light in weight, and are supported only by a thermocouple, not coming in contact with the wall of the metal block. The effects have been described of the variation in heating rate and in sample amount. The peak areas of the benzoic acid melting curve are proportional to the sample amount. The melting temperature can be measured with a precision of ±1°C if the heating rate is less than 2°C/min. The

improvement of the quality of the microcell has also been considered.

The author wishes to express his thanks to Dr. Kazuo Amaya, Dr. Taichi Sato, Mrs. Kazuko Sasaki, Mr. Akira Suzuki, and Mr. Kenjiro Kodama of this Institute for their valuable discussions. He also wishes to thank Dr. Yo-ichiro Mashiko for his kind encouragement.

# Semiconducting Properties of Tetramethylammonium Polyiodides and the Irradiation Effect*

By Shichio KAWAI, Ryôiti KIRIYAMA, Madoka UCHIDA, Shigekazu KUSABAYASHI and Hiroshi MIKAWA

(Received October 2, 1964)

Polyiodides, a remarkable group of salts, are of the $MI_n$ type, in which M is one of the larger alkali metal ions, a substituted ammonium ion or an arsonium ion, and $n=3$, 4, 5, 7 or 9. In triiodide crystals of a kown structure, the triiodide anions exist as separated individuals. In the higher polyiodides, the anion assembly is made up of a number of sub-units ($I^-$, $I_3^-$ and $I_2$ molecules) which are loosely held together to form the more complex $I_n$ system. The triiodide ion has been found to be linear in a number of salts with a large cation.[1] In tetramethylammonium pentaiodide,[2] there are approximately square nets of iodine atoms. An even more complex arrangement is found in tetramethylammonium enneaiodide;[3] five-ninths of the iodine atoms form rather densely-packed layers, while the remaining iodine atoms exist in the form of diatomic iodine pairs, which act as props between those layers. It is to be expected that the electrical behavior of polyiodide crystals will change in parallel with the transition in the nature of the intermolecular or interionic bond in polyiodides; $I_3^-$ ions exist in more or less isolated units, $I_5^-$ ions exist in a layered structure, and $I_9^-$ ions form a three-dimensional network. It was pointed out in a preceding paper that, in organic polyiodides, the electrical resistivity and the activation energy for electronic conduction decreases with the increasing number of iodine atoms in the polyiodide ion, the influence of the cations being of subordinate importance.[4] The present study is concerned with the interrelation between the crystal structure and the electrical behavior in tetramethylammonium polyiodides and especially with the anisotropy of electrical properties in different crystallographic directions.

The effects of irradiation with charged particles or neutrons on semiconducting properties have been studied extensively for many semiconductors; such investigations have provided valuable information above the defects which behave as acceptor levels or as donor levels.[5,6] Studies of the effects of high-energy irradiation on electrical properties are also useful for an understanding of the nature of rather weak bonds in solids. Several examples studied in this line in relation to the dielectric relaxation phenomena of some mineral dielectrics have already been reported.[7,8] In the present investigation, the effects of X- and $\gamma$-irradiations on the electrical conductivity of tetramethylammonium pentaiodide will be studied.

## Experimental

**The preparation of the Compounds.**—Crystals of tetramethylammonium polyiodide were grown by a

slow cooling of an alcoholic solution of tetramethylammonium iodide from its boiling point with an excess of iodine, as has been described in a previous report.[4] Single crystals, composed of thin flakes 0.5—1 mm. thick and suitable for d. c. measurement, were obtained by cooling a solution with an adequate concentration from 80 to 35°C over a period of several weaks. The melting points agreed with those reported in the literature. Each individual crystalline phase was also identified by X-ray diffraction.

**Measurements.**—The temperature-dependence of anisotropic d. c. conductivity was measured in different crystallographic directions, perpendicular to and parallel to the iodine net in both $(CH_3)_4NI_5$ and $(CH_3)_4NI_9$. In $(CH_3)_4NI_3$, the measurements were carried out in two directions, perpendicular to and parallel to the cleavage plane. Various electrode materials were tested: indium amalgam, copper plate, silver paste and graphite. Graphite powder electrodes were used for the direct current measurement, because it was inert against iodine. The d. c. conductivity of the specimen was measured by a micro-micro ammeter, capable of measuring current down to $10^{-13}$ amp. with an applied potential of 90 V.

Preliminary experiments showed that iodine sublimed from polyiodide crystal on heating. This sublimation of iodine may be a cause of the time-dependent of the d. c. conduction. The time-dependence current could be avoided by enclosing the sample and electrodes in a 3 cc.-capacity glass tube tightly covered with Teflon plates and silicon grease at both openings. On both edges or both sides of a platy single crystal, graphite powder was pressed through platinum plates with wire springs. The electrode assembly was then put in a shield box connected to the ground side of the circuit in order to eliminate any stray field effects. The temperature was measured with a copper-constantan thermocouple located as close as possible to the specimen. The specimen was heated to about 20°C below the melting point, and then the conductivity measurements were made as it was slowly cooled.

The measurement of the thermoelectric power was also attempted for these materials. A test piece 13 mm. in dameter and about 1—2 mm. thick was molded by pressing the crystalline powder of polyiodide under 5 ton/cm$^2$.

**Irradiation.**—The radiation effect on the electric conductivity of $(CH_3)_4NI_5$ was also investigated. The crystal was subjected to about $4.1\times10^6$ r. of X-rays from a copper target tube with a beryllium window operated at 15 kVp and 15 mamp. $\gamma$-Irradiation was performed at about 5°C in order to avoid the annealing effect which appeared at higher temperatures. A brass container with the specimen was immersed into a water pool, at the bottom of which $^{60}Co$ has been placed, and kept there for the required period of time. The total dose attained was from $2\times10^6$ to $10^7$ r.

## Results and Discussion

**The Temperature-dependence of the Conductivity.**—When an external electric field was applied below 0°C, the current decreased with time and reached a steady value after 1 min. This phenomenon, however, could not be observed above 0°C, and the relaxation time of the anomalous current observed below 0°C is in the order of sec.-min.

Sufficient ohmic contact is attained with graphite electrodes below about 200 V./cm. of an applied field. As the thin single crystal was brittle and small, the application of a guard ring in order to eliminate the surface leakage current was abandoned. When a single crystal of $(CH_3)_4NI_5$ was kept in an evacuated condition for 20 min. at room temperature, a little iodine sublimed out from the surface of the crystal and a reddish-brown layer of $(CH_3)_4NI_3$ covered the surface of the crystal. This effect was useful as a means of knowing if the surface leakage current, if any, has any influence on activation energy. No change in the activation energy for d. c. conduction was detected, even when a $(CH_3)_4NI_5$ crystal was used which had been kept for 2 hr. in a vacuum prior to the measurement, until the color of the crystal surface changed sufficiently. The activation energies obtained in the present experiment must, therefore, be reliable values for the real bulk conduction.

The variation in the conductivity with the temperature was found to obey the usual equation of electrical conduction:

$$\sigma=\sigma_0\exp(-\varepsilon/2kT)$$

Figure 1 shows the temperature-dependence of the conductivity with an applied field parallel to and perpendicular to the iodine nets in the cases of $(CH_3)_4NI_5$ and $(CH_3)_4NI_9$ and to the cleavage plane in the case of $(CH_3)_4NI_3$. It is noticeable that the systematic increase in the number of iodine atoms within the polyiodide ion from $(CH_3)_4NI_3$ to $(CH_3)_4NI_9$ is accompanied by a gradual increase in the electronic conductivity.

The activation energies calculated from the conductivity data are given in Table I. As for $(CH_3)_4NI_3$, it may be seen in Fig. 1 that the

Open circles indicate that along the nets (pentaiodide and enneaiodide) and cleavage planes (triiodide). 9) tetramethylammonium enneaiodide, 5) tetramethylammonium pentaiodide, 3) tetramethylammonium triiodide.

plot of the logarithm of the conductivity versus the reciprocal temperature in the direction parallel to the cleavage plane gives two straight lines, with a break around 40°C. The activation energy for the upper part of the break is 1.68 eV., and for the lower part, 2.15 eV. Although a number of runs have been made on several samples, the same results were always obtained, and so, there was a good reproducibility. On the other hand, the temperature-dependence of the conductivity in the direction perpendicular to the cleavage plane gives a single straight line, and the energy of activation is 2.15 eV. It is remarkable that the activation energy in the low temperature range is apparently isotropic. In $(CH_3)_4NI_5$, the activation energy is smaller than that in $(CH_3)_4NI_3$. The values of the activation energy are almost the same both parallel to and perpendicular to the iodine nets. In $(CH_3)_4NI_9$, the values of the activation energy depend on the crystallographic direction; the value perpendicular to the iodine net is larger than that parallel to it, and the latter is the same as that of $(CH_3)_4NI_5$ within the range of experimental error.

**Thermoelectric Power.**—In order to determine the sign of the majority carriers, preliminary measurements of the thermoelectric power were performed on $(CH_3)_4NI_3$, $(CH_3)_4NI_5$ and $(CH_3)_4NI_9$. For all these compounds, the sign of thermo-voltage suggests that a positive-charge carrier is more mobile than a negative one at room temperature. This is quite analogous to the case of solid iodine, where the hole conduction also seems to be predominant judging from a study of space-charge-limited photocurrent.[9]

**The Interrelation between Structure and Conductivity.**—The crystal structures of $(CH_3)_4NI_5$ and $(CH_3)_4NI_9$ are similar to that of solid iodine, all the compounds have a layer structure composed of iodine atoms (Figs. 2, 3). In $(CH_3)_4NI_5$, the I—I distances with in the V-shaped $I_5^-$ ion are 2.93 and 3.14 Å, larger than the I—I distance in the $I_2$ molecule in crystalline iodine (2.68 Å) and considerably smaller than the van der Waals distance. Therefore, the interaction between the iodine atoms within the ions is expected to be strong enough to a partial charge transfer through the resonance of the covalent bond. The shortest distance between neighboring polyiodide ions is shown in Table II, the value for solid iodine being also included for purposes of comparison.[10] The distance between the neighboring polyiodide ions in $(CH_3)_4NI_5$ and also in $(CH_3)_4NI_9$ is shorter than the van der Waals distance, so some direct inter-anionic bonding must be

involved. The bond angle within and between polyiodide ions, 90° and 180° respectively, is direct evidence for the covalent nature originated by p orbitals of iodine atoms, as in solid iodine.[11,12]

The distance between polyiodide ions in a single net in $(CH_3)_4NI_5$, 3.63 Å, is slightly larger than the $I_2$—$I_2$ distance reported for the $I_2$ crystal, 3.56 Å. It is, therefore, understandable that the activation energy for $(CH_3)_4NI_5$ (1.36—1.39 eV.) is somewhat higher than that for solid iodine (1.24—1.30 eV., the energy separation between $\pi^*$ and $\sigma^*$ bands).[13] It may be expected that the fundamental process of the conduction will be the same in both polyiodide and solid iodine.

When different polyiodides are compared, it is interesting to note that the shorter the shortest distance between polyiodide ions, the smaller the activation energy for hole conduction. The energy band gaps are considered, therefore, to be determined essentially by the shortest distance between polyiodide ions.

12) J. L. Rosenberg, ibid., **40**, 1707 (1964).
13) T. S. Moss, "Photoconductivity in the Elements," Butterworths Scientific Publications, London (1952).

The activation energy in $(CH_3)_4NI_5$ is almost the same both parallel to and perpendicular to the iodine net. The mechanism of electrical transport perpendicular to the layer is difficult to explain in the terms of a hopping mechanism because of the marked anisotropy of the atomic arrangement; that is, the distance between iodine layers is about 0.7 Å longer even than the interatomic distance in the layer. The semiconducting nature across the iodine layer in $(CH_3)_4NI_5$ suggests that the adjacent layers are held not only by the van der Waals force but also by another sort of intermolecular interaction. Although the shorter atomic distance of 4 Å between the layered iodine and the nearest molecular iodine $I_2$ interleaved in the $(CH_3)_4 \cdot NI_9$ lattice is shorter than that of the interlayer spacing of $(CH_3)_4NI_5$, the activation energy perpendicular to the layer of $(CH_3)_4NI_9$ is 0.3 eV. larger than that parallel to the layer. This discrepancy may be attributed to the following causes. The first is the imperfection of the crystal; that is, some sorts of stacking disorder in the direction perpendicular to the sheets should occur, because $I_2$ molecules lying between the layers sublime out rather easily. The second is that the I—I distance within the interleaved $I_2$ molecule is almost equal to that observed in the gaseous $I_2$ molecule. Thus the interatomic interaction within the iodine net through the interleaved $I_2$ molecule in $(CH_3)_4NI_9$ must be relatively weak compared with that between layers in $(CH_3)_4NI_5$.

As has been stated previously, an anomalous current was observed below 0°C, one which was characterized by the relaxation time in the order of sec.-min. Such a time-dependent polarization phenomenon is due to the relative displacement of ionic species rather than to than of electrons or holes.

**Radiation Effects on Semiconducting Properties.**—Since $(CH_3)_4NI_5$ forms a typical layer structure and is more stable than $(CH_3)_4NI_9$, the meaurements were carried out mainly on $(CH_3)_4NI_5$. It is interesting to note that the radiation-induced effect on the electrical conductivity is significantly different between X-rays and $\gamma$-rays; X-rays exert an increasing effect on the conductivity, while $\gamma$-rays exert a decreasing one.

The conductivity and the temperature-dependence of the crystal subjected to about $4.1 \times 10^6$ r. of X-rays are shown in Fig. 4. The X-rays used here are perfectly absorbed at the surface region of the crystalline specimen, because the absorption coefficient of iodine is very large. It seems, therefore, likely that the radiation damage caused by the incident X-rays is concentrated near the surface exposed to X-rays. In Fig. 4, the open circles on a

straight line denote the unirradiated specimen and the solid ones, the X-irradiated specimen. It is clear from this figure that the irradiation with X-rays considerably increases the conductivity. If the temperature of the irradiated specimen is raised above room temperature, an appreciable portion of the increment of conductivity will gradually vanish. The activation energy for the conduction of the annealed specimen, however, is greater than that of the unirradiated one (Table III).

Table III. Activation energy for the conductivity of tetramethylammonium pentaiodide irradiated by X- and $\gamma$-rays

| | $\varepsilon_{\parallel}$, eV.* | $\varepsilon_{\perp}$, eV.* |
|---|---|---|
| After the annealing for 24 hr. at room temp., X-irradiation of $4\times10^6$ r. | 2.1 | — |
| $\gamma$-rays, $2\times10^6$ r. | 1.93 | — |
| $\gamma$-rays, $4.8\times10^6$ r. | 1.90 | — |
| $\gamma$-rays, $1.2\times10^7$ r. | 1.87 | 1.96 |
| After annealing at 46°C, $\gamma$-irradiation of $4.8\times10^6$ r. | 1.90 | — |

* $\varepsilon_{\perp}(\varepsilon_{\parallel})$ is the activation energy obtained in the direction perpendicular (parallel) to the nets of iodine atoms.

The temperature-dependence of the conductivity of a $\gamma$-irradiated specimen exposed to about $2\times10^6$ r. is shown in Fig. 4. The conductivity is now actually lowered, and the apparent activation energy for the conduction is larger than that for the original specimen. However, the conductivity of the $\gamma$-irradiated specimen increases gradually with time when kept at room temperature. It happens, therefore, that the apparent activation evergy (3.12 eV.) of the $\gamma$-irradiated sample calculated directly from the $\log_{10} R$ against $T^{-1}$ plot for the heating cycle includes the activation energy for the spontaneous change of the conductivity; the value must be larger than the true one. It has been found that a temperature of measurement of about 0°C or less is required in order to avoid such an annealing effect. Therefore, the true temperature-dependence of the conductivity of the irradiated materials should be measured in a low temperature region, thus avoiding any annealing process. The activation energies obtained for the specimens irradiated up to $1.2\times10^7$ r. are almost the same in both directions, parallel to and perpendicular to the iodine net (Table III).

If an irradiated crystal is stored at particular temperature, an appreciable portion of the radiation-induced change in conductivity is annealed out slowly, at a rate depending on the annealing temperature, and the value reaches a steady value asymptotically (Fig. 5b, 6). The curves of Fig. 6 indicate two types

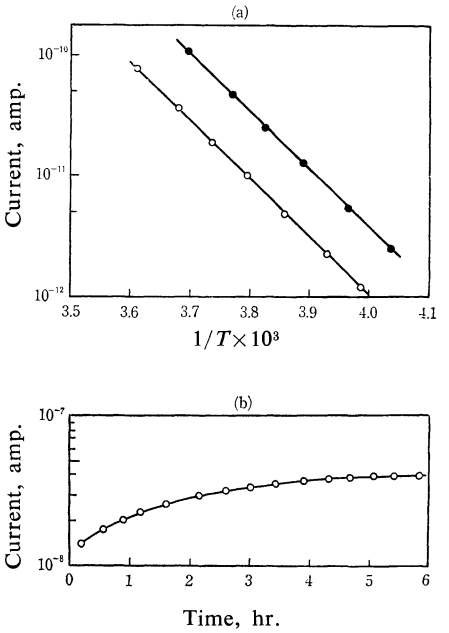

Fig. 5. Effects of annealing on the conductivity of specimen exposed to $\gamma$-rays of $4.8\times10^6$ r.
(a) Open circles indicate the temperature-dependence of the conductivity below 0°C just after $\gamma$-irradiation, solid circles that of specimen annealed out for about 8 hr. at 46°C.
(b) The variation of the conductivity of $\gamma$-irradiated specimen with time at 46°C.

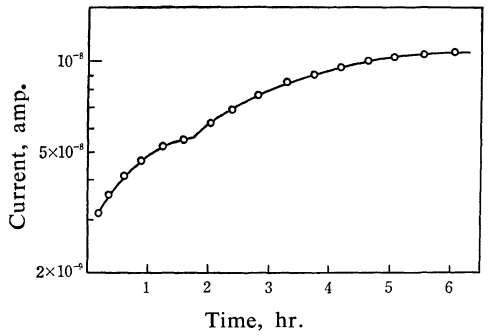

Fig. 6. The variation of the conductivity with time at 40°C for specimen irradiated by $\gamma$-rays of $4.8\times10^{6}$ r.

of annealing process; (i) at a higher annealing temperature, the curve is monotonous, (ii) when the temperature of annealing is decreased, there seems to be a tendency to have an intermediate step. Therefore, it is suggested that there are two separate processes involved in the recovering of the radiation-induced change. Such a long period of time was required for annealing at far lower temperatures that no exact measurements of the rate of annealing could be made. The magnitude of the conductivity at the starting point of annealing can, however, be estimated on the basis of the coductivity data obtained in the temperature region lower than 0°C. The logarithm of time taken to reach half the initial value in the second-stage annealing is plotted as a function of $1/T$. The $\log_{10} T_{1/2}$ versus $T^{-1}$ plot is linear (Fig. 7). The activation energy obtained in the $k=A\exp(-E/kT)$ expression from the slope of the line in Fig. 7 is 1.55 eV.

The true activation energy thus estimated does not change between before and after the annealing, as Fig. 5 shows. It may be concluded that two types of radiation effects exist together, the first being a radiation-induced change which is gradually annealed out, even at room temperature, and the second being an effect which remains unchanged, even up to about 70°C.

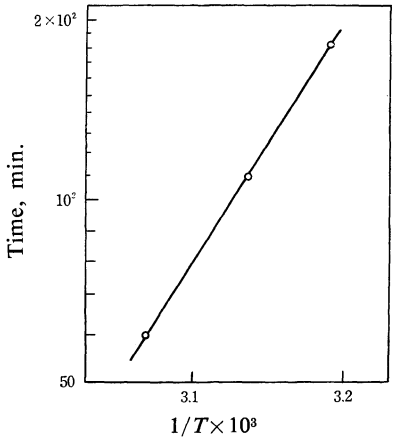

Fig. 7. The time to reach half the initial conductivity plotted as a function of $1/T$ for tetramethylammonium pentaiodide.

**Possible Lattic Imperfections Produced by X- and $\gamma$-Irradiation.**—Upon X-irradiation the conductivity of $(CH_3)_4NI_5$ increased, whereas upon $\gamma$-irradiation the conductivity decreased. Such facts can be understood if one assumes that the number of holes in the valence band is increased or decreased by the respective irradiations. The addition of acceptor levels below the Fermi level will increase the hole concentration in $p$-type semiconductors like $(CH_3)_4NI_5$, while, on the other hand, the addition of donor levels above the Fermi level will reduce the hole concentration in $p$-type semiconductors.

The passing of X-rays or $\gamma$-rays through the specimen must bring about extensive ionization and/or electronic excitation in the crystal lattice, which in turn will lead to bond rupture or bond rearrangement and atomic displacement. Cations, like $I^+$ or $I_2^+$, will be formed easily by the ionization action of moderate X-rays. These charged ions may act as an acceptor level in the crystal. Bond rearrangement will be caused, especially by $\gamma$-irradiation, as a resuls of the slight atomic displacement in the iodine net. Consequently, some anions, like $I_2^-$ or $I_3^-$, may appear in the original polyiodide lattic.

The value of the activation energy of annealing may serve as a clue for the explanation of the conduction mechanism, although the true features of the actual radiation damage will be considerably complicated. The good agreement between the activation energy of annealing, 1.55 eV., and the bond energy in the iodine molecule, 1.57 eV.,[14] suggests that the dissociation of the $I_2$ molecule takes place in the second stage of annealing. If the formation of the iodine molecule, $I_2$, in several sites of the iodine net is a true picture of the $\gamma$-irradiated effect, the electrical conduction in the original pentaiodide crystal, which may be attributed in part to some sort of charge transfer between V-shaped $I_5^-$ ions, will decrease to a certain extent because of the presence of the isolated $I_2$ molecule.

No significant change was observed in the diffraction pattern of the polyiodide crystal between before and after the irradiation. Therefore, the atomic displacement or the damage caused by irradiation must be negligibly

14) L. P. Pauling, "The Nature of the Chemical Bond," 3rd Ed., Cornell University Press, New York, (1960), p. 81.

small within the limits of diffractometer-sensitivity. Thus, it may be concluded that the main effect of the irradiation is the local formation of ions in the matrices of the complex overlapping of the electron clouds of polyiodide ions.

## Summary

Measurements of the temperature-dependence of d.c. conductivity have been made with tetramethylammonium polyiodide in different crystallographic directions, perpendicular to and parallel to the nets of iodine atoms. The systematic increase in the number of iodine atoms from tetramethylammonium triiodide to tetramethylammonium enneaiodide is accompanied by a gradual increase in conductivity. The activation energy for the conductivity along the iodine net is determined mainly by the shortest distance between polyiodide ions. Such as in the case of crystalline iodine, hole conduction is predominant in polyiodide crystals. From the standpoint of structural considerations and the values of the activation energies, the fundamental process in the hole conduction seems essentially be the same in both polyiodides and solid elementary iodine.

The irradiation effects on the electrical conduction may be classified distinctly into two types: (i) the effects of irradiation which can easily be removed by annealing above about 30°C, and (ii) the effects which can not be overcome by heat treatment below 70°C. The conductivity increases on X-irradiation, indicating the production of some acceptor levels, while the conductivity decreases with $\gamma$-irradiation, a phenomenon which may be attributed to some sort of donor level formation.

# Estimation of Anharmonic Potential Constants. I. Linear $XY_2$ Molecules

By Kozo KUCHITSU and Yonezo MORINO

(Received October 10, 1964)

Within the framework of the Born-Oppenheimer approximation, the motions of the nuclei in a molecule can be fully understood if the potential function, *iuclnding the anharmonicity*, of the molecule is known. The fundamental importance of the anharmonic (usually cubic and quartic) potential constants for molecular spectroscopy is, as is well recognized,[1] that they are closely related to the dependence, $\alpha_i$, of the rotational constants on the vibrational quantum numbers; to the vibrational anharmonic constants, $x_{ij}$; to the anharmonic resonance, and to the effects of vibrations on the molecular structure.[2,3]

Potential functions, including anharmonicity, have been the subject of extensive studies concerning diatomic molecules,[4-6] whereas little information has yet been obtained concerning polyatomic molecules; no parameters $\alpha$ and $x$ have been determined by spectroscopic studies under high resolution except for only a few of the simplest molecules. Nor has the physical significance of cubic and quartic potential constants been fully explored, in contrast to the case of the quadratic force constants,[7] which have been studied in relation to the intramolecular force field. In view of the recent development of rotation and rotation-vibration spectroscopy, it seems of practical utility for spectroscopic analyses to investigate the basic relations which exist among the anharmonic potential constants; by means of such relations, one may make quantitative, or at least semiquantitative, estimates of the magnitude of anharmonic constants and those of the $\alpha$ and $x$ parameters for which sufficient experimental data have not been determined.

7) E. B. Wilson, Jr., J. C. Decius and P. C. Cross, "Molecular Vibrations," McGraw-Hill, New York (1955).

Studies in this direction were originated by Adel and Dennison[8] and by Redlich,[9] and after a long intermission their idea was successfully extended by Pliva.[10] He suggested a potential function of internal coordinates based on the general valence-force field and determined the values of adjustable parameters by using observed spectroscopic constants. The results of the application to $CO_2$, $H_2O$, and HCN show that the function reproduces the vibrational constants very well and may serve for the prediction of the rotation-vibration coupling constants. Kuchitsu and Bartell[11] developed a method by which cubic constants were estimated by using the elements of the $\boldsymbol{L}$ matrix and force constants derivable even in the absence of complete spectroscopic analyses, and they applied their method to $H_2O$ and $D_2O$. Herschbach and Laurie's empirical study[12] of the anharmonic force constants of diatomic molecules led to reasonable predictions of the available cubic constants for bond stretching in polyatomic molecules. Suzuki, Pariseau, and Overend[13] have recently made extensive least-squares calculations for the determination of anharmonic constants from the observed band origins and rotational constants of fundamentals, overtones and combination tones for $CO_2$, $H_2O$, HCN, and $C_2H_2$.

In the present series of papers, a systematic study will be made of the physical significance of the cubic and quartic constants of simple polyatomic molecules in order to set up a simple model for predicting these constants. The linear $XY_2$ molecules may be the most suitable for starting the investigation of this problem. Precise experimental values have been reported for $CO_2$ and $CS_2$, and transformations among the coordinate systems are simple and unique, since the elements of the $L$ matrix depend only on the masses of the component atoms. Accordingly, although $CO_2$[8-10] and $CS_2$[14] have been the subject of previous studies for similar purposes, the anharmonic constants of these molecules will be further examined in the present paper.

The potential function will be expanded in terms of internal coordinates. It has often been pointed out[8-11] that this expansion allows one to use chemical intuition in handling the problem and to correlate the anharmonic constants of isotopic molecules. Even for more complex molecules, it is not difficult, at least in principle, to relate the coefficients of this expansion by appropriate transformation of coordinates to the anharmonic potential constants (in the normal-coordinate system), which are most conveniently applied to theoretical problems.[1]

## Expansion of Internal Coordinates

If the z axis is taken along the equilibrium molecular axis of the $XY_2$ molecule, the displacements of the X-$Y_i$ bond ($i=1, 2$) in the directions parallel and perpendicular to the $z_i$ axis, $\Delta z_i$ and $\Delta\rho$ respectively, are shown to be expanded in terms of the normal coordinates, of which $Q_1$ denotes the totally symmetric stretching vibration; $Q_3$, the antisymmetric stretching, and $Q_{2a}$ and $Q_{2b}$, the degenerate bending vibrations:

$$\left.\begin{aligned}\Delta z_1 &= g_1Q_1+g_2Q_3\\ \Delta z_2 &= g_1Q_1-g_2Q_3\\ \Delta\rho^2 &= g_2^2Q_2^2\end{aligned}\right\} \quad (1)$$

where $g_1=(1/2m_Y)^{1/2}$, $g_2=(1/2m_Y+1/m_X)^{1/2}$

and $Q_2^2=Q_{2a}^2+Q_{2b}^2$

Since the instantaneous changes in the X-$Y_i$ bond length, $\Delta r_i$, and in the $Y_1$-X-$Y_2$ angle, $\Delta\alpha$, are given by:

$$\left.\begin{aligned}\Delta r_i &= \Delta z_i+\Delta\rho^2/2r_e-\Delta z_i\Delta\rho^2/2r_e^2+\cdots\\ r_e\Delta\alpha &= 2\Delta\rho-\Delta\rho(\Delta z_1+\Delta z_2)/r_e\\ &\quad+\Delta\rho(\Delta z_1^2+\Delta z_2^2)/r_e^2-2\Delta\rho^3/3r_e^2+\cdots\end{aligned}\right\} \quad (2)$$

where $r_e=r_e$(X-Y), they may also be expanded in terms of the normal coordinates. The internal symmetry coordinates are shown to be:

$$\left.\begin{aligned}S_1 &= \frac{1}{\sqrt{2}}(\Delta r_1+\Delta r_2)=\sqrt{2}\,g_1Q_1\\ &\quad+\frac{1}{\sqrt{2}\,r_e}g_2^2Q_2^2-\frac{g_1g_2^2}{\sqrt{2}\,r_e^2}Q_1Q_2^2+\cdots\\ S_2^2 &= (r_e\Delta\alpha)^2=4g_2^2Q_2^2-\frac{8}{r_e}g_1g_2^2Q_1Q_2^2\\ &\quad+\frac{1}{r_e^2}(12g_1^2g_2^2Q_1^2Q_2^2\\ &\quad-\frac{8}{3}g_2^4Q_2^4+8g_2^4Q_2^2Q_3^2)+\cdots\\ S_3 &= \frac{1}{\sqrt{2}}(\Delta r_1-\Delta r_2)=\sqrt{2}\,g_2Q_3\\ &\quad-\frac{1}{\sqrt{2}\,r_e^2}g_2^3Q_2^2Q_3+\cdots\end{aligned}\right\} \quad (3)$$

8) A. Adel and D. M. Dennison, *Phys. Rev.*, **44**, 99 (1933).
9) O. Redlich, *J. Chem. Phys.*, **9**, 298 (1941).

14) J. Pliva, Symposium on Molecular Structure and Spectroscopy, R5, Columbus, Ohio, June, 1960.

It is important to note that higher-order terms of the normal coordinates must be included in the above expressions in order to discuss anharmonic terms.

## Anharmonic Constants

The potential function of the molecule, expanded in terms of the internal coordinates, is given by:

$$V=\frac{1}{2}f_r(\Delta r_1^2+\Delta r_2^2)+f_{r'}\Delta r_1\Delta r_2+\frac{1}{2}f_\alpha r_e^2\Delta\alpha^2 + \frac{1}{r_e}[f_{rrr}(\Delta r_1^3+\Delta r_2^3)+f_{rrr'}(\Delta r_1+\Delta r_2) \times \Delta r_1\Delta r_2+f_{r\alpha\alpha}(\Delta r_1+\Delta r_2)r_e^2\Delta\alpha^2] + \frac{1}{r_e^2}[f_{rrrr}(\Delta r_1^4+\Delta r_2^4)+f_{rrrr'} \times(\Delta r_1^2+\Delta r_2^2)\Delta r_1\Delta r_2+f_{rrr'r'}\Delta r_1^2\Delta r_2^2 +f_{rr\alpha\alpha}(\Delta r_1^2+\Delta r_2^2)r_e^2\Delta\alpha^2 +f_{rr'\alpha\alpha}\Delta r_1\Delta r_2 r_e^2\Delta\alpha^2+f_{\alpha\alpha\alpha\alpha}r_e^4\Delta\alpha^4]+\cdots \quad (4)$$

In terms of the internal symmetry coordinates, on the other hand, it is shown to be:

$$V=\frac{1}{2}(f_1S_1^2+f_2S_2^2+f_3S_3^2) + \frac{1}{r_e}(f_{111}S_1^3+f_{122}S_1S_2^2+f_{133}S_1S_3^2) + \frac{1}{r_e^2}(f_{1111}S_1^4+f_{1122}S_1^2S_2^2+f_{1133}S_1^2S_3^2 +f_{2222}S_2^4+f_{2233}S_2^2S_3^2+f_{3333}S_3^4)+\cdots \quad (5)$$

where the interrelations among the coefficients of Eq. 4 and Eq. 5 are given in Eq. A-1. From Eqs. 3 and 4, it is easy to derive the cubic and quartic potential constants in the expression of the potential function in terms of the dimensionless normal coordinates,[1] $q_i$:

$$V/hc=\frac{1}{2}(\omega_1q_1^2+\omega_2q_2^2+\omega_3q_3^2)+k_{111}q_1^3 +k_{122}q_1q_2^2+k_{133}q_1q_3^2+k_{1111}q_1^4+k_{1122}q_1^2q_2^2 +k_{1133}q_1^2q_3^2+k_{2222}q_2^4+k_{2233}q_2^2q_3^2 +k_{3333}q_3^4+\cdots \quad (6)$$

as is given in the Appendix. These potential constants are related to the $\alpha$ and $x$ in Eq. A-3 of the Appendix, as has been shown by Dennison.[8,15]

Since there are twelve observables and twelve constants, the anharmonic constants, $k$, and the force constants, $f$, can be determined uniquely from the observed values of $\omega$, $\alpha$, and $x$.

The experimental values of $\alpha$ and $x$, reported by Courtoy for $CO_2$,[16] and by Agar et al.[17] and by Stoicheff[18] for $CS_2$, are taken for calculating the anharmonic constants, $k$ (shown in Table I) by using Eq. A-2. The $k$ values for $CO_2$ are in agreement with those calculated by Pliva[10] except for $k_{1122}$ and $k_{2222}$, which are here obtained from $x_{12}+4x_{22}$ and $x_{22}+x_{ll}$ instead of from $x_{12}$ and $x_{22}$ in order to eliminate the effect of the Fermi resonance. The higher-order constants are obtained from the $k$ constants by Eqs. A-1 and A-2; they are listed in Table II. The contributions to $k$ from individual terms in Eq. A-2 are listed in Table III.

It is shown in Eq. A-2 and in Table III that the anharmonic constants which are related to the bending vibration, $\nu_2$, namely, $k_{122}$, $k_{1122}$, $k_{2222}$, and $k_{2233}$, depend on both the quadratic and the higher-order constants. For $k_{122}$ and $k_{2222}$, in particular, the contribution from the quadratic constant, $f_r$, is predominant. The dependence of the $k$ on the quadratic force constants originates from the nonlinear dependence of the internal coordinates, $\Delta r$ and $\Delta\alpha$, on the Cartesian coordinates, $\Delta z$ and $\Delta\rho$, which, on the contrary, transform linearly into the normal coordinates.[10,11] A simple illustration of this situation is given in Fig. 1. Suppose

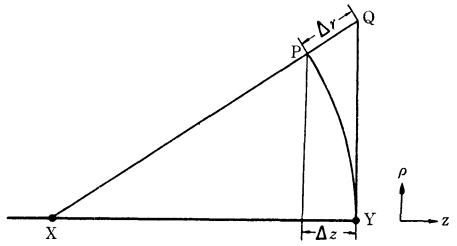

Fig. 1 A model representing the displacement of the Y atom in the X–Y bond relative to the X atom.
Y: Equilibrium position
Y→P: A pure bending displacement
Y→Q: A perpendicular displacement

the atom Y is displaced to the position P by a pure bending displacement. An increase in the total potential energy will not depend on $f_r$, since $\Delta r$ is zero. The quadratic part of the potential energy, however, has a finite term, $(1/2)f_r(\Delta z)^2$, since the projection of the bond on the z axis, $\Delta z$, is finite ($\Delta z<0$). This positive contribution must be compensated for by the negative contributions from the anharmonic

terms, $k_{122}$, etc.; these terms must, therefore, depend on $f_r$. If, on the other hand, the atom Y is displaced to the point Q, a part of the increase in the potential energy will come from $(1/2)f_r(\Delta r)^2$, since the X-Y bond is stretched ($\Delta r>0$). Since $\Delta z$ is zero, the quadratic part which depends on $f_r$ is zero. The above increase in the potential energy must, therefore, come from the anharmonic terms, mainly from $k_{2222}$ in this case. The physical significance of this problem in relation to the mean bond displacement has been discussed in more detail by Bartell.[19]

A problem to be explored by the valence theory is presented by the observation that the force constant $f_{r\alpha\alpha}$ is negative in the case of $CO_2$ and $CS_2$. This implies that the X-Y bond is likely to be stretched when the molecule is bent. At the root-mean-square angle of the zero-point bending vibration, $\langle\Delta\alpha^2\rangle^{1/2}$, the average lengthening of the bond for this reason, $-f_{r\alpha\alpha}r_e\langle\Delta\alpha^2\rangle/(f_r+f_{r'})$, is about 0.0003 Å for $CO_2$ and $CS_2$.*1

The potential function for the bending vibration is found to be very nearly harmonic, since the fourth-order constant $f_{\alpha\alpha\alpha\alpha}$ is small. At the angle of $\langle\Delta\alpha^2\rangle^{1/2}$, the quartic part of the potential energy, $f_{\alpha\alpha\alpha\alpha}r_e^2\Delta\alpha^4$, is less than 1% of the quadratic contribution, $(1/2)f_\alpha r_e^2\Delta\alpha^2$.

The constants $k$ which are not related to the $\nu_2$ vibration originate exclusively from the higher-order constants, $f_{rrr}$ or $f_{rrrr}$. As is shown in Table II, the constants $f_{rrr}$ and $f_{rrrr}$ are much larger than the others. This can be understood by a model in which each bond executes a stretching vibration with little interaction (higher than the quadratic) with the other bond. The magnitudes of $f_{rrr}$ and $f_{rrrr}$ are found to be approximately equal to those of the corresponding constants of a diatomic X-Y molecule; this confirms similar statements given in previous papers.[9-12] Since a method for predicting the anharmonic constants based on as simple a potential function as possible is aimed at, an approximate potential function based on the diatomic potential constants will be studied in some detail in the next section.

## An Approximate Potential Function

The potential function of a diatomic molecule is in general expanded around the equilibrium distance as:

19) L. S. Bartell, *J. Chem. Phys.*, **38**, 1827 (1963).

*1 In another expression, the force constant of the bending vibration, $f_\alpha$, is apparently decreased (or increased) as the bonds are symmetrically stretched (or compressed). For the displacement of the root-mean-square amplitude of the bond, ±0.035 Å for $CO_2$ and ±0.039 Å for $CS_2$, the increase in $f_\alpha$ is about 11%.

a) Case I: Estimated by using the constants (D) listed in Table II. Case II: Estimated by using the constants (D) plus $f_{r\alpha\alpha}=-0.544$ md./Å ($CO_2$) and $-0.264$ md./Å ($CS_2$) in order to make $\alpha_2$ agree with the observed values.

$$V(\Delta r)=\frac{1}{2}f_r\Delta r^2-\frac{1}{2}a_3 f_r\Delta r^3+\frac{7}{24}a_4{}^2 f_r\Delta r^4+\cdots \tag{7}$$

An advantage of taking $a_3$ and $a_4$ as independent parameters lies in the approximate equality of $a_3$ and $a_4$; the above expression (Eq. 7) is taken by analogy to the Morse function:[20]

$$V(\Delta r)=D_e[\exp(-2a\Delta r)-2\exp(-a\Delta r)] \tag{8}$$

in which case it follows that $a_3=a_4=a$.

As a natural extension to the $XY_2$ molecule, the following expression of the anharmonic force constants of Eq. 4 are derived by taking the higher-order terms of Eq. 7, other cross-interaction terms simply being ignored:

$$\left.\begin{aligned} &f_{rrr}=-\frac{1}{2}a_3 f_r r_e,\quad f_{rrrr}=\frac{7}{24}a_4{}^2 f_r r_e{}^2\\ &f_{rrr'}\sim 0\quad f_{rrrr'}\sim 0\ \text{and}\ f_{rrr'r'}\sim 0 \end{aligned}\right\} \tag{9}$$

In order to estimate $f_{rrr}$ and $f_{rrrr'}$, $f_r$ and $r_e$ may be taken to be equal to those of the $CO_2(CS_2)$ molecule,*2 and the parameters $a_3$ and $a_4$ may be approximated by those of the CO(CS) molecule, while the parameters $a_3$ and $a_4$ may be approximated by those of the CO (CS) molecule, which are determined by the method to be described in the next section. The constants obtained from Eq. 9 in this way are listed in Table II as a "Diatomic Approximation (D)". The constants $k$, $\alpha$, and $x$ calculated from Eqs. A-2 and A-3 by using the approximate potential constants (D) of Table II are compared in Table IV with the corresponding observed values. The agreement in the order of magnitude is good except for $\alpha_2$ and $x_{23}$. This indicates the practical usefulness of this simple potential function. A better agreement for $x_{23}$ may result, as shown in Table IV, by the introduction of a negative $f_{r\alpha\alpha}$ to make $\alpha_2$ agree with the experimental $\alpha_2$; this adjustment, however, makes the agre ement of $x_{22}+x_{ll}$ and $x_{12}+4x_{22}$ somewhat worse.

There is no analogous principle at present for estimating the constants which are left undetermined in the "diatomic approximation": $f_{rrr'}$, $f_{r\alpha\alpha}$, $f_{rrrr'}$, $f_{rrr'r'}$ $f_{rr\alpha\alpha}$, $f_{rr'\alpha\alpha}$, and $f_{\alpha\alpha\alpha\alpha}$. It is an important problem for future studies to establish a scheme by which plausible estimates may be made for the higher-order terms of the stretching-stretching, stretching-bending, and bending-bending interactions.

20) P. M. Morse, *Phys. Rev.*, **34**, 57 (1929).

*2 An alternative process is to take $f_r$ and $r_e$, as well as the $a_3$ and $a_4$ parameters, to be equal to those of the CO(CS) molecule; the constants, $f_r$ and $r_e$, of CO(CS) are appreciably different from those of the $CO_2(CS_2)$ molecule. There is no definite physical reason for choosing whether we should transfer $a_3$ and $a_4$ or $a_3 f_r r_e$ and $a_4{}^2 f_r r_e{}^2$ from the corresponding diatomic molecule. According to our experience, however, a better agreement is usually obtained by transfering $a_3$ and $a_4$.

### The Parameters $a_3$ and $a_4$

It was shown in the preceding section that the estimation of $a_3$ and $a_4$ is a key step in predicting the anharmonic constants of the stretching vibrations. Some characteristic features of these parameters will, therefore, be discussed in the present section.

The parameters $a_3$ and $a_4$ of a diatomic molecule are readily determined by the following equations, if the constants $\omega_e$, $\alpha_e$, and $\omega_e x_e$ are known by spectroscopic measurements;

$$\left.\begin{aligned} &a_3=\frac{2}{3}\pi\omega_e(c\mu/2hB_e{}^3)^{1/2}(\alpha_e+6B_e{}^2/\omega_e)\\ &a_4=(15a_3{}^2/7-64\pi^2 c\mu\omega_e x_e/7h)^{1/2} \end{aligned}\right\} \tag{10}$$

where $\mu$ is the reduced mass.

From the parameters for various diatomic molecules determined in this way (Tables V and VI), the following general features of $a_3$ and $a_4$ may be observed.

First, the magnitude of $a_3$ is about $2\text{Å}^{-1}$; for most diatomic molecules for which spectroscopic values are available,[4,6,21] $a_3$ is in the range 1.6—2.4$\text{Å}^{-1}$, the largest and the smallest values being 2.55$\text{Å}^{-1}$ (NO) and 1.34$\text{Å}^{-1}$ ($Si_2$) respectively. The only exceptions*3 are those molecules which contain alkali atoms as one or both of their components; their $a_3$ values are much smaller, in many cases less than $1\text{Å}^{-1}$. Second, $a_4$ is equal to, or slightly larger than, $a_3$. For the diatomic molecules studied here, the ratio $a_4/a_3$ is 1.03, with an average deviation of 0.03. Third, an additivity rule, $a_i(\text{X-Y})=(1/2)[a_i(\text{X-X})+a_i(\text{Y-Y})]$ ($i=3$ or 4), is applicable to molecules X-Y, except for alkali hydrides. As for the ratio $[a_i(\text{X-X})+a_i(\text{Y-Y})]/2a_i(\text{X-Y})$, the following average values and average deviations are obtained:

| | $a_3$ | $a_4$ |
|---|---|---|
| Nonhydrides | 1.00±0.04 | 0.98±0.04 |
| Hydrides | 1.05±0.06 | 1.04±0.07 |

These rules may be useful for a simple order-of-magnitude estimation of these parameters.

For estimating the $a_3$ and $a_4$ values of a bond X-Y for which no spectroscopic values of the corresponding diatomic molecules are known, probably a more reliable method than the above additivity rule is the use of an analytical function obtained by a systematic fit to various spectroscopic data of diatomic molecules. For example, for the function proposed by Steele

21) E. R. Lippincott and R. Schroeder, *J. Chem. Phys.*, **23**, 1131 (1955).

*3 Other peculiar exceptions are BrF, SnO, ZrO, and PbS, for which $a_3\sim 3\ \text{Å}^{-1}$ and $a_4\sim 4\ \text{Å}^{-1}$.

TABLE V. PARAMETERS $a_3$ AND $a_4$ OF CO AND CS (in Å$^{-1}$)

and Lippincott[21,22] (Eq. 5b of their paper[22]), it follows that:

$$\left.\begin{aligned} a_3 &= 1/r_e + ab(n/2r_e)^{1/2} \\ a_4 &= \{(3/7r_e)\,[6a_3 - 2/r_e + n(2ab^2-1)]\}^{1/2} \end{aligned}\right\} \quad (11)$$

where the parameters $a$, $b$, and $n$ for any molecule may be evaluated by the method described in their papers. On the other hand, by the use of the exponential function proposed by Herschbach and Laurie,[12] $a_3$ and $a_4$ (in Å$^{-1}$ units) can be estimated from the $a_{ij}(n)$ and $b_{ij}(n)$ values listed in their Table II:

$$\left.\begin{aligned} \log_{10} a_3 &= [a_{ij}(3) - r_e]/b_{ij}(3) \\ &\quad - [a_{ij}(2) - r_e]/b_{ij}(2) \\ \log_{10} a_4 &= 0.1170 + \frac{1}{2}\{[a_{ij}(4) - r_e]/b_{ij}(4) \\ &\quad - [a_{ij}(2) - r_e]/b_{ij}(2)\} \end{aligned}\right\} \quad (12)$$

The $a_3$ and $a_4$ values of CO and CS estimated by various methods are listed in Table V; they are in substantial agreements with one another.

### Anharmonicity of $NH_2$, $ND_2$, and $BO_2$

Among the linear $XY_2$ radicals which have recently been identified by spectroscopic studies,[23] $NH_2$, $ND_2$ and $BO_2$ have been the

a) Present estimates. Assumed values are enclosed in parentheses.
b) Refs. 24 and 25.
c) Ref. 26.

subject of detailed vibrational analyses. Dressler and Ramsay[24,25] have reported on the $\omega_1^0+x_1^0$, $\omega_2^0$, $x_{12}^0$, $x_{22}^0$, $\alpha_1$, $\alpha_2$, and $B_0$ values of $NH_2$ and $ND_2$ in the $^2A_1\Pi_u$ excited electronic state, while Johns[26] has given $\omega_1$, $\omega_2$, $(1/2)(2\nu_3)$, $\alpha_1$, $\alpha_2$, $\alpha_3$, $x_{22}$, and $x_{12}$ of $BO_2$ in the $A^2\Pi_u$ state. Although exact $\omega_3$ values are unknown, it seems worthwhile to apply the present technique to these molecules in order to make an approximate prediction of the orders of magnitude of the $\alpha$ and $x$ values.

On the basis of a preliminary estimation of $x$ and the product rule of the $NH_2$ and $ND_2$ frequencies, $f_1$ and $f_2$ are estimated to be 7.16 and 0.085 md./Å respectively. With the further assumption that $f_{r'}=0$, $\omega_3$ is found to be $3.7_1\times10^3\,cm^{-1}$ ($NH_2$) and $2.7_9\times10^3\,cm^{-1}$ ($ND_2$). The parameters $a_3$ and $a_4$ are estimated, by the method discussed in the preceding section, to be $2.19\,Å^{-1}$ and $2.28\,Å^{-1}$ respectively. The $f_{rrr}$ and $f_{rrrr}$ constants are, then, 7.64 and 10.32 md./Å respectively. Higher-order potential constants, $f_{r\alpha\alpha}$, $f_{rr\alpha\alpha}$, $f_{rr'\alpha\alpha}$ and $f_{\alpha\alpha\alpha\alpha}$, are adjusted to make the outputs of $\alpha_2$, $x_{12}$, and $x_{22}$ nearly agree with the observed values; they are thus taken to be −0.37, 0.96, 0.41, and 0.03 md./Å respectively.

The estimates of the anharmonic constants resulting from the present crude approximations are given in Table VII.

For $BO_2$, a preliminary estimation based on the vibrational data of Johns suggests that $\omega_3\sim2422\,cm^{-1}$, $f_r\sim11.73$, $f_{r'}\sim-2.42$, and $f_\alpha\sim0.30$ md./Å. With the parameters $a_3$ and $a_4$ transferred from those of the BO radical listed in Table VII, and with $f_{r\alpha\alpha}$ arbitrarily assumed to be $f_{r\alpha\alpha}(CO_2)\cdot f_\alpha(BO_2)/f_\alpha(CO_2)\sim0.28$, the anharmonic constants $\alpha$ and $x$ are predicted (Table VII). The magnitude of $k_{122}(\sim60\,cm^{-1})$ indicates the presence of the strong Fermi resonance observed by Johns, which must influence the observed values of $\alpha_1$ and $\alpha_2$ by intermixing the $\nu_1$ and $2\nu_2$ vibrational states. The agreement of $\alpha_3$ is fair.

## Summary

On the basis of a normal-coordinate analysis of a series expansion of the anharmonic potential field, a set of general expressions has been derived for a linear $XY_2$ molecule for relating the cubic and quartic potential constants ($k$) to the coefficients ($f$) of the potential function expanded in terms of the internal coordinates. The constants $k$ and $f$ for $CO_2$ and $CS_2$ have been calculated by using the observed values of $\alpha$ and $x$ taken from the literature, and the physical significance of the dependence of $k$ on $f$ has been studied.

The anharmonic constants related to the C-O(C-S) bond-stretching vibrations are represented as functions of the parameters of anharmonicity, $a_3$ and $a_4$, which are shown to be transferable from the CO(CS) diatomic molecule. Most of the $k$, $\alpha$, and $x$ values for $CO_2$ and $CS_2$ can be predicted quantitatively by assuming a simple potential function, comprised of ordinary quadratic terms and the anharmonic terms for the bond-stretching vibrations mentioned above, with all other higher-order potential terms ignored.

A number of methods for estimating the parameters $a_3$ and $a_4$, and a general rule regarding their relative magnitudes, have been discussed. The $k$, $\alpha$, and $x$ values of the linear radicals, $NH_2$, $ND_2$, and $BO_2$, may be predicted

## Appendix

The interrelations among the coefficients of the potential function in terms of the internal symmetry and normal coordinates are given by the following sets of equations:

$$\left.\begin{aligned}
&f_r=\frac{1}{2}(f_1+f_3),\quad f_{r'}=\frac{1}{2}(f_1-f_3),\quad f_\alpha=f_2\\
&f_{rrr}=\frac{1}{2\sqrt{2}}(f_{111}+f_{133})\\
&f_{rrr'}=\frac{1}{2\sqrt{2}}(3f_{111}-f_{133}),\quad f_{r\alpha\alpha}=\frac{1}{\sqrt{2}}f_{122}\\
&f_{rrrr}=\frac{1}{4}(f_{1111}+f_{1133}+f_{3333})\\
&f_{rrrr'}=f_{1111}-f_{3333},\\
&f_{rrr'r'}=\frac{1}{2}(3f_{1111}-f_{1133}+3f_{3333})\\
&f_{rr\alpha\alpha}=\frac{1}{2}(f_{1122}+f_{2233}),\quad f_{rr'\alpha\alpha}=f_{1122}-f_{2233}\\
&f_{\alpha\alpha\alpha\alpha}=f_{2222}
\end{aligned}\right\}\quad\text{(A-1)}$$

The cubic and quartic constants in Eq. 6 depend on the force constants of Eq. 5:

$$\left.\begin{aligned}
&k_{111}=\frac{2\sqrt{2}}{r_e}h_{111}g_1^3f_{111}\\
&k_{122}=\frac{1}{r_e}h_{122}g_1g_2^2(f_1-4f_2+4\sqrt{2}f_{122})\\
&k_{133}=\frac{2\sqrt{2}}{r_e}h_{133}g_1g_2^2f_{133}\\
&k_{1111}=\frac{4}{r_e^2}h_{1111}g_1^4f_{1111}\\
&k_{1122}=\frac{1}{r_e^2}h_{1122}g_1^2g_2^2(-f_1+6f_2+3\sqrt{2}f_{111}\\
&\qquad-8\sqrt{2}f_{122}+8f_{1122})\\
&k_{1133}=\frac{4}{r_e^2}h_{1133}g_1^2g_2^2f_{1133}\\
&k_{2222}=\frac{1}{r_e^2}h_{2222}g_2^4\left(\frac{1}{4}f_1-\frac{4}{3}f_2+2\sqrt{2}f_{122}\right.\\
&\qquad\left.+16f_{2222}\right)\\
&k_{2233}=\frac{1}{r_e^2}h_{2233}g_2^4(4f_2-f_3+\sqrt{2}f_{133}+8f_{2233})\\
&k_{3333}=\frac{4}{r_e^2}h_{3333}g_2^4f_{3333}
\end{aligned}\right\}\quad\text{(A-2)}$$

where $h_{ijj}=h^{1/2}/8\pi^3c^{5/2}\omega_i^{1/2}\omega_j$
and $h_{iijj}=h/16\pi^4c^3\omega_i\omega_j$

It has been shown by Dennison[8,15] that these cubic and quartic constants are related to $\alpha$ and $x$ by the following expressions:

$$\left.\begin{aligned}
&\alpha_1=-6B_e^2/\omega_1-3(2B_e/\omega_1)^{3/2}k_{111}\\
&\alpha_2=B_e^2[1/\omega_2-2/(\omega_3+\omega_2)+2/(\omega_3-\omega_2)]\\
&\qquad-(2B_e/\omega_1)^{3/2}k_{122}\\
&\alpha_3=2B_e^2[1/\omega_3-2/(\omega_3+\omega_2)-2/(\omega_3-\omega_2)]\\
&\qquad-(2B_e/\omega_1)^{3/2}k_{133}\\
&x_{11}=\frac{3}{2}k_{1111}-(15/4\omega_1)k_{111}^2\\
&x_{33}=\frac{3}{2}k_{3333}-\frac{1}{8}[4/\omega_1+1/(2\omega_3+\omega_1)\\
&\qquad-1/(2\omega_3-\omega_1)]k_{133}^2\\
&x_{13}=k_{1133}-(3/\omega_1)k_{111}k_{133}-\frac{1}{2}[1/(2\omega_3+\omega_1)\\
&\qquad+1/(2\omega_3-\omega_1)]k_{133}^2\\
&x_{23}=k_{2233}-(1/\omega_1)k_{122}k_{133}\\
&\qquad+[\omega_3/\omega_2+\omega_2/\omega_3]B_e\\
&x_{22}+x_{ll}=k_{2222}-(1/2\omega_1)k_{122}^2\\
&x_{12}+4x_{22}=k_{1122}+6k_{2222}-(3/\omega_1)k_{111}k_{122}\\
&\qquad-[2/\omega_1+1/(2\omega_2+\omega_1)]k_{122}^2
\end{aligned}\right\}\quad\text{(A-3)}$$

The last two equations are adopted in order to eliminate the resonance contribution, $1/(2\omega_2-\omega_1)$, from the expressions.

# Estimation of Anharmonic Potential Constants. II. Bent $XY_2$ Molecules

By Kozo KUCHITSU and Yonezo MORINO

(Received October 10, 1964)

In the preceding paper, Part I,[1] the anharmonic potential constants of the linear $XY_2$ molecules have been estimated on the basis of a simple potential function. That procedure will here be extended to the bent $XY_2$ molecules, for which previous theoretical studies of the anharmonic constants[2-5] have been limited to $H_2O$ and $D_2O$. The purpose of the present study is to set up a convenient method for a quantitative or at least a semi-quantitative prediction of the anharmonic constants in order to achieve a better understanding of the physical significance of these constants. It is also intended to seek for a simple and plausible representation of the anharmonic force field of polyatomic molecules.

The estimation of anharmonic constants is more complicated in this case than in the case of the linear $XY_2$ molecule, because the coordinate transformation depends on the off-diagonal elements of the $L$ matrix (two-dimensional in this case); moreover, the potential constants which depend on the odd power of the angular displacement do not vanish by symmetry requirement, while they do in the case of linear $XY_2$. These circumstances, however, do not seriously disturb the present analysis; in addition, the quadratic force constants for most of the bent $XY_2$ molecules are generally much better known than those for more complex molecules.

The importance of the bent $XY_2$ molecules for the study of anharmonicity is twofold. First, relatively abundant, although far from complete, experimental data have been reported concerning their $\alpha$ and $x$ values, especially for those of $H_2O$, $D_2O$, and $SO_2$, and further information will be obtained in the near future. Secondly, the bent $XY_2$ molecule is one of the few simple systems for which the cubic and most of the quartic potential constants can be determined uniquely, provided all $\alpha$ and $x$ values are known. The following sections will, therefore, present a general formulation necessary for the analysis, a formulation by means of which the "anharmonic constants" of the potential function expressed in the normal-coordinate system can be transformed into the "higher-order constants" in the internal-coordinate system. A simple method for estimating the anharmonic constants will then be presented on the basis of an examination of the physical significance of these higher-order potential constants.

## Expansion of Internal Coordinates

The internal coordinates are expanded in terms of the normal coordinates by the method discussed in Ref. 5. The displacements of the $X\text{-}Y_i$ ($i=1, 2$) bond length, $\Delta r_i$, and that of the $Y_1\text{-}X\text{-}Y_2$ angle, $\Delta\alpha$, from their equilibrium values are first expanded in terms of the Cartesian displacement coordinates shown in Fig. 1; $\Delta z_i$ and $\Delta x_i$ are taken to be the projections of the instantaneous displacement of the $Y_i$ atom with respect to the X atom along and perpendicular to the equilibrium direction of the $X\text{-}Y_i$ bond respectively. The out-of-plane displacements, $\Delta y_i$, are of course zero. It is shown in Eq. 14 of Ref. 5 that:

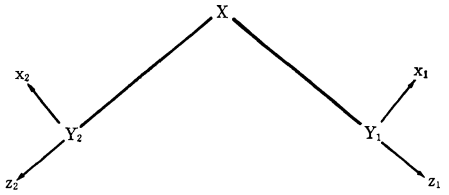

Fig. 1. Cartesian coordinates for the bent $XY_2$ molecule. The $z_i$ axis ($i=1$ or 2) is taken in the direction of the bond $X\text{-}Y_i$ at their equilibrium positions, and the $x_i$ axis is taken on the molecular plane and perpendicular to the $z_i$ axis outwards. The displacement of the $Y_i$ atom relative to the X atom is described in the $x_i$, $z_i$ coordinates.

$$\left.\begin{aligned}
\Delta r_i &= \Delta z_i + \Delta x_i^2/2r_e - \Delta z_i \Delta x_i^2/2r_e^2 + \cdots \\
r_e\Delta\alpha &= \Delta x_1 + \Delta x_2 - (\Delta x_1\Delta z_1 + \Delta x_2\Delta z_2)/r_e \\
&\quad + [\Delta x_1\Delta z_1^2 + \Delta x_2\Delta z_2^2 \\
&\quad - \frac{1}{3}(\Delta x_1^3 + \Delta x_2^3)]/r_e^2 + \cdots
\end{aligned}\right\} \quad (1)$$

$$+ \begin{pmatrix} \lambda^3 & \lambda^3 & \alpha\lambda^2 & \alpha\lambda^2 & \alpha^2\lambda & \alpha^3 \\ 3\lambda\mu^2 & 3\lambda\mu^2 & \mu(\alpha\mu+2\beta\lambda) & \mu(\alpha\mu+2\beta\lambda) & \beta(2\alpha\mu+\beta\lambda) & 3\alpha\beta^2 \\ 3\lambda\nu^2 & -\lambda\nu^2 & \alpha\nu^2 & -\alpha\nu^2 & 0 & 0 \\ 3\lambda^2\mu & 3\lambda^2\mu & \lambda(2\alpha\mu+\beta\lambda) & \lambda(2\alpha\mu+\beta\lambda) & \alpha(\alpha\mu+2\beta\lambda) & 3\alpha^2\beta \\ \mu^3 & \mu^3 & \beta\mu^2 & \beta\mu^2 & \beta^2\mu & \beta^3 \\ 3\mu\nu^2 & -\mu\nu^2 & \beta\nu^2 & -\beta\nu^2 & 0 & 0 \end{pmatrix} \begin{pmatrix} 2f_{rrr}/r_e \\ 2f_{rrr'}/r_e \\ 4f_{rr\alpha}/r_e \\ 2f_{rr'\alpha}/r_e \\ 8f_{r\alpha\alpha}/r_e \\ 8f_{\alpha\alpha\alpha}/r_e \end{pmatrix}$$

Units: $k$: $cm^{-1}$; $h_{ijj}=N^{3/2}h^{1/2}/8\pi^3c^{5/2}\omega_i^{1/2}\omega_j$; $\alpha$, $\beta$, $\gamma$, $\lambda$, $\mu$, $\nu$: a. m. u.
$f$: dyne/cm.; $r_e$: cm.

On the other hand, the following linear relations exist between the Cartesian and normal coordinates, $Q$:

$$\left.\begin{aligned} \Delta x_i &= \alpha Q_1+\beta Q_2 \pm \gamma Q_3 \\ \Delta z_i &= \lambda Q_1+\mu Q_2 \pm \nu Q_3 \end{aligned}\right\} \quad (2)$$

where the positive and negative signs of $\gamma$ and $\nu$ apply to $i=1$ and 2 respectively, and where the coefficients are related to the $\boldsymbol{L}$ and the $\boldsymbol{G}$ matrices as follows:

$$\left.\begin{aligned} &\alpha=\frac{1}{2}L_{21}, \quad \beta=\frac{1}{2}L_{22}, \quad \gamma=-G_{12}/2L_{33} \\ &\lambda=\frac{1}{\sqrt{2}}L_{11}, \quad \mu=\frac{1}{\sqrt{2}}L_{12}, \quad \nu=\frac{1}{\sqrt{2}}L_{33} \end{aligned}\right\} \quad (3)$$

The desired expansion of the internal coordinates is, therefore, straightforward.

## Potential Function

The vibrational potential function of the bent $XY_2$ molecule can be expanded in terms of the internal coordinates in the following way:

$$\begin{aligned} V=&\frac{1}{2}f_r(\Delta r_1^2+\Delta r_2^2)+f_{r'}\Delta r_1\Delta r_2 \\ &+f_{r\alpha}(\Delta r_1+\Delta r_2)r_e\Delta\alpha+\frac{1}{2}f_\alpha r_e^2\Delta\alpha^2 \\ &+\frac{1}{r_e}[f_{rrr}(\Delta r_1^3+\Delta r_2^3)+f_{rrr'}(\Delta r_1+\Delta r_2) \\ &\times\Delta r_1\Delta r_2+f_{rr\alpha}(\Delta r_1^2+\Delta r_2^2)r_e\Delta\alpha \\ &+f_{rr'\alpha}\Delta r_1\Delta r_2 r_e\Delta\alpha+f_{r\alpha\alpha}(\Delta r_1+\Delta r_2) \\ &\times r_e^2\Delta\alpha^2+f_{\alpha\alpha\alpha}r_e^3\Delta\alpha^3] \\ &+\frac{1}{r_e^2}[f_{rrrr}(\Delta r_1^4+\Delta r_2^4)+f_{rrrr'} \\ &\times(\Delta r_1^2+\Delta r_2^2)\Delta r_1\Delta r_2+f_{rrr'r'}\Delta r_1^2\Delta r_2^2 \\ &+f_{rrr\alpha}(\Delta r_1^3+\Delta r_2^3)r_e\Delta\alpha \\ &+f_{rrr'\alpha}(\Delta r_1+\Delta r_2)\Delta r_1\Delta r_2 r_e\Delta\alpha \\ &+f_{rr\alpha\alpha}(\Delta r_1^2+\Delta r_2^2)r_e^2\Delta\alpha^2 \\ &+f_{rr'\alpha\alpha}\Delta r_1\Delta r_2 r_e^2\Delta\alpha^2 \\ &+f_{r\alpha\alpha\alpha}(\Delta r_1+\Delta r_2)r_e^3\Delta\alpha^3+f_{\alpha\alpha\alpha\alpha}r_e^4\Delta\alpha^4] \\ &+\cdots \end{aligned} \quad (4)$$

The quadratic force constants, $f_r$, $f_{r'}$, $f_{r\alpha}$, and $f_\alpha$, can be determined uniquely if the elements of the $\boldsymbol{F}$ matrix,

$$\left.\begin{aligned} &f_r=\frac{1}{2}(F_{11}+F_{33}) \qquad f_{r'}=\frac{1}{2}(F_{11}-F_{33}) \\ &f_{r\alpha}=\frac{1}{\sqrt{2}}F_{12} \quad \text{and} \quad f_\alpha=F_{22} \end{aligned}\right\} \quad (5)$$

are known.

