Commercial dichloromethane was washed with concentrated sulfuric acid, then with a dilute solution of sodium hydroxide and finally with pure water. The washed solvent was dried over calcium chloride and distilled in a 60 cm. Widmer column.[9]

**Absorption Spectra.**—Visible and ultraviolet absorption spectra were measured with Beckman Model DU spectrophotometer. Infrared absorption spectra were obtained on an infrared spectrophotometer Model IR-S of the Japan Spectroscopic Co.

**Analysis of the Precipitate.** — The precipitate produced by the reaction between the copper chelate and bromine was dissolved in aqueous ammonia and allowed to stand overnight. The solution was then treated with a small quantity of sodium hydroxide and heated. The precipitate of copper(II) oxide was filtered off, dissolved in nitric acid and submitted to electrolytic analysis. The above filtered solution was acidified and treated with silver nitrate to determine the bromine content gravimetrically.

## Results

**Reaction of Bis(acetylacetonato)copper(II) with Bromine at Room Temperature.** — The reaction was carried out in dichloromethane solution. Bis(acetylacetonato)copper(II) solution was prepared in the same concentration, $3.48\times10^{-2}$ mol./l., as that of bromine. A desired amount of the bromine solution was added from a burette to a given amount of the chelate solution under vigorous agitation. Mole ratios of 1 : 1, 1 : 1.5, and 1 : 2 copper chelate to bromine were examined. When 1 mol. of bromine was added to 1 mol. of the chelate, the solution still showed the light blue color of residual chelate, but after 1.5 mol. or more of bromine had been added the solution was slightly yellow. A white precipitate was produced when the mole ratios were 1 : 1 and 1 : 1.5, but a brownish black precipitate resulted from a 1 : 2 mol. ratio. Analitical results for the precipitate from each experiment are summarized in Table I.

The white precipitate formed in the 1 : 1 and 1 : 1.5 reaction mixtures was copper(I) bromide; the black one formed in the 1 : 2 reaction mixture was found to consist mainly of copper(II) bromide. However, when the latter was allowed to remain in the reaction mixture for a long time, the precipitate gradually turned white and was found to be copper(I) bromide.

After the precipitate had been filtered off from the reaction mixture in Exp. Nos. 3 and 4, most of the solvent was driven off at room temperature under reduced pressure. The residual yellow liquid was submitted to infrared spectroscopy. Frequencies of the main absorption bands are listed in Table II (product A) together with those for acetylacetone. Absorption bands due to the methylene group in acetylacetone are not exhibited by this product. The absorption bands at 1720 and 1701 $cm^{-1}$, which are assigned to the two carbonyl groups in the keto-form of actylacetone, are shifted by 15 and 5 $cm^{-1}$, respectively, to the higher frequency side. This coincides with the shift of the carbonyl stretching frequency of a haloketone, suggesting the liquid product to be 3-bromoacetylacetone. That this is indeed so was unequivocally demonstrated by the preparation and analysis of its copper(II) chelate as descrived in the Experimental.

**Reaction of Bis(3-bromoacetylacetonato)copper(II) with Bromine.**—The reaction between bis(3-bromoacetylacetonato)copper(II) and bromine in dichloromethane solution was carried out in a manner similar to that described in the preceeding section. Bromine was added to the chelate solution in mole ratios of 1 : 1, 1.5 : 1, and 2 : 1. In each case the precipitate was analyzed for copper and bromine, and the filtrate was examined by infrared spectroscopy after evaporation of the solvent.

Bis(3-bromoacetylacetonato)copper(II) reacts with bromine as rapidly as bis(acetylacetonato)copper(II) does and gives quite similar precipitates (Table III). When 2 mol. or more of bromine is used for 1 mol. of the chelate, copper(II) bromide is precipitated, but when 1.5 mol. or less bromine is employed, copper(I) bromide results.

The main infrared absorption bands of the liquid product in Exp. Nos. 10, 11 and 12 are listed in Table II (product B) together with literature data for 3, 3-dichloroacetylacetone.[10] The absorption bands due to the two carbonyl groups appear at 1737 and 1714 $cm^{-1}$, exhibiting shifts of 17 and 13 $cm^{-1}$, respectively, compared with those of acetylacetone. This shift can be ascribed to the effect of halogen substitution in the 3-position; the magnitude of the shift is larger than that observed for product A, suggesting a dibromo substitution product. The strong absorption band around 1600 $cm^{-1}$, which was observed for the enol-form of acetylacetone and the product A, is not observed for the product B indicating the absence of an enol-form. Similar features were also reported for 3, 3-dichloroacetylacetone by Mecke

and Funck.[10)] Product B can thus reasonably be regarded as 3, 3-dibromoacetylacetone.

**Reaction of Bis(acetylacetonato)copper(II) with Bromine at a Low Temperature.** — When the reaction was conducted in chloroform at about −60°C, the color of the solution changed from blue to green, to brown, and eventually to red, but no precipitate was formed after two moles of bromine had been added per mole of the chelate. However, when the solution was warmed to room temperature, a dark precipitate of copper(II) bromide appeared and the solution became colorless.

## Discussion

When bis(acetylacetonato)copper(II) is attacked by bromine in organic solvents, the chelate ring is broken resulting in copper bromides and 3-bromoacetylacetone. When two moles or more of bromine is added to one mole of the chelate, copper(II) bromide is produced (Exp. No. 5). The reaction is represented by the equation,

$$Cu(HA)_2 + 2Br_2 = CuBr_2 + 2HABr \quad (1)$$

where $H_2A$ stands for acetylacetone and

$HA^-$ for the acetylacetonate anion $(CH_3CO\text{-}CHCOCH_3)^-$. Copper(II) bromide thus formed can further react with the other product 3-bromoacetylacetone (HABr) at a much lower rate, and thus is completely converted to copper(I) bromide when allowed to stand for a long period in the reaction mixture (Exp. Nos. 6 and 7).

$$2CuBr_2 + HABr = 2CuBr + ABr_2 + HBr \quad (2)$$

When 1.5 mol. of bromine is employed for 1 mol. of the chelate, the following reaction occurs (Exp. Nos. 3 and 4).

$$Cu(HA)_2 + {}^3/_2Br_2 = CuBr + 2HABr \quad (3)$$

In these cases the copper chelate employed is consumed completely, but when 1 mol. of bromine is added to 1 mol. of the chelate, the excess of the chelate remains unchanged in the solution.

Bis(3-bromoacetylacetonato)copper(II) reacts with bromine in a similar fashion to bis(acetylacetonato)copper(II), producing 3, 3-dibromoacetylacetone and copper bromide. The reaction in the mole ratio of 1 : 1.5 is represented by

$$Cu(ABr)_2 + {}^3/_2Br_2 = CuBr + 2ABr_2 \quad (4)$$

Similarly the reaction in the mole ratio of 1 : 2 is written as

$$Cu(ABr)_2 + 2Br_2 = CuBr_2 + 2ABr_2 \quad (5)$$

In this case the product 3, 3-dibromoacetylacetone has no active hydrogen to react with copper(II) bromide, and thus the latter remains unchanged even after standing a long time in the product solution.

Thus copper(II) chelates, not only of acetylacetone but also of 3-bromoacetylacetone, react instantaneously with bromine in dichloromethane giving 3-bromoacetylacetone and 3, 3-dibromoacetylacetone, respectively. The reason why copper(II) ion does not show any catalytic activity in the second step of the bromination of ethyl acetoacetate in aqueous solution[4] might be due to the instability of the intermediate copper(II) chelate of the ester in these reaction conditions. In fact, crystalline copper(II) chelate of ethyl $\alpha$-bromoacetoacetate could not be isolated[11] in contrast to good stability of the chelate of the nonsubstituted ester. However, the copper(II) chelate of 3-bromoacetylacetone is very stable and can be synthesized in good yield as described in the present paper, and thus the copper(II) ion may be expected to promote the second step of the bromination of acetylacetone.

In the reaction of bis(acetylacetonato)copper-(II) with bromine, copper(I) bromide is formed when less than two moles of bromine is employed for one mole of the chelate. This is very interesting in view of the oxidizing characteristic of bromine. The mechanism of the reactions represented by Eqs. 1 and 2 is not at all clear, but they seem to proceed through a common intermediate. The experiment performed at a low temperature indicates that the intermediate species is quite stable at about $-60°C$. Further investigation of the reaction mixture at a low temperature should shed light on the nature of the intermediate.

## Summary

In the reaction of bis(acetylacetonato)-copper(II) with bromine the chelate ring is broken and 3-bromoacetylacetone and copper-(I) or copper(II) bromide are formed depending on the mole ratio of the reactants.

Bis(3-bromoacetylacetonato)copper(II) also reacts with bromine in a similar fashion resulting in 3, 3-dibromoacetylacetone and copper(I) or copper(II) bromide. The possibility of the copper(II) ion functioning as a catalyst in the second step of the bromination of acetylacetone is suggested.

# Hydroxylation of Olefins with Hydrogen Peroxide in the Presence of Selenium Dioxide Catalyst

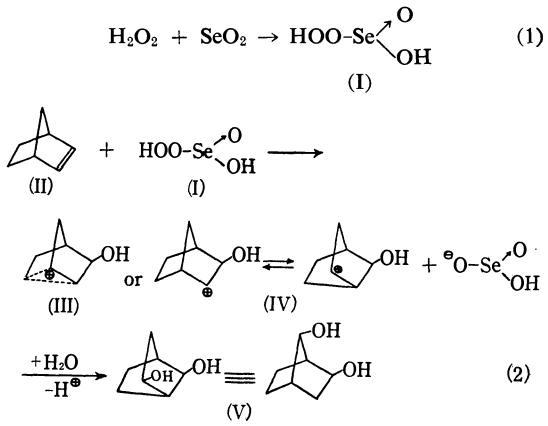
By Noboru SONODA and Shigeru TSUTSUMI

(Received October 23, 1964)

Oxidation by hydrogen peroxide in the presence of a metal oxide catalyst is known as one of the simplest procedures for effecting the hydroxylation of olefins.[1]

$$>C{=}C< + H_2O_2 \xrightarrow[\text{catalyst}]{\text{metal oxide}} >\underset{\underset{OH}{|}}{C}-\underset{\underset{OH}{|}}{C}<$$

Although many catalysts for this reaction are known, osmium tetroxide and tungstic acid (or tungsten trioxide) are especially useful for the practical syntheses of *cis*- and *trans*-$\alpha$-diols from the corresponding olefins. Selenium dioxide, which can be used in organic or aqueous solution, has found favor with some investigators,[2-5] but is not so well established a catalyst as osmium tetroxide or tungstic acid. Mugdan and Young[2] have suggested that it may be possible to hydroxylate allyl alcohol with hydrogen peroxide in the presence of selenium dioxide. It has been confirmed that cyclohexene and cyclopentene are hydroxylated to give the corresponding *trans*-$\alpha$-diols[3,4] under similar conditions; recently we also have reported the hydroxylation of some gaseous olefins.[5]



The purpose of the present investigation is to study the use of selenium dioxide as a catalyst in the hydroxylation of olefins with hydrogen peroxide, and also to extend the application of this catalyst.

In order to examine the ionic character of the hydroxylation, oxidation of norbornene was undertaken, because addition of a cation to the double bond of norbornene should cause a Wagner-Meerwein rearrangement via the norbornyl cation.[6,7]

When norbornene (II) was oxidized with 30% hydrogen peroxide in tertiary butyl alcohol in the presence of a catalytic amount of selenium dioxide, the only product was *exo-syn*-norbornane-2, 7-diol (V) which was identified by comparison with an authentic sample. The diol was best isolated as the diacetate (62% yield based on the norbornene used) which was obtained by treatment of the crude product with acetic anhydride. The formation of *exo-syn*-norbornane-2, 7-diol (V) may be due to the hydration of a norbornyl cation (III or IV) produced by the cationic addition of a hydroxyl group to the double bond of norbornene.[6] Although it is still not clear whether rearrangement of the norbornyl cation proceeds via a nonclassical structure (III) or an equilibrium of classical structures (IV),[8] it is evident that the high propensity and stereospecificity of the rearrangement, in this oxidation, indicate the cationic nature of the reaction,[6] since no rearrangement product is known to arise from a radical addition to norbornene[9,10] or in reactions of the norbornyl free radical.[10,11]

On the other hand, the formation of the norbornyl cation (III or IV) suggests that some active oxidizing species having a peroxy acid function may be formed from the selenium dioxide and hydrogen peroxide in the reaction system, and the mechanism of the hydroxylation may be analogous to that proposed for oxidations with organic peracids[12,13] or pertungstic acid.[14] We have assumed[15,16] that peroxyselenious acid (I) is probably the active oxidizing species in the oxidation of ketones under the above reaction conditions. Thus, a likely mechanism for the hydroxylation of norbornene (II) is that shown below.

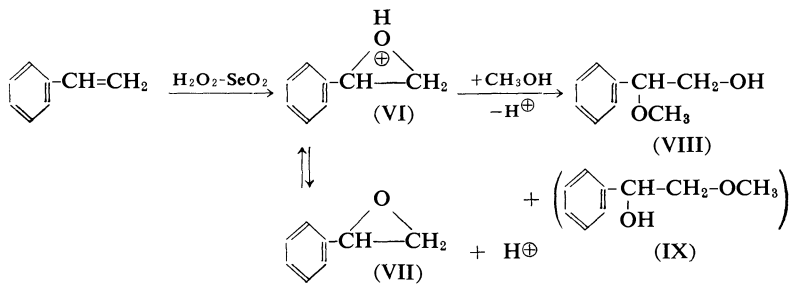
These results suggest that hydroxylation of ordinary olefins, which do not suffer a Wagner-Meerwein rearrangement through attack of a cationic species, may proceed via the corresponding epoxide, a stable intermediate produced by the epoxidation with the active oxidizing species in a similar fashion to the first step of the oxidation of norbornene (II). Oxidation of styrene, with hydrogen peroxide and selenium dioxide in methanol, gave mainly 2-phenyl-2-methoxyethyl alcohol (VIII);[17] this may have been formed by methanolysis of the hydronium ion (VI) which is in equilibrium with styrene oxide (VII) as shown below.



Further evidence for the presence of an epoxide intermediate was obtained by the hydroxylation of cyclohexene in various alcohols. The oxidation of cyclohexene with hydrogen peroxide and selenium dioxide in

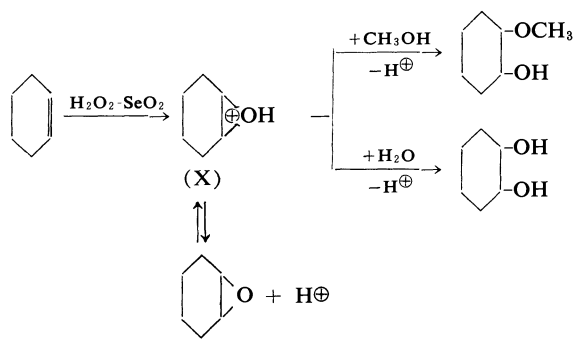


Table I. Hydroxylation of cyclohexene with hydrogen peroxide in the presence of selenium dioxide in various alcohols

| Isopropanol | 24 | 47 |
| *t*-Butyl alcohol | <1** | 65 |

* Yields are based on the hydrogen peroxide used.

** The pure product was not isolated.

17) Identification of 2-phenyl-2-methoxyethyl alcohol (VIII) was established by elementary analysis, and by the mixed melting point of the α-naphthylurethan derivative with an authentic sample, m. p. 119°C (lit.[18] m. p. 119.5°C). Acid or base catalyzed methanolysis of styrene oxide[7] gave generally a mixture of 2-phenyl-2-methoxyethyl alcohol (VIII) and 1-phenyl-2-methoxyethyl alcohol (IX) (α-naphthylurethan, m. p. 105°C[18]), and it has been reported[18] that the α-naphthylurethan of a sample of 2-phenyl-2-methoxyethyl alcohol (VIII) containing a small amount of the 1-phenyl isomer (IX) also showed a m. p. of 119.5°C, identical with that of the α-naphthylurethan of a pure sample of the 2-phenyl isomer (VIII). Accordingly, it is possible that a small amount of the 1-phenyl isomer may have been formed in this experiment, but no attempt was made to determine the content of the 1-phenyl isomer.

18) W. Reeve and I. Christoffel, *J. Am. Chem. Soc.*, **72**, 1480 (1950).

methanol gave α-methoxycyclohexanol as a main product and *trans*-cyclohexane-1, 2-diol in a small amount. α-Methoxycyclohexanol may be fomed by the methanolysis of the hydronium ion intermediate (X), and the production of *trans*-cyclohexane-1, 2-diol may be attributable to competitive hydrolysis of the same intermediate (X).

The results obtained for the oxidation of cyclohexene with 30% hydrogen peroxide in various alcohols are summarized in Table I.

The yields of α-alkoxycyclohexanol and *trans*-cyclohexane-1, 2-diol shown in Table I are comparable to those obtained by Payne and Smith,[19] and the decrease in the yields of α-alkoxycyclohexanol with the kind of alcohol used can be attributed to the decrease in the polarity of the alcohol.

## Experimental

**Hydroxylation of Norbornene.**—To a solution of hydrogen peroxide in tertiary butyl alcohol, prepared by dilution of 5 ml. (0.05 mol.) of 30% hydrogen peroxide with the alcohol, was added 0.1 g. of selenium dioxide. After the selenium dioxide was dissolved completely, 5 g. (0.04 mol.) of norbornene was added and the solution was heated at 70°C for 13 hr. Most of the solvent and unreacted norbornene was removed by distillation, 50 ml. of ethyl acetate was added to the residue and the ethyl acetate solution was extracted with 10 ml. of 10% sodium hydroxide solution to remove the catalyst. After the ethyl acetate solution had been dried over anhydrous magnesium sulfate, the solvent was removed by distillation under reduced pressure. Sublimation of a small part of the residual crystalline solid gave *exo-syn*-norbornane-2, 7-diol, m. p. 176—177°C (sealed tube) (lit.[20] m. p. 174—176°C), the mixed melting point with an authentic sample (m. p. 176—177°C), synthesized by the procedure described by Kwart,[20] showed no depression, and the infrared spectrum of the product was identical with that of the authentic sample.

Found: C, 65.38; H, 9.32. Calcd. for $C_7H_{12}O_2$: C, 65.59; H, 9.44%.

Since the crude *exo-syn*-norbornane-2, 7-diol was slightly hygroscopic, the diol was acetylated. The residual crystalline solid obtained by the removal of solvent was added to 50 ml. of acetic anhydride containing one drop of sulfuric acid; a slightly exothermic reaction was observed. After the reaction mixture had been allowed to stand overnight at room temperature, a small amount of calcium carbonate was added to neutralize the sulfuric acid, and then filtered off. Removal of the unreacted acetic anhydride by distillation under reduced pressure, gave 5.2 g. of *exo-syn*-2, 7-diacetoxynorbornane in a yield of 62% based on the norbornene used; b. p. 128—132°C (10 mmHg), $n_D^{20}$ 1.4626 (lit.[14] b.p. 130—134°C (11 mmHg), $n_D^{25}$ 1.4620), the infrared spectrum was identical with that of an authentic sample.

**Oxidation of Styrene in Methanol Solution.**—To a solution of 400 ml. of methanol containing 30 ml. (ca. 0.3 mol.) of 30% hydrogen peroxide was dissolved 0.5 g. of selenium dioxide. Then 31.2 g. (0.3 mol.) of styrene was added to the solution and the reaction mixture was gently refluxed for 20 hr. After decantation to remove the polystyrene deposited in the flask, the solvent and unreacted styrene were removed by distillation under reduced pressure, and the residual liquid was distilled; 8.5 g. of a fraction boiling at 108—113°C (6 mmHg) was collected. Purification by redistillation of this fraction gave 7.8 g. of 2-phenyl-2-methoxyethyl alcohol[17] (60% yield based on the unrecovered styrene); the infrared spectrum was practically identical with that of an authentic sample.

Found: C, 70.88; H, 7.72. Calcd. for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

The α-naphthylurethan melted at 119°C (lit.[18] m. p. 119.5°C), the mixed melting point with an authentic sample (m. p. 119°C) showed no depression and the infrared spectrum was identical with that of an authentic sample.

Found: C, 74.92; H, 5.90. Calcd. for $C_{20}H_{19}NO_3$: C, 74.74; H, 5.96%.

**Hydroxylation of Cyclohexene in Methanol Solution.**—To a solution of 18.4 ml. (0.18 mol.) of 30% hydrogen peroxide in 365 ml. (9.0 mol.) of methanol was added 0.8 g. of selenium dioxide and 29.5 g. (0.36 mol.) of cyclohexene. After the solution had been refluxed for 10.5 hr. (at this stage, hydrogen peroxide was completely consumed), the solvent and unreacted cyclohexene were removed by distillation under reduced pressure. The residual product was separated by distillation into the following three fractions: fraction A, b. p. 106—116°C (65 mmHg); fraction B, b. p. 105—128°C (20 mmHg); fraction C, b. p. 128—133°C (20 mmHg), which crystallized at once. Fraction B, on being allowed to stand overnight at 0°C, deposited a white crystalline solid which was filtered off; the filtrate was combined with fraction A. Redistillation of this mixture gave 18.2 g. of α-methoxycyclohexanol (78% yield based on the hydrogen peroxide used), b. p. 107—111°C (65 mmHg), $n_D^{20}$ 1.4604 (lit.[19] b. p. 122—124°C (100 mmHg), $n_D^{20}$ 1.4595). The infrared spectrum was identical with that of an authentic sample.

Found: C, 64.46; H, 10.78. Calcd. for $C_7H_{14}O_2$: C, 64.58; H, 10.84%.

The crystalline solid collected from fractions A and B was recrystallized from ether to give 2.0 g. (10% yield) of *trans*-cyclohexane-1, 2-diol, m. p. 103—103.5°C (lit.[21] m. p. 103.5—104°C). The mixed melting point with an authentic sample (m. p. 103—103.5°C) was not depressed.

Found: C, 61.85; H, 10.83. Calcd. for $C_6H_{12}O_2$: C, 62.04; H, 10.41%.

**Hydroxylation of Cyclohexene in Ethanol Solution.**—To a solution of 18.4 ml. (0.18 mol.) of 30% hydrogen peroxide in 420 ml. (7.2 mol.) of ethanol

containing 0.8 g. of selenium dioxide was added 29.5 g. (0.36 mol.) of cyclohexene. The reaction mixture was heated at 55—60°C for 13.5 hr. The reaction products were separated in the same manner as described for the hydroxylation in methanol solution, and 14.5 g. (56% yield based on the hydrogen peroxide used) of α-ethoxycyclohexanol was obtained, b. p. 80—85°C (15 mmHg), $n_D^{20}$ 1.4566 (lit.[19] b. p. 65—67°C(4 mmHg), $n_D^{20}$ 1.4562).

Found: C, 66.78; H, 11.21. Calcd. for $C_8H_{16}O_2$: C, 66.63; H, 11.18%.

*trans*-Cyclohexane-1, 2-diol (4.2 g.) was also isolated in a yield of 20%, m. p. 103—103.5°C. The mixed melting point with an authentic sample showed no depression.

**Hydroxylation of Cyclohexene in *n*-Propanol Solution.**—To a solution of 18.4 ml. (0.18 mol.) of 30% hydrogen peroxide in 540 ml. (7.2 mol.) of *n*-propanol containing 0.8 g. of selenium dioxide was added 29.5 g. (0.36 mol.) of cyclohexene. The reaction mixture was heated at 55—60°C for 16 hr. The reaction products were separated in the same manner as described for the hydroxylation in methanol solution, and 14.4 g. (51% yield based on the hydrogen peroxide used) of α-*n*-propoxycyclohexanol was isolated, b. p. 92—96°C (14 mmHg), $n_D^{20}$ 1.4571 (lit.[22] b. p. 205°C, $n_D^{20}$ 1.4580).

Found: C, 67.89; H, 11.40. Calcd. for $C_9H_{18}O_2$: C, 68.31; H, 11.47%.

*trans*-Cyclohexane-1, 2-diol (4.9 g.) was also isolated in a yield of 23%, m. p. 103—103.5°C. The mixed melting point with an authentic sample was not depressed.

**Hydroxylation of Cyclohexene in *n*-Butanol.**—To a solution of 18.4 ml. (0.18 mol.) of 30% hydrogen peroxide in 660 ml. (7.2 mol.) of *n*-butanol containing 0.8 g. of selenium dioxide was added 29.5 g. (0.36 mol.) of cyclohexene. The reaction mixture was heated at 55—60°C for 17 hr. The reaction products were separated in the same manner as described for the hydroxylation in methanol solution, and 10.8 g. (35% yield based on the hydrogen peroxide used) of α-*n*-butoxycyclohexanol was obtained, b. p. 106—110°C (13 mmHg), $n_D^{20}$ 1.4562 (lit.[23] b. p. 113—115°C (15 mmHg)).

Found: C, 69.49; H, 11.60. Calcd. for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%.

*trans*-Cyclohexane-1, 2-diol (5.7 g.) was also isolated in a yield of 27%, m. p. 103—103.5°C. The mixed melting point with an authentic sample showed no depression.

**Hydroxylation of Cyclohexene in Isopropanol Solution.**—To a solution of 18.4 ml. (0.18 mol.) of 30% hydrogen peroxide in 550 ml. (7.2 mol.) of isopropanol containing 0.8 g. of selenium dioxide was added 29.5 g. (0.36 mol.) of cyclohexene. The reaction mixture was heated at 55—60°C for 14 hr. The reaction products were separated in the same manner as described for the hydroxylation in methanol solution, and 6.7 g. (24% yield based on the hydrogen peroxide used) of α-isopropoxycyclohexanol was isolated, b. p. 89—93°C (18 mmHg), $n_D^{20}$ 1.4520 (lit.[19] b. p. 94—96°C (20 mmHg), $n_D^{20}$ 1.4506).

Found: C, 68.22; H, 11.36. Calcd. for $C_9H_{18}O_2$: C, 68.31; H, 11.47%.

*trans*-Cyclohexane-1, 2-diol (9.9 g.) was also isolated in a yield of 47%, m. p. 103—103.5°C. The mixed melting point with an authentic sample showed no depression.

**Hydroxylation of Cyclohexene in *t*-Butyl Alcohol Solution.**—To a solution of 18.4 ml. (0.18 mol.) of 30% hydrogen peroxide in 680 ml. (7.2 mol.) of *t*-butyl alcohol containing 0.8 g. of selenium dioxide was added 29.5 g. (0.36 mol.) of cyclohexene. The reaction mixture was heated at 55—60°C for 16 hr. The reaction products were separated in the same manner as described for the hydroxylation in methanol solution, and 0.4 g. of liquid, b. p. 86—91°C (14 mmHg), $n_D^{20}$ 1.4598, was obtained as a first fraction. Although the infrared absorption of this fraction showed strong bands at 3350 $cm^{-1}$ (O-H) and 1250 $cm^{-1}$ (C-O-C), elementary analysis as α-tertiary-butoxy-cyclohexanol gave slightly unsatisfactory result which might be due to the presence of some impurities.

*trans*-Cyclohexane-1, 2-diol (13.5 g.) was also isolated in a yield of 65%, m. p. 103—103.5°C. The mixed melting point with an authentic sample showed no depression.

# The Electronic Spectra of Aniline and *N*-Methylaniline Adsorbed on Aluminum Chloride. I

By Hiroyasu SATO,*1 Kozo HIROTA and Saburo NAGAKURA

(Received October 27, 1964)

Recently, the electronic spectra of organic molecules adsorbed on solid catalysts, especially on such cracking catalysts as silica gel and silica-alumina, have been investigated by several authors.[1] The adsorbates studied include benzene derivatives, cata-condensed hydrocarbons, and aromatic amines. On silica gel, these molecules are adsorbed physically or interact with the surface hydroxyl group of the catalysts. On silica-alumina, on the other hand, chemically-adsorbed species are also found. The Lewis-acid nature of silica-alumina is now well known. The molecules chemically adsorbed on silica-alumina either give an electron to the catalyst surface, thus forming cation-radicals, or form a sigma-bond with some electron-accepting center on the catalyst surface by sharing an electron-pair. Such cata-condensed hydrocarbons as anthracene and perylene give cation radicals other than the carbonium ions.[2,3] Aromatic amines form sigma complexes because of the Lewis-base nature of these compounds. In their investigation of aniline adsorbed on silica-alumina, Kotov and Terenin attributed the hypsochromic shift of the 2800Å band of aniline to the interaction of the adsorbed aniline molecule with some electron-accepting center on the catalyst surface.[4] The aim of the present study is to investigate the interaction of the aniline molecule with aluminum chloride, one of the typical Lewis acids, extending the measurement over the vacuum ultraviolet region.*2

## Experimental

**Materials.** — Aluminum chloride was prepared from silver chloride and aluminum foils in vacuo according to Wallace and Willard's procedure.[5] Aniline and *N*-methylaniline of Tokyo-Kasei, G.P. grade, were dried with sodium hydroxide and distilled in vacuo before use. The middle fraction was used for the experiment.

**Procedure.** — Since the system studied here is very sensitive to moisture, all preparations and measurements were carried out in vacuo. The apparatus used in this experiment is shown in Fig. 1. Aluminum chloride was sublimed, via a break-off seal, into a quartz cell by heating it over a free flame.*3 The vapor of aniline (or *N*-methylaniline) was then introduced into the cell by opening the stopcock. After evacuation, the electronic spectrum was recorded.

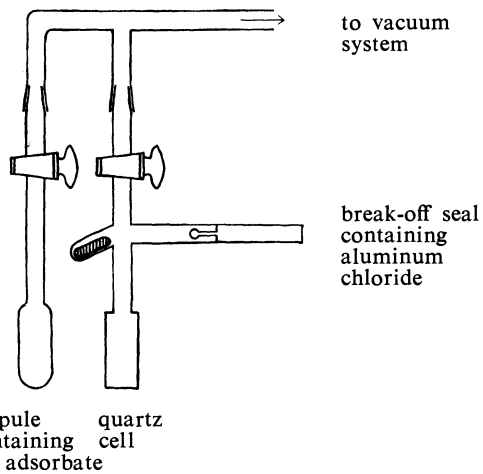

Fig. 1. Apparatus for the absorption study.

The electronic spectra were recorded by a Hitachi recording spectrophotometer model EPS-2 for the 220—340 mμ range; by a Cary recording spectrophotometer model 15 being flushed with dry nitrogen for the 180—300 mμ range, and by a vacuum ultraviolet spectrophotometer constructed in the Institute for Solid State Physics (reported on earlier)[6] for the 150—220 mμ range.

## Experimental Results

The observed electronic spectra of adsorbed aniline and *N*-methylaniline are, in Fig. 2,

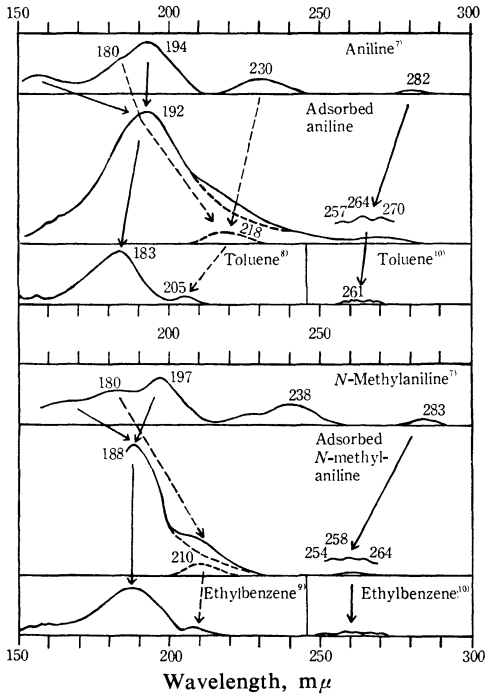

Fig. 2. The electronic spectra of adsorbed aniline and *N*-methylaniline.
Ordinate: optical density (in arbitary units). The enlarged spectra near 260 mμ are also shown. The spectra of aniline, *N*-methylaniline (Kimura et al.[7]), toluene (Kimura et al.[8], Am. Petr. Inst.[10]), and ethylbenzene (Hammond et al.[9]) are shown for purposes of comparison. For ethylbenzene, the spectrum around 260 mμ is drawn according to the data of the isooctane solution (Am. Petr. Inst.[10]). The arrows, → and ⇢, indicate the corresponding bands among these spectra. As to the reference spectra, the ordinates indicate qualitatively the strength of the absorption.

compared with those of vapor aniline, vapor *N*-methylaniline, and vapor alkylbenzenes (cf. Kimura, Tsubomura and Nagakura,[7] Kimura and Nagakura,[8] Hammond, Price, Teegan and Walsh,[9] Am. Petr. Inst.[10]). Because evaporated film was used, no quantitative measurement of the extinction coefficient of the adsorbates could be made. The spectrum of adsorbed aniline consists of a strong band at 192 mμ and a weak band with a vibrational structure around 265 mμ. The former band seems to be accompanied with a band hidden near 218 mμ.

The spectrum of adsorbed *N*-methylaniline consists of a strong band at 188 mμ, with a shoulder near 210 mμ, and a weak band with a vibrational structure around 260 mμ.

## Discussion

The spectrum of aniline has been the subject of many investigations,[7,11-14] and its correlation with the spectra of benzene and alkylbenzenes seems to be well-established. The spectra of adsorbed species can also be interpreted in terms of this correlation (see Fig. 3).

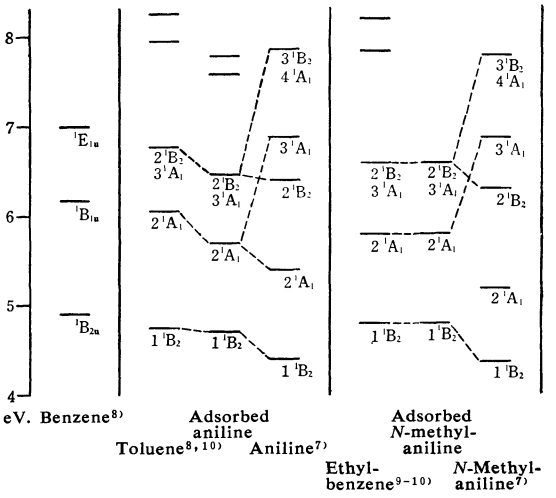

Fig. 3. Correlation diagram of excited states.

The spectrum of adsorbed aniline can be interpreted as follows. The weak band around 265 mμ (with a vibrational structure) is situated just between the 282 mμ band of aniline (broad), and the 261 mμ band of toluene (with a vibrational structure). The strong band at 192 mμ may be correlated with the 194 mμ band of aniline and 183 mμ band of toluene, and the hidden band near 218 mμ, which has something of a charge-transfer character, with the 180 mμ band of aniline and the 205 mμ band of toluene.

The spectrum of adsorbed *N*-methylaniline is nearly the same as that of ethylbenzene.

Another striking feature of these spectra is the disappearance of the 230 mμ band of aniline and the 238 mμ band of *N*-methylaniline, i.e., the intramolecular charge-transfer bands of the two.

These characteristics in the spectra of aniline and *N*-methylaniline can be consistently interpreted in terms of the electron donation from

the nitrogen atom in the aniline (or *N*-methylaniline) molecule to some electron accepting center on aluminum chloride-evaporated film. This view is supported by the fact that, in the spectrum of adsorbed aniline, the position of the absorption band draws nearer to that of the anilinium ion, which has peaks at 203 m$\mu$ and 254 m$\mu$.[15] It has been shown by many investigators that, in a sigma complex with Lewis acid, the absorption spectrum is like that of the proton complex, but it generally accompanies some shift.[1,16,17] The electron-accepting center is assumed to be the vacant $sp^3$-orbital of the aluminum atom. This interaction will reduce the electron density on the nitrogen atom, making the intramolecular charge-transfer band vanish and the other part of the spectrum draw nearer to that of alkylbenzenes.

A brief qualitative discussion of the positions of the absorption bands in these spectra will be given here.[18] Attention should be paid to the relative location of the intramolecular charge-transfer (CT) configurations and locally excited (LE) configurations in these molecules. In the case of aniline, two CT configurations ($^1A_1$ and $^1B_2$) lie in the region of 5—6 eV., amidst the LE configurations. These lift the degeneracy of the $^1E_{1u}$ state of benzene and cause hypso- and bathochromic shifts of the absorption bands compared with those of benzene, as Fig. 3 shows. In the case of toluene, however, with the CT configurations beyond the LE configurations, the degeneracy of the $^1E_{1u}$ state of benzene is lifted to a much smaller extent and all the absorption bands shift slightly in the red direction. In the case of adsorbed aniline, just the intermediate case can be expected as to the location of CT configurations; i.e., the CT configurations lie higher than in case of aniline, but lower than in the case of toluene. This will make the spectrum nearer to that of toluene, but with a larger red shift of some absorption bands.

The spectra of *N*-methylaniline, adsorbed *N*-methylaniline and ethylbenzene can be discussed in a similar way. In these cases, however, a larger rise in the energy of the CT configurations of adsorbed *N*-methylaniline reduces its spectrum to almost the same as that of ethylbenzene.

18) A more detailed discussion will be published later in this Bulletin.

## Summary

The electronic spectra of aniline and *N*-methylaniline adsorbed on evaporated film of aluminum chloride have been measured (150—300 m$\mu$ for the former adsorbate and 185—300 m$\mu$ for the latter). In the case of *N*-methylaniline, a spectrum which is nearly the same as that of ethylbenzene has been obtained. In the case of adsorbed aniline, the spectrum shows features intermediate between those of the aniline vapor spectrum and those of the toluene vapor spectrum. These results can be interpreted in terms of the electron donation from the lone-pair electrons on the nitrogen atom of these molecules to some electron-accepting center on aluminum chloride, presumably to the vacant $sp^3$-orbital of the aluminum atom on the surface, resulting in the weakening of the conjugation between the amino- (or *N*-methylamino-) group and the benzene ring. The positions of the absorption bands are interpreted qualitatively in terms of the relative location of charge-transfer and locally-excited configurations in these molecules.

The authors wish to express their gratitude to Dr. Katsumi Kimura*1 and Mr. Koji Kaya, the Institute for Solid State Physics, the University of Tokyo, for their kind measurement in the vacuum ultraviolet region. Dr. Kimura was very kind also in giving valuable, unpublished information on the vacuum ultraviolet spectral data of aniline, *N*-methylaniline and toluene. The authors are also indebted to Professor Hiroshi Tsubomura, Faculty of Engineering Science, Osaka University, by whose kindness measurement by the Cary spectrophotometer was possible. Thanks are also due to Mr. Toshinobu Imanaka,*2 Faculty of Science, Osaka University, for his useful suggestions concerning experimental techniques for preparing the evaporated film of aluminum chloride.

# Near and Vacuum Ultraviolet Absorption Spectra and Electronic Structures of Nitrosobenzene and Its Derivatives

By Katsumi TABEI* and Saburo NAGAKURA

(Received October 29, 1964)

The electronic absorption spectra of nitrosobenzene and its derivatives are interesting subjects from both experimental and theoretical points of view. Nitrosobenzene is colorless in its crystal form but turns green when it is melted or dissolved in some solvents. This phenomenon has been studied spectroscopically and thermochemically by several investigators.[1] It has been found from these studies that the monomer shows a weak $n\rightarrow\pi^*$ transition band at about 750 m$\mu$; this band, which is responsible for the green color, disappears in the colorless dimer.

The $n\rightarrow\pi^*$ transition band of nitrosobenzene has been studied in detail in connection with the above-mentioned color change. Concerning the ultraviolet absorption spectrum of nitrosobenzene, however, only a few experimental and theoretical studies have hitherto been carried out.[2] This might be because nitrosobenzene and some of its derivatives are rather unstable and because, moreover, their ultraviolet absorption spectra are too complicated to be understood by analogy with that of benzene.

Under these circumstances, we have undertaken to study in more detail the absorption spectra of nitrosobenzene and its derivatives from both experimental and theoretical points of view, in order to bring about a better understanding of their electronic structures and clarify the characteristics of the nitroso group as a chromophoric or electron-accepting group.

## Experimental

**Materials.**—Nitrosobenzene and the following *p*-substituted nitrosobenzenes are studied in the present work : nitrosobenzene, *p*-nitrosotoluene, *p*-nitrosochlorobenzene, *p*-nitrosobromobenzene, *p*-nitrosoanisole, *p*-nitrosophenetole, *p*-nitrosophenol, *p*-nitrosoaniline, *p*-nitroso-*N*, *N*-dimethylaniline, *p*-nitroso-*N*, *N*-diethylaniline, *p*-nitroso-*N*-ethyl-*N*-benzylaniline and *p*-nitrosodiphenylamine.

Nitrosobenzene, *p*-nitrosotoluene, *p*-nitrosochlorobenzene, *p*-nitrosobromobenzene, *p*-nitrosoanisole and *p*-nitrosophenetole were derived from the corresponding nitro compounds via. hydroxylamino compounds by the method of Bamberger et al.[3] The products were separated by steam distillation and were purified by repeated recrystallizations from an ethanol-water mixture.

Commercial G.R. grade *p*-nitrosophenol, *p*-nitroso-*N*, *N*-dimethylaniline and *p*-nitrosodiphenylamine were purified by recrystallization with a ligroin-benzene mixture. *p*-Nitrosoaniline was prepared from *p*-nitrosophenol, ammonium acetate and ammonium chloride following the directions of Fischer and Hepp.[4] *p*-Nitroso-*N*, *N*-diethylaniline and *p*-nitroso-*N*-ethyl-*N*-benzylaniline were prepared from the corresponding anilines by a usual nitrosation with sodium nitrite and hydrochloric acid.[5] The products were recrystallized from ligroin. The melting points of the compounds used in the present study are listed in Table I.

*n*-Heptane used as a solvent was shaken with concentrated sulfuric acid and washed with aqueous sodium hydroxide and thereafter with water repeatedly. After being kept standing over calcium chloride for a day or so, it was fractionally distilled over sodium metal.

Commercial ethanol, chloroform, dioxane, ethyl ether and acetonitrile of a G.P. grade were purified by distillation.

**Measurement.**—A Cary recording spectrophotometer model 14-M was used for measuring the visible and near ultraviolet absorption spectra of the solutions with concentrations of the respective nitroso compounds of $10^{-5}$—$10^{-3}$ mol./l. The measurements were made at room temperature by using silica cells with light paths 1 cm. and 0.1 cm. long.

The vacuum ultraviolet absorption spectrum of nitrosobenzene in a *n*-heptane solution was measured by using handmade vacuum ultraviolet spectrophotometer.[6]

* represents absorption shoulders.

## Experimental Results

A weak absorption band ($\varepsilon=40$—$70$) was observed in the 680—760 mμ wavelength region for all the compounds given in Table I. It has been assigned to the $n\rightarrow\pi^*$ transition band.[7]

The ultraviolet absorption spectra of nitrosobenzene in the gaseous state and in *n*-heptane and ethanol solutions are given in Fig. 1. The peak wavelengths and molar extinction coefficients observed with the *n*-heptane solution are tabulated in Table I. Nitrosobenzene exhibits in the ultraviolet region five absorption maxima, at 301.4 mμ ($\varepsilon=5200$), 280.5 mμ ($\varepsilon=10330$), 218 mμ ($\varepsilon=6480$), 194 mμ ($\varepsilon=11890$), and 174 mμ ($\varepsilon=\sim45000$), and two shoulders at 272 mμ and 222 mμ. The absorption spectra of *p*-nitrosotoluene, *p*-nitrosochlorobenzene and *p*-nitrosobromobenzene shown in Fig. 2 are similar to that of nitrosobenzene.

On the other hand, *p*-nitrosophenol, *p*-nitrosoanisole, *p*-nitrosophenetole, *p*-nitrosoaniline and its *N*-substituted derivatives have more intense absorption bands at a longer wavelength region than nitrosobenzene does. The spectra of some of these compounds are shown in Figs. 2 and 3.

As is revealed by Fig. 1, the 300 mμ band of nitrosobenzene is sensitive to solvents.[8]

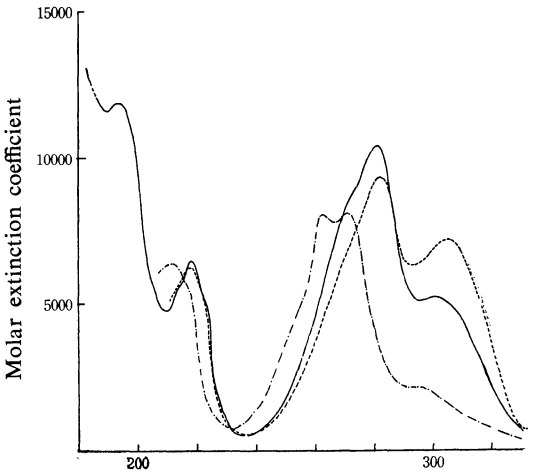

Fig. 1. The ultraviolet absorption spectra of nitrosobenzene in gaseous state, *n*-heptane solution and ethanol solution.
—·—·—·— in gaseous state
———— in *n*-heptane solution
- - - - - - - - - in ethanol solution

The band shows a small red shift and a great increase in intensity with the polarity of the solvent; i. e., the 294 mμ band of nitrosobenzene in the gaseous state shifts to 301.4 mμ

in the *n*-heptane solution and to 304 mμ in the ethanol solution, while the absorption intensity increases from 5200 in the *n*-heptane solution to 7200 in the ethanol solution.

In order to clarify the nature of this solvent effect, we measured the spectrum of nitrosobenzene in ethanol - *n*-heptane mixed solvents. The results are shown in Fig. 4. The 300 mμ and 280 mμ bands respectively increase and decrease in intensity with the concentration of ethanol. This suggests that the following equilibrium might exist between the free nitrosobenzene molecule and the hydrogen-bonded one:

and that the formation of the hydrogen-bonded molecule might be the reason for the change in the above-mentioned absorption spectrum of nitrosobenzene. In order to check this point, we have measured the absorption spectrum of nitrosobenzene in various kinds of solvents with different dielectric constants. The observed maximum wavelengths and molar extinction coefficients are given in Table II.

From the results given in Table II, it is clear that dioxane, chloroform and acetonitrile, in spite of their lack of a proton-donating ability, have an effect on the 300 mμ and 280 mμ bands of nitrosobenzene similar to that of

ethanol. Therefore, we can safely disregard the possibility that the above-mentioned solvent effect upon the absorption band of nitrosobenzene might be caused by hydrogen bonding. At least, it may be said that hydrogen bonding is not an important factor in the solvent effect. Furthermore, this solvent effect can not be due to the dimer formation because the $n\rightarrow\pi^*$ transition band at 760 mμ does not change in intensity when ethanol is added to the *n*-heptane solution. Therefore, it may be said that the change in the 300 mμ and 280 mμ bands of nitrosobenzene may be regarded as a general solvent effect caused by the polarity of the solvents.*

* In this case the polarity of the solvents has a wide meaning. Besides the average polarity represented by the dielectric constant or refractive index, the local polarity may take part in the solvent effect.

In this connection, it is noteworthy that the electron-donating group at the para position has the same effect upon the intensity of the 300 mμ band of nitrosobenzene. For instance, the corresponding band of *p*-nitrosotoluene, which appears at 310.8 mμ, has the molar extinction coefficient of 8800. This value is apparently larger than that of nitrosobenzene ($\varepsilon=5200$). This means that the methyl substitution brings about the red shift and intensity increment of the 300 mμ band of nitrosobenzene, as the polar solvents do. The above-mentioned solvent and substituent effects may be explained in terms of the stabilization of the charge-transfer structure which is caused by an electron transfer from the benzene ring to the nitroso group. This point will be discussed in detail below.

## Theoretical

The electronic structure of nitrosobenzene has been studied by taking eight π-electrons into account. First, the molecule was divided into two components; the benzene ring and the nitroso group. The molecular orbitals of these components were determined. Then the interaction between the two components was considered by means of the configurational interaction among such electron configurations as the ground, locally excited and charge-transfer configurations.[9] The eight electron configurations taken up in the present study are given in Table III. A similar calculation was made by Tanaka,[10] but he disregarded the locally excited configuration within the nitroso group.

First of all, let us evaluate the energy of each configuration, taking the energy of the ground configuration as the standard; $H_G=0$. The energies of the four locally excited configurations of benzene, $H_{E_{1u}}$, $H_{E_{1u'}}$, $H_{B_{1u}}$, and $H_{B_{2u}}$, were taken from the observed transition energies of the corresponding absorption bands of benzene.[11] Their values are shown in Table

| | $H_{CT'} = 4.52$ | $\Psi_{CT'} = (1/2)^{1/2}\{\lvert 1\bar{1}2\bar{2}3\bar{w}s\bar{s}\rvert + \lvert 1\bar{1}2\bar{2}w\bar{3}s\bar{s}\rvert\}$ |

* G; ground configuration, LE*; locally (in benzene) excited configurations, LE; locally (in the nitroso group) excited configuration, CT; charge-transfer configurations.

** The precise form is as follows:

$$\Psi_G = (1/8!)^{1/2}\sum(-1)^p P\begin{Bmatrix}\phi_1(1)\phi_1(2)\phi_2(3)\phi_2(4)\phi_3(5)\phi_3(6)\phi_s(7)\phi_s(8)\\ \alpha(1)\ \beta(2)\ \alpha(3)\ \beta(4)\ \alpha(5)\ \beta(6)\ \alpha(7)\ \beta(8)\end{Bmatrix}$$

The molecular orbitals of benzene; $\phi_1$, $\phi_2$, $\phi_3$, $\phi_4$, and $\phi_5$ are given as follows:

$$\phi_1 = (1/6)^{1/2}(\chi_1+\chi_2+\chi_3+\chi_4+\chi_5+\chi_6)$$
$$\phi_2 = (1/12)^{1/2}(2\chi_1+\chi_2-\chi_3-2\chi_4-\chi_5+\chi_6)$$
$$\phi_3 = 1/2(\chi_2+\chi_3-\chi_5-\chi_6)$$
$$\phi_4 = 1/2(\chi_2-\chi_3+\chi_5-\chi_6)$$
$$\phi_5 = (1/12)^{1/2}(2\chi_1-\chi_2-\chi_3+2\chi_4-\chi_5-\chi_6)$$

The molecular orbitals of the nitroso group, $\phi_s$, $\phi_w$ are as follows[10]:

$$\phi_s = 0.6000\chi_N + 0.8000\chi_O$$
$$\phi_w = 0.8000\chi_N - 0.6000\chi_O$$

where $\chi_N$ and $\chi_O$ are the $2p\pi$ atomic orbitals of nitrogen and oxygen of the nitroso group respectively.

III. Furthermore, we assumed the energy of the locally excited configuration of the nitroso group, $H_{LE}$, as 8.00 eV. on the basis of the energy of the $\pi\rightarrow\pi^*$ transition band of chloronitrosocyclohexane. This compound exhibits a $\pi\rightarrow\pi^*$ transition band at about 160 m$\mu$ together with an $n\rightarrow\pi^*$ band at 650 m$\mu$.[12]

The energies of two charge-transfer configurations, $H_{CT}$ and $H_{CT'}$, which are caused by an electron transfer from the benzene ring to the nitroso group, are evaluated by the following equations:

$$H_{CT} = I_B - A_N - \Delta_{CT}$$
$$H_{CT'} = I_B - A_N - \Delta_{CT'}$$

where $I_B$ and $A_N$ are the ionization potential of benzene and the electron affinity of the nitroso group respectively, and where $\Delta_{CT}$ and $\Delta_{CT'}$ are the electrostatic interaction energies between the positive and negative charges caused by the electron transfer. The value of $I_B$ is set at 9.24 eV., a value which was determined by Watanabe[13] from a photoionization experiment. The electron affinity of the nitroso group was assumed to be 0.55 eV. The values of $\Delta_{CT}$ and $\Delta_{CT'}$ were calculated as 4.59 and 4.17 eV. respectively. The two-center

a) The values observed with the *n*-heptane solution. * Vibrational structure

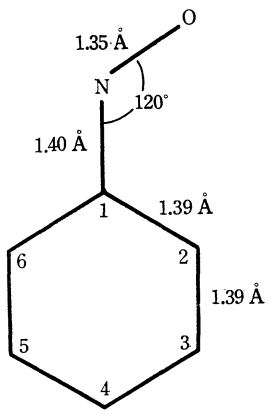

Fig. 5. The geometrical structure of nitrosobenzene.

Coulomb integrals of the (CC|NN) and (CC|OO) types necessary for the evaluation of $\Delta_{CT}$ and $\Delta_{CT'}$ were calculated by the aid of the quadratic equation of an atomic distance derived by Pariser and Parr's method.[14] For the actual calculations, the geometrical structure of nitrosobenzene was reasonably assumed to be as shown in Fig. 5, by making use of the X-ray crystal analysis data of the *p*-bromonitrosobenzene dimer.[15] Thus, the energies of the two charge-transfer configurations, $H_{CT}$ and $H_{CT'}$ were determined to be 4.10 eV. and 4.52 eV. respectively.

The off-diagonal matrix elements of the Hamiltonian of the total electrons were calculated following the procedure developed by Pople[16] and by Longuet-Higgins and Murrell[17]. The results are shown in Table IV, where $\beta$'s are the core resonance integrals; they were estimated on the assumption of the proportionality of the core resonance integrals to the overlap integrals.

The integrals (sw|35) in Table IV can be reduced to two center Coulomb integrals concerning appropriate atomic orbitals, which can be evaluated by the Pariser-Parr method mentioned above.

The energy levels and the wave functions finally evaluated by the aid of a FACOM 202 electronic computer are shown in Table V.

The oscillator strength, *f*, was calculated by means of the usual equation: [18]

$$f_{calc.}=1.085\times10^{-5}\times\nu Q^2$$

where $Q$ and $\nu$ are the transition moment (in

units of Å) and the evaluated transition energy (in units of $cm^{-1}$) respectively. The evaluated oscillator strength values are, in Table VI, compared with the observed ones obtained by the following equation:

$$f_{obs.} = 4.32 \times 10^{-9} \times \int \varepsilon(\nu) d\nu$$

where $\varepsilon$ is the molar extinction coefficient.

### Theoretical Results and Discussion

When the calculated transition energy and the oscillator strength are compared with the observed values, the 174 m$\mu$ band, which was newly found by the present authors, can safely be assigned to the superposed $W_0 \rightarrow W_5$ and $W_0 \rightarrow W_6$ transitions, and the 194 m$\mu$ band, to the $W_0 \rightarrow W_4$ transition. Judging from the wave functions of the $W_4$, $W_5$ and $W_6$ levels, the former may be regarded as the shifted band of the $A_{1g} \rightarrow E_{1u}$ transition band of benzene, and the latter, as that of the $A_{1g} \rightarrow B_{1u}$ transition band of benzene.

The 218 m$\mu$ band corresponding to the $W_0 \rightarrow W_3$ transition may be said to have the nature of the $A_{1g} \rightarrow B_{2u}$ transition band of benzene, but the contribution from one of the charge-transfer configurations ($\phi_3^{-1}\phi_w$) amounts to 25%.

The 280.5 m$\mu$ band can be ascribed to the $W_0 \rightarrow W_2$ transition. The contributions of the charge-transfer configurations to the $W_2$ level amount to 62% (CT) and 17% (CT') respectively. Therefore, the 280.5 m$\mu$ band may safely be regarded as the charge-transfer absorption band, although there are small contributions of such other components as local excitations in the nitroso and benzene groups.

The 301.4 m$\mu$ band corresponding to the $W_0 \rightarrow W_1$ transition may be thought to have a character mixing locally excitation within the benzene ring ($B_{2u}$) and the charge-transfer excitation, since the contributions of the charge-transfer and $B_{2u}$ locally excited configurations are 49% (CT'), 18% (CT) and 20% ($B_{2u}$) respectively.

As was previously stated, the 280 m$\mu$ and 300 m$\mu$ bands are sensitive to the polarity of the solvent. In polar solvents, the absorption bands have a tendency to become similar to those of the *p*-nitrosotoluene and other simple *p*-substituted nitrosobenzene derivatives, as is shown in Fig. 4.

In order to explain the polar solvent effect, we calculated the energy levels and wave functions, changing the energy values of the two charge-transfer configurations, $H_{CT}$ and $H_{CT'}$. The results are tabulated in Table VII. It can be seen that the decrease in the energies of the two charge-transfer configurations brings about a decrease in the transition energies for the $W_0 \rightarrow W_1$ and $W_0 \rightarrow W_2$ and $W_0 \rightarrow W_3$ transitions and causes an increase in the oscillator strength for the $W_0 \rightarrow W_1$ transition. On the other hand, in the $W_0 \rightarrow W_2$ transition which corresponds to the 280 m$\mu$ band of nitrosobenzene, the oscillator strength very slightly decreases in the order of cases 1, 2, 3, and 4.

The above-mentioned theoretical results seem to explain the effects of solvents and of *p*-substituted electron-donating groups. That is to say, the wavelength shifts and intensity changes of the 300 m$\mu$ and 280 m$\mu$ bands may be thought to be caused by the fact that the energies of the charge-transfer configurations change with the polarity of solvents or when an electron-donating group is substituted for the hydrogen atom at the para position.

The authors wish to express their deep thanks to Dr. Katsumi Kimura for the measurement of the vacuum ultraviolet absorption spectrum.

# Effects of Pressure on the Chemical Properties of the Solid Surface. I. Surface Acidities of Some Compressed Sulfates and Bisulfate

By Yoshisada OGINO and Takeshi KAWAKAMI

(Received August 31, 1964)

The effects of pressure on the chemical properties of gases and liquids have been thoroughly investigated. Furthermore, recent advances in high pressure chemistry have revealed an enhanced reactivity of solid substances at high pressures. However, except for some contributions from the Russian researchers,[1] no systematic investigations concerning the effect of pressure on the surface properties of solids have been reported. These circumstances have prompted the authors to investigate the chemical properties of the surface of a compressed solid. In the present paper, which is the first of a series, the effect of pressure on the surface acidity of some sulfates and a bisulfate is investigated.

Some solids have characteristic surface acidities, and it is believed that this acidity plays an important role in some surface catalyses where hydrocarbons or their derivatives are the reactants and products. Thus, it becomes important to increase the acidity to improve the catalytic activity. Attempts have been made to achieve this,[2,3] but application of high pressure to the solid has not yet been tested.

A well known fact[4] that the application of high pressure to an acidic solution makes the solution more acidic suggests that the surface acidity of solids might also be increased by compression. Of course, the detailed mechanism of the compression of solids should be different from that of liquids, and knowledge about a liquid system under high pressure can not always be extended to a solid system under high pressure. Nevertheless, the suggestion seems worth testing experimentally.

In the experimental work in this research, several metal sulfates and potassium bisulfate served as samples. The sample material was pulverized and the powder was compressed in a piston-cylinder apparatus at a pressure of 0—3000 kg./cm$^2$. The surface acidity, the water content, and the X-ray diffraction pattern were obtained for both the compressed sample and the uncompressed one. With some samples, the acidity was increased by the compression, whereas with other samples the acidity remained unchanged. In this paper, details of the experimental results are described and some possible explanations are discussed.

## Experimental

**Apparatus.** — The apparatus used for this study was essentially a piston-cylinder device employing a hardened chromium steel piston and a cylinder assembly of stainless steel. A cross section of the apparatus is given in Fig. 1. The piston consists of a head (20 mm. diam.) and a stem (8 mm. diam.). The cylinder is assembled from a body, a bottom cover, and four sets of nuts and bolts. The body cavity, in which the piston is to be inserted, consists essentially of two concentric vertical holes; the larger hole (20.1 mm. diam.) accomodates the piston head, and the smaller hole (8.1 mm. diam.) houses the piston stem, thus permitting vertical motion of the piston head.

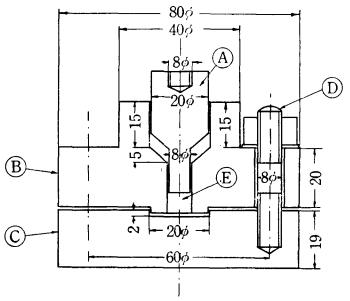

Fig. 1. A cross section of apparatus.
A: Piston B: Body
C: Bottom cover D: Bolt and nut
E: Sample room

The sample is compressed in the space bounded by the upper surface of the bottom cover, the wall of the smaller hole, and the face of the piston stem.

Pressure was applied to the piston by means of a commercial 4 ton scale oil press having two parallel beds, viz. a stationary bed and a moving bed. The load was measured by a Bourdon-gauge which is connected to the oil chamber of the press.

4) S. D. Hamann, "High Pressure Physics and Chemistry," Vol. 2, Ed. by R. S. Bradley, Academic Press, London and New York (1963), p. 148.

The pressure generated at the sample was estimated by dividing the load by the piston area (0.503 $cm^2$).

**Sapmle.** — The samples used in this study were colorless, commercial, metal sulfates (reagent grade) and potassium bisulfate (reagent grade). The material was gently pulverized in an agate mortar, and about 1 g. of the powder was packed into the sample room of the apparatus. Then, the apparatus was sandwiched between the two beds of the press, and the desired load was applied to the piston during 10 min., at room temperature. After compression, the sample was taken out from the apparatus, pulverized again, weighed and dried in a desiccator for 6 hr. Immediately after the drying,* the sample was submitted to the tests described below.

Uncompressed samples were also prepared by the above procedure but omitting the application of load.

**Surface Acidity.**—The qualitative effect of pressure on the surface acidity was observed by comparing the color of an indicator adsorbed on the sample compressed at 3000 kg./$cm^2$ with that of the same indicator adsorbed on the uncompressed sample. The comparison was carried out in the following way.

A given amount of sample powder was transferred to a 50 ml. conical flask containing 10 ml. of purified benzene. Then, several drops of an 0.1% indicator solution in benzene were added and the surface color of the sample was observed. At the same time, a similar observation was carried out with the uncompressed sample. The difference between the colors of the two samples was recorded. In this comparison, three indicators, i. e. *p*-dimethylaminoazobenzene ($pK_a$=3.3), benzeneazodiphenylamine ($pK_a$=1.5) and dicinnamalacetone ($pK_a$=−3.0) were used.

A quantitative determination of the surface acidity was carried out with four aluminum sulfate samples, compressed at 0, 1000, 2000 and 3000 kg./$cm^2$, respectively. For neutralization of the surface acid, a 1/100 or 1/1000 N solution of *n*-butylamine in benzene was used, and Benesi's method[5] was adopted to determine the quantity of *n*-butylamine required to neutralize the surface acid. In addition to the three indicators described above, phenylazonaphthylamine ($pK_a$=4.0) was also used in each of the determinations.

**Water Content.**—The content of the metal element in the desired sample was determined by a conventional chemical analysis, and on the basis of this result the water content in the sample was calculated. Six aluminum sulfate samples, compressed at 0, 1000, 2000, 3000, 4000 and 5000 kg./$cm^2$ respectively, were analyzed. Samples of magnesium sulfate, zinc sulfate, and potassium bisulfate, each compressed at 3000 kg./$cm^2$, as well as uncompressed samples of the above sulfates were similarly analyzed.

**Identification by X-Rays.**—The X-ray diffraction patterns of the powdered samples were determined with an X-ray diffractometer, employing Cu-$K\alpha$ radiation at 30 kV. and 15 mamp.** All those samples analyzed as above were used in this study.

## Results

**Surface Acidity.**—*Qualitative Results.*—Surface colors of the various samples are given in Table I; the samples are classified into three groups, i. e. I, II and III.

Potassium sulfate, barium sulfate, lead sulfate, and magnesium sulfate fall into group I. Both in the compressed and uncompressed

Table I.* Surface colors of various samples

| Indicator | *p*-Dimethylaminoazobenzene | | Benzeneazodiphenylamine | | |
|---|---|---|---|---|---|
| Pressure kg./$cm^2$ | 0 | 3000 | 0 | 3000 | |
| $BaSO_4$ | No color | No color | No color | No color | I |
| $PbSO_4$ | No color | No color | No color | No color | |
| $K_2SO_4$ | No color | No color | No color | No color | |
| $MgSO_4 \cdot 7H_2O$ | No color | No color | No color | No color | |
| $SrSO_4$ | Pink | Pink ♯ | Red | Red ♯ | II |
| $CaSO_4 \cdot 2H_2O$ | Pink | Pink ♯ | Red | Red ♯ | |
| $MnSO_4 \cdot 4H_2O$ | Pink (faint) | Pink ♯ (faint) | No color | No color | |
| $ZnSO_4 \cdot 7H_2O$ | Red | Red ♯ | Red (faint) | Red ♯(faint) | |
| $CdSO_4 \cdot 8H_2O$ | Red | Red + | Red | Red + | III |
| $Ce_2(SO_4)_3 \cdot 8H_2O$ | Red | Red + | Red (faint) | Red +(deep) | |
| $Fe_2(SO_4)_3 \cdot xH_2O$ | Red | Red + | Red (faint) | Red + | |
| $Al_2(SO_4)_3 \cdot 18H_2O$ | No color | Red + | No color | Red + | |
| $KHSO_4$ | Red | Red + | Red (faint) | Red + | |

* In this table, the mark ♯ indicates a case where the difference between the surface color of the uncompressed sample and the color of the compressed sample is uncertain, and the mark + indicates that the surface color was increased by compression.

* By the use of such a procedure reproducible experimental results were obtained.

5) H. A. Benesi, *J. Phys. Chem.*, **61**, 970 (1957).

** The following experimental conditions were used in the X-ray diffraction study: count full scale 1000 c. p. s., time constant 2 sec., scanning speed 1° 2$\theta$/min., chart speed 1.0 cm./min., divergence slit 0.2 mm., receiving slit 1.0 mm., room temperature 25°C.

states, these sulfates were nonacidic to all the indicators.

Strontium sulfate, calcium sulfate, zinc sulfate and manganese sulfate form group II. Both in the compressed and uncompressed states, all these sulfates were acidic to all the indicators, except for dicinnamalacetone, but the difference in surface color between the two states was hardly recognizable.

The surface acidity of the group III samples, i. e. cadmium sulfate, cerous sulfate, ferric sulfate, aluminum sulfate, and potassium bisulfate, was significantly increased by compression of the samples at 3000 kg./cm$^2$. A typical example of this group is aluminum sulfate. This sulfate in the uncompressed state was nonacidic, whereas in the compressed state it was acidic to all indicators except for dicinnamalacetone.

*Quantitative Results.*—Acid strength distribution curves for the aluminum sulfate samples, compressed at 1000 and 2000 kg./cm$^2$ respectively, are given in Fig. 2. The abscissa is

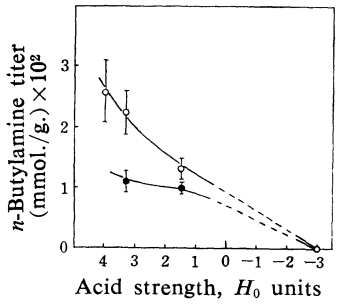

Fig. 2. *n*-Butylamine titers vs. acid strength for two aluminum sulfate samples compressed at 1000 kg./cm$^2$ (●) and 2000 kg./cm$^2$ (○), respectively.

Hammett's $H_0$ function[6] and the ordinate is the *n*-butylamine titer. The figure shows that the acid, which has appeared on the compressed aluminum sulfate, has an $H_0$ value not less than −3.0. This means that the acid on the sample surface is moderately strong. In a separate experiment, it has been shown that even by the compression at 3000 kg./cm$^2$ the $H_0$ value can not be decreased to a value less than −3.0.

The surface acidity of the aluminum sulfate sample at $H_0=3.3$ as a function of the compacting pressure is given in Fig. 3. The figure shows that the acidity is nearly proportional to the compacting pressure up to 2000 kg./cm$^2$, but beyond this pressure the increment of the acidity diminishes with increase of compacting pressure.

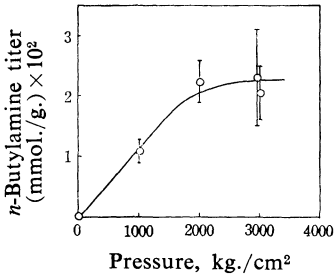

Fig. 3. *n*-Butylamine titers at $H_0=3.3$ vs. compacting pressure for aluminum sulfate.

**Water Content.**—*Aluminum Sulfate.*—The relation between the water content in the aluminum sulfate sample and the compacting pressure is given in Fig. 4 and Table II. In the figure, the water content is expressed as the number of moles of water per two gram atoms of aluminum. This figure shows a nearly proportional decrease of the water content with the compacting pressure in the range of 0—2000 kg./cm$^2$, but beyond 2000 kg./cm$^2$ the decrement of the content becomes smaller with increase of the compacting pressure, and at a pressure of 3000 kg./cm$^2$ or above, the content remains at a constant level.

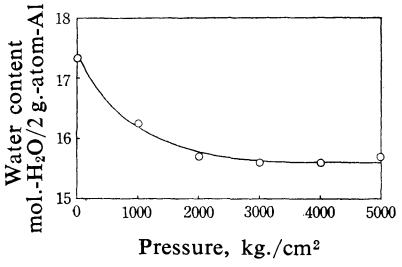

Fig. 4. Water contents of aluminum sulfate samples as a function of compacting pressure.

TABLE II. THE RATIO OF THE WATER CONTENT IN THE COMPRESSED SAMPLE TO THE WATER CONTENT IN THE UNCOMPRESSED SAMPLE

| | Pressure, kg./cm$^2$ | | | | | |
|---|---|---|---|---|---|---|
| Sulfate | 0 | 1000 | 2000 | 3000 | 4000 | 5000 |
| Aluminum sulfate | 1 | 0.94 | 0.91 | 0.90 | 0.90 | 0.91 |
| Magnesium sulfate | 1 | — | — | 0.98 | — | — |
| Zinc sulfate | 1 | — | — | 0.97 | — | — |

6) C. Walling, *J. Am. Chem. Soc.*, **72**, 1164 (1950).

*Potassium Bisulfate.*—A potassium determination showed that the potassium content, $K_0$, in the uncompressed sample is less than the content, $K$, in the compressed sample. Namely, the ratio of $K_0$ to $K$ was 0.96.

*Magnesium Sulfate and Zinc Sulfate.*—The results of the chemical analyses of a magnesium sulfate sample and a zinc sulfate sample given in Table II. For both sulfates, the water content in the compressed sample differed little from the content in the uncompressed sample.

**X-Ray Diffraction Studies.**—*Aluminum Sulfate.*—The X-ray diffraction pattern for an uncompressed aluminum sulfate sample is given in Fig. 5a. A sharp peak at $2\theta=20.1°$ was identified as the most characteristic peak of aluminum sulfate octadecahydrate. Further, each of the other main peaks, except for the peaks at $2\theta=24.8°$, 25.9°, 29°, and 36.8°, had a diffraction angle which corresponds well to the angle of the octadecahydrate, though its relative intensity against the peak height at $2\theta=20.1°$ did not strictly agree with that of the standard value.[7]

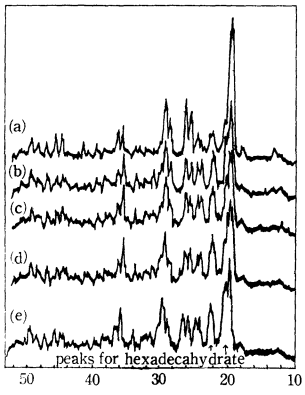

Fig. 5. X-Ray diffraction patterns for aluminum sulfate samples compressed at various pressures.
(a) Uncompressed sample
(b) 1000 kg./cm² (c) 2000 kg./cm²
(d) 3000 kg./cm² (e) 4000 kg./cm²

X-Ray diffraction patterns for aluminum sulfate samples compressed at various pressures are given in Figs. 5b—5e. Almost all the peaks which appear in Fig. 5a are also present in these patterns, though the peak at $2\theta=20.1°$ in Figs. 5b—5e has a low peak height in comparison with the corresponding peak height in Fig. 5a. Further, some peaks, especially peaks at $2\theta=20.3°$ and 22.7°, are more evident in the patterns for the compressed samples than in the pattern for the uncompressed sample. These two peaks were identified as the peaks which belong to the aluminum sulfate hexadecahydrate crystal.[8]

*Potassium Bisulfate.*—The X-ray diffraction pattern for uncompressed potassium bisulfate is given in Fig. 6a. A sharp peak at $2\theta=23°$ was identified as the most characteristic peak of potassium bisulfate. Except for some trivial peaks, e. g. peaks at $2\theta=20.2°$, 20.7°, 21.4°, 25°, and 25.6°, all of the other peaks were identified as the peaks of potassium bisulfate, though the observed diffraction angles and relative intensities against the peak at $2\theta=23°$ were somewhat irregular in comparison with the standard values.[9]

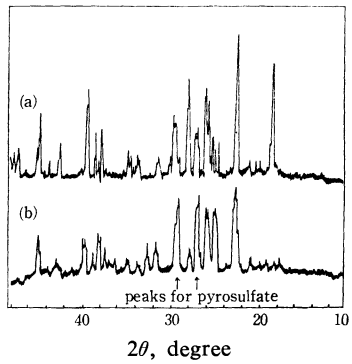

Fig. 6. X-Ray diffraction patterns for potassium bisulfate samples.
(a) Uncompressed sample
(b) Compressed sample (3000 kg./cm²)

The X-ray diffraction pattern for a compressed potassium bisulfate sample is given in Fig. 6b. In comparison with Fig. 6a, a general broadening in peak widths and reductions in peak heights for almost all peaks are seen in this figure. The most remarkable reduction in peak height is seen at $2\theta=23°$. Only a few peaks, e. g. peaks at $2\theta=25.3°$, 27.4° and 29.5°, are more evident in Fig. 6b than the corresponding peaks in Fig. 6a.

*Magnesium Sulfate and Zinc Sulfate.*—X-Ray diffraction patterns for an uncompressed magnesium sulfate sample and a compressed magnesium sulfate sample are given in Figs. 7a and 7b, respectively. In both figures sharp peaks due to magnesium sulfate heptahydrate are present, and small differences in the diffraction angle, in the relative intensity, and in Fig. 7b can be recognized.

X-Ray diffraction patterns of an uncompressed zinc sulfate sample and a compressed zinc sulfate sample are given in Figs. 8a and

8b, respectively. There are some differences between these two figures. However, no evidence for the appearance of a new substance in the compressed sample can be seen from an inspection of Fig. 8b.

## Discussion

A brief survey of the experimental results presented in Table I might give the impression that the presence of a large quantity of crystallization water in the original material is the cause of the increase in acidity on compression. However, this impression is incorrect since the surface acidity of potassium bisulfate, which has no crystallization water in its original state, was increased markedly by compression.

Dehydration of the sample on compression seems to correlate with the acidity change on compression. For example, as can be seen from Table II, analysis of the aluminum sulfate samples, which showed a typical increase in acidity on compression, indicates that a considerable amount of water has disappeared from the compressed sample. Further, as is seen in Fig. 3 and Fig. 4, the relation between the water content of the aluminum sulfate sample and the compacting pressure parallels the relation between the acidity at $H_0=3.3$ and the compacting pressure.

The dehydration from the compressed aluminum sulfate samples might also be proved by the results of X-ray diffraction studies. Namely, X-ray diffraction patterns in Figs. 5b—5e show that the compressed aluminum sulfate sample is composed of aluminum sulfate octadecahydrate and aluminum sulfate hexadecahydrate, whereas Fig. 5a shows that the uncompressed aluminum sulfate sample may be regarded as a single phase which is composed of aluminum sulfate octadecahydrate. Irregularities* recognized in Fig. 5a are trivial, and they may be ignored in this discussion. Thus, it seems to be plausible to consider that the hexadecahydrate was formed through compression of the original octadecahydrate by the reaction

$$Al_2(SO_4)_3\cdot 18H_2O \rightarrow Al_2(SO_4)_3\cdot 16H_2O + 2H_2O \qquad (1)$$

It is well known that this sort of reaction can occur under a high pressure.[10]

With the aluminum sulfate sample, an interesting fact was deduced from a comparison of the results of the X-ray diffraction study and chemical analysis. Namely, as is seen in Fig. 4, at about 1300 kg./cm² or above, the water content in the compressed aluminum sulfate sample is less than 16, which corresponds to the number of moles of water in one mole of pure hexadecahydrate, whereas the X-ray diffraction pattern indicated that crystallites of the octadecahydrate and the hexadecahydrate coexist in the compressed sample. This leads to a contradiction, if the compressed sample is regarded as a mixture of these two hydrates with their pure forms. Therefore, a nonstoichiometric water content in either the octadecahydrate or the hexadecahydrate, or in both hydrates, must be assumed in order that the result of the X-ray diffraction study be compatible with the result of the chemical analysis. The surface property of a solid is often attributed to its nonstoichiometric composition, or a defective structure of the surface. Similarly, the deficiency of water in the compressed

10) S. D. Hamann, "Physico-Chemical Effects of Pressure," Butterworths Scientific Publications, London (1957), p. 208.

* Preferred orientations of cleavage planes by compression or structural changes of sample materials by air moisture etc. might be considered as the cause of irregularities of X-ray diffraction patterns of aluminum sulfate sample or other samples.

aluminum sulfate sample is suspected to play an important role in the appearance of acid centers on the surface of this sulfate.

A dehydration from the compressed potassium bisulfate sample is also possible, though this sample has no crystallization water in its original state. For instance, a dehydration through the reaction

$$2KHSO_4 \rightarrow K_2S_2O_7 + H_2O \qquad (2)$$

might occur, because the equivalent volume* of potassium bisulfate is 121.6, and the values for potassium pyrosulfate and water are 112 and 18 respectively, hence, according to Le Chatelier's principle, in a system where liberated water can escape out of the system, a shift of the equilibrium of the reaction 2 towards the right may be expected.

Indirect evidence for the occurrence of reaction 2 can be seen in the results of chemical analysis. Namely, the potassium content of the compressed potassium bisulfate sample is larger than that of the uncompressed sample, indicating that some of the original constituents, presumably water, have disappeared during compression.

The results of the X-ray diffraction study give additional evidence for the dehydration from the compressed potassium bisulfate sample. As is seen in Fig. 6b, the peak at $2\theta=23°$ is broad and low in comparison with the corresponding peak in Fig. 6a. This shows that compression has caused partial destruction of the original crystal structure. Further, the peaks at $2\theta=27.4°$ and 29.5° in Fig. 6b are more evident than the corresponding peaks in Fig. 6a. These two peaks were identified as the peaks of potassium pyrosulfate, though a minor deviation of the diffraction angle from the standard value[11] exists for each peak.

In contrast to the cases where the surface acidity was increased by compression, in cases where the acidity was not altered by compression, only minor dehydration of the compressed sample had occurred and changes in the crystal structure were trivial.

For instance, as is seen in Table II, the difference between the water contents of the compressed and the uncompressed samples of magnesium sulfate is slight. Further, the X-ray diffraction patterns in Figs. 7a and 7b show that little change in the crystal structure has resulted from compression of the magnesium sulfate. These results correspond well with the fact that the surface acidity of this sulfate was not increased by compression. In addition, Figs. 7a and 7b show that well developed crystallites of magnesium sulfate heptahydrate exist in both the compressed and the uncompressed samples, from which it can be concluded that surface defects would be sparse in both samples. This supposition is consistent with the result of the previous discussion in which the surface acidity of the compressed sample was interpreted in terms of a surface defect.

As is seen in Table II, the water content in the compressed zinc sulfate sample is only slightly different from that in the uncompressed sample. Thus, the small effect of pressure on the surface acidity of this sulfate may be attributed to the small extent of dehydration in the compressed sample.

On the other hand, as is seen in Figs. 8a and 8b, there are small differences in the X-ray diffraction patterns of the uncompressed and the compressed zinc sulfate samples; the former pattern has two sharp peaks at $2\theta=16.7°$ and 25.8°, while in the latter pattern these two peaks are broad and low. From this result, some differences in the surface acidities of the two samples might be expected. However, the expected increase in surface acidity could hardly be recognized from a color comparison. This apparent discrepancy may be partly ascribed to the existence of a considerable amount of surface acidity in the original sample, and partly to the small extent of dehydration in the compressed sample. Namely, any small increase in the surface acidity would be insignificant compared to the original high surface acidity of the sample and would not be detected simply by an indicator color change.

The surface acidity of the original zinc sulfate sample may be explained in terms of the X-ray diffraction data. As is seen in Fig. 8a, the peak at $2\theta=21.1°$ is low. If the uncompressed zinc sulfate has a perfect crystal structure, this peak should be the highest.[12] Therefore, it appears that the crystal structure of the uncompressed zinc sulfate is imperfect. As noted previously, imperfect crystal structures may be a cause of surface acidity.

Previously, Kiyama and Yanagimoto[13] reported that neither the chemical composition nor the crystal structure of calcium sulfate dihydrate was altered by compression. As might have been predicted from their results, compression of calcium sulfate dihydrate did not cause any change in its surface acidity (see Table I).

* The equivalent volume is defined by the following formula (Molec. wt./Specific wt.)×(No. of mol. of a reactant or a product in the stoichiometric eq.). (cf. Ref. 10).

**Summary**

Compression of potassium bisulfate and certain other metal sulfate has been shown to cause an increase in their surface acidities. This increase in surface acidity has been correlated with dehydration of the compressed sample, and X-ray diffraction studies have revealed that dehydration is accompanied by minor structural changes involving the formation of a less hydrated substance.

In those sulfates where compression produced little or no change in the surface acidity, the extent of the dehydration from the compressed sample was meager, and X-ray diffraction studies proved that neither the formation of a new substance nor a great change in the crystal structure resulted from the compression.

# Initial Stage of the Oxidation Reaction of Polyethylene by Nitrogen Dioxide

By Taeko OGIHARA, Soji TSUCHIYA and Kenji KURATANI

(Received September 24, 1964)

In a previous paper,[1] the oxidation of polyethylene by nitrogen dioxide was investigated by means of infrared absorption spectroscopy, and the production of nitro, nitrite ester, nitrate ester, carbonyl and hydroxyl groups in polyethylene was recognized. The nitro and nitrite ester groups were produced in the early stage of the degradation by the addition of nitrogen dioxide to the reaction site in polyethylene, and then the nitrate ester, carbonyl and hydroxyl groups were formed as the decomposition products of the nitrite ester group. In that paper, however, no explanation was given of the nature of the reaction sites to which nitrogen dioxide reacted. The present report will attempt to clarify the reaction mechanism in the initial stage of the oxidation reaction of polyethylene by nitrogen dioxide. Particularly, an effort has been made to find out what structure in polyethylene is active in reacting with nitrogen diaxide.

## Experimental

The following polyethylenes were used: 1) high pressure polyethylene (HPE), relatively highly-branched polyethylene, called Yukalon, the molecular weight of which as obtained viscosity measurement, was 34000; 2) Phillips-type polyethylene (PhPE), very little-branched polyethylene, called Sholex, the molecular weight of which, as determined by the end group analysis of the infrared spectrum, was 13000; 3) Ziegler-type polyethylene (ZPE), called Hizex, the molecular weight of which as obtained by melt viscosity measurement, was 76000. None of them contained an anti-oxidant. A commercially-available polypropylene called Carlna, was used, from it an anti-oxidant was extractd by propyl alcohol.

The procedure of the reaction of polymers with nitrogen dioxide was the same as that reported in the earlier work.[1] The reaction temperature was 25—120°C, and the partial pressure of nitrogen dioxide in the reaction vessel was 1/3 atm.

Commercial *n*-heptane, decene-1, heptene-2 and 2-ethylhexene-1 were used and purified by fractional distillation. The reaction of the above alkenes with nitrogen dioxide was carried out in the medium of *n*-heptane as follows: the *n*-heptane solution of nitrogen dioxide was added to the *n*-heptane solution of the sample, and the reaction between the sample and nitrogen dioxide was allowed to proceed at 25°C, while the mixture was shaken for an hour. The infrared spectra of the reaction products in the solution of *n*-heptane were measured. Under these conditions, nitrogen dioxide did not react with *n*-heptane. The reaction of *n*-eicosane with nitrogen dioxide was carried out in a sealed tube at 25 and 100°C. The reaction products were dissolved in *n*-octane, washed by an aqueous sodium hydrogen carbonate solution, and water, and dried by sodium sulfate. The products obtained were identified by infrared absorption spectroscopy. Since the infrared spectra of the reaction products of those low molecular hydrocarbons were observed in the solution of *n*-heptane or *n*-octane, the wave number shift of the absorption peak due to the solvent effect was assumed to be similar to that of the reaction products in polyethylene.

1) T. Ogihara, This Bulletin, 36, 58 (1963).

The infrared spectra were measured by Perkin Elmer model 13 and Hitachi EPI-S spectrometers, equipped with NaCl and $CaF_2$ prisms. As the absorption band of the nitro group produced by the reaction was a doublet or had a complex shape, the absorption intensity of the band was of an apparent value. In the present experiment, the absorption intensity of the nitro group produced in polyethylene was the one relative to that of the C-H stretching absorption at 2650 $cm^{-1}$, i.e., $D(\nu_{NO_2})/D(2650\,cm^{-1})$; therefore, this value represented the absorption intensity of the nitro group formed in a polyethylene film of a constant thickness.

## Results and Discussion

Figures 1 and 2 show the absorption band of the N-O anti-symmetric stretching of the nitro group produced by the reaction. The wave number of the band depends on the reaction temperature and on the sample used. It may be seen in Figs. 1 and 2 that the absorption band of the nitro group formed by

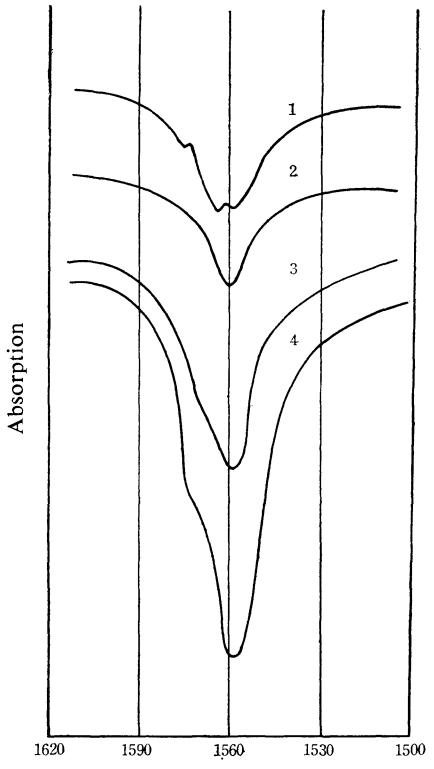

Fig. 1. Absorption band of the anti-symmetric vibration of the nitro group produced in HPE.
The samples are 1: HPE which was heated to 380°C in the atmosphere of nitrogen gas for 1 hr., and 2, 3, 4: untreated HPE. The reaction conditions were 1, 2: 25°C, 0.5 hr., 3: 80°C, 0.5 hr., 4: 109°C, 0.5 hr.

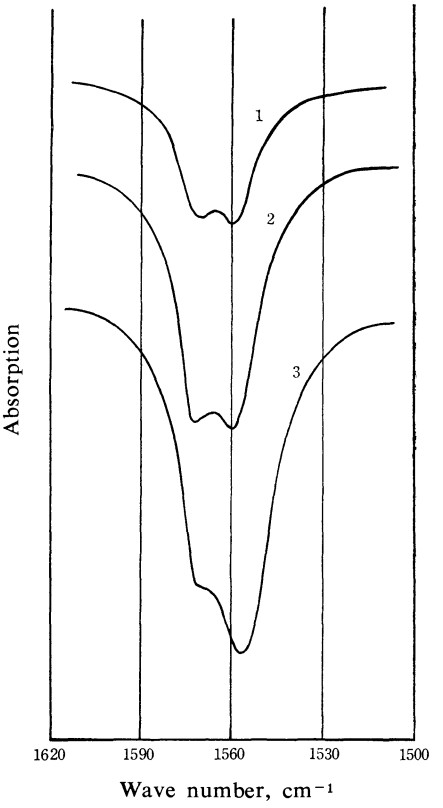

Fig. 2. Absorption band of the anti-symmetric vibration of the nitro group produced in PhPE.
The reaction conditions were 1: 25°C, 0.5 hr., 2: 80°C, 0.5 hr., 3: 120°C, 0.5 hr.

the reaction has two peaks, i.e., in the region A (1555—1560 $cm^{-1}$) and in the region B (1568—1570 $cm^{-1}$). The results are summarized in Table I. All of the polyethylene used, when treated with nitrogen dioxide at various temperatures, showed the absorption peak in the region A. The B absorption band of the nitro group was found in Phillips-type polyethylene (PhPE) oxidized by nitrogen dioxide at both 25 and 120°C. On the contrary, the B band appeared in high-pressure polyethylene (HPE) oxidized above 100°C, while no absorption peak in the region B was observed in HPE treated with nitrogen dioxide at 25°C.

The rate of increase in the absorption intensity of the nitro group formed in PhPE and HPE is given in Fig. 3 as a function of the reciprocal of the reaction temperature. The increment of the rate obtained against the reciprocal of the reaction temperature was not constant in the temperature range of the present experiment; i.e., the negative slope at a high temperature was steeper than that at a low temperature.

TABLE I. WAVE NUMBER OF THE ANTI-SYMMETRIC VIBRATION OF THE NITRO GROUP IN THE REACTION PRODUCTS

| Sample* | Reaction temp. and time | | Wave number of absorption peak | |
|---|---|---|---|---|
| | | | Region A | Region B |
| | °C | hr. | $cm^{-1}$ | $cm^{-1}$ |
| HPE | 25 | 0.5 | 1557 | — |
| | 109 | 0.5 | 1555 | 1568 |

* HPE : high pressure polyethylene.
Degraded HPE : HPE which was heated to 380°C in the atmosphere of nitrogen gas for 1 hr.
PhPE : Phillips type polyethylene.
ZPE : Ziegler type polyethylene.

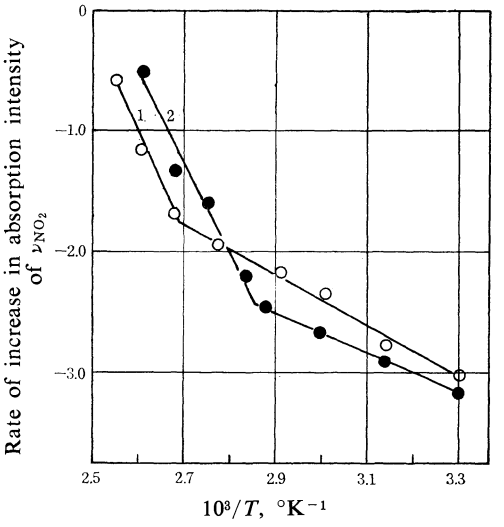

Fig. 3. Rate of increase in the absorption intensity of the nitro group formed in polyethylene. Increasing rate is represented by $\ln d\{D(\nu_{NO_2})/D(2650\,cm^{-1})\}/dt$ $hr^{-1}$.
1 : PhPE, 2 : HPE

The absorption intensity of the nitro groups in PhPE and HPE reached a maximum value in a certain reaction time when the reaction with nitrogen dioxide was carried out at 25°C, as may be seen in Fig. 4. However, the

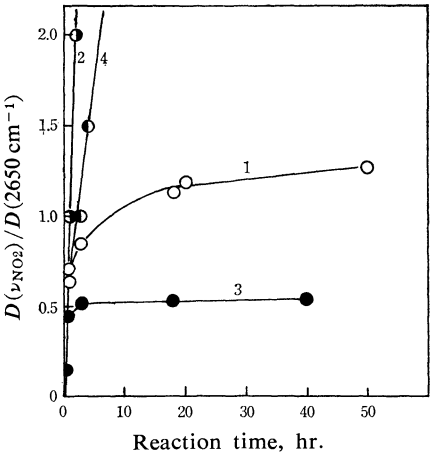

Fig. 4. Rate of formation of the nitro group in polyethylene.
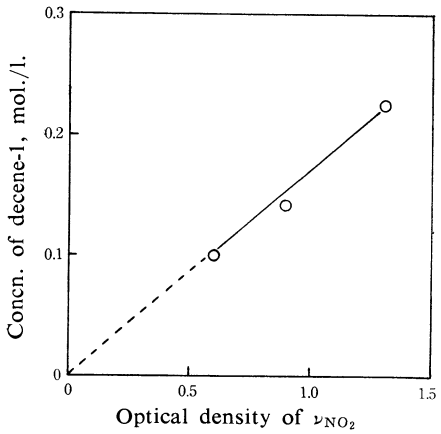
1 : PhPE at 25°C, 2 : PhPE at 100°C, 3 : HPE at 25°C, 4 : HPE at 100°C

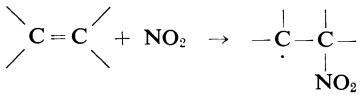
absorption intensity of the nitro group increased at an almost constant rate at a high temperature, and the obtained intensity was much larger than that obtained at a low temperature. These results show that the reaction mechanism of polyethylene with nitrogen dioxide at a high temperature differs from that at a low temperature. First, the reaction at low temperature will be discussed.

**The Addition Reaction of Nitrogen Dioxide with a Double Bond in Polyethylene.** — The absorption intensity of the nitro group which was formed by the reaction with nitrogen dioxide at 25°C did not exceed a certain value, even if a specimen of polyethylene was placed in contact with nitrogen dioxide for a long time, as Fig. 4 shows. This indicates that only a limited number of reaction sites which are active in reacting with nitrogen dioxide at 25°C exist in polyethylene.

The nitro group was not formed in *n*-eicosane (*n*-$C_{20}H_{42}$), which was left alone in an atmosphere of nitrogen dioxide at 25°C for 24 hr. or longer. Therefore, nitrogen dioxide did not react with the main methylene chain in polyethylene at 25°C. It is well known that polyethylene contains a small amount of structural irregurarity in the main chain, e. g., branchings and double bonds. Nitrogen dioxide, which has an odd electron, easily undergoes the addition reaction with double bonds in olefin. Decene-1, heptene-2 and 2-ethylhexene-1, all of which had double bonds at various positions, reacted with nitrogen dioxide at 25°C, and the products had an absorption band of the nitro group, while the absorption band due to the out-of-plane vibration of a double bond disappeared in the

infrared absorption spectra of the products. In that case, after all of the double bonds in the olefin solution had disappeared as a result of the addition reaction of nitrogen dioxide, the absorption intensity of the nitro group in the products retained a constant value even if a longer reaction time and a higher concentration of nitrogen dioxide were adopted. That is, there is a linear relationship between the absorption intensity of the nitro group in the products and the initial amount of olefin in the solution. This is illustrated in Fig. 5. Furthermore, polypropylene, in which double bond was not identified by the infrared spectroscopy, did not react with nitrogen dioxide at 25°C, and no formation of the nitro group could be observed.





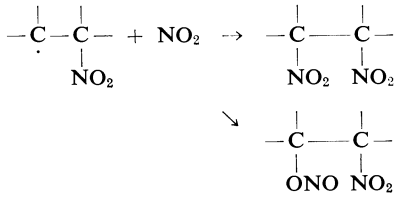


Fig. 5. Relationship between the concentration of decene-1 and the absorption intensity of the nitro group produced. The infrared spectra were measured in *n*-heptane solution and the absorption cell of 0.098 mm. in thickness.