Upon replacing $\Delta r_i$ and $r_e\Delta\alpha$ by $\Delta z_i$ and $\Delta x_i$ and the latter by $Q$, by the use of Eqs. 1 and 2, the cubic and quartic constants of the potential function in terms of the dimensionless normal coordinates[6]:

$$\begin{aligned} V/hc=&\frac{1}{2}(\omega_1q_1^2+\omega_2q_2^2+\omega_3q_3^2) \\ &+k_{111}q_1^3+k_{122}q_1q_2^2+k_{133}q_1q_3^2 \\ &+k_{211}q_2q_1^2+k_{222}q_2^3+k_{233}q_2q_3^2 \\ &+k_{1111}q_1^4+k_{1122}q_1^2q_2^2+k_{1133}q_1^2q_3^2 \\ &k_{2222}q_2^4+k_{2233}q_2^2q_3^2+k_{3333}q_3^4 \end{aligned} \quad (6)$$

where

$$q_s=2\pi(c\omega_s/h)^{1/2}Q_s$$

can be expressed in the matrix form shown in Tables I and II.*1 On the other hand, the

*1 Similar expressions for other nonvanishing quartic constants, $k_{1112}$, $k_{1222}$, and $k_{1233}$, are not listed in Table II, since they are not included in $x$ as far as the ordinary second-order perturbation theory is concerned[6-8] and, hence, remain unknown. The orders of magnitude of $k_{1112}$, $k_{1222}$, and $k_{1233}$ may, however, be estimated by an extension of the method given below, if such an estimate is necessary for a discussion of higher-order interactions.

a) Calculated in the present study from the data given in Table III.
b) Calculated from the equilibrium moments of inertia listed in Eq. 14 of Allen and Plyler's paper.[10] The $r_e$ distance of H-S given in their paper, 1.328Å, seems to be in error.

relations between the anharmonic constants and the $\alpha$ and $x$ values have been derived by Darling and Dennison[6-8] as follows:

$$\left.\begin{aligned}
\alpha_1^A &= A_1 + 3a_1k_{111} + a_2k_{211}\\
\alpha_2^A &= A_2 + a_1k_{122} + 3a_2k_{222}\\
\alpha_3^A &= A_3 + a_1k_{133} + a_2k_{233}\\
\alpha_1^B &= B_1 + 3b_1k_{111} + b_2k_{211}\\
\alpha_2^B &= B_2 + b_1k_{122} + 3b_2k_{222}\\
\alpha_3^B &= B_3 + b_1k_{133} + b_2k_{233}\\
\alpha_1^C &= C_1 + 3c_1k_{111} + c_2k_{211}\\
\alpha_2^C &= C_2 + c_1k_{122} + 3c_2k_{222}\\
\alpha_3^C &= C_3 + c_1k_{133} + c_2k_{233}
\end{aligned}\right\} \quad (7)$$

and:

$$\left.\begin{aligned}
x_{11} &= \frac{3}{2}k_{1111} - \frac{15k_{111}^2}{4\omega_1} - \frac{k_{211}^2(8\omega_1^2-3\omega_2^2)}{4\omega_2(4\omega_1^2-\omega_2^2)}\\
x_{22} &= \frac{3}{2}k_{2222} - \frac{15k_{222}^2}{4\omega_2} - \frac{k_{122}^2(8\omega_2^2-3\omega_1^2)}{4\omega_1(4\omega_2^2-\omega_1^2)}\\
x_{33} &= \frac{3}{2}k_{3333} - \frac{k_{133}^2(8\omega_3^2-3\omega_1^2)}{4\omega_1(4\omega_3^2-\omega_1^2)}\\
&\quad - \frac{k_{233}^2(8\omega_3^2-3\omega_2^2)}{4\omega_2(4\omega_3^2-\omega_2^2)}\\
x_{12} &= k_{1122} - \frac{3k_{111}k_{122}}{\omega_1} - \frac{3k_{211}k_{222}}{\omega_2}\\
&\quad - \frac{2k_{211}^2\omega_1}{4\omega_1^2-\omega_2^2} - \frac{2k_{122}^2\omega_2}{4\omega_2^2-\omega_1^2}\\
x_{13} &= k_{1133} - \frac{3k_{111}k_{133}}{\omega_1} - \frac{k_{211}k_{233}}{\omega_2}\\
&\quad - \frac{2k_{133}^2\omega_3}{4\omega_3^2-\omega_1^2} + C_e\zeta_{13}^2\left(\frac{\omega_3}{\omega_1}+\frac{\omega_1}{\omega_3}\right)\\
x_{23} &= k_{2233} - \frac{k_{122}k_{133}}{\omega_1} - \frac{3k_{222}k_{233}}{\omega_2}\\
&\quad - \frac{2k_{233}^2\omega_3}{4\omega_3^2-\omega_2^2} + C_e\zeta_{23}^2\left(\frac{\omega_3}{\omega_2}+\frac{\omega_2}{\omega_3}\right)
\end{aligned}\right\} \quad (8)$$

where*2

$$A_1 = -\frac{6A_e^2}{\omega_1}\sin^2\Gamma, \quad a_1 = -\left(\frac{2A_e}{\omega_1}\right)^{3/2}\sin\Gamma$$

$$A_2 = -\frac{6A_e^2}{\omega_2}\cos^2\Gamma, \quad a_2 = -\left(\frac{2A_e}{\omega_2}\right)^{3/2}\cos\Gamma$$

$$A_3 = -\frac{6A_eC_e}{\omega_3}$$

$$B_1 = -\frac{6B_e^2}{\omega_1}\cos^2\Gamma, \quad b_1 = -\left(\frac{2B_e}{\omega_1}\right)^{3/2}\cos\Gamma$$

a) Derived from the observed $\alpha$ and $x$ values listed in Tables XII and XIII by using Eqs. 7 and 8.
b) Quoted uncertainties represent the standard errors estimated by a least-squares fit of the observed $\alpha$ values to Eq. 7 (with equal statistical weights for $\alpha^A$, $\alpha^B$, and $\alpha^C$). Because of the inconsistencies among $\alpha^A$, $\alpha^B$, and $\alpha^C$, larger uncertainties have to be assigned to some of the $k_{122}$ and $k_{133}$ constants.
c) The standard errors, which are propagated from those of the cubic constants by the application of Eq. 8, are taken as uncertainties. They are probably somewhat underestimated, because the errors involved in the experimental $x$ values, which are not given in the original references, are left out of consideration.

a) Calculated from Table VI by the matrix equations given in Tables I and II with the assumption that the contributions from the $f_{rrr\alpha}$, $f_{rrr'\alpha}$, and $f_{r\alpha\alpha\alpha}$ constants to the quartic constants listed in Table VI are zero. The uncertainties are represented somewhat arbitrarily by twice the standard errors estimated from those of the anharmonic constants given in Table VI. The uncertainties introduced by the above assumption are included in the uncertainties of the fourth-order constants.

| Total | −44.31 | 11.96 | −159.18 | −19.04 | −6.92 | 4.62 |

$$B_2=-\frac{6B_e^2}{\omega_2}\sin^2\Gamma,\quad b_2=-\left(\frac{2B_e}{\omega_2}\right)^{3/2}\sin\Gamma$$

$$B_3=-\frac{6B_eC_e}{\omega_3}$$

$$C_1=-\frac{6C_e^2}{\omega_1}+\frac{8C_e^2\omega_3^2}{\omega_1(\omega_3^2-\omega_1^2)}\zeta_{13}^2$$

$$C_2=-\frac{6C_e^2}{\omega_2}+\frac{8C_e^2\omega_3^2}{\omega_2(\omega_3^2-\omega_2^2)}\zeta_{23}^2$$

$$C_3=\frac{2C_e^2}{\omega_3}-8C_e^2\omega_3\left(\frac{\zeta_{13}^2}{\omega_3^2-\omega_1^2}+\frac{\zeta_{23}^2}{\omega_3^2-\omega_2^2}\right)$$

$$c_1=C_e^2(a_1/A_e^2+b_1/B_e^2)$$

$$c_2=C_e^2(a_2/A_e^2+b_2/B_e^2)$$

and $A_e$, $B_e$, $C_e$ are the equilibrium rotational constants. It is easily shown that:

$$\sin\Gamma=(c\lambda-s\alpha)(1/m_X+1/2m_Y)^{1/2}$$

$$\cos\Gamma=(s\beta-c\mu)(1/m_X+1/2m_Y)^{1/2}$$

$$\zeta_{13}^2=(\beta\gamma+\mu\nu)^2/(\beta\lambda-\alpha\mu)^2$$

and

$$\zeta_{23}^2=1-\zeta_{13}^2=(\alpha\gamma+\lambda\nu)^2/(\beta\lambda-\alpha\mu)^2$$

where

$$c=\cos\frac{1}{2}(Y_1\text{-}X\text{-}Y_2)\quad\text{and}\quad s=\sin\frac{1}{2}(Y_1\text{-}X\text{-}Y_2)$$

## Determination of the Higher-Order Potential Constants

The vibrational frequencies, the quadratic force constants, and the coefficients of Eq. 3 used in the following analysis[8-20] are summarized in Tables III—V. Since the normal frequencies for $D_2S$, $H_2Se$, and $D_2Se$ are not available in the literature, they are estimated from the fundamental frequencies by the method described in a previous paper,[21] by

a) Contributions from the $f_{rrr\alpha}$, $f_{rrr'\alpha}$, and $f_{r\alpha\alpha\alpha}$ constants are assumed to be zero.

the product rule, and by the $x$ values estimated in the present study. The cubic and the quartic constants listed in Table VI are calculated, by using Eqs. 7 and 8, from the observed $\alpha$ and $x$ values. They are then transformed into the constants in the internal-coordinate system by solving the simultaneous equations based on Tables I and II.*3 The results, with

*3 The solution of the simultaneous equations is unique for the six third-order constants, whereas for the fourth-order constants the number of unknowns (nine) exceeds that of the observed quartic constants (six), since the $k_{1112}$, $k_{1222}$, and $k_{1233}$ constants have not been observed. As Tables II and V indicate, all the matrix elements of Table II related to the $f_{rrr\alpha}$, $f_{rrr'\alpha}$, and $f_{r\alpha\alpha\alpha}$ constants have at least one $\alpha$ or $\mu$ parameter and, hence, are relatively small. The contributions from these constants are, accordingly, assumed to be zero in the course of determining the rest of the fourth-order constants from the simultaneous equations. This assumption, however, does not necessarily mean that these constants are negligibly small; as Table VII shows, the order of magnitude of these constants may be as much as ± 2md./Å. In that case, the three constants may contribute as much as $\pm 10\,cm^{-1}$ to the $k_{1122}$ of $D_2O$ and $H_2S$ and to the $k_{2222}$ of $H_2O$ and $H_2S$, $\pm 5\,cm^{-1}$ to the $k_{1122}$ of $H_2O$ and to the $k_{2222}$ of $D_2O$, and $\pm 3\,cm^{-1}$ to the $k_{1122}$ of $SO_2$. All other contributions are negligible. The effect of this indeterminacy on the determination of the rest of the constants, which is found to be important only in the case of $SO_2$, is, therefore, included in their final uncertainties. The $f_{rrr\alpha}$, $f_{rrr'\alpha}$, and $f_{r\alpha\alpha\alpha}$ constants of $H_2O$ and $D_2O$ can be determined if at least six fourth-order constants of $H_2O$ are assumed to be equal to the corresponding constants of $D_2O$. It is not likely, however, that more definite values of these constants can be obtained by this process because of the smallness of the matrix elements related to these constants and because of the errors involved in the original quartic constants.

TABLE X. COMPARISON OF THE $a_3$ AND $a_4$ PARAMETERS (in Å$^{-1}$)

| | $a_3$ | | $a_4$ | |
|---|---|---|---|---|

estimated uncertainties, are given in Table VII.

Tables VIII and IX analyze the anharmonic constants into the contributions from various quadratic and higher-order constants on the basis of Tables I and II, expressing which potential constants are the principal contributors to a particular anharmonic constant. For example, $k_{111}$ and $k_{133}$ depend almost exclusively on the $f_{rrr}$ term, and $k_{1111}$, $k_{1133}$, and $k_{3333}$, on the $f_{rrrr}$ term. The rest of the anharmonic constants, on the other hand, are hybrids to a greater or lesser extent. For example, the $k_{122}$ and $k_{1122}$ constants depend strongly on the quadratic force constants. The dependence of $f_r$ on $k_{122}$ originates from the second term of the expansion of $\Delta r^2$ in Eq. 1 and represents the effect of the perpendicular (arc) motion of the X–Y bond. The physical

significance of this term has been discussed in Part I in connection with a similar situation involving the $k_{122}$ constant of linear $XY_2$.

Table VII indicates that the $f_{rrr}$ and $f_{rrrr}$ constants are more than ten times as great as the rest of the higher-order constants, and that they are determined with accuracies of about two significant figures. As has been discussed in Part I, these constants originate from the anharmonic stretching vibrations of the $X\text{-}Y_1$ and $X\text{-}Y_2$ bonds, and they may be expressed in terms of the $a_3$ and $a_4$ parameters, introduced in Part I, as follows:

$$f_{rrr} = -\frac{1}{2}a_3 f_r r_e \quad \text{and} \quad f_{rrrr} = \frac{7}{24}a_4^2 f_r r_e^2 \qquad (9)$$

As is shown in Table X, the $a_3$ and $a_4$ parameters of the X-Y bond agree closely (to within 12%) with those of the X-Y diatomic molecule taken from Table VI of Part I. This affords direct support to similar statements presented in previous studies.[1-5]

Table VII further shows that some of the other third-order constants listed in the table are determined significantly. For example, all the $f_{rr'\alpha}$ and $f_{\alpha\alpha\alpha}$ constants are negative, as are all the third-order constants of $SO_2$*4. The third-order constants of $H_2O$ and $H_2Se$ agree with those of the corresponding deuterides within the listed uncertainties (except for the $f_{rr'\alpha}$ constants of $H_2O$ and $D_2O$). The fourth-order constants (except for $f_{rrrr}$), on the other hand, are indeterminate.

It is more difficult to put forward an intuitive model for interpreting the physical significance of the third-order potential constants other than $f_{rrr}$. They are, nevertheless, important, since previous discussions of the molecular potential field have almost always been based on the quadratic part of the potential, and, consequently, an examination of the higher-order constants may give a novel insight into the nature of the potential field. Some discussion of the physical significance of these constants will be given as a separate paper.[23,*5]

## Estimation of Anharmonic Constants

The above findings for the $f_{rrr}$ and $f_{rrrr}$ constants suggest that the simple "diatomic approximation" discussed in Part I may also be used in this case for predicting the anharmonic constants. This method approximates the total potential function (Eq. 4) by the

*4 The same trend has been observed for the $OF_2$ molecule recently studied in our laboratory.[22] All the third-order constants are found to be negative, and they are of an order of magnitude very similar to that of the corresponding constants of the $SO_2$ molecule.[23]

22) Y. Morino and S. Saito, *J. Mol. Spectry*, to be published.

23) K. Kuchitsu and Y. Morino, *Spectrochim. Acta*, to be published.

*5 Note added in proof: The experimental values of $\omega$, $\alpha$ and $x$ of $H_2Se$ have recently been published: R. A. Hill and T. H. Edwards, *J. Chem. Phys.* **42**, 1391 (1965). Some of their $\omega$ and $x$ values of $H_2{}^{80}Se$ ($\omega_1$=2438.66, $\omega_3$=2453.77, $x_{11}$=−21.43, $x_{33}$=−21.71, and $x_{13}$=−84.90 $cm^{-1}$) are in good agreement with the corresponding estimates given in Tables III and XV respectively, while their $x_{12}$(−17.69 $cm^{-1}$) and $x_{23}$(−20.20 $cm^{-1}$) are not, in line with the discussion in the text. Their $\alpha$ values differ from Palik's $\alpha$ values[12]; the third-order constants and the cubic constants based on their $\alpha$ values are accordingly different from those based on Palik's values given in Tables VI, VII and XII by as much as the uncertainties listed in the tables. See Ref. 23.

four quadratic terms plus the $f_{rrr}$ and $f_{rrrr}$ terms and ignores all the other higher-order terms. The constants $f_{rrr}$ and $f_{rrrr}$ are estimated by Eq. 9 with the $a_3$ and $a_4$ parameters transferred from those of the corresponding diatomic radical. The use of the matrices given in Tables I and II then gives approximate values of the cubic and quartic constants and those of $\alpha$ and $x$. It can be expected from Tables VIII and IX that this method will be effective for predicting $k_{111}$, $k_{133}$, $k_{1111}$, $k_{1133}$, and $k_{3333}$ provided the $a_3$ and $a_4$ parameters are estimated properly, while it will give somewhat poorer results for the other constants except when the contributions from the disregarded higher-order constants accidentally cancel one another.

Calculations by means of this method have been made for ten bent $XY_2$ molecules. The estimations of $a_3$ and $a_4$ by the various methods[1,3,24] discussed in Part I are given in Table XI. A comparison of the results with the corresponding observed values in Tables XII–XV verifies the above expectation; the agreement is particularly good for the above five anharmonic constants and for $x_{11}$, $x_{13}$, and $x_{33}$, which almost exclusively depend on these constants. It is shown in the tables that at least the signs and the orders of magnitude are correctly estimated by this method, even for the rest of the constants of all the molecules, except for $k_{222}$, $x_{22}$, and $x_{12}$. It seems that it will be necessary to introduce higher-order cross terms, which are here ignored, in order to make quantitative estimates for these three constants.

This method may be regarded as a primitive but practical representation of the anharmonic potential field. The role of this model may be compared with that of the "valence-force" representation of the quadratic field which prevailed in the early stage of the studies of molecular normal vibrations.

## Application of the Method

The present method for estimating anharmonic constants has been applied in this laboratory to the microwave studies of the $SO_2$ and $OF_2$ molecules in their excited vibrational states. The prediction of the $k_{133}$ and $k_{233}$ constants of the $SO_2$ molecule made it easier to discover and assign the relatively weak absorption lines which belong to the $\nu_3$ state of this molecule, as was reported in a previous paper.[8] In a similar way, the detection and analysis of the lines which belong to the $\nu_1$ and $\nu_3$ states of the $OF_2$ molecule would have been more difficult without the preliminary but approximately correct estimates of the $k_{111}$, $k_{133}$, $k_{211}$, and $k_{233}$ constants obtained by the present method. The details of the analysis will be published as a forthcoming paper.[22]

## Summary

The vibrational potential function of the bent $XY_2$ molecule has been expanded in terms of the internal coordinates to the fourth order, and a general formulation which relates the coefficients of this expansion (second-, third-, and fourth-order potential constants) to the cubic and quartic constants in the normal-coordinate system has been derived. The third- and fourth-order constants in the internal-coordinate system for $H_2O$, $D_2O$, $H_2Se$, $D_2Se$, and $SO_2$ have been determined by using the experimental $\alpha$ and $x$ values taken from the literature. It has been shown that the third- and fourth-order constants which represent the anharmonic bond-stretching vibration, $f_{rrr}$ and $f_{rrrr}$, are much larger than the other higher-order constants and that they are nearly equal (to within 12 per cent) to the anharmonic potential constants of the corresponding diatomic radicals. The method presented in Part I of this paper, which makes use of the "diatomic approximation" for estimating the anharmonic constants and the $\alpha$ and $x$ values, has been applied to the bent $XY_2$ molecules. A comparison of the results with currently available experimental data has shown that the signs and the orders of magnitude are in most cases correctly predicted by this approximation. This method has been further applied as an aid for the detection and analysis of the microwave absorption lines in the case of the $SO_2$ and $OF_2$ molecules in their excited vibrational states.

# The Electron Spin Resonance and Electronic Absorption Spectra of the 3-Nitropyridine Anion Radical

By Michiya Itoh and Saburo Nagakura

(Received October 23, 1964)

In a previous paper,[1] the present authors and Okamoto studied the ESR and electronic absorption spectra of the 4-nitropyridine anion radical. In the present paper, a similar study has been made of the 3-nitropyridine anion radical.

## Experimental

**Material.**—3-Nitropyridine was prepared by the oxidation of 3-aminopyridine by Caro's acid, and it was purified by repeated recrystallizations. The melting point (41°C) was in good agreement with that reported in the literature.[2]

**The Preparation of the Anion Radical and Measurements.**—The 3-nitropyridine anion radical was prepared at room temperature by the reduction of the parent compound with potassium metal in 1, 2-dimethoxy ethane (DME). The details of the preparation of the anion radical and of the measurements of its ESR and electronic absorption spectra are the same as those reported in the previous paper.[1]

## Experimental Results

The ESR spectrum observed with the DME solution of the 3-nitropyridine anion radical is shown in Fig. 1. From the spectrum, the hyperfine coupling constants associated with the nitrogen and hydrogen atoms were determined to be as shown in Table I.

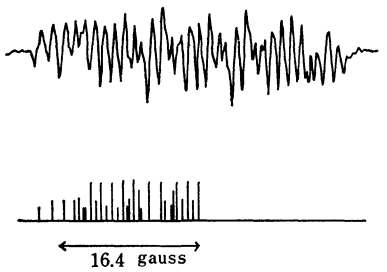

Fig. 1. The ESR spectrum (first derivative) of 3-nitropyridine anion and the reconstruction based on the coupling constants.

The electronic absorption spectrum of the DME solution of the 3-nitropyridine anion has also been measured; the results are shown in Fig. 2. The absorption bands at 304 and 460 mμ can safely be ascribed to the 3-nitropyridine anion, since the intensities of these bands change in parallel with that of the ESR spectrum.

## Theoretical

Molecular orbital calculation has been carried out with the $\pi$-electron system of the 3-nitropyridine anion radical in order to ascertain the assignment of the observed electronic spectrum and to obtain some knowledge about the electronic structure of this anion. The present calculation of the 3-nitropyridine anion has been performed by a method similar to that employed in the case of the 4-nitropyridine anion.[1] The anion radical was separated into two components, the pyridine anion as an electron donor and the nitro group as an electron acceptor. The interaction between the components was considered by the aid of the configurational interaction among ground, locally excited and charge-transfer configurations. The electron configurations and energies of these configurations are given in Table II. The procedure for evaluating these energies is not described in the present paper, since the details have been mentioned in the previous paper.[1]

The off-diagonal matrix elements, $H_{ij}$'s, of the total electronic Hamiltonian were evaluated by the aid of the method presented by Pople[3] and by Murrell and Longuet-Higgins.[4] The results are shown in Table III. The repulsion integrals necessary for the evaluation of the interaction energies between locally

| $W_4=3.006$ eV. | $\Phi_4=0.958\Psi_3+0.078\Psi_2+0.135\Psi_{6a}+0.234\Psi_7$ |

TABLE V. THE CALCULATED AND OBSERVED RESULTS FOR THE LOWEST THREE ELECTRONIC TRANSITIONS OF THE 3-NITROPYRIDINE ANION

| Transition | $\lambda_{max}$, eV. calcd. | obs. | Calcd. oscillator strength | Direction of transition moment |
|---|---|---|---|---|
| $W_1 \rightarrow W_2$ | 1.32 | — | $3.60\times10^{-2}$ | $\Theta=30°27'$ |
| $W_1 \rightarrow W_3$ | 2.46 | 2.69 | $4.33\times10^{-1}$ | $\Theta=40°39'$ |
| $W_1 \rightarrow W_4$ | 4.94 | 4.04 | $3.29\times10^{-1}$ | $\Theta=40°17'$ |

excited configurations were obtained in the same way as in the case of the 4-nitropyridine anion studied in the previous paper.[1] The core resonance integral between $2p\pi$ atomic orbitals of the carbon atom on the 3-position and the neighboring nitrogen atom of the nitro group was estimated to be $-3.0$ eV.[1,6]

The energy levels and wave functions can be evaluated by solving the secular equation constructed by the diagonal and off-diagonal matrix elements given in Tables II and III. The actual calculation was made by the aid of a Facom 202 electronic computer in our Institute. The four lowest energy levels and wave functions of the 3-nitropyridine anion are given in Table IV. Oscillator strengths were calculated for the three longest wavelength absorption bands by the method mentioned in the previous paper.[1] The calculated transition energies and oscillator strengths are shown in Table V.

## Discussion

The ESR hyperfine coupling constants associated with the nitrogen atom in the aromatic ring and with that of the nitro group depend not only on the spin densities on the respective atoms, but also on the spin densities on the adjacent atoms via indirect polarization.[7] Fraenkel et al.[8] proposed the following equation for the coupling constant due to the nitrogen nucleus of the nitro group:

$$A_N=Q_N\rho_N+Q_O\rho_O+Q_C\rho_C \qquad (1)$$

where the $\rho_N$, $\rho_O$ and $\rho_C$ are the spin densities of the nitrogen and oxygen atoms of the nitro group, and that of the carbon atom attached to the nitro group, respectively. $Q_N$, $Q_O$ and $Q_C$ are constants; they were determined as follows:

$$Q_N=\pm(99.0\pm10.2)\quad Q_O=\mp(35.8\pm5.9)\quad Q_C\fallingdotseq0$$

from a comparison of the observed nitrogen coupling constants of a the anions of several nitro compounds with the spin densities on the nitro groups calculated by the simple Hückel molecular orbital method.

According to our calculations, the ratio of the $\rho_N$ to $\rho_O$ is always constant, because the molecular orbital wave functions for the nitro group are fixed in the present calculations. Furthermore, we can reasonably assume that the $\rho_C$ term in Eq. 1 may be negligibly small, Thus, Eq. 1 can be reduced to the following equation:

$$A_N=Q_N'\rho_N \qquad (1')$$

where $Q_N'$ is constant. The value of $Q_N'$ was taken to be 40 gauss in the previous paper.[1] The same value has also been adopted in the present paper.

Now let us turn to the coupling constant associated with the nitrogen nucleus of the hetero aromatic ring. Carrington and Santos-Veiga proposed the following equation for the nitrogen-coupling constant, $A_N^{ring}$, and the spin density, $\rho_N^{ring}$, on the nitrogen atom, and estimated the value of $Q_N^{ring}$ to be 25.3 gauss:[9]

$$A_N^{ring}=Q_N^{ring}\rho_N^{ring} \qquad (2)$$

By the aid of Eqs. 1' and 2, the spin densities on the two nitrogen atoms were evaluated from the observed coupling constants; they are shown in Table I. Furthermore, the spin densities on the ring carbon atoms were obtained by the

use of the following well-known relation for the proton coupling constant: [10] $A_H = Q_H \rho_C$ ($Q_H = -22.5$ gauss). The theoretical values of the spin densities evaluated by the aid of the ground state wave function are also given in Table I for purposes of comparison. It may be said that the spin densities on the two kinds of nitrogen atoms of the 3-nitropyridine anion as estimated from the ESR coupling constants are in good agreement with the calculated values.

As is shown in Table I, the spin density on the nitrogen atom of the nitro group is larger in the 3-nitropyridine anion than in the 4-nitropyridine anion. This result is consistent with the theoretical conclusion that the contribution of the charge-transfer configuration caused by the electron transfer from the pyridine anion ring toward the nitro group increases in the 3-nitropyridine anion in comparison with that in the 4-nitropyridine anion.

The electronic absorption spectrum of the 3-nitropyridine anion shows two absorption bands at 304 and 460 m$\mu$ which can be ascribed to the $W_1 \rightarrow W_4$ and $W_1 \rightarrow W_3$ transitions respectively. Since, in the wave function of the $W_4$ state, the contribution of the locally excited configuration within the pyridine ring amounts to 92%, the 304 m$\mu$ band corresponding to the $W_1 \rightarrow W_4$ transition can be interpreted as the shifted band of the 355 m$\mu$ band of the 3, 5-lutidine (pyridine) anion.[1] This blue shift is caused by the fact that the ground configuration is largely stabilized by resonance interaction with the charge-transfer configuration. Furthermore, from the wave functions, $\Phi_1$ and $\Phi_3$, it can easily be seen that the 460 m$\mu$ band corresponding to the $W_1 \rightarrow W_3$ transition may be regarded as the intramolecular charge-transfer band. The absorption band corresponding to the $W_1 \rightarrow W_2$ transition could not be observed despite careful experimentation. This may be because the $W_1 \rightarrow W_2$ transition band is weak, as is revealed by the calculated oscillator strength value, and is, therefore, covered by other absorption bands due to reaction products.

The authors wish to express their deep thanks to Mr. Koichi Itoh of this Institute for his kind help in measuring the ESR spectra. One of the authors (M. I.) also gratefully acknowledges the encouragement of Professor Toshihiko Okamoto, Faculty of Pharmaceutical Sciences, the University of Tokyo.

# Stability Order in Metal Chelate Compounds. IV.[1] 2-Pyridylmethanol Complexes*,**

By Yukito MURAKAMI and Makoto TAKAGI

(Received October 26, 1964)

As a part of our investigation of the stability order of the metal chelates formed by the bivalent metals of the first transition series, 2-pyridylmethanol as a chelating agent has been chosen for this study. One of the interesting aspects of this ligand lies in the behavior of the alcoholic hydroxyl group toward metal ions in the process of complex formation. Much work has been done recently on the coördination ability of an alcoholic hydroxyl group present in alkanol-substituted amines. Martell and his coworkers[2] have postulated that the direct coördination of the alkoxy group in its anionic form to the metal ion occurs in a relatively high pH region in aqueous media.

Hall and his associates[3-6] investigated the

* Contribution No. 79 from the Department of Organic Synthesis, Faculty of Engineering, Kyushu University.

** Presented in part at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

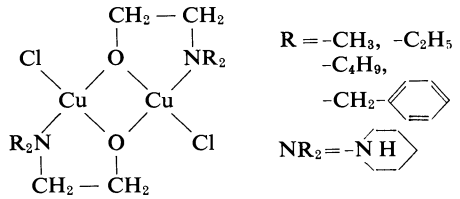
reaction between alkanol-substituted ethylenediamines and bivalent metal ions in the presence of a strong base by means of spectrophotometric, conductometric and potentiometric methods. The alcoholic hydroxyl group was found to coördinate to the metal ion on the liberation of its proton, thus forming a new and stable chelate ring which involves an amine-nitrongen and an anionic hydroxyl oxygen as donor atoms. The acid dissociation constants of various metal chelates of such alkanol-substituted ethylenediamines have also been estimated.[6]



The behavior of *N*-substituted ethanolamine-copper(II) systems upon the addition of a strong base was studied by Ojima and Sone[7] by the spectrophotometric measurement in the visible region and by the paper electrophoresis method. They detected the formation of electrically-neutral chelate species and assigned structure I to them:

R=-H, -$CH_3$ -$C_2H_5$

I

Hall et al.[8,9] have also studied the interaction between copper(II) and ethanolamines, such as monoethanolamine (MEA), diethanolamine (DMA), and triethanolamine (TEA), in the presence of a strong base. The methods employed in their study were polarography, spectrophotometry and electrical migration. The presence of neutral and anionic species of metal complexes was detected in a relatively high pH region, and the corresponding equilibrium constants were evaluated. The metal complexes reported are as follows: $[Cu(MEA)_2(OH)_2]$, $[Cu(DEA)_2(OH)_2]$, $[Cu(TEA)(OH)_2]$ and $[Cu(TEA)(OH)_3]^-$, where OH represents the coordination of either the hydroxide ion or the alkoxide ion. Further information on the behavior of ethanolamines was added by Hein and Beerstecher.[10] Upon the reaction of *N*, *N*-disubstituted ethanolamines with cupric chloride in absolute ethanol, a series of crystalline metal chelates was obtained; the dinuclear structure II was proposed for these materials:

R=-$CH_3$, -$C_2H_5$ -$C_4H_9$, -$CH_2$-⟨⟩, $NR_2$=-NH⟨⟩

II

From the above survey, it is clear that the hydroxyl group of amine-containing ligands is a good donor group and is more likely to undergo coördination in the anionic form under suitable conditions.

Since 2-pyridylmethanol is likely to form a chelate ring similar to those of ethanolamine and other alkanol-substituted amines, there remains a good chance for its hydroxyl group in its anionic form to coördinate with metal ions when experimental conditions are adjusted suitably. So far, two research groups[11,12] have investigated potentiometrically the interaction of 2-pyridylmethanol with one or two bivalent metal ions to a limited extent in an attempt to evaluate the formation constants of the corresponding metal chelates. In the present work, cadmium(II), magnesium(II) and several bivalent first transition metals (manganese, cobalt, nickel, copper and zinc) were employed, and a detailed potentiometric investigation was carried out in order to determine the complexing behavior of 2-pyridylmethanol with these metal ions. In addition, in order to clarify the behavior of the hydroxyl group of the ligand toward metal ions, several copper chelates were isolated and their properties investigated.

## Experimental

**2-Pyridylmethanol.** — 2-Pyridylmethanol (III) was prepared from 2-picoline through the intermediate compounds, 2-picoline-*N*-oxide and 2-pyridylmethanol acetate in this order, by a method described by Boekelheide and Linn;[13] b. p. 88—93°C at 4 mmHg (reported[14] b. p. 111—112°C at 15 mmHg); the picrate, m. p. 160.2—161.5°C (reported[13] m. p. 160.5—161°C); a total yield of 40%. The product is a hygroscopic and colorless liquid, but it gradually turnes yellow in the air. III was, therefore, transformed into the corresponding nitrate salt (IV) by adding concentrated nitric acid to the acetone solution, the salt being isolated as colorless crystals; after repeated recrystallizations

from ethanol, m. p. 116.2—116.7°C; neutralization equivalence, 172.9 (calcd. 172.2).

Found: C, 42.03; H, 4.83; N, 16.16. Calcd. for $C_6H_8O_4N_2$: C, 41.86; H, 4.68; N, 16.27%.

The nitrate IV was dissolved in carbonate-free water in order to prepare a stock solution for potentiometric measurements.

The nitrate was reconverted to its free form for the preparation of the various copper chelates. An aqueous solution of IV was made alkaline with potassium carbonate and extracted with chloroform. After the chloroform solution had been dried over anhydrous potassium carbonate, chloroform was removed from the solution under reduced pressure in order to isolate III. This III was used either in its isolated state or as the chloroform extract mentioned above for the preparation of metal chelates.

**Acetato(2-pyridylmethanolato)copper(II).** — Five grams of copper acetate (monohydrate) was dissolved in concentrated aqueous ammonia and evaporated to dryness under reduced pressure on a water bath at 50°C or lower. The violet crystals of tetraammineacetatocopper(II) thus obtained was mixed with 2-pyridylmethanol isolated from 5 g. of the corresponding nitrate. A homogeneous deep blue solution was prepared by adding 50 cc. of methanol, and then it was evaporated to dryness under reduced pressure below 50°C. The residue was extracted with chloroform (50 cc.), and the volume of the extract was reduced to 5—10 cc. after the insoluble material had been filtered off. A fine blue precipitate separated from the solution as acetone was added (crude yield, 4.3 g.). This crude product was purified by re-precipitation from the chloroform solution with acetone. The intermediate crop obtained in the process of re-precipitation was used for further study. The product (V) is a fine, blue, crystalline material, stable in the air, which decomposes at 180°C. It is soluble in water, alcohols (yellow solution) and chloroform, and slightly soluble in trichloroethylene, but insoluble in acetone, dioxane, ether, benzene, carbon tetrachloride and ligroin.

Found: C, 41.36; H, 4.02; N, 5.98; Cu, 26.68 (as CuO). Calcd. for $C_8H_9O_3NCu$: C, 41.65; H, 3.93; N, 6.07; Cu, 27.54%.

This chelate was also analyzed for 2-pyridylmethanol content by means of spectrophotmetry. The absorption intensity was measured in 0.6 N hydrochloric acid at 262 mμ, where free 2-pyridylmethanol has an absorption maximum of $\varepsilon=6830$; N, 6.10% (converted to nitrogen content). The molecular weight of this chelate was measured by means of a vapor pressure osmometer Model 301A (Mechrolab Inc., Mountain View, Calif., U. S. A.) at 37°C in chloroform; 893 (dibenzoyl as standard); 918 (tris(2,4-pentanedionato)chromium(III) as standard); calcd. for the tetramer, 922.8.

An attempt was made to prepare sodium diacetato(2-pyridylmethanolato)cuprate(II). A concentrated sodium acetate solution and aqueous V were mixed together and allowed to stand for several days. The deep blue crystals which separated from the solution were identified as the hydrated form of V.

**Bis(2-pyridylmethanolato)copper(II).** — Into a chloroform solution of 2-pyridylmethanol freshly isolated from the corresponding nitrate (0.8 g.), sufficient anhydrous potassium carbonate and V (0.5 g.) were added. The blue mixture, when shaken vigorously in a well-stoppered flask, turned violet in a few minutes. After approximately 30 min. of shaking, the reaction mixture was filtered on a glass filter, and the filtrate was condensed to 2 cc. under reduced pressure on a steam bath below 40°C. Bluish-violet needle-like crystals precipitated out as acetone was added to the concentrated solution; the yield was quantitative. The anhydrous product is hygroscopic enough to absorb one mole of water per mole of copper in the air. It decomposes at 150°C, but more slowly below 150°C in the air. This product was recrystallized from water as its hydrated form,* which was then reconverted to the anhydrous form at 56°C in vacuo. The hydrate is insoluble in ordinary organic solvents except for alcohols.

Found: C, 50.96; H, 4.23; N, 9.91; Cu, 22.29 (as CuO). Calcd. for $C_{12}H_{12}O_2N_2Cu$ (anhydrous form): C, 51.52; H, 4.32; N, 10.01; Cu, 22.71%.

**Chloro(2-pyridylmethanolato)copper(II).** — An aqueous solution of V and a concentrated potassium chloride solution were mixed, and the resulted precipitate was washed several times with water; green powder; insoluble in organic solvents.

Found: C, 34.33; H, 3.09; N, 6.73. Calcd. for $C_6H_6ONClCu$: C, 34.79; H, 2.92; N, 6.76%.

**Iodo(2-pyridylmethanolato)copper(II).** — This material was prepared in a manner similar to that used for the corresponding chloro complex; dark yellowish powder; insoluble in water and organic solvents.

Found: C, 24.32; H, 2.21; N, 4.90. Calcd. for $C_6H_6ONICu$: C, 24.14; H, 2.03; N, 4.69%.

**Nitrito(2-pyridylmethanolato)copper(II).** — The procedure for the preparation of this complex was similar to that used for the chloro complex; green powder; slightiy soluble in water and insoluble in organic solvents.

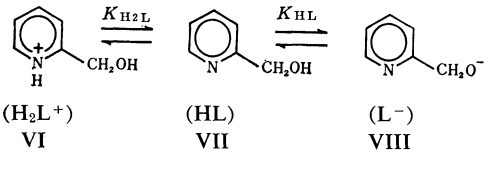
Found: C, 33.22; H, 2.94; N, 13.04. Calcd. for $C_6H_6O_3N_2Cu$: C, 33.11; H, 2.78; N, 12.87%.

**Thiocyanato(2-pyridylmethanolato)copper(II).** — To an aqueous solution of V, a concentrated solution of potassium thiocyanate was added. The bulky precipitate which formed on mixing was repeatedly washed with water by decantation and then allowed to remain in solution for several days. On standing, the precipitate turned to fine deep greenish blue crystals, which were separated by centrifugation; insoluble in water and organic solvents.

Found: C, 36.44; H, 2.81; N, 12.32. Calcd. for $C_7H_6N_2OSCu$: C, 36.59; H, 2.63; N, 12.19%.

**Metal Salts.**—The bivalent metal ions employed in the present work were magnesium, manganese, cobalt, nickel, copper, zinc and cadmium in their salt forms of $Mg(NO_3)_2\cdot 6H_2O$, $MnSO_4\cdot nH_2O$, $Co(NO_3)_2\cdot 6H_2O$, $Ni(NO_3)_2\cdot 6H_2O$, $Cu(NO_3)_2\cdot 3H_2O$, $Zn(NO_3)_2\cdot 6H_2O$ and $Cd(NO_3)_2\cdot 4H_2O$ of analytical

* This hydrate was found to be identical with that isolated from the aqueous mixture of copper salt and 2-pyridinemethanol. The latter procedure was reported by H. Ojima et al. (presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, 1964).



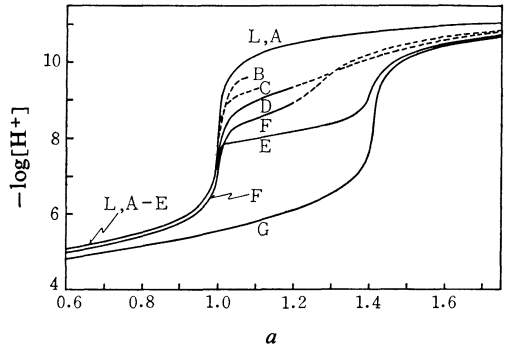
grade obtained from the Wako Pure Chemical Industries, Ltd. These salts were dissolved in carbonate-free water in order to prepare stock solutions which were standardized by the usual methods of chelatometric titration.[15]

**Potentiometric Measurements.** — The apparatus and procedures for potentiometric measurements have been described in a previous paper.[16] All the titrating solutions in this work were maintained at 25.0±0.1°C and at the ionic strength of 0.10 M (by the addition of potassium nitrate) and were kept under a nitrogen atmosphere throughout the titrations. Titrations of the 2-pyridylmethanol chelate systems of various bivalent metals were performed for 1 : 1, 2 : 1 and 5 : 1 molar ratios of ligand to metal ion.

**Spectral Measurements.**—The infrared spectra of various copper chelates were measured in Nujol mull with a Koken model DS-301 spectrophotometer equipped with sodium chloride optics. Ultraviolet and visible spectral measurements were performed in aqueous media with a Hitachi EPS-2-type recording spectrophotometer.

## Results and Discussion

**Acid Dissociation Constant.**—The protonated 2-pyridylmethanol may have two processes of proton dissociation; VI → VII, and VII → VIII. The protonated proton undergoes dissociation in a relatively low pH range, as may be seen in Fig. 1. However, the dissociation of an alcoholic proton was hardly detected at all under the present experimental conditions. Thus the cationic species was treated as a monobasic acid, and its dissociation constant was estimated in a usual manner. The estimated $pK_{H_2L}$ of 2-pyridylmethanol at 25°C is 4.89. This is lower than the $pK$ values for pyridine and $\alpha$-picoline in 0.5 M potassium nitrate which are 5.45 and 6.20 respectively.[17] Although the hydroxymethyl group would change the basicity of a pyridine-nitrogen to a certain limited extent through inductive and resonance interactions,* the lower value of $pK_{H_2L}$ in the present compound seems primarily to be due to strong intramolecular hydrogen bonding between the pyridine-nitrogen and the hydroxyl group.



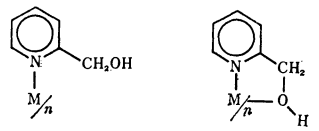


Fig. 1. Potentiometric titration of bivalent metal complexes of 2-pyridylmethanol (nitrate salt) at total ligand concentration of $2.50\times10^{-3}$ M with 5 : 1 molar ratio of ligand to metal ion: A, Mg; B, Mn; C, Cd; D, Co; E, Zn; F, Ni; G, Cu; L, ligand alone; $a$=moles of base added per mole of ligand; $t$=25°C; $\mu$=0.10 M ($KNO_3$).
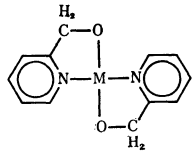
Dotted curves represent non-equilibrated titrations.

**The Interaction of 2-Pyridylmethanol with Bivalent Metal Ions.**—A family of titration curves are shown in Fig. 1 for the 2-pyridylmethanol chelate systems of magnesium(II), manganese(II), cobalt(II), nickel(II), copper(II), zinc(II), and cadmium(II) for a 5 : 1 molar ratio of ligand to metal ion. In all the metal chelate systems except the copper system, a distinct inflection region was found at $a$=1.0. In the lower buffer regions lying below $a$=1.0, all the potentiometric titrations immediately reached equilibrium and were quite reproducible. Thus, a metal complex either of the ammine type (IX) or of the chelate type, with a hydroxyl group as another donor group (X), is presumably forming in this region.

IX X



Judging from the extent of the depression of the titration in reference to with that for the free ligand, the stability of the metal chelates with respect to metal ions follows the sequence:

$$Cu(II) > Ni(II) > Co(II) > Zn(II) > Mn(II) > Cd(II)$$

Since titration curves for the free ligand and the magnesium system coincide well with each

* The electron-releasing effect of the hydroxymethyl group described by Lane et al.[12] is not quite convincing to the authors. Further study is needed to clarify this matter.

other over the whole pH range studied, magnesium(II) does not seem to form a chelate with the ligand. Beyond $a=1.0$, where the protonated proton of the conjugate acid is completely neutralized, the downward deviation of the titration curves for manganese and cadmium systems started immediately, followed by the precipitation of the metal hydroxide. For both the cobalt and nickel systems, titration curves demonstrated similar time-dependent behavior. Although no precipitates were observed for these two systems throughout the titrations, equilibrium was not reached in a short period of time beyond $a=1.2$. This sluggish equilibration is considered to be due to the slow formation of the chelates of structure XI and to hydrolytic reactions of the various chelates formed.

XI

In contrast, the titration curve of the zinc chelate system shows another significant inflection around $a=1.4$ in Fig. 1, and it is quite reproducible except in a small region immediately beyond the first inflection ($a>1.0$). Since the hydrolytic tendency of zinc is no greater than those of nickel and cobalt, this second inflection is most probably due to the formation of the 2:1(ligand to metal) chelate of structure XI.

The titration of a solution containing a 5:1 molar ratio of ligand to copper ion resulted in a large pH depression over the whole pH range studied (especially in $1.0<a<1.4$) and in only one steep inflection at $a=1.4$, as is shown in Fig. 1. Since neither pH drifting nor precipitation was observed throughout the titrations, this inflection may be considered to correspond to the formation of the 2:1 chelate, the structure of which may be represented by XI.

From the behavior of titration curves shown in Fig. 1, the interaction of 2-pyridylmethanolate anions with bivalent metal ions can be seen to increase in the following order:

$$\text{Co(II)},\ \text{Ni(II)} < \text{Zn(II)} \ll \text{Cu(II)}$$

Titration curves for all the bivalent metal chelate systems of the present study were also obtained for the first buffer region (and for the whole pH range with the copper system) at a 2:1 molar ratio of ligand to metal ion; they were found to behave in a manner similar to the 5:1 systems. The copper chelate system was also titrated at a 1:1 molar ratio. pH drifting was observed to start beyond $a=1.5$, followed by the precipitation of copper hydroxide.

**Equilibrium Constants.**—In the first buffer region ($a<1.0$) of the chelate systems of manganese, cobalt, nickel, zinc, cadmium and in the early part of the titration curve of the copper chelate system, two types of reactions are considered to compete with each other. One is the acid dissociation of the ligand (VI→VII), and the other is the formation of metal complexes of either structure IX or X. Thus the stability constants were calculated by the usual algebraic method, assuming 2:1 and 1:1 complex formations. The evaluated data are summarized in Table I. The stability constants of these metal complexes are greater than the corresponding pyridine complexes (Table II)[17] by one unit in $\log K$, with the exception of the cadmium complexes. Since the hydroxymethyl group does not seem to increase the basicity of a pyridine-nitrogen to a significant extent, the increased stability of the present complexes may be ascribed to chelate ring formation involving the hydroxyl group. Thus, structure X is prefered to the ammine-type complex, IX.

For the equilibrated region of the copper chelate system at a 1:1 molar ratio, the

TABLE I. STABILITY CONSTANTS OF THE METAL COMPLEXES OF 2-PYRIDYLMETHANOL
25.0±0.1°C, $\mu=0.10$ M ($KNO_3$)

| Metal ion | $\log K_1$ | $\log K_2$ |
|---|---|---|
| Mn(II) | ~1 | — |
| Co(II) | 2.1 | — |
| Ni(II) | 2.79 | 2.60 |
| Cu(II) | 3.41 | 2.81 |
| Zn(II) | 1.9 | — |
| Cd(II) | <1 | — |

$$K_1=\frac{[M(HL)^{2+}]}{[M^{2+}][HL]};\quad K_2=\frac{[M(HL)_2^{2+}]}{[M(HL)^{2+}][HL]}$$

HL stands for the neutral species of 2-pyridylmethanol.

TABLE II. STABILITY CONSTANTS OF THE METAL COMPLEXES OF PYRIDINE[17]
25°C, $\mu=0.5$ M ($C_5H_5N$, $HNO_3$)

| Metal ion | $\log K_1$ | $\log K_2$ |
|---|---|---|
| Co(II) | 1.14 | 0.4 |
| Ni(II) | 1.78 | 1.05 |
| Cu(II) | 2.41 | 1.88 |
| Zn(II) | 0.95 | 0.5 |
| Cd(II) | 1.27 | 0.8 |

$$K_1=\frac{[ML^{2+}]}{[M^{2+}][L]};\quad K_2=\frac{[ML_2^{2+}]}{[ML^{2+}][L]}$$

L stands for the neutral species of pyridine.

following two successive reactions were considered:

$$Cu^{2+} + HL \rightleftarrows Cu(HL)^{2+} \qquad K_1 = \frac{[Cu(HL)^{2+}]}{[Cu^{2+}][HL]}$$

$$Cu(HL)^{2+} \rightleftarrows CuL^{+} + H^{+} \qquad K^{H}_{MHL} = \frac{[CuL^{+}][H^{+}]}{[Cu(HL)^{2+}]}$$

Treating the titration data in the region, $a=0.4$—$1.1$, it was estimated that $pK^{H}_{MHL}=5.5$.

Since the copper ion is known to form rather stable chelates of structure X, the two acid dissociation reactions of the 2:1 chelate were considered to occur in addition to the neutralization of the protonated free ligand in the buffer region lying near the inflection of the 5:1 titration (Fig. 1). These two reactions are:

$$Cu(HL)_2^{2+} \rightleftharpoons CuL(HL)^{+} + H^{+}$$

$$K^{H}_{M(HL)_2} = \frac{[CuL(HL)^{+}][H^{+}]}{[Cu(HL)_2^{2+}]}$$

$$CuL(HL)^{+} \rightleftharpoons CuL_2 + H^{+}$$

$$K^{H}_{ML(HL)} = \frac{[CuL_2][H^{+}]}{[CuL(HL)^{+}]}$$

The estimated dissociation constants are $pK^{H}_{M(HL)_2}=5.55\pm0.01$, and $pK^{H}_{ML(HL)}=6.36\pm0.01$.*

These $pK$ values are slightly lower than those of the alkanol-substituted copper chelates of a 1:1 composition: *N*-hydroxyethylethylenediamine, 7.21,[6] 7.30[18]; *N*, *N'*-dihydroxyethylethylenediamine, 7.18,[6] 7.15[18]; *N*,*N'*-dihydroxypropylethylenediamine, 7.34[6]; *N*, *N*, *N'*, *N'*-tetrahydroxypropylethylenediamine, 6.77.[6] The resonance interaction of the pyridine ring with the chelate ring would produce an additional stabilization of the chelate ring. This stabilization presumably results in an increased labilization of the hydroxyl proton of the chelate.

Although several attempts have been made to analyze the zinc chelate system in its second buffer region (Fig. 1), they have not provided any reasonable results.

**The Coördination Ability of the Alcoholic Hydroxyl Group.**—There have been several discussions of the coördinating behavior of an alcoholic hydroxyl group. As has already been mentioned, several alkanol-substituted amines are likely to chelate with metal ions, involving an alcoholate anion as a donor group. It has been shown in the present work that 2-pyridylmethanol also acts as a bidentate ligand in its anionic form under appropriate conditions. The evidence for this will now be described.

(1) The copper chelate system demonstrated a sharp inflection in its titration curves at the 2:1 and 5:1 molar ratios. This corresponds to the liberation of one proton from each ligand molecule which is already coördinated to the metal ion.

(2) The color of the solutions of the copper chelate system was light blue at the start of titration in the presence of 5 mol. of the ligand per mole of copper ion. As a base was added to the titrating system, the blue color deepened, while a violet coloration was noticed beyond $a=1.2$. The solution finally turned violet at the inflection point, $a=1.4$; the addition of more base did not bring about any further color change. These color changes were followed spectrophotometrically; the $\lambda_{max}$ was nearly 800 m$\mu$ at the beginning and reached 575 m$\mu$ at the end.* The absorption band at 575 m$\mu$ may well correspond to the formation of the 2:1 chelate, which involves the alcoholate anion as a donor group.

(3) The 2-pyridylmethanol-copper(II) chelate of a molar ratio of 2:1 was isolated. This neutral chelate contains only 2-pyridylmethanol and copper(II); other constituents, such as hydroxide ions, do not seem to be involved in this chelate.

(4) Several 1:1 (2-pyridylmethanol: copper) chelates, which also contain inorganic anions, have been prepared. Infrared spectral measurements of these chelates did not provide any supporting evidence for the presence of the OH group.

An abnormally high molecular weight was obtained for acetato(2-pyridylmethanolato)-copper(II) in chloroform. Although this molecular weight corresponds to the tetrameric form of the chelate, a stereochemical structure has not been assigned to this species at the present time.

## Summary

The complexing behavior of 2-pyridylmethanol with magnesium(II), manganese(II), cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) has been studied in aqueous media at 25.0±0.1°C and an ionic strength of 0.10 M ($KNO_3$). The stability constants for the 1:1 (ligand to metal) complexes of manganese(II), cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) with the

* There may be some uncertainty involved in these values, although good constants were obtained from the data of the 5:1 titration. The above two reactions are simplified versions of the system; some other reactions such as chelate formation would actually be involved in the system. Some further study would clarify this problem.

18) R. C. Courtney, R. L. Gustafson, S. Chaberek, Jr., and A. E. Martell, *J. Am. Chem. Soc.*, **81**, 519 (1959).

* Spectroscopic work, and conductometric and electrophoresis studies of this copper chelate system have also been made by Ojima et al. (presented at the 17th Annual Metting of the Chemical Society of Japan, Tokyo, 1964).

neutral 2-pyridylmethanol and also for the 2:1 complexes of nickel(II) and copper(II) have been evaluated. The resulting stability order with respect to the bivalent metals has been found to follow the sequence:

$$Cd(II) < Mn(II) < Zn(II) < Co(II) < Ni(II) < Cu(II)$$

The higher stability of the present complexes relative to the corresponding pyridine complexes may be ascribed to the formation of a chelate ring which involves the hydroxyl group of the ligand.

After the complex formation between metal ions and the neutral ligand has proceeded to a certain extent, the liberation of a hydroxyl proton from the complex was observed to occur in several metal complex systems. This tendency was greatest for the copper complex, followed by the zinc, nickel and cobalt complexes in this order. Acid dissociation constants for the 1:1 and 2:1 copper complexes have also been evaluated.

Several pieces of evidence have been obtained in support of the coördination ability of the hydroxyl group of the present ligand in its anionic form.

The neutral copper chelate, bis(2-pyridylmethanolato)copper(II), as well as other various copper 2-hyridylmethanolate chelates which involve acetate, chloride, iodide, nitrite and thiocyanate ions as the third component, has been isolated. Acetato(2-pyridylmethanolato)-copper(II) has been found to exist as the tetrameric form in chloroform.

# Direct Preparation of Partially Fluorinated Methane*

By Shunji NAGASE, Kiyoshi TANAKA and Hajime BABA

(Received September 8, 1964)

Numerous methods are available for the preparation of partially fluorinated methane. Some of them[1,2] use the Swarts reaction which consists of the replacement of the original halogens in an organic molecule with fluorine by halides of antimony. Indirect fluorination of halogenated methane with other inorganic fluorides is frequently used.[3-6] Potassium methyl sulfate[7] and methyl tosylate[8] were shown to be a good source of fluoromethane by their reaction with potassium fluoride. Hydrogenolysis,[9] reduction,[10] disproportionation,[11] or pyrolysis[12] of fluorinated compounds has also been reported. Perhaps the most significant method for direct preparation of partially fluorinated methane was described by Bigelow and his co-worker[13] in one of the important papers on fluorination of organic compounds by elementary fluorine. They obtained, besides the expected $C_1$ derivatives, hexafluoroethane and octafluoropropane.

In the present paper, accomplishment of partial fluorination of methane by electrochemical fluorination is described. Mono- and di-fluoromethane were obtained directly from methane in a reasonable conversion and current efficiency, using the electrolytic cell equipped with a specially devised "bubbler," one of the important features of the apparatus.

Little attention has been paid to partial fluorination of organic compounds or to fluorination of slightly soluble gases in hydrogen fluoride by an electrochemical process. Simons observed the formation of partially fluorinated methanes as the cleavage products from acetic acid, acetone, trimethylamine, etc., in his.

pioneering work on electrochemical fluorination.[14] Sartori reported a successful attempt at the electrochemical fluorination of gases.[15] Methane, however, was shown to yield tetrafluoromethane and trifluoromethane with very small amounts of di- and mono-fluorinated products.

In the present work, the bubbler type of electrolytic cell afforded as high as 60% (mol.) of monofluoromethane in the fluorinated product, with an anodic current density of 2.2 amp./dm$^2$ and cell temperature of 5—6°C. This result may be regarded as a significant step in the partial fluorination of organic compounds by an electrochemical process.

The metered methane was introduced, with or without diluent helium, into hydrogen fluoride in the cell through the "bubbler" and fluorinated, after which the products were freed from hydrogen fluoride and oxygen difluoride, condensed, and rectified. The bubbling arrangement was found to be very effective for controlling the fluorination reaction, which is frequently explosive in nature, increase both the conversion and current efficiency during the fluorin ation of methane.

## Experimental

**Materials.**—Methane, from a commercial cylinder, was of over 99.5% pure. Hydrogen fluoride, rated better than 99%, was donated by Daikin Industries Co. The diluent employed was Airco helium (grade for gas chromatograhy use). The other, commonly available, reagents used were either of guaranteed or of first grade.

**Apparatus.**—The apparatus used for this fluorination reaction consisted essentially of the electrolytic cell, an iron tube for sodium fluoride pellets, three Ichinose gas washing bottles containing a saturated solution of sodium sulfite in which a small amount of potassium iodide and potassium hydroxide had been added, and glass traps immersed in ice and in liquid air. The size and the kind of the materials composing the electrolytic cell were the same as the one fully described earlier,[16,17] except that the cell body was constructed of Monel Metal, and a bubbling arrangement, termed "bubbler", was provided at the bottom of the cell body. The bubbler was placed just below the end of the nickel electrodes (whose effective surface area was 9.2 dm$^2$) at about 20 mm. distance from them, and standing vertically. The bubbler consisted of $6\phi \times 15$ mm. polyethylene tube, with an internal diameter of 4 mm., whose tip was enlarged to 8 mm. in diameter and capped with a filter paper made of polytetrafluoroethylene (courtesy of Daikin Industries Co.). During operation, the gaseous sample, with or without a metered current of helium, was introduced into hydrogen fluoride, from the bottom of the cell through the drain cock, whose central hole is 4 mm. in diameter, and which is connected directly to this bubbling arrangement. In a preliminary experiment, an attempt was made to produce innumerable minute bubbles in liquid hydrogen fluoride by various methods and materials. Such bubbles should accelerate favorable increase in the concentration of the slightly soluble sample in hydrogen fluoride. Macroscopic observation was made using a semi-transparent polyethylene vessel; the bubbler just described above gave the best results.

Other instruments used in this work were low temperature distillation, gas chromatographic, and infrared spectroscopic apparatus. Rectification unit used was substantially the same as the one described by Calfee, Fukuhara and Bigelow.[18] A Podbielniak low temperature distillation column was the essential part. Analytical chromatographic separation was made with a Hitachi KGL-2A model chromatograph.

Infrared absorption spectra were measured on a Perkin-Elmer model 21 double-beam spectrophotometer.

**Typical Procedure.** — Run 2 is taken as an example. Hydrogen fluoride (1 l.) was placed in the cell and, in order to remove a trace of impurity (mainly water), electrolysis was carried out in a nitrogen atmosphere, prior to the introduction of the sample, with an anodic current density of 2.7 amp./dm$^2$ and at 5—6°C, until the cell voltage rose to 6.0 V. Then 10 g. of sodium fluoride was added, and the metered sample was introduced from the bottom of the cell into the hydrogen fluoride in the cell, maintained at 5—6°C, through the bubbler at an average flow rate of 0.0029 mol./min. In two experiments, metered helium was admitted simultaneously with the sample into the bubbler.

Then the sample was fluorinated at an anodic current density of 2.2 amp./dm$^2$.

When the cell voltage became almost steady at 6—6.5 V., traps were placed in ice and liquid air respectively, and electrolysis was carried out for 71 amp. hr.

Fluorinated gas evolved from the cell was passed through a reflux condenser kept at −20°C, and over sodium fluoride, and then bubbled through an aqueous sodium sulfite solution in an Ichinose gas washer to eliminate a trace of explosive oxygen difluoride, passed through a trap immersed in ice, and finally condensed in two consecutive liquid-air traps. Although fluctuation due to a small explosion was sometimes observed on the flow meter of the sample, performance of this electrofluorination unit was very satisfactory for the fluorination of methane.

The product thus obtained was carefully rectified in the low-temperature rectification unit. The molecular weight of each fraction was often measured to aid in identification of the components. The amounts of the rectified products were measured by volume, and subsequently weighed in

a glass ampule. The mixture was further separated by gas chromatography, using an activated charcoal column, 2 m. long, maintained at 70°C. Activated charcoal was of 30—60 mesh. The carrier gas was helium and the flow rate was at 147 ml./min. Infrared measurements were frequently carried out on components eluted from the column by transferring the highly diluted components into a 5-cm. cell.

## Results and Discussion

The results from the example (run 2) described above and those from a series of similar runs under various operating condition are summarized in the following tabulation.

TABLE I. RECTIFICATION OF FLUORINATED METHANE

| Fraction. No. | B. p., °C | Vol. ml. | Wt. g. | Component |
|---|---|---|---|---|
| 1 | −162—−159 | 13 | 5.6 | $CH_4$ |
| 2 | −128—−126 | 3.8 | 6.7 | $CF_4$[b] |
| 3[a] | −80—−76 | 4.8 | 6.1 | $CH_3F$[c], $CHF_3$[b] |
| 4[a] | −70—hold up | 1.5 | 2.0 | $CH_3F$, $CHF_3$ $CH_2F_2$[b] |

a) This fraction was further resolved chromatographically.

b), c) The infrared spectra of these products agree with those listed in D. G. Weiblen's "Fluorine Chemistry," Ed. by J. H. Simons, Vol. II, Academic Press. Inc., New York (1954), p. 469, and G. Herzberg's "Molecular Spectra and Molecular Structure. II. Infrared and Raman Spectra of Polyatomic Molecules," D. Van Nostrand Inc., New York (1949), p. 315 respectively.

Table I gives the results obtained by rectifying the product of run 2. In Table II, operating conditions for various runs, conversion and current efficiencies, and composition of the products are presented.

Fractions 1 and 2 usually consisted of essentially pure $CH_4$, and $CF_4$, respectively. Fraction 2 in run 6, however, was contaminated with $CH_3F$, and the boiling range was −130 to −90°C. Fractions 3 and 4 came over as a mixture and were further separated chromatographically. Fraction 3 sometimes showed a wider range of boiling point, −80—−51°C, depending on the proportion of the components. Detectable amounts of other components, such as $C_2F_6$ or $C_3F_8$ which are obtained in the reaction of fluorine with methane,[13] were not found in this electrochemical fluorination reaction.

Quantitative analysis of the components separated by chromatography was made on the assumption that the ratio of the peak areas in the chromatogram is a direct measure of the weight per cent of the components.[19,20] The results obtained by this analysis were subsequently converted into mole per cent.

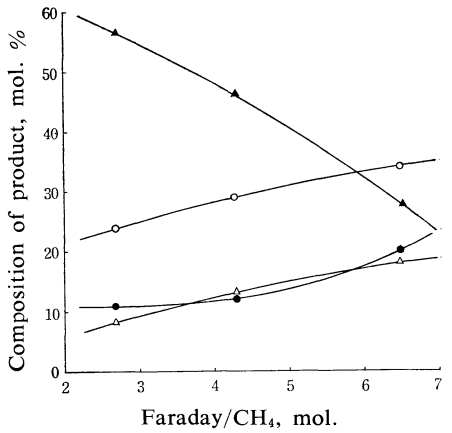

Fig. 1. Relationship between composition of product and Farady/$CH_4$ (mol.).

-△- $CH_2F_2$ mol. %
-▲- $CH_3F$ mol. %

**Effect of Sample Feed Rate.** — Though a definite mechanism for electrochemical fluorination has not yet been established,[21] the products obtained by the present fluorination reaction appeared to be rather close to those expected from a very mild fluorination of methane with elementary fluorine. It appears, that sufficient agitation and effective dispersion of the heat of reaction takes place in this electrochemical process. An increase in the number of sample bubbles should increase the efficiency of this agitation. It is apparent from Table II that the fluorination reaction becomes milder with an increase in the supply of $CH_4$. This relation is well illustrated in Fig. 1, where the composition of the products obtained in runs 1, 2, and 3 is plotted against the feed factor represented by faraday/$CH_4$(mol.).

It has been reported that agitation has a profound effect on the milder electrochemical fluorination of chloro-olefins.[22]

Electrochemical fluorination is certainly an anodic reaction, therefore the concentration of the sample near the electrode should play an important role in determining the distribution

a) Cell temperature was kept at 15—16°C.
b) In runs 5 and 6, diluent helium was used at flow rates of 104 ml./min. ($CH_4$ : He = 1 : 1.6 by vol.) and 150 ml./min. ($CH_4$ : He = 1 : 3 by vol.), respectively.
c) The reaction was carried out without using the "bubbler."
d) NaF (50 g.) was used.
e) Calculation of the current efficiency was based on the amount of electricity assumed to be required to liberate fluorine from a discharging fluoride ion which would substitute hydrogen in $CH_4$ and combine with it to from HF. The total current efficiency shown is the sum of the individual current efficiencies for $CF_4$, $CHF_3$, $CH_2F_2$, and $CH_3F$.

and yield of the products as well as the efficiency of the reaction. Especially for a gaseous sample sparingly soluble in hydrogen fluoride, it is important to consider the effective concentration of the sample in the reaction zone. A higher feeding rate tends to increase the concentration of the sample. On the other hand, it also increases the amount of escaping sample. These consideration could explain the fact that an increased rate of feeding resulted in a decreased conversion and increased current efficiency.

**Effect of Temperature.**—The conductivity of hydrogen fluoride solution increases as the temperature rises. Run 4 proceeded at the lower cell voltage of 5.3—5.5 V. at 15—16°C. A decrease in the voltage would lead to milder fluorination. Furthermore, higher temperatures are expected to decrease the solubility of the gases, and hence the products would probably be liberated from the reaction zone at a less fluorinated stage. An opposing factor to the milder reaction might exist due to an increased reaction temperature. The net result was a milder fluorination reaction with a large amount of partially fluorinated products and a small amount of $CF_4$.