Therefore, it can be concluded that the reaction sites, which react with nitrogen dioxide at 25°C, are double bonds in polyethylene. The nitro group is formed in polyethylene by the addition of nitrogen dioxide to the double bond. Gray and Yoffe have proposed the following mechanism of the addition reaction of nitrogen dioxide with a low molecular olefin[2] first, the nitro group is formed by the reaction:

and the radical produced is subjected to the further addition of nitrogen dioxide:

The products are dinitro and nitro-nitrite compounds in almost equal amounts, and the proportion of the nitro to the nitrite ester group of the products is 3 : 1. This explanation is compatible with the present experimental observation that the absorption intensity of the nitrite ester group is much smaller than that of the nitro group in polyethylene treated with nitrogen dioxide at 25°C. However, a quantitative discussion of the number of the nitro group produced from one double bond in polyethylene is difficult as a result of the complex shape of the absorption band of the nitro group. The nitrite ester group is unstable, and it often changes into a nitrate or carbonyl group, as has already been mentioned.[1]

Figure 6 shows the absorption band of the nitro group which has been produced in decene-1, heptene-2 and 2-ethylhexene-1 by the addition of nitrogen dioxide to their double bonds at 25°C. The absorption band of the nitro group formed in decene-1 had two peaks, at 1562 and 1568 $cm^{-1}$; a similar finding was obtained regarding the absorption band of the nitro group in PhPE, which underwent the addition reaction with nitrogen dioxide at 25°C, as Fig. 2 shows. This can be explained by the fact that most of the double bonds in PhPE are positioned at the terminals of the polymer chains;[3] that is, the double bond in PhPE is of the vinyl type and exactly the same as decene-1. Therefore, the reaction products of PhPE with nitrogen dioxide can be expected to have the same structure as those of decene-1; in other words, it gives the same infrared absorption spectrum. It may be seen in Figs. 1, 2 and 6 that no example of a doublet absorption band of the nitro group, which has been found in the reaction products at 25°C, exists except for the reaction products of PhPE and decene-1. This leads to the conclusion that the absorption band, in which two peaks are observed in the wave number regions A and B is characteristic of the additional reaction product of nitrogen dioxide to the double bond of the terminal vinyl-type in polyethylene. The wave number of the absorption band of the primary nitro compound is slightly larger than that of the secondary or tertiary one.[4] This is probably one of the reasons why the

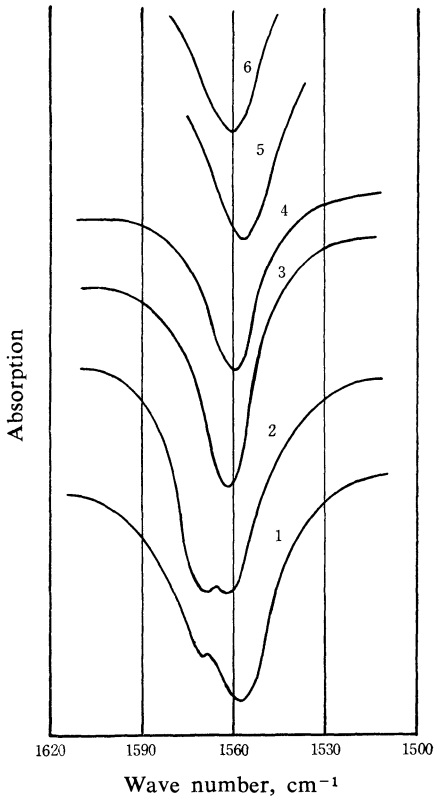

Fig. 6. Absorption band of the anti-symmetric vibration of the nitro group produced in low molecular compounds.
1 : *n*-eicosane, treated with nitrogen dioxide at 100°C for 24 hr., 2 : decene-1, 25°C, 1 hr., 3 : 2-ethylhexene-1, 25°C, 1 hr., 4 : heptene-2, 25°C, 1 hr., 5 : 2-nitropropane, 6 : 1-nitropropane.

nitro group produced in the terminal double bond has two absorption peaks in the regions A and B. Another conceivable reason is the coupling of the $NO_2$ anti-symmetric stretching vibration of the two nitro groups at the chain terminal. This coupling causes the splitting of the two nitro group vibrations.

The absorption band of the nitro group, which was produced in HPE by the reaction at 25°C, had only one peak in the region A. The same result was obtained in the reaction products of heptene-2 and 2-ethylhexene-1, when nitrogen dioxide was added at 25°C. This result is reasonable, since most of the double bonds in HPE are vinylene and vinylidene in type.[3] The dinitro compound obtained from the double bond of the vinylidene type may have primary and tertiary nitro groups, while only one absorption peak in the region A has been observed here. No satisfactory explanation for this fact has been obtained in the present experiment.

Ziegler-type polyethylene (ZPE) has double bonds of the above-mentioned three types,[3] while the absorption band of the nitro group produced in ZPE has two peaks in the regions A and B as Table I shows. However, the absorption intensity of the B band was smaller than that of the A band, since the nitro group produced from double bonds of vinylene and vinylidene types contributed only to the A band.

Though the nitro group produced in HPE at 25°C had no infrared absorption peak in the region B, a specimen of HPE showed a small absorption peak in the region B when heated to 380°C for 1 hr. in an atmosphere of nitrogen gas and reacted with nitrogen dioxide at 25°C after cooling, as is shown in Fig. 1. This result can be interpreted by means of the fact that double bonds of the vinyl-type are formed at the terminal of the polyethylene chain, probably as a result of the scission of the polymer chain.

**Hydrogen Abstraction Reaction by Nitrogen Dioxide.**—At a high reaction temperature, the absorption intensity of the nitro group formed in polyethylene was much stronger than that at a low temperature, and it increased linearly with the reaction time, as may be seen in Fig. 4. This finding shows that the reaction site of polyethylene is not double bond, which exists in a limited amount in polyethylene. Both *n*-eicosane and polypropylene, which did not react with nitrogen dioxide at 25°C, produced the nitro group by the reaction at a high temperature. Therefore, it is evident that the reaction site, which has not existed originally in polyethylene, is formed by nitrogen dioxide at a high temperature. The reaction site cannot be expected to be formed by the thermal decomposition of polyethylene at the present reaction temperature. However, it is probable that the hydrogen atom is abstracted by nitrogen dioxide from polyethylene and that the free radical thus produced becomes the reaction site for the addition reaction of nitrogen dioxide.

In the reaction of PhPE with nitrogen dioxide at a high temperature, both A and B absorption bands of the nitro group were observed, while the intensity of the A absorption band was much stronger than that of the B band. The absorption intensity of the A band increased as the reaction temperature was raised, as may be seen Fig. 2. This means that the hydrogen atom in the methylene chain in the polymer is abstracted and that the radical so produced reacts with nitrogen dioxide to form the secondary nitro group, which has an infrared absorption peak only in the region A. Similarly, the increase in the

absorption intensity of the A band was observed in the reaction of HPE at 110°C, where the absorption shoulder in the region B was found as shown in Fig. 1. This is considered to be due to the formation of the nitro group bonded to the terminal carbon atom of the polymer chain; it can be explained by the assumption that the scission of the polymer chain occurs in the process of the oxidation by nitrogen dioxide.

In the initial stage of the reaction with nitrogen dioxide at a high temperature, the following reactions are conceivable:

$$RH + NO_2 \xrightarrow{k_1} R + HNO_2 \quad (1)$$

$$R + NO_2 \xrightarrow{k_2} RNO_2 \quad (2)$$

$$R + NO_2 \xrightarrow{k_3} RONO \quad (3)$$

where reaction 1 represents the formation of the free radical as the result of the abstraction of the hydrogen atom from polyethylene by nitrogen dioxide. Nitrogen dioxide adds immediately to the radical produced, and the nitro and nitrite ester groups are formed by reactions 2 and 3. In reactions 1—3, the rate-determining step is reaction 1, since the radical recombination rate of reactions 2 and 3 are considered to be fast. The thermal decomposition of the nitro group does not occur in the temperature range of the present experiment, so that the information about the rate of reaction 1 can be obtained by the measurement of the concentration of the nitro group produced in polyethylene. In the present experiment, the increasing rate of the absorption intensity of the nitro group was observed to be independent of the film thickness in the 0.05—0.2 mm. range, where the absorption intensity of the nitro group was relative to that of the 2650 $cm^{-1}$ band and the effect of film thickness was removed. Therefore, it can be assumed that the diffusion of nitrogen dioxide into a polyethylene film has no considerable effect on the rate of the reaction.

The rate of the formation of the nitro group is represented by the following equation:

$$d[RNO_2]/dt = k_1[RH][NO_2]/\{1 + (k_3/k_2)\}$$

where $k_1$, $k_2$ and $k_3$ are the rate constants of reactions 1, 2 and 3 respectively, and a steady condition is assumed. It has been reported in a previous paper[5] that the ratio of the nitro to the nitrite ester group formed in the reaction at 100°C is about 2:1; it is reasonable to consider that this ratio does not vary upon a small change in the reaction temperature. Therefore, $k_3/k_2$ can be assumed to be independent of the reaction temperature. Figure 3 shows the increasing rate of the absorption intensity of the nitro group in the initial stage of the reaction. Here the absorption intensity of the nitro group is approximately proportional to the concentration of the nitro group in polyethylene, and it is further assumed that polyethylene and nitrogen dioxide exist in excess in the reaction system. As has already been mentioned, it may be seen in Fig. 3 that the slope of the straight line in the high temperature region differs from that in the low temperature region. The former slope corresponds to the activation energy of the hydrogen abstraction reaction by nitrogen dioxide, while the latter corresponds to that of the addition reaction of nitrogen dioxide to the double bonds contained in polyethylene.

The apparent activation energy obtained is shown in Table II. The present value of the activation energy is not very accurate, because a number of samples should be used in following the reaction process at a given temperature and so it has been difficult to obtain the complete reproducibility of the reaction. However, the activation energy of the hydrogen abstraction reaction from HPE or ZPE seems smaller than that of PhPE. This is perhaps due to the existence of branching in the polymer chain of HPE or ZPE. Harnsberger[6] obtained the activation energy of the overall reaction, $CH_4 + NO_2 \rightarrow CH_3NO_2$, as 21 kcal./mol. Semenov's empirical formula[7] to obtain the activation energy of the hydrogen abstraction reaction gives a value of 19 kcal./mol. in the $C_3H_8 + NO_2 \rightarrow iso\text{-}C_3H_7 + HNO_2$ reaction. Compared with these values, the present result is considered to be reasonable. Of course, it is

Table II. Apparent activation energy in kcal./mol.*

| Sample** | Hydrogen abstraction reaction | Addition reaction with double bond |
|---|---|---|
| HPE | 14 | 2 |
| PhPE | 17 | 4 |
| ZPE | 14 | 2 |
| Polypropylene | 15 | — |

* The error in activation energy is about ±2 kcal./mol.

** See Table I for abbreviations.

unlikely that the present experimental value is the activation energy of the elementary reaction, because the present reaction system is not homogeneous and many assumptions are made.

## Conclusion

The reaction mechanism in the initial stage of the reaction between polyethylene and nitrogen dioxide differs with the reaction temperature. At room temperature, nitrogen dioxide adds to the double bond which exists originally in polyethylene, and dinitro or nitro-nitrite compounds are produced. At a high temperature, above 100°C, in addition to the above reaction, nitrogen dioxide reacts with the methylene chain of polyethylene. That is, the reaction is initiated by the hydrogen abstraction from polyethylene, and the free radicals produced undergo the combination reaction with nitrogen dioxide. The activation energy of hydrogen abstraction reaction by nitrogen dioxide is estimated to be 14—17 kcal./mol. on the basis of the measured data of the absorption intensity of the nitro group.

# Formation Constants of Sulfato, Acetato and Sulfatoacetato Complexes of Copper(II) at Ionic Strength 1.0

By Nobuyuki TANAKA, Yu SAITO and Hiroshi OGINO

(Received November 6, 1964)

In the previous papers,[1,2] new polarographic methods were presented for the determination of the formation constants of metal acetato complexes. They were based on the quantitative analysis of the effect of acetate ions on the equilibria of the reaction,

$$M + L \rightleftarrows ML$$

or $$M + M'L \rightleftarrows ML + M'$$

where L represents a suitable complex-forming substance such as nitrilotriacetate or ethylenediaminetetraacetate.

The method was extended to the analysis of the effects of acetate ions and co-existing ions Z on the equilibria of the first reaction to determine the formation constants of the complexes with Z ions and those of the mixed ligand complexes with acetate and Z ions.[3,4]

In this study, the method in which the equilibrium of the second reaction is used has been developed and it has been applied to the determination of the formation constants of copper(II) complexes with acetate and/or sulfate ions.

The formation constants of sulfatocopper(II) complexes have been reported by Fronaeus[5,6] and by Näsänen and Lumme[7] and that of sulfatoacetatocuprate(II) by Fronaeus.[5] The values obtained in this study have been compared with those data.

## Theoretical

Let us consider the acetate buffer solution which contains two different metal ions, $M^{m+}$ and $M'^{m'+}$, and ethylenediaminetetraacetate (EDTA) ions and co-existing ions Z. There exist the following equilibria:

$$M^{m+} + M'Y^{(m'-4)+} \rightleftarrows MY^{(m-4)+} + M'^{m'+} \quad (1)$$

$$MY^{(m-4)+} + H^+ \rightleftarrows MHY^{(m-3)+} \quad (2)$$

$$M'Y^{(m'-4)+} + H^+ \rightleftarrows M'HY^{(m'-3)+} \quad (3)$$

$$M^{m+} + i\,OAc^- + j\,Z^{z-} \rightleftarrows M(OAc)_i(Z)_j^{(m-i-zj)+} \quad (4)$$

$$M'^{m'+} + i'OAc^- + j'Z^{z-} \rightleftarrows M'(OAc)_{i'}(Z)_{j'}^{(m'-i'-zj')+} \quad (5)$$

1) N. Tanaka and K. Kato, This Bulletin, **32**, 516 (1959).
2) N. Tanaka and K. Kato, ibid., **33**, 417 (1960).
3) N. Tanaka and H. Ogino, ibid., **34**, 1040 (1961).
4) N. Tanaka, Y. Saito and H. Ogino, ibid., **36**, 794 (1963).
5) S. Fronaeus, Diss. Lund (1948); *Acta Chem. Scand.*, **4**, 72 (1950).
6) S. Fronaeus, ibid., **5**, 859 (1951).
7) R. Näsänen and P. Lumme, ibid., **5**, 13 (1951).

where $Y^{4-}$ means a completely dissociated EDTA anion and $Z^{z-}$, a co-existing ion such as sulfate. As was mentioned previously,[3] the concentrations that can be determined from the polarographic measurement are $[M^{m+}]_{app}$ and $[M'^{m'+}]_{app}$ given by the equations,

$$[M^{m+}]_{app} = \sum_{i=0}^{n}\sum_{j=0}^{p} M(OAc)_i(Z)_j^{(m-i-zj)+} \quad (6)$$

$$[M'^{m'+}]_{app} = \sum_{i'=0}^{n'}\sum_{j'=0}^{p'} M'(OAc)_{i'}(Z)_{j'}^{(m'-i'-zj')+} \quad (7)$$

respectively.

In the present case when the equilibria given by Eqs. 1 to 5 are dealt with, the following equations were obtained by the procedure which is a combination of the procedure for Eq. 14 in Ref. 2 and that for Eq. 13 in Ref. 3 and by replacing $\beta$ and $\beta'$ by $\alpha_{MHY}$ and $\alpha_{M'HY}$ respectively.

$$\frac{1}{K^{M}_{M'app}}\sum_{i'=0}^{n'}\sum_{j'=0}^{p'} K_{M'(OAc)_{i'}(Z)_{j'}}[OAc^-]^{i'}[Z^{z-}]^{j'} = \frac{\alpha_{M'HY}}{\alpha_{MHY}K^{M}_{M'}}\sum_{i=0}^{n}\sum_{j=0}^{p} K_{M(OAc)_i(Z)_j}[OAc^-]^i[Z^{z-}]^j \quad (8)$$

$$K^{M}_{M'app} = \frac{[M'^{m'+}]_{app}\{[MY^{(m-4)+}]+[MHY^{(m-3)+}]\}}{[M^{m+}]_{app}\{[M'Y^{(m'-4)+}]+[M'HY^{(m'-3)+}]\}} \quad (9)$$

$$K^{M}_{M'} = \frac{[M'^{m'+}][MY^{(m-4)+}]}{[M^{m+}][M'Y^{(m'-4)+}]} \quad (10)$$

$$\alpha_{MHY} = 1 + K^{H}_{MHY}[H^+],\ \alpha_{M'HY} = 1 + K^{H}_{M'HY}[H^+] \quad (11)$$

where $K_{M(OAc)_i(Z)_j}$ and $K_{M'(OAc)_{i'}(Z)_{j'}}$ represent the overall formation constants of $M(OAc)_i(Z)_j^{(m-i-zj)+}$ and $M'(OAc)_{i'}(Z)_{j'}^{(m'-i'-zj')+}$, respectively.

Under the condition that $[M]_t + [M']_t > [EDTA]_t$ where subscript t means the total concentration of the species, the concentration of the uncombined EDTA is negligibly small as compared with those of other species in the solution, and consequently $K^{M}_{M'app}$ given by Eq. 9 is obtained by the determination of either $[M^{m+}]_{app}$ or $[M'^{m'+}]_{app}$.

Equation 8 is rewritten as,

$$F_0 = \frac{\alpha_{M'HY}}{\alpha_{MHY}K^{M}_{M'}}\sum_{i=0}^{n}\sum_{j=0}^{p} K_{M(OAc)_i(Z)_j}[OAc^-]^i[Z^{z-}]^j \quad (8')$$

where the left-hand side of Eq. 8 is replaced by $F_0$. The values of $F_0$ are calculated with the known values of $K_{M'(OAc)_{i'}(Z)_{j'}}$ and the $K^{M}_{M'app}$ values which are determined at the given pH, the given ionic strength and various concentrations of acetate and $Z^{z-}$ ions. Equation 8' is essentially the same as the $F_0$ function reported previously.[3] Therefore, all of $K_{M(OAc)_i(Z)_j}$ can, at least theoretically, be determined by means of the same procedure reported previously.[3] On the other hand, when the formation constants of $M(OAc)_i(Z)_j^{(m-i-zj)+}$ are known, similar relations are derived, and the values of $K_{M'(OAc)_{i'}(Z)_{j'}}$ can also be determined by the same procedure as for those of $K_{M(OAc)_i(Z)_j}$.

## Experimental

**Reagents.**—Preparations and standardizations of the solutions of copper(II) nitrate, nickel(II) nitrate and ethylenediaminetetraacetate were made in principle by the same procedures as described in the previous paper.[2] A solution of sodium sulfate was prepared from the guaranteed grade reagent, and the sulfate concentration was determined by the conventional gravimetric method.[8] All other chemicals used were of an analytical reagent grade.

**Apparatus and procedure.**—A Yanagimoto PB-4 pen-recording polarograph was used for the measurement of the current-voltage curves. All measurements were made in the acetate buffer solutions of pH 4.74±0.02 containing sulfate, copper(II), nickel(II) and EDTA at 25°C and ionic strength 1.0. The ionic strength was adjusted with sodium perchlorate. Total concentrations of copper(II), nickel(II) and EDTA were $1.00_6\times10^{-3}$ M, $9.9_0\times10^{-4}$ M and $1.10_8\times10^{-3}$ M respectively. Gelatin was added as maximum suppressor by 0.01% in concentration.

In the preliminary experiments, the rate of the substitution reaction between copper(II) ions and nickel(II)-EDTA complexes was investigated. The result showed that the equilibrium of the reaction was attained within approximately 80 hours after the initiation of the reaction. Therefore, the reaction mixtures were kept standing at the given temperature for nearly four days after the preparation and, then, subjected to the measurement.

## Results and Discussion

The values of $[Cu^{2+}]_{app}$ were obtained at various concentrations of acetate and the given concentrations of sulfate. The left-hand side of Eq. 8 ($F_0$ in Eq. 8') was calculated with the $[Cu^{2+}]_{app}$ obtained and the formation constants of sulfatonickel(II), acetatonickel(II), and sulfatoacetatoniccolate(II) complexes which were previously determined.[4] The $F_0$ values thus calculated were plotted against the acetate concentration.

8) F. P. Treadwell and W. T. Hall, "Analytical Chemistry," Vol. 2, John Wiley and Sons, New York (1951), p. 393.

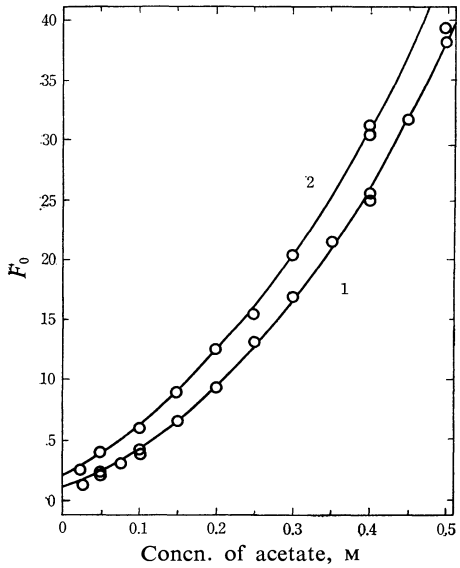

Fig. 1. $F_0$ (Eq. 8') as a function of acetate concentration at 25°C.
Concentrations of sulfate are: 0 (1) and 0.193 M (2).
— indicates the calculated, and ○ the experimental value.

Two typical examples of the $F_0$ plots are shown in Fig. 1. By extrapolating the $F_0$ plots to the zero acetate concentration, the values for

$$\frac{\alpha_{\mathrm{NiHY}}}{\alpha_{\mathrm{CuHY}} K_{\mathrm{Ni}}^{\mathrm{Cu}}}\left(1+\sum_{j=1}^{p} K_{\mathrm{Cu(SO_4)}_j}[\mathrm{SO_4^{2-}}]^j\right)$$

were determined. The $F_1(\mathrm{OAc})$,

$$F_1(\mathrm{OAc}) \equiv \frac{F_0-\dfrac{\alpha_{\mathrm{NiHY}}}{\alpha_{\mathrm{CuHY}} K_{\mathrm{Ni}}^{\mathrm{Cu}}}\left(1+\sum_{j=1}^{p} K_{\mathrm{Cu(SO_4)}_j}[\mathrm{SO_4^{2-}}]^j\right)}{[\mathrm{OAc^-}]}$$

$$=\frac{\alpha_{\mathrm{NiHY}}}{\alpha_{\mathrm{CuHY}} K_{\mathrm{Ni}}^{\mathrm{Cu}}}\sum_{i=1}^{n}\sum_{j=0}^{p} K_{\mathrm{Cu(OAc)}_i(\mathrm{SO_4})_j} \times [\mathrm{OAc^-}]^{i-1}[\mathrm{SO_4^{2-}}]^j \qquad (12)$$

was calculated from the $F_0$ plots and plotted against the acetate concentration, as is given in Fig. 2. Figure 2 shows that the $F_1$ plots are linear. This fact indicates that $n$ is equal to 2 and that no appreciable amount of the complexes with three acetate or more coordinated is present in the solutions investigated. The same result was also obtained with other concentrations of sulfate.

The $F_0$ values were also calculated with the $[\mathrm{Cu^{2+}}]_{\mathrm{app}}$ obtained at various concentrations of sulfate and the given concentrations of acetate. They were plotted against the sulfate concentration, which are given in Fig. 3.

By extrapolating $F_0$ plots to the zero sulfate concentration, the values for

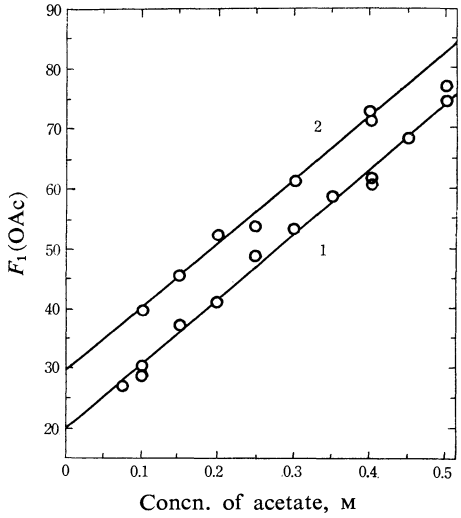

Fig. 2. $F_1$(Eq. 12) as a function of acetate concentration at 25°C.
Concentrations of sulfate are: 0 (1) and 0.193 M (2).

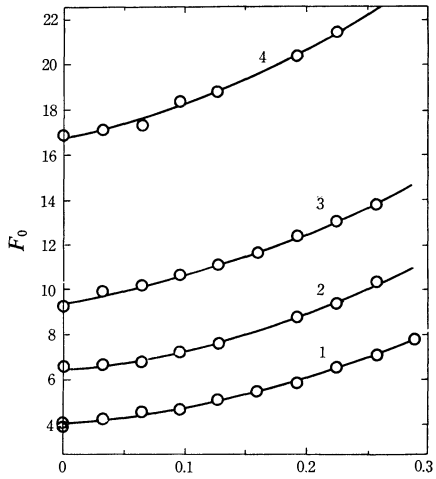

Fig. 3. $F_0$(Eq. 8') as a function of sulfate concentration at 25°C.
Concentrations of acetate are: 0.100 M (1), 0.149 M (2), 0.199 M (3) and 0.299 M (4).
— indicates the calculated, and ○ the experimental value.

$$\frac{\alpha_{\mathrm{NiHY}}}{\alpha_{\mathrm{CuHY}} K_{\mathrm{Ni}}^{\mathrm{Cu}}}\sum_{i=0}^{2} K_{\mathrm{Cu(OAc)}_i}[\mathrm{OAc^-}]^i$$

were obtained. The $F_1(\mathrm{SO_4})$,

$$F_1(\mathrm{SO_4}) \equiv \frac{F_0-\dfrac{\alpha_{\mathrm{NiHY}}}{\alpha_{\mathrm{CuHY}} K_{\mathrm{Ni}}^{\mathrm{Cu}}}\sum_{i=0}^{2} K_{\mathrm{Cu(OAc)}_i}[\mathrm{OAc^-}]^i}{[\mathrm{SO_4^{2-}}]}$$

$$=\frac{\alpha_{\mathrm{NiHY}}}{\alpha_{\mathrm{CuHY}} K_{\mathrm{Ni}}^{\mathrm{Cu}}}\sum_{i=0}^{2}\sum_{j=1}^{p} K_{\mathrm{Cu(OAc)}_i(\mathrm{SO_4})_j} \times [\mathrm{OAc^-}]^i[\mathrm{SO_4^{2-}}]^{j-1} \qquad (13)$$

was calculated from the $F_0$ plots and plotted against the sulfate concentration (Fig. 4). The $F_1$ plots were found to be linear, which indicate that $p$ is equal to 2 and that no appreciable amount of complexes with three sulfates or more coordinated is present in the solutions investigated. These conclusions were confirmed by the direct calculation of $n$ and $p$ of the $F_0$ function with the aid of an electronic computor NEAC 2230 (the Computing Center, Tohoku University).

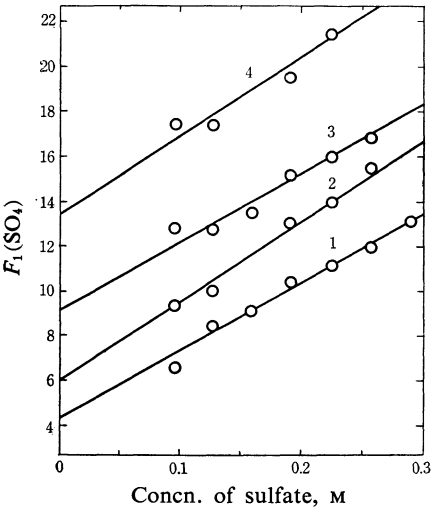

Fig. 4. $F_1$(Eq. 13) as a function of sulfate concentration at 25°C.
Concentrations of acetate are: 0.100 M (1), 0.149 M (2), 0.199 M (3) and 0.299 M (4).

The result that both $n$ and $p$ are equal to 2 suggests that the complex species, $CuOAc^+$, $Cu(OAc)_2$, $CuSO_4$, $Cu(SO_4)_2^{2-}$, $Cu(OAc)(SO_4)^-$, $Cu(OAc)(SO_4)_2^{3-}$, $Cu(OAc)_2(SO_4)^{2-}$ and $Cu(OAc)_2(SO_4)_2^{4-}$, may exist in the solution. However, it was concluded that $Cu(OAc)_2(SO_4)^{2-}$ and $Cu(OAc)_2(SO_4)_2^{4-}$ are not present in appreciable concentrations : The value of $(\alpha_{NiHY}/(\alpha_{CuHY}K_{Ni}^{Cu}))K_{Cu(OAc)_2}$, the coefficient of $[OAc^-]^2$ in the absence of sulfate was found to be identical, within experimental error, with that of $(\alpha_{NiHY}/(\alpha_{CuHY}K_{Ni}^{Cu}))(K_{Cu(OAc)_2} + K_{Cu(OAc)_2(SO_4)}[SO_4^{2-}] + K_{Cu(OAc)_2(SO_4)_2}[SO_4^{2-}]^2)$, the coefficient of $[OAc^-]^2$ in the presence of sulfate, both the coefficients being obtained by a least square method. An agreement of these values indicates that the terms, $K_{Cu(OAc)_2(SO_4)}[SO_4^{2-}]$ and $K_{Cu(OAc)_2(SO_4)_2}[SO_4^{2-}]^2$, are negligible and, consequently, no appreciable amount of $Cu(OAc)_2(SO_4)^{2-}$ and $Cu(OAc)_2(SO_4)_2^{4-}$ is present under the experimental conditions.

The formation constants of other species and the value of $\alpha_{NiHY}/(\alpha_{CuHY}K_{Ni}^{Cu})$ were determined by a least square method with the plots of $F_0$ vs. $[OAc^-]$ and $F_0$ vs. $[SO_4^{2-}]$.

**Determination of the Formation Constants of Acetatocopper(II) Complexes.**—The $F_0$ function obtained in the absence of sulfate is written as

$$F_0=\frac{\alpha_{NiHY}}{\alpha_{C\ HY}K_{Ni}^{Cu}}(1+K_{Cu(OAc)}[OAc^-]+K_{Cu(OAc)_2}[OAc^-]^2) \quad (14)$$

Therefore, the formation constants of $K_{CuOAc}$ and $K_{Cu(OAc)_2}$ and the value of $\alpha_{NiHY}/(\alpha_{CuHY}K_{Ni}^{Cu})$ were determined from curve 1 in Fig. 1 by a least square treatment. Using Eq. 14, the uncertainties of the determined values were examined by a graphical treatment.[9,10]

**Determination of the Formation Constants of Sulfato and Sulfatoacetatocopper(II) Complexes.**—The values of $(K_{CuSO_4}+K_{Cu(OAc)(SO_4)}[OAc^-])$ and $(K_{Cu(SO_4)_2}+K_{Cu(OAc)(SO_4)_2}[OAc^-])$ were determined by a least square method from the coefficients of $[SO_4^{2-}]$ and $[SO_4^{2-}]^2$ in the plots in Fig. 3, respectively. From the value of $(K_{CuSO_4}+K_{Cu(OAc)(SO_4)}[OAc^-])$ obtained for the given concentration of acetate, $K_{CuSO_4}$ and $K_{Cu(OAc)(SO_4)}$ were determined by a graphical treatment.[9,10] $K_{Cu(SO_4)_2}$ and $K_{Cu(OAc)(SO_4)_2}$ were also determined by the same procedure as in the case of the determination of $K_{CuSO_4}$ and $K_{Cu(OAc)(SO_4)}$.

The value of $\alpha_{NiHY}/(\alpha_{CuHY}K_{Ni}^{Cu})$ was obtained to be 1.0 at pH 4.74, and the formation constants obtained are given in Table I. Using

Table I. Formation constants of copper(II) complexes at 25°C and ionic strength 1.0

| | | |
|---|---|---|
| $K_{CuOAc}$ | $2.0\times10$ | $1.\ mol^{-1}$ |
| $K_{Cu(OAc)_2}$ | $1.1\times10^2$ | $1.^2\ mol^{-2}$ |
| $K_{CuSO_4}$ | $<3$ | $1.\ mol^{-1}$ |
| $K_{Cu(SO_4)_2}$ | $\sim3\times10$ | $1.^2\ mol^{-2}$ |
| $K_{Cu(OAc)(SO_4)}$ | $4\times10$ | $1.^2\ mol^{-2}$ |
| $K_{Cu(OAc)(SO_4)_2}$ | $\sim7\times10$ | $1.^3\ mol^{-3}$ |

these values, the values of $F_0$ can be calculated at various concentrations of acetate and/or sulfate. All the solid curves in Figs. 1 and 3 indicate that these calculated values are in satisfactory agreement with the values obtained experimentally.

In the previous study,[2] the formation constants of $K_{CuOAc}$ and $K_{Cu(OAc)_2}$ at 25°C and ionic strength 0.2 were obtained to be 52 and 93, respectively. The value of $K_{CuOAc}$ at ionic strength 1.0 is considerably smaller than that at ionic strength 0.2, while the value of the $K_{Cu(OAc)_2}$ is approximately equal to that at ionic strength 0.2. The value of $\alpha_{NiHY}/\alpha_{CuHY}$

was calculated with the equilibrium constants, $K^{H}_{CuHY}$ and $K^{H}_{NiHY}$, given by Schwarzenbach, Gut and Anderegg[11] and was found to be approximately unity for this system at pH 4.74. The $K^{Cu}_{Ni}$, the equilibrium constant of the substitution reaction represented by Eq. 1, was obtained to be 1.0 in the present experimental conditions. This value is also smaller than 2.2 which was obtained at 25°C and ionic strength 0.2.[2]

Fronaeus reported the formation constants of copper(II) complexes with acetate and/or sulfate which were determined by the potentiometric method[5] and by the ion-exchange measurements[6] at 20°C and ionic strength 1. The formation constants of sulfatocopper(II) complexes were reported which were obtained by solubility measurements[7] at 20°C and ionic strength 1. These formation constants are given in Table II. It may be seen that the values of $K_{Cu(SO_4)_2}$ given by Fronaeus and Näsänen are considerably smaller than the value obtained in this study.

TABLE II. THE REPORTED VALUES OF FORMATION CONSTANTS OF COPPER(II) COMPLEXES AT 20°C AND IONIC STRENGTH 1

## Summary

The polarographic method for the determination of the formation constants which is based on the measurement of the effects of acetate and/or other co-existing ions on the equilibrium of the substitution reaction, $M+M'L \rightleftarrows ML+M'$, has been developed, and applied to the study of the copper(II) complexes with acetate and/or sulfate ions. The formation constants obtained at 25°C and ionic strength 1.0 are: $2.0\times10$ for $K_{Cu(OAc)}$, $1.1\times10^2$ for $K_{Cu(OAc)_2}$, $< 3$ for $K_{CuSO_4}$, $\sim3\times10$ for $K_{Cu(SO_4)_2}$, $4\times10$ for $K_{Cu(OAc)(SO_4)}$ and $\sim7\times10$ for $K_{Cu(OAc)(SO_4)_2}$.

# The Spectrophotometric Determination of Anions by Solvent Extraction with Metal Chelate Cations. VIII.* A New Method for the Determination of Cadmium

By Keiya KOTSUJI

(Received November 7, 1964)

In a previous paper of this series, it has been shown that cadmium iodide complex, as well as mercuric iodide complex, can be extracted into 1,2-dichloroethane with 2,2'-dipyridyl iron(II) chelate.[1] Consequently, a method for the determination of cadmium has been investigated, in which the metal ion in aqueous solution is extracted into dichloroethane with dipyridyl iron(II) chelate in the presence of excess iodide and the absorbance of the resulting chelate in the organic phase is measured.

Many reagents have been used for the

* Presented at the 12th Annual Meeting of the Japan Society for Analytical Chemistry, Kanazawa, October, 1963.

colorimetric determination of cadmium, the most favored being dithizone.[2,3] Other reagents which have been suggested include di-β-naphthylthiocarbazone,[4] 4-hydroxy-3-nitrobenzenearsonic acid,[5] 1-(6-bromobenzothiazol-2-ylazo)-2-naphthol,[6] "Cadion," a triazine dye,[7] glyoxal bis(2-hydroxy-anil),[8] and diethyldithiocarbamate.[9,10] Although a differential ultraviolet spectrophotometric method using 1, 10-phenanthroline has also been devised, numerous interference have been found.[11] However, the proposed method is different from the known methods described above in the mechanism of color reaction.

## Experimental

**Apparatus and Reagents.** — Unless otherwise stated, apparatus and reagents were the same as those described in a previous paper.[12]

*Standard Cadmium Solution.*—Guaranteed cadmium sulfate ($3CdSO_4 \cdot 8H_2O$) was dissolved in distilled water, containing sufficient sulfuric acid to prevent hydrolysis, and diluted with distilled water to a concentration of 1000 p. p. m. of cadmium. The cadmium content was determined by an EDTA titration. This standard solution was diluted to the concentration required for the experiments.

All other reagents of analytical grade were used without further purification.

**Procedure.** — Mix 2,2'-dipyridyl ($8\times10^{-3}$ M), ferrous ammonium sulfate ($2\times10^{-3}$ M), sodium acetate (3 M), potassium iodide (0.3 M), and standard cadmium solution in the proper concentration. Adjust the pH of the solution to the required value with dilute sulfuric acid or dilute sodium hydroxide solution and then dilute it to 25 ml. with distilled water. To this, add 10.0 ml. of dichloroethane and shake the solution for 4 min. After standing the solution for 20 min., transfer the organic layer into a flask containing 1 g. of anhydrous sodium sulfate and shake it vigorously to make the solution transparent. Then transfer it into a 10 mm. cell. Measure the absorbance of the solution at 526 mμ using a reagent blank solution or dichloroethane as a reference. Measure the pH of the aqueous layer after the separation.

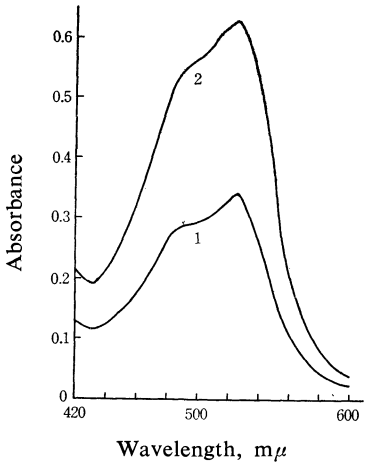

Fig. 1. Absorption spectra.
Reference: Dichloroethane, pH: 6.5
Curve 1: Spectrum of organic phase extracted from the aqueous solution (25 ml.) contained Dip. $6.4\times10^{-4}$ M, Fe(II) $1.6\times10^{-4}$ M, NaAc 0.24 M, KI $8.4\times10^{-2}$ M but Cd is absent.
Curve 2: Spectrum of organic phase extracted from the aqueous solution (25 ml.) containing 1.6 p. p. m. of Cd in addition to the same component as that of curve 1.

## Results and Discussion

**Absorption Spectrum.** — The spectral absorbance curves using dichloroethane as a reference are shown in Fig. 1. Curve 1 is a spectrum of the extract when cadmium ions are absent, while curve 2 is that of the extract with cadmium ions. It is observed that the presence of cadmium ions leads to a considerable increase in the absorbance and that both curves have a maximum absorbance at 526 mμ. The maximum absorbance is shifted from 522 mμ, the value in aqueous solution,[13] to 526 mμ in dichloroethane solution. This slight red shift in the organic layer may be attributed to the effect of the association between the chelate cation and the complex anion in dichloroethane. Feigl[14] has shown that 2,2'-dipyridyl iron(II) chelate can be precipitated as red crystals with a divalent complex anion such as tetra-iodocadmium. From these facts, the chemical formula of the extracted species is assumed to be $Fe(Dip.)_3 \cdot CdI_4$.

The maximum difference in absorbance for curve 1 and curve 2 is found at 526 mμ. Therefore, the absorbance was measured at this wavelength.

*Iron(II) Chelate and Potassium Iodide Concentration.*—The formation of extractable species may be mainly governed by the concentration of the 2,2'-dipyridyl iron(II) chelate cation as well as the tetraiodo-cadmium complex anion. Moreover, a large excess of potassium iodide is necessary to obtain a quantitative formation of tetraiodo-cadmium complex. The effect of such variables on the extraction was investigated.

To a solution containing a constant amount of cadmium, were added varying amounts of potassium iodide, ferrous ammonium sulfate, and 2,2'-dipyridyl, the mole ratio of dipyridyl to ferrous iron being kept at 4 to 1. In this case, it seems reasonable to assume that the concentration of ferrous iron is approximately equal to that of 2,2'-dipyridyl iron(II) chelate because of the high stability of the chelate.[15] The pH of the solutions was kept at 6.5 and the extraction procedure was carried out for such solutions. The results are shown in

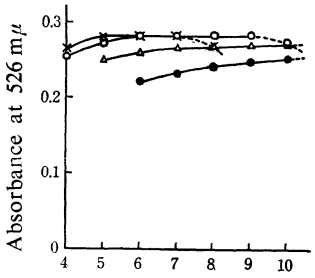

Fig. 2. Effect of 2,2'-dipyridyl iron(II) chelate and potassium iodide concentrations.

Fig. 2. When the final concentration of the ferrous ammonium sulfate was lower than $8\times10^{-5}$ M, rather low recovery was observed although the recovery increased with rise of potassium iodide concentration. When the concentration of ferrous ammonium sulfate was kept in the range of $1.6\times10^{-4}$—$2.4\times10^{-4}$ M, the recovery reached a maximum provided the iodide concentration was higher than $7.2\times10^{-2}$ M. However, a large excess of iodide or of chelate caused a decrease in the absorbance. Therefore, the concentrations of ferrous ammonium sulfate and potassium iodide were kept at $1.6\times10^{-4}$ M and $8.4\times10^{-2}$ M, respectively, in this work.

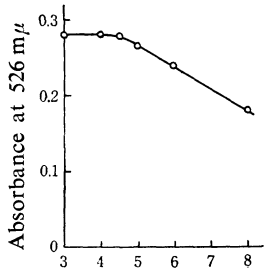

Fig. 3. Effect of mole ratio of Dip. to iron(II).

*Effect of 2,2'-Dipyridyl Concentration.*—While keeping other variables constant, differing amounts of dipyridyl were added, and the extraction was carried out according to the procedure described above. The results are shown in Fig. 3. When the mole ratio of dipyridyl to iron(II) was higher than 4.5, a decrease in the absorbance was observed. This may be caused by the formation of colorless 2,2'-dipyridyl cadmium chelate, which is more stable than tetraiodo-cadmium complex,[15,16] by the reaction of excess amounts of dipyridyl with tetraiodo-cadmium complex in the presence of excess iodide. On the other hand, a slight excess of dipyridyl is necessary for the stoichiometric formation of the dipyridyl iron(II) chelate cation. Therefore, this mole ratio was kept at 4 in this work.

*Effect of Sodium Acetate Concentration.*—Sodium acetate was effective in keeping the pH of the solution constant. When the acetate concentration was maintained at 0.2 to 0.3 M in the solution to be extracted, no effect on the recovery was observed. The concentration of the acetate was kept at 0.24 M in this work.

**Effect of Shaking Time.**—The shaking time during the extraction was varied from 2 to 20 min., while the other variables were kept constant. Variation in the shaking time did not produce any measurable change in the

Reference, Reagent blank

absorbance of the extracts. The shaking time was thus chosen to be 4 min. in this work.

**Effect of pH.**—The effect of the pH of the aqueous layer on the extraction is shown in Fig. 4. Low recoveries were obtained in the pH ranges below 4.5 and above 8.5. The pH of the solution was adjusted to 6.5 in this work.

**Stability of Color.** — Color developed immediately at room temperature and the intensity was not influenced by a temperature at 15—20°C. The color of the extract in the stoppered transmission cell was stable for more than 6 hr.

**Choice of Organic Solvent.** — Besides 1, 2-dichloroethane, various other solvents were tested for the extraction. They were chloroform, carbon tetrachloride, isoamyl alcohol, methylisobutyl ketone, cyclohexanone, benzene, and nitrobenzene. Only 1, 2-dichloroethane proved satisfactory. Although nitrobenzene behaved similarly to dichloroethane in this system, the reagent blank was too high to obtain a satisfactory net absorbance value.

**Percentage of Extraction.** — The degree of extraction of cadmium was checked by stripping cadmium from an aliquot of the dichloroethane extract with 1 N sulfuric acid. The amount of stripped cadmium was determined as follows. The aqueous layer was heated with nitric acid and sulfuric acid until strong fumes were observed. After cooling, the solution was neutralized with sodium hydroxide and diluted to a standard volume. Then an aliquot containing less than 20 μg. of cadmium was taken. The cadmium was determined by the photometric dithizone method, as described by Saltzman.[3]

The degree of the extraction using 10.0 ml. of dichloroethane was about 99%.

**Calibration Curve.** — Two milliliters of the 2, 2′-dipyridyl solution, 2 ml. of the ferrous ammonium sulfate solution, 2 ml. of the sodium acetate solution, 7 ml. of the potassium iodide solution, and varying amounts (1—7 ml.) of the standard cadmium solution (10 p. p. m.) were mixed and diluted to 25 ml. with distilled water. Then 10.0 ml. of dichloroethane was added, and the mixture was treated according

pH of aqueous layer: 6.5, other variables were the same as that of the calibration curve.
* The absorbance of 0.8 p. p. m. of cadmium without diverse ions.

to the procedure described above. The absorbance of each of the standard extracts was measured at 526 mμ against the reagent blank. As shown in Fig. 5, Beer's law is followed in the 0.4—2.8 p. p. m. range of cadmium ions.

**Effect of Diverse Ions.**—A study was made on the effects of several cations and anions. Absorbance measurements were made on the dichloroethane extracts obtained from the solutions containing various amounts of diverse ions with 0.8 p. p. m. of cadmium. The results are given in Table I. Nitrate, chloride and sulfate do not interfere even when the concentration is as high as 1500 p. p. m. Zinc ion may be present in the concentration of 40 p. p. m. without interference. Interferences by lead(II), mercury(II), and bismuth(III) ions may be due to the behavior of their iodo-complexes being similar to that of the tetraiodo-cadmium complex anion. Ethylenediaminetetraacetate causes serious interference, even when only a small amount is present, because the cadmium chelate of ethylenediaminetetraacetate[17] is more stable than the tetraiodo-cadmium complex.

**Summary**

A new method for the determination of cadmium has been proposed. The method is based upon solvent extraction of the associated complex formed between 2, 2'-dipyridyl iron(II) chelate cation and tetraiodo-cadmium complex anion and upon estimation of the absorbance due to the chelate cation in the organic phase.

# The Vertical Distribution of Chlorine in a Lava Flow from the O-sima Volcano in the Izu Islands

By Bunji IWASAKI

(Received November 9, 1964)

The horizontal distribution of chlorine in a lava flow has been reported by Iwasaki and Ozawa.[1] They found that the chlorine content of approximately 120 rock samples was quite homogeneous irrespective of the appearance and locality of the samples.

The vertical distribution of chlorine in a lava flow has also been studied by Kuroda and Sandell,[2] and Yoshida et al.[3] The number of rock samples employed in their studies was too small to permit a detailed study to be made.

Recently, many core holes were drilled in the northwestern part of the O-sima caldera in the Izu Islands. The drill-hole samples were studied by Issiki et al.[4] from standpoints of geology, geophysics, and petrography. As one of the results of their studies, several thick basaltic lava flows were distinguished.

We have determined the chlorine content of two of those lava flows in order to study the vertical distribution of chlorine in such a volcanic body. In addition, the uniformity of major chemical components in the two lava flows is discussed on the basis of the total iron content.

## Experimental

**Selection and Preparation of Rock Samples.**—The rock samples of the two lava flows used in this study originated from two core holes, termed

1) I. Iwasaki and T. Ozawa, read at the Meeting of the Volcanological Society of Japan, May, 1959.

2) P. K. Kuroda and E. B. Sandell, *Bull. Geol. Soc. Am.*, **64**, 879 (1953).

3) M. Yoshida, T. Ozawa and T. Katsura, read at the Meeting of the Volcanological Society of Japan, March, 1963.

4) N. Issiki, K. Nakamura, M. Hayakawa, K. Hirasawa, T. Yukutake, Y. Arai and B. Iwasaki, *Bull. Volcanological Soc. Japan, 2nd Series*, **8**, 61 (1963).

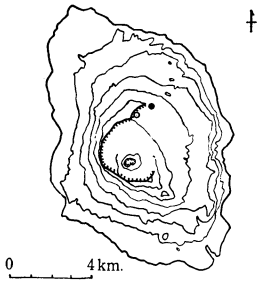

Fig. 1 The locations of the two core holes.
● OH 1 ○ OY 4

OH 1 and OY 4, respectively. The locations of those core holes are given in Fig. 1.

These drill-hole samples, weighing about 1 kg., were taken at about 2 m. intervals through the lava flow. A total of 65 samples, involving 38 samples in one lava flow (OH 1-2) and 27 samples in the other lava flow (OY 4-2), was collected. About 15 g. of each core-hole sample was selected for chemical analysis from the central part of the core to avoid cavities. Then, these rock samples were crushed in a steel mortar and ground to fineness in an agate mortar. In particular, precaution was taken throughout the whole procedure of selection and preparation of rock samples, to avoid any possibility of chlorine contamination.

**Method of Analysis.**—Two or more repeated determinations of the total chlorine content in each rock sample were made by the method of Iwasaki et al.[5] with some improvements, while the water-soluble chlorine in the rock was determined by the thiocyanate method,[6] according to the procedure previously described.[7] By these methods, it is possible to ascertain the chlorine content of the rock within a precision of ±5% for the whole range analyzed.

The total iron in the rock was determined colorimetrically by the $\alpha, \alpha'$-dipyridyl method,[8] within a precision of ±1% in a range of 10.0 to 15.0%.

## Results and Discussion

**The Uniformity of the Two Lava Flows.**—According to the geological observations of Issiki et al.,[4] the two lava flows involved in this study are considered to be uniform, on accunt of the smallness and rareness of phenocrysts such as olivine and augite, and to have formed through ponding into a depression on the caldera floor.

The uniformity of a lava flow can also be determined by the method of Iwasaki et al.,[9] involving chemical analysis. Their results have shown that determination of one of the major chemical components, in a large number of samples from the lava flow, is useful in deciding whether a lava flow containing infrequent and small phenocrysts is uniform in major chemical composition. Accordingly, the total iron contents in each of 14 rock specimens were determined to ascertain the uniformity of the two lava flows. The results obtained are shown in Table I.

Table I. The total iron content in the two lava flows

| Sample | $Fe_2O_3$*, % |
|---|---|
| OH 1-2-1 | 14.1 |
| OH 1-2-3 | 14.4 |
| OH 1-2-9 | 14.3 |
| OH 1-2-14 | 14.3 |
| OH 1-2-17 | 14.4 |
| OH 1-2-20 | 14.4 |
| OH 1-2-23 | 14.4 |
| OH 1-2-25 | 14.2 |
| OH 1-2-31 | 14.1 |
| OH 1-2-34 | 14.4 |
| OH 1-2-38 | 14.3 |
| OH 1-2[4] | 14.4 |
| Mean value | $14.3_1$ |
| Standard deviation | 0.11 |
| OY 4-2-1 | 14.0 |
| OY 4-2-12 | 14.0 |
| OY 4-2-27 | 14.0 |
| OY 4-2[4] | 14.1 |
| Mean value | $14.0_3$ |

$Fe_2O_3$*: Total iron content

In the case of OH 1-2, the total iron content (as $Fe_2O_3$) ranges from 14.1 to 14.4%, and in the case of OY 4-2, from 14.0 to 14.1%. Judging from the total iron content, the two lava flows are considered to be uniform in major chemical composition.

**Chlorine Content.**—The total chlorine content in the rock samples from the two lava flows are shown in Table II.

The rock samples analyzed are presented in order of increasing depth beneath the surface. The water-soluble chlorine in the rock was determined to see whether chlorine is present by contamination in the rock specimens. The results obtained are shown in Table III.

The water-soluble chlorine content in 9 rock samples ranges from 0.001 to 0.003%. As this amount of water-soluble chlorine is normally present in fresh rock specimens,[2,10] it may be said that the chlorine in these rock samples does not come from the cooling water applied

to drill holes, etc. Figures 2 and 3 show the relationship between the chlorine content of the rock samples and the depth of the drill core.

The chlorine content of the rock samples from one lava flow (OY 4-2) ranges from

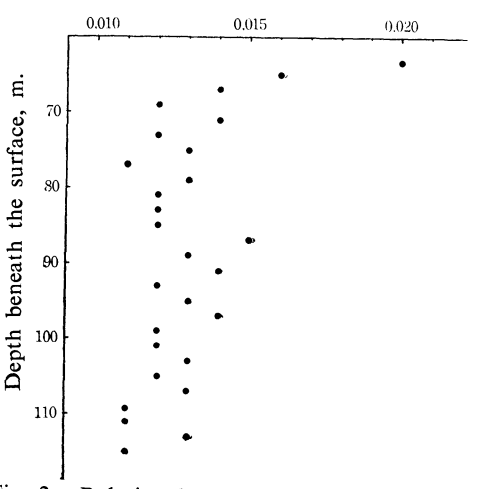

Fig. 2. Relation between the chlorine content of rock samples and the depth of drill core (OY 4-2).

0.011 to 0.020%, and averages 0.012%. It has been reported by Issiki et al.[4] that the base of this lava flow has been intruded by a dike. However, because of the low heat conductivity of rock, it is considered that the effect of this dike intrusion would have introduced no serious change in the vertical distribution of chlorine in the lava flow. Provided that the chlorine content of the basement rock is the same as that of the lower region of the lava flow. With the exception of two rock samples, all the samples would have a nearly uniform chlorine content. The two exceptional samples had been collected from the uppermost parts and are red

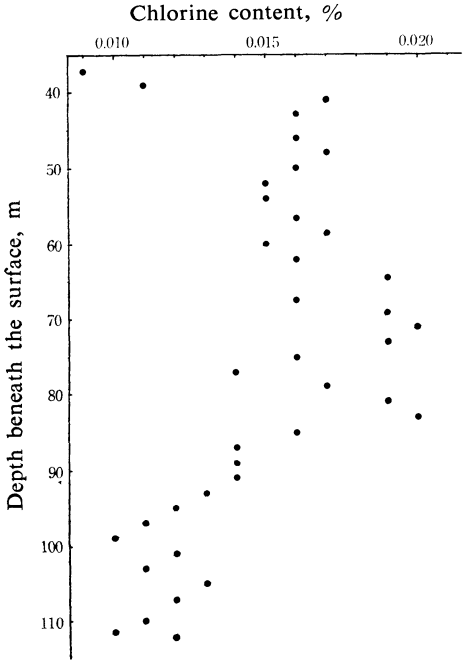

Fig. 3. Relation between the chlorine content of rock samples and the depth of drill core (OH 1-2).

in color. The presence of sublimates containing halogen compounds in these samples might explain the high amount of chlorine present.

On the other hand, the chlorine content of the rock samples from the other lava flow (OH 1-2) ranges from 0.009 to 0.020% and averages 0.014%. As seen from Fig. 3, the variation of chlorine is as follows: the chlorine content increases from the lower part to the middle part, and then, slightly decreases towards the uppermost part, where the chlorine content shows much lower values. The chlorine content in the rock samples from the uppermost parts shows a striking contrast to that found in similar regions of OY 4-2. Some of the rock specimens from the middle parts of the lava flow (OH 1-2) possess many cavities (showing the presence of volatile components) and many spots, which consist of glasses about 0.5 mm. in diameter, according to the microscopic observations of Issiki.* Furthermore, most of the rock specimens possessing these spots show higher amounts of chlorine, as seen in Table II, while the rock samples without the spots show lower amounts of chlorine. Since the former samples are not particularly enriched with apatites, it is considered that a relationship exists between the extent of occurrence of these spots and the chlorine content of the rock samples. Thus, the enriched chlorine content of the middle part is considered to be due to the fixation of chlorine in the glass, rather than the contribution of apatite as a chlorine carrier. A possible explanation for the vertical variation of chlorine content in the lava flow might be as follows: at high temperatures, the lava flow builds up to a thickness of about 76 m. during a short time, and then, begins to cool rapidly from the outside, i. e., the upper part and the lower part. This is supported by the fact that the crystals in the ground masses are very small and phenocrysts have not accumulated at the base. During such a cooling process, chlorine compounds may vaporize and be lost from the surface of the lava to the air; this would encourage diffusion of the chlorine compounds from the lower part to the upper part, and a concentration gradient of chlorine compounds would result in the lower and middle parts of the lava. As the chlorine compounds in the melt are prevented from escaping by the solidified lava surface, they would tend to diffuse downwards to be distributed uniformly in the melt. However, the diffusion rate in the lower part would be decreased by solidification of the lava in this region. Accordingly, the concentration gradient of chlorine compounds in the lower part may remain unchanged during solidificantion of the melt, whereas chlorine compounds in the melt at the upper and middle parts may be distributed uniformly. On the other hand, as the solidifying uppermost lava is heated by the underlying melt, chlorine compounds may be vaporized from the surface of the lava to the air. In this way, the solidification of the lava proceeds. At the final stage of the cooling process, those portions of the lava melt containing a high amount of chlorine compounds solidify as glasses, because chlorine compounds do not enter the rockforming minerals except apatite in this case.

**Frequency Distribution of Chlorine Content.**—Figure 4 shows two cumulative distributions of the chlorine content in the two lava flows

* Personal communications.

(OH 1-2, OY 4-2) and also shows that for the 1950—1951 lava in O-sima for comparison.

They show approximately normal distributions. In other words, a frequency distribution of the chlorine content in a lava flow seems to show a normality. This contrasts exceedingly with the frequency distributions found for the chlorine content in many lava flows in other regions, for example, Hawaiian and Japanese lava flows[7,10] show a lognormality. Perhaps, the difference is due to the much larger variation of the chlorine content in the latter than in the former. As seen from the slope of the lines in Fig. 4, OH 1-2 shows the largest variation, while OY 4-2 shows a variation close to that of the 1950—1951 lava. Judging from the latter fact, the formation of OY 4-2 may have been by a repeated accumulation of thin layers, as in the 1950—1951 lava, rather than by the generation of a lava lake.

○ OY 4-2 ● OH 1-2
◑ the 1950—1951 lava

## Conclusion

1) The chlorine content of the first lava flow (OY 4—2) is uniform with some exceptions.

2) The chlorine content of the second lava flow (OH 1—2) shows a vertical variation, increasing from the lower part to the middle part and decreasing towards the uppermost part.

3) The enrichment of chlorine in the middle part of the second lava flow is considered to be due to the fixation of chlorine in the glass.

4) The frequency diagrams of the chlorine content in the two lava flows show approximately normal distributions.

5) The two lava flows are uniform on the basis of total iron content.

# Current-Voltage Characteristics in Phenanthrene Single Crystals*1

By Shoichi MATSUMOTO

(Received November 14, 1964)

The nature of semiconduction in organic solids has not been as yet elucidated satisfactorily, though many experiments have been made on aromatic hydrocarbons and related organic compounds. Further experimental studies are needed to establish the mechanism of electrical conduction in these materials. One such study is to find out how much impurity exists in an organic crystal to be measured, whether it is chemical or physical, and, further, what role it plays.

Information about trapping centers in anthracene has been obtained through the conductivity glow-curve method by Bryant, Bree, Fielding and Schneider,[1] the measurement of space-charge-limited currents has been carried out for anthracene by Mark and Helfrich,[2] and the behavior of bulk currents in metal-free phthalocyanine has recently been interpreted as the currents by Heilmeier and Warfield.[3]

In this paper, the current-voltage characteristics of phenanthrene single crystals are studied in detail, and the results are analyzed as space-charge-limited currents phenomena. The information for trapping centers of phenanthrene obtained through the above-mentioned analysis will be discussed in comparison with the related results previously obtained for organic solids.

## Experimental

**Sample Crystals.** — The starting material was Eastman Kodak chemical-purpose-grade phenanthrene, which was purified by recrystallization and sublimation in a manner described previously.[4] As it was desired to obtain rather thin crystals in order to observe current-voltage characteristics up to very high electric fields, the crystals used in these experiments were sublimation flakes grown in the vessel shown in Fig. 1. A small quantity of purified phenanthrene was placed in a glass vessel equipped with conduit pipes for the flow of nitrogen gas,

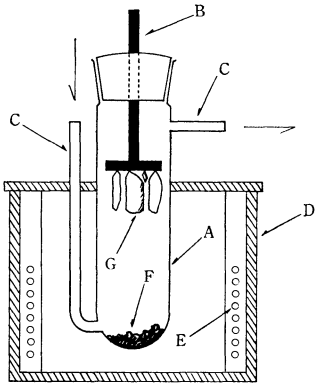

Fig. 1. Apparatus used to grow flaky single crystals of phenanthrene.

A: Glass vessel
B: Copper rod with a round plate
C: Conduit pipe
D: Heating furnace
E: Heating coil
F: Phenanthrene powder
G: Flaky crystals

and the vessel was sealed with a glass stopper bearing a copper rod with a round copper plate. Purified nitrogen was used as the ambient gas in order to prevent the oxidation of phenanthrene. The whole assembly was then placed in a heating furnace. Phenanthrene began to sublime at about 65°C, and flaky crystals grew on the copper plate, which remained nearly at room temperature.

The crystals were approximately 10 $\mu$ thick and had surface areas of 36—100 mm$^2$. About six hours were required to grow these crystals, which were confirmed to be single crystals by examination with a polarizing microscope. It was found that their developed plane coincided with the ab plane of the crystal without exception.

**Specimen Cell and Measuremnts.**—An electrical conductivity cell of the sandwich type was prepared on a teflon block in a manner reported previously.[4] Silver paste (Ecco Bond), which was found to make ohmic contact with these samples, was applied as electrodes, and a guard-ring electrode was grounded in order to prevent an effect of the surface current.

The measuring apparatus consisted of a vibrating-reed electrometer (Takeda TR-88), and a dry-cell power supply. As the bulk current of guard-ringed samples was found to show no difference between the current in air and that in nitrogen gas within the

range of experimental error,*2 the measurements were carried out in air.

The circuit shown in Fig. 2 was used to determine more exactly the voltage at which a steep increase of current through a sample crystal occurs; when the circuit is closed by a switch, the effect is merely to charge the capacitor so that a voltage is slowly built up across the capacitor and, at the same time, across a sample crystal. On the other hand, it can be observed that, when the voltage reaches a higher value where the current through a sample crystal rises steeply, the discharge of the capacitor occurs suddenly, and the built-up voltage across the capacitor falls. The above-mentioned phenomena were observed with a oscilloscope.

## Results and Discussion

The current-voltage characteristics obtained can typically be divided into three regions, as is shown in Fig. 3: (1) at low voltages, up to $2\times10^4$ V. per cm., the dependence of the current on the voltage obeyed Ohm's law, (2) at intermediate voltages, the current increased with the square of the voltage, and (3) at higher voltages, over $5\times10^4$ V. per cm., the current rose steeply with the voltage. This behavior is similar to the currnt-voltage relation characteristic of the space-charge-limited currents in solids.

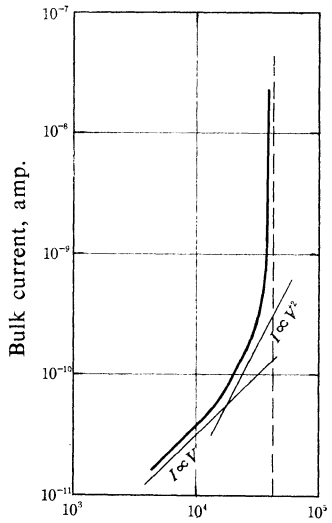

Fig. 3. Typical current-voltage characteristics of phenanthrene single crystal.

The theoretical treatment of space-charge-limited currents has been developed by Rose[5] and Lampert[6]. Smith and Rose also experimentally demonstrated space-charge-limited currents with crystals of cadmium sulfide.[7] Ruppel observed that with zinc sulfide,[8] and so forth.

When a sufficiently large field is applied to an insulator with ohmic contact electrodes, carriers will be injected into the bulk of the material to form a current which is limited by space-charge effects. The following equation can be given for the space-charge-limited current in a solid,

$$I=10^{-12}\,V^2\mu\varepsilon A/4\pi l^3 \qquad (1)$$

where $\mu$ and $\varepsilon$ are the drift mobility and the dielectric constant respectively, $V$ is the applied voltage, $l$ is the electrode spacing, and $A$ is the cross-sectional area. The magnitude of this current in a trap-free material can be quite large, but in practice it is reduced by trapping effects; trapping centers capture the injected carriers, thus reducing the density of free carriers.

As long as the Fermi level, which rises when current injection occurs, is further from the bottom of the conduction band than $E_t$, the trap depth, and moves in a region of the forbidden gap where the level density is much less than $N_t$, the trap density, the ratio of free electrons, $n$, to trapped electrons, $n_t$, is constant and independent of the applied voltage. In this region, the current is given by:

$$I_t=10^{-12}\,V^2\mu\varepsilon Ar/4\pi l^3 \qquad (2)$$

where, if $N_c$ is the effective density of the state in the conduction band, $r$ is approximately given by:

$$r=n/n_t=(N_c/N_t)\exp(-E_t/kT) \qquad (3)$$

Thus, the transition from the ohmic region of current-voltage characteristics to the square-law dependence of the current on the voltage at a higher field is associated with the condition where the space-charge-limited currents become comparable with the intrinsic bulk-current.

*2 The same result for the effect of an ambient atmosphere on the current through the guard-ringed samples of phenanthrene has been explained in a previous paper.[4]

5) A. Rose, *Phys. Rev.*, **97**, 1538 (1955).
6) M. A. Lampert, ibid., **103**, 1648 (1956).
7) R. W. Smith and A. Rose, ibid., **97**, 1531 (1955).
8) W. Ruppel, *Helv. Phys. Acta*, **31**, 311 (1958).

Accordingly, if $V_t$ is the voltage at which the above-mentioned transition occurs, the concentration of bulk-free carriers, $n_o$, which means that of free carriers before injection, is given by:

$$n_o = 10^{-12} V_t \varepsilon r / 4\pi e l^2 \qquad (4)$$

The extremely steep rise of the current at more higher fields corresponds to the condition in which the traps have been essentially filled; the current rises very steeply with the voltage toward the curve characteristic of trap-free behavior. The density of traps which have been filled is calculated from the voltage, $V_{tf}$, where the current rises steeply:

$$eN_t = CV_{tf}/1A = 10^{-12} V_{tf}/4\pi l^2 \qquad (5)$$

where $C$ is the capacity of a sample, and $A$ is the cross-sectional area.

The current-voltage characteristics obtained from sample 63-5 and sample 63-7 are illustrated in Fig. 4. These results were analyzed as space-charge-limited currents phenomena.

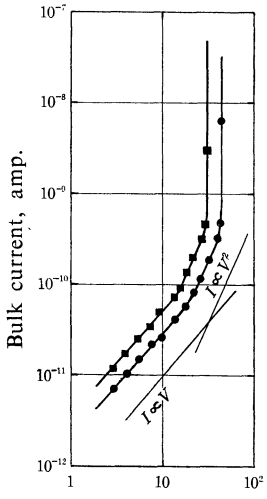

Fig. 4. Current-voltage characteristics of sample 63-5 (■) and sample 63-7 (●).

If the crystal of sample 63-5 is absolutely trap-free, the theoretical space-charge-limited current $I$ at 22 V. is calculated to be $5.89\times10^{-3}$ amp. with Eq. 1, where the values of $\varepsilon=3$ is adopted,[9] and $\mu$ is assumed to be 0.1 $cm^2/V.\cdot sec.$*3 The experimentally-observed current in Fig. 4, that is, $I_t$ for this sample at the same voltage, is $1.15\times10^{-10}$ amp. Therefore, $1.95\times10^{-8}$ is evaluated as the value of $r$.

In Fig. 4, $V_t$, at which point the transition from the ohmic region to square-law behavior occurs, is observed to be about 15 V. Thus, a value of $1.2\times10^6$ $cm^{-3}$ is obtained from Eq. 4 as the concentration of bulk-free carriers. The resistivity $5.2\times10^{13}$ Ω cm., calculated from the formula $\rho=(en_o\mu)^{-1}$ by using $n_o=1.2\times10^6$ $cm^{-3}$ obtained above, is in good agreement with the observed resistivity, $5.4\times10^{13}$ Ω cm., for the ohmic region of current-voltage characteristics of sample 63-5. This self-consistence may support the applicability of space-chage-limited currents analysis for the results of sample 63-5. This consistence is found to exist also for sample 63-7.

The trap density, $N_t$, can be determined from the voltage, $V_{tf}$. $V_{tf}$ was determined by using the circuit of Fig. 2. When the observed value of $V_{tf}$, 30 V., for sample 63-5 is inserted in Eq. 5, the value of $N_t$ can be calculated as $1.24\times10^{14}$ $cm^{-3}$.

Here, the trap-depth, $E_t$, can be evaluated from Eq. 3, if the effective density of the state in the conduction band, $N_c$, is known. If we adopt $N_c=5.76\times10^{15}$ $cm^{-3}$, which is obtained by inserting $n_o=1.2\times10^6$ $cm^{-3}$ and $\Delta\varepsilon=1.14$ eV.[4] into relation, $n_o=N_c\exp(-\Delta\varepsilon/2kt)$, $E_t$ for sample 63-5 is estimated to be 0.55 eV.

Similar results were also obsained for sample 63-7 through analyzing its current-voltage characteristics. The results are summarized in Table I.

Table I

| | $n_o\cdot cm^{-3}$ | $N_t\cdot cm^{-3}$ | $E_t\cdot$eV. |
|---|---|---|---|
| Sample 63-5 | $1.2\times10^6$ | $1.2\times10^{14}$ | 0.55 |
| Sample 63-7 | $1.1\times10^6$ | $1.0\times10^{14}$ | 0.55 |
| Average | $1.2\times10^6$ | $1.1\times10^{14}$ | 0.55 |

The trap density, $N_t=1.1\times10^{14}$ $cm^{-3}$, for phenanthrene obtained here is comparable to the corresponding value for anthracene, $7.6\times10^{13}$ $cm^{-3}$, obtained by Mark and Helfrich,[2] and to that for phthalocyanine, $10^{12}-10^{14}$ $cm^{-3}$, obtained by Heilmeier and Warfield.[3] It is worthy of notice that the value of the trap density is in the order of $10^{12}-10^{14}$ $cm^{-3}$ for all of these organic molecular crystals, and that the trap density of this order seems to be rather low for an organic solid in which some chemical impurity is generally difficult to remove and in which the imperfection of crystal is likely to occur because of the weak binding strength characteristic of molecular crystals. Both facts, their low trap-densities and their agreement, being of the order of $10^{12}-10^{14}$ $cm^{-3}$, might give a key to the establishment of the nature of the trap in organic molecular crystals, although further experimental studies are needed to solve the problem.

9) H. Kronberger and J. Weiss, *J. Chem. Soc.*, Part II, **1944**, 464.

*3 This value of $\mu$ is estimated from the observed mobility of similar aromatic hydrocarbons. Although whether the assumed value is reasonable or not has to be examined by measuring the mobility, the accurate value is not indispensable in the following discussion.

The question of whether electrons or holes are trapped in phenanthrene can not as yet be decided either.

## Summary

The obtained current-voltage characteristics of phenanthrene single crystals exhibited three distinct types of behavior: (1) at low voltages, up to $2\times10^4$ V. per cm., the dependence of the current on the voltage obeyed Ohms' law, (2) at intermediate voltages, the current increased with the square of the voltage, and (3) at higher voltages, over $5\times10^4$ V. per cm., the current rose steeply with the voltage. These results have been analyzed as space-charge-limited currents phenomena, and a value of $1.2\times10^6$ cm$^{-2}$ has been obtained as the concentration of the bulk-free carriers from the transition voltage between the ohmic region and the square-law behavior. The resistivity calculated by applying this value is in good agreement with the resistivity observed for the ohmic region of current-voltage characteristics.

The trap density of $1.1\times10^{14}$ cm$^{-3}$ has been evaluated from the voltage where the current rose steeply. Although this value seems to be rather low for an organic solid, it is comparable to the trap densities for organic molecular crystals ever obtained.

The author wishes to express his thanks to Dr. Haruo Kuroda for his valuable advice, and Dr. Tsutomu Takamura for his encouragement.

# An Automatic Adiabatic Calorimeter for Low Temperatures. The Heat Capacity of Standard Benzoic Acid[1)]

By Hiroshi SUGA and Syûzô SEKI

(Received November 4, 1964)

In recent years there has been an increasing interest in the heat capacities of crystals at low temperatures as a means to determine, for example, third law entropies, the purity of materials, and the frequency spectra of the lattice modes of vibration. Numerous methods of measuring the low-temperature heat capacity of the crystal have been reported. In the "adiabatic"-type calorimeter, two operators, at least, and tedious labor are required in order to obtain highly accurate results. The development of electronics in recent years has, however, made it possible to replace manual regulation with automatic control and also manual observation with automatic recording, without any general loss of the claimed accuracy. Stull[2)] has, in fact, recently developed such an automatic calorimeter. This report stimulated us to construct such a one-man-operated type low-temperature calorimeter with a high accuracy.

The present paper will report the construction and the operational procedure of this low-temperature calorimeter and will also present the results of our heat-capacity measurement of a standard sample of the benzoic acid crystal, which is used for checking the reliability and accuracy of our results.

## Apparatus

**Calorimeter and Cryostat.**—A schematic cross section of the calorimeter and the cryostat is shown in Fig. 1. The apparatus is of the adiabatic type, consisting of a vacuum-insulated calorimeter surrounded by an adiabatic shield whose temperature is maintained at essentially the same level as that of the calorimeter during heat-capacity measurements. The sample container, A, is made of gold plate, with walls 0.3 mm. thick and with a central re-entrant well into which a combined thermometer-heater is set. In order to obtain good heat conduction between the container and the specimen, six radial fins of platinum 0.1 mm. thick are attached with silver solder to the outside of the well and also to the inside of the container. A brass cap with capillary copper tubing is unsoldered and resoldered in order to change samples.

The calorimeter temperature is measured with a Leeds and Northrup 25-ohm "four

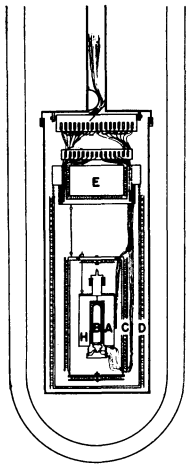

Fig. 1. Schematic diagram of low-temperature adiabatic calorimeter (13—300°K).

lead" platinum-resistance thermometer, 5 mm. in diamerter and 50 mm. long. Around the outside of this thermometer, the calorimeter heater, formed of approximately 100 ohms of #36 B and S constantan wire, for the supply of electrical energy is wound non-inductively and insulated with G. E. adhesive #7031. The surface is coated with gold foil, and the thermometer-heater is set rigidly into the central well of the calorimeter with Wood's metal. Around the protruded bottom of the calorimeter, all the lead wires from the thermometer-heater are wrapped tightly, insulated with the G. E. adhesive, and then soldered to copper lugs. The container is hung from the top of the inner adiabatic shield, C, with three nylon threads, the length of which can be adjusted externally. The empty weight of the container, including the thermometer-heater, is about 100 g.

The inner adiabatic shield is made of brass, 1 mm. thick, and it is chromium-plated on both sides. It consists of three portions, top, sides and bottom. The side portion is fitted with copper lugs to which are connected all the lead wires coming from the container to the outside. All the wires from this connecter are bundled together and wound on the outer surface of the side portion of the shield for four turns and then secured with the adhesive. These wires and the whole of the outer surface of the shield are wrapped with a heater made of #32 B and S constantan wire. The heater is wrapped in three sections. The resistance around the cyrindrical side portion is about 100 ohms, while that of the top and bottom portions is approximately 40 ohms. The entire surface is coated with the adhesive, covered with a heavy grade of aluminum foil.

Difference thermocouples between the container and the inner adiabatic shield are of the Chromel-P constantan type, formed of #38 and #36 B and S wires, and they are placed in seven different positions within the adiabatic shield. The other junctions are gathered together and secured to, but electrically insulated from, the pocket of the sample container.

The inner adiabatic shield is hung with three nylon threads from the upper block, E, which is in turn hung by adjustable nylon cords from the vacuum jacket. This block consists of brass (3 kg.), an embedded constantan heater, copper lugs, and two Chromel-P constantan difference thermocouples whose other junctions are secured to the inner adiabatic shield. Surrounding the inner adiabatic shield, an outer shield, D, is hung with detachable chains from the upper block. The outer shield, 60 mm. in diameter and 250 mm. high, constantan heater and two difference thermocouples whose other junctions are placed on the inner adiabatic shield. In order to obtain good performance in the temperature control of the inner shield, the temperature of the outer shield is kept somewhat below that of the inner shield so as to offer a necessary cold head. All the lead wires from the calorimeter assembly are, after being wrapped to the inner shield, in intimate contact with the upper block and are secured with the adhesive and then passed through a hole to copper lugs attached to the bakelite ring. Hereafter, the wires passed through stainless steel tubing, 25 mm. in diameter and 900 mm. long to the top closure, where they emerge through a vacuum seal made of bees wax.

For the refrigeration, the calorimeter assembly is mounted in the glass dewar, 110 mm. in outer diameter and 1200 mm. long. Liquid nitrogen or liquid hydrogen as a refrigerant is transferred by means of a transfer siphon entering the equipment through the top plate.

**Measuring and Control Circuits.**—A schematic diagram of measuring and control circuits is given in Fig. 2. The resistance of the thermometer could be recorded continuously on a Leeds and Northrup "High-Precision" resistance recorder, by means of which the temperature of the sample could be read to $\pm 0.01$°K at room temperature. When more precision was needed in the temperature measurement, the resistance was measured with a Leeds and Northrup-type G-2 Mueller Bridge in conjunction with a high sensitive galvanometer and lamp scale. At all except the lowest temperatures, the resistance of the thermometer could be read to a precision of one or two parts per ten thousands with this equipment.

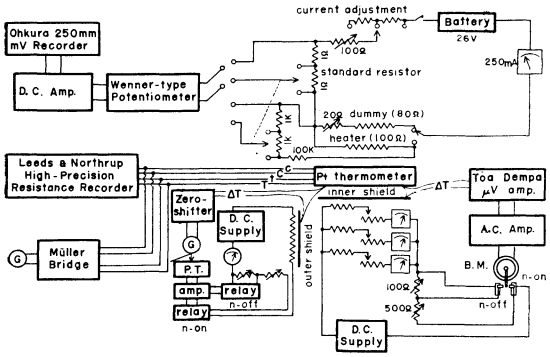

Fig. 2. Circuits diagram for heat capacity measurements.

The electrical energy for heating the calorimeter was supplied by four storage batteries (capacity: 120 amp. hr. at 26 V.). The current was adequately adjusted by means of a six-dial decade resistor and a variable resistor. The current was determined by the potential drop across a 2-ohm (or 1-ohm) series resistor. The potential drop across the calorimeter heater was divided by a 100000-ohm volt box, which had a 100 : 2 (or 100 : 1) ratio certified to 0.01 per cent. These two potential drops were mostly compensated for, respectively, by means of a Leeds and Northrup Wenner potentiometer; the residual differences were, after amplifying by a d.c. amplifier, recorded continuously on a Ōkura 250-mm. voltage recorder. All the necessary standard resistors were contained in a box held at the constant temperature of 32±0.5°C, where the temperature coefficient of the resistance of manganin wire is essentially zero. Since the resistance of the calorimeter heater was not constant over even one heating period, the current and the voltage through and across the heater were recorded alternatively in this period according to Giauque's schedule,[3] i.e., currents at $0.21\,\tau$ and $0.79\,\tau$, and the voltage at $0.50\,\tau$, where $\tau$ means the total heating period. To allow for the small amount of heat generated in the current leads between the calorimeter and the inner adiabatic shield, one of the potential leads was attached to a terminal on the calorimeter, and the other to a terminal on the inner shield. If the resistances of the current leads are similar, this procedure accounts for that part of the heat generated in them which flows to the calorimeter. When the heater was not energized, the current was kept at the same value as that through the heater by connecting the circuit to a dummy heater composed of fixed and variable constantan resistors. The energy input was automatically started and stopped by an electric timer synchronized with a transistor clock, as is shown in Fig. 3. The input interval was held to integral seconds by synchronizing the heater switch with a relay which was closed once each second. The interval was measured by a counter and was found to be accurate to 0.05% or better.

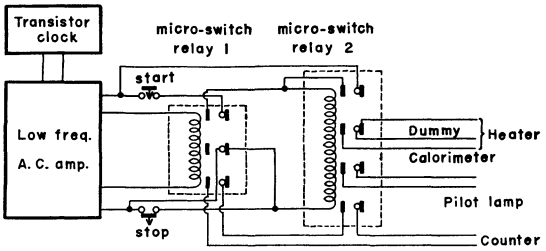

Fig. 3. Circuits of electronic timer.

The precise control of the temperature difference between the calorimeter and the inner shield is essential for accurate measurements in the adiabatic-type calorimeter. For this purpose, a signal from a seven-junction Chromel-P constantan thermocouple which registered any temperature difference between them was fed to a Tôa Dempa AD-4 d.c. amplifier and an a.c. amplifier, the output of the latter amplifier being used to operate a balancing motor (Fig. 4). When the thermocouple thus signaled that the shield was colder than that calorimeter, the balancing motor converted a "normally open" relay to the "closed" state, thus shortening the series resistor in the heater circuit, resulting in an increase in the heater current. In the reverse case, the balancing motor turned off another "normally closed" relay, resulting in zero current. The currents in each step were regulated so as to minimize the "hunting" or temperature swings about the zero point and also to

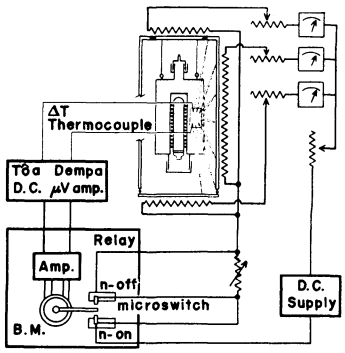

Fig. 4. Control circuits for inner adiabatic shield.

make the length of time spent in the colder state equal to the time spent in the hotter state. The heater current in three parts of the inner shield was separately adjusted to be proportional to the heat capacity of each part. The design of the controller of this type is similar to that of Stull.[2] Manual refinements have been added to permit closer control at the beginning and end of the heating period.

Besides the inner shield, the temperatures of the outer shield and brass block were regulated by another control system. Two-junction Chromel-P constantan thermocouples for detecting any temperature difference between the inner shield and the outer shield and also between the inner shield and the brass block were connected to a highly sensitive galvanometer (the control circuit of the block is not shown in Fig. 2). The light beam from the source was reflected by the mirror of the galvanometer, and then projected on to two photo-transistors, which served to operate two microswitchs attached to heater circuit. By this arrangement, the heater current was adjusted automatically in three steps so as to give no temperature difference between the inner shield and the block. On the other hand, the temperature of the outer shield was adjusted somewhat below that of the inner shield by adding an adjustable bucking potential to the e.m.f. of the difference thermocouple. The temperature of the inner adiabatic shield was kept automatically the same as that of the sample container within $\pm 0.003$°K at room temperature and within $\pm 0.01$°K at 30°K.

## Experimental Procedure

**The Calibration of the Platinum Resistance Thermometer in the Temperature Range from 13 to 300°K.** — It is necessary to calibrate a working platinum resistance thermometer against the international or the thermodynamical temperature scale, since the accuracy of the measurement of the temperature has an important bearing on the precision claimed for the calorimetry. The procedure for calibrating the thermometer is described below.

Above 90°K, the International Temperature Scale (I.T.S.) has been used as a practical scale of temperature in order to give a greater reproducibility and a far simpler realization of the scale than would otherwise be obtained on the gas scale. On the other hand, in only one part of the scale below 90°K has an agreed method of interpolation been adopted internationally, namely, from 0.5 to 5.2°K a scale based on the vapor pressure temperature scale of $He^4$.[4] At the National Bureau of Standards a provisional scale has, however, been established in terms of a gas thermometer with the aim of seeking the uniformity of the temperature scales of the various laboratories doing low-temperature work.

For this purpose a series of Pt resistance thermometers has been made by the Leeds and Northrup Company; they were calibrated at the National Bureau of Stndards,* based on the I.T.S. of 1948 between the boiling points of sulfur and of oxygen, and on the NBS scale of Hoge and Brickwedde[5] below the oxygen boiling point. One of these, No. 1510628, was purchased by our University and served as the standard for the calibration of the working thermometers used in our laboratory. The working thermometer, No. 1526483, was calibrated against the standard thermometer by an intercomparison method at any fixed temperature. For this purpose, two thermometers were fixed with Wood's metal into reentrant wells in a copper block. This copper block was hung in the place of the sample container within the inner adiabatic shield of the calorimeter assembly described above. The measurements of the resistance were carried out by the use of the Mueller Bridge with an accuracy of $\pm 0.00001$ ohm by keeping the temperature difference between the block and the adiabatic shield as small as possible. Practically all the intercomparison experiments were performed with temperature drifts less than $\pm 0.0001$°C/min. of the copper block. The precise $R_0$ value, the resistance at the ice point, was measured in the conventional manner by the use of the apparatus, which is essentially the same as that described by Stimson.[6]

For the smoothing of the intercomparison data, the resistance differences $\Delta R$ between the standard (S) and the working (W) thermometers were plotted against $R_S$. Fortunately, fairly linear relationship was observed between $\Delta R$ and $R_S$ in the measured temperature range, as may be seen in Fig. 5. The scatters of the experimental points from the straight line derived by the method of least squares were nowhere smaller than 0.00007 ohm; they are plotted in Fig. 6. The linear relationship between $\Delta R$ and $R$ is to be expected if the "Z function" method proposed by Cragoe[7] can be

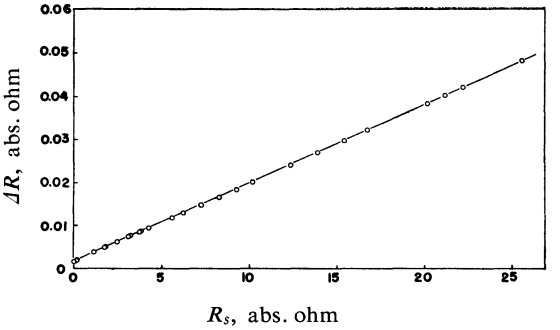

Fig. 5. Plots of $\Delta R(R_x - R_S)$ against $R_S$.

exactly applied to these thermometers. That is, if the resistances of the two thermometers obey the Matthiessen rule, and if the temperature dependent components of the resistances can be described with the same function of temperature, the linear relationship follows that between $\Delta R$ and $R$.

It was now possible make a resistance-temperature table directly for the working thermometer through the formula: $R_w = R_s(1+A)+B$, the numerical factors, $A$ and $B$, being determined to be 0.0018325 and 0.001556 respectively. The tabulation was made with intervals of temperature 0.1°K below 90°K and 1°K above 90°K. Also, the temperature variation of the resistance, $dR/dT$, was tabulated by the formula; $dR_w/dT = (1+A)dR_s/dT$. This value served for making a linear interpolation of the resistance at any temperature.

**Measurements of the Heat Capacity.** — After setting the sample in the container, the closure was fastened with soft solder. Then helium gas at the desired pressure was introduced through the copper tubing attached to the closure, and the tubing was pinched off so as to keep helium gas tight. The calorimeter was then assembled, and the insulating vacuum space was pumped for several days at room temperature. The pressure was read on a Phillips gauge with a liquid nitrogen trap.

In order to cool the calorimeter, liquid nitrogen was added to the dewar, and helium gas of about 1 mmHg pressure was introduced into the vacuum space. By pumping off the liquid nitrogen in the dewar vessel, the sample was cooled to about 55°K. In the course of this cooling process, the "High-Precision" resistance recorder was operated in such a manner as to draw a continuous cooling curve of the sample, a curve useful for checking the presence of any thermal anomaly that might be encountered. When the measurements were to be made at lower temperatures, liquid hydrogen was introduced into the dewar vessel through a transfer siphon after the liquid nitrogen had been drawn off and the vacuum space flushed with hydrogen gas. A small amount of helium gas was again introduced into the vacuum space; by pumping on the hydrogen bath, the temperature of the calorimeter could be lowered to about 12°K. The in-

sulating vacuum space was then evacuated, and after the sample showed an upward temperature drift a series of measurements were started.

In an individual measurement, the temperature drift was measured before and after the heating period. The rate of energy input was varied from about 0.01 degrees to 0.2 degrees per minute. A series of measurements in the temperature range from 15 to 310°K usually required about 100—150 hr. Additional runs were made on the empty container over the whole temperature range. To obtain the heat capacity of the sample itself, the heat capacity of the filled calorimeter was corrected for the smooth heat capacity of the empty can.

## Experimental Results

In order to verify the performance and the accuracy of this low temperature calorimeter, the heat capacity of the benzoic acid crystal was measured from 15 to 310°K. The sample was obtained through the courtesy of E. J. Prosen of the Chemistry Division of the National Bureau of Standards as a Calorimetry Conference Standard specimen. About 23 g. of this sample was transferred into the sample container.

Figure 7 illustrates an example of heat capacity measurement. In general, the time taken to attain equilibrium after the energy input was between 3 and 5 min. Above 50°K, most of the experiments were carried out with a small thermal leakage, resulting in temperature drifts within ±0.0003—0.0005 deg./min. On the other hand, some experimental difficulties were encountered below 50°K as a result of the decrease in the heat capacities of the specimen and also the increase in the heat exchange between the calorimeter and the surroundings.

The experimental heat capacities, listed in Table I are the ratio of the increment in enthalpy to the increment in temperature, $\Delta H/\Delta T$, and must be corrected for curvature if the differential heat capacities are needed. In the case of the benzoic acid crystal, the correction is for all points less than a change of one in the last figure entered in the table. Also listed in this table are the approximate temperature rise, $\Delta T$, in an individual measurement and $T_{av}$, the arithmetic mean of the initial and final temperatures. The deviation of each measured point from a smooth curve is plotted in Fig. 8 as a function of the temperature; the dotted lines mean a one per cent deviation. An examination of the figure indicates that the greatest divergence is found below 50°K. The reason for this seems to be the difficulties of maintaining the adiabatic conditions of the calorimeter in this temperature range; the equipment becomes insensitive, and the thermal leakages between the assembly and the surroundings increase, while the heat capacities of the constituent materials decrease progressively as the temperature is lowered.

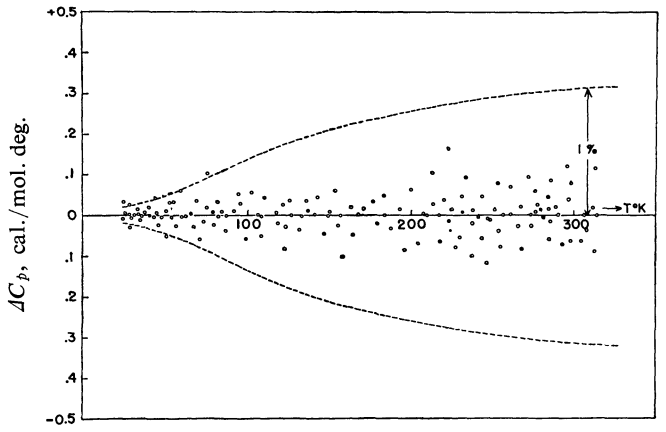

Fig. 8. Deviations of experimental heat capacities of benzoic acid from a smoothed curve.

Above 100°K all the points fall within ±0.5%, and most of them within ±0.3%.

Measurements of the heat capacity of the Calorimetry Conference Standard benzoic acid have hitherto been reported by Furukawa et al.[8], Stout et al.[9], Osborne et al.[10] and by Busey[11]. The smooth curve derived from the present measurements coincides well (within 1%) with their results above 20°K. Remarkable disagreements have been reported among the heat capacity data reported hitherto at temperatures below 20°K. The present data seems to lie between the NBS and Stout data. The increase in the scattering of each measured point, however, makes it impossible to deduce a quantitative conclusion in this temperature range at the present stage.

## Summary

An adiabatic calorimeter for the measurements of the heat capacity of a solid and liquid over the temperature range from 13 to 300°K has been constructed. In order to minimize the operating manpower, all the temperature controls were recorded semiautomatically. The energy input was started and stopped automatically by a timer driven by a signal from a transistor clock. The working platinum resistance thermometer was calibrated against a laboratory standard thermometer which had been calibrated by the National Bureau of Standards. In order to verify the performance and the accuracy of this one-man-operated calorimeter, the heat capacity of a Calorimetry Conference Standard sample of benzoic acid crystal has been measured from 15 to 310°K. The results have compared with the data from the NBS and from other laboratories; this comparison served to establish the reliability of this equipment. The estimated errors are ±2% at 20°K, ±1% below 50°K, and ±0.3% above 50°K.

This work was supported in part by the Scientific Research Expenditure Fund of the Ministry of Education, to which the authors' thanks are due. The authors also wish to express their thanks to Mr. Nobuo Nakamura for his kind help in the numerical calculations.

# Heat Capacity and Thermodynamic Functions of $K_2CuCl_4 \cdot 2H_2O$ and $(NH_4)_2CuCl_4 \cdot 2H_2O$ from 13 to 310°K*

By Hiroshi SUGA, Michio SORAI, Tadashi YAMANAKA** and Syûzô SEKI

(Received November 4, 1964)

There have been many investigations of the orientational order-disorder phenomena of ammonium ions in the crystalline state. Among these, the most comprehensive have been those of ammonium halides. In the case of ammonium chloride, it has been revealed from various experimental facts[1-4] and from theoretical considerations[5] that a $\lambda$-type anomaly at $-38$°C in the heat capacity curve can be explained by the co-operative transition from an uniquely defined orientational state to two equally-probable states with respect to the $NH_4^+$ ion.

X-Ray structural study of the $(NH_4)_2CuCl_4 \cdot 2H_2O$ crystal[6] shows that the crystal lattice is, roughly speaking, composed of three units $NH_4^+$, $Cl^-$, and $CuCl_2 \cdot 2H_2O$, with the result that the inter-ammonium distance of ammonium chloride is enlarged two-dimensionally by the introduction of $CuCl_2 \cdot 2H_2O$. It will, therefore, be of some interest to study an orientational ordering process of such a linearly-arranged ammonium ion system and to compare the results with those of an isotropically-arranged one found in ammonium chloride.

The present paper will report on the thermodynamic properties of $(NH_4)_2CuCl_4 \cdot 2H_2O$ and $K_2CuCl_4 \cdot 2H_2O$ crystals from 13 to 310°K. The latter crystal was selected as a reference material because it belongs to the same crystal system ($D_{4h}^{14}$-P4/mnm) as the former and involves a spherical cation, $K^+$, with an ionic radius nearly equal to that of the $NH_4^+$ ion.

## Experimental and Results

**The Preparation of Samples.**—The potassium copper chloride dihydrate, $K_2CuCl_4 \cdot 2H_2O$, is the double salt of KCl and $CuCl_2 \cdot 2H_2O$, while the ammonium copper chloride dihydrate, $(NH_4)_2CuCl_4 \cdot 2H_2O$, is that of $NH_4Cl$ and $CuCl_2 \cdot 2H_2O$. $(NH_4)_2CuCl_4 \cdot 2H_2O$ ($NH_4$-salt) was prepared from a mixed solution of their component substances and was purified by repeated recrystallizations.[7] In the case of $K_2CuCl_4 \cdot 2H_2O$ (K-salt), the crystal was prepared according to the phase diagram[8] of the $KCl$–$CuCl_2$–$H_2O$ system. Commercial analytical reagents of the Wakō Pure Chemical Industry Company were used for the preparation.

**Differential Thermal Analysis.**—The freshly prepared specimens of $NH_4$-salt are reported to exhibit a thermal anomaly at about $-22$°C on cooling.[9] This anomaly is due to the freezing of occluded water, since there is no thermal anomaly in partly-dehydrated samples. In order to eliminate the excess water, the sample was dried over partly-dehydrated $NH_4$-salt in a desiccator for several weeks. In order to determine the temperature of dehydration, differential thermal analysis (DTA) and thermogravimetric analysis (TGA) methods were applied to both crystals; some interesting features due to the process of dehydration were thus found. The results are shown in Fig. 1. As the temperature is raised, K-salt exhibits two apparently separate peaks, at about 93°C and 116°C. In the case of $NH_4$-salt, however, only one peak appears, at about 143.5°C, with a shoulder at 138°C.

Meyerhoffer[10] has found, from dilatometric study, a phase change for K-salt at 92.4°C and has suggested the following decomposition mechanism*:

$$K_2CuCl_4 \cdot 2H_2O \rightleftarrows KCuCl_3 + KCl + 2H_2O$$

* Presented in part at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

* This decomposition mechanism was recently confirmed by us from Debye-Scherrer photographs taken below and above 93°C. Fairly intensive diffraction lines ascribed to KCl crystal appeared on the photograph taken at about 100°C. We are greatly indebted to Mr. Takemi Yamada of our University for his kind arrangements for taking high-temperature X-ray photographs.