**Effect of Dilution.**—In vapor phase fluorination of organic compounds with elementary fluorine, the sample or fluorine is often diluted with nitrogen or helium to make the reaction milder. The same technique was applied in the present electrochemical fluorination (runs 5 and 6), with the hope that partial fluorination would proceed favorably. Helium should also help the stripping of the product from hydrogen fluoride at a less fluorinated stage, in addition to creating sufficient agitation in the reaction zone. As expected, runs 5 and 6 gave the highest yield of $CH_3F$.

**Effect of the Bubbler.**—Run 7 was carried out without using the bubbler. It was very difficult to control this reaction and frequent explosions were observed.

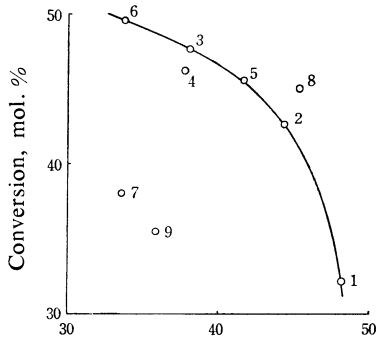

Fig. 2. Relationship between conversion and current efficiency.
The numberals in the diagram indicate run no.

The conversion and current efficiency decreased markedly. Figure 2 is a plot of conversion versus current efficiency and reveals the successful result brought about by the bubbler. It appears that approach of the sample to the electrode is neither steady nor smooth without the bubbler.

**Effect of the Amount of NaF.** — Since hydrogen fluoride which contains hydrocarbons is nonconducting, electrolysis of this solution

is usually carried out by the use of conductivity additives. In the present experiments, NaF (10 g.) was used as the additive, but for run 8, a larger amount of NaF (50 g.) was used with the expectation that the electrolysis could be carried out at a lower voltage for a milder reaction. Run 8, however, proceeded at the same voltage (6—6.5 V.) as that of the others. However, milder fluorination was accomplished and the smallest yield of $CF_4$ obtained. This might be attributed to the decreased solubility of partially fluorinated products in hydrogen fluoride.

**Effect of the Anodic Current Density.** — A smaller current density should make the reaction milder, but run 9, on the contrary, indicates a severe reaction with a smaller conversion and current efficiency.

The lesser degree of agitation may account for this, since the decreased amount of the total gases evolved under this electrolysis condition is not sufficient to cause efficient agitation in the hydrogen fluoride. A similar tendency was observed in the electrochemical fluorination of 2, 2, 3, 3-tetrafluoro-1-propanol.[23]

The overall results seem to demonstrate clearly the usefulness of electrochemical fluorination as a tool for fluorination of gases.

23) S. Nagase, H. Baba and R. Kojima, This Bulletin, **36**, 29 (1963).

**Summary**

Partially fluorinated methanes were obtained directly from methane in a reasonable conversion and current efficiency by electrochemical fluorination, using a cell equipped with a bubbling arrangement. This fluorination unit worked satisfactorily for controlling the fluorination reaction of gases slightly soluble in hydrogen fluoride.

Performance and effect of the bubbler, and the effect of sample feed rate, electrolysis temperature, dilution of the sample with helium, the amount of sodium fluoride, and the anodic current density, on the fluorination reaction are described and discussed in detail.

The authors wish to express their sincere thanks to Daikin Industries Co. for supplying some materials, and Dr. Kan Inukai of this Institute for his interest in this work.

# The Kinetics of the Acid-catalyzed Transformation of Peroxybenzoic Acids to Acetyl Benzoyl Peroxides in Acetic Acid*

By Yoshiro OGATA, Yoshiaki FURUYA and Keizo AOKI

(Received September 24, 1964)

It is well-known that peroxy acids are obtained by the hydrolysis of the corresponding peroxides.[1-3] However, the reverse reactions of peroxy acids to form peroxides have scarcely been studied at all. The present authors have reported previously on the acid-catalyzed reversible transformation of peroxyacetic acid to acetyl peroxide in acetic acid.[4]

It has been analogously supposed that peroxybenzoic acid in acetic acid may be reversibly transformed to acetyl benzoyl peroxide in the presence of sulfuric acid:

$$C_6H_5CO_3H + CH_3CO_2H \overset{H^+}{\rightleftarrows} C_6H_5COO_2COCH_3 + H_2O \quad (1)$$

As expected, it was observed that the reaction led to acetyl benzoyl peroxide, which was identified by paper chromatography. The reaction rate followed the first-order kinetics if the reversibility of the reaction was taken into account. The present paper will describe the results of a kinetic study of this and related reactions by the iodometric determination of peroxybenzoic acid and acetyl benzoyl peroxide. Thus far, acetyl benzoyl peroxide has been

prepared by the reaction of peroxybenzoic acid with acetic anhydride[5] or by the autoxidation of benzaldehyde in acetic anhydride.[6]

## Experimental

**Materials.**—Peroxybenzoic acid, m. p. 41°C, was prepared by the hydrolysis of benzoyl peroxide.[3] Substituted peroxybenzoic acids were obtained by an analogous procedure from the corresponding benzoyl peroxides, prepared by the reaction of benzoyl chlorides with hydrogen peroxide.[7] Acetyl benzoyl peroxide was prepared by the autoxidation of a mixture of benzaldehyde and acetic anhydride,[6] m. p. 35.5°C. Acetyl peroxide was obtained by the reaction of acetic anhydride with barium peroxide in an ethereal solution at 0°C, the solvent being exchanged with acetic acid for safe storage.[8]

**A Typical Run for the Rate Measurements.**—Peroxybenzoic acid (ca. 0.138 g., 0.001 mol.) was introduced into an acetic acid solution (50 ml.) of 3.6 N sulfuric acid after the solution had been brought to a temperature equilibrium. Aliquots (5 ml. each) were taken out and worked up in a manner reported previously[4] in order to estimate peroxybenzoic acid and acetyl benzoyl peroxide. It was confirmed in a blank test that only 1% of acetyl benzoyl peroxide was hydrolyzed to peroxybenzoic acid under the same conditions after 2 min., although it was completely hydrolyzed after 15 hr. at 20°C.

**Reaction Products Criterion.**—A solution of the reaction products was developed with a mixture of acetic acid and water (2 : 3 in vol.) on acetylated Toyo Filter paper No. 54.[9] When sprayed with a methanolic solution of 3% *p*-dimethylaminoaniline dihydrochloride, the initial reaction mixture gave a single spot corresponding to peroxybenzoic acid ($R_f$: 0.66), while the mixture after 2 hr. gave two spots corresponding to peroxybenzoic acid (0.66) and acetyl benzoyl peroxide (0.45) and no appreciable spots for benzoyl peroxide (0.15), acetyl peroxide (0.92), peroxyacetic acid (0.97) or hydrogen peroxide (0.88). In the reverse reaction, the initial mixture of acetyl benzoyl peroxide in acetic acid gave a spot for acetyl benzoyl peroxide alone (0.45), while the mixture after 2 hr. gave two spots for acetyl benzoyl peroxide (0.45) and peroxybenzoic acid (0.66). Hence, the presence of equilibrium 1 is confirmed. Under these conditions, there was no appreciable interconversion between peroxybenzoic acid and acetyl benzoyl peroxide in the absence of sulfuric acid.

## Results and Discussion

Since there is a large excess of acetic acid and water, the kinetics follow the pseudo first-order equation for reversible reactions, $\ln [z/(z-x)]=kt$, where $z$ is the concentration of consumed peroxybenzoic acid at equilibrium, and $x$ is the concentration of consumed peroxybenzoic acid at time $t$.

Assuming the pseudo first-order rate constants for forward and reverse reactions to be $k_1$ and $k_{-1}$ respectively, the following rate and equilibrium equations are obtained[10]:

$$\ln [z/(z-x)]=(k_1+k_{-1})t=kt$$
$$z/(a-z)=k_1/k_{-1}$$

where $a$ is the initial concentration of peroxybenzoic acid. Therefore, the forward rate constant, $k_1$, is expressed as:

TABLE II. THE CONSTANCY OF APPARENT EQUILIBRIUM CONSTANT WITH VARYING CONCENTRATION OF WATER IN THE REACTION MIXTURE WITH 3.6 N SULFURIC ACID AT 45°C

| $H_2O$ added vol. % | $[H_2O]$ M | $[CH_3CO_2H]$[a] M | $\frac{z}{a-z}$[b] | Equilibrium constant[c] $K\times10^2$ |
|---|---|---|---|---|
| 0 | 0.498 | 15.694 | 1.262 | 4.00 |
| 1 | 1.054 | 15.694 | 0.5504 | 3.70 |
| 3 | 2.160 | 15.172 | 0.3193 | 4.55 |
| 5 | 3.272 | 14.822 | 0.1468 | 3.24 |
| 10 | 6.040 | 13.952 | 0.0776 | 3.36 |

a) Concn. of acetic acid was calculated by means of the equation: [volume of $CH_3CO_2H$ (ml.)] × [Sp. gr.]/[Mol. wt. of $CH_3CO_2H$] where sp. gr. is 1.049 at 20°C.

b) The value was calculated from the value of $[CH_3COO_2COC_6H_5]/[C_6H_5CO_3H]$ at equilibrium.

c) The constant was calculated by means of the following equation:

$$K=\frac{[CH_3COO_2COC_6H_5][H_2O]}{[C_6H_5CO_3H][CH_3CO_2H]}=\frac{z}{a-z}\cdot\frac{[H_2O]}{[CH_3CO_2H]}$$

where $[H_2O]$ is the sum of the concentrations of water in original acetic and sulfuric acids and the concentrations of added and formed water.

$$k_1=kz/a$$

As Table I shows, the value of $k_1$ holds constancy.

Moreover, the sum of the concentrations of peroxybenzoic acid and acetyl benzoyl peroxide ($[C_6H_5CO_3H]+[C_6H_5COO_2COCH_3]$) is very nearly constant during the reaction, as is shown in Table I; this means that the reaction is a transformation instead of a decomposition. The rate constant, $k_1$, holds constancy with varying initial concentrations of peroxybenzoic acid ($0.615—1.846\times10^{-2}$ M) with added benzoic acid ($4\times10^{-2}$ M).

As expected, equilibrium 1 moved to the left-hand side when the concentration of water was increased. The constancy of the calculated equilibrium constants in various concentrations of water is apparent from Table II.

The energy and entropy of activation were calculated to be 16.8 kcal. $mol^{-1}$ and −25.7 e. u., respectively, from the following average values of $k_1\times10^4$ $sec^{-1}$: 40°C, 1.01; 45°C, 1.66; 50°C, 2.34; 55°C, 3.42.

The plot of $\log k_1$ vs. $H_0$ gave a straight line, with a slope of −0.96, as is shown in Fig. 1. Therefore, an activated complex with a proton may be suggested for the reaction.

The introduction of an electron-attracting group into the peroxybenzoic acid retarded the reaction, and the Hammett plot (Fig. 2) gave a negative $\rho$-value of −0.37. The introduction of an electron-releasing group, on the other hand, accelerated the reaction. The latter reaction, however, was accompanied by a side reaction, probably such as the cleavage

TABLE III. SUBSTITUENT EFFECT OF THE TRANSFORMATION OF SUBSTITUTED PEROXYBENZOIC ACIDS TO ACETYL BENZOYL PEROXIDES IN ACETIC ACID AT 45°C

Concn. of $H_2SO_4$, 3.6 N ($H_0$, −3.430)

| Substituent | Forward first-order rate const. $k_1\times10^4$ $sec^{-1}$ |
|---|---|
| *p*-$OCH_3$ | (5.20)[a,b] |
| *p*-$CH_3$ | (1.96)[a] |
| *p*-H | 1.66 |
| *p*-Cl | 1.41 |
| *m*-$NO_2$ | 0.92 |
| *p*-$NO_2$ | 0.87 |

a) These data do not seem to express the true substituent effects because of possible side reactions.

b) The reaction for *p*-methoxyperoxybenzoic acid was done at 25°C.

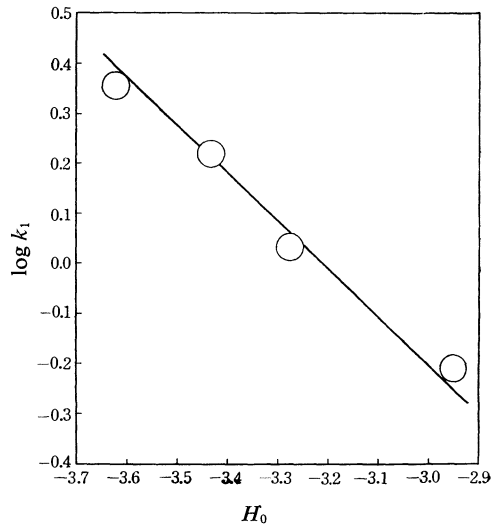

Fig. 1. The plots of $\log k_1$ vs. $H_0$ for the transformation of peroxybenzoic acid to acetyl benzoyl peroxide in acetic acid at 45°C.

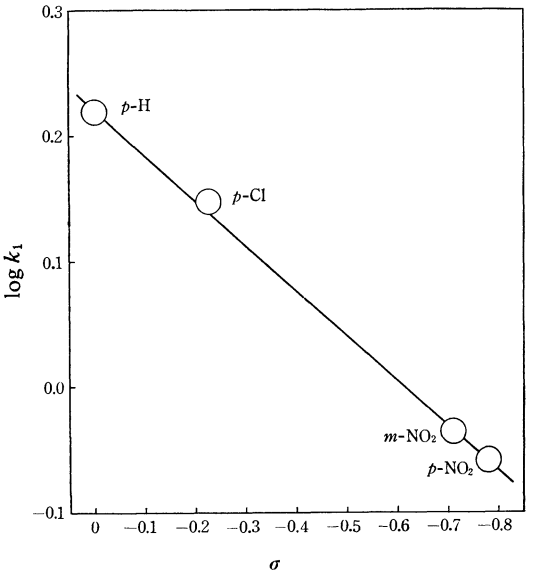

Fig. 2. Hammett plots for the transformation of substituted peroxybenzoic acid to the corresponding acetyl benzoyl peroxide in acetic acid at 45°C. ($H_0$, −3.430)

of the ether linkage of the methoxy group or the oxidation of the methyl group, since the active oxygen content of the system decreased during the reaction.

These facts suggest a mechanism analogous to that postulated for the acid-catalyzed transformation of peroxyacetic acid.[4]

$$CH_3COOH + H^+ \overset{\text{fast}}{\rightleftarrows} CH_3\text{-}\overset{+}{C}(OH)_2 \qquad (2)$$

$$CH_3\text{-}\overset{+}{C}(OH)_2 + Ar\text{-}\overset{O}{\overset{\|}{C}}OOH \rightleftarrows Ar\text{-}\overset{O}{\overset{\|}{C}}\overset{+}{O}OH \quad \underset{\text{(I)}}{CH_3\text{-}C(OH)_2} \qquad (3)$$

$$Ar\text{-}\overset{O}{\overset{\|}{C}}\overset{+}{O}OH \quad \underset{CH_3\text{-}C(OH)_2}{} \rightleftarrows Ar\text{-}\overset{O}{\overset{\|}{C}}\text{-}OO\text{-}\overset{O}{\overset{\|}{C}}\text{-}CH_3 + H_3O^+ \qquad (4)$$

The substituent effect with a negative $\rho$-value is consistent with a rate-determining attack of protonated acetic acid on peroxybenzoic acid (step 3). Moreover, complex I resembles the ortho acid monoester, which is the unstable intermediate in esterification; therefore, step 4 may be much faster than step 3.

The solvent effect was examined with formic, propionic, butyric, isobutyric or isovaleric acid as a solvent. The reactions in these solvents were all faster than that in acetic acid. However, side-reactions such as the oxidation of the solvent seem to occur quite often in these solvents.

## Summary

It has been confirmed by paper chromatography that peroxybenzoic acid in acetic acid is transformed reversibly to acetyl benzoyl peroxide in the presence of a catalytic amount of sulfuric acid. The rate satisfies the first-order equation for reversible reactions. The plot of the logarithm of the forward rate constant vs. the acidity function has given a straight line with a slope of −0.96. The rate decreases upon the introduction of an electron-attracting group to the benzene ring of peroxybenzoic acid, the Hammett's $\rho$-value being −0.37. A mechanism analogous to that postulated previously with peroxyacetic acid, which involves a rate-determining attack of protonated acetic acid on peroxybenzoic acids, is consistent with these facts.

# The Mechanism of the Electrical Conduction in Solid Acetamide*

By Koichi HIRANO

(Received February 25, 1961 ; in revised form November 26, 1964)

The electrical conductivity of ice and solid alcohols has been studied by several investigators;[1-6] it has been concluded that the proton transfer across the hydrogen bonds plays an important role in the conduction mechanism. It would, however, be desirable to obtain further information about the conduction mechanism in crystals with >NH···O< hydrogen bonds, since studies thus far have concerned only the case of OH···O hydrogen bonds.

In the present paper the temperature dependence of solid state acetamide will be described; the conduction mechanism in the >HN···O< hydrogen bond crystal will then be discussed on the basis of the proton transfer model.

## Experimental

After fractional distillation, acetamide was recrystallized thrice from hot benzene by the Lewin and Vance's method[7] and then dried in a Abderhalden drier for five hours. The sample was melted in the cell; it was solidified gradually from its own melt. The cell was then kept at 82°C to remove the strain of the sample which originated from solidification. In comparison with the results reported hitherto by other authors, the a.c. conductivity of molten acetamide at 83.2°C and 87.5°C were measured.

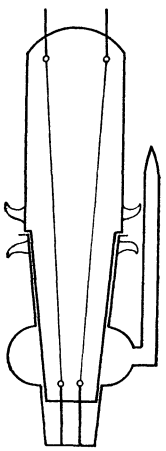

Fig. 1. The conductivity cell.

On the other hand, the temperature dependency of the d.c. conductivity of solid acetamide was measured within the temperature range from 60 to 90°C by the bridge method. The cell, made of pyrex-glass with platinum electrodes,[4,8] is illustrated in Fig. 1.

The cell was calibrated with a potassium chloride solution, and the cell constant was determined to be 0.1408 $\Omega^{-1}cm^{-1}$ at 25°C.

## Results

**The A. C. Conductivity of Molten Acetamide.** —The values of a. c. conductivity at $10^3$ c. p. s. for molten acetamide are presented in Table I, in which are also included the results reported in the literature.

TABLE I. THE SPECIFIC CONDUCTIVITY OF MOLTEN ACETAMIDE

| Specific conductivity at $10^3$ c. p. s. $\sigma\Omega^{-1}cm^{-1}$ | Temp. °C | Author |
|---|---|---|
| $8.8\times10^{-7}$ | 83.2 | Hirano |
| $1.0\times10^{-6}$ | 87.5 | Hirano |
| $3\times10^{-3}$ | 80 | Walden (1903)[9] |
| $4.3\times10^{-5}$ | 100 | Walker (1905)[10] |
| $1.5\times10^{-5}$ | 90 | Belladen (1927)[11] |
| $8.6\times10^{-6}$ | 94 | Grüttner (1952)[12] |
| $2.6\times10^{-6}$ | 94 | Jander and Winkeler (1959)[13] |

From Table I it is obvious that the results here obtained are fairly different from those previously reported by Walden[9] and by others,[10-12] but comparable with the results given by Jander and Winkeler.[13] The wide divergence of Walden's result may, however,

* A part of this paper was presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

13) G. Jander and G. Winkeler, *J. Inorg. Nucl. Chem.*, **9**, 24 (1959).

be attributed to impure materials, since the conductivity is strongly affected by a small amount of impurities. The very low values obtained by the present author are attributable to the high purity of the specimens used.

**The Temperature Dependency of the D. C. Conductivity of Solid Acetamide.**— In Table II the results of d. c. conductivity for solid acetamide obtained at various temperatures are listed.

Table II. The specific conductivity of solid acetamide

| Specific conductivity D. C. $\kappa\Omega^{-1}cm^{-1}$ | Temp. °C |
|---|---|
| $1.4\times10^{-9}$ | 61.5 |
| $3.5\times10^{-9}$ | 71.0 |
| $5.9\times10^{-9}$ | 73.0 |
| $7.3\times10^{-9}$ | 75.2 |
| $1.2\times10^{-8}$ | 77.4 |
| $3.0\times10^{-8}$ | 79.8 |
| $5.6\times10^{-8}$ | 82.2 |

Judging from the data of a. c. conductivity in the molten state, the purity of specimens is sufficiently high, so the data listed in Table II seem to be rather consistent, though no data which can be compared with have been reported.

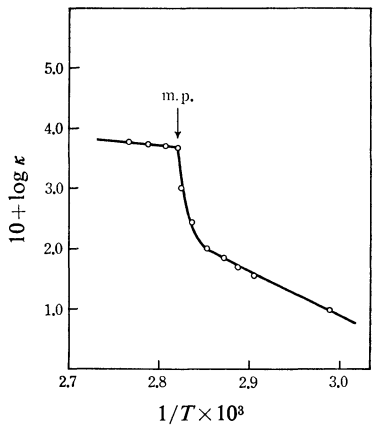

Fig. 2. $10+\log\kappa$ plotted against $1/T$.

In Fig. 2 the plots of $\log\kappa$ against the reciprocal of temperature, $1/T$, are illustrated. In the curve there are lower and upper slopes and a steeper slope just below the melting point, as is general for the solid state. The lower slope corresponds to the molten liquid, and the upper one, to the solid state, while the abrupt change seems to originate from the homophase premelting.[14] This feature is very similar to that with ice. The linear plot of $10+\log\kappa$ vs. $1/T\times10^3$ for the solid state is represented well by the following equation;

$$\kappa=1.7\exp-\{34\times10^3/RT\}\ \Omega^{-1}cm^{-1} \quad (1)$$

where $34\times10^3$ cal./mol. is the activation energy of electrical conduction; $R$, the gas constant, and $T$, the absolute temperature.

## Discussion

In the present paper the author would like to interpret the mechanism of the electrical conduction in solid acetamide from the point of view of proton transfer.

It has been well established by Senti and Harker[15] that the crystal structure of rhombohedral acetamide consists of planar molecules of the keto form arranged in rings of six members, as is shown in Fig. 3. In the rings the adjacent molecules are held together by hydrogen bonds of >NH···O=C<, and along the c-axis of the hexagonal cell the molecules are linked together by the hydrogen bonds in infinite chains. Thereby, the net transfer of protons traveling along the hydrogen bonds in the axis may be expected when the external electrical field is applied. If the proton transfer causes the conduction, however, three kinds of reactions must follow:

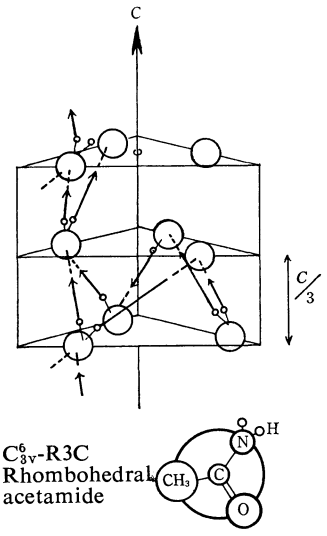

Fig. 3. Crystal structure of acetamide.

**Proton Supply to the Molecular Chains of Hydrogen Bonds.** — The proton supply would be initiated by the ionogenic reaction involving step 2:[16]

14) W. Davis, S. Rogers and A. R. Ubbelohde, *Proc. Roy. Soc.*, **A220**, 14 (1953).

15) F. Senti and D. Harker, *J. Am. Chem. Soc.*, **62**, 2008 (1947).

16) K. Wirtz, *Z. Naturforsch.*, **2b**, 94 (1947).

$$\rangle NH\cdots O{=}C\langle \xrightarrow{\Delta E_1} \rangle \overset{-}{N}: + H\overset{+}{O}C\langle \qquad (2)$$

where $\Delta E_1$ denotes the activation energy, which is identical with the height of the potential barrier between the two positions of equilibrium in the hydrogen bonds in Fig. 4.

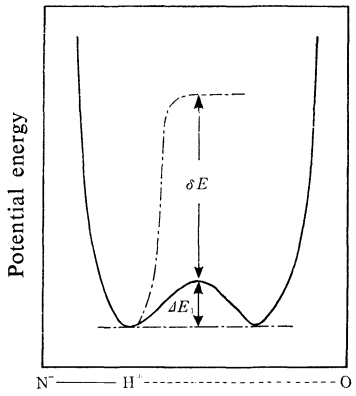

Fig. 4. Potential barrier between the two positions of equilibrium in the hydrogen bonds.
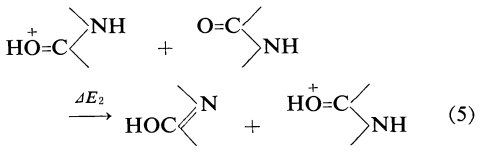
$\Delta E_1 \simeq 20$ kcal./mol.

Consequently, $\Delta E_1$ is represented by:



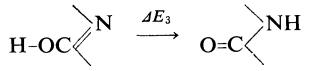
$$\Delta E_1 \simeq (D - \delta E) \qquad (3)$$

where $D$ denotes the energy required to liberate the proton from the restraining negative force field around a given nitrogen atom and $\delta E$, the energy changes associated with the hydrogen bond formation.

Assuming that $D$ would not be so different from the energy of the dissociation of >N-H linkage: hence, $\Delta E_1$ may be estimated from Eq. 4:

$$\Delta E_1 \simeq (104 - \delta E) \text{ kcal./mol.} \qquad (4)$$

**Proton Transfer.** — In the case of ice, the oxonium ion, $H_3O^+$, is intermediate in the proton transfer between the adjacent molecules. In acetamide, however, such ions would not be produced; hence, another scheme must be considered. The following scheme 5, with the protonated amide molecules acting as intermediates, are considered to be the most probable one:



(5)

Here $\Delta E_2$ is the activation energy of proton transfer, and it may be estimated as nearly equal to 3—5 kcal./mol., judging from the quite similar quantity for ice.

**The Recovery of the Hydrogen Bonds.** — According to schemes 2 and 5, it is evident that, after the proton transference, the members of the molecular chain were replaced by molecules of the enol form. It must then be remembered that the further transference of protons does not proceed unless the recovery of the hydrogen bonds has been established in the molecular chain.

In the present paper we assumed keto-enol transformation (6) to be the key reaction in the recovery process; then, the activation energy, $\Delta E_3$, can be estimated to be equal to 5—10 kcal./mol. in analogy with the similar quantity estimated from cis-trans transformation in esters and amines.[17]

(6)

Admitting the above, the activation energy of conduction, $\Delta E$, in the overall reactions 2, 5 and 6, is given in Eq. 7;

$$\Delta E = \Delta E_1 + \Delta E_2 + \Delta E_3 \qquad (7)$$

From the experimental results, 34 kcal./mol. is determined as the value of $\Delta E$. Using the data of $\Delta E$, $\Delta E_2$ and $\Delta E_3$, 20 kcal./mol. is given as the data of $\Delta E_1$; then we immediately determined $\delta E \simeq 80$—85 kcal./mol.

In Table III the activation energies related to the respective processes are summarized.

Table III. Activation energies

| Activation energy | Process | kcal./mol. |
|---|---|---|
| $\Delta E$ | Overall process | 34 |
| $\Delta E_1$ | Liberation of proton | 20 |
| $\Delta E_2$ | Proton transfer | 5 |
| $\Delta E_3$ | Recovery process | 10 |
| $\delta E$ | Changes in the dissociation energy of the >N-H bond associated with hydrogen bond formation | 80—85 |

The value of $\Delta E_1$, the potential barrier in Fig. 4, is consistent with the theoretical estimations of the similar quantities for the N-H···O or O-H···O hydrogen bonds in the liquid state.

Since the height of the potential barrier of this kind does not vary much with the states of the molecular aggregation, $\Delta E_1 \simeq 20$ kcal./mol. is fairly reasonable as the potential barrier between the two positions of equilibrium in the hydrogen bond of solid acetamide.

Accordingly, it may be concluded that the

proton transfer plays an important role in the electrical conduction in solid amide; this conception makes it possible to consider the electrical conduction observed in proteins or related compounds.

## Summary

1) Conductivity measurements of solid acetamide have been carried out over the temperature range of 60—90°C and the specific conductivity, $\kappa = 1.7 \exp -\{34 \times 10^3/\boldsymbol{RT}\}\ \Omega^{-1} \cdot \mathrm{cm}^{-1}$, has been determined.

2) The mechanism of conduction has been discussed in terms of the proton transfer, and the value of the potential barrier between two positions of equilibrium in the NH···O hydrogen bonds has been estimated.

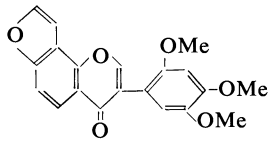
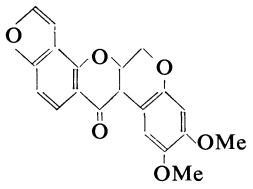
# NOTES



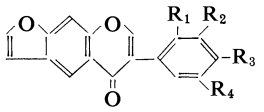
## The Synthesis of Isoelliptol Isoflavone*1

By Kenji FUKUI, Mitsuru NAKAYAMA, Atsushi TANAKA and Shigeo SASATANI



(Received July 27, 1964)

Elliptol isoflavone (furano(2'', 3''; 7, 8)-2', 4', 5'-trimethoxyisoflavone) (I)[1] was prepared from elliptone (II)[2] by Harper. Isoelliptol isoflavone (furano(2'', 3''; 6, 7)-2', 4', 5'-trimethoxyisoflavone) (III) may be obtained similarly from isoelliptone (IV), which was recently isolated by Ollis.[3]



In a previous paper,[4] I was obtained from 7-hydroxy-2', 4', 5'-trimethoxyisoflavone.[5] In the present paper, the synthesis of III will be described. The method used here was virtually identical with that reported for dehydronepseudin (V).[6]

of polyphosphoric acid to give 6-hydroxy-5-(2, 4, 5-trimethoxyphenylacetyl)-2, 3-dihydrobenzo[b]furan (VII) (m. p. 176—177°C). The treatment of VII with ethyl orthoformate-pyridine-piperidine[9] gave the dihydrofurano-isoflavone (VIII) (m. p. 197—198°C). The dehydrogenation of VIII with *N*-bromosuccinimide in carbon tetrachloride gave the furanoisoflavone (III) (m. p. 190—190.5°C) in a 53% yield. The ultraviolet spectra of I, III and VIII are shown in Fig. 1. There are two absorption bands at ca. 230—250 m$\mu$ (band I) and at ca. 300—310 m$\mu$. Band I is due to furano benzenoid and dihydrofurano benzenoid. The dehydrogenation of the dihydrofurano nucleus showed a marked hyperchromic effect. This phenomenon was well exemplified by pachyrrhizin and dihydropachyrrhizin[10] and similar substances[6]. On an alkaline hydrolysis, III gave 6-hydroxy-5-(2, 4, 5-trimethoxyphenylacetyl)benzo[b]furan (IX) (m. p. 169—170°C). The parent isoflavone, III, could be reconstructed from IX by Venkataraman's method.[9] On the basis of this fact, the structure of III was established.

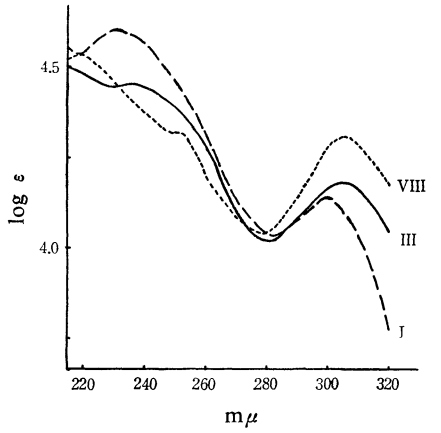

Fig. 1. Ultraviolet Spectra of I, III and VIII.

## Experimental*2

**6-Hydroxy-5-(2, 4, 5-trimethoxyphenylacetyl)-2, 3-dihydrobenzo[b]furan (VII).** — A mixture of VI[7] (1.0 g.), homoasaronic acid[8] (1.6 g.) and polyphosphoric acid ($n$=2.5) (10 g.) was warmed on a steam bath for 15 min. The dark red solution was then poured into ice water, and the resulting product was collected. After being washed with aqueous sodium bicarbonate and then with water, the residue was recrystallized from ethanol to give VII in the form of colorless prisms (m. p. 176—177°C),[11] which were reddish brown in a ferric chloride test in ethanol; yield, 1.1 g. (45%). IR; 1628 (C=O) cm$^{-1}$. UV; $\lambda_{max}$ m$\mu$(log $\varepsilon$); 235 (4.22), 284 (4.18), 332 (4.00).

Found: C, 66.18; H, 5.90. Calcd. for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%.

**4'', 5''-Dihydrofurano (2'', 3''; 6, 7)-2', 4', 5'-trimethoxyisoflavone (VIII).**—To a solution of VII (2.2 g.) and ethyl orthoformate (8.8 ml.) in pyridine (33 ml.), piperidine (1.1 ml.) was added; the mixture was then refluxed for 24 hr. The cooled reaction mixture was poured into ice-cold dilute hydrochloric acid, and the resulting precipitates were collected. After being washed with water, the residue was recrystallized from ethanol to give VIII in the form of colorless needles (m. p. 197—198°C); yield, 1.7 g. (75%). IR: 1648 ($\gamma$-pyrone) cm$^{-1}$. UV: $\lambda_{max}$ m$\mu$ (log. $\varepsilon$); $250_1$ (4.32), 305 (4.28).

Found; C, 67.95; H, 5.31. Calcd. for $C_{20}H_{18}O_6$: C, 67.79; H, 5.12%.

9) V. R. Sathe and K. Venkataraman, *Current Sci. (India)*, **18**, 373 (1949); *Chem. Abstr.*, **44**, 8916 (1950).

10) E. Simonitsch, H. Frei and H. Schmid, *Monatsh*, **88**, 541 (1957).

*2 All melting points are uncorrected; the infrared spectra were measured in Nujol, while the ultraviolet spectra were measured in an ethanol solution.

11) Y. Kawase, M. Nanbu, M. Uchida and Y. Kugo, 17th Annual Meeting of the Chemical Society of Japan, Tokyo, 1964.

**Isoelliptol Isoflavone (Furano(2'',3'' ; 6,7)-2',4',5'-trimethoxyisoflavone) (III).**—The mixture of VIII (1.7 g.), *N*-bromosuccinimide (0.85 g.) and benzoyl peroxide (0.05 g.) in carbon tetrachloride (130 ml.) was refluxed gently for 2.5 hr. After they had cooled, the precipitates were filtered off, and the filtrate was washed with a sodium bisulfite solution and with water and dried over calcium chloride. The evaporation of the filtrate under reduced pressure left a light yellow solid. After the addition of acetic acid (70 ml.) and potassium acetate (10 g.), the mixture was refluxed for one hour and then poured into water (1000 ml.). The resulting precipitates were collected and recrystallized from ethanol to give III in the form of colorless needles (m. p. 190—190.5°C) ; yield, 0.9 g. (53%). IR : 1634 ($\gamma$-pyrone) $cm^{-1}$. UV $\lambda_{max}$ m$\mu$ (log $\varepsilon$) ; 236 (4.44), 304 (4.18).

Found : C, 67.93 ; H, 4.69. Calcd. for $C_{20}H_{16}O_6$ : C, 68.18, H, 4.58%.

**6-Hydroxy-5-(2, 4, 5-trimethoxyphenylacetyl)-benzo[b]furan (IX).**—A mixture of III (0.6 g.), a 5% aqueous sodium hydroxide solution (40 ml.) and ethanol (60 ml.) was refluxed for 2 hr. on a steam bath. After the solvent had been evaporated, the residue was extracted with ethyl acetate. The resulting precipitates were recrystallized from ethanol to give IX in the form of pale yellow needles (m. p. 169—170°C), which were reddish brown in a ferric chloride test in ethanol ; yield, 0.4 g. (69%). IR : 1639 (C=O) $cm^{-1}$. UV : $\lambda_{max}$ m$\mu$ (log $\varepsilon$) ; 236 (4.41), 283 (4.13), 331 (3.98).

Found : C, 66.49 ; H, 5.58. Calcd. for $C_{19}H_{18}O_6$ : C, 66.66 ; H, 5.30%.

**The Recyclization of IX.**—By a reaction similar to that of VII, III was prepared from IX (0.2 g.), ethyl orthoformate (1 ml.), pyridine (10 ml.) and piperidine (5 drops). Recrystallization from ethanol gave III (m. p. 189—190°C), which was identical with the above sample ; yield, 0.15 g. (71%).

The authors are grateful to Professor Tetsuo Mitsui, Kyoto University, for making the microanalyses. This work was supported in part by a grant-in-aid from the Ministry of Education.

# Use of the Synergic Solvent Extraction System for the Determination of the Stability Constants of Metal Complexes

By Tatsuya SEKINE, Mitsuo SAKAIRI, Fumitake SHIMADA and Yuko HASEGAWA

(Received August 14, 1964)

The liquid-liquid partition method has been used for the determination of the stability constants of metal complexes.

When a metal ion, $M^{m+}$, is extracted with an organophilic chelating acid, HA, the net distribution ratio, $D=[M]_{total,\,org}/[M]_{total,\,aq}$, and the extraction constant, $K_0$, can be described as:

$$M^{m+}+mHA(org)\rightleftarrows MA_m(org)+mH^+ \quad (1)$$

$$D=[MA_m]_{org}/[M^{m+}] \quad (2)$$

$$K_0=D[H^+]^m[HA]_{org}^{-m} \quad (3)$$

where the suffix "org" denotes the chemical species in the organic phase and "0" denotes no complex formation in the aqueous phase.

Metal complex formation in the aqueous phase with a ligand, $L^{l-}$, decreases the concentration of the free metal ion and:

$$[M]_{total,aq}=[M^{m+}](1+\sum_1^n\beta_n[L^{l-}]^n) \quad (4)$$

$$K=[MA_m]_{org}[H^+]^m[HA]_{org}^{-m}/[M^{m+}](1+\sum_1^n\beta_n[L^{l-}]^n) \quad (5)$$

Here, $\beta_n$ is the over-all stability constant of the $n$th complex:

$$\beta_n=[ML_n^{m-nl}]/[M^{m+}][L^{l-}]^n \quad (6)$$

Therefore, the stability constants can be calculated by the following equation:

$$K_0/K=1+\sum_1^n\beta_n[L^{l-}]^n \quad (7)$$

However, the metal ion in the aqueous phase sometimes forms complexes not only with the ligand to be studied, $L^{l-}$, but also with the extracting chelating acid, HA, which has been distributed from the organic phase into the aqueous phase; the latter complexes, $MA^{m-1}$, $MA_2^{m-2}$, ..., also decrease the concentration of the free metal ion, just as has been shown in Eq. 4:

$$[M]_{total,\ aq}=[M^{m+}](1+\sum_{1}^{n}\beta_n'[A^-]^n) \quad (8)$$

Here, $\beta_n'=[MA_n^{m-n}]/[M^{m+}][A^-]^n$ and the distribution ratio in such systems can be written from Eq. 8, using $K_a=[H^+][A^-]/[HA]$, $K_D=[HA]_{org}/[HA]$, as:

$$D=[MA_m]_{org}/[M^{m+}]\{1+\sum_{1}^{n}\beta_n'(K_a[HA]_{org}/K_D[H^+])^n\} \quad (9)$$

and the distribution constant becomes:

$$K_0'=K_0/\{1+\sum_{1}^{n}\beta_n'(K_a[HA]_{org}/K_D[H^+])^n\} \quad (10)$$

Equation 10 indicates that the extraction constant, $K_0$, calculated by Eq. 3 is decreased by the increase in $[HA]_{org}/[H^+]$ and that thus the aqueous chelate complexes may cause a systematic error in the stability constants calculated by Eq. 7.

This deviation of $K_0$ from the constant value by the aqueous chelate complexes would be decreased by the use of the "synergic" solvent extraction system.*

When a neutral organophilic ligand, N, is added to a chelate extraction system, adduct complexes are sometimes formed:

$$MA_m(org)+nN(org)\rightleftarrows MA_mN_n(org) \quad (11)$$

$$[M]_{total,\ org}=[MA_m]_{org}(1+\sum_{1}^{n}\beta_n''[N]_{org}^n) \quad (12)$$

where $\beta_n''$ is the stability constant of the $n$th adduct complex; that is,

$$\beta_n''=[MA_mN_n]_{org}/[MA_m]_{org}[N]_{org}^n \quad (13)$$

Therefore, the net distribution ratio is:

$$D=[MA_m]_{org}(1+\sum_{1}^{n}\beta_n''[N]_{org}^n)/[M^{m+}] \quad (14)$$

Thus the adduct formation of the chelate complexes in the organic phase makes the metal extraction $(1+\sum_{1}^{n}\beta_n''[N]_{org}^n)$ times higher, and so one can obtain a certain distribution ratio of the metal at a lower $[HA]_{org}/[H^+]$ value.

## Experimental

All the reagents used were of analytical or reagent grade. Europium 152+154 in a tracer concentration was used for the determination of the net distribution ratio. Stoppered glass tubes were added with each 5 ml. of the organic and aqueous solutions and were then agitated mechanically in a thermostatted room at 25°C. Thenoyltrifluoroacetone (TTA) was used as the chelating ligand, and tributylphosphate (TBP) was used as the adduct-forming ligand, the organic solvent being hexane. The aqueous phase was a 0.1 M sodium perchlorate solution buffered with a small amount of sulfanilate or acetate. The hydrogen ion concentration was measured potentiometrically, and the $\gamma$ count-rate was determined with a well-type scintillation counter.

## Results and Discussion

Figure 1-a gives the plot of log $D$ vs. log $[H^+]^{-1}$, while Fig. 1-b gives the corresponding extraction constant calculated by Eq. 3. Figure 2 gives the increase in the extraction constant brought about by the addition of the adduct-forming ligand when the concentration of the chelating ligand is constant.

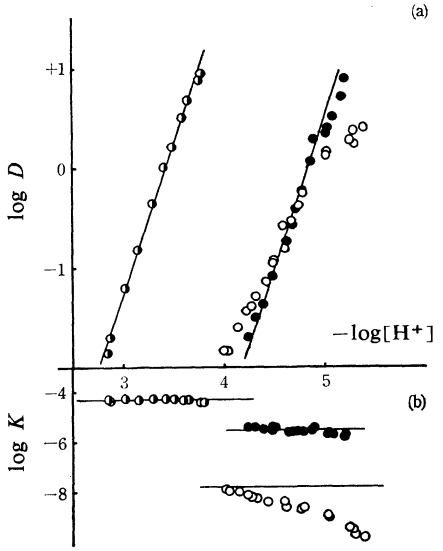

Fig. 1. (a) Distribution ratio of europium(III) as a function of a log $[H^+]^{-1}$. (b) Extraction constant of europium(III) calculated from the data in Fig. 1-a. (cf., Eq. 3).
Aqueous phase: 0.1 M $NaClO_4$
Organic phase: ○, 0.01 M TTA; ●, 0.001 M TTA + $3\times10^{-5}$ M TBP; ◐, 0.01 M TTA + $1\times10^{-4}$ M TBP; in hexane.

Equation 3 shows that $D$ should be proportional to $[H^+]^{-3}$ if $Eu^{3+}$ is the only metal species in the aqueous phase at a constant $[HA]_{org}$ value. However, it may be seen in Fig. 1-a that the plot of log $D$ vs. log $[H^+]^{-1}$ of the extraction with 0.01 M TTA (open circles) deviates somewhat from slope 3, this

* The synergic effect has been reported on the extraction of the actinides in various oxidation states, trivalent lanthanides, $Ca^{2+}$, $Sr^{2+}$, $Cu^{2+}$, $Zn^{2+}$, etc., with several chelating ligands and neutral ligands. A short review of the synergic solvent extraction systems was given in Ref. 1.

1) T. Sekine and D. Dyrssen, *J. Inorg. Nucl. Chem.*, **26**, 1727 (1964).

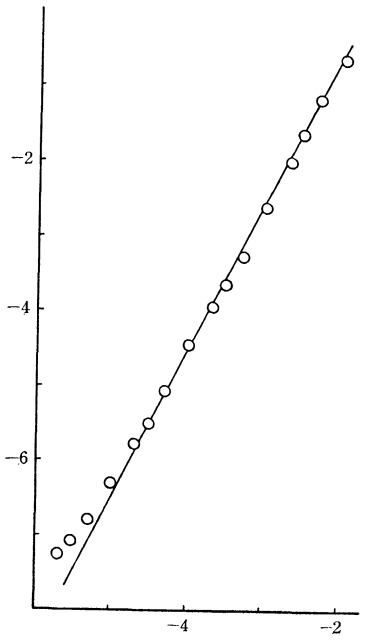

Fig. 2. Variation of the extraction constant (cf., Eq. 3) of europium(III) with 0.01 M TTA in hexane by the addition of TBP.

deviation may be due to the aqueous chelate complex formation. On the other hand, the $D$ is proportional to $[H^+]^{-3}$ in the synergic extraction systems (closed and semiclosed circles); this may be expected from the facts that the $[HA]_{org}/[H^+]$ value for a certain $D$ value is smaller in the synergic extraction systems and that, consequently, the concentration of the aqueous chelate complexes is smaller in these systems.

The extraction constants calculated from these data seem to show this more clearly. In Fig. 1-b, the extraction constant, $K_0$, in the single extraction system deviates very much from the constant value, but those in the synergic systems give nearly constant values (the log $K_0$ value is $-5.52$ for 0.001 M TTA+$3\times10^{-5}$ M TBP and $-4.32$ for 0.01 M TTA+$1\times10^{-4}$ M TBP). Thus, it may be concluded that the determination of $\beta_n$ by Eq. 7 is possible only by the use of the synergic extraction system in the present case.

There is another advantage in the use of the synergic extraction system. As may be seen in Fig. 2, the extraction constant in the metal extraction system can be varied very widely only by changing the concentration of the adduct-forming ligand. For example, one can obtain the 50% extraction of europium(III) with 0.01 M TTA in hexane between log $[H^+]^{-1}$ at 5.0($[TBP]_{org}$ is zero) and at 2.0($[TBP]_{org}$ is about 0.03 M). Thus, the use of one mixed ligand extraction system is worth several single extraction systems with different abilities of metal extraction.

Examples of the determination of stability constants by the synergic extraction system can be seen in Ref. 2.

# Synthesis of ε-Caprolactam from Cyclohexanecarboxylic Acid by Using Liquid Sulfur Dioxide*

By Niichiro TOKURA, Tetsuyo KAWAHARA and Tadao SATO

(Received September 4, 1964)

Recently two attractive ways of ε-caprolactam syntheses have been disclosed by research groups, one being the synthesis of cyclohexanone oxime via the photonitrosochlorination of cyclohexane,[1] and the other the so-called SNIA process.[2] The latter process consists of the production of ε-caprolactam from cyclohexanecarboxylic acid and a related compound by the action of nitrosylsulfuric acid;

* The Beckmann Rearrangement in Liquid Sulfur Dioxide, Part XII. Part XI: N. Tokura, K. Shiina and T. Terashima, This Bulletin, 35, 1986 (1962).

1) A. E. Müller, *Angew. Chem.*, 71, 229 (1959); *Chem. Ber.*, 90, 1179 (1959); ibid., 92, 63 (1959). B. M. Ito, *J. Soc. Org. Synth. Chem., Japan*, 21, 160 (1963).

2) SNIA Viscosa, Ital. Pat. 603606 (1960); *Chem. Abstr.*, 59, 11273 (1963); Belg. Pat. 582793 ((1960).

the mechanism has also been discussed.[3] Cyclohexane derivatives other than cyclohexanecarboxylic acid, such as cyclohexyl aryl ketones and cyclohexanesulfonic acid, have also been suggested as possible starting materials.[2]

This paper will present a simpler method for converting cyclohexanecarboxylic acid into ε-caprolactam, using liquid sulfur dioxide as the solvent as well as the reagent. When cyclohexanecarboxylic acid was stirred into a mixture of liquid sulfur dioxide, nitric acid and sulfuric acid and the reaction was carried out at a moderate temperature for an appropriate time, ε-caprolactam could be prepared in a fair yield. In the procedure described above, it seems likely that nitrosylsulfuric acid or a reagent which could behave like nitrosylsulfuric acid may be prepared in situ in the reaction mixture from nitric acid and liquid sulfur dioxide.

## Experimental

**Materials.**—Liquid sulfur dioxide was dried with phosphorus pentoxide and distilled. Commercial fuming nitric acid (sp. gr. 15°, 1.50) was used without further purification. Cyclohexanecarboxylic acid was distilled in vacuo; m. p. 31°C, b. p. 232—233°C. Sulfur trioxide was used after one distillation. Sulfuric acid (100% or sulfur trioxide monohydrate) was prepared from 95% sulfuric acid and sulfur trioxide. Chloroform and ether were purified by the ordinary recipes.

**A Typical Procedure.**—Two hundred milliliters of sulfur dioxide was distilled while being stirred into a three-necked flask cooled to −20°C, placed in a dry ice bath and equipped with a deep-freezing cooler. To this solution, 18.9 g. (0.30 mol.) of fuming nitric acid was added slowly; the white crystals which separated in the bottom of the flask dissolved again upon the addition of fuming sulfuric acid. After the dropping of nitric acid was over, fuming sulfuric acid, prepared by mixing 39.2 g. (0.4 mol.) of 100% sulfuric acid and 11.2 g. (0.14 mol.) of sulfur trioxide, was added. To this mixture, 25 g. (0.20 mol.) of cyclohexanecarboxylic acid was added slowly. The temperature was gradually raised to 68—70°C, while the excess sulfur dioxide was purged through the top of the cooler. The mixture was stirred for one more hour, cooled, and poured into ice-water.

The resultant solution was extracted with ether several times to recover the unchanged cyclohexanecarboxylic acid. The aqueous layer was neutralized with a sodium hydroxide solution, and the separated crystal of sodium sulfate was filtered off. Then the solution was repeatedly extracted with chloroform. The chloroform extract was dried over anhydrous sodium sulfate and distilled. ε-Caprolactam distilled under reduced pressure at 120—130°C/5.6 mmHg and solidified to white needles, m. p. (recrystallized from petroleum ether) and mixed m. p. 68—70°C. The infrared spectrum of this sample was superimposable on that of the authentic ε-caprolactam; yield, 12.7 g. (60%, based on the consumed carboxylic acid; 3.7 g. of cyclohexanecarboxylic acid was recovered).

Below 30°C the reaction does not take place. Among the factors which may affect the yield, the reaction temperature seems to be most important.

## Results and Discussion

The process employed here for the synthesis of ε-caprolactam is similar to that employed in the SNIA process except that the former uses liquid sulfur dioxide with fuming nitric acid instead of nitrosylsulfuric acid. It was obvious that, by adding fuming nitric acid to chilled sulfur dioxide, either nitrosylsulfuric acid or a reagent which would behave like nitrosylsulfuric acid was produced in the mixture. A number of methods for preparing nitrosylsulfuric acid have been published.[4] Among them, the introduction of sulfur dioxide gas into nitric acid is the most popular.[4b] However, the present authors believe that the method described in this article is without doubt a simpler method for the conversion of the carboxylic acid to the lactam.

Though the structure of the white crystals formed in the reaction mixture when fuming nitric acid was added to liquid sulfur dioxide have not yet been confirmed, it is believed to be nitrosylsulfuric acid, since the decomposition temperature of the crystal was 68—73°C (literature; [4a] 73.5°C) and the solubility (soluble in sulfuric acid and insoluble in liquid sulfur dioxide) resembled that of nitrosylsulfuric acid. An experiment was carried out using nitrosylsulfuric acid synthesized by the method of Ref. 4b to find out whether the yield was comparable to the above case. In part, a complex formed in situ from sulfur dioxide and nitric acid or a precursor of nitrosylsulfuric acid may also be the effective reagent for the reaction, since the separated crystals were small in amount and since the heat of reaction seemed to be very little.

At the beginning of this project the present authors expected a smooth running of the reaction at below-zero temperatures, since the process is thought to be a combination of nitrosation and the Beckmann rearrangement, which can occur even at −70°C. However, the reaction cannot be carried out below +30°C. This means that the nitrosation needs a somewhat higher energy of activation. A yield of 26% was recorded by the reaction at 30°C. The yield much improves at 68—70°C which

is near the decomposition temperature (73.5°C) of nitrosylsulfuric acid. In such a temperature range the concentration of the effective nitrosonium ion ($NO^+$) may become higher. A search for better conditions and an elucidation of the reaction mechanism is now under way.

The authors wish to acknowledge the gift of liquid sulfur dioxide by the Seitetsu Kagaku Co.

# Pulse Radiolysis Applied to Polymerization Reactions: The Intermediate in the Radiation-Induced Polymerization of $\alpha$-Methylstyrene*

By Meiseki KATAYAMA, Motoyoshi HATADA, Kozo HIROTA, Hatsuo YAMAZAKI and Yasutomo OZAWA

(Received September 12, 1964)

A reaction intermediate of radiation-induced polymerization has been observed for the first time in extremely dried $\alpha$-methylstyrene by means of pulse radiolysis. The indication that an anion radical plays an important role in the $\gamma$-ray-induced polymerization arose during the study of sodium-dried $\alpha$-methylstyrene at room temperature,[1] in which a $G$(-monomer) value as high as 36500 was obtained. The main bases on which the intermediate was postulated were; 1) a radical scavenger such as DPPH practically inhibited the reaction, as did an ion scavenger, water, and 2) no copolymer was found in the mixture of $\alpha$-methylstyrene and isobutylene which is known to polymerize through a cationic intermediate, while a copolymer had been found in the mixture of $\alpha$-methylstyrene and methylmethacrylate,[2] which is known to polymerize through a radical intermediate.

There has been a dispute about the reaction mechanism for some time. It seems that much of the discussion has been concerned with the radical and the cationic intermediates; the importance of the anion radical has been overlooked entirely. Although in only a few cases is the anion radical suggested in the radiation-induced polymerization, there are several examples of such an intermediate in such cases as the so-called anionic polymerization initiated by alkali metal.[3] The present investigation has had the purpose of confirming the anion radical mechanism in the radiation-induced polymerization[1] and of obtaining quantitative rate data by the direct observation of the reaction intermediate.

The experimental method is only briefly explained below, because the details will be published elsewhere. The monomer, dried by passing it through a sodium-potassium alloy,** and sealed into a high-purity quartz cell provided with optically-flat windows, was irradiated by a 1.6 $\mu$sec. electron pulse from a Fuji Denki lineac modified to give a single pulse, the energy of which was 4 MeV.; the peak current was $7.5\times10^{-2}$ amp. The electron beam was collimated on the wall of the cell with a diameter of about 1 cm. In the determination of spectra, the cell was irradiated cross-wise. The light source, a quartz tube equipped with tungsten electrodes, containing 75 mmHg xenon, was flashed by discharging a 2 $\mu$f condenser charged to 6 kV. by means of a 2G22P hydrogen thyratron.[4] It was triggered by a signal from the lineac at any delayed time designed by utilizing the delayed trigger circuit of a synchroscope. The duration of the flash was estimated to be 20 $\mu$sec.

** A novel technique for drying the monomer has been developed in the Chemistry Lab. of Hokkaido University. It was found quite satisfactory for drying styrene; details will be given in a coming publication.

4) J. H. Callomon and D. A. Ramsay, *Can. J. Phys.*, 35, 129 (1957).

The spectra was taken on a spectroscopic process-type Fuji plate by means of a Shimadzu quartz spectrograph. The plate was developed and subsequently fixed according to the recommendations of the manufacturer.

It has been reported[5] that when α-methylstyrene is brought in contact with sodium metal, it turns pale yellow and has an absorption maximum at 3275Å, while after a long time has elapsed or when it is heated it turns red, with the maximum shifting to 5100Å.

In the present investigation, a broad transient absorption below 3500Å was observed in

3: in the presence of DPPH

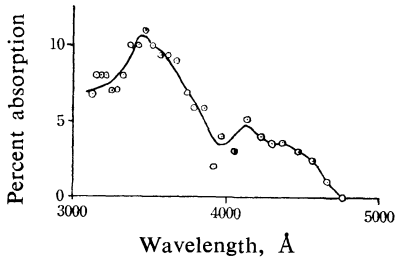

Fig. 2. Absorption spectrum of transient species in extremely dried α-methylstyrene.

the dried α-methylstyrene. 1a and 1b in Fig. 1 show spectra typical of such investigations. The 1a is the spectrum taken 1.6 μsec. after the irradiation of a pulse, while 1b is the spectrum taken without irradiation. The difference in the densitometer reading between 1a and 1b shows (Fig. 2) an absorption maximum at 3500Å, as was visually observed in 1a with a shoulder at about 4200Å. The lower the beam current of the pulse, the weaker became the absorption, and it practically disappeared after a few tenths of a millisecond. We believe that this maximum is in good correspondence with that of 3275Å observed in the sodium-α-methylstyrene system, considering the possible solvent effects, ion pair formation, etc., in the latter system, and that this constitutes a support for the existence of an anion radical in the radiation-induced polymerization of α-methylstyrene.

There still is uncertainty, however, that the absorbing species might not be the one which leads to the polymerization. Since it is known, as has been stated above, that the reaction is practically inhibited by the addition of a small amount of water or DPPH, the transient absorption observed in the dried monomer should diminish upon the addition of these compounds if it is caused by the reaction intermediate. This point has been tested, and this has been found to be the case. 2a and 2b in Fig. 1 show the effect of added water. The spectrum 2a in the figure was obtained 1.6 μsec. after the pulse, and 2b, without it. A visual comparison of these spectra shows that there is hardly any absorption. The densitometer reading also showed only a very weak absorption at the lower wavelength. In the experiment, water was added by the equilibration of the dried monomer with atmospheric moisture. 3a and 3b show the effect of added DPPH in less than $10^{-4}$ M. The notations a and b correspond to those used with the earlier pairs. The densitometer reading revealed that the absorption was greatly diminished, as can be seen by a visual comparison.

In conclusion, new support for the postulated anion radical mechanism in the radiation-induced polymerization of α-methylstyrene has been obtained by the present investigation.

# A Simple Method for Preparing Metallocenes

By Hamao WATANABE, Izumi MOTOYAMA and Kazuo HATA

(Received September 26, 1964)

Many sorts of metallocenes have already been synthesized in various methods by many investigators. However, only a one-step method for the preparation of ferrocene has been proposed;[1] this method consists of a direct reaction between ferric chloride and cyclopentadiene in the presence of an organic base, without the reduction procedure of ferric chloride to ferrous chloride. No simple and convenient method for the direct preparation of metallocenes other than ferrocene has yet been reported.

The present authors wish to report on a simple method for the preparation of such metallocenes as cobaltocene and nickelocene as well as of ferrocene. They can be synthesized in good yields by this convenient procedure.

The reactions of ferric chloride, cobaltous chloride, and nickel chloride with cyclopentadiene were carried out in the presence of an excess of diethylamine. The yields of metallocenes were 84% for ferrocene, 28% for cobaltocene, and 66% for nickelocene. In this procedure the formation of the metallocenes is considered to proceed through the following mechanism: by the reaction of the metal chloride and diethylamine, a corresponding ammine-complex salt of the metal is formed, and the complex salt reacts with cyclopentadiene, which has previously been de-protonated by strongly basic diethylamine.[2]

The infrared spectra of all these metallocenes have essentially identical absorption peaks at 3100 ($\nu_{C-H}$), 1430—1400 ($\nu_{C-C}$ ring), 1110—1100 (ring breathing), 1000 ($\delta_{C-H}$), 820—760 ($\delta_{C-H}$) and 1800—1550 $cm^{-1}$.

**The Synthesis of Ferrocene.**—Anhydrous ferric chloride (210.5 g., 1.30 mol.) was placed in a three-necked flask, equipped with a dropping funnel, a nitrogen inlet tube, a reflux condenser, and a stirrer. A stream of nitrogen was introduced, and dry diethylamine (320.5 g., 4.38 mol.) was added dropwise with stirring and cooling in an ice-water bath. A dark brown suspension was obtained. A mixture of dry cyclopentadiene (320.5 g., 4.85 mol.) and dry diethylamine (420.7 g., 5.76 mol.), previously cooled to 0——15°C with an ice-salt bath, was added with vigorous stirring into the suspension over several minutes. After vigorous stirring for an hour, additional gentle stirring was continued for 3 hr. The entire reaction mixture was then heated so as to evaporate almost to dryness, and then it was submitted to steam distillation in order to collect the ferrocene. During the distillation, a part of separated ferrocene was apt to accumulate in the condenser tube. It was dissolved out by benzene, which was occasionally supplied into the distilling flask. The combination of the steam distillation and the dissolution with benzene was continued until no more ferrocene was distilled out.[3] A mixture of ferrocene and other materials was then collected as a benzene solution. On concentration and cooling, ferrocene was crystallized from the solution, collected on a filter, washed with a small amount of ether, and air-dried. The mixture of the filtrate and the ethereal washing was further concentrated, and a second crop of ferrocene was obtained by a similar treatment. The procedure was repeated several times; the total yield of ferrocene amounted to 210.4 g. (84% based on ferric chloride).

**The Synthesis of Cobaltocene.**—In the same manner as was used with ferrocene, a deep blue mixture was prepared in a stream of nitrogen by the reaction of blue anhydrous chloride[4] obtained from its hydrate ($CoCl_2 \cdot 6H_2O$, 48.2 g., 0.20 mol.) and dry diethylamine (117.0 g., 1.60 mol.). After this mixture had been stirred for half an hour, a cold mixture of dry cyclopentadiene (49.3 g., 0.75 mol.) and dry diethylamine (64.9 g., 0.89 mol.) was added with stirring into the mixture over a 15-min. period. After the reaction mixture had been stirred for an hour, it was refluxed for 15 min. with stirring. The reaction mixture was then cooled to room temperature, and hexane was added in 3 portions (100, 100, and 50 ml.) which

3: Nickelocene in a KBr disk

has been previously deoxygenated by treatment with nitrogen. After each addition, the combined mixture was agitated thoroughly and left to stand until a violet-brown organic phase was separated as an upper layer. The organic layer was transferred to a round-bottomed flask by means of nitrogen pressure through a siphon, the inlet tube of which was covered with glass wool. The entire violet-brown organic solution was evaporated in a stream of nitrogen to give 12.0 g. of crude cobaltocene, which was then submitted to vacuum sublimation to obtain 10.5 g. (yield, 28%) of the pure substance as large, black-violet, glittering crystals.

**The Synthesis of Nickelocene.**—A deep violet-blue mixture was obtained by the reaction between yellow anhydrous nikel chloride[4] prepared from its hydrate ($NiCl_2 \cdot 6H_2O$, 47.7 g., 0.20 mol.) and dry diethylamine (117.0 g., 1.60 mol.) in the same as manner described above. The following procedure was similar to that used with cobaltocene, except for the addition of 250 ml. deoxygenated petroleum ether in place of hexane. The entire reaction mixture was then filtered, in air, as rapidly as possible. The deep green filtrate thus obtained was evaporated in a stream of nitrogen to give crude nickelocene, which was submitted to vacuum sublimation to obtain 25.1 g. (yield, 66%) of the pure substance as large, deep green, glittering crystals.

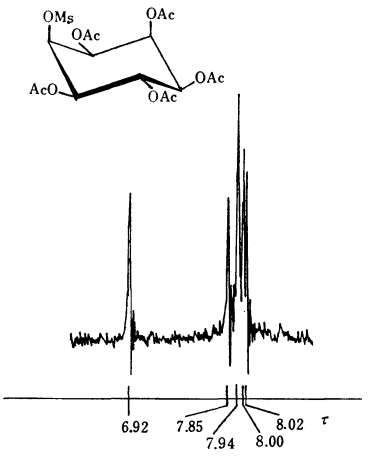
# Aminocyclitols. VII. A New Synthetic Route to *myo*-Inosamine-4

By Tetsuo SUAMI and Kenji YABE

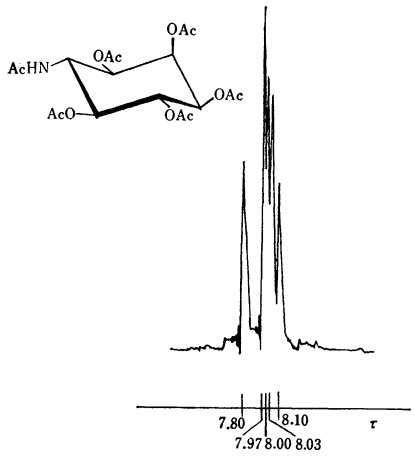
(Received October 1, 1964)



In a previous paper of this series,[1] the replacement of the mesyloxy group of 1-*O*-mesyl-*myo*-inositol pentaacetate by a highly nucleophilic azide ion has been described. In the present paper, the displacement of the mesyloxy group of (±)-2-*O*-mesyl-*epi*-inositol pentaacetate (II) by an azide ion is the main subject. II is prepared in 89% yield from (±)-1, 3, 4, 5, 6-penta-*O*-acetyl-*epi*-inositol (I)[2] by an ordinary procedure of mesylation.

The structure of II is substantiated by the NMR spectrum; as Fig. 1-A shows, the spectrum reveals a sharp signal at 7.85 $\tau$, corresponding to an axial acetoxy group, and sharp signals with a 2 : 1 : 1 relative intensity at 7.94, 8.00 and 8.02 $\tau$, corresponding to four equatorial acetoxy groups.[3] The protons of the mesyloxy group on C-2 reveals a sharp signal at 6.92 $\tau$, as is to be expected from an axial mesyloxy group.[4]

II is then treated with sodium azide in boiling aqueous 2-methoxyethanol for 20 hr. Since the product has been partially deacetylated during the course of the reaction, the product is acetylated with acetic anhydride and pyridine to give the azido derivative (III), m. p. 149—150°C, in 47% yield; this shows an infrared absorption characteristic of an azide group at 2100 $cm^{-1}$.[5] III is reduced with Raney nickel in a hydrogen stream. The reduction product is further acetylated with acetic anhydride and pyridine, giving hexaacetyl-inosamine (IV), m. p. 235—237°C, in 58% yield. *N*-Acetyl-inosamine (V), m. p. 268—269°C (decomp.), is obtained by the selective deacetylation of IV with methanolic ammonia.



Since both of the vicinal acetoxy groups with respect to the mesyloxy group are located in anchimerically unassisted cis positions in II, the replacement of the mesyloxy group by an azide ion must occur through a direct $S_N2$ mechanism,[6] as has been shown in the case of 1, 3-di-*O*-acetyl-2-*O*-mesyl-*cis*-1, 2, 3-cyclohexanetriol.[4] Therefore, the product, IV, is probably identical with (±)-*myo*-inosamine-4 hexaacetate, which has been described by Anderson et al.[7] The configuration of IV is substantiated by its NMR spectrum. The NMR spectrum of IV, as shown in Fig. 1-B, reveals a sharp signal at 7.80 $\tau$, corresponding to an axial acetoxy group, signals at 7.97 8.00 and 8.03 $\tau$, with a 2 : 1 : 1 relative intensity corresponding to four equatorial acetoxy groups, and one at 8.10 $\tau$, as is to be expected from an equatorial acetamido group.[3]

## Experimental

All melting points were measured on a Mitamura Riken micro hot plate. The NMR spectra were determined at a frequency of 60 Mc. p. s. with Japan Electron Optics JNM-C-60 and Hitachi Model H-6013 spectrometers in deuteriochloroform. Tetramethylsilane was used as an internal reference, and peak positions were given in $\tau$-values.

(±)-**2-*O*-Mesyl-*epi*-inositol Pentaacetate (II).**—To a mixture of 2.3 g. of (±)-1,3,4,5,6-penta-*O*-acetyl-*epi*-inositol and 30 ml. of pyridine, 1.0 g. of methanesulfonyl chloride was added under agitation at 0°C. After it had settled overnight in a refrigerator, the mixture was added to 45 ml. of ice cold water. The precipitate was then collected by filtration. The crude product (2.7 g.) was recrystallized from methanol to give 2.4 g. (89%) of needles melting at 196—197°C.

Found: C, 43.52; H, 5.36; S, 6.63. Calcd. for $C_{17}H_{24}O_{13}S$: C, 43.59; H, 5.16; S, 6.85%.

(±)-**4-Deoxy-4-azido-*myo*-inositol Pentaacetate (III).**—A mixture of 2.0 g. of II, 0.9 g. of sodium azide and 50 ml. of 80% aqueous 2-methoxyethanol was refluxed for 20 hr. The mixture was then evaporated to dryness in vacuo. The residue was repeatedly extracted with ethanol. The combined ethanol extract was evaporated, and the residue was added to a mixture of 20 ml. of acetic anhydride and 20 ml. of pyridine. The mixture was then evaporated in vacuo, and the residue was recrystallized twice from ethanol to give 0.84 g. of needles (46.6%) melting at 149.5—150°C.

Found: C, 46.47; H, 5.33; N, 10.07. Calcd. for $C_{16}H_{21}N_3O_{10}$: C, 46.26; H, 5.10; N, 10.12%.

(±)-**Hexaacetyl-*myo*-inosamine-4 (IV).**—A solution of 0.68 g. of III in 100 ml. of ethanol was hydrogenated with Raney nickel T4[8] in hydrogen at an initial pressure of 50 p. s. i. g. for 20 hr. Then the catalyst was removed by filtration, and the filtrate was evaporated in vacuo. The residue was acetylated with a mixture of acetic anhydride and pyridine. The crude product was repeatedly recrystallized from ethanol to give 0.33 g. of needles melting at 235—237°C. (Lit. m. p. 236—239°C).[7] (Found: C, 50.12; H, 5.71; N, 3.25%.)

(±)-***N*-Acetyl-*myo*-inosamine-4 (V).**—A 0.4 g. portion of IV was added to 50 ml. of methanol which had been previously saturated with ammonia. After it had settled overnight at room temperature, the mixture was evaporated under reduced pressure. The residue was washed with ethanol and then recrystallized from a mixture of ethanol and water (2 : 1), giving 0.18 g. (92.7%) of needles melting at 268—269°C (decomp.). [Lit. m. p. 270—271°C (decomp.)].[7] (Found: C, 43.54; H, 7.08; N, 6.40%.)

**Paper Chromatography.**—IV was hydrolyzed with boiling 6 N hydrochloric acid for 6 hr. Then the hydrolyzate was evaporated to dryness in vacuo. The residue was developed in an acetic acid - ethyl acetate - pyridine - water (3 : 5 : 5 : 1) system[9] in ascending paper chromatography. The hydrochloride showed a single spot of $R_f$ 0.24 at 22°C ($R_f$ of D-glucosamine hydrochloride: 0.46). $R_f/R_f$ glucosamine: 0.52 (Lit. $R_f$ DL-*myo*-inosamine-4/$R_f$ glucosamine: 0.53).[10]

The authors wish to thank Professor Sumio Umezawa for his helpful advice, Mr. Saburo Nakada for his elemental analyses, and the Japan Electron Optics Co., Ltd., and Hitachi, Ltd., for the NMR spectra. This research has been supported in part by a grant of the Ministry of Education, to which the authors' thanks are due.

# The Mechanism of the Photochromism and Thermochromism of 2, 2′, 4, 4′, 5, 5′-Hexaphenyl-1, 1′-biimidazolyl in a Solid State

By Taro HAYASHI, Koko MAEDA and Takako KANAJI

(Received October 3, 1964)

Photochromism and thermochromism are exhibited by 2, 2′, 4, 4′, 5, 5′-hexaphenyl-1, 1′-biimidazolyl in the solid state as well as in the solution. The pale yellow substance becomes reddish purple upon irradiation or when heated in a solid state[1], although the color is paler than that in the solution. The mechanism of these phenomena in the solution was previously reported[2] to be the reversible dissociation to the free radical, 2, 4, 5-triphenylimidazolyl.

An electron-spin resonance of hexaphenylbiimidazolyl which became pale reddish purple upon irradiation in a solid state with sunlight at 15°C for 10 min. was observed in a solid state at 15.0°C, the first derivative of a single absorption line where the $g$ value is 2.002 and the line width (from peak to peak) is about 7.8 gauss being measured.[3] Since hexaphenylbiimidazolyl which had been kept in the dark after recrystallization exhibited no ESR signal, this ESR measurement shows that the mechanism of the photochromism of hexaphenylbiimidazolyl in a solid state involves a free radical, probably 2, 4, 5-triphenyl-imidazolyl, as in a solution.

The absorption spectrum of hexaphenylbiimidazolyl in a solid state was measured in the visible region immediately after irradiation with a mercury vapor lamp at 15°C for 10 min. with a Hitachi recording spectrophotometer, the absorption maximum (554 m$\mu$) obtained by the reflection spectroscopic method[4] and the absorption maximum (562 m$\mu$) obtained by the opal glass transmission method[5] and the potassium bromide disk method[6] being shown respectively. The absorption maximum (554 m$\mu$) coincides with the one shown by 2, 4, 5-triphenylimidazolyl in an irradiated benzene solution, whereas the absorption maximum measured with the transmission method, the shift may be attributed to a weak absorption, extending from the ultraviolet region to 620 m$\mu$, by hexaphenyl-biimidazolyl, which exists (562 m$\mu$) shows a red shift of 8 m$\mu$. The species exhibiting the photochromic color in a solid state is most probably 2, 4, 5-triphenylimidazolyl, which shows an absorption maximum of 554 m$\mu$ in benzene. The mechanism of the photochromism of hexaphenyl-biimidazolyl in a solid state can, therefore, be concluded to be the radical dissociation of its N-N bond to triphenylimidazolyl radicals, similar to the mechanism in a solution.

Considering the thermochromic color in a solid state to be similar to the photochromic color, the exhibition of an ESR signal in the thermochromism in a solid state and the mechanism of the thermochromism in a solution,[2] the same mechanism can be applied to the thermochromism in a solid state.

The photochromic color in a solid state hardly faded in the dark at room temperature, whereas it gradually reverted to its original pale yellow color at about 40°C at which temperature the thermochromism is not observed. The decay rate of the intensity of the first derivative ESR spectrum, which is the rate of the recombination of the free radical, 2, 4, 5-triphenylimidazolyl, was measured in the dark at 46.0 and 62.5°C. Unlike the rate in a benzene solution,[2] the rate in a solid state did not obey the rate expression of the second-order reaction.

1) The photochromic color appears upon irradiation with sunlight or with a mercury lamp at room temperature, whereas the thermochromic color begins to appear at about 180°C, and the sample becomes intensely reddish purple when fused at 198—200°C. The rate of the disappearance of the color is very slow at room temperature.

3) Its spin concentration was about $8\times10^{17}$ spin/g.

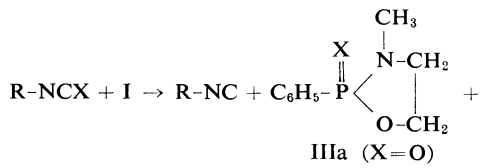
4) The mixture of hexaphenyl-biimidazolyl, (0.0149 g.) and magnesium oxide (1 g.) was used.

5) Hexaphenyl-biimidazolyl (1.5 mg.) was used.

6) A mixture of the sample (1.3 mg.) and potassium bromide (200 mg.) was used.

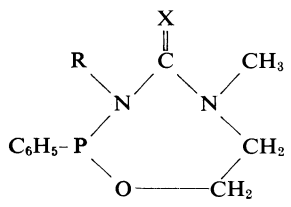
## SHORT COMMUNICATIONS

# The Deoxygenation of Isocyanates by 2-Phenyl-3-methyl-1, 3, 2-oxazaphospholidine. A Convenient Method for the Preparation of Isonitriles



By Teruaki MUKAIYAMA and Yukio YOKOTA

(Received January 25, 1965)



The preparation of 2-phenyl-3-methyl 1, 3, 2-oxazaphospholidine (I) and its application to a synthesis of isonitriles will be described.

The oxazaphospholidine, b. p. 72—75°C/0.3 mmHg (Found: C, 60.21; H, 6.64; N, 7.82. Calcd. for $C_9H_{12}ONP$: C, 59.66; H, 6.68; N, 7.72%), was prepared by treating phenylphosphonous dichloride[1] with 2-methylaminoethanol in the presence of two molecular equivalents of triethylamine (41% yield), or by heating a mixture of phenyl-di-diethylaminophosphine and 2-methylaminoethanol at 120—130°C for two hours (83% yield).

In a previous paper,[2] it was reported that several isonitriles were obtained in 20—57% yields by treating isocyanates with triethyl phosphite above 150°C. In the present study, it was found that I reacted with isocyanates or isothiocyanates at low temperatures (5—36°C) to form the corresponding isonitriles

IIIa (X=O)
IIIb (X=S)

IVa (X=O)
IVb (X=S)

(II) and 2-phenyl-3-methyl-1, 3, 2-oxyzaphospholidine-2-one (IIIa) or 2-phenyl-3-methyl-1,3,2-oxazaphospholidine-2-thione (IIIb) in high yields. IIIa or IIIb was always contaminated with a small amount of 3-substituted-per-2-phenyl-5-methyl-1, 3, 5, 2-oxadiazaphosphepine-4-one (IVa) or -4-thione (IVb). For example, when phenyl isocyanate was added drop-by-drop to a solution of I in petroleum ether (b. p. 34—36°C), the solution began to reflux. After the reaction mixture had been refluxed on a water bath for half an hour under nitrogen, the mixture was fractionated into two fractions. Fraction I was phenylisocyanide (b. p. 70—72°C/31 mmHg), and the yield was 57%. Fraction II consisted mainly of IIIa (b. p. 135—138°C/0.1 mmHg, m. p. 73—75°C) (Found: C, 54.94; H, 6.36; N, 7.26. Calcd. for $C_9H_{12}O_2NP$: C, 54.84; H, 6.11; N, 7.11%), plus a small amount of IVa.

Similarly, phenylisocyanide, *o*-tolylisocyanide, and *p*-chlorophenylisocyanide were obtained in 93, 70 and 51% yields respectively by a reaction of I with phenylisothiocyanate,* *o*-tolylisocyanate, and *p*-chlorophenylisocyanate in refluxing petroleum ether.

On the other hand, a solution of cyclohexylisocyanate and I in ligroin (b. p. 72—80°C) was refluxed on a water bath for two hours under nitrogen; a mixture of cyclohexylisocyanide and cyclohexylisocyanate, and IIIa (82%) were thus obtained, and 5% of I was recovered. The respective yields of cyclohexylisocyanide (74%) (b. p. 76—78°C/27 mmHg) (Found: C, 76.48; H, 10.64; N, 12.60. Calcd. for $C_7H_{11}N$: C, 77.01; H, 10.16; N, 12.83%) and cyclohexylisocyanate (8%) were determined by the addition of cyclohexylamine to the

# The Polymerization of Acetylene with Dicyclopentadienyl-titanium

By Kaiji YOKOKAWA and Keiichi AZUMA

(Received February 18, 1965)

It has previously been discovered that ethylene and propylene can easily be polymerized to polymers of a high crystallinity with a catalyst of titanium trichloride, polymethylhydrosiloxane and dicyclopentadienyl-titanium (DCT).[1] It has now been discovered that DCT is a good catalyst for the polymerization of acetylene also. Although a similar finding has been reported on the catalysis of dicyclopentadienyl-vanadium (DCV),[2] it is less reactive than DCT in the polymerization of acetylene under mild conditions.

DCT was prepared by the reduction of dicyclopentadienyl-titanium dichloride with sodium amalgam (the sodium concentration was 0.1 wt. % in mercury) in toluene under an argon atmosphere.[1]

As a typical experiment, 40 ml. of a toluene solution containing 0.24—1.0 mmol. of DCT was added to a 100-ml. three-necked flask equipped with a gas inlet, a gas outlet and a thermometer, under an argon atmosphere. Acetylene was then introduced, with vigorous agitation, through the gas inlet from a gas burette. The polymerization proceeded rapidly but was stopped after 60 min. at 30°C. Black or reddish-black solid polymers were obtained; no liquid products were found. No polymers were obtained with DCV under similar conditions. The results of the experiments are shown in Table I.

In an attempt to ascertain the properties of the polyacetylene obtained, 3.5% of it was extracted by boiling it with benzene for 12 hr. under an argon atmosphere. From infrared examinations it was elucidated that it contained trans-double bonds and that carbonyl groups were formed by exposure to air for a long time. The X-ray diffraction showed a sharp peak at $d=3.8$ Å, indicating the high crystallinity of the polymer. According to the thermal differential analysis, it was gradually oxidized by air, but it was stable in inert gas up to about 300°C. Those properties were the

| 12*** | 1.0 | 25 | 770 | 75 | 180 | 0.0 |

* The amount of DCT in the toluene solution was determined by the concentration of titanium as titanium dioxide. Forty milliliters solution was used in each experiment except No. 10.

** 240 ml. solution was used in a 300-ml. three necked flask.

*** In the experiments of No. 11 and No. 12, DCV was used in place of DCT. It was prepared in the same method as DCT, by the reduction of dicyclopentadienyl-vanadium dichloride with sodium amalgam.

same as those of the conjugated *trans*-polyacetylene obtained by Natta et al.[3] and by Hatano[4]. The polyacetylene obtained with DCT may be assumed to be similar to that obtained with DCV.[2]

In considering the catalytic behavior of metallocene, it is very interesting that acetylene polymerizes more easily with DCT than with DCV.

# The Constituents of the Flower Oil of Lily of the Valley[1)]

By Seiji WAKAYAMA and Satoshi NAMBA

(Received March 4, 1965)

The absolute oil of lily of the valley (*Convallaria keisukei Miq.*), which it is known, can not be obtained by steam distillation, has not well been investigated.[2)]

The extraction of the flower (100 kg.) with hexane afforded a yellowish-colored concrete (0.26% of the flower) which was then a digested with methanol.

The methanol-insoluble wax (0.13%) was found to contain palmitone triacontanol, wax with a m. p. of 68—69°C and nonacosane by the comparison of the infrared spectra with those of authentic specimens, by comparing the melting points of the derivatives, and by the elementary analyses.

The methanol-soluble part afforded a pale brown-colored essential oil (0.13%) on the removal of the methanol. About a half weight of the essential oil was a mixture of aliphatic acids; this mixture was collected by the treatment of the oil with sodium carbonate and was found to be composed of acetic, caproic, palmitic, stearic and linoleic acids.

The oil obtained on the removal of the acids had the properties of AV 6.3, EV 90.3, and HV 89.3 and gave no distillate under the diminished pressure of 2 mmHg. The essential oil (5.571 g.)

was subjected to separation by chromatography on alumina* (300 g.). The elutions were made with hexane, hexane-benzene (1 : 1), benzene and benzene-ethanol successively. Some fractions eluted with hexane gave a mixture of esters of aliphatic acids which was one of the major components of the oil (20—25%). It should be noted that these esters have afforded, on saponification, a mixture of fresh, lily-like scented alcohols, although the esters themselves smell faintly like the essence. The chromatography of the mixture of the alcohols on alumina with benzene resulted in the isolation of citronellol, nerol and cinnamyl alcohol. Those alcohols were identified on the basis of both the comparison of the infrared spectra with those of the respective authentic samples and the transformation into the derivatives; citronellol was converted into the silver salt of the acid phthalate[3] (m. p. 124.5—125°C); nerol, into the tetrabromide[4], (m. p. 115—117°C) and the allophanate[4] (m. p. 98.5—99.5°C), and cinnamyl alcohol, into the 3,5-dinitrobenzoate (m. p. 124.2—124.8°C). The acidic constituent consisted mainly of stearic acid.

Some fractions eluted with hexane-benzene afforded a mixture of esters. On saponification, it gave as an acidic component only phthalic acid, which melted at 213°C with decomposition into the anhydride (m. p. 130—131°C). The acid was also identified by derivation into the phenacyl ester (m. p. 152—152.7°C).

Fractions eluted with benzene emitted a lily-like scent, and the infrared spectra suggested that they were a mixture of citronellol and nerol. Rechromatography on alumina with benzene led to the isolation of those alcohols, which were identified as has been mentioned above.

Finally, cinnamyl alcohol was isolated by elution with benzene containing 1% ethanol, followed by rechromatography on alumina with benzene.

In summary citronellol, nerol and cinnamyl alcohol are the principal fragrant constituents of "lily of the valley," and they are present in the plant as both free alcohols and stearates.

Investigations of the other constituents are now in progress.

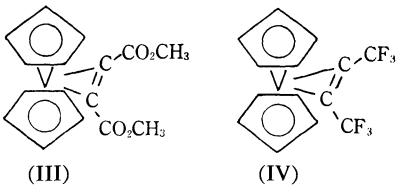
# Acetylene Complexes of Dicyclopentadienyl-vanadium

By Ryuichiro TSUMURA and Nobue HAGIHARA

(Received March 15, 1965)

Previous work has demonstrated a catalytic polymerization[1] of acetylenes with dicyclopentadienyl-vanadium[2] (I) and the preparation[3] of a series of acetylene complexes of vanadium, such as $\pi$-$C_5H_5(HC_2H)V(CO)_2$. The present communication will deal with the preparation of a few acetylene complexes of I as a model substance of an intermediate in the polymerization of acetylene with I. Although a great variety of transition metal-acetylene complexes are known,[4] the acetylene complexes described here may be the first examples of compounds in which the acetylenic bond is directly bonded to the metal coordinated by two $\pi$-cyclopentadienyl rings.



To a stirred, violet solution of 2.79 g. of I in 60 ml. of benzene, 2.40 g. of dimethyl acetylenedicarboxylate (II) was added drop by drop at a room temperature under nitrogen. The reaction solution almost instantaneously turned dark green, with a slight evolution of heat, and some dark-colored crystals precipitated spontaneously. After having been stirred at 50°C for 1 hr., the resulting reaction mixture was evaporated to dryness under reduced pressure. The residue was then recrystallized from toluene to yield 4.20 g. (84.5% yield) of air-sensitive, dark green crystals (III); m. p., 146—147°C (decomp.) (Found: C, 59.33; H, 4.99;

mol. wt. (cryoscopic in benzene), 314. Calcd. for $C_{16}H_{16}O_4V$: C, 59.45; H, 4.99%; mol. wt., 323).

The elemental analysis and molecular weight determination indicated a mononuclear vanadium complex with the composition: $(C_5H_5)_2VC_2(CO_2CH_3)_2$. The complex III is paramagnetic, and its electron paramagnetic resonance spectrum showed a *g*-factor of 1.9976 and a hyperfine splitting of 44.0 gauss. The treatment of III with chlorine in carbon tetrachloride gave the original acetylene II and dicyclopentadienyl-vanadium dichloride in 37 and 68% yields respectively. The reduction of III with a large excess of lithium aluminum hydride gave the starting complex I in a 6% yield. These facts suggest that, in the acetylene complex III, both of the $\pi$-cyclopentadienyl rings are left coordinated to vanadium, to which also the acetylene II itself is bonded.

The infrared spectrum of III showed a strong absorption at 1821 $cm^{-1}$; this is probably to be assigned to a carbon-carbon stretching vibration of a multiple bond of the acetylene. This absorption is shifted toward a lower frequency by the coordination of II to vanadium in a cis-type and is increased in intensity through conjugation with two adjacent keto-carbonyls of the esters groups. It may thus reasonably be concluded, in comparison with a proposed structure of the above-mentioned complex $\pi$-$C_5H_5(HC_2H)V(CO)_2$, that the new acetylene complex III has the structure represented in Fig. 1 (III), in which the acetylene is bonded via two $\sigma$-bondings to vanadium, simultaneously having two $\pi$-cyclopentadienyl rings.

(III) (IV)

Fig. 1. Acetylene complexes of dicyclopentadienyl-vanadium.

A similar reaction of I with perfluoro-2-butyne also gave air-sensitive, brown crystals of the corresponding acetylene complex (IV); m. p., 124—126°C (decomp.) (from *n*-hexane and toluene); yield; 87.0% (Found: C, 48.89; H, 3.07; mol. wt. (cryoscopic in benzene), 332. Calcd. for $C_{14}H_{10}F_6V$: C, 49.00; H, 2.94%; mol. wt., 343). The complex IV gave a paramagnetic resonance spectrum with a *g*-factor of 1.9971 and a hyperfine splitting of 46.0 gauss. The infrared spectrum of IV showed a strong absorption near 1800 $cm^{-1}$. This absorption may reasonably be assigned to the stretching vibration of the acetylenic bond, this assignment is consistent with its assignment in the case of the complex III. These facts suggest that the acetylene complex IV also possesses a structure similar to that of III, as is shown in Fig. 1 (IV).

The acetylene complexes III and IV are therefore presumed to reveal a model structure of an initial intermediate in the catalytic polymerization of acetylenes with I.

# Combination of Sulfuric Acid with Cellulose during the Hydrolysis with a Small Amount of Concentrated Sulfuric Acid

By Yoshio SAKAI

(Received August 1, 1963)

In the usual process of wood saccharification with concentrated sulfuric acid, the first stage of the process involves removal of hemicellulose from wood by mild hydrolysis and is called prehydrolysis. Cellulose in the residue of the first process is dissolved and hydrolyzed to a soluble glucose polymer[1] with concentrated sulfuric acid in the second process called mainhydrolysis. Finally, the polymer is hydrolyzed to glucose by dilute acid hydrolysis called posthydrolysis. In the mainhydrolysis a large amount of sulfuric acid is consumed.[2-5] This is a disadvantage of the concentrated sulfuric acid process, although the process has advantages such as large hydrolysis rate[6] and little erosion problem[7].

In order to determine the minimum quantity of sulfuric acid required in the mainhydrolysis, a diagram of the equilibrium relations of the system, soluble glucose polymer - sulfuric acid - water, has been obtained.[8] The dissolving power of sulfuric acid was not so large; for example, 100 parts of 72% sulfuric acid could dissolve and hydrolyze only 49 parts of cellulose to form the soluble glucose polymer, and 100 parts of 84% sulfuric acid was required for 82 parts of cellulose. The formation of a sulfuric acid - cellulose compound was observed in the course of hydrolysis and this compound seemed to play some chemical role in dissolving and hydrolyzing the cellulose, the extent of the combination of sulfuric acid with cellulose being an important factor in determining the yield of the soluble glucose polymer. In order to confirm this point the present work was undertaken. It was also expected to find out the reason why such large amounts of sulfuric acid are consumed during the hydrolysis.

## Material and Method

The experiments were carried out in a manner similar to that in the previous work, using the same material.[8]

Filter paper (Tôyô Roshi, No. 2), after being grated, was used as the cellulose sample. The cellulose flakes dried at 105°C (ca. 5 g.) were immersed in dilute sulfuric acid (20—50% concentration), and then filtered; the content of cellulose and sulfuric acid in the wet material was then calculated. The wet sample (ca. 1 g.) thus obtained was freeze-dried in a test tube for a few hours, until the weight loss reached the desired amount, and the test tube was then sealed under vacuum at low temperature. The weight of cellulose and sulfuric acid was calculated.

The sealed tube was heated in a water bath at 50°C for different periods of time. The tube was immediately cooled, the contents rinsed out with water, and centrifuged, and the insoluble sediment washed with water slightly acidified with hydrochloric acid; the centrifuging and the washing were repeated four times. The combined solution thus obtained was made up to 100 ml. with the requisite amount of hydrochloric acid to give a 2.5% hydrochloric acid concentration (solution I). A portion of solution I was heated at 100°C for 3 hr. to complete the hydrolysis of the soluble glucose polymer.[1]

Reducing sugar in solution I and in hydrolyzed solution I was determined by Somogyi's method.[9] From the amount of reducing sugar in hydrolyzed solution I, the weight of the soluble glucose polymer (as potential reducing sugar) dissolved in concentrated sulfuric acid was estimated. The value obtained by dividing the reducing power of hydrolyzed solution I by that of unhydrolyzed solution I was used as the average degree of polymerization of the soluble glucose polymer. Not only cellulose but also glucose polymer, both soluble and insoluble, are referred to as potential reducing sugars throughout this report.

Four determinations of sulfuric acid were carried out. (1) Sulfate ion in solution I; eqiuvalent to the amount of free sulfuric acid present in the concentrated sulfuric acid saturated with the soluble glucose polymer. (2) Sulfuric acid in the sediment decomposed by nitric acid; sulfuric acid combined with the insoluble glucose polymer.

(3) Sulfuric acid in solution I after the destruction of organic matter; total sulfuric acid (free acid plus combined acid) in the soluble glucose polymer - sulfuric acid - water system. (4) Sulfuric acid in solution I which had been hydrolyzed in 2.5% hydrochloric acid at 100°C for 3 hr.; values agree with those of (3) (Table I, t-test[10]). The amount of sulfuric acid obtained by (3) or (4) plus sulfuric acid by (2) agreed with the amount of sulfuric acid found by weighing the cellulose - sulfuric acid mixture, although they showed some fluctuations, as shown in Table I (t-test[10]). That the combined sulfuric acid is present as ester sulfate is shown from these results.

The sulfuric acid determinations were carried out by Morgulis and Hemphill's iodometric micro method.[11] Combined sulfuric acid was determined according to Hoffpauir and Guthrie's method[12] involving decomposition of the organic material with nitric acid to which a small amount of perchloric acid had been added.

## Results

The cellulose-concentrated sulfuric acid mixtures prepared by the freeze-drying process described above were heated at 50°C for different periods. Hydrolysis of the cellulose was accompanied by the formation of a cellulose - sulfuric acid compound. When the extent of hydrolysis of cellulose vs. time curve reached a plateau, the extent of sulfuric acid combination vs. time curve also leveled off. An example of the results is shown in Fig. 1. Soluble glucose polymer (SGP), sulfuric acid combined and average degree of polymerization of SGP in the equilibrium state were obtained from the straight lines in the figure. Table II lists the results of the reaction in different sulfuric acid concentrations. A higher extent of sulfuric acid combination was observed with higher concentrations of sulfuric acid. During the hydrolysis and the combination of sulfuric acid, water must have been consumed or formed. Therefore, the sulfuric acid concentration shown here is the initial one.

**Boundary between Concentrated and Dilute Sulfuric Acid in Cellulose Hydrolysis.** — Table III shows that when cellulose was hydrolyzed in 60 or 57% sulfuric acid, no sulfuric acid combines with the soluble glucose polymer and monomer, and only a slight amount is combined with the insoluble glucose polymer. On the other hand, when the concentration was 65% or higher, a significant amount of sulfuric acid combined with the soluble and the insoluble glucose polymers (Table II). Although the hydrolysis product of cellulose in 57% sulfuric acid consisted chiefly of glucose monomer (Table III, Fig. 5), the product in sulfuric acid of 60% or higher concentration had a significantly higher degree of polymerization (Table II). The action of sulfuric acid at about 60% or higher concentrations appears to be different from that at lower concentrations. This is supported by another experiment

which indicated that the hydrolysis rate constant of pentosan in 60% sulfuric acid deviates from the relationship between rate constant and acid concentration obtained in 50% and lower concentrations.[13]

**Effect of Sulfuric Acid Concentration on the Ratio of Combined Sulfuric Acid to Total Sulfuric Acid.** — When an equilibrium was established in hydrolysis of the cellulose with sulfuric acid of 66% or higher concentration, as shown in Fig. 1 (89% sulfuric acid), the ratio of the combined sulfuric acid to the total sulfuric acid showed a definite value. When the ratios (Table II) are plotted against the "initial" concentration of sulfuric acid, Fig. 2 is obtained. The following empirical equation is obtained from Fig. 2,

$$\log x = -3.047 + 0.0299\,C$$

or

$$x = 0.000897 \times \exp(0.0689\,C) \qquad (1)$$

13) T. Kobayashi, Y. Sakai and S. Mutoh, *Agr. Biol. Chem.*, **26**, 378 (1962).

TABLE III. COMBINATION OF SULFURIC ACID WITH CELLULOSE DURING HYDROLYSIS IN 60°C AND 57% SULFURIC ACID ($H_2SO_4$ : Cellulose=1.0)

| Initial concn. of $H_2SO_4$ | $H_2SO_4$ added to cellulose | $H_2SO_4$ in sol. part | | $H_2SO_4$ in insol. part | | Av. D. P. of sol. glucose polymer | Hydrolysis time at 50°C |
|---|---|---|---|---|---|---|---|
| | | Free $H_2SO_4$ | Combined $H_2SO_4$ | Combined $H_2SO_4$ | Combined $H_2SO_4$ per one glucose unit | | |
| % | mg. | mg. | mg. | mg. | mol./mol. | | hr. |
| 60 | 334 | 333 | 0 | 4 | 0.024 | 1.5 | 18 |

| | 332 | 331 | −1 | 4 | 0.024 | 1.8 | 48 |
| 57 | 334 | 332 | −2 | — | — | 1.0 | 63 |
| | 333 | 336 | 7 | 5 | 0.030 | 1.3 | 89 |
| | 360 | 353 | 2 | — | — | 0.9 | 96 |

where $C$ is "initial" concentration of sulfuric acid (%) and $x$, the ratio of combined sulfuric acid to total sulfuric acid. This equation indicates, for example, that when 100 g. of cellulose is hydrolyzed at 50°C in 72% sulfuric acid containing 50 g. of sulfuric acid, $50\times0.128=6.4$ g. of sulfuric acid reacts to form the cellulose - sulfuric acid compound.

**Ratio of Sulfuric Acid Combined with Soluble Glucose Polymer to Sulfuric Acid Combined with Insoluble Glucose Polymer.** — A part of the combined sulfuric acid is in combination with the soluble glucose polymer (SGP) and the other part with the insoluble glucose polymer (IGP). As shown in Fig. 1, the ratio of sulfuric acid combined with the SGP to that combined with the IGP is constant when the hydrolysis of cellulose is at equilibrium. This ratio (Table II) is shown in Fig. 3 against the "initial" concentration of sulfuric acid. The following empirical equation is obtained from the figure.

$$\log y = 0.0354\,C + 1.76\,r - 2.88$$

or
$$y = 0.00132 \exp(0.0815\,C + 4.06\,r) \qquad (2)$$

where $r$ is sulfuric acid : cellulose ratio and $y$, the ratio of sulfuric acid combined with SGP to that with IGP. This equation indicates, for example, that in the hydrolysis of cellulose in 72% sulfuric acid at 50°C, a proportion of $3.5/(3.5+1)$ to one of the combined sulfuric acid is in combination with SGP. So,

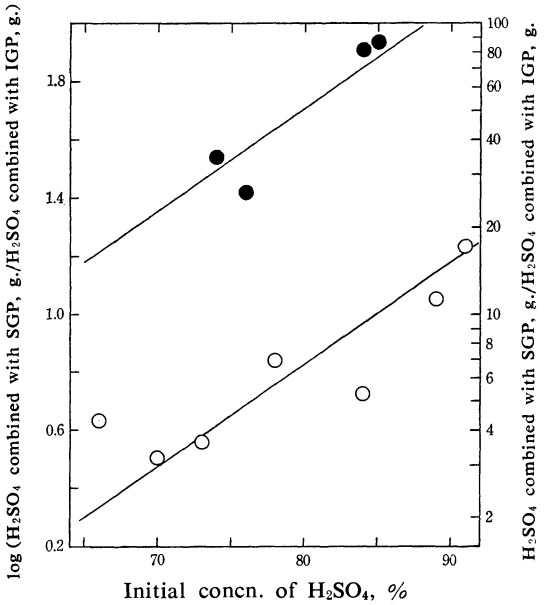

Fig. 3. Ratio of sulfuric acid combined with soluble glucose polymer to sulfuric acid combined with insoluble glucose polymer in different concentration of sulfuric acid.
$H_2SO_4$/Cellulose : ● 1.0, ○ 0.5

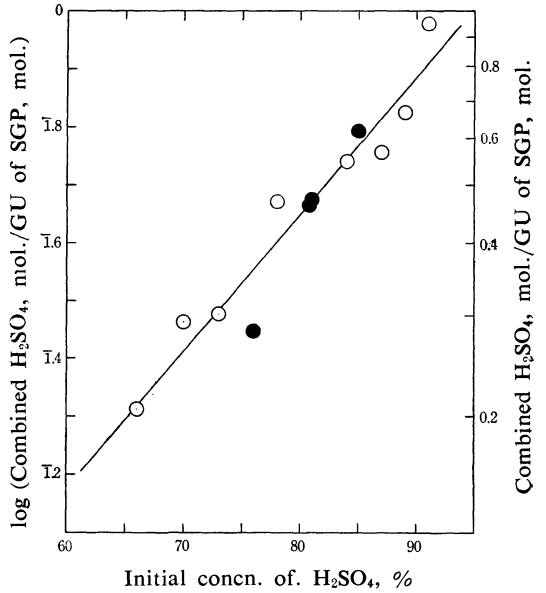

Fig. 4. Ratio of molecules of sulfuric acid combined with soluble glucose polymer (SGP) to glucose units (GU) of soluble glucose polymer.
$H_2SO_4$/Cellulose : ● 1.0, ○ 0.5

when 100 g. of cellulose is hydrolyzed at 55°C in 72% sulfuric acid containing 50 g. of sulfuric acid, $50\times0.128\times3.5/4.5=5.0$ g. of sulfuric acid is in combination with the SGP and $50\times0.128\times1/4.5=1.4$ g. is in combination with IGP.

**Combined Sulfuric Acid Molecules per Glucose Unit of Soluble Glucose Polymer.** — The number of sulfuric acid molecules fixed to one glucose unit (GU) of SGP showed a definite value when the hydrolysis of cellulose was at equilibrium, as shown in Fig. 1. This value depends on the "initial" concentration of sulfuric acid (Table II), as shown in Fig. 4. The following empirical equation is obtained from Fig. 4.

$$\log z = -2.247 + 0.0237C$$
$$z = 0.00566\exp(0.0546C) \qquad (3)$$

where $z$ is the number of sulfuric acid molecules fixed to one GU of the SGP. The equation indicates, for example, that when 100 g. of cellulose is hydrolyzed at 50°C in 72% sulfuric acid containing 50 g. of sulfuric acid, 0.288 mol. of sulfuric acid is fixed to 1 mol. of GU of the SGP. Then, $50\times0.128\times(3.5/4.5)\times(180/98)\times(1/0.288)=32$ g. of cellulose is converted into the SGP.

**Average Degree of Polymerization of Soluble Glucose Polymer.**—When the conversion of cellulose to the SGP reached an equilibrium, the average degree of polymerization (av. D. P.) of the SGP showed a definite value (Fig. 1). Figure 5, a plot of logarithm of av. D. P. of the SGP (Table II) against the "initial" concentration of sulfuric acid, shows a straight line.

$$\log u = -2.218 + 0.0396C$$
$$u = 0.00605\exp(0.0911C) \qquad (4)$$

where $u$ is av. D. P. of the SGP. In a ratio of sulfuric acid to cellulose ranging from 0.5 : 1 to 1.0 : 1, sulfuric acid of higher concentrations yields SGP of larger D. P., for example, 65% sulfuric acid gives SGP having av. D. P. 2.2 and 85% sulfuric acid 13.

**Concentration of Aqueous Sulfuric Acid in the Cellulose - Sulfuric Acid - Water System.** — On the assumption that water is consumed or formed during the hydrolysis according to the following equations,

$$C_6H_{10}O_5 + H_2SO_4 \rightarrow C_6H_9O_5SO_3H + H_2O$$
$$C_6H_{10}O_5 + H_2O \rightarrow C_6H_{12}O_6$$

the "corrected" concentration of sulfuric acid in the cellulose - sulfuric acid mixture was calculated by use of Eqs. 3 and 4. Figure 6 shows this value against the "initial" concentration of sulfuric acid. The "corrected" sulfuric acid concentration in the cellulose-sulfuric acid-water system can not exceed 75%, even when the initial concentration exceeds 85%.

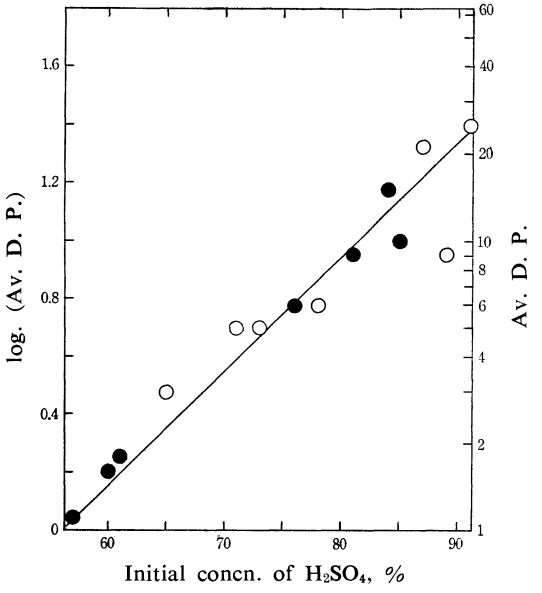

Fig. 5. Relation of average degree of polymerization of soluble glucose polymer to sulfuric acid concentration.
$H_2SO_4$/Cellulose: ● 1.0, ○ 0.5

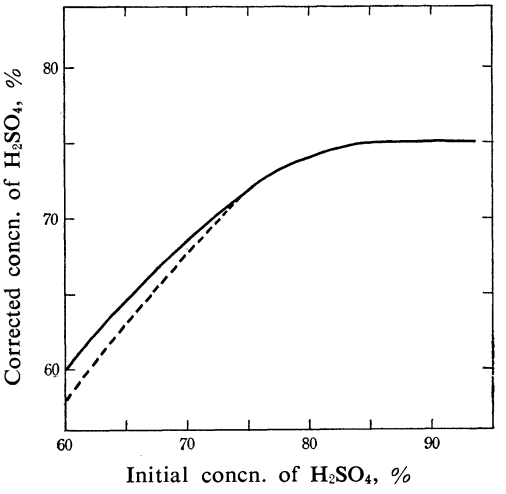

Fig. 6. Corrected concentration of sulfuric acid in cellulose - conc. sulfuric acid system.
$H_2SO_4$/Cellulose: —— 1.0, - - - 0.5

**Yield of Soluble Glucose Polymer and the "Initial" Concentration of Sulfuric Acid and the Sulfuric Acid : Cellulose Ratio.** — The amount of SGP (g.) produced when 100 g. of sulfuric acid is used is:

$$\text{SGP(g.)} = 100\text{(g.)}\left(\frac{\text{combined } H_2SO_4 \text{ (g.)}}{\text{total } H_2SO_4 \text{ (g.)}}\right)$$

$$\times\left(\frac{\text{H}_2\text{SO}_4 \text{ combined with SGP (g.)}}{\text{combined H}_2\text{SO}_4 \text{ (g.)}}\right)$$

$$\times\left(\frac{\text{GU of SGP (mol.)}}{\text{H}_2\text{SO}_4 \text{ combined with SGP (mol.)}}\right)$$

$$\times\left(\frac{180\text{(g./mol.)}}{98\text{(g./mol.)}}\right)$$

$$=100\text{(g.)}\,(x)\left(\frac{y}{1+y}\right)\left(\frac{1}{z}\right)\left(\frac{180}{98}\right)$$

$$=\frac{0.0384 \times \exp(0.0958\,C + 4.06\,r)}{1 + 0.00132 \times \exp(0.0815\,C + 4.06\,r)} \quad (5)$$

The yield of the SGP produced from cellulose in sulfuric acid of various "initial" concentration is shown in Fig. 7 as a function of the sulfuric acid : cellulose ratio.

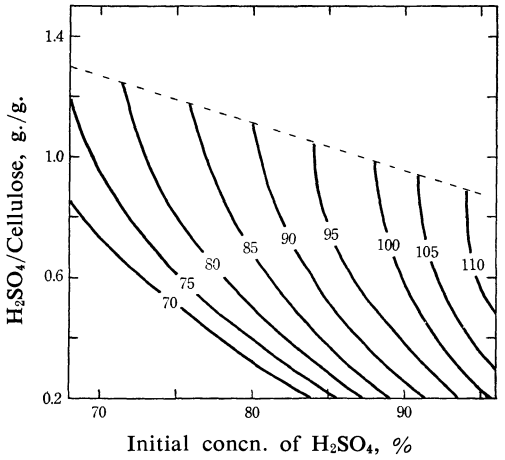

Fig. 7. Soluble glucose polymer yield expressed as a function of sulfuric acid concentration and $H_2SO_4$ : cellulose ratio.

## Discussion

In Table IV the data obtained from some pilot plant tests are compared with the values calculated from Eq. 5. This table shows that, in the ordinary concentrated sulfuric acid process, the reaction did not reach completion. It is considered that this can be attributed to the fact that diffusion of acid into the wood did not reach completion. Kuzuoka[3] has reported that when the mixture of saw dust and concentrated sulfuric acid was treated through the rolls, the larger the number of treatments the higher the yield of reducing sugar (Table IV). On the other hand, in Odincov's experiments,[14] the reducing sugar yield greatly exceeded the equilibrium value calculated from Eq. 5. This suggests that a mechanical force is effective in accelerating the diffusion of sulfuric acid into the wood and the hydrolysis of cellulose.

## Summary

The combination of sulfuric acid with cellulose occurring during the hydrolysis of cellulose in a small amount of concentrated sulfuric acid has been investigated. The amounts of the soluble and the insoluble glucose polymers produced from cellulose, and the amount of sulfuric acid combined with them, have been estimated. To obtain an effective concentration of sulfuric acid on the cellulose, the concentration of the sulfuric acid must be greater than about 60%. The sulfuric acid concentration in the cellulose - sulfuric acid - water system can not exceed 75%, even when the initial concentration exceeds 85%. The amount of soluble glucose polymer (g.) produced by the action of 100 g. of sulfuric acid is given by $0.0384\ \exp(0.0958\,C+4.06\,r)/[1+0.00132\ \exp(0.0815\,C+4.06\,r)]$ ($C$ is "initial" concentration of sulfuric acid (%) and $r$, sulfuric acid - cellulose ratio).

# Absorption of Carbon Dioxide in a Centrifugal Absorber by Mono- and Diethanolamine Solutions[1]

By Mamoru MATSUDA and Yoshio FUJIOKA

(Received October 21, 1963)

The carbon dioxide concentration in a closed circuit increases upon the respiration of the inhabitants. The rate of carbon dioxide generated by an adult is almost 0.95 mol. per hour, that is, about 25 l. at 30°C under atmospheric pressure.[2]

The effects of the continuous exposure of carbon dioxide on humans have been much investigated. The results may be summarized by saying that the activities of people are considerably reduced when more than three percent of carbon dioxide is present.[3] It is, therefore, indispensable to install a carbon dioxide removal plant and an oxygen generator in a closed circuit when the duration of stay is long.

Solutions of ethanolamines and potassium carbonate are used as regenerative carbon dioxide absorbents, since they absorb carbon dioxide at room temperature and expel the carbon dioxide at a high temperature of about 140°C.[4]

We have constructed new centrifugal absorbers for the removal of carbon dioxide in a closed circuit, using regenerative ethanolamine liquids as absorbents.

The present paper will report on the effects of such variable conditions as the gas flow rate, the liquid flow rate, the composition of the liquid, rotor revolutions per minute, and rotor design on the mass transfer coefficients of the absorbers.

## Experimental

**Apparatus and Procedure.** — On the carbon dioxide absorber, it is advisable to increase the frequency of contacts between carbon dioxide and the liquid. Therefore, a centrifugal-type absorber, which has a large liquid surface,[5] was used with some modifications.

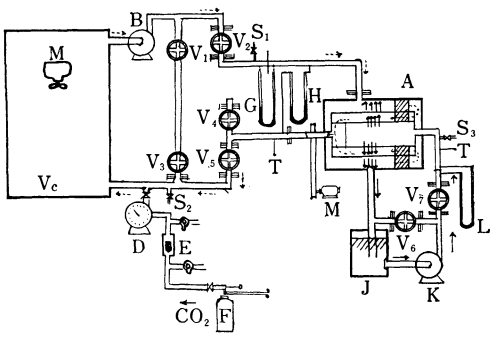

Fig. 1. Experimental arrangement of apparatus.

Figure 1 shows the arrangement of the experimental apparatus. A closed chamber Vc, has a volume of about 3.8 m³. A motor M rotates a perforated rotor of a centrifugal absorber A. The rotating rotor tangentially sprays absorbing liquid, which is introduced by a pump K from a tank J. The liquid flow is controlled by a flowmeter L, and valves, $V_6$ and $V_7$. When the carbon dioxide concentration of the closed chamber becomes 1.5 to 3.0%, the gas is introduced to the liquid-spraying space by a blower B. The gas flow rate and the carbon dioxide concentration are controlled by flowmeters D, E, G, and valves $V_1$, $V_2$, $V_3$, and $V_5$, A cylinder F feeds in carbon dioxide. The gas samples collected from the inlet $S_1$, and the outlet $S_2$ are analyzed for $CO_2$ by a $CO_2$ analyzer.

**The Determination of the Carbon Dioxide Content in a Liquid.**—Carbon dioxide in a liquid was determined according to the method of Reed and Wood,[6] which measures volumetrically the carbon dioxide evolved on the addition of sulfuric acid to the sample.

## Results and Discussion

**Part 1.**—There exist a number of variables which effect the over-all mass transfer coefficient, $K_Ga$, as defined by Eq. 1:

$$K_Ga=\frac{G_M}{VP}\int_{p_2}^{p_1}\frac{dp}{p-p^*} \qquad (1)$$

where

$G_M$ = average rate of gas flow (l./sec.)
$V$ = volume of absorbing space (l.)
$P$ = total pressure of gas flow (atm.)

TABLE I. CENTRIFUGAL CARBON DIOXIDE ABSORBER

| Type | Dia. of stator | Dia. of rotor | Cross sectional area of absorbing space | Length of absorbing space | Volume of absorbing space | Characteristics of openings | Number of cylinder |
|---|---|---|---|---|---|---|---|
| $D_e$ | $D_S$, cm. | $D_R$, cm. | $S_A$, cm$^2$ | cm. | $V$, l. | | |
| I | 18 | 10 | 176 | 7 | 1.232 | dia. 0.8 mm. $N_h$, 128 | 1 |
| II | 18 | 10 | 176 | 7.5 | 1.320 | dia. 0.8 mm. $N_h$, 960 | 1 |
| III | ca. 28 | $D_{R1}$ 18<br>$D_{R2}$ 10 | 1023.4 | 9.5 | 9.722 | dia. 0.8 mm. $N_h$, 3840 | 2 |
| IV | 55 | $D_{R1}$ 40<br>$D_{R2}$ 18 | 2110 | 30 | 63.300 | #1. Slit<br>#2. Screen<br>#3. Conical perforated plates | 2<br>Packed<br>Packed |
| V | 55 | $D_{R1}$ 43<br>$D_{R2}$ 33<br>$D_{R3}$ 23<br>$D_{R4}$ 10 | 2190 | 57 | 124.800 | perforated aluminum plate dia. 0.5 mm. $N_h$, 90/cm$^2$ plate | 4 |

$p$ = partial pressure of $CO_2$ in absorbing space (atm.)
$p_1$ = partial pressure of $CO_2$ in influent-gas flow (atm.)
$p_2$ = partial pressure of $CO_2$ in effluent-gas flow (atm.)
$p^*$ = partial pressure of $CO_2$ in equilibrium with an amine solution[7] (atm.)

For this report the effects of the following factors on the transfer coefficient were investigated:

Absorbent: monoethanolamine (MEA) and Diethanolamine (DEA) (A)
Solvent: water and glycerol (S)
Concentration of absorbent ($N$, mol./l.)
Concentration of carbon dioxide in the liquid ($M$, mol. $CO_2$/mol. amine)
Liquid flow rate ($L$, l./sec.)
Initial concentration of carbon dioxide in gas stream ($P_1$, atm.)
Revolution rate of rotor ($R_n$, r.p.m.)
Gas flow rate ($G$, l./sec.)
Number of openings of the rotor ($N_h$, —)
Type of rotor ($D_e$, —)

Table I shows the dimensions of the rotors. Tables II and III show the experimental conditions and results.

*The Effect of Revolution.* — The relation between the number of revolutions per minute of a rotor and the transfer coefficients, $K_Ga$, calculated according to Eq. 1, were studied in runs No. 1 to 6. The transfer coefficient dependence on the gas velocity is shown in Fig. 2.

The transfer coefficient, $K_Ga$, increases with the number of revolutions per minutes. When the number of revolutions is less than $1\times10^3$ r.p.m., the increase in gas velocity hardly changes the transfer coefficient, or even decreases it. The decrease may be explained as occuring because the gas stream goes unreacted through the absorbing space near the stator as a result of the insufficient density of liquid, as the revolution rate is small. When the number of revolutions is more than $1\times10^3$ r.p.m., the transfer coefficient rises with the gas velocity.

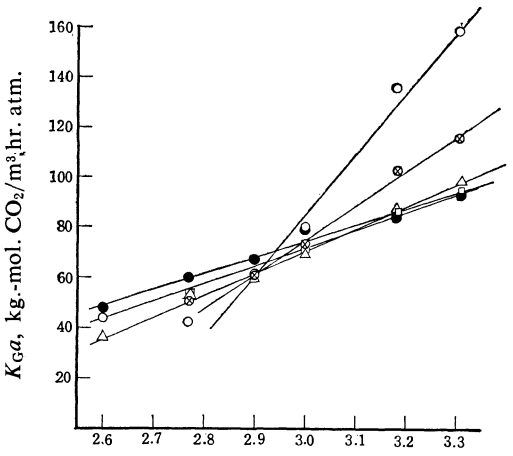

Fig. 2. Relation between coefficient and log $R_n$.
Gas velocity: ● 4.6, □ 7.0, △ 9.5, ⊗ 18.5, ○ 38.0 cm./sec.

*The Concentration of DEA.*—Run No. 10 was carried out under the same conditions as No. 7 except for the normality.

Comparing the transfer coefficients with the normality ($N$) and kinematic viscosity ($\mu$), we obtained:

$$K_Ga \propto \frac{N}{\mu^{0.5}} \qquad (2)$$

a) D=DEA, M=MEA, W=Water, G=Glycerol
c) Data in parentheses are settled levels of factors.

*The Number of Openings.* — In run No. 7 a type II absorber was used, which had 960 openings, while type I had 128 while it had 960 in run No. 10 and 448 in No. 12.

Figure 3 compares the coefficients of No. 7 and No. 1, and No. 10 and No. 12. If the variation in $K_Ga$ with normality is taken into account, it may be concluded that the increase in the openings does not necessarily increase the transfer coefficient.

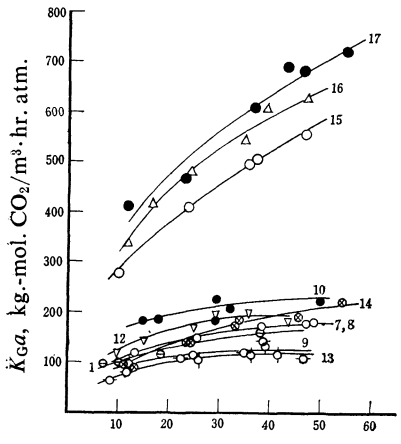

Fig. 3. Relation between gas velocity and coefficient.

*The Type of Rotor.*—Run No. 14 was taken in order to determine the increase in the centrifugal force on a liquid. When it is compared with No. 13 (Fig. 3), the favorable effect of the 50-mesh stainless screen can be observed.

In the runs Nos. 15, 16 and 17, MEA liquid was used. The liquid flow rate effected the transfer coefficient.

The small effect of the gas velocity on the coefficient, $K_Ga\sqrt{S_A/G}$, as shown in Fig. 4, indicates that the rate-determining step is substantially the diffusion of carbon dioxide in the gas stream.

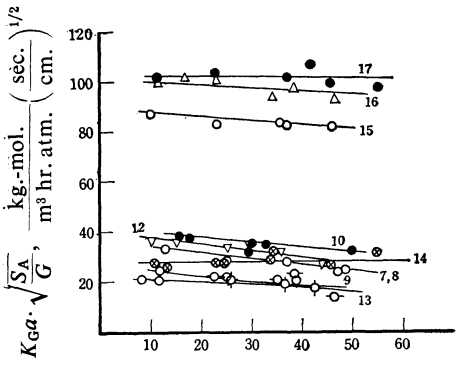

Fig. 4. Relation between $K_Ga\sqrt{S_A/G}$ and coefficient.

*Concentration of MEA.* — In runs No. 182 to No. 186, a closed chamber was used. Assuming that the efficiency, $E$, of the absorber remains constant and that the mixing in the chamber is perfect, the following differential equation can be derived by considering the mass valance in the system:

$$g_A dt - GEp dt = V_C dp \tag{3}$$

When $p=p_0$ at $t=0$, and $p=p_1$ at $t=t$, the solution of Eq. 3 is:

$$p_1 = p_0 \exp\left(-\frac{GE}{V_C}t\right) + \frac{g_A}{GE}\left\{1-\exp\left(-\frac{GE}{V_C}t\right)\right\} \tag{4}$$

$$E=(p_1-p_2)/p_1$$

where $p_0$ is the initial partial pressure (atm.) of carbon dioxide in the closed chamber; $p_1$ is the partial pressure (atm.) of carbon dioxide in the closed chamber at time $t$ (sec.); $p_2$ is the partial pressure of carbon dioxide at the outlet of the absorber; $V_C$ is the volume of the closed chamber (l.); $g_A$ is the rate at which carbon dioxide is added to the closed chamber (l./sec.), and $G$ is the rate of gas flow (l./sec.).

The concentrations of the MEA liquids applied were 9.8, 8.3, 6.2, 4.1 and 0.45 normal. The variation in the carbon dioxide concentration in the chamber with the time is given

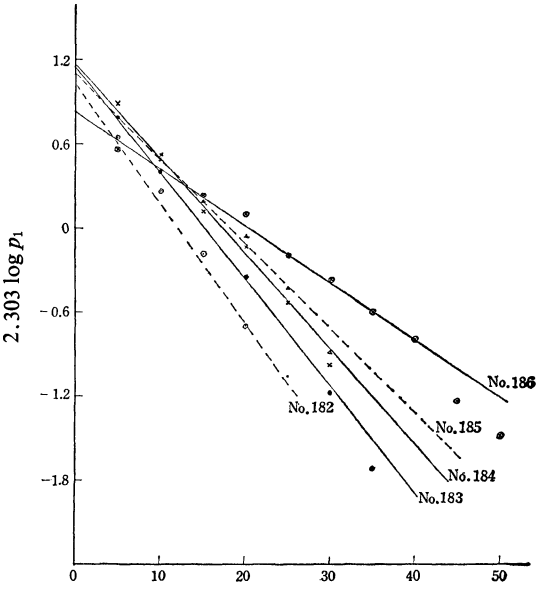

Fig. 5. Variation of $CO_2$ concentration with time in the closed chamber.

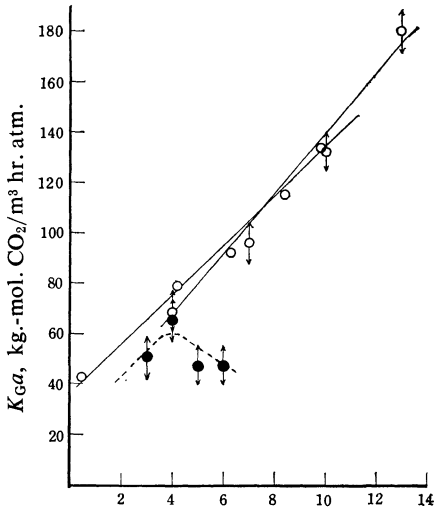

Fig. 6. Relation between liquid concentration and coefficient.
○ Nos. 182—186, MEA
○ Part 2, MEA ● Part 2, DEA

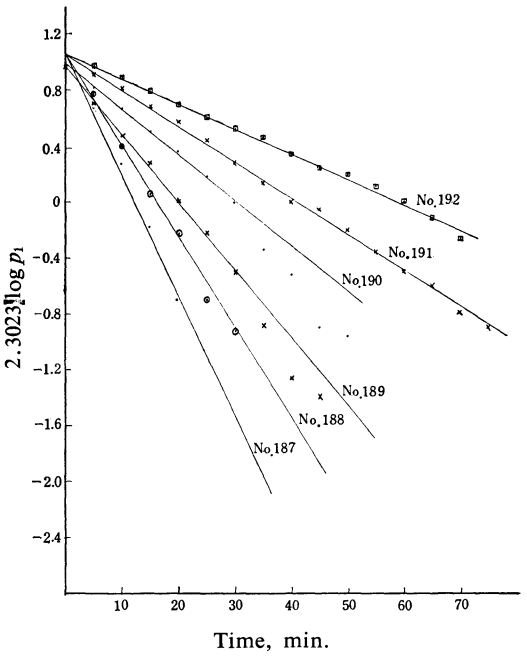

Fig. 7. Variation of $CO_2$ concentration with time in a closed chamber.

in Fig. 5. From Eq. 4, where $g_A$ is zero, the efficiencies of the absorber, $E$, and the transfer coefficients, $K_Ga$, were calculated.

Figure 6 shows that the transfer coefficient increases linearly with the concentration of the MEA solution.

Goodridge[8] described a similar relation between the absorption rate and the concentration.

From the lines of Fig. 5, the efficiency of the absorber can be seen to be independent of the concentration of carbon dioxide in the gas stream. The assumption for Eq. 3 was, therefore, sound.

*The Concentration of Carbon Dioxide in a Liquid.*—In runs No. 187 to No. 192, the closed chamber was used again. The concentrations of carbon dioxide in the liquid were 0.095, 0.197, 0.279, 0.330, 0.375 and 0.425 mol. $CO_2$/mol. MEA.

Figure 7 shows the relation of the carbon dioxide concentration in the chamber to the time. The efficiencies of the absorber and the transfer coefficients were calculated according to Eq. 4. In Fig. 8 the effect of the carbon dioxide concentration in a liquid on the transfer coefficient is plotted. From the slope, the following equation has been obtained:

$$K_Ga \propto e^{-6.56M} \qquad (5)$$

**Part 2.** — In Part 1, carbon dioxide absorption behavior was studied with a small centrifugal absorber (rotor dimensions: ca. 10 cm. in diameter × 7.5 cm.). These investigations into the process of absorption with a chemical reaction have distinguished the effects of several factors on the transfer coefficient. However, effects of these factors on the transfer coefficient were deduced from experiments in which a certain factor was varied while the others were kept constant. We have thus manufactured a centrifugal absorber of a large scale (rotor dimensions: ca. 55 cm. in diameter × 30—57 cm.; Table I, types IV and V).

The experimental design of the orthogonal table[9] is shown in Table III, where settled

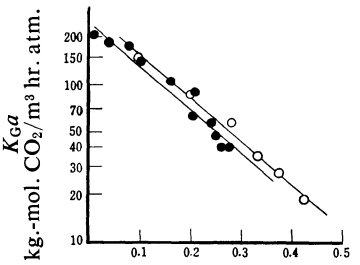

Fig. 8. Relation between $CO_2$ concentration in liquid and coefficient.

8) F. Goodrige, *Trans. Faraday Soc.*, **51**, 1703 (1955).

9) G. Taguchi, "Method of Experimental Design," Maruzen Book Co., Tokyo (1962).

levels are in parentheses, along with the experimental values and the results. The other experimental procedures were the same as in Part 1.

It was possible to adjust the actual levels of the factors to the settled levels within ±5% deviation. The main effects of each factor are calculated and plotted according to the usual method[9] in Figs. 9 to 12. The arrows shows the range of experimental error.

The dependence of the transfer coefficient on the concentration of the MEA solution is shown in Fig. 6, indicating the same tendency as in Part 1.

Figure 6 shows also the relation between the concentration of DEA and the transfer coefficient.

In both liquids, MEA and DEA, the transfer coefficients show substantially the same magnitude up to a concentration of about four normal. When the normality increases more than 4 N, the transfer coefficient of DEA decreases because the viscosity influences the coefficient, as was stated in Part 1.

Equation 2 is verified by the fact that the $K_G a \mu^{0.5}/N$ for 3, 4, 5 and 6 N DEA solutions with kinematic viscosities of 3.5, 5.6, 10 and 20 c. s., are 31.8, 38.5, 30.0 and 36.0 respectively.

Certainly, the influence of viscosity depends upon the centrifugal force produced by the revolution. The transfer coefficients are plotted against the gas flow rate in Fig. 9. The coefficient increases with the gas flow rate in the MEA system, indicating that the rate-controlling step is still in the gas film, while it changed little in the DEA system, indicating that the step there has been shifted to that in the liquid film.

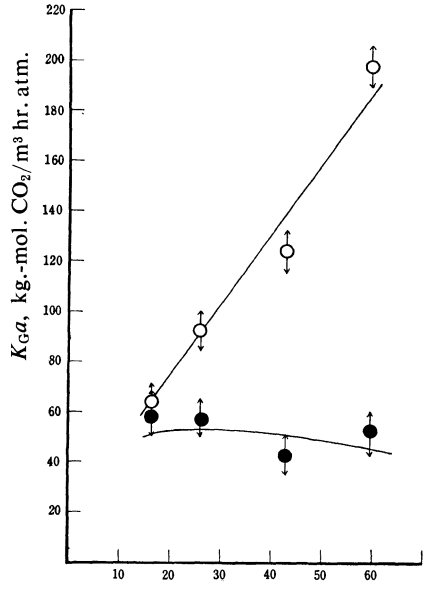

Fig. 9. Relation between gas velocity and coefficient.

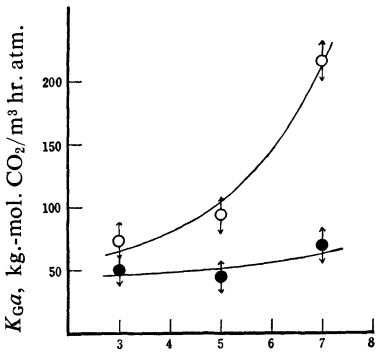

Fig. 10. Relation between liquid flow rate and coefficient.

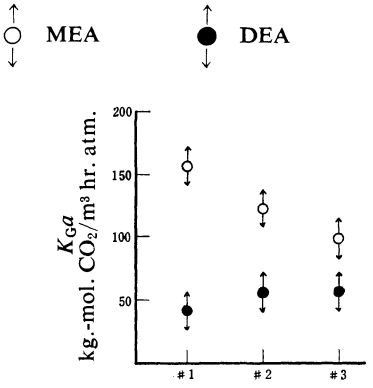

Fig. 11. Relation between type of rotor and coefficient.

#1 Slit, unpacked #2 Screen, packed,
#3 Conical perforated plate, packed

MEA DEA

In Fig. 10 the transfer coefficient increases considerably with the MEA liquid flow rate, but only slightly with the DEA liquid flow rate. Figure 11 shows the effects of the differences of rotors on the transfer coefficient. Generally, it is advantageous to choose a packed rotor when the absorbing liquid is viscous and the liquid flow rate is small.

Figure 12 shows the dependence of the transfer coefficient on the solvent, the revolution rate of the rotor, and the initial concentration of carbon dioxide in the gas stream.

The differences between water and glycerol have hardly any effect on the transfer coefficient. As for the revolution rate and the carbon dioxide concentration, tendencies

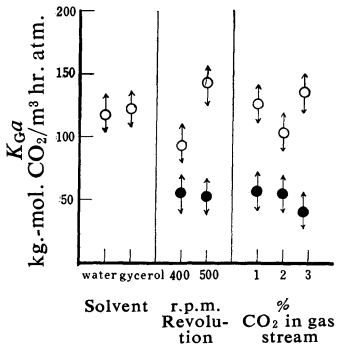

Fig. 12. Effects on coefficients of solvent, revolution rate, and $CO_2$ concentration in gas stream.

similar to those in Part 1 were observed. Additionally, the concentration of carbon dioxide in MEA glycerol solutions affected the transfer coefficient in the same manner as in Part 1 (Fig. 8, Table III, No. 200).