This mechanism was also verified by Vriens[11] from vapor pressure measurements of K-salt and saturated solutions containing K-salt, KCl and $KCuCl_3$. This transition corresponds just to the first peak in the DTA curve. The released water dissolves parts of the crystals and forms a saturated solution, so shat the solution evaporates at a much higher temperature than does the free water. The second peak which appeared on the DTA curve seems to correspond to the evaporation process, because its temperature depends markedly on the pressure of the surroundings. The temperature of the first peak, on the other hand, is almost not influenced at all when the pressure is reduced to 350 mmHg. The thermo-gravimetric analysis of K-salt revealed that the weight of the sample is the same, within the range of experimental error, before and after the first peak I, corresponding to the A- and B-stages in Fig. 1(a) respectively. However, when

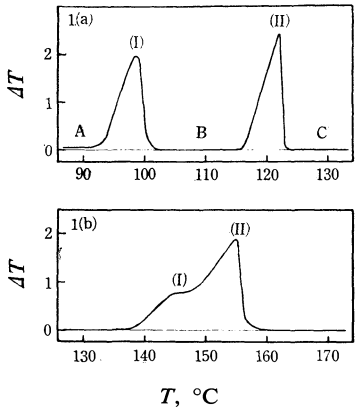

Fig. 1. Curves of the differential thermal analysis: 1(a) for $K_2CuCl_4 \cdot 2H_2O$ and 1(b) for $(NH_4)_2CuCl_4 \cdot 2H_2O$.

passing through the second peak II, at the C-stage in the figure, the sample loses weight nearly equal in amount to the crystalline water involved. From these facts we may regard the phase changes at the I and II peaks to be as follows:

(I) $K_2CuCl_4 \cdot 2H_2O \rightarrow KCuCl_3 + KCl + 2H_2O$ (satd. soln.)

(II) $2H_2O$ (satd. soln.) $\rightarrow 2H_2O$ (vapor)

The occurrence of extra peaks in the DTA curve of hydrates due to the formation of a saturated solution is not uncommon.[12]

In the case of $NH_4$-salt, the first peak appears on a shoulder of the second, so that a similar TGA method can not be applied to this salt. From the fact that the crystal structure of $NH_4$-salt is isomorphous with that of K-salt, we may also assume similar phase changes at the two successive peaks.

**The Heat Capacity of $(NH_4)_2CuCl_4 \cdot 2H_2O$ and $K_2CuCl_4 \cdot 2H_2O$.** — The low temperature calorimeter and the method of measurement are the same as those described in the previous report.[13] The calorimeter contains 26.967 g. (0.09719 mol.) of $(NH_4)_2CuCl_4 \cdot 2H_2O$ and 31.127 g. (0.09740 mol.) of $K_2CuCl_4 \cdot 2H_2O$ with helium exchange gas, respectively, in each experiment.

The experimental heat capacities listed in Tables I and II are the ratios of the increase in enthalpy, $\Delta H$, to the rise in temperature, $\Delta T$, and are equal to the differential heat capacity, $C_P$, only when the correction for curvature is negligible. Here, a defined calorie equal to 4.1840 absolute joules is used, and the ice point temperature is taken as 273.15°K. Also listed in Tables I and II are $T_{av}$, the arithmetic mean of the initial and final temperatures of each measurement, and the approximate temperature rise, $\Delta T$. The experimental heat capacities and the smoothed curves of both crystals are shown in Figs. 2 and 3.[14] The deviation plot of measured points from the smoothed curve are given in Fig. 4 for the sake of reference.

As is shown in Fig. 2, the $(NH_4)_2CuCl_4 \cdot 2H_2O$ crystal exhibits a heat capacity maximum at 200.50°K. The shape of the heat capacity curve around this temperature is similar to that of

14) The only heat capacity data on K-salt available for comparison is given by Kopp ("Landolt-Börnstein Physikalisch-Chemische Tabellen II," Berlin, 1923), whose value, 63.0 cal./deg. mol. at about 35°C, lies on the extrapolated curve of the present data.

the aniline hydrobromide crystal[15] at the $\lambda$-point, indicating that the phase transition is of a higher order. On the other hand, the $K_2CuCl_4 \cdot 2H_2O$ crystal does not show any thermal anomaly over the entire temperature range investigated.

**Thermodynamic Propertier of $(NH_4)_2CuCl_4 \cdot 2H_2O$ and $K_2CuCl_4 \cdot 2H_2O$.**—The values of the heat capacity, entropy, enthalpy and the free energy function for $NH_4$-salt and K-salt have been derived from the experimental heat capacities with the standard technique; they are summarized in Tables III and IV. The extrapolation to 0°K was made by using the Debye formula. The error of the smoothed heat capacity data is estimated to be ±1% below 60°K and ±0.3% above 60°K. The values of entropy and free energy listed in Tables III and IV do not include the magnetic contributions from copper ions. Haseda[16] has recently reported the magnetic transition of K-salt at about 0.8°K, corresponding to the magnetic transition of the copper ion from the antiferromagnetic to the paramagnetic state. If the magnetic contributions were included in the thermodynamic functions of Tables III and IV, the values of entropy would become greater than the present values by about 1.3 e. u., while the values of free energy would be scarcely changed. On the other hand, the corresponding magnetic transition of $NH_4$-salt has not yet been reported. The $NH_4$-salt has an isomorphous crystal structure with the K-salt, and has lattice constants nearly equal to that of the K-salt, that is, $a_0=7.58$ Å and $c_0=7.96$ Å for the former and $a_0=7.45$ Å and $c_0=7.88$ Å

15) H. Suga, This Bulletin, 34, 426 (1961).

16) T. Haseda, private communication.

for the latter. The corresponding magnetic transition can, accordingly, also be expected for the $NH_4$-salt around 1°K.

**The Anomalous Heat Capacity of $(NH_4)_2CuCl_4 \cdot 2H_2O$.**—As is mentioned above, $NH_4$-salt gives a heat capacity anomaly. The excess heat capacity seems to rise at about 120°K, reaches a maximum value at 200.50°K, and then drops rather rapidly. The anomalous heat capacity, $(\Delta C_p)_{tr}$, at this maximum temperature amounts to 13.24 cal. $deg^{-1}$ $mol^{-1}$. On the other hand, K-salt does not show any such thermal anomaly. Accordingly, the thermal anomaly seems to be associated with a movement of the ammonium group of $NH_4$-salt.

The entropy of transition, $\Delta S_{tr}$, amounts to 1.945 e. u., and the enthalpy of transition, $\Delta H_{tr}$, to 387.7 cal. $mol.^{-1}$ The procedure for calculating these values may be worth mentioning in more detail, so it will be described below.

In order to calculate the entropy and the enthalpy of transition, as well as the heat capacity associated with the ordering phenomena of the ammonium group, it is necessary to subtract the "normal" heat capacity from the experimentally-measured one. An ammonium ion has an excess of twelve internal degrees of freedom compared with a potassium ion. First of all, the contributions from these internal and torsional vibrations must be subtracted from the experimental heat capacity. Infrared or Raman data are, unfortunately, not yet known for this substance. However, it may not be unreasonable to assume that the values of the vibrational frequencies of the ammonium group in $NH_4$-salt will be replaced by those of other ammonium salts, in which the situation of the ammonium ion is similar to that of the present salt; i. e., each of ammonium ions is surrounded by a slightly distorted cube consisting of eight chlorine ions. The present crystal has an N-Cl distance of 3.35 Å and an N-N distance of 3.98 Å, distances which are comparable with those for ammonium chloride, where the N-Cl distance is 3.32 Å and the N-N distance, 3.87 Å. Thus, the values of the vibrational frequencies of the ammonium chloride crystal[3] may be assumed for the present crystal in calculating the contributions arising from the ammonium groups. The adopted values are as follows: $\nu_1=3040\,cm^{-1}$ (1), $\nu_2=1670$ (2), $\nu_3=3100$ (3), $\nu_4=1403$ (3), and $\nu_6$ (torsional) $=310$ (3) (the numbers in parentheses indicate degeneracy).

Now, $C_{int}(NH_4^+)$, the contribution from the internal vibrations and torsional oscillations of the ammonium ions to the heat capacity, can be calculated by using the Einstein function:

$$C_{int}(NH_4^+) = 2R \sum_i d_i \frac{x_i^2 e^{-x_i}}{(1-e^{-x_i})^2} \qquad (1)$$

where $d_i$ is the degeneracy of an $i$-th mode of vibration and $x_i=h\nu_i/kT$. The $\Delta C_P$ (anomal) $= C_P$ ($NH_4$-salt) $- C_{int}(NH^+_4) - C_P$ (normal) quantity should be approximately the extra heat capacity contribution from the orientational motion of the ammonium ion as a whole. Usually the $C_P$ (normal) quantity is estimated graphically rather arbitrarily. In the present case, however, the anomalous heat capacity extends over a considerable temperature range, and there is some latitude in drawing the normal heat capacity of the ammonium salt.

Osborne and Westrum[17,18] have assumed that the lattice contribution to the heat capacities of $UO_2$ and $NpO_2$ equals the heat capacity of the isomorphous diamagnetic, $ThO_2$, in estimating the anomalous magnetic contribution, and also, in another example, that the heat capacity of $ThF_4$ represents the lattice contribution for $UF_4$. This kind of assumption is not tenable for the present case, however, since at a low temperature the observed heat capacity of *K*-salt exceeds that of $NH_4$-salt, and a high temperature the situation is reversed. Stout and Catalano[19] have applied a law of corresponding states in order to estimate the normal heat capacity of antiferromagnetic $MnF_2$, $FeF_2$, $COF_2$ and $NiF_2$ by utilizing the heat capacity data of isomorphous, diamagnetic $ZnF_2$. Although the difference in structural parameters between the present two crystals is not very large,[6] the crystal structure of these salts is too complicated to apply such a simplified treatment in the present case.

In order to carry out a tentative but rather

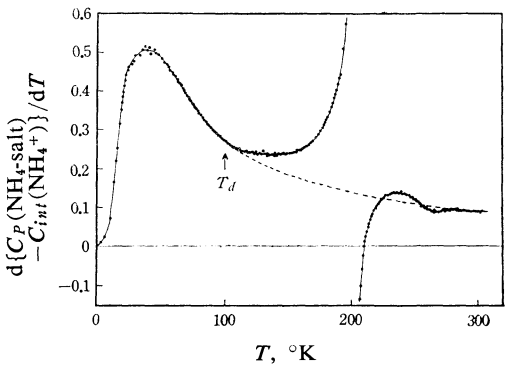

Fig. 5. $d\{C_P(NH_4\text{-salt}) - C_{int}(NH_4^+)\}/dT$ vs. temperature plot for $(NH_4)_2CuCl_4 \cdot 2H_2O$ crystal.

19) J. W. Stout and E. Catalano, *J. Chem. Phys.*, **23**, 2013 (1955).

agreeable treatment for estimating the normal heat capacity of the $NH_4$-salt, the following procedure was adopted. The differential quantity, $d\{C_P(NH_4\text{-salt}) - C_{int}(NH_4^+)\}/dT$, was plotted against the temperature over the entire temperature range; the results are drawn in Fig. 5. The corresponding value for K-salt, $dC_P(\text{K-salt})/dT$, is given in Fig. 6 for the sake of comparison. This procedure magnifies the effect of the phase transition on the graph. If there is no heat capacity anomaly, the behavior of the $dC_P/dT$ in the $NH_4$-salt should be similar to that of K-salt, which is a monotonous function of the temperature.

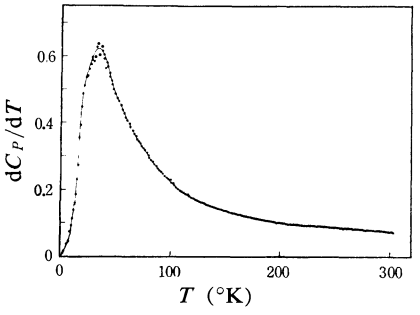

Fig. 6. $dC_P$(K-salt)/$dT$ vs. temperature plot for $K_2CuCl_4 \cdot 2H_2O$ crystal.

There is also some latitude in drawing the dotted curve in Fig. 5, which represents the trend of the normal heat capacity of the $NH_4$-salt. However, there are at least two restrictions to eliminating some of the arbitrariness involved. One is that the curve corresponding to the normal heat capacity, the dotted curve in Fig. 5, must be a monotonously decreasing function; the other is that the normal heat capacity obtained by integrating the differential quantity should not exceed the value, $C_P(NH_4\text{-salt}) - C_{int}(NH_4^+)$, at any temperature. This means that the anomalous heat capacity, $\Delta C_P$(anomal), can not be negative. Consequently, the normal heat capacity at $T$°K was calculated as follows:

$$C_P(\text{normal}) \text{ at } T^\circ\text{K} = \{C_P(NH_4\text{-salt}) - C_{int}(NH_4^+)\} \text{ at } T_d^\circ\text{K} + \int_{T_d}^{T} \frac{dC_P(\text{normal})}{dT}\, dT \qquad (2)$$

where $T_d$ is the temperature at which the $dC_P(\text{normal})/dT$ curve deviates from the $d\{C_P(NH_4\text{-salt}) - C_{int}(NH_4^+)\}/dT$ curve. The anomalous heat capacity, estimated by using Eqs. 1 and 2 and the experimental heat capacity data, is shown in Fig. 7. This curve presumably corresponds to the lower limit of the anomalous heat capacity, in view of the two assumed requirements mentioned above. Above 300°K the dotted curve in Fig. 7 was extrapolated somewhat arbitrarily. The contribution from this part to the entropy of the transition amounts merely to 2.5 per cent of the total. The values of $\Delta S_{tr}$ and $\Delta H_{tr}$ were then calculated from the $\Delta C_P$(anomal) versus temperature curve.

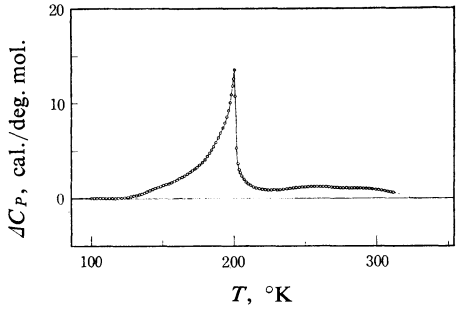

Fig. 7. Anomalous heat capacity of $(NH_4)_2CuCl_4 \cdot 2H_2O$ around 200.50°K.

## Discussion

In order to discuss the nature of the phase transition of $NH_4$-salt, it is desirable to compare with each other the crystal structures of the two crystals.[6] The crystallographic data are summarized in Tables V, while the projections on the (010) and (001) planes of the crystal structure of $NH_4$-salt are depicted in Figs. 8 and 9. As has been mentioned already, each ammonium ion is surrounded by a slightly distorted cube consisting of eight chlorine ions. The N–Cl and N–N distances in the $NH_4$-salt are comparable to those of the ammonium chloride crystal. Therefore, an orientational order-disorder-type phase transition associated with the ammonium ions in ammonium chloride may also be expected for this $NH_4$-salt.

Table V. Crystallographic data of $NH_4$-salt and K-salt[6]

| $(NH_4)_2CuCl_4 \cdot 2H_2O$ | $K_2CuCl_4 \cdot 2H_2O$ |
|---|---|
| $D_{4h}^{14}$ (P4/mnm) | |
| $Z=2$ | |
| $a_0=7.58$ Å | $a_0=7.45$ Å |
| $c_0=7.96$ Å | $c_0=7.88$ Å |
| Cu: 0,0,0; 1/2,1/2,1/2, | |
| $NH_4$ or K: 0,1/2,1/4; 1/2,0,1/4; 0,1/2,3/4, | |
| Cl (1): $\pm(u,u,0; u+1/2,1/2-u,1/2)$ | |
| Cl (2): $\pm(v,v,1/2; v+1/2,1/2-v,0)$ | |
| $H_2O$: $\pm(0,0,w; 1/2,1/2,w+1/2)$ | |
| $u=0.217$ | $u=0.220$ |
| $v=0.221$ | $v=0.220$ |

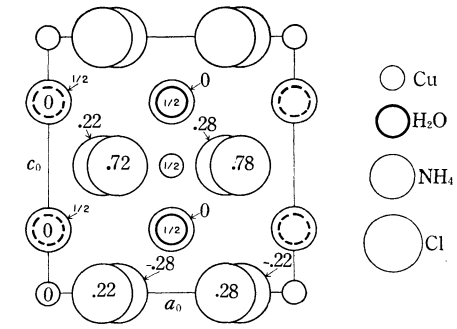

Fig. 8. A projection on the (010) plane of the crystal structure of $(NH_4)_2CuCl_4 \cdot 2H_2O$ (after Wyckoff).

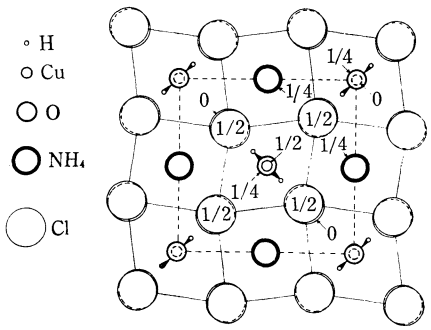

Fig. 9. A projection on the (001) plane of the crystal structure of $(NH_4)_2CuCl_4 \cdot 2H_2O$.

Itoh and Kamiya[20] have recently reported on the temperature variation of the proton nuclear magnetic resonance spectra of the $NH_4$-salt and have observed a motional narrowing associated with the protons of the ammonium group at about 150°K. They found that the situation of the barrier height hindering the flipping motion of the ammonium ion is very similar to that with ammonium chloride. If the nature of the transition of this crystal is very similar to that of the ammonium chloride, the entropy of transition could amount to 2.68 ($2R \ln 2$) e. u. The experimental value is, however, 1.945 e. u., about two thirds of 2.68 e. u.

In the case of ammonium chloride, all chlorine ions are equivalent with respect to the $NH_4^+$ ion, while for the present crystal, Itoh et al.[21] have reported that there are two kinds of chlorine ions; one makes a hydrogen bond with the proton of crystalline water, while the other does not. Other differences from the ammonium chloride are that the present crystal has a tetragonal symmetry and that the N–N distance is quite different in each direction. The N–N distance along the [001] axis is 3.98 Å, while along the [110] axis it is 5.36 Å. Thus, only along the direction of the c-axis is the N–N distance comparable with that of ammonium chloride.

In other words, the principle of the framework of the present crystal is that the $NH_4Cl$ is diluted by $CuCl_2 \cdot 2H_2O$ and the interaction between the ammonium ions is weakened two-dimensionally. In such a pseudo-linear chain of $NH_4^+$ ions, the order parameter describing the randomness with respect to the orientation of ammonium ions is expected to change much less co-operatively than a three-dimensionally-arranged system, as in the case of ammonium chloride. The extraordinary broadness of the anomaly, as well as the much smaller jump of $C_P$ at the transition point, may be ascribed to the weakened interaction between the ammonium ions in this crystal. The maximum anomalous heat capacity of the present crystal amounts merely to 13.24 cal. $deg^{-1}$ $mol^{-1}$, while in the case of ammonium chloride[1] it reaches about 159 cal. $deg^{-1}$ $mol^{-1}$.

It should be mentioned that above the transition point there is a rather broad and small hump in the $\Delta C_P$(anomal) versus temperature curve. It is more magnified in the curve of the derivative of the heat capacity than in the heat capacity curve itself (see Fig. 5). If the residual anomalous part of the heat capacity curve above the phase transition point is exclusively due to the short range order remaining, it may not show such a maximum point. Therefore, we may assume, as one explanation, that the hump arises from the Shottky anomaly, based on the population difference of the individual ammonium ion between the two sites of different energies, associated with the different chlorine ions in the disordered state; in one possible orientation of the ammonium ion, all four protons are directed to the chlorine ions hydrogen-bonded with the crystalline water, while in the other all protons are directed to the free chlorine ions. If the hump is ascribed to the Shottky anomaly, the energy difference between the two possible orientations of the ammonium ions is calculated to be about 1.3 kcal. $mol^{-1}$.

We have not given here the theoretical treatment needed to interpret the transition mechanism of the pseudo one-dimensional ionic array of the present crystal. In order to develop such a treatment, the ordered structure of ammonium ions must be known precisely. Because of the rather small value of the apparent transition entropy ($\fallingdotseq 2/3 \times 2R \ln 2$), however, it is supposed that there still

20) J. Itoh and Y. Kamiya, *J. Phys. Soc. Japan*, **17**, Supplement B-I, 512 (1962).

remains a much larger degree of disorder with respect to the orientation of ammonium groups in the low temperature phase. Further investigations of, for example, neutron diffraction, neutron inelastic scattering, or some other spectroscopic techniques will be useful in understanding more quantitatively the nature of the phase transition.

## Summary

The heat capacity of copper potassium chloride dihydrate and copper ammonium chloride dihydrate crystals have been measured between 13 and 310°K. The latter crystal shows a $\lambda$-type anomaly in the heat capacity curve which seemed to be due to the orientational order-disorder process of ammonium groups. The heat capacity of $(NH_4)_2CuCl_4 \cdot 2H_2O$ exhibits a maximum value of 76.290 cal. deg.$^{-1}$ mol$^{-1}$ at 200.50°K. By plotting the temperature derivative of heat capacities, the normal contribution from the lattice to the heat capacity of $(NH_4)_2CuCl_4 \cdot 2H_2O$ has been estimated. In this case the corresponding values for $K_2CuCl_4 \cdot 2H_2O$ has been taken as a reference. By subtracting the estimated normal heat capacity from the experimentally measured one, approximate values of the entropy change, $\Delta S =$ 1.945 cal. deg.$^{-1}$ mol$^{-1}$, and the heat capacity jump, $\Delta C_P = 13.24$ cal. deg$^{-1}$ mol$^{-1}$, associated with the orientational ordering of the linearly-arranged ammonium ion system have been given.

The values of the heat capacity, entropy, enthalpy, and Gibbs free energy of both crystals have been tabulated at selected temperatures. The standard values of the entropy and enthalpy are: $K_2CuCl_4 \cdot 2H_2O$, $S^0 = 84.95$ cal. deg$^{-1}$ mol$^{-1}$, $H^0 - H_0^0 = 11980$ cal. mol$^{-1}$; $(NH_4)_2 \cdot CuCl_4 \cdot 2H_2O$, $S^0 = 92.30$ cal. deg.$^{-1}$ mol$^{-1}$, $H^0 - H_0^0 = 14220$ cal. mol$^{-1}$.

# Switch-over of the Mechanism of the Primary Processes in the Photo-oxidation of Xanthene Dyes as Revealed by the Oxygen Consumption Experiments

By Yoshiharu Usui, Keiko Itoh and Masao Koizumi

(Received November 17, 1964)

As early as 1933 Blum and Spealman[1] studied the photo-oxidative bleaching of xanthene dyes by oxygen. Some of their findings on aerated $2.8\times10^{-4}$ M aqueous solutions of eosine were, 1) production of hydrogen peroxide, 2) existence of an induction period in the bleaching course of the dye, 3) decrease of the rate at high concentrations of oxygen. They inferred from the findings 1 and 2, that the reaction may proceed according to the following scheme, $D^*+O_2 \rightarrow D+O_2^*$, $O_2^*+H_2O \rightarrow OH+HO_2$ followed by the decomposition of dye by OH and $HO_2$. Since then no kinetic studies had been made on similar systems until. Imamura and one of the present authors (M. K.) investigated the aerated $1\times10^{-5}$ M solution of dye.[2] They found that all the above phenomena were absent at this concentration, the rate of reaction being simply proportional to the absorbed light and increasing monotonously to a certain constant value as the concentration of oxygen increased. They concluded therefore, that the primary process of the photo-oxidation at this concentration of dye is attack of the oxygen on the triplet dye, resulting in destruction of the dye structure. They did not, however, attempt to interpret the differing results of Blum et al., only attributing them to the experimental conditions, particularly to the different concentration of dye.

Now the flash photolytic investigations made by Lindqvist[3] and Grossweiner et al.[4], the former on fluorescein and the latter on eosine,

1) H. F. Blum and C. R. Spealman, *J. Phys. Chem.*, **37**, 1123 (1933).

2) M. Imamura and M. Koizumi, This Bulletin, **28**, 117 (1955); M. Imamura, *J. Inst. Polytech. Osaka City Univ.*, **5**, 85 (1956).

3) L. Lindqvist, *Arkiv Kemi*, **16**, 79 (1960); V. Kaoshe and L. Lindqvist, *J. Phys. Chem.*, **68**, 817 (1964).

4) E. F. Zwicker and L. I. Grossweiner, ibid., **67**, 549 (1963).

have afforded kinetic data for the various elementary reactions and have revealed much of the details of the photochemical behaviors of these dyes. In particular, Lindqvist proposed an epoch-making view that electron transfer can take place between the triplet dye and the ground state dye of fluorescein. Following this work, Koizumi et al. presented strong evidence for the occurcence of such a process in the actual photochemical reduction of thiazine dyes.[5,6] Further, Ohno and Koizumi[7] found that in the photoreduction of eosine by allyl thiourea, a switch-over of mechanism does take place; the attack of reducing agent on triplet dye (D-R mechanism) predominates at lower concentrations of dye, whereas electron transfer between the triplet and the ground-state dyes (D-D mechanism) becomes the main process at higher concentrations.

The purpose of the present investigation is to provide additional evidence of a switch-over from D-O* to D-D mechanism by studying the photo-oxidative behavior of rather concentrated aqueous solutions of xanthene dye, and further, to give a reasonable correlation between Blum's and Imamura's results.

For this purpose the oxygen up-take of the irradiated aqueous solutions has been investigated by means of Warburg's apparatus and the results are compared with those obtained previously. The results, which are somewhat similar to those of Blum et al., can now be interpreted very satisfactorily and the differences in the results of the two groups of investigators are well interrelated with each other on the basis of the switch-over of the mechanism from a D-O mechanism at low concentrations of dye to a D-D mechanism at higher concentrations. A reinterpretation of Imamura's data is also given.

## Experimental

**Sample.** — *Eosine.* — Merck's G. R. sample was recrystallized twice from ethanol. The maximum molar extinction, $\varepsilon_{max}$ for an aqueous solution is $9.6\times10^4$.

*Erythrosine.*— Merck's G. R. reagent was used without further purification. $\varepsilon_{max}$ was $6.7\times10^4$.

*Fluorescein.*—The Sodium salt of Tokyo Kasei was recrystallized three to four times from ethanol containing a small quantity of sodium hydroxide. $\varepsilon_{max}$ in the phosphate buffer solution was $6.8\times10^4$ (pH 7.65).

**Apparatus and Procedure.**—Warburg's apparatus was the one supplied by Ōtake Co. The light source consisted of three 30W. daylight fluorescent lamps 60 cm. in length placed below the reaction cells with a suitable filter in between. The filters were $30\times100$ cm. plastic plates; the one for eosine and erythrosine cuts off below 480 m$\mu$, and the one for fluorescein cuts off below 340 m$\mu$. Reaction cells, each containing 20.0 ml. of the dye solution $5.0\times10^{-5}$—$8.0\times10^{-3}$ M in concentration, were immersed in a Warburg thermostat at $30.0\pm0.02$°C and after 20—25 min. the illumination was started. The depth of the solutions being about 2 cm., the absorption of light is practically complete in the wavelength region of the visible absorption spectra. The cell constants of all cells are about 2. The quantity of absorbed gas was measured by a push-up method. Correction of atmospheric pressure and temperature was made by means of a thermobarometer. This is necessary, because of the long duration of irradiation and the rather small quantity of absorbed gas. The quantity of bleached dye was measured spectroscopically, after diluting to about $10^{-5}$ M, on a Hitachi EPU-2A spectrophotometer or EPS-3 autorecording spectrophotometer.

The saturated solution of oxygen under 1 atm. was prepared as follows. The sample solution was flushed for fifteen minutes with 1 atm. of oxygen and 20.0 ml. of it was poured into the reaction cell, the operation being done in the current of oxygen.

## Results

**Effect of the Dye Concentration on the Rate of Oxygen Consumption.** — Using the plain aqueous solutions of eosine and erythrosine and the phosphate buffer solutions of fluorescein (pH 7.65), all at various dye concentration, two series of experiments were performed for each dye, one series with the air-saturated solutions ($[O_2]\approx2.5\times10^{-4}$ M) and the other with the solutions saturated with 1 atm. of oxygen ($[O_2]\approx1.2\times10^{-3}$ M).

*Eosine.*—As seen from Fig. 1, oxygen consumption by the air-saturated solution takes place linearly with time. The slope which gives the rate, increases with the dye concentration up until about $\sim5\times10^{-4}$ M is reached but becomes practically constant beyond $10^{-3}$ M of dye.

The results are similar for the oxygen-saturated solutions except for the fact that the limiting rate is attained at a somewhat higher concentration of dye. Figure 2 gives the plots of the rate against the dye concentration. It is worth while to note that the limiting value is practically the same for the air-saturated and the oxygen-saturated solutions.

*Erythrosine.*—Figure 3 shows the results for erythrosine. In this case the limiting value

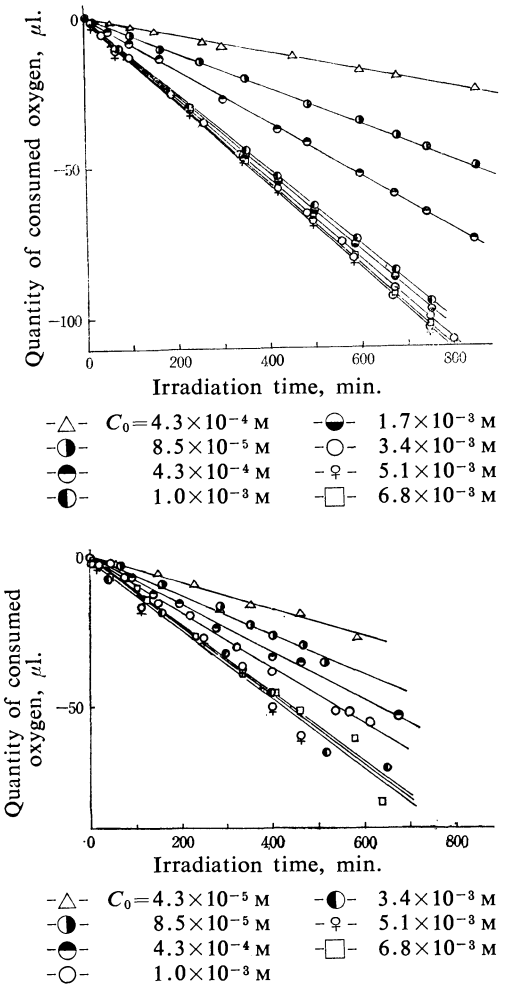
7) T. Ohno, Y. Usui and M. Koizumi, ibid., 38, 1022 (1965).
* O denotes oxidant (oxygen). In this case oxygen attacks the triplet dye instead of th reducing agent.



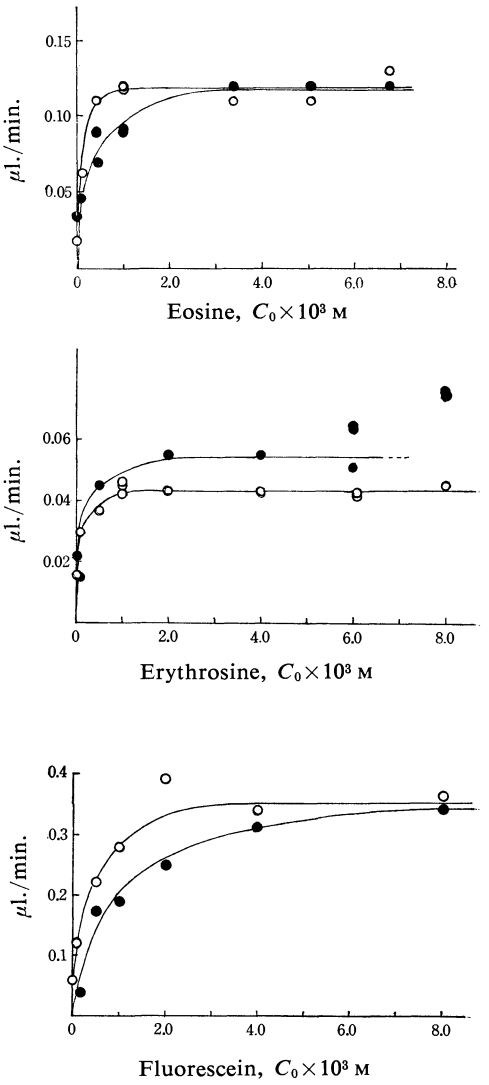


Fig. 1. Examples of oxygen consumption in the air saturated (upper), and oxygen saturated (under) solution of eosine.

Figs. 2, 3 and 4. Dependence of the rate of oxygen consumption on the dye concentration. -●- oxygen saturation, -○- air saturation

for the oxygen-saturated solution seems to be a little higher than that for the air-saturated solution, although its magnitude lies close to the experimental error.

*Fluorescein.*—Figure 4 gives the results for fluorescein at pH 7.65. The main features of the curve are essentially the same as those in the case of eosine except that the attainment of the critical value seems to be realized at a somewhat higher concentration of dye.

Summing up the above results, one can say that all the xanthene dyes behave essentially the same in the neutral region and that the rate of oxygen consumption is constant when the dye concentration is much larger than that of oxygen but begins to fall rather sharply in the region $[D] \approx [O_2]$.

**The Bleaching Rate of the Dye.**—Measurements were made choosing dye concentrations in the region $10^{-5}$ to $10^{-4}$ M, since accurate experiments with more concentrated solutions, which undoubtedly are very desirable, require quite a new technique and, besides, Imamura has pointed out[2] that a simple rate formula ceases to hold near $10^{-4}$ M of dye. A 75V.-500W. tungsten projection lamp was used as a light source and the experiments were made at 30.0°C. A spacer 9.0 mm. in width was used for measuring the optical density of the $10^{-4}$ M solutions. The results are given in Fig. 5 and in Table I. In Fig. 5, the linearity of the curves implies that the rate is simply proportional to the absorption of light. As this figure shows, the linear relation holds as long as $r=[D_0]/[O_2]$ is less than ~0.2. The results at lower $r$-values are in excellent

* Koizumi and Imamura[2]

agreement with those of Imamura. In two experiments on the air-saturated solutions for $8.0\times10^{-5}$ and $1.0\times10^{-4}$ M of dye, for which $r$ is respectively 0.32 and 0.40, the initial rate is somewhat larger and, besides, the simple rate formula does not hold, the rate increasing as the reaction progresses. It is estimated that the final rate is several times larger than that at the initial stage. It is remarkable that an oxygen-saturated solution of the same concentration of dye still obeys the simple rate formula with the same slope as the others. There is no doubt, therefore, that the above anomalous behavior is due to the higher value of $r$.

Figure 6 gives the relation between the initial rate and the concentration of oxygen when the dye concentration is fixed at $10^{-4}$ M. It is seen from the figure that the rate increases with the oxygen concentration, reaching a maximum at about $1.5\times10^{-4}$ M of oxygen

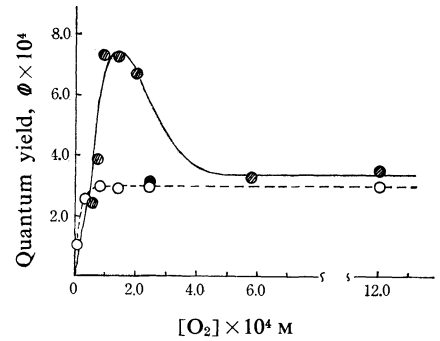

Fig. 6. Oxygen concentration effect on the quantum yield of bleaching.
Eosine concn.:
-●- $1.0\times10^{-4}$ M, -○- $1.0\times10^{-5}$ M

and then falls to a constant value beyond $\sim2.5\times10^{-4}$ M of oxygen.

From the above results one can say that at high concentrations of dye, the rate of the oxydative bleaching of dye decreases when the oxygen concentration exceeds a certain value which is close to the dye concentration.

Such a phenomenon had not been observed in Imamura's experiment on $1\times10^{-5}$ M of dye. This was reconfirmed by the present authors, as shown by a dotted curve in Fig. 6.

**Quantum Yield of the Oxygen Up-take and the Ratio of Oxygen Consumption and the Dye Bleaching.**—The quantity of light absorption in the oxygen consumption experiment was determined by measuring the oxidative photobleaching of dye in the Warburg apparatus under conditions similar to those used in Imamura's experiment and by using the value for the quantum yield reported by Imamura[2] and confirmed by Grossweiner.[4] Then the quantum yields for oxygen consumption are easily calculated from the results given in Figs. 2, 3, 4 and 5. The ratio of the consumed oxygen to the bleached dye was determined by measuring the dye concentration after the oxygen up-take experiment. Table II gives the results.

Although the data for $\Delta[O_2]/\Delta[D]$ scatter to a large extent, it seems that they are from 1 to 2 for eosine and fluorescein, while for erythrosine they are about 1.

There is no doubt from this table, that the value for the photobleaching at $10^{-4}-10^{-3}$ M of dye, as judged from the quantum yield for oxygen consumption and $\Delta[O_2]/\Delta[D]$, is in most cases a few times larger than that at $10^{-5}$ M.

**Production of Hydrogen Peroxide and Its Effect on the Rate.**—The quantity of hydrogen peroxide produced was analyzed by the ordinary iodometry. Some of the results are given in Table III.

Table II. Quantum yields of oxygen-up-take and the values of $\Delta[O_2]/\Delta[D]$

Table III. Production of hydrogen peroxide

| Dye | Dye-concentration M | Quantity of bleached dye $\mu$M/300 min. | Quantity of produced $H_2O_2$ $\mu$M/300 min. |
|---|---|---|---|
| Fluorescein (phosphate-buffer) | $2.0\times10^{-3}$ | | 2.4 |
| | $1.0\times10^{-3}$ | 2.5 | 2.2, 3.0 |
| | $1.0\times10^{-4}$ | (4.4) | 0 |
| Eosine | $1.0\times10^{-3}$ | 1.4 | 2.6 |
| | $1.0\times10^{-4}$ | 0.5 | 1.4 |
| Erythrosine | $1.0\times10^{-3}$ | 0.7 | 0 |
| | $1.0\times10^{-4}$ | 0.4 | 0 |

It can be said that hydrogen peroxide is really produced when the dye concentration is high, and its quantity is of about the same order as that of the bleached dye. To examine the effect of hydrogen peroxide on the rate, hydrogen peroxide in concentrations as high as $1\times10^{-3}$ M was added to the $1\times10^{-3}$ M solution of eosine. The result was that the rate was the same within the experimental error.

## Discussion

**Reinterpretation of Imamura's Results.**— According to Lindqvist,[3] the triplet state ($D^T$) of fluorescein dianion is deactivated by oxygen or the ground state dye, as follows.

(1) $D^T+O_2\rightarrow D+O_2$ $k_1=1.7\times10^9$ M$^{-1}$ sec$^{-1}$

(2) $D^T+D\rightarrow D+D$ $k_2=1\times10^8$ M$^{-1}$ sec$^{-1}$

Ohno and Koizumi estimated the rate constant of the process 2 for eosine dianion to be $5.5\times10^8$ M$^{-1}$ sec$^{-1}$. These results imply that the lifetimes of the triplet state of these dianions are greatly reduced at $10^{-5}$ M of dye by the bimolecular deactivation process.

In 1955, when nothing was known about the rate constants of various elementary reactions, Imamura and Koizumi supposed that the genuine triplet lifetime is so short that the process 2 need not be taken into account. Hence their data must now be reinterpreted in such a way that, instead of self-deactivation, competitive deactivation is taking place with oxygen and the ground state dye. By slightly modifying the method given by Imamura, one can easily evaluate the ratio $k_1/k_2$ from the previous data for the oxygen concentration effect on the oxidative photobleaching of dye. The results are given in Table IV. These data refer to the solutions with pH near 7. From the above data one can say that the two deactivation processes have in general the same order of magnitude and hence it is very plausible that they are approximately diffusion controlled. A value of $k_1/k_2$ larger than 1 also supports this view.

Table IV

| Dye | Temp, °C | $k_1/k_2$ |
|---|---|---|
| Fluorescein | 30 | 1.8 |
| Eosine | 30 | 1.4* |
| | 40 | 5.3 |
| Erythrosine | 30 | 3.4 |
| (Methylene blue)** | 30 | 1.3 |

* Evaluated from the new data.

** The result for methylene blue is added for comparison.

Lindqvist's result for fluorescein at pH= 0—5.5, $k_1=1.2\times10^9$ M$^{-1}$ sec$^{-1}$ and $k_2=2.5\times10^9$ M$^{-1}$ sec$^{-1}$, as well as the above data for the alkaline region are not inconsistent with the above view. Grossweiner's value for $k_1$ of eosine is rather small, being $2.3\times10^7$ M$^{-1}$ sec$^{-1}$. This was evaluated by analyzing the data on the competitive reaction of $D^T$ with oxygen and phenol and it is suspected that this small value of $k_1$ has resulted from neglections to consider the simple deactivation of $D^T$ by phenol.

**Interpretation of the Oxygen Consuming Reaction.** — Assuming the triplet dye to be simultaneously deactivated by oxygen and the ground state dye, and assuming the occurrence of a genuine reaction between $D^T$ and D such that $D^T+D\rightarrow R+X$ where R and X are the

half-reduced and half-oxidized dyes, respectively, then, during oxidative photobleaching, the D-O mechanism would occur when $[D] \ll [O_2]$ and the D-D mechanism would prevail in the opposite situation.

Now the present experimental conditions are such that the above switch-over of the mechanism should naturally occur. Hence the data will be treated along this line. The reaction scheme for lower concentrations of dye is

$$\text{A}\begin{cases} D \rightarrow D^* & & \text{(i)} \\ D^* \rightarrow D^T & \varphi_{sT} I_{ab} & \text{(ii)} \\ D^T \rightarrow D & k_d & \text{(iii)} \\ D^T + O_2 \rightarrow D^T \cdots O_2 & k_{O_2} \} k^s_{O_2} & \text{(iv)} \\ D^T + O_2 \rightarrow D + O_2 & k_{O_2}^{(d)} \} k^s_{O_2} & \text{(v)} \end{cases}$$

while with higher concentrations of dye, one plausible scheme after the step ii may be written as follows.

$$\text{B}\begin{cases} D^T + D \rightarrow D^+ \cdots D^- & k_D \} k^s_D & \text{(vi)} \\ D^T + D \rightarrow D + D & k_D^{(d)} \} k^s_D & \text{(vii)} \\ D^+ \cdots D^- \rightarrow D + D & k'_d & \text{(viii)} \\ D^+ \cdots D^- + O_2 \rightarrow \text{Prod.} & k'_{O_2} \} k'^s_{O_2} & \text{(ix)} \\ D^+ \cdots D^- + O_2 \rightarrow 2D + O_2 & k'^{(d)}_{O_2} \} k'^s_{O_2} & \text{(x)} \end{cases}$$

In the general case where both A and B are taking place simultaneously, the rate of oxygen consumption (expressed by the concentration dissolved oxygen), $R_{O_2}$, is easily derived as follows,

$$R_{O_2} = \{k_{O_2}[D^T][O_2] + k'_{O_2}[D^+ \cdots D^-][O_2]\}$$
$$= \frac{\varphi_{sT} I_{ab} k_{O_2}[O_2]}{k_d + k^s_{O_2}[O_2] + k^s_D[D]} \times \left\{1 + \frac{k_D k'_{O_2}[D]}{k_{O_2}(k'_d + k'^s_{O_2}[O_2])}\right\} \quad (1)$$

The scheme B is still provisional but it is thought that the resultant expression will not be essentially affected by the details of the scheme. Quantum yield $\gamma_{O_2} = R_{O_2}/I_{ab}$ is given as follows after the neglection of $k_d$ which is very small compared with the competitive terms.

$$\gamma_{O_2} = \frac{\varphi_{sT} k_{O_2}[O_2]}{k^s_{O_2}[O_2] + k^s_D[D]} \left\{1 + \frac{k_D k'_{O_2}[D]}{k_{O_2}(k'_d + k'^s_{O_2}[O_2])}\right\} \quad (2)$$

In an extreme case where $[D] \gg [O_2]$

$$\gamma_{O_2}(\text{D-O}) = \frac{\varphi_{sT} k_{O_2}}{k^s_{O_2}} \quad (2a)$$

and in the other extreme case where $[D] \gg [O_2]$

$$\gamma_{O_2}(\text{D-D}) = \varphi_{sT} \frac{k_D}{k^s_D} \frac{k'_{O_2}[O_2]}{k'_d + k^s_{O_2}[O_2]} \quad (2b)$$

The condition for 2b to hold is fully satisfied when the concentration of dye is large enough, and quite reliable values for $\gamma_{O_2}(\text{D-D})$ can be evaluated directly from Figs. 2, 3 and 4. But this is not so with $\gamma_{O_2}(\text{D-O})$. To estimate this value the following procedure is conventionally adopted. If one puts $\alpha = k^s_{O_2}/k^s_D$, Eq. 2 can rewritten as follows,

$$\{\alpha[O_2] + [D]\} = \frac{\varphi_{sT} k_{O_2}[O_2]}{k^s_D} \times \left\{1 + \frac{k_{O_2}[D] k'_{O_2}}{k_{O_2}(k'_d + k^s_{O_2}[O_2])}\right\} \quad (3)$$

By using the $\alpha$-values given in Table V a plot of the left-hand side of Eq. 3 against [D] can be drawn and this should give a straight line. One can evaluate $\gamma_{O_2}(\text{D-O})$ and $\gamma_{O_2}(\text{D-D})$ from the slope and intercept respectively, although the former is not so reliable as the latter. As Fig. 7 shows, this method is fairly satisfactory and the results are given in Table V. It was checked that moderate change of $\alpha$ does not affect the result so much (cf*). For comparison, Imamura's data on the quantum yield of photobleaching at $[D] = 10^{-5}$ M are added in the last column. It is interesting that $\gamma_{O_2}(\text{D-D})$ for eosine and fluorescein is the same for the air-saturated and oxygen saturated solutions, while this is not so for erythrosine. This may be due to the difference in stability of the D-D redox intermediate.

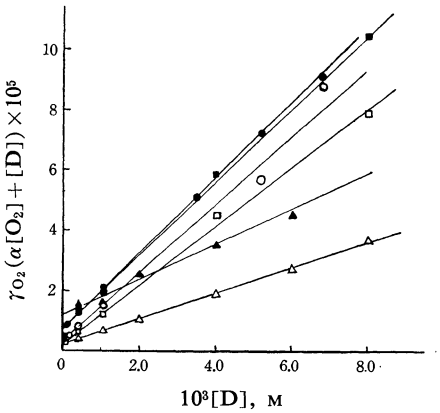

Fig. 7. Estimation of $\gamma_{O_2}(\text{D-O})$ and $\gamma_{O_2}(\text{D-D})$. Dark point is to the case of oxygen saturation and blank point to air saturation.
□■ uranine, ○● eosine, △▲ erythrosine

**Interpretation of the Bleaching Curve.**—As Fig. 5 shows, the rate of bleaching begins to increase when $\gamma = [D_0]/[O_2]$ exceeds about 0.2, and in such cases, the rate increases rapidly with the progress of the reaction. On the basis of the present view that a switch-over from the D-O to the D-D mechanism takes place, the above phenomena are just what is expected, because the D-D mechanism is considered to begin to contribute to the whole

TABLE V. QUANTUM YIELDS OF OXYGEN CONSUMPTION FOR D-O AND D-D MECHANISM

| | $\alpha$ | Air-saturation | | Oxygen saturation | | $\gamma_{dye-bleach}$ |
|---|---|---|---|---|---|---|
| | | $\gamma_{O_2}(D\text{-}O)$ | $\gamma_{O_2}(D\text{-}D)$ | $\gamma_{O_2}(D\text{-}O)$ | $\gamma_{O_2}(D\text{-}D)$ | |
| Eosine | 1.4 | $4\times10^{-3}$ | $1.2\times10^{-2}$ | $6\times10^{-3}$ | $1.3\times10^{-2}$ | $2.7\times10^{-4}$ |
| Erythrosine | 1.5 | $2.8\times10^{-3}$ | $4.3\times10^{-3}$ | $2.2\times10^{-3}$ | $6\times10^{-3}$ | $5.0\times10^{-4}$ |
| | 2.4* | $2.5\times10^{-3}$ | $4.5\times10^{-3}$ | $3.4\times10^{-3}$ | $7\times10^{-3}$ | — |
| Fluorescein (pH 7.65) | 1.8 | $4.4\times10^{-4}$ | $1.1\times10^{-2}$ | $3.7\times10^{-4}$ | $1.2\times10^{-2}$ | $1.3\times10^{-4}$ |

bleaching reaction when $[D_0]$ approaches $[O_2]$, and further, because the oxygen concentration decreases as the reaction proceeds (the experimental condition is static in the bleaching experiment), thus increasing the contribution of the D-D process. Broadly speaking, the bleaching reaction is thought to proceed according to a scheme similar to that of the oxygen consumption reaction, hence it is very plausible that the bleaching rate via the D-D mechanism is several times larger than that via the D-O mechanism, and this is also just what is observed in Fig. 5.

The above view is further supported by the experiments in which the rate of bleaching is measured at a constant dye concentration of $10^{-4}$ M, and at various oxygen concentrations. As Fig. 6 shows, the rate increases with $[O_2]$ in the low $[O_2]$ region, reaches a maximum and finally falls to a constant value which of course corresponds to $\gamma_{O_2}(D\text{-}O)$. The different behavior at $1\times10^{-5}$ M of dye will be considered later.

**Interpretation of Blum's Results and General Discussions.**—Our results reconfirm Blum's observations mentioned at the beginning of this paper and make them more quantitative. Blum in addition, suggested that the formation of hydrogen peroxide is not directly connected with the decomposition of dye. This is clearly understood on the basis of a D-D mechanism. Thus at higher concentrations of dye, the reaction proceeds as follows:

$$D^T + D \rightarrow D^+ \cdots D^-$$

$$D^+ \cdots D^- + O_2 + H^+ \rightarrow HO_2\cdot + D^+ + D$$

Alternatively,

$$D^T + D \rightarrow D^+ + D^-$$

$$D^- + H^+ + O_2 \rightarrow HO_2\cdot + D$$

and hydrogen peroxide is produced from $HO_2\cdot$, while most of $D^+$ is converted into the colorless form. Lindqvist proposed the view that dimerization of $D^+$ occurs. $D^+$ may, however, alternatively lose its dye structure by reacting with oxygen or it may revert to the original dye upon the attack of $HO_2\cdot$ as suggested by Lindqvist. Thus the formation of hydrogen peroxide and the destructive bleaching of dye proceed independently of each other in the later stage. The magnitude of oxidative bleaching and accordingly $\Delta[O_2]/\Delta[D]$ are thought to depend upon the fate of the half-oxidized dye. On the other hand, at low dye concentrations, oxygen directly attacks the triplet state leading to the decomposition of dye without the production of hydrogen peroxide. In this case the kinetic features of the bleaching are very simple.

Lastly, some speculative discussions will be added on the lifetime of the redox intermediate and on the general features of the photooxidative bleaching of the dye. In Imamura's experiments at $[D]=10^{-5}$ M, and as reconfirmed by the present investigation, the rate of the oxidative photobleaching decreases monotonously with the decrease of oxygen concentration below $[O_2]=10^{-5}$ M. But under such circumstances, the D-D mechanism should become appreciable, and if oxygen effectively attacks the D-D redox intermediate, a larger rate than that for the D-O mechanism should be expected. The experimental results thus require the D-D redox intermediate to have such a short lifetime that it has no chance to react with oxygen. Putting $[O_2] \sim 10^{-6}$ M and assuming that the reaction between oxygen and the intermediate is diffusion controlled, the decay constant of the D-D intermediate should be larger than $10^9\times10^{-6}=10^3\,sec^{-1}$. When $[O_2]$ is $10^{-4}$ M, the D-D intermediate of eosine should have enough chance to be attacked by oxygen, because $\gamma_{O_2}(D\text{-}D)$ is independent of the oxygen concentration. Thus the decay constant of the D-D intermediate must be far less than $10^5\,sec^{-1}$. From the above argument, the decay constant of the D-D intermediate for eosine should be of the order of $10^4\,sec^{-1}$. In case of erythrosine this is a little larger since the dependence on $[O_2]$ is really observed. If one assumes that instead of the formation of $D^+\cdots D^-$, the reaction $D^T+D \rightarrow D^+ + D^-$ occurs very effectively, yielding free semiquinone and semi-oxidized dye, then the steady concentration of these species in the present experimental condition is estimated to be of the order of $10^{-9}$ M assuming that the reaction between these species is diffusion-controlled. Hence the lifetime of such species should be of the

order of 1 sec. The present results completely reject this possibility and one can safely conclude that most of the redox intermediate $D^+\cdots D^-$ reverts to the original dye via the reverse reaction without forming separate radical ions.

The lifetime of $D^+\cdots D^-$ and its tendency to form free radical ions will depend sensitively on the experimental conditions as well as on the nature of the dye, and this is perhaps one of the reasons why dyes of the same group show sometimes very different behavior and why the general nature of the reaction is often difficult to understand.

## Summary

The oxygen up-take of irradiated aqueous solutions of xanthene dyes has been investigated by means of Warburg's apparatus, and evidence for a switch-over from a D-O to a D-D mechanism is obtained from the variation of dye-concentration. This view is supported by the photobleaching rate and the oxygen concentration effect at high eosine concentrations ($\sim 10^{-4}$ M).

The quautum yields ($\gamma_{O_2}$) of the consumption are estimated and it is found that $\gamma_{O_2}$ (D-D) is larger than $\gamma_{O_2}$(D-O).

# An Attempt to Determine Eosine's S*→T Transition Probability and Evidence for the Participation of a D–D Redox Mechanism

By Takeshi OHNO, Yoshiharu USUI and Masao KOIZUMI

(Received November 17, 1964)

The primary processes in the photochemical reactions of xanthene dyes have been studied by several workers[1,2] by means of the steady illumination, and the ratios of the rate constants for some elementary reactions have been evaluated. Very few attempts, however, have been made to determine exactly the rate constant of each particular elementary process, and of these attempts the flash photolytic investigations of Lindqvist[3] and Grossweiner[4,5] are the most prominent. The former was concerned with fluorescein while the latter dealt with eosine.

The decay constant of the triplet state and the transition probability of the singlet excited state to the triplet state, i. e., $\varphi_{S\to T}$ are believed to be the most fundamental. If the exact values of these two are known, many of the other rate constants can be evaluated very easily from their ratios.

One method to determine the value of $\varphi_{S\to T}$ is to make use of the kinetic data from a suitable reaction. In principle, the method consists of evaluating the quantum yield under conditions such that all the triplet state dyes react in one definite way. For example, if the photochemical reduction proceeds according to the following scheme,

$$\begin{array}{ccccccc} D & \rightarrow & D^* & \rightarrow & D^t & \xrightarrow{k_r[R]} & \text{Leuco dye} \\ & & \downarrow & & \downarrow k_d & & \\ & & D & & D & & \end{array}$$

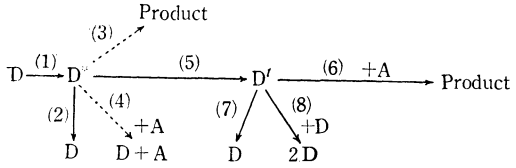
where $D^*$, $D^t$ are respectively the singlet excited state and the triplet state of the dye, and R is a reducing agent, then the quantum yield, $\Phi$ is expressed as follows

$$\Phi = \varphi_{S\to T}\frac{k_r[R]}{k_d + k_r[R]} \qquad (1)$$

Hence

$$\frac{1}{\Phi} = \frac{1}{\varphi_{S\to T}} + \frac{1}{\varphi_{S\to T}}\cdot\frac{k_d}{k_r[R]}$$

and the plot of $1/\Phi$ against $1/[R]$ gives $1/\varphi_{S\to T}$ as an intercept. For the above method to be used effectively, certain conditions must be fulfilled. 1) The reducing agent R should



1) M. Imamura and M. Koizumi, This Bulletin, **29**, 899 (1956).
2) G. Oster and A. H. Adelman, *J. Am. Chem. Soc.*, **78**, 913 (1956).
3) L. Lindqvist, *Arkiv Kemi*, **16**, 79 (1960).
4) L. I. Grossweiner and E. F. Zweicker, *J. Chem. Phys.*, **34**, 1411 (1961).
5) E. F. Zwicker and L. I. Grossweiner, *J. Phys. Chem.*, **67**, 549 (1963).

not appreciably affect the ground state or the singlet excited state of the dye. 2) Mere deactivation should not result from the attack of R on $D^t$. 3) The final product must be produced by a one step attack of R on $D^t$ or else the succeeding steps must be known completely.

On the basis of the above principles, Oster obtained the values 0.092 0.020 for $\varphi_{S\to T}$ of eosine and fluorescein, respectively, at pH 7.0.[2] He used allylthiourea (ATU) as a reducing agent and investigated the photoreduction of these dyes in aqueous solution. Oster proposed the following rate formula,

$$\text{rate} = \frac{I_{ab}[A]}{\alpha+\beta[A]} \qquad (2)$$

where $\alpha$, $\beta$ are constants, $I_{ab}$ is the absorbed light per second per liter, and [A] is the concentration of ATU. The scheme for the reaction is

(3)

where dashed arrows indicate processes having negligible rates. The process 8 was added to take into account the fact that the rate decreases with increase of dye concentration. On the basis of the above scheme, he derived the following rate formula,

$$\text{rate} = \frac{I_{ab}k_5k_6[A]}{(k_2+k_5)(k_7+k_6[A]+k_8[D])} \qquad (4)$$

which is the same as the experimental rate formula except for the term $k_8[D]$, and he estimated some of the rate constants.

In view of the importance of $\varphi_{S\to T}$, it seems desirable to repeat this experiment and to ascertain whether in fact the above conditions are fulfilled. In addition, there is a possibility that the reaction scheme is dependent on experimental conditions such as the concentration of dye as well as that of the reducing agent.

It is desirable, therefore, to examine the rate formula for a run and to study the behavior of the intermediate and of the final product before the above method is used.

In this paper we have attempted to determine $\varphi_{S\to T}$ for eosine in aqueous solution at pH= 7.2, paying attention to the above meniioned points. Broadly speaking, we have carried out experiments similar to those of Oster, using ATU and EDTA as reducing agents, and have examined the applicability of 2 and 4. Although we could not get a satisfactory result for $\varphi_{S\to T}$, we have found strong evidence for the participation of a D-D mechanism in this system.

## Experimental

**Materials.**—*Eosine.*—Grübler's product was used. Stock solution ($1\times10^{-4}$ M) which had been kept in the dark was diluted to $4.5\times10^{-6}$ M—$2.4\times10^{-6}$ M for each experiment. Allylthiourea (ATU) was recrystallized from water three times. To avoid degradation of the ATU, it was stored in the ice box. Ethylenediaminetetraacetic acid disodium salt (EDTA) was prepared by dissolving Dotite 2 NA. Disodium hydrogen phosphate ($Na_2HPO_4\cdot12H_2O$) and potassium hydrogen phosphate ($KH_2PO_4$) were recrystallized three times.

**Procedure.**—All the solutions were prepared from 1/25 M phosphate buffer at pH=7.2. Most of the solutions were degassed by use of a mercury diffusion pump, freezing and thawing (in a dry ice bath) being repeated four to six times. The degassed sample in a cell ($1\times1\times4$ cm.) was irradiated with a tungsten projection lamp (50 V. 125 W.) having a yellow glass filter cutting off $<470$ m$\mu$. For solutions with initial dye concentrations in the range $2.4\times10^{-6}$ M—$10^{-5}$ M, the concentration of residual dye was measured colorimetrically without stopping the irradiation. With initial concentrations of dye greater than $10^{-5}$ M, a 7 mm. spacer was inserted into the cell, and the measurements were carried out as above.

A temperature of 25°C was chosen. To determine the quantity of light absorbed by the dye, a calibrated Kipp and Zonen thermopile having a sensitivity of $1.02\times10^{-5}$ V./m$^2$ watt was used, and the output measured with a potentiometer.

## Results

**ATU.**—*Rate Formula for a Run.*—Equation 4 derived from Oster's scheme 3 is not strictly of the same form as Eq. 2 and, moreover, it can not be integrated in a simple way. However, if $k_8[D]\ll k_7+k_6[A]$, then 4 is reduced to 2 and the rate is simply proportinal to the absorption of light. In this case the rate formula for a run can be derived as follows.

Putting

$$I_{ab}=I_o(1-e^{-\alpha cd})$$

where $I_o$ is the number of photons per cm$^2$ and $\alpha$ is the average molar absorbancy, one can write

$$-\frac{dC}{dt}=\Phi\frac{I_o}{d}(1-e^{-\alpha cd})1000 \qquad (2)$$

Integration gives

$$\ln(e^{\alpha cd}-1)=-1000\alpha\Phi\frac{I_o}{d}t+\ln(e^{\alpha c_o d}-1) \qquad (5)$$

Hence the plot $\ln(e^{acd}-1)-t$ should give a straight line with a slope of $1000\,\alpha\Phi I_0$.

Now, as long as the concentration of ATU is in the range $5\times10^{-4}$ M—$2.0\times10^{-2}$ M and the dye concentration is $10^{-5}$ M, the rate formula 5 accommodates the experimental data very satisfactorily until up to 40% of the dye has been bleached. Thus the rate is simply proportional to the absorption of light. When [ATU] becomes less, however, Eq. 5 appears to become less satisfactory and a second order rate formula in regard to dye holds better, although the initial part of the rum can still be expressed by 5. Some examples are shown in Figs. 1 and 2.

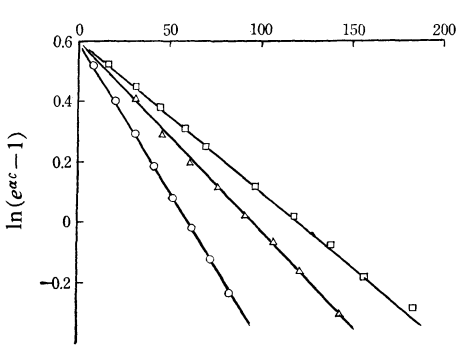


Fig. 1. Fading curves of eosine in vacuo for various concentration of ATU. At 25°C.

△: ATU, $1.67\times10^{-3}$ mol./l.
□: ATU, $1.25\times10^{-3}$ mol./l.

Now if $k_8$[D] in the denominator of Eq. 4 is not negligible, then the rate should increase in the later stage and should be larger than that calculated from 5, whereas the actual deviation from 5 in the later stage is always in the opposite direction. This strongly suggests that Eq. 4 needs to be modified in some way. To make this point clear, the effect of various factors upon the quantum yield obtained from the initial slope of the $\ln(e^{acd}-1)-t$ plot was examined.

*The Effect of the Dye Concentration.*—With the concentration of ATU fixed at $5.0\times10^{-3}$ M, $1.0\times10^{-3}$ M and $0.50\times10^{-3}$ M, respectively, the effect of the dye concentration on $\Phi$ was investigated. The dye concentration was varied from $2.6\times10^{-6}$ M to $4.4\times10^{-5}$ M. As Fig. 3 shows, the reciprocal of the quantum yield is in a linear relation to the concentration of the dye when [ATU] is $5\times10^{-3}$ M. But when the concentration of ATU is decreased, this linearity deteriorates. Thus the deviation becomes notable at ca. $2\times10^{-5}$ M of dye for $10^{-3}$ M of ATU and at an even lower dye concentration (ca. $10^{-5}$ M) for $0.5\times10^{-3}$ M of ATU. The initial slopes of the curves for [ATU]$=5\times10^{-4}$M and $10^{-3}$ M agree quite well with that calculated from the slope for [ATU]$=5\times10^{-3}$ M by the use of Eq. 4 (see below). From the slopes in the low concentration region of dye and from the tentative value of $\varphi_{S\to T}$ (0.032, see below), $k_8/k_6$ was evaluated to be $1.8\times10^3$. Table I gives values for the quantum yield under differing conditions. The above deviation in Fig. 3, together with the rather large value of $k_8/k_6$ clearly implies that Eq. 5 does not hold when the concentration of dye becomes large in relation to that of ATU.

TABLE I. QUANTUM YIELDS AT VARIOUS DYE CONCENTRATIONS

| Concn. of ATU $\times 10^{-3}$ M | Concn. of dye $\times 10^{-6}$ M | $\Phi$ $\times 10^{-3}$ |
|---|---|---|
| 5.0 | 25.4 | 3.1 |
| 5.0 | 4.2 | 13.0 |
| 1.0 | 8.0 | 2.5 |
| 1.0 | 40.0 | 0.52 |
| 0.5 | 12.0 | 0.77 |
| 0.5 | 20.0 | 0.51 |

*The Effect of the Reaction Product on the Rate.*—Because of the rather large value of $k_8/k_6$ and the ratio of the concentration of the dye to that of the reducing agent, Eq. 4 would require that as the reaction proceeds, the rate would deviate and become larger than that given by the plot $\ln(e^{acd}-1)$—$t$.

But contray to this expectation, the experimental data fits quite well in the initial stage and deviates in the opposite direction in the later stages. This suggest the existence of an inhibiting action due to some reaction product. To check this point, the following experiment was performed. A solution of the dye which had been irradiated until about 30% of the dye had bleached, was added to a fresh sample of dye and the rate of bleaching was measured. In Fig. 3 cross notations refer to such experiments for which the sum [Product]+[dye] was taken as abscissa. The points lie close to the line. It is inferred therefore that the term $k_8[D]$ in 4 should be replaced by $k_8[D]+k_9[\text{product}]$. Assuming $k_8 \approx k_9$ and approximating $[\text{product}]=[D]_o-[D]$, this term may be rewritten as $k_8[D]_o$ where $[D]_o$ is the initial concentration of the dye. The rewritten equation will be denoted as 4'.

$$\Phi=\varphi_{S\to T}\times\frac{k_6[A]}{k_7+k_6[A]+k_8[D]_o} \qquad (4')$$

*The Effect of the Concentration of ATU and the Value of $\varphi_{S\to T}$.*—The concentration of ATU was varied from $10^{-3}$ M to $4\times10^{-2}$ M at some fixed dye concentrations. Figure 4 gives the plots of $1/\Phi$ against 1/[ATU], which are satisfactorily linear. This implies that Eq. 4' holds under the present experimental conditions and this is consistent with the results shown in Fig. 3.

From 4'

$$\frac{1}{\Phi}=\frac{k_2+k_5}{k_5}\left(1+\frac{k_7+k_8[D]_o}{k_6[A]}\right)$$

one can evaluate $k_5/(k_2+k_5)$ from the intercept which is $\varphi_{S\to T}$ and $(k_7+k_8[D])_o/k_6$ from the inclination. In Table II, some of the quantum yield are given, and in Table III, the values of $\varphi_{S\to T}$ and $(k_7+k_8[D]_o)/k_6$ are tabulated. The value in parenthesis is Oster's.

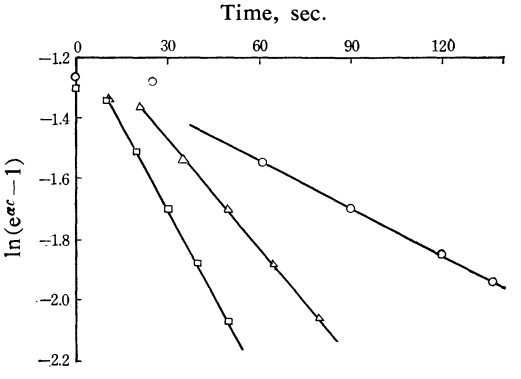
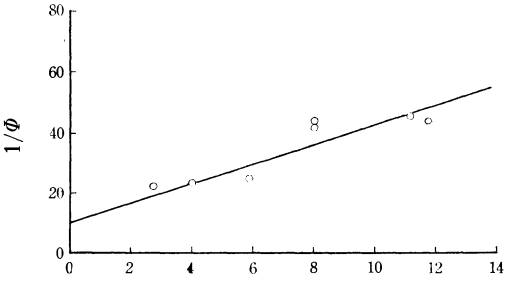
| 298 | $8.1\times10^{-3}$ |
| 308 | $7.9\times10^{-3}$ |
| 320 | $7.3\times10^{-3}$ |

**EDTA.**—*The Rate Formula for a Run.*—It is notable that a certain induction period exists in the case of EDTA. After the induction period, however, the results are satisfactorily reproduced by the plot of Eq. 5, indicating that the rate is simply proportional to the absorption of light. Some typical examples are shown in Fig. 5.





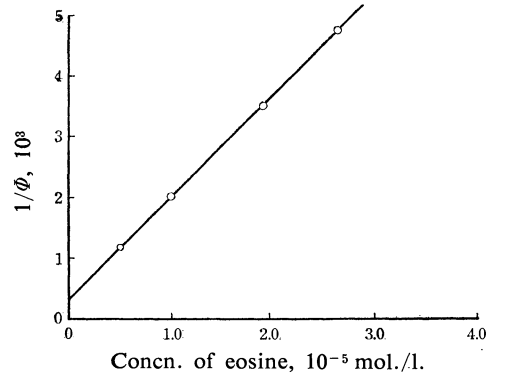


Fig. 5. Fading curves of eosine in vacuo for various concentration of EDTA. Dye concentration, $8\times10^{-6}$ mol./l.
Concn. of EDTA, ○: $2.0\times10^{-3}$ mol./l.
△: $3.3\times10^{-3}$ mol./l.
□: $5.0\times10^{-3}$ mol./l.

*The Effect of the Dye Concentration.*—Figures 6a and 6b give the plot of $1/\Phi$ aginst the dye concentration. Although the data in Fig. 6a show a fair amount of scatter, it is evident that the effect of the dye concentration is much less than in the case of ATU. In Fig. 6b, where a lower concentration of EDTA was used, the linearity is excellent. This result is in sharp contrast with that in the case of ATU for which the deviation from linearity is notable at $[ATU]=0.5\times10^{-3}$ M and $10^{-3}$ M. From the slope and the intercept of the plot in b and from the value (0.080) of $\varphi_{S\to T}$, $k_8/k_6$ was calculated to be $1.3\times10^3$. The result from 6a is $k_8/k_6=1.1\times10^3$, which is in agreements with the above value.

*The Effect of the Concentration of EDTA.*—The concentration of EDTA was varied from $6.7\times10^{-3}$ M to $2\times10^{-2}$ M at two fixed dye concentrations, $8.0\times10^{-6}$ M and $5.5\times10^{-6}$ M. As Fig. 7 shows, the plots are satisfactorily linear and in this case, the two intercepts are exactly the same. Table V gives the quantum yilds under various conditions and Table VI gives $\varphi_{S\to T}$ and the value of $(k_7+k_8[D]_0)/k_6$.

## Supplementary Experiments and Discussion

As will be described later, the finding, that for ATU the linearity between $1/\Phi$ and $[D]_0$ does not hold when $[D]_0$ exceeds a certain value, leads to the conclusion that a switch-over of the mechanism is taking place in this

case. But in most cases Eq. 4′ holds or approximately holds and in such cases, the values of $\varphi_{S\to T}$ can be obtained by formally applying this equation to the experimental data. The rate constants of some elementary reactions can also be estimated in a simple manner. Therefore, we will first discuss these data before entering on a critical discussion of the procedure.

From 4′, the intercept and the inclination of the plots in Fig. 3 and Fig. 6 should be expressed by $\frac{1}{\varphi_{S\to T}}\times\left\{1+\frac{k_7}{k_6[R]}\right\}$ and $\frac{1}{\varphi_{S\to T}}\times\frac{k_8}{k_6[R]}$, respectively. By utilizing the tentative values of $\varphi_{S\to T}$, one can evaluate the ratio $k_8/k_6$ from the inclination. The result, as already stated, is $1.8\times10^3$ M for ATU and $1.3\times10^3$ M for EDTA. Furthermore, it is possible to evaluate $k_6$ by putting[4] $k_7=4.2\times10^2$ in the expression for the intercept. But this procedure is not so reliable, firstly because the value of the intercept is subject to a large error and secondly because this error profoundly affects the value of $k_6$. Hence the following conventional procedure was adopted. The average value of $k_8$ from several determinations for both EDTA and ATU was taken as $5.5\times10^8$ ($\pm1.0\times10^8$) and the value of $k_6$ was calculated from the value of $k_8/k_6$. This results in a value of $k_6=3.1\times10^5$ for ATU, and $4.1\times10^5$ in the case of EDTA.

To check these results, the value of $k_6$ is recalculated from the inclination of the plot $1/\Phi$—$1/[R]$ by inserting the above values of $k_8$ and $k_7$ into the expression $(k_7+k_8[D]_o)/k_6$. The results are as follows.

| Reducing agent | Concn. of dye $\times10^{-6}$ M | The value of $k_6$ |
|---|---|---|
| ATU | 2.4 | $3.8\times10^5$ |
| ATU | 4.0 | $3.4\times10^5$ |
| EDTA | 5.5 | $5.4\times10^5$ |
| EDTA | 8.0 | $4.1\times10^5$ |

In spite of the crudeness of the method, there is no doubt that $k_6$ and $k_8$ are of the order of $10^5$ and $10^8$ respectively, and it seems that the choice of reducing agent makes little difference in these values. But judging from the data given in Table II and Table V, the quantum yield for EDTA is several times larger than that for ATU under otherwise similar conditions. The following data refer to such results. It appears from the above argument that this difference is closely connected with the value of $\varphi_{S\to T}$.

TABLE VII

| $[Dye]\times10^6$ | 4 | 8 | 12 | 16 |
|---|---|---|---|---|
| $\Phi_{EDTA}/\Phi_{ATU}$ | 3.1 | 3.3 | 3.6 | 3.8 |

Next, we will discuss the various conditions necessary for obtaining a reliable value of $\varphi_{S\to T}$ (see the introduction). The first point, which concerns the possibility of the singlet excited state being attacked by R, need not be considered, because neither ATU nor EDTA quenches the fluorescence of eosine appreciably,[2] and also because the $1/\Phi$—$1/[R]$ plots, given in Fig. 4 and Fig. 7, do not show any deviation in the high concentration region of ATU or EDTA.

To investigate the second point which concerns the behavior of the intermediate, a few supplementary experiments were carried out.

In the air-saturated solution, the reaction was found to be completely interrupted in the case of EDTA, but with ATU, for example at $2\times10^{-2}$ M, the reaction proceeds with a quantum yield of 0.005, which is about a quarter of that in the degassed solution under otherwise similar conditions. Such a difference is due, without doubt, to different behaviors of the intermediates in the two cases. In view of the fact that semiquinone produced in ethanol solution is very sensitive to a minute amount of oxygen,[1] the same effect would be expected also in aqueous solution. Therefore, there is a great possibility that semiquinone in a free state is formed in the case of EDTA but not in the case of ATU.* The induction period, which was observed in the case of EDTA, might therefore be due to a small quantity of residual oxygen.

Although the formation of semiquinone in a free state is improbable in the case of ATU, the following experiment strongly suggests the formation of some sort of intermediate with absorption near 360 mμ. Thus when the reaction cell was illuminated from the back with Hg 365 mμ during the reaction, the rate was found to increase by about 20%.

In both cases the behavior of the final product also appears to be quite different. In the case of EDTA, the product had an absorption maximum near 290 mμ and is most probably a leuco dye. But it was found that when the solution was kept in the dark, the oxidized form was regained very slowly. Figure 8 shows that this reversion proceeds as a first order reaction in respect to the photobleached product. This might be due to the formation of a complex composed of molecules of the leuco dye and the oxidized product of EDTA closely held together. The introduction of air increased the rate by about 10%. It is regrettable that in the case of ATU, a spectroscopic investigation could not be carried out due to

* In case of fluorescein, this was really verified by comparing the quantity of semiquinone produced in the two cases. See next paper.

the existing absorption of ATU up to ~290mu. But it was confirmed that the final product is quite stable. All the observations on the intermediate and the final product, although they are still preliminary in nature, suggest that the reaction in question is not so simple and differs from case to case.

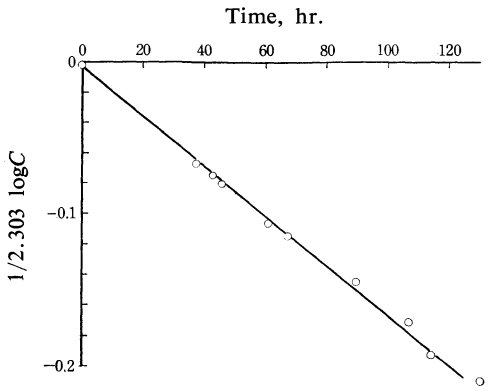

Fig. 8. Reversion curve of eosine according to the first order formula in respect to the photobleached product after eosine was completely photobleached.

As far as the behaviors of the intermediates and final products are concerned, one can not say that the formal procedure of evaluating $\varphi_{S\to T}$ is amply justified. We are at present planning more systematic flash experiments to elucidate the detailed mechanism of the reaction.

Next to be discussed is the switch-over of the mechanism. As has already been clarified by investigations in our laboratory,[6] the photoreduction of methylene blue can proceed by a D-D redox mechanism or a D-R redox mechanism; thus according to the concentration of dye and the type of reducing agent, the primary step of the photoreduction of methylene blue is a) $D^t+D \rightarrow$ semi-reduced dye + semi-oxidized dye (D-D redox mechanism) or b) $D^t+R \rightarrow$ semi-reduced dye + semi-oxidized R (D-R redox mechanism).

Now with the xanthene dyes, photoreduction in the degassed solution does not occur in the absence of a reducing agent.[5] Yet, it was confirmed in the present experiment that deactivation of $D^t$ by the ground state dye occurs, as Oster proposed,[2] and further, it was established that deactivation by leuco dye also occurs, the rate constants for both deactivation processes being close to that controlled by diffusion. This makes us suspect that, with some suitable reducing agents, the photoreduction of this dye may also proceed via a D-D mechanism. This suspicion is further strengthened if one considers Lindqvist's discovery that half-reduced and half-oxidized flurorescein is produced by flash illumination, without addition of any reducing or oxidizing agents.[3]

Now the present results strongly suggest that such a switch-over of the mechanism really exists, in the case of ATU, but not in the case of EDTA, under the present experimental conditions. Thus the findings that the plot of $1/\Phi$—$[D]_o$ begins to deviate at a concentration of $2.4\times10^{-5}$ M of dye when [ATU]$=10^{-3}$, and at $1.2\times10^{-5}$ M dye at $0.5\times10^{-3}$ M ATU, seems to be understandable only on this basis. If the photoreduction in the small concentration region of ATU occurs exclusively by a D-D mechanism, then the rate formula would presumably be given by

$$-\frac{d[D]}{dt}=\frac{\varphi_{S\to T}I_{ab}k_8'[D]}{k_7+k_8[D]_o+k_6[A]}\times\frac{k_r'[A]}{k_d'+k_r^{s'}[A]} \quad (6)$$

where $k_8'$ is the rate constants for $D^t+D\rightarrow D^++D^-$ redox intermediate, and $k_d'$, $k_r'$ are respectively the rate constants for monomolecular deactivation of this intermediate and the rate constants of the reaction with ATU, and $k_r^{s'}$ is the sum of the rate constants for the reaction and deactivation with ATU. According to the following analysis it seems unnecessary to take into account the deactivation of the redox-intermediate by the ground state dye. In the usual condition, $k_8[D]_o \gg k_7$ and $k_8[D]>k_6[A]$, hence one can put approximately

$$\Phi^o{}_{D-D}=\frac{k_r'[A]}{k_d'+k_r^{s'}[A]}\times\frac{k_8'}{k_8}\varphi_{S\to T}$$

In the general case where the D-R and D-D mechanisms occur simultaneously, $\Phi$ is given by

$$\Phi=\Phi_{D-R}+\Phi_{D-D}=\varphi_{S\to T}\times\frac{k_6[A]}{k_7+k_6[A]+k_8[D]_o}+\varphi_{S\to T}\frac{k_8'[D]}{k_7+k_6[A]+k_8[D]_o}\times\frac{k_r'[A]}{k_d'+k_r^{s'}[A]} \quad (7)$$

Since $k_6$ $k_8$ are respectively ~$10^5$ and ~$10^8$, the second term cannot be neglected at $[D]_o \gg 10^{-5}$ M and at [ATU] ~$10^{-3}$ M unless $\Phi_{D-D}{}^o$ is very small, and this view interprets the results given in Fig. 3. Thus the deviation can safely be attributed to the contribution of a D-D process in the entire reaction. Further information about the D-D process can be obtained as follows, although the analysis is still provisional in nature.

From the results shown in Fig. 3, one can easily estimate the dye concentration at which

6) S. Kato, M. Morita and M. Koizumi, This Bulletin, 37, 117 (1964); M. Koizumi, H. Obata and S. Hayashi, ibid., 37, 108 (1964).

$\Phi_{D-D}/\Phi_{D-R}$ attains a value of 0.3 (chosen conventially) for a given concentration of ATU. The results are given in Table VIII.

TABLE VIII

| ATU | Initial slope | $[D]_0$ for $\Phi_{D-D}/\Phi_{D-R}=0.3$ |
|---|---|---|
| $5.0\times10^{-3}$ M | $1.4\times10^{7}$ | — |
| $1.0\times10^{-3}$ | $6.6\times10^{7}$ | $3.5\times10^{-5}$ |
| $0.5\times10^{-3}$ | $14.5\times10^{8}$ | $1.7\times10^{-5}$ |

Now $\Phi_{D-D}/\Phi_{D-R}$ is expressed as follows,

$$\frac{\Phi_{D-D}}{\Phi_{D-R}}=\frac{k'_8[D]}{[A]k_6}\quad\frac{k_r'[A]}{k_d'+k_r^{s'}[A]} \tag{8}$$

By substituting the values of [D], [A], $k_6(=3.8\times10^5)$ and $\Phi_{D-D}/\Phi_{D-R}(=0.3)$ into Eq. 8, one can calculate the value of $k_8'\times k_r'/k_d'+k_r^{s'}[A]$, which is $3.3\times10^9$ for ATU $10^{-3}$ M (9—a) and $7\times10^9$ for ATU $=5\times10^{-4}$ (9—b)
From the ratio of the above two values,

$$\frac{k_d'+k_r^{s'}\times5\times10^{-4}}{k_d'+k_r^{s'}\times10\times10^{-4}}\approx\frac{1}{2}$$

Hence

$$k_r^{s'}\times5\times10^{-4}\gg k_d'$$

This implies that most of the intermediates produced from $D^t$ and D attacked by ATU molecules. The values of $k_8'\times k_r'/k_r^{s'}$, evaluated from (9—a) and (9—b), are respectively $3.3\times10^6$ and $3.5\times10^6$. If this is compared with the value of $k_8'$, the value of $k_8'$ lies in the range $10^8$—$3.3\times10^6$ and the corresponding value of $k_r'/k_r^{s'}$ in the range 1/100—1.

From the above analysis there is scarcely any doubt that in the case of ATU the reaction proceeds via a D-D mechanism, whereas in the case of EDTA no such reaction occurs. The reason for the different behavior is unknown at present, but we have already found a similar result in the photoreduction of methylene blue.[6] It is to be noted that the data in Table VIII are consistent with the result that the rate formula for a run obeys Eq. 5 quite well as long as the concentration of ATU is in the range $10^{-3}$—$2\times10^{-2}$ M and the dye concentration is $\sim10^{-5}$ M.

Finally a brief comment will be given on the value of $\varphi_{S\to T}$. As Fig. 4 and Table III show, the value of $\varphi_{S\to T}$ for ATU appears to depend on the concentration of dye and to increase regularly with it. An interpretation which occurred to us at first was to consider that the higher the dye concentration the greater becomes the contribution of the D-D process, resulting in an apparent increase in the $\varphi_{S\to T}$ value. But the quantitative investigation given above, as well as the values of $k_8$ and $k_6$, completely reject this idea. Although the reason is still unknown, it seems worth metioning that Oster's value at $[D]_0=10^{-5}$ M agrees quite well with ours if one takes the dependence of $\varphi_{S\to T}$ on [D] into consideration. The value $\varphi_{S\to T}=0.032$ for the lowest concentration of dye is close to the value (0.023) that Parker obtained from the phosphorescence experiment using ethanol as solvent[7] and to our own value (0.046) using the same solvent. On the other hand, the value for EDTA (0.080) is about three times larger than the above value for ATU. Since the features of the reaction in the case of EDTA are rather simple, one is tempted to consider the value 0.080 more reliable. But this is not conclusive. The smaller value for ATU might be due to the fact that mere deactivation of $D^t$ is produced much more so by ATU than by EDTA. At present we have no information at all on how the two reducing agents attack $D^t$. Further experiments employing more suitable reducing agents will be necessary to solve this question and to obtain a more reliable $\varphi_{S\to T}$ value.

## Summary

Using ATU and EDTA as a reducing agent, an attempt was made to determine the transition probability of the singlet excited state to the triplet state. The values obtained are 0.032 for ATU and 0.080 for EDTA. The cause of this difference is not known at present.

Deactivation of the triplet state by a leuco dye as well as by the ground state dye was confirmed. In the case of ATU, it was established that a D-D mechanism operates when the concentration of ATU islow and the con centration of dye is high. This conclusion was supported by the fact that at a constant low concentration of ATU the $1/\Phi$—$[D]_0$ plot deviates from linearity, when the dye concentration becomes high.

# NOTES

## The Synthesis of α-Amino Acids from Ethyl Alkylidenecyanoacetates

By Akio SAKURAI, Minoru IGARASHI and Hiroshi MIDORIKAWA

(Received June 24, 1964)

The present paper will describe the synthesis of new α-amino acids (2-amino-3, 6-dimethylheptanoic acid (VIIc) and 2-amino-3-isobutyl-5-methylhexanoic acid (VIIe)) through α-keto acids. The α-keto acids were prepared by a method virtually identical with that previously reported by two of the present authors.[1,2]

I (c) II (a, c, e) III IV (a, c, e) V (a, c, e) VI (a, c, e)

VII (a, b, c, d, e)

a $\begin{cases} R=CH_3 \\ R'=iso\text{-}C_3H_7 \end{cases}$ b $\begin{cases} R=CH_3 \\ R'=iso\text{-}C_4H_9 \end{cases}$

c $\begin{cases} R=CH_3 \\ R'=iso\text{-}C_5H_{11} \end{cases}$ d $\begin{cases} R=n\text{-}C_3H_7 \\ R'=n\text{-}C_3H_7 \end{cases}$

e $\begin{cases} R=iso\text{-}C_4H_9 \\ R'=iso\text{-}C_4H_9 \end{cases}$

The reaction sequence is shown in the Chart.

Ethyl alkylidenecyanoacetates (I) were obtained by the condensation of ketones with ethyl cyanoacetate according to the method of Cope and his co-workers.[3] The epoxidation of ethyl alkylidenecyanoacetates with hydrogen peroxide was carried out in the presence of sodium tungstate or trisodium phosphate. In the case of ethyl (1-isobutyl-3-methylbutylidene)cyanoacetate (Ie), the epoxidation could be affected only in the presence of trisodium phosphate. The resulting α-keto acids were converted into the corresponding oximes by the usual method.

The catalytic hydrogenation of the oximes was performed in warm ethanol in the presence of a Raney-nickel as a catalyst. The α-amino acids thus obtained showed a reddish-purple color with ninhydrin and formed the corresponding *N*-benzoyl derivatives.

3, 4-Dimethylnorvaline (VIIa),[4] 3, 5-dimethylnorleucine (VIIb)[4] and 3-*n*-propylnorleucine (VIId)[5] were also prepared by this method (see Tables I—IV).

### Experimental

**Ethyl Alkylidenecyanoacetates** were prepared, according to the method described in the literature[3], from ethyl cyanoacetate and ketones. The cyanoacetate described below is a new compound.

*Ethyl(1,4-dimethylpentylidene)cyanoacetate (Ic)*; b. p. 136—138°C/4 mmHg; yield, 76%.

Found: C, 68.66; H, 9.12; N, 6.84. Calcd. for $C_{12}H_{19}O_2N$: C, 68.90; H, 9.09; N, 6.70%.

**The Epoxidation of Ethyl Alkylidenecyanoacetates.** — To a mixed solution of I (0.1 mol.), ethanol (200 g.) and 30% hydrogen peroxide (200 g.), sodium tungstate dihydrate (0.02 mol.) was added. The mixture was then heated on a steam bath for 1—4 hr. to afford II as colorless crystals or as a pale yellow oil.

**The Preparation of α-Keto Amides.**—To a solution of 10% alcoholic potash (50 g.), II (0.05 mol.) was added at room temperature. The resulting potassium salt of III was dissolved in water and then acidified with dilute hydrochloric acid to give III as colorless crystals. III (0.05 mol.) was dissolved in water (40 cc.) and heated for 20—40 min. After it had been cooled, α-keto amide was obtained as colorless crystals.

**The Preparation of α-Keto Acids.**—A mixture of IV (0.03 mol.) and 10% hydrochloric acid (50 cc.) was heated on a water bath for about 3—4 hr. The product was obtained by fractionation.

**The Preparation of Oximes.**—To a mixture of sodium hydroxide (0.03 mol.) in 4 ml. of water and V (0.02 mol.), a solution of hydroxylamine hydrochloride (0.025 mol.) in a mixture of 4 ml. of water and 5 ml. of ethanol was added. The above mixture was then refluxed on a water bath for 1 hr. After cooling, the reaction mixture was acidified with dilute hydrochloric acid to give the product as colorless crystals.

**The Catalytic Hydrogenation of Oximes.** — A solution of VI (0.01 mol.) in ethanol (15 ml.) was shaken with hydrogen in the presence of a Raney nickel as a catalyst (prepared from 1 g. of nickel-aluminum alloy (50 : 50)) at 50°C under an ordinary pressure. The theoretical amount of hydrogen was absorbed within 5—7 hr. After the catalyst had been removed by filtration, the filtrate was concentrated to a small volume and dry ether was added. The reulting precipitate of α-amino acid was collected by filtration. Recrystallization from dilute ethanol gave colorless crystals.

The authors wish to express their hearty thanks to Dr. Taro Hayashi and Dr. Tatsuo Takeshima for their kindly advice. Thanks are also to Dr. Haruo Homma and his staff for microanalyses.

# Chlorination by Sulfuryl Chloride. V.[1] Reaction with Benzyl Alcohols

By Mannosuke ARAI

(Received July 18, 1964)

McBee et al.[2] reported that the reaction of fluorine-containing alcohols with elemental chlorine in an inert solvent yielded the corresponding aldehydes or ketones as follows:

$$CF_3CF_2CF_2CH_2OH \xrightarrow[h\nu]{Cl_2} CF_3CF_2CF_2CHO + 2HCl$$

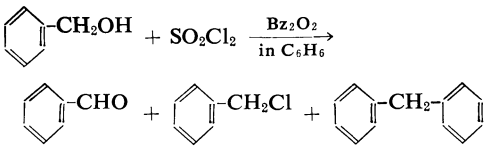
These reactions have been considered to be a radical-chain reaction involving the following steps:

$$Cl\cdot + RCH_2OH \longrightarrow R\dot{C}HOH + HCl$$

$$R\dot{C}HOH + Cl_2 \longrightarrow R\dot{C}H\boxed{O}\boxed{H} + Cl$$

$$\boxed{Cl}$$

$$\downarrow$$



$$RCHO + HCl$$

Lecomte and Defour succeeded in obtaining aldehydes and ketones from primary and secondary aromatic alcohols with the hydroxy group in the $\alpha$-position of the aromatic nucleus, by means of the reaction with *N*-bromoacetoamide in the presence of pyridine.[3]

Similarly it may be expected that the reaction with sulfuryl chloride in the presence of a radical initiator will result in the formation of the corresponding aldehydes or ketones. On the other hand, it is known that sulfuryl chloride reacts with the hydroxyl group of aliphatic alcohols as a chlorosulfonating agent, the products being alkyl chlorosulfonate,[4a] dialkyl sulfate, alkylsulfuric acid and alkyl chloride.[4b] The present paper will study whether or not the reaction of benzyl alcohols with sulfuryl chloride in the presence of benzoyl peroxide yields the corresponding aldehyde.

The reaction of benzyl alcohol with an equivalent amount of sulfuryl chloride in benzene results in the formation of benzaldehyde

4) a) P. Behrend, *Ber.*, **9**, 1334 (1876); W. W. Binkley and E. F. Degering, *J. Am. Chem. Soc.*, **60**, 2810 (1938); **61** 3250 (1939). b) R. Levaillent and L. Simon, *Compt. rend.*, **169**, 854 (1919).

(10%), diphenylmethane (23%) and benzyl chloride (15%).

However, the reaction in carbon tetrachloride gives only a chlorine-containing viscous substance. The reaction which is carried out without a solvent gives benzaldehyde and benzyl chloride.

The formation of diphenylmethane can be explained as resulting from the reaction of benzyl chlorosulfonate with benzene on the basis of the fact that it takes place only in benzene, and that the reaction between benzyl benzene sulfonate and benzene gives diphenylmethane in a good yield.[5]

These results suggest that sulfuryl chloride probably reacts as a homolytic chlorinating agent as well as a chlorosulfonating agent for benzyl alcohol, under these reaction conditions.

A similar reaction of anisalcohol in benzene gives anisaldehyde (60%) and a small amount of 3-chloroanisaldehyde. The total yield of aldehydes is 70%. Moreover, it might be noted that no product such as *p*-methoxybenzyl chloride was isolated from the reaction with the hydroxyl group. This striking effect of the substituent is interesting and makes this reaction suitable for the oxidation of various benzyl alcohols to the corresponding aldehydes.

Similar reactions with $\alpha$-phenylethyl alcohol, $\alpha$-phenylpropyl alcohol and benzhydrol give acetophenone, propiophenone and benzophenone in yields of 30%, 30% and 40% respectively.

## Experimental

**Materials and Reagents.**—Benzyl alcohol (reagent grade), anisalcohol (reagent grade), $\alpha$-phenylethyl alcohol (first grade) and $\alpha$-phenylpropyl alcohol (first grade) were purifide by vacuum distillation under a nitrogen atomosphere before use. Benzhydrol (reagent grade) was used after recrystallization.

Sulfuryl chloride (first grade) was distilled, stored in a bottle wrapped with aluminum foil, and kept in a desiccator.

5) Z. Foeldi, *Ber.*, **61**, 1609 (1928).

**The Reaction of Benzyl Alcohol and Sulfuryl Chloride.** — *1) Reaction in Benzene.* — 10.8 g. (0.1 mol.) of benzyl alcohol was dissolved in 20 ml. of benzene. After the air in the system had been replaced by dry nitrogen, 50 mg. of benzoyl peroxide was added to the solution. Then the system was heated at 70°C, and an equivalent amount of sulfuryl chloride (8.2 ml.) was dropped through the dropping funnel while the solution was being stirred. After the reaction mixture had stood about 4 hr., when the evolution of gas had ceased, it was cooled and washed with water. The benzene layer, dried with anhydrous sodium sulfate, was then distilled under reduced pressure, yielding 2.80 g. of liquid A (b. p. 45°C/5 mmHg), 3.80 g. of substance B (b. p. 103—105°C/5 mmHg) and a viscous substance which could not be distilled.

The treatment of A with 2,4-dinitrophenylhydrazine sulfate gave a reddish-orange crystalline substance m. p. 237°C, which was identified as benzaldehyde 2,4-dinitrophenylhydrazone by a mixed-melting point test. The yield of benzaldehyde as 2,4-dinitrophenylhydrazone was 10%. The residue of A, from which benzaldehyde had been removed, gave benzyl chloride (yield, 15%); it was identified by the following experiments: benzoic acid formed by oxidation with potassium permanganate, and the reaction with $\beta$-naphtol in the presence of sodium hydroxide in ethanol, yielded a crystalline substance which was further converted into a yellow crystalline when treated with picric acid. The yellow crystalline substance, m. p. 123°C, was identified as the picrate of $\beta$-naphthol benzyl ether by a mixed-melting point test. As for B, it was crystallized out on cooling, its melting point being 26°C. The ultraviolet absorption spectrum and the infrared absorption spectrum indicate that B is diphenyl methane.

Found: C, 92.36; H, 7.25. Calcd. for $C_{13}H_{12}$: C, 92.81; H, 7.19%.

*2) Reaction without the Solvent.*—The same reaction was carried out in the absence of the solvent, using 10.8 g. of benzyl alcohol and 8.2 ml. of sulfuryl chloride. By distillation under reduced pressure, 3.60 g. of a liquid (b. p. 45°C/5 mmHg) was isolated from the remaining viscous substance. This liquid was identified as a mixture of benzaldehyde and benzyl chloride by the same procedure as that performed in 1). The yields were 10% and 20% respectively.

*3) Reaction in Carbon Tetrachloride.* — The same reaction was also carried out in carbon tetrachloride (20 ml.). All attempts to isolate the reaction mixture under reduced pressure failed. Only a dark colored substance was obtained in this procedure, a substance which could not be further purified.

**Reaction with Anisalcohol.**—In an atmosphere of nitrogen, 6.9 g. (0.05 mol.) of anisalcohol, dissolved in 10 ml. of benzene, was treated with 30 mg. of benzoyl peroxide and 4.1 ml. (0.05 mol.) of sulfuryl chloride at 70°C. After the termination of the reaction, the reaction mixture was distilled under reduced pressure, 4.10 g. of substance A (b. p. 86—88°C/3 mmHg) and 0.95 g. of B (b. p. 101—104°C/3 mmHg) being thus obtained. A was identified as anisaldehyde-2,4-dinitrophenylhydrazone.