Runs No. 501 to 503 in Table III were obtained with a large, modified centrifugal absorber which had a rotor (55 cm. in diameter $\times$ 57 cm.) comprised of four perforated aluminum cylinders.

The length of the absorbing space, the number of cylinders, and especially the number of openings were increased. From a comparison between No. 501 and Nos. 5 and 16, between No. 502 and Nos. 7 and 17, and between No. 503 and Nos. 8 and 9, it may be concluded that the increase in the number of both openings and cylinders has little effect on the mass transfer coefficient.

## Summary

After a description of a centrifugal carbon dioxide absorber, the effects of variables on the mass transfer coefficient of the absorber have been reported. For the experimental conditions examined, the following conclusions may be arrived at:

(1) When the rate-determining step is gas diffusion, the MEA and DEA liquid of the same concentration have the same mass transfer coefficient as long as the effect of viscosity is negligible.

(2) The transfer coefficient increases linearly as the concentration of an MEA aqueous solution increases.

(3) The relation between the coefficient and the concentration of a viscous DEA aqueous solution is given as:

$$K_Ga \propto N/\mu^{0.5}$$

(4) The relation between the coefficient and the concentration of carbon dioxide in a MEA liquid is given as:

$$K_Ga \propto e^{-6.56M}$$

(5) So long as the gas diffusion is the rate-determining step, the coefficients for two solvents, water and glycerol, differ little.

(6) The coefficient for MEA increases greatly with the liquid flow rate; however, the coefficient for DEA increases only a little.

(7) The coefficient is initially in direct proportion to the square root of the gas flow rate.

(8) The efficiency of the centrifugal absorber remains constant even if the carbon dioxide concentration in the gas stream changes from 3 to 0.2%.

(9) The coefficient is in direct proportion to the logarithm of the rotor revolutions per minute.

(10) Slight modifications, except for packing on the rotor, with the aim of increasing the surface area of a liquid do scarcely anything to improve the absorber.

# Copolymerization of Propylene with Butene-1 Catalyzed by Triethylaluminum and Vanadium Trichloride or Vanadyl Trichloride

By Wasaburo KAWAI

(Received November 6, 1963)

Natta et al.[1] have studied the copolymerization of ethylene with propylene by using triethylaluminum and vanadium tetrachloride or vanadyl trichloride; Phillips and Carrick[2] have also synthesized the random copolymer of ethylene and propylene by using a hydrocarbon soluble catalyst, $VCl_4$-$(C_6H_5)_4Sn$-$AlBr_3$. Junghanns et al.[3] have reported the copolymerization of ethylene with propylene by using alkylaluminum chloride ($AlRCl_2$ or $1/2Al_2R_3Cl_3$) and vanadyl chloride.

Studies of the copolymerization of other olefins were described by Dunham,[4] who examined the effect of side-chain structure on the properties of poly-$\alpha$-olefin, and by Reding[5] who synthesized the copolymer of 3-methylbutene-1 and 4-methylpentene-1 by using triisobutyl-aluminum and vanadium trichloride. Anderson et al.[6,7] carried out the copolymerization of styrene with 4-methylpentene-1 or 5-methylhexene-1 and determined the monomer reactivity ratio of the monomers. Mark[8] commented on the usefulness of the copolymer of propylene and butene-1.

The present author has been interested in the characterization of the copolymer of propylene and butene-1, whose homopolymers have the same identity period (6.5Å) as the orientated polymers.[9] In the present paper, the copolymerization of propylene with butene-1 by using triethylaluminum combined with vanadium trichloride or vanadyl trichloride will be reported.

## Experimental

**Polymerization.**—A given quantity of vanadium trichloride or vanadyl trichloride and a glass ampoule containing triethylaluminum were charged with *n*-hexane (2—5 cc.) in a stainless steel autoclave. After the autoclave had been flushed with a nitrogen stream, liquid propylene and butene-1 were introduced through a steel pipe into the autoclave cooled to −78°C, and the amounts of the monomers were determined by weight. As soon as the glass ampoule in the autoclave had been broken by vigorous shaking, the autoclave was dipped in a thermostatic bath. The polymers obtained were then washed repeatedly by boiling methanolic hydrochloric acid or methanol and dried in a vacuum. As a control, the isotactic polypropylene sample for X-ray diffraction measurement was prepared by the same procedure.

**Samples for Infrared Spectrum and X-Ray Diffraction.**—The polymer dissolved in toluene or xylene was cast on mercury, and the solvent was gradually evaporated by heating. The films thus obtained were used for infrared spectrum and X-ray diffraction measurements. The optical densities at 970 $cm^{-1}$ were determined according to the base line method.

**Intrinsic Viscosity.**—The copolymers were fractionated by solvent extraction with a Soxhlet extractor, and the intrinsic viscosity of each fraction was determined in toluene at 100°C.

## Results and Discussion

The results of copolymerization with various monomer ratios are listed in Tables I and II. In the propylene-butene-1 copolymer, there are two characteristic bands, at 970 $cm^{-1}$ and 760 $cm^{-1}$, in the infrared spectrum which are independent of the crystallinity of the copolymers. The former band, at 970 $cm^{-1}$, has been attributed to the $CH_2$ rocking, C-C stretching, $CH_3$ wagging and rocking modes of polypropylene,[10] while the later band 760 $cm^{-1}$ may be attributed to the $CH_2$ rocking vibration of the ethyl group of polybutene-1.[11] Therefore the optical density ratio, $D(970\ cm^{-1})/D(760\ cm^{-1})$, may be accepted as a measure of the

b) All samples for optical density measurements were not fractionated.

polypropylene content of the copolymers. The infrared spectra of the typical unfractionated copolymers obtained by using triethylaluminum combined with vanadium trichloride or vanadyl trichloride catalysts are shown in Fig. 1.

According to Luongo[12] and Nishioka et al.[13], the determination of the isotactisity of polypropylene and polybutene-1 can be made by the measurement of the optical density ratios, $D(995\,cm^{-1})/D(974\,cm^{-})$ and $D(917\,cm^{-1})/D(1148\,cm^{-1})$ respectively. Both the isotactic sensitive band at $917\,cm^{-1}$ from the butene-1 unit sequence and that at $995\,cm^{-1}$ from the propylene unit sequence are inclined to weaken in the spectra of copolymers obtained by using triethylaluminum and vanadium trichloride catalysts, as may be seen in Fig. 1 (spectrum II). This suggests that a new crystalline copolymer is formed by using the above catalyst, a theory supported by the X-ray diffraction patterns shown in Fig. 2 and Table IV. In the copolymers from triethylaluminum and vanadyl trichloride catalysts, the isotactic-sensitive bands from the butene-1 unit and propylene unit sequences are recognized to be much weakened in optical density. Therefore, these copolymers have scarcely any of the isotactic chains of either monomer unit sequence;

III: Mixed polymer (polybutene-1/polypropylene=7/3)

moreover, they are found to be new amorphous copolymers by the X-ray diffraction mearurements. The infrared absorption spectra of the copolymers and mixed homopolymers are compared in Fig. 1. Copolymers lack the absorption at 1170 $cm^{-1}$, whereas the mixed homopolymers show two absorptions, at 1150 $cm^{-1}$ and 1170 $cm^{-1}$, which are due to the component homopolymers. It may be noted also that the copolymers show an absorption at 970 $cm^{-1}$ instead of that at 974 $cm^{-1}$ which is due to the isotactic polypropylene. Consequently, it is clear that the polymers here obtained are not mixtures of polypropylene and

polybutene-1 but are copolymers.

The copolymers were fractionated by solvent extraction (diethyl ether, *n*-hexane, isooctane) into four portions, as is shown in Table III. It was found, from the spectrum change between 1150 $cm^{-1}$ and 1170 $cm^{-1}$, that the portion extracted by a lower boiling solvent (diethyl ether) showed the absorption at 1150

a) The intrinsic viscosities were measured in toluene at 100°C.

Table IV. d-Spacing of copolymer and homopolymer

| Isotactic polypropylene | | Polypropylene ($AlEt_3$, $VOCl_3$) | | Polybutene-1 ($AlEt_3$, $VCl_3$) | | Polybutene-1 ($AlEt_3$, $VOCl_3$) | | Copolymer (No. 6) ($AlEt_3$, $VCl_3$) | |
|---|---|---|---|---|---|---|---|---|---|
| 2θ | d | 2θ | d | 2θ | d | 2θ | d | 2θ | d |
| 14.3 | 6.17 | 14.3 | 6.17 | 10.0 | 8.84 | 10.0 | 8.84 | 13.8 | 7.19 |
| 17.1 | 5.48 | 17.0 | 5.48 | 11.8 | 8.64 | 17.4 | 5.47 | 16.2 | 5.52 |
| 18.7 | 4.90 | 18.7 | 4.90 | 17.4 | 5.47 | 20.4 | 4.42 | 18.0 | 4.93 |
| 21.4 | 4.38 | 21.3 | | 20.4 | 4.42 | 21.4 | 4.38 | 21.3 | 4.39 |
| 21.6 | | 21.7 | | 21.4 | 4.38 | | | | |
| 22.2 | | | | | | | | | |

$cm^{-1}$ of polybutene-1. On the other hand, that extracted by a higher boiling solvent (isooctane) showed the absorption at 1167 $cm^{-1}$, which was near to that at 1168 $cm^{-1}$ ascribed to polypropylene. The polymer extracted by *n*-hexane had the absorption in the middle, between 1168 $cm^{-1}$ and 1150 $cm^{-1}$. It was also ascertained that the polymer extracted by a lower boiling solvent was richer in the butene-1 unit sequence, while that extracted by a higher boiling solvent was richer in the propylene unit sequence. The optical density ratio, $D(970\,cm^{-1})/D(760\,cm^{-1})$ was lower for the portion extracted by a lower boiling solvent than for that extracted by a higher boiling solvent.

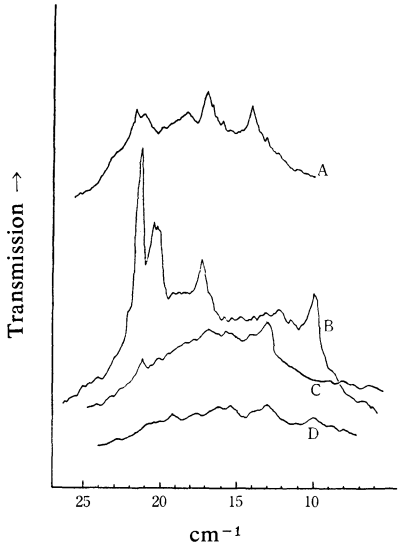

Fig. 3. X-ray diffraction patterns of polypropylene, polybutene-1 and copolymer obtained by using triethylaluminum and vanadyl trichloride catalyst
A: Polypropylene
B: Polybutene-1 (No. 8)
C: Unfractionated propylene-butene-1 copolymer (No. 10)
D: *n*-Hexane extractable propylene-butene-1 copolymer (No. 9)

It was found that the copolymers obtained from propylene and butene-1 had different X-ray diffractions from those of the homopolymers. The copolymer obtained by using triethylaluminum and vanadium trichloride is crystalline; the d-spacing is indicated in Table IV together with that of homopolymers. The X-ray diffraction patterns of crystalline copolymers are shown in Fig. 2. The copolymer prepared with the triethylaluminum-vanadyl trichloride catalyst was amorphous; the X-ray diffraction patterns are shown in Fig. 3.

From the infrared spectra and X-ray diffraction of the copolymers, may it be concluded that the triethylaluminum-vanadium trichloride catalytic system is a stereospecific one, one which produces the crystalline copolymers in the copolymerization of propylene with butene-1, while, on the other hand, the triethylaluminum-vanadyl trichloride catalytic system is a less stereospecific one, one which produces the amorphous copolymers in the copolymerization of the same monomers.

# A Kinetic Study of the Redox System Containing Citric Acid and Manganic Acetate

By Gur PRASAD

(Received May 27, 1964)

Waters and his co-workers[1] have studied the oxidation of some carboxylic acids and other organic compounds by using manganese-(III) in the form of pyrophosphate. Manganic acetate has been employed for the oxidation of organic compounds by Zonis and his co-workers.[2] In the present study, manganic acetate has been used as an oxidant for citric acid.

2) S. A. Zonis et al., *J. Gen. Chem.* (*U. S. S. R.*), **20**, 1301 (1950); **24**, 815 (1954); *Zhur., Obschei Khim.*, **24**, 814, (1954).

## Experimental

All the chemicals used were of B.D.H., A.R. quality, and fresh solutions of citric acid were prepared in boiled distilled water. Manganic acetate was prepared by the oxidation of manganous nitrate under suitable conditions. It was stored in blackened Pyrex bottles at a low temperature to prevent disproportioning ($2Mn^{3+} \rightleftarrows Mn^{2+} + Mn^{4+}$). Calculated amounts of the reactants (i. e., citric acid

and manganic acetate) were placed separately in a thermostat maintained at ($t\pm0.05$)°C, where $t$ is the desired temperature. Reaction was started by thoroughly mixing the two reactants in a solvent containing 90 per cent glacial acetic acid and 10 per cent water. Five milliliters of the reaction mixture were pipetted out at different intervals, and the concentration of manganese(III) was estimated colorimetrically by using Unicam Photoelectric colorimeter with a Filter No. 303. Lambert-Beer's law was found to hold for the concentration ranges employed in the experiment. The kinetics of the reaction has been followed by varying the concentration of the reactants and the temperature.

## Results and Discussion

It has been found that one molecule of citric acid requires 9.5 equivalents of manganic acetate in order to be oxidized in the temperature range from 20 to 30°C. The rate constants have been determined graphically. $k_1$ and $k_2$ represent the rate constants for the first and second order reactions respectively. Some of the data are reproduced in Tables I, II and III.

TABLE I

| Reactant | Temp. °C | Rate constant | Figure |

| Citric acid : 0.005 N<br>Mn(III) : 0.005 N | 30 | $k_2=0.1354$ | 1(b) |
| Citric acid : 0.005 N<br>Mn(III) : 0.0005 N | 20 | $k_1=0.1497$ | 2(a) |
| Citric acid : 0.02 N<br>Mn(III) : 0.0025 N | 20 | $k_1=0.2917$ | 2(b) |

TABLE II

| Reactant | $t_{1/2}$, min. | $k'$ |
|---|---|---|
| Citric acid : 0.005 N<br>Mn(III) : 0.005 N | 15.2 | 0.07429 |
| Citric acid : 0.005 N<br>Mn(III) : 0.0025 N | 12.1 | 0.07293 |
| Citric acid : 0.005 N<br>Mn(III) : 0.0016 N | 9.4 | 0.07361 |

TABLE III

Temp., : 20°C

| Reactant | | $k_2\times10^{-4}$ |
|---|---|---|
| Citric acid : 0.005 N ; | Mn(III) : 0.005 N | 801 |
| Citric acid : 0.005 N ; | Mn(III) : 0.0016 N | 835 |
| Citric acid : 0.005 N ; | Mn(III) : 0.00125 N | 909 |
| Citric acid : 0.0025 N ; | Mn(III) : 0.0025 N | 674 |
| Citric acid : 0.005 N ; | Mn(III) : 0.0025 N | 752 |
| Citric acid : 0.01 N ; | Mn(III) : 0.0025 N | 806 |

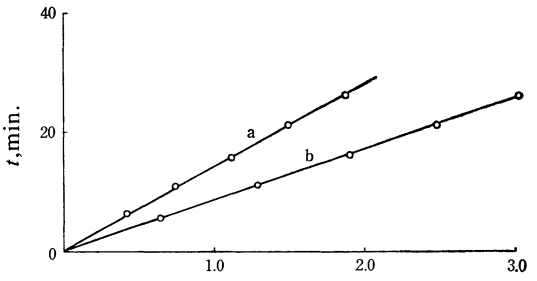

Fig. 1.

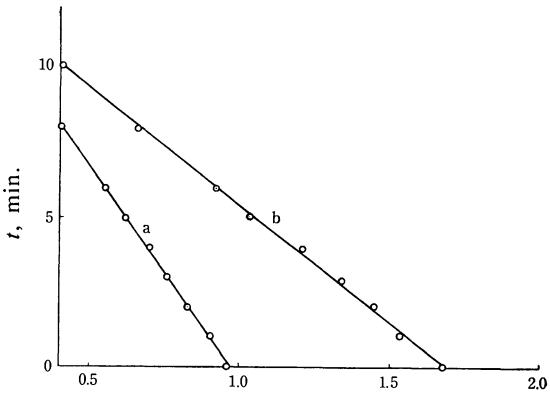

Fig. 2.

It has been noted that if the concentrations of the reactants are approximately equal, the total order of the reaction is two—one with respect to each reactant separately. There is a slight increase in the total value of the rate constant as the concentration of manganese(III) is decreased. It appears that a complex is formed between manganese(III) and citrate which slowly decomposes, giving the reaction product. The temperature coefficient for a 10°C rise in temperature is slightly less than two.

The authors wishes to thank the University Grants Commission, New Delhi, for the award of a Senior Research Fellowship. Thanks are also due to Dr. Y. K. Gupta, Reader, University of Rajasthan, for his helpful suggestions.

# A Simple Method for the Analysis of a Homologous Series of Alcohols using Gas Chromatography

By Mikio SATO, Hiroshi MIYAKE, Mitsuyuki MITOOKA and Koichi ASANO

(Received July 31, 1964)

Gas chromatography has been a useful means for the analysis of complex mixtures of reasonably volatile compounds, and many analyses of lower fatty alcohols are available.

This report will present a study concerning the gas chromatographic analysis of an alcohol mixture which is produced by Ziegler's process.[1-4] This mixture consists of the normal even carbon-numbered alcohols ranging from $C_6$ through $C_{22}$. As the mixture contains components with high boiling points, gas chromatographic separation must be made at quite a high temperature. Therefore, the stationary liquid should be virtually non-volatile at a column temperature of 200—250°C, and, at the same time, the liquid must be stable against thermal decomposition at such a high temperature. From these considerations, acetate-washed grease,[5] Apiezon grease[6,7] or Reoplex[8,9] was expected to be appropriate for this purpose.

On chromatograms, free alcohols usually give rise to asymmetric peaks; they have a drawn-out "trail," a shape obviously unfavorable to their sharp separation and to the quantitative analysis of the components with lower concentrations. The tailing of peaks may be attributed to the polarity of the solid support and to the association of alcohol molecules.[10] Hence, in order to avoid these unfavorable aspects, it was recommended that the alcohols, prior to analysis, be converted to their acetates, which show no tailing and are more stable against the thermal decomposition than the original alcohols. Furthermore, the acetates of $C_6$ and higher alcohols have lower melting points than those of the corresponding alcohols, and a mixture of them is more easily injected into the instrument.

It thus becomes important to convert the individual alcohol in the sample mixture quantitatively to its acetates. However, by the ordinary acetylation method, for example, by the use of acetic anhydride or acetyl chloride, it was found that the distribution of the acetates obtained does not correspond to that of the starting alcohol mixture, mainly because of the difference in the solubility of each acetate into an aqueous solution, which is formed by the washing of the reaction mixture with water after the acetylation process in order to remove the catalysts and excess reagents from the acetates produced.

This paper will report on an attempt to

find a quantitative analytical method for a homologous series of alcohols through acetylation by the use of ketene gas. It was generated from acetone, along with methane gas, and was passed through a sample volume of an alcohol mixture for a short time in order to acetylate it. The acetate mixture obtained was, without needing any more treatment, immediately subjected to gas chromatographic analysis.

It was confirmed that, by the ketene-acetylation, alcohols were converted to their acetates quantitatively and yet with the same conversion velocity. Consequently, the operation of the analysis was greatly simplified by this acetylation process. The accuracy of this analytical method was found to be satisfactory, as Tables II and III show.

## Experimental

**Gas Chromatography.** — In this work, silicone grease (Dow Corning High Vacuum Silicone Grease) was used as the stationary substrate, while aqua-regia-treated[11] Chromosorb (Johns-Manville), 35- to 60-mesh size, was used as the solid support. The packing was prepared by adding 80 g. of Chromosorb to 20 g. of silicone grease dissolved in ethyl ether. The solvent was evaporated on a steam-bath, and finally the packing was dried in an air oven at 110°C. The columns were constructed from the packing and stainless steel tubings 0.75, 1.50, 2.25 and 3.00 m. long and 5 mm. in inner diameter, and they were tested at temperatures of 180, 200, 220 and 240°C.

A Shimadzu model GC-1A gas chromatograph equipped with a filament-wire thermal-conductivity cell was used without modification. Helium was used as the carrier gas, and its flow rates were constantly checked with a soap-film flowmeter. In this work the flow rate was controlled at 20, 40 or 66 ml. per minute.

For the standard samples of the higher $n$-alcohols, $C_6$ through $C_{18}$, and of their acetates, commercial alcohols were purchased from the Wako Pure Chemical Co., and purified in our laboratory through their borates and thereafter by the fractional distillation (Podbielniak) of alcohols obtained from the hydrolysis or of their esters acetylated by the ordinary method.

**The Apparatus for and Operation of the Ketene Acetylation of an Alcohol Sample.** — Figure 1 illustrates a ketene generator and acetylation apparatus. At the start, the cock A is opened and the reactor B (5.5 mm.×60 mm., glass), is charged with 1 ml. of an alcohol mixture. Then the acetone in a 3 l.-flask is gently refluxed, and 50-60 V-AC. is supplied to the 300 W.-nichrome wire, hung in the 3 l.-flask, in order to maintain the dark red color of the wire throughout the acetylation. The vapor of the refluxing acetone comes in contact with the hot wire and undergoes cracking. When the evolution of ketene gas mixture becomes stationary, the cock A is closed and the flow rate of the gas is immediately set at an appropriate rate by controlling the by-pass flow rate (level D) by moving the vessel C up and down according to the reading of the scale differences of an orifice meter E, which has been preliminarily graphed against the flow rate of the ketene gas mixture. When the flow rate is 300 ml. and 600 ml. per hour,

11) A. Zlatkis, Su-Yu Ling and H. R. Kaufman, *Anal. Chem.*, **31**, 945 (1959).

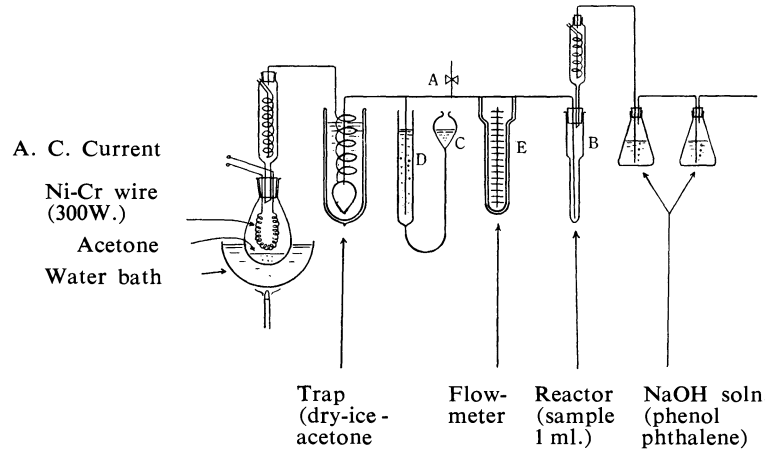

Fig. 1. Keten generator and acetylation apparatus.

it took 2.5 and 1.5 hr. respectively to complete the acetylation of 1 ml. of the alcohol mixture.

## Results and Discussion

**The Accuracy of the Ketene Acetylation Process.**—In order to estimate the loss of the sample during the acetylation process, only the losses of hexyl alcohol and its acetate, which are the most volatile among the compounds under consideration in each series, were investigated. It was found that when flow rate of nitrogen (in place of ketene-metane gas) was 300 ml. per hour, hexylalcohol and its acetate were lost at the rates of 0.7—0.8 mg. and 2.5—3.0 mg. per hour respectively when accompanied by a gas stream. Because, under actual conditions, about 1/4.5 of ketene gas is calculated to be absorbed as a result of the reaction with alcohol, only ca. 0.5 wt.% of the $C_6$-compounds should be lost during the acetylation process. The loss due to the acetylation of $C_8$ and higher alcohols, therefore, should be less than 0.5 wt.% respectively, and there should be essentially no difference in composition between the alcohol mixture and the acetate one during the process.

At times during the acetylation process, portions of the sample were taken out and submitted to gas chromatography in order to check the disappearance of alcohols. At the end of the reaction, each peak of the homologous alcohols disappeared completely and simultaneously, and no peaks other than those due to the acetates were produced. It is obvious, therefore, that the conversion of each alcohol to its acetate is perfectly quantitative, and yet that its conversion velocity is the same in all the alcohols concerned.

**Gas Chromatographic Analysis.** — In the analysis of samples with a very wide boiling range, if complete separation of the lower boiling components is desired the retention times of the higher-boiling components necessarily become too long and, consequently, the peaks of these components become wider. Under such conditions, the limit of detection is undesirably high, and no high accuracy of analysis could be expected. Therefore, the retention time as well as the separation efficiency must be taken into consideration in the determination of analytical conditions. In this work the optimum conditions were selected on the basis of the following evidence; a) analytical time through the retention times of the highest-boiling components, b) separation efficiencies through the height equivalent to a theoretical plate[12] of the components, and c) the stability of the stationary liquid at a high temperature.

As the analytical time is decided by the retention time of the last eluting component, the time of $n$-$C_{22}H_{45}OAc$ must be restricted within definite limitations. The retention times of $n$-$C_6H_{13}OAc$ through $n$-$C_{18}H_{37}OAc$ were measured under various analytical conditions. For a homologous series of organic compounds, it has been shown that a plot of the logarithm of the retention volume or of the time against the number of carbon atoms yields an almost straight line.[13-15] On the basis of the experimental results in this work, it was recognized that a similar relationship is proper for $n$-$C_6H_{13}OAc$ through $n$-$C_{18}H_{37}OAc$. By an extrapolation of the line, the retention times of $n$-$C_{20}H_{41}OAc$ and $n$-$C_{22}H_{45}OAc$ were presumed

12) A. I. M. Keulemans and A. Kwants, "Vapor Phase Chromatography," Butterworths, London (1957), p. 15.

14) A. T. James and A. J. P. Martin, *Biochem. J.*, **50**, 679 (1952).
15) N. H. Ray, *J. Appl. Chem.*, **4**, 21 (1954).

for each condition. The analytical conditions at which the retention time of $n$-$C_{22}H_{45}OAc$ becomes longer than 180 min. seemed to be unsuitable for a routine analysis.

The relation between the height equivalent to a theoretical plate (HETP) and the gas flow rate ($u$) is given by the following equation.[16]

$$\mathrm{HETP} = A + B/u + Cu$$

where $A$, $B$ and $C$ are constants. Therefore, a plot of the HETP versus $u$ shows a curve with a minimum, at which point the column reaches its highest efficiency. In this work, the values of HETP for 40 and 66 ml. per minute were generally smaller than that for 20 ml. per minute. Therefore, the minimum value seems to be obtained for the flow rate of near 40 or 66 ml. per minute.

At the temperature of 240°C silicone grease was not stable enough for the retention times of the components to decreased in a short time. Therefore, the column temperature should not be maintained at 240°C or over.

In view of these points the analytical conditions shown in Table I were selected for the analysis of $n$-$C_6H_{13}OAc$ through $n$-$C_{22}H_{45}OAc$.

16) J. J. van Deemter, F. J. Zuiderweg and A. Klinkenberg, *Chem. Eng. Sci.*, 5, 271 (1956).

A linear relationship was observed between the weight of each component and its peak area.

**The Accuracy of the Gas Chromatography (Repeatability).**—Table II shows the analytical results of the gas chromatography of a known sample of $n$-$C_6H_{13}OAc$ - $n$-$C_{18}H_{37}OAc$. It is clear from these results that the repeatability of this method is fairly good.

**The Accuracy (Repeatability) of Acetylation by Ketene Gas by Means of Gas Chromatography.**—Table III shows the repeatability of the ketene-acetylation of the known sample of $n$-$C_6H_{13}OH$ - $n$-$C_{16}H_{33}OH$ by the use of gas chromatography. It is clear from these results that the repeatability of this method is also fairly good.

The authors wish to express their appreciation to the Maruzen Oil Co., Ltd., for permission to publish this work, and to Mr. Tsunehide Kozuma and Dr. Hiroshi Hasegawa of the company for their valuable advice and discussions.

# The Synthesis of Irisolone

By Kenji FUKUI and Takashi MATSUMOTO

(Received August 15, 1964)

Irisolone, a colorless substance, was isolated from the rhizomes of *Iris nepalensis* D. Don by Gopinath et al.[1] They also established its structure as 4'-hydroxy-5-methoxy-6, 7-methylenedioxyisoflavone (I) on the basis of analytical, spectroscopic and degradative studies. It is one of the few isoflavones which contain a methylenedioxy group in the condensed benzene ring, the only others so far known being tlatlancuayin[2] and maxima substance A.[3] Further, it is an unusual type of isoflavone in that the oxygenation pattern is at positions 5, 6 and 7. This class includes irigenin,[4] tectorigenin,[5] muningin,[6] podospicatin,[7] caviunin,[8] and tlatlancuayin as well as irisolone. The present paper will describe the total synthesis of irisolone, its methyl ether and some related compounds.

The methylation of irisolone has yielded the methyl ether (II), which can be converted by dilute alkali hydrolysis into 6-hydroxy-2-methoxy-3, 4-methylenedioxyphenyl 4-methoxybenzyl ketone (III).[1] The ether II has been reformed by the treatment of the deoxybenzoin III with sodium and ethyl

formate.[1] The synthesis of the deoxybenzoin III was achieved in two ways. The first method involved the condensation reaction of 3-methoxy - 4, 5 - methylenedioxyphenol (IV). The phenol IV underwent the Hoesch reaction with 4-methoxybenzyl cyanide to give a deoxybenzoin. In previous papers[9] it was demonstrated that the phenol IV was substituted not at the 6-position but at the 2-position in the Hoesch condensation. Therefore, the condensation product was thought to be the ketone III. In order to elucidate the structure of the product, a second, unambigous method of synthesis was explored. 5, 7-Dihydroxy-4'-methoxy - 2 - methylisoflavone (V),[10] when subjected to para hydroxylation, afforded 5, 7, 8-trihydroxy-4'-methoxy-2-methylisoflavone (VI). Subsequent methylenation using the potassium hydroxide - acetone method gave 5-hydroxy-4'-methoxy-7,8-methylenedioxy-2-methylisoflavone (VII). The benzylation of VII with benzyl chloride yielded 5-benzyloxy-4'-methoxy-7, 8 - methylenedioxy - 2 - methylisoflavone (VIII), which was then smoothly converted by boiling dilute alkali into 6-benzyloxy-2-hydroxy-3, 4-methylenedioxyphenyl 4-methoxybenzyl ketone (IX). The ketone IX was first methylated in the 2-position, using the potassium carbonate - acetone method, to a methyl ether (X), and then debenzylated with hydrogen to give the deoxybenzoin III identical with the above ketone. The melting point of the deoxybenzoin was the same as that reported in the literature for the ketone obtained from natural irisolone methyl ether by Gopinath et al.[1] Irisolone methyl ether could be obtained according to the method of Gopinath et al.[1] (Table I).

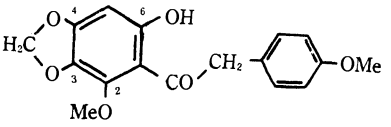

TABLE I. THE MELTING POINTS OF IRISOLONE AND ITS DERIVATIVES (°C)

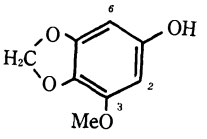
| | Synthetic compound | Natural compound |
|---|---|---|
| Irisolone (I) | 251—252 | 250—251*1 (269—270)[1] |
| Acetate of I | 162—163 | 156—157[1] |
| Irisolone methyl ether (II) | 182—183 | 179—181*1 (184—185)[1] |
| 5-Demethyl deriv. of II | 211—212 | 214—215[1] |



The methylation of VII with dimethyl sulfate yielded 4',5-dimethoxy-7,8-methylenedioxy-2-methylisoflavone (XI), which was then converted into 2-hydroxy-6-methoxy-3,4-methylenedioxyphenyl 4-methoxybenzyl ketone (XII).

The resulting ketone gave the original isoflavone XI with acetic anhydride and was condensed with ethyl formate to give 4', 5-dimethoxy-7, 8-methylenedioxyisoflavone (XIII), an isomer of irisolone methyl ether (II).

The phenol IV underwent the Hoesch reaction with 4-hydroxybenzyl cyanide to give 6-hydroxy-2-methoxy-3, 4-methylenedioxyphenyl 4-hydroxybenzyl ketone (XIV). The same ketone XIV was also obtained from the corresponding amine XV, which was synthesized by the catalytic reduction of a nitroketone XVI; the ketone XVI was derived in turn from 4-nitrobenzyl cyanide by the Hoesch condensation. The ketone XIV was indentical with that obtained from the degradation of natural irisolone by Gopinath et al.[1] The resulting ketone XIV underwent ring closure with ethyl orthoformate or ethyl formate to give 4'-hydroxy-5-methoxy-6, 7-methylenedioxyisoflavone (I), which agreed with natural irisolone (Table I). The identity of the product was established by methylation as well as by demethylation to known products.

The ring closure of the ketone XIV with acetic anhydride gave a monoacetate (XVII), which was then smoothly converted into the 2-methyl derivative (XVIII) of irisolone. By similar methods, 4'-nitroisoflavones (XIX and XX) were also obtained from the ketone XVI.

The ultraviolet absorption spectra of natural and synthetic methylenedioxyisoflavones are shown in Figs. 1 and 2 and Table II. In most

cases, there are two characteristic peaks, at ca. 260 (band I) and ca. 325 mμ (band II). The displacement effect of the substitution is similar to that reported in previous papers.[11] The absorption curve of XIII (a methylenedioxy group in the 7, 8-positions) is different from that of II (the group in the 6, 7-positions) (Fig. 2).

## Experimental*3

**5, 7, 8-Trihydroxy-4′-methoxy-2-methylisoflavone (VI).**—To a cooled, stirred solution of 5, 7-dihydroxy-4′-methoxy-2-methylisoflavone (V)[10] (4.5 g.) in aqueous sodium hydroxide (4%, 120 ml.), an aqueous solution of potassium persulfate (7.5 g. in 150 ml.) was added drop by drop over a 2 hr. period at 15—20°C. The mixture was allowed to stand at room temperature for 24 hr. and then acidified to litmus with dilute hydrochloric acid. The unchanged compound which had separated out was filtered off, and the filtrate was then heated with concentrated hydrochloric acid (90 ml.) and sodium sulfite (9.0 g.) on a steam bath for 30 min. On cooling, the brown precipitates were collected, washed with water, and then recrystallized from acetone to give VI as yellow needles (or prisms), m. p. 288—289°C (decomp.); yield, 1.2 g. It gave a green ferric chloride reaction in ethanol.

Found: C, 64.87; H, 4.61. Calcd. for $C_{17}H_{14}O_6$: C, 64.96; H, 4.47%.

**5-Hydroxy-4′-methoxy-7, 8-methylenedioxy-2-methylisoflavone (VII).**—Into a mixture of VI (1.6 g.), potassium hydroxide (0.9 g.) and ethanol (15 ml.) in water (15 ml.), air having been excluded by a stream of nitrogen gas, methylene sulfate (1.1 g.) in acetone (20 ml.) was stirred at 45—50°C. The mixture was kept at 45—50°C for another 80 min. and then diluted with aqueous potassium hydroxide. The yellow precipitates were collected, washed with dilute hydrochloric acid, and then water, and recrystallized from aqueous acetone to give VII as yellow needles, m. p. 190—191°C; yield 450 mg. It gave a green ferric chloride reaction in ethanol. IR: 1665 (C=O), 1034 (=C-O-C), 923 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 66.16; H, 4.43. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

**5-Benzyloxy-4′-methoxy-7, 8-methylenedioxy-2-methylisoflavone (VIII).**—The isoflavone VII (1.1 g.) was refluxed with dry acetone (100 ml.), benzyl chloride (450 mg.), sodium iodide (0.1 g.) and anhydrous potassium carbonate (15 g.) for 30 hr. Inorganic salts were filtered off and washed with warm acetone, and the combined acetone solution was distilled off. The residue was washed with water and recrystallized from acetone to give VIII as colorless needles, m. p. 195—196°C; yield 0.7 g. IR: 1646 (C=O), 1028 (=C-O-C), 915 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 72.42; H, 4.99. Calcd. for $C_{25}H_{20}O_6$: C, 72.10; H, 4.84%.

**6-Benzyloxy-2-hydroxy-3,4-methylenedioxyphenyl 4-Methoxybenzyl Ketone (IX).**—A mixture of VIII (600 mg.), aqueous potassium hydroxide (10%, 10 ml.) and ethanol (100 ml.) was refluxed for 2 hr. under a stream of nitrogen gas. The solvent was removed in vacuo, and the residue was acidified with dilute hydrochloric acid. The yellow precipitates were collected, washed with water, and then crystallized from aqueous acetone to give IX as pale yellow needles, m. p. 148—149°C; yield 420 mg. It gave a green ferric chloride reaction in ethanol.

11) K. Fukui and T. Matsumoto, *J. Sci. Hiroshima, Univ., Ser. A-II*, **28**, 47 (1964); *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **85**, 793 (1964); This Bulletin, **38**, 612 (1965).

*3 All melting points are uncorrected; the ultraviolet spectra were measured in ethanol, while the infrared spectra were measured in Nujol.

IR: 1663 (C=O), 1031 (=C-O-C), 915 $cm^{-1}$ (O-$CH_2$-O). UV: $\lambda_{max}^{EtOH}$ m$\mu$ (log $\varepsilon$); 247 (4.12), 296 (4.10), 351 (3.53).

Found: C, 70.70; H, 5.28. Calcd. for $C_{23}H_{20}O_6$: C, 70.40; H, 5.14%.

**6-Hydroxy-2-methoxy-3, 4-methylenedioxyphenyl 4-Methoxybenzyl Ketone (III).**—*From IV.*—3-Methoxy-4, 5-methylenedioxyphenol (IV)[12] (3.7 g.) and 4-methoxybenzyl cyanide (3.7 g.) were dissolved in dry ether (70 ml.), and then fused zinc chloride (1.0 g.) was added. The mixture was saturated with dry hydrogen chloride in an ice bath and allowed to stand overnight. After the ether layer had been decanted, the ketimine hydrochloride was washed with dry ether and then hydrolyzed by heating it with water (40 ml.) on a water bath for 30 min. The solid which had separated on cooling was extracted with ethyl acetate; the extract was washed with aqueous sodium bicarbonate and then with water. After the solvent had been evaporated, the residue was distilled. The distillate (bath temperature 180—240°C/0.01 mm. Hg.) was collected and recrystallized from methanol to give III as yellow needles, m. p. 114—115°C (reported m. p. 113—114°C[1]); yield, 820 mg. It gave a green ferric chloride reaction in ethanol. IR: 1662 (shoulder), 1632 (C=O), 1035 (=C-O-C), 936 $cm^{-1}$ (O-$CH_2$-O). UV: $\lambda_{max}^{EtOH}$ m$\mu$ (log $\varepsilon$); 245.5 (4.08), 286.5 (4.14), 355 (3.72).

Found: C, 64.39; H, 5.10. Calcd. for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10%.

*From IX.*—The ketone IX (360 mg.) was refluxed with dry acetone (40 ml.), dimethyl sulfate (4 drops), and anhydrous potassium carbonate (4.0 g.) for 27 hr. The crude product X, was dissolved into ethyl acetate, and the solution was washed with aqueous potassium hydroxide (5%) and then with water. After the solvent had been evaporated, the residue was dissolved into ethanol (50 ml.) and in the presence of Pd-C (10%, 1.0 g.), the solution was shaken with hydrogen at room temperature for 5 hr. The reaction mixture was filtered, and the filtrate was evaporated. The residue was recrystallized from methanol to give III as yellow needles, m. p. 114—115°C; yield 90 mg. This compound was identical with the above sample.

**4', 5-Dimethoxy-6, 7-methylenedioxyisoflavone (Irisolone Methyl Ether) (II).**—The ketone III (150 mg.) was condensed with ethyl formate (15 ml.) and sodium (0.2 g.) as described by Gopinath et al.[1] Recrystallization from methanol gave II (40 mg.) as colorless plates, m. p. 182—183°C*4 reported m. p. 184—185°C[1]). It was found identical with the natural irisolone methyl ether (m. p. 179—181°C*1,*4)) which had been supplied by Gopinath, by mixed melting point measurement and infrared and ultraviolet spectral comparisons. This substance dissolves into concentrated sulfuric acid to give a yellow solution. IR: 1647 (C=O), 1021 (=C-O-C), 925 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 66.04; H, 4.21. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

12) A. F. Wagner, E. Walton, A. N. Wilson, J. O. Rodin and F. W. Holly, *J. Am. Chem. Soc.*, **81**, 4983 (1959).

*4 The sample was dried in vacuo at 110°C for 2 hr.

**4', 5-Dimethoxy-7, 8-methylenedioxy-2-methylisoflavone (XI).**—A mixture of VII (830 mg.), dimethyl sulfate (2.0 ml.), anhydrous potassium carbonate (10 g.) and dry acetone (80 ml.) was refluxed for 30 hr. The reaction mixture was then filtered, and the inorganic residue was washed with hot acetone. The evaporation of acetone left a solid which was triturated with water, filtered, and crystallized from aqueous acetic acid to give XI as colorless needles, m. p. 214—215°C; yield 750 mg. It dissolves into concentrated sulfuric acid to give a yellow solution. IR: 1668 (C=O), 1029 (=C-O-C), 923 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 67.08; H, 4.94. Calcd. for $C_{19}H_{16}O_6$: C, 67.05; H, 4.75%.

**2-Hydroxy-6-methoxy-3, 4-methylenedioxyphenyl 4-Methoxybenzyl Ketone (XII).**—A mixture of the isoflavone XI (560 mg.), potassium hydroxide (1.0 g.), water (10 ml.) and ethanol (60 ml.) was refluxed for 2 hr. under a stream of nitrogen gas. The reaction mixture was then treated in the usual manner. The product was recrystallized from ethanol to give the ketone XII as yellow plates, m. p. 133—134°C; yield, 460 mg. It gave a green ferric chloride reaction in ethanol. IR: 1671 (C=O), 1033 (=C-O-C), 915 $cm^{-1}$ (O-$CH_2$-O). UV: $\lambda_{max}^{EtOH}$ m$\mu$ (log $\varepsilon$); 246.5 (4.11), 295.5 (4.15), 349 (3.56).

Found: C, 64.49; H, 5.31. Calcd. for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10%.

When the ketone XII (200 mg.) was heated with anhydrous sodium acetate (200 mg.) and acetic anhydride (10 ml.), the parent isoflavone, XI (80 mg., m. p. 214—215°C), was obtained.

**4', 5-Dimethoxy-7, 8-methylenedioxyisoflavone (XIII).**—The ketone XII (600 mg.) in ethyl formate (25 ml.) was added to sodium powder (0.6 g.) at −10°C and left in the refrigerator for 3 days; then the product was worked up. The ether residue gave the isoflavone XIII, which crystallized from aqueous acetone as colorless needles, m. p. 179—181°C; yield 250 mg. It was soluble in concentrated sulfuric acid to give a reddish yellow solution and depressed to 150—152°C on admixture with natural irisolone methyl ether (m. p. 179—181°C*1). IR: 1651 (C=O), 1030 (=C-O-C), 920$cm^{-1}$ (O-$CH_2$-O).

Found: C, 66.47; H, 4.47. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

**6-Hydroxy-2-methoxy-3, 4-methylenedioxyphenyl 4-Nitrobenzyl Ketone (XVI).**—To a solution of 3-methoxy-4, 5-methylenedioxyphenol (IV) (4.4 g.) in dry ether (100 ml.), a mixture of 4-nitrobenzyl cyanide (4.4 g.) and anhydrous zinc chloride (3.0 g.) in dry chloroform (100 ml.) was added. The resulting mixture was saturated with dry hydrogen chloride at 0°C. The reaction mixture was then treated in the usual manner. Recrystallization from aqueous acetone gave the ketone XVI as yellow needles, m. p. 165—167°C; yield, 3.2 g. It gave a green ferric chloride reaction in ethanol. IR: 1623 (C=O), 1515, 1331 ($NO_2$), 1039 (=C-O-C), 923 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 58.04; H, 4.13; N, 4.21. Calcd. for $C_{16}H_{13}O_7N$: C, 58.01; H, 3.96; N, 4.23%.

**6-Hydroxy-2-methoxy-3, 4-methylenedioxyphenyl 4-Aminobenzyl Ketone (XV).**—A solution of the ketone XVI (2.0 g.) in ethyl acetate (120 ml.) was submitted to catalytic reduction at room temperature in the presence of Pd-C (10%, 1.5 g.). After the catalyst had been filtered, the filtrate was evaporated; the residue was then recrystallized from methanol to give XV as yellow plates, m. p. 170—172°C; yield 1.5 g. It gave a green ferric chloride reaction in ethanol. IR: 3453, 3373, 1595, 1340 ($NH_2$), 1623 (C=O), 1044 (=C-O-C), 929 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 63.58; H, 5.35; N, 4.68. Calcd. for $C_{16}H_{15}O_5N$: C, 63.78; H, 5.02; N, 4.65%.

**6-Hydroxy-2-methoxy-3, 4-methylenedioxyphenyl 4-Hydroxybenzyl Ketone (XIV).**—*From IV.*—From the ketone IV (600 mg.), 4-hydroxybenzyl cyanide (700 mg.) and anhydrous zinc chloride (0.3 g.) in dry ether (20 ml.), synthesis was carried out by a method similar to that used for XVI. The product was extracted with ethyl acetate, and the extract was washed with aqueous sodium bicarbonate and then water. After the solvent had been evaporated, the residue was distilled. The distillate (bath temperature 180—240°C/0.04 mmHg) was collected and recrystallized from ether-petroleum ether to give XIV as yellow needles, m. p. 152—153°C (reported m. p. 159—160°C[1]); yield, 70 mg. It gave a ferric green chloride reaction in ethanol. IR: 1630 (C=O), 1051 (=C-O-C), 934 $cm^{-1}$ (O-$CH_2$-O). UV: $\lambda_{max}^{EtOH}$ m$\mu$ (log $\varepsilon$); 245 (4.07), 287 (4.14), 355 (3.72).

Found: C, 63.40; H, 4.89. Calcd. for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67%.

*From XV.*—A solution of sodium nitrite (400 mg.) in water (12 ml.) was added to a suspension of the ketone XV (800 mg.) in dilute sulfuric acid (25%, 55 ml.) at 0°C. After the solution had been stirred at 0—5°C for another hour, the excess nitrous acid was decomposed with urea (350 mg.). The solution was added drop by drop into a boiling solution of cupric sulfate (40 g.) in water (50 ml.). The reaction mixture was cooled and extracted with ether. The ether solution was washed with water, dried, and evaporated, and the residue was distilled. The distillate (bath temperature 180—220°C/0.01 mmHg) was collected and then recrystallized from ether-petroleum ether to give XIV as yellow microneedles, m. p. 152—153°C; yield, 80 mg. This substance was identical with the above sample.

An acetate (m. p. 89—90°C) was obtained by the acetic anhydride-pyridine method. IR: 1762, 1723 (OAc), 1623 (C=O), 1021 (=C-O-C), 915 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 62.14; H, 4.60. Calcd. for $C_{20}H_{18}O_8$: C, 62.17; H, 4.70%.

**4'-Hydroxy-5-methoxy-6, 7-methylenedioxyisoflavone (Irisolone) (I).**—a) The ketone XIV (2.0 g.) in ethyl formate (60 ml.) was added to sodium (2.0 g.) at −10°C, left in a refrigerator for 3 days, and the product worked up. Recrystallization from aqueous pyridine gave I as colorless prisms, m. p. 251—252°C (reported m. p. 269—270°C[1]); yield, 1.1 g. This substance was soluble in aqueous sodium hydroxide (5%) and dissolves into concentrated sulfuric acid to give a yellow solution. It was found identical with the natural irisolone (m. p. 250—251°C*[1]) which was supplied by Gopinath, by mixed melting point measurement and infrared and ultraviolet spectral comparisons. IR: 1645 (C=O), 1028 (=C-O-C), 920 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 65.47; H, 3.85. Calcd. for $C_{17}H_{12}O_6$: C, 65.38; H, 3.87%.

b) A mixture of the ketone XIV (600 mg.), ethyl orthoformate (1.5 ml.), dry pyridine (4.0 ml.) and piperidine (0.3 ml.) was refluxed for 4 hr. under a stream of nitrogen gas. The product which had separated on cooling was recrystallized from aqueous pyridine to give I as colorless prisms, m. p. 251—252°C; yield, 40 mg. It was identical with the above sample.

**The Reaction of Synthetic Irisolone (I).**—An acetate (m. p. 162—163°C) was prepared according to the Gopinath method[1] (reported m. p. 156—157°C[1]). IR: 1767 (OAc), 1649 (C=O), 1026 (=C-O-C), 926 $cm^{-1}$ (O-$CH_2$-O).

Found: C, 64.26; H, 3.92. Calcd. for $C_{19}H_{14}O_7$: C, 64.40; H, 3.98%.

The acetate (310 mg.) was refluxed with aqueous sodium hydroxide (10%, 3.0 ml.) and methanol (40 ml.) for 5 min. The parent isoflavone, I (m. p. 251—252°C, 240 mg.), was thus obtained.

According to the method of Gopinath et al.,[1] the isoflavone I was easily converted into II (m. p. 182—183°C) with dimethyl sulfate. II was demethylated with aluminum chloride in ether to give 5-hydroxy-4'-methoxy-6, 7-methylenedioxyisoflavone (m. p. 211—212°C, pale yellow plates) (reported m. p. 214—215°C[1]) according to the method of Gopinath et al.[1]

Found: C, 65.43; H, 3.84. Calcd. for $C_{17}H_{12}O_6$: C, 65.38; H, 3.87%.

**4'-Acetoxy-5-methoxy-6, 7-methylenedioxy-2-methylisoflavone (XVII).**—A mixture of the ketone XIV (80 mg.), anhydrous sodium acetate (200 mg.) and acetic anhydride (4.0 ml.) was refuxed for 30 hr. The excess acetic anhydride was removed in vacuo. The residue was washed with water and then recrystallized from methanol to give XVII as colorless plates, m. p. 201—202°C; yield 60 mg.

Found: C, 65.27; H, 4.36. Calcd. for $C_{20}H_{16}O_7$: C, 65.21; H, 4.38%.

**4'-Hydroxy-5-methoxy-6, 7-methylenedioxy-2-methylisoflavone (XVIII).**—A mixture of the acetate XVII (420 mg.), ethanol (60 ml.) and an aqueous sodium hydroxide solution (5%, 5.0 ml.) was refluxed for 5 min. After the solvent had been removed in vacuo, the residue was dissolved in water and then acidified. The precipitates were collected, washed with water, and recrystallized from methanol or acetone to give XVIII as colorless prisms, m. p. 284—285°C; yield, 230 mg. It dissolves into concentrated sulfuric acid to give a yellow solution.

Found: C, 66.12; H, 4.15. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

**5-Methoxy-6, 7-methylenedioxy-4'-nitroisoflavone (XIX).**—A mixture of the ketone XVI (1.0 g.), ethyl orthoformate (5.0 ml.), dry pyridine (8.0 ml.) and piperidine (0.5 ml.) was refluxed for 6 hr. The brown precipitates which separated on cooling were

collected, washed with ethanol, and then recrystallized from ethyl acetate to give XIX as pale yellow needles, m. p. 209—211°C; yield, 0.5 g. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 241*[2] (4.28), 289 (4.36), 315*[2] (4.23).

Found: C, 59.70; H, 3.44; N, 4.20. Calcd. for $C_{17}H_{11}O_7N$: C, 59.82; H, 3.26; N, 4.10%.

**5-Methoxy-6, 7-methylenedioxy-2-methyl-4′-nitroisoflavone (XX).**—A mixture of the ketone XVI (1.0 g.), acetic anhydride (25 ml.) and anhydrous sodium acetate (1.0 g.) was refluxed for 24 hr. The reaction mixture was treated in the usual manner. The product was recrystallized from acetone to give XX as yellow rhombic plates, m. p. 219—220°C; yield, 0.8 g. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 241.5*[2] (4.35), 284.5 (4.33), 312*[2] (4.11).

Found: C, 60.67; H, 3.80; N, 3.69. Calcd. for $C_{18}H_{13}O_7N$: C, 60.85; H, 3.68; N, 3.94%.

The authors are grateful to Dr. K. W. Gopinath, Muslim University, for his gifts of natural irisolone and its methyl ether. Grateful acknowledgement is also made to the members of the Microanalytical Laboratory, Faculty of Pharmacy, Nagasaki University, for the microanalyses.

# Oxidation of Alcohols with *t*-Butyl Chromate. I. The Oxidation of Primary Aliphatic Alcohols*[1]

By Takayuki SUGA, Keiichi KIHARA*[2] and Tamon MATSUURA

(Received September 5, 1964)

Oppenauer and Oberrauch[1] have recorded that *t*-butyl chromate[2] in a nonpolar solvent converts primary alcohols, such as cetyl alcohol, geraniol and benzyl alcohol, into the corresponding aldehydes in 80—94% yields, and also that this oxidant in a nonpolar solvent containing such an organic acid as acetic acid oxidizes to a ketone group a methylene group adjacent to a double bond. *t*-Butyl chromate has been employed for the preparation of $\alpha,\beta$-unsaturated ketones.[3] Among primary alcohols, the *t*-butyl chromate oxidation of 2-isopropyl-5-methylhexanol and 3-isopropyl-1-heptenol[4] has been recorded to afford only the corresponding aldehyde in a low yield. However, the action of *t*-butyl chromate on alcohols appears not to have been examined in detail as yet. We have now attempted the oxidation of a variety of aliphatic alcohols with *t*-butyl chromate.

The oxidation was undertaken on a series of aliphatic alcohols, which are shown to have the general formula of $R\cdot CH_2OH$, where R is $CH_3$, $CH_3(CH_2)_2$, $CH_3(CH_2)_3$, $CH_3(CH_2)_4$, $CH_3(CH_2)_{10}$, $CH_3(CH_2)_{14}$ and $CH_3(CH_2)_{16}$. When cetyl alcohol (Exp. 1) was oxidized in benzene for a shorter time (see Table I) than that used by Oppenauer and Oberrauch,*[3] it gave palmitic acid (54%; based on the sample taken) and cetyl palmitate (39%), but not palmitaldehyde. Since Oppenauer et al. have used petroleum ether as a solvent in this oxidation, the oxidation of *n*-lauryl alcohol in petroleum ether (Exp. 2) for a shorter time than that in Exp. 1 was carried out, giving lauraldehyde (3%), lauric acid (52%) and *n*-lauryl laurate (28%); the results resemble those of Exp. 1. Even when *n*-lauryl alcohol was oxidized in benzene with ice-cooling for 6 hr. (Exp. 3), the reaction product consisted of the aldehyde (38%), the

*3 The oxidation recorded by Oppenauer et al. has been carried out at room temperature over a 14-day period, using a petroleum ether solution of *t*-butyl chromate prepared in the 1:2.5 mol. ratio of cetyl alcohol to this chromate and in a 28% concentration, and using a petroleum ether solution of cetyl alcohol in the same concentration as in Exp. 1.

TABLE I. CONDITIONS OF THE OXIDATION

| Exp. | Sample: Alcohol | Sample: Concentration[a] % | Oxidant: Sample to *t*-Bu. chrom.[b] (mol. ratio) | Oxidant: Concentration % | Temp. °C | Time |
|---|---|---|---|---|---|---|
| 1 | Cetyl | 0.9 | 1 : 2.5 | 23 | ca.30 | 5 days |
| 2[c] | *n*-Lauryl | 1.2 | 1 : 2.5 | 28 | ca.25 | 2 days |
| 3 | *n*-Lauryl | 4.5 | 1 : 1 | 36.5 | 1—2 | 6 hr. |
| 4 | *n*-Hexyl | 4.5 | 1 : 1 | 36.5 | 1—2 | 6 hr. |
| 5 | *n*-Butyl | 4.5 | 1 : 1 | 36.5 | 1—2 | 6 hr. |
| 6 | Ethyl | 4.5 | 1 : 1 | 36.5 | 1—2 | 6 hr. |
| 7 | *n*-Amyl | 2.3 | 1 : 1 | 23 | 1—2 | 6 hr. |
| 8 | Isoamyl | 4.5 | 1 : 1 | 36.5 | 1—2 | 6 hr. |
| 9 | Isobutyl | 4.5 | 1 : 1 | 36.5 | 1—2 | 6 hr. |
| 10 | Neopentyl | 4.5 | 1 : 1 | 36.5 | 1—2 | 6 hr. |
| 11 | Geraniol | 4.5 | 1 : 1 | 36.5 | 1—2 | 6 hr. |
| 12 | Isobutyl | 6.8 | 1 : 1.5 | 38 | ca.15 | 66 hr. |

a) Mole in 1000 g. of benzene or petroleum ether.
b) *t*-Bu. chrom.=*t*-Butyl chromate.
c) Petroleum ether was used as a solvent.

carboxylic acid (23%) and the ester (38%). The oxidation of *n*-hexyl alcohol (Exp. 4) under the same conditions as in Exp. 3 gave caproaldehyde (25%), caproic acid (37%) and *n*-hexyl caproate (34%); *n*-butyraldehyde (29%), *n*-butyric acid (32%) and *n*-butyl *n*-butyrate (35%) were also produced in the oxidation of *n*-butyl alcohol (Exp. 5). The oxidation of ethyl alcohol (Exp. 6) afforded acetaldehyde (17%), acetic acid (20%) and ethyl acetate (23%). In all these cases, only a small percentage of unchanged alcohol was recovered. Moreover, *n*-amyl alcohol (Exp. 7), diluted by a double quantity of benzene used in Exp. 3—6, was oxidized under the same conditions as above with a benzene solution of *t*-butyl chromate in a low concentration. The reaction product consisted of *n*-valeraldehyde (43%), *n*-valeric acid (17%) and *n*-amyl *n*-valerate (29%).

The oxidation was tried with alcohols with a variety of $\alpha$- or $\beta$-substituents. The oxidation of isoamyl alcohol (Exp. 8) under the same conditions as in Exp. 3 gave isovaleraldehyde (31%), isovaleric acid (29%) and isoamyl isovalerate (34%). When isobutyl alcohol (Exp. 9) was used, the products were isobutyraldehyde (17%), isobutyric acid (26%), isobutyl isobutyrate (29%) and acetone (4%). The formation of acetone was remarkable in Exp. 12 (17%); it is probably a result of the occurrence of the cleavage reaction. Furthermore, the oxidation of neopentyl alcohol (Exp. 10) yielded trimethylacetaldehyde (36%), trimethylacetic acid (5%) and neopentyl trimethylacetate (13%), and left unchanged the alcohol (38%). This is likely to have been the result of an attack of *t*-butyl chromate on the hydroxymethyl group interrupted by the bulky *t*-butyl group around the hydroxyl group.

Oppenauer et al.[1] have obtained citral in a 80% yield on the *t*-butyl chromate oxidation of geraniol at 28°C for 3 days. A reexamination of the oxidation of geraniol under the same conditions as in Exp. 3 gave citral (77%), geranic acid (2%) and 2-methyl-2-hepten-6-one (3%), but the ester was not obtained. This methylheptenone is presumably produced by an ethylenic bond fission at the allylic position of the sample alcohol.

On oxidation with *t*-butyl chromate, the alcohol with an olefinic double bond on the carbon adjacent to the hydroxymethyl group afforded the corresponding aldehyde in a high yield, but not the ester. On the other hand, saturated primary alcohols with the formula of $X\text{–}CH_2\cdot CH_2OH$ (X: H or alkyl), $\begin{matrix}R\\R\end{matrix}\!\!>\!CH\cdot CH_2OH$ or $\begin{matrix}R\\R\end{matrix}\!\!>\!C\cdot CH_2OH$ were found to produce aldehyde, carboxylic acid and ester corresponding to the alcohol in comparable yields. The formation of an ester was newly recognized in the *t*-butyl chromate oxidation of a saturated aliphatic primary alcohol. The course of the formation of the ester will be discussed in the near future in Part IV of this series.

## Experimental

**Sample Alcohols.**—Neopentyl alcohol was prepared from *t*-butyl chloride and formaldehyde by Grignard reaction;[5] it showed b. p. 110.5—111.5°C

a) Only benzene is represented by volume (ml.).
b) Petroleum ether (ml.) was used as a solvent.
c) The product is acetone.
d) The product is 2-methyl-2-hepten-6-one.

and m. p. 55—56°C after it had been rectified. Geraniol supplied by the Takasago Perfumery Co., Ltd., was purified following the literature method[6] and showed b. p. 111.8—112°C/11 mmHg, $n_D^{25}$ 1.4714 and $d_4^{25}$ 0.8760. The rest of the sample alcohols were obtained from a commercial source and were purified by distillation or recrystallization.

**Oxidant.**—*t*-Butyl chromate was prepared by adding chromium trioxide in small portions to *t*-butyl alcohol under ice-cooling, diluting the resultant with benzene or petroleum ether, and drying the resultant benzene or petroleum ether solution of *t*-butyl chromate over anhydrous sodium sulfate. The quantity of each component used is shown in Table II. The concentration of *t*-butyl chromate in this solution and the mole ratio of a sample alcohol to this chromate are shown in Table I.

**Oxidation and Treatment of a Reaction Mixture.**—Into the benzene or petroleum ether solution of a sample alcohol (the concentration of the alcohol is shown in Table I), the oxidant prepared as above was stirred over a period of 0.5 hr., keeping the internal temperature at 1—2°C; it was then stirred continuously at the same temperature or at room temperature for a further 5.5 hr. or for a period shown in Table I under an atmosphere of nitrogen. Then the whole reaction mixture was treated with water and oxalic acid, except in Exp. 10 (see below), in order to hydrolyze the residual oxidant. The mixture was separated into a benzene layer and an aqueous one, and the latter was repeatedly extracted with benzene or petroleum ether. The removal of the solvent from the combined benzene or petroleum ether solution, after drying over anhydrous sodium sulfate, left a reaction product. The constituents of the reaction product were examined in a manner shown in each experiment. Each of the constituents was identified by a comparison of its infrared spectrum with that of an authentic sample and by a mixed melting point determination of a constituent or its crystalline derivatives. The yield of the constituents of the reaction product is shown in Table II.

**Oxidation of Cetyl Alcohol (Exp. 1).** — The removal of the solvent from the separated benzene solution gave the reaction product (m. p. 51—54°C), from which palmitic acid (m. p. 61—62°C) was then taken out as the lead salt.[7] The neutral product free from the acid was subjected to liquid-column chromatography on silica gel with a mixture of *n*-hexane and ethyl acetate in order to separate cetyl palmitate (m. p. 51—52°C; $\nu_{max}^{KBr}$ 1735, 1186 $cm^{-1}$) and unchanged cetyl alcohol. No isolated palmitaldehyde could be observed in spite of a careful examination.

**Oxidation of *n*-Lauryl Alcohol (Exp. 2 and 3).** —The distillation of the reaction product gave lauraldehyde (b. p. 103—110°C/3 mmHg), unchanged alcohol (b. p. 115—122°C/3 mmHg) and lauric acid (b. p. 150—151°C/3 mmHg) as the distillate, and *n*-lauryl laurate (m. p. 27—28°C; $\nu_{max}^{KBr}$ 1740, 1161 $cm^{-1}$) as the residue.

**Oxidation of *n*-Hexyl Alcohol (Exp. 4).** — The distillation of the reaction product gave caproaldehyde (120—140°C), caproic acid (b. p. 111—112°C/20 mmHg) and *n*-hexyl caproate (b. p. 129—130.5°C/20 mmHg; $\nu_{max}^{KBr}$ 1736, 1171 $cm^{-1}$). Caproaldehyde was also contained in removed benzene; it was estimated by the hydroxylamine method.[8]

**Oxidation of *n*-Butyl Alcohol (Exp. 5).**—An ether solution of the reaction product (b. p. 99—102°C/81 mmHg) obtained by the removal of the

6) E. Guenther, "The Essential Oils," D. Van Nostrand Company, Inc., New York (1952), p. 171.

7) J. D. Piper, A. G. Fleiger, C. C. Smith and N. A. Kerstein, *Ind. Eng. Chem.*, **31**, 307 (1939); W. F. Whitmore and M. Lauro, ibid., **22**, 646 (1930).

8) W. M. Bryant and D. M. Smith, *J. Am. Chem. Soc.*, **57**, 57 (1935).

solvent from the separated benzene solution was extracted with a 10% sodium carbonate solution. The sodium carbonate extracts gave *n*-butyric acid (b. p. 161—163°C) on acidification, while the removal of the solvent from the neutral ether solution afforded *n*-butyl *n*-butyrate (b. p. 97—99°C/80.5 mmHg; $\nu_{max}^{liq.}$ 1737, 1183 $cm^{-1}$). *n*-Butyraldehyde was separated as the 2,4-dinitrophenylhydrazone[9] from the solvent so removed; it was then estimated.

**Oxidation of Ethyl Alcohol (Exp. 6).**—After the reaction mixture had been treated with oxalic acid and water, acetaldehyde in the separated aqueous solution was estimated by the 2,4-dinitrophenylhydrazine method,[9] while acetic acid was determined by titrating the steam-distillate of the aqueous solution with a standard solution of sodium hydroxide. The separated benzene solution was subjected to gas chromatographic analysis in order to estimate acetaldehyde and ethyl acetate.

**Oxidation of *n*-Amyl Alcohol (Exp. 7).**—The distillation of the reaction product gave *n*-valeraldehyde (b. p. 91—111°C), unchanged alcohol (b. p. 131—145°C), *n*-valeric acid (b. p. 101—103°C/30 mmHg) and *n*-amyl *n*-valerate (b. p. 106—108°C/29 mmHg; $\nu_{max}^{liq.}$ 1735, 1178 $cm^{-1}$).

**Oxidation of Isoamyl Alcohol (Exp. 8).** — The reaction product obtained by the evaporation of the solvent was examined in the same manner as that in Exp. 5; it was seen to consist of isovaleric acid (b. p. 97—99°C/38.5 mmHg) and isoamyl isovalerate (b. p. 100—102°C/39 mmHg; $\nu_{max}^{liq.}$ 1735, 1188 $cm^{-1}$). Isovaleraldehyde contained in the distilled solvent was estimated by the 2, 4-dinitrophenylhydrazine method.

**Oxidation of Isobutyl Alcohol (Exp. 9 and 12).**—The reaction product obtained by the removal of the solvent was found, by the same manner as in Exp. 5, to consist of isobutyric acid (b. p. 152—153°C) and isobutyl isobutyrate (b. p. 146—148°C; $\nu_{max}^{liq.}$ 1156 and 1198 (doublet), 1739 $cm^{-1}$). Acetone and isobutyraldehyde were caught as a mixture of the corresponding 2,4-dinitrophenylhydrazone from the solvent removed, and then the dinitrophenylhydrazone was separated by chromatography on a silica gel column.[10]

**Oxidation of Neopentyl Alcohol (Exp. 10).**—After the oxidation, the reaction mixture was treated with hydrazine sulfate (40 g.) and dilute sulfuric acid in order to hydrolyze the residual oxidant. The distillation of the reaction product gave unchanged alcohol (b. p. 110.5—115°C), trimethylacetic acid (m. p. 34—35°C) and neopentyl trimethylacetate (b. p. 165°C; $\nu_{max}^{liq.}$ 1723, 1154 $cm^{-1}$). The acid and the ester were separated from each other by extracting a fraction (b. p. 161—166°C) of the distillate with a sodium carbonate solution. Trimethylacetaldehyde and also a small amount of unchanged alcohol contained in removed benzene were estimated by gas chromatographic analysis.

**Oxidation of Geraniol (Exp. 11).**— The separated benzene solution was extracted with a 3% sodium bicarbonate solution. Geranic acid was obtained from this alkaline solution on acidification. The distillation of the neutral product obtained from the neutral benzene solution gave 2-methyl-2-hepten-6-one (b. p. 60.2—65°C/11.5 mmHg) and citral (b. p. 107—112°C/11.5 mmHg). No ester could be detected, even by thin layer chromatography and gas chromatography of the distillate and the residue.

## Summary

Oxidation with *t*-butyl chromate has been carried out on the straight-chain alcohols with the general formula of $R \cdot CH_2OH$, where R is $CH_3$, $CH_3(CH_2)_2$, $CH_3(CH_2)_3$, $CH_3(CH_2)_4$, $CH_3(CH_2)_{10}$, $CH_3(CH_2)_{14}$ and $CH_3(CH_2)_{16}$, on branched-chain alcohols with a variety of substituents at the carbon alpha or beta to the hydroxymethyl group, and on unsaturated alcohol with an allylic hydroxymethyl group. Thus, a saturated primary alcohol containing the grouping of $-CH_2 \cdot CH_2OH$, $>CH \cdot CH_2OH$ or $>C \cdot CH_2OH$ has been found to produce mixtures of the corresponding aldehyde, acid and ester in comparable yields. On the other hand, an unsaturated primary alcohol with an olefinic double bond on the carbon adjacent to the hydroxymethyl group produces the corresponding aldehyde in a high yield, but not the ester.

The authors wish to express their hearty thanks to the Takasago Perfumery Co., Ltd., for supplying them with a sample of geraniol. This research was aided by a grant from the Ministry of Education.

# The Synthesis and the Reactions of 2, 4, 6-Tri-(ω-hydroxyalkyl)-1, 3, 5-triazines

By Hiroyuki NOHIRA, Yoshihiro NISHIKAWA, Yoshiaki FURUYA and Teruaki MUKAIYAMA

(Received September 5, 1964)

The present study will deal with the synthesis and the reactions of 2, 4, 6-tri-(ω-hydroxyalkyl)-1, 3, 5-triazines. The formation of the triazines was found in the cours of an experiment to prepare *N*-unsubstituted cyclic iminoethers, which had been expected to afford polyamides by the 1, 4-addition type ring-opening polymerization,[1-4] by treating their hydrochlorides with triethylamine.

The hydrochlorides of cyclic iminoethers (I) were prepared from the corresponding ω-cyanohydrines by the action of hydrogen chloride (Table I). The hydrochlorides decomposed to give the corresponding ring-opening products, ω-chloroalkylamides (II), in high yields when they were heated above their melting points (Table II).

$$N\equiv C-(CH_2)_n-OH + HCl \longrightarrow \underset{HCl}{HN=C}\overset{(CH_2)_n}{\underset{O}{\diagup\diagdown}} \quad n=3,4,5 \qquad (I)$$

$$I \xrightarrow[heat]{} H_2N-\overset{O}{\overset{\|}{C}}-(CH_2)_n-Cl \qquad (II)$$

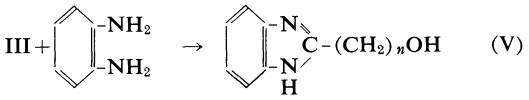
Several attempts to prepare free cyclic iminoethers from the hydrochlorides were made according to the ordinary procedures. When the hydrochlorides were treated with an aqueous solution of potassium carbonate or sodium hydroxide, they were mainly hydrolyzed to give the corresponding lactones and ammonia; free cyclic iminoethers could not be isolated. On the other hand, when the hydrochlorides were treated with anhydrous triethylamine, viscous liquids with a high boiling point resulted. The infrared spectra of these liquids showed strong absorptions at 3350 (OH), 1060 ($CH_2$-OH) and 1545 $cm^{-1}$ (*sym*-triazine ring). Further examinations by means of elementary analyses, ultraviolet spectra and the determination of molecular weight confirmed their structures to be 2, 4, 6-tri-($\omega$-hydroxyalkyl)-1, 3, 5-triazines (III). From the hydrochlorides of the five-, the six- and the seven-membered cyclic iminoethers, the corresponding *sym*-triazines were obtained in fairly good yields, as Table III shows.

(III)

A crystalline derivative (IV) was obtained from the reaction of 2,4,6-tri-($\gamma$-hydroxypropyl)-1, 3, 5-triazine and three equivalent moles of phenylisocyanate:

III + $3C_6H_5$-NCO →
$n=3$

(IV)



The similar triazine formation reaction of iminoethers reported by Cramer et al.[5] has been developed by Schaefer and Peters[6] into a convenient synthetic method for the preparation of 2, 4, 6-trisubstituted-1, 3, 5-triazines. A possible mechanism of these trimerization reactions of the iminoethers has been proposed by Schaefer and Peters. It does not seem unlikely that the cyclic iminoethers which are formed from their hydrochlorides trimerized by essentially the same mechanism. However, one of the significant features in the trimerization reaction of the cyclic iminoethers is that the cyclic iminoethers trimerize more easily than typical non-cyclic iminoethers. This seems to be attributable to the ring strain of the cyclic systems.

In conclusion, it has now been found that the *N*-unsubstituted cyclic iminoethers tend to trimerize more easily in such a fashion as to give *sym*-triazines, rather than to polymerize so as to give polyamides by the 1, 4-addition-type ring-opening polymerization. As a result, a convenient synthetic method for the preparation of $\omega$-hydroxyalkyl-derivatives of *sym*-triazine has been established.

Next, further study was carried out of the reaction of the 2, 4, 6-tri-($\omega$-hydroxyalkyl)-1, 3, 5-triazines thus obtained.

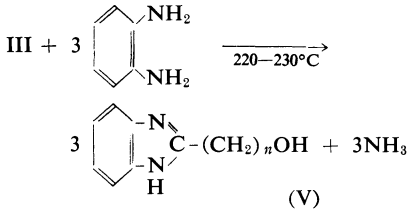
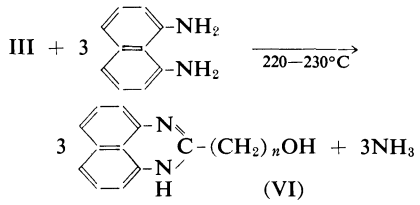
Crundmann[7] has suggested a convenient synthesis of various heterocyclic compounds by the use of unsubstituted *sym*-triazine, as is shown in the following general equation:



X= -NH-, -O-, -S-

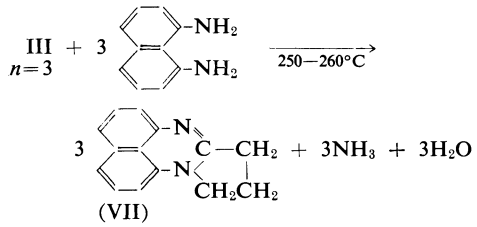
7) C. Grundmann, *Angew. Chem.*, **75**, 393 (1963).

The same investigator and Kreuzberger[8] have reported that this type of ring cleavage is not applicable to 2, 4, 6-trisubstituted-1, 3, 5-triazines; for example, 2, 4, 6-trimethyl-1, 3, 5-triazine does not react with aniline up to 200°C. In the present investigation, however, it has been found that the above-mentioned 2, 4, 6-tri-(ω-hydroxyalkyl)-1, 3, 5-triazines react with diamines when the reactions are carried out above 200°C. That is, when III was heated with three equivalent moles of *o*-phenylenediamine at 220-230°C in a nitrogen atmosphere, the evolution of ammonia was observed, and



8) C. Grundmann and A. Kreuzberger, *J. Am. Chem. Soc.*, **77**, 6559 (1955).

2-($\omega$-hydroxyalkyl)benzimidazoles (V) were obtained in good yields (Table IV).



(V)

In a similar fashion, III reacted with 1,8-naphthylenediamine to give 2-($\omega$-hydroxyalkyl)-perimidines (VI) (Table V).

(VI)

At higher temperatures, 250—260°C, however, azolidino[1,2-a]perimidine (VII), a dehydrated product of VI ($n=3$), was obtained by the reaction of 2,4,6-tri-($\gamma$-hydroxypropyl)-1,3,5-triazine (III, $n=3$) with 1,8-naphthylenediamine.

(VII)

## Experimental

**Trimethylen Cyanohydrin.**—This compound was prepared by the reaction of trimethylene chlorohydrin and potassium cyanide in a mixed solvent of ethanol and water;[9] b. p. 107—108°C (11 mmHg); yield, 30%.

**Tetramethylene Cyanohydrin.** — The reported method,[10] which is essentially analogous to the above reaction, gave the cyanohydrin in poor yields only (5—10%). An improved method is given as follows. A mixture of tetramethylene chlorohydrin (22 g., 0.2 mol.), potassium cyanide (33 g., 0.5 mol.), glycerol (50 ml.) and water (25 ml.) was heated while being mechanically stirred at 100—110°C for 15 min. After it had cooled, the mixture was extracted four times with 50 ml. portion of tetrahydrofuran. The extract was then dried over anhydrous magnesium sulfate, and the solvent was subsequently removed. The residue was distilled under reduced pressure; b. p. 86—88°C (0.5 mmHg); yield, 7.0 g. (35%).

When the distillation was carried out without extracting soon after the reaction was complete, another liquid (b. p. 65—66°C) was obtained. This liquid was identified as tetrahydrofuran by comparing its infrared spectrum with that of an authentic specimen. The formation of this liquid can be explained in terms of the cyclization of the chlorohydrin used, with the loss of hydrogen chloride. The yield of this by-product amounted to almost 30%. This seems to be one of the main factors lowering the yield of the tetramethylene cyanohydrin.

**Pentamethylene Cyanohydrin.**—This compound was prepared from pentamethylene chlorohydrin and potassium cyanide by method analogous to that described above; b. p. 97—98°C (3 mmHg); yield, 83%.

**Hydrochloride of 2-Iminotetrahydrofuran (I, $n=3$).**—Dry hydrogen chloride was passed into a solution of 8.5 g. of trimethylene cyanohydrin in 300 ml. of dry ether maintained at 10—15°C with external cooling. The flask was tightly stoppered and allowed to stand at room temperature for 2 days. The crystals were then collected and washed with dry ether; yield, 11.5 g (Table I).

Similarly, hydrochloride of 2-iminotetrahydropyrane (I, $n=4$) was prepared from tetramethylene cyanohydrin and hydrogen chloride. In this case, however, it was necessary to carry the reaction out in a more dilute (1.5—2.0%) ethereal soultion.

**Hydrochloride of 2-Iminooxepan (I, $n=5$).**—Dry hydrogen chloride was passed into a solution of 4.5 g. of pentamethylene cyanohydrin in 150 ml. of dry ether and 80 ml. of dry, glycol acetal-free dioxane with external cooling. The reaction mixture was allowed to stand at room temperature for 4 days, and then refluxed for 3 hr. The solvent was subsequently removed under reduced pressure. The crystals were washed with cold and dry dioxane and successively with dry ether; yield, 5.1 g. (Table I).

**$\omega$-Chloroalkyl Amides (II).**—These compounds were obtained from the corresponding hydrochlorides of cyclic iminoethers (I) by heating them at 150—160°C for about 5 min. or by refluxing them in toluene. They were then recrystallized from ligroin or ligroin-benzene (Table II).

**2,4,6-Tri-($\gamma$-hydroxypropyl)-1,3,5-triazine (III, $n=3$).**—In a 200 ml. flask, 9.6 g. (0.08 mol.) of hydrochloride of 2-iminotetrahydrofuran (II, $n=3$), 16.0 g. of triethylamine and 80 ml. of absolute tetrahydrofuran were placed, and then the flask was tightly closed with a stopper. It was allowed to stand at room temperature with intermittent shaking for 3 days. After the precipitate of the hydrochloride of triethylamine had been filtered off, the solvent and the excess triethylamine were removed by distillation. The residual viscous liquid was distilled under reduced pressure; b. p. 196—198°C (0.1 mmHg), yield, 3.6 g. (53%).

Similarly, 2,4,6-tri-($\delta$-hydroxybutyl)-1,3,5-triazine (III, $n=4$) and 2,4,6-tri-($\varepsilon$-hydroxypentyl)-1,3,5-triazine (III, $n=5$) were obtained from the corresponding hydrochlorides of cyclic iminoethers.

9) G. Aksnes and J. E. Prue, *J. Chem. Soc.*, **1959**, 103.
10) C. C. Price, G. A. Cypher and I. V. Krishnamurti, *J. Am. Chem. Soc.*, **74**, 2987 (1952).

Their yields, boiling points, analyses and infrared and ultraviolet absorptions are summarized in Table III.

**2, 4, 6-Tri-[γ-(phenylaminocarboxy)propyl]-1,3,5-triazine (IV).**—To a solution of 0.5 g. of 2, 4, 6-tri-(γ-hydroxypropyl)-1, 3, 5-triazine in 10 ml. of tetrahydrofuran, 0.7 g. of phenylisocyanate was added. After the mixture had been allowed to stand for 2 days, the solvent was evaporated and the precipitate was recrystallized from 95% ethanol. Yield, 1.1 g. (92%) ; m. p. 124—125°C.

Found : C, 64.00, H, 6.03 ; N, 14.45, Calcd. for $C_{33}H_{36}N_6O_6$ : C, 64.69, H, 5.92 ; N, 13.72%.

**The Reaction of 2, 4, 6-Tri-(ω-hydroxyalkyl)-1, 3, 5-triazine with *o*-Phenylenediamine or 1, 8-Naphthylenediamine.**—A general procedure employed was as follows. A triazine (III) was heated with three equivalent moles of *o*-phenylenediamine or 1, 8-naphthylenediamine in a nitrogen atomsphere in an oil bath maintained at 220—230°C. After a while, the evolution of ammonia gas began ; the heating was continued until the evolution of gas had ceased (15—60 min.). The reaction mixture was then washed with ether, and the precipitate was recrystallized from a suitable solvent, as is shown in Tables IV and V.

*O*-Acetyl-derivatives of V were obtained from the reaction of V and 1.2 equivalent moles of acetic anhydride in pyridine at room temperature.

*O*-, *N*-Diacetyl-derivatives of V were obtained from the reaction of V and 2.5 equivalent moles of acetic anhydride in pyridine at 100°C.

**Azolidino[1, 2-a]perimidine (VII).**—A mixture of 0.5 g. of 2,4,6-tri-(γ-hydroxypropyl)-1,3,5-triazine (III, $n=3$) and 0.7 g. of 1, 8-naphthylenediamine was heated in a nitrogen atmosphere at 250—260°C for one hour. The reaction mixture was then washed with ether, and the precipitate was recrystallized from tetrahydrofuran. Yield, 0.5 g. (34%) ; m. p. 143—144°C.

Found : C, 80.30, H, 6.87; N, 13.71, Calcd. for $C_{14}H_{12}N_2$ : C, 80.74, H, 5.81 ; N, 13.45%.

## Summary

2, 4, 6-Tri-(ω - hydroxyalkyl) - 1, 3, 5 - triazines have been prepared by the reaction of hydrochlorides of cyclic iminoethers, such as 2-iminotetrahydrofuran, 2-iminotetrahydropyrane or 2-iminooxepan, with triethylamine. The reactions of the triazines with *o*-phenylenediamine or 1, 8-naphthylenediamine to give 2-(ω-hydroxyalkyl)benzimidazoles or 2-(ω-hydroxyalkyl)perimidines have also been described.

The authers wish to express their hearty thanks to Miss Toshiko Aoyagi, Miss Setsuko Iimura and Miss Yoko Ota for their microanalyses.

# Detection of the Atomic Oxygen Evolved in the Decomposition of Some Metallic Oxides*

By Kazuo MITANI and Yuji ASAKURA

(Received September 7, 1964)

Atomic oxygen was found to be evolved from the surface of a platinum ribbon, when it is heated to 1400°C in vacuo, if the ribbon has been treated previously with nitrous oxide or discharged oxygen gas.[1-4] It was believed that platinum dioxide is formed on the platinum surface, and that atomic oxygen is given off by the decomposition of platinum dioxide when the ribbon is heated to a high temperature in vacuo. Afterwards, atomic oxygen was found to be evolved when platinum dioxide prepared from ammonium chloroplatinate and sodium nitrate was decomposed in vacuo at a high temperature.[5] This experimental finding was believed to support the above conclusion. Then, various metallic oxides were examined to determine whether they would similarly evolve atomic oxygen when decomposed at a high temperature in vacuo. It was found that some metallic oxides evolve atomic oxygen, while others do not.[6] In order to clarify these phenomena, oxides of chromium, iron, manganese, cobalt and cadmium will be investigated in the present experiment.

## Experimental

**Apparatus.**—The main part of the apparatus is shown in Fig. 1. P is a coil (1 mm.×3.5 mm.×

* Presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, March, 1963.

12 mm.) made of a platinum ribbon (1.3 mm.× 0.10 mm.×62 mm.) which is spot-welded to platinum wires sealed into a glass stem. These platinum wires are subsequently connected to copper wires. A sample of metallic oxide placed on a quartz plate ((0.3—0.4) mm.×2.5 mm.×8 mm.) is inserted into the platinum coil, and then heated by an electric current. The glass tube A can be taken off from the ground joint, and the samples dropping from P can be removed easily.

D is a thin glass plate hung in the side tube of the reaction vessel. Molybdenum trioxide has been deposited on one side of D. Atomic oxygen is detected by the change in the color of molybdenum trioxide from pale yellow to blue.

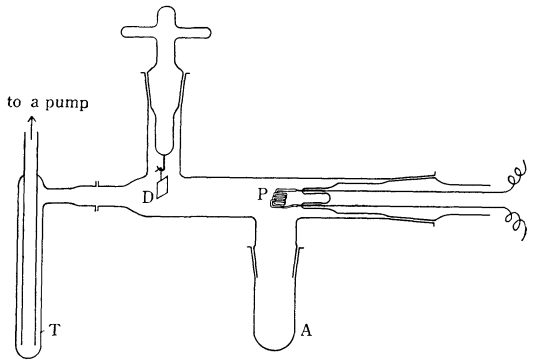

Fig. 1 The main part of the apparatus.

The apparatus can be evacuated by a mercury diffusion pump through a trap cooled by dry ice.

The sensitivity of molybdenum trioxide to atomic oxygen varies with the state of deposition on a glass plate. It seems that the thicker the layer of molybdenum trioxide, the larger its sensitivity. Molybdenum trioxide was deposited uniformly on a thin glass plate in the apparatus shown in Fig. 2. D is a piece of cover-glass for microscopic use, in the middle of one edge of which a small glass hook is attached. When molybdenum wire M is heated by an electric current to red heat, molybdenum is oxidized by air, and the glass bell-jar is filled with the smoke of the molybdenum trioxide thus formed. As tiny lumps of molybdenum trioxide crystals, entangled like cotton, fall to the bottom at first, a glass plate B is placed (as is shown in Fig. 2) in order to catch them. After some time, a uniform smoke is left behind in the bell-jar when the glass plate B is removed. Minute crystals of molybdenum trioxide settle down slowly on pieces of cover-glass, until the required thickness is obtained, whereupon the glass plate B is inserted again to stop further deposition. The molybdenum trioxide deposited on a glass plate by the method mentioned above is white or pale yellow; it changes to blue by atomic oxygen, probably according to the following equation: [7]

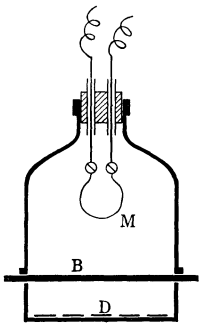

Fig. 2. The device for obtaining a uniform deposit of molybdenum trioxide.

$$3MoO_3+O\rightarrow Mo_3O_8+O_2$$

**Materials.**—Commercial chromic oxide was used at first. Later, chromic oxide was prepared by the following method. Potassium dichromate was heated with sulfur in a porcelain crucible, and the chromic oxide ($Cr_2O_3$) formed was washed free from potassium sulfate and dried.

Ferric oxide ($Fe_2O_3$) was made by heating ferrous sulfate, or by heating ferric hydroxide obtained by the action of excess ammonium hydroxide upon ferric chloride.

Manganese dioxide ($MnO_2$) was prepared by heating manganous nitrate which had been obtained by the action of concentrated nitric acid on manganous carbonate. Manganous nitrate was heated in a porcelain crucible until the evolution of brown gas ceased completely; the residue in the crucible was then boiled with dilute nitric acid, filtered, and washed. The residue was heated again in a crucible to ca. 500°C for an hour. Manganese dioxide was obtained as a black powder.

Cobalt oxide was prepared by heating cobalt nitrate. After being washed with water, the black powder obtained was heated again to 500—600°C in a crucible. The composition of this sample was not definite, but it was supposed to be near $Co_3O_4$.

Cadmium oxide (CdO) was made by heating cadmium carbonate in a platinum crucible until no further change in weight occurred.

Hydrogen was purified by diffusion through a heated palladium tube.

**Procedure.**—Whether atomic oxygen is evolved or not is judged in every case by the change in the color of molybdenum trioxide, when the platinum ribbon is heated to 1400°C for 20 min. in vacuo.

After atomic oxygen is once given off in the thermal decomposition of metallic oxide inserted into the platinum coil, atomic oxygen is found to be evolved from the platinum surface heated in vacuo for a long time.[1,2,8] It is believed that platinum dioxide is formed on the platinum surface, and that atomic oxygen is given off by the decomposition of platinum dioxide when the ribbon is heated to a high temperature in vacuo. Therefore, the following preliminary treatment of the platinum ribbon is necessary before every experiment. After the apparatus is sufficiently evacuated, hydrogen is admitted to a pressure of 3 mmHg and the platinum ribbon is heated to 1400°C for 30 min. Subsequently, the ribbon is degassed at 1400°C for 30 min. in

vacuo. Then, whether or not atomic oxygen is still given off from the platinum surface is determined by the change in the color of molybdenum trioxide, the platinum ribbon being heated to 1400°C for 20 min. If molybdenum trioxide changes its color, the above-mentioned treatment is repeated until no atomic oxygen is given off from the platinum ribbon.

The weight of metallic oxide placed at one time on a quartz plate is about 1 mg. The quartz plate once used reacts with the sample placed on it, and substances difficult to be removed completely by most reagents form. As these substances seem to give off atomic oxygen in some cases, a new quartz plate is used in each experiment. A new one does not give off atomic oxygen when heated to high temperatures.[6]

The sample of metallic oxide placed on a quartz plate is heated in the platinum coil. The temperature of the platinum ribbon is measured with an optical pyrometer. The temperature of the sample, although it can not be determined accurately, is thought to be slightly lower than that of the ribbon.

As the samples appear as powder, it is possible that they adsorb air or water vapor. Therefore, the samples are, in some cases, degassed at 500—700°C for 30 min. in vacuo prior to being heated to 1400°C.

To detect atomic oxygen formed as an intermediate substance of a chemical reaction, a new method has been devised in the authors' laboratory. This method is based upon the fact that a platinum ribbon once in contact with atomic oxygen evolves it for a long time when heated to high temperatures in vacuo. Atomic oxygen has already been confirmed by this method to exist as an intermediate, when nitrous oxide is decomposed at relatively high pressures (10—50 mmHg) on the platinum surface,[1,4] and when carbon monoxide is oxidized by a platinum catalyst.[9] Therefore, in the present investigation, after the experiment of heating a sample of metallic oxide in the platinum coil, the sample and the quartz plate were removed and the platinum ribbon alone was heated to 1400°C for 20 min. in vacuo. If atomic oxygen was evolved in the latter case, it was regarded as further confirmation that atomic oxygen was evolved by the decomposition of metallic oxide.

## Results and Discussion

**Chromic Oxide.**—Chromic oxide was heated several times on a quartz plate, as has been mentioned above, and also to 1400°C directly on the surface of the platinum ribbon. Molybdenum trioxide scarcely changed its color in any case. It is believed that chromic oxide does not give off atomic oxygen. The appearance of a sample remained unchanged even after the experiment, so probably chromic oxide was not decomposed by the heating.

**Ferric Oxide.**—When ferric oxide placed on a quartz plate was heated to 1400°C for 20 min. in the platinum coil, molybdenum trioxide distinctly changed its color from pale yellow to blue. In some cases a sample of ferric oxide was degassed at about 700°C for 30 min. in vacuo before being heated to 1400°C, but the same result was obtained, irrespective of the procedure.

Ferric oxide is red-brown, but a sample after being heated to 1400°C becomes black. It was confirmed that the latter can be attracted by a magnet, while the former can not. From these facts, it is certain that ferric oxide is decomposed by heat, forming ferrosoferric oxide $Fe_3O_4$.

The portion of a quartz plate with which the sample was in contact became somewhat dark during heating.

**Manganese Dioxide.**—Molybdenum trioxide turned blue while manganese dioxide placed on a quartz plate was heated to 1400°C in the platinum coil.

After the experiment, the quartz plate, together with the sample, was removed, and the platinum ribbon alone was heated. Molybdenum trioxide turned blue in this case also.

Manganese dioxide was prepared by the dry method and, moreover, heated to about 500°C in air, so that probably it was not hydrated. Therefore, manganese dioxide was usually heated at once to 1400°C, without a preliminary degassing. To make sure, however, a sample of manganese dioxide was degassed at about 500°C in vacuo, and then heated to 1400°C. In this case, molybdenum trioxide turned blue in the same manner.

A sample of manganese dioxide in the platinum coil was observed through a magnifying glass during heating. When manganese dioxide began to be heated to high temperatures, it was decomposed rapidly, violently evolving gas and jumping about, and in a short time almost all the sample fell from the quartz plate.

The portion of the quartz plate with which the sample was in contact became dark during heating.

**Cobalt Oxide.**—Molybdenum trioxide turned blue in the case of cobalt oxide heated to 1400°C in vacuo.

After the experiment, the quartz plate, together with the sample, was removed, and the platinum ribbon alone was heated. Molybdenum trioxide turned even a deeper blue than when the sample was inserted in the platinum coil.

The sample of cobalt oxide before being heated was black. After the experiment, the surface of the sample was dark brown, while the interior had turned a lighter brown. This

9) Y. Haranō, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **82**, 316 (1961).

brown substance is thought to be cobaltous oxide CoO.

As the composition of the cobalt oxide used in this experiment was not definite, samples of cobalt oxide were heated to various temperatures between 500°C and 800°C in air at 1 atm. in order to oxidize them to the higher oxide $Co_3O_4$. The results of the experiments using these samples were the same as the above.

**Cadmium Oxide.**—Molybdenum trioxide turned blue, in the case of cadmium oxide, if the amount of the sample used was very small or if the sample was heated to lower temperatures (700—1100°C). Molybdenum trioxide, however, turned dark gray in a short time if the same amount as the other oxides was heated to 1400°C. Thereafter, the quartz plate was removed, and the platinum ribbon alone was heated. The color of molybdenum trioxide remained unchanged.

Cadmium oxide is easily decomposed by heat. When it is heated to 1400°C in vacuo, it evaporates rapidly and the vapor of the metallic cadmium formed by the decomposition condenses as a metallic mirror with a black tint on the wall of the reaction vessel. Therefore, it appears that the change in the color of molybdenum trioxide is not due to atomic oxygen, but to the vapor of metallic cadmium. Metallic cadmium distilled in vacuo was placed on a quartz plate and inserted into the platinum coil. When the platinum ribbon began to be heated to 1400°C in vacuo, molybdenum trioxide got a bluish tint at first, but in a short time it turned dark gray.

A silver plate was hung up, together with molybdenum trioxide, and cadmium oxide was heated as usual, but the silver plate did not become black.

From the foregoing facts, it is believed that cadmium oxide does not give off atomic oxygen at the time of thermal decomposition, and that the change in the color of molybdenum trioxide is due to the reduction by the vapor of the metallic cadmium produced by the decomposition.

## Conclusion

The results of the present investigation show that chromic oxide and cadmium oxide do not give off atomic oxygen, but that ferric oxide, manganese dioxide, and cobalt oxide do give off atomic oxygen when heated strongly in vacuo.

Previously, Haranō[5,6] investigated whether or not atomic oxygen was evolved when various metallic oxides were heated to high temperatures in vacuo. He concluded that alumina ($Al_2O_3$), silica ($SiO_2$), magnesium oxide (MgO), cuprous oxide ($Cu_2O$), lead monoxide (PbO), lead dioxide ($PbO_2$), silver oxide ($Ag_2O$), and silver peroxide ($Ag_2O_2$) do not evolve atomic oxygen, but that zinc oxide (ZnO), mercuric oxide (HgO), cupric oxide (CuO), and platinum dioxide ($PtO_2$) do evolve atomic oxygen at high temperatures.

When the results of the present investigation are considered together with his results, it is evident that oxides difficult to decompose, i. e., alumina, silica, magnesium oxide, cuprous oxide, and chromic oxide, do not give off atomic oxygen. It can be said at least that atomic oxygen can not be evolved without the decomposition of the sample. This is quite reasonable. On the other hand, atomic oxygen is not found to be given off from lead monoxide, lead dioxide, silver oxide, silver peroxide, and cadmium oxide, though these oxides can be decomposed with ease. After all, atomic oxygen is given off in the thermal decomposition of zinc oxide, mercuric oxide, cupric oxide, platinum dioxide, ferric oxide, manganese dioxide, and cobalt oxide.

Molybdenum trioxide does not turn blue when the platinum ribbon alone is heated to 1400°C in oxygen. Therefore, it is not true that molecular oxygen formed by the decomposition of metallic oxides comes into contact with the platinum ribbon at a high temperature and so is dissociated into atoms.

It is believed that the oxygen given off by the decomposition of metallic oxides at high temperatures is not in equilibrium, and that a part of the oxygen is evolved in the atomic state from the beginning.

As to the detailed mechanism, however, further investigations will be necessary.

A part of the expenses for this investigation have been defrayed by a grant-in-aid from the Ministry of Education.

# Synthesis of Some Antituberculars: *N*-Aryl-*N'*-2-(4-arylthiazolyl)-thioureas

By Prithwi Nath BHARGAVA and Suresh Chandra SHARMA

(Received September 7, 1964)

A number of thioureas and their phenyl and sulphanilyl[1] derivatives are found to possess a definite in vitro antitubercular activity and the outstanding tuberculostatic properties of *N*, *N'*-di-(*p*-*n*-butoxyphenyl)-thioureas[2-5] has considerably revived the interest in thioureas derivatives. In view of the findings and the facts that many thiazole derivatives have been found to possess high degree of antitubercular activity,[6-10] the authors have synthesised a series of hitherto thiazolyl thiourea of the formula:

R-NH-CS-NH-R'

where R is 2-(4-arylthiazolylnucleus) and R' is aryl or substituted aryl group.

The compounds of this type have been synthesised by condensing 2-amino-4-phenyl-, -4-*p*-chlorophenyl-, -4-*p*-bromophenyl-, -4-*p*-tolyl-4-*p*-methoxyphenylthiazoles with ten different aryl isothiocyanates in benzene medium. The thiazoles were prepared by the method of Dedson and King[11] from acetophenone and substituted acetophenones.

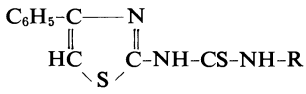
These synthesised compounds have been tested against Mycobacterium tuberculosis var *hominis* strain $H_{37}Rv$ on Steenken's modification of Proskauer and Beck's medium (one month old growth) at Central Drug Research Institute, Lucknow (India). The in vitro and in vivo (of eight compounds only) antitubercular activities of these compounds were compared with the standard, S.U. 1906 (Ciba): 1-(*p*-*N*, *N'*-dimethylaminophenyl-3-(*p*-*n*-butoxyphenyl)-2-thioureas). A number of compounds have shown sufficiently high degree of activity in vitro (equivalent to that of the standard).

As carbodiimides with a 2-thiazolyl group as substituent do not appear to be known, some of these have been prepared. The procedure followed for the preparation was the usual dehydrosulphurisation[12] of *N*-aryl-*N'*-2-(4-arylthiazolyl)-thioureas with yellow lead oxide in benzene.

## Experimental

2-Amino-4-phenyl-, -4-*p*-chlorophenyl-, -4-*p*-bromophenyl-, -4-*p*-tolyl-, -4-*p*-methoxyphenylthiazoles were prepared from acetophenone, *p*-chloro-, *p*-bromo-, *p*-methyl-, and *p*-methoxy-acetophenones by condensing with simple thiourea and iodine on a water bath for 12 hr.

**Preparation of Aryl Isothiocyanates.**—Phenyl-, *o*-, *m*-, and *p*-tolyl-, *m*-, and *p*-chlorophenyl-, *o*-, *m*-, and *p*-methoxyphenyl-*p*-ethoxyphenyl-isothiocyanates were prepared from the ammonium salt of the corresponding dithiocarbamates by the action of lead nitrate.[13]



***N*-Phenyl-*N'*-2-(4-phenylthiazolyl)-thiourea.**—In a dry flask 8.8 g. of 2-amino-4-phenylthiazole, 6 ml. of phenylisothiocyanate were taken in 60 ml. of dry benzene and heated on a water bath for 6 hr. The crude product, *N*-phenyl-*N'*-2-(4-phenylthiazolyl)-thiourea, obtained as a precipitate, was filtered and washed well with ether and dilute hydrochloric acid to remove the unreacted phenylisothiocyanate and thiazole respectively. The compound was crystallised from ethanol as slightly yellow crystals, m. p. 255°C.

Similarly, other *N*-aryl-*N'*-2-thiazolylthioureas were prepared by interaction of different 2-amino-4-arylthiazoles and arylisothiocyanates. The results of physical properties and analytical date are mentioned in Tables I—V.

Refluxing time differed for different substituted 2-aminothiazoles and aryl isothiocyanates. The reactivity of aryl isothiocyanates having substituents in different positions lies in order $p>m>o$. In the case of 2-amino-4-*p*-chlorophenyl-, -4-*p*-bromophenylthiazoles the reaction is very slow and it requires sometimes 10—15 hr. heating. In the case of 2-amino-4-*p*-methoxyphenylthiazole this reaction did not take place at all with *o*-tolyl-, *o*-, *m*-, and *p*-methoxyphenyl- and *p*-ethoxyphenyl-isothiocyanates.

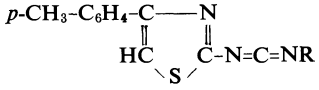
**N-Phenyl-N'-2-(4-phenylthiazolyl)-carbodiimides.** —A mixture of finely powdered 3.1 g. of *N*-phenyl-*N'*-2-(4-phenylthiazolyl)-thiourea and 4.5 g. of yellow lead oxide was suspended in 50 ml. of benzene and heated under reflux on the water bath for about 8 hr. Desulphurisation was complete when no blackening occurred on addition of a further small quantity of lead oxide. The reaction mixture was filtered hot. The filtrate on keeping deposited beautiful colourles crystals of carbodiimide. It was recrystallised from benzene, m. p. 205°C.



Other *N*-aryl-*N'*-2-(4-arylthiazolyl)-carbodiimides were prepared similarly and their properties and analytical data are recorded in Tables VI—VIII.

**Antitubercular Activity Screening.**—*Standard Thiourea against which Assayed.*—S. U. 1906 (Ciba) : 1-(*p*-*N*,*N'*-dimethylaminophenyl-3-(*p*-*n*-butoxyphenyl)-2-thiourea).

**'In Vitro' Test (Neotetrazolium Test).**—*Medium.*—Modified Sula's medium. Sodium hydrogenphosphate, 0.05% ; Potassium dihydrogenphosphate, 0.075% ; Magnesium sulphate, 0.025% ; Sodium citrate, 0.125% ; Tryptone, 0.5% ; Asparagin, 0.5% ; Sodium glutamate, 0.25% ; Ferri et ammonium citras, 0.0025% ; Glycerine, 1.25% ; Tween 80, 0.05% ; Malachite green, 0.02% ; Distilled water add to 100 ml.

*Inoculum.*—A 3 mm. loopful of Mycobacterium tuberculosis var *Hominis* strain $H_{37}Rv$ on Steenken's Modification of Proskauer and Beck's medium. The growth was a month old.

*Steenken's Modification of Proskauer and Beck's Medium.*—Dipotassium phosphate, 0.5% ; Aspargine, 0.5% ; Magnesium sulphate, 0.06% ; Magnesium citrate, 0.25% ; Glycerol, 2% ; Aqua add to 100.

*Period of Incubation* at 37°C - 4 days.

After incubation 0.25 ml. of 1% 2, 3, 5-triphenyltetrazolium chloride in Sorensen's phosphate buffer pH 7 was added to each dilution of drug and incubated for a further period of 2 hr. 0.25 ml. of tetrazolium was added to 5 ml. of media containing drug.

*End Point.*—Formation of red coloured precipitate (formozan) indicated bacterial growth. In bacterial inhibition the precipitate remained colourless.

Results, reported in Table IX, have been confirmed by the Resazurin Test of Pital.[14]

**'In Vivo' Test.**—*Animal Used.*—White mice.

*Culture Used.*—M. tuberculosis strain $H_{37}Rv$ (human).

*Inoculum.*—$2.2 \times 10^6$ organisms per mouse intravenously.

*Therapy.*—Subcutaneous injections for 28 days.

Only compounds No. 1, 3 (Table I) ; 1 (Table II) ; 1, 3, 4 (Table III) and 1, 4 (Table IV), have been tested for in vivo activity, and the rest are under study. The compound No. 1 in Table I : *N*-phenyl-*N'*-2-(4-phenylthiazolyl)-thiourea has only shown antitubercular activity.

The compounds containing halogens are found to possess pronounced antitubercular activity equal to the standard S. U. 1906 (Ciba) when tested for in vitro using the culture, M. tuberculosis strain

# Some Possible Antihistaminics and Antispasmodics. I. Synthesis of Mannich Bases

By Prithwi Nath BHARGAVA and Suresh Chandra SHARMA

(Received September 7, 1964)

In view of the findings and facts, that all the antihistaminic compounds contain the structural unit $R_2N$–C–C–X in which X is a group beginning with oxygen ($R_2N$–C–C–O), nitrogen ($R_2N$–C–C–N=) or carbon ($R_2N$–C–C–C≡), and the presence of sulphur containing groups like thienyl, thiazolidionyl, thiazolyl, etc., may promote antispasmodic activity as indicated by the observation of Blicke and Tsao,[1] Anderson and Green,[2] Bhargava and Singh[3] and Tripathi et al.[4] and also the musculotropic activity exhibited by thiazoles as described by Chance, Dirnhumber and Robinson,[5] the thiazoles have been taken as the starting material for the synthesis of a number of possible antihistaminics and antispasmodics.

Ketones containing an active methyl or

methylene group have been shown by Mannich[6-8] to condense with formaldehyde and secondary bases. Compounds other than ketones but containing methyl or methylene group, may be induced to go under Mannich reaction.[9] The hydrogen atom at 5-C in thiazole nucleus is very reactive to be a key point for the preparation of Mannich bases from thiazoles.

In the present study 2-acetylamino-4-aryl-thiazoles have been condensed with ten different secondary bases and formalin in absolute ethanol. Mannich base was precipitated out on treatment of the reaction mixture with the saturated solution of potassium carbonate. The bases have been converted into their hydrochlorides by the usual method. The results of the pharmacological tests will be published elsewhere after proper screening.

## Experimental

2-Amino-4-phenyl-, -4-*p*-bromophenyl-, -4-*p*-tolyl, -4-*p*-methoxyphenyl-, -4-$\alpha$-naphthyl-, and -4-$\beta$-naphthyl-thiazoles were prepared by the method of Dodson and King.[10]

2-Acetylamino-4-aryl-thiazoles were prepared by acetylation of 2-amino-4-aryl-thiazoles with acetic anhydride.

**2-Acetamido-4-phenyl-5-diethylaminomethylthiazole.**—In a dry flask 2.2 g. of 2-acetamido-4-phenyl-thiazole was taken and 1 ml. of diethylamine in 5 ml. of acetic acid and 1 ml. of formalin were added into it. The reaction mixture was refluxed for five hours on a water bath. After cooling, 15 ml. of water was added and the reaction mixture was then treated with the saturated solution of potassium carbonate. The precipitate, thus obtained, was filtered, washed well with water and finally recrystallised from ethanol and dried in vacuum desiccator, m. p. 129°C, yield 68% (Found: C, 52.89; H, 5.30; S, 11.58. Calcd. for $C_{14}H_{17}ON_3S$: C, 53.00; H, 5.38; N, 15.27; S, 11.64%).

Similarly other 2-acetamido-4-aryl-thiazoles were condensed with diethylamine, morpholine, piperidine, methylaniline, ethylaniline, *N*-benzylaniline, benzimidazole, 2-methyl-*N*-benzimidazole and piperazine. The bases, obtained on condensation, were converted into their hydrochloride by the usual method. The properties and analytical data of these bases as well as their hydrochlorides are recorded in Table I.

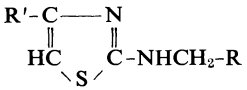
# Some Possible Antihistaminics and Antispasmodics. II. Synthesis of Mannich Bases



By Prithwi Nath BHARGAVA and Suresh Chandra SHARMA

(Received September 7, 1964)

A definite antispasmodic activity of pyrazolone derivatives,[1,2] certain substituted β-aminoalkylaryl ketones,[3,4] pyridyl and thiazolyl quinoline derivatives[5,6] and quinolyl and pyrazolone derivatives of thiazolidiones,[7] has created an interest in the syntheses of thiazole and thiazolidione derivatives—Mannich bases, and also to study, how the attachment of an additional therapeutically active quinoline and pyrazolone nuclei adds to the importance of thiazole in therapy, particularly their usefulness as antihistaminics and antispasmodics.

A few 2-amino-4-aryl thiazoles have been condensed with acetophenone, *p*-methyl-acetophenone, 8-hydroxy-quinoline and 1-phenyl-3-methyl-5-pyrazolone along with paraformaldehyde and hydrochloric acid in absolute ethanol. Another series of derivatives starting from 3-aryl-2 : 4-thiazolidiones has also been synthesised by condensing thiazolidiones with different secondary amine-hydrochlorides and paraformaldehyde. These thiazoles and thiazolidiones were prepared as per procedures laid down by Dodson and King[8] and Bhargava et al.[9-11] respectively. The results of the pharmacological screening of these compounds for antihistaminics and antispasmodic activities will be published elsewhere.

## Experimental

**Condensation of 2-Amino-4-*p*-tolylthiazole with Formaldehyde and Acetophenone.**—In a r. b. flask a mixture of 1.9 g. of 2-amino-4-*p*-tolylthiazole, 1.2 g. of acetophenone and 0.9 g. of paraformaldehyde in 3 ml. of hydrogen chloride and 30 ml. of ethanol was heated on a water bath under reflux for two hours. An addition amount of 0.6 g. of paraformaldehyde was then added and refluxing was continued for three hours more. Ethanol was distilled off and the residue solidified on keeping in contact with ammonia for four hours. It was washed with water and crystallized from ethanol m. p. d. 219°C, yield 58%.

In the case of 1-phenyl-3-methyl-5-pyrazolone, the mixture was heated directly over an asbestos wire gauge for eight hours.

The properties and analytical data of the other products obtained on condensation of acetophenone, *p*-methylacetophenone, 8-hydroxy quinoline and 1-phenyl-3-methyl-5-pyrazolone with different 2-amino-4-arylthiazoles are mentioned in Table I.

**5-(2'-Methyl-*N*-benzimidazolyl-methyl)-3-phenyl-2 : 4-thiazolidione.**—A mixture of 1.9 g. of 3-phenyl-2 ; 4-thiazolidione, 1.3 g. of 2-methyl-*N*-benzimidazolyl, 1.2 g. of paraformaldehyde and 3 ml. of hydrogen chloride in 25 ml. of absolute ethanole was heated under reflux on a water bath for eight hours. The solvent was distilled off and the pasty mass was obtained which on keeping in contact with concentrated ammonia for one to two hours solidified. It was washed well with water and then crystallised from ethanol, m. p. 173°C, yield 66% (Found : C, 63.92; H, 4.43; N, 12.38; S, 9.53. Calcd. for $C_{18}H_{15}O_2N_3S$ : C, 64.09; H, 4.45; N, 12.46; S, 9.50%).

Similarly, other 3-aryl-2 : 4-thiazolidiones were condensed with *N*-benzimidazole, methyl-, ethyl-, and benzyl-anilines. The properties and analytical data of these compounds are reported in Table II.

It is experienced during the course of work that the isolation of the bases sometimes becomes very difficult specially with products obtained on condensation with methyl-, and ethylanilines. A few compounds were obtained as hydrochlorides only because their bases could not be isolated from the reaction product.

**Preparation of the Hydrochlorides of the Above Bases.** — The hydrochlorides of the bases were prepared by the usual procedure of passing dry hydrogen chloride gas into the solution of the base in benzene, or dry ether. These hydrochlorides are recorded in Table III.

Thanks are due to the authorities of the Banaras Hindu University for providing necessary facilities and also to the Council of Scientific and Industrial Research, New Delhi, India for the award of a Junior Research Fellowship to one of us (S. C. S.).

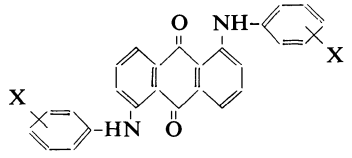
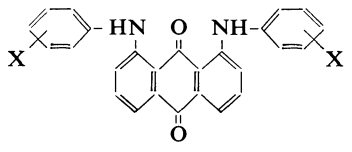
# Spectroscopic Studies of Bis(arylamino)anthraquinones

By Takayuki HAYASHI and Takao TOKUMITSU

(Received September 18, 1964)



In a previous paper,[1] 1-arylaminoanthraquinones (I) with $NO_2$, Cl, Me, OMe, and $NH_2$ as substituents in the aryl group were prepared, and their visible absorption spectra in solution and infrared spectra in the solid state were measured and discussed. On the basis of these results, the effects of the substituent groups were discussed in view of various properties, such as visible absorption maxima or infrared C=O and N–H frequencies. In this paper, the preparation and spectral characteristics of 1, 4-, 1, 5- and 1, 8-bis(arylamino)anthraquinones (II,



(I)

(II)

(III)

(IV)

III, IV) with the above-mentioned groups as substituents (X) in the aryl group will be reported. These are parent compounds of anthraquinone acid or polyester dyes. As was the case with 1-arylaminoanthraquinones, on the basis of the results of the visible and infrared absorption spectra for bis(arylamino)-anthraquinones, the relations between the shifts of the visible absorption peaks, the C=O or N–H frequencies and their structures will be discussed.

## Results and Discussion

**Visible Absorption Spectra.**—The visible absorption peaks of bis(arylamino)anthraquinones in *o*-dichlorobenzene are shown in Table I. On the basis of these results, relations between the wavelengths or intensities of the absorption maxima and the positions of the arylamino groups have been discussed. Furthermore, for each series of 1, 4-, 1, 5- and 1, 8-bis(arylamino)-anthraquinones, the effects of the substituent (X) upon the wavelength and the intensity of the absorption maximum have been discussed. Compounds I and III give one visible absorption peak, as in the cases of the corresponding amino- and acylamino-anthraquinones.[1-4] The wavelength of the absorption maximum of III (X=H) is somewhat longer than that of I (X=H), but the intensity of the former is approximately twice that of the latter. Such a relation is also seen with other III's. As was shown by Hartmann's results,[5] the absorption maximum of 1, 8-diaminoanthraquinone appeared in the same wavelength region as that of the 1, 5-isomer, and the absorption spectrum was characterized by twin peaks of a lower definition with a shoulder at a lower wavelength, peaks which were similar to those observed for the 1, 4-isomer. The absorption spectral character of 1, 8-diaminoanthraquinone, therefore, appears to be intermediate between those of 1, 4- and 1, 5-isomers. On the contrary, IV (X=H) showed only one absorption band, located at a somewhat longer wavelength than that of the 1, 5-isomer; the intensity of the former absorption is slightly lower than that of the latter, but approximately twice that of I (X=H). II (X=H) gives twin peaks of a similar intensity, unlike those of I (X=H), III (X=H) and IV (X=H). Such a relation is seen with other II's. I, III and IV, each with a strongly electron-attracting $-NMe_3^+$ group as a substituent, gave only one absorption peak in dioxane, but the corresponding II gave a peak at 593 m$\mu$ (12400)* with a shoulder in the region

TABLE I. VISIBLE ABSORPTION PFAKS OF 1-ARYLAMINO-, 1,4-, 1,5- AND 1,8-BIS-(ARYLAMINO)ANTHRAQUINONES

| Substituent of the aryl group (X) | 1,4-Derivative 1st Band $\lambda_{max}$, mμ ($\varepsilon_{max}$) | | 1,4-Derivative 2nd Band $\lambda_{max}$, mμ ($\varepsilon_{max}$) |
|---|---|---|---|
| H[a] | 607 (13000) | | 647 (14300) |
| *p*-$NO_2$[b] | 547* | 615 | 630 |
| *p*-Cl | 550 (5770) | | 605 (12900) 644 (13600) |
| *p*-Me[c] | 551 (6230) | | 617 (14500) 650 (15900) |
| *p*-OMe | 621 (13800) | | 651 (14700) |
| *p*-$NH_2$[b] | 615 | | 629 656 |

| Substituent of the aryl group (X) | 1-Derivative[1] $\lambda_{max}$, mμ ($\varepsilon_{max}$) | 1,5-Derivative $\lambda_{max}$, mμ ($\varepsilon_{max}$) | 1,8-Derivative $\lambda_{max}$, mμ ($\varepsilon_{max}$) |
|---|---|---|---|
| H | 508 (5920) | 538 (13700)[d] | 558 (13500)[d] |
| *m*-$NO_2$ | 489 (6460) | 517 (14900) | |
| *p*-$NO_2$ | 487 (10700) | | 535[b] |
| *m*-Cl | 501 (7220) | 531 (13900) | |
| *p*-Me | 514 (6190) | 544 (14400)[e] | 561 (14100)[f] |
| *p*-OMe | 516 (6000) | 546 (13500) | |
| *p*-$NH_2$ | 525 (5990) | 555[b] | |

* An underlined numerical value denotes a shoulder.

a) 1,4-Bis(phenylamino)anthraquinone gave two peaks at 595 and 632 mμ with a shoulder at 550 mμ in ethanol,[6] two peaks at 602.5 and 640 mμ in chlorobenzene[7] and at about 605 and 645 mμ in 1,2,4-trichlorobenzene.[8]

b) In the saturated solution.

c) 1,4-Bis(*p*-tolylamino)anthraquinone gave two peaks at 600 and 638 mμ with a shoulder at 550 mμ in ethanol,[6] two peaks at 610 and 645 mμ in chlorobenzene,[7] two peaks at 600 and 640 mμ in dioxane,[9] and two peaks at 610 and 645 mμ.[10]

d) Both 1,5- and 1,8-bis(phenylamino)anthraquinones gave a peak at 530 mμ in chlorobenzene.[7]

e) 1,5-Bis(*p*-tolylamino)anthraquinone gave a peak at 540 mμ in chlorobenzene,[7] and a peak at about 530 mμ in dioxane.[9]

f) 1,8-Bis(*p*-tolylamino)anthraquinone gave a peak at 550 mμ in chlorobenzene.[7]

of 610—630 mμ (11600).[11] Hence, this broad shoulder seems to correspond to the two absorption peaks of II (X=*p*-$NO_2$). I, III and IV, with strongly electron-donating $-NMe_2$ substituents, gave a single absorption peak in dioxane.[12] On the other hand, the corresponding II gave a peak at 638 mμ (15300) with a shoulder at 590 mμ (11000) in dioxane, and a peak at 600 mμ (15500) with a shoulder at 590 mμ and a broad peak in the region of 640—655 mμ in ethanol.[11,12] Here, too, these results are similar to the results for II (X=*p*-$NH_2$). Consequently, the relations between the wavelengths or intensities of the absorption maxima and the positions of the arylamino groups agree with those for amino- and acylaminoanthraquinones.[2-4]

In the case of the compound I previously reported,[1] a plot of the wave numbers of the absorption maxima versus the Hammett σ values[13] of the substituents in the aryl group gave a linear relationship, but the plot of the wave numbers varsus the Brown $\sigma^+$ values[14,15] was concave; this was different from the case of acylaminoanthraquinones.[4] Here, too, for the peaks of each series, a plot of the wave numbers versus the former substituent constants gave a linear relationship, as is indicated in Figs. 1 and 2. These results can be explained in the same way as in the case of compound I.[1] It is interesting that the linear

relationship is established for the plots for both the first and the second peaks of II.

**Infrared Absorption Spectra.**—Three $\mu$ bands of the infrared absorption spectra of a few 1,4-bis(arylamino)anthraquinones as Nujol mull have been observed.[16] In this work, the infrared absorption spectra of 1,4-, 1,5- and 1,8-bis(phenylamino)anthraquinones and their related derivatives as Nujol mull were observed, and information about molecular structures in the solid was obtained.

It has been known that 1,4-, 1,5- and 1,8-disubstituted anthraquinones as Nujol mull show characteristic absorption bands at 820—840 and 720—730, 800—820 and 690—710, and 830—850 and 730—750 $cm^{-1}$ respectively, and that these bands have intensities ranging from medium to very strong.[17] Absorption bands in the region of 800—850 and of 690—750 $cm^{-1}$ for II (X=H), III (X=H) and IV (X=H) are shown in Table II. The respective characteristic absorption bands of II (X=H), 829.9 and 728.3 $cm^{-1}$, appeared in the corresponding regions of 1,4-disubstituted anthraquinones, and the same results were obtained for III (X=H) and IV (X=H). The intensities of these absorption bands, except the one of the 829.9 $cm^{-1}$ band, were medium or very strong.

Table II. Absorption bands in the region of 800—850 and of 690—750 $cm^{-1}$ for 1,4-, 1,5- and 1,8-bis(phenylamino)-anthraquinones

| | | | |
|---|---|---|---|
| 1,4-Derivative | 841.8(w), 744.6(m), | 829.9(w), 728.3(vs), | 815.0(w), 695.9(s) |
| 1,5-Derivative | 842.5(s), 695.9(vs) | 806.5(vs), | 714.3(vs), |
| 1,8-Derivative | 844.6(w), 809.7(m), 719.4(w), | 838.9(m), 744.6(vs), 700.8(s), | 819.7(m), 729.9(w), 694.0(vs) |

The absorption bands in the 3 and 6 $\mu$ regions of bis(phenylamino)anthraquinones are shown in Table III, and also in Figs. 3, 4 and 5. Compound III (X=H) gave only one C=O band, this being due to the fact that the strengths of the two C=O bands are equal. For IV (X=H), two C=O bands appeared, and,

as was the case with 1-substituted anthraquinones with electron-donating groups as substituents, this splitting of the C=O absorption would appear to be the result of electronic dissymmetry.[18,19] The first C=O band at a higher frequency is assigned to the C=O(a)* vibration, since the frequency is closer to the C=O frequency of anthraquinone, and the second C=O band at a lower frequency is assigned to the C=O(b) vibration in the peri-position of the phenylamino group.

Table III. N-H and C=O Frequencies of Solid Phenylaminoanthraquinones

| | N-H Frequencies $cm^{-1}$ | C=O Frequencies $cm^{-1}$ | |
|---|---|---|---|
| | | (a) | (b) |
| Anthraquinone[18] | | 1676 | |
| 1-Phenylaminoanthraquinone[1] | 3236 | 1672 | 1634 |
| 1,4-Bis(phenylamino)-anthraquinone | 3058 | | 1603 |
| 1,5-Bis(phenylamino)-anthraquinone | 3236 | | 1623 |
| 1,8-Bis(phenylamino)-anthraquinone | 3236 | 1684 | 1621 |

In this connection, it is interesting that the N-H and C-H stretching bands of III (X=H) and IV (X=H) appear at about 3.1 and 3.25 μ respectively, while II (X=H) has only one discrete band at the lower wavelength in this region. If the 3058 $cm^{-1}$ band of II (X=H) is assigned to the C-H vibration, its structure must be indicated by IId (X=H)

instead of IIa (X=H).

Frequencies for the C=N groups[20] are most probably found between 1690 and 1640 $cm^{-1}$, and the influence of conjugation is usually small. For the IId (X=H) structure, therefore, the observed frequency in II (X=H) at 1603 $cm^{-1}$ should be attributed to the C=N vibration. However, this may be too low a frequency to be normally attributed to the C=N vibration. Furthermore, the absorption of 1,4-diamino- and 1,4-bis(methylamino)-anthraquinones,[18] 1,1'-dianthrimide,[21] indanthrone,[8] and 3,4-phthaloylacridone[22] did not show the C=N band. Thus, there is no precedent for assigning the 1603 $cm^{-1}$ band to the C=N vibration; it should probably be assigned to the C=O vibration. Consequently, this band can not be used to support the IId (X=H) structure containing the C=N bond.

Frequencies of the O-H groups are usually found in the frequency range between 3650 and 3450 $cm^{-1}$, and the influence of conjugation is quite large.[23] Many of the frequencies for O-H groups of oxanthrone, anthraquinol and their substituted derivatives in a solid[18] were found in the frequency range from 3500 to 3300 $cm^{-1}$, but the shifts of the frequencies of these O-H groups were not due to conjugation, but mainly to hydrogen bonding. Moreover, the absorptions of 1-arylamino-[1] and 1-benzoylaminoanthraquinones[4], 1,1'-dianthrimide,[21] indanthrone,[8] 1,2- and 3,4-phthaloylacridones,[22] and indigo[24] did not show the O-H band. The 3058 $cm^{-1}$ band

24) G. M. Wyman, *J. Am. Chem. Soc.*, **78**, 4599 (1956); W. R. Brode, E. G. Pearson and G. M. Wyman, ibid., **76**, 1034 (1954).

of II (X=H) seems, therefore, to be too low a frequency to be normally assigned to the O–H vibration; thus, this band can not be used to support the structure IId (X=H). Consequently, the 3058 $cm^{-1}$ band should be assigned to the N–H vibration of the arylamino-type structure IIa (X=H). This molecular structure, assigned to its solid state, agrees with that concluded in solution on the basis of the results of visible absorption; moreover, the chemical evidence favors the arylamino-type structure IIa (X=H).

The C=O(b) frequency in the peri-position of the phenylamino group in Table III increases in the order of II (X=H), IV (X=H), III (X=H) and I (X=H); the C=O(b) bond is also strengthened in this order. This result for phenylaminoanthraquinones can be satisfactorily explained by means of the same electronic interpretation as for the shifts of the visible absorption peaks for these derivatives in solutions.

As is indicated in Table IV with 1-(*m*- and *p*-substituted phenyl)aminoanthraquinones, the C=O(b) frequency shifted lower when an arylamino group with electron-donating substituents is placed in the peri-position to the C=O group, while the reverse was found to be true when one with electron-attracting substituents is placed in the same position. A similar result was also obtained for 1-arylamino-5-chloro- and 1,5-bis(arylamino)-anthraquinones. Furthermore, the C=O frequencies of 1-arylamino-5-chloroanthraquinones were much the same as for corresponding 1-arylaminoanthraquinones, this being deduced from the fact that the effects of a chlorine atom on the C=O frequency for 1- and 2-chloroanthraquinones were quite small.[8]

TABLE IV. N–H AND C=O FREQUENCIES OF SOLID 1-ARYLAMINO-, 1-ARYLAMINO-5-CHLORO- AND 1,5-BIS(ARYLAMINO)-ANTHRAQUINONES

| Substituent of the aryl group (X) | 1-Arylamino-[1] | | 1-Arylamino 5-chloro- | | 1,5-Bis-(arylamino)- | |
|---|---|---|---|---|---|---|
| | $\nu_{C=O(a)}$ $cm^{-1}$ | $\nu_{C=O(b)}$ $cm^{-1}$ | $\nu_{C=O(a)}$ $cm^{-1}$ | $\nu_{C=O(b)}$ $cm^{-1}$ | $\nu_{N-H}$ $cm^{-1}$ | $\nu_{C=O}$ $cm^{-1}$ |
| H | 1672 | 1634 | 1675 | 1631 | 3236 | 1623 |
| *p*-$NH_2$ | 1672 | 1639 | 1675 | 1639 | | |
| *m*-$NO_2$ | 1675 | 1637 | | | 3279 | 1634 |
| *p*-Cl | 1678 | 1637 | 1678 | 1634 | | |
| *m*-Cl | 1681 | 1637 | 1681 | 1637 | 3247 | 1629 |
| *p*-Me | 1684 | 1629 | 1678 | 1626 | 3236 | 1621 |
| *p*-OMe | 1678 | 1626 | | | 3226 | 1616 |

For 1-substituted anthraquinones (V, substituents: Y), the wavelengths of the visible absorption maxima in solution and the C=O stretching frequencies increased in the following order:[1]

maximum wavelengths of the visible spectra:

$$V\ (Y=NHCOC_6H_5) < V\ (Y=NH_2) < V\ (Y=NHCH_3) \lesssim V\ (Y=NHC_6H_5)$$

frequencies of the C=O stretching bands:

$$V\ (Y=NH_2) < V\ (Y=NHC_6H_5) \lesssim V\ (Y=NHCH_3) < V\ (Y=NHCOC_6H_5)$$

The fact that the C=O frequencies of V (Y=$NHCH_3$) and V (Y=$NHC_6H_5$) were higher than those of V (Y=$NH_2$) should not be attributable to steric hindrance, but to the reduction by the methyl or the phenyl group of resonance within the chromophoric system of V (Y=$NHCH_3$) and V (Y=$NHC_6H_5$).[1]

TABLE V. N–H AND C=O FREQUENCIES OF SOLID 1,4- AND 1,5-DISUBSTITUTED ANTHRAQUINONES

| Disubstituted anthraquinone | N–H Frequencies $cm^{-1}$ | C=O Frequencies $cm^{-1}$ |
|---|---|---|
| 1,4-Diamino-[18] | 3370, 3250 | 1610 |
| 1,4-Bis(methylamino)-[18] | 3240 | 1610 |
| 1,4-Bis(phenylamino)- | 3058 | 1603 |
| 1,4-Bis(benzoylamino)-[a] | 3125 | 1686 |
| 1,5-Diamino- | 3425, 3311[b] | 1610 |
| 1,5-Bis(methylamino)- | 3333 | 1623 |
| 1,5-Bis(phenylamino)- | 3236 | 1623 |
| 1,5-Bis(benzoylamino)-[a] | 3226 | 1689 |

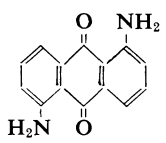
a) The C=O frequencies of 1-benzoylaminoanthraquinone[4] were observed at 1681, 1669 and 1637 $cm^{-1}$; the highest frequency was assigned to the free C=O group; the middle, to the chelated C=O group, and the lowest, to the benzoyl C=O group.[4,18] On the other hand, the C=O frequencies of 1,4- and 1,5-bis(benzoylamino)anthraquinones[4] were observed at 1686 and 1639, and 1689 and 1639 $cm^{-1}$, respectively. As the free C=O group was absent in them, the respective higher frequencies were assigned to the chelated C=O groups and the respective lower frequencies to the benzoyl C=O groups,[4] as in the case of 1-benzoylaminoanthraquinone.

b) Shigorin[16] gives 3430 and 3310 $cm^{-1}$.