Found: N, 17.90. Calcd. for $C_{14}H_{12}O_5N_4$: N, 17.72%.

B was crystallized out on cooling; recrystallization from ligroin gave needles, m. p. 52°C. The infrared spectrum shows a strong absorption at 1690 $cm^{-1}$ ($\nu_{C=O}$), and moderate intensity bands at 815, 885 $cm^{-1}$ ($\delta_{CH}$), and at 640 $cm^{-1}$ attributable to the C-Cl bond, suggesting 3-chloroanisaldehyde. It was also identified as 2,4-dinitrophenylhydrazone.

Found: N, 16.21. Calcd. for $C_{14}H_{11}O_4N_4Cl$: 15.98%.

**Reaction with α-Phenylethyl Alcohol.**—2.44 g. of α-phenylethyl alcohol in 15 ml. of benzene was submitted to the reaction described above with an equivalent amount of sulfuryl chloride. After the evaporation of the solvent, treatment with 2,4-dinitrophenylhydrazine sulfate gave 1.72 g. of the 2,4-dinitrophenylhydrazone, m. p. 251—253°C.

**Reaction with α-Phenylpropyl Alcohol.** — In a way similar to that used with α-phenylethyl alcohol, 1.79 g. of the 2,4-dinitrophenylhydrazone, m. p. 190—191°C, was yielded by 2.72 g. of α-phenylpropyl alcohol.

**Reaction with Benzhydrol.**—In a way also similar to that used with α-phenylethyl alcohol, 2.45 g. of the 2,4-dinitrophenylhydrazone, m. p. 239—240°C, was yielded by 2.72 g. of benzhydrol.

The author wishes to express his gratitude to Professor Mamoru Yamaguchi of Tohoku University for his constant guidance in the course of this work.

# Deviation from Lambert's Law in Measuring the Intensity of 3.5 $\mu$ Bands of Barium Stearate Films

By Shun-ichi IKAWA and Shiro MAEDA

(Received August 31, 1964)

In studying the absolute infrared intensity in pure liquids and solids, it sometimes occurs that a sample has to be chosen considerably less thick than the wavelength. In such a case, the effect of multiple reflections upon the observed absorption coefficients comes to be appreciable, disturbing an accurate application of Lambert's law. It can be inferred from a recent study[1] that the effect of multiple reflections gives rise to a variation in apparent peak intensity depending on the sample thicknesses, in some oscillatory way, and in general converging to a maximum at zero thickness.

In order to examine this phenomenon in practice, it seems appropriate to measure the intensity of a sufficiently intense and well-isolated absorption band in samples of various thicknesses. Films of barium stearate built by the successive deposition of monomolecular layers are fairly suitable for this purpose, as the film has very intense bands at 3.51 and 3.43 $\mu$ and can be easily built up to any thickness.

The films used in the present measurements were built, following Blodgett,[2] by the repeated "dip and lift" of quartz plates across the surface of water covered with a monomolecular layer. The layer was formed by dropping a 0.1% solution of stearic acid in benzene onto the clean surface of water containing minute barium chloride and potassium bicarbonate. It is known that the monomolecular layer of barium stearate formed in this way has a thickness of 24.4Å and contains a molecule in each 20Å$^2$ when deposited on a substrate.[2]

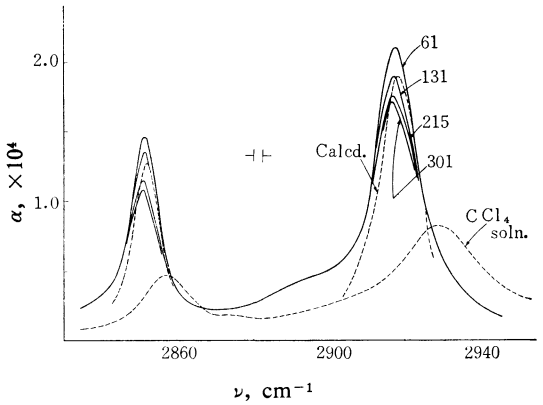

Fig. 1. 61—301: Number of monomolecular layers contained in each film.

The spectra of marked bands were obtained using a Perkin-Elmer model 112 spectrometer

1) S. Maeda, G. Thyagarajan and P. N. Schatz, *J. Chem. Phys.*, **39**, 3474 (1963); S. Maeda, *Bull. Tokyo Inst. Tech.*, **59**, 17 (1964).

2) K. Blodgett, *J. Am. Chem. Soc.*, **57**, 1007 (1935); T. Tachibana, "Jikken Kagaku Kôza," Vol. 7, Maruzen, Tokyo (1950), p. 296.

equipped with a LiF prism; they are given in the figure by apparent absorption coefficients, $\alpha_{app}=(1/d)\ln(I'_0/I)$, where $I'_0$ is the intensity of the light transmitted by the blank substrate. "Apparent" implies the conventional use of Lambert's law without taking the multiple reflection effect into consideration. The upper and lower limits of thickness were chosen so as to give the transmittance at the peak with a reasonable accuracy. A steady increase in apparent peak intensity with diminishing thickness can be seen, indicating the characteristic features of the multiple reflection effect in extremely thin samples.

For a thin sample in which the thickness, $d$, is sufficiently smaller than the wavelength, $\lambda$, the following expression is valid for the reciprocal of transmittance:

$$I'_0/I=1+(2\varepsilon_2/1+\phi)(2\pi d/\lambda)+[1/(1+\phi)^2][(\varepsilon_1-1)(\varepsilon_1-\phi^2)+\varepsilon_2{}^2]\times(2\pi d/\lambda)^2-[2\varepsilon_2(\varepsilon_1-\phi)/3(1+\phi)]\times(2\pi d/\lambda)^3+\cdots\cdots$$

where $\varepsilon_1$ and $\varepsilon_2$ denote the real and the imaginary parts of the dielectric constant of the sample, and $\phi$ is the refractive index of the substrate.[1] For the thinnest film, with 61 layers, the expansion parameter $(2\pi d/\lambda)$ is small enough, so that the fourth and further terms on the right-hand side may be discarded with very little error. Then, if one assumes the function of a damped oscillator model for each band, it is possible to estimate the true absorption coefficients in a good approximation, which is given by a broken-line curve in the figure.

For the sake of comparison, the absorption curve of stearic acid in a dilute carbon tetrachloride solution is given for the same region. It is strikingly different from the "built up" film, while the distinction between the acid and the barium salt is expected to be very little for the spectral features in this region. Such a marked change in an absorption intensity due to a change of state is not unusal, but it has not yet been statisfactorily explained in most cases.

We would like to thank Professor Kunio Kozima, who suggested this work to us, and also Professor Taro Tachibana for his valuable advice on building up the films. Our thanks are also due to Dr. Yoshiko Takeoka for her kind assistance.

# Antioxidant Activity of Glycerylphosphatides* and Their Hydrolysis Products. IV. Reaction of Methyl Oleate Hydroperoxide Concentrate with Phosphoric Acid and β-Glycerylphosphoric Acid and the Isolation of a Phosphorus-containing, Oil-soluble Product from Autoxidized Methyl Oleate in the Presence of β-Glycerylphosphoric Acid

By Chieko URAKAMI, Yoshiko GOTO** and Haru KAMEYAMA**

(Received September 7, 1964)

Phosphate ester as well as phosphatides have tentatively been classified as decomposers of peroxides,[1] but no significant evidence has been presented. Therefore, such a generalization must be subjected to further tests. In connection with this, it has been sugested that a secondary phosphorus-containing, oil-soluble product formed as the result of a reaction of glycerylphosphoric acid with methyl oleate or its oxidation products in the early stages of autoxidatation might be responsible for its antioxidant activity.[2,3]

It was observed that β-glycerylphosphoric acid did not decompose the methyl oleate hydroperoxide concentrate, much as is shown

* The "lecithin" used in the previous papers[2,3] will be changed to this term in future publications.

Table I. Analysis of the ether-soluble fraction of the reaction products of the methyl oleate hydroperoxide concentrate with phosphoric acid and with β-glycerylphosphoric acid at 45°C in a nitrogen stream

| Reactants | Mol. ratio[a] | Time, hr. | Peroxide value[b] | Iodine value | $R_f$[c] | Phosphorus[d] |
|---|---|---|---|---|---|---|
| P. C. | | 0 | 261 | 61.2 | | |
| P. C. : $H_3PO_4$ | 1 : 1 | 1/3 | 21.8 | 36.2 | 0—0.51 | + |
| | | | | | 0.92 | + |
| P. C. : β-GP[e] | 1 : 0.018 | 1/2 | 234 | 59.8 | | |
| P. C. : β-GP[e] | 1 : 1 | 2 | 245 | 66.5 | 1.00 | − |
| P. C. : β-GP[e] | 1 : 0.7 | 5 | 239 | 67.1 | 1.00 | − |

P. C. stands for the methyl oleate hydroperoxide concentrate[4] and β-GP for β-glycerylphosphoric acid.[2]

a) Based on hydroperoxide oxygen.
b) Expressed in mmol./100 g.
c) Developed with *n*-propanol - water (8 : 1, v/v) and sprayed with bromothymol blue.
d) The sections corresponding to the $R_f$ values were incinerated for phosphorus determination along with a blank, another section of the same size: + indicates the presence of a significant amount, and −, the absence of phosphorus.
e) Glass beads and *n*-heptane were added, and the entire contents were mixed a motor-driven stirrer. For analysis, each of the reaction mixtures was diluted with dry ether, washed with water, dried over anhydrous sodium sulfate, and concentrated.

Table II. The $R_f$ values of the isolated compound and its decomposition and hydrolysis products

| Sample | Days[a] | System | $R_f$ | | | |
|---|---|---|---|---|---|---|
| | | | P | Rh-6G | $(AcO)_2Hg$ | Fuchsine |

| $H_3PO_4$ | | II | 0.19 | | | |

System I: Toyo No. 51 paper impregnated with silicic acid with a solvent system of diisobutyl ketone - acetic acid - water (40 : 25 : 5 by vol.). System II: Toyo No. 50 paper with a solvent system of *n*-propanol - acetic acid - water (8 : 1 : 1 by vol.). The $R_f$ values are an average of several runs. β-GP stands for β-glycerylphosphoric acid. The − sign indicates a negative reaction with the reagent for the spot on the corresponding row. (?) For some unknown reason the reaction was negative; it should have been positive, as for sample I. a) A number of days elapsed since the end of autoxidation. The relative intensity of the color of the spots was b>c.

in Table I, in comparison with the hydroperoxide decomposing property of orthophosphoric acid, but it gave rise to a very unstable phosphorus-containing, oil-soluble compound in the early stages of the autoxidation of the methyl oleate containing it. The compound, initially isolated, sample II in Table II, was found to be very readily soluble in a mixture of chloroform and methanol and carbon tetrachloride, somewhat soluble in chloroform and methanol, slightly soluble in acetone, and insoluble in isopropanol. Its ultraviolet spectrum showed a $\lambda_{max\ 1}$ at a wavelength shorter than 240 mμ and a $\lambda_{max\ 2}$ at 276 mμ, with a shoulder at 282 mμ. The infrared absorption bands that appear to be characteristic of the initially-isolated compound (sample II) are as follows: 1730 $cm^{-1}$ for a carbonyl group, the doublet at 1575 and 1595 $cm^{-1}$ for a conjugated double-bond system, 1385 $cm^{-1}$ for the methyl group (presumably the terminal group of a long alkyl

4) J. E. Coleman, H. B. Knight and D. Swern, *J. Am. Chem. Soc.*, 74, 4886 (1952).

chain), and 1285 $cm^{-1}$ for the P=O stretching vibration. All these bands are absent, however, in the spectrum of β-glycerylphosphoric acid. The presence of the P-O-C(alkyl) in the molecule is indicated by the absorption bands at 1170, 1190, and possibly 1040 $cm^{-1}$, and at others in the lower frequencies.

## Experimental

**Isolation of a Phosphorus-containing, Oil-soluble Compound.** — In a reaction tube were placed 16.493 g. of methyl oleate (b. p. 152—156°C/0.9 mmHg., iodine number 89.3, and saponification number 185.3) and an ethanol solution containing 5.207 mg. of β-glycerylphosphoric acid (0.03% in the methyl oleate); the solvent was removed at a temperature not exceeding 50°C. The tube was placed in a bath maintained at 50°C, and the mixture was autoxidized for 192 hr. by passing dry air through a sintered glass gas bubbler; its peroxide value was 50±2.4. After adding a small amount of a 0.05% ethanol solution of hydroquinone, the reaction mixture was dissolved in 200 ml. of freshly-distilled dry ether, and the solution washed successively with 50, 25, and 10 ml. of distilled water to remove unreacted water-soluble β-glycerylphosphoric acid; 1% of the initially-added phosphorus was removed in the combined water washings. After drying the ether solution over anhydrous sodium sulfate, it was diluted further with an equal volume of dry ether and the solution applied to a column (10 mm.×100 mm.) packed with 5.5 g. of a mixture of silicic acid and filter aid (2 : 1 by wt.), followed by elution with fresh dry ether; 10% of the initially added phosphorus was found in the eluate. The adsorbent in the upper half of the column was extracted three times with chloroform-methanol (4 : 1 by vol.). The combined extract (sample I in Table II) was concentrated under mild conditions, and the residue treated with dry carbon tetrachloride. An insoluble fraction was found to be a colored wax and to contain phosphorus. The carbon tetrachloride-soluble fraction was concentrated in the usual manner, and the colored oil thus obtained (sample II in Table II) was subjected to various analyses. A small amount of this oil was hydrolyzed with 5% solution of ethanolic sodium hydroxide, and the reaction mixture deionized with IRC-50 ($H^+$) (sample VI in Table II).

# Intramolecular Hydrogen Bonds. II.[1] On the Configuration of Isomeric Methyl 9, 10-Dihydroxyoctadecanoates

By Nobuo Mori, Satoshi Ōmura* and Yojiro Tsuzuki

(Received September 21, 1964)

A high-melting isomer (I: m. p. 131°C) of two 9, 10-dihydroxyoctadecanoic acids was obtained by the oxidation of oleic acid with permanganate and another isomer (II: m. p. 95°C) was obtained similarly from elaidic acid. On the basis of the cis addition of the two hydroxyl groups, the former was assigned to the erythro form and the latter to the threo form.[2]

Further evidence for the configuration was the difference in the rates of the oxidation between the acids with lead tetraacetate[3] and with periodic acid[4], although the relative rates (II/I) were not so high as those of isomeric cycloalkane-1, 2-diols. Also, Swern and his co-workers[5] deduced the above configuration from the strikingly high ability of compound II to form a complex with urea and boric acid.

The present paper provides other support for the assignments through the infrared measurements of their methyl esters III and IV in the O-H stretching region of 3400—3700 $cm^{-1}$, together with those of ethyl $\omega$-hydroxy-pelargonate V and -caprinate VI for the purpose of comparison. The measurements were carried out with a solution in 0.004 mol./l. in carbon tetrachloride at 25°C with a Perkin-Elmer 21 spectrophotometer equipped with a lithium fluoride prism and with a cell 3 cm. long; the observed frequencies

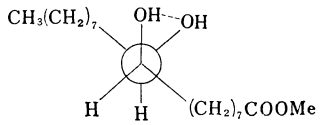
| VIII | $C_5H_{11}CH(OH)-CHC_5H_{11}$ (meso) OH | | 3636 | 3593 | 6 |
| IX | $C_5H_{11}CH(OH)-CHC_5H_{11}$ (rac.) OH | | 3636 | 3583 | 6 |



* $\varepsilon = 1/cl \cdot \log I_0/I$ for the apparent OH band.

were calibrated against that of atmospheric vapor. At that concentration, all of the esters were free from intermolecular hydrogen bonding, and only a very weak broad band was observed at 3462 or 3466 $cm^{-1}$; this may be the first overtone of a carbonyl group.

The hydroxyl band of the methyl esters III and IV was a doublet with almost the same intensity, but compounds V and VI had only one sharp band in the region of the free primary alcoholic hydroxyl group. Thus, the esters III and IV had no intramolecular hydrogen bond between the hydroxyl and the methoxycarbonyl group; substantially all of their molecules exist in the conformation containing an intramolecular hydrogen bond between the two hydroxyl groups:

(III)

(IV)

In general, threo 1,2-diols (racemic form) form a stronger hydrogen bond between the hydroxyl groups than do the corresponding erythro diols (meso form)[6,7] because of the conformational preference of the former for intramolecular hydrogen bonding,[6] as is seen in the case of the dodecane-6,7-diols, VIII and IX, in Table I. As the table shows, the separation ($\Delta\nu$) between the two peaks is 43 $cm^{-1}$ for compound III and 50 $cm^{-1}$ for compound IV; this supports the above assignment of the configuration for compounds I and II.

The authors thank Mr. Teruo Kajiura and Mr. Tadao Tamura, Government Chemical Industrial Research Institute Tokyo, for infrared measurements.

# The Interactions of Some Cations with Deoxyribonucleic Acid Observed by the Use of Toluidine Blue as an Indicator

By Yukiko HUSE, Komei MIYAKI and Masamichi TSUBOI

(Received September 24, 1964)

There have been several studies of the metachromasy of basic dyes induced by deoxyribonucleic acid (DNA)[1,2] and of the effects of inorganic or organic cations on the metachromasy.[3-5]

We have recently observed that toluidine blue shows a marked metachromasy with DNA in solution and that this metachromasy can often be hindered by adding another substance, one which interacts with DNA, to the solution. The degree of hindrance is found to depend upon how strongly the added substance interacts with DNA. This finding suggests a simple and easy method of the semiquantitative analysis of interactions between DNA and other substances of a certain type.

As may be seen in Fig. 1, toluidine blue ($5\times10^{-5}$ mol./l.) in an aqueous soulution at pH 6 shows two absorption peaks, at 600 and 630 m$\mu$ (curve a). When DNA (from salmon sperm) is added, both of these peaks disappear, and a broad and lower peak appears at 570 m$\mu$ (curve b). The maximum metachromatic change is observed with the DNA concentration of $2.5\times10^{-5}$ mol./l. (in *P*), i.e., with the concentration ratio [DNA]/[T. B.]=0.5. When poly-L-lysine is added to the solution, the original features of the toluidine blue spectrum is restored (curves c—e) to an extent depending upon the amount of poly-L-lysine added.

It is very probable that the metachromasy of toluidine blue occurs through its binding to the phosphate group with a negative charge of DNA. When poly-L-lysine is added to the solution, it will be more strongly bound by the DNA molecule through the $N^+$-H$\cdots$$^-$O–P hydrogen bond and polycationic effect than will the toluidine blue molecule, and the latter will be released from DNA. This explains the fact that its original color is restored. It is interesting that the addition of $2.5\times10^{-5}$ mol./l. (in a lysine residue) poly-L-lysine causes a nearly complete restoration of the original spectrum of toluidine blue, because this amount is equal to that of DNA in the solution. This fact suggests that every $NH_3^+$ group of poly-L-lysine added is bound by a $PO_2^-$ group of DNA.

The above simple explanation of what we have observed needs a provisory statement. Toluidine blue seems to interact slightly with poly-L-lysine. This is shown by the fact that the further addition of poly-L-lysine causes a spectrum of toluidine blue somewhat different from the original spectrum (curve a of Fig. 1.). It is quite similar in general features to the original one, but it shows a higher intensity at both peaks, 600 and 630 m$\mu$ (curves f—i in Fig. 1). The spectral change due to the slight interaction of toluidine blue and poly-L-lysine may be more clearly seen by comparing curves a and j in Fig. 1, where curve j is obtained with a mixed solution of toluidine blue and poly-L-lysine without DNA. The fact that no

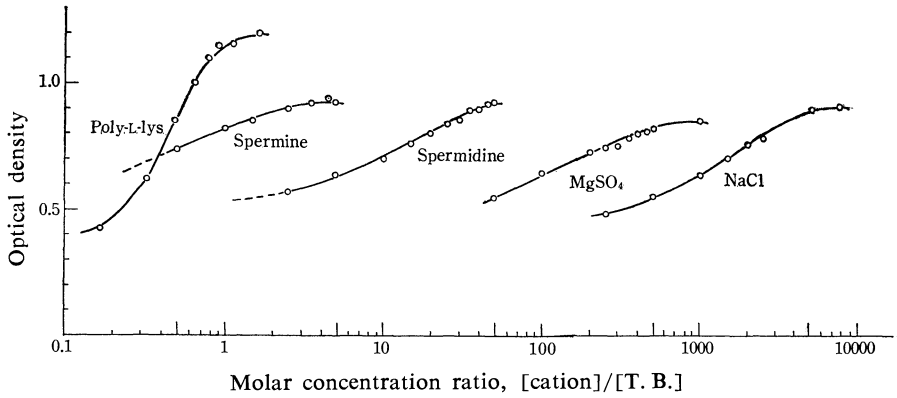

Fig. 2. Optical density of toluidine blue (at 630 mμ or at 600 mμ) in an aqueous solution containing toluidine blue $5\times10^{-5}$ mol./l., Na-DNA $2.5\times10^{-5}$ mol./l. and one of the substances indicated, plotted against the molar concentration ratio [added substance]/[toluidine blue]. The wavelength at which the optical density was observed is 630 mμ for poly-L-lysine, spermine, and spermidine, and is 600 mμ for $MgSO_4$ and NaCl.

distinct isosbestic point is observed in the series of the spectra given in Fig. 1 may be related to this weak interaction between toluidine blue and poly-L-lysine.

We have made similar experiments by adding spermine, spermidine, magnesium sulfate, and sodium chloride to the toluidine blue-plus-DNA system. In every case, a hindrance of the metachromasy of toluidine blue takes place at a certain concentration of the added substance. By adding a sufficient amount, a spectrum is obtained which is very similar to the spectrum of the solution of toluidine blue only. In the case of magnesium sulfate or sodium chloride, however, a slight but appreciable diminution of optical density at 630 mμ compared with the original spectrum is observed; therefore, in these cases, it would be preferable to observe and evaluate the optical densities at 600 mμ instead of at 630 mμ. Thus, the optical density at 630 mμ (or 600 mμ) gives a measure of how much toluidine blue is released from DNA and, therefore, how much the added substance is bound by DNA. This is plotted against the molar concentration of the added substance in Fig. 2. It may readily be seen that spermine is bound by DNA much more strongly than spermidine, and that $Mg^{2+}$ is bound by DNA much more strongly than $Na^+$.

The Na-DNA used in the present experiment was obtained from the California Corporation for Biochemical Research, Los Angeles, and the toluidine blue, from the Merck Co., Inc. The poly-L-lysine hydrobromide, with a molecular weight of 60000, was obtained from Pilot Chemicals, Inc. The spermine tetrahydrochloride was from the Sigma Chemical Company, while the spermidine trihydrochloride was obtained from the Nutritional Biochemicals Corporation.

This work was partly supported by a grant from the U. S. Public Health Service, No. GM-10024-1, and partly by agrant from the Ministry of Education of Japan.

# PMR Studies of Bromothiophenes*

By Kensuke TAKAHASHI, Tyo SONE, Yasuo MATSUKI and Genjiro HAZATO

(Received October 6, 1964)

At the beginning of the study of thiophene derivatives by PMR, 2, 5- and 3, 4-dibromothiophenes were measured in order to estimate the chemical shift between $\alpha$- and $\beta$-hydrogens in thiophene.[1,2] In this note we will present the experimental results for all bromothiophenes. Tables I and II list the results for the chemical shifts and the coupling constants in cyclohexane solutions at 60 Mc./sec. Chemical shifts for all protons of bromothiophenes occur at a higher applied magnetic field than do those of thiophene itself. Table I shows that the chemical shifts of $\beta$-hydrogens fall into the 5.26—5.43 p. p. m. range with reference to cyclohexane, whereas those of $\alpha$-hydrogens fall at 5.54—5.72 p. p. m., so that the $\alpha$- and $\beta$-hydrogens in bromothiophenes can readily be distinguished from each other by measuring the chemical shifs. The results obtained here are quite useful from the standpoint of the identification of bromothiophenes. The substitution effect of bromine has been discussed in benzene derivatives by many authors and summarized in Smith's paper.[3] Diehl expressed the effect of the X substituent as $S_{o,x}$ or $S_{m,x}$ and stated that the substitution effects in *p*- and *m*-disubstituted benzenes are additive.[4] The $S_o$, $S_m$ and $S_p$ values estimated by Diehl for bromine in some benzene derivatives are 0.22, $-0.11$ and $-0.06$ p. p. m. In thiophene, those effects must be expressed as $S(\mathrm{X})_{ab}$, where *a* and *b* are the positions of the substituent and of the hydrogen in question respectively. By comparing the chemical shifts of the monosubstituted thiophenes with those of the unsubstituted one, $S_{23}$, $S_{24}$, $S_{25}$, $S_{32}$, $S_{34}$ and $S_{35}$ for bromine are estimated as $-0.07$, $-0.28$, $-0.13_5$, $-0.12_5$, $-0.09$ and $-0.11$ p. p. m. respectively, in which the negative values of $S(\mathrm{Br})$ indicate the displacement toward a higher applied magnetic field. The most pronounced effect appears in 4-hydrogen of 2-bromothiophene as about a shift of $-0.28$ p. p. m. The additivity of the substitution effect is also roughly valid in the cases of 2, 4- and 2, 5-dibromothiophenes. In other cases of di- and tribromothiophenes, however, the additional effects on the chemical shift of the proton coming from the interaction between the substituents must be considered.

Now if we only consider the interaction between the *ortho*-positioned substituents, the so-called *ortho*-effect, this additional effect may be expressed as follows: $S(\mathrm{X,Y})_{abc}$, where *a*, *b* and c are the positions of the substituents X and Y and the hydrogen in question. From the shifts of 2, 3- and 3, 4-dibromothiophenes, we can estimate $S_{234}$, $S_{235}$ and $S_{342}$ for the effects of two ortho-positioned bromines, which are 0.16, 0.13 and 0.18 p. p. m. respectively. Using this additional effect, we can estimate the chemical shifts of 2, 3, 4- and 2, 3, 5-tribromothiophenes by additivity in agreement with the experimental values as follows:

$$\delta_5(2,3,4\text{-Br}_3) = 5.73_5 + S_{25} + S_{35} + S_{32} + S_{235} + S_{345}$$
$$= 5.67_5 \quad (\delta_{\mathrm{exp}} = 5.72)$$

$$\delta_4(2,3,5\text{-Br}_3) = 5.54 + S_{24} + S_{34} + S_{23} + S_{234}$$
$$= 5.26 \quad (\delta_{\mathrm{exp}} = 5.32)$$

The observed coupling constants between the ring protons in bromothiophenes have the usual magnitude[1,5] and the values for 3, 4- and 2, 5-dibromothiophenes have been observed in the spectra of the $^{13}$CH satellites in pure liquid.

Another fact of interest is the magnitude of $J(^{13}\mathrm{CH})$. $J(^{13}\mathrm{CH}_\alpha)$ is somewhat larger than $J(^{13}\mathrm{CH}_\beta)$ by about 15 c. p. s., as is shown in Table II. Many more experimental values are needed before we can discuss these results. However, it should be noted that this $J(^{13}\mathrm{CH})$ is concerned with the bond length and s-character of the C-H bond.[6] Therefore, it is assumed that the C-H$_\alpha$ bond has a somewhat larger s-character than the C-H$_\beta$ bond, and also that the latter is somewhat longer than the former in thiophene and its derivatives. Some results for thiophene and its derivatives have been reported by Goldstein and Reddy, and discussed in connection with the magnetic

anisotropy of the compounds.[7] The difference of about 15 c.p.s. measured in bromothiophenes corresponds to the difference in bond length of about 0.006 Å. The microwave analysis of thiophene suggests about the sameorder of difference in bond length between C-$H_\alpha$ and C-$H_\beta$.[8]

The solvent effects on the chemical shifts for ring protons were also observed. Three typical solvents were used. The measured samples are pure liquid containing 10 wt. % cyclohexane, a 10 wt. % solution in carbon tetrachloride containing 0.5 wt. % cyclohexane, and a 14 wt. % solution in acetone containing 14 wt. % cyclohexane. The results are summarized in Table III. The value in cyclohexane shown in Table I was used as a reference for each compound. The displacements of the chemical shifts in acetone are large and can be divided into two groups. One is that of $\beta$-hydrogen, which falls into the 0.27—0.40 p.p.m. range, while, the other is that of $\alpha$-hydrogen, which falls into the 0.55—0.67 p.p.m. range; the latter shows larger displacement than the former. However, the

displacements in carbon tetrachloride and in pure liquid are rather small and can not so clearly be divided into groups. These results are similar to those obtained in methylthiophenesulfonylchlorides.[9] The displacement of the chemical shift in acetone is practically dependent on the position of the hydrogen rather than on that of the substituent. It seems that

the interaction between thiophenes and acetone occurs usually near the position of the sulfur atom in thiophene. The origin of the displacement of the chemical shifts of these compounds in the polar solvents has not yet been made clear; however, the experimental results concerning the solvent effect, especially in an acetone solution, can be used as criteria for estimating the position of the hydrogen in an unknown thiophene derivative which is $\alpha$ or $\beta$.

# The Identity of Leprotene with Isorenieratene

By Nobuhisa OKUKADO and Masaru YAMAGUCHI

(Received October 23, 1964)

A carotenoid hydrocarbon, leprotene, was first isolated from a strain of the acid-resistant bacteria of a leper in 1937[1]; later it was shown to be a common carotenoid pigment of the *Mycobacterium* genus[2], e. g., *M. phlei*[3] or *M. tuberculosis*[4]. Leprotene has a similar spectral property to that of β-carotene, but it differs in melting point, in chromatographic behavior and in the absence of vitamin A activity.[5] Takeda and Ohta proposed the formula $C_{40}H_{54}$ for leprotene on the basis of their analytical and microhydrogenational results and suggested that leprotene is a dehydrogenated β-carotene.[6] This suggestion has never been established because of a lack of data. Recently, however, one of the present authors, Masaru Yamaguchi, found aromatic carotenoids in a sea sponge[7] and pointed out that one of these aromatic carotenoids, isorenieratene (I), closely resembled leprotene in its properties.[8]

I

In the present study, leprotene was extracted from *M. phlei* and compared with isorenieratene. It was proved that leprotene is completely identical with isorenieratene in mixed melting point determination, ultraviolet- and infrared-spectra, mixed chromatography and CH-analysis.

This result not only clarifies the chemical constitution of leprotene, which has been unknown for a long time, but also establishes the second occurence of an aromatic carotenoid in nature, indicating an even wider distribution of this unique group of carotenoids.

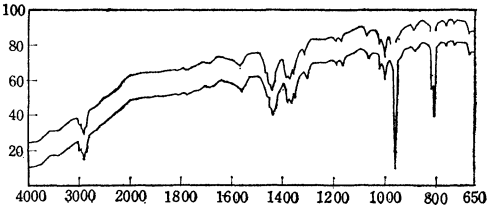

Fig. 1. IR-Spectra of leprotene (upper) and isorenieratene (lower) (KBr disk).

## Experimental

A pure strain of typical *M. Phlei* was cultivated at 35°C for thirteen to fifteen days until the deepest coloration developed on Sauton's medium, which contained sodium glutamate (8 g.), citric acid (2 g.), dipotassium hydrogen phosphate (0.5 g.), magnesium sulfate (0.5 g.), ferrous ammonium citrate (0.05 g.), and glycerol (60 g.) in water (1000 g.). The cells were collected by suction, washed with methanol, and extracted with acetone (the dry weight of the residue of the extraction was 800 g.). Pigments were transferred into petroleum benzine by the addition of water, and the benzine layer was washed with water, dried, and evaporated under a vacuum. The deep red oily concentrate separated a minute quantity of a brown precipitate on standing, this was removed by filtration. The concentrate was then

# The Spectrophotometric Determination of Thallium(III) with Xylenol Orange[1]

By Makoto Otomo*

(Received November 6, 1964)

Thallium(III) has been determined spectrophotometrically by extracting the thallium(III)-complexes of *p*-phenetidine,[2] *p*-aminophenol,[3] rhodamine B,[4,5] brilliant green,[6] methylviolet[7] and bis(dimethylaminophenyl)-antipyrylcarbinol[8] into a suitable organic solvent. In the present paper, a very sensitive reagent, xylenol orange, which forms a water-soluble complex with thallium(III), is used for the spectrophotometric determination of trace amounts of thallium.

## Experimental

**Reagents and Apparatus.**—*Standard Thallium(III) Solution.*—An about 0.01 M thallium(III) nitrate solution was prepared by dissolving freshly prepared thallium(III) oxide, which had been precipitated from a thallium(III) chloride solution by adding a diluted aqueous ammonia solution and then carefully washed with water until the filtrate became free from ammonium and chloride ions, in concentrated nitric acid and diluting it with water. The solution was standardized against a standard EDTA solution.[9] The concentration of nitric acid in the solution was about 0.5 M. A working thallium(III) solution was prepared by diluting the above solution with 0.05 M nitric acid.

All the other reagents and the apparatus used were the same as those reported on previously.[10]

**Standard Procedure for the Determination.**—To a solution in a 25 ml. volumetric flask which contained 20 to 150 $\mu$g. of thallium, 3 to 8 ml. of a 2 M acetic acid solution and 3 to 5 ml. of a $1\times10^{-3}$ M xylenol orange solution were added. The solution was then diluted to the mark with water and mixed. After 15 min., the absorbance of the solution was measured at 520 m$\mu$, using a reagent blank as the reference.

## Results and Discussion

**Absorption Curve.**—The maximum absorption of the thallium - xylenol orange complex was observed at about 520 m$\mu$, when it was measured against a reagent blank as the reference.

**The Effect of the Concentration of Acetic Acid and the Color Stability.**—The effect of the concentration of acetic acid on the absorbance of the solution was examined; the results are shown in Fig. 1. The maximum absorbance

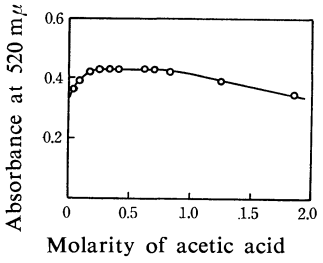

Fig. 1. Effect of concentration of acetic acid
Tl taken: 103 $\mu$g
XO concn.: $1.61\times10^{-4}$ M

is obtained when the acid concentration is adjusted to 0.25 to 0.7 M. In all the concentrations of acetic acid, the color formation was almort instantaneous. However, the intensity of the color of the resulting solution tended to decrease slowly with time; the change in abrorbance with time is indicated in Table I.

TABLE I. EFFECT OF TIME OF STANDING

Thallium taken: 124 $\mu$g.
Xylenol orange concn.: $1.60\times10^{-4}$ M
Acetic acid concn.: 0.41 M

| Time of standing, min. | Absorbance at 520 m$\mu$ |
|---|---|
| 5 | 0.539 |
| 10 | 0.536 |
| 15 | 0.531 |
| 20 | 0.528 |
| 30 | 0.522 |
| 45 | 0.517 |
| 60 | 0.512 |
| 120 | 0.500 |
| 180 | 0.492 |
| 240 | 0.489 |
| 400 | 0.463 |

10) M. Otomo, This Bulletin, 37, 504 (1964).

The effect of the concentration of other acids was also examined. At relatively lower concentrations, nitric acid and perchloric acid gave almost the same absorbance as that obtained with acetic acid. However, the color was unstable; the absorbance decreased by about 10% during the first 15 min. when the concentration of nitric acid was 0.2 M, and by about 4%, at the same concentration, of perchloric acid. Hydrochloric acid, at any concentration, is not adequate as the solvent, because thallium(III) forms stable chloro-complexes with chloride ions.

**The Effect of the Addition of the Reagent.**—Figure 2 shows the effect of the amount of the reagent. A high and almost constant absorbance is obtained when more than 3 ml. of a $1\times10^{-3}$ M xylenol orange solution is added.

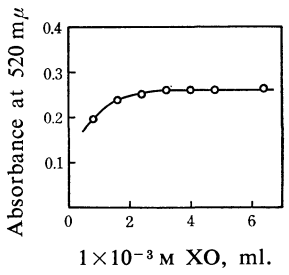

Fig. 2. Effect of addition of xylenol orange.
Tl taken: 62 $\mu$g.
$CH_3CO_2H$ concn.: 0.41 M

**Adherence to Beer's Law.**—As is shown in Fig. 3, Beer's law is oveyed ober the range from 20 to 150 $\mu$g. of thallium in 25 ml.

The apparent molar extinction coefficient of the thallium(III) - xylenol orange complex is 21300 at 520 m$\mu$. The sensitivity of the color reaction at this wavelength is 0.01 $\mu$g. of thallium per cm$^2$.

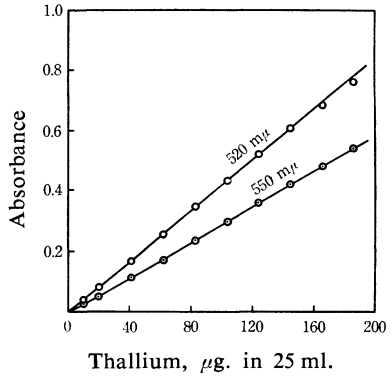

Fig. 3. Calibration curves.
XO concn.: $1.61\times10^{-4}$ M
$CH_3CO_2H$ concn.: 0.41 M

**The Effect of Diverse Ions.**—The effect of diverse ions was examined with solutions containing 103 $\mu$g. of thallium. Of the anions tested, the following did not interfere under the described conditions: fluoride up to 50 $\mu$mol., nitrate up to 500 $\mu$mol., and sulfate up to 100 $\mu$mol. Chloride, bromide, iodide, NTA and EDTA interfere seriously with the determination.

Of the 32 cations, including bi-, ter- and quadrivalent metal cations, bismuth(III), gallium(III), indium(III), iron(III), thorium(IV), vanadium(IV) and zirconium(IV) interfere with the determination by forming colored solutions. The interference of thorium and zirconium can, however, be eliminated by the addition of fluoride ions.

The proposed method, which is rapid and sensitive, seems to be applicable to the determination of traces of thallium in many samples after thallium has been preliminarily separated from the interfering ions by an appropriate method.

**The Composition of the Complex.**—The composition of the thallium(III) - xylenol orange complex was determined by the method of continuous variations as well as by the mole ratio method. Both methods showed that a 1 to 1 complex is formed between thallium(III) and xylenol orange at the acetic acid concentration described above.

The author is indebted to Professor Kôichi Tonosaki for his kind guidance throughout the course of this study.

# The Dipole Moments of Bromothiophenes

By Takashi SHIMOZAWA

(Received November 21, 1964)

The molecular structures of bromothiophene derivatives were determined by dipole moment measurements. On the basis the results of these values, the bond nature of C-Br bonds can be discussed. The bond moment of the C-Br bond in the $\alpha$-position of the thiophene is 1.08 D., while that of the bond in the $\beta$-position is 1.53 D. The ortho-effect causes the C-Br moment to decrease by about 12%. The bond angle of C-Br bonds in tetrabromothiophene may be increased by steric hindrance.

A number of bromine derivatives of thiophene synthesized by Professor Eiji Imoto of Osaka Prefectural University[1] were used for dipole moment measurements without further purification.

The dipole moments were observed by the solution method at 25.0°C, using benzene as a solvent. The method has been reported previously in detail.[2] The observed and the calculated dipole moments are listed in Table I.

The values listed in column A of Table I were calculated by making the following assumptions: 1) the C-Br bond moment is 1.20 D.; 2) the dipole moment of the thiophene ring is 0.53 D.[3] and has its negative end at the sulfur atom, and 3) the bond angles are the same as in the thiophene ring[4] (Fig. 1). The agreement between the observed and calculated values is fairly good, so that the molecular structures of these molecules may be obtained by the dipole moment measurement. However, it can be expected that the bond moments of the C-Br bonds will change

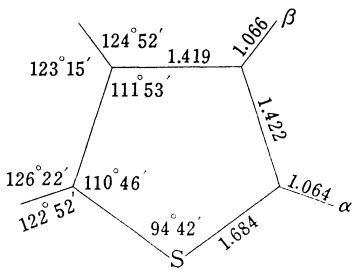

Fig. 1. The molecular structure of thiophene. (Cumper et al., Ref. 4)

their values according to their positions. In fact, the observed values of dipole moments are different for the two kinds of monobromothiophenes. These two C-Br bond moments were calculated from the observed values using the second assumption above. The C-Br bond moment of the α-position is 1.08 D., while that of the β-position is 1.53 D. The latter is nearly the same as that of the C-Br bond moment of about 1.5 D. in benzene derivatives. On the other hand, the C-Br bond moment at the α-position is smaller than the usual value. It has been reported[6] that the electron charge density of a carbon atom in the α-position of the thiophene ring is larger than that in the β-position; this would make the bond moment of the C-Br bond at the α-position smaller than that at the β-position.

The values calculated for molecules III and IV by the use of moments described above are listed in Table I (column B). They do not agree with the observed values. As is well known, the value of the dipole moment of ortho di-substituted benzenes is smaller than the values calculated by the vector addition of the dipole moment of mono-substituted compounds; i. e., in the case of ortho-dibromobenzene, for example, the C-Br bond moment calculated from the observed value is 12% smaller than the value for bromobenzene (the so-called the "ortho effect"). It may be assumed that the "ortho-effect" affects the dipole moments of compounds III and IV, too. The dipole moments of these molecules were recalculated using the smaller C-Br bond moments for each pair. These results are also listed in Table I (column C). These values agree with the observed values quite well, except for compound V.

In the case of 2, 3, 4, 5-tetrabromothiophene (V), the observed value of the dipole moment is 0.12 D., which differs greatly from the calculated value. As the experimental error involved in this value of the dipole moment is about ±0.2 D., the difference between the observed and the calculated values is worth further consideration.

If the C-Br bond is assumed to be 1.89 Å, and the valence angles, to be the same as in thiophene, the Br···Br distance is found to be 3.59 Å, which is much smaller than the sum of the van der Waals' radii of two bromine atoms (3.80 Å[7]). Therefore, the steric hindrance between Br···Br atoms would be exerted rather strongly. Thus, in order to avoid this steric hindrance, the C-Br bonds must be bent mutually in-plane or out-of-plane with respect to the thiophene ring. It can easily be shown that the in-plane bending of C-Br bonds strongly affects the value of the dipole moment; on the other hand, the out-of-plane bending does not appreciably change the dipole moment. The bending angles were obtained by a comparison of the observed and the calculated (column C) dipole moments. The results are shown in Fig. 2, where θ is calculated to be

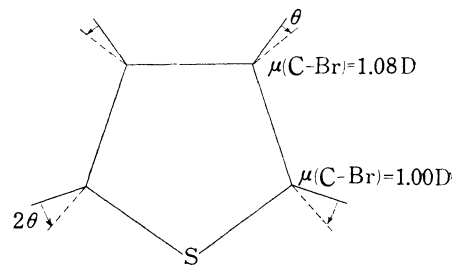

Fig. 2. The C-Br bond moments and in-plane deformations of 2, 3, 4, 5-Tetrabromothiophene.

about 5°. This value of θ seems to be unusually large. However, the Br···Br distance was calculated as 3.83 Å by using this new angle. Since this value is practically the same as the van der Waals value, the steric hindrance mentioned above does not seem to exist under this deformation. Therefore, the discrepancy between the observed and the calculated values (column C) might be due to the deformation. In order to determine the molecular structure of compound V, it is, of course, desirable to investigate its crystal structure by X-ray

SHORT COMMUNICATIONS

# The Formation of the Anion Radicals of Pyromeritonitrile and Tetracyanoethylene by Flash Irradiation

By Mitsutaka SOFUE and Saburo NAGAKURA

(Received March 2, 1965)

It is well known that pyromeritonitrile (1, 2, 4, 5-tetracyanobenzene)[1] and tetracyanoethylene[2] are strong electron-acceptors. Furthermore, these electron acceptors are known to give stable anion radicals by reduction with alkalimetals in appropriate solvents.[3,4] In the course of their study of the effect of flash light upon charge-transfer-type complexes, the present authors have found that pyromeritonitrile and tetracyanoethylene can produce anion radicals by the irradiation of flash light, even in the absence of a definife electron donor.

**Pyromeritonitrile.**—Pyromeritonitrile was dissolved in purified acetonitrile in a concentration of $10^{-2}$—$10^{-3}$ M; the resulting solution was thoroughly degassed and used as the sample. As a flash-light source, a flash photolysis apparatus provided with argon flash lamps was utilized. An electric charge of 10—15 kV. in a 10 $\mu$F condenser was discharged through the lamps, and the light pulse generated (500—1200 joule/flash) was irradiated to the degassed sample solution contained in a quartz reaction vessel.

After the irradiation with flash light, the solution showed new absorption bands at 270, 375 and 462 m$\mu$ (see Fig. 1),* and an ESR spectrum with a hyperfine structure of 9 lines.** The electronic absorption spectrum and ESR spectrum observed with the irradiated solution

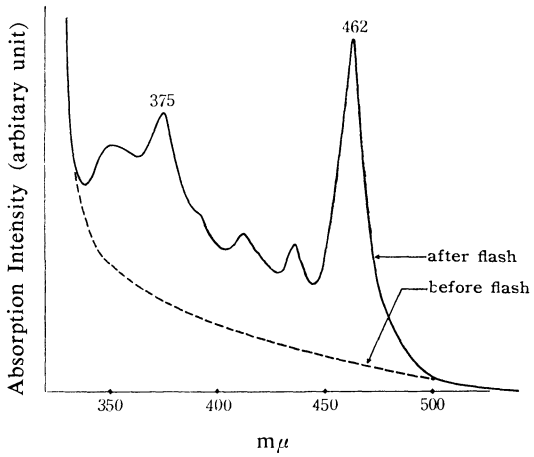

Fig. 1 Ultraviolet absorption spectrum of pyromeritonitrile before and after flash irradiation.

3) A. Ishitani and S. Nagakura, to be published.
4) W. D. Phillips, J. C. Rowell and S. I. Weissman, *J. Chem. Phys.*, **33**, 626 (1960).

* The electronic spectra were measured with a Cary recording spectrophotometer, Model 14 M.

** The ESR spectra were measured with a Hitachi ESR spectrometer, Model MPV-2B (X-band, 100 kc. modulation).

are completely identical with those of the pyromeritonitrile anion produced by the alkali metal reduction method.[3] Thus, it was confirmed that the pyromeritonitrile anion radical was produced by the irradiation of the acetonitrile solution of the parent molecule with an intence flash light.

The electronic absorption spectrum of the anion radical solution slowly decreased in intensity in vacuo and returned to that of the original neutral molecule. The lifetime was estimated to be 5 hr. This anion vanishes quickly if oxygen was introduced into the system.

Similar results were obtained with the ethanol and ethyl ether solutions. The lifetimes of the anions formed in these solvents were estimated to be 40 min. and 3 hr. respectively.

**Tetracyanoethylene.**—A degassed solution of tetracyanoethylene in acetonitrile, when irradiated with an intense flash light, showed a new absorption band at 250—400 m$\mu$ (see Fig. 2), and the sample solution turned pale yellow. The new absorption band was completely identical with that of the tetracyanoethylene anion produced by the alkali metal reduction method; therefore, the formation of the anion was confirmed.

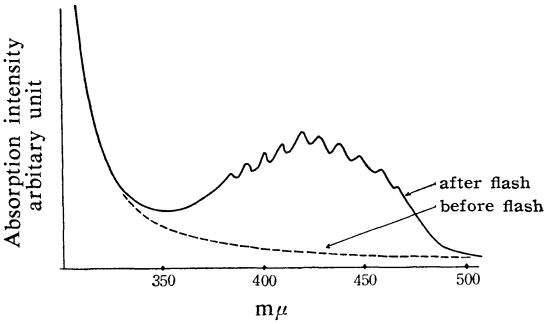

Fig. 2 Ultraviolet absorption spectrum of tetracyanoethylene before and after flash irradiation.

In the cases described above, no counter cations, which may be presumed to be produced simultaneously with the anions, could be detected.

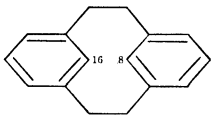
# The Photochemical Transannular Reaction of [2.2]Metacyclophane

By Takeo SATO, Ei-ichi YAMADA, Yoshio OKAMURA, Teruo AMADA and Kazuo HATA

(Received March 27, 1965)

A recent report[1] describing the occurrence of a photochemical equilibrium between *trans*-15, 16-dimethyldihydropyrene and its valence tautomer with a metacyclophane structure has prompted us to submit our findings on the photochemical transannular reaction of [2.2]-metacyclophane (I), which leads to 4, 5, 9, 10-tetrahydropyrene (II), in a preliminary form.



The irradiation of compound I, which had been prepared in a 45% yield by a modification of the method of Müller and Röscheisen[2] using a high dilution condition, was carried out in a quartz vessel placed in a circulating-water jacket housing a 1000 W. mercury arc lamp (Wako Denki Co., HBC-1000). Under a current of nitrogen, a mixture of 53.5 mg. (0.257 mmol.) of compound I, 68.1 mg. (0.268 mmol.) of iodine, and 700 mg. (excess) of sodium bicarbonate in 40 ml. of cyclohexane was irradiated for 44 hr.; it gave 45.5 mg. of colorless plates, m.p. 135—136°C (from methanol-ethanol), the NMR spectra of which in carbon disulfide showed only two singlets at 3.05 (6H) and 7.20 $\tau$ (8H). The disappearance of the characteristic peak of compound I at 5.77 $\tau$ ($C_8$ and $C_{16}$ protons) indicated that the transannular reaction occurred. The compound was shown to be 4, 5, 9, 10-tetrahydropyrene (II) by its identical infrared spectra and by a mixed melting point determination with an authentic specimen, m. p. 137—138°C. The yield reached 85.9%. A series of experiments confirmed that the formation of compound II in a somewhat lower yield was also possible by the irradiation of compound I and iodine in cyclohexane, *n*-hexane or ethanol under nitrogen as well as under oxygen. Compound I itself, however, was shown to be quite stable toward irradiation, and it could be recovered

(2 E. Müller and G. Röscheisen, *Chem. Ber.*, **90**, 543 (1957).

in a 56% yield after irradiation for 20 hr. under oxygen.

It is assumed that the mechanism of this reaction is different from that of the related photochemical cyclization,[3] the formation of phenanthrenes from *cis*-stilbenes in the presence of a suitable oxidant (molecular oxygen or iodine), since the mechanism that has been formulated[3] requires the presence of the conjugated system. Further, the fact that the formation of II was best achieved by the reaction with one mole equivalent of iodine in the presence of the base suggested the participation of iodine to give iodinated radicals as the intermediate, followed by transannular reaction and dehydroiodination. Moreover, the driving force of this cyclization step may be sought in the unique features of the metacyclophane structure, namely, the proximity of $C_8$ and $C_{16}$ atoms and the presence of a highly strained ten-membered ring system, which is relieved by going into bicyclic. Thus no reaction occurred when bibenzyl, the open-chain model of compound I, was irradiated under the conditions described above.

(I)

(III)

The attempted iodination reaction of compound I with iodine and silver perchlorate in ether was also shown to give compound II in a 60% yield. Apparently the first step of this reaction is the electrophilic substitution by the iodonium ion, accompanied by the transannular reaction, giving an intermediate III.[4] Compound II is formed by a loss of the proton, followed by dehydroiodination.

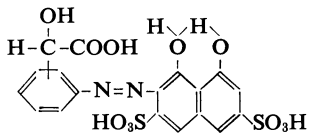
# Syntheses of 2-, 3- and 4-(1, 8-Dihydroxy-3, 6-disulfo-2-naphthylazo)-mandelic Acids as New Reagents, and the Thorium Complex of the 2-Isomer*



By Kyoji TÔEI, Haruo MIYATA and Tadayasu MITSUMATA**

(Received March 30, 1965)

In a series of phenylazochromotropic acid derivatives, the one with the $-AsO_3H_2$ or $-OCH_2COOH$[1] group is an especially sensitive reagent for thorium ion.

The present paper will describe the preparation of those reagents which have the $-CH(OH)COOH$ group in the ortho-, meta- or para-position to the azo group, and the determination of the acid dissociation constants of the reagents and of the constitution of the thorium complex formed with the 2-isomer.

**The Syntheses of the Reagents.**—The reagents, 2-, 3- and 4-(1, 8-dihydroxy-3, 6-disulfo-2-naphthylazo)mandelic acids, were obtained from the corresponding diazotized amino mandelic acids which were coupled with chromotropic acid respectively; the structures of the reagents were as follows:

**The Determination of the Acid Dissociation Constants of the Reagents.**—The acid dissociation constants of the reagents have been estimated spectrophotometrically; their values are shown in Table I.

The $pK_{a_3}$ value corresponds to the dissociation of the hydrogen ion from the carboxyl group of mandelic acid in the reagents, while

# A Novel Copper(II) Complex of Diketopiperazine

By Akitsugu NAKAHARA, Ken-ichi SAKURAI, Ken-ichi SUZUKI and Yasuo NAKAO

(Received April 12, 1965)

The molecular structure of diketopiperazine has been extensively studied[1-3] and as a result, it is regarded as a resonance hybrid of I and II. X-Ray study has shown that the molecule is nearly planar and has a center of symmetry.[2] Since there are two peptide linkages in the molecule, diketopiperazine is expected to form several types of complexes with metal ions according to the way functional groups are used as donor atoms. No paper has, however, been published to report on the formation of any type of complex, even in solutions.

Recently we have succeeded in preparing one of these diketopiperazine complexes in the crystalline state. The new complex is potassium bis(diketopiperazinato)cuprate(II); on the basis of spectroscopic investigations, it is considered to have a very interesting structure. In this paper we will report on the preparation and on the properties of this new compound, and we will also consider its peculiar structure.

A one-to-two mixture of diketopiperazine and potassium hydroxide in an aqueous solution was treated at room temperature with an excess of freshly precipitated copper(II) oxide to give an intense blue solution as a result of the complex formation. The solution was then gently evaporated in a vacuum. The new complex is obtained as beautiful purple prisms, the color of which is fairly sensitive to moisture. In a humid atmosphere, it appears blue-purple, while in a comparatively dry atmosphere it is red-purple.

Judged from this color of the crystal, it is conceivable that all the four donor atoms around copper(II) are nitrogen, as in the bis(ethylenediamine)copper(II) complex. In fact, the wavelength for the maximum absorption in the visible region obtained by the reflection method strongly supports this theory. On the other hand, elemental analyses indicate that the ratio of copper(II) to diketopiperazine is one-to-two. Thus, the structure of the complex has been supposed to be a kind such as is illustrated in Fig. 1, in which two considerably-bent diketopiperazinato ions are coordinated around copper(II) through peptide nitrogens. The validity of this kind of structure is supported not only by the Stuart

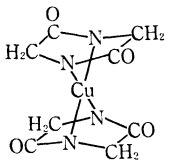

Fig. 1. The sandwich type structure of bis(diketopiperazinato)cuprate(II) ion.

model but also by the infrared study. The spectrum of diketopiperazine in the fingerprint region is very simple, while that of the complex differs in many respects and has a number of additional bands of a weak or medium intensity. These changes are consistent with the change in the conformation of the diketopiperazine molecule from the centrosymmetric to the boat configuration, a change caused by chelation with the copper(II) ion.

This may be a novel type of complex, having a structure of sandwich-type like ferrocene and other so-called $\pi$-complexes. However, the nature of the bondings between nitrogen and copper(II) may be supposed to be, rather, the $\sigma$-type on the basis of spectroscopic and stereochemical considerations. In this respect, the new complex bears a strong resemblance to the palladium(II) and platinum(II) complexes of piperazine reported by Mann and Watson.[4]

# The Photochemistry of Hexacyanoferrate(II) Ions in Aqueous Solutions

By Shin-ichi OHNO and Gen-ichi TSUCHIHASHI*

(Received April 15, 1965)

Aqueous hexacyanoferrate(II) solutions decompose in ultraviolet light to give the aquopentacyanoferrate(II) ion.[1] Recently, Matheson et al.[2] observed a transient absorption due to the hydrated electron, $e^-_{aq}$, in the flash photolysis of aqueous hexacyanoferrate(II) solutions. We have studied the photo-induced reaction of aqueous hexacyanoferrate(II) solutions at various pH values, employing two light sources of different wavelengths. We have observed that illumination with a 3660 Å light causes only a ligand substitution reaction:

$$[Fe(CN)_6]^{4-} \xrightarrow[H_2O]{3660\text{Å}} [Fe(CN)_5OH_2]^{3-} + CN^- \quad (1)$$

* Present Adress: Sagami Chemical Research Center, Onuma, Sagamihara-shi, Kanagawa.

1) S. Ašperger, *Trans. Faraday Soc.*, **48**, 617 (1952).

2) M. S. Matheson, W. M. Mulac and J. Rabani, *J. Phys. Chem.*, **67**, 2613 (1963).

As a result of activation with a 2537 Å light, on the other hand, a photo-oxidation reaction was found to take place, giving hexacyanoferrate(III) and "reducing species (r. s.)":

$$[Fe(CN)_6]^{4-} \xrightarrow[H_2O]{2537\ Å} [Fe(CN)_6]^{3-} + \text{"r.s."}(e^-_{aq}) \quad (2)$$

The reducing species thus formed displayed a reactivity similar to that of the hydrated electron produced in water irradiated by fast electrons or $\gamma$-rays.[3]

The pH-buffered solutions of $10^{-2}$ M potassium hexacyanoferrate(II) were irradiated with a 3660 Å light from a high pressure mercury lamp, the solution being stirred by bubbling nitrogen gas. The quantum yield of the initial formation of aquopentacyanoferrate(II) was 0.89 at pH 4.0, the maximum value obtained, and 0.52 at pH 0.65.

Photo-oxidation reaction 2 was studied by using a 2537 Å light from a low pressure mercury lamp. The irradiation of the deaerated solution of $10^{-3}$ M potassium hexacyanoferrate(II) alone caused no significant change in the optical density at 420 m$\mu$. The same solution, however, became colored when irradiated in the presence of nitrous oxide or nitrate ions.[5] The absorption spectra of the solution, as well as the results of thin-layer chromatography, clearly indicate the formation of hexacyanoferrate(III) ions, which may be attributed to reaction 2, followed by:

$$e^-_{aq} + N_2O \longrightarrow N_2 + OH + OH^- \quad (3)$$

$$OH + [Fe(CN)_6]^{4-} \longrightarrow [Fe(CN)_6]^{3-} + OH^- \quad (4)$$

or

$$e^-_{aq} + NO_3^- \longrightarrow NO_2 + 2OH^- \quad (5)$$

$$NO_2 + [Fe(CN)_6]^{4-} \longrightarrow [Fe(CN)_6]^{3-} + NO_2^- \quad (6)$$

The yield of hexacyanoferrate(III) ions increased with the increase in the concentration of nitrous oxide or nitrate ions to reach a limiting value. The quantum yield of the formation of $e^-_{aq}$ was determined to be 0.35. We also noted that no noticeable amount of hexacyanoferrate(III) was produced with a 3660 Å light, regardless of whether an electron scavenger, such as $N_2O$ or $NO_3^-$, was present or not.

Further, acetone appeared to compete with reaction 3 or 5 for $e^-_{aq}$, and ethanol, with reaction 4 for OH. From kinetic data, the rate constant ratios were calculated te be $k(e^-_{ap}+\text{acetone})/k_3=1.5$, $k(e^-_{ap}+\text{acetone})/k_5=0.45$ and $k(OH+\text{ethanol})/k_4=0.16$. Agreements with the reported values are satisfactory.[3]

We may, therefore, conclude that the irradiation of hexacyanoferrate(II) ions with a 2537 Å light (the charge-transfer-to-solvent type of excitation[4]) brings about an electron release to the solvent, while activation by a 3660 Å light (the ligand-field transition type) causes only a ligand substitution reaction. The present photochemical study offers a new method of investigating, in a direct manner, the reactions of hydrated electrons with a variety of inorganic and organic substances: several such studies are now in progress.

# Stability Constants of Some Substitution-inert Cobalt(III) Complexes

By Nobuyuki TANAKA and Hiroshi OGINO

(Received May 8, 1965)

Only a few investigations have been made on the stability constants of cobalt(III) complexes.[1] This is because cobalt(III) forms mostly substitution-inert complexes; the formation of such complexes discourages considerably the determination of the stability constant. In this communication, the stability constants of cobalt(III) complexes with ethylenediaminetetraacetate ($edta^{4-}$), propylenediaminetetraacetate ($pdta^{4-}$) and trimethylenediaminetetraacetate ($trdta^{4-}$), which are all substitution-inert, are presented, and compared with the stability constants of some divalent metal ions reported previously.[2]

The equilibrium potentials of the reaction

$$Co^{II}Y^{2-} \rightleftarrows Co^{III}Y^{-} + e \qquad (1)$$

were measured at the dropping mercury electrode with the solutions which contain varied concentrations of $Co^{II}Y^{2-}$ and $Co^{III}Y^{-}$, where $Y^{4-}$ denotes $edta^{4-}$, $pdta^{4-}$ or $trdta^{4-}$ anion. From these values, the standard oxidation-reduction potentials of Eq. 1 ($E^{\circ}_{CoY}$) were calculated. These values agreed to the half-wave potentials of the reduction waves of $Co^{III}Y^{-}$ and the oxidation waves of $Co^{II}Y^{2-}$. The stability constants of $Co^{III}Y^{-}$ ($K_{Co(III)Y}$) were calculated by using the values of $E^{\circ}_{CoY}$, the stability constants of $Co^{II}Y^{2-}$ ($K_{Co(II)Y}$)[2] and the standard oxidation-reduction potential of the $Co(aq.)^{2+}$ - $Co(aq.)^{3+}$ couple (+1.842 V. vs. NHE).[3] The results are given in Table I.

The stability constant of $Co^{III}edta^{-}$ obtained in this study is in satisfactory agreement with that reported by Reilley et al.[4] The stability constant of $Co^{III}pdta^{-}$ is larger than that of $Co^{III}edta^{-}$ by 1.5 in log $K$ unit. This tendency, which agrees essentially with that reported previously,[2] is considered to be attributed to the inductive effect of the methyl group of coordinated $pdta^{4-}$ ion.[2,5] On the other hand, the stability constants of $Co^{III}edta^{-}$ and $Co^{III}trdta^{-}$ are almost the same in maguitude. This supports the previous conclusion that the decrease in the size of metal ion favors the formation of trimethylenediaminetetraacetato complex;[2] the ionic radius of cobalt(III) is smaller than those of manganese(II), cobalt(II), nickel(II), copper(II), zinc(II), cadmium(II), and lead(II). In addition, it should be noted that cobalt(III) gives a stability constant considerably larger than chromium(III),[6] manganese(III)[7] and iron(III)[8] in the case of EDTA complexes and also than iron(III)[9] in the case of TRDTA complexes. This may relate to the fact that EDTA forms a spin-paired complex with cobalt(III),[10] but not with chromium[10]-(III), manganese(III),[11] and iron(III).[10] The details of the study will be reported later.

TABLE I. THE STABILITY CONSTANTS OF COBALT(III) COMPLEXES WITH ETHYLENEDIAMINETETRAACETATE, PROPYLENEDIAMINETETRAACETATE AND TRIMETHYLENEDIAMINETETRAACETATE*

| Couple | $E^{\circ}_{CoY}$ V. vs. SCE | log $K_{Co(II)Y}$[2] | log $K_{Co(III)Y}$ |
|---|---|---|---|
| $Co^{II}edta^{2-}$-$Co^{III}edta^{-}$ | +0.13 | 15.71 | 40.6 |
| $Co^{II}pdta^{2-}$-$Co^{III}pdta^{-}$ | +0.12 | 17.07 | 42.1 |
| $Co^{II}trdta^{2-}$-$Co^{III}trdta^{-}$ | +0.05 | 14.48 | 40.7 |

* The measurements were made with the solution containing 0.05 M acetate buffer (pH 4.6 to 5.4) at ionic strength 0.2 ($KNO_3$) and 25°C.

# The Calculation of the State Energies of Benzaldehyde. II. The SCF Molecular Orbital Method

By Kōzō Inuzuka and Toshio Yokota

(Received May 16, 1964)

In the previous paper,[1] we calculated the state energies of benzaldehyde by the Pariser-Parr method[2] and assigned electronic transitions by adopting a model with $C_{2v}$ symmetry for the sake of simplicity. In the actual molecule of benzaldehyde, however, the carbon atom of the carbonyl group is combined with the carbon atom of the benzene ring, where the bond angle of C–C=O is 120°, as is shown in Fig. 1.

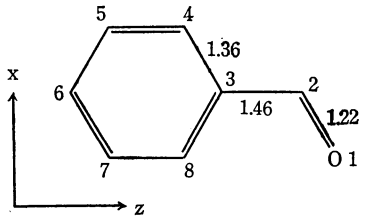

Fig. 1. A model* of benzaldehyde with $C_s$ symmetry.

* Ref. 1

In this paper, therefore, the state energies of benzaldehyde with $C_s$ symmetry are calculated by using the SCF-MO method.[3,4] The bond distances used are the same as those in the previous model.[1]

## Calculation Procedure

The SCF-MO, $\varphi_i$, and its energy, $\varepsilon_i$, are obtained by the following formulas:

$$\varphi_i = \sum_\mu c_{i\mu}\chi_\mu$$

$$\sum_\nu F_{\mu\nu}c_{i\nu} = \varepsilon_i c_{i\mu}$$

$$F_{\mu\mu} = \alpha_\mu + \frac{1}{2}p_{\mu\mu}(\mu\mu/\mu\mu) + \sum_{\nu\neq\mu}(p_{\nu\nu}-1)(\mu\mu/\nu\nu)$$

$$F_{\mu\nu} = \beta_{\mu\nu} - \frac{1}{2}p_{\mu\nu}(\mu\mu/\nu\nu)$$

$$p_{\mu\nu} = 2\sum_i c_{i\mu}c_{i\nu}$$

where $\chi_\mu$ is 2p$\pi$AO of the $\mu$th-atom, $\alpha_\mu$ is the ionization potential of the atom, $\mu$, in the atomic valence state and $\beta_{\mu\nu}$ is the resonance integral over the nearest neighbor atoms, $\mu$ and $\nu$.

The value of the resonance integral, $\beta_{CO}$, over carbon and oxygen atoms is calculated by using Kon's formula,[6] while the value of $\beta_{CC}$ over carbon and carbon atoms is obtained from Pariser and Parr's formula.[2] $(\mu\mu/\nu\nu)$ is the Coulomb repulsion integral; that is,

$$(\mu\mu/\nu\nu) = \int\chi^*_\mu(1)\chi_\mu(1)(e^2/r_{12})\chi^*_\nu(2)\chi_\nu(2)dv$$

It is evaluated from the equations derived by Roothaan[7] and by Anno et al.[5] for $r>2.80$Å and $r\leqq 2.80$Å respectively. The calculations were done using a digital computer. The iteration process in the calculation of SCF-MO's and MO energies started with Hückel MO's and continued until the energies converged.

The excitation energies corresponding to the $i$–$k$ transition are expressed for singlet and triplet states respectively as follows:

$$^1E_{i\text{-}k} = \varepsilon_k - \varepsilon_i - [ii/kk] + 2[ik/ki]$$

$$^3E_{i\text{-}k} = \varepsilon_k - \varepsilon_i - [ii/kk]$$

where

$$[ii/kk] = \int\varphi_i(1)^*\varphi^*_k(2)(e^2/r_{12})\varphi_i(1)\varphi_k(2)dv.$$

Neglecting the differential overlap, the integrals, $[ii/kk]$ and $[ik/ki]$, may be expressed in terms of the Coulomb repulsion integrals over such atomic orbitals as $(\mu\mu/\nu\nu)$.

In addition to the above MO's, the benzaldehyde molecule has a nonbonding orbital which may be represented approximately as follows:

$$\varphi_n = \chi_n$$

where $\chi_n$ is the 2p$\bar{\pi}$ AO of the oxygen atom. Its nodal plane is perpendicular to the molecular plane and contains the CO axis.

The transition moment between the ground state, $\psi_0$, and an excited state, $\psi_i$, is defined by:

$$M^r{}_{0i}=\int\psi_0 r\psi_i \mathrm{d}v \quad (r=x,y,z)$$

where $\psi_i$ is expressed approximately by a linear combination of singly-excited configuration functions. The oscillator strength, $f$,[8] is given by:

$$f=1.085\times10^{11}\times\omega_{0i}\sum_r M^r{}_{0i}{}^2,$$

where $\omega_{0i}$ is the frequency of the transition in $cm^{-1}$.

## Results

**State Energies without Configuration Interaction.**—The SCF-MO's and the MO energies so obtained are listed in Table I. The $\pi$-$\pi$ transition energies in singlet and triplet states are calculated from the above equation; the $n$-$\pi$ transition energies are also calculated by the Pariser-Parr method using the above SCF-MO's. In Table II, we show all the energies of $n$-$\pi$ transitions and the lower lying energies of $\pi$-$\pi$ transitions.

**State Energies with Configuration Interaction.**—In large molecules, multiply-excited configurations should make negligibly small contributions to the lower excitation energies. In the present calculation we take account of a singly-excited configurations only. In the $\pi$-$\pi$ transition, all calculations of singly-excited configurations were carried out by solving a 16th-order secular equation for each of the singlet and triplet states. Similarly, in the calculation of the $n$-$\pi$ transition energies, four configurations were taken for each of the singlet and triplet states. The lower-lying state energies and their wave functions as obtained from these four secular equations are listed in Tables III and IV.

The charge densities, bond orders and free valences for the ground state of benzaldehyde

| $^3A''$: | 1 | 3.370 | | 3.22[d] | 1.8 $\times 10^{-7}$ [d] |

a) Ref. 9, b) Ref. 10, c) Ref. 11, d) Ref. 13, e) Ref. 12

The $\pi$-electronic states belong to the irreducible representation, A', of the symmetry group $C_s$, while the $n$–$\pi$ single excitation belongs to the symmetry type A'', since the symmetry of the $n$ orbital is a''. Therefore, the transition moment is perpendicular to the molecular plane, that is, parallel to the $y$ axis.

Benzaldehyde has four absorption bands in the region from 400 to 190 m$\mu$. In a previous

paper,[1] we tried to assign these absorption bands using the $C_{2v}$ model with Hückel MOs. The results for state energies and oscillator strengths in the present calculation are listed in Table IV, along with the observed values. From these results, the band at 285 m$\mu$ (4.50 eV.)[9] corresponds to the calculated energy of 4.771 eV. The bands at 233 m$\mu$ (5.32 eV.)[9] and 195 m$\mu$ (6.36 eV.)[10,11] are correlated with the state energies, 5.032 and 6.313 eV. respectively. On the basis of the above correspondence, they may be assigned to $^1A'$–$^1A'$ transitions. The calculated energy values are in good agreement with the observed values, as compared with the previous values,[1] but the calculated values of the oscillator strengths of the first and second transitions are smaller than the observed values.

The electronic transition at 26929 $cm^{-1}$ (3.34 eV.)[12] corresponds to the calculated energy of 3.860 eV. Therefore, the transition may be assigned to $^1A'$–$^1A''$. This calculated value should be compared with the previous value (3.614 eV.). The calculated state energy, 3.370 eV., is the lowest of the $n, \pi$ state energies and corresponds to $^1A'$–$^3A''$. This value is correlated with the S−T absorption band at 25195 $cm^{-1}$ (3.22 eV.)[13] and should be compared with the previous value (3.124 eV.). On the other hand, the calculated values for the $\pi,\pi$ triplet states are lower than the previous values;[1] however, no experimental data are available.

The reactivity indices for the ground state are shown in Fig. 2. The charge density of the meta position is higher than those of the ortho and para positions. This result indicates a tendency of the carbonyl group to meta orientation for electrophilic reagents, in accordance with the previous calculation.[1] The high-charge densities of ortho positions suggest that they also have a high reactivity for electrophilic reagents. The free valence in carbon atoms is the highest at the carbon atom 2, as is shown in Fig. 2. This suggests that position 2 is reactive in the case of radical reaction, as has been observed in the photo-oxidation reaction of benzaldehyde. The charge densities in two lower excited states are shown in Fig. 3. These results are very different from those of the previous calculations.[1]

## Summary

The state energies, charge densities, bond orders and free valences of benzaldehyde have been elucidated by the use of the SCF-MO method with a model of $C_s$ symmetry, including interactions of all the singly-excited configurations. In the singlet state, the numerical values of state energies are more reliable than the previous results, which were derived from the $C_{2v}$ model by the use of Hückel MO. In the triplet state, however, the numerical values of state energies seem to be lower than the previous results.

The authors wish to express their sincere thanks to Mr. Masuo Suzuki and Dr. Toshinori Munakata for their kind assistance in carrying out the digital computations. The present study was partially financed by the Scientific Research Fund of the Ministry of Education.

# Formation Constants of Chromium(III)-Oxalato Complexes

By Kyoichi NAGATA,* Akira UMAYAHARA and Ryokichi TSUCHIYA

(Received June 20, 1964)

There have been published a great number of investigations of the syntheses[1] and the properties[2] of oxalato complexes of various metals; the data of the formation constants concerned have been summarized in a review.[3] However, these data concern only the bivalent cations. The formation constants of the oxalato complexes of tervalent metal cations are scarcely known except for a few examples.

In a preceding paper the formation constants of chromium(III) complexes with ethylenediamine were reported;[4] this is the simplest chelating agent which coordinates to the central chromium by means of two nitrogen atoms. In the present study, the formation constants of chromium(III) complexes with oxalate ion, the simplest chelating agent coordinating by two oxygen atoms, have been determined in order to compare them with those published in the previous report.[4] The results found have also been compared with the data of the corresponding complexes of other first-transition metals already known.

## Experimental

**Hexaaquochromium(III) Perchlorate.**—Chromium trioxide was precipitated by adding concentrated sulfuric acid to potassium bichromate. When it was reduced with formic acid[5] in the presence of perchloric acid, the hexaaquochromium(III) perchlorate which was the starting material in the present study was obtained. Since it was very hygroscopic, it was stored in a vacuum desiccator.

The analysis of the chromium in the hexaaquochromium(III) perchlorate prepared as above was carried out by oxidizing the tervalent chromium to bichromate by ammonium persulfate in the presence of a trace of silver nitrate as a catalyst, and by measuring the absorbancy of the solution at 420 mμ with a Hitachi FPW-4 photoelectric photometer after adjusting the pH of the solution to 2. The analysis of the perchlorate ion was made by titrating the elute passed through the cation exchange resin "Amberlite IR-120" with a standard sodium hydroxide solution.

By these analyses it was found that the crystalline hexaaquochromium(III) perchlorate prepared above as the sarting material had the following composition, if the adsorbed water was excluded:

| | |
|---|---|
| $[Cr(H_2O)_6](ClO_4)_3$ | 48.66 mol.% |
| $HClO_4$ | 51.34 mol.% |

**Sodium Oxalate.**—Salt of the highest commercial grade was further purified by recrystallization.

**Procedure.**—The determination of the formation constants was carried out by pH measurement. Mixed solutions of various concentrations of hexaaquochromium(III) perchlorate and sodium oxalate, to which some quantities of sodium hydroxide had been added to make the pH of the solution higher and an appropriate amount of sodium perchlorate, to make the ionic strength of the solution 0.1, were kept at 25°C in a thermostat for one or one-and-a-half months. The pH of the solution was measured with a Toa Denpa pH meter, model HM-8, after the equilibrium in the solution had been attained.

## Results

**Acid Dissociation Constants of Oxalic Acid.**—If the oxalic acid is represented as $H_2ox$, the acid dissociation constants, $K_1$ and $K_2$, may be expressed by:

$$K_1 = [H^+][Hox^-]/[H_2ox] \quad (1)$$

$$K_2 = [H^+][ox^{2-}]/[Hox^-] \quad (2)$$

where [ ] expresses the concentration in moles per liter. If the total concentration of ionizable hydrogen atoms and that of oxalate ions are expressed by $C_H$ and $C_{ox}$ respectively, $\bar{n}_H$, denoted as the average number of hydrogen atoms attached to each oxalate ion, is given by the following equation:

$$\bar{n}_H = \frac{[Hox^-] + 2[H_2ox]}{[ox^{2-}] + [Hox^-] + [H_2ox]} = \frac{C_H - [H^+]}{C_{ox}} \quad (3)$$

On the other hand, $C_H$ is expressed by the equation as:

$$C_H = C_{ox} + C_a - C_{OH} \quad (4)$$

where $C_a$ and $C_{OH}$ are the concentrations of perchloric acid and of sodium hydroxide added respectively.

The determination of the acid dissociation

constants was carried out by titrating the mixed solution of oxalic acid and sodium oxalate with perchloric acid or with a sodium hydroxide solution. By inserting the values of $C_H$ calculated from the titre of perchloric acid or sodium hydroxide and the $[H^+]$ values obtained from the pH measurement into Eqs. 3 and 4, the value of $\bar{n}_H$ was obtained. The plot of $\bar{n}_H$ vs. pH is shown in Fig. 1.

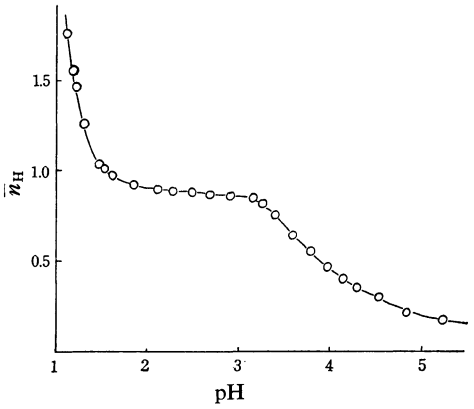

Fig. 1. The relation between $\bar{n}_H$ and pH

The values of the acid dissociation constants of the first and second steps, $pK_1$ and $pK_2$, are obtained from Fig. 1 as 1.13 and 3.85 respectively. These values are in good agreement with the $pK_1=1.14$[6] ($\mu=0.2$, 25°C) and $pK_2=3.85$[6] ($\mu=0.2$, 25°C) already known, although the ionic strength is somewhat different.

**Formation Constants of Oxalato-chromium(III) Complexes.**—When the total concentration of chromium is expressed by $C_M$, that of the oxalate ion as ligand is given by:

$$C_{ox}=[ox^{2-}]+[Hox^-]+[H_2ox]+\bar{n}C_M \quad (5)$$

where $\bar{n}$ is the average number of ligands attached to each chromium. The total concentration of ionizable hydrogen is also given by the following equation:

$$C_H=C_a-C_{OH} \quad (6)$$

On the other hand, $\bar{n}$ is expressed as follows:

$$\bar{n}=\left\{C_{ox}-\frac{C_H-[H^+]}{\bar{n}_H}\right\}\Big/C_M \quad (7)$$

where $\bar{n}_H$ is denoted as the number of ionizable hydrogen atoms attached to oxalate ions against the number of oxalate ions which do not coordinate to chromium. It is calculated by using Eqs. 1, 2 and 3 and by applying the values of the acid dissociation constants of oxalic acid and $[H^+]$.

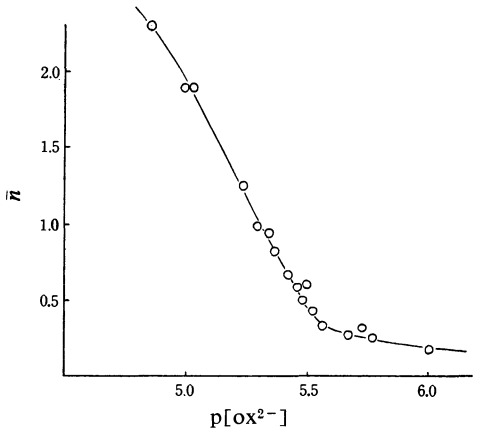

Fig. 2. The formation curve, $\bar{n}$—$p[ox^{2-}]$, concerning with chromium(III) oxalato complexes.

By measuring the pH in mixed solutions of hexaaquochromium(III) perchlorate and sodium oxalate and by applying Eqs. 1, 2, 5, 6 and 7, the values of $\bar{n}$ and $[ox^{2-}]$ were calculated. The formation curve, $\bar{n}-p[ox^{2-}]$, is plotted in Fig. 2. As the slope of this formation curve is relatively steep, the successive oxalato complexes formed seem to have overlapped each other. Since Bjerrum's simplified method cannot be applied in this case, the calculation of the formation constants was carried out in the following way.[7]

In the successive formation of the complexes, there exists the following relationship:

$$\bar{n}=\sum nK_n[ox^{2-}]^n/\{1+\sum K_n[ox^{2-}]^n\} \quad (8)$$

where $K_n=\Pi k_n$, the products of the successive formation constants. Equation 8 can be rearranged to:

$$\bar{n}=(n-\bar{n})[ox^{2-}]^nK_n=\sum J_nK_n \quad (9)$$

where

$$J_n=(n-\bar{n})[ox^{2-}]^n \quad (10)$$

By inserting the values of 0.5, 1.5 and 2.3 into $\bar{n}$ and the corresponding values into $[ox^{2-}]$ in Eqs. 9 and 10, three simultaneous equations are established. By solving these equations, the successive formation constants are obtained as $\log k_1=5.34$, $\log k_2=5.17$ and $\log k_3=4.93$ respectively.

## Discussion

The values of the formation constants of chromium(III) oxalato complexes in the first and second steps are compared with the known values of those of the first transition metals in Table I.

7) B. P. Block and G. H. McIntyre, Jr., *J. Am. Chem. Soc.*, **75**, 5667 (1953).

TABLE I. THE FORMATION CONSTANTS OF THE OXALATO COMPLEXES OF THE FIRST TRANSITION METALS

| | $\log k_1$ | $\log k_2$ | $\log k_3$ | Ionic strength $\mu$ | Temp. °C | Ref. |
|---|---|---|---|---|---|---|
| $TiO^{+}$ | 2.65 | | | — | 23 | 8 |
| $Cr^{3+}$ | 5.34 | 5.17 | 4.93 | 0.1 | 25 | Present study |
| $Mn^{3+}$ | 9.98 | 6.59 | 2.85 | 2 | 25 | 9 |
| $Fe^{3+}$ | 9.4 | 6.8 | 4.0 | — | — | 10 |
| $Co^{3+}$ | | $\log k_1k_2k_3 \cong 20$ | | — | — | 11 |
| $Al^{3+}$ | 7.25 | | | 0 | — | 12 |
| | | $\log k_1k_2$ | | $\mu$ | °C | Ref. |
| $Mn^{2+}$ | | 5.25 | | 0 | 25 | 13 |
| $Fe^{2+}$ | | 4.52 | | 0.5 | 25 | 14 |
| $Co^{2+}$ | | 6.7 | | 0.002 | 25 | 15 |
| $Ni^{2+}$ | | 6.51 | | 0.002 | 25 | 15 |
| $Cu^{2+}$ | | 10.32 | | — | ~20 | 16 |
| $Zn^{2+}$ | | 7.36 | | 0 | 25 | 17 |

It may be found from Table I that the formation constants of oxalato complexes of tervalent metal ions are remarkably larger than those of the corresponding complexes of bivalent metal ions. This is due to the fact that the ionic radii of the former are smaller than those of the latter; this confirms that the covalencies of the former are much stronger than those of the latter. The bivalent metal ions form four coordinated complexes, whereas the tervalent metal ions form six coordinated complexes.

It is found in the second that the formation constants of oxalato complexes become larger in the order of the tervalent titanium, chromium and manganese, iron or cobalt. That is to say, the formation constants of chromium complexes are smaller than those of manganese, iron and cobalt; they are comparable with those of aluminum complexes.

The formation constants of chromium(III) oxalato complexes are remarkably smaller than those of the corresponding ethylenediamine complexes reported in the preceding paper.[4] This suggests that the chelate group with two nitrogen atoms as the donor forms a more stable complex with chromium than does the chelate group with two oxygen atoms as the donor.

## Summary

The formation constants of chromium(III) complexes with the oxalate ion, which is the simplest bidentate ligand coordinating by two oxygen atoms, have been determined by the pH method.

It has been shown that the formation constants of oxalato chromium(III) complexes are larger than those of the corresponding titanium(III) complexes, but smaller than those of the corresponding manganese(III), iron(III) and cobalt(III) complexes in the first transition series.

The formation constants of oxalato chromium(III) complexes have been found to be remarkably smaller than those of the ethylenediamine chromium(III) complexes. This result suggests that two nitrogen atoms form a more stable complex with chromium than do the two oxygen atoms serving as donors in the bidentate chelate.

# Studies of Gas Chromatography with Mixed Stationary Liquids. IV. The Analysis of Aromatic Hydrocarbons from $C_6$ to $C_{10}$ with a Capillary Column*

By Hiroshi MIYAKE, Mitsuyuki MITOOKA and Tadashi MATSUMOTO

(Received July 30, 1964)

The gas chromatographic analysis of aromatic hydrocarbon mixtures through $C_{10}$ needs to be carried out with columns of excellent resolving powers, because these mixtures contain many groups of isomers with similar physical properties. It seems appropriate, for the analysis of such a complex mixture, to use a capillary column. Indeed, it has already been reported that fairly good separation was obtained for many types of hydrocarbon mixtures by the use of such a column,[1-3] but all of the aromatics through $C_{10}$ have not been separated by a single column, although various types of liquids of different polarities have been investigated as stationary phases. Several authors have reported that in these cases the mixed stationary liquid is effective. By changing the composition of the mixed liquid, the selectivities for the solutes were altered widely and continuously, and a column which has a pertinent selectivity may be prepared as an aid in investigating the effects of the composition on the partition coefficients of the solutes in question.[4-6] For all the paraffins, mono-olefins, di-olefins, cycloparafins and acetylenes through $C_4$, an appproximate linearity was observed between the logarithm of the partition coefficient and the composition (wt.%) of the mixed phase. Accordingly, when the retention times on two stationary liquids are known, the retention time of the solute on the mixed liquid of any composition may be presumed.

The presence of similar relationships may be expected from the behaviors of aromatic hydrocarbons on some mixed liquids, and the complex mixtures of aromatic isomers might be efficiently separated by the use of the appropriate mixed liquid.

## Experimental

**Apparatus.** — A Perkin-Elmer Model 188 vapor fractometer equipped with a flame-ionization detector was used without modification. Helium was used as the carrier, and the pressure was adjusted to a gauge pressure of 30 or 60 p. s. i. at the inlet of the column. A column consists of a 45.7 m. (or 91.4 m.) by 0.254 mm. stainless-steel capillary and is coated with squalane (SQ), dinonyl phthalate (DNP), 7, 8-benzoquinoline (BQ), polyethylene glycol 600 (PEG 600), di-*n*-propyl tetrachlorophthalate (DPTCP), 2, 4-dinitrochlorobenzene (DNCB) or a binary solution composed of these components.

**Coating the Capillary.**—Each of the substrates was coated in the capillary tubing as follows: a weighed amount of the refined liquid was dissolved in ether or methanol to prepare a 10—20% solution, and then this solution was injected into the capillary tubing by the aid of a 5-ml. injection cylinder. After the tubing had been completely filled with the solution, the solvent and the excess substrate were purged out in a stream of helium gas at room temperature. Consequently, the thin substrate was deposited on the inner wall of the capillary tubing. The film thickness obtained was influenced not only by the concentration of the solution, but, contrary to the reported result,[7] strongly by the speed of coating. Namely, as the rate was increased by raising the purging gas, the amount of liquid coated was increased. Therefore, this step is important in the preparation of a column which has an appropriate retention time for the sample component.

## Results and Discussion

**Retention Times on the Single Liquid Phase.** —The relative retention times of aromatic hydrocarbons from $C_6$ to $C_{10}$ and their chromatograms on the six liquid phases with different selectivities are shown in Table I and Fig. 1 respectively. The retention times in Table I have been corrected for the dead volume of the apparatus by substracting the retention time of methane. On all the liquid phases, there are several overlapping peaks: isobutylbenzene - *s*-butylbenzene and 1, 4-diethylbenzene - 1, 2-ethylbenzene on the SQ

column; *t*-butylbenzene - 1-methyl-2-ethylbenzene-1, 3, 5-trimethylbenzene and 1-methyl-2-isopropylbenzene - 1, 2, 3-trimethylbenzene on the DNP column; 1, 3-diethylbenzene - 1-methyl-3-*n*-propylbenzene - 1-methyl-4-*n*-propylbenzene, 1, 2, 3-trimethylbenzene - 1, 4-diethylbenzene and 1,3-dimethyl-5-ethylbenzene - 1,2-diethylbenzene on the BQ column; 1-methyl-2-isopropylbenzene - 1-methyl-3-*n*-propylbenzene on the PEG 600 column, and *t*-butylbenzene-isobutylbenzene and others on the DNCB column.

In the case of SQ, which is almost nonpolar and does not have a marked selectivity for solutes, the aromatic hydrocarbons are eluted approximately in order of their boiling points. DNP and PEG have weak polarities and show small selectivities. In the case of BQ, which forms inclusion complexes with aromatic hydrocarbons, the heat of mixing is small and the solute molecules adopt less random configurations.[8] It can be surmised that DPTCP and DNCB form molecular complexes with aromatic hydrocarbons.[9] The heats of the mixing of aromatic hydrocarbons for these two stationary liquids, therefore, must be negative and large; also, the change in the activity coefficients with the temperature must be large. Consequently, it may be expected that the selectivities of these liquids will change considerably with the temperature.

that for $C_1$ to $C_4$ hydrocarbons exists for aromatic hydrocarbons, it is possible to deduce the relative retention times on the mixed phases of any composition from Fig. 2. Table II shows the observed values on the mixed phases as compared with the presumed values from the figure. The points in Fig. 2 represent the observed values. These results show that the presumed values are in fair agreement with the observed values. The considerably large differences between the presumed and the observed values of benzene may be due to errors in the measurement of its small retention times. It may be expected that similar linearities also exist in the other sets of liquids.

Table III shows the sets of the six liquids.

To constitute a mixed phase for a capillary column, the two liquids must be soluble in each other. Using the presumed diagrams of

○: All hydrocarbons can be separated.

retention times in Fig. 2 on each set of two liquids, a mixed phase which gives a separation of all the aromatic hydrocarbons from $C_6$ to $C_{10}$ has been sought.

*SQ-BQ System.* — As may be observed in Fig. 3, there are possibilities of the separation of all solutes in the 10—15% range of BQ. Experiments show, however, that isobutylbenzene overlapped with 1, 2, 4-trimethylbenzene on the BQ 12% column. On the BQ 15% column, these components could be separated, but 1, 2, 4-trimethylbenzene overlapped with *s*-butylbenzene. All the other solutes were separated in both cases.

*BQ-DPTCP System.*—As may be observed in Fig. 4, there are possibilities of the separation in the 20—25% range of BQ. However, the mixture of BQ and DPTCP, when allowed to stand, gave a white crystalline material which seems to be a molecular complex of these compounds. In the case of two liquids which constitute a mixed phase interacting strongly with each other, it was doubtful that the linear relationship described above would be present. However, the observed values on the BQ 21% column agreed well with the presumed values. On this column, *n*-butylbenzene and 1-methyl-4-*n*-propylbenzene are unseparated. On a BQ-enriched column, these were separated, while isobutylbenzene and *s*-butylbenzene became inseparable from each other.

*DNP-DNCB System.*—As is described above, the separation on this system might be influenced by the charge transfer interaction between DNCB and the aromatic hydrocarbons to be separated. In these cases, the temperature effect on selectivity seems to be more remarkable. Therefore, retention times were measured at three different temperatures; 70, 80 and 90°C.

Figure 5 is the presumed diagram for retention times at 70°C. In this diagram, there are possibilities of the separation of all the solutes on the mixed phase of DNCB concentration near 10%. As a result of the retention time measurement with three mixed phases, DNCB 9%, 10% and 11%, all the aromatics from $C_6$ to $C_{10}$ (except for 1, 3-dimethyl-2-ethylbenzene) were successfully separated on the DNP 90% - DNCB 10% column. As no standard sample of 1, 3-dimethyl-2-ethylbenzene could be obtained, the retention time of the compound will be presumed afterwards by the use of another relationship. The chromatogram is shown in Fig. 6. The observed

and the presumed values of the relative retention times are shown in Table IV. *t*-Butylbenzene - 1 - methyl - 2 - ethylbenzene - 1, 3, 5-trimethylbenzene and 1-methyl-2-isopropylbenzene - 1, 2, 3-trimethylbenzene, which were unresolved on the DNP column, were separated and eluted in the order of the supposed stabilities of the complexes with DNCB.

Table V shows the gradients of the lines which are calculated from the logarithm of the observed relative retention times of the hydrocarbons on the DNP 100% column and the DNP 90% - DNCB 10% column. These values seem to represent roughly the relative stabilities of the complexes. Hydrocarbons of the same type have close values. Tetramethylbenzenes, the nucleous basicities of which are the highest, have the highest values, while trimethylbenzenes are the next in values. The relatively low values of dimethylethylbenzenes may be due to the steric effects of alkyl groups. It may also stem from the same reason that methylethylbenzenes have higher values than diethylbenzenes, and xylenes have still higher values. Generally, as the alkyl groups of the side chain become longer, the values become higher. In the di-substituted isomers, the values decrease in the order of *o*-(1, 2), *p*-(1, 4) and *m*-(1, 3). These tendencies agree well with that of the interactions of picric acid in chloroform with these aromatic hydrocarbons.[10]

*The Presumption of the Retention Time of 1, 3-Dimethyl-2-ethylbenzene.*—The elution time of 1, 3-dimethyl-2-ethylbenzene on the DNP 90% - DNCB 10% column has been presumed, for its standard sample alone could not be obtained.

For a homologous series of compounds the ratios of the heat of solution and the heat of vaporization of which are constant, a linear relationship between the logarithm of the retention times obtained on the same column and the logarithm of vapor pressures has been

10) H. D. Anderson and O. L. Hammick, *J. Chem. Soc.*, **1950**, 1089.

shown by Hoare and Purnell.[11] This relation is mathematically induced as follows. The gas-liquid partition coefficient ($K$) is given by:

$$K=\frac{\rho RT}{M\gamma^0 P^0} \tag{1}$$

where $\rho$ is the specific gravity of the solvent at the column temperature, $T$ (°C); $M$ is the molecular weight of the solvent; $\gamma^0$ is the activity coefficient of the solute at an infinite dilution, and $P^0$ is the saturation vapor pressure of the solute. If the excess free energy of the mixing of the solute is designated as $\Delta G_m$, the heat of mixing, as $\Delta H_m$, and the entropy of mixing, as $\Delta S_m$, thermodynamics gives the following equations;

$$\Delta G_m=\Delta H_m-T\Delta S_m$$

and

$$\Delta G_m=RT\ln\gamma^0$$

If $\gamma^0=\gamma_t\gamma_a$, it can be written:

$$\ln\gamma_t=\frac{\Delta H_m}{RT},\quad \ln\gamma_a=-\frac{\Delta S_m}{R} \tag{2}$$

where $\gamma_a$ is the athermal activity coefficient. The heat of the vaporization ($\Delta H_v$) of the solute is given by the Clapeyron-Clausius equation as follows:

11) M. R. Hoare and J. H. Purnell, *Trans. Faraday Soc.*, 52, 222 (1956).

$$\ln P^0 = -\frac{\Delta H_v}{RT} + C_1 \quad (3)$$

while the heat of solution ($\Delta H_s$) is:

$$\Delta H_s = \Delta H_m - \Delta H_v \quad (4)$$

From Eq. 1, the logarithm of the relative partition coefficient is given by:

$$\ln K/K_{n\text{-PB}} = \ln \frac{(\gamma_t \gamma_a P^0)_{n\text{-PB}}}{\gamma_t \gamma_a P^0}$$

or $$\ln K/K_{n\text{-PB}} = -\ln \gamma_t - \ln P^0 - \ln \gamma_a + \ln A$$

where $A = (\gamma_t \gamma_a P^0)_{n\text{-PB}}$

The insertion of Eqs. 2 and 3 in this equation then gives:

$$\ln K/K_{n\text{-PB}} = -\frac{\Delta H_s}{RT} - \ln \gamma_a - C_1 + \ln A \quad (5)$$

The rearrangement of Eq. 3 becomes:

$$\Delta H_v = -RT \ln P^0 + C_1 RT \quad (6)$$

and if a constant $a$ is defined as follows:

$$a = -\frac{\Delta H_s}{\Delta H_v}$$

then Eq. 6 will become:

$$-\Delta H_s = -aRT \ln P^0 + C_1 aRT \quad (7)$$

If this is substituted into Eq. 5, the result is:

$$\ln K/K_{n\text{-PB}} = -a \ln P^0 + C_1(a-1) - \ln \gamma_a + \ln A \quad (8)$$

Therefore, it may be recognized from this equation that the plots of $\log K/K_{n\text{-PB}}$ against $\log P^0$ yield a straight line if $\gamma_a$, which is related to the magnitude of the solute and the solvent molecules, changes little and if $a$ is constant for a homologous series of solutes.