Here, too, for 1,5-disubstituted anthraquinones (VII, substituents: Y), the wavelengths of the visible absorption maxima in solution increased in the following order:

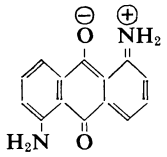
$$VII\ (Y=NHCOC_6H_5) < VII\ (Y=NH_2) < VII\ (Y=NHCH_3) \lesssim VII\ (Y=NHC_6H_5)$$

while, as is indicated in Table V, the C=O stretching frequencies increased in the following order:



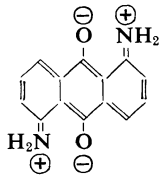
$$\text{VII } (Y=NH_2) < \text{VII } (Y=NHCH_3) = \text{VII } (Y=NHC_6H_5) < \text{VII } (Y=NHCOC_6H_5)$$

As will be clear from the establishment of simple additivity between the two chromophoric systems within VII, the fact that the C=O frequencies of VII ($Y=NHCH_3$) and VII ($Y=NHC_6H_5$) are higher than that of VII ($Y=NH_2$) can be interpreted in the same way as in the case of V.[1]

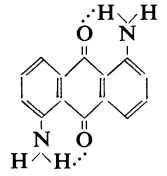


As is indicated in Table V, the N-H frequencies of VII increased in the following order:

$$\text{VII } (Y=NHCOC_6H_5) < \text{VII } (Y=NHC_6H_5) < \text{VII } (Y=NHCH_3) < \text{VII } (Y=NH_2)$$



and the reverse was found to be true for their C=O frequencies. This fact can be interpreted in the same way as in the case of V;[1] namely, for VIIa ($Y=NH_2$) it seems that it is impossible to form a powerful hydrogen bonding, as in



VIIa ($Y=NH_2$)

VIIb ($Y=NH_2$)

VIIc ($Y=NH_2$)

VIId ($Y=NH_2$)

VIId ($Y=NH_2$), between the amino and C=O groups, and that, therefore, a contribution of the ionic structure VIIb ($Y=NH_2$) and VIIc ($Y=NH_2$) to the resonance, rather than the weak hydrogen bonding, is responsible for the considerable lowering of the C=O frequency, the hydrogen bondiag serving only to stabilize the ionic structures. On the other hand, for VII ($Y=NHCH_3$) and VII ($Y=NHC_6H_5$), such resonance within chromophoric systems was reduced by the methyl and phenyl groups respectively. The above-mentioned order of the increase in N-H frequencies, therefore, suggests that the smaller the contribution of the ionic structure to the resonance becomes, the greater the contribution of the hydrogen bonding, as in the case of V.[1]

For monosubstituted anthraquinones, with electron-donating groups as substituents, Peters and Sumner,[2] using a correlation of the Hixon-Johns type,[25] showed the following: An arbitrary straight line was drawn the ordinate scale of which represented the wavelength of the absorption maximum, the abscissa being undefined. The points corresponding to the wavelengths of the visible absorption maxima of 2-substituted anthraquinones were marked on this line, and an arbitrary scale of abscissa was then constructed labelled with the names of the substituents. A plot of the wavelengths of the visible absorption maxima for V versus the scale of the substituents so defined gave a straight line, but a considerable deviation from the linear relation was observed with V with substituents (Y) having internal hydrogen-bonding possibilities. This fact suggests that the latter 1-substituted anthraquinones have wavelengths with absorption maxima greater than would be expected from the electron-donating abilities of their substituents, the excess being attributable to the resonance of the chelate structure.[25] For the latter 1-substituted anthraquinones, the extents of deviation from the straight line were calculated by Hida[26] as follows:

| | kcal./mol. |
|---|---|
| 1-Acetylaminoanthraquinone | 3.3 |
| 1-Methylaminoanthraquinone | 1.5 |
| 1-Phenylaminoanthraquinone* | 1.5 |
| 1-Aminoanthraquinone | 1.3 |

Consequently, it is probable that the magnitude of these values is closely related with the hydrogen-bonding energy between their substituent groups and the C=O groups of the latter 1-substituted anthraquinones.[26] Here, for VII, therefore, it seems that this fact has given other evidence for the above-mentioned interpretation of the extent of the contribution of the ionic structure and of the hydrogen bonding to the increase in N-H frequencies.

For 1,4-disubstituted anthraquinones (VI, substituents: Y), the wavelengths of the visible absorption maxima in solution increased in the following order:

$$\text{VI } (Y=NHCOC_6H_5) < \text{VI } (Y=NH_2) < \text{VI } (Y=NHCH_3) \lesssim \text{VI } (Y=NHC_6H_5)$$

The visible absorption maxima of VI ($Y=NH_2$) and VI ($Y=NHCOC_6H_5$) in solution were, moreover, located at far longer wavelengths than those of the corresponding VII ($Y=NH_2$) and VII ($Y=NHCOC_6H_5$). As is indicated in

25) R. M. Hixon and I. B. Johns, *J. Am. Chem. Soc.*, **49**, 1786 (1927).

26) M. Hida, *Dyestuffs and Chemicals* (*Senryo to Yakuhin*), **8**, 493 (1963).

* Peaks of 1- and 2-phenylaminoanthraquinones appeared at 507 and 465 mμ respectively in methanol. From these results, the extent of the deviation for the former was calculated by the present authors.

Table V, however, the C=O stretching frequencies of VI ($Y=NH_2$) and VII ($Y=NH_2$) are the same, and those of VI ($Y=NHCOC_6H_5$) and VII ($Y=NHCOC_6H_5$) are alike. The C=O stretching frequencies for VI, moreover, increased in the following order:

$$\text{VI } (Y=NHC_6H_5) < \text{VI } (Y=NHCH_3) = \text{VI } (Y=NH_2) < \text{VI } (Y=NHCOC_6H_5)$$

This order was, then, the reverse of the increase in the wavelengths of their visible absorption maxima, these being different from the cases of those for V and VII. Furthermore, the order of the increase of the N-H frequencies for VI is not in the decreasing order of their C=O frequencies, this being different from the case of those for VII. It is interesting, moreover, that both the N-H and C=O frequencies of 1,4-bis(phenylamino)anthraquinone are the lowest among VI's investigated. Because of interaction between their two chromophoric systems, these VI's do not obey the simple additivity rule observed with VII; this interaction is supposed to produce a new chromophore. The above-mentioned results may, therefore, be attributable to the contribution of the ionic structures IIb (X=H) and IIc (X=H), and to the fact that the decreasing effect of the resonance by the phenyl group in the chromophoric system of 1,4-bis(phenylamino)anthraquinone is smaller than in that of 1,5-bis(phenylamino)anthraquinone. By X-ray study, no steric hindrance was estimated in II (X=H), and the coplanarity of the phenyl groups was concluded;[27] it seems that these facts have given support to the above-mentioned interpretation.

## Experimental

**Materials and Apparatus.**—The compounds used in this investigation were purified by repeated crystallization and then by chromatography or hot chromatography on alumina in suitable solvents.

The visible absorption spectra were recorded with a Shimadzu spectrophotometer, type QB-50. The infrared absorption spectra of the solid samples were obtained using a Perkin-Elmer Model 21 double-beam spectrophotometer fitted with a rock-salt prism. *o*-Dichlorobenzene was purified by the method recommended for the purification of chlorobenzene.[28]

The authors wish to express their hearty thanks to Mr. Akira Hara of the Tokuyama Research Laboratory of the Idemitsu Kōsan Co. for the infrared measurements.

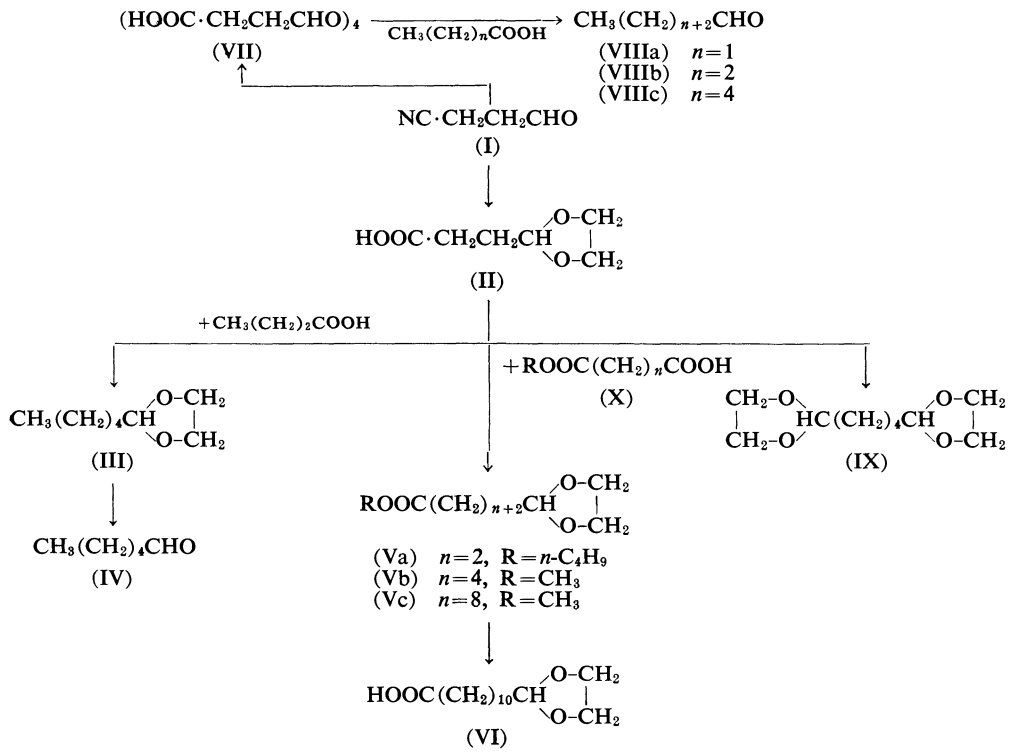
# Synthetic Studies starting from β-Cyanopropionaldehyde. II. The Syntheses of Aliphatic Aldehydes and ω-Aldehydic Acids

By Shinichi MOTOKI, Sadayoshi SATSUMABAYASHI and Hajime KUSANO



(Received September 22, 1964)

The preceding paper in this series,[1] dealt with the Kolbe electrolysis of the ethylene acetal of β-formylpropionic acid (II) which had been derived from β-cyanopropionaldehyde (I). Electrolysis of this acetal acid gives the diethylene acetal of adipic dialdehyde (IX). Only a few examples of the Kolbe electrolysis of such aldehydic acids have been recorded[2,3] and the crossed electrolysis of aldehydic acids with ordinary carboxylic acids does not appear to have been described. The present paper involves a further extension of the Kolbe reaction as summarized in the accompanying flow sheet.

Electrolysis of the ethylene acetal of β-formylpropionic acid (II) in the presence of butyric acid was found to give the expected product, caproaldehyde ethylene acetal (III), in 25% yield.

The Kolbe electrolysis of the ethylene acetal (II) with succinic acid monobutyl ester

1) S. Motoki, S. Satsumabayashi and I. Tajima, This Bulletin, 37, 646 (1964).
2) M. Stoll and A. Rouvé, *Helv. Chim. Acta*, 20, 525 (1937).
3) A. Wohl and H. Schweizer, *Ber.*, 39, 890 (1906).

gave the ethylene acetal of adipinaldehydic acid butyl ester (Va). When the monomethyl ester of succinic acid was used, the boiling points of the three products (adipinaldehydic acid methyl ester ethylene acetal, dimethyl adipate and adipic dialdehyde diethylene acetal) were too close to isolate the expected aldehydic acid by fractional distillation.

Similar electrolysis of a mixture of adipic acid monomethyl ester and an excess of the acetal (II) gave suberinaldehydic acid methyl ester ethylene acetal (Vb), whereas the compound II and an excess of monomethyl adipate led to a mixture which was difficult to separate. In the latter case, separation of Vb from the large amount of dimethyl sebacate formed was unsuccessful.

Crossed electrolysis of the acetal (II) with sebacic acid monomethyl ester afforded ω-formylundecylic acid methyl ester ethylene acetal (Vc) without any difficulties in separation.

As seen in Table I, the yields of ω-aldehydic acids are better in the presence of II excess of than in the presence of excess of monoesters. ω-Aldehydic acids are generally inaccessible compounds* the properties of which have rarely been described in the literature[4], so these electrolytic reactions starting from β-cyanopropionaldehyde may provide a new convenient synthetic route.

On the other hand, the cyclic tetramer (VII)[5] of β-formylpropionic acid has recently been prepared by the hydrolysis of β-cyanopropionaldehyde tetramer. Since the tetramer (VII) is more easily accessible than the previously reported β-formylpropionic acid ethylene acetal[1] and is inert to oxidation, its possible usefulness in a Kolbe reaction was examined.

Attempted electrolysis of the tetramer itself turned out to be unsuccessful, but the tetramer underwent a normal Kolbe reaction in the presence of fatty acids to give the corresponding aldehydes in relatively good yields; the results are summarized in Table II. In general, it is known that the Kolbe reaction of a polybasic acid results in olefine formation or in evolution of oxygen at the anode, rather than in the formation of a coupling product. As VII can be regarded formally as a polybasic acid, the results obtained here seem to be of much interest.

## Experimental

**Apparatus.** — Electrolysis was carried out with the apparatus previously described.[1]

***n*-Caproaldehyde Ethylene Acetal (III).**—Twenty grams (0.137 mol.) of II and 35 g. of butyric acid (0.4 mol.) were electrolyzed in 130 ml. of methanol containing 3.1 g. of potassium hydroxide until the electrolyte became slightly alkaline. At the end of the electrolysis the solvent was removed and the residue was washed with water, extracted with ether and dried over anhydrous sodium sulfate. Fractional distillation of the extract gave 5 g. of III, b. p. 78—80°C/34 mmHg, yield 25.4%. Found: C, 66.39; H, 11.41. Calcd. for $C_8H_{16}O_2$: C, 66.63; H, 11.18%.

III was mixed with the same amount of 3% hydrochloric acid and refluxed for one hour. After hydrolysis, the organic layer was extracted with ether and dried over anhydrous sodium sulfate. By distillation caproaldehyde (IV) was obtained. B. p. 130—131°C. 2,4-Dinitrophenylhydrazone, m. p. 106°C.

Found: C, 51.12; H, 6.09; N, 20.03. Calcd. for $C_{12}H_{16}O_4N_4$: C, 51.42; H, 5.75; N, 19.99%.

**Adipinaldehydic Acid Butyl Ester Ethylene Acetal (Va), Suberinaldehydic Acid Methyl Ester Ethylene Acetal (Vb) and ω-Formylundecylic Acid Methyl Ester Ethylene Acetal (Vc).** — A mixture of II and the monoester of the dibasic acid was electrolyzed in methanol, to which sufficient potassium hydroxide had been added to neutralize about 10% of the total acid. At the end of the electrolysis, the solvent was removed and the residue

6) S. Swann, R. Oehler and R. J. Buswell, "Organic Syntheses," Coll. Vol. II, 276 (1943).

was washed with water, extracted with ether and dried. Fractional distillation gave the results shown in Table I.

**ω-Formylundecylic Acid Ethylene Acetal (VI).** — Ten grams of Vc was saponified by refluxing for 3 hr. with 20 ml. of a 50% methanolic solution containing 2 g. of sodium hydroxide. Methanol was then removed by distillation and the aqueous solution was acidified to pH 3 with dilute hydrochloric acid. The crude product which precipitated was recrystallized from 50% aqueous methanol to give 7.7 g. of pure VI, m. p. 73—75°C, yield 81.1%.

Found: C, 65.19; H, 10.28. Calcd. for $C_{14}H_{26}O_4$: C, 65.08; H, 10.14%.

***n*-Valeraldehyde (VIIIa), *n*-Caproaldehyde (VIIIb) and *n*-Caprylaldehyde (VIIIc).** — Twenty grams of β-formylpropionic acid tetramer (VII) and 0.6 mol. of a fatty acid were electrolyzed in 130 ml. of methanol containing 4.5 g. of potassium hydroxide. At the end of the electrolysis, the solvent was removed and the residue was directly hydrolyzed by refluxing with 20 ml. of 5% sulfuric acid for 3 hr. The oily product which separated was taken up in ether and dried over anhydrous sodium sulfate. Distillation of the extract gave the results shown in Table II.

## Summary

Electrolysis of the ethylene acetal of β-formylpropionic acid with butyric acid gave caproaldehyde ethylene acetal as a result of crossed coupling. Crossed electrolysis with monoesters of succinic, adipic and sebacic acid were then studied. The expected products, adipinaldehydic, suberinal dehydic and ω-formylundecylic acid, were obtained as their ethylene acetal ester respectively. As ω-aldehydic acids are usually inaccessible compounds, these electrolytic reactions may provide a new convenient synthetic route.

Furthermore, it has been found that the tetramer of β-formylpropionic acid underwent the normal electrolytic reaction in the presence of fatty acids and the corresponding aliphatic aldehydes were obtained in relatively good yields.

The authors wish the thank Professor Yojiro Tsuzuki for his helpful advice and encouragement. Acknowledgment is also made to the Ajinomoto Co., Ltd. for a grant and for a supply of raw materials.

# Study of Nickel Oxide - Silica - Alumina Catalysts for Ethylene Polymerization. III. The Performance of the Catalysts in Ethylene Polymerization and Butene Isomer Formation and Its Dependence on the Nickel Oxide Content

By Hisao IMAI and Hiroshi UCHIDA

(Received September 26, 1964)

The activity of a particular series of nickel oxide-silica-alumina catalysts for ethylene polymerization and the selectivity in the formation of butene isomers have already been studied.[1,2] The catalysts used differed in aluminum content, though they all had the same nickel content.

To obtain more detailed knowledge about the relation between the catalyst performance and the catalyst composition, the study has recently been extended to another series of catalysts which are the same in aluminum content but different in nickel content. The results of this study will be presented here, and the effects of the addition of aluminum and nickel upon the catalyst performance will be discussed on the basis of these and the previously-obtained results.

Although the performance of nickel-containing catalysts has been studied by some other investigators,[3-7] most of their papers deal with

the catalytic activity and not with the selectivity. The only exception is the paper recently published by Takahashi et al.,[7] who state that a high selectivity in the 1-butene formation can be obtained by the use of a nickel oxide-silica-alumina catalyst suspended in a medium of cyclohexane.

## Experimental

The catalysts required for this study were prepared in the same way as those designated as "catalysts A" in the previous paper.[1] In other words, they were prepared by mixing a solution of sodium silicate with a solution of aluminum and nickel nitrates and then forming the resulting precipitate into granules 1—2 mm. in size. In this case, the aluminum content of the catalyst, expressed as the Al/(Al+Si) atomic ratio, was fixed at 0.05, and the nickel content, expressed as atom.% nickel (defined by $100\times$Ni/(Ni+Si+Al)), was varied over the range from 0 to 8.

Their catalytic performance was studied by conducting two series of experiments on ethylene polymerization with the catalysts. One series of experiments (Series A) was carried out in order to determine the catalytic activity, while the other series (Series B) was carried out in order to determine the selectivity in the formation of butene isomers. The apparatus used for these experiments, which included a circulatory flow system, was the same as that used in our previous study.[1] In the two series of experiments, the reaction temperature was 40°C and the initial ethylene pressure was 345 mmHg. In the experiments of Series A, 5 ml. of a catalyst was used to form the catalyst bed in the cell (catalyst cell), and the two U-shaped traps, joined, respectively, to the entrance and exit tubes of the cell, were cooled in a dry ice - methanol bath. During each experiment, the pressure drop in the system was recorded at intervals. In the experiments of Series B, 1 ml. of a catalyst was used to form the catalyst bed in the cell, and the traps were cooled in an ice bath so that the butenes formed might be maintained in the circulating gas. A small portion of the circulating gas was withdrawn at intervals from the gas circulation system and analyzed for butene isomers by gas chromatography.

The following physical properties of the catalysts were measured by the methods described in previous papers:[1,2] catalyst acidity, specific surface area, and total pore volume. The total pore volume as measured by the present method represents the sum of the volumes of pores smaller than 300Å in radius. Moreover, in order to see the effects of the addition of nickel on the physical properties of catalysts, samples of the catalysts were depleted of nickel, and then the resultant changes in physical properties were measured. The nickel was removed by the method described in a previous paper,[2] namely, by reducing the original catalyst in a stream of hydrogen and then treating the reduced catalyst at 150°C with carbon monoxide under high pressure until it showed no sign of the presence of nickel.

## Results

**Activity for Ethylene Polymerization.**—From the data obtained in the experiments of Series A, the rate constant for ethylene polymerization at 40°C over a unit quantity of a catalyst, hereafter denoted by $k_g$, is calculated by the aid of the equation proposed by Koizumi et al.[8] (Eq. 1):

$$-dP/dt = k_g wP/\{1+(P_0-P)\} \qquad (1)$$

where $P_0$ (mmHg) is the initial pressure of ethylene; $P$ (mmHg), the ethylene pressure at the reaction time, $t$ (min); $w$, the quantity of catalyst used, and $b$, a constant. The rate constant, $k_g$, thus calculated is plotted against the nickel content of the catalyst in Fig. 1.

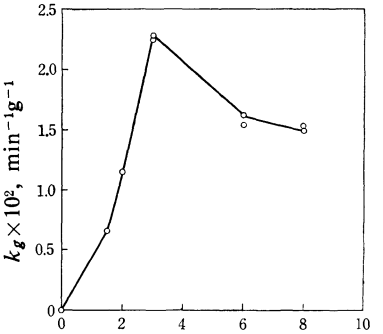

Fig. 1. Dependence of catalyst activity for ethylene polymerization on nickel content.

The plot shows a maximum at about 3 atm.% nickel; this finding is consistent with that of Holm et al.[6]

**Selectivity in the Formation of Butene Isomers.**—From the data obtained in the experiments of Series B, three butene-isomer ratios (concentration ratios), *trans*-2-/1-butene, *cis*-2-/1-butene, and *trans*-2-/*cis*-2-butene, were calculated and plotted against the reaction time, $t$. The plots were then extrapolated to $t=0$ to give the initial butene-isomer ratios.[9] The initial butene-isomere ratios thus obtained are given in Fig. 2 as functions of the nickel content of the catalyst. With the increase in the nickel content, the *cis*-2-/1-butene and *trans*-2-/1-butene ratios both decrease very slowly in nearly the same manner, and then rapidly. In contrast, the *trans*-2-/*cis*-2-butene ratio remains nearly the same (about 1) over the whole range of nickel content studied, though it becomes slightly greater at 3 atm.% nickel, where the highest value of $k_g$ was found.

8) M. Koizumi and S. Taga, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kwagaku Kwaishi*), **64**, 794 (1943).
9) For details of this procedure, see Ref. 1.

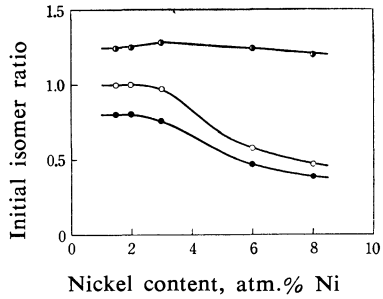

Fig. 2. Dependence of initial butene-isomer ratios on nickel content.
Initial isomer ratio
○ *trans*-2-/1-butene
● *cis*-2-/1-butene
◑ *trans*-2-/*cis*-2-butene

**Catalyst Acidity.**—The catalyst acidity is expressed in millimole equivalents (meq.) of quinoline chemisorbed on a specified quantity of a catalyst sample. In the case of the original catalyst sample containing all three oxides, nickel(II) oxide, silicon oxide, and aluminum oxide, the acidity, $A_g$, is the numerical value determined for 1 g. of the catalyst sample. On the other hand, in the case of the nickel-depleted catalyst sample (which contains only two oxides, silica and alumina), the acidity, $A_g'$, is the numerical value determined for that quantity of the nickel-depleted catalyst sample which has been produced from 1 g. of the original catalyst (i. e., the catalyst containing all three component oxides). In Fig. 3, the acidity values, $A_g$ and $A_g'$, determined for the catalysts used in this study are plotted against the nickel content of the original catalyst. The plot of $A_g$ shows a maximum at 3 atm.% nickel. Whereas the plot of $A_g'$ shows a minimum at the same nickel content. Therefore, it may be seen that the removal of nickel results in a decrease in the catalyst acidity,

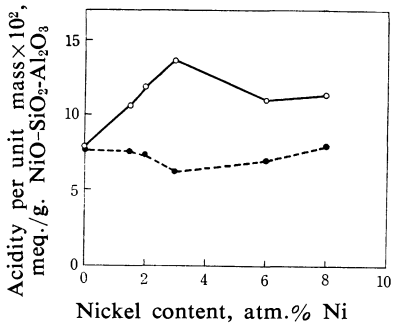

Fig. 3. Acidities per unit mass plotted against nickel content.
—○— Acidity before removal of nickel ($A_g$)
···●··· Acidity after removal of nickel ($A_g'$)

though the extent of the decrease is not directly related to the nickel content of the catalyst.

**Specific Surface Area and Total Pore Volume.**—When the original catalyst contains all three component oxides, the specific surface area, $S$, and the total pore volume, $V$, are the surface area (in $m^2$) and the total pore volume (in ml.) of 1 g. of the catalyst. On the other hand, in the case of a nickel-depleted catalyst sample, the specific surface area, $S'$, and the total pore volume, $V'$, are the surface area (in $m^2$) and the total pore volume (in ml.) of that quantity of the nickel-depleted catalyst sample which has been produced from 1 g. of the original catalyst. In Fig. 4, the four

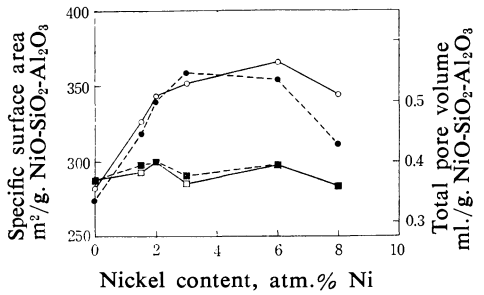

Fig. 4. Specific surface area ($S$) and total pore volume ($V$) of the catalyst samples before and after nickel oxide removal plotted against nickel content.
Circle, $S$ Square, $V$
Empty mark, before the removal
Full mark, after the removal

quantities, $S$, $S'$, $V$, and $V'$, are plotted against the nickel content of the original catalyst. As the nickel content increases, both $S$ and $S'$ first increase, then vary less markedly over the range from 2 to 6 atm.% nickel, and finally decrease. On the other hand, both $V$ and $V'$ remain nearly the same over the whole range of nikel content studied. Except for a pair of catalyst samples—an original catalyst and the nickel-depleted sample produced from this, the specific surface area of a nickel-depleted catalyst ($S'$) is generally smaller than the specific surface area of the original ($S$); on the other hand, the total pore volume of a nickel-depleted catalyst ($V'$) is a little greater than the total pore volume of the original ($V$).

## Discussion

**The Relationship between Activity and Acidity.**—Before considering the relationship between the catalytic activity for ethylene polymerization and the catalyst acidity, let us study, for a moment, the relation between the specific activity, $k_s$, and the specific acidity, $A_s$. The specific activity, i. e., the activity based on the

unit surface area of the catalyst, is obtained by dividing $k_g$ by $S$. Similarly, the specific acidity, i. e. the acidity based on the unit surface area of the catalyst, is obtained by dividing $A_g$ by $S$.

Figure 5 shows a plot of $k_s$ as a function of the nickel content. Since, in the case of

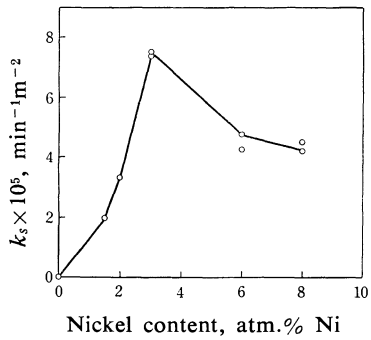

Fig. 5. Specific activity ($k_s$) as a function of nickel content.

acid catalysts,[10-12] $k_s$ is linearly correlated with $A_s$, one may suspect that a similar relationship will be found between the $k_s$ and $A_s$, or more roughly between $k_g$ and $A_g$, for the present catalysts. However, no such correlation can be found in the present case.

On the other hand, we have already found that, for a series of nickel oxide-silica-alumina catalysts with different aluminum contents, $k_s$ is more closely related to the difference between the specific acidity values before and after the removal of nickel, $A_s-A_s'$ (where $A_s'=A_g'/S$) than to $A_g$ or $A_g$ itself, and that

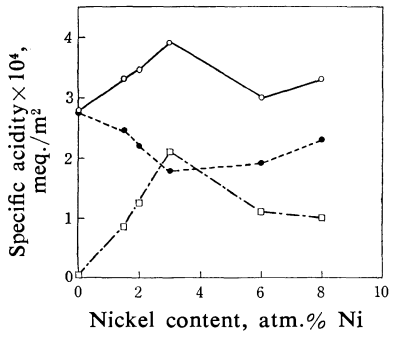

Fig. 6. Specific acidities plotted against nickel content.
—○— Acidity before removal of nickel ($A_s$)
--●-- Acidity after removal of nickel ($A_s'$)
—·□·— Difference between the above two values ($A_s-A_s'$)

10) M. W. Tamelle, *Discussions Faraday Soc.*, **87**, 270 (1950).
11) O. Johnson, *J. Phys. Chem.*, **59**, 827 (1955).
12) E. Echigoya, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **76**, 1049 (1955).

the relationship between $k_s$ and $A_s-A_s'$ is approximately linear.[2] To see whether such a correlation would hold for the present series of catalysts, we have evaluated the specific acidity difference, $A_s-A_s'$, and plotted the values against the nickel content of the catalyst in Fig. 6.

A comparison of this plot with the plot of $k_s$ in Fig. 5 shows a parallel relationship between them. Moreover, a plot of $k_s$ vs. $A_s-A_s'$ for the present series of catalysts agrees with the straight line obtained for the series of nickel oxide-silica-alumina catalysts with different aluminum contents (see Fig. 7).

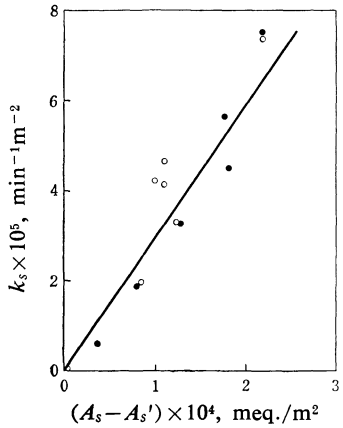

Fig. 7. Specific activity ($k_s$) plotted against the specific acidity difference ($A_s-A_s'$).
● Previously obtained results[2]

These facts indicate that only the acidity produced by the addition of nickel is closely related to the activity of ethylene polymerization, in other words, only the acid sites due to nickel contribute to the ethylene polymerization. However, it must here be noted that the nickel content is not always proportinal to $A_s-A_s'$, and, hence, to $k_s$.

**The Rates of the Formation of Butene Isomers at the Initial Stage of Polymerization and Their Dependence upon the Nickel Content.**—From the data of Figs. 2 and 5, the rates of the formation of three *n*-butene isomers per unit surface area of catalyst at the initial stage of ethylene polymerization can be calculated by the aid of the following equations:

$$r_{02}/r_{01}=[cis\text{-2-}]/[\text{1-butene}] \text{ at } t=0$$

$$r_{03}/r_{01}=[trans\text{-2-}]/[\text{1-butene}] \text{ at } t=0$$

$$r_{03}/r_{02}=[trans\text{-2-}]/[cis\text{-2-butene}] \text{ at } t=0 \quad (2)$$

$$r_0=k_sP_0 \quad (3)$$

$$r_0=r_{01}+r_{02}+r_{03} \quad (4)^{13}$$

13) In the earlier stage of polymerization, where the fraction of ethylene polymerized remained below 0.1, more than 95% of the reaction product was butene.

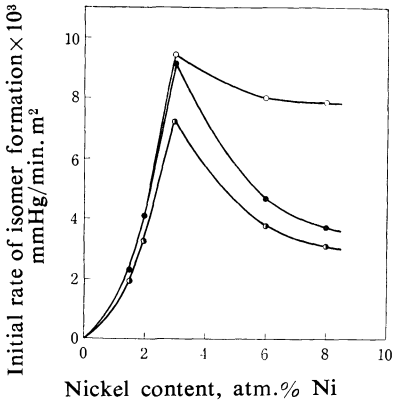

Fig. 8. Dependence of $r_{01}$, $r_{02}$ and $r_{03}$ on nickel content.
○ : $r_{01}$, ◑ : $r_{02}$, ● : $r_{03}$

where $r_{01}$, $r_{02}$, and $r_{03}$ are the rates of the formation of the butene isomers per unit surface area of the catalyst, respectively referring to 1-butene, *cis*-2-butene, and *trans*-2-butene; $r_0$ is the rate of ethylene polymerization per unit surface area of the catalyst, and the brackets indicate the concentration. In Fig. 8, the rates thus calculated, i.e., $r_{01}$, $r_{02}$, and $r_{03}$, are plotted against the nickel content of the catalyst. As the nickel content is increased, all these rates increase up to their respective maxima at 3 atm.% nickel and then decrease. An interesting fact to note here is that, in the range of nickel content above 3 atm.%, the rate $r_{01}$ decreases more slowly than the rates $r_{02}$ and $r_{03}$. This fact seems to indicate the possibility of producing 1-butene selectively by the use of a catalyst containing nickel greatly in excess of a certain amount of aluminum.

**Active Sites for Dimerization and Isomerization.**—For the purpose of explaining the catalytic performance observed in the formation of butene isomers (from ethylene) over nickel oxide-silica-alumina catalysts differing only in aluminum content, it has been postulated in a previous paper[2] that two kinds of active sites, $H^+X^-$ and $H^+Y^-$, as pictured by (≻Si-O-Ni≺) and (≻Si-O-Al≺) respectively, might be present on the catalyst surface, and that the first-named site would participate in the formation of chemisorbed species of 1-butene from ethylene, while the second site would participate in the rearrangement of the chemisorbed species to form the other *n*-butene isomers as the primary products. The concept of the active site $H^+X^-$ serves to explain the straight line relationship observed between the specific activity, $k_s$, and the specific acidity difference, $A_s$—$A_s'$. However, since three *n*-butene isomers were formed as primary products in ethylene dimerization over the catalyst containing no aluminum,[14] it might be necessary to correct this concept as follows: the site $H^+X^-$ contributes not only to the formation of 1-butene but also, in some degree, to the rearrangement of the chemisorbed species of 1-butene which forms the other *n*-butene isomers as the primary products. Nevertheless, we can safely say that only the site $H^+X^-$ contributes to the dimerization of ethylene and that all the sites of this type contribute in equal degree, whatever the aluminum and nickel contents of the catalyst may be.

On the other hand, as the following discussion will show, it has now been found that the data hitherto obtained on the selectivity in the formation of butene isomers are too complicated to allow us to assign the site $H^+Y^-$ simply to the silica-alumina combination, ≻Si-O-Al≺. In the butene-isomer formation over the catalysts described in the previous paper, both *cis*-2-/1-butene and *trans*-2-/1-butene ratios at the initial reaction stage (reaction time: $t=0$) rise rapidly as the aluminum content of the catalyst (expressed as Al/(Al+Si) atomic ratio) increases up to 0.1, while above this value of aluminum content, they remain nearly constant. On the other hand, in the butene-isomer formation over the catalysts described in this paper, these isomer ratios decrease, at first very slowly and then rapidly, as the nickel content of the catalyst increases up to a certain limit. These facts suggest that the selectivity might be related to the Al/Ni ratio rather than to either of the other two factors, aluminum content and nickel content.

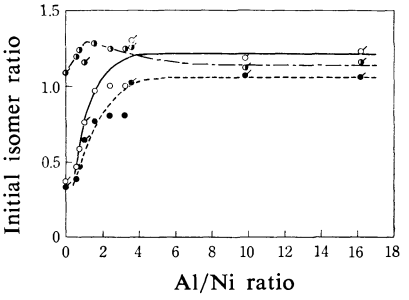

Fig. 9. Dependence of initial isomer ratio on Al/Ni ratio.
○ ♂ *trans*-2-/1-butene
● ♂ *cis*-2-/1-butene
◑ ♂ *trans*-2-/*cis*-2-butene
The marks with dash indicate the previous date with a series of catalysts containing varying amount of aluminum and a fixed amount of nickel.[2]

14) There is a possibility that the catalyst described as containing no aluminum may happen to be contaminated with a minute quantity of aluminum or some other substance, an impurity which might come from the sodium silicate used as a raw material.

In fact, as Fig. 9 shows, both *cis*-2-/1-butene and *trans*-2-/1-butene ratios (at $t=0$) increase as the Al/Ni ratio increases up to 4, but above this Al/Ni ratio they remain nearly constant. On the other hand, the *cis*-2-/*trans*-2-butene ratio is nearly the same throughout the range of the Al/Ni ratio studied, except at an Al/Ni ratio of about 1, where a slight maximum appears in the plot. The trend of the first two plots suggests that all the aluminum in a catalyst can not always be the constituent of the active site capable of accelerating the double-bond shift to form 2-butenes, but that only the aluminum associated in some manner with the nickel, presumably the aluminum joined by an oxygen bond to the nickel as in (≻Si-O-Al-O-Ni≺), can be the constituent.

Moreover, the fact that both *cis*-2-/1-butene and *trans*-2-/1-butene ratios (even their highest values) are much smaller than the corresponding ratios calculated from the thermodynamical data for the chemical equilibrium between butene isomers at 40°C[15] leads us to conclude that the aluminum present in excess of an Al/Ni atomic ratio of 4 cannot accelerate the initial double-bond shift. This conclusion is consistent with the geometry of the aluminum-nickel combination, because, on the basis of the reasonable assumption[16] that one nickel atom is located in the center of a tetrahedron with four oxygen atoms at the corners, it may be considered that four aluminum atoms are joined to one nickel atom by oxygen bridges.

In his study of the selectivity in olefin isomerization over acid catalysts, Brouwer[17] explained the variation in the selectivity with the kind of catalyst by applying the concerted or switch mechanism proposed by Turkevich and Smith[18] and by Horiuchi[19]. Our explanation based on the concept of two active sites is similar to Brouwer's in that two kinds of acid sites, $H^+X^-$ and $H^+Y^-$, are considered. However, the former differs from the latter in that the two acid sites considered in our explanation have different properties, whereas the sites considered by Brouwer are the same. The concerted mechanism alone does not suffice to explain our observation that the activity for ethylene polymerization and the selectivity in the formation of butene isomers change in different ways as the catalyst composition is changed.

The reaction scheme presented in a previous paper[1] can be applied to explain the constancy of the *cis*-2-/*trans*-2-butene ratio observed nearly all over the range of the Al/Ni ratio studied. However, it is not possible to account for the slight maximum appearing in the plot of the isomer ratio at an Al/Ni ratio of about 1.

## Summary

The activity of nickel oxide - silica - alumina catalysts in ethylene polymerization and the selectivity in the formation of three *n*-butene isomers as the primary products have been studied by employing a series of catalysts with identical aluminum contents but different nickel contents. Also studied have been the changes brought about by nickel removal in the catalyst acidity and in the specific surface area.

In the series of catalysts studied, the specific activity, i.e., the activity per unit surface area of the catalyst, increases with the increasing nickel content of the catalyst, attaining a maximum at 3 atm.% nickel. When the specific activity is plotted against the difference between the specific acidity values observed before and after the removal of nickel, the plot falls approximately on the straight line obtained with a series of catalysts which are the same in nickel content but different in aluminum content. On the other hand, for all the catalysts used in the present and previous studies, the selectivity is more closely related to the Al/Ni ratio than to either aluminum content or nickel content.

Two kinds of active sites have been presented in order to explain the present observations. One kind of active site is the nickel acid site, which contributes to the polymerization of ethylene while facilitating the isomerization to some extent. The other site is the aluminum acid site in contact with the former; it contributes to the initial-bond shift.

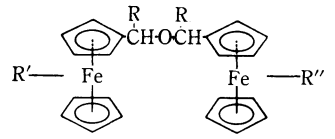
# Ferrocene-containing Polymers. IV. Polymeric Ethers as Intermediates in the Self-condensation of Ferrocenyl Carbinols

By Eberhard W. NEUSE and Edward QUO

(Received September 26, 1964)



A previous paper[1] described the acid-catalyzed polycondensation of ferrocenyl carbinols of the type I. The reaction, which can be summarized by Eq. 1, was found to lead to polymers II.[2] An ionic mechanism was believed to be operative, with monomeric and polymeric[2] ether structures III occurring as intermediates. Monomers IIIa and IIIb were intercepted; however, under the experimental conditions chosen, no polymeric ethers IIId—f could be isolated.

In the present study, using carbinol Ic,[3]

polycondensation reactions were conducted as before, but under milder experimental conditions, i. e., at lower temperatures and shorter reaction times in the presence of catalytic amounts of mineral acids or, less advantageously, organic acids.[4] The reaction could thus be controlled so as to give the postulated polymeric ether IIIf in addition to the monomeric main product IIIc.

In a typical run, catalyzed by hydrochloric acid, Ic was heated under nitrogen for 15 min. at 95°C. After the catalyst had been removed by water extraction, the melt was separated into a major portion containing monomeric constituents and two small fractions of low-molecular-weight polymeric material. The polymeric fractions, obtained in a total yield of 4.0%, showed number-average molecular weights and analytical data[13] as listed in the first two lines of Table I. The findings are well in accord with the calculated composition of ether IIIf.

From the monomeric portion essentially consisting of ether IIIc, the latter was isolated by chromatography in a 83% yield[5] as a mixture of two diastereomers,[6] which were separated by fractional crystallization from hexane. The analytical data for both isomers are given in the last two lines of Table I. The less soluble species, constituting nearly 75% of the total IIIc, melted at 136—138°C and exhibited proton magnetic resonance signals at $\tau$ 2.72 (ten phenyl protons; singlet, broadening to the high-field side), 5.08 (two methine protons; singlet) and at 6.09 (18 ferrocene protons; singlet, broadening to the low- and high-field sides). The second, slightly

2) The notation of the left-hand substituent in II (and also of R' and R'' in III) was discussed earlier (Ref. 1).

3) The bulkier R allows for more enhanced manifestation of compositional changes.

4) Strong organic acids such as oxalic and *p*-toluenesulfonic acid, while giving similar results as mineral acids (if applied in somewhat higher concentrations), were frequently found to be partially incorporated into the polymer through esterification.

5) 92% after 5 min. at 85°C. No IIIf isolated in this case.

6) The possibility of polymorphism for the two species is ruled out by the difference in their high-resolution NMR spectra and the absence of heat-of-transition peaks in the differential thermogram. Only heat-of-fusion endotherms were shown at 110—112°C and 134—136°C, respectively. (DTA thermograms recorded by Mr. R. P. Colburn at a heating rate of 10°C/min. in argon, using a du Pont model 900 differential thermal analyzer). See also Ref. 8.

more soluble isomer,[7] melting at 111—113°C, gave NMR signals in the region $\tau$ 2.6—2.8 (ten phenyl protons; essentially a doublet structure with peaks at 2.68 and 2.76), at 4.95 and 5.08 (two methine protons; two peaks of an equal intensity), and in the region 5.9—6.2 (18 ferrocene protons; complex multiplet with two predominant peaks at 6.10 and 6.17).[8] The infrared spectra of both diastereomers IIIc, recorded on the solid compounds, were nearly identical. The spectrum of the higher melting isomer[9] is given in the lower curve of Fig. 1. Both species showed strong ether absorption at 7.85 and 9.60 $\mu$ and exhibited the typical intensity enhancement of the methine C–H stretching mode at 3.49 $\mu$. Also strongly enhanced were the phenyl band at 8.40 $\mu$ and the 9.5-$\mu$ ferrocene band. In the skeletal range 10.7—11.0 $\mu$, absorption was noticed at 10.80 $\mu$. A characteristic, strong doublet appeared in the 13.5-$\mu$ region[10]; similarly intense was the phenyl $\delta_{C-H}$ band at 14.25 $\mu$.

These spectroscopic correlations for monomeric IIIc served to corroborate the structural assignment of polymeric IIIf. The infrared spectrum of IIIf (Fig. 1, upper curve), besides showing the essential bands of the oxygen-free polymer IIc[1] presented in Fig. 2 for comparison (lower curve), exhibited low-intensity ether bands at 7.85 and 9.60 $\mu$, the latter partially overlapping the 9.65-$\mu$ ferrocene band. Additional absorption appeared at 10.80 $\mu$ and in the 13.3-$\mu$ region, coupled with enhancement of the aforementioned bands at 3.49, 8.39 and 9.5 $\mu$. The high intensity of the C–H deformation band at 14.25 $\mu$, superimposing upon the analogous absorption shown in the 14.0—14.3-$\mu$ region by IIc, gave rise to a highly characteristic doublet pattern, with the high-wavelength peak dominating in intensity.

Further support of structure IIIf resulted from NMR data. The phenyl proton resonances appeared as a broad, poorly-resolved doublet, with a high-field peak near $\tau$ 2.82 corresponding to the signals of oxygen-free IIc ($\tau$ 2.86) or model compounds phenyldiferrocenylmethane[11] ($\tau$ 2.88) and 1,1′-bis(phenylferrocenylmethyl)-ferrocene[12] (IV, $\tau$ 2.80), and a somewhat stronger low-field signal centered at $\tau$ 2.72 corresponding to the more deshielded signal average of isomers IIIc. Two separate methine resonances were shown; the weak high-field signal near $\tau$ 5.6 corresponds to the broad resonance at 5.5—5.7 in IIc and to the singlets at $\tau$ 5.40 in phenyldiferrocenylmethane and 5.49 in IV, whereas the more intense low-field peak at 5.03 is the counterpart to the average methine proton signal of IIIc. For a more quantitative evaluation of the relative intensities, IIIf was fractionally precipitated so as to give a subfraction with $M_n = 830$, i.e., roughly composed of the trinuclear homologs (analytical data[13] given in third line of Table I). The integrated intensities of the phenyl/methine/ferrocenyl protons for this fraction were in the expected 15 : 3 : 26 ratio. The low-field/high-field phenyl proton ratio was ~1.4. Similarly, the low-field/high-field methine proton ratio was found to be ~1.3. Both ratios are lower than required for IIIf, suggesting contamination by IIc. The presence of IIc is not unexpected in view of the various competing propagation steps[1] operative even under the mild condensation conditions applied. Accordingly, enhanced proportions of IIc, coupled with higher $M_n$ and increased yields

7) N. Weliky and E. J. Gould (*J. Am. Chem. Soc.*, **79**, 2742 (1957)) assigned structure IIIc to a compound with m. p. 52—56°C obtained by treating Ic with $PBr_3$. These workers also mentioned an unidentified by-product melting at 110—112°C. While under present experimental conditions the former substance was not isolated, the latter compound is probably identical with our isomer IIIc, m. p. 111—113°C.

8) Assuming diastereoisomerism for both species IIIc, the three staggered conformations of the *d,l*-form will each give rise to a singlet signal in the methine proton region due to pair-wise equivalence of the two methine protons. At temperatures sufficiently high to ensure rapid interconversion and equal population of the conformers, one may thus expect a single time-average proton signal to occur in the mentioned region. For the meso-form, in contrast, the same temperature conditions will lead to two gauche conformers, each with two non-equivalent methine protons, which, hence, may give a doublet signal due to different shielding, and a trans conformer with two equivalent methine protons, exhibiting a singlet resonance. On this basis, it would appear tempting to assign the meso structure to the lower melting isomer. Such conclusion, however, would rest on the unproven and questionable assumption that the temperatute chosen for measurement (ambient) be high enough to preclude the occurrence of preferred conformations (e.g., trans with respect to methine H), and, hence, would have to be borne out by a study of the temperature function of the methine proton shifts.

9) The isomer with m. p. 111—113°C exhibited additional weak absorption at 11.60 $\mu$, but failed to show the small peak at 7.65 $\mu$. Both compounds gave identical spectra in $CS_2$ solution.

10) Also shown by the corresponding ethers with H or $CH_3$ in lieu of $C_6H_5$.

11) Prepared by condensation of ferrocene with benzaldehyde (E. W. Neuse and D. S. Trifan, Abstr. of papers presented at 148th National Meeting, A. C. S., September 1964, p. 5 S.); identical in infrared spectrum and elemental composition with the compound described by Weliky and Gould (Ref. 7; infrared spectrum kindly furnished by Dr. Weliky).

12) Prepared by Mrs. E. Carter in this laboratory; m. p. 190—193°C (sealed cap.). Found: C, 71.49; H, 5.38; Fe, 22.60, $M_n$, 720. Calcd. for $C_{44}H_{38}Fe_3$ (IV; mol. wt. 734.3): C, 71.97; H, 5.22; Fe, 22.82%. %-Homoannularity, 69.2; X-ray diffractogram, Å: 4.98; 5.57—5.65 (doublet); 6.79; 4.22; 5.37; 3.95.

13) The percent-homoannularity values (for definition and experimental determination see Ref. 1) for fractions IIIf listed in Table I and other fractions of IIIf not mentioned in this paper were consistent with those for fractions of IIc in comparable molecular weight ranges. This identity is to be expected on account of like composition and sequence distribution of the recurring units in polymer chains R′ and R″ of ether IIIf on the one hand and in the backbone of polymer IIc on the other hand.

of polymeric products, resulted from extended heating periods under otherwise unchanged experimental conditions. Consistent with this observed trend, it was possible to post-condense IIIf, resulting in the elimination of the internal ether bridge. To this end, in a series of experiments, IIIf was fused for several hours at 100—135°C in the presence of Lewis acids. In all instances, work-up in a manner which has been described[1] gave a polymer identical in composition and spectroscopic behavior with the oxygen-free product IIc prepared earlier.[1] A typical infrared spectrum is presented in the upper curve of Fig. 2.

The described isolation of IIIf and its post-condensation to the polymer IIc devoid of an ether bridge corroborate the mechanistic inferences set forth in an earlier paper[1] regarding the intermediary role of polymeric ethers in polycondensations of ferrocenyl carbinols.

## Experimental[14]

Ferrocenylphenylcarbinol (Ic) was prepared by the sodium borohydride reduction of benzoylferrocene in a manner which has been described earlier[1]; two recrystallizations from hexane gave m.p. 79—81°C. Alcoa-grade F-20 activated alumina was used for chromatography.

**Polycondensation of Ic.**—In an exemplifying experiment, a mixture of 5.0 g. (0.0171 mol.) of carbinol Ic and 0.025 g. of hydrogen chloride (as 1.0 N aqueous hydrochloric acid) was heated for 15 min. at 95°C. A slow stream of nitrogen was passed over the melt during this operation. The vigorously-stirred homogeneous mixture solidified after about 10 min., blocking the stirrer. Extraction of the pulverized melt with water for catalyst removal was followed by fractional extraction with cold hexane. The final residue least soluble in hexane, no longer containing low-molecular ethers or the starting material, was taken up in benzene. Freeze-drying of the concentrated solution furnished a first fraction of IIIf as an orange-brown resin, which was then vacuum-dried for 7 days at 45°C; melting range, 100—125°C. The yield was 0.09 g. (1.9%). A second, lower-molecular fraction of IIIf deposited in a resinous form upon concentration of the combined initial hexane extracts. After the monomer had been removed by hexane trituration, the product, 0.10 g. (2.1%), melted at 80—100°C. For both fractions, $M_n$ and analytical data are collected in Table I.

The supernatant hexane solution, combined with the hexane washings from the trituration of the first fraction IIIf and concentrated to ca. 150 ml., was chromatographed on alumina, using hexane as the eluent. From the lower, major band,[15] 4.02 g. (83.0%) of crude ether IIIc was obtained; melting

14) Melting points uncorrected. Carbon-hydrogen analyses by G. I. Robertson, Jr., Florham Park, N. J. Number-average molecular weights determined by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y., in benzene solution on a Mechrolab model 301A vapor pressure osmometer; values rounded off to nearest 10. X-Ray diffractograms recorded on Norelco X-ray Diffractometer, using vanadium-filtered $K\alpha$ chromium radiation; only six strongest peaks (interplanar spacings d) within $2\theta$ range 10—35° listed in decreasing order of intensity (mean error at $2\theta = 20°, \pm 0.04$ Å). Proton magnetic resonance spectra recorded over a sweep width of 500 c.p.s. in carbon tetrachloride solution on Varian Associates model A-60 NMR spectrometer operating at 60 mc./sec. (tetramethylsilane used as internal standard with $\tau = 10.00$ p. p. m.).

Infrared spectra taken on Baird-Atomic spectrophotometer, model NK-1 equipped with rock salt optics. Quantitative measurements (%-homoannularity. Ref. 1) conducted in spectrograde carbon disulfide, employing a cell-thickness of 0.05 cm. We are indebted to Messrs. W. M. Rade and R. L. Harvey for scanning the X-ray diffractograms and infrared spectra. Dr. S. Manatt, Jet Propulsion Laboratory, Pasadena, Calif., kindly obtained the NMR spectra.

15) Beside trace amounts of IIIf and Ic, benzoylferrocene (0.1%; m. p. 104—106°C) was isolated from the chromatogram, probably formed by oxidation of Ic on the column as repeatedly observed while purifying this carbinol. From an additional, slightly lower band, light yellow and very narrow, 1.9 mg. of an unidentified yellow, infusible crystalline compound were isolated; X-ray diffractogram, Å: 4.87; 5.62; 5.84; 8.49; 4.57; 4.08.

range, 80—125°C; $M_n$, 550.

Found: C, 72.15; H, 5.52; Fe, 19.76. Calcd. for $C_{34}H_{30}Fe_2O$ (IIIc; mol. wt. 566.3): C, 72.11; H, 5.34; Fe, 19.72%.

By fractional crystallization from hexane, the crude isomer mixture was separated into the two diastereomers. This tedious operation was facilitated by the X-ray diffractometric characterization of individual fractions. The less-soluble isomer crystallized as large orange prisms melting at 136—138°C (DTA endotherm,[6] sharp peak at 134—136°C); X-ray diffractogram, Å: 5.70; 6.64; 4.92; 5.43; 4.43; 5.17. The more soluble isomer, melting at 111—113°C (sharp DTA endotherm[6] at 110—112°C), was collected as small, orange-yellow crystal clusters; X-ray diffractogram, Å: 6.05; 4.83; 5.22; 5.34; 5.73; 4.69. The $M_n$ values and elemental analytical findings for both diastereomers are listed in Table I. The two isomers were obtained in a weight ratio of approximately 3:1 (high-melting to low-melting species).

A 70 mg. portion of the second fraction of IIIf listed in Table I was subfractionated from a hexane solution by incremental volume reduction, using a rotating evaporator (environmental water bath maintained at 30±2°C). The four resinous deposits obtained successively were dried in vacuo for 7 days at 45°C. The major cut, 45 mg., showed the melting range of 80—95°C. $M_n$ and analytical data are given in Table I (center line). The iron analyses were performed on material recovered from the $M_n$ determination, which in turn had previously been recovered from NMR and infrared work.

Results similar to those described above, except for lower yields in IIIc, were obtained in condensation reactions catalyzed by 0.5% sulfuric acid (as 1.0 N sulfuric acid; 0.4 hr. heating at 100°C), 2.0% oxalic acid (2 hr. at 110°C) or 1.8% *p*-toluenesulfonic acid (2 hr. at 100°C). In the last-named two cases employing organic acids, these catalysts were partially incorporated into the polymeric reaction products, as is indicated by the elemental analyses and the appearance of ester absorption bands in the infrared spectra. Other experiments were performed in the presence of hydrochloric acid; they were similar to those which have been described but were conducted over extended heating periods. Here, the original polymer fractions isolated exhibited higher $M_n$ values (total yields up to ~30%), and their infrared spectra increasingly resembled, but never became quite superimposable with, those of IIc. For instance, heating for one hour at the started temperature gave a polymer, melting range 100—130°C, $M_n$ 1360, in a total yield of 9.7%.

Found: C, 73.91; H, 5.30; Fe, 20.09. Calcd. for IIIf (for IIc in parentheses): C, 73.51 (74.48); H, 5.23 (5.15); Fe, 20.11% (20.37%).

**Post-Condensation of IIIf.** — A typical fraction of IIIf (0.225 g.) prepared from Ic by sulfuric acid catalysis ($M_n$, 990. Found: C, 73.01; H, 5.28; Fe, 19.88%), was ground together with 0.011 g. of anhydrous zinc chloride[16] and fused for 1.0 hr. at 120°C in a test-tube under a blanket of dry nitrogen. The melt, liquid in the initial stage, finally became highly viscous and "stringy" and solidified on cooling. The mass was ground and extracted with water to remove the catalyst and was then worked up in a manner described in an earlier paper[1] to give two polymer fractions. The major fraction (0.105 g.), a yellow-tan solid, had a melting range of 150—180°C (partial melting); $M_n$, 2020.

Found: C, 74.43; H, 5.22; Fe, 20.20. Calcd. for IIc: C, 74.48; H, 5.15; Fe, 20.37%.

The infrared spectrum is presented in Fig. 2 (upper curve). The somewhat smaller second fraction, 0.070 g., a yellow solid, gave $M_n$ 880. Found: C, 74.16; H, 5.09%. The infrared spectrum, while essentially superimposable with that of the first fraction, showed shoulders at 7.85, 9.60 and near 13.3 $\mu$, indicating the presence of an ether bridge in a very low concentration. When the heating period in this experiment was extended to 2.0 hr., ether absorption vanished completely in both fractions.

## Summary

The acid-catalyzed polycondensation of ferrocenylphenylcarbinol Ic under controlled, mild reaction conditions gives rise to the formation of low-molecular, ferrocene-containing polymeric ethers, to which, on the basis of elemental analysis, infrared and NMR spectroscopic data, the structure IIIf is assigned. Monomeric ether IIIc is isolated in addition under these conditions. In the presence of Lewis acids at elevated temperatures, ethers IIIf continue to react, with the elimination of the ether bridge, to give polymers identical with the previously reported oxygen-free compounds IIc, which were obtained directly from Ic under more rigorous conditions. In the previous work, polymers IIIf containing an ether group were postulated as intermediates but were not isolated. The observed formation of such polymers under the present experimental conditions, coupled with their successful post-condensation to IIc, is thus in accord with the earlier mechanistic implications.

*Missile & Space Systems Division*
*Douglas Aircraft Company, Inc.*
*Santa Monica, California*

16) Comparable results obtained in post-condensation reactions catalyzed by anhydrous aluminum chloride (4% by wt. of IIIf), but large portion (—10% by wt. of IIIf) of insoluble, crosslinked polymer and decomposition products isolated in addition.

# A Shock-Tube Study of the Acetylene-Oxygen Reaction

By Tetsu TAKEYAMA and Hajime MIYAMA

(Received October 2, 1964)

Kistiakowsky and his collaborators have extensively investigated the acetylene-oxygen reaction in shock waves, using a wide variety of techniques to follow reaction processes, i. e., mass spectrometry,[1] X-ray densitometry,[2] vacuum ultraviolet emission spectroscopy,[3] and Langmuir probe technique.[4] They proposed that the rate of the main process operating in the induction period is determined by the reaction, $H+O_2 \rightarrow OH+O$, as in the hydrogen-oxygen reaction.

Observing visible or ultraviolet emission and OH absorption simultaneously, Stubbeman and Gardiner[5] have recently found that OH appears much later than the emission pulse and have explained that the high reactivity of OH is responsible for its delayed appearance. Since both Kistiakowsky's group and Stubbeman and Gardiner studied the reaction at higher temperatures and lower pressures, it now seems worth while to study the reaction under conditions similar to those chosen by us for the hydrogen-oxygen reaction,[6] i. e., at lower temperatures and higher pressures.

In this paper we will report the results obtained from simultaneous measurements of OH absorption, visible emission and pressure over the temperature range 820−1630°K and the pressure range 1.8−5.6 atm.

## Experimental

**Shock Tube and Instrumentation.** — The shock tube used was the same one as that described previously[7] except for a minor change in the observation system : an auxiliary observation station for emission measurement was installed in the lower part of the tube 5.5 mm. from the end plate, the same position as that for OH absorption and pressure measurement. For experiments in incident stock waves, a 1.2 m. tube of the same diameter was connected to the downstream end. A Shimadzu QR-50 monochromator with an R 106 photomultiplier (Hamamatsu TV Company) was used to isolate spectral regions of light transmitted through or emitted from the shock-heated gas at the principal observation station. The width of the exit slit of the monochromator was set at 0.15 mm. for the OH absorption measurement and at 0.50 mm. for the visible emission, the band widths being 7 and 65 Å respectively. The induction period for the onset of visible emission was measured by an 1P28 photomultiplier placed 30 cm. under the tube ; the optical system consisted of a quartz window, a 1 mm. wide slit, an interference filter (Vacuum Optics Corporation of Japan) (peak 4305 Å ; half-band width of 65 Å ; peak transmission 52%), a 1 mm. wide slit, and an 1P28 photomultiplier. A quartz-pressure transducer (Kistler model 603) was used for the pressure measurement 5.5 mm. from the end plate. Two platinum-film resistance thermometers and an electronic counter (Takeda Riken 4247) were used to measure the shock velocities.

**The Calculation of Shock Parameters.**—Temperatures, pressures and other parameters of the gas behind the incident and reflected shock waves were calculated by means of the one-dimensional theory described in a previous paper.[7]

**Materials.**—Matheson acetylene (99.66% min.) was used after being passed through two dry ice traps and having been determined to be free from acetone by a mass spectrometer. Nippon Sanso oxygen (99.5% min.) and argon (99.999% min.) were used without further purification.

## Results

**The Measurement of the Induction Period.**— By using reflected or incident shock waves, the induction periods for the OH appearance, the onset of visible emission and the pressure increase were measured simultaneously at the same location in the tube. The experimental conditions are summarized in Table I.

TABLE I. SUMMARY OF EXPERIMENTAL CONDITIONS

| Mixture | % Ar | $[C_2H_2]/[O_2]$ | Temp. range °K | $[O_2]$ range $10^{-3}$ mol./l. |
|---|---|---|---|---|
| I | 90 | 0.67 | 820—1300 | 1.63—4.08 |
| II | 93 | 0.40 | 970—1630 | 1.13—1.86 |
| III | 95 | 1.5 | 1110—1480 | 0.842—1.21 |
| IV | 94 | 1.0 | 1130—1520 | 1.16—1.76 |

A sample of the oscillograms obtained is shown in Fig. 1. The OH appearance, the onset of visible emission and the increase in

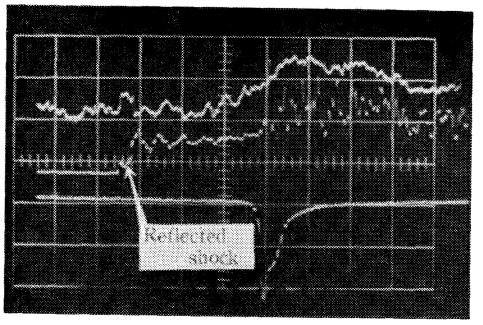

Fig. 1. Sample oscillogram. Mixture I, initial pressure 109.8 mmHg, shock temperature 1060°K, sweep rate 100 $\mu$sec./division. Top trace represents OH absorption, middle trace pressure change and bottom trace emission at 4320Å.

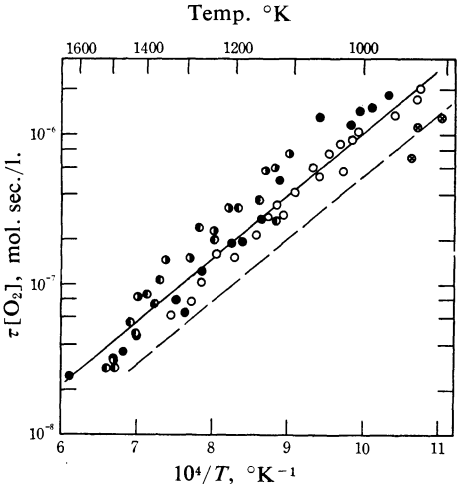

Fig. 2. Induction periods for appearance of OH absorption. Solid line is the least-squares line through the points and dashed line is the one obtained in the hydrogen-oxygen reaction.[6] The points are identified as follows:

| Symbol | Mixture | Type of shock |
|---|---|---|
| ○ | I | reflected |
| ⊗ | I | incident |
| ● | II | reflected |
| ◑ | III | reflected |
| ◐ | IV | reflected |

pressure occurred almost concurrently after an induction period, $\tau$, over the whole temperature range studied. In Fig. 2, the results for $\tau$ measured by OH absorption spectroscopy are shown as a plot of $\log(\tau[O_2])$ vs. $1/T$. The induction periods measured in incident shock experiments were multiplied by the density ratio in order to convert the laboratory time into particle time. Although there are few data from incident shock experiments because of the experimental difficulties encountered, the data we do have fall close to those obtained from reflected shock experiments. It should also be noted that, over the 0.4—1.5 range of acetylene to oxygen ratio there exists a linear relationship between $\log(\tau[O_2])$ and $1/T$; hence, the induction periods are dependent upon the oxygen concentration, as has been reported in the literature.[3,4] The equation of the least-squares line through these points is:

$$\log(\tau[O_2])\ (\text{mol. sec./l.}) = -10.16\pm0.15+(4160\pm140)/T \qquad (1)$$

The dashed line in Fig. 2 is the least-squares line obtained by us in the hydrogen-oxygen reaction.[6]

**The Intensity Distribution of Visible Emission.**—In order to identify the visible emitter, the intensities of emission were measured with the monochromator which had been used for OH absorption spectroscopy; 80 mmHg of gas mixture I (see Table I) was heated by reflected shock waves to 1210±30°K, and the wavelength setting of the monochromator was varied from run to run through the region 4100—4500Å. The intensities measured were corrected with the spectral response of the R106 photomultiplier; they are shown in Fig. 3. There exists a sharp peak at about 4320Å.

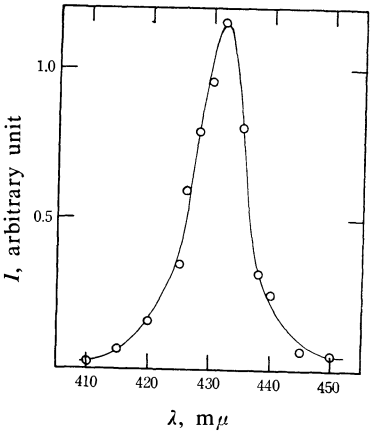

Fig. 3. Emission intensity vs. wavelength.

**The Temperature Dependence of the Intensity of Visible Emission.**—The intensities of visible emission were measured at 4200, 4320 and 4450Å over the temperature range 900—1270°K by using 80 mmHg of gas mixture I (see Table I) as the driven gas and 2.8—3.2 atm. of helium as the driver gas. The results are shown in Fig. 4. Although the intensities observed at 4200 and 4450Å are almost independent of the temperature those at 4320Å show a slight dependence, one which corresponds to an activation energy of about

6 kcal./mol. In these experiments, the concentrations of oxygen were kept nearly constant, ranging from $1.19\times10^{-3}$ to $1.58\times10^{-3}$ mol./l.; hence, it can be considered that no factors other than the temperature are involved in the results shown in Fig. 4.