Figure 7 illustrates the plots of $\log K/K_{n\text{-PB}}$ obtained on the DNP column against $\log P^0$ for $C_7$ to $C_{10}$ aromatic hydrocarbons. These plots fall on a nearly straight line. It may be considered that the separation of aromatic hydrocarbons on the DNP column does not deviate much from the distillation with an ideal degree of separation because the slope of this straight line is almost unity ($a=0.95$).

For a homologous series of mono-substituted compounds, viz., toluene, ethylbenzene, *n*-propylbenzene and *n*-butylbenzene, a more strict linear relationship is observed. Moreover, since five dimethylethylbenzenes fall on a nearly straight line, it may possibly be thought that 1, 3-dimethyl-2-ethylbenzene will also fall on this line; that is to say, the elution time of 1, 3-dimethyl-2-ethylbenzene on the DNP column may be given by the intersecting point of this line with the dotted line corresponding to $\log P^0$ of 1, 3-dimethyl-2-ethylbenzene, as is shown in Fig. 7.

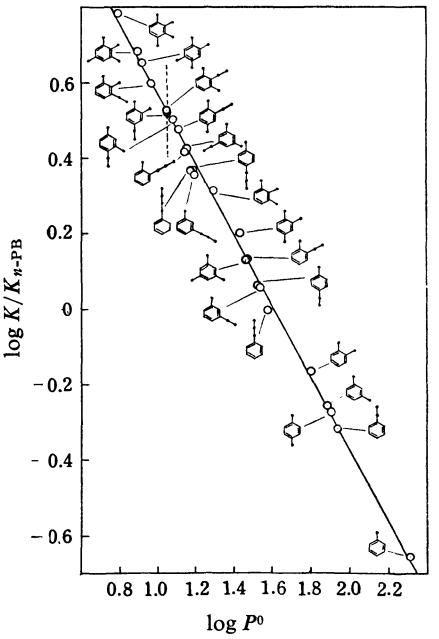

Fig. 7. The relation between the partition coefficient and vapor pressure on the DNP column (70°C).

On the other hand, as is shown clearly in Fig. 8, such plots for the data obtained on the DNCB column do not fall on a straight line. As the number of substituents increases within the compounds of the same carbon number, the plots of the $\log K/K_{n\text{-PB}}$ fall in the upper part of the figure. In $C_9$ aromatic hydrocarbons, for example, the value becomes higher in the order of propylbenzenes, methylethylbenzene and trimethylbenzenes. For xylenes and methylethylbenzenes, it becomes higher in the order of *m*-(1, 3), *p*-(1, 4) and *o*-(1, 2)-substituted.

As Fig. 8 shows, all of the lines connecting the points of a homologous series of compounds are almost linear, and they are parallel to each other.

The elution time of 1, 3-dimethyl-2-ethylbenzene (0.73) was presumed by finding the point corresponding to the vapor pressure ($P^0$) of 1, 3-dimethyl-2-ethylbenzene at the column temperature on the line drawn from the point of 1, 2, 3-trimethylbenzene parallel with the line connecting the points of 1, 2, 4-trimethylbenzene and its homologues. By inserting the presumed values of $\log K_{1,3\text{-DM-2-EB}}/K_{n\text{-PB}}$ on the DNP (0.53) and DNCB (0.73) column into Fig. 5, the presumed relative retention time of 1, 3-dimethyl-2-ethylbenzene on the DNP 90% - DNCB 10% column was found to be 3.55. This shows that 1, 3-dimethyl-2-ethylbenzene will be eluted in the middle

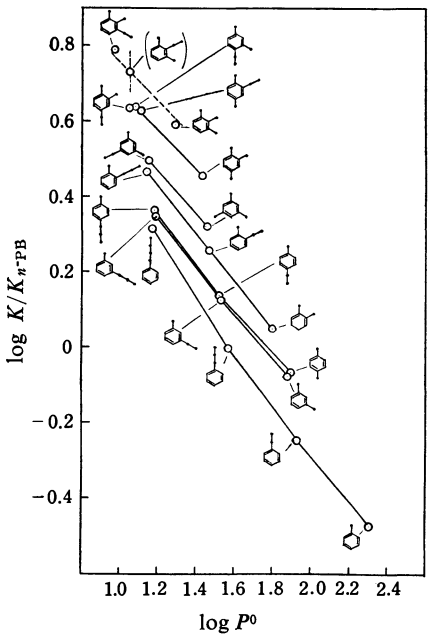

Fig. 8. The relation between the partition coefficient and vapor pressure on the DNCB column (70°C).

of 1,2-dimethyl-4-ethylbenzene and 1,2-dimethyl-3-ethylbenzene and will be overlapped by neither of them.

**The Analysis of Aromatic Hydrocarbons in Crude Oil.**—Aromatic hydrocarbons through $C_{10}$ in several crude oils were analyzed using a capillary column coated with a DNCB 10%-DNP 90% mixed stationary liquid, thus making possible the effective separation of all these compounds. In the beginning, a 45—250°C fraction of each crude oil was collected by distillation, and then aromatic fractions were separated from the distillate by silica-gel chromatography.

On the chromatograms of these samples, several small peaks which do not correspond to any of the components studied in this paper were observed. It might be thought from their relatively longer elution time that all of these peaks except one correspond to the $C_{11}$ aromatic hydrocarbons. Figure 9 shows a part of the chromatogram obtained with the aromatic fraction of Bunju Crude Oil. In this figure, the position corresponding to the presumed retention time of 1,3-dimethyl-2-ethylbenzene is shown by an arrow. It seems that peak A (relative retention time=3.52)

possibly corresponds to 1, 3-dimethyl-2-ethylbenzene and that pear B (4.01) corresponds to any of the $C_{11}$ aromatic hydrocarbon isomers.

The volume fractions of the distillates of several crude oils and the results of the quantitative analyses of aromatic hydrocarbons in these fractions are shown in Table VI. The 1, 3-dimethyl-2-ethylbenzene content is calculated from peak A. In addition to some main components, such as benzene, toluene, xylenes, methylethylbenzenes and trimethylbenzenes, these crude oils contain almost all of the components discussed above, although only small quantities of each.

# Electrometric Studies on the Reaction between Silver and Alkali Metavanadate

By R. S. SAXENA and O. P. SHARMA

(Received August 17, 1964)

In earlier publications[1-4] the authors have studied the reaction between $Ag^+$ and $VO_4^{3-}$, $V_2O_7^{4-}$ ions and some of their analytical applications by electrometric methods. In continuation of previous investigations, the present work has been undertaken with a view to study the formation and composition of silver metavanadate by the interaction of silver nitrate and alkali metavanadate solutions, and to examine the possibility of developing this as an analytical method for the determination of vanadium as silver metavanadate.

## Experimental

Anal. R. (BDH) reagents, vanadium(V) oxide, sodium hydroxide, silver nitrate, and reagent grade nitric acid were used and their solutions prepared in air-free conductivity water. Furthermore a standard solution of sodium orthovanadate was prepared by dissolving the requisite amount of vanadium(V) oxide in a boiling solution of sodium hydroxide of the required strength. Orthovanadate solution thus prepared was treated with a calculated quantity of nitric acid at 100°C to yield standard sodium metavanadate solution.

**Amperometric Titrations.**—A manual polarograph with scalamp galvanometer as a current recorder was used for the amperometric titrations. A dropping mercury electrode having the following characteristics: $m=2.416$ mg./sec., $t=3.58$ sec., and $m^{2/3}t^{1/6}=2.226$ mg$^{2/3}$ sec$^{-1/2}$ at $E_{d.e.}=-1.0$ V. (vs. SCE) was used in conjunction with a SCE connected to the cell by an agar-potassium nitrate bridge. All amperometric titrations were performed in the presence of the base electrolyte sodium nitrate, 0.005% thymol as maximum supressor, and 40% alcoholic media, at $E_{d.e.}=-0.3$ V. (vs. SCE). At this potential under the above conditions, $VO_3^-$ ion does not produce any measurable diffusion current, whereas $Ag^+$ ion yields a diffusion current almost proportional to its concentration. Twenty milliliters of the titer solution was taken in the cell each time and deaerated and stirred by bubbling hydrogen. The diffusion current obtained after each addition of titrant was corrected for the dilution effect and plotted against the volume of titrant in millilitre. The end-point was located graphically. The results of amperometric titrations are summarised in Table I.

**Potentiometric and Glass Electrode Titrations.** —The E. M. F. and pH of the solutions were measured on a Cambridge (null deflection type) pH meter by means of a bright silver electrode and a glass electrode of the range 0—9 respectively, in conjunction with a saturated calomel electrode connected to the cell by a low resistance salt bridge. After each addition of the titrant, the E. M. F. and pH were measured and plotted against the volume of titrant added, the end point was obtained from the sharp inflection in the titration curves and also from the pronounced maxima in $dE/dV$ and $dpH/dV$ respectively. A series of E. M. F. and pH titrations was performed, using the same concentrations of the reactants for the sake of comparison, both by the direct and inverse methods. Only reverse glass electrode titrations yielded dependable results. The results or the investigations carried out are tabulated below. Only two representative graphs are given for the sake of brevity.

## Discussion

The pH of silver nitrate and $Na_2O \cdot V_2O_5$ was measured with a glass electrode and found to be 6.30 and 7.50 respectively. The titration curves (Fig. 3, curves I and II) illustrate the changes occurring in $H^+$ ion concentration when $Na_2O \cdot V_2O_5$ is added to silver nitrate solution. A sharp change in pH was observed at the stoichiometric end point where the molecular ratio of $Ag^+$ and $VO_3^-$ ions is 1 : 1 corresponding to the formation of silver metavanadate $Ag_2O \cdot V_2O_5$ in the pH-range 6.25—7.0.

An examination of the results of potentiometric titrations (Fig. 2 curves I(D) and II (R)) reveals that the reaction between silver nitrate and $Na_2O \cdot V_2O_5$ can be suitably followed using a bright silver electrode. As the titration proceeds, the E. M. F remains almost constant until in the vicinity of the end point a marked change in E. M. F. occurs; beyond that it remains practically constant.

Conductometric titrations between silver nitrate and $Na_2O \cdot V_2O_5$ were also tried but they failed to provide any conclusion regarding the composition of silver metavanadate.

The same concentrations of reactants were used in potentiometric and pH titrations for the sake of comparison. After each addition of the titrant, it takes a little time for the E. M. F., and pH values to become steady. The results are accurate and reproducible.

The amperometric titration betweens silver nitrate and $Na_2O \cdot V_2O_5$ were performed at an electric tension of $-0.3$ V. vs. SCE. In the direct titrations (Fig. 1, curve I(D)), when $Na_2O \cdot V_2O_5$ is used as the titer, $VO_3^-$ ion does not yield any measurable diffusion current and hence no change in current is observed on the addition of silver nitrate solution untill the stoichiometric end point is reached, after which the diffusion current due to $Ag^+$ ions increases with the addition of silver nitrate. In the case of reverse titrations (Fig. 1, curve II(R)), the diffusion current due to $Ag^+$ ion

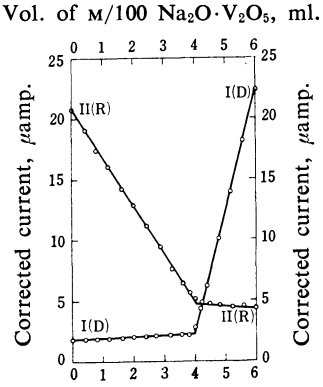

Fig. 1. Direct (I(D)) and reverse (II(R)) amperometric titrations beween $AgNO_3$ and $Na_2O \cdot V_2O_5$.
Curve I(D), M/25 $AgNO_3$ vs. M/250 $Na_2O \cdot V_2O_5$; Curve II(R) M/100 $Na_2O \cdot V_2O_5$ vs. M/250 $AgNO_3$

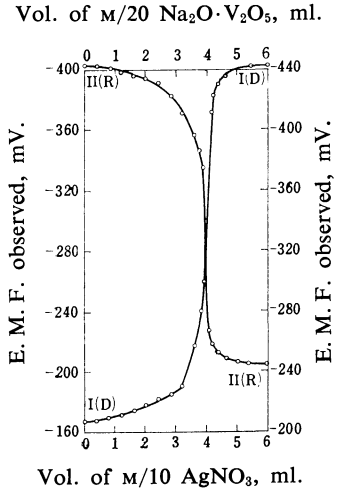

Fig. 2. Direct (I(D)) and reverse (II(R)) potentiometric titrations between $AgNO_3$ and $Na_2O \cdot V_2O_5$.
Curve I(D), M/10 $AgNO_3$ vs. M/100 $Na_2O \cdot V_2O_5$; Curve II(R) M/20 $Na_2O \cdot V_2O_5$ M/50 $AgNO_3$

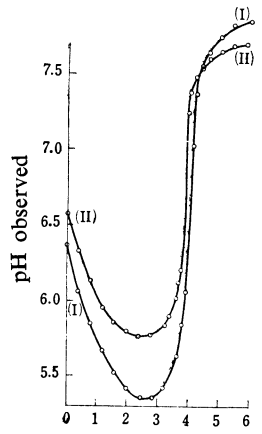

Fig. 3. Reverse pH titrations between $AgNO_3$ and $Na_2O \cdot V_2O_5$.
Curves I M/20 $Na_2O \cdot V_2O_5$ vs. M/50 $AgNO_3$; II M/75 $Na_2O \cdot V_2O_5$ vs. M/200 $AgNO_3$

gradually decreases on the addition of alkali metavanadate solution and reaches a minimum at the end point, beyond which the current almost remains constant. Amperometric titration curves are L shaped; a sharp break is obtained at the end point corresponding to the formation of silver metavanadate $Ag_2O \cdot V_2O_5$ in the pH range 6.25—7.0. The accuracy and reproducibility of these titrations has been found to be excellent even at low concentrations (0.5 mM) [of $Na_2O \cdot V_2O_5$. The presence of 40% ethanol improves the end point as the compound formed is appreciably soluble.

A comparative study of the electrometric experiments clearly suggests that pH and potentiometric titrations yield accurate results only with concentrated solutions of the reactants; at greater dilutions, the breaks and inflections are not strongly defined. Amperometric titrations, however, give very accurate end points even with low concentrations of reactants (Table I). In view of the simplicity, rapidity and accuracy of the titrations, the amperometric method may be recommended for the determination of $V^{5+}$ as silver metavanadate in the pH-range 6.25—7.0.

## Summary

The reaction between $Ag^+$ and $VO_3^-$ ions has been investigated by means of electrometric techniques involving amperometric, potentiometric and glass electrode titrations between silver nitrate and $Na_2O \cdot V_2O_5$ in 40% alcoholic media. The end point obtained from the sharp breaks and inflections in the titration curves, occurs at a stage where the molecular ratio of $Ag^+$ and $VO_3^-$ ions is 1:1 and corresponds to the formation and precipitation of silver metavanadate, $Ag_2O \cdot V_2O_5$, in the pH range 6.25—7.0. Amperometric titrations yield very accurate results and offer a simple and rapid method of determining vanadium(V) as silver metavanadate.

# The Pectic Acid from the Pulp of Jackfruit (*Artocarpus Integrifolia*). II

By U. K. Sen GUPTA and A. DAS

(Received September 1, 1964)

The constitution of the pectic acid and the associated glucan present in the fleshy pulp of ripe jackfruit has been reported earlier.[1] Additional evidence will be given in the present paper in further confirmation of the proposed structure of the polysaccharide.

When the methylated methyl pectate was subjected to methanolysis, a mixture of methyl glycosides was obtained. Instead of separating the neutral components from the acidic one, we reduced the whole mixture (containing the methyl ester of the acids) with lithium aluminium hydride. The neutral methyl glycosides were then hydrolysed with 1 N hydrochloric acid, and the methyl sugars were repeatedly separated on cellulose columns (vide "Experimental") to give the methyl sugars shown in Table I.

TABLE I. METHYL SUGARS OBTAINED FROM THE METHYLATED PECTIC ACID

| Spot No. | $R_G$ | Name of the component | Yield mg. |
|---|---|---|---|
| 1 | 1.00 | 2,3,4,6-Tetra-*O*-metyl-D-glucose | 19 |
| 2 | 0.82 | 2,3,6-Tri-*O*-methyl-D-glucose | 190.5 |
| 3 | 0.76 | 2,4,6-Tri-*O*-methyl-D-glucose | 178.9 |
| 4 | 0.66 | 2,3,4-Tri-*O*-methyl-D-galactose | 42.2 |
| 5 | 0.56 | 2,3-Di-*O*-methyl-D-glucose | 19.3 |
| 6 | 0.49 | 2,3-Di-*O*-methyl-D-galactose | 3718.8 |

$R_G$ values are with reference to 2,3,4,6-tetra-*O*-methyl-D-glucose in solvent C.

The fact that 2, 3-di-*O*-methyl-D-galactose was obtained in large quantities was in agreement with the structure proposed. The reduction of the methyl ester of galacturonic acid left the $C_6$ position free, and therefore 2, 3-di-*O*-methyl-D-galactose was formed.

Attempts were also made to prepare a neutral polymer from the pectic acid itself. This was achieved through the preparation of ethylene glycol pectate,[2] the pectic acid was treated with ethylene oxide to give the glycol ester, $[\alpha]_D^{29}$ +190° (in water) (anhydrouronic acid 71.6%; equivalent wt. 251).

The ester, on reduction with sodium borohydride, yielded a neutral polysaccharide, mainly a galactan, $[\alpha]_D^{30}$ +240° (in water) (anhydrouronic acid 9.7%). The polysaccharide on hydrolysis yielded 78.3% galactose, 9.75% glucose and a trace of arabinose.

The partially-reduced polysaccharide was methylated, and during methylation the remaining acid portion was reduced with lithium aluminium hydride (vide "Experimental") to yield a methylated galactan, $[\alpha]_D^{29}$ +164° (in chloroform) and $-OCH_3$, 42.1%. The methylated polysaccharide was methanolysed, and the mixture of methyl glycosides was hydrolysed to give a mixture of methyl sugars. This mixture was then separated on a cellulose column in an automatic-fraction collector collecting the 15 ml. in each tube into the following fractions (Table II), from which pure sugars could be isolated and characterised.

The characterisation of tri-*O*-methyl-galactose as 2, 3, 6-tri-*O*-methyl-D-galactose shows that the linkage of the uronic acid units in the original pectic acid is of the 1→4 type. It is evident that the 2, 3, 4, 6-tetra-*O*-methyl-D-galactose originated from the non-reducing end of the galactan and the isolation of a small amount of 2, 3-di-*O*-methyl-D-galactose may be due to the

TABLE II. METHYL SUGARS OBTAINED FROM THE METHYLATED GALACTAN

| Fraction No. | Tube No. | Compound | Yield mg. |
|---|---|---|---|
| 1 | 18—19 | 2,3,4,6-Tetra-*O*-methyl-D-glucose | 7.1 |
| 2 | 20—31 | 2,3,4,6-Tetra-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-glucose | 79.7 |
| 3 | 32—49 | 2,3,6-Tri-*O*-methyl-D-glucose, 2,4,6-tri-*O*-metyl-D-glucose and 2,3,6-tri-*O*-methyl-D-galactose | 485.0 |
| 4 | 50—61 | 2,3,6-Tri-*O*-methyl-D-galactose | 905.0 |
| 5 | 63—64 | 2,3-Di-*O*-methyl-D-glucose and 2,3-di-*O*-methyl-D-galactose | 16.1 |

1) U. K. Sen Gupta and C. V. N. Rao, This Bulletin, **36**, 1683 (1963).

incomplete methylation of the reduced polysaccharide. The presence of 2,3,4,6-tetra-, 2,3,6- and 2,4,6-tri-, and 2,3-di-*O*-methyl-D-glucose is in keeping with the structure assigned to the repeating units of the glucan.[1] During the reduction and the methylation, no change in the structure of the methylated polysaccharide takes place.

## Experimental

All specific rotations are equilibrium values. Unless otherwise stated, all evaporations were carried out in vacuo at 30—40°C. Paper partition chromatography was carried out on Whatman No. 1 filter paper with the following solvent systems (v/v) : (A) ethyl acetate : pyridine : water (8 : 2 : 1); (B) ethyl methyl ketone - water azeotrope ; (C) *n*-butanol : ethanol : water (5 : 1 : 4) upper layer. Unless otherwise stated, the $R_G$ values were calculated with reference to 2,3,4,6-tetra-*O*-methyl-D-glucose in solvent C. Demethylation was carried out with hydrobromic acid.[3] The amounts of individual sugars in a mixture were calculated from the specific rotation of that mixture.

**The Methanolysis, Reduction and Hydrolysis of Methylated Methyl Pectate.**—Methylated methyl pectate (5.8 g.) in methanolic hydrogen chloride (4%, 125 ml.) was heated (8 hr.) in a sealed tube on a boiling water bath. The solution was then neutralised with silver carbonate, and the precipitate was removed by a centrifuge. The resulting dry sirup was dissolved in dry tetrahydrofuran (160 ml.), and lithium aluminium hydride (2.5 g.) in dry tetrahydrofuran (60 ml.) was added slowly to the boiling solution over a one-hour period. After the mixture had been refluxed for one hour and kept at room temperature for two hours, the mixture was treated with water. The solvent was then removed, and the residue was shaken with acetone and ethanol. The extracts were dialysed against distilled water, deionised with Amberlite IR-120(H) and IR-45(OH), and evaporated to a sirup. N Hydrochloric acid (200 ml.) was added, and the mixture was heated (6 hr.) on a boilng water bath. After neutrarisation (silver carbonate) and deionisation (Amberlite resins IR-120(H) and IR-45(OH)), the resulting solution was evaporated to a sirup (4.39 g.).

The mixture of methyl sugars (ca. 4.35 g.) was separated through a cellulose column (70×3.5 cm.) using solvent B. It was found that only one pure fraction could be collected in a good quantity; most of the other fractions were mixtures of two or more components. The major pure fraction (3.52 g.), with $[\alpha]_D^{30}$ +78.5° (*c* 1.1, water), $-OCH_3$, 29.7% (calcd. for $C_8H_{10}O_6$: $-OCH_3$, 29.8%), gave only galactose on demethylation. It was characterised as 2,3-di-*O*-methyl-D-galactose through the crystalline *N*-phenyl-2,3-di-*O*-methyl-D-galactosylamine, m. p. and mixed m. p. 152—153°C. The remaining fractions were converted to a combined sirup (790 mg.) and separated through a similar cellulose column into eleven fractions, which were individually evaporated to sirups.

3) L. Hough, J. K. N. Jones and W. H. Wadman, *J. Chem. Soc.*, **1950**, 1702.

**The Examination of the Fractions and Identification of the Methyl Sugars.** — *Fraction 1.*—The chromatographically-pure sirup (17 mg.) had $[\alpha]_D^{30}$ +82° (*c* 0.2, water), $-OCH_3$, 52% (calcd. for tetramethyl hexose : $-OCH_3$, 52.5%), and $R_G$, 1.0, and on demethylation it gave glucose. It was identified as 2,3,4,6-tetra-*O*-methyl-D-glucose by preparing its crystalline *N*-phenyl-2,3,4,6-tetra-*O*-methyl-D-glucosylamine, m. p. and mixed m. p. 136—137°C.

*Fraction 2.*—This fraction (25.5 mg.), with $[\alpha]_D^{30}$ +69° (*c* 0.25, water), produced only glucose on demethylation ; it was chromatographically (solvent B) identified as a mixture of 2,3,4,6-tetra- (2 mg.) and 2,3,6-tri-*O*-methyl-D-glucose (23.5 mg.).

*Fraction 3.*—This chromatographically-pure fraction had $[\alpha]_D^{30}$ +67° (*c* 0.4, water), and $R_G$ 0.82, $-OCH_3$, 41.2% (calcd. for trimethyl hexose : $-OCH_3$, 41.8%), and on demethylation it produced glucose only. It was characterised as 2,3,6-tri-*O*-methyl-D-glucose through its crystalline 2,3,6-tri-*O*-methyl-D-glucose-1,4-di-*p*-nitrobenzoate, m. p. and mixed m. p. 190—191°C.

*Fraction 4.* — This sirup (40.6 mg.), with $[\alpha]_D^{30}$ +70.2° (*c* 0.45, water), furnished only glucose on demethylation ; it was paper chromatographically identified as a mixture of 2,3,6- (21.2 mg.) and 2,4,6-tri-*O*-methyl-D-glucose (19.4 mg.).

*Fraction 5.* — This chromatographically-pure fraction (142.2 mg.), with $[\alpha]_D^{30}$ +72° (*c* 0.5, water), $R_G$ 0.76, $-OCH_3$, 41.1% (calcd. for trimethyl hexose : $-OCH_3$, 41.8%), on demethylation gave only glucose ; it was identified as 2,4,6-tri-*O*-methyl-D-glucose through the crystalline *N*-phenyl-2,4,6-tri-*O*-methyl-D-glucosylamine, m.p. and mixed m.p. 162—163°C.

*Fraction 6.* — The sirup (22.8 mg.), with $[\alpha]_D^{30}$ 82.4° (*c* 0.4, water), produced glucose and galactose on demethylation; it was paper chromatographically identified as a mixture of 2,4,6-tri-*O*-methyl-D-glucose (17.3 mg.) and 2,3,4-tri-*O*-methyl-D-galactose (5.5 mg.).

*Fraction 7.* — The chromatographically-pure sirup (28.5 mg.) had $[\alpha]_D^{30}$ +110° (*c* 0.42, water), $R_G$ 0.66, $-OCH_3$, 41.05%, and furnished galactose only on demethylation. The sugar was characterised as 2,3,4-tri-*O*-methyl-D-galactose by preparing the crystalline *N*-phenyl-2,3,4-tri-*O*-methyl-D-galactosylamine derivative, m. p. and mixed m. p. 163—164°C.

*Fraction 8.*—This fraction (10.3 mg.), with $[\alpha]_D^{30}$ +102° (*c* 0.3, water), produced glucose and galactose on demethylation; it was paper chromatographically identified as a mixture of 2,3,4-tri-*O*-methyl-D-galactose (8.2 mg.) and 2,3-di-*O*-methyl-D-glucose (2.1 mg.).

*Fraction 9.*—The sirup (17.3 mg.) was chromatographically-pure, with $[\alpha]_D^{30}$ +66° (*c* 0.4, water), $R_G$ 0.55, and on demethylation it gave only glucose. The sugar was identified as 2,3-di-*O*-methyl-D-glucose by preparing the crystalline 2,3-di-*O*-methyl-D-gluconophenylhydrazide, m. p. and mixed m. p. 160—161°C.

*Fraction 10.*—This fraction (42.4 mg.) with $[\alpha]_D^{30}$ +76° (*c* 0.5, water), produced glucose and galactose on demethylation ; it was paper chromatographically identified as a mixture of 2,3-di-*O*-methyl-D-glucose (trace) and 2,3-di-*O*-methyl-D-galactose.

*Fraction 11.*—The chromatographically-pure sirup (156.4 mg.), with $[\alpha]_D^{30}$ +78° (*c* 1.0, water), and $R_G$ 0.49, $-OCH_3$, 29.3% (calcd. for dimethyl hexose: $-OCH_3$, 29.8%) gave galactose only on demethylation; it was characterised as 2,3-di-*O*-methyl-D-galactose through the crystalline *N*-phenyl-2,3-di-*O*-methyl-D-galactosylamine derivative, m. p. and mixed m. p. 152—153°C.

**Preparation of Ethylene Glycol Pectate.**[2] — Ethylene oxide (40 ml.) was added to a suspension of pectic acid (sample A,[1] 12.5 g.) in water (250 ml.), and the mixture was shaken (10 days) at room temperature until it became neutral. The resulting glycol ester was precipitated by acetone. The product was redispersed in water and precipitated by ethanol, The glycol ester (9 g.) had $[\alpha]_D^{30}$ +190° (*c* 0.96, water), anhydrouronic acid,[4] 71.6% (≡85.9% anhydrouronic acid in pectic acid), and equivalent wt. 251 (≡70.1% anhydrouronic acid in glycol ester and 84.1% anhydrouronic acid in pectic acid).

**Reduction of Ethylene Glycol Pectate.**—Ethylene glycol pectate (8 g.) in water (250 ml.) containing glycerol (4 g.) was treated with sodium borohydride[5] (2.5 g.) in water (20 ml.); the mixture was then kept overnight at 2°C. The solution was passed through columns of Amberlite IR-120(H) and Amberlite IR-45(OH), and the partially-reduced polysaccharide (6 g.) was isolated by the addition of acetone. This had $[\alpha]_D^{30}$ +236° (*c* 0.9, water), and was 21.32% anhydrouronic acid. The product subjected to four further reductions when the resulting galactan (2.8 g.), with $[\alpha]_D^{30}$ +240° (*c* 0.8, water) and 9.7% anhydrouronic acid, was obtained. The reduced polysaccharide (0.298 mg.) was hydrolysed, and the amounts of individual sugars were estimated by the periodate method,[6] which showed the presence of galactose (78.3%), glucose (9.75%), and arabinose (trace).

**Methylation of Galactan, Hydrolysis and the Separation of Methyl Sugars.** — Partially-reduced pectic acid (anhydrouronic acid, 21.32%; 5g.) was methylated[4,7,8] with methyl sulphate and sodium hydroxide. After dialysis, the solution of the partially-methylated polysaccharide was deionised through Amberlite IR-120(H) and then neutralised with silver carbonate to the silver salt. Silver oxide (30 g.) was added in several lots over a 6-hr. period to a boiling solution of dry silver salt in methyl iodide (100 ml.) containing dry methanol (5 ml.). The mixture was refluxed for 4 hr., and product was extracted with chloroform after distilling off the methyl iodide. The above process was repeated once more to yield a methylated polysaccharide (3.1 g., $-OCH_3$, 40.8%).

The methylated polysaccharide (3 g.) was dissolved in boiling tetrahydrofuran (70 ml.), and lithium aluminium hydride (2 g.) in tetrahydrofuran (100 ml.) was slowly added to it with occasional shaking. The mixture was refluxed for one hour. After the removal of the inorganic salts and deionisation, the reduced methylated polysaccharide was twice subjected to methylation with methyl iodide and silver oxide. The resulting methylated galactan (2.1 g.) had $[\alpha]_D^{29}$ +164° (*c* 1.4, chloroform) and $-OCH_3$, 42.1%. A solution of methylated galactan (2 g.) in 5% methanolic hydrogen chloride (125 ml.) was refluxed for 8 hr. The solution was evaporated to a sirup under reduced pressure. N Hydrochloric acid (100 ml.) was added, and the mixture was heated (6 hr.) on a boiling-water bath. The solution was cooled, neutralised (silver carbonate), and filtered. The filtrate was deionised (Amberlite IR-120(H) and Amberlite IR-45(OH)) and evaporated to give a sirup (1.7 g.), which was then, by using solvent B, separated on a cellulose column (60× 3.5 cm.) into five fractions.

*Fraction 1.*—The sirup (7.1 mg.) had $[\alpha]_D^{30}$ +81° (*c* 0.25, water) and was identified as 2,3,4,6-tetra-*O*-methyl-D-glucose by paper chromatography and its specific rotation.

*Fraction 2.* — The sirup (79.7 mg.), with $[\alpha]_D^{30}$ +72.5° (*c* 0.6, water), on demethylation produced glucose and galactose. Paper chromatography (solvent C) of the sirup separated it into two components ($R_G$ 0.87 and 0.84) corrresponding to 2,3,4,6-tetra-*O*-methyl-D-galactose and 2,3,6-tri-*O*-methyl-D-glucose. The mixture (ca. 50 mg.) was separated on 3MM filter paper with solvent C. Strips corresponding to trimethyl sugar and tetramethyl sugar were eluted with water, and the solutions concentrated. The component which corresponded to 2,3,4,6-tetra-*O*-methyl-D-galactose had $[\alpha]_D^{30}$ +106° (*c* 0.25, water), and the other, which corresponded to 2,3,6-tri-*O*-methyl-D-glucose, had $[\alpha]_D^{30}$ +64° (*c* 0.4, water).

*Fraction 3.* — This fraction (458 mg.), with $[\alpha]_D^{30}$ +77.9° (*c* 0.8, water), was paper chromatographically (solvent C) found to be a mixture of three components ($R_G$ 0.84, 0.77 and 0.70). Demethylation gave galactose and glucose. The mixture (ca. 200 mg.) was separated on 3MM filter paper. The major component (160 mg.) had $[\alpha]_D^{30}$ +79° (*c* 1.05, water) and was identified as 2,3,6-tri-*O*-methyl-D-galactose through the crystalline 2,3,6-tri-*O*-methyl-D-galactonolactone, m. p. and mixed m. p. 96—97°C. The other two components (about 15 mg. each), corresponding to 2,3,6-tri-*O*-methyl-D-glucose and 2,4,6-tri-*O*-methyl-D-glucose, had $[\alpha]_D^{30}$ +65° (*c* 0.32, water) and $[\alpha]_D^{30}$ +73° (*c* 0.37, water) respectively.

*Fraction 4.* — The chromatographically-pure sirup (905 mg.), with $[\alpha]_D^{30}$ +79° (*c* 1.5, water), and $-OCH_3$, 41.6% (calcd. for trimethyl hexose: $-OCH_3$, 41.8%), on demethylation gave galactose only; it was characterised as 2,3,6-tri-*O*-methyl-D-galactose by converting into 2,3,6-tri-*O*-methyl-D-galactonolactone, m. p. and mixed m. p. 96—97°C.

*Fraction 5.*—Paper chromatography of the sirup, which had $[\alpha]_D^{30}$ +70.5° (*c* 0.3, water), showed it to be a mixture of two components ($R_G$ 0.56 and 0.50). Demethylation gave glucose and galactose. The mixture (ca. 10 mg.) was sepapated on 3MM papers, and the components identified as 2,3-di-*O*-methyl-D-glucose (5 mg.), $[\alpha]_D^{30}$ +65° (*c* 0.25, water) and 2,3-di-*O*-methyl-D-galactose (5 mg.), $[\alpha]_D^{30}$ +77° (*c* 0.2, water).

**Summary**

The jackfruit pectic acid has been converted into ethylene glycol ester, which, on reduction with sodium borohydride, gives a galactan. Methylation studies of the original polysaccharide and of the reduced pectic acid suggest the presence of chains of 1→4 linked α-D-galacturonic acid residues in the pectic acid which is associated with a glucan.

# Structure of the Polysaccharides from Unripe Mango (*Mangifera Indica* LINN). III

By A. Das and U. K. Sen Gupta

(Received September 1, 1964)

Crude polysaccharide was isolated in a 7% yield from the mesocarp of unripe mango (*Mangifera Indica* LINN) by extracting it with hot water and precipitating it with ethanol, as has been described in an earlier communication.[1] The material had a $[\alpha]_D^{30}$ +151.3° in 2% sodium hydroxide (*c* 0.5) and uronic anhydride, 12.3%. On hydrolysis, the neutral portion of the above polysaccharide was found to contain glucose (79.3%) and arabinose (6.98%), while the acidic portion was found to contain galacturonic acid. These results show that the percentages of arabinose and uronic anhydride are greater than those present in the crude polysaccharide isolated from ripe mango.[1]

The polysaccharide did not yield any complex with calcium chloride, cetavlon or Fehling's solution. Hence, the purification of the crude polysaccharide was effected by dissolving it in water and precipitating it with ethanol (70%), which has been reported[2] to dissolve the araban preferentially. After four successive precipitations, the uronic anhydride content decreased to 8.78% and the specific rotation changed to +158.8°. On quantitative hydrolysis and estimation, the percentages of anhydro glucose and anhydro arabinose were found to be 85.9 and 3.5 respectively. Further repetition of the fractionation process could not bring about any appreciable change in the percentage composition of the sugar components or in the specific rotation value of the polysaccharide. It was shown in the case of ripe mango polysaccharide that the trace of arabinose which originally appeared in the crude polysaccharide completely disappeared after purification, and that the uronic acid portion originated from an associated uronan component (pectic acid). In the present case also, since the arabinose and uronic anhydride content gradually decrease during fractionation, it is reasonable to believe that the galacturonic acid and arabinose come from galacturonan and araban components, associated as pectic constituents with the glucan.

The purified polysaccharide gives a violet colour with iodine, but it remains unaffected on diastase treatment. This behaviour is similar to that of the glucan from ripe mango.[1]

The purified polysaccharide was methylated according to the procedure of Falconer and Adams.[3,3a] The fully methylated product, obtained in the form of light yellow flakes, was highly soluble in chloroform; $OCH_3$, 42.3%, $[\alpha]_D^{30}$ +173.5°, in chloroform (*c* 1). The methylated product was methanolised and separated into neutral and acidic components. The neutral sugars were identified as shown in the Table I.

The uronic acid portion was identified as 2, 3-di-*O*-methyl-D-galacturonic acid. The isolation of only 2, 3-di-*O*-methyl-D-galacturonic acid from the hydrolysate of the methylated

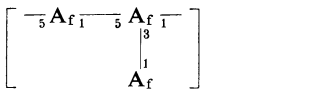
TABLE I. NEUTRAL METHYL SUGARS FROM METHYLATED POLYSACCHARIDE

| Spot No. | Component | Derivative | $R_G$* |
|---|---|---|---|
| 1 | 2,3,4,6-Tetra-*O*-methyl-D-glucose | Anilide | 1.0 |
| 2 | 2,3,5-Tri-*O*-methyl-L-arabinose | Amide | 0.94 |
| 3 | 2,3,6-Tri-*O*-methyl-D-glucose | 1,4-Di-*p*-nitrobenzoate | 0.82 |
| 4 | 2,4,6-Tri-*O*-methyl-D-glucose | Anilide | 0.75 |
| 5 | 2,3-Di-*O*-methyl-L-arabinose | 1,4-Di-*p*-nitrobenzoate | 0.62 |
| 6 | 2,3-Di-*O*-methyl-D-glucose | Phenylhydrazide | 0.55 |
| 7 | 2-*O*-Methyl-L-arabinose | Pheylhydrazone | 0.37 |
| 8 | L-Arabinose | | 0.14 |



* $R_G$ values are with respect to 2,3,4,6-tetra-*O*-methyl-D-glucose in solvent E.

polysaccharide corroborates the earlier contention that the galacturonic acid originates from the pectic acid component associated with the neutral polysaccharide.

Hence, in view of the above results, it is reasonable to believe that the polysaccharide is a mixture of three components, viz., a glucan, an araban and a galacturonan. On the basis of this, structures for the repeating units of the glucan and araban can be assigned.

The methyl sugars of glucose, viz., 2, 3, 4, 6-tetra-, 2, 3, 6- and 2, 4, 6-tri-, and 2, 3-di-*O*-methyl-D-glucose, occur in the ratio of 1 : 8.84 : 9.0 : 1.14, which is the same as that found in the case of the glucan from ripe mango. Also, the behaviour of this polysaccharide towards diastase and iodine is the same. Hence in view of similar arguments,[1,1a] it is rational to assign the same structure to the repeating unit of the glucan portion.

It has already been mentioned that arabinose occurs from an associated araban; otherwise, it is difficult to account for the isolation of three different methyl sugars of arabinose in sufficient quantities. The mole ratio between the methyl sugars of arabinose (2, 3, 5-tri- : 2, 3-di- : 2-*O*-methyl-L-arabinose) was 1 : 1.15 : 0.94. The characterisation of 2, 3, 5-tri-*O*-methyl-L-arabinose shows that the non-reducing ends of the araban are occupied by arabinofuranose residues. The presence of only one kind of dimethyl sugar, viz., 2, 3-di-*O*-methyl-L-arabinose, indicates that the backbone chain is probably constituted of 1→5 linked arabinofuranose residues. That the araban is highly branched and that the arabinose unit at the branch point is linked through $C_1$, $C_3$ and $C_5$ is proved by the isolation of considerable amounts (about 33% of the total araban) of 2-*O*-methyl-L-arabinose. The isolation of a very small amount of arabinose (from the hydrolysate of the methylated polysaccharide) that might have come from a doubly-branched unit in the araban or might have resulted from incomplete methylation and/or demethylation, seems to have no structural significance. Hence, one of the simplest structures for the repeating unit of the araban, one which satisfactorily fits the above facts, is as follows:

where $A_f$ represents an arabinofuranose unit. From the specific rotation of the polysaccharide (a mixture of three components), it is not logical to draw any conclusion about the type of linkage ($\alpha$ or $\beta$). However, the glucan and the galacturonan in the polysaccharide from ripe mango have been shown to be predominantly $\alpha$-linked; arabans of a similar structure isolated from other sources[4,5] were found to contain $\alpha$-linkage. Hence, in this case also, all the three components of the polysaccharide can be regarded as having predominantly an $\alpha$-type of linkage. From these results, it appears that the pectic constituents gradually decrease with ripening.

## Experimental

Paper chromatography was carried out with Whatman No. 1 filter papers, by the descending method, the solvent being allowed to run against the machine line. The following solvent mixtures (v/v) were used: (A) ethyl acetate : pyridine : water (8 : 2 : 1); (B) *n*-butanol : acetic acid : water (4 : 1 : 5), upper layer; (C) ethyl acetate : acetic acid : water (9 : 2 : 2); (D) ethyl methyl ketone-water azeotrope; (E) *n*-butanol : ethanol : water (4 : 1 : 5), upper layer.

The crude polysaccharide was a white amorphous powder with the following characteristics: moisture, 10.9%; ash, 0.56%, uronic anhydride,[6] 12.3%, methoxyl, 1.3%, nitrogen, traces, lignin,[7] nil, $[\alpha]_D^{30}$ +151.3° in a 2% sodium hydroxide solution (*c* 0.5). A small portion (ca. 0.5 g.) of the above product was hydrolysed (while being followed iodometrically) with N sulphuric acid by heating it (12 hr.) on a boiling water bath. After neutralisation (barium

7) C. Doree, ibid., p. 369.

carbonate) and filtration, the solution was concentrated to a small volume (10 ml.). Paper chromatography with solvent A indicated the presence of glucose and arabinose, while that with solvents B and C indicated galacturonic acid in addition to glucose and arabinose.

**Estimation of the Components in the Polysaccharide.**—The polysaccharide (659.5 mg.) was hydrolysed with N sulphuric acid (65 ml.) by heating it (12 hr.) in a sealed tube on a boiling water bath. The hydrolysate was then neutralised (barium carbonate) in the presence of D-ribose (200.8 mg.), filtered, and concentrated (25 ml.). An aliquot portion (0.1 mol.) of the solution was separated on a paper chromatogram (solvent A), and strips corresponding to glucose and arabinose were eluted with water and the sugars therein estimated by the periodate method.[8] Results: anhydro arabinose, 6.98% and anhydro glucose, 79.3%.

**Separation and Identification of the Components.**—The polysaccharide (1 g.) was hydrolysed (N sulphuric acid, 100 ml.) by heating it (12 hr.) on a boiling water bath. The solution was neutralised (barium carbonate) and deionised through Amberlite IR-120(H).* The acidic component from the resulting solution was absorbed on a column of Dowex 1-X4,** and the neutral solution was evaporated to a syrup (0.86 g.). The latter was put on top of a cellulose column (2.5×60 cm.) and resolved (solvent A) into three fractions. Fraction 1 (63.4 mg.), with $[\alpha]_D^{30}$ +104° in water (*c* 1), $R_G$, 1.6 (with reference to D-glucose, solvent A) was chromatographically pure and was identified as L-arabinose through the preparation of crystalline *p*-nitro-*N*-phenyl-L-arabinosylamine; m. p. and mixed m. p. 200—201°C; lit.[9] 202°C. Fraction 2 (35.5 mg.) had $[\alpha]_D^{30}$ +63.5° in water (*c* 0.6) and was paper chromatographically found to be a mixture of glucose and arabinose. Fraction 3 (721 mg.), with $[\alpha]_D^{30}$ +52° in water (*c* 1), $R_G$, 1 (with respect to D-glucose, solvent A), was chromatographically pure and identified as D-glucose through the preparation of crystalline *p*-nitro-*N*-phenyl-D-glucosylamine; m. p. and mixed m. p. 182—183°C, lit.[9] 184°C; $[\alpha]_D^{30}$ −199° in pyridine (*c* 1), lit.[9] −201°.

**Characterisation of the Acidic Component.**—The acidic component was eluted from the Dowex 1-X4 column after thorough washing with water (20 l.), neutralised (barium carbonate), and deionised (Amberlite IR-120(H)). The resulting solution was evaporated to a syrup (105 mg.) with an equivalent weight, 205 (calcd. for monouronic acid, 194). The syrup (ca. 50 mg.) was then converted to its methyl ester methyl glycoside and reduced with lithium aluminium hydride[10] to the corresponding neutral sugar, which was identified as D-galactose through the preparation of crystalline *p*-nitro-*N*-phenyl-D-galactosylamine; m. p. and mixed m. p. 217—218°C, lit.[9] 219°C; $[\alpha]_D^{30}$ −245°C in pyridine (*c* 0.5), lit.[9] −248°.

**Purification of the Polysaccharide.**—The crude polysaccharide (25 g.) was dispersed in water (2 l.) by heating it (4 hr.) on a boiling water bath. The resultant slightly hazy solution was passed through the super centrifuge twice, and the polysaccharide was precipitated by pouring the solution into acidified (pH 4) alcohol whose final volume had been adjusted to 70% with respect to alcohol. The precipitate was collected by centrifugation, followed by the usual process. This product was found to contain uronic anhydride, 9.3%, $[\alpha]_D^{30}$ +152.8° in 2% sodium hydroxide (*c* 0.5). On hydrolysis and quantitative estimation, the material was found to contain anhydro glucose (82.2%) and anhydro arabinose (5.4%). The process of precipitation was repeated three times, after which the final product was found to have the following characteristics: moisture, 11.2%; ash, 0.47%; uronic anhydride, 8.78%; methoxyl, 0.5%; nitrogen, nil; $[\alpha]_D^{30}$ +158.8° in 2% sodium hydroxide (*c* 0.5); anhydro glucose, 85.9%, and anhydro arabinose, 3.5%. Further fractionation could not bring about any substantial change in the relative proportions of the constituent sugars.

**Treatment of the Polysaccharide with Diastase.**[1]—The polysaccharide (112 mg.) was dissolved in an acetate buffer (25 ml., pH 4.6); diastase (98 mg.) was added and incubated at 35°C. It was found that, even after 24 hr., the iodine-staining power remained intact; paper chromatographic examination of the digest failed to detect the presence of any reducing sugars.

**Methylation and Methanolysis of the Polysaccharide.**—The polysaccharide (10 g.) was methylated by the procedure of Falconer and Adams[3,3a] to yield a product (5.3 g.) with $-OCH_3$, 42.3% and $[\alpha]_D^{20}$ +173.5° in chloroform (*c* 1). The methylated product (2 g.) was methanolysed by refluxing it with methanolic hydrogen chloride (200 ml., 2%) for 16 hr., whereupon the optical rotation became constant. The solution was neutralised (silver carbonate) and evaporated to a syrup. The syrup was then heated with a saturated solution of barium hydroxide[11] (50 ml.) on a water bath. Baryta was precipitated out by carbon dioxide and the uronic acid portion was absorbed on a column of Dowex 1-X4 after the usual treatments. The neutral sugar glycosides were hydrolysed to the corresponding methyl sugars by heating them (14 hr.) with N hydrochloric acid on a water bath. The hydrolysate was neutralised (silver carbonate), filtered, and deionised (Amberlite IR-120(H) and IR-45(OH)). The resulting solution was evaporated to a syrup (1.78 g.).

The syrup (1.78 g.) was resolved (solvent D) through a cellulose column (3.5×70 cm.) into fourteen fractions, in which the amounts of methyl sugars of arabinose, in the pure state, were 9.3 mg. of 2,3,5-tri-*O*-methyl-L-arabinose, 10.6 mg. of 2,3-di-*O*-methyl-L-arabinose, and 11.2 mg. of 2-*O*-methyl-L-arabinose, along with 3.4 mg. of arabinose, therefore, another lot of the methylated polysaccharide (2 g.)

was hydrolysed in the same way, and the neutral fraction of methyl sugars was separated on a similar column. Fractions corresponding to pure methyl sugars of arabinose were combined with the previous pure fractions and used in the characterisations. The ratio between the methyl sugars of glucose and that between the methyl sugars of arabinose were determined from the amounts of each sugar obtained from first column chromatography (the amount of a sugar in a mixture was calculated from the specific rotation of the mixture).

*Fraction 1* (58.5 mg.), with $[\alpha]_D^{30}$ +81° in water (*c* 1) and -$OCH_3$, 51.8%, was chromatographically (solvent D) homogeneous, and the sugar in it was identified as 2,3,4,6-tetra-*O*-methyl-D-glucose through the preparation of a crystalline aniline derivative, m. p. and mixed m. p. 136—138°C; lit.[12] 136—138°C.

*Fraction 2* (28.8 mg.) had $[\alpha]_D^{30}$ +64° in water (*c* 0.4) and was chromatographically (solvent E) identified as a mixture of 2,3,5-tri-*O*-methyl-L-arabinose (4.6 mg.) and 2,3,4,6-tetra-*O*-methyl-D-glucose (24.2 mg.).

*Fraction 3* (9.3 mg.), with $[\alpha]_D^{29}$ −35.5° in water (*c* 0.5), lit.[18] −39.5°, and -$OCH_3$, 48.2% (calcd. for a tri-*O*-methyl pentose: OMe, 48.4%), was chromatographically (solvent D) pure. On demethylation, it produced arabinose, along with some partially demethylated sugars. The fraction was identified as 2,3,5-tri-*O*-methyl-L-arabinose through the preparation of crystalline 2,3,5-tri-*O*-methyl-L-arabonamide, m. p. and mixed m. p. 134—136°C, lit.[4] 138°C.

*Fraction 4* (33.2 mg.), with $[\alpha]_D^{29}$ +58.9° in water (*c* 0.5), gave glucose and arabinose on demethylation; it was identified by paper chromatography as a mixture of 2,3,5-tri-*O*-methyl-L-arabinose (3.2 mg.) and 2,3,6-tri-*O*-methyl-D-glucose (30 mg.).

*Fraction 5* (661.7 mg.), with $[\alpha]_D^{29}$ +67° in water (*c* 1), $OCH_3$, 42% (corresponding to that of a tri-*O*-methyl hexose), was found to be pure 2,3,6-tri-*O*-methyl-D-glucose through the preparation of crystalline 2,3,6-tri-*O*-methyl-D-glucose-1,4-di-*p*-nitrobenzoate, m. p. and mixed m. p. 190°C, lit.[14] 190—192°C; $[\alpha]_D^{27}$ −33° in chloroform (*c* 0.6), lit.[14] −34°.

*Fraction 6* (70 mg.), with $[\alpha]_D^{30}$ +69.1° in water (*c* 0.5), on demethylation yielded glucose; it was paper chromatographically (solvent E) identified as a mixture of 2,3,6- (40 mg.) and 2,4,6-tri-*O*-methyl-D-glucose (30 mg.).

*Fraction 7* (689.2 mg.), with $[\alpha]_D^{30}$ +72° in water (*c* 1), $OCH_3$, 41.5%, was identified as pure 2,4,6-tri-*O*-methyl-D-glucose through the preparation of a crystalline aniline derivative, m. p. and mixed m. p. 161—163°C, lit.[15] 162—166°C; $[\alpha]_D^{28}$ −111° in methanol (*c* 0.6), lit.[15] −113°.

*Fraction 8* (28.7 mg.), with $[\alpha]_D^{30}$ +74° in water (*c* 0.34), on demethylation produced glucose and arabinose; it was identified by paper chromatography (solvent E) as a mixture of 2,4,6-tri-*O*-methyl-D-glucose (25 mg.) and 2,3-di-*O*-methyl-L-arabinose (3.7 mg.).

*Fraction 9* (10.6 mg.), with $[\alpha]_D^{30}$ +88° in water (*c* 0.5), $OCH_3$, 34.2% (calcd. for a di-*O*-methyl pentose: $OCH_3$, 34.8%), was chromatographically pure, and on demethylation it gave arabinose. The sugar in it was identified as 2,3-di-*O*-methyl-L-arabinose through the preparation of a crystalline 1,4-di-*O*-*p*-nitrobenzoate derivative, m. p. and mixed m. p. 150—151°C; lit.[16] 150—153°C.

*Fraction 10* (13.2 mg.), with $[\alpha]_D^{30}$ +75° in water (*c* 0.45), on demethylation furnished glucose and arabinose; it was identified by paper chromatography as a mixture of 2,3-di-*O*-methyl-L-arabinose (5.4 mg.) and 2,3-di-*O*-methyl-D-glucose (7.8 mg.).

*Fraction 11* (78 mg.), had $[\alpha]_D^{29}$ +66.5° in water (*c* 1) and $OCH_3$, 29.8% (calcd. for a di-*O*-methyl hexose: $OCH_3$, 29.8%). The syrup gave glucose on demethylation, and it was identified as 2,3-di-*O*-methyl-D-glucose through a crystalline phenylhydrazide derivative, m. p. and mixed m. p. 159—160°C; lit.[12] 160—162°C.

*Fraction 12* (14.2 mg.) with $[\alpha]_D^{28}$ +85.7° in water (*c* 0.5), produced glucose and arabinose on demethylation; it was identified by paper chromatography (solvent D) as a mixture of 2,3-di-*O*-methyl-D-glucose (9.2 mg.) and 2-*O*-methyl-L-arabinose (5 mg.).

*Fraction 13* (11.2 mg.), with $[\alpha]_D^{29}$ +98° in water (*c* 0.45) and $OCH_3$, 18% (calcd. for a mono-methyl pentose: $OCH_3$, 18.9%), produced arabinose on demethylation. The sugar in it was identified as 2-*O*-methyl-L-arabinose through its crystalline phenylhydrazine derivative, m. p. and mixed m. p. 114—115°C; lit.[4,17] 115—116°C.

*Fraction 14* (3.4 mg.), with $[\alpha]_D^{29}$ +103° in water (*c* 0.25), had the same mobility in the paper chromatogram as that of authentic L-arabinose.

**Characterisation of Methyl Uronic Acid Portion.** —The uronic acid portion was eluted out of the Dowex 1-X4 column with N sulphuric acid (500 ml.) after the column had been thoroughly washed with water. The acid was neutralised (barium carbonate), and the solution after neutralisation (Amberlite IR-120(H)) was evaporated to a syrup (163.8 mg.). This was hxdrolysed with N sulphuric acid and neutralised (barium carbonate), and the resulting solution after deionisation (Amberlite IR-120(H)) was evaporated to a syrup (157 mg.). The syrup ($OCH_3$, 27.3%, equivalent, 230) was found to be paper chromatographically homogeneous.

The acid (ca. 100 mg.) was converted to its methyl ester methyl glycoside by refluxing it with methanolic hydrogen chloride (2%) and reduced[10] with lithium aluminium hydride in an ethereal solution. The corresponding neutral methyl sugar solution, after hydrolysis and usual treatment, was evaporated to a syrup (88 mg.) which was chromatographically homogeneous and which had $[\alpha]_D^{30}$

$+80°$ in water (*c* 0.5), $OCH_3$, 29.6%. The demethylation of the syrup produced galactose. The sugar in the syrup was finally identified as 2,3-di-*O*-methyl-D-galactose through its crystalline aniline derivative, m. p. and mixed m. p. 152—153°C; lit.[18] 152—154°C.

## Summary

The polysaccharide isolated from the mesocarp of unripe mango has been found to be a mixture of three component polysaccharides, viz., a glucan, and araban and a galacturonan. By a methylation study, the glucan has been found to have the same structural pattern as that of the glucan isolated from ripe mango. The araban portion yielded 2, 3, 5-, 2, 3- and 2-*O*-methyl-L-arabinose. On the basis of these results, a probable structure has been assigned to the araban. The isolation of only 2, 3-di-*O*-methyl-D-galacturonic acid shows that the galacturonan portion is 1→4 linked.

The authors are thankful to Dr. P. Bagchi Director of Research, East India Pharmaceutical Works, Ltd., Calcutta, for his valuable suggestions and to Dr. C. V. N. Rao for his active cooperation.

# Selective Reduction of Phosphatides with Lithium Aluminum Hydride. II. Reductive Cleavage of the Glycerylphosphorylcholine Linkage

By Haru KAMEYAMA* and Chieko URAKAMI

(Received September 7, 1964)

Reduction of egg yolk lecithin with lithium aluminum hydride under mild conditions, using one-molar excess of the hydride at 10°C for 20 min., gave rise to L, $\alpha$-glycerylphosphorylcholine,[1] the optical purity of which was confirmed later by van Deenen et al.[2] During the course of this study it was observed that the choline moiety of the lecithin and of glycerylphosphorylcholine molecules was released, to an extent of 20% in the case of the latter compound, on either raising the temperature or prolonging the reaction time. It would be of interest, therefore, to investigate this reaction further to see whether optically pure L, $\alpha$-glycerylphosphoric acid is produced under appropriate reaction conditions.

The difficulty of reducing the phosphoryl group with lithium aluminum hydride has been reported by Freeman and Doak.[3] Furthermore, in the literature are found the observations that neither the sulfonyl group of 2-(ethylsulfonyl)ethanol[4] nor the nitro group of methyl 4-nitropentanoate[5] are reduced with this reagent under mild conditions. It may be assumed, therefore, that these phosphorus, sulfur, and nitrogen atoms, which are shielded with oxygen atoms of higher electron densities, form complexes less readily with $AlH_4^-$ or $AlH_3$.[6],* In the lecithin molecule, however, the choline moiety may offer a site for such a coordination with either species, as we have suggested earlier[1] (Fig. 1). This suggestion was based on the fact that at least one extra mole of lithium aluminum hydride, over that required theoretically, had to be used for reductive cleavage of the two fatty acid ester groups of the lecithin molecule; the extra amount of the reagent was assumed to be consumed for complexing with the choline nitrogen. This may be supported in part by the fact that amines form complexes quite readily with aluminum hydride at low temperatures.[7,8]

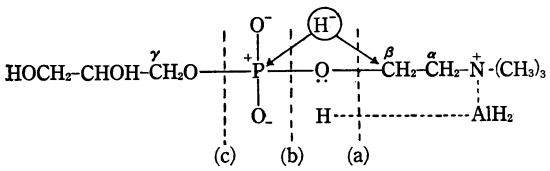

Fig. 1

There are three possible sites for cleavage by the reducing agents; (a), (b) and (c) as shown in Fig. 1. A carbon-oxygen fission (a) has been suggested previously[1] as the most favored one since the hydride ion may readiy attack the $\beta$-carbon which is more electropositive than the $\gamma$-carbon atom of the glyceryl moiety owing to the inductive effects of both the phosphoryl and quaternary ammonium groups. The products of such a cleavage would be ethyltrimethylammonium ion and $\alpha$-glycerylphosphoric acid. A fission at (b), on the other hand, would give choline and a reduced form (or forms) of glycerylphosphoric acid. This cleavage may be brought about either by complexing of the hydride reagent with the ammonium nitrogen as just mentioned, or with the phosphorus atom, followed by attack of hydride ion on the phosphorus atom. The latter mechanism may also bring about a cleavage at (c), giving rise to glycerol and reduced forms of phosphorylcholine. It is less likely, however, that the cleavages proceed through a complex formation with the phosphorus atom under the mild conditions being considered in the present study.

Since this reaction had been found to be quite sensitive to reaction temperature and mole ratios of the reactants, care was taken in controlling these two factors; the temperature was kept in a range of 10—15°C and mole ratios were raised from four to fifteen moles of the reducing reagent per mole of lecithin depending on the extent of cleavage of the choline moiety.

However, the results obtained were contrary to those expected. Instead of a carbon-oxygen fission, a phosphorus-oxygen fission occurred with the formation of choline and reduced forms of the phosphate group.

## Experimental

**Lecithin.**—The sample of hydrogenated egg yolk lecithin was prepared according to Hanahan's method[9] after purifying the crude material through a column of alumina with the solvent system of Rhodes and Lea.[10] The product was recrystallized twice from warm dioxane. This sample showed an $R_f$ value of 0.67 according to the method of Lea,[11] phosphorus: choline=1.0:0.95 (calculated as distearoyllecithin). Another sample without hydrogenation was prepared according to the method described by Nelson.[12]

**DL-$\alpha$-Glycerylphosphorylcholine.**—This compound was synthesized by the method of Baer and Kates.[13] The free base was liberated from its cadmium chloride complex by passing its aqueous solution through columns of Amberlite IRC-50 and Dowex-3.

**Barium $\alpha$-Glycerylphosphate.**—The calcium salt procured from Delta Chemical Works, Inc. (New York) was purified by adsorption chromatography on a small column of alumina and converted to the barium salt.[14] The sample was thoroughly dried for infrared analysis.

**Choline Chloride Reineckate.**—This was prepared for infrared analysis, by a modification of the method used for estimation of choline, and dried over phosphorus pentoxide in a vacuum tube for 24 hr. at the boiling temperture of acetone. The free base released by the reduction was treated similarly.

**Estimation of Choline.**—The base released on reductive cleavage and the choline in glycerylphosphorylcholine were determined according to Schmidt's method,[15] and that in lecithin by Glick's method.[16]

**Determination of Phosphorus.**—Organic samples were digested by the conventional method using 10 N sulfuric acid solution and a few drops of hydrogen peroxide and the inorganic phosphorus released was determined according to the method of Ernester and his co-workers.[17] Phosphorus in the products formed on cleavage was also determined by Burmaster's method.[18]

**$\alpha$-Glycol.** — The periodate oxidation method described by Voris[19] was used.

**Paper Chromatography.**—Paper chromatography for deacylated glycerylphosphatides and the cleaved *phosphorus-containing product(s)* was carried out according to Wheeldon's method,[20] using acid-washed Toyo No. 51 paper and water-saturated phenol containing 1% ammonia as the developing solvent system. The phosphatide samples prepared were examined by both Lea's method[11] and Marinetti's,[21] using Toyo No. 51 paper impregnated with silicic acid in conjunction with the solvent systems of chloroform-methanol (4:1, v/v) and diisobutylketone-acetic acid-water (40:20:3, v/v/v).

* Ch stands for choline and GPC for glycerylphosphorylcholine.

**Reaction with Lithium Aluminum Hydride.**—The procedure employed for the reaction was essentially the same as that described previously,[1] except that a small amount of chloroform was used to dissolve the sample of hydrogenated lecithin. The reaction mixture was made acidic with 2—3 ml. of a 10 N sulfuric acid solution, the organic phase separated from the aqueous phase, and each made up to a known volume. The former was analyzed for total phosphorus and the latter for total phosphorus and choline, both in free and ester-bound form. For separation of the individual components of the water-soluble products, the aqueous phase separated without the acid treatment was passed through a column of Amberlite IR-112 (H), and collected eluate a was made up to a known volume for analysis of phosphorus and choline. The column was then washed with a sufficient amount of a normal hydrochloric acid solution to give eluate b, which was made up to a known volume and analyzed for free choline.

Since good separation with a minimum loss of each component was achieved as shown in Table I, this procedure was employed for isolation of the products. The free base in eluate b was converted to the reineckate salt as mentioned earlier. Eluate a (pH 2.4) contaning both glycerylphosphorylcholine and the cleaved *phosphorus-containing product* was passed through a column of Amterlite IR-4B (OH). The glycerylphosphorylcholine which came through was converted to its cadmium chloride complex and recrystallized. The average recovery of glycerylphosphorylcholine, based on analysis for phosphorus, was 95%. The column was then washed with a sufficient amount of a 0.28% solution of ammonia to elute the *phosphorus-containing product*. The last procedure, when tested with the sodium salt of glycerylphosphoric acid, gave an almost quantitative recovery of phosphorus. The eluate was concentrated under mild conditions and the residue treated with barium hydroxide. The barium salt was recrystallized several times from water and alcohol. These isolated products were dried over phosphorus pentoxide in a vacuum desiccator.

## Results

**The Cadmium Chloride Complex of the Isolated Glycerylphosphorylcholine.**—Sample wt. 29 mg. Found: total choline 8.0 mg. (0.066 mmol.); total phosphorus 1.4 mg. (0.045 mmol.); $\alpha$-glycol 0.067 mmol. Calcd.: choline, phosphorus and $\alpha$-glycol 0.063 mmol. $R_f$ value was 0.84 for the isolated sample; 0.84 for the synthetic sample of DL-glycerylphosphorylcholine.

**The Reineckate Salt of the Free Base.**—Found: C, 25.88; H, 4.80; N, 24.57; Cr, 14.60. Calcd. for choline reineckate, $C_5H_{14}N[(NH_3)_2Cr(CNS)_4]$, mol. wt. 422.58: C, 25.60; H, 4.76, N, 23.20; Cr, 14.00%. The infrared absorption spectrum of the salt was found to be identical with that of the reineckate salt of choline, both showing an absorption band at 1080—1075 $cm^{-1}$ for the C–OH stretching vibration of the primary alcohol group.

**The Phosphorus-containing Products.** — See Table III for the analytical results and Table IV for the characteristic infrared absorption bands.

## Discussion

The maximum extent of cleavage of the choline ester linkage appeared to be about 50% as shown in Table II and beyond this extent a loss of the water-soluble phosphorus was observed in separate experiments, perhaps due to further degradation to phosphine.[23] Since it is reasonably certain that this cleavage proceeds via L, $\alpha$-glycerylphosphorylchloline,[1]

TABLE III. ANALYSIS OF THE PHOSPHORUS-CONTAINING PRODUCTS ISOLATED FROM THE REACTION MIXTURE

| Product | $R_f$ | mmol. | | | | $[\alpha]_D$ |
|---|---|---|---|---|---|---|
| | | Total P[a] | Total P[b] | α-GP P | Glycol | |
| A | 0.21 | 0.022 | 0.023 | 0.014 | 0.016 | |
| E | | 0.032 | 0.024 | 0.016 | 0.027 | +0.12±0.5 |
| C | 0.28 | | | | | |
| D | 0.53 | | | | | |
| α-GP | 0.25 | | | | | −1.0[c] |

A was prepared under the reaction conditions—lecithin: the hydride reagent 1 : 10, 10°C, 60 min. B 1 : 15, 15°C, 120 min. C and D were separated from B by the paper chromatographic technique of Wheeldon.[20] a) Ernester's method.[17] b) Burmaster's method.[18] c) The reported value for a saturated solution of the silver salt.[22]

The optical activity of B is so small that it is considered to have no optical activity (measured with a Rudolph polarimeter).

α-GP means the barium salt of α-glycerylphosphoric acid.

(d) Stands for doublet, (sh) shoulder, (w) weak, (br) broad. For A, B and C refer to Table III. The absorption bands of D were not very distinct due to some impurities and thus omitted.

its insolubility in anhydrous ether propably prevented the reaction from going to completion.

The isolation of choline evidently indicates that a phosphorus-oxygen fission occurred in this cleavage reaction. Such a fission, therefore, should be accompanied by reduction of the phosphate moiety. This is supported in part by the following observations; the *phosphorus-containing products* isolated differ from α-glycerylphosphoric acid with respect to optical activity, behavior on periodate oxidation (Table III), and infrared absorption bands (Table IV).

Since the interpretations given for the shift in the absorption bands of the P→O and P-O-C groups (pentavalent and trivalent phosphorus) due to modification of the alkyl moiety are still open to discussion, only the absorption bands of interest will be pointed out here to show differences between the spectrum of α-glycerylphosphoric acid and those of the *cleaved products*. In the region indicated by I, Table IV, glycerylphosphorylethanolamine shows an absorption band at 2910—2860 $cm^{-1}$ and glycerylphosphorylcholine at 2865 $cm^{-1}$ [24] but these have not been correlated so far with the groups attached to these molecules. One of the characteristic differences between α-glycerylphosphoric acid and the *products* is shown in the region II. Daasch and Smith[25] have suggested that the absorption band at 1665 $cm^{-1}$ is associate with phosphonic acid and thus the bands in II may indicate the presence of reduced forms of the phosphate group. The absorption bands in the regions III and IV are common to all the compounds under consideration and the former bands have been reported to be associated with the $CH_2$ group.[26] The characteristic P→O stretching vibration in the region V is absent in samples A and B but present in C; its presence in the last sample annot be explained but the P→O group might have been formed on exposure to air during its separation and isolation from the paper chromatogram. Daasch and Smith,[25] however, have pointed out that these bands are so broadened in the case of phosphonic and phosphinic acids that it is difficult to distinguish them from each other, particularly in the spectra of the solid samples. Accordingly, A and B may be considered here again to be reduced forms of the phosphate. The P-O-C (alkyl) group is reported to show absorption bands in the regions 1163 to 1156 $cm^{-1}$ and 1050 to 995 $cm^{-1}$ [26] but the bands (VI and VII) appear to be shifted in α-glycerylphosphoric acid and the *products*. Recently, Chapman and Harper[27] have attributed absorption bands at 990—980 $cm^{-1}$ and 875—855 $cm^{-1}$ to the P-O-C (alkyl) group in phosphites, and Ackerman and his co-workers[28] report that a band near 794 $cm^{-1}$ is due to the same group in acylphosphonates. Since α-glycerylphosphoric acid shows some of these bands (VIII), no comments will be made on the similar band observed in these products.

The fact that the characteristic absorption bands of A differ from those of B and C may indiate that B (or C) is in a more reduced state than A, since the reaction conditions employed for preparation of B were somewhat more drastic than those employed for A (see also Table III). The loss of phosphorus observed on raising the temperature might have resulted from fission at both (b) and (c), Fig. 1, giving rise to phosphine as has been observed by Karrer[23] during the use of drastic conditions.

Brockerhoff[29] attributed the ease of removal of choline in the alkaline hydrolysis of glycerylphosphorylcholine to the following two factors; (1) the influence of the quaternary ammonium group which can balance in part the negative charges on the phosphate oxygens and thus facilitates approach of a nucleophilic reagent, and (2) the initial attack on the phosphorus by the nucleophilic oxygen of the secondary hydroxyl group of the glyceryl moiety. In the present case, however, ionization of the secondary alcohol would be less likely in such a medium as anhydrous ether. Instead, intramolecular hydrogen bonding between the hydroxyl hydrogen of the β-carbon of the glyceryl moiety and the P→O oxygen atom plus an ionic effect of the quarternary ammonium group on the $P-O^-$, or the latter alone, probably distort the normal tetrahedral bond angles of the phosphorus atom[30] in such a manner that the central phosphorus atom, of large radius, might readily be attacked by hydride ion. This may bring about fission at the phosphorus-oxygen linkage, (b) in Fig. 1. The stronger cationic nature of the phosphorus atom, compared with that of the β-carbon of the choline moiety, may also play a role in this cleavage.

**Summary**

Reduction of egg yolk lecithins with lithium aluminum hydride under the following reaction conditions resulted in release of choline in about 50% based on the total water-soluble phosphorus; mole ratios of lecithin : lithium aluminum hydride of 1 : 10 or 1 : 15 at 10—15°C for 60—120 min. were used. Unexpectedly, the reaction did not give any glycerylphosphoric acid. Instead, the analytical results indicated that a phosphorus-oxygen fission of the cholin-phosphate linkage is accompanied by reduction of the phosphate moiety.

# 1-Hydroxy-1, 2, 3-benzotriazoles as Analytical Reagents. I. 4-Nitro-1-hydroxy-1, 2, 3-benzotriazole as a Specific Reagent for Silver

By H. L. SHARMA and S. K. MUKERJI

(Received September 16, 1964)

Comparatively few organic reagents afford precipitates with silver which can be directly weighed for estimation of the metal. Only *p*-dimethylaminobenzalrhodamine and some other compounds containing the grouping >NOH have been reported.[1-7] Out of the few hydroxybenzotriazoles, which are under investigation for analytical purposes by one of the authors (H. L. S.), the use of 4-nitro-1-hydroxy-1, 2, 3-benzotriazole (R) in the gravimetric estimation of silver is described in the present communication.

The aqueous-ethanolic (1 : 4 v/v) solution of this reagent R gave a scarlet red precipitate with silver ions. The precipitation was quantitative between pH 2.8—4.3 and the precipitate was stable enough to be dried at 110—125°C to a stoichiometric composition of $AgC_6H_3O_3N_4$.

The chief advantage of the reagent R over existing ones for estimation of silver is that the estimation of silver, when present singly or even in the presence of other metal ions, is fairly rapid and takes only one hour. Filtration of the precipitate is easy and quick and variation of the interval between precipitation and filtration does not affect the results.

The advantages over the recently reported reagent I[7] are that our reagent is specific for silver and that the reagent R is more soluble than I.* Moreover the precipitation of the silver salt could be well effected with reagent R in alcoholic solution, and finally it could also be dried completely whereas the precipitate of silver salt, with the reagent I, cannot be freed from $^1/_2\,C_2H_5OH$ even when dried at 120°C.**

## Experimental

**Preparation and the Solubility of the Reagent R.**—The reagent R, viz. 4-nitro-1-hydroxy-1, 2, 3-benzotriazole was prepared by the method reported earlier.[9] The results in Table I show that the average solubility of reagent R per 100 g. of water at 30°C is 0.21344 g. but an 0.4% solution of R in aqueous ethanol (1 : 4 v/v) was used for all estimations.

7) D. S. Deorha, N. K. Kulshrestha and B. B. Varma, *Indian J. Appl. Chem.*, **27**, 4 (1964).

* The recently reported reagent, 6-chloro-4-nitro-1-hydroxy-1, 2, 3-benzotriazole (I) by Deorha et al.,[7] appears to be more than 0.8—1% soluble as 1% aqueous solution of the reagent I was used by them for all estimation. In comparison to I, we selected R as the reagent with an assumption that it should be more soluble than I. Surprisingly R was found to be only 0.2134% soluble at 30°C, a result under controversy. As such I was also prepared by the method reported earlier[8] and was found to be only 0.0708% soluble at 30°C.

8) S. S. Joshi and D. S. Deorha, *J. Indian Chem. Soc.*, **29**, 548 (1952).

** Deorha et al.,[7] also report that when precipitation was done with an alcoholic solution of the reagent I, the precipitate corresponds to the composition $AgC_6H_2O_3N_4Cl \cdot 1/2C_2H_5OH$, and that the precipitate could not be freed from alcohol even when dried at 120°C. However, such abnormality was not observed in our case.

TABLE I

Temp.: 30

| Wt. of the solvent (water) used., g. | Wt. of the solute R after evaporation, g. | Solubility g./100 g. at 30°C |
|---|---|---|
| 10 | 0.02134 | 0.21340 |
| 20 | 0.04271 | 0.21355 |
| 40 | 0.08536 | 0.21340 |
| 60 | 0.12804 | 0.21340 |
| 80 | 0.17074 | 0.21342 |
| 100 | 0.21348 | 0.21348 |

**Silver Nitrate Solution.**—Stock solution of N/20 silver nitrate was prepared and estimated by the usual classical methods. In order to get concordant results, estimations were made in duplicate.

**Composition of the Precipitate.**—The scarlet red precipitate obtained by mixing an excess of the solution of R with a solution of silver nitrate was washed with alcohol to remove excess of the adsorbed reagent R and was analysed after drying at 110°C. It was noted that the precipitate explodes whenever heated in a silica crucible over a flame. So the silver was estimated by obtaining silver as silver chloride from the precipitate by decomposing it with 50% hydrochloric acid. The triazole thus liberated was removed by washing the combined precipitate repeatedly with ethanol until the filtrate gave a negative test for chloride ions.

Found: N, 19.18; Ag, 37.578. Calcd. for $AgC_6H_3N_4O_3$: N, 19.52; Ag, 37.59% (Conversion factor for silver being 0.3759).

**Procedure for Estimation of Silver.**—An aliquot quantity of silver nitrate was diluted to about 100 ml. and the pH was adjusted to about 3—4. Excess of the solution of R was then added with constant stirring. The precipitate was digested on a boiling water bath for about half an hour, filtered through a sintered crucible (No. G3), washed with cold 0.06% solution of the reagent and then with 95% ethanol. It was then dried at 110—120°C to a constant weight. Table II summarizes the results of some experiments.

**Effect of Reagent Concentration.**—By keeping the amount of silver constant and varying that of the reagent, it was found that the precipitation of silver with the reagent R was not complete unless double the stoichiometrically required amount of the latter was used. Refer Table III.

**Effect of pH.**—Table IV shows that the most suitable pH range for the precipitation is between 2.8—4.3. The negative error increases as we go above pH 4.6 and below pH 2.8. It has been found that the precipitate is soluble in dilute alkalies.

**Effect of Diverse Metal Ions.**—A known amount of a standard solution of silver was taken in a beaker and diluted to 100 ml. with distilled water. Solutions of diverse metal ions were prepared by using nitrates and acetates of the metals. Difinite quantities of these solutions were added to the beaker. Estimation of silver was carried out as described earlier. Hydrolyses of $Bi^{3+}$, $Sb^{3+}$, $Sn^{4+}$ and $Ti^{4+}$ were prevented by using sodium potassium tartarate. In the case of cerium, a small amount of ammonium sulphate was added to keep the cerium salt in solution as the double sulphate.

The results of Table V clearly indicate that there is no interference by other metal ions.

## Summary

4-Nitro-1 - hydroxy - 1, 2, 3 - benzotriazole (R) has been used as a reagent for the gravimetric estimation of silver. The precipitation of the metal by this reagent is complete between pH 2.8—4.3, and after drying at 120°C the composition of the precipitate corresponds to the formula $AgC_6H_3O_3N_4$. The presence of other metal ions does not interfere in the estimation. For complete precipitation of the metal, double the stoichiometrically required amount of R was used and it was found that variation of the interval between the precipitation and filteration does not effect the result. The solubility of R is 0.2134 g./100 g. of water at 30°C.

The authors' sincere thanks are due to Professor Dr. R. C. Mehrotra, Head of the Chemistry Department, University of Rajasthan, Jaipur, Shri B. B. Mathur (H. M.), and Shri P. D. Goswami (S. I.) for providing facilities and to Mrs. Sushama Sharma for carrying out nitrogen estimations.

# Phosphorylation of Alcohols by the Use of Benzyldiethyl Phosphite and Monobromocyanoacetamide or *N*-Bromosuccinimide

By Teruaki MUKAIYAMA, Teisuke OBATA and Oyo MITSUNOBU

(Received October 5, 1964)

It has been demonstrated in the previous papers[1,2] that various phosphites (I) and phosphines are easily oxidized by means of monobromocyanoacetamides (II) and allyl or benzyl alcohol (III). The reactions are considered to proceed through the formation of reactive quaternary phosphonium salts (V), which in turn decompose to yield the corresponding phosphates (VI) or phosphine oxides and allyl or benzyl bromide (VII) (Eq. 1).

It is to be noted that allyl or benzyl cation which is considered to be stable might preferentially be split off from the quaternary phosphonium salts (V), resulting in the formation of allyl or benzyl bromide (VII) and oxidized products, pentavalent phosphorus compounds (VI).

(1)

In view of the results, it is expected that the successful phosphorylation of alcohols would

1) T. Mukaiyama, O. Mitsunobu and T. Obata, *J. Org. Chem.*, **30**, 101 (1965).
2) O. Mitsunobu, T. Obata and T. Mukaiyama, *J. Org. Chem.*, **30**, 1071 (1965).

Table I. Reaction of monobromocyanoacetamide with benzyldiethyl phosphite and alcohols

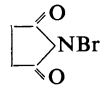
| Alcohol | Charge ml. | Product | | |
|---|---|---|---|---|
| | | Phosphate | Yield, % | B. p., °C/mmHg |
| Ethanol | 2 | $EtOP(O)(OEt)_2$ | 55 | 84—90/7.3 |
| Ethanol* | 2 | $EtOP(O)(OEt)_2$ | 55 | 87—92/7.3 |
| *n*-Propanol | 2 | *n*-$PrOP(O)(OEt)_2$ | 37 | 63—65/0.5 |
| *n*-Butanol | 2 | *n*-$BuOP(O)(OEt)_2$ | 47 | 68—75/0.3 |

* Alcohol was added an hour later to the reaction mixture of monobromocyanoacetamide and benzyldiethyl phosphite at room temperature.

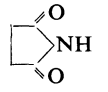
result from the reaction of benzyldiethyl phosphite (VIII) with monobromocyanoacetamide and alcohols through the quaternary phosphonium salts (IX), as is shown in the following Eq. 2.

$$(EtO)_2POCH_2C_6H_5 + NCCHBrCONH_2 + ROH$$
(VIII)

$$\longrightarrow \left[\begin{matrix} EtO \\ EtO \end{matrix}\!\!>\overset{+}{P}<\!\!\begin{matrix} OCH_2C_6H_5 \\ OR \end{matrix}\; Br^-\right] \longrightarrow$$
(IX)

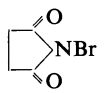


$$(EtO)_2\overset{O}{\overset{\|}{P}}\text{-}OR + C_6H_5CH_2Br \qquad (2)$$

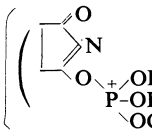


Indeed, when benzyldiethyl phosphite (VIII) was treated with monobromocyanoacetamide in the presence of ethyl alcohol in ether at room temperature, triethyl phosphate was obtained in a 55% yield, and both benzyl bromide (84%) and cyanoacetamide (51%) were also isolated (Eq. 2, R=Et). A similar reaction was observed in the case of the other alcohols (see Table I).

In the above reaction, the initially formed enol quaternary phosphonium salt (IV) is assumed to be rather stable, because there is no noticeable difference in the yield of phosphate even when ethyl alcohol was added an hour later to the reaction mixture of benzyldiethyl phosphite and monobromocyanoacetamide.



In the second experiment, phosphorylation of alcohols by the use of benzyldiethyl phosphite and *N*-bromosuccinimide was tried under the assumption that the reaction may proceed through an enol phosphonium salt[3] analogous to that of monobromocyanoacetamide (Eq. 3).

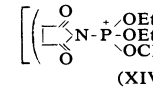


When benzyldiethyl phosphite was added to a suspension of equimolar amounts of *N*-bromosuccinimide and ethyl alcohol in ether, triethyl phosphate (X, R=Et) was obtained in a 61% yield along with benzyl bromide (85%) and succinimide (72%), as expected (Eq. 3); *n*-propyl and *n*-butyl alcohols were also phosphorylated to the corresponding alkyldiethyl phosphates (X, R=$C_3H_7$, $C_4H_9$) in yields of 60% and 31%, respectively (see Table II).

$$\text{  } + (EtO)_2POCH_2C_6H_5 + ROH \longrightarrow$$

$$(EtO)_2\overset{O}{\overset{\|}{P}}\text{-}OR + C_6H_5CH_2Br + \text{  } \qquad (3)$$
(X)

Contrary to the case of monobromocyanoacetamide, when ethyl alcohol was added an hour later to the reaction mixture of *N*-bromosuccinimide and benzyldiethyl phosphite, triethyl phosphate could not be isolated, and diethylphosphorosuccinimidate (XIII) was obtained in a quantitative yield by fractionation. In this case, the unstable quaternary phosphonium salt (XI) may decompose spontaneously, yielding benzyl bromide and imidoyl phosphate



$$\text{  } + (EtO)_2POCH_2C_6H_5 \longrightarrow$$

$$\left[\left(\text{  }\right)^{*}Br^-\right] \xrightarrow{R'OH}$$
(XI)

$$\left[\begin{matrix} EtO \\ EtO \end{matrix}\!\!>\overset{+}{P}<\!\!\begin{matrix} OR' \\ OCH_2C_6H_5 \end{matrix}\; Br^-\right] \longrightarrow$$
(IX)

$$C_6H_5CH_2Br + (EtO)_2\overset{O}{\overset{\|}{P}}\text{-}OR' \qquad (4)$$

* Two alternative structures, the *O*-phosphonium salt (XI) or the *N*-phosphonium salt (XIV), are conceivable for the structure of this quaternary phosphonium salt.

$$\left[\left(\text{  }\right)Br^-\right]$$
(XIV)

The *O*-phosphonium form (XI) is preferred to the *N*-phosphonium form (XIV) in this case, by analogy with the case of the monobromocyanoacetamide. But recent investigation supports the latter structure on the basis of a NMR spectrum (A. K. Tsolis et al., *Tetrahedron Letters*, **1964**, 3217).

3) S. Trippett, *J. Chem. Soc.*, **1962**, 2337.

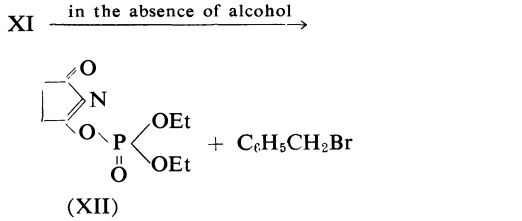


TABLE II. REACTION OF *N*-BROMOSUCCINIMIDE WITH BENZYLDIETHYL PHOSPHITE AND ALCOHOLS

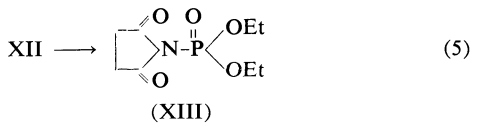
| Alcohol | Charge ml. | Product | | |
|---|---|---|---|---|
| | | Phosphate | Yield, % | B. p., °C/mmHg |
| Ethanol | 2 | $EtOP(O)(OEt)_2$ | 61 | 105—108/27 |
| *n*-Propanol | 1.5 | *n*-$PrOP(O)(OEt)_2$ | 60 | 107—108/7 |
| *n*-Butanol | 1.5 | *n*-$BuOP(O)(OEt)_2$ | 31 | 65—67/0.65 |



(XII), which is considered to rearrange rapidly to a more stable diethylphosphorosuccinimidate (XIII) (Eq. 5).

Whereas, the diethylphosphorosuccinimidate (XIII) did not react with alcohols at all even when they were refluxed for five hours; the starting materials were recovered.

From these results, it may be stated that imidoyl phosphonium salt (XI) is a necessary intermediate for the reactive quaternary phosphonium salt (IX), from which alkyl-diethyl phosphate may be produced by the elimination of benzyl bromide (Eq. 4).

(XII)

(XIII) (5)

## Experimental

All boiling points are uncorrected.

**Reagents.**—Benzyldiethyl phosphite was prepared by the transesterification of triethyl phosphite with benzyl alcohol.[4] Monobromocyanoacetamide[5] and *N*-bromosuccinimide[6] were prepared by the procedures given in the literature. Alcohols and solvents used were dried and distilled by the ordinary procedures.

**Reaction of Monobromocyanoacetamide with Benzyldiethyl Phosphite and Alcohols.**—To a vigorously stirred suspension of monobromocyanoacetamide (1.63 g., 0.01 mol.) in ethyl alcohol (2 ml.) and ether (20 ml.), an ethereal solution (10 ml.) of benzyldiethyl phosphite (2.28 g., 0.01 mol.) was added drop by drop over a period of 10 min., at room temperature. A white precipitate of cyanoacetamide, soon separated. After the addition was completed, the mixture was stirred at room temperature for 2 hr. and then allowed to stand overnight. Cyanoacetamide (m. p. 110—116°C, 430 mg., 51%) was removed by filtratain. The filtrate was concentrated under reduced pressure, and the resulting oil was treated with dry ether (10 ml.) to remove the residual cyanoacetamide. After concentration, the solution was distilled under reduced pressure, yielding benzyl bromide (b. p. 65—75°C/7.3 mmHg, 1.43 g., 84%) and triethyl phosphate (b. p. 84—90°C/7.3 mmHg, 1.00 g., 55%).

Similarly, *n*-propyldiethyl and *n*-butyldiethyl phosphates were prepared from monobromocyanoacetamide, benzyldiethyl phosphite and the corresponding alcohols. The physical constants of these compounds together with the yields obtained are summarized in Table I.

When ethyl alcohol was added an hour later to the mixture of monobromocyanoacetamide and benzyldiethylphosphite at room temperature, 55% of triethyl phosphate was also obtained via the same procedure as in the above reaction.

**Reaction of *N*-Bromosuccinimide with Benzyldiethyl Phosphite and Alcohols.**—A solution of benzyldiethyl phosphite (2.28 g., 0.01 mol.) in 10 ml. of dry ether was added drop by drop with vigorous stirring to a suspension of *N*-bromosuccinimide (1.78 g., 0.01 mol.) in 1.5 ml. of anhydrous *n*-propyl alcohol and ether (15 ml.). The temperature was controlled at about −40°C by cooling in an ethanol - dry ice bath. After addition was completed, the mixture was stirred for an additional 30 min., and allowed to warm slowly to room temperature. After being stirred for an additional 2 hr., the mixture was concentrated under reduced pressure, and the resulting pale yellow oil was treated with dry ether (2 ml.) at −20°C to separate the succinimide. The white crystalline succinimide (m. p. 124—126°C, 770 mg., 78%) was filtered off and the filtrate was concentrated and distilled. Benzyl bromide (b. p. 75—78°C/7 mmHg, 1.37 g., 80%) and *n*-propyldiethyl phosphate (b. p. 107—108°C/7 mmHg, 1.17 g., 60%) were obtained. The distillation residue was filtered and washed with 5 ml. of ether yielding crude succinimide (m. p. 115—118°C, 180 mg., 18%).

In a similar fashion, ethanol and *n*-butyl alcohol were phosphorylated, yielding triethyl phosphate and *n*-butyldiethyl phosphate. These results are summarized in Table II.

**Reaction of *N*-Bromosuccinimide with Benzyldiethyl Phosphite in the Absence of Alcohol.**—Benzyl diethyl phosphite (25.0 g., 0.11 mol.) was added drop by drop to a suspension of *N*-bromosuccinimide (17.8 g., 0.1 mol.) in dry ether (150 ml.) over a period of 20 min., at room temperature. After refluxing for an additional 3 hr., the solution

was concentrated and distilled under reduced pressure; benzyl bromide (b. p. 80—83°C/15 mmHg, 5.1 g., 88%) and diethylphosphorosuccinimidate (b. p. 140—155°C/0.03 mmHg, 19.3 g., 82%) were obtained. Redistillation gave white crystalline diethylphosphorosuccinimidate (m. p. 60—62°C, b. p. 145—150°C/0.03 mmHg, 15.3 g., 65%). Found: N, 6.10. Calcd. for $C_8H_{14}O_5NP$: N, 5.96%.

**Summary**

The phosphorylation of alcohols with benzyldiethyl phosphite and monobromocyanoacetamide has been investigated. By this method, the corresponding alkyldiethyl phosphates were obtained in fairly good yields along with benzyl bromide and cyanoacetamide. Similarly, it has been established that *N*-bromosuccinimide can be successfully used in the place of monobromocyanoacetamide in the above phosphorylation.

# Phosphorylation by the Use of Diethylphosphorosuccinimidate

By Teruaki MUKAIYAMA, Teisuke OBATA and Oyo MITSUNOBU

(Received October 13, 1964)

In previous papers,[1,2] it has been shown that the oxidation of various phosphines and phosphites by means of monobromocyanoacetamide and allyl or benzyl alcohol gave the corresponding phosphine oxindes and phosphates in good yields.

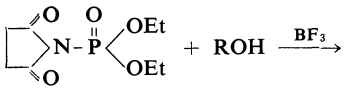
It was shown[2] that *N*-bromosuccinimide could also be used successfully in the place of monobromocyanoacetamide in the above reactions. During the course of the experiment, it was found that diethylphosphorosuccinimidate (III) was obtained in a good yield when benzyldiethyl phosphite (I) was treated with an equimolar amount of *N*-bromosuccinimide (II) in the absence of the alcohols (Eq. 1).

(I) (II) (III)

$$(EtO)_2POCH_2C_6H_5 + \text{NBr-succinimide} \rightarrow \text{N-P(O)(OEt)}_2\text{-succinimide} + C_6H_5CH_2Br \quad (1)$$

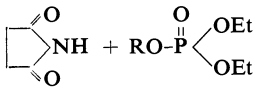
Since diethylphosphorosuccinimidate (III) is a kind of acid anhydride derived from a weak acid and a strong acid, it is expected that its phosphoroimidate bond would be reactive towards active hydrogen compounds, such as alcohols and phenols.

In the present experiment, phosphorylation of alcohols, phenol, and phosphates, by the use of diethylphosphorosuccinimidate was tried.



Contrary to expectation, no reaction was observed when diethylphosphorosuccinimidate was refluxed in a large excess of ethyl alcohol for five hours, and the starting materials were recovered. Further, reactions of diethylphosphorosuccinimidate (III) with alcohols in the presence of several catalysts were tried. Firstly, acid catalysts were employed on the consideration that the phosphoroimidate bond might be activated under acidic conditions. Among the catalysts examined, a protonic acid such as *p*-toluene sulfonic acid was found to be ineffective; while Lewis acids such as boron trifluoride and aluminum trichloride were shown to promote the reaction. In the case of aluminum trichloride, succinimide separated quantitatively, although the yield of alkyldiethyl phosphates (IV) was always lower than that in the case of boron trifluoride. Accordingly, the following reactions were tried with boron trifluoride as catalyst.

For example, when diethylphosphorosuccinimidate (III) was treated with a large excess of ethyl alcohol in the presence of a catalytic amount of boron trifluoride etherate under reflux for five hours, triethyl phosphate (IV, R=Et) was obtained in a 72% yield (Eq. 2). The results of phosphorylation of other alcohols by means of diethylphosphorosuccinimidate in the presence of boron trifluoride are summarized in Table I.

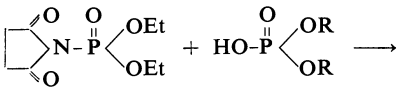


1) T. Mukaiyama, O. Mitsunobu and T. Obata, *J. Org. Chem.*, **30**, 101 (1965).
2) T. Mukaiyama, T. Obata and O. Mitsunobu, This Bulletin, **38**, 1088 (1965).

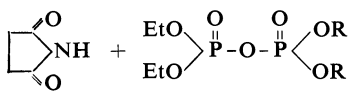
TABLE I. PHOSPHORYLATION OF ALCOHOLS OR PHENOL BY MEANS OF DIETHYLPHOSPHOROSUCCINIMIDATE IN THE PRESENCE OF BORON TRIFLUORIDE

| Material | Product | | |
|---|---|---|---|
| | Phosphate | Yield, % | B. p., °C/mmHg |
| EtOH | $EtOP(O)(OEt)_2$ | 72 | 98—102/13 |
| *n*-PrOH | *n*-$PrOP(O)(OEt)_2$ | 84 | 104—110/12 |
| *i*-PrOH | *i*-$PrOP(O)(OEt)_2$ | 73 | 98—105/12 |
| *n*-BuOH | *n*-$BuOP(O)(OEt)_2$ | 85 | 120—125/13 |
| $C_6H_5OH$ | $C_6H_5OP(O)(OEt)_2$ | 34 | 80—95/0.3 |

(III)



(IV) (2)



On the other hand, when diethylphosphorosuccinimidate (III) and ethyl alcohol were refluxed in the presence of a catalytic amount of basic catalysts such as sodium or triethyl amine, no reaction was observed and the starting materials were recovered.

In the second place, the reaction of phenol ($pK_a=9.9$) with diethylphosphorosuccinimidate (III) in the presence of a catalytic amount of boron trifluoride was tried. In this case, diethylphenyl phosphate (IV, $R=C_6H_5$) was isolated with some difficulty in only a 37% yield from the viscous greenish-black reaction mixture. But when phenol was treated with an equimolar amount of diethylphosphorosuccinimidate in the absence of catalyst, diethylphenyl phosphate was obtained in a 82% yield.

These results suggest that acidic compounds such as phenol are more readily phosphorylated by diethylphosphorosuccinimidate. This suggestion was confirmed by the fact that diethyl and di-*n*-butyl hydrogen phosphates, with $pK_a$ value about 2.1, were easily phosphorylated with diethylphosphorosuccinimidate (III), yielding tetraethyl pyrophosphate and *unsym.* di-*n*-butyl diethyl pyrophosphate (V, R=Et, *n*-Bu), respectively, in high yields (Eq. 3).

(III)

(V) (3)

In another reaction, preparation of acyl phosphates by the reaction of diethylphosphorosuccinimidate with butyric or valeric acids ($pK_a=4.8$) was tried. Unexpectedly when the carboxylic of acids and diethylphosphorosuccinimidate were refluxed for five hours in benzene, they did not react at all and the starting materials were recovered.