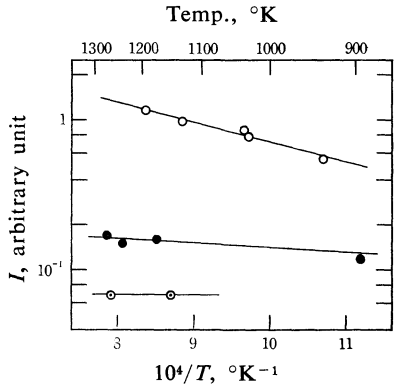

Fig. 4. Emission intensity vs. reciprocal temperature. Intensities measured at 432, 420 and 445 mμ are represented by ○, ●, and ⊙, respectively.

**Ionization.**—In the course of incident shock experiments, the output signals from the thin-film thermometers were found to be unreasonably delayed when the shock Mach number was increased. The oscillogram of these outputs revealed, as Fig. 5 shows, that negative signals occur when the shock front passes the thermometers and that the increase in the resistances of the thermometers due to temperature rise are delayed a few hundred micro seconds. This anomaly is attributable to the ionization of gases surrounding the thermometers ; it was therefore considered necessary to examine the details of ionization.

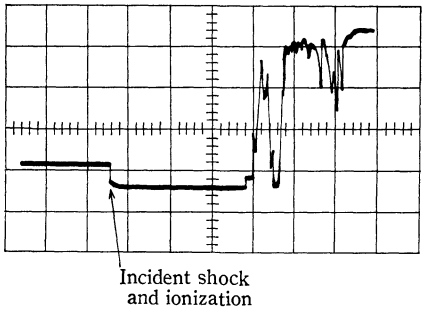

Fig. 5.—Oscillogram of thin-film thermometer showing ionization on arrival of shock. Mixture I, initial pressure 70.7 mmHg, shock temperature 1210°K, sweep rate 200 μsec./division.

A series of experiments was conducted using 100—40 mmHg of mixture I (see Table I) as the driven gas and 5 atm. of helium as the driver. The temperature range thus covered was 850—1200°K. According to the oscillograms obtained at temperatures higher than 1030°K, i. e., $P_1\leq83$ mmHg, the ionization begins as soon as the shock front has arrived.

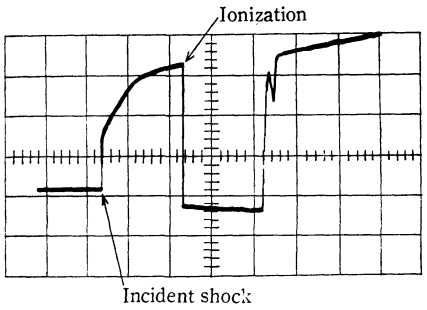

Fig. 6. Oscillogram of thin-film thermometer showing induction period for ionization. Mixture I, initial pressure 87.6 mmHg, shock temperature 920°K, sweep rate 200 μsec./division.

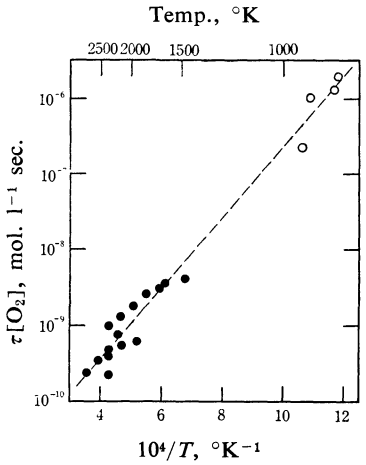

Fig. 7. Induction periods for ionization. Open circles are obtained in the present study with thin-film thermometer and solid circles by Hand and Kistiakowsky with Langmuir probe.

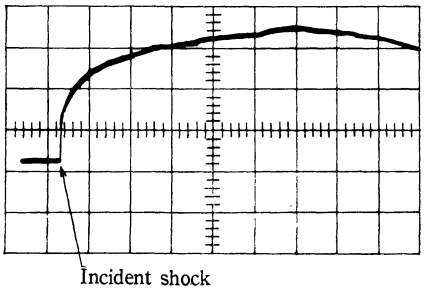

Fig. 8. Oscillogram of thin-film thermometer showing no ionization. Argon, initial pressure 20.0 mmHg, shock temperature 2030°K, sweep rate 100 μsec./division.

However, below this temperature the ionization occurs after an induction period, as Fig. 6 shows. This induction period is of the same order of magnitude as that measured by the pressure transducer at the same time, and it becomes longer as the temperature is lowered. In Fig. 7, the present results are compared with those of Hand and Kistiakowsky (cf. Fig. 4 of their paper[4]). The present data fall just on the line which is an extrapolation of theirs. For purposes of comparison, a strong shock was generated in 20 mmHg of argon or air. No ionization was found in these cases, as is shown in Fig. 8, although the temperatures were much higher than those for the cases where ionization was found in an acetylene-oxygen mixture.

## Discussion

Kistiakowsky and his collaborators[1,3] proposed the following scheme as operating during the induction period of acetylene-oxygen reaction in shock waves:

$$H+O_2 \rightarrow OH+O$$
$$\Delta H=17 \text{ kcal./mol.} \quad \text{(I)}$$
$$O+C_2H_2 \rightarrow C_2H+OH$$
$$\Delta H\leqq 20 \text{ kcal./mol.} \quad \text{(II)}$$
$$OH+C_2H_2 \rightarrow C_2H+H_2O$$
$$\Delta H\leqq 1 \text{ kcal./mol.} \quad \text{(III)}$$
$$C_2H+C_2H_2 \rightarrow C_4H_2+H$$
$$\Delta H=-23 \text{ kcal./mol.} \quad \text{(IV)}$$

Reaction I was considered to be rate-controlling, since the induction period behaves very similarly to that in the hydrogen-oxygen reaction.[8]

The present results shown in Fig. 2 do indicate that, in the range of conditions $820° \leqq T \leqq 1630°K$, $1.8 \leqq P \leqq 5.6$ atm., $8.4\times10^{-4} \leqq [O_2] \leqq 4.1\times10^{-3}$ mol./l., and $0.4 \leqq [C_2H_2]/[O_2] \leqq 1.5$, the induction period depends upon the oxygen concentration and that the activation energy derived from Eq. 1 is $19.0\pm0.6$ kcal./mol. Furthermore, the present data fall close to those obtained by us for a hydrogen-oxygen reaction.[6] Thus, reaction I is also rate-determining under the conditions of the present study.

In the hydrogen-oxygen reaction,[6] it was found that the induction period for an abrupt increase in pressure is much longer than that for OH absorption at temperatures below about 1100°K, and that it depends on the hydrogen rather than on the oxygen concentration. These findings were attributed to the participation of $HO_2$, radicals in the reaction processes at lower temperatures. However, the present study of the acetylene-oxygen reaction revealed no such effects. It is probably due to exothermic side reaction,[9] which prevent the accumulation of $HO_2$ radicals.

Although Stubbeman and Gardiner[5] found that the OH appearance is much later than the emission and ascribed it to the high reactivity of OH radicals, the present study has shown that OH absorption, visible emission and pressure increase occurred simultaneously over the whole temperature range studied. Since OH absorption increases much less rapidly than visible emission, as Fig. 1 shows, the induction period for the appearance of OH absorption is much more dependent upon such experimental conditions as the pressure, temperature, and the detectability of the measuring system. Therefore, we would explain the discrepancy between the present results and those of Stubbeman and Gardiner on the grounds of difference in facilities for detecting OH radicals.

Glass[10] has inferred from experiments with several interference filters that there should be a peak at about 4300Å, and he has suggested that the principal emitter of visible radiation must be the CH radical instead of the reaction $CO+O \rightarrow CO_2+h\nu$ proposed by Stubbeman and Gardiner.[5] The present results obtained with a monochromator give strong evidence, as Fig. 3 shows, that there is a sharp peak at about 4320Å. Accordingly, the visible emission observable in the acetylene-oxygen reaction in shock waves can be assigned to the $^2\Delta \rightarrow {}^2\pi$ transition of CH, as is the case with hydrocarbon-oxygen flames.[11] The probable reactions which cause chemiluminescence are considered to be:

$$C_2H+O_2 \rightarrow CO_2+CH^* \quad \text{(V)}$$

or:

$$C_2H+O \rightarrow CO+CH^* \quad \text{(VI)}$$

However, it is impossible to decide on the basis of the present results which of these is predominant.

The temperature dependence of the maximum intensity in Fig. 4 corresponds to 6 kcal.; it is much smaller than the energy required for placing the CH radical in the $^2\Delta$ state (66.6 kcal.). Therefore, as has been suggested for vacuum ultraviolet emission and ionization,[4] a high collisional yield must be assumed in order to explain the strong visible emission.

The ionization encountered in the course of

incident shock experiments is apparently chemical in origin, since it was observed only in the case of the acetylene-oxygen mixture and since, moreover, the induction period for ionization was of the same order of magnitude as that for the pressure increase. As is shown in Fig. 7, this chemi-ionization should be essentially the same as that observed by Hand and Kistiakowsky[4] with a Langmuir probe, and the reaction

$$CH^* + O \rightarrow CHO^+ + e^-$$

should be responsible. Thus, it is prospective to use a thin-film resistance thermometer as a detector of chemi-ionization.

## Summary

Acetylene-oxygen reaction in shock waves has been studied over the range of conditions $820° \leq T \leq 1630°K$, $1.8 \leq P \leq 5.6$ atm., $8.4 \times 10^{-4} \leq [O_2] \leq 4.1 \times 10^{-3}$ mol./l. and $0.4 \leq [C_2H_2]/[O_2] \leq 1.5$. Visible emission, OH absorption, and pressure have been measured simultaneously at the same location in the tube. The induction periods obtained from these measurements have been found to be identical with each other and to be dependent upon the oxygen concentration. It has also been found that the activation energy derived from the $\log(\tau[O_2])$ vs. $1/T$ plot is equal to $19.0 \pm 0.6$ kcal./mol. Thus, the reaction $H + O_2 \rightarrow OH + O$ is considered to be rate-determining during the induction period, as in the hydrogen-oxygen reaction.

The visible emission has been found to have a sharp peak at about 4320Å and has been attributed to the $^2\Delta - ^2\pi$ transition of CH radicals.

The authors are grateful to Mr. Akio Sawa for his help in the experiments and to Mr. Daisuke Miura and Mrs. Yukiko Takemura for their computations of shock parameters.

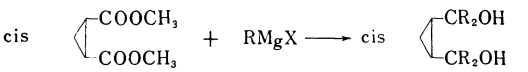
# Small Ring Compounds. VII. The Syntheses of 3-Oxabicyclo-[3. 1. 0]hexane and Its Derivatives

By Tatsuya SHONO, Akira OKU, Takeshi MORIKAWA, Masatoshi KIMURA and Ryohei ODA

(Received October 6, 1964)

The cyclopropane ring has been reasonably considered to be different from other alicyclic rings in its electronic structure and to show characteristic chemical and physical properties. In order to clarify these points, the authors have reported in the preceding paper[1] of this series on the syntheses of cyclopropane derivatives and on some of their characteristic reactions. In the present paper the syntheses and properties of some cyclic ethers, which include the cyclopropane ring, that is, 3-oxabicyclo-[3. 1. 0] hexane (I) derivatives, will be reported.

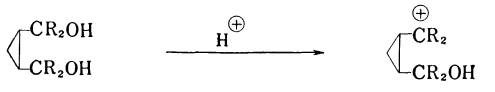
Two methods are available for the syntheses of these bicyclic ethers. One of them is the dehydration of *cis*-1, 2-dimethylolcyclopropane and its derivatives (Eq. 1), while the other is the addition of some carbenes to 2, 5-dihydrofuran (Eq. 2):



(1)

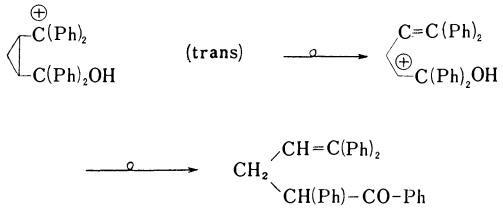
(2)

The synthesis of *cis*-1, 2-dimethylolcyclopropane was reported in the previous paper,[1] and $\alpha, \alpha, \alpha', \alpha'$-tetrasubstituted homologs were prepared from the corresponding *cis*-diester by Grignard reaction (Eq. 3):



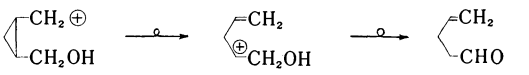
(3)

For the dehydrating ring closure of these glycols, four methods were examined: The use of potassium bisulfate, phosphoric acid and



1) Small Ring Compounds. VI. T. Shono, T. Morikawa, R. Okayama and R. Oda, *Makromol. Chem.*, in press.

dimethyl sulfoxide as dehydrating agents, and the alkaline fusion of the tosylate of the glycols. Among these methods, that employing potassium bisulfate gave the best result; by the alkaline fusion of tosylate, the ether was not obtained at all. It is of interest that the dehydration of the glycols in acidic media was affected by the substituents and that sometimes rearranged products were formed. In acidic dehydration, the first-formed cation (see Eq. 4) would be the so-called "cyclopropyl carbinyl"-type cation, which is known to exhibit a complicated behavior in the course of reaction.[2]

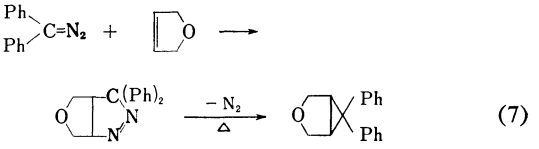


(4)

The cyclopropylcarbinyl cation may be considered to belong to a nonclassical carbonium ion; hence, ring-opening and rearrangement should occur. When the cation has some substituents at appropriate positions, the substituents have a great effect on its character; that is, the substituents determine whether it is a nonclassical or a localized cation. In our results, bicyclic ether was obtained almost quantitatively in the case of $R=CH_3$ (cf. Eq. 4), whereas in the case of $R=H$ or $C_6H_5$, some ring-opened products were obtained besides bicyclic ether. For example, *cis*-1,2-di($\alpha$,$\alpha$-diphenyl)methylolcyclopropane was rearranged through dehydration to give 1,1,4-triphenyl-4-benzoylbutene-1 (80%), which is the same as the product obtained in the acidic dehydration of the trans isomer[3] (Eq. 5):

(5)

The yield of the normally dehydrated product, bicyclic ether, was only 20%. These results show that two competing reactions, i.e., cyclization and rearrangement, occurred. In addition, the dehydrated products from a glycol, where $R=H$, had a very complicated composition. The yield of the expected product, 3-oxabicyclo[3.1.0]hexane, was only 35%, and the formation of an aldehyde (abt. 4%) and a large amount of oligomer containing a carbonyl group was observed. The mechanism of the formation of this aldehyde seems similar to that where $R=C_6H_5$ (Eq. 6):

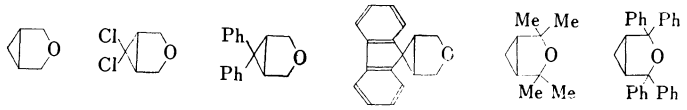


(6)

The 2,4-dinitrophenylhydrazone of this aldehyde gave the same elementary analysis data and melting point as did an authentic sample.

On the other hand, it has been reported that, when methyl group is present at an appropriate position of the cyclopropyl carbinyl cation, this methyl group effects the localization of the cation and diminishes the contribution of the non-classical character.[2] This fact agrees with our finding that no rearrangement was observed in the dehydration of the glycol where $R=CH_3$. The courses of dehydration of these glycols, both cis- and trans-, are now under investigation and will be reported on elsewhere.

The methods of the syntheses of bicyclic ethers through carbene addition to 2,5-dihydrofuran differed according to the character of the carbene. For example, dichlorocarbene was generated by two methods, (1) $CHCl_3$+$t$-$C_4H_9OK$ and (2) $Cl_3CCOOCH_3+CH_3ONa$. Method 2 gave a better result, but in both cases the products were a mixture of two isomeric compounds, which could be separated only by vapor-phase chromatography. One of them was 6,6-dichloro-3-oxabicyclo[3.1.0]-hexane; the structure of the other isomeric product could not be elucidated, though it can be considered to be an insertion product. On the other hand, fluorenyl carbene was generated from the corresponding diazo compound in a solution of 2,5-dihydrofuran with a copper catalyst. Under similar conditions, however, diphenyldiazomethane was directly added to 2,5-dihydrofuran to form a pyrazoline derivative, which lost its nitrogen easily upon heating and afforded the bicyclic ether (Eq. 7):



(7)

In addition, the Simmons-Smith[4] method was adopted as a modified procedure for the synthesis of 3-oxabicyclo[3.1.0]hexane, instead of using diazomethane as a carbene source. A zinc-copper couple was prepared by the wet method. The yield was only 5%, though it

has been reported that in the case of dihydropyran the yield reached up to 65%.

The NMR spectra of compounds II, III and IV had only two peaks, near $\tau=7.7$ and 6.0 (see Table II) (Fig. 1). These peaks correspond to the bridge-head protons and to the methylene protons adjacent to oxygen respectively. Further, each peak showed a negligibly small fine-structure, indicating that the spin-spin coupling between $H_{(1)}$ and $H_{(2)}$ (or $H_{(5)}$ and $H_{(4)}$) is negligibly small in these bicyclic compounds. In these compounds the three-membered ring and the five-membered ring do not lie on the same plane; hence, the two hydrogens at position 2 or 4 would not be equivalent, and the spectrum of these hydrogens would be of the type AB. In the spectra of 6,6-disubstituted bicyclic ethers, however, the chemical shifts of the two hydrogens of position 2 or 4 were nearly equal, and hence the AB-type spectrum was not confirmed. However, in the case of compound I (X=H), the spectrum of $H_{(2)}$ (or $H_{(4)}$) was clearly of the AB type, and still the coupling between $H_{(1)}$ and $H_{(2)}$ (or $H_{(5)}$ and $H_{(4)}$) (Fig. 2) was negligibly small.

The infrared spectra of these bicyclic ethers showed the presence of a characteristic band near 1090 $cm^{-1}$ (Fig. 3).

Attempts to polymerize these bicyclic ethers (particularly I and II) with phosphorous pentafluoride, antimony pentachloride or a thionyl chloride - ferric chloride complex were unsuccessful. The reason why they could not be polymerized is uncertain. Moreover, neither I nor II copolymerized with 3,3-bischloromethyloxethane in the presence of a modified catalyst of triethyl aluminum ($AlEt_3+H_2O+$ Epichlorohydrin).

## Experimental

**3-Oxabicyclo[3.1.0]hexane (I).**—*a) By Dehydration using Potassium Bisulfate.*—In a 50 ml. distilling flask 2.6 g. (3/160 mol.) of calcined potassium bisulfate was placed. The flask was then heated at 150—160°C, and 7.6 g. (3/40 mol.) of *cis*-1,2-dimethylolcyclopropane was added drop by drop over a 15-min. period. The distillate separated in two layers, and the organic layer was dried successively over sodium bicarbonate and Drierite (raw yield; 43%). By fractional distillation I was obtained in a 35% yield, b. p. 85—90°C, it contained a slight amount of an aldehyde.

Found (for I): C, 70.78; H, 9.67. Calcd. for $C_5H_8O$: C, 71.39; H, 9.58%.

*b) By Dehydration using Phosphoric Acid.*—Into a flask heated to 260°C, a mixture of 23 g. (0.23 mol.) of *cis*-1,2-dimethylolcyclopropane and 0.25 ml. of 80% phosphoric acid was added drop by drop. The distillate was dried over anhydrous magnesium sulfate and distilled. A fraction with the boiling range of 70—80°C was proved to be pure I by gas chromatography (yield, 5%).

*c) By Dehydration using Dimethyl Sulfoxide (DMSO).*—A mixture of 16 g. (0.16 mol.) of *cis*-1,2-dimethylolcyclopropane and 150 g. of DMSO was heated at 160—170°C under refluxing for 18 hr. Then the mixture was distilled below the boiling point of DMSO, the distillate was extracted with petroleum ether, and the organic layer was dried over anhydrous magnesium sulfate. After fractional distillation, a fraction with the boiling range of 60—106°C was obtained; in this fraction I was detected by gas chromatography and infrared absorption (yield, 2%).

*d) By the Simmons-Smith Reaction.*—The procedure was almost analogous to that of the synthesis of norcarane. The yield was only 3—5% (by gas chromatography).

**6,6-Dichloro-3-oxabicyclo[3.1.0]hexane (II).**—*a) Using Chloroform as the Source of Carbene.*—Dichlorocarbene was generated by the usual method[5] from chloroform and potassium *t*-butoxide in an ether solution of 2,5-dihydrofuran. The reaction mixture was then treated with aqueous phosphoric acid and extracted with ether. The ethereal solution was dried over anhydrous magnesium sulfate and distilled to give a fraction with the boiling range of 80—94°C/60 mmHg; from this fraction II was separated by preparative gas chromatography (yield, 7%).

*b) Using Methyl Trichloroacetate as the Carbene Source.*—The procedure was almost analogous to that of ethyl trichloroacetate.[6] The yield of II was 37% (b. p. 81—85°C/25 mmHg) after it had been purified by gas chromatography.

5) W. von E. Doering and A. K. Hoffmann, *J. Am. Chem. Soc.*, **76**, 6162 (1954).

6) J. C. Anderson and C. B. Reese, *Chem. & Ind.*, **1963**, 575.

**6, 6-Diphenyl-3-oxabicyclo[3. 1. 0]hexane (III).**—Diphenyldiazomethane was prepared according to the usual method.[7] To a solution of 8 g. (0.04 mol.) of diphenyldiazomethane in 27 g. (0.4 mol.) of 2,5-dihydrofuran, a catalytic amount of copper powder was added; then the mixture was heated under refluxing for 10 hr. After the excess dihydrofuran, had been removed, the remaining solid was recrystallized from ligroin and proved to be a pyrazoline derivative. Yield, 2.2 g. (21%). M. p. 119.5 —121°C.

Found: C, 77.12; H, 6.21. Calcd. for $C_{17}H_{16}N_2O$: C, 77.25; H, 6.10%.

When this pyrazoline derivative was heated, a rapid evolution of nitrogen occurred. The recrystallization of the residue gave 1.8 g. (92%) of III. M. p. 86.5—87.5°C.

Found: C, 86.40; H, 6.82. Calcd. for $C_{17}H_{16}O$: C, 86.72; H. 6.83%.

**3, 4-(9, 9-Fluorenylidene)tetrahydrofuran (IV).**—Diazofluorene,[8] prepared from 3 g. of the corresponding hydrazone, was dissolved in 5 g. of dihydrofuran and refluxed for 3 days in the presence of a copper catalyst. After dihydrofuran had been evaporated, the residue was recrystallized from benzene and ether successively to afford 0.2 g. (5%) of IV. M. p. 169—170.5°C.

Found: C, 87.42; H, 5.95. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

**2, 2, 4, 4-Tetramethyl-3-oxabicyclo[3. 1. 0]hexane (V).**—*cis*-1,2-Di($\alpha$, $\alpha$-dimethyl)methylolcyclopropane (V') was prepared by the usual method from methylmagnesium iodide and *cis*-dimethyl 1,2-cyclopropane dicarboxylate. Yield, 44%. M. p. 85.5—87°C.

Found (for V'): C, 68.33; H, 11.76. Calcd. for $C_9H_{18}O_2$: C, 68.31; H, 11.47%.

A mixture of 11 g. (0.07 mol.) of V' and 5 g. (0.035 mol.) of calcined potassium bisulfate was heated in a distilling flask; then the distillate was collected and dried over calcium chloride. Distillation gave 7.5 g. of V (77%). B. p. 91—91.5°C/164 mmHg.

Found (for V): C, 76.83; H, 11.34. Calcd. for $C_9H_{16}O$: C, 77.09; H, 11.50%.

**2, 2, 4, 4-Tetraphenyl-3-oxabicyclo[3. 1. 0]hexane (VI).**—To a Grignard solution prepared from 24 g. (0.15 mol.) of bromobenzene and 3.7 g. (0.15 mol.) of magnesium, 5.0 g. (0.031 mol.) of *cis*-dimethyl 1,2-cyclopropane dicarboxylate in 10 ml. of ether was added drop by drop while the mixture was being refluxed and stirred. After vigorous stirring for two hours, the reaction mixture was hydrolyzed with a saturated aqueous ammonium chloride solution and extracted with ether. After the ether had been evaporated off, 7.5 g. (61%) of *cis*-1,2-di($\alpha$, $\alpha$-diphenyl)methylolcyclopropane (VI') was obtained. M. p. 198—201°C, recrystallized from ethanol.

Found: C, 86.20; H, 6.64. Calcd. for $C_{29}H_{26}O_2$: C, 85.68; H, 6.45%.

A mixture of 1 g. of VI' and 0.3 g. of calcined potassium bisulfate was melted at 130°C under reduced pressure for 5 min. After the gas evolution had ceased, the reaction mixture was crushed and extracted with petroleum ether. The extract was recrystallized from the same solvent, and two kinds of crystals, white block and fine grain, were obtained. The latter was picked up and recrystallized to give 0.2 g. (21%) of VI. M. p. 166—167°C.

Found (for VI): C, 89.60; H, 6.69. Calcd. for $C_{29}H_{24}O$: C, 89.65; H, 6.23%.

The former was 1,1,4-triphenyl-4-benzoylbutene-1. Yield, 0.75 g. (76%). M. p. 129—131°C. No depression in melting point was observed when it was admixed with an authentic sample.

## Summary

Some bicyclic ethers containing a cyclopropane ring, i. e., 3-oxabicyclo[3. 1. 0]hexane derivatives, have been synthesized. Two methods have been used in the syntheses of these compounds. One of them has been the dehydration of *cis*-1, 2-dimethylolcyclopropane derivatives, and the other, the addition of some carbenes to 2, 5-dihydrofuran. The Simmons-Smith method has also been adopted. The NMR spectra of these bicyclic ethers have been examined. The types of their spectra are fairly simple. The chemical shifts and the coupling constant of some protons have also been measured. Attempts to polymerize these bicyclic ethers, unfortunately, have been unsuccessful.

We are indebted to the Fuji Photo Film Company, Ltd., for its financial support. Thanks are also due to Mr. Tsuneaki Hirazima for his skilled help in the measurement of the nuclear magnetic resonance spectra, and to Mr. Mamoru Narui for his assistance in the experimental work.

# A Nuclear Magnetic Resonance Study of the Water in Calcium Silicate Pastes

By Hiroshi OCHIAI, Hitoshi YAMAMURA, Kenji FUKUNAGA,* Iwao MAKI* and Kozaburo WATANABE*

(Received October 7, 1964)

For a better understanding of the setting and hardening processes of cement, it is very significant to study its hydration mechanism. A number of new techniques have been developed in this field.[1-6] However, the application of thermal techniques, such as the methods of vapor pressure and differential thermal analysis, is severely limited, since a sample is degraded by heating. Furthermore, in such techniques as infrared spectra and the dielectric behavior of hydrated water molecules, it is difficult for the measurements to permit a distinct identification of the individual components contributing to the multi-phase hydration system. The use of the proton magnetic resonance technique may be more directly able to resolve these individual components.

The absorption-line width and shape are profoundly influenced by the magnetic environment of the nuclei. The spin-spin relaxation time, $T_2$, is the line-width parameter associated with the life-time of a given nuclear spin state, and a measure of the interactions between the low frequency component of the local field and the nuclei. Thus, these NMR measurements give us much information about the proton in different states and an important clue to the various hydrated products produced during the hydration process.

The application of this technique to the study of the hydration process of cement has been described by only a few authors.[7-9] Kawachi and his co-workers have reported on the relationship between the absorption line and the mechanical strength of portland cement.[8] Watanabe and Sasaki have observed three absorption lines which can be ascribed to the protons of the free, adsorbed and bounded water respectively, in the order of line width,[9] although they have not confirmed the assignment of these absorption lines satisfactorily.

Under these circumstances, we attempted to shed some light on these problems by making proton magnetic resonance studies of $\beta$-di- and tri-calcium silicates, the main constituents of portland cement. Tricalcium silicate, the first hardening constituent of portland cement, has a high hardening rate. $\beta$-Dicalcium silicate, the second, has a low hardening rate.

It has been supposed that these calcium silicates react with added water, and that then some hydrates contributing to the hardening process are produced as follows.[10]

$$3CaO\cdot SiO_2+(n+2)H_2O = CaO\cdot SiO_2\cdot nH_2O+2Ca(OH)_2$$

$$2CaO\cdot SiO_2+(n+1)H_2O = CaO\cdot SiO_2\cdot nH_2O+Ca(OH)_2$$

$$aCa(OH)_2+bSiO_2\cdot mH_2O = aCaO\cdot bSiO_2\cdot nH_2O$$

In this work, we will measure the spin-spin relaxation time, $T_2$, and the temperature dependence of the line width for the two calcium silicates pastes mentioned above; we will also discuss the hydration process for hardening by comparing its data with the data involving $Ca(OH)_2$ powder, $Ca(OH)_2+H_2O$ paste, $SiO_2+H_2O$ paste, and water.

## Experimental

The $\beta$-di- and tri-calcium silicates used in this investigation were prepared from a mixture of calcium carbonate and silicon dioxide by heating it at 1550°C several times; they were confiremed to be $Ca_3SiO_5$ and $\beta$-$Ca_2SiO_4$, as had been reported by Sasaki, by X-ray analysis.[11] $\beta$-$Ca_2SiO_4$ is stabilized by adding $Na_2O$.

The calcium silicate samples employed in the measurements were of a form of paste prepared with a solid-to-water ratio of 0.4 in weight. The calcium hydroxide and silicon dioxide samples were also paste and had the same mixing ratio. Another calcium hydroxide sample was powder which had been dried for several hours in a vacuum at 80°C. All the samples were sealed in glass tubes about 10 mm. in diameter in order to prevent the vaporization of the added water, and then stored in an air-conditioned room at 20°C. Line-width measurements were carried out from room temperature to −160°C by making use of liquid nitrogen, while $T_2$-measurements were made at room temperature.

The apparatuses used were Pound-Watkins- and Bridge-type broad-line NMR spectrometers at 30 Mc./sec., and $T_2$-measurements, a spin-echo NMR spectrometer at 30 Mc./sec., manufactured by the Japan Electron Optics Laboratry Co., Ltd.

## Results

In the NMR absorption spectra of the samples of the β-dicalcium silicate, which have various storage periods at room temperature, a single sharp absorption line, the width of which corresponds to the modulation amplitude, was observed at nearly every room temperature. From the results obtained here, it might be considered that real absorption line width of the samples is very narrow, and that a modulation broadening takes place. As the measuring temperature was lowered, the absorption line became broader due to the superposition of more than two absorption lines in a portion of the wing. The temperature dependence of the maximum slope width ($\Delta H_{m.s}$) of the absorption line for this sample is shown in Fig. 1.

At −70°C, the absorption line became more complex; it had three peaks with widths of about 1, 10 and 17 gauss, hereafter to be referred as the narrow, medium and broad absorption lines respectively. In the lower temperature range, the narrow absorption line, 1 gauss wide, became wider and could not be observed, but the width of the other two remained unchanged down to −160°C. In spite of the different storage periods of the samples, the same temperature dependence was observed. The same result was also obtained in the case of the tricalcium silicate paste.

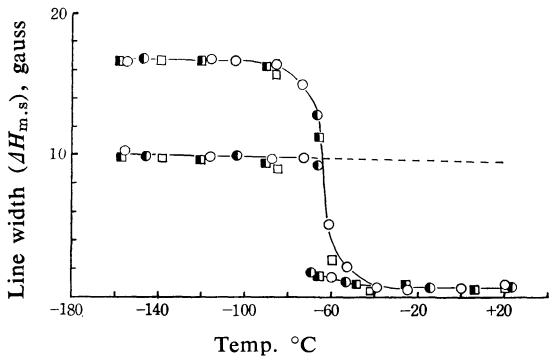

Fig. 1. Line width versus temperature curve for β-di- and tri-calcium silicate.
○ β-$Ca_2SiO_4$ stored 1 day
◑ β-$Ca_2SiO_4$ stored 20 days
□ $Ca_3SiO_5$ stored 1 day
◧ $Ca_3SiO_5$ stored 20 days

In order to clarify the influence of the storage period on the reacted water, we determined the ratio of the areas of the peaks in the decomposed absorption curves, assuming the gaussian curve for absorption line shape and a proportionality between the area of the absorption line and the fraction of protons in the various hydrated states. The narrow line is much affected by modulation broadening and so is not included in Table I, which gives the results for the broad and medium absorption lines, though the decomposition of the absorption line was not simple.

Table I. The ratio of the decomposed absorption lines for β-dicalcium silicate paste at −70°C

| Storage periods | 1 day | 20 days |
|---|---|---|
| The broad line | 23% | 7.8% |
| The medium line | 77% | 92.2% |

Furthermore, in order to clarify the details of the storage effect, the spin-spin relaxation time, $T_2$, was measured at room temperature. The relation of the storage period to $T_2$ in each case of β-di- and tri-calcium silicate pastes is shown in Fig. 2. As this figure shows, the $T_2$-value of β-dicalcium silicate paste decreases very slowly, whereas that of tricalcium silicate decreases very rapidly, as the storage period increases.

To make clear what proton states correspond

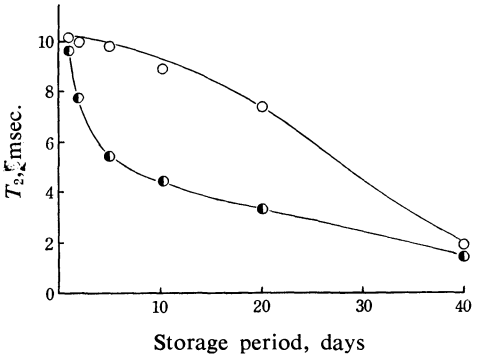

Fig. 2. $T_2$-Value versus storage period at room temperature.
○ β-$Ca_2SiO_4$ ◑ $Ca_3SiO_5$

to the three absorption lines observed in the low temperature region, we carried out broad-line NMR measurements of $Ca(OH)_2$ powder, $Ca(OH)_2+H_2O$, $SiO_2+H_2O$ paste, and water. The results are shown in Fig. 3.

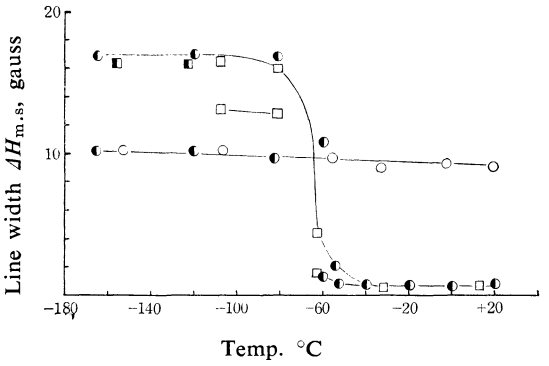

Fig. 3. Line width versus temperature curve for various reference samples.
○ $Ca(OH)_2$ powder ◐ $Ca(OH)_2$ paste
□ $SiO_2$ paste ◧ $H_2O$

The absorption line of water has a width of 16.5 gauss in the low temperature range, a value which is compatible with the results reported by other authors.[12,13]

Calcium hydroxide powder gives an absorption line 9.5 gauss wide, even at room temperature. On the other hand, the paste sample gives the same sharp absorption line as the calcium silicate pastes at room temperature, and also gives the superimposed absorption lines, with widths of 10 and 17 gauss, in the low temperature range.

The absorption line of silicon dioxide paste shows a temperature dependence similar to that of both calcium silicates and calcium hydroxide paste, with line widths of 13 and 17 gauss in the low temperature range.

It is of interest that an absorption line 17 gauss wide is observed in all the paste samples and water studied in this work.

## Discussion

As shown in Fig. 1, the same temperature dependence of the absorption line width was observed for each paste of the two calcium silicates, even when they were stored for different periods. In agreement with the assumption that both silicates form a similar hydrated gel in the hydration process of cement,[10] this result may indicate that the two calcium silicates form similar hydration products.

Table I shows the ratio of the area of the medium absorption line to that of the broad line for storage periods of 1 day and 20 days. The ratio seems to represent the amount of water in the hydrated gel state and in the nonhydrated state, because the area of the medium line increases as the storage period becomes longer. These results show that the hydration process of the samples can be followed from the temperature dependence of the line width. However, it is difficult to investigate their hydration process by the broad line method without setting the samples at a lower temperature, because all the samples give a single sharp absorption line in the room temperature range, regardless of the kinds of silicate and the storage periods of the pastes.

The $T_2$-value obtained at room temperature may be ascribed to some relaxation mechanisms of the protons of the adsorbed or free water.[14] It is a measure of the molecular motion in the corresponding states in which the added water suffers restriction by the ions eluted in the hydration process. Therefore, the change in $T_2$-value may be correlated with the hardening rate of calcium silicates. Namely, $T_2$-value decreases with the progress of hardening. The result in Fig. 2 corresponds to the facts that tricalcium silicate is the first hardening constituent of portland cement and has a high hardening rate, while $\beta$-dicalcium silicate is the second one and has a low hardening rate. The fact that both samples, when stored for forty days, have the same $T_2$-value, 2.5 msec., may be considered, from the viewpoint of nuclear magnetic resonance, to show that the added water is restricted to a similar extent in both the samples.

Let us now consider the three absorption lines observed in the low temperature range. The broad absorption line observed in the calcium silicate pastes is ascribed to the protons in a more immobile state of free water; thus, they do not take part in hydration directly. This absorption line corresponds to the one hitherto ascribed to the protons of the hydrated water in cement paste by some of the present authors.[8] It it reasonable to infer, however, that the broad absorption line is associated with the protons of the free water with an ice structure at the lower temperature, as is shown in the data on ice given by Bloembergen et al.,[12] by Kume[13] and by us.

The medium absorption line, 10 gauss wide at a low temperature, can be ascribed to the protons of a solid chemical structure, such as hydroxyl ion or hydrated water, formed by the reaction between the silicates and added water. This medium absorption line could not

14) T. Shaw and R. Elsken, *J. Chem. Phys.*, 21, 565 (1953).

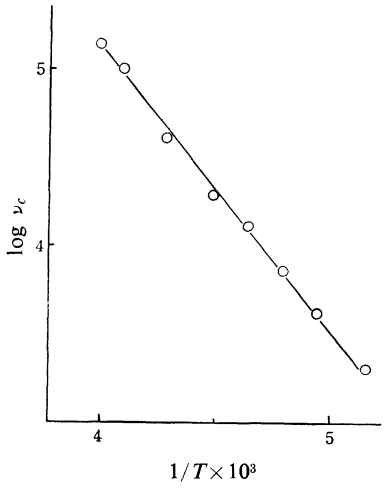

Fig. 4. The temperature dependence of the correlation frequency for the broad absorption line.

be observed at room temperature because the signal of unhydrated water is highyl intense at room temperature. However, this line is considered to appear even in the room temperature range, as is shown in Fig. 1 with an extrapolated broken line.

The narrow absorption line observable at temperatures as low as $-70°C$ may be associated with the freely-moving protons in ice, because the lattice defects in ice crystals produced by various ionic impurities would facilitate the motion of protons, as has been reported by Kume.[13]

An attempt has been made to relate the absorption line width to the motional correlation time of the protons by means of the B.P.P. relaxation theory.[12] The activation energy, $V$, for the motion of the proton is estimated by applying Eyring's theory of rate process as follows;[15]

$$\nu_c = \nu_0 \exp(-V/RT)$$

where $\nu_c$ is the correlation frequency. Figure 4 shows the temperature dependence on $\nu_c$ for the broad absorption line. The slope yields $V=6.53$ kcal./mol. This is in agreement with the activation energy for the proton motion in ice,[13] and supports the abovementioned assignment of the absorption lines.

The authors wish to express their appreciation to Mr. Ichiro Murakami for his valuable guidance and discussions on this work.

# A New Method to Determine Relative Surface Area by Gas Chromatography. I

By Yoshio KUGE and Yozaburo YOSHIKAWA

(Received October 8, 1964)

Two kinds of methods have been employed to determine the surface area of an adsorbent, the common B.E.T. static method, and the B.E.T. flow method* using gas chromatography.

During the investigation of the relation between the sample size and the peak shape, using the same column packing in gas chromatography we found that the displacement point from monolayer- to multilayer-adsorption appeared in the change in peak shape. Therefore, the relative surface area of adsorbent per gram was calculated from the sample size at the displacement point. By this procedure, we determined the relative surface area of a copper complex compound, $Cu(Py)_2(NO_3)_2$.** The results obtained will be discussed.

When this method can be used, the surface area can be more easily determined compared with the results obtained with the methods mentioned above.

## The Estimation of Relative Surface Area

In general, the relation between the sample size and the retention time can be described

* For example, F. M. Nelson and F. T. Eggertsen, *Anal. Chem.*, **30**, 1387 (1958).

** This substance has been found to be a new adsorbent for the analysis of hydrocarbons in gas chromatography by L. B. Rogers and A. G. Altenau (*Anal. Chem.*, **35**, 915 (1953)).

as follows: When a Langmuir-type adsorption isotherm is established, it is observed that the larger the sample size, the shorter the retention time. In the case of an anti-Langmuir-type adsorption isotherm, the larger the sample, the longer the retention time. The shapes of the peak in both cases are shown in Fig. 1.

When the two types of adsorption isotherms are combined, the second type of B.E.T. adsorption isotherm will be obtained, as Fig. 2 shows. This expectation was realized in our experiments. When the sample size is small, the peak shape is symmetrical. As the sample size is increased, however, the peak shape

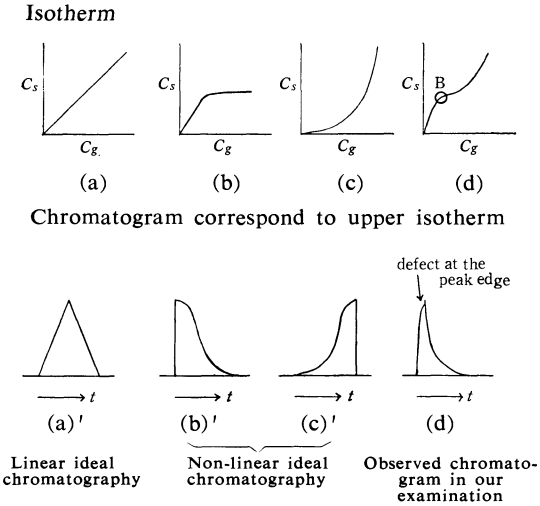

Fig. 1. The relation between peak shapes and the adsorption isotherms.

$C_s$ Concentration in stationary phase
$C_g$ Concentration in moving phase
$t$ Time

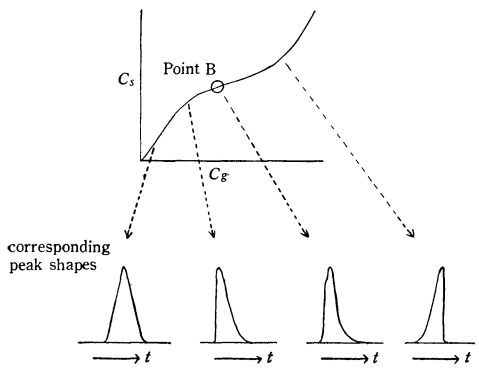

Fig. 2. The second type of B.E.T. adsorption isotherm and corresponding peak shapes.

$C_s$ Concentration in stationary phase
$C_g$ Concentration in moving phase
$t$ Time

acquires a sharp front and a diffuse tail, and a defect at the front side of the peak top; then it obtains a diffuse front and a sharp tail. That the peak begins to have a defect at the front side of the top indicates the point of the displacement from monolayer- to multilayer-adsorption. This point corresponds to the B-point of the B.E.T. II-type adsorption isotherm.

Therefore, the relative surface area of the adsorbent covered with a monolayer of an adsorbate at the displacement point may be calculated by Eq. 1.

$$S=\frac{V}{V_m}\cdot N_A\cdot s \tag{1}$$

where

$S$: the surface area of the adsorbent ($cm^2$)
$V$: the volume of the adsorbate which forms the monolayer (cc.)
$N_A$: Avogadro's number
$s$: the surface area that was occupied by one molecule of the adsorbate ($cm^2$)
$V_m$: the molecular volume (cc.)

Provided the sample is adsorbed in the form of the closest packing of the face-centered cubic lattice on the adsorbent, the surface area ($s$) is expressed as follows:[1]

$$s=\frac{6}{\sqrt{3}}\left(\frac{M}{4\sqrt{2}N_A\cdot D}\right)^{2/3} \tag{2}$$

where

$D$: the density of the adsorbate at the adsorbed temperature
$M$: the molecular weight

The surface area must be reduced to that per gram of the adsorbent, so the authors assumed the next Eq. 3:

$$S_g=\frac{S}{W\cdot\dfrac{w}{\left(\dfrac{a\cdot L}{F}\right)}}=S\left(\frac{1}{W}\cdot\frac{a}{w\cdot F}\cdot L\right) \tag{3}$$

where

$S_g$: the surface area per gram of the adsorbent ($cm^2$/g.)
$W$: the weight of the adsorbent (g.)
$F$: the flow rate of the carrier gas (cc./min.)
$L$: the column length (cm.)
$a$: the cross section area of the column ($cm^2$)
$w$: the peak width

and the term $(aL/F)$ means the time required for the carrier gas to pass through the column.

1) P. H. Emmett and S. Brunauer, *J. Am. Chem. Soc.*, **59**, 1553 (1937).

## Apparatus and Materials

A Yanagimoto gas chromatograph GCG-2 was employed.

The detector used was of the thermal-conductivity type with a tungsten filament. The column was made of U-shaped stainless steel and was 2 m. long and 5 mm. in inside diameter. The flow rate of the carrier gas was measured by a soap-film flow meter.

Di-pyridine-copper nitrate $Cu(Py)_2(NO_3)_2$, used as an adsorbent, was prepared through $Cu(Py)_4(NO_3)_2$ according of Pfeiffer's method.[2] The blue-violet crystals of $Cu(Py)_4(NO_3)_2$ were sorted with a 32—48 mesh and then heated at 100°C for six hours to give a light blue di-pyridine salt.

The change from tetrapyridine salt to di-pyridine salt was observed at 70—83°C by means of the differential thermal analysis of pyridine copper salt, and the identity of the dipyridine salt produced was confirmed by the quantitative analysis of pyridine, that is, by the measurement of the weight change of the sample and by the ultraviolet absorption spectrometric method.*

## Results

Benzene, carbon tetrachloride, cyclohexane and *n*-hexane were used as adsorbates.

The heats of the adsorption of these substances on $Cu(Py)_2(NO_3)_2$ were found to be 8.4, 8.1, 8.4 and 8.0 kcal./mol. respectively, in the temperature range from 30 to 60°C,[3] suggesting the physical adsorption.

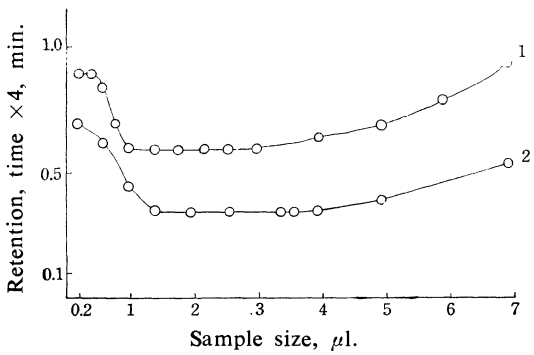

Fig. 3. The change of retention times with increasing sample sizes.

1 Benzene
2 Carbon tetrachloride
cell current 150 mamp, column inlet pressure 0.2 kg./cm², cell temp. 100°C, carrier gas $H_2$, 57.7 cc./min., inlet temp. 118°C, column temp. 50°C, adsorbent $Cu(Py)_2(NO_3)_2$, 32—48 mesh 29.3 g.

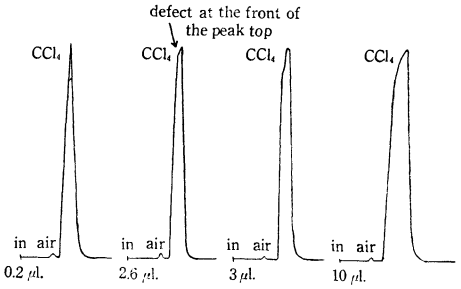

Fig. 4. The change of peak shapes with increasing sample sizes.

cell current 150 mamp., column inlet pressure 0.2 kg./cm², cell temp. 80°C, inlet temp. 118°C, carrier gas $H_2$, 41.7 cc./min. (22.5°C), adsorbent $Cu(Py)_2(NO_3)_2$ 32—48 mesh 29.3 g., column temp. 48°C

The relation between the sample size and the retention time in the cases of benzene and carbon tetrachloride is shown in Fig. 3, while the change in peak shape in the case of carbon tetrachloride is shown in Fig. 4.

The displacement point from monolayer- to multilayer-adsorption may be affected by the flow rate of the carrier gas, the column temperature and the properties of the adsorbate.

First, the relation between the flow rate of the carrier gas and the displacement point was examined.

When the flow rate was increased up to 60 cc./min., the peak width became narrow, but the displacement point of the peak shape showed no change. On the other hand, the flow rate was decreased less than 20 cc./min., the peak changed to a symmetrical shape under the influence of axial dispersion,[4,5] and the displacement point could not be found. Therefore, the experiments were carried out in the flow rate range from 20 to 60 cc./min.

Next, the relation between the sample size at the displacement point and the column temperature was investigated. In the case of cyclohexane, the sample size was found to be 1.4 μl. when the temperature was below 50°C, while the sample size was as large as double that when the temperature rose above 50°C, as is shown in Table I. The results suggest that the relative surface area may be calculated as too large when the temperature rises above 50°C it also calls into question the assumption that the sample molecules are adsorbed in the

Table I. The correlation of sample size with the temperature at the displcement point

Adsorbate : cyclohexane

| Column temp. °C | Flow rate cc./min. | Sample size $\mu$l. |
|---|---|---|
| 32 | 57.7 | 1.4 |
| 46 | 55.6 | 1.4 |
| 50.5 | 56.6 | 2.4 |

the form of the closest packing of the face-centered cubic lattice at a higher temperature.

At about the boiling points of adsorbates (near 80°C), the peak changed to a symmetrical shape and the displacement point was hardly observed. The range of the temperature applicable for the determination of the relative surface area by this method has not yet been generalized.

With such precautions, the relative surface area of adsorbents was calculated, according to Eq. 3, on the basis of the results obtained when the column temperature was 50°C and the flow rate of the carrier gas was 60 cc./min. The values obtained are listed in Table II.

As Table II shows, the values of the relative surface area were found to be nearly equal for planer and for spherical molecules, such as benzene, carbon tetrachloride and cyclohexane, while a larger value was found for chain molecules such as *n*-hexane. Similar

Tale II. The relative surface area of 29.3 g. of $Cu(Py)_2(NO_3)_2$ for several adsorbates

| Adsorbate | Sample size $\mu$l. | $s \times 10^{16}$ cm$^2$ | Relative surface area m$^2$/g. | Shape of molecule |
|---|---|---|---|---|
| Benzene | 2.7 | 30.6 | 1.75 | Planar |
| Carbon tetrachloride | 2.6 | 33.1 | 1.68 | Spherical |
| Cyclohexane | 2.5 | 34.9 | 1.50 | Planar |
| *n*-Hexane | 5.7 | 38.7 | 3.44 | Chain |

results have been obtained by the ordinary B.E.T. static method.

In this report, we have used the term "relative surface area" instead of "surface area" because the values obtained have not been compared to those obtained by the ordinary B.E.T. method.

The determination of the absolute surface area by static and dynamic B.E.T. methods using gas chromatography is now under way.

The authors wish to express their hearty thanks to Dr. Akitsugu Nakahara and Miss Kimiko Arita for their criticism, and to Dr. Matsuji Takebayashi for his encouragement throughout this work.

# Polyesters Containing Carbazole Rings in the Main Chain. I. Syntheses of Diacylcarbazoles and Carbazoledicarboxylic Acids*

By Yoshio NAGAI and Chin-Chuan HUANG

(Received October 13, 1964)

Despite the numerous heterocyclic compounds such as thiophene-, furan-, and pyridinedicarboxylic acids that have been claimed to be useful in the preparation of high melting polyesters suitable for fibermaking, the carbazole derivatives have never been in much demand as starting materials for such a purpose.

To prepare polyesters containing carbazole rings in the main chains, the authors first synthesized a series of carbazole derivatives and several carbazoledicarboxylic acids by oxidizing the corresponding diacylcarbazoles.

Descriptions appearing in the literature on the synthesis of 3, 6-diacetylcarbazole (I) usually give neither exact yields nor information on 3-acetyl- or 9-acetylcarbazoles which has been shown to be one of the main acylation products. By carefully following the methods of Plant et al.,[1, 2] we have found that under the described conditions, I was obtained only in poor yields, while a large amount of monoacetylcarbazole was isolated. The experimental data also indicated that at higher reaction

* A part of this paper was presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, March, 1964.

temperatures, acylation of carbazole tended to give more 9-acetylcarbazole, though carbazole is considered to resemble a secondary aromatic amine in chemical reactivity, with substitution groups preferably entering into para positions to the nitrogen. In the syntheses of 3,6-diacetyl-9-alkylcarbazoles, however, the sole product was the disubstituted 9-alkylcarbazole.

Of the three acylating agents employed, acetyl bromide appeared to be best suited for the preparation of diacetylcarbazoles.

Oxidation of 3,6-diacetyl- and 3,6-diacetyl-9-alkylcarbazoles with an appropriate amount of sodium hypochlorite solution, as shown in Table III, yielded almost quantitatively carbazole-3,6-dicarboxylic and 9-alkylcarbazole-3,6-dicarboxylic acids, previously reported as being obtained only in much lower yields via other reactions.[1-3]

## Experimental

**3,6-Diacetylcarbazole (I).**—A mixture of 6.0 g. of carbazole (m. p. 245°C), 9.0 g. of acetyl bromide, 50 cc. of dry carbon disulfide, and 10 g. of pulverized aluminum chloride was refluxed at the boiling point of the solvent for an hour and then the solvent was distilled off. By treating the residue with ice-dilute hydrochloric acid, I was obtained as a brown solid, which gave almost colorless crystals, 3.0 g.; m. p. 235—237°C, after two recrystallizations from ethanol (decolorizing charcoal added). The reaction of carbazole and acetyl chloride, however, gave I in much poorer yields in the presence of the same catalyst. As shown in Table I, the reaction of 60 g. of carbazole with 105 g. of acetic anhydride at 0 ± 1°C for 6 hr. with stirring also afforded I in 14.1% yield. Use of about two molecular proportions of aluminum chloride per mole of anhydride as a catalyst at 0°C gave 3-acetyl- and 9-acetylcarbazoles besides I, whereas at 5°C the reaction led mainly to 9-acetylcarbazole. An increase in the amount of catalyst, as recommended by Groggins and Nagel,[4] did not increase the yields of I. Prolonging the reaction time also did not cause much improvement of the yield; even the yield from a reaction of 6 hr. compared favorably with that of 8 hr. or longer. Acetylation of carbazole with acetic anhydride in the presence of 3.5 mol. of aluminum chloride gave more 9-acetylcarbazole.

Found: C, 76.46; H, 5.16; N, 5.45. Calcd. for $C_{16}H_{13}O_2N$: C, 76.55; H, 5.17; N, 5.58%.

During crystallization of the crude acylation product from ethanol, 3-acetylcarbazole, m.p. 166—168°C, came out first; concentration of the filtrate afforded I. After removal of the solvent by distillation, the residue, temperature range of m. p. 69—115°C, was recrystallized from methanol to give 9-acetylcarbazole as light yellowish white crystals, m. p. 77—78°C. When a solution of 9-acetylcarbazole in benzene was passed through a column (1.8 cm. inner diameter) packed with alumina (15 cm. in height), and the column successively eluted with benzene, 9-acetylcarbazole was recovered as carbazole.

**Carbazole-3,6-dicarboxylic Acid (II).***—A solution of 5 g. of I in 30 cc. of pyridine was poured into a flask containing 100 cc. of 5% aqueous sodium hydroxide solution. This mixture was kept at 20°C while 44 cc. of 6 N sodium hypochlorite solution was added with stirring. The reaction mixture was stirred for an additional 100 min. and the excess of oxidizing agent decomposed by pouring the product into sodium bisulfite solution, after unaltered I had been removed by filtration. On addition of hydrochloric acid to the filtrate, II came out as a white precipitate, 5.1 g., m. p. above 375°C (decomp.)

Found: C, 65.51; H, 3.63; N, 5.33. Calcd. for $C_{14}H_9O_4N$: C, 65.84; H, 3.55 N, 5.49%.

**Diethyl Carbazole-3,6-dicarboxylate (III).**—A suspension of 10 g. of II in a mixture of 200 cc. of dry ethanol and 30 cc. of concentrated sulfuric acid was refluxed with stirring for 6 hr. and then

4) P. H. Groggins and R. H. Nagel, *Ind. & Eng. Chem.*, **1934**, 26.

* According to the modified method of Uematsu, unpublished paper, this laboratory.

the excess of ethanol removed by distillation. The residue was treated with dilute aqueous sodium carbonate solution to dissolve unchanged acid, and the insoluble residue was recrystallized from ethanol (decolorizing charcoal added) to give III as almost colorless crystals, 8.0 g., m. p. 206—207°C.

Found: C, 69.32; H, 5.49; N, 4.38. $C_{18}H_{17}O_4N$ requires C, 69.47; H, 5.51; N, 4.49%.

**3, 6-Diacetyl-9-methylcarbazole (IV) and 3, 6-Diacetyl-9-ethylcarbazole (V).**—A solution of 1 g. of I in 30 cc. of acetone and aqueous potassium hydroxide (1.5 g. of potassium hydroxide in 1 cc. of water) was refluxed with stirring for 5 min.; then 2.2 g. of dimethyl sulfate was added and the mixture was allowed to react at 35°C for 10 min. The reaction product was poured into 300 cc. water to give a white precipitate, 1.1 g., m. p. 198—200°C.

Found: C, 76.85; H, 5.59; N, 5.23. Calcd. for $C_{17}H_{15}O_2N$: C, 76.98; H, 5.66; N, 5.28%.

IV was also obtained by reaction of 9-methylcarbazole with an acyl halide, such as acetyl chloride or acetyl bromide, in the presence of aluminum chloride. A mixture of 14 g. of I in 280 cc. of acetone with aqueous potassium hydroxide (21 g. of potassium hydroxide in 10 cc. of water) and diethyl sulfate was stirred at room temperature for 10 min.; subsequent dilution of the product with water precipitated V, 15 g., m. p. 181—182°C.

Found: C, 77.16; H, 5.89. Calcd. for $C_{18}H_{17}O_2N$: C, 77.42; H, 6.09%.

V was also synthesized from the reaction of 9-ethylcarbazole with acyl halides, such as acetyl chloride or acetyl bromide, using aluminum chloride as a catalyst. Acetyl bromide reacted with 9-ethylcarbazole and gave V usually in higher yields than did acetyl chloride.

**9-Methylcarbazole-3, 6-dicarboxylic Acid (VI).**—A solution of 1 g. of IV in 10 cc. of pyridine was poured into 20 cc. of 5% aqueous sodium hydroxide solution, and the temperature of the mixture maintained at 20°C while 12 cc. of NaOCl solution (6 N) was added; the reaction mixture was then stirred for one hour and forty minutes at 25°C. Unchanged material was filtered off and the filtrate treated with sodium bisulfite solution. Addition of hydrochloric acid to the filtrate precipitated VI as a white powder, 1.0 g., m. p. above 395°C (decomp.).

Found: C, 66.78; H, 4.21. $C_{15}H_{11}O_4N$ requires C, 66.92; H, 4.09%.

**Diethyl 9-Methylcarbazole-3, 6-dicarboxylate (VII).**—After a suspension of 1.0 g. of VI in a mixture of 25 cc. of ethanol and 2.5 cc. of concentrated sulfuric acid had been refluxed for 6 hr. with stirring, the excess ethanol was removed by distillation. The residue was then treated with 5% aqueous sodium carbonate solution to dissolve unchanged acid and the mixture filtered. The residue after crystallization (decolorizing charcoal added) yielded VII as light yellowish white crystals, 0.7 g., m. p. 163—165°C.

Found: C, 70.18; H, 5.61. Calcd. for $C_{19}H_{19}O_4N$: C, 70.16; H, 5.85%.

**9-Ethylcarbazole-3, 6-dicarboxylic Acid (VIII).**—A mixture of 1.0 g. of V in 7 cc. of pyridine and 200 cc. of 5% sodium hydroxide solution was treated with 14 cc. of 3 N sodium hypochlorite solution at 20°C under stirring for one hour and forty minutes. The resulting reddish orange solution was filtered to remove any unaltered V and discharged into sodium bisulfite solution. VIII was obtained as a white precipitate upon addition of hydrochloric acid. Yield, 1.0 g., m. p. above 380°C (decomp.).

Found: C, 67.22; H, 4.63. $C_{16}H_{13}O_4N$ requires C, 67.56; H, 4.57%.

**Diethyl 9-Ethylcarbazole-3, 6-dicarboxylate (IX).**—The procedure for the preparation of IX was similar to that used in the synthesis of III. Yield, 83%; melting point after crystallization from ethanol (decolorizing charcoal added), 173—174°C.

Found: C, 70.95; H, 6.18. Calcd. for $C_{20}H_{21}O_4N$: C, 70.80; H, 6.19%.

## Summary

Acetylation of carbazole with acetyl halide or acetic anhydride gave both monoacetyl- and diacetylcarbazoles. Several carbazoledicarboxylic acids were prepared in quantative yields by oxidizing the corresponding diacetylcarbazoles.

Acknowledgment is made for the kind cooperation of the Nihon Kayaku Company and the Yahata Kagaku Company in supplying carbazole for this study. The authors also wish to thank Associate Professor Nobuyuki Goto for valuable suggestions and Mr. M. Ishida of this laboratory for experimental help.

# Reaction of Bis(acetylacetonato)copper(II) with Bromine*

By Yukio NAKAMURA and Shinichi KAWAGUCHI

(Received October 20, 1964)

The halogenation of β-dicarbonyl compounds such as acetylacetone and ethyl acetoacetate proceeds in two steps:[1]

$$R_1COCH_2COR_2 + X_2 = R_1COCHXCOR_2 + HX$$

$$R_1COCHXCOR_2 + X_2 = R_1COCX_2COR_2 + HX$$

These reactions were found to be of first order with respect to the β-dicarbonyl compound, independent of the halogen concentration, and catalyzed by bases in general.[2] Bell and his collaborators analyzed these reactions in aqueous solution and determined the catalytic constants of various bases.[3]

Pedersen investigated the bromination of ethyl acetoacetate in aqueous solution and found that the first of the two consecutive reactions was catalyzed by copper(II)[4] and other divalent metal ions.[5] The intermediate metal chelate of the keto-form of the ester was assumed to transfer a proton to the catalyst base more easily than the substrate itself does. However, details of the succeeding reaction, that is, the bromination of the normal metal enolate ester are not yet clear. Furthermore, the reason why the second bromination step is not catalyzed by these metal ions is not certain at all. The present paper reports reactions of bromine with copper(II) chelates of acetylacetone and 3-bromoacetylacetone which were studied for the purpose of obtaining some information about these points.

## Experimental

**Materials.** — Bis(acetylacetonato)copper(II) was prepared[6] by adding an ammoniacal solution of copper(II) acetate to an ethanolic solution of acetylacetone and was recrystallized from chloroform. (Found: Cu, 23.86; C, 45.90; H, 5.38%)

Bis(3-bromoacetylacetonato)copper(II) can be prepared either by the reaction between 3-bromoacetylacetone and copper(II) ion,[7] or by bromination of bis(acetylacetonato)copper(II) with *N*-bromosuccinimide.[8] We adopted the former route, but prepared 3-bromoacetylacetone in higher purity by the reaction of bis(acetylacetonato)copper(II) with an appropriate quantity of bromine. To a vigorously stirred solution of 33 g. (0.125 mol.) of bis(acetylacetonato)copper(II) in 1.3 l. of chloroform, 250 ml. of a chloroform solution of bromine (0.76 mol./l.; 0.19 mol. bromine) was added dropwise from a burette. The precipitate, copper(I) bromide, was filtered off and most of the solvent was distilled under reduced pressure at room temperature. The residual yellow liquid was then added drop by drop to an acetone solution of copper(II) acetate (0.125 mol. in 400 ml.) under vigorous agitation. The reaction mixture was kept at 0°C for 24 hr. The resulting green powder was filtered off, dried, and then recrystallized twice from benzene. M. p. 180—182°C (decomp.).

Found: Cu, 15.19; C, 28.92; H, 3.30; Br, 37.00. Calcd. for $Cu(C_5H_6O_2Br)_2$: Cu, 15.14; C, 28.39; H, 2.88; Br, 38.09%.

In Fig. 1 the absorption spectrum of bis(3-bromoacetylacetonato)copper(II) in chloroform is compared with that of bis(acetylacetonato)copper(II).

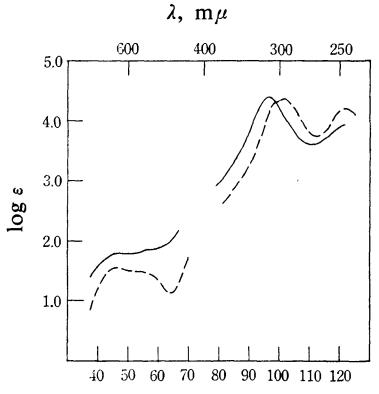

Fig. 1. The absorption spectra of bis(acetylacetonato)copper(II) (dashed curve) and bis(3-bromoacetylacetonato)copper(II) (full curve) in chloroform.