In conclusion, it is noted that phosphorylation alcohols by the use of diethylphosphorosuccinimidate could only be carried out in the presence of certain acid catalysts. On the other hand, more acidic substances such as phenol and dialkyl hydrogen phosphates were readily phosphorylated in quantitative yields even in the absence of catalysts.

## Experimental

The melting points and boiling points are uncorrected.

**Reagents.**—The solvents and alcohols were dried and purified by ordinary procedures. *N*-Bromosuccinimide, and butyric and valeric acids were obtained from a commercial source and purified by recrystallization or distillation. Diethyl hydrogen phosphate[3] and di-*n*-butyl hydrogen phosphate[4] were prepared according to the literature.

**Preparation of Diethylphosphorosuccinimidate by the Reaction of *N*-Bromosuccinimide and Benzyldiethyl Phosphite.**—Benzyldiethyl phosphite (25.0 g., 0.11 mol.) was added drop by drop to a suspension of *N*-bromosuccinimide (17.8 g., 0.1 mol.) in dry ether (150 ml.) over a period of 20 min. at room temperature. After the solution had been refluxed for 3 hr., it was concentrated and distilled under reduced pressure; benzyl bromide (b. p. 80—83°C/15 mmHg, 5.1 g., 88%) and diethylphosphorosuccinimidate (b. p. 140—150°C/0.03 mmHg, 19.3 g., 82%) were obtained. Redistillation gave white crystalline diethylphosphorosuccinimidate (m. p. 60—62°C, b. p. 145—150°C/0.03 mmHg, 15.3 g., 65%).

Found: N, 6.10. Calcd. for $C_8H_{14}O_5NP$: N, 5.96%.

IR-spectrum in Nujol: 1770, 1725, 1300, 1130, 1030 $cm^{-1}$.

Diethylphosphorosuccinimidate decomposes when

3) A. D. F. Toy, *J. Am. Chem. Soc.*, **70**, 3882 (1948).

TABLE II. PHOSPHORYLATION OF PHENOL OR DIALKYL HYDROGEN PHOSPHATES BY MEANS OF DIETHYLPHOSPHOROSUCCINIMIDATE IN THE ABSENCE OF BORON TRIFLUORIDE

| Material | Product | | |
|---|---|---|---|
| | Phosphate or Pyrophosphate | Yield, % | B. p., °C/mmHg |
| $C_6H_5OH$ | $C_6H_5OP(O)(OEt)_2$ | 82 | 95—105/0.4—0.6 |
| $(EtO)_2P(O)OH$ | $(EtO)_2P(O)OP(O)(OEt)_2$ | 94 | 115—118/0.3 |
| $(BuO)_2P(O)OH$ | $(BuO)_2P(O)OP(O)(OEt)_2$ | 76 | 124—125/0.03 |

heated above 220°C, but prolonged heating at lower temperature (ca. 180—190°C) may at times have the same effect. For this reason, distillation should be carried out under high vacuum, not more than 50 g. being distilled in one operation; care should also be taken as regards the purity of *N*-bromosuccinimide.

**Reaction of Diethylphosphorosuccinimidate with Alcohols or Phenol in the Presence of Boron Trifluoride.**—To a solution of diethylphosphorosuccinimidate (2.15 g.) in anhydrous *n*-propyl alcohol (2 ml.) was added five drops of boron trifluoride etherate, and the mixture was heated at 100°C for 5 hr. Dry ether (10 ml.) was added to the mixture, which was then allowed to stand at room temperature for some time to permit separation of the resulting succinimide. After separation of the succinimide (1.48 g., 84%), the colorless oil was distilled under reduced pressure and *n*-propyldiethyl phosphate (b. p. 104—110°C/12 mmHg, 1.40 g., 84%) was obtained.

Similarly, triethyl, isopropyldiethyl and *n*-butyldiethyl phosphates were prepared from the reactions of diethylphosphorosuccinimidate with the corresponding alcohols.

In the case of phenol, the reaction mixture turned brown within 30 min. and a small amount of succinimide separated. After heating at 100°C for 5 hr., the resulting viscous greenish-black oil was extracted carefully with several portions of dry ether (20 ml.). The extract was concentrated and diethylphenyl phosphate (b. p. 80—95°C/0.3 mmHg, 0.78 g., 34%) was obtained by distillation. These results are summarized in Table. I

**Reaction of Phenol with Diethylphosphorosuccinimidate.**—Freshly distilled phenol (1.0 g.) was mixed with diethylphosphorosuccinimidate (2.15 g.), and the mixture was heated at 100°C for 5 hr. When dry ether (10 ml.) was added, white crystalline succinimide (0.74 g., 83%) soon separated. The filtrate was concentrated and distilled under reduced pressure. An 82% yield of diethylphenyl phosphate (b. p. 95—105°C/0.4—0.6 mmHg, 1.58 g.) was obtained.

**Reaction of Diethylphosphorosuccinimidate with Diethyl Hydrogen Phosphate, or Di-*n*-butyl Hydrogen Phosphate.**—A mixture of equimolar amounts of diethylphosphorosuccinimidate (2.15 g.) and diethyl hydrogen phosphate (1.40 g.) in dry toluene (5 ml.) was heated at 100°C. The reaction took place rapidly. After heating for 5 hr., a quantitative amount of succinimide (870 mg., 97%) precipitated and was filtered off. From the concentrated filtrate, tetraethyl pyrophosphate (b. p. 115—118°C/0.3 mmHg., 2.43 g., 94%) was obtained by fractionation. This compound was identical with an authentic specimen prepared by the procedure given in the literature.[3]

Similarly, *unsym.* diethyl di-*n*-butyl pyrophosphate (b. p. 124—125°C/0.03 mmHg, 2.26 g., 76%) was obtained from di-*n*-butyl hydrogen phosphate (1.76 g.) and diethylphosphorosuccinimidate (1.97 g.). The results are summarized in Table II.

## Summary

Phosphorylation of alcohols, phenol, and dialkyl hydrogen phosphates by means of diethylphosphorosuccinimidate has been described. Phorphorylation of alcohols with diethylphosphorosuccinimidate could only be carried out in the presence of certain acid catalysts; while more acidic compounds such as phenol and dialkyl hydrogen phosphates were readily phosphorylated to give the corresponding phosphate and *sym.*- or *unsym.*-pyrophosphate in quantitative yields even in the absence of catalysts.

# The Cationic Copolymerization of Styrene and α-Methylstyrene in Liquid Sulfur Dioxide*

By Masashi IINO and Niichiro TOKURA

(Received October 12, 1964)

When liquid sulfur dioxide has been used as a solvent in the cationic polymerization of styrene, several characteristic features have been observed;[1] (1) the rate of the polymerization is exceedingly fast, (2) the polymer produced is of a high degree of polymerization and of a nearly mono-disperse distribution, and (3) even alkyl, aralkyl or acyl halide can initiate the poymerization in this solvent.[2]

This behavior of liquid sulfur dioxide may adequately be explained by its protophobic nature or by the inertness of this solvent toward the cationic species. In this cationic polymerization, monomer- and solvent-transfer reactions may be considered to be very small and the solvation of this solvent to anionic species may be very strong.

The present article will describe a study of the cationic copolymerization of styrene and α-methylstyrene, since the study of a copolymerization in a solvent can often provide many instructive suggestions on the nature of the solvent used and on the interactions among the cationic polymerizing species and the solvent.

The cationic copolymerizations in liquid sulfur dioxide of some pairs of copolymers, such as styrene-*p*-bromostyrene,[1c] styrene-isobutene,[3] and styrene-methylacrylate,[4] have already been studied, and a number of papers have been published elsewhere.

It has also been recognized that α-methylstyrene polymerizes readily in liquid sulfur dioxide without any catalyst,[5] as do *p*-methyl- and *p*-isopropyl-styrenes.[6]

In the study of the copolymerization of styrene and α-methylstyrene, NMR spectrometry has been adopted for the identification of the monomer units in the copolymer chain, according to the method of Bovey et al.[8a] The copolymerization in liquid sulfur dioxide is compared with that in methylene dichloride.

## Experimental

**Materials.** — Commercially-available styrene was distilled twice in a nitrogen atmosphere under reduced pressure. α-Methylstyrene was washed with a 10 per cent sodium hydroxide solution and water successively, dried with potassium carbonate, and distilled twice under reduced pressure in a nitrogen stream just before use.

Boron trifluoride etherate was used after repeated distillation in vacuo in a dry nitrogen stream and after having been stored in a glass ampule. Liquid sulfur dioxide was dehydrated with phosphorus pentoxide and distilled.

**Polymerization.** — The cationic copolymerization has been carried out at −40°C in liquid sulfur dioxide, since α-methylstyrene polymerizes spontaneously even at −20°C, while it does not undergo such spontaneous polymerization at −40°C. For a comparative study, a similar cationic copolymerization in methylene chloride was also carried out at −20°C, using the same procedure and the same apparatus.

The procedure of the polymerization was the same as in the case of the copolymerization of styrene and *p*-bromostyrene,[1c] using boron trifluoride etherate as a catalyst.

**Analyses of the Copolymer.**—The monomer composition of the copolymer was determined by NMR spectrophotometry, employing a Varian V-4300 B, 60 MC instrument, at 22—23°C. As the solvent for the spectrometry, carbon tetrachloride was used, dioxane being used as an internal reference. Figure 1 presents the NMR spectra in the carbon tetrachloride solutions (0.06 g. polymer in 1 ml. carbon tetrachloride) of polystyrene, poly-α-methyl styrene, a nearly equimolar mixture of the two homopolymers (polystyrene 54.3 mol. %), and a copolymer of styrene and α-methylstyrene (styrene in feed 82.0 mol. %, polymerized in liquid sulfur dioxide) respectively.

The assignment of the proton absorptions in the spectra of polystyrene and poly-α-methylstyrene has already been made.[8] The peak positions of the protons of the respective functional groups of the polymer or the copolymer are tabulated in Table I. As may be seen in Table I, the positions of the respective proton absorptions do not vary, even if

TABLE I. THE NMR SPECTRA OF HOMOPOLYMERS, COPOLYMER AND A MIXTURES OF POLYSTYRENE AND POLY-α-METHYLSTYRENE

| Polymer | Peak position (τ value) | | | |
|---|---|---|---|---|
| | $-C_6H_5$ | | $CH_2$ and CH | $-CH_3$ |
| Polystyrene (liq. $SO_2$) | 3.01 | 3.50 | 8.49 | — |
| Polystyrene ($CH_2Cl_2$) | 2.92 | 3.37 | 8.27 | — |
| Poly-α-methylstyrene (liq. $SO_2$) | 2.97 | — | 8.51 | 9.87 |
| Poly-α-methylstyrene ($CH_2Cl_2$) | 2.97 | — | 8.46 | 9.81 |
| Mixture of homopolymers (polystyrene 91.5%)* | 3.01 | 3.50 | 8.51 | 9.88 |
| Mixture of homopolymers (polystyrene 33.7%)* | 3.00 | 3.47 | 8.51 | 9.88 |
| Copolymer (styrene feed 53.2%)* | 2.99 | — | 8.51 | 9.89 |
| Copolymer (styrene feed 22.2%)* | 2.99 | — | 8.51 | 9.89 |

* Mole per cent

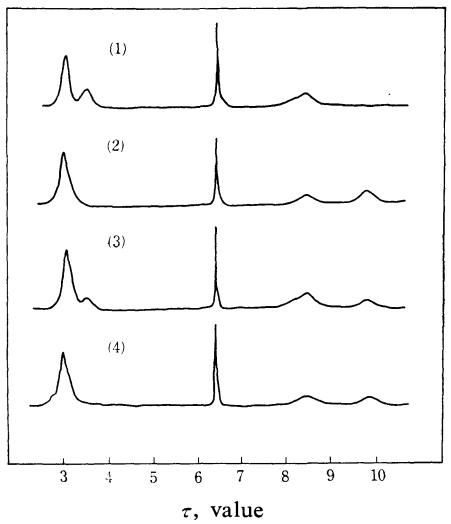

Fig. 1. NMR spectra of polystyrene, poly-α-methylstyrene, a mixture of the homopolymers and a copolymer, in $CCl_4$ (0.06 g. in 1 ml.).

(1) Polystyrene
(2) Poly-α-methylstyrene
(3) Mixture of polystyrene (54.3 mol. %) and poly-α-methylstyrene
(4) Copolymer of styrene (82.0 mol. % in feed) and α-methylstyrene

the polymer is a homopolymer, a mixture of homopolymers or copolymers is not affected by the kind of the solvent (liquid sulfur dioxide or methylene dichloride) used in the polymerization.

Tau (τ) values were calculated from the spectra of the protons, dioxane (τ=6.43) or cyclohexane (τ=8.56 p.p.m.) being used as an internal reference. No specific interaction between the samples and the reference was confirmed in the spectra. The content of each monomer in the copolymer chain of styrene and α-methylstyrene can be estimated either by the dimensional ratio of the proton absorption spectra of the phenyl- to the methyl protons, or by the dimensional ratio of the methyl protons to the methylene and methine protons. The latter method of estimation was chosen, because the estimation was simpler and subject to less error, as will be discussed later.

For the convenience of the experimental performance, a calibration line was prepared (Fig. 2), in which $(A_{CH_3}/A_{CH_2})_{obs}$, (the ratio of methyl- to methylene- and methine-protons) values in various mixtures of polystyrene and poly-α-methylstyrene were examined; the calculated values $(A_{CH_3}/A_{CH_2})_{calcd}$ (from the mixed ratios of the two homopolymers) were then plotted against the observed values $(A_{CH_3}/A_{CH_2})_{obs}$ (from the NMR measurements) on the rectangular coordinates. The fair coincidence between the calculated and the observed values in Fig. 2 may well support the validity of this technique for the estimation of the proportion of the components in the copolymer, as long as the mixture of the homopolymers behaves in a manner similar to that of the copolymer of the same monomers in the NMR phenomena. The NMR measurement was carried out in the concentration range of the polymer, 0.3 to 0.4 g. per 1 ml. of carbon tetrachloride. The dimensions of each proton-absorption area were estimated by weighing the NMR spectrum cut out from the chart of the spectra. Four to six measurements of the spectra of a copolymer were averaged in calculating the value of $(A_{CH_3}/A_{CH_2})_{obs}$.

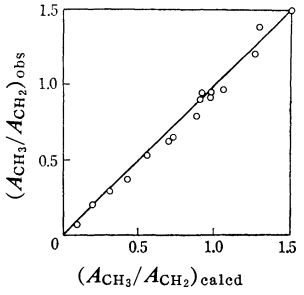

Fig. 2. Calibration line of calculated vs. observed values of $(A_{CH_3}/A_{CH_2})$.

$A_{CH_3}$ NMR absorption area of methyl protons.
$A_{CH_2}$ NMR absorption area of methylene and methine protons.

Harwood's method for the estimation of the comonomer proportion in the styrene-methylmethacrylate copolymer by NMR spectrometry[7] was modified and applied. The relationship between the molar fraction of styrene in the copolymer and the observed or calculated value of $(A_{CH_3}/A_{CH_2})$ is as follous:

$$x=\frac{3-(A_{CH_3}/A_{CH_2})\times 2}{3+(A_{CH_3}/A_{CH_2})}\times 100 \quad (1)$$

or

$$(A_{CH_3}/A_{CH_2})=(100-x)\times 3/(100\times 2+x) \quad (2)$$

where $x$ is the styrene mol.% in the copolymer.

**The Sequences of the Copolymer.** — The mole per cent in the copolymer of the sandwiched styrene ($S$), in the form of the -M-St-M- triad, where St and M are styrene and $\alpha$-methylstyrene units respectively, was estimated by using the following procedure;

$$(b/a)_{calcd}=\frac{2x}{5(100-x)+3x} \quad (3)$$

where $a$ and $b$ are the areas of the meta and para protons, and of ortho protons, respectively.

$$(b/a)_{obs}=2(x-S)/3(x-S)+5S+5(100-x) \quad (4)$$

or

$$S=\frac{x(2-x(b/a)_{obs})-5(b/a)_{obs}(100-x)}{x(2+2(b/a)_{obs})} \quad (5)$$

The derivation and the meaning of these formulae will be discussed later.

## Results and Discussion

**The Reactivity Ratio.**—Figures 3 and 4 show the feed-copolymer composition curves in liquid sulfur dioxide and methylene dichloride respectively. The monomer reactivity ratios, $r_1$ and $r_2$, were estimated by the trial and error method. The results is listed in Table II. In order to suppress the reaction rate, a lower temperature (−40°) was used in liquid sulfur dioxide. On the other hand, in methylene dichloride −20°C was needed to assure good solubility for monomers, though it has been reported that in liquid sulfur dioxide the M.R.R.'s are almost independent of the temperature of the copolymerization.[1c] However, some scattered results in Figs. 3 and 4 are perhaps due to such experimental difficulties as the fast reaction rates, the lesser solubilities of the monomers, and unavoidable error in the NMR determinations.

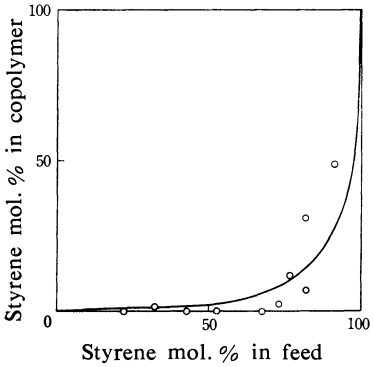

Fig. 3. Copolymer composition curve.

$BF_3$ etherate: $6.6\times10^{-3}$ mol./l.
Temperature: −20°C

Table II. The monomer reactivity ratios of the copolymerization of styrene and $\alpha$-methylstyrene in two solvents

| Solvent | $r_1$ | $r_2$* |
|---|---|---|
| liq. $SO_2$ (−40°C) | 0—0.1 | over 20 |
| Methylene dichloride (−20°C) | 0.2—0.5 | 12±2 |

* $M_1$: Styrene, $M_2$: $\alpha$-Methylstyrene

It has been confirmed, in spite of the above-discussed defect, that a non-alternating tendency prevails between styrene and $\alpha$-methylstyrene in both the solvents, the tendency being far more conspicuous in liquid sulfur dioxide. In view of the behavior of this solvent hitherto experienced by the present authors, the results are not unexpected.

**The Identification of the Sequence of the Monomer Unit in the Copolymer.**—The NMR spectra of phenyl groups of polystyrene, poly-$\alpha$-methylstyrene, the mixture of homopolymers and the copolymer can be recognized in the lower fields of the respective spectra, 1, 2, 3 and 4, of Fig. 1, where two peaks are observed as these of phenyl protons. These were assigned as the para- and the meta protons (lower field) and the ortho protons (higher field) by Bovey

et al,[8a] since the ratio of the respective areas is approximately 3 to 2 (Fig. 5).

The phenyl proton spectra afford two peaks because of the difference in the magnetic shielding effected by the adjacent benzene nucleus on the ortho protons and on the para- and meta protons.[8a] However, the spectra of α-methylstyrene do not afford the two peaks, but only one peak, because of the decrease in the interaction of the neighboring phenyl group because of the presence of the α-methyl group.[8a] In the mixture of the two homo-polymers or in the copolymer, the positions of the two peaks due to the phenyl protons are always the same (Table I); such a observation allows us to analyze the monomer sequences in the copolymer.

The dimensional ratios of the two peaks, $b/a$, were calculated (Fig. 5), where $a$ and $b$ are the area of the peak in the lower field and that in the higher one respectively. Therefore, in poly-α-methylstyrene, $b/a$ was 0, while in polystyrene $b/a$ was 2/3. The relation of the styrene mole per cent in the mixed homopolymers or that in the copolymer to the $b/a$ value is presented in Table III.

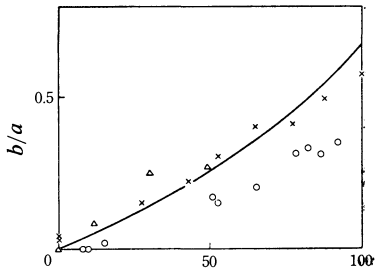

Fig. 6. Relations between styrene content vs. $b/a$ ratio in copolymers.
× Polystyrene, poly-α-methylstyrene-mixture
△ Copolymer in liquid sulfur dioxide
○ Copolymer in methylene dichloride

Figure 6 also demonstrates the relation of the styrene mole per cent in the polymer and the $b/a$ value, where the full line (the calculated plot) agrees well with the crossed dots (the observed values of the mixture of homopolymers). However, the plot of the copolymer (circle dots) is not like this, the points

8) a) F. A. Bovey, G. V. Tiers and G. Fieipovich, *J. Polymer Sci.*, **38**, 73 (1959); ibid., **62**, 197 (1962); b) A. Nishioka, ibid., **62**, 10 (1962); c) S. Brownstein, S. Bywater and D. J. Worsfold, *Makromol. Chem.*, 127 (1961).

here being somewhat below the theoretical curve and this being supposed beyond the range of experimental error.

Such a deviation may be accounted for by the difference in the sequence of the styrene unit in the copolymer, where some styrene units did not demonstrate the two separated peaks in the NMR spectra. The NMR spectrum of the phenyl group in styrene-polysulfone is also shown in Fig. 5 as a reference. Styrene-polysulfone is obtained by a radical polymerization of styrene in liquid sulfur dioxide.[9] The molar ratio of the styrene unit to the sulfur dioxide unit in the copolymer is said to be strictly 2 to 1, the arrangement of the monomer sequence in the chain being believed to be:

$$-SO_2-St-St-SO_2-St-St-$$

where St is the styrene and $SO_2$ is the sulfur dioxide monomer.

From the considerations mentioned above and from the NMR spectrum of the styrene-homopolymer, it may be anticipated that the polymer chain consisting of two and more succssive styrene units will exhibit two separated peaks in the NMR absorption. Therefore, the styrene unit in the copolymer which presents only one peak is likely to have the structure of a styrene unit sandwiched between the two $\alpha$-methylstyrene units, such as:

$$\cdots CH_2-\underset{\underset{C_6H_5}{|}}{\overset{\overset{CH_3}{|}}{C}}-CH_2-\underset{\underset{C_6H_5}{|}}{CH}-CH_2-\underset{\underset{C_6H_5}{|}}{\overset{\overset{CH_3}{|}}{C}}\cdots \qquad (S)$$

If this assumption is reasonable, the proportion of the sandwiched styrene (S) may be calculated by Eq. 5 from the observed curves in Fig. 6. The S value denotes the proportion of the sequences (S). The results are listed in Table III. As may be seen in Table III, the copolymer (equimolarly feed) afforded in methylene dichloride has as much as about 38.3% fragments (S). On the other hand, the copolymer produced in liquid sulfur dioxide seems to be a non-alternate copolymer, where $(b/a)_{obs} \fallingdotseq (b/a)_{calcd}$, and (S) is approximately zero. Such results agree well with the large value of $r_2$. The reaction in liquid sulfur dioxide favors the activity of cationic species remarkably. At a higher temperature, $\alpha$-methylstyrene can be polymerized spontaneously in liquid sulfur dioxide.[5],** This phenomenon is to be attributed to the low $e$ value (of the $Q$, $e$ scheme) of $\alpha$-methylstyrene. Thus, in the mixture of styrene and $\alpha$-methylstyrene, the latter monomer initiates the cationic polymerization faster than does styrene. In addition, styrene in liquid sulfur dioxide may be solvated by sulfur dioxide molecules more strongly than $\alpha$-methylstyrene in the same solvent, whereas the difference in the solvation between the two monomers is supposed to be not as distinguished as in methylene dichloride.

Secondly, in liquid sulfur dioxide, the $\alpha$-methylstyrene would be more reactive toward the growing carbonium ion end than styrene, since the electron density on the vinyl group in the former may be larger than that of styrene due to the $\alpha$-methyl inductive effect and the lesser solvation by a sulfur dioxide solvent on $\alpha$-methylstyrene. The non-alternative nature of such a polymerization is well elucidated by the above discussion.

## Summary

The copolymerizations of styrene and $\alpha$-methylstyrene in liquid sulfur dioxide have been carried out at $-40°C$ using boron trifluoride etherate as a catalyst, and the results compared with the same copolymerizations in methylene dichloride at $-20°C$. The $r_1$ and $r_2$ values have been estimated by NMR spectrometry as 0—0.1 and over 20 in liquid sulfur dioxide, and 0.2—0.3 and $12\pm2$ in methylene chloride. The styrene unit sandwiched between two $\alpha$-methylstyrene units has been calculated by a comparison of the phenyl doublet with phenyl singlet absorptions. The (S) per cent (S is the sandwiched styrene sequence, M-St-M, in the copolymer, where St is the styrene unit and M is the $\alpha$-methylstyrene unit) has been estimated. In liquid sulfur dioxide, S is approximately zero. This fact agrees well with the large $r_2$ value. The reason for such a non-alternative nature of the copolymerization in liquid sulfur dioxide had also been discussed.

** The present authors are inclined to believe in the initiation of the cationic polymerization without the Lewis acid catalyst, as the $H^+$ is derived from the trace of water in liquid sulfur dioxide as.

$$SO_2 + H_2O = H^+ + HSO_3^-$$

# Studies of Thio Acids. V.[1] The Reaction of Distearoyl Sulfide with Alcohol and Alkali*1

By Yoshio HIRABAYASHI, Masateru MIZUTA and Tetsuro MAZUME*2

(Received October 12, 1964)

In the course of an investigation of the mechanism of the formation of stearic esters from thiostearic acid and alcohols by heating, the formation of distearoyl sulfide as an intermediate in the reaction was confirmed.*3 However, detailed knowledge of the properties of diacyl sulfide was still lacking. Therefore, the present authors synthesized distearoyl sulfide and clarified its properties by investigating the products obtained by heating it in alcohol or by neutralizing it in organic solvents with ethanolic or aqueous potassium hydroxide, thus determining each reaction mechanism. The above mechanisms will be discussed in this paper.

Distearoyl sulfide (m. p. 79.5—80.5°C) was synthesized from potassium thiostearate and stearoyl chloride. Its ultraviolet absorption curve in cyclohexane (Fig. 1) exhibits an absorption maximum at 240 mμ ($\varepsilon=4030$) and an inflection in the 280—320 mμ region; the former is undoubtedly associated with conjugation between the $\pi$ electrons of the carbonyl group and the unshared valency electrons of the sulfur atom, while the latter is probably an R-band due to the carbonyl group. The neutralization value (N. V.) of distearoyl sulfide as determined by neutralization with ethanolic potassium hydroxide in benzene-ether using phenolphthalein as an indicator*4 was 100.4, a value which shows that the reaction between distearoyl sulfide and potassium hydroxide occurs at an equimolar ratio under the above conditions. The sulfur content (in the SH form) of distearoyl sulfide as determined by titration with an iodine solution in ethanol-ether or ethanol-benzene was naught, but that determined by titration with an iodine solution after neutralization with ethanolic potassium hydroxide in the above solvent was 5.70%, in good accord with the sulfur content as determined by Kitamura's method. (The sulfur contents determined by the above methods will be described below as S(J), $S(J)_{NV}$, and S(K) respectively.)

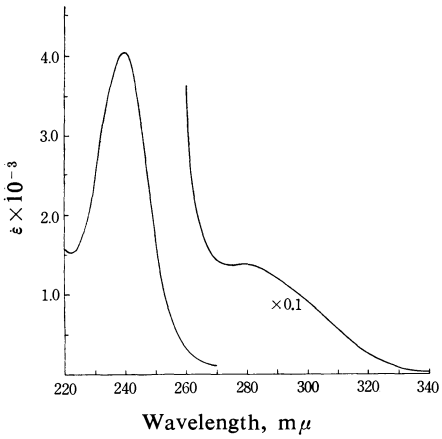

Fig. 1. Ultraviolet absorption spectrum of distearoyl sulfide in cyclohexane.

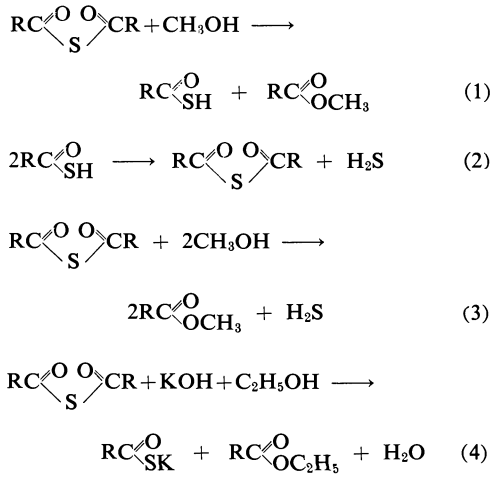
When distearoyl sulfide (3 g.) had been refluxed with absolute methanol (300 ml.) for 30 hr., the reaction product obtained was found to be composed of distearoyl sulfide (5%), thiostearic acid (35%) and methyl stearate (60%), but methyl thiostearate could not be isolated. This result suggests the following mechanism: When distearoyl sulfide is heated with methanol, methanolysis occurs as shown in Eq. 1, and methyl stearate and thiostearic acid are formed. Starting from the thiostearic acid, distearoyl sulfide is reformed by the elimination of hydrogen sulfide, as is shown in Eq. 2, and then the reaction of Eq. 1 is repeated.*5 It is still unknown whether the reaction of Eq. 3 occurs or not, but the reaction of Eq. 1 is firmly supported by the formation of a large amount of thiostearic acid.

When distearoyl sulfide in benzene or benzene-ether was neutralized with ethanolic potassium hydroxide, it was confirmed that

1) Part IV of this series: Y. Hirabayashi, This Bulletin, 38, 175 (1965).

*1 Most of this study was presented at the 11th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1958.

*2 Present address: Shimogamo-kishimotocho, Sakyo-ku, Kyoto.



*3 When thiostearic acid is heated with alcohol, first hydrogen sulfide is evolved and distearoyl sulfide is formed as an intermediate, and then the stearic ester and thiostearic acid are formed by the reaction of the intermediate and alcohol. This reaction mechanism will be discussed in the following paper of this series.

*4 In the following experiments, all neutralizations were carried out using phenolphthalein as an indicator.

*5 This will be discussed in the following paper of this series.

potassium thiostearate and ethyl stearate are formed in an equimolar ratio, as in Eq. 4. Therefore, it may be reasonably explained that the observed N. V. of distearoyl sulfide corresponds well with the value calculated by the equimolar ratio described above. It is also confirmed that the difference between the S(J) and the $S(J)_{NV}$ values is caused by the thiostearic acid formed by neutralization with ethanolic potassium hydroxide.

When a small amount (very different from the neutralization equivalent as a 1 : 1 mole ratio) of aqueous potassium hydroxide was added to a solution of distearoyl sulfide in benzene-ethanol, the reaction product was found to be composed of equimolar amounts of ethyl stearate and thiostearic acid (containing potassium thiostearate corresponding to the potassium hydroxide added); that is, alcoholysis occurs between a large amount of alcohol and distearoyl sulfide upon the addition of a small amount of alkali as a catalyzer, and then thiostearic acid and stearic acid ester are formed. This fact shows that when neutralization is carried out in benzene or benzene-ether with ethanolic potassium hydroxide, first alcoholysis occurs upon the addition of alcoholic potassium hydroxide, and then the acid thus formed is neutralized. However, a sufficient amount of alcohol in the solvent or in an alkali solution is needed for alcoholysis. The presence of a large amount of benzene and an equimole of alcohol to distearoyl sulfide does not accelerate the neutralization with aqueous potassium hydroxide. In a benzene - aqueous potassium hydroxide solution, distearoyl sulfide was not changed, even when vigorously stirred while being warmed and the hydrolysis shown in Eq. 5 did not occur. However, it still can not be known whether or not hydrolysis should occur by the regulation of the alkali concentration and the reaction temperature.

## Experimental*6

**The Synthesis of Distearoyl Sulfide.**—Potassium thiostearate was prepared by the neutralization of thiostearic acid with ethanolic potassium hydroxide in ethanol-ether (1 : 1) and by distilling off the solvent. Stearoyl chloride (9.2 g.) was added drop by drop to a suspension of the potassium thiostearate (10.4 g.) in anhydrous hexane (200 ml.), and then the mixture was refluxed for 7 hr. under a cooler with a calcium chloride tube. After the reaction mixture had been filtered while hot, hexane was distilled off from the filtrate, and the residue was recrystallized from benzene to give distearoyl sulfide (14 g.); m. p. 79.5—80.5°C, colorless plate crystals, N. V. 100.4 (Calcd. by $C_{36}H_{70}O_2S$ : KOH = 1 : 1 mol., 98.95).

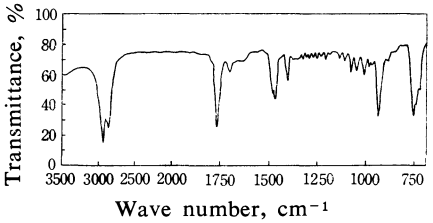

Fig. 2. Infrared absorption spectrum of distearoyl sulfide in KBr disk (1.05 mg./200 mg. KBr).

Found: C, 76.08; H, 12.33; S, 0·S(J), 5.68 $S(J)_{NV}$, 5.70 S(K)%. Calcd. for $C_{36}H_{70}O_2S$: C, 76.26; H, 12.44; S, 5.65%.

UV (cf. Fig. 1): $\lambda_{max}^{cyclohexane}$ 240 mμ (ε=4030); inflection 280—320 mμ. IR (KBr disk, cf. Fig. 2): $\nu_{C=O}$ 1766 $cm^{-1}$.

**The Reaction of Distearoyl Sulfide with Absolute Methanol by Heating.**—A solution of distearoyl sulfide (3 g.) in absolute methanol (300 ml.) was refluxed for 30 hr., and the following product I was obtained by distilling off the methanol under reduced pressure; m. p. 33.5—34.5°C, N. V. 68.3, S(J) 3.33%, $S(J)_{NV}$ 3.58%, S(K) 3.58%.

Its ultraviolet absorption spectrum (curve a, Fig. 3) exhibits a low-intensity absorption maximum at 221 mμ, but the absorption maximum at 240 mμ due to distearoyl sulfide is not seen.

The product I (2.8 g.) was recrystallized several times from hexane and benzene; the properties and the ultraviolet absorption spectrum of each fraction are shown in Table I and Fig. 3 respectively. The composition of each fraction was thus found to be as follows:

*6 All melting points are uncorrected. The ultraviolet absorption spectra were measured with a Shimadzu quartz-spectrophotometer, model QB-50, and silica cells (1 cm.), while the infrared absorption spectrum was measured with a Hilger-H-800 infrared spectrophotometer.

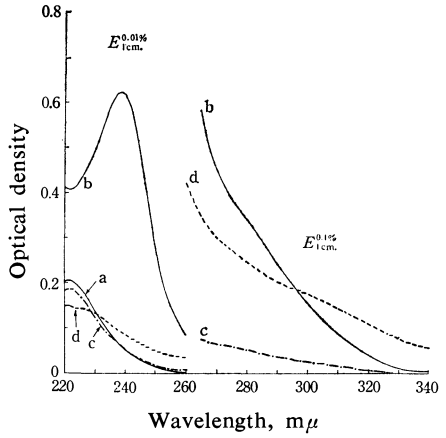

Fig. 3. Ultraviolet absorption spectra in cyclohexane.
a: Product I
b: Fraction 1 in Table I
c: Fraction 3 in Table I
d: Fraction N-2 in Table II

Table I. The properties of fractions obtained from the product I (2.8 g.)

| | Yield g. | M. p. °C | N. V. | $S(J)_{NV}$ | S(K) |
|---|---|---|---|---|---|
| (1) | 0.1 | 79—80 | — | — | 6.02 |
| (2) | 0.05 | 71—77 | — | — | — |
| (3) | 0.8 | 34.5—35.5 | 62.7 | 3.11 | 3.14 |
| (4) | 1.8 | 33—34 | 74.9 | 3.90 | 3.92 |

(1): Unreacted and reformed distearoyl sulfide
(2): Mainly distearoyl sulfide
(3) and (4): Thiostearic acid and ester (RCOOR' or RCOSR')

It was difficult to purify fractions 3 and 4 further by recrystallization. The mixture of 3 and 4 (1.6 g.) was neutralized with ethanolic potassium hydroxide in ethanol*7 and separated into an acidic part A and a neutral part N by the usual method. Each part was then recrystallized; the results of recrystallization are shown in Table II. The fractions A and N-1 were identified as thiostearic acid and methyl stearate respectively. (Neither of them showed any depression of melting point upon admixture with an authentic sample, and the ultraviolet spectrum of A was identical with that of thiostearic acid.) The fraction N-2 was slightly yellow and exhibited the weak absorption in the 260—400 mμ region. This fraction was found to consist mainly of methyl stearate, together with a small amount of an unidentified substance.

Table II. The properties of fractions obtained from the mixture (1.6 g.) of (3) and (4) in Table I

| | Yield g. | M. p. °C | N. V. | $S(J)_{NV}$ | S(K) |
|---|---|---|---|---|---|
| (A) | 0.6 | 39.5—40.5 | 186.4 | 10.54 | 10.57 |
| (N-1) | 0.9 | 38.5—39.0 | 1.5[a] | 0.09 | 0.08 |
| (N-2) | 0.1 | 39.5—40.5 | 41.2[b] | 1.81 | — |

Saponification value (S. V.): a), 185.5; b), 179.5 (calcd. for methyl stearate: 188.0).

*7 Since no difference is found between the S(J) and $S(J)_{NV}$ values, it can be said that no distearoyl sulfide exists in the product, and that no new products are formed by the neutralization of the product.

On the basis of the above results, the compositions of the product I were as follows: unreacted or reformed distearoyl sulfide 5%, methyl stearate 60%, and thiostearic acid 35%.

**The Reaction of Distearoyl Sulfide in Benzene or Benzene-Ether with Ethanolic Potassium Hydroxide.**—A solution of distearoyl sulfide (1.07 g.) in benzene (30 ml.) or benzene (20 ml.) - ether (10 ml.) was neutralized with 0.1 N ethanolic potassium hydroxide; the neutralization value was determined to be 100.5. The reaction mixture was then allowed to stand at room temperature for 2 hr., after which the solvent was distilled off under reduced pressure and water (200 ml.) was added to the residue. The resulting mixture was acidified with dilute hydrochloric acid and extracted with ether. The following product II was obtained by distilling off the ether: m. p. 30.0—31.0°C, N. V. 98.1, S(J) 5.60%, $S(J)_{NV}$ 5.60%.*7

A solution of this product II (0.94 g.) in ether (20 ml.) was neutralized with 0.5 N ethanolic potassium hydroxide (3.25 ml.), and the reaction mixture was allowed to stand at room temperature for 1 hr. Then the deposit part was filtered off. The filtrate (ether solution) was washed with water, and the neutral part N was obtained by distilling off the ether. The above deposit part, combined with washings of the filtrate, was acidified, and the mixture was extracted with ether. The acidic part A was obtained by washing the ether solution with water, followed by distilling off the ether. The same procedures were repeated for three times in each part in order to separate the neutral part from the acidic part as much as possible. The properties of each part are shown in Table III. It was deduced from the above results that almost equal amounts of potassium thiostearate and ethyl stearate are formed by the neutralization reaction of distearoyl sulfide in benzene or benzene-ether with ethanolic potassium hydroxide.

Table III. The properties of fractions obtained from the product II (0.94 g.)

| | Yield g. | M. p. °C | N. V. | $S(J)_{NV}$ |
|---|---|---|---|---|
| (A) | 0.43 | 39.5—40.5 | 184.8 | 10.28 |
| (N) | 0.45 | 34.5—35.5 | 1.0[a] | 0 |

S. V.: a) 180.9 (calcd. for ethyl stearate: 179.5).

**The Neutralization Reaction of Distearoyl Sulfide in Benzene with Aqueous Potassium Hydroxide.**—a) A solution of distearoyl sulfide (1 g.) in methanol (equal mole to distearoyl sulfide) and benzene (50 ml.) was titrated with 0.1 N aqueous potassium hydroxide, using phenolphthalein as an indicator. The titre was less than 0.03 ml.

b) To a solution of distearoyl sulfide (2 g.) in benzene (50 ml.), 36 ml. (calcd. value as 1 : 1 mol. ratio, 35.18 ml.) of 0.1 N ($f$=1.073) aqueous potassium hydroxide was added drop by drop, and then

the mixture was heated while being vigorously stirred at 50°C for 2 hr. Then it was acidified with dilute hydrochloric acid. The benzene layer separated was washed with water and dried, and the benzene was distilled off. The product obtained was distearoyl sulfide.

**The Reaction of Distearoyl Sulfide in Benzene-Ethanol with Aqueous Potassium Hydroxide.**—To a solution of distearoyl sulfide (1 g.) in benzene (80 ml.) and ethanol (20 ml.), 0.15 ml. of 0.5 N aqueous potassium hydroxide was added (distearoyl sulfide : potassium hydroxide = 1 mol.: ca. 0.02mol.). The mixture was heated at 40—50°C for 3 hr. and then allowed to stand overnight at room temperature. It was then acidified with dilute hydrochloric acid. The benzene layer separated was washed with water and dried, and the following product III was obtained by distilling off the benzene; m. p. 29.5—30.5°C, N. V. 97.6, S(J) 5.41%, $S(J)_{NV}$ 5.41%.*[7] A solution of the product III (0.91 g.) in benzene was repeatedly washed with aqueous potassium hydroxide, and the acidic part A and the neutral part N were obtained from the washings and the benzene layer respectively in the usual way. The results are shown in Table IV. It may be deduced from the results that almost equal amounts of thiostearic acid and ethyl stearate were formed by the reaction of distearoyl sulfide in benzene-ethanol with aqueous potassium hydroxide.

Table IV. The properties of fractions obtained from the product III (0.91 g.)

# On the Sn–H Bond in Some Organotin Hydrides

By Yoshikane KAWASAKI, Katsuhiko KAWAKAMI and Toshio TANAKA

(Received October 28, 1964)

Many investigations have been carried out with organometallic compounds by the method of nuclear magnetic resonance in order to study the effect of alkyl groups on the shielding of a metal nucleus or of hydrogen bound directly to a metal. The effect of the alkyl group in trialkylsilane or dialkylmercury has been found to be somewhat complicated. In the case of dialkylmercury,[1] the effect of the alkyl group on the shielding of the $^{199}Hg$ nucleus cannot be explained by a simple mechanism, such as the inductive or the hyperconjugation effect. It has been found that the apparent shielding of the $^{199}Hg$ nucleus is a function of the number of the $\beta$ protons of the alkyl group; the shielding increases in the order $CH_3 < n\text{-}C_3H_7 < C_2H_5 < i\text{-}C_3H_7$, and the spin-spin coupling of the $^{199}Hg$ nucleus with the $\beta$ protons was greater than that of the $\alpha$ protons or $\gamma$ protons. The same effect of the alkyl group was found on the shielding of the (Si-)H proton in the trialkylsilane.[2] On the contrary, however, in trialkylphosphines[3] the shielding value of the $^{31}P$ nucleus decreases with an increase in the number of the $\beta$ protons of the alkyl group.

In the case of dialkyltin dichloride, the increasing shielding value of the $^{119}Sn$ nucleus has been reported[4] to be $n\text{-}C_4H_9 < C_2H_5 < CH_3$. This order is different from that of the dialkylmercury or trialkylsilane. In the NMR spectrum of alkyltin compounds, therefore, hyperconjugation seems to be a predominant factor. In order to clarify the effect of the alkyl group in the alkyltin compounds, we studied the proton magnetic resonance and the infrared spectra of the Sn–H bond of some alkyltin hydrides.

## Experimental

**Material.**—All the organotin hydrides were prepared from the corresponding chlorides by reduction with lithium aluminum hydride in ethyl ether or in dioxane. The chlorides were kindly supplied by the Nitto Kasei Co., Ltd. The properties of the alkyltin hydrides used in our experiments are given in Table I.

**Nuclear Magnetic Resonance Spectra.** — The measurements were made at a fixed frequency of 60 Mc./sec. on two spectrometers, a Varian model

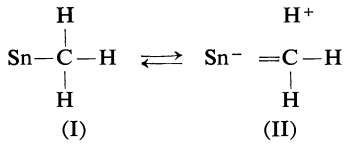
A-60 and a Japan Electron Optical Laboratory Co., Ltd., model 3H-60. Carbon disulfide was used as the solvent and the tetramethylsilane as the internal standard throughout. Measurements in a cyclohexane solution or in a neat liquid were also carried out in order to check the solvent effect.* The sample with a 2—10% concentration and with 1% tetramethylsilane was mixed in a Pyrex tube 5 mm. in diameter. The temperature was maintained at 20°C. The position of the peak was measured to the nearest 0.1 cycle/sec., the average of at least two determinations being used for each value recorded.

**Infrared Absorption Spectra.**—The infrared spectra were recorded by using a Perkin-Elmer (model 21) double-beam spectrophotometer equipped with sodium chloride optics, or a Hitachi EPI-2G infrared spectrophotometer equipped with gratings. The neat sample was used, and all spectra were calibrated by using known peaks of a polystyrene film.

* Carbon tetrachloride, a usual solvent in the proton magnetic resonance measurement. cannot be used because of its reactivity toward organotinhydrides (D. H. Lorenz and E. I. Becker, *J. Org. Chem.*, **27**, 3370 (1962)).



## Results and Discussion

The observed shielding values, in parts per million (p. p. m.), of the resonance of the proton attached directly to the tin atom in various organotin hydrides are shown in Table II together with the values in the literature. The results show that the shielding of the (Sn-)H proton increases in the order of $i\text{-}C_3H_7 < n\text{-}C_4H_9 \simeq n\text{-}C_3H_7 \simeq C_2H_5 < CH_3$ in trialkyltin hydrides. These results may be interpreted by considering such contributions as that of II in the ground state of the molecule, in which a considerable amount of $d_\pi$-$p_\pi$ bonding may take part:

(I) (II)

Thus, the Sn-C bond would be strengthened, the electron density on the proton bound directly to the tin atom may be increased, and at the same time the Sn-H bond would probably be strengthened. Support for this explanation is found in the recent thermochemical data.[5] The mean dissociation energy, $\bar{D}$(Sn-C), in the tetraalkyltin increases as follows; $C_2H_5 \simeq n\text{-}C_4H_9 \simeq n\text{-}C_3H_7 < CH_3$, which is almost consistent with the above explanation. This order found in organotin hydrides is different from that of the trialkylsilane or dialkylmercury, as has been described already. The low-lying vacant d-orbitals which can accept electrons from the alkyl group through the $d_\pi$-$p_\pi$ bonding are not very different in the tin atom and the silicon atom, although they are a little lower in the former than in the latter. It is not clear why the effect of the hyperconjugation is a predominant factor in the alkyltin hydride but not in the alkylsilane. The $\tau$ value in triphenyltin hydride is smaller than that in trialkyltin hydrides; this may be explained in terms of the electronegativity of the phenyl group.[2] The ring current of the phenyl group may also play a role.

In the shielding of the protons bound directly to the tin atom, the successive replacement of the hydrogen of the $SnH_4$ molecule by an alkyl group results in a progressive decrease in the $\tau$ value, as Table II shows. This tendency is smilar to those in hydrocarbons and might have some correlation with the dissociation energy of the carbon and hydrogen concerned, for some electronic strain may be accumulated on the C-H bond by the replacement of the hydrogen with the alkyl group. The dissociation energies of several kinds of C-H bonds are as follows; $\bar{D}$(C-H) = 101, 96, 94 and 89 kcal./mol. for $CH_3$-H, $CH_3CH_2$-H, $(CH_3)_2CH$-H and $(CH_3)_3C$-H respectively.[6] The result is parallel to the $\tau$ value of the corresponding proton. The same might be true in the alkyltin hydrides. The difference in the $\tau$ value of the (Sn-)H or (C-)H protons cannot be explained by the difference in the electronegativities of the tin atom and the carbon atom; for example, the $\tau$ values in the $(CH_3)_3XH$ molecule decrease independently of the electronegativity of the X atom; (X-)H = 8.46, 6.15, 5.36 and 2.32[7] for

X=C, Si, Sn and Pb respectively. One factor which influences these $\tau$ values may be the paramagnetic effect of the central atom X, for the paramagnetic effect seems to increase with an increase in the atomic number.

The frequencies of the Sn-H stretching vibration in the infrared absorption spectra of the alkyltin hydrides are given in Table III, together with the values reported in the literature. In the trialkyltin hydride, the positions of the Sn-H stretching vibration bands are in the order of $i$-$C_3H_7 < n$-$C_4H_9 \simeq n$-$C_3H_7 \simeq C_2H_5 < CH_3$, paralleling the order in the nuclear magnetic resonance spectra. This will support the assumption of the hyperconjugation of the alkyl group, which increases the overlap charge between the tin atom and the hydrogen atom. The position of the Sn-H stretching band in triphenyltin hydride, however, is exceptional, as it is in the case of the silicone analogues. In the dialkyltin or monoalkyltin hydride, only one Sn-H stretching band was found,* although two bands may be predicted from the selection rule. This might be due to the overlapping of the two kinds of Sn-H stretching bands as a result of a relatively small coupling between Sn-H vibrations. The Sn-H stretching band in the dialkyltin or monoalkyltin hydride shifts to a wave number relatively higher than that of the trialkyltin hydride. This tendency is parallel to that of the $\tau$ value.

* H. C. Clark et. al. have reported a doublet, but others do not (see Tables III).

## Summary

The nuclear magnetic resonance spectra of the proton attached directly to the tin atom in several organotin hydrides ($R_nSnH_{4-n}$; $n$= 1, 2, 3) have been measured. The observed shielding values increase in the order of $i$-$C_3H_7 < n$-$C_4H_9 \simeq n$-$C_3H_7 \simeq C_2H_5 < CH_3$ in trialkyltin hydrides. This order is consistent with that of the hyperconjugation effect of the alkyl group. On the other hand, the change in the shielding of the protons bound directly to the tin atom with a step-by-step substitution of $SnH_4$ by an alkyl group is similar to that of hydrocarbons or alkylsilanes. The infrared spectra of organotin hydrides show that there is a close correlation between the $\tau$ values and the Sn-H stretching frequencies.

# Vibrational Assignments and Intramolecular Force Field of Trimethylaluminum*

By Teiichiro OGAWA, Kozo HIROTA and Tatsuo MIYAZAWA

(Received October 30, 1964)

Trimethylaluminum is the simplest member of the trialkylaluminum series, all of which are important components of the Ziegler-type catalyst. Accordingly, this compound has been extensively investigated, although its reactivity is low in olefin polymerization. The reaction and the structure of trimethylaluminum-diphenylamine complex have been reported on previously.[1]

Trimethylaluminum has been found to be in a bridged structure by an X-ray diffraction method.[2] The vibrational spectra and their assignments have been studied by several authors.[3-10] Onishi et al.[7,9] have measured the infrared spectra in the region 700—280 $cm^{-1}$ and have calculated the normal vibrations on the basis of a modified Urey-Bradley field. Ogawa et al.[6,10] have measured the far infrared

spectra in the region 700—65 $cm^{-1}$ and have calculated the normal vibrations by the use of the Urey-Bradley potential function as supplemented with a few correction terms. In the present study the treatment of the normal vibrations was refined, and the vibrational spectra were reassigned.

The standard errors of potential constants may be used in discussing the reliability of a potential field and in studying the transferability of the potential terms. The uncertainties in potential constants arise not only from experimental errors, but also from deficiencies in the physical model of the potential field. The standard errors which are due to the latter source have previously been discussed, and a general formula has been derived.[11] This formula was used, in the present study, for the calculation of the standard errors of the potential constants of trimethylaluminum.

## Experimental

In studying the reaction mechanism, it is interesting to measure the infrared spectra of reactive substances or intermediate species. Since unstable organic samples react with or dissolve a vacuum grease, it was not practical to construct a vacuum liquid cell with alkali halide crystals. Therefore, a new device was worked out for the infrared measurement of extremely reactive substances.

This cell was made of polyethylene and could be kept in a vacuum of about $10^{-2}$ mmHg for a few days. The margin of polyethylene films, 10 cm.× 8 cm.×0.5 mm., was heated and pressed by a brass press in order to form an envelope; a glass tube 4 mm. in diameter had been inserted between the films in advance. Polyethylene films were readily melted and adhered to each other and to the glass tube. The cells thus constructed are satisfactorily airtight. In addition, vacuum resin was spread all over the outer surface of the cell, except for the optical path, in order to ensure the vacuum and to prevent the cell from accidentally breaking. The liquid sample was distilled in a side arm near the cell and poured through the glass tube into the cell in a vacuum. When it was necessary to increase the sample thickness, nitrogen gas was introduced in order to help more liquid squeeze into the cell. With this cell, the infrared spectra could be measured in the 4000—3100 $cm^{-1}$, 2500—1500 $cm^{-1}$, 1250—750 $cm^{-1}$, and below 700 $cm^{-1}$ regions.

## Normal Vibration Treatment

The molecular structure of trimethylaluminum (Fig. 1) belongs to the point group $D_{2h}$, and the geometrical parameters are $a=1.99$Å, $b=2.24$Å, $l=2.57$Å, $\angle\alpha=124°$ and $\angle\beta=110°$.[2] This structure of trimethylaluminum is quite similar to that of diborane, and so is the procedure of calculation.[11] The normal vibrations were treated by Wilson's GF matrix method.[12] The methyl group of this molecule was assumed to be a single dynamic unit. This molecule has eight symmetry species. The $B_{1u}$, $B_{2u}$ and $B_{3u}$ vibrations are infrared-active, and the $A_{1g}$, $B_{1g}$, $B_{2g}$ and $B_{3g}$ vibrations are Raman-active, but the $A_{1u}$ vibration is inactive.

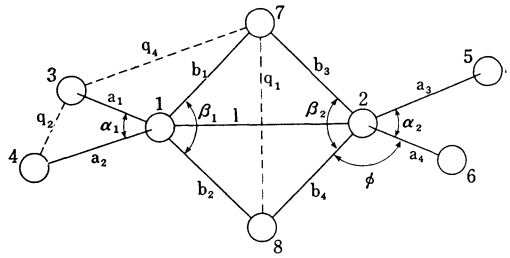

Fig. 1. The structure of the trimethylaluminum molecule, indicating the numbering of the atoms and the internal coordinates.
1, 2, Al; 3, 4, 5, 6, 7, 8, $CH_3$.
$\phi_1$ ∠713, $\phi_2$ ∠714, $\phi_3$ ∠813, $\phi_4$ ∠814, $\phi_5$ ∠826, $\phi_6$ ∠825, $\phi_7$ ∠726, $\phi_8$ ∠725
$\tau_1$ 8172, $\tau_2$ 8271, $\tau_3$ 7182, $\tau_4$ 7281

The internal coordinates are also given in Fig. 1. The symmetry coordinates were constructed as linear combinations of the internal coordinates, $S=UR$. The orthogonal $U$ matrices have been described previously.[11] A modified Urey-Bradley potential function was assumed as follows;

$$\begin{aligned}2V=&\sum_{i=1}^{4}K_a(\Delta a_i)^2+\sum_{i=1}^{4}K_b(\Delta b_i)^2+K_l(\Delta l)^2\\&+\sum_{i=1}^{2}H_\alpha(a\Delta\alpha_i)^2+\sum_{i=1}^{2}H_\beta(b\Delta\beta_i)^2\\&+\sum_{i=1}^{8}H_\phi(b\Delta\phi_i)^2+\sum_{i=1}^{4}H_\tau(b\Delta\tau_i)^2\\&+2tb^2(\Delta\phi_1\Delta\phi_7-\Delta\phi_1\Delta\phi_8+\Delta\phi_2\Delta\phi_3\\&-\Delta\phi_2\Delta\phi_7+\Delta\phi_3\Delta\phi_5-\Delta\phi_3\Delta\phi_6+\Delta\phi_4\Delta\phi_6\\&-\Delta\phi_4\Delta\phi_5)+\sum_{i=1}^{11}F(\Delta q_i)^2\end{aligned}\qquad(1)$$

where $K$, $H$ and $F$ are stretching, bending and repulsive constants respectively, and $t$ is the trans-interaction constant (the cis-interaction constant was set as equal to $-t$). There are three kinds of short $CH_3\cdots CH_3$ distances, as Fig. 1 shows. However, since their intergroup distances are nearly equal, a common repulsion constant, $F$, was used. The linear repulsion term, $F'(=-F/10)$, was omitted. The interaction terms, $k_1$, $f_1$ and $f_2$, in the potential function of diborane[11] were not included in the

present treatment because available experimental data were not sufficient for determining these terms. Although there were apparently nine parameters in the present potential function, $H_\beta$ was set as zero (cf. diborane[11]) and $H_\tau$ was assumed to be 0.02 md./Å. The seven remaining potential parameters were adjusted by the least-squares treatment.[13] A NEAC 2101 computer (Nippon Electric Company, Tokyo) was used for the numerical calculation.

## Results and Discussion

The vibrational assignments made by Hoffmann,[4] Ogawa et al.,[6] Gray[8] and Onishi et al.[9] are shown in Table I, together with the observed spectra and the present assignments.

As was shown in our previous paper,[10] no band was found in the region 400—65 $cm^{-1}$ except for the two at 367 and 175 $cm^{-1}$. All the vibrations except the puckering mode, $\nu_{10}$, are expected to lie in the region above 65 $cm^{-1}$. The rocking mode, $\nu_9$, may well, however, be very weak, since the corresponding band of diborane has not yet been observed.[14] Nevertheless, Hoffmann's assignments need three bands in this region, whereas Gray's assignments need only two. In this respect, Gray's assignments give a one-to-one correspondence between the observed bands and the expected vibrations.

One of the characteristics of Gray's assignments is that the frequencies of the infrared-active vibrations are appreciably higher than those of the corresponding Raman-active vibrations. That makes it very difficult to construct a reasonable potential function and to determine the force constants satisfactorily. A set of Urey-Bradley force constants always predicts higher frequency values for $\nu_1$, $\nu_2$ and $\nu_3$ than those for $\nu_{16}$, $\nu_{17}$ and $\nu_{18}$ respectively, partly because some of the diagonal $G$ matrix elements for the $A_{1g}$ species are larger than the corresponding elements for the $B_{3u}$ species. Therefore, Gray's assignments of Raman lines were tentatively modified; the weak line at 632 $cm^{-1}$ or 725 $cm^{-1}$ was assigned to $\nu_1$, and the lines at 592 $cm^{-1}$, 453 $cm^{-1}$ and 313 $cm^{-1}$ were assigned to $\nu_2$, $\nu_3$ and $\nu_4$ respectively. In some preliminary calculations, however, it was not yet possible to obtain a reasonable potential function in accordance with such assignments.

The isotope shifts of vibrational frequencies have been measured by Gray and used in discriminating the skeletal vibrations from methyl vibrations. Thus, the infrared band at 616 $cm^{-1}$ was assigned to $\nu_{16}$,[8] although in previous studies[4-7,9] the band at 562 $cm^{-1}$ had been assigned to $\nu_{16}$. The infrared band at 772 $cm^{-1}$ had been assigned to $\nu_8$ by Gray.[8] However, this frequency appears to be too high for a skeletal vibration. Accordingly, the band at 697 $cm^{-1}$ was again assigned to $\nu_8$ in the present study.

Onishi and Shimanouchi[9] assigned the infrared band at 367 $cm^{-1}$ to $\nu_{17}$, and the Raman lines at 153 and 185 $cm^{-1}$, to $\nu_4$ and $\nu_{12}$ respectively. They treated the skeletal vibrations on the basis of the Urey-Bradley field modified

with the resonance term. This term mainly affects the $\nu_6$ vibration, which has not been observed experimentally for trimethylaluminum. Accordingly, this term was not included in the present potential function.

In the present study the vibrational assignments were carried out with reference to the results of the frequency calculation. As for the Raman bands at 683, 592, 453 and 313 $cm^{-1}$, Hoffmann's assignments were used. The $\nu_4$ vibration is expected to be very strong, since this vibration belongs to the totally-symmetric species and since the corresponding Raman line of diborane is very strong. In agreement with Onishi's assignment, the strong line at 153 $cm^{-1}$ was thus assigned to $\nu_4$, although it is practically depolarized. As in the case of diborane, the $B_{1g}$ vibrations are not expected to be very strong. Two other Raman-active vibrations, $\nu_{12}$ and $\nu_{15}$, are also expected to lie above 70 $cm^{-1}$. In the case of diborane, the $\nu_{12}$ vibration has not been observed in the Raman effect, whereas the $\nu_{15}$ Raman vibration was of medium intensity. Accordingly, the Raman line of trimethylaluminum at 185 $cm^{-1}$ was tentatively assigned to the $\nu_{15}$ mode.

(This line had been assigned to $\nu_{12}$ by Onishi and Shimanouchi.[7,9]) The infrared bands at 697, 480 and 616 $cm^{-1}$ were assigned to $\nu_8$, $\nu_{13}$ and $\nu_{16}$ respectively, as has been mentioned before. Some of the preliminary assignments[6] were revised in consideration of refined experimental results,[10] and the bands at 367 and 175 $cm^{-1}$ were assigned to $\nu_{17}$ and $\nu_{18}$ respectively.

The results of the normal vibration calculation are shown in Table II, both for trimethylaluminum and for the fully deuterated derivative. The calculated $\nu_{14}$ frequency lies near $\nu_{18}$ with the present potential field. Accordingly, the observed frequencies of the $\nu_{14}$ and $\nu_{18}$ vibrations were both taken to be 175 $cm^{-1}$. The $\nu_{12}$ vibration calculated at 173 $cm^{-1}$ may partly contribute to the broad Raman band at 153—185 $cm^{-1}$. The potential energy distributions ($F_{tt}L_{ta}^2/\lambda_a$)[15] for trimethylaluminum are shown in Table III.

TABLE IV. THE CALCULATED FORCE CONSTANTS AND THEIR STANDARD ERRORS

| | Calculated values md./Å | Standard errors $\sigma_1$ | $\sigma_2$ | $\sigma$(total) |
|---|---|---|---|---|
| $K_a$ | 2.16 | 0.04 | 0.14 | 0.15 |
| $K_b$ | 0.88 | 0.02 | 0.03 | 0.04 |
| $K_l$ | 1.24 | 0.07 | 0.22 | 0.23 |
| $H_\alpha$ | 0.054 | 0.003 | 0.013 | 0.013 |
| $H_\beta$ | 0 | — | — | — |
| $H_\phi$ | 0.040 | 0.006 | 0.016 | 0.017 |
| $H_\tau$ | 0.020 | — | — | — |
| $t$ | 0.013 | 0.001 | 0.000 | 0.001 |
| $F$ | 0.080 | 0.010 | 0.030 | 0.032 |

$\sigma_1$; Standard errors which arise from experimental uncertainties.
$\sigma_2$; Standard errors which arise from deficiencies in the physical model of the potential field.

The force constants adjusted by the least-squares refinements are shown in Table IV, together with their standard errors. As was indicated by preliminary calculations of trimethylaluminum and diborane,[6] the frequency fit was improved by a decrease in the value of the bending constant, $H_\beta$. Therefore, this constant, $H_\beta$, was also set as equal to zero. There are no experimental data on the puckering vibration; accordingly, the value of $H_\tau$ was set arbitrarily at 0.02 md./Å. The trans- and cis-interaction terms were introduced rather arbitrarily and set so as to yield the best agreement between the observed and the calculated $\nu_{15}$ frequencies. Without these interaction terms, the $\nu_5$ and $\nu_{12}$ frequencies would be considerably lower than the calculated values and the $\nu_9$ and $\nu_{15}$ frequencies, higher than the calculated values.

The standard errors of potential constants were calculated by the formula:[11]

$$\sigma^2(K_h) = \frac{n}{n-q} \times \{(\boldsymbol{J}^*\boldsymbol{W}\boldsymbol{J})^{-1}\boldsymbol{J}^*\boldsymbol{W}\rho^2\boldsymbol{W}\boldsymbol{J}(\boldsymbol{J}^*\boldsymbol{W}\boldsymbol{J})^{-1}\}_{hh} \quad (2)$$

where $n$ and $q$ are the numbers of the observed frequencies and adjustable force constants respectively. $\boldsymbol{J}$ is the Jacobian matrix, and $\rho$ is the diagonal matrix of the residuals between the calculated and the observed data. In the calculation of standard errors of potential constants, the standard errors of the observed frequencies were assumed to be one per cent.

The similarity of the molecular structure of trimethylaluminum to that of diborane was repeatedly used in the vibrational assignments or normal vibration treatments. The formula of the potential function and also the relation of the magnitude of the potential constants are similar in the two molecules. However, the methyl group of trimethylaluminum is larger than the hydrogen atom of diborane, and the mutual repulsion terms among methyl groups were taken into account.

In the present potential function, there were several characteristics which were similar to those of diborane. The first was that the terminal-bond stretching constant ($K_a$) was more than twice as great as the bridge-bond stretching constant ($K_b$). This shows that the bridge half-bond was considerably weaker than the terminal single bond. The second was that in-plane angle-deformation potential terms ($H_\beta$) of the bridge may be neglected in the potential function of this molecule. The bridge bond was not expected to have much directional property, and the infinitesimal change in the bridge angle was not expected to be confronted by a strong restoring force. The third was that the stretching constant ($K_l$) between two aluminum atoms was large enough for us to confirm the existence of a bond between them. In fact, the interatomic distance, 2.57Å, is approximately equal to the sum (2.52Å) of Pauling's tetrahedral covalent radii.[2,16]

Because of the lack of enough observed data for deuterated species, the values of the standard errors of the potential constants were greater than those in the case of diborane, but they were nevertheless satisfactory since all constants were essentially determined.

16) L. Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, New York, U. S. A. (1960), p. 246.

The present assignments were finally set on the basis of Hoffmann's assignments, taking Gray's data on isotope shift into consideration.

## Summary

A vacuum infrared cell for reactive or intermediate species has been devised by the use of polyethylene sheets as optical windows. The infrared spectra in the 4000—3100 $cm^{-1}$, 2500—1500 $cm^{-1}$, 1250—750 $cm^{-1}$ and 700—65 $cm^{-1}$ regions can be measured with this liquid cell.

The vibrational assignments of the observed spectra have been carried out. The band at 367 $cm^{-1}$ has been assigned to $\nu_{17}$, and the band at 175 $cm^{-1}$, to $\nu_{18}$ and $\nu_{14}$.

The normal vibrations have been calculated, and the potential function of this molecule has been studied. A bond has been concluded to lie between two aluminum atoms. The characteristics of the potential function and the bond structure of trimethylaluminum have also been discussed.

The authors are indebted to Miss Yoshiko Ideguchi for her assistance in the numerical calculations.

# Studies of the Liquid-Liquid Partition Systems. I. The Distribution of Radon(0) between Various Organic Solvents and Aqueous Solutions

By Tatsuya SEKINE* and Akira YAMASAKI**

(Received October 31, 1964)

The partition of a chemical species between two equilibrated immiscible liquid phases has been studied for a long time, and the constants have been determined for various distribution, association, or dissociation equilibria. At the same time, the partition method has been applied in many different fields, and the "solvent extraction method" has been recognized as one of the most rapid and effective methods for the separation or the purification of various materials.

The present series will present the results of our study of the liquid-liquid partition systems. In them chemical species are distributed between two phases; usually one is an aqueous solution which contains non-electrolytes, complex-forming ligands, or electrolytes, while the other is an organic solvent with various extractants.

The first paper of this series will report on the distribution of radon(0) between aqueous solutions and pure organic solvents. Inert gases were chosen as one of the simplest molecules, and radon was chosen because it may be most easily polarized or most easily interacted with other molecules among the inert gas elements.

**The Previous Work.**—Even though the inert gases show a very poor interaction with other atoms or molecules, it has been established that they have some solubility in water. The distribution ratio of radon between the air and water was determined at different temperatures,[1-5] and it was reported to be affected by solutes in the water.[6] It was also found that radon is distributed from air to various solvents better than to water.[7] These findings were reviewed by Bonner and Kahn.[8]

Recently, some authors have studied the behavior of inert gases in solutions. Lawrence

and his co-workers[9] described how xenon is twice as soluble in water and fat as nitrogen, while helium shows a lower solubility. They reviewed the solubilities of hydrogen, oxygen, carbon dioxide, nitrogen, helium, argon, krypton, xenon and radon in water and oil. Semenchenko[10] described a theory for the solubility of gases and discussed that of radon. Morrison and Billet[11,12] described the salting-out of non-electrolytes and discussed the solubility of gases. Friedman[13] determined the solubility of rare gases, sulfur hexafluoride and osmium tetroxide in nitromethane and gave an equation which, in his opinion, correlated the solubility with two terms that depend on the solvents and gases. Diamond and Tuck[14] gave an indirect estimation of the distriribution of helium, neon, argon, krypton and xenon between water and nitromethane on the basis of Friedman's data. Clever and his co-workers[15] reported on the solubility of helium, neon, argon, krypton and xenon in methylcyclohexane and perfluorocyclohexane, and Nussbaum and Hursh[16] reported on the solubility of radon in fatty acids and triglycerides. Namiot[17] discussed the solubility of nonpolar gases in water.

The formation of inert gas hydrates or deuterates[18-21] has been observed and explained in terms of the dipole-induced dipole attraction. The hydration numbers of these compounds, $G \cdot xH_2O$ and $G \cdot yD_2O$, $x$ and $y$, were reported to be approaching six, but becoming so only with the heaviest inert gases. The crystals of these compounds are obtained only when water and inert gases are cooled at a low temperature under pressure. Other examples of such solvates have been also reported, for instance, phenol derivatives, $Kr \cdot 2C_6H_5OH$, $Xe \cdot 2C_6H_5OH$, and $Rn \cdot 2C_6H_5OH$.[22] Among other examples of the interaction between the inert gas atom and other atoms or molecules, the most remarkable are the xenon compounds with fluorine or oxygen, or krypton with fluorine.[23]

**The Present Work.**—The present work will first describe the distribution of radon between various organic solvents and water; next, it will describe the distribution of radon between carbon tetrachloride and calcium chloride solutions of various concentrations at 25°C. Finally, it will suggest the use of solvent extraction as a convenient separation or concentration technique for radon in various aqueous solutions where radium and its daughter nuclides coexist.

## Experimental

**Reagents and Solutions.**—All of the reagents used in this study were of reagent grade. The calcium content in the stock calcium chloride solution was determined by complexametry using a murexide indicator, while the chloride ion was titrated by argentometry using a fluorescein indicator. The calcium and chloride ion contents thus determined agreed with each other very well. Calcium chloride solutions of various concentrations were made by the addition of a weighed portion of water to a weighed portion of a calcium chloride stock solution.

The organic radon stock solution was prepared as follows: A pure radium nitrate solution in a bottle with a stopper had been left standing for a few days after the chemical separation from the daughter nuclides; then an organic solvent was added, and the whole was shaken for a few minutes. Then the organic phase was pipetted out and transferred into a stoppered centrifuging tube. Water was then added, and the tube was shaken again and centrifuged. The organic phase was pipetted off and used as the radon organic stock solution. In the earlier stage of the work, radon was emanated from a radium sulfate-barium sulfate precipitate into pure water. Radon was extracted from the supernatant solution with the various solvents to be studied.

**Procedures.**—All of the experiments were carried out in a thermostated room at 25°C. Ten milliliters of one of the organic radon solutions and 10 ml. of water were added to a glass stoppered centrifuging tube. The volume of the tube was about 21—22 ml. The two phases in the tube were equilibrated by mechanical agitation for about one hour and they separated by centrifugation. An 8 ml. portion was pipetted off from each phase and transferred into a small glass-stoppered 10 ml. test tube. Then 2 ml. of a non-radioactive organic solvent or water was added into the test tube to expel the air left at the top in order to avoid any changes in the geometrical efficiency of the radioactivity measurement which could be caused by the escape of radon into the gas phase.

The distribution ratio of radon between carbon tetrachloride and calcium chloride solutions of various concentrations was determined in just the

same way as has been described above, except that the calcium chloride solutions were used as the aqueous phase instead of pure water.

**The Measurement of Radioactivity.**—After the samples in the small glass-stoppered test tubes for radioactivity measurements had been left stand more than six hours, the $\gamma$-radioactivity was measured with a well-type scintillation counter with a sodium iodide(Tl) scintillator.

## Results

**The Decay of the $\gamma$-Radioactivity.**—Figure 1 gives an example of the decay curves of the $\gamma$-radioactivity. The half-life of the $\gamma$-radioactivity in all samples properly prepared agreed with the literature value (3.825 days for $^{222}Rn$) after the radioactive equilibrium was reached. Six hours' standing after the phase separation was enough for both phases to reach the radioactive equilibrium.

**The Distribution Constant for Radon between Water and Various Solvents.**—The distribution constants, $K_D$, was defined as follows:

$$K_D=[Rn]_{org}/[Rn]_{aq} = \frac{\gamma\text{-count rate per ml. of org. soln.}}{\gamma\text{-count rate per ml. of aq. soln.}} \quad (1)$$

Table I gives the distribution constants of radon between water and various organic solvents.

**The Distribution of Radon between Carbon Tetrachloride and Calcium Chloride Solutions of Different Concentrations.**—Table II gives the results of the distribution ratio of radon between carbon tetrachloride and aqueous solutions of calcium chloride at various concentrations. Figure 2 gives the plot of the distribution ratio against the calcium chloride concentration.

Table I. Distribution constants of radon between water and various organic solvents at 25°C

## Discussion

**The Measurement of $\gamma$-Radioactivity.**—The decay chain of $(4n+2)$ series after $^{226}Ra$ has been well established. As the radium stock solution was purified from $^{210}Pb$ (half-life is 22 years.) before use, the radioactivity of the daughter nuclides after $^{210}Pb$, $^{210}Bi$, $^{210}Po$ and $^{206}Tl$ can be neglected in this experiment.

Figure 1 seems to show the following; (i) the distribution of radon into the organic phase is very high, but that of its $\gamma$-radioactive daughter nuclides is low. (ii) The $\gamma$-radioactive daughter nuclides in the decay products of $^{222}Rn$, $^{214}Pb$ (RaB, 26.8 min.) and $^{214}Bi$ (RaC, 19.7 min.) grow in the organic phase during the radon decays to $^{218}Po$ (RaA, 3.05 min.). On the other hand, these nuclides in the aqueous phase decrease, until finally the radioactive equilibrium is reached between the $^{222}Rn$ and these nuclides. (iii) The radioactive equilibrium between $^{222}Rn$ and these $\gamma$-radioactive daughter nuclides is first reached in the organic phase, but it takes longer in the aqueous phase because a large amount of $^{214}Pb$ and $^{214}Bi$ are back-extracted from the organic phase, which contains a much larger amount of $^{222}Rn$ than does the aqueous phase.

From these results, it may be concluded that the distribution ratio of $^{222}Rn$ in a liquid sample in an air-tight container can be determined by the direct measurement of the $\gamma$-radioactivity with a welltype scintillation counter if the samples are left standing until the radioactive equilibrium between the $^{222}Rn$ and its $\gamma$-radioactive daughter nuclides, $^{214}Pb$ and $^{214}Bi$, is reached.

**The Distribution of Radon between Water and Varous Organic Solvents.**—In a liquid-liquid partition system, the $K_D$ value generally gives the ratio of the relative solubility of radon in the two phases when they are mutually saturated; that is,

$$K_D=\frac{\text{the solubility of Rn in the organic solvent satd. with water}}{\text{the solubility of Rn in the water satd. with the organic solvent}} \quad (2)$$

and when the distribution constant of radon between air and a liquid, $K$, is defind as follows:

$$K=\frac{\text{the concn. of Rn in the liquid}}{\text{the concn. of Rn in air } (\sim 1 \text{ atm.})} \quad (3)$$

Therefore, one may calculate $K_D'$ as follows:

$$K_D'=\frac{\text{the solubility of Rn in a pure organic solvent}}{\text{the solubility of Rn in pure water}}=\frac{K_{org}}{K_{aq}} \quad (4)$$

The difference between $K_D$ in Eq. 2 and $K_D'$ in Eq. 4 depends on whether or not the two phases are mutually saturated. Table III gives $K_D'$ values calculated from previous data by Eq. 4.

Table III. Calculated distribution constants of radon between water and various organic solvents at 18°C from previous work

$K_D'=K_{org}/K_{aq}$

$K=\dfrac{\text{(concn. of Rn in liq. phase)}}{\text{(concn. of Rn in air (ca. 1 atm.))}}$

| Solvent | $K_{org}$ | $K_D'$ | Ref. |
|---|---|---|---|
| Chloroform | 15.1 | 53.0 | 7 |
| Chloroform | 15.08 | 52.9 | 1 |
| Carbon disulfide | 23.1 | 81.1 | 7 |
| Hexane | 16.56 | 58.1 | 7 |
| Benzene | 12.82 | 45.0 | 7 |
| Toluene | 13.24 | 46.5 | 1 |
| Toluene | 13.2 | 46.3 | 7 |
| Xylene | 12.75 | 44.7 | 1 |
| Xylene | 15.4 | 54.0 | 7 |
| Cyclohexane | 18.04 | 65.3 | 7 |
| Ethyl acetate | 7.35 | 25.8 | 7 |
| Ethyl acetate | 7.35 | 25.8 | 1 |
| Ethyl ether | 15.1 | 53.0 | 7 |

The $K_D$ values in Table I (present work) and the $K_D'$ values in Table III do not agree well, except for chloroform. Until now it has not been possible to ascertain whether these differences were caused by the mutual saturation or by some other reasons.

The total recovery of radon was found to be nearly quantitative; that is, the escape of radon from the two phases was small. However, if some part of the aqueous phases escapes into the air during the operation, it

causes a large error in $K_D$ even though it causes only a small loss in the total recovery because the aqueous phase contains an only small part of the total radon.

The results for benzene, toluene, and xylene were scattered, and so no values are given for these solvents in Table I, but the data obtained are shown at the foot of the table.

The results in Table I can be summarized as follows: (i) The distribution constant of radon is generally smaller when the solvent is more soluble in the water (methyl isobutyl carbinol $\sim$ methyl isobutyl ketone $<$ hexane). (ii) Bromine-containing solvents give smaller distribution constants than their chlorine homologues (bromoform $<$ chloroform, bromobenzene $<$ chlorobenzene). (iii) The distribution constants are much larger than unity; that is, the relative solubility of radon in the organic solvents is much higher than that in water.

The interaction between radon and water has been explained by the dipole-induced dipole interaction.[21] However, radon interacts with the organic solvents better than with water, although the solvents show smaller dipole moments than the water. Further information seems to be necessary in order to explain these results.

**The Distribution of Radon between Calcium Chloride Solutions and Carbon Tetrachloride.**—It was observed in the present work that the addition of calcium chloride to the water increases the extraction of radon even when the concentration is less than 10%. This agrees with the observation of Kofler.[24] He described how the solubility of radon in water is decreased by the addition of even a very small amount of salts. For example, he reported that the addition of 1% sodium chloride decreases the relative solubility of radon, $K$ in Eq. 3, to 88.5% of that in pure water (0.270 at 18°C).

Radon in the aqueous phase may be hydrated (cf. Refs. 18—21), whereupon some or all of the water molecules combined with radon will be dissociated when the radon is distributed from the aqueous phase to the organic phase. It may also happen that the hydration number of radon changes with the change in the water activity. Thus the change in the water activity may be one of the reasons for this strong salting-out. Figure 2 also shows the water activity in the solution described in the literature.[25]

**A Solvent Extraction Method for the Separation and the Concentration of Radon from Aqueous Radium Solution.**—From the results of the present work, the following solvent extraction procedure can be suggested for the separation and the concentration of radon in aqueous solutions of radium(II).

*Solvents.*—Any of the organic solvents in Table I can be used. However, those which are not very soluble in water are more useful, and the use of carbon tetrachloride or hexane, for example, is recommended.

*Aqueous Solution.*—Any radium(II) aqueous solution can be used. The addition of a small amount of acid or a complexing agent (such as disodium ethylenediaminetetraacetate) will prevent the radiocolloid formation which sometimes causes the loss of radium or the contamination of the organic phase. The addition of electrolytes may improve the recovery of radon into the organic phase.

*Recommended Procedure.*—The aqueous radium solution and the organic solvent are placed in a small, stoppered tube. The space occupied by air should be minimized for a good recovery. The tube is then rotated mechanically to agitate the phases, and centrifuged. The organic phase is taken as a radon solution and, if necessary, the organic solution is washed with an aqueous solution containing acid or some complexing reagent in order to make further purification from radium and the daughter nuclides. When no quantitative recovery of radon is necessary, radon can be extracted only by shaking an aqueous solution of radium with an organic solvent in a glass-stoppered bottle or a separatory funnel.

## Summary

(1) The distribution of radon between various organic solvents and water has been determined at 25°C. Radon is always distributed better into the organic phase. The distribution constants of radon in these liquid-liquid partition systems are in the range from 25 to 80.

(2) The distribution of radon between aqueous calcium chloride solution of various concentrations and carbon tetrachloride has been determined at 25°C. A remarkable salting-out effect for radon has been observed.

(3) A solvent extraction method for the separation of radon from radium(II) and the decay products in aqueous solutions has been suggested.

# Thermodynamic Properties and Order-Disorder Phase Transitions of the Potassium Cyanide Crystal

By Hiroshi SUGA, Takasuke MATSUO and Syûzô SEKI

(Received November 4, 1964)

Potassium cyanide, though it consists of spherical $K^+$ and spheroidal $CN^-$ ions, has a cubic symmetry[1] ($O_h^5$; NaCl-type) at room temperature. When the crystal is cooled, it undergoes a phase transition[2] at 168.3°K, with an entropy change approximately equal to $R \ln 4$. According to Bijvoet and his collaborators,[1] the cyanide ions either rotate freely or are orientated randomly in eight body-diagonal directions in the cubic phase, while they are all parallel to the b-axis of the orthorhombic lattice of the low temperature phase. Matsubara and Nagamiya[3] have calculated the lattice energies for both phases and have determined the transition point between them from the theoretical point of view. They have also calculated the potential barrier hindering the rotation of cyanide ions in both phases and concluded that the cyanide ions are subjected to hindered rotation with a barrier height of approximately 1.4 kcal. $mol^{-1}$ in the cubic phase. These results imply that the cyanide ions have an orientational entropy of $R \ln 8$ in the cubic phase. If one takes the difference between the carbon and the nitrogen atoms of the cyanide ion into consideration also, it may be expected that, when the crystal is cooled further, it will undergo another phase transition, one which corresponds to the orientational order-disorder rearrangement of the cyanide ion with respect to its head and tail. Otherwise, the crystal would have a residual entropy of $R \ln 2$ at the lowest temperature, as in the case of carbon monoxide[4] and nitrogen suboxide[5] crystals.

On the other hand, in the course of the X-ray structural analysis of the potassium cyanide crystal at the transition temperature range, Ubbelohde and his collaborators[6] have recently observed the occurrence of an intermediate phase which appears when the crystal is subjected to a composite temperature cycle around 168°K. The new phase has been reported to belong to the monoclinic system, which was eventually transformed into the stable orthorhombic system at about 158°K when the crystal was cooled and to the stable cubic system at 166°K when it was heated. They also found the co-existence of various domains of the low temperature form in "hybrid" single crystals, as well as of domains of the low and high temperature forms over a range of temperatures.

The object of the present research was to study the thermal properties of the stable potassium cyanide crystal at lower temperatures and also those of the above-mentioned new phase around the transition region.

## Experimental

"Pro analysi" potassium cyanide (Merck reagent) was recrystallized twice from an absolute methyl alcohol solution by evaporating it under a stream of nitrogen gas.[7] The purity of the sample was assured by the method of purification.[7] The specimen was dried in a vacuum ($10^{-5}$ mmHg) at 110—130°C for several hours. In a spectrochemical analysis of the specimen, the only metallic impurities found were traces of silicon, manganese and iron, all less than 0.05 per cent. The predominant impurity was the $CO_3^{2-}$ ion, since a fairly intensive C=O stretching vibration appeared on the infrared absorption spectra. The amount was analyzed by a comparison

of the intensity of the spectra with those involving a given amount of carbonate ions; it was thus revealed that the specimen used for heat capacity measurement contained 0.3 per cent of $CO_3^{2-}$ ions. In order to avoid possible contamination by humidity and carbon dioxide in the air, the procedure of transferring the sample was carried out in a vacuum-type dry-box under an atmosphere of nitrogen gas.

All measurements were made on a single loading of 20.5785 g. or 0.31596 mol., taking 65.120 as the molecular weight of potassium cyanide. The heat capacity was measured in the temperature range from 15 to 310°K by means of a low-temperature adiabatic calorimeter, the details of which have been reported previously.[8]

The occurrence of the intermediate, monoclinic phase was re-examined by a differential thermal analysis (DTA) apparatus[9] that operates automatically at low temperatures.

In order to follow the appearance and disappearance of the domains around the transition temperature, the intensity of natural light with a wavelength in the neighborhood of 5000Å transmitted through the crystal was measured by means of a photo-tube. A schematic diagram of the apparatus is given in Fig. 1. Specimen B in the disk

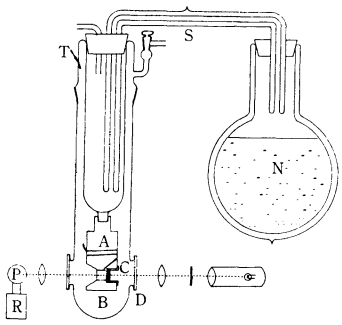

Fig. 1. Schematic diagram of apparatus for investigating transmission of natural light.

form is placed inside the hole fitted in a copper block, A, which is connected with the inside of a modified Dewar vessel by means of a "Housekeeper" seal so as to make vacuum tight. A fairly transparent disk specimen is obtained by compressing the powdered specimen, as in making infrared measurements of the KBr disk. In order to obtain better thermal contact, a thin film of "silicon" grease is coated over the edge of the specimen and the cap, C. In order to cool the crystal, cold gas from the storage vessel, N, containing liquid nitrogen was run through the transfer siphon, S. The temperature of the specimen was measured with a Chromel-P constantan thermocouple; it could be maintained for a long period of time within ±0.1°C at any temperature by adjusting the flow rate of cold gas. The photocurrent from a PL 50 V phototube was recorded on a voltage recorder.

## Experimental Results

**Heat Capacity.**—The observed heat capacity data are listed in Table I in chronological order. These values are expressed in terms of the defined thermochemical calorie, equal to 4.1840 absolute joules. The ice point is taken to be 273.15°K. The heat capacities listed in the table are the ratios of the increase in enthalpy, $\Delta H$, to the rise in temperature, $\Delta T$. Also listed in Table I are the values of the approximate temperature rise in each measurement. The temperature given for each point is the arithmetic mean of the initial and the final temperatures. These results are plotted graphically in Fig. 2.

Series I comprises several exploratory measurements after the initial cooling of the calorimeter to liquid nitrogen temperatures. The calorimeter was then cooled to 12°K and the data of series II taken. In this measurement a new heat capacity anomaly was found at about 83°K. In order to define more closely the shape and the reproducibility of the curve in the anomalous region, measurements of series III were made. No evidence was found from the measurements for checking the dependence of the observed heat capacity on the thermal history of the sample, and the points obtained from all the series coincide with each other within the expected range of error. In the neighborhood of the maximum heat capacity, there was no evidence of sluggishness in the attainment of thermal equilibrium.

Series III also involves the upper thermal anomaly, corresponding to the orthorhombic-cubic phase transition reported previously by Bijvoet et al.[1] and Ziegler et al.[2]

Parallel to the heat capacity measurements, the occurrence of the intermediate, monoclinic phase around the upper transition temperature was re-examined by the DTA method. The results are reproduced in Fig. 3. Run 1 shows a heating curve up to about 30°C higher than the transition temperature, and run 2 is for the subsequent cooling curve. Runs 3, 4 and 5 all give heating curves which follow just after runs 2, 3 and 4 respectively are over. In this process, a new upheaval appears a few degrees below the orthorhombic-cubic transition temperature. As the temperature cycles are repeated further, this lower component of thermal anomaly increases with the consumption of the upper component, which eventually disappears (see run 5). Run 6 corresponds to the cooling curve just after the repeated temperature cycles; this is same procedure as that adopted by Ubbelohde et al.[6] Accordingly, the broad thermal anomaly located at about

158°K corresponds to the monoclinic-orthorhombic transformation. These results agree well with the X-ray findings by Ubbelohde et al.

The monoclinic-cubic transformation was then studied more precisely by the calorimetric method. The results are grouped as series IV. The heat capacity anomaly corresponding to this transformation is plotted in Fig. 4, together with those for the orthorhombic-cubic transformation. In the neighborhood of both heat capacity maxima, the rate of attainment to the equilibrium was too slow for the final

TABLE II. TEMPERATURES, ENTHALPIES AND ENTROPIES OF TRANSITIONS OF KCN CRYSTAL

| Monoclinic-cubic transition | 166.5±0.1 | 291 ±5 | |

state to be reached in a reasonable period of time. The heat capacity values in these regions are, therefore, inferior in accuracy to the other results.

The heat capacity in the cubic phase keeps essentially a constant value. Such temperature-independent behavior of the heat capacity in the cubic phase has also been found by us in other alkali cyanides;[10] for example, sodium cyanide, rubidium cyanide, cesium cyanide and thallium cyanide. These results will be reported in the near future.

The only data available for comparison with these results are the measurements by Ziegler and Messer[2] on potassium cyanide from 100 to 340°K. Their data deviate 1.5 per cent at 100°K and are 2 per cent lower at 300°K than ours.

The lower anomaly in heat capacity, which has not been observed hitherto, has the lambda shape characteristic of processes where a co-operative ordering is taking place. The question as to whether the curve near the maximum is continuous, or cusped, can not be unambiguously decided on the basis of the present data. Because of the finite temperature increment in an individual measurement, it appears that a cusped curve would be smoothed out. It appears from a magnified scale plot of the data in the immediate neighborhood of the maximum that the data are better represented by a smooth curve, taking into account the finite resolution and precision of the measurement. The heat capacity reaches a maximum value of 17.25 cal. mol$^{-1}$ deg$^{-1}$ at 82.9±0.2°K.

The temperatures, enthalpies, and entropies of the phase transition are summarized in Table II. The transition temperature was taken as the one where the heat capacity reached a maximum value. The enthalpy of the transition was evaluated by integrating the excess heat capacity over the normal heat capacity, represented by the dotted line in Fig. 2. The method of estimating the normal heat capacity will be described later. The enthalpy of the transition, corresponding to the monoclinic-cubic transformation, was evaluated by assuming that the heat capacity of the monoclinic crystal had the same value as that of the orthorhombic crystal. It follows immediately that the enthalpy of the intermediate, monoclinic form is higher than that of the orthorhombic form by 53.9±0.5 cal. mol$^{-1}$ at 159.6°K.

A short comment should be added here about the small hump in the heat capacity observed around 190°K. This anomaly is very broad and so small as to make it almost invisible in Fig. 2. Six series of heat capacity measurements were made to ascertain its reality on specimens having different thermal history. These results are omitted from Table I, since they are reproduced in Fig. 5 on a magnified scale. It is of interest to point out that this thermal anomaly appears only for the cubic crystal which has been brought into the orthorhombic or the monoclinic phase prior to the measurement. This endothermic anomaly is presumable associated with some higher-order structural defect created by the phase transition.

**The Thermal Transition of the Transparency around 168°K.**—Successive temperature cycles for the transmission of the disk specimen are recorded in Fig. 6. The transmission is plotted on an arbitrary scale, taking the room temperature form value as 100. The curve also affords a sensitive way of following the progress of the transformation. By taking readings at intervals and at a constant temperature, it was found that an equilibrium was attained for a considerably long time in the neighborhood of the transition point. There is a wide

hysteresis loop in the thermal transition of the transparency. Similar results were also obtained for the monoclinic-cubic transformation. The transition point on heating, taken as the maximum slope temperature of the transmission curve, does not agree exactly with the results of heat capacity measurement. The difference seems to be due to the less accurate temperature measurement resulting from the poorer thermal contact in this apparatus. The difference seems also to be due to the disk specimen employed, which may presumably not be free from the strain sustained when it is pressurized to form the disk. The width of this hysteresis loop is, however, consistent with those of the X-ray results obtained by Ubbelohde et al. and of the thermal findings by DTA.

## Thermodynamic Properties of Potassium Cyanide

The values of the heat capacity, the entropy and the enthalpy and Gibbs energy functions of the potassium cyanide crystal at selected temperatures are listed in Table III. The values of $C_p^\circ$ were determined at round temperatures on the smoothed curve drawn through the measured heat capacity data. These values may well be regarded as the true differential heat capacity, except for the anomalous regions, where they change very rapidly and require correction for curvature. In order to make the extrapolation to the absolute zero of temperature, plots were made of $C_p/T^3$ against the temperature in the range from 13 to 40°K. The extrapolated contribution to the entropy below 15°K is merely 0.307 cal. $mol^{-1}$ $deg^{-1}$.

The error of the smoothed heat capacity data is estimated as 2 per cent at 20°K and 0.3 per cent above 50°K. Although the in-

accuracy of the functions $S^\circ$, $(H^\circ-H_0^\circ)/T$ and $-(G^\circ-H_0^\circ)/T$ is about 0.3 per cent above 50°K, the numbers in Table III are given to a higher precision than this so that they will be internally consistent.

## Discussion

**Thermal Anomaly around 190°K.** —Concerning the nature of the upper phase transition at 168.3°K, Matsubara and Nagamiya[3] have proposed a suitable model, one upon which they calculated its transition point and obtained fairly satisfactory results. On this topic, therefore, there is further comment to be added. Here, however, a brief account may be given of the nature of the heat capacity anomaly around 190°K.

Ubbelohde and his collaborators[6] have found that the intermediate, monoclinic form was always produced by applying a particular, composite temperature cycle. This involved the direct cooling of a crystal from room temperature to below the transition temperature, then warming it to about 3°C above the transition onset temperature, and subsequently recooling it through the transition range. The intermediate form was never observed during any direct cooling. They also found that various

domains of the orthorhombic form co-exist when the crystal is directly cooled through the transition point. These observations led them to the conclusion that "scars," resulting from the effects of strain within the domains, exist in the cubic phase just above the transition point.

The "critical temperature," 3°C higher than the transition onset temperature, seems to depend markedly on the physical states of the crystal, as well as on the heating rate employed and on the period of time spent at that temperature. In fact, we have found from another series of DTA measurements that in the specimen raised even above 25°C higher than the transition temperature, followed by immediate recooling, the monoclinic form was formed, though the heating rate employed in this case, 0.5—0.8°C $min^{-1}$, is much higher than that of the heat capacity measurement, 0.03—0.1°C $min^{-1}$.

The heat capacity anomaly around 190°K seems to correspond exactly to the "critical temperature." The reasons are as follows. In the first place, this thermal anomaly appears only for the cubic crystal brought into the orthorhombic or the monoclinic crystal prior to the measurement. Two series of measurements made on a specimen cooled to just above the transition temperature showed no sign of heat capacity anomaly. Additional evidence is offered by the experimental findings on the thermal transition of the transparency. The transparency of the scarred cubic crystal is somewhat lower than one directly cooled from room temperature. The scarred cubic crystal seems, therefore, to be a state in which the inter-domain walls produced by the formation of the orthorhombic form are not perfectly recovered. This state persists to higher temperature but ultimately changes into the cubic crystal, losing its scars around the "critical temperature."

The free energy of a crystal can by no means be expressed fully by only its volume, temperature and pressure. It may be also a functions of the strain and of the internal surface energy[11] when the crystal is composed of "sub-structure" or domains. The excess free energy assumed in the scarred cubic crystal seems to be responsible for the preferential formation of the intermediate phase on subsequent recooling.

A simple calculation was made on the average size of domains, based on the assumption that the cyanide ion located at the domain surfaces had less configurational entropy by the amount of $k \ln 2$ than that of the bulk phase, and also on the assumption that the entropy increment at the "critical temperature" was caused by a gain in the entropy of such ionic groups. The total entropy change around 190°K, merely about 0.005 cal. $mol^{-1}$ $deg^{-1}$, combined with the above assumption, leads to the value of 4000Å for the average domain size. Although this rough estimation, neglecting entirely the contribution from vibrational aspects of the ions, has no significance other than as an order of magnitude, the derived value is well in the range estimated by the X-ray method.[6] In order to obtain more quantitative knowledge on the average size as well as on its distribution, single crystal and monochromatized light should be used.[12] Such an experiment is being planned in our laboratory.

**The Nature of the Phase Transition at 83°K.** —The heat capacity anomaly takes place over a wide temperature range, with a maximum at 82.9°K, and has the lambda shape characteristic of processes where co-operative ordering is taking place. This phase transition resembles in thermal properties the lower phase transition at 172°K in the sodium cyanide crystal.[2] In the orthorhombic phase ($D_{2h}^{25}$ Immm) of both crystal,[1,13] all the C-N bonds in cyanide ions are arrayed along the b-axis of the unit cell. The orientations of the cyanide ions with respect to its head and tail have not, however, been clarified in the present stage of X-ray structural analysis. Preliminary Debye-Scherrer photographs* taken below and above the lambda point of the potassium cyanide crystal indicate only that there is no appreciable change in the atomic arrangement of either phase. Similar results have been reported also for the sodium cyanide crystal.[14]

Such a minor change in structure may be explained by assuming that the co-operative rearrangement with respect to the head and tail of the cyanide ion takes place over the anomalous heat capacity region, since there is no appreciable difference in the atomic scattering factor between the carbon and nitrogen atoms. Thus, we may picture the temperature effect as follows. At the lowest temperatures, all the cyanide ions are arranged along the b-axis with a uniquely defined orientation (a completely ordered state), and as the temperature is raised, the flipping motion between the two orientations with respect to the head and tail of the cyanide ion is excited progressively;

at the transition point these two orientations of the cyanide ion become exactly equal energetically (a completely disordered state). The magnitude of the entropy change associated with this phase transition, which is nearly equal to $R \ln 2$ ($=1.38$ cal. mol$^{-1}$ deg$^{-1}$), affords strong support for such an explanation of the mechanism of the phase transition.

The mode of the relative arrangement of cyanide ions in the completely ordered state is, however, not exactly clear at the present stage. Preliminary calculations involving the dipole-dipole interaction among the cyanide ions of the potassium cyanide crystal suggest strongly that the polar structure of the cyanide ions along the b-axis (space group; $C_{2v}^{20}$ Imm2) seems to be the most stable.** This polar structure was also suggested by Siegel[14] for the lowest modification of the sodium cyanide crystal.

**The Torsion-Rotational Motion of Cyanide Ions.**—In order to get more detailed knowldge about the thermal motion of cyanide ions in the crystalline state, the Eucken-Morrison type of analysis was applied to the present case. In the first place, the heat capacity at a constant volume, $C_v$, was computed from the observed $C_p$ value by the usual procedure. Here, the correction was made by use of the relation $C_p - C_v = 1.1 \times 10^{-5} C_p T^2$, the numerical factor being estimated rather arbitrarily.[2] It may easily be seen that this crystal has $6N$ degrees of the translational freedom, $2N$ degrees of the torsional or the rotational freedom, and $N$ degrees of the internal-vibrational freedom of cyanide ions. The contribution from the last freedom to the heat capacity was evaluated by the Einstein function, using the wave number of 2085 cm$^{-1}$, obtained by the infrared spectroscopic method.[15] This vibrational heat capacity does not contribute in any significant degree within the temperature range measured. After subtracting this contribution from the total, the apparent Debye temperature $\Theta_D$ was calculated on the assumption that the other $8N$ degrees of freedom could be represented by a single Debye temperature. The $\Theta_D$ value thus obtained is given in Fig. 7 as a function of the temperature. The influence of the phase transition on this $\Theta_D$ - $T$ curve is much more sensitive than that on the heat capacity curve itself, so the ambiguities in the estimation of the "normal" lattice part of the heat capacity are considerably reduced when we utilize

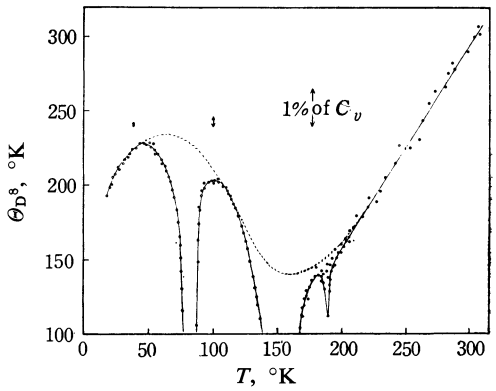

Fig. 7. Debye temperature versus temperature curve of KCN crystal, taking degree of freedom as 8.

$\Theta_D$ - $T$ relationship for this purpose. The assumed dotted line in this figure is for the temperature variation of the normal heat capacity. The procedure adopted above for estimating the normal heat capacity is, of course, not severely rigorous, but it may be nevertheless looked upon as a convenient method for determining the effect of phase transitions on the total heat capacity.

Having excluded the effect of the phase transition, we shall now try to separate the torsion-rotational heat capacity. The principal difficulty encountered in an analysis of a heat capacity curve in an effort to determine frequencies other than those of the lattice vibration arises from the necessity for an accurate representation of the heat capacity of the lattice itself. This difficulty is minimized by assuming that the contribution from the translational degree of freedom to the heat capacity of the present crystal is well represented by the heat capacity of a suitable alkali halide crystal. The $\Theta_D$-$T$ curves of potassium chloride and potassium bromide[16] were selected as references since they are crystals of a similar nature with no torsional degree of freedom. Figure 8 summarized the variations of the Debye temperatures for potassium chloride, potassium bromide and potassium cyanide crystals. In this figure, the wide temperature variations of $\Theta_D$ for potassium chloride and potassium bromide crystals are a consequence of the procedure in which the heat capacity of the alkali halide crystal, with $6N$ degrees of freedom, is expressed by a single Debye temperature. It is presumably possible to describe the total heat capacity by a combination of the Einstein function with a single value of the Einstein temperature for the $3N$ degrees

** The results of our calculations will be given in a later paper. At any rate, it is desirable to determine the ordered arrangement of cyanide ions by an experimental method such as the neutron diffraction technique.

of freedom (optical modes), and the Debye function with a single value of the Debye temperature for the other $3N$ degrees of freedom (accoustic modes), both characteristic temperatures being temperature-insensitive. If one assumes only $6N$ translational degrees of freedom in the computation of the $\Theta_D$ of the potassium cyanide crystal, one obtains a steeply declining curve (the $F=6$ curve in Fig. 8). This decrease can be regarded as the result of a progressively-increasing torsional contribution of the cyanide ions. The hypothetical $\Theta_D$ curve of potssium cyanide, if there were no torsional modes, would go somewhere between the $\Theta_D$ curves of potassium chloride and potassium bromide. Two curves (KCN-A and KCN-B) in Fig. 8 are such hypothetical extrapolations from the low temperature region; this seemed to be a reasonable spread. Actually, the choice of either of the two does not make any significant difference in the evaluation of the torsion-rotational contribution, since $\Theta_D$ is far more sensitive than the heat capacity itself.

In Fig. 9 we compare the calculated and the observed torsion-rotational heat capacities. In the low temperature region, the observed torsional heat capacity values lie well on the calculated curve based on the model of two independent harmonic oscillators with the wave number of $160\,cm^{-1}$. For the harmonic oscillator approximation, this torsional frequency corresponds to 7.5 kcal. $mol^{-1}$ of barrier height if we employ the usual cosine-type hindering potential. As the temperature is raised, the difference between them becomes progressively more conspicuous; there can never be any model which explains the difference as long as we retain a simple harmonic oscillator model. One satisfactory explanation of the torsion-rotational heat capacity may, however, be given by a hindered rotator model. It is well known by Pitzer's treatment[17] that the heat capacity of a hindered rotator can rise to a maximum value greater than $R$ cal. $deg^{-1}$ per rotational degree of freedom and then falls off with an increase in the temperature, approaching the $1/2\,R$ cal. $deg^{-1}$ per degree of freedom, the value for a classical free rotator.

This treatment was recently extended to the two-dimensional hindered rotator by Stepakoff and Coulter[18] with adequate approximations. The application of their results to the present case shows that the rotational heat capacity in the cubic phase may be well represented by the contribution from the two-dimensional hindered rotator with a barrier height of 1.30—1.35 cal. $mol^{-1}$ over a wide temperature range. This barrier height agrees well with the theoretical calculation by Matsubara and Nagamiya.[3] (In passing, we should like to point out that a recent study of the potassium cyanide crystal by Elliott and Hastings,[19] using neutron diffraction techniques, led them to the conclusion that the free rotational model is satisfactory for the cubic phase. Their analysis, however, has entirely neglected the Debye-Waller temperature factor in calculating the intensity data. Accordingly, we may say that their model may not be looked upon as conclusive.)

17) K. S. Pitzer and W. D. Gwinn, *J. Chem. Phys.*, **10**, 428 (1942).
18) G. L. Stepakoff and L. V. Coulter, *J. Phys. Chem. Solids*, 1435 (1963).
19) N. Elliott and J. Hastings, *Acta Cryst.*, **14**, 1018 (1961).

The rotational heat capacity data in the intermediate temperature region, however, can never be represented by a single value of barrier height, even with the two-dimensional hindered rotator model. It varies continuously from 7.5 kcal. $mol^{-1}$ at 60°K to 1.40 kcal.$mol^{-1}$ at 168°K. This continuous variation in barrier height merely reflects the continuously varying estimated "normal" heat capacity. Actually, the barrier height would change abruptly with the phase transition phenomenon accompanying an abrupt volume change. Although such variation in the barrier height can not be clarified quantitatively and in detail by an analysis of the heat capacity data alone, and although the present model is merely a very simple one, a variation in barrier height with the temperature does not seem to be at all improbable. Actually, the crystal is subject to thermal expansion in a single phase, and the lattice parameter changes abruptly at the transition point. A simple calculation of the hindering potential demonstrates easily that a slight decrease in the lattice constant causes a marked change in the barrier height, since the repulsive part of the hindering potential varies with the inter-atomic distance, $r$, in the $r^{-9}$ form.[20] Such situations differ distinctly from the case of the internal hindered rotation of methyl groups in ethane, for example, where the hindering potential arises from its intramolecular interaction and is, therefore, very insensitive to the temperature variation.

These results may be summarized as follows. In the lowest temperature region, the cyanide ions undergo torsional oscillation with the wave number of 160 $cm^{-1}$. As the temperature is raised, this torsional motion is gradually excited, the barrier height diminishing gradually in a single phase or abruptly via the transition points; the torsional motion changes into a hindered rotational motion with a barrier height of approximately 1.35 kcal. $mol^{-1}$ in the cubic phase, and eventually into the state of free rotation at much higher temperatures.

## Summary

The heat capacities of the potassium cyanide crystal have been measured over the temperature range from 13 to 310°K by using a low temperature adiabatic calorimeter. It has been found that there are two regions of anomalous heat capacity, with maxima at 82.9±0.2°K and 168.3±0.1°K respectively. The heats and entropies of transition have been evaluated by utilizing a $\Theta_D$-versus-temperature plot. The entropy of the lower transition amounts to about $R \ln 2$, which means that the transition is due to the orientational order-disorder rearrangement of the cyanide ion with respect to its head and tail. A perfectly-ordered structure for the orientation of the cyanide ions has been suggested. A certain small anomaly in heat capacity has been found around 190°K, one which seems to be associated with some change in higher-order structural defects created by the upper transition phenomenon.

The torsion-rotational heat capacity of the cyanide ions has been separated from the total on some reasonable assumptions. The results show that the cyanide ions below the lower transition point are subjected to torsional oscillation with the wave number of about 160 $cm^{-1}$, a value which corresponds to the barrier height of 7.5 kcal. $mol^{-1}$ based on a simple harmonic oscillator model. On the other hand, they are in a hindered rotational state with a barrier height of approximately 1.35 kcal. $mol^{-1}$ in the cubic phase, the barrier height diminishing from 7.5 kcal. $mol^{-1}$, gradually in a single phase or abruptly via the transition points.

The thermodynamic functions for this crystal have been evaluated by integrating the heat capacity data. The values at 298.15°K are, in units of cal. $mol^{-1}$ $deg^{-1}$: $C_p^\circ = 15.84$, $S^\circ = 30.71$, $(H^\circ - H_0^\circ)/T = 13.94$ and $-(G^\circ - H_0^\circ)/T = 16.77$ respectively.

The authors wish to express their deep thanks to Mr. Nobukatsu Fuzino of the Sumitomo Metal Manufacturing Co., Ltd., for taking care of the spectrochemical analysis.

# Phase Transition in the Ammonium Bromide Crystal: The Thermal Motion of the Ammonium Ion*

By Michio SORAI, Hiroshi SUGA and Syûzô SEKI

(Received November 4, 1964)

Ammonium halide crystals are well-known as typical substances which exhibit various kinds of polymorphism in the solid state. Among them, it has been established that in bromides[1-6] the following transformations occur:

$NH_4Br$: Phase I (NaCl) $\xrightarrow{411°K}$ Phase II (CsCl) $\xrightarrow{235°K}$ Phase III (tetragonal) $\xrightarrow{108°K}$ Phase IV (CsCl ?)

$ND_4Br$: Phase I (NaCl) $\xrightarrow{398°K}$ Phase II (CsCl) $\xrightarrow{215°K}$ Phase III (tetragonal) $\xrightarrow{169°K}$ Phase IV (CsCl)

It is noticeable that $ND_4Br$ again takes the cesium chloride modification when it is cooled down through the tetragonal phase to a lower temperature. Stephenson and Adams[5] reported a new transition in ammonium bromide also at about 78°K on cooling and at about 108°K on warming. This seems to correspond to the transformation at 169°K in $ND_4Br$.[6] The possibility of the occurrence of this transition was also confirmed by Stevenson[7] through high-pressure experiments. Concerning the present material, Simon et al.[1] measured the heat capacity in the temperature range from −70°C to room temperature. Although Stephenson and Adams[5] reported briefly on the discovery of the new transition, as has been mentioned above, they have not yet published any detailed data on the heat capacities.

The purpose of our present investigation is to obtain detailed thermal data on ammonium bromide in the temperature range from 13°K to 305°K, and, in particular, to study the rotational motion or the torsional vibration of ammonium ions in crystals by analyzing our thermal and infrared data.

## Experimental

**Material.** — A chemically pure-grade reagent ammonium bromide (Wakō Pure Chemical Industries, Ltd.) was recrystallized twice from distilled water and then sublimed under a vacuum of $10^{-4}$ mmHg at about 240°C. The specimen obtained was further recrystallized from distilled water and dried under a vacuum at about 50°C for several hours. About 30 g. of the specimen was then packed into the calorimeter cell.

For the measurement of the infrared absorption spectra, thin films of ammonium bromide on a rocksalt plate were used. The film was prepared by subliming the purified ammonium bromide through a loose glass wool plug onto a polished rocksalt plate under a pressure of about $10^{-2}$ mmHg at 110—130°C.[8]

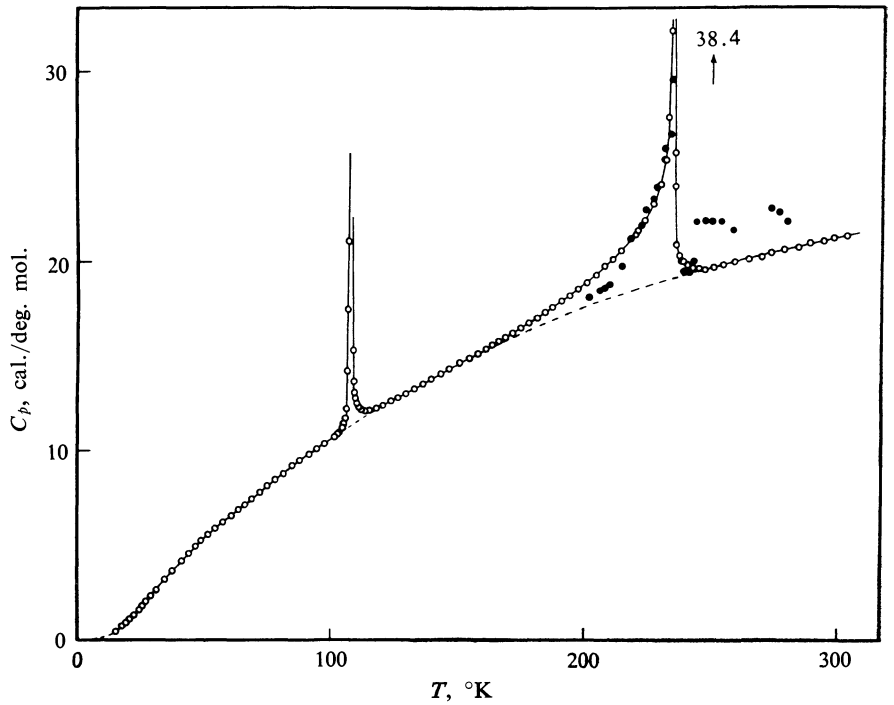

Fig. 2. Heat capacities of $NH_4Br$ between the temperature range from 13°K to 305°K.
Broken lines represent "normal" heat capacity.
○ This work, ● Simon et al. (1927)

**Apparatus.**—The heat capacity measurements were carried out by the low-temperature automatic and adiabatic calorimetry techniques. A detailed description of them has already been given in the previous paper.[9]

The infrared spectra were recorded on a Nihon Bunkō Co. Double-beam spectrometer (model DS-402G). The cryostat for a low temperature measurement is illustrated in Fig. 1.

## Results

**The Heat Capacities of Ammonium Bromide.**—The heat capacities of ammonium bromide were measured in the temperature range from

9) H. Suga and S. Seki, This Bulletin, 38, 1000 (1965).

13 to 305°K. The calorie defined as equal to 4.1840 absolute joules was used. The ice-point temperature was taken as 273.15°K. The calorimeter contained 28.5387 g. (0.29136 mol.) of ammonium bromide and helium gas for heat exchange. The experimental heat capacities, listed in Table I, are the ratios of the increase in enthalpy, $\Delta H$, to the rise in temperature, $\Delta T$, and are equal to the differential heat capacity, $C_p$, only when the correction for curvature is negligible. Also listed in Table I are $T_{av}$, the arithmetic mean of the initial and the final temperatures of each measurement, and the approximate temperature rise, $\Delta T$. Our values for the heat capacities of ammonium bromide, together with those of Simon, von Simson, and Ruhemann,[1] are plotted in Fig. 2. We thus reconfirmed the new transition phenomenon reported by Stephenson, and also an unusually wide hysteresis effect associated with it. Here the broken lines are drawn as the "normal" heat capacity. The method of estimating these broken lines will be described later. We can see that the values given by Simon et al. are considerably scattered, so we are convinced that our values are much more accurate.

Anomalous heat capacities arising from the gradual phase transition at 235°K are reproducible in the repeated measurements. In the temperature region of normal heat capacity, including the anomalous region around 235°K, the calorimeter attained thermal equilibrium within a few minutes after an individual energy input. In the transition region at 108°K, however, the calorimeter established the thermal equilibrium only with difficulty, even after several hours. The approach to the thermal equilibrium in this region is compared with

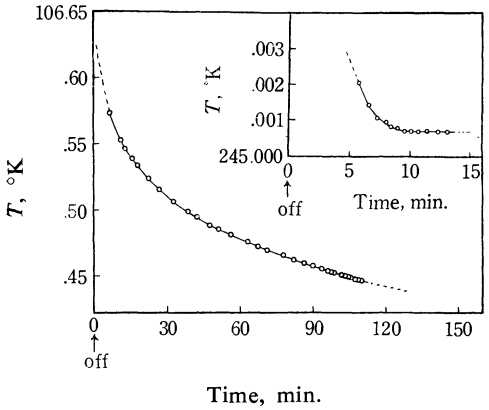

Fig. 3. Typical temperature drift curves showing behavior approaching to thermal equilibrium after an energy input. Upper one; ordinary temperature region. Lower one; transition region at 107.5°K.

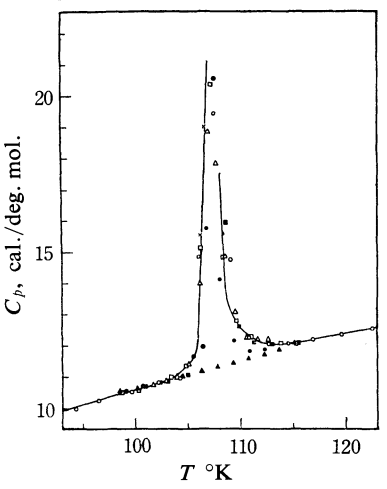

Fig. 4. Heat capacity of $NH_4Br$ around the phase transition at 107.5°K.

that of a normal case in Fig. 3 for the sake of reference. The measurements of the heat capacity of ammonium bromide in the anomalous region around 108°K are plotted in Fig. 4. In this region the heat capacity values are not as accurate as in normal temperature regions.

**The Thermodynamic Properties of Ammonium Bromide.**—Smoothed values of the heat capacity, entropy, enthalpy, and Gibbs energy functions, and also of the standard thermodynamic values at 298.15°K, are listed in Table II. The differential heat capacity, $C_p^\circ$, listed in the table, which is obtained from the observed values of $\Delta H/\Delta T$, was not corrected for curvature because of the small rise in temperature, $\Delta T$.

**The Anomalous Heat Capacities of Ammonium Bromide at 235°K and 108°K.** — As is shown in Fig. 2, the heat capacity anomaly around 235°K covers a considerable temperature range, so there is some latitude in drawing a broken curve to obtain the normal heat capacity. To subtract the anomalous part, it is often useful to describe the heat capacity of a solid in terms of the Debye function. For this purpose, the experimentally-observed heat capacities, $C_p$, were represented by the apparent Debye characteristic temperature, $\Theta_D$, with arbitrary degrees of freedom. The Debye characteristic temperature is known to be more sensitive than the heat capacity itself for the same amount of uncertainty in the heat capacity. Figure 5 shows the temperature dependence of the apparent Debye characteristic temperature, ${}_{12}\Theta_D$, the degrees of freedom

being assumed to be twelve. The broken lines in Fig. 5 are assumed to represent reasonably the course of the normal Debye characteristic temperature corresponding to the normal heat capacity. The enthalpy and entropy of transition, $\Delta H_{tr}$ and $\Delta S_{tr}$ respectively, the transition temperature, $T_{tr}$, and the transition range are given in Table III. The heat of transition was evaluated from the combined method of total heat input analysis and graphical integration.

**Infrared Spectra at Low Temperatures.**—The infrared spectra of thin, non-scattering films of ammonium bromide were obtained at 298°K (phase II), 100°K and 88°K (phase III), and

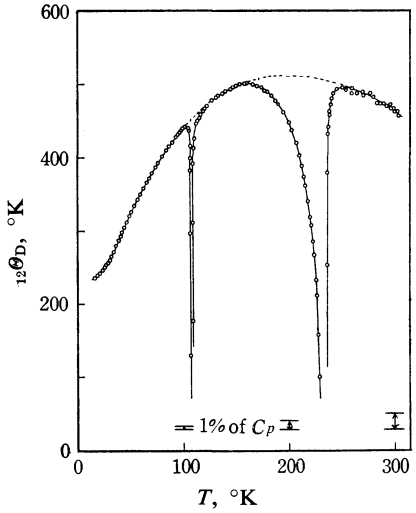

Fig. 5. The temperature dependence of the apparent Debye characteristic temperature, $_{12}\Theta_D$, where the degrees of freedom is arbitrarily chosen to be twelve.

40°K and 18°K (phase IV) respectively. The temperature of the specimen in the low temperature region was measured with an Allen-Bradley carbon resistance thermometer (nominal 47Ω, 1/10W.) which had been calibrated previously by using Clement-Quinell's equation. The two constants in this equation were determined by means of the resistance values at fixed temperatures, the boiling points of liquid helium and nitrogen. A copper: constantan thermo-couple, calibrated with a standard platinum resistance thermometer,[9] was used in the temperature region above the boiling point of liquid nitrogen.

The Wagner-Hornig assignments were employed for the analysis of the torsional frequency of the ammonium ion. The observed and inferred frequencies are summarized in Table IV. The spectrum of ammonium bromide in phase IV at 18°K is illustrated in Fig. 6 as an example. The combination band,

(a) In these cases the specimen was cooled from room temperature down to these temperatures and did not experience the phase transition at about 78°K.
(w) Very weak shoulder.

($\nu_4'$ or $\nu_4$) + ($\nu_6'$ or $\nu_6$), gets sharper gradually and the fine structures appear progressively as the sample is cooled.

## Discussion

The degrees of freedom contributing to the heat capacity at a constant pressure, $C_p$, for the ammonium halide crystal may be the following: $6N$ degrees for translational freedom (lattice vibrations ($C_v^L$)); $9N$ degrees for internal vibrations ($C_v^I$); $3N$ degrees for torsional vibrations of ammonium ions ($C_v^t$); and $C_p-C_v$ correction. The heat capacity, $C_p$, is then given by:

$$C_p=C_v^L+C_v^I+C_v^t+(C_p-C_v) \quad (1)$$

We should like to discuss each term on the right hand side of Eq. 1 separately.

**$C_p-C_v$ Correction.**—The quantity measured is the heat capacity at a constant pressure; this is the basic result from which other quantities may be derived. The heat capacity at a constant volume, which is the quantity most suitable for comparisons with available theory, may be computed from the well-known thermodynamic relation:

$$C_p-C_v=\alpha^2VT/\chi \quad (2)$$

where $\alpha$ is the cubical coefficient of thermal expansion; $V$, the molar volume, and $\chi$, the isothermal compressibility. Unfortunately, thermal expansion and compressibility data are incomplete in the present temperature region. Therefore, it is necessary to have recourse to the quasi-thermodynamic relation:

$$C_p-C_v\simeq AC_p^2T \quad (3)$$

where $A$ is a constant. From Eqs. 2 and 3, the constant $A$ is determined:

$$A\simeq\alpha^2V/\chi C_p^2 \quad (4)$$

The numerical value of the constant, $A=9.547\times10^{-6}$ mol./cal., was computed from the following values at 0°C:

$$\alpha^{10,11)}=16.20\times10^{-5}\ deg^{-1}$$

$$\chi^{12)}=6.188\times10^{-6}\ cm^2/kg.$$

$$V^{10,13)}=40.107\ cm^3/mol.$$

$$C_p=20.435\ cal./deg.\ mol.$$

The differences between $C_p$ and $C_v$ were calculated from Eq. 3.

**Internal Vibrations in Ammonium Ions ($C_v^I$).**—The contributions of the internal vibrations in ammonium ions to the heat capacity are usually best represented by the summation of the Einstein functions corresponding to the normal vibrational modes. That is:

$$C_v^I=\sum g_iE(\Theta_{E_i}/T) \quad (5)$$

where the summation is extended over the

nine normal vibrational modes, the degeneracy, $g_i$, being taken from Wagner-Hornig's data[8] and $\Theta_{E_i}=h\nu_i/kT$. Their values are:

$\nu_1=3040\,cm^{-1}$ (degeneracy 1); $\nu_2=1640$ (2); $\nu_3=3130$ (3), and $\nu_4=1410$ (3).

**Correction for Thermal Expansion.** — The quantity, $C_v$, mentioned above corresponds to the heat capacity at a constant volume at each temperature. For comparisons with available theory, this quantity, $C_v$, must be reduced to a fixed volume at 0°K. The heat capacity at a constant volume less the contribution from internal vibrations is $C_v^L+C_v^t$. The quantity $C_v^L+C_v^t$ is represented by the apparent Debye characteristic temperatures, ${}_9\Theta_D(V_T)$, for nine degrees of freedom, as a function of the temperature. In order to reduce the ${}_9\Theta_D(V_T)$ values to the volume at 0°K, the following approximate formula is used:

$$ {}_9\Theta_D(V_O)/{}_9\Theta_D(V_T)=(\rho_O/\rho_T)^\gamma=(V_T/V_O)^\gamma \fallingdotseq 1+\gamma\Delta V/V_O \qquad (6) $$

where $V_O$ and $\rho_O$ are, respectively, the volume and density at 0°K, and $\gamma$ is the Grüneisen parameter defined by Kittel[14] as follows:

$$ \gamma=\alpha V/\chi C_v \qquad (7) $$

For lack of data on the temperature dependence of the molar volume and the Grüneisen parameter for ammonium bromide, we assumed that the behavior of the temperature dependence for ammonium bromide would be similar to that for potassium bromide.[15] The absolute values of $V_T$ and $\gamma$ for ammonium bromide, which, of course, are different from those for potassium bromide, are calculated by multiplying the factors determined at 0°C. The magnitude of the correction for ammonium bromide is illustrated in Fig. 7.

**The Torsional Frequency of the Ammonium Ion and the Potential Barrier.**—As has already been mentioned, the bromide in phase IV (below 107.5°K) may be regarded as of the CsCl-type on analogy with the neutron diffraction study[2] of deuterated ammonium bromide. In contrast to the same modification at room temperature, here the orientation of tetrahedral ammonium ions which are located at the center of a cube determined by eight halogen ions will be regularly ordered, and each ammonium ion will undergo torsional vibration about the two-fold symmetry axis of the ion in this modification.[2,16]

Recently Wulff[17] determined the barrier heights for the rotation of the methyl groups in some organic crystal by using the heat capacity data. Suga, Matsuo, and Seki[18] in our laboratory also estimated the torsional frequency of the $CN^-$ ions in the potassium cyanide crystal and discussed the contribution of the rotational vibration to the heat capacity. In both these cases, however, no direct comparison of the frequency determined from the thermal data with that determined from the spectroscopic data has been made. In the present case the pure torsional vibration of ammonium ions is spectroscopically inactive, but fortunately the quite sharp bands arising from the combination band can be observed. Therefore, there is a distinct possibility of a comparison of the torsional vibration frequency of $NH_4^+$ ions derived from the analysis of the thermal data with those obtained from the infrared and Raman data. Moreover, the potential barrier height hindering the internal rotation of the ammonium ion about the two-fold symmetry axis obtained from the thermal data for the solid phase may also be compared with the NMR data of Gutowsky, Pake and Bersohn,[16] and Sachs.[19]

For these purposes, we have tried the following analysis for phase IV, working below 107.5°K, because of the complicated effects due to the phase transitions and the anharmonicity of vibrations at higher temperatures. The heat capacity, $C_v(V_O)$, calculated from the Debye temperature, ${}_9\Theta_D(V_O)$, in Eq. 6 consists of the "translational" effect for six degrees of freedom and the "torsional vibration" for three degrees of freedom, with the fixed volume at 0°K. As we have no "a priori" methods for separating the contribution arising from the

torsional vibration and that from the translational motion, empirical assumptions are needed to calculate the torsional frequency and the potential barrier heights from the analysis of the thermal data. The first assumption is that the behavior of the temperature dependence of the Debye characteristic temperature, $\Theta_D$, which corresponds to the "translational heat capacity" of ammonium bromide, may be similar to those of alkali halides, the crystal structure of which is of the CsCl-type at low temperatures, as in the case of ammonium bromide. Cesium bromide and chloride presumably satisfy this condition. As we have no suitable thermal data, however, about cesium bromide and cesium chloride in hand, the data for potassium bromide[20] and rubidium bromide[21] are used for the sake of comparison, although the crystal structure of both compounds is of the NaCl-type. The temperature dependences of the Debye characteristic temperatures of potassium bromide and rubidium bromide are reproduced in Fig. 8. The curves for both compounds are almost flat in the temperature range between 50 and 140°K for potassium bromide, and from 40 to 90°K for rubidium bromide, which means that the Debye model is applicable to these substances in these temperature ranges. The contribution to the heat capacity arising from the torsional vibration of the $NH_4^+$ ion may be approximately represented by an Einstein function, $E(\Theta_E/T)$, for three degrees of freedom with an empirically-chosen $\Theta_E$. The "translational" or "lattice" heat capacity is then given by:

$$C_v^L = C_v(V_0) - E(\Theta_E/T) \qquad (8)$$

By trial and error, an adequate Einstein characteristic temperature, $\Theta_E$, was determined, so that the curve of the temperature dependence of the apparent Debye temperature, $\Theta_D$, corresponding to the heat capacity, $C_v^L$, might be flat in some temperature regions. The value of $\Theta_E$ determined in such a way is 490 ±10°K, which corresponds to the torsional oscillation of the $NH_4^+$ ion about its two-fold symmetry axes with the wave number of 340 ±7 cm$^{-1}$. The value of 340±7 cm$^{-1}$ is consistent with the infrared data obtained by us and by Hornig et al.[8] and also with Raman data[22] extrapolated to the lowest temperature (see Fig. 9). One can see that in Fig. 9 there are rather small but significant differences between the infrared frequencies and those of Raman data. According to the discussion by Wagner and Hornig,[8] the torsional vibration of the ammonium ion, the $\nu_6$ mode (triply degenerated in phases II and IV), splits into two components, $\nu_6(A_2)$ and $\nu_{6'}(E)$, in the tetragonal modification with the point group $V_d$ (phase III), the latter mode ($\nu_{6'}$) being active in both the infrared and Raman spectra. The Raman frequencies[22] shown in Fig. 9 are the fundamental vibrations ($\nu_{6'}$ mode). The infrared data, however, are the results of the analysis of the complicated combination bands, whose assignments have not yet been fully established. In fact, the combination band gets sharper gradually, and

20) W. T. Berg and J. A. Morrison, *Proc. Roy. Soc.*, **A242**, 467 (1957).

the fine structures appear progressively when the specimen is cooled down to a lower temperature. This band has a width of about 50 $cm^{-1}$ even at the lowest temperatures, so there is some uncertainty involved in resolving the combination bands into their component frequencies. In addition, the two spectra (infrared and Raman) should not be expected to coincide unless the coupling between ammonium ions is very weak.[8] Thus, one can not compare the absolute values of the two spectra directly until the complete assignment is established. Curve A in Fig. 9 represents approximately the temperature dependence of the torsional frequency as determined by an analysis of the combination bands. We can find that the frequency of the torsional oscillation shows almost no temperature dependence in the low temperature region. This fact justifies our treatment of the thermal data with a harmonic Einstein function. Curve B in the figure was drawn for the fundamental torsional oscillation by assuming the same temperature dependence as that of curve A in phase IV. The extrapolated fundamental values of the Raman data to the lowest temperatures compare quite well with those determined by the analysis of the thermal data. To check the results, it is also very desirable to measure the fundamental vibration in phase III (tetragonal modification) by the method of infrared absorption.

Now, we should like to proceed to the problem of the potential barrier. We have adopted the following potential function,[23] which is usually taken for such internal rotation or torsional oscillations as $CH_3$–, OH–, or $C_2H_5$– groups:

$$U(\phi)=\frac{1}{2}U_0(1-\cos n\phi) \tag{9}$$

where $\phi$ is the angle of rotation; $n$, the symmetry number; and $U_0$, the potential barrier height.

In the case of ammonium bromide, the symmetry number, "$n$," is approximately four, judging from the crystal structure. In phase II, the crystal structure of the ammonium bromide is of the CsCl-type. The orientations of the ammonium ions in this phase are found to be disordered. In the temperature region of phase III, the structure of the bromide is tetragonal[3,4] and the orientations are still in the ordered state. Below 107.5°K, the structure (phase IV) is of the CsCl-type and of the ordered orientations, analogous with the results of the neutron diffraction study[2] of deuterated ammonium bromide.

23) K. S. Pitzer, "Quantum Chemistry," Prentice-Hall, New York (1953).

As to the possible orientations of the tetrahedral ammonium ion which is located at the center of a cube determined by eight halogen ions, there are two possibilities. In the disordered phase II, these two orientations are equally probable and are distributed statistically at random over the whole lattice. On the other hand, in the ordered phase IV, all the ammonium ions have one and the same orientation.

In the disordered phase the symmetry number is exactly four, and the potential function is well represented by Eq. 9. In the ordered phase, however, the potential energy between two orientations is slightly different. The potential function, then, is better represented by:

$$U(\phi)=\frac{1}{2}U_0(1-\cos n\phi)+\frac{1}{2}U_1S\left(1-\cos\frac{1}{2}n\phi\right) \tag{10}$$

where $S$ is an order parameter concerning the orientations of ammonium ions, and $U_1$ is the potential energy difference between the two orientations at 0°K.

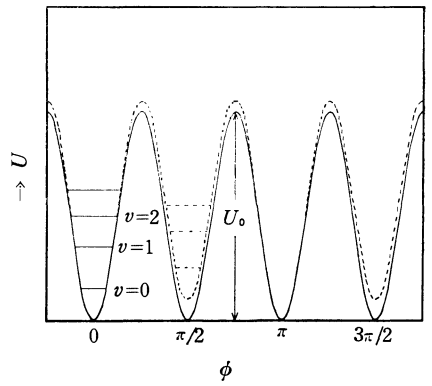

Fig. 10. Potential curves hindering rotation of ammonium ion about its two-fold symmetry axis.
——: $U(\phi)=(1/2)U_0(1-\cos 4\phi)$
----: $U(\phi)=(1/2)U_0(1-\cos 4\phi)+(1/2)U_1S(1-\cos 2\phi)$

The potential curves given by Eqs. 9 and 10 are illustrated in Fig. 10. Equation 10 requires knowledge about the temperature dependence of the $S$ parameter. We assumed also the periodic function, with $n=4$, even in the ordered phases (phases III and IV). When the ions undergo torsional oscillation at a low temperature, the angle of rotation, $\phi$, may be small. Then one can expand the potential function in a power series in $\phi$ as follows:

Table V. Potential barriers to rotation of the $NH_4^+$ ion in the ammonium halides (CsCl modification), in kcal./mol.

| Compound | $U_0$(Eq. 14) | $U_0$(elec.)[a] | $U_0(\nu)$[b] | $U_0(T_1)$[c] |
|---|---|---|---|---|
| $NH_4Br$ | 4.00±0.16 | 3.73 | 4.18 | 4.65 |
| $NH_4Cl$ | 6.24±0.26[d] | 5.40 | 5.25 | 6.41 |

a) These values are entirely from an electrostatic calculation; Refs. 15 and 17.
b) These results obtained from the observed torsional frequencies; Ref. 15.
c) $U_0(T_1)=E$(activation energy from $T_1$)$+(3/2)h\nu_{obs.}$; Refs. 15 and 16.
d) This value is calculated by using Eq. 14 and the smoothed $C_p$-curve determined by Simon.[1]

$$U(\phi)=\frac{1}{2}U_0\left(\frac{n^2\phi^2}{2!}-\frac{n^4\phi^4}{4!}+\frac{n^6\phi^6}{6!}-\cdots\right) \quad (11)$$

By using the first-order perturbation theory, the energy levels of this anharmonic oscillator are calculated to be:

$$E_v=h\nu_0\left(v+\frac{1}{2}\right)-\frac{1}{2U_0}\frac{1}{4!}(h\nu_0)^2(6v^2+6v+3)+\frac{1}{2U_0^2}\frac{1}{6!}(h\nu_0)^3(20v^3+30v^2+40v+15) \quad (12)$$

and

$$\nu_0=\frac{n}{2\pi}\sqrt{\frac{U_0}{2I}} \quad (13)$$

where $\nu_0$ is the frequency corresponding to the simple harmonic oscillator approximation; $I$ is the moment of inertia of the ammonium ion, and $v$ is the quantum number of the vibration.

If the torsional wave number $\nu=340\pm7\ cm^{-1}$, as determined from thermal data, is assumed to be the difference between $v=1$ and $v=0$, i.e., $h\nu=E_{v=1}-E_{v=0}$, then we have:

$$h\nu=h\left(\frac{n}{2\pi}\sqrt{\frac{U_0}{2I}}\right)-\frac{6h^2}{4!U_0}\left(\frac{n}{2\pi}\sqrt{\frac{U_0}{2I}}\right)^2+\frac{45h^3}{6!U_0^2}\left(\frac{n}{2\pi}\sqrt{\frac{U_0}{2I}}\right)^3 \quad (14)$$

and the potential barrier height, $U_0$, is 4.00± 0.16 kcal./mol. On the other hand, a simple harmonic oscillator approximation using Eq. 13 gives the value of $U_0=3.52\pm0.16$ kcal./mol., and the potential function given by Eq. 10 gives a value of several per cent[24] smaller than 4.00±0.16 kcal./mol.

In calculating the potential barrier height, the numerical values of $I=4.778\times10^{-40}$ g. cm$^2$, the N-H distance=1.035Å,[16] and $U_1=kT_C$ ($T_C=235$°K) were used.

Gutowsky, Pake, and Bersohn[16] and Sachs[19] calculated the potential barriers to rotation of the $NH_4^+$ ions in the ammonium halides (CsCl modification) by measuring the spin-lattice relaxation time, $T_1$, by means of NMR studies. They also estimated the potential barrier by electrostatic calculation. The values of the potential barrier obtained are all summarized in Table V. We ourselves determined the value of $U_0$ for ammonium chloride with the above-mentioned technique by using the heat capacity data of Simon[25] and Eq. 14.

**The Contribution of the Torsional Oscillation to the Heat Capacity.**—If the periodic potential function given by Eq. 9 is assumed, the heat capacity, $C_v^t$, arising from the torsional vibration is a function of the temperature, $T$, of the symmetry number, $n$, and of the potential barrier $U_0$; i.e., $C_v^t=f(n, U_0, T)$.

Pitzer and Gwinn[23] have tabulated the thermodynamic functions for the contribution of the rotation. By using their table instead of the Einstein function, $E(\Theta_E/T)$, we have computed $C_v^t$. Figure 11 shows two cases of the temperature dependence of the "torsional" heat capacities, $f(n, U_0, T)$ and $E(\Theta_E/T)$.

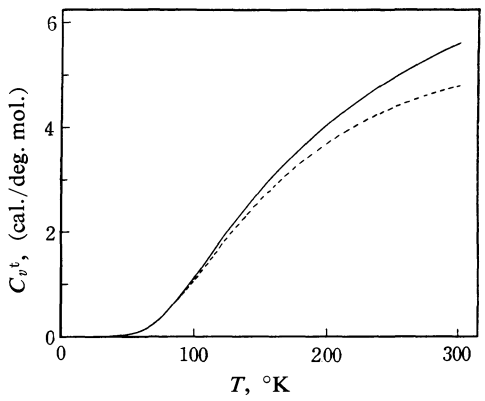

Fig. 11. Contribution from torsional oscillation to heat capacity.
——: $f(n, U_0, T)$, $n=4$, $U_0=4.00$ kcal./mol.
----: $E(\Theta_E/T)$, $\Theta_E=490$°K, $\nu=340\ cm^{-1}$

Finally, the "translational" or "lattice" heat capacity is computed by using this equation:

$$C_v^L=C_v(V_0)-f(n, U_0, T) \quad (15)$$

24) For instance, assuming $S=1$ and $U_1=kT_C$ for phase IV, we get a value of $U_0$ several per cent smaller than 4.00 ±0.16 kcal./mol.

25) F. Simon, *Ann. Phys.*, **68**, 241 (1922).

Figure 8 shows the temperature dependence of the Debye characteristic temperatures, $\Theta_D(V_O)$ and ${}_6\Theta_D(V_O)$, which correspond to the heat capacities $C_v^L$ and $C_v^L+C_v^t$ respectively.

**Phase Transition.**—As is well known, neutron diffraction studies,[2] and theoretical consideration[26] of the anomalous changes of the heat capacities, and also of various other physical quantities at the gradual phase transition point ($\lambda$-point) (235°K for the bromide and 243°K for the chloride), have confirmed that the transitions are of the order-disorder type with relation to the orientations of the $NH_4^+$ ions in the crystalline lattice. If the orientations of the $NH_4^+$ ions are fully disordered above the $\lambda$-point and are completely ordered below it, the treatment of the Bragg-Williams type by Nagamiya[26] requires $R\ln 2$ e. u. as the entropy of transition.

In the case of ammonium chloride, the crystal structure in phase III is of the ordered CsCl-type and that of phase II, of the disordered CsCl-type. Moreover, the volume change at the transition point is very small. Thus the observed transition entropy may be only the contribution from a co-operative phenomenon arising from the order-disorder nature. The observed value, $\Delta S_{tr}=1.2$ e. u.,[27] is nearly equal to $R\ln 2$, which thus confirming the validity of the interpretation.

In the case of ammonium bromide, however, the crystal structures below and above the $\lambda$-transition point are slightly different from each other. The observed entropy change consists of the contributions from the order-disorder phenomenon and from the difference between the lattice energies of the two modifications. Staveley[28] estimated the entropy change of 0.34 e. u. for ammonium bromide by using Simon's heat capacity data.[1] However, as has already been mentioned, this value is not very reliable. The entropy change obtained in our measurements is 0.714 e. u., which is still much less than $R\ln 2$. To interpret this feature in ammonium bromide, we may take into account the fact that the orientations of $NH_4^+$ ions in phase III are already disordered by a considerable amount far below the $\lambda$-point; we also have a lower temperature modification (phase IV) in the case of this substance, while in ammonium chloride there is no such intermediate state.

On the other hand, the phase transition at 107.5°K is very likely of the first-order type, in view of the wide hysteresis[29] phenomenon and the slow establishment of thermal equilibrium near the transition point.

## Summary

We have measured the heat capacities of the ammonium bromide crystal from 13°K to 305°K and have found two phase transitions in this temperature region. From the results, the heat and entropy of transitions at the transition points, 107.5°K and 235.0°K, have been derived: for the lower transition, $\Delta H_{tr}=29.29$ cal. mol.$^{-1}$ and $\Delta S_{tr}=0.271$ cal. deg$^{-1}$ mol$^{-1}$; for the upper one, $\Delta H_{tr}=156.1$ cal. mol$^{-1}$ and $\Delta S_{tr}=0.714$ cal. deg$^{-1}$ mol$^{-1}$. The values of the entropy and enthalpy function at 298.15°K are: $S^\circ=26.97$ cal. deg$^{-1}$ mol$^{-1}$ and $(H^\circ-H_0^\circ)/T=13.56$ cal. deg$^{-1}$ mol$^{-1}$. The torsional motions of the ammonium ions may well be represented in terms of a periodic potential function at the lowest temperature modification. The torsional frequency, $340\pm 7$ cm$^{-1}$, and the potential barrier height, $4.00\pm 0.16$ kcal. mol$^{-1}$, as determined on the basis of the thermal data, agree well with the values obtained in other experiments.

The infrared spectra of thin, non-scattering films of ammonium bromide have been obtained at 298°K, 100°K, 88°K, 40°K and 18°K. The torsional frequencies determined from the spectra by adopting Wagner-Hornig's assignments have been found to be almost independent of the temperature in the lowest modification.

The authors would like to express their sincere thanks to Dr. Takeshi Okuno of the Institute of Scientific and Industrial Research, Osaka University, who kindly permitted them to use and modify his cryostat for their spectroscopic measurement. The authors are also grateful to the members of their laboratory for their useful discussions.

## Note Added in Proof

(i) In order to interpret the small but significant difference between the torsional frequencies determined from infrared and Raman spectra, we measured the far-infrared spectra of ammonium bromide at about 100°K (phase III) and at room temperature (phase II) after the completion of

26) T. Nagamiya, *Proc. Phys. Math. Soc. Japan*, **24**, 137 (1942); **25**, 540 (1943).
27) C. C. Stephenson, R. W. Blue and J. W. Stout, *J. Chem. Phys.*, **20**, 1046 (1952).
28) L. A. K. Staveley, *Quart. Rev.*, **3**, 65 (1949).
29) Stephenson et al. found that this transition takes place at 108.5°K on heating and 78°K on cooling. We also reconfirmed the fact by differential thermal analysis.

this work. For the measurement a film of ammonium bromide on polyethylene plate was used. The spectra at 100°K show two peaks reproducibly; one is a considerably intensive peak at 345 $cm^{-1}$ and the other is a weak one at 335 $cm^{-1}$. These two peaks, however, vanish at room temperature. From these facts, two peaks might be concerned with the active fundamental torsional frequency predicted by Wagner and Hornig.[8]

The authors would like to express their grateful acknowledgment to Dr. Tatsuo Miyazawa of the Institute for Protein Research, Osaka University, who permitted them to use Perkin Elmer Spectrometer (model 201 C) in his laboratory and gave them helpful advice.

(ii) Stephenson, Wulff and Lundell[30] reported quite recently the torsional frequencies of ammonium halide crystals determined from thermal analysis. For the torsional frequency in ammonium bromide they have quoted the Ph.D. thesis by A. G. Cole.[31] The heat capacity of ammonium bromide by Dr. Cole is about one per cent smaller than ours in the whole temperature region. With respect to the torsional frequency, however, the value, $335\pm5$ $cm^{-1}$, reported in Dr. Cole's thesis agrees rather well the result by us, $340+7$ $cm^{-1}$, within their experimental errors. In passing, we should like to remark that his value of the entropy of transition at 234.5°K is overestimated due to the no subtraction of the normal heat capacities from the total observed values. The authors are indebted to Microreproduction Laboratory of Massachusetts Institute of Technology for sending them the microfilm of Dr. Cole's thesis.

# Polyesters Containing Carbazole Rings in the Main Chain. II. The Syntheses of Polyesters from Carbazole Keto Acids*

By Yoshio NAGAI and Chin-Chuan HUANG

(Received November 4, 1964)

As has been described previously,[1] to prepare polyesters containing carbazole rings in the main chain, the authors first synthesized several carbazole- and *N*-alkylcarbazole-dicarboxylic acids. Carbazole-dibasic acids of the general formula X-R-X, where X is $-COC_2H_4CO_2H$ or $-(CH_2)_3CO_2H$ and R is carbazole or a 9-methylcarbazole ring, were also synthesized in better yields by a modification of the method of Mitchell and Plant.[2]

New polyesters were derived from diethyl carbazole- and diethyl 9-methylcarbazole-3, 6-$\gamma,\gamma'$-diketobutanoates in the presence of various catalysts.

## Experimental

**The Preparation of Monomers.** — *Carbazole-3,6-$\gamma,\gamma'$-diketobutanoic Acid (I).*—The succinoylation of carbazole according to the method of Mitchell and Plant[2] gave I in yields lower than 40 per cent. These results indicated that the use of at least 2.5 molecular proportions of aluminum chloride per mole of succinic anhydride is a requisite and that the extension of the reaction time up to 16 hr. is preferable in increasing the yield of I. Table I shows the molecular proportions of aluminum chloride per mole of succinic anhydride and the relative per cent yields of keto acid.

Found: C, 65.71; H, 4.65. Calcd. for $C_{20}H_{17}O_6N$: C, 65.32; H, 4.64%.

*Carbazole-3,6-dibutanoic Acid (II).*[7] — Reducing I also by the Clemmensen method, Mitchell and Plant[2] prepared II in a 50 per cent yield. As Table II shows that, when I was reduced in an aqueous acetic acid, II was obtained in a more than 80 per cent yield. II can be alternatively synthesized from the ethyl ester of I by the Clemmensen method. A zinc amalgam was prepared by mixing 300 g. of zinc powder, 300 cc. of a 10% aqueous mercuric chloride solution, and 10 cc. of concentrated hydrochloric acid. The mixture was stirred for 5 min., and then the residue which remained after the decantation of the aqueous solution was covered with 300 cc. of water. To this mixture was added 30 g. of I and 300 cc. of glacial acetic acid; then the

a) $d$=1.175 g./cc. b) Toluene c) Xylene d) Water e) Diethyl ester of I.
I, Carbazole-3,6-$\gamma,\gamma'$-diketobutanoic acid.

whole was refluxed and stirred while 300 cc. of concentrated hydrochloric acid was added, drop by drop, over a 4-hr. period. After the completion of the reaction, the upper layer of the product was decanted and the residual amalgamated zinc was refluxed with glacial acetic acid to take up any product remaining on the top of the amalgam or on the wall of the flask. On cooling, the combined solution of the filtrate and the decanted layer yielded II as white flakes; 22.5 g., m. p. 198—200°C.

Found: C, 70.59; H, 6.20; N, 5.73. Calcd. for $C_{20}H_{21}O_4N$: C, 70.80; H, 6.19; N, 5.81%.

*Diethyl Carbazole-3,6-$\gamma,\gamma'$-diketobutanoate (III).*—The reaction of I with a mixture of ethanol and concentrated sulfuric acid for 6 hr. gave III as white plates; m. p. 175—176°C after crystallization from ethanol (decolorizing charcoal added).

Found: C, 68.12; H, 5.92. Calcd. for $C_{24}H_{25}O_6N$: C, 68.10; H, 5.92%.

*Diethyl 9-Methylcarbazole-3,6-$\gamma,\gamma'$-diketobutanoate (IV).*—A solution of 1.5 g. of III in 300 cc. of acetone was poured into a flask containing 1.5 g. of an aqueous potassium hydroxide in 1.0 cc. of water, and to this mixture was added 2.0 cc. of dimethyl sulfate. The mixture was then stirred for 12 min. at 25°C, and the product was poured into 2 l. of water to give white precipitates which yielded IV as white crystals (1.5 g.; m. p. 145—146°C after recrystallization from ethanol).

Found: C, 67.37; H, 6.11. Calcd. for $C_{25}H_{27}O_6N$: C, 67.09; H, 6.04%.

*9-Methylcarbazole-3,6-dibutanoic Acid (V).*[7]—For this synthesis, a zinc amalgam was prepared as has been described in the preparation of II. The procedure was also essentially the same except that IV was reduced instead of I. The melting point of V is 227—229°C.

Found: C, 71.06; H, 6.58. Calcd. for $C_{21}H_{17}O_4N$: C, 71.35; H, 6.52%.

**Polycondensation.** — *General Procedure.* — Polyesters were obtained by heating a mixture of ethylene glycol and III or IV in a glass flask. The

ester exchange reaction in the presence or in the absence of a catalyst was effected under such condition that the displaced alcohol could be removed by distillation; this involved the use of a reaction temperature below the boiling point of ethylene glycol, but well above that of the alcohol to be displaced. In carrying out the reaction, at least two molecular proportions of ethylene glycol per molecular proportion of III or IV were used, and the heating in a stream of nitrogen was continued until the distillation of the displaced alcohol ceased. The resulting low polymeric products could be converted to polyesters by heating them, at a temperature above the boiling point of ethylene glycol, under reduced pressure (below 1 mmHg). The polyesters thus prepared were reprecipitated several times in order to increase the homogeneity.

For the following polycondensations, ethylene glycol was first dried over anhydrous sodium sulfate and then purified by dissolving metallic sodium in it (1.0 g. per 100 cc.) and refluxing it in an atmosphere of nitrogen for 1 hr. and then distilling it (b. p. 99—100°C/15 mmHg).

In syntheses of the polyesters PX-1 to PX-18, 10 g. of III and 3 g. of ethylene glycol were used. Various catalysts and the corresponding weights for each preparation are shown in Table III. Two preparations will be described as examples; the rest are essentially the same.

*PX-4.*—The following ingredients were introduced into a hard glass flask: III, 10.0 g.; ethylene glycol, 3.0 g.; calcium acetate, 0.041 g. and antimony trioxide, 0.01 g. The mixture was then heated in a stream of oxygen-free nitrogen in a vapor bath of 195°C for 2 hr., until most of the ethanol distilled off. The low polymeric product was then heated further at an elevated temperature, 210°C at the early stage and finally at 280°C, over a period of 5 hr. in the full vacuum used at the last phase of the reaction. The resulting condensation product exhibited an intrinsic viscosity of 0.18 in *m*-cresol at 30°C.

*PX'-1.* — A mixture of 10.5 g. of IV, 3.0 g. of ethylene glycol, and 0.005 g. of lead acetate was allowed to react in a stream of oxygen-free nitrogen for 2 hr., while the ethanol was being continuously removed; then it was polycondensed under the same conditions as in the previous example and over the same period to give, in *m*-cresol at 30°C a polyester with the intrinsic viscosity of 0.23.

solvents, III and IV were used in the practical polycondensation.

In the absence of a catalyst, merely a low polymeric condensation product was obtained. Among several catalysts, e.g., lead monoxide,[3] calcium acetate,[4] germanium dioxide,[5] and antimony trioxide,[3] which have been proclaimed as excellent catalysts for preparing white aromatic polyesters when applied either singly or in combination, lead monoxide has proved to be inadequate in the synthesis of poly(ethylene carbazole-3,6-$\gamma,\gamma'$-diketobutanoate) (PECKB) from the viewpoint of the color of the product. The use of lead monoxide less than 0.6% by weight of III yielded only a low polymeric product, and an attempt to synthesize high polymeric PECKB by adding more lead monoxide resulted in a product the color of which was usually very dark amber. In preparations of PECKB and 9-MePECKB, the catalytic effect of germanium dioxide compared favorably with that of cobaltous acetate or lead acetate, which is generally considered to be a good accelerator in polycondensation. In the presence of about 0.6% by weight of lead acetate, a relatively high polymeric PECKB was obtained, as is illustrated in Fig. 2, though

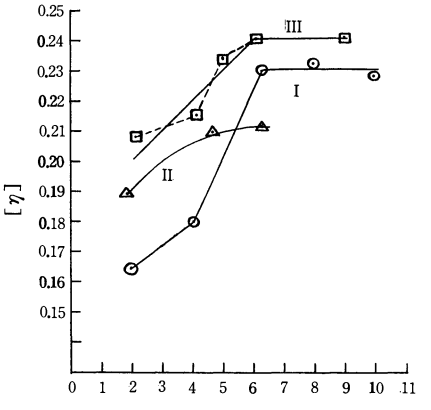

Fig. 2. Relation between the weight of catalyst and the intrinsic viscosity.
I Germanium dioxide II Cobaltous acetate
III Lead acetate

a rather irregular increase in viscosity in accordance with the increment of the catalyst was observed. The color of PECKB or 9-MePECKB tends to become darker upon the addition of more than 0.1% by weight of lead acetate or germanium dioxide; the addition of more than 0.06% by weight of cobaltous acetate to the reaction mixture also is apt to give a polyester of a very dark amber color. The use of more than 5 times by weight of calcium acetate in comparison with other catalysts was necessary, as is clearly shown in Figs. 1 and 3; otherwise, the viscosity increased steadily up to 0.18 with the increase in the weight of the catalyst.

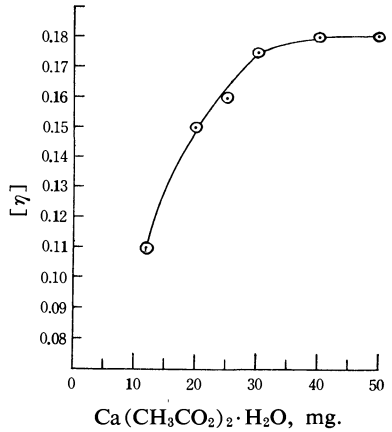

Fig. 3. Relation between the weight of catalyst and the intrinsic viscosity.

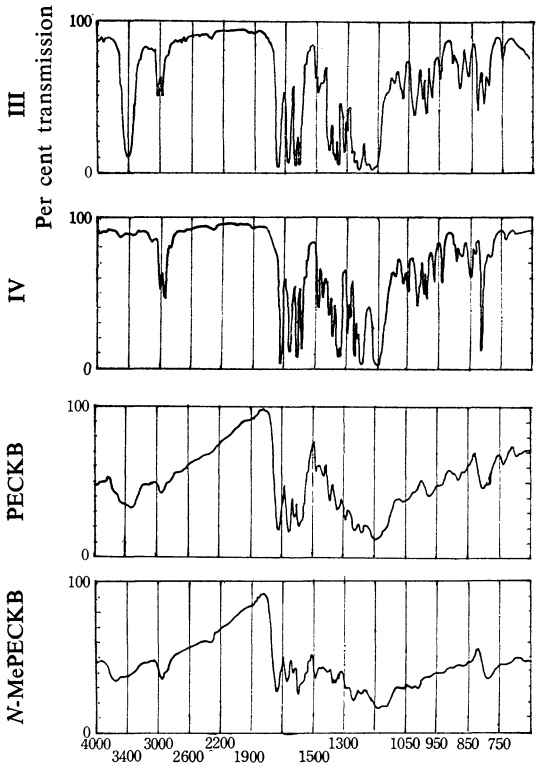

Fig. 4. Infrared spectra of III, IV, PECKB, *N*-MePECKB.

Infrared spectrum of III was obtained on the pressed disk of 3.8 mg. of III/700 mg. KBr; and that of IV on the pressed disk of 3.9 mg. of IV/700 mg. KBr.

Infrared spectra of PECKB and 9-MePECKB were obtained on the pressed disks of 4.5 mg. of PECKB/700 mg. KBr and 5.5 mg. of 9-MePECKB/700 mg. KBr respectively.

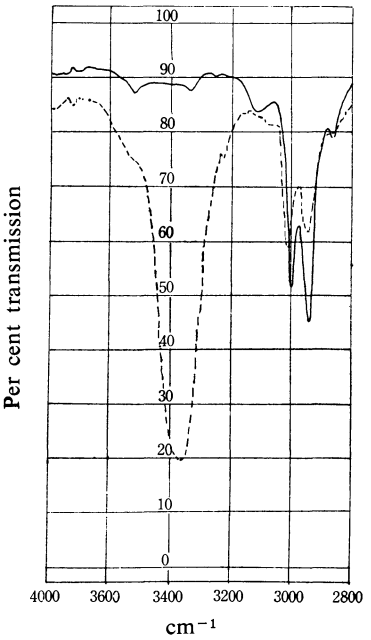

Fig. 5. Infrared spectra of III* and IV**.
* On pressed disk of 3.5 mg. III/700 mg. KBr.
** On pressed disk of 3.5 mg. IV/700 mg. KBr.

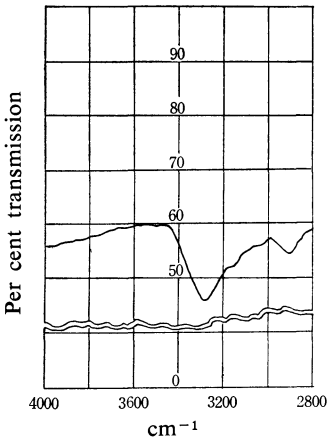

Fig. 6. Infrared spectrum of poly(ethylene carbazole-3,6-$\gamma,\gamma'$-diketobutanoate)*, PECKB.
* On pressed disk of 3.5 mg. PECKB/700 mg. KBr.

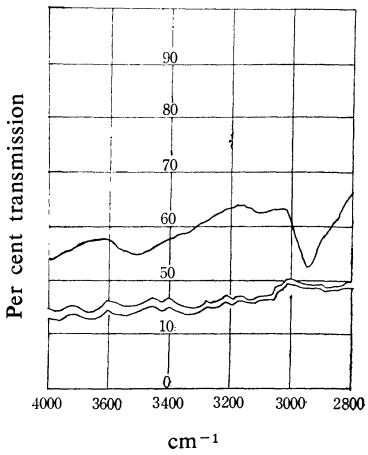

Fig. 7. Infrared spectrum of poly(ethylene 9-methylcarbazole-3,6-$\gamma,\gamma'$-diketobutanoate)*, 9-MePECKB.

* On pressed disk of 3.5 mg. 9-MePECKB/700 mg. KBr.

PECKB and 9-MePECKB have, in general, good resistance to many organic solvents, though not to pyridine, phenol and cresol. Condensation products exhibiting an intrinsic viscosity lower than 0.14 dissolve in pyridine at the boiling point of the solvent, whereas PECKB and 9-MePECKB, which show an intrinsic viscosity of 0.15 or higher, dissolve in only phenol or cresol at the boiling point of the solvent; all the polyesters synthesized dissolve slowly in concentrated sulfuric acid.

The wide temperature range of polymer melting points shown in Table III seems to indicate that polyesters based on III or IV are largely amorphous. Figures 4, 5, 6, and 7 show the infrared spectra of III, IV, PECKB, and 9-MePECKB. The data from elementary analyses of the polycondensation product and the characteristic absorption bands shown in these figures indicate that synthesized PECKB and 9-MePECKB are linear plyesters with the following recurring units:

PECKB,

$$-(OCC_2H_4CO-C_{12}H_7N-COC_2H_4CO_2C_2H_4O)-$$

9-MePECKB,

$$-(OCC_2H_4CO-C_{13}H_9N-COC_2H_4CO_2C_2H_4O)-$$

The authors wish to thank the kind cooperation of Nihon Jōriu Company, Nihon Kayaku Company, and Yahata Kagaku Company in supplying carbazole for this study. We are also grateful for the experimental help, in preparation of monomers, of Messrs. Y. Yoshida, S. Fujinami and Y. Ikeda of the Nagai Laboratory, Institute of Industrial Science, the University of Tokyo.

# Oxidation of Alcohols with *t*-Butyl Chromate. II. The Oxidation of Primary Aromatic Alcohols*1

By Takayuki SUGA, Keiichi KIHARA*2 and Tamon MATSUURA

(Received November 10, 1964)

The oxidation of benzyl alcohol with *t*-butyl chromate has been reported to give benzaldehyde in a quantitative yield[1] and to be accelerated by pyridine.[2] In the preceding paper of this series,[3] the *t*-butyl chromate oxidation of the primary aliphatic alcohols with the $-CH_2 \cdot CH_2OH$, $>CH \cdot CH_2OH$, or $\equiv C \cdot CH_2OH$ groups was found to yield a mixture of the corresponding aldehyde, acid and ester in a comparable yield. On the other hand, the oxidation of the primary allylic alcohol was established as giving the corresponding aldehyde in a high yield, but not the ester. We have now tried the oxidation of benzyl alcohol and its *p*-substituted derivatives, β-phenylethyl alcohol, and *trans*-cinnamyl alcohol with *t*-butyl chromate.

*1 The oxidation of benzyl alcohol has been recorded in *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **80**, 653 (1959), by one of the present authors. An other part of this work was presented at the 3rd Symposium on Perfume, Terpene and Essential Oil Chemistry of the Chemical Society of Japan, Tokyo, October, 1959.

*2 Present address: The Tôyô Sôda Manufacturing Company, Ltd., Nanyô-chô, Tsuno-gun, Yamaguchi-ken.

3) Part I: T. Suga, K. Kihara and T. Matsuura, This Bulletin, **38**, 893 (1965).

The re-examination of the oxidation of benzyl alcohol (Exp. 1) under conditions similar to those reported by Oppenauer et al.[1],*3 gave benzaldehyde (81% yield based on the alcohol) and benzoic acid (17%). When this alcohol was oxidized (Exp. 2) at 1—2°C for 6 hr. with the oxidant solution prepared in the 1 : 1 mol. ratio of the alcohol to *t*-butyl chromate, as employed in many cases of a primary aliphatic alcohol,[3] the yield of benzaldehyde increased to 90% and the formation of benzoic acid was suppressed to 7%. No such ester as produced in the case of a saturated primary aliphatic alcohol[3] was formed in Exps. 1 and 2.

The effect of the para substituent on the formation of the aldehyde and the ester was checked with *p*-chlorobenzyl alcohol and *p*-isopropylbenzyl alcohol. The oxidation of *p*-chlorobenzyl alcohol (Exp. 3) under the same conditions as in Exp. 2 gave *p*-chlorobenzaldehyde (83%) and *p*-chlorobenzoic acid (10%), but it did not yield the ester. When this oxidation was repeated using a benzene solution with a lower concentration of the oxidant and the sample alcohol (Exp. 4), the yield of *p*-chlorobenzoic acid decreased to 5%, and *p*-chlorobenzaldehyde was obtained in a 91% yield. The oxidation of *p*-isopropylbenzyl alcohol (Exp. 5) under the same conditions as in Exp. 4 afforded *p*-isopropylbenzaldehyde (79%) and *p*-isopropylbenzoic acid (10%), but no ester was obtained. Thus, the electron-attractive or the electron-repulsive group in the para position was found neither to affect remarkably the yield of the aldehyde nor to cause the formation of the ester.

The oxidation of β-phenylethyl alcohol (Exp. 6) gave the corresponding ester, i. e., β-phenylethyl β-phenylacetate (46%), β-phenylacetaldehyde (3%) and β-phenylacetic acid (3%), accompanied by anomalous oxidation products, such as benzaldehyde (2%) and benzoic acid (7%). The formation of the anomalous products is probably due to the cleavage of the side chain. Besides, a resinous substance, probably a polymer of β-phenylacetaldehyde, was obtained in ca. 10% yield. The different oxidation mode between benzyl alcohol and β-phenylethyl alcohol will be discussed, together with the course of the formation of the ester, in Part IV of this series.

The oxidation of *trans*-cinnamyl alcohol (Exp. 7) under the same conditions as in Exp. 2 produced *trans*-cinnamaldehyde (61%) and *trans*-cinnamic acid (1%). In addition, benzaldehyde (6%) and benzoic acid (2%), presumably formed by the allylic double-bond fission, were obtained. Oxidation (Exp. 8) similar to that of Exp. 7, with a reaction time of 2 hr., gave the corresponding aldehyde (49%), the corresponding acid (1%), benzaldehyde (5%) and benzoic acid (3%). When *t*-butyl chromate dissolved in benzene containing glacial acetic acid and acetic anhydride was used as an oxidant (Exp. 9), *trans*-cinnamaldehyde was obtained in a 59% yield, even with a short oxidation time similar to that of Exp. 8, and the original alcohol was almost entirely exhausted. In this case, the yields of cinnamic acid, benzaldehyde and benzoic acid were 8, 10 and 1%. The oxidation (Exp. 10) with a neutral benzene solution of the oxidant under the same conditions as in Exp. 1 afforded cinnamaldehyde (52%), cinnamic acid (6%), benzaldehyde (6%) and benzoic acid (2%), but no original alcohol. The formation of the ester was not observed with cinnamyl alcohol (Exps. 7—10).

Therefore, when a primary aromatic alcohol with a phenyl group or an ethylenic double bond adjacent to the hydroxymethyl group was oxidized with *t*-butyl chromate, the aldehyde corresponding to the sample alcohol was obtained as the main reaction product, but the corresponding ester was not formed. On the other hand, the oxidation of an aromatic alcohol with a methylene between the phenyl group and the hydroxymethyl group produced the aldehyde, the acid and the ester corresponding to the sample alcohol, as in the oxidation of a saturated primary aliphatic alcohol.[3]

## Experimental

**Sample Alcohols.** — Benzyl alcohol and β-phenylethyl alcohol were obtained from a commercial source. Cinnamyl alcohol (m. p. 33—34°C; $\lambda_{infl.}^{EtOH}$ 249 and $\lambda_{max}$ 251 mμ, log ε 4.272 and 4.274) was supplied by the Takasago Perfumery Co., Ltd. Its melting point and ultraviolet absorption spectrum indicated this alcohol to be a trans-form.[4] *p*-Chlorobenzyl alcohol (m. p. 70.5—71°C) and *p*-isopropylbenzyl alcohol (b. p. 124—125°C/13 mmHg) were prepared from the corresponding benzoic acids by reduction with lithium aluminum hydride in ether.[5,6] All the sample alcohols were purified by distillation or recrystallization just before use.

*3 The oxidation recorded by them has been carried out at room temperature over a 7-day period, using a benzene solution of *t*-butyl chromate prepared in the 1 : 1.3 mol. ratio of benzyl alcohol to this chromate.

a) Mol. in 1000 g. of benzene.
b) The mol. ratio of the sample alcohol to *t*-butyl chromate was 1 : 1.3 and the oxidation was carried out at 22—25°C. Only benzene is represented by volume (ml.).
c) To the benzene solution of *t*-butyl chromate, 15 g. of glacial acetic acid and 10 g. of acetic anhydride were added.
d) The cocentration in the acidified benzene solution is shown.

**Oxidation, and the Treatment of a Reaction Mixture.**—A benzene solution of *t*-butyl chromate was prepared in the same manner as that in the preceding paper.[3] The quantity of each component and the concentration of *t*-butyl chromate in this solution are shown in Table I, which also lists the quantities of the sample alcohol and its solvent. The oxidation was carried out under the conditions described above in a manner similar to that described in Ref. 3. After the oxidation, the reaction mixture was treated with oxalic acid and water, except in Exp. 1, and then separated into a benzene solution and an aqueous one (see Ref. 3). The separated benzene solution containing a reaction product was subjected to the examinations described in each experiment. Each of the constituents of the reaction product was identified by the same method as used in the preceding study;[3] the yield of the constituents has been shown above.

**The Oxidation of Benzyl Alcohol (Exp. 1).**—After the oxidation, the reaction mixture was treated with hydrazine sulfate and 20% sulfuric acid instead of oxalic acid and water. An ether solution of the reaction product, obtained by the removal of the solvent from the separated benzene solution, was extracted with a 5% sodium carbonate solution, which gave benzoic acid on acidification. The removal of the solvent from the ether solution gave a neutral reaction product, which consisted of benzaldehyde (15%) and dibenzalhydrazine (85%). The steam distillation of this dibenzalhydrazine in the presence of dilute sulfuric acid gave benzaldehyde quantitatively. The formation of dibenzalhydrazine is considered to result from the reaction of hydrazine sulfate with benzaldehyde while the residual oxidant was hydrolyzed with this reagent.

**(Exp. 2).**—The reaction mixture was treated with oxalic acid and water, and then the separated benzene solution was repeatedly extracted with a 5% sodium carbonate solution, which gave benzoic acid on acidification. The neutral reaction product was obtained from the neutral benzene solution by the removal of the solvent. Thin-layer chromatographic analysis (silica gel) as well as infrared and ultraviolet spectroscopic analyses indicated the neutral product to be only benzaldehyde.

**The Oxidation of *p*-Chlorobenzyl Alcohol (Exps. 3 and 4).**—The separated benzene solution was treated in the same manner as in Exp. 2. *p*-Chlorobenzoic acid (m. p. 234—235°C) was obtained from the sodium carbonate extracts. Thin-layer chromatography (silica gel) indicated that the neutral product consisted of *p*-chlorobenzaldehyde (m. p. 45—46°C) and unchanged alcohol (0.2 and 4% in Exps. 3 and 4 respectively). The aldehyde was estimated by the 2,4-dinitrophenylhydrazine method.[7]

**The Oxidation of *p*-Isopropylbenzyl Alcohol (Exp. 5).**—The reaction product was examined in a manner similar to that used in Exps. 2—4. The boiling point of *p*-isopropylbenzaldehyde isolated was 98—100°C/8 mmHg, and *p*-isopropylbenzoic acid melted at 115—116°C. The unchanged alcohol amounted to 8.5%.

**The Oxidation of β-Phenylethyl Alcohol (Exp. 6).**—The distillation of a reaction product obtained from the separated benzene solution gave benzaldehyde (b. p. 73—78°C/22 mmHg), β-phenylacetaldehyde (b. p. 90—95°C/22 mmHg), unchanged alcohol (21% yield; b. p. 110—113°C/22 mmHg) and a residue (20.5 g.). Liquid-column chromatography on silica gel with a mixture of ethyl ether and

7) H. A. Iddles, A. W. Low, B. D. Rosen and R. T. Hart, *Ind. Eng. Chem., Anal. Ed.*, **11**, 102 (1939).

*n*-hexane indicated that this residue contained benzoic acid (m. p. 120—121°C), β-phenylacetic acid (m. p. 76—76.5°C), β-phenylethyl β-phenylacetate (b. p. 180—182°C/5 mmHg; $\nu_{max}^{liq.}$ 1730, 1150 $cm^{-1}$), and a resinous substance, probably a polymer of β-phenylacetaldehyde.

**The Oxidation of *trans*-Cinnamyl Alcohol (Exps. 7—10).**—The reaction product was distilled to separate as five fractions, and then some fractions and the residue were individually subjected to liquid-column chromatography on silica gel with a mixture of ethyl acetate and *n*-hexane. The reaction product consisted of *trans*-cinnamaldehyde[8] (b. p. 96—100°C/3.5 mmHg; $\lambda_{max}^{EtOH}$ 287 mμ, log ε 4.36), *trans*-cinnamic acid (m. p. 132—132.5°C), benzaldehyde, benzoic acid and unchanged alcohol (2, 19 and 2% in Exps. 7, 8 and 9 respectively).

## Summary

The oxidation with *t*-butyl chromate has been carried out with benzyl alcohol, its *p*-substituted derivatives and *trans*-cinnamyl alcohol, and also with β-phenylethyl alcohol. In the former alcohols, the corresponding aldehyde was obtained as the main product, but the corresponding ester was not formed. On the other hand, the latter alcohol, containing a methylene group adjacent to the hydroxymethyl group, produced the corresponding ester, aldehyde and acid, as in the case of a saturated primary aliphatic alcohol.

The authors wish to express their hearty thanks to Messrs. Tadahisa Yanagihara and Yoshinobu Nakamura, who assisted in a part of this research, and to the Takasago Perfumery Co., Ltd., for supplying a sample of cinnamyl alcohol. This research was aided by a grant from the Ministry of Education.

# The Dimerization of Benzoic Acid in Carbon Tetrachloride and Chloroform

By Yasumasa I'HAYA and Tai-ichi SHIBUYA*

(Received November 10, 1964)

Although the dimerization equilibria of benzoic acid in various solvents have been spectroscopically studied by many authors,[1-6] the equilibrium constants obtained so far extend over a wide range. In the very dilute solutions which are often used for ultraviolet spectroscopy, the interaction of the carboxylic group of the acid with a small amount of water present in the solvents might have a considerable effect on the dimerization equilibrium.

We have studied the dimerization of benzoic acid in the concentration range from 0.0001 mol. to 0.1 mol. in carbon tetrachloride and chloroform by infrared spectroscopy, and have calculated the dimerization constant from the integrated intensities of the carbonyl-stretching vibration bands corresponding to the monomer and the dimer forms of benzoic acid. Barrow and Yerger[7] used the same infrared technique to obtain the dimerization constant of acetic acid in carbon tetrachloride and chloroform from the optical densities at the absorption maxima of the respective carbonyl absorption bands. Davies and Sutherland[1] obtained the dimerization constant of benzoic acid from the integrated intensity of the hydroxyl-stretching vibration band.

The purpose of the present paper is two-fold: to apply the integrated intensity technique for the determination of the monomer and dimer concentrations to the carbonyl-stretching band, using a high resolution infrared spectrometer, and to compare the effect of carbon tetrachloride upon acid dimerization with that of

chloroform. Barrow and Yerger[7] assumed that a weak association of acetic acid with chloroform occurs through hydrogen bonding to the monomer carbonyl. The present paper will examine whether a like association exists in the benzoic acid - chloroform system.

## Experimental

**The Measurement of Dimerization Constants.**—The basic equation from which infrared intensity measurements proceed is:

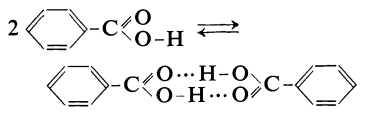
$$A=(Cl)^{-1}\int \ln(I_0/I)_\nu d\nu \qquad (1)$$

where $A$ is the *true* integrated intensity; $C$, the molar concentration of an absorbing species; $l$, the optical path length, and $I_0$ and $I$, the incident and transmitted intensity of the monochromatic radiation of the frequency, $\nu$, respectively. In practice, because of the use of a finite slit width, the radiation is not monochromatic and the intensity measured experimentally is not $I$ but the apparent intensity, $T$. Therefore, Eq. 1 should be replaced by:

$$B=S/Cl, \text{ with } S=\int \ln(T_0/T)_\nu d\nu \qquad (2)$$

where $B$ is the *apparent* integrated intensity. As Ramsay has shown,[8] the apparent band intensity, $B$, determined in this way is not the true physical constant of the absorbing species but depends upon the instrumental conditions employed. However, if one assumes that the $(T_0/T)_\nu/(I_0/I)_\nu$ ratio does not significantly depend upon the ratio of the apparent half-intensity band width to the slit width, one can reasonably determine the concentration of the absorbing species from Eq. 2 by putting an appropriate value into $B$. In fact, when this was checked by measuring the carbonyl band of ethyl methyl ketone, the deviation of the apparent integrated intensity from the true integrated intensity was found not to be significant, the decrease in peak intensity produced by the finite slit width being approximately compensated for by an increase in the half-intensity band width.

All measurements were made with a Koken DG 201 infrared spectrophotometer equipped with a grating or a rock-salt prism. Dry air was led into the instrument after it had passed through a column packed with a molecular sieve in order to remove the carbon dioxide and water present in the air. A set of rock salt cells was used; the cell thickness was 0.190 mm., as determined by interference patterns, and 1.20, 3.10, 9.9, and 20.0 mm., as determined by direct measurement with a micrometer.



The acetic acid concentrations used were in the range from $7.35\times10^{-2}$ to $3.03\times10^{-4}$ mol. in carbon tetrachloride and $7.64\times10^{-2}$ to $1.31\times10^{-4}$ mol. in chloroform. The temperature of the samples was not specifically controlled but was between room temperature, 23°C, and that of the instrument, 25°C.

**Materials.**—Wako special-grade benzoic acid was recrystallized from water, dried under a vacuum, and sublimated in a flask. The carbon tetrachloride was Kanto Kagaku reagent grade, washed several times with concentrated sulfuric acid, a sodium hydroxide aqueous solution and water, dried over calcium chloride and then over phosphorus pentoxide, and finally passed through a column packed with aluminum oxide. It was stored in a brown desiccator placed in a dark and cool place and used within two day.

The chloroform was of the same grade and was purified in the same manner as carbon tetrachloride.

## Results and Discussion

The dimerization equilibrium of benzoic acid in non-dissociating solvents is assumed to be:

(3)

The infrared absorption spectrum of benzoic acid has been fairly well established.[9] The O–H stretching vibration band was found at 3525 $cm^{-1}$, which corresponds to that of monomer benzoic acid, and the out-of-plane O–H deformation, at 945 $cm^{-1}$. The C=O stretching vibration bands used to determine the monomer and dimer concentrations were found at 1737 $cm^{-1}$ for the monomer and at 1692 $cm^{-1}$ for the dimer in carbon tetrachloride, and at 1725 and 1690 $cm^{-1}$ for the

monomer and dimer, respectively, in chloroform. These assignments are consistent with those already reported.

In Fig. 1 plots of $\log_{10}(T_0/T)_\nu$ versus the frequency, $\nu$, are shown for the C=O stretching vibration bands of benzoic acid in carbon tetrachloride and chloroform. In this frequency region, benzoic acid does not show any absorption except for the two C=O stretching bands of the free and associated species, so one may regard the $g$ shown in the figure as the base line. The broken lines, a and b, show the position of the absorption maxima corresponding to the monomer and dimer forms. The area intensity, $S_m$, is taken to be twice the shaded area to the left of line a in Fig. 1; similarly, $S_d$ is taken to be twice the shaded area to the right of line b. This procedure was utilized because the two absorption bands overlapped in the region between lines a and b in Fig. 1. (Hereafter the suffixes m and d will be used to specify quantities concerning the monomer and dimer respectively). The shaded parts of the figure were then cut off and weighed. The area intensities thus obtained for a set of experiments are shown in Table

TABLE III. THE APPARENT INTEGRATED INTENSITIES OF THE CARBONYL STRETCHING BANDS OF THE BENZOIC ACID MONOMER AND DIMER (1. $mol.^{-1}$)

| | in $CCl_4$ | in $CHCl_3$ |
|---|---|---|
| $B_m\times10^{-4}$ | 1.44 | 3.55 |
| $B_d\times10^{-4}$ | 6.36 | 5.91 |

I for the carbon tetrachloride solution and in Table II for the chloroform solution.

To obtain the apparent integrated intensity, $B_m$ (or $B_d$), it is necessary to make an extrapolation of the ($S_m/lM$ or $2S_d/lM$) measured for a series of different concentrations to a zero (or finite) concentration, $M$ being the total concentration of benzoic acid in carbon tetrachloride and chloroform. A difficulty lies in the fact that these extrapolations are very sensitive to measurements of the area intensities at small concentrations, where the experimental errors in determining band areas are quite large. In fact, the approximate values of the extrapolated ($S_m/lM$) and ($2S_d/lM$) as obtained for the carbon tetrachloride solution, for example, range from 0.9 to $1.5\times10^4$ and from 5.8 to $6.5\times10^4$ $1.\,mol^{-1}\,cm^{-2}$ respectively. These uncertainties can not be eliminated by even the inclusion of more experimental data gathered at small concentrations.

Therefore, it is advisable to determine the apparent integrated intensities, $B_m$ and $B_d$, by the method of least squares so as to satisfy the stoichiometrical relations:

$$S_m/lB_m + 2S_d/lB_d = M \qquad (4)$$

for a set of different concentrations. The values of $B_m$ and $B_d$ thus obtained are listed in Table III. With these values of $B_m$ and $B_d$ and with the observed area intensities listed in the third and fourth columns of Table I and Table II, the monomer and dimer concentrations of benzoic acid are calculated from Eq. 1 for a set of benzoic acid concentrations. The equilibrium constants, $K$, for the dimerization of benzoic acid are then obtained. The results are shown in the fifth, sixth, and the last columns of Tables I and II.

The equilibrium constants for both carbon tetrachloride and chloroform solutions are satisfactorily constant; the value as averaged over a set of benzoic acid concentrations is 2300 $1.\,mol^{-1}$ for the former and 400 $1.\,mol^{-1}$ for the latter. These values of $K$ seem to be more reliable than those obtained by Harris and Hobbs[2] or even by Barrow and Yerger,[7] who showed the concentration dependence of the equilibrium constant, in particular, at high dilutions. For instance, Barrow and Yerger gave, for the dimerization equilibrium of acetic acid in carbon tetrachloride, values between 1000 and 2650 $1.\,mol^{-1}$ for concentrations in the range from 0.17 mol. to 0.000112 mol. (Note that they treated not the integrated intensity but the optical density of the carbonyl stretching band maxima.) The values of the equilibrium constant obtained in the present paper are smaller than those previously reported by several authors; for example, Davies and Sutherland[1] gave the values of 13700 $1.\,mol^{-1}$ at 19.5°C and 220 $1.\,mol^{-1}$ at 76.5°C for the carbon tetrachloride solution, while Harris and Hobbs obtained a value of about 7000 $1.\,mol^{-1}$ at room temperature for the same solution.

The equilibrium constant in chloroform is smaller than that in carbon tetrachloride by a factor of about ten. This trend is parallel with the results obtained by Barrow and Yerger for acetic acid. As is shown in Fig. 1, the position of the carbonyl-stretching vibration band of the monomer in carbon tetrachloride is considerably different from that in chloroform. Moreover, the band width of the monomer band is broader in chloroform than in carbon tetrachloride, while the dimer bands have almost the same width in the two solvents. This agrees with the general observations that the position of a stretching vibration band of a hydrogen-bonded chromophore tends to shift to the lower frequency side and that the band width becomes broader than that of a free species. Therefore, one might expect a weak association in the chloroform solution. The values of the apparent integrated intensity give further support to this conclusion; as Table III shows, $B_d$ is about the same in magnitude in both solvents, while the $B_m$ in chloroform is larger than that in carbon tetrachloride by a factor of 2.5.

## Summary

The dimerization equilibrium of benzoic acid has been studied by high resolution infrared spectroscopy over a wide range of acid concentrations. The concentrations of the monomer and the dimer fractions have been determined from the integrated intensities of the respective carbonyl-stretching vibration bands. The calculated equilibrium constant is 2300 $1.\,mol^{-1}$ for carbon tetrachloride and 400 $1.\,mol^{-1}$ for chloroform, both values being considered more reliable than that determined by peak intensity measurements. A weak association of chloroform with benzoic acid has been suggested as occurring through hydrogen bonding to the monomer carbonyl.

# Syntheses of Peptides Related to the *N*-Terminal Structure of Corticotropin. V. Synthesis of the Peptide Fragments, His-Phe-Arg-Try, His-Phe-Arg-Try-Gly and Glu-His-Phe-Arg-Try-Gly

By Ken INOUYE

(Received November 11, 1964)

It has been shown in our previous communications that the tetrapeptide sequence His-Phe-Arg-Try, which occupies the positions 6 to 9 in the molecules of corticotropin and the $\alpha$-type of melanocyte-stimulating hormone ($\alpha$-MSH), provides an essential core for eliciting the MSH and the lipolytic activities with these hormones.[1] In connection with the synthesis of the tetrapeptide L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophan (I), we have next achieved the synthesis of a pentapeptide L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine (II) and a hexapeptide L-glutamyl-L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine (III), which corresponds to the amino acid sequences of positions 6—10, and 5—10, respectively, of the corticotropin and $\alpha$-MSH molecules, together with a new synthesis of the tetrapeptide I, in order to try the comparative tests of the biological properties among these three peptides. An intermediate product to the hexapeptide III, namely $\gamma$-*t*-butyl-L-glutamyl-L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine (XVII), is a key fragment for the synthesis of adrenocorticotropically active peptides.[2,3] The present synthesis has improved the procedure to obtain this key material.

The tetrapeptide and the pentapeptide were built up stepwise from their carboxyl terminal residues, where *t*-butyloxycarbonyl-nitro-L-arginine (IV) was utilized to incorporate the arginine residue and the *N*,*N'*-dicyclohexylcarbodiimide (DCCI) method[4] was employed except for the last coupling step. In the last step to introduce the histidine, a crystalline active ester $N^{\alpha}$, $N^{Im}$-dicarbobenzoxy-L-histidine *p*-nitrophenyl ester (V), gave excellent results. The protected hexapeptide was synthesized by coupling of the phenylalanyl tetrapeptide ester (X) with carbobenzoxy-$\gamma$-*t*-butyl-L-glutamyl-L-histidine azide which was derived from a new crystalline compound carbobenzoxy-$\gamma$-*t*-butyl-L-glutamyl-$N^{Im}$-carbobenzoxy-L-histidine methyl ester (XIII).

Figure 1 outlines the synthetic steps for the

pentapeptide II. Carbobenzoxy-L-tryptophylglycine methyl ester (VI) was obtained in an excellent yield (88%) by coupling of the hydrochloride of glycine methyl ester with the soluble tri-*n*-butylamine salt of carbobenzoxy-L-tryptophan, which was formed in a methylene chloride solution. *t*-Butyloxycarbonyl-nitro-L-arginine (IV), which crystallized from an ethyl acetate solution, was found to combine a half mole of the solvent molecule. Compound IV was linked with the dipeptide ester, which was prepared from the hydrogenolysis product of compound VI, to obtain *t*-butyloxycarbonyl-nitro-L-arginyl-L-tryptophyl-glycine methyl ester (VII). Compound VII failed to crystallize, but it could easily be purified by reprecipitation from ethyl acetate. The trifluoroacetic acid treatment[5] of VII afforded the tripeptide trifluoroacetate (VIII). A small amount of a colored by-product, which gave an anomalous color reaction with the Ehrlich reagent and which ran a little faster than the desired product VIII on paper in the system of 1-butanol - acetic acid - water (4 : 1 : 2), was removed by simple extraction of the aqueous solution with ethyl acetate. The purified tripeptide ester was then condensed with *t*-butyloxycarbonyl-L-phenylalanine to obtain the crystalline protected tetrapeptide *t*-butyloxycarbonyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine methyl ester (IX). The diacyl-L-histidine *p*-nitrophenyl ester V was prepared in the form of fine needles by two different methods. One of these was the ordinary DCCI method, by which $N^{\alpha}$,$N^{Im}$-dicarbobenzoxy-L-histidine[6] was condensed with *p*-nitrophenol in an excellent yield. Another procedure involved transesterification between the diacyl-L-histidine and *p*-nitrophenyl trifluoroacetate, which was very recently utilized by Sakakibara and Inukai for the preparation of carboxylic acid *p*-nirophenyl esters.[7] The latter method also gave the desired compound in a moderate yield, especially with high purity. This active ester was allowed to react in an acetonitrile solution with the phenylalanyl tetrapeptide ester (X), which was derived from the protected peptide IX by the trifluoroacetic acid treatment, affording in a yield of 72.3% the pentapeptide $N^{\alpha}$,$N^{Im}$-dicarbobenzoxy-L-histidy-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine methyl ester (XI), which crystallized as the monohydrate upon treating with hot 90% methanol. Saponification of the methyl ester XI yielded carbobenzoxy-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine (XII), accompanied by splitting of the $N^{Im}$-carbobenzoxy group.

The procedure for synthesis of the hexapeptide III is shown in Fig. 2. Carbobenzoxy-$\gamma$-*t*-buty-L-glutamyl-$N^{Im}$-carbobenzoxy-L-histidine methyl ester (XIII) was synthesized by the coupling of carbobenzoxy-$\gamma$-*t*-butyl-L-glutamic acid[8] with $N^{Im}$-carbobenzoxy-L-histidine methyl ester, the preparation of which has already been described.[6] The yield amounted to 90 per cent after recrystallization. Hydrazinolysis in the next step brought about an immediate cleavage at the $N^{Im}$-carbobenzoxy bonding to result in the formation of benzyl carbazate which was isolated subsequent to the desired carbobenzoxy-$\gamma$-*t*-butyl-L-glutamyl-L-histidine hydrazide (XIV). Compound XIV

7) S. Sakakibara and N. Inukai, This Bulletin, **37**, 1231 (1964).
8) R. Schwyzer and H. Kappeler, *Helv. Chim. Acta*, **44**, 1991 (1961); H. Kappeler and R. Schwyzer, ibid., **44**, 1136 (1961).

was obtained in an 83 per cent yield as the monohydrate which melted first at 85—95°C, resolidified at 105—115°C and melted again at 144—146°C. The hydrazide XIV and the phenylalanyl tetrapeptide ester trifluoroacetate X (1.1 : 1.2 molar ratio) were converted into the corresponding azide and the free base, respectively, and these were allowed to react in an acetonitrile-ethyl acetate (2 : 5 by volume) mixture to obtain the protected hexapeptide carbobenzoxy-$\gamma$-*t*-butyl-L-glutamyl-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine methyl ester (XV) in an excellent yield (80%). The methyl ester of compound XV was preferentially saponified to give carbobenzoxy-$\gamma$-*t*-butyl-L-glutamyl-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine (XVI), which was purified by reprecipitation from dimethylformamide-methanol to remove the unreacted diester XV. The monoacid monoester XVI gave a single round spot ($R_f$=0.68) on silica gel in the system of dimethylformamide-ethyl acetate (1 : 1 by volume), whereas the diester XV had an $R_f$ value of 0.92 in the same solvent system.

Figure 3 summarizes the present synthesis of the tetrapeptide I, an outline of which has

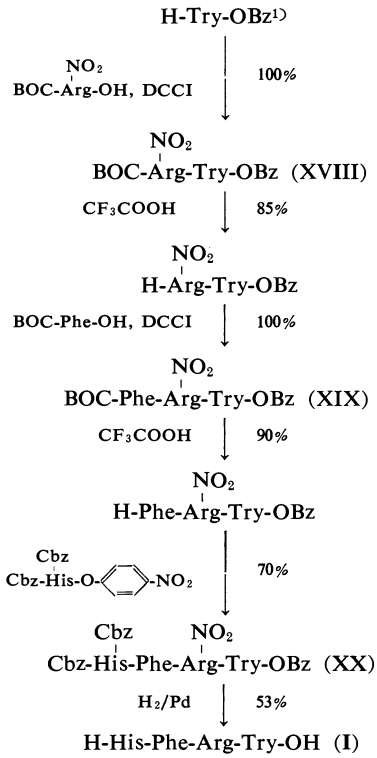

Fig. 3. Scheme for the synthesis of L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophan.
Cbz, carbobenzoxy; BOC, *t*-butyloxycarbonyl, Bz, benzyl; DCCI, *N*, *N'*-dicyclohexylcarbodiimide.

already been cited in the previous paper dealing with the first synthesis of I.[1] The synthetic steps for each intermediate product are substantially identical with those employed in the course of the synthesis of compound XI. The carbodiimide coupling reactions afforded the protected dipeptide *t*-butyloxycarbonyl-nitro-L-arginyl-L-tryptophan benzyl ester (XVIII) and the tripeptide *t*-butyloxycarbonyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophan benzyl ester (XIX) in quantitative yields; the occurrence of unfavorable side reactions seemed to be slight since they were not detectable by thin-layer chromatography on silica gel. Both of these products, however, resisted all attempts at crystallization. The protected tripeptide XIX was found to be contaminated with a small amount of an impurity which gave an anomalous yellow color reaction with the Ehrlich reagent and which had chromatographic behaviors very similar to the desired product. It appeared most likely that the impurity was derived from a side product which had formed through the trifluoroacetic acid treatment prior to the coupling reaction. Compound XIX was then used in the subsequent reaction without further purification. The reaction of $N^{\alpha}$ $N^{\mathrm{Im}}$-dicarbobenzoxy-L-histidine *p*-nitrophenyl ester (V) with the tripeptide ester, which was derived form XIX in the usual way, was carried out in an acetonitrile solution to obtain the protected tetrapeptide $N^{\alpha}$, $N^{\mathrm{Im}}$-dicarbobenzoxy-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophan benzyl ester (XX), the greater part of which separated in a pure form from the reaction medium. In contrast to the tosylated tetrapeptide derivative $N^{\alpha}$, $N^{\mathrm{Im}}$-dicarbobenzoxy-L-histidyl-L-phenylalanyl-$N^{\mathrm{G}}$-*tosyl*-L-arginyl-L-tryptophan benzyl ester,[1] which was freely soluble even in ethyl acetate, compound XX had very low solubilities in most of the ordinary solvents.

The carbobenzoxy, nitro, and benzyl ester groups were removed by subsequent catalytic hydrogenolysis to liberate the free tetrapeptide (I) and the free pentapeptide (II) from compounds XX and XII, respectively, and the partially protected hexapeptide (XVII) was obtained from compound XVI in the same way. The free hexapeptide (III) was obtained from XVII by the treatment with trifluoroacetic acid.

Each of these fully deblocked peptide preparations was purified on a carboxymethyl cellulose (CMC) column by means of step-by-step elution with ammonium acetate buffers, where it was found especially in case of the tetrapeptide that a clear-cut separation of the pure material by the CMC column chromatography could be easily performed when the crude sample had previously been purified by partitioning on a

Sephadex column with a solvent system such as 1-butanol - acetic acid - water (4 : 1 : 2 by volume). The results typical of the chromatographic experiments with the tetrapeptide are presented in Figs. 4 and 5. The purified peptides I, II and III gave in each case a single ninhydrin, Pauly, Ehrlich, and Sakaguchi reactive spot on paper chromatography in the different solvent systems and on paper electrophoresis at different pH values. These peptide preparations were also found to be completely digestible by leucine aminopeptidase to give the amino acids in molar ratios consistent with the theoretical values. The biological investigations of these synthetic peptides will be presented in a separate communication in the near future.

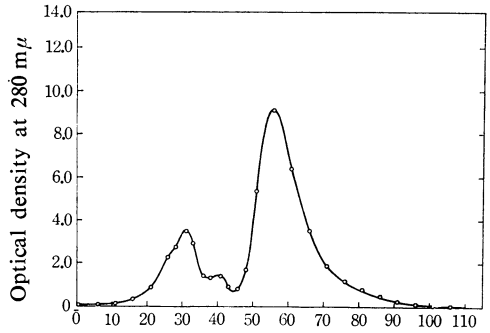

Fig. 4. Partition chromatography of crude L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophan on a Sephadex G-25 column.
Material: Synthetic tetrapeptide, 0.350 g.
Column: Sephadex G-25 (coarse), 2.8×105 cm.
Solvent system: 1-Butanol - acetic acid - water (4 : 1 : 2 by vol.)
Flow rate: 0.8 ml./min.

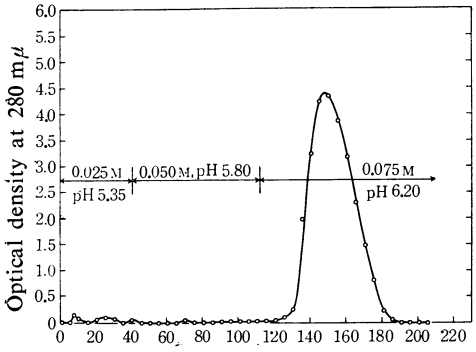

Fig. 5. Rechromatography of purified L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophan on a carboxymethyl cellulose column.
Material: Synthetic tetrapeptide, 0.430 g.
Column: CM-cellulose (Serva, 0.44 meq./g.), 1.7×40 cm.
Buffer: Ammonium acetate
Flow rate: 2 ml./min.

## Experimental

All melting points were uncorrected.

***t*-Butyloxycarbonyl-nitro-L-arginine (IV).**—Nitro-L-arginine (32.9 g., 0.15 mol.) and 19.1 g. (0.18 mol.) of sodium carbonate were dissolved in 300 ml. of water at 60—70°C and dioxane (300 ml.) was introduced. To this solution was added - dropwise 25.8g. (0.18 mol.) of *t*-butyl azidoformate[9,10] at a bath temperature of 45°C and the mixture was stirred for 18 hr. at the same temperature. The reaction mixture was then cooled in an ice-bath and neutralized with 90.0 ml. of ice-cold 4 N hydrochloric acid (pH 4). After the fine precipitates of unreacted nitro-L-arginine had been removed by filtration (6.0 g., 0.028 mol.) the filtrate was concentrated to about 200 ml. at 40—45°C in vacuo. The concentrated solution was acidified to below pH 2 with ice-cold 4 N hydrochloric acid in the presence of ethyl acetate (300 ml.) at 0°C. The aqueous phase was extracted three times with 150 ml.-portions of cold ethyl acetate. The ethyl acetate extracts were pooled, dried over anhydrous sodium sulfate, and evaporated at 35°C in vacuo. The resultant sirupy residue crystallized upon treatment with 150 ml. of ethyl acetate. After storage in a refrigerator overnight the crystals were filtered off, washed with cold ethyl aetate and ether, and dried at room temperature in vacuo to give the product, which combined about a half mole of ethyl acetate; yield 30.20 g. (68.2% as calculated for 0.122 mol.), m. p. 98—102°C (resolidified at 165—166°C followed by decomposition at 237—238°C). A methanolic solution of the 0.50 g. sample was evaporated in vacuo and the sirupy residue was crystallized from ethyl acetate and air-dried to give a sample for analyses; m. p. 98—100°C, $[\alpha]_D^{25.5}$ +2.8±1° (*c* 2.296, methanol), $[\alpha]_D^{23.5}$ −3.0±1° (*c* 1.614, water), $[\alpha]_D^{23.5}$ −0.7±0.5° (*c* 1.597, acetic acid).

Found: C, 42.67; H, 7.03; N, 19.69; $CH_3CO$, 5.21. Calcd. for $C_{11}H_{21}N_5O_6 \cdot 1/2CH_3COOC_2H_5$: C, 42.97; H, 6.93; N, 19.27; $CH_3CO$, 5.92%.

A sample was treated with trifluoroacetic acid followed by neutralization with ammonia to give, in a 93% yield, nitro-L-arginine which had $[\alpha]_D^{25.5}$ +23.9±0.5° (*c* 4.031, 2 N hydrochloric acid); lit.[11] $[\alpha]_D^{25}$ +24.5° (*c* 4.12, 2 N hydrochloric acid).

***N*$^{\alpha}$, *N*$^{\mathrm{Im}}$-Dicarbobenzoxy - L - histidine *p* - Nitrophenyl Ester (V).**—*By the DCCI Method.*—*N*$^{\alpha}$, *N*$^{\mathrm{Im}}$-Dicarbobenzoxy-L-histidine[6] (12.70 g., 0.03 mol.) and 4.18 g. (0.03 mol.) of *p*-nitrophenol were dissolved in 60 ml. of warm ethyl acetate and to this mixture was added an ethyl acetate solution of 6.20 g. (0.03 mol.) of *N*, *N'*-dicyclohexylcarbodiimide (DCCI) at 0°C. The reaction mixture was then

9) L. A. Carpino, *J. Am. Chem. Soc.*, **79**, 98 (1957); L. A. Carpino, C. A. Giza and B. A. Carpino, ibid., **81**, 955 (1959).

*By the Use of Sakakibara's Reagent.*[7]—To a solution of 2.117 g. (5 mmol.) of $N^{\alpha}$, $N^{Im}$-dicarbobenzoxy-L-histidine[6] in 5 ml. of pyridine was added 1.176 g. (5 mmol.) of *p*-nitrophenyl trifluoroacetate[7] at 0°C, and the mixture was allowed to stand at room temperature for 30 min. Most of the solvent was removed in vacuo at a bath temperature of 40°C; the oily residue was then treated with 15 ml. of anhydrous ethanol. The Amorphous precipitates which formed crystallized slowly. After storage in a refrigerator overnight the crystals were filtered off, washed with anhydrous ethanol, and dried in vacuo; yield 1.904 g. (70.0%), m. p. 104—106°C. Recrystallization from anhydrous ethanol gave, in a recovery of 85%, a sample with a m. p. of 110—111°C; $[\alpha]_D^{24.5}$ −15.9±1° (*c* 2.018, ethyl acetate), $[\alpha]_D^{24.5}$ −13.3±1° (*c* 1.948, chloroform).

Found: C, 61.72; H, 4.55; N, 10.30. Calcd. for $C_{28}H_{24}N_4O_8$: C, 61.76; H, 4.44; N, 10.29%.

**Carbobenzoxy-L-tryptophyl-glycine Methyl Ester (VI).**—To a suspension of 4.06 g. (0.012 mol.) of carbobenzoxy-L-tryptophan in 40 ml. of methylene chloride was added 2.86 ml. (0.012 mol.) of tri-*n*-butylamine. The resultant clear solution was kept in an ice-bath and to this were added 1.51 g. (0.012 mol.) of glycine methyl ester hydrochloride and a methylene chloride solution of 2.48 g. (0.012 mol.) of DCCI with stirring. The reaction mixture was then allowed to stand at 0°C overnight.*1 The separated dicyclohexylurea was removed by filtration (2.55 g., 94.8%) and the filtrate was evaporated in vacuo to afford a foamy residue, which was redissolved in ethyl acetate. The solution was washed with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate, and finally with water, and dried over anhydrous sodium sulfate. The crystalline precipitate, which separated during concentration of the ethyl acetate solution, was collected to give a yield of 4.69 g. (95.5%); m. p. 153—157°C. Recrystallization from ethyl acetate-ether gave, in a recovery of 92.5%, crystals with m. p. 156—158°C, $[\alpha]_D^{24}$ −12.1±0.7° (*c* 3.058, glacial acetic acid). Lit. m. p. 158—159°C, $[\alpha]_D^{27}$ −11.0° (*c* 2, glacial acetic acid);[14] m. p. 156—158°C, $[\alpha]_D^{22}$ −11.0±0.5° (*c* 3, glacial acetic acid).[15]

Found: C, 64.47; H, 5.84; N, 10.34. Calcd. for $C_{22}H_{23}N_3O_5$: C, 64.54; H, 5.66; N, 10.26%.

***t*-Butyloxycarbonyl-nitro-L-arginyl-L-tryptophyl-glycine Methyl Ester (VII).**—A suspension of 11.25 g. (0.0275 mol.) of compound VI in 180 ml. of methanol containing 3 ml. of acetic acid was hydrogenated over palladium black catalyst for 2.5 hr. After the catalyst had been removed by filtration the filtrate was evaporated in vacuo at 35°C. The resultant foamy residue was dissolved in 50 ml. of water and the aqueous solution was washed with 15 ml. portions of ethyl acetate. A mixture of this aqueous solution and 80 ml. of methylene chloride was shaken with 40 ml. of ice-cold 50% (w/v) potassium carbonate at 0°C. The aqueous phase was extracted again with methylene chloride. The organic extracts were combined, dried over anhydrous sodium sulfate and concentrated to about 60 ml. at 20°C in vacuo to give a solution of the dipeptide ester. To this was then added a solution of 9.32 g. (0.025 mol.) of compound IV in 25 ml. of dimethylformamide and a methylene chloride solution of 5.68 g. (0.0275 mol.) of DCCI at 0°C. The reaction mixture (total volume ca. 120 ml.) was kept in a refrigerator for 34 hr. The gelatinous precipitate which formed was collected by filtration and washed with cold methylene chloride; the mother liquor and washings were pooled. The precipitate was redissolved in 150 ml. of hot ethyl acetate and the solution was carefully filtered to remove the insoluble urea (5.32 g., 95.0%). The mother liquor was washed successively with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate, and water. The gelatinous precipitate which separated during these washes was collected, washed with water and redissolved in 100 ml. of hot ethyl acetate, and this solution, after being dried quickly over anhydrous sodium sulfate, was combined with the ethyl acetate solution obtained above. The combined solution (total volume 300 ml.) was allowed to stand in a refrigerator overnight and the separated precipitate was filtered off, washed with cold ethyl acetate and with ether, and dried over phosphorus pentoxide at 60°C in vacuo to constant weight; yield 13.21 g. (91.7%), hygroscopic powder, m. p. 111—114°C. Thin-layer chromatography on silica gel in a solvent system of chloroform-methanol (85:15) gave a single round spot ($R_f$=0.7). A sample was reprecipitated from ethyl acetate, dried as above and stabilized in the air for analyses; m. p. 112—114°C, $[\alpha]_D^{24.5}$ −21.7±0.7° (*c* 3.022, methanol).

Found: C, 51.93; H, 6.68; N, 19.00. Calcd. for $C_{25}H_{36}N_8O_8 \cdot 1/2H_2O$: C, 51.27; H, 6.37; N, 19.14%.

**Nitro-L-arginyl-L-tryptophyl-glycine Methyl Ester Trifluoroacetate (VIII).**—To a solution of 7.22 g. of the anhydrous compound VII in 7 ml. of glacial acetic acid was added 40 ml. of anhydrous trifluoroacetic acid and the mixture was allowed to

12) F. Sakiyama, This Bulletin, **35**, 1943 (1962).

stand under nitrogen at room temperature for 45 min., after which time 500 ml. of ether was introduced under ice-cooling. The resultant precipitate was collected by filtration, washed thoroughly with ether, and dried to give the crude tripeptide ester trifluoroacetate; yield 6.79 g. (92.0%). This crude preparation was dissolved in 80 ml. of water and the aqueous solution was washed three times with 20 ml. portions of ethyl acetate and then lyophilized, affording a pale yellow fluffy powder (4.93 g.) which gave a single ninhydrin and Ehrlich reactive spot on paper [$R_f$=0.74 (BAW)]*2; m. p. 122—126°C, $[\alpha]_D^{23.5}$ +16.1±1° (*c* 1.918, methanol).

Found: C, 44.13; H, 5.12; N, 18.78. Calcd. for $C_{20}H_{28}N_8O_6 \cdot CF_3COOH$: C, 44.75; H, 4.95; N, 18.98%.

The ethyl acetate washings were combined and evaporated in vacuo to afford a light brown solid, which gave a minor spot ($R_f$=0.85) in addition to a major one ($R_f$=0.74) on paper in the same solvent system as above. The minor component was positive to ninhydrin but it gave an anomalous bluish color reaction with the Ehrlich reagent.

***t*-Butyloxycarbonyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine Methyl Ester (IX).**—A solution of 5.02 g. (8.5 mmol.) of compound VIII in 10 ml. of water was mixed with 8 ml. of 1-butanol and 40 ml. of ethyl acetate. The mixture was shaken with 20 ml. of ice-cold 50% (w/v) potassium carbonate at 0°C. The aqueous phase was extracted again with 1-butanol-ethyl acetate (1:5). The organic extracts were combined, dried over anhydrous sodium sulfate, and evaporated in vacuo. The oily residue was triturated with ether and the resulting white solid was dried over sodium hydroxide pellets in vacuo. The tripeptide ester so obtained was dissolved in acetonitrile together with *t*-butyloxycarbonyl-L-phenylalanine (prepared from 3.795 g. (8.5 mmol.) of the dicyclohexylamine salt)[1] and to this solution was added an acetonitrile solution of 1.75 g. (8.5 mmol.) of DCCI at 0°C. The reaction mixture (total volume ca. 50 ml.) was kept in a refrigerator overnight. The urea which formed was removed (1.73 g., 91.2%) and the solution was evaporated in vacuo. The residue was redissolved in 60 ml. of ethyl acetate and the solution was washed successively with ice-cold N hydrochloric acid, water, M sodium bicarbonate, and water, dried briefly over anhydrous sodium sulfate, and then allowed to stand in a refrigerator overnight. The gelatinous precipitate was filtered off, washed with cold ethyl acetate and ether, and dried in vacuo to afford 5.28 g. (85.9%) of the tetrapeptide, which crystallized readily from hot acetonitrile. Recrystallization from acetonitrile was repeated twice to give colorless needles in a recovery of 80%; m. p. 172—173°C, $[\alpha]_D^{25}$ −20.1±1° (*c* 2.054, methanol).

Found: C, 56.24; H, 6.57; N, 17.35. Calcd. for $C_{34}H_{45}N_9O_9$: C, 56.42; H, 6.27; N, 17.42%.

**L-Phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine Methyl Ester Trifluoroacetate (X).**—To a solution of 1.810 g. of IX in 2 ml. of acetic acid was added 8 ml. of anhydrous trifluoroacetic acid at 0°C and the mixture was kept under nitrogen at room temperature for 45 min., after which time 100 ml. of ether was introduced. The resultant precipitate was filtered off, washed thoroughly with ether, and dried in vacuo to give the tetrapeptide trifluoroacetate as a slightly cream-colored powder; yield 1.765 g. (96.0%). An aqueous solution of a small amount of this crude material was twice washed with ethyl acetate and then lyophilized to give an almost colorless fluffy powder; $[\alpha]_D^{27}$ −1.5 ±1° (*c* 1.384, methanol).

Found: C, 49.27; H, 5.34; N, 16.68. Calcd. for $C_{29}H_{37}N_9O_7 \cdot CF_3COOH \cdot H_2O$: C, 49.79; H, 5.52; N, 16.50%.

***N*$^{\alpha}$, *N*$^{\mathrm{Im}}$-Dicarbobenzoxy-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine Methyl Ester (XI).**—A 1.476 g. sample (2.0 mmol.) of the crude trifluoroacetate X obtained just above was dissolved in 4 ml. of 1-butanol and 20 ml. of ethyl acetate, and this solution was shaken vigorously with 5 ml. of ice-cold 50% (w/v) potassium carbonate at 0°C. The separated organic phase was dried over anhydrous sodium sulfate and evaporated in vacuo at 30°C. The oily residue, which solidified upon addition of ether, was dried in vacuo. The ensuing free ester was dissolved in acetonitrile and this was mixed with an acetonitrile solution of 1.090 g. (2.0 mmol.) of *N*$^{\alpha}$, *N*$^{\mathrm{Im}}$-dicarbobenzoxy-L-histidine *p*-nitrophenyl ester (V). The reaction mixture (total volume 22 ml.) was kept in a refrigerator for 56 hr. The precipitate, which had separated during the storage, was filtered off, washed with cold acetonitrile and ether, and dried in vacuo; wt. 0.800 g., m. p. 145—147C (decomp.) (sintering at 131°C). The filtrate and washings were combined and evaporated in vacuo to give a foamy residue, which was dissolved in ethyl acetate and washed with 12 ml. portions of ice-cold N ammonia (4 times). The precipitate, which separated during these washes, was collected, washed with ethyl acetate and water, and dried over phosphorus pentoxide in vacuo; wt. 0.960 g., m. p. 145—146°C decomp. (sintering at 132°C). Total yield amounted to 1.760 g. (85.9%). A suspension of the product (1.760 g.) in 15 ml. of acetone was stirred for several minutes at the boiling point of the solvent and then refrigerated overnight. The precipitate was treated again with hot acetone to obtain the pure pentapeptide; wt. 1.487 g. (recovery 84.5%), m. p. 157—159°C (decomp.) (sintering at 150°C), $[\alpha]_D^{25.5}$ −22.7±0.5° (*c* 3.179, dimethylformamide).

Found: C, 59.25; H, 5.75; N, 16.20. Calcd. for $C_{51}H_{56}N_{12}O_{12}$: C, 59.52; H, 5.49; N, 16.33%.

An additional treatment with hot 90% methanol caused the compound to crystallize as the monohydrate; recovery 97%, m. p. 158—159°C (decomp.) (sintering at 136°C), $[\alpha]_D^{25.5}$ −21.5±0.5° (*c* 2.429, dimethylformamide).

Found: C, 58.27; H, 6.06; N, 16.00. Calcd. for $C_{51}H_{56}N_{12}O_{12} \cdot H_2O$: C, 58.50; H, 5.58; N, 16.05%.

**Carbobenzoxy-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine (XII).**—To a suspension of 0.515 g. (0.5 mmol.) of compound XI in 6 ml. of 90% dioxane was added 1.5 ml. of N sodium

*2 Abbreviation for the solvent systems employed in paper chromatography is as follows: BAW=1-butanol-acetic acid-water (4:1:2 by vol.). BAPW=1-butanol-acetic acid-pyridine-water (30:6:20:24 by vol.).

hydroxide and the mixture was shaken at room temperature for 30 min., after which time ice-cold water (25 ml.) was introduced and the resultant solution was neutralized (pH 4) with 1.5 ml. of N hydrochloric acid. The gelatinous precipitate was filtered off, washed with water, and then reprecipitated from hot acetic acid - water; yield 0.453 g. (98.0%), m. p. 212—213°C (decomp.). A sample for analyses was reprecipitated again from acetic acid - water, dried over phosphorus pentoxide at 80°C and 2—3 mmHg pressure for several hours, and then equilibrated in the air overnight; m. p. 222—227°C (decomp.), $[\alpha]_D^{25.5}$ $-26.0\pm2°$ (*c* 1.065, dimethylformamide). Lit. m. p. 246—249°C, $[\alpha]_D^{26}$ $-29.2°$ (*c* 1.2, dimethylformamide);[16] m. p. 226—228°C (decomp.), $[\alpha]_D^{22}$ $-26.8\pm0.5°$ (*c* 3, dimethylformamide).[15]

Found: C, 54.79; H, 5.71; N, 18.75; $H_2O$, 4.60; $CH_3CO$, 0.00. Calcd. for $C_{42}H_{48}N_{12}O_{10}\cdot2.5H_2O$: C, 54.48; H, 5.77; N, 18.15; $H_2O$, 4.86; $CH_3CO$, 0.00%.

**Carbobenzoxy-γ-*t*-butyl-L-glutamyl-$N^{1m}$-carbobenzoxy-L-histidine Methyl Ester (XIII).**—To a solution of 4.74 g. (0.01 mol.) of $N^{\alpha}$, $N^{1m}$-dicarbobenzoxy-L-histidine methyl ester hydrochloride[6,17] in 10 ml. of glacial acetic acid was added 30 ml. of 33% (w/w) hydrogen bromide in acetic acid and the mixture was kept at room temperature for 15 min. with occasional shaking. At the end of this period anhydrous ether (200 ml.) was introduced and the resultant precipitate was filtered off, washed with methylene chloride and with ether, and dried in vacuo to give the dihydrobromide of $N^{1m}$-carbobenzoxy-L-histidine methyl ester;[6] wt. 4.40 g. (94.7%). To an aqueous solution of this product in 30 ml. of water were added 60 ml. of methylene chloride and 4 ml. of ice-cold 28% aqueous ammonia, and the mixture was shaken vigorously at 0°C. The aqueous phase was extracted again with cold methylene chloride. The organic extracts were pooled, dried over anhydrous sodium sulfate at 0°C and evaporated in vacuo at a bath temperature of 25°C. The resultant sirupy residue was dissolved in methylene chloride together with carbobenzoxy-γ-*t*-butyl-L-glutamic acid (prepared from 4.15 g. (0.008 mol.) of the dicyclohexylamine salt by treatment with Dowex-50)[8] and to this was added a methylene chloride solution of 1.65 g. (0.008 mol.) of DCCI at 0°C. The reaction mixture was then allowed to stand in a refrigerator overnight. After removal of the separated urea (1.73 g., 96.6%) the solvent was evaporated in vacuo. The sirupy residue was dissolved in ethyl acetate and the solution was washed successively with ice-cold N hydrochloric acid, water, ice-cold 5% sodium bicarbonate, and with water, dried over anhydrous sodium sulfate, and evaporated to afford a sirupy residue, which crystallized from ethyl acetate - petroleum ether; yield 4.57 g. (91.8%), m. p. 100—102°C. Recrystallization from the same solvent gave 4.48 g. (90.0%); m. p. 101—102°C, $[\alpha]_D^{24}$ $-6.1\pm1°$ (*c* 2.475, methanol).

Found: C, 61.87; H, 6.30; N, 9.38. Calcd. for $C_{32}H_{38}N_4O_9$: C, 61.75; H, 6.15; N, 9.00%.

**Carbobenzoxy-γ-*t*-butyl-L-glutamyl-L-histidine Hydrazide (XIV).**—Compound XIII (12.45 g., 0.02 mol.) was suspended in 60 ml. of anhydrous ethanol and to this was added 6.0 ml. of hydrazine hydrate at 0°C. The reaction mixture was stirred at 0°C until the solid disappeared within several minutes. After the mixture had been allowed to stand in a refrigerator for 68 hr., water (240 ml.) was introduced. The ensuing sirupy precipitate soon crystallized and the crystals were filtered off, washed with cold water and dried; wt. 8.51 g. Concentration of the mother liquor gave an additional 0.735 g. of crystals; total yield amounted to 9.245 g. (91.3%). These crystals were recrystallized from ethanol-water (1 : 4) to give a yield of 8.425 g. (83.2%). The pure sample melted first at 85—95°C, resolidified at 105—115°C, and melted again at 144—146°C, $[\alpha]_D^{23}$ $-41.0\pm1°$ (*c* 2.075, N hydrochloric acid). Lit.[8] m. p. 140—142°C (sintering at 75°C), $[\alpha]_D^{26}$ $-40.5\pm0.5°$ (*c* 1.91, N hydrochloric acid).

Found: C, 54.40; H, 6.98; N, 16.71. Calcd. for $C_{23}H_{32}N_6O_6\cdot H_2O$: C, 54.53; H, 6.77; N, 16.59%.

Refrigeration of the mother liquor, from which the second crop of the compound XIV had been separated, afforded thin needles of *benzyl carbazate*; wt. 1.40 g., m. p. 62—66°C.

Found: C, 57.71; H, 6.21; N, 16.95. Calcd. for $C_8H_{10}N_2O_2$: C, 57.82; H, 6.07; N, 16.86%.

**Carbobenzoxy-γ-*t*-butyl-L-glutamyl-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine Methyl Ester (XV).**—To a solution of 5.57 g. (0.011 mol.) of the hydrazide XIV in ca. 10 ml. of dimethylformamide, which had been previously cooled in an ice-salt bath, were added 45 ml. of ice-cold N hydrochloric acid and 6.05 ml. (0.012 mol.) of ice-cold 2 M sodium nitrite, and the mixture was stirred for 4 min., after which time 45 ml. of ice-cold M sodium carbonate and 30 ml. of ice-cold saturated sodium chloride were added. The ensuing precipitate of the azide was taken up into ice-cold ethyl acetate. The ethyl acetate extracts were pooled, dried over anhydrous sodium sulfate, and mixed with a solution of L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine methyl ester (prepared from 8.87 g. (0.012 mol.) of the tritfluoroacetate X in the same manner as described in the synthesis of XI) in 95ml. of acetonitrile. The reaction mixture (total volume 350 ml.) was then kept at 0—4°C for 48 hr. The gelatinous precipitate, which formed, was filtered off, washed with ethyl acetate and with ether, and dried; yeild 9.52 g. (80.1%), m. p. 183—186°C (sintering at 173°C). The crude product (9.42 g.) was suspended in 110 ml. of acetonitrile and this was stirred for several minutes at the boiling point of the solvent to afford a homogeneous mixture, which was allowed to stand in a refrigerator overnight. The precipitate was filtered off, washed with acetonitrile and with ether, and dried to give the pure hexapeptide derivative; wt. 9.21 g. (recovery 97.8%), $R_f$=0.92 in thin-layer chromatography on silica gel in the system of dimethylformamide - ethyl acetate (1 : 1 by vol.), m. p. 185—186°C (sintering at 180°C), $[\alpha]_D^{27.5}$ $-33.0\pm1°$ (*c* 1.999, dimethyl-

16) K. Hofmann and S. Lande, *J. Am. Chem. Soc.*, **83**, 2286 (1961).
17) A. Patchornik, A. Berger and E. Katchalski, ibid., **79**, 6416 (1957).

formamide), $[\alpha]_D^{27.5}$ $-33.1\pm4°$ (*c* 0.592, methanol). Lit.[8] m. p. 176—178°C (sintering at 170°C), $[\alpha]_D$ $-30.9\pm0.5°$ (*c* 2.01, methanol).

Found: C, 56.83; H, 6.24; N, 16.83. Calcd. for $C_{52}H_{65}N_{13}O_{13}\cdot H_2O$: C, 56.87; H, 6.15; N, 16.58%.

**Carbobenzoxy-γ-*t*-butyl-L-glutamyl-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophyl-glycine (XVI).**—Compound XV (3.85 g., 3.5 mmol.) was dissolved in 50 ml. of 75% dioxane and to this was added 4.0 ml. of N sodium hydroxide. The mxiture was shaken at room temperature for 30 min., after which time ice-cold water (300 ml.) was introduced. The solution was then neutralized with 4.15 ml. of N hydrochloric acid to separate the desired product as a gelatinous precipitate. After refrigeration for a few hours the precipitate was filtered off, washed with water and dried to give 3.76 g. (99.2%), m. p. 215—216.5°C (decomp). (sintering at 190°C). The precipitate was reprecipitated from 15 ml. of dimethylformamide and 105 ml. of methanol; yield 3.44 g. (90.8%), m. p. 217—218°C (decomp.). A small sample was reprecipitated from a large volume of 90% methanol resulting in partial crystallization as needles; $R_f$= 0.68 in thin-layer chromatography on silica gel in the system of dimethylformamide-ethyl acetate (1 : 1 by vol.), m. p. 217°C (decomp.), $[\alpha]_D^{26.5}$ $-26.8\pm1°$ (*c* 2.141, dimethylformamide), lit.[8] m. p. 210°C, $[\alpha]_D$ $-22.2\pm1°$ (*c* 1.056, dimethylformamide).

Found: C, 56.12; H, 6.46; N, 16.46; $H_2O$, 2.89. Calcd. for $C_{51}H_{63}N_{13}O_{13}\cdot1.5H_2O$: C, 56.03; H, 6.09; N, 16.66; $H_2O$, 2.47%.

**γ-*t*-Butyl-L-glutamyl-L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine Monoacetate (XVII).**—A solution of 1.084 g. (1.0 mmol.) of XVI in 40 ml. of 90% acetic acid was stirred under hydrogen in the presence of palladium-black catalyst for 17 hr. Fresh catalyst was added after 6 hr. of hydrogenolysis. The catalyst was removed from the clear solution which was then evaporated at a bath temperature of 40—45°C, and the resultant oily residue was dissolved in a small volume of methanol. The peptide was precipitated by the addition of ether, lyophilized, and dried over phosphorus pentoxide and sodium hydroxide pellets at room temperature in vacuo; yield 0.977 g. (99.4%). A sample for analyses was dried over phosphorus pentoxide at 60°C and 2—3 mmHg pressure for 8 hr. and then equilibrated in the air overnight. Paper chromatography: $R_f$=0.60 (BAPW); 0.375 (BAPW) after the trifluoroacetic acid treatment. $[\alpha]_D^{27}$ $-10.3\pm4°$ (*c* 0.624, dimethylformamide); lit.[15] $[\alpha]_D^{20}$ $-13.5\pm1°$ (*c* 1, dimethylformamide).

Found: C, 54.26; H, 7.30; N, 17.13; $CH_3CO$, 4.16. Calcd. for $C_{43}H_{58}N_{12}O_9\cdot CH_3COOH\cdot2.5H_2O$: C, 54.48; H, 6.81; N, 16.94; $CH_3CO$, 4.34%.

***t*-Butyloxycarbonyl-nitro-L-arginyl-L-tryptophan Benzyl Ester (XVIII).**—A 4.00 g. sample (0.011 mol.) of *t*-butyloxycarbonyl-nitro-L-arginine (IV) was dissolved in 30 ml. of hot acetonitrile and the solution was cooled in an ice-bath. To this were added 3.24 g. (0.011 mol.) of L-tryptophan benzyl ester[1] and an acetonitrile solution of 2.27 g. (0.011 mol.) of DCCI, and the mixture was kept in a refrigerator overnight. The urea which formed was removed by filtration (2.28 g., 92.7%) and the filtrate was evaporated in vacuo. The resultant foamy residue was dissolved in ethyl acetate and this was washed successively with ice-cold N hydrochloric acid, water, M sodium bicarbonate and water, dried over anhydrous sodium sulfate and evaporated in vacuo. The residue was redissolved in a small volume of acetonitrile and a small amount of urea, which separated upon chilling, was filtered off. Evaporation of the solvent gave a foamy residue, which was dried over phosphorus pentoxide in vacuo to give an amorphous powder; yield 6.77 g. (100%), homogeneous to the Ehrlich reagent in thin-layer chromatography on silica gel in ethyl acetate, $[\alpha]_D^{22}$ $-4.2\pm1°$ (*c* 2.565, methanol).

Found: C, 59.16; H, 6.61; N, 15.61. Calcd. for $C_{29}H_{37}N_7O_7$: C, 58.48; H, 6.26; N, 16.46%.

The above analysis suggests that the product is contaminated with a small amount of urea, but it was utilized in the subsequent reaction without further purifiaction.

***t*-Butyloxycarbonyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophan Benzyl Ester (XIX).**—Compound XVIII (4.47 g., 7.5 mmol.) was dissolved in 4 ml. of acetic acid and to this solution was added 25 g. of anhydrous trifluoroacetic acid. The mixture was allowed to stand at room temperature for 60 min. under dry nitrogen. The dipeptide ester trifluoroacetate was then precipitated by the addition of 200 ml. of ether. The precipitate was filtered off, washed with cold methylene chloride and ether, and dried in vacuo; wt. 3.89 g. (85.2%), $[\alpha]_D^{25}$ $+11.6\pm1.5°$ (*c* 1.409, methanol).

Found: N, 15.91. Calcd. for $C_{24}H_{29}N_7O_5\cdot CF_3COOH$: N, 16.09%.

A solution of 3.74 g. (6.14 mmol.) of the trifluoroacetate in 50 ml. of 1-butanol-methylene chloride (1 : 3 by vol.) was cooled in an ice-bath and shaken with 10 ml. of 50% (w/v) potassium carbonate. The organic phase was dried over sodium sulfate and evaporated in vacuo to afford a sirupy residue, which was triturated and washed thoroughly with ether, and then dried in vacuo to give nitro-L-arginyl-L-tryptophan benzyl ester (3.19 g.). This free ester was then dissolved in 20 ml. of acetonitrile containing *t*-butyloxycarbonyl-L-phenylalanine (prepared from 2.90 g. (6.5 mmol.) of the dicyclohexylamine salt)[1] and to this was added an acetonitrile solution of 1.34 g. (6.5 mmol.) of DCCI at 0°C. The reaction mixture was allowed to stand in a refrigerator overnight. The dicyclohexylurea, which formed, was removed by filtration (1.34 g., 92.1%) and the filtrate was evaporated in vacuo to give an amorphous solid residue; the subsequent treatment was carried out in the same manner as for XVIII. Yield 4.78 g. (100%), $[\alpha]_D^{25}$ $-11.8\pm1°$ (*c* 2.272, methanol). Thin-layer chromatography on silica gel in ethyl acetate revealed the presence of a small amount of an impurity which moved ahead of and overlapped the desired tripeptide, and which gave a yellow color reaction with the Ehrlich reagent.

Found: C, 62.06; H, 6.73; N, 14.11. Calcd. for $C_{38}H_{46}N_8O_8$: C, 61.44; H, 6.24; N, 15.09%.

**$N^{\alpha}$, $N^{Im}$-Dicarbobenzoxy-L-histidyl-L-phenylalanyl-nitro-L-arginyl-L-tryptophan Benzyl Ester**

(**XX**).—To a solution of 1.860 g. (2.5 mmol.) of XIX in 2 ml. of acetic acid was added 8 ml. of anhydrous trifluoroacetic acid and the mixture was allowed to stand at room temperature for 45 min. under nitrogen. To this was then added 80 ml. of ether with ice-cooling; the resultant precipitate was collected, washed thoroughly with ether, and dried in vacuo to give 1.695 g. (89.8%) of the tripeptide ester trifluoroacetate. A suspension of the trifluoroacetate (1.695 g., 2.24 mmol.) in 20 ml. of ethyl acetate was shaken with 5 ml. of ice-cold 50% (w/v) potassium carbonate at 0°C. The organic phase was separated, dried over sodium sulfate and evaporated in vacuo. The resultant foamy residue was dissolved in 10 ml. of acetonitrile and this solution was combined with a solution of 1.220 g. (2.24 mmol.) of $N^{\alpha}$, $N^{\mathrm{Im}}$-dicarbobenzoxy-L-histidine *p*-nitrophenyl ester (V) in 15 ml. of acetonitrile and the mixture was then kept in a refrigerator for 44 hr. The precipitate which formed was filtered off, washed with cold ethyl acetate and with ether, and dried in vacuo; wt. 1.244 g. Evaporation of the filtrate gave a foamy residue, which was washed in an ethyl acetate solution with 12 ml. portions of ice-cold N ammonia (6 times), ice-cold N hydrochloric acid and with water, dried quickly over anhydrous sodium sulfate, and concentrated to about 15 ml. in vacuo. The precipitate, which separated during storage in a refrigerator, was collected and amounted to 0.699 g.; total yield 1.943 g. (82.7%), m. p. 161—163°C (decomp.). A suspension of the product in 20 ml. of ethyl acetate was stirred for several minutes at the boiling point of the solvent and then kept in a refrigerator overnight. The precipitates (1.686 g., m. p. 164—165°C (decomp.)) were treated again with hot ethyl acetate to afford the pure protected tetrapeptide; wt. 1.650 g. (recovery 85.0%), m. p. 167—168°C (decomp.), $[\alpha]_{\mathrm{D}}^{24\cdot5}$ $-12.3\pm1°$ (*c* 2.080, dimethylformamide).

Found: C, 63.25; H, 5.59; N, 14.78. Calcd. for $C_{55}H_{57}N_{11}O_{11}$: C, 63.03; H, 5.48; N, 14.70%.

**L-Histidyl-L-phenylalanyl-L-arginyl-L-tryptophan Monoacetate (I).**—The protected tetrapeptide XX (0.500 g.) was dissolved in 20 ml. of 90% acetic acid and the solution was stirred under hydrogen in the presence of palladium black for 18 hr. After the catalyst had been removed the solvent was evaporated at a bath temperature of 45°C and the residue was lyophilized twice to give 0.375 g. of fluffy powder. This crude tetrapeptide (0.350 g.) was dissolved in 5 ml. of a mixture 1-butanol - acetic acid - water (4 : 1 : 2 by vol.) and the solution was applied onto a column (2.8×105 cm.) of Sephadex G-25 (coarse, dry wt. 180 g.), which had been equilibrated with the BAW mixture. The column was then eluted with the same solvent system at a flow rate of 0.8 ml. per min.; 10 ml. fractions were collected. The chromatogram is shown in Fig. 4. The fractions in Tubes No. 51—95 were pooled and evaporated at 50°C in vacuo. The residue was then lyophilized twice to afford 0.430 g. (recovery 57% as calculated from the absorbance at 280 mμ) of fluffy powder. This purified peptide was next submitted to ion-exchange chromatography for further purification. The partially purified material (0.43 g.) was dissolved in 10 ml. of 0.025 M ammonium acetate (pH 5.35) and the solution was applied onto a column (1.7×40 cm.) of carboxymethyl cellulose (Serva, 0.44 meq./g.) which had been equilibrated with the same buffer solution. The column was then eluted successively with the following ammonium actate buffers: 0.025 M (pH 5.35), 400 ml.; 0.050 M (pH 5.80), 700 ml. (0.075 M (pH 6.20), 1000 ml. Individual fractions (10 ml. each) were collected at a flow rate of approximately 2 ml. per min. The chromatographic pattern is illustrated in Fig. 5. The fractions in Tubes No. 131—185 corresponding to the major peak were pooled and the bulk of water was removed at 50—55°C using a rotatory evaporator. The rest was then lyophilized three times affording a colorless fluffy powder; yield 0.188 g. (53% as based on XX used). The purified peptide behaved as a single ninhydrin, Pauly, Ehrlich, and Sakaguchi reactive spot in paper chromatography [$R_f$=0.48 (BAW), 0.49 (BAPW)], and in paper electrophoresis at pH 3.8, 6.6 and 11.1. A sample for analyses was dried over phosphorus pentoxide at 60°C and 2—3 mmHg pressure for 8 hr. and then equilibrated in the air overnight. $\lambda_{max}^{0.1\mathrm{N\ HCl}}$=280 mμ (ε=5450), 288 mμ (ε=4600); $\lambda_{max}^{0.1\mathrm{N\ NaOH}}$=280 mμ (ε=5500), 288 mμ (ε=4700). $[\alpha]_{\mathrm{D}}^{25}$ $-7.8\pm1.5°$ (*c* 1.484, N hydrochloric acid).*3 Amino acid ratios in acid hydrolyzate: His 1.00, Phe 0.91, Arg 0.95, Try 0.71 (decomposed partially with acid); amino acid ratios in leucine aminopeptidase*4 digest: His 1.00, Phe 0.94, Arg 0.94, Try 0.95.[18]

Found: C, 52.30; H, 6.56; N, 18.46. Calcd. for $C_{32}H_{40}N_{10}O_5\cdot CH_3COOH\cdot 4H_2O$: C, 52.57; H, 6.75; N, 18.03%.

**L-Histidyl-L-phenylalanyl-L-arginyl-L-tryptophylglycine Monoacetate (II).**—A suspension of 0.250 g. of XII in 20 ml. of 90% acetic acid was stirred under hydrogen in the presence of palladium-black catalyst for 14 hr. The catalyst was removed by filtration and the filtrate was evaporated at a bath temperature of 40—45°C in vacuo. The resultant oily residue was lyophilized and dried over phosphorus pentoxide and sodium hydroxide pellets affording 0.220 g. of fluffy powder. This crude pentapeptide was dissolved in 25 ml. of 0.025 M ammonium acetate (pH 5.35) and the solution was aplied to a column (1.2×50 cm.) of carboxymethyl cellulose (Serva, 0.6 meq./g.) which had been equilibrated with the same buffer solution. The column was then eluted successively with the following ammonium acetate buffers: 0.025 M (pH 5.35), 300 ml.: 0.05 M (pH 5.80), 600 ml.; 0.075 M (pH 6.20), 1600 ml. Individual fractions (10 ml. each) were collected at a flow rate of 2 ml. per min. Absorbancy measurements at 280 mμ revealed the presence of one major peak in Tubes No. 201—235 in the chromatogram. These fractions

*3 In our preceding papers the value, $[\alpha]_{\mathrm{D}}^{24\cdot5}$ $-5.4\pm2°$ (*c* 0.947, N hydrochloric acid), was given for this peptide as a result of a single measurement.[1] The present result appeared more reliable than the former, because the value was reproducible in repeated measurements.

18) D. H. Spackman, W. H. Stein and S. Moore, *Anal. Chem.*, 30, 1191 (1958).

corresponding to the major peak were pooled and the bulk of water was removed at a bath temperature of 50—55°C in vacuo resulting in the separation of a gelatinous precipitate of the peptide. The rest was lyophilized three times to give a colorless fluffy powder; yield 0.125 g. (58% as based on XII used). The purified material behaved as a single nihydrin, Pauly, Ehrlich, and Sakaguchi reactive spot in paper chromatography [$R_f$=0.38 (BAW), 0.41 (BAPW)], and in paper electrophoresis at pH 3.8, 6.6 and 11.1. A sample for analyses was dried over phosphorus pentoxide at 60°C and 2—3 mmHg. pressure for 8 hr. and equilibrated in the air overnight. $\lambda_{max}^{0.1N\ HCl}$=280 mμ (ε=5500), 288 mμ (ε=4650); $\lambda_{max}^{0.1N\ NaOH}$=280 mμ (ε=5650), 288 mμ (ε=4800). $[\alpha]_D^{26.5}$ −11.9±3° (*c* 0.606, N hydrochloric acid); lit. $[\alpha]_D^{26}$ −11.8° (*c* 0.9, N hydrochloric acid),[16] $[\alpha]_D^{22}$ −11.7±0.5° (*c* 1, N hydrochloric acid).[15] Amino acid ratios in acid hydrolyzate: His 1.00, Phe 0.90, Arg 0.97, Try 0.73 (decomposed patially with acid), Gly 0.98; amino acid ratios in leucine aminopeptidase*4 digest: His 1.00, Phe 0.92. Arg 0.91, Try 0.92, Gly 0.93.[18]

Found: C, 51.71; H, 6.88; N, 18.12; $CH_3CO$, 6.81; $H_2O$, 8.62. Calcd. for $C_{34}H_{43}N_{11}O_6 \cdot CH_3COOH \cdot 4H_2O$: C, 51.85; H, 6.65; N, 18.48; $CH_3CO$, 5.61; $H_2O$, 8.64%. Calcd. for $C_{34}H_{43}N_{11}O_6 \cdot 1.5CH_3COOH \cdot 4H_2O$: C, 51.44; H, 6.65; N, 17.84; $CH_3CO$, 7.47; $H_2O$, 8.34%.

**L-Glutamyl-L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine (III).**—An 0.250 g. sample of XVII was dissolved in 4 ml. of anhydrous trifluoroacetic acid and the solution was allowed to stand at room temperature for 30 min., after which time, ether was introduced to precipitate the hexapeptide trifluoroacetate. The precipitate was dissolved in a few milliliters of water and the solution was passed through a small Amberlite IR-45 column (acetate form). The column was washed with water and the eluate were pooled and lyophilized, affording the hexapeptide; wt. 0.234 g. This crude peptide was dissolved in 20 ml. of 0.025 M ammonium acetate (pH 5.35) and the solution was added to a column (1.2×50 cm.) of carboxymethyl cellulose (Serva, 0.6 meq./g.) which had been equilibrated with the same buffer solution. The column was then eluted successively with the following ammonium acetate buffers: 0.025 M (pH 5.35), 450 ml.; 0.0375 M (pH 5.35), 1600 ml.; 0.050 M (pH 6.45), 600 ml. Individual fractions (10 ml. each) were collected at a flow rate of approximately 2 ml. per min. Absorbancy measurements at 280 mμ revealed the presence of one major peak in Tubes No. 146—190 in the chromatogram. These fractions corresponding to the major peak were pooled and the bulk of water was removed at a bath temperature of 50—55°C in vacuo. The rest was lyophilized three times affording a colorless fluffy powder; yield 0.199 g. (86% as based on XVII used). This material was twice reprecipitated from water-ethanol to give 0.123 g. (recovery 62%). The purified peptide behaved as a single ninhydrin, Pauly, Ehrlich, and Sakaguchi reactive spot in paper chromatography [$R_f$=0.30 (BAW), 0.25 (BAPW)], and in paper electrophoresis at pH 3.8, 6.6 and 11.1. A sample for analyses was dried over phosphorus pentoxide at 60°C and 2—3 mmHg pressure for 8 hr. and then equilibrated in the air overnight. $\lambda_{max}^{0.1N\ HCl}$=280.5 mμ (ε=5500), 288 mμ (ε=4700); $\lambda_{max}^{0.1N NaOH}$=280.5 mμ (ε=5600), 288 mμ (ε=4800). $[\alpha]_D^{26.5}$ −18.0±3° (*c* 0.621, N acetic acid); lit. $[\alpha]_D$ −15.1±1° (*c* 0.1042, N acetic acid),[8] $[\alpha]_D^{25}$ −17.3° (*c* 1, acetic acid).[19]

Amino acid ratios in acid hydrolyzate: Glu 1.00, His 1.04, Phe 0.97, Arg 1.07, Try 0.71 (decomposed partially with acid), Gly 1.00; amino acid ratios in leucine aminopeptidase*4 digest: Glu 1.00, His 1.11, Phe 1.03, Arg 1.03, Try 1.02, Gly 0.96.

Found: C, 51.15; H, 6.92; N, 18.13; $H_2O$, 9.66. Calcd. for $C_{39}H_{50}N_{12}O_9 \cdot 5H_2O$: C, 50.86; H, 6.57; N, 18.25; $H_2O$, 9.78%.

## Summary

1) Synthesis of the peptides L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophan, L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine and L-glutamyl-L-histidyl-L-phenylalanyl-L-arginyl-L-tryptophyl-glycine, which corresponded to the amino acid sequences of positions 6—9, 6—10 and 5—10, respectively, of the corticotropin and α-MSH molecules, has been described.

2) The synthetic procedure for γ-*t*-butyl-L-glutamyl-L-histidyl-L-phenylalanlyl-L-arginyl-L-tryptophyl-glycine, a key intermediate to the higher peptides eliciting the adrenocorticotropic activity, has been improved.

3) An active ester $N^{\alpha}$, $N^{Im}$-dicarbobenzoxy-L-histidine *p*-nitrophenyl ester has been found to be of value for the synthesis of histidyl peptides.

4) An effective use of partition chromatography on a Sephadex column for purification of peptides has been cited.

The author expresses his deep gratitude to Dr. Hideo Otsuka for unfailing guidance throughout the course of this work. Thanks are also due to Dr. Mitsuo Ebata for amino acid analyses, Dr. Kaoru Kuriyama and staff for optical rotation measurements, Dr. Satoshi Mizukami and staff for elemental microanalyses, and Mr. Makoto Kanayama, Miss Fusako Shinozaki and Miss Yoshiko Jono for valuable technical assistance.

# A Note on the Stereospecific Formation of α-Aminoalcohols*

By Akitami ICHIHARA, Haruki MAEKAWA, Reiko KANDA, Haruhisa SHIRAHAMA and Takeshi MATSUMOTO

(Received November 16, 1964)

In previous papers[1a] the present authors have reported on the synthesis of *dl*-muscarine and its stereoisomers. In connection with synthetic studies in this field,[1b] the synthesis of a compound described as Ia, which probably possesses an erythro configuration, was performed. The structure Ib was erroneously proposed for muscarine by Kögl[2] in 1931.

First, attempts were made to prepare bromoacetal (III) through bromoaldehyde (II), which was obtained by the bromination of the sodium salt of acetoacetaldehyde.[3] The latter salt was conveniently prepared by the alkaline hydrolysis of commercially-available 1, 1-dimethoxybutanone-3.[4] However, since the overall yield of the sequence of reactions was quite poor, another method for obtaining bromoacetal (III) from butanonal acetal directly by means of a suitable brominating agent was next attempted. For this purpose we examined pyridine perbromide, which is expected to keep the reaction medium nearly neutral, thus minimizing undesirable side reactions. Although the resultant products consisted of various substances, the products were separable through fractional distillation into the desired bromoacetal (16%), methylmethoxybromovinyl ketone ($\lambda_{max}^{EtOH}=237$) and bromoaldehyde (II). The formation of these products indicates that the reaction was accompanied by elimination and hydrolysis reactions, and suggested that the addition of methanol to the reaction system would be favorable for the formation of the desired product. In fact, by the addition of methanol, the yield was raised to 37%.

Dimethylaminoketoacetal (IV) was readily

3) The compound has been obtained by N. K. Kochetkov and E. E. Nifant'ev through the following sequence. *Doklady Akad. Nauk U. S. S. R.*, **121**, 462 (1958):

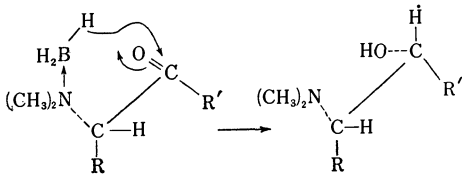
$$CH_3COCH_2CH(OCH_3)_2 \xrightarrow[BaCO_3\text{-}H_2O]{Br_2} II$$

4) In general, β-ketoaldehyde dimethylacetal affords β-hydroxyvinyl ketone by alkaline hydrolysis (H. Shirahama and T. Matsumoto, in preparation).

obtained by the treatment of bromoacetal (III) with dimethylamine in benzene. Besides the expected product (IV) (b. p. 34—36°C/0.2 mmHg), a small amount of a fraction (b. p. 67—72°C/4 mmHg) was obtained through distillation. Since the latter compound showed in the infrared spectrum strong bands at 1640, 1605 ($\alpha,\beta$-unsaturated carbonyl system), 1050 $cm^{-1}$ (ether), and a positive test to sodium tetraphenylboronate, indicating the presence of the dimethylamino group, the structure V was tentatively assigned. The structure of this compound will be studied in the near future.

The dimethylaminoketone (IV) was next converted to a dimethylaminoalcohol (VI) by means of sodium borohydride in methanol. In this reaction, the formation of a mixture of two diastereoisomers is to be expected. However, gas chromatography of the product indicated only one peak. Moreover, the methiodide (VIIIa) derived from VI showed a melting point of 123.5—125°C, which did not change after repeated recrystallizations.

Therefore, the reduction proceeded in a stereospecific manner, producing only one stereoisomer. A similar stereoselective reduction of aminoketone hydrochloride to erythro-aminoalcohol by sodium borohydride has been observed and explained as the attack on the least-hindered site with the participation of a lone pair of nitrogen atom, as is expressed by the following formula[5] (Fig. 2):



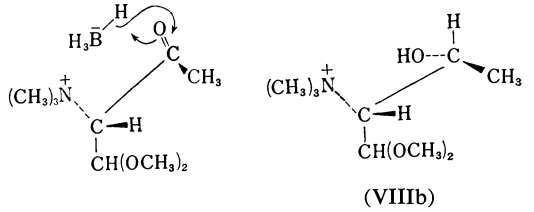


Fig. 2

Since a similar steric course can be assumed for the case of dimethylaminoketone (IV), the product VI most probably possesses the erythro configuration.

On the other hand, the reduction of trimethylammonium ketone (VII), derived from IV by means of methyl iodide under the same conditions gave a hydroxy compound (VIIIb), whose infrared spectra in the solid state and in solution and whose melting point (122—124°) were identical with those of trimethylammonium iodide (VIIIa) derived from the dimethylaminoalcohol (VI) obtained above. These results suggest that the product from VII is also an erythro isomer. The preferential formation of the erythro isomer may be accounted for by the mechanism involving an ion pair (Fig. 3):

(VIIIb)

Fig. 3

All attempts to hydrolyze the methiodide (VIIIa, b) of dimethyl aminoalcohol (VI) to the desired aldehyde (Ia) were unsuccessful. Even when it was refluxed for several hours, the formation of the aldehyde group could not be detected with tetrazolium chloride. This may be explained in terms of the presence of a charged quarternary nitrogen atom.[6] On the other hand, tertiary aminoalcohol (VI) was slowly but gradually hydrolyzed with 6 N hydrochloric acid to the aldehyde (IX).

Finally, the desired Ia was obtained by the treatment of IX with methyl iodide.

Although the methiodide Ia of 2-dimethylamino-3-hydroxybutanal was not obtained in a crystalline state, reineckate was crystallized and gave the correct analytical values.

## Experimental

**2-Bromo-3-keto-*n*-butyraldehyde (II).**—*By Claisen Condensation.*—The sodium salt of 3-keto-*n*-butyraldehyde was prepared in the usual manner from 27 g. of sodium methoxide, 29 g. of acetone and 38 g. of ethyl formate in 300 ml. of absolute ether. After the completion of the reaction, the ether was removed and the residue was dried in a vacuum desiccator. To a suspended solution of 20 g. of the sodium salt in 150 ml. of carbon tetrachloride, 29.6 g. of bromine in 50 ml. of carbon tetrachloride was added slowly under ice cooling. The precipitate was then filtered off, and the filtrate was poured into an equal volume of petroleum ether. After the precipitate had been removed, the filtrate was concentrated in vacuo. The solidified residue was crystallized from carbon tetrachloride to afford 1.2 g. of II; m. p. 108—109°C (decomp.), $\lambda_{max}^{EtOH}$ 228 mμ (ε 9570), (lit.[3] m. p. 109—110°C (decomp.)).

Found: C, 29.40; H, 3.15, mol. wt. (Rast) 161. Calcd. for $C_4H_5O_2Br$: C, 29.12; H, 3.05%, mol. wt. 164.

*From 3-Keto-n-butyraldehyde Dimethylacetal.* — A mixture of 1.6 g. of acetal, 0.48 g. of sodium hydroxide and 4 ml. of water was shaken for 10 hr. at room temperature. The solution was then evaporated

5) D. J. Cram and K. R. Kopecky, *J. Am. Chem. Soc.*, **81**, 2748 (1959); T. Matsumoto, T. Nishida and H. Shirahama, *J. Org. Chem.*, **27**, 79 (1962).

6) R. B. Woodward, *Angew. Chem.*, **69**, 50 (1957).

in vacuo and dried in a vacuum desiccator. The sodium salt thus obtained (1.1 g.) was treated in the manner described above to give 0.2 g. of a crystalline bromide, m. p. 108—109°C (decomp.), which was identical with the II prepared by the Claisen condensation.

**2-Bromo-3-keto-*n*-butyraldehyde Dimethylacetal (III).**—*From 2-Bromo-3-keto-n-butyraldehyde (II).*—A mixture of 2.1 g. of bromoaldehyde (II) and 24 ml. of 6.6% methanolic hydrogen bromide was gently refluxed for 8 hr. on a water bath. The reaction mixture was then concentrated in vacuo and the residue extracted several times with petroleum ether. The combined petroleum solution was dried over magnesium sulfate and distilled to give 0.7 g. of III, b. p. 73—75°C (6 mmHg).

*From 1,1-Dimethoxybutanone-3.*—Pyridine perbromide was prepared by the procedure of McElvain and Morris.[7] A mixture of 21 g. of powdered dry pyridine perbromide, 10 g. of 1,1-dimethoxybutanone-3 and 1 ml. of absolute methanol was shaken for 10 min., and the orange-colored solution was allowed to stand for 2 hr. under ice-cooling. The reaction mixture was extracted with several portions of warm petroleum ether. The turbid petroleum solution was clarified with celite. After the solvent had been removed, the residue was distilled under reduced pressure to give 5.9 g. (yield 37%) of bromoacetal, b. p. 70—74°C (7 mmHg).

Found: C, 33.67; H, 5.22. Calcd. for $C_6H_{11}O_3Br$: C, 34.14; H, 5.25%.

**2-Dimethylamino-3-keto-*n*-butyraldehyde Dimethylacetal (IV).**—To a solution of dimethylamine (ca. 30%, 50 ml.) in benzene was added, drop by drop, 2 g. of bromoacetal (III) in 5 ml. of benzene; the mixture was then allowed to stand for 24 hr. at room temperature. The resulting precipitates of dimethylamine hydrobromide were filtered off, and the filtrate was concentrated in vacuo. The residue was extracted with several portions of benzene, and the combined extracts were dried over anhydrous potassium carbonate. After the solvent had been removed, the crude product was distilled, yielding 1.1 g. of the desired aminoketone, b. p. 34—36°C (0.2 mmHg) and a small amount of a fraction with a b. p. of 67—72°C (0.4 mmHg). The infrared spectrum of the former compound exhibited absorption bands at 2820, 2660, 1704, and 1073 $cm^{-1}$, while the latter compound did at 1640, 1605, and 1060 $cm^{-1}$, suggesting the presence of a COC=C system.

**Tetraphenylboronate of IV.**—A small amount of IV was dissolved in 1 ml. of water and slightly acidified with acetic acid. To this solution a 50% aqueous solution of sodium tetraphenylboronate was added to give white precipitate which, on being recrystallized from water-ethanol, gave pure tetraphenylboronate of IV, m. p. 123—124°C (decomp.).

Found: N, 2.83. Calcd. for $C_{32}H_{38}O_3NB$: N, 3.03%.

**The Reduction of Dimethylaminoketone (IV).**—A mixture of 0.6 g. of dimethylaminoketone in 4 ml. of methanol and a few drops of a 10% aqueous solution of sodium hydroxide was added to a solution of 0.6 g. of sodium borohydride in 6 ml. of methanol. The solution was then allowed to stand overnight at room temperature. After the solvent had been removed, the residue was repeatedly extracted with ethyl acetate, and the combined solutions were dried over anhydrous sodium carbonate and distilled to give 0.48 g. of hydroxyaminoacetal (VI), b. p. 68—71°C (4 mmHg). Vapor phase chromatography showed only one peak with the retention time of 15 min. on a PEG 1000 column at 152°C (carrier gas, $H_2$). The Reinecke salt of VI was recrystallized from ethanol; m. p. 135—136°C (decomp.).

Found: C, 28.99; H, 4.92; N, 19.56. Calcd. for $C_{12}H_{26}O_3N_7S_4Cr$: C, 29.02; H, 4.87; N, 19.74%.

**The Methiodide (VII) of Dimethylaminoketone.**—An excess of methyl iodide was added to a solution of 1 g. of dimethylaminoketone (IV) in 3 ml. of absolute methanol. The resulting mixture was then allowed to stand for 3 hr. at room temperature. After the solvent had been evaporated to dryness, the red-colored residue was solidified by rubbing it with a glass rod. The recrystallization of the crude product from absolute ethanol yielded 1.5 g. of plates, m. p. 152—153°C (decomp.).

Found: C, 34.30; H, 6.48; N, 4.09. Calcd. for $C_9H_{20}O_3NI$: C, 34.08; H, 6.36; N, 4.42%.

**The Methiodide (VIIIa) of VI.**—A small amount of hydroxydimethylaminoacetal (VI) was dissolved in methanol, and to this solution an excess of methyl iodide was added. The reaction mixture was then allowed to stand at room temperature for 3 hr. After the solvent had been removed, the residue was dried in a vacuum desiccator for several hours to give an amorphous solid, which, on being recrystallized from ethanol, afforded white crystals, m. p. 120—124°C. Further purification of this compound with chloroform-ethylacetate raised the m. p. to 123.5—125°C (decomp.).

Found: C, 33.70; H, 6.68; N, 4.65. Calcd. for $C_9H_{22}O_3NI$: C, 33.86; H, 6.95; N, 4.45%.

**The Reduction of VII to VIIIb.**—The compound VII (0.6 g.) in 6 ml. of methanol was added, drop by drop, to 9 ml. of methanol containing 500 mg. of sodium borohydride. The reaction mixture was then allowed to stand overnight at room temperature. After the solvent had been removed, the reduction product was extracted with several portions of warm chloroform. The recrystallization of the crude product with absolute ethanol gave hydroxytrimethylammonium iodide, m. p. 122—124°C, undepressed upon the admixture of VIIIa.

Found: C, 34.34; H, 7.40; N, 4.51. Calcd. for $C_9H_{22}O_3NI$: C, 33.86; H, 6.95; N, 4.45%.

**The Hydrolysis of Hydroxydimethylaminoacetal (VI).**—Hydroxydimethylaminoacetal (0.26 g.) was dissolved in 2 ml. of 6 N hydrochloric acid and allowed to hydrolyze at room temperature for 5 hr. After the reaction mixture had then been concentrated in a vacuum desiccator, the residue was dissolved in 1 ml. of methanol, and to this solution 31 mg. of sodium in 1 ml. of methanol was added. The separated layer was extracted with several portion of chloroform. The combined chloroform solutions were dried over anhydrous potassium carbonate and concentrated under reduced pressure

7) S. M. McElvain and Leo R. Morris, *J. Am. Chem. Soc.*, **73**, 206 (1951).

to leave IX as an oil. The reineckate of IX was purified by recrystallization from water-ethanol; m. p. 232—233°C (decomp.).

Found: C, 26.54; H, 4.57; N, 21.23. Calcd. for $C_{10}H_{20}O_2N_7S_4Cr$: C, 26.64; H, 4.43; N, 21.35%.

**The Methiodide of IX.**—To an ethanolic solution of the aldehyde (IX), excess methyl iodide was added and the mixture was allowed to stand overnight. The removal of the solvent left a red-colored residue which exhibited, in the infrared spectrum, bands for aldehyde at 2740 and 1717 $cm^{-1}$. The reineckate of Ia was obtained in a crystalline state and showed a m. p. of 221—222°C after recrystallization from water-ethanol.

Found: C, 28.04; H, 5.11. Calcd. for $C_{11}H_{22}O_2N_7S_4Cr$: C, 28.43; H, 4.77%.

## Summary

The synthesis of the compound which was erroneously proposed for muscarin by Kögl in 1931 has been described.

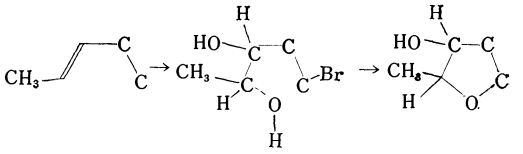
# The Synthesis of *dl*-Muscarine and *dl*-Allomuscarine[1,2]

By Haruki MAEKAWA, Akitami ICHIHARA and Takeshi MATSUMOTO

(Received November 16, 1964)

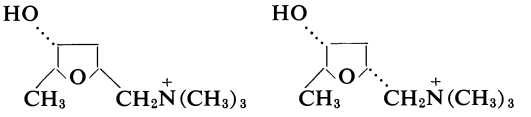
Since the structure and stereochemistry of muscarine (I) have been determined by X-ray analysis,[3] extensive studies of the synthesis of muscarine and its stereoisomers have been made by European workers.[4] However, none of them have completed the synthesis in a stereospecific manner. In the present paper, the authors would like to describe a new synthetic method in which hydroxyl and methyl groups are introduced in trans orientation by a stereospecific method.



The principle underlying the present synthesis is as follows:

(A) (B)

Fig. 1



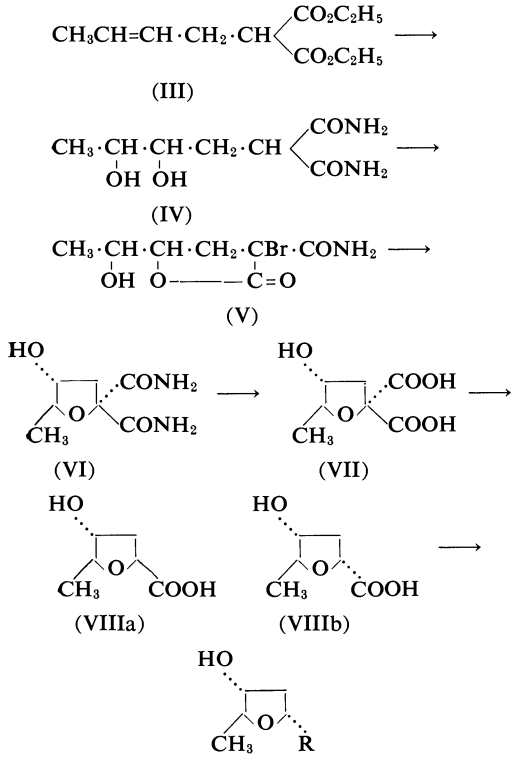
In the cyclization of A to form B (Fig. 1), the relative configuration of the methyl group at $C_2$ and of the hydroxyl group at $C_3$ in the tetrahydrofurane derivative, B, is determined by the stereochemistry of its precursors, the butane derivatives A. As is shown in Fig. 2,

(C) (D) (E)

Fig. 2

a trans compound, E, should be produced from an erythro compound, D, which, in turn, should be obtained by the dihydroxylation of a trans olefinic compound, C, with peracid. From the above considerations, ethyl crotylmalonate (III) was used as the starting material.

(I) (II)



The oxidation of III with performic acid and the subsequent treatment of the product with alcoholic ammonia gave the dihydroxydiamide IV, m.p. 164—165.5°C, which is expected to be an erythro compound. On treatment with bromine in acetic acid, IV was converted to the bromolactone V, m.p. 110—111°C. Although two stereoisomers are possible for V, the relative configuration of methyl and hydroxyl groups in V should be independent of the stereochemistry of the $\alpha$ carbon atom of the bromolactone V and remain unchanged during the recyclization of V to VI. Therefore, no attempt was made to examine the configuration of the $\alpha$ carbon atom of V.

Fig. 3

The ammonolysis of V in alcoholic ammonia proceeded smoothly to give the tetrahydrofurandiamide VI, m. p. 204—205°C. The hydrolysis of VI was carried out in a 10% sodium hydroxide solution to afford the acid VII, which was purified through the lead salt or by ion exchange chromatography.

The acid VII, m. p. 170—176°C, was then decarboxylated by heating it 15 min. at 175—180°C in a sealed tube to give an amorphous solid. The careful recrystallization of the solid from a large volume of dichloroethane gave a monocarboxylic acid VIIIa as needles, m. p. 145°C, after the concentration of the filtrate, an isomeric monocarboxylic acid VIIIb, m. p. 109—111°C, was obtained as granular crystals from the mother liquor. Since these two acids have the same molecular formula, $C_6H_{10}O_4$, and show similar infrared spectra (Fig. 4, VIIIa and VIIIb), they are clearly the expected two stereoisomers, VIIIa and VIIIb. However, no reliable evidence of their stereochemistry was obtained at this stage.

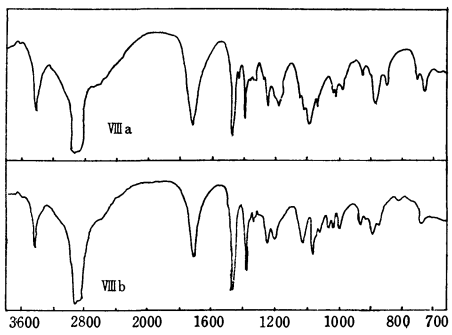

Fig. 4. Infrared absorption spectra of VIIIa and VIIIb (Nujol).

The esterification of these two acids with diazomethane afforded extremely hygroscopic methyl esters, IXa and IXb respectively. The NMR spectra of these esters were different from each other, but no decisive information about the stereochemistry could be derived therefrom. On the other hand, the inspection of the infrared spectra of IXa and IXb in a high dilute condition showed that IXa has an absorption band at 3617 $cm^{-1}$ (0.0024 mol. in carbon tetrachloride) due to a free hydroxyl group, while IXb has a rather broad absorption band at 3480 $cm^{-1}$ (0.0024 mol. in carbon tetrachloride) attributable to an intramolecularly hydrogen-bonded hydroxyl group, as is shown in Fig. 5. Therefore, it may be concluded that

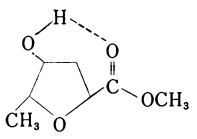

Fig. 5

the 145°C and 111°C compounds should be represented by VIIIa and VIIIb respectively.

By means of dimethylamine, IXa and IXb were converted to dimethylamides, Xa and Xb. In this reaction, the ester IXb, in which hydroxyl and methyl ester groups have the cis orientation, was converted to Xb about four times faster than the IXa isomer. At first, the slow reaction of IXa was attributed to the steric hindrance exerted by the bulky methyl group on the same side as the ester group. However, since the same phenomenon was also

observed in dimethyl ester series,[5] it is more reasonable to ascribe the acceleration to the neighboring participation of the hydroxyl group.[6,7]

The reduction of the dimethylamides Xa and Xb with lithium aluminum hydride gave normuscarine (XIa) and allonormuscarine (XIb). Finally *dl*-muscarine iodide (XIIa) and *dl*-allomuscarine iodide (XIIb) were prepared by the treatment of the noramines XIa and XIb with methyl iodide. Further, *dl*-muscarine chloride (XIVa) (m. p. 148—149°C) and *dl*-allomuscarine chloride (XIVb) (m. p. 143—144°C) were derived from the tetraphenylboronates (XIIIa and XIIIb) of the quarternery amines, and the chloride XIVa was shown to be identical with a sample prepared from natural material in infrared spectrum.[4c] *dl*-Muscarine chloride XIVa showed a marked physiological activity in the isolated heart of a frog, while that of *dl*-allomuscarine chloride was about one-half physiologically active as *dl*-muscarine.[1]

## Experimental

**Ethyl Crotylmalonate (III).**—This was prepared by the method of Linstead.[8]

**3, 4-Dihydroxypentane-1, 1-dicarbonamide (IV).**—To a solution of 32 g. of III in 135 ml. of formic acid (80% solution), 73 g. of hydrogen peroxide (28% solution) was added slowly under ice-cooling. The mixture was stirred for 20 min. and then allowed to stand for 12 hr. at room temperature. After the solvent had been removed, the residue was mixed with 100 ml. of dry benzene and the solvent was slowly removed under reduced pressure. The residue was dissolved in 50 ml. of absolute ethanol, and the solution was added to 500 ml. of an ethanol solution saturated with ammonia at 0°C. The mixture was then swirled gently and allowed to stand overnight at room temperature. The resultant precipitates were recrystallized from ethanol (95%) to give 20 g. of IV, m. p. 164—165.5°C. Infrared spectrum: $\nu_{max}^{Nujol}$ 3430, 3420, 1665, 1040 $cm^{-1}$.

Found: C, 44.55; H, 7.43; N, 14.59. Calcd. for $C_7H_{14}O_4N_2$: C, 44.20; H, 7.42; N, 14.73%.

**2-Bromo-2-carbamoyl-3, 4-dihydroxypentanoic Acid Lactone (1→4).**—A solution of 20 g. of diamide (IV) in 100 ml. of glacial acetic acid was refluxed gently on an oil bath, and then 17 g. of bromine in 10 ml. of glacial acetic acid was added drop by drop. After the mixture had been cooled, the separated ammonium bromide was removed and the filtrate was concentrated under reduced pressure. The oily residue was washed several times with a small amount of benzene and allowed to stand overnight, thus giving an amorphous solid which was recrystallized from chloroform to give 25 g. of V, m. p. 110—111°C. Infrared spectrum: $\nu_{max}^{Nujol}$ 3430, 1788, 1758, 1683, 1599, 1206, 1003 $cm^{-1}$.

Found: C, 33.45; H, 3.86; N, 5.95. Calcd. for $C_7H_{10}O_4NBr$: C, 33.35; H, 4.00; N, 5.95%.

**2-Methyl-3-hydroxy-5, 5-tetrahydrofurandicarbonamide (VI).**—To a solution of 500 ml. of ethanol saturated with ammonia at 0°C, 25 g. of V in 50 ml. of ethanol was added; the mixture was then allowed to stand for 12 hr. at room temperature. After the solution had been cooled, the precipitated crystals were collected by means of a funnel and recrystallized from ethanol (95%) to give 16 g. of VI, m. p. 204—205°C. Infrared spectrum: $\nu_{max}^{Nujol}$ 3380, 3200, 1680, 1585, 1140, 1009 $cm^{-1}$.

Found: C, 45.05; H, 6.60; N, 14.87. Calcd. for $C_7H_{12}O_4N_2$: C, 44.68; H, 6.43; N, 14.88%.

**2-Methyl-3-hydroxy-5, 5-tetrahydrofurandicarboxylic Acid (VII).**—In 80 ml. of an aqueous solution (10%) of sodium hydroxide, 10 g. of VI was hydrolyzed on a water bath for 4 hr. After the reaction mixture had been cooled, the solution was acidified with acetic acid added to 25 g. of lead acetate dissolved in a small amount of water, and then allowed to stand for 10 hr. at −5°C. The resultant precipitates were collected and washed with a small amount of water. After the hydrogen sulfide was led into the suspension of the lead salts, the filtrate was concentrated to leave plates which were recrystallized from glacial acetic acid to give 7 g. of VII. Another purification was carried out by eluting the reaction mixture through an ion exchange resin IR-120 column. The removal of water from the eluted solution gave pure acid (VII), m. p. 175—176°C. Infrared spectrum: $\nu_{max}^{Nujol}$ 3385, 2650, 1702, 1202, 1087 $cm^{-1}$.

Found: C, 44.39; H, 5.33. Calcd. for $C_7H_{10}O_6$: C, 44.21; H, 5.30%.

**2-Methyl-3-hydroxy-5-tetrahydrofurancarboxylic Acids (VIIIa) and (VIIIb).**—A solution of 5 g. of VII in 50 ml. of water was heated at 175—180°C for 15 min. in a sealed tube, and then the solution was concentrated to leave an amorphous solid which was recrystallized from 100 ml. of ethylene dichloride to give needles of VIIIa, (m. p. 143—145°C, yield, 1.0 g.

Found: C, 49.12; H, 6.81. Calcd. for $C_6H_{10}O_4$: C, 48.97; H, 6.90%.

The further concentration of the solution yielded VIIIb as granules, m. p. 109—111°C, yield 0.9 g.

Found: C, 49.16; H, 7.00. Calcd. for $C_6H_{10}O_4$: C, 48.97; H, 6.90%.

**Methyl 2-Methyl-3-hydroxy-5-tetrahydrofurancarboxylate (IXa).**—One gram of VIIIa in 10 ml. of methanol was added to 36 ml. of an ethereal solution of diazomethane (ca. 4%), and then the mixture was allowed to stand for 2 hr. at room temperature. The solution was concentrated to leave a residue which was distilled under reduced pressure to yield 1.0 g. of IXa (hygroscopic; b. p. 113—115°C/3.5 mmHg). The infrared spectrum of IXa in carbon tetrachloride (0.0021 mol.) showed an absorption

7) The kinetic study will be published in another paper. T. Yamanaka, A. Ichihara, K. Tanabe and T. Matsumoto, in preparation.

8) E. N. Eccott and R. P. Linstead, *J. Chem. Soc.*, **1929**, 2153.

band at 3717 $cm^{-1}$ due to a free secondary hydroxyl group; NMR spectrum: $\tau$ 8.80d ($CH_3$), 7.8q ($CH_2$), 6.27s ($CO_2CH_3$), 6.02s (OH), 5.48t (proton $\alpha$ to the ester group).

**Methyl 2-Methyl-3-hydroxy-5-tetrahydrofurancarboxylate (IXb).**—This was prepared in the same way as the cis acid VIIIb described above. The reaction of 0.9 g. of VIIIa with diazomethane gave 0.8 g. of ester (IXb), b. p. 109—111°C/3.5mmHg. IXb showed absorption bands at 3617 $cm^{-1}$ (free OH) and 3480 $cm^{-1}$ (broad, bonded OH) in carbon tetrachloride (0.0024 mol.); NMR spectrum: $\tau$ 8.82d ($CH_3$), 7.25—8.22 m ($CH_2$), 6.25s ($-CO_2CH_3$), 6.10s (OH), 5.53q (proton $\alpha$ to the ester group).

**2-Methyl-3-hydroxy-5-tetrahydrofurancarboxylic Acid Dimethylamide (Xa).**—One gram of IXa dissolved in 10 ml. of dry benzene was added to 50 ml. of a benzene solution of dimethylamine (ca. 30%) and allowed to stand for 25 hr. at 100°C in a sealed tube. The solvent was then evaporated to leave a residue which was washed with a small amount of ether to give Xa. Infrared spectrum: $\nu_{max}^{film}$ 3370, 1638, 1079 $cm^{-1}$.

**2-Methyl-3-hydroxy-5-tetrahydrofuran Carboxylic Acid Dimethylamide (Xb).**—To 40 ml. of a benzene solution of dimethylamine was added 0.8 g. of IXb in 10 ml. of benzene. The mixture was heated for 6 hr. at 100°C in a sealed tube. After the evaporation of the solvent, the resulting residue was washed with ether to give 0.7 g. of Xb. Infrared spectrum: $\nu_{max}^{film}$ 3360, 1640, 1071 $cm^{-1}$.

***dl*-Normuscarine (XIa).**—A solution of Xa (0.8 g.) in 5 ml. of tetrahydrofurane was added drop by drop to a solution of lithium aluminum hydride (1 g.) in 80 ml. of tetrahydrofurane and refluxed for 6 hr. on a water bath. After the excess lithium aluminum hydride had been decomposed by adding ethyl acetate, the reaction mixture was concentrated and the residue was dissolved in an aqueous solution of sodium hydroxide (20%). After several extractions with ether, the combined solution was dried over anhydrous potassium carbonate and evaporated to give Xa, b. p. 88—92°C/4 mmHg. Infrared spectrum: $\nu_{max}^{CCl_4}$ 3390, 1456, 1085, 1035 $cm^{-1}$. Reineckate of XIa: recrystallized from ethanol-water; m. p. 161—162°C (decomp.).

Found: C, 30.07; H, 5.23; N, 20.49. Calcd. for $C_{12}H_{24}O_2N_7S_4Cr$: C, 30.11; H, 5.54; N, 20.49%.

***dl*-Allonormuscarine (XIb).**—XIb was prepared in the same manner as XIa from 0.7 g. of Xb, b. p. 65—66°C/4 mmHg. Yield, 0.5 g. Infrared spectrum: $\nu_{max}^{CCl_4}$ 3200, 1460, 1158, 1105, 1063, 1033, 1015, 910, 858 $cm^{-1}$. Reineckate of XIb: recrystallized from ethanol-water, m. p. 164—165°C (decomp.).

Found: C, 29.99; H, 5.51; N, 19.70. Calcd. for $C_{12}H_{24}O_2N_7S_4Cr$: C, 30.11; H, 5.54; N, 20.49%.

***dl*-Muscarine Iodide (XIIa).**—To 0.1 g. of XIa in 1 ml. of ethanol, 0.3 g. of methyl iodide was added; the resultant solution was allowed to stand for 1 hr. at room temperature. After the excess methyl iodide and the solvent had been evaporated an oily residue was obtained. The rubbing of the residue with a glass rod gave crystals which were recrystallized from ether-isopropanol to yield 50 mg. of *dl*-muscarine iodide (XIIa), m. p. 116—118°C (the lit.[4c] has reported an m. p. of 107—108°C). Infrared spectrum: $\nu_{max}^{KBr}$ 3400, 1085, 1001, 970, 920 $cm^{-1}$.

Found: C, 36.14; H, 6.74; N, 4.64. Calcd. for $C_9H_{20}O_2NI$: C, 35.89; H, 6.69; N, 4.69%.

***dl*-Allomuscarine Iodide (XIIb.)**—By treating 0.3g. of XIb the same as XIa we obtained 0.2 g. of *dl*-allomuscarine iodide (XIIb), m. p. 131—132°C (Ref. 9 reported an m. p. of 131—132°C). Infrared spectrum: $\nu_{max}^{KBr}$ 3400, 1095, 1062, 995, 964, 910 $cm^{-1}$.

Found: C, 36.01; H, 6.66; N, 4.47. Calcd. for $C_9H_{20}O_2NI$: C, 35.89; H, 6.69; N, 4.65%.

***dl*-Muscarine Tetraphenylboronate (XIIIa).**—Recrystallized from acetone-ethanol; m. p. 174—175°C (lit.[4c] 173—174°C).

Found: N, 3.11. Calcd. for $C_{33}H_{40}O_2NB$: N, 2.84%.

***dl*-Allomuscarine Tetraphenylboronate (XIIIb).**—Recrystallized from acetone-ethanol; m. p. 176—177°C (lit.[9] 175—176°C).

Found: N, 3.04. Calcd. for $C_{33}H_{40}O_2NB$: N, 2.84%.

***dl*-Muscarine Chloride (XIVa).**—Upon treatment with cesium chloride, 0.3 g. of XIIIa was converted to muscarine chloride which was then recrystallized by ether-isopropanol; m. p. 148—149°C (lit.[4c] m. p. 147—148°C). The infrared spectrum was identical with those of a natural sample and of a synthetic specimen of Eugster. Infrared spectrum: $\nu_{max}^{KBr}$ 3250, 1485, 1105, 1075, 1056, 918 $cm^{-1}$.

Found: C, 51.29; H, 9.68; N, 6.72. Calcd. for $C_9H_{20}O_2NCl$: C, 51.54; H, 9.62; N, 6.68%.

***dl*-Allomuscarine Chloride (XIVb).**—XIIIa (0.4 g.) was converted to allomuscarine chloride. The recrystallization of the product from ether-isopropanol gave 0.2 g. of XIVb, m. p. 152.5—153.5°C (lit.[9] 153—154°C). Infrared spectrum: $\nu_{max}^{Nujol}$ 3300, 1090, 1065, 977, 959, 928 $cm^{-1}$.

Found: C, 51.33; H, 9.60; N, 6.47. Calcd. for $C_9H_{20}O_2NCl$: C, 51.54; H, 9.62; N, 6.68%.

## Summary

The synthesis of *dl*-muscarine (I) and *dl*-allomuscarine (II) starting from ethyl crotylmalonate has been described. Trans oriented methyl and hydroxyl groups in these compounds have been introduced stereospecifically into the tetrahydrofurane ring.

We wish to thank Professor Akira Ooga, Hokkaido University, for the pharmacological proof of our samples. Thanks are also due to Mr. Tsutomu Yamanaka and Mr. Noriki Ito for their assistance in the experimental work.

# The Synthesis of *cis*- and *trans*-Demethylmuscarines[1]

By Akitami ICHIHARA, Tsutomu YAMANAKA and Takeshi MATSUMOTO

(Received November 16, 1964)

In previous papers[2,3] we reported the synthesis and pharmacological activities of *dl*-muscarine and its stereoisomers. Since the activities were found to depend sensitively upon the structure, it appeared of interest to synthesize *dl*-demethylmuscarines and investigate their physiological activities.

The route previously described for the synthesis of *dl*-muscarine and *dl*-allomuscarine was applied to the preparation of *dl*-demethylmuscarine, starting with ethyl allylmalonate (I).

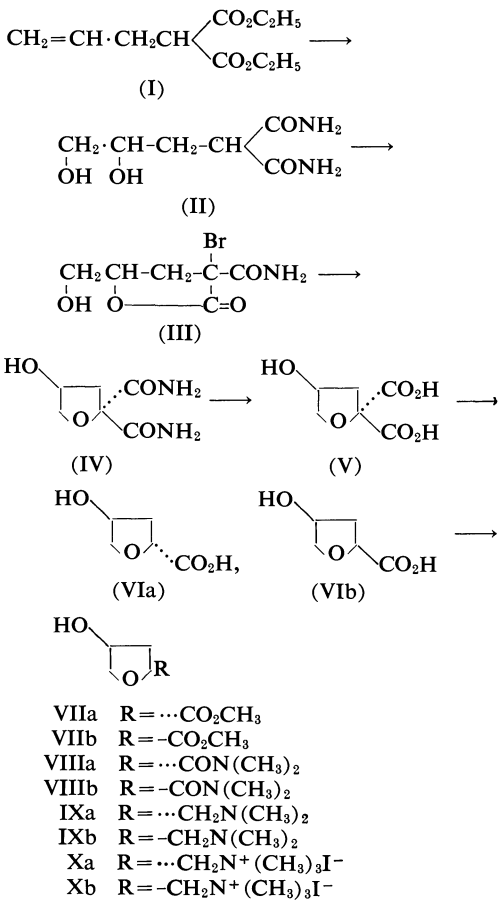

Fig. 1

The oxidation of ethyl allylmalonate (I) with performic acid gave an oily product which was without purification, allowed to react with ammonia in ethanol to form dihydroxydiamide II. Bromolactonamide III, prepared by the reaction of dihydroxydiamide with bromine,[4] was then subjected to ammonolysis in order to give tetrahydrofurandicarboxylic acid diamide IV, which was subsequently hydrolyzed to dicarboxylic acid V.

The decarboxylation of this acid, V, by heating it at 150—160°C in a sealed tube gave an amorphous solid, from which two acids were isolated in the ratio 1 : 1; one of these acids was crystallized from ethyl acetate as rhombic crystals, m. p. 127—129°C, while the other acid was obtained as a granular crystals, m. p. 142—143°C, by further concentration of the filtrate. These two compounds have the same molecular formula, $C_5H_8O_4$, and similar absorption bands in infrared spectra (Fig, 2, VIa and VIb). Therefore, these are the

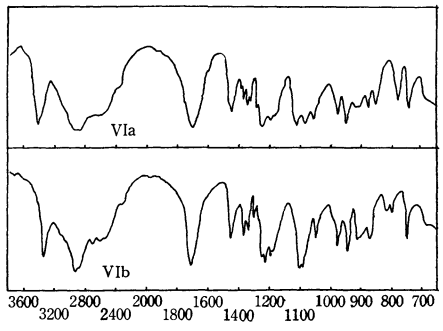

Fig. 2. Infrared absorption spectra of VIa and VIb (Nujol).

expected stereoisomers VIa and VIb. The treatment of these acids, VIa and VIb, with ethereal diazomethane gave the corresponding methyl esters, VIIa and VIIb respectively. The infrared spectrum of VIIb exhibited a broad absorption band at 3482 $cm^{-1}$ (0.077 mol. in carbon tetrachloride) attributable to the presence of an intramolecular hydrogen bond between the carbonyl group and the secondary hydroxyl group. On the other hand, the compound VIIa showed two absorption bands at

1) Short communication: T. Matsumoto and A. Ichihara, This Bulletin, 33, 1015 (1960).
2) a) T. Matsumoto and H. Maekawa, *Angew. Chem.*, 70, 507 (1958); b) H. Maekawa, A. Ichihara and T. Matsumoto, This Bulletin, 38, 1161 (1965).
3) T. Matsumoto and A. Ichihara, *Biochem. Z.*, 331, 589 (1959).
4) W. Traube, *Ber.*, 37, 4540 (1904).

3620 $cm^{-1}$ (sharp, free OH) and 3485 $cm^{-1}$ (broad, bonded OH, 0.068 mol. in carbon tetrachloride); the intensity of the band at 3620 $cm^{-1}$ relative to the band at 3485 $cm^{-1}$ is increased with further dilution. Therefore, VIa is a trans compound and VIb is cis compound. The tetrahydrofurancarboxylic acid esters, VIIa and VIIb, were then converted with dimethylamine to tetrahydrofurancarboxylic acid dimethylamides, VIIIa and VIIIb. In these reactions an interesting difference in the rate of reaction was observed; the cis ester was converted to VIIIb about three or four times faster than the trans isomer. The effect of acceleration in cis-ester should be ascribed to the presence of an hydroxyl group near the ester group.[5] A similar facilitation by hydroxyl groups has been reported in other compounds.[6]

The reduction of the dimethylamides VIIIa and VIIIb with lithium aluminum hydride gave the dimethylamines IXa and IXb respectively. A stereoisomeric mixture of cis and trans amines, IXa and IXb, resulting from the sequence of reactions VIa and VIb to IXa and IXb, is also easily separable by chromatography on alumina.

Since the infrared spectrum of the cis isomer IXb also exhibits a broad absorption band at 3194 $cm^{-1}$ (0.0072 mol. in carbon tetrachloride) ascribed to the intramolecular hydrogen bond between dimethylamino and hydroxyl groups, it has been ascertained that the reactions in the sequence VI to IX proceeded without any configurational changes.

Finally, by means of methyl iodide, the IXa and IXb amines were converted to *trans-dl*-demethylmuscarine (Xa) (m. p. 119—120°C) and *cis-dl*-demethylmuscarine (Xb) (m. p. 117—118°C) respectively, whose infrared spectra were identical with those of Eugster's specimens.[7] In physiological activity for an isolated heart of a frog, *trans*-demethylmuscarine is slightly stronger than the cis-isomer, but rather weaker than *dl*-muscarine itself.

## Experimental.[8]

**Ethyl Allylmalonate (I).**—This was prepared by the procedure of Linstead.[9]

**3, 4-Dihydroxybutane-1, 1-dicarbonamide (II).** — To a solution of 120 g. of ethyl allylmalonate in 540 ml. of formic acid (80% solution), 73 g. of hydrogen peroxide (28% solution) was added slowly under ice cooling. The mixture was stirred for 20 min. and allowed to stand for 12 hr. at room temperature. After removal of the solvent, the residue was mixed with 200 ml. of dry benzene, and the benzene was slowly removed under reduced pressure. The residue was then added to 2 l. of ethanol saturated with ammonia at 0°C, and the mixture was swirled gently and allowed to stand overnight at room temperature. The precipitated crystals were recrystallized from ethanol (95%) to give 72 g. of II, m. p. 157—158°C; infrared spectrum: $\nu_{max}^{Nujol}$ 3330, 1765, 1664, 1593, 1178, 1070 $cm^{-1}$.

Found: C, 40.76; H, 6.84; N, 15.66. Calcd. for $C_{16}H_{12}O_4N_2$: C, 40.90; H, 6.78; N, 15.90%.

The compounds III, IV and V were prepared by the method of Traube.[4] 3-Hydroxy-5, 5-tetrahydrofurandicarboxylic acid (V) recrystallized from glacial acetic acid showed a m. p. of 138—140°C.

Found: C, 41.13; H, 4.67. Calcd. for $C_6H_8O_5$: C, 40.91; H, 4.58%. (Ref. 3 described an m. p. of the hydrate but not of the anhydrous compound).

***trans*- and *cis*-4-Hydroxy-2-tetrahydrofurancarboxylic Acid (VIa and VIb).** — A solution of 10 g. of tetrahydrofurandicarboxylic acid V in 100 ml. of water was heated for 1 hr. in a sealed tube at 150—160°C. The removal of water under reduced pressure left a residue which was solidified by rubbing it with glass rod to give 6.8 g. of an amorphous solid, m. p. 108—111°C. The solid was carefully recrystallized from 50 ml. of ethyl acetate to afford 2.6 g. of VIb as rhombic crystals, m. p. 127—129°C, infrared spectrum: Fig. 2, VIa.

Found: C, 45.59; H, 5.99. Calcd. for $C_5H_8O_4$: C, 45.45; H, 6.10%.

The trans acid VIa, m. p. 142—143°C, was obtained as granular crystals by concentrating the above filtrate. Infrared spectrum: Fig. 2, VIb.

Found: C, 45.50; H, 6.10. Calcd. for $C_5H_8O_4$: C, 45.45; H, 6.10%. (Ref. 4 reports a mixture of VIa and VIb, m. p. 110°C).

***trans*-Methyl-4-hydroxy-2-tetrahydrofurancarboxylate (VIIa).** — A solution of 0.9 g. of *trans* acid (VIa) in 10 ml. of methanol was added slowly to 100 ml. of ethereal solution (ca. 8%) of diazomethane at room temperature. A reaction took place, smoothly evolving nitrogen. After the mixture had been allowed to stand for 1 hr., the solvent was evaporated and the residue was distilled under reduced pressure to give 0.8 g. of *trans*-methyl ester (VIIa), b. p. 110—115°C/7 mmHg.

The infrared spectrum of VIIa in carbon tetrachloride (0.068 mol.) showed absorption maxima at 3620 and 3485 $cm^{-1}$ attributable to free hydroxyl and intermolecularly-associated hydroxyl groups respectively. With further dilution (0.0024 mol.), the intensity of the former band relative to the latter one was increased.

Found: C, 49.27; H, 7.15. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 7.15%.

***cis*-Methyl-4-hydroxytetrahydrofuran-2-carboxylate (VIIb).** — This was prepared, in the way described above, from 0.6 g. of *cis*-tetrahydrofurancarboxylic acid, VIb. The distillation of the crude

8) Melting points are uncorrected. The infrared spectra in high dilution condition were measured on a Nippon Bunko grating infrared spectrometer model DS-401G, using 50 mm. KBS cell under high resolution condition.

9) E. N. Eccott and R. P. Linstead, *J. Chem. Soc.*, **1929**, 2153.

product gave 0.5 g. of the *cis*-ester VIIb, b. p. 105—110°C/7 mmHg, whose infrared spectrum showed an absorption band at 3482 $cm^{-1}$ due to an intramolecularly-hydrogen-bonded hydroxyl group in carbon tetrachloride (0.077 mol.).

Found: C, 49.22; H, 6.87. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 6.90%.

***trans*-4-Hydroxy-2-tetrahydrofurancarboxylic Acid Dimethylamide (VIIIa).** — The *trans*-methyl ester (0.5 g.) was added to 35 ml. of a solution (30%) of dimethylamine in absolute ethanol, and the mixture was heated for 25 hr. in a sealed tube at 80—90°C. The cooled reaction mixture was then concentrated to leave an oily residue, whose infrared absorption showed bands at 3350, 1638, 1105, 1077 $cm^{-1}$ for amide VIIIa and a rather weak absorption at 1730 $cm^{-1}$ for the unchanged ester (VIIa), which was removed by extracting it with ether.

***cis*-4-Hydroxy-2-tetrahydrofurancarboxylic Acid Dimethylamide (VIIIb).** — *cis*-Amide (VIIIb) was prepared in a way similar to that used for the trans-isomer described above. *cis*-Methyl ester (0.47 g.) was added to 30 ml. of an ethanolic solution (30%) of dimethylamine, and the mixture was heated for 8 hr. in a sealed tube at 80—90°C. The oily residue obtained by the evaporation of the solvent exhibited the following bands in the infrared spectrum: $\nu_{max}^{film}$ 3370, 1640, 1092, 1075 $cm^{-1}$. No absorption bands attributable to the ester VIIb were observed.

***trans*-(4-Hydroxy-2-tetrahydrofurfuryl)methyldimethylamine (IXa).** — To a solution of 0.6 g. of lithium aluminum hydride in 21 ml. of dried tetrahydrofuran, *trans*-dimethylamide (0.7 g.) in 5 ml. of tetrahydrofurane was added drop by drop under ice cooling; the mixture was then refluxed for 4 hr. on a steam bath. After the excess lithium aluminum hydride had been decomposed by adding 20 ml. of ethyl acetate to the cooled reaction mixture, the solvent was evaporated and the residue was treated with a solution (20%) of sodium hydroxide. The undissolved material was extracted several times with ethyl acetate. The extracts were combined, dried over anhydrous potassium carbonate, and evaporated to leave an oily residue. The residue was then chromatographed on 40 g. of deactivated alumina, using a mixture of benzene and methanol (0.5—10%) as a developer. Elution with benzene-methanol (5%) gave 0.45 g. of the *trans*-dimethylamine IXa. Infrared spectrum: $\nu_{max}^{CCl_4}$ 3400, 1103, 1070, 1035, 976 $cm^{-1}$. Reineckate of IXa: m. p. 167—187°C (decomp.)

Found: C, 28.55; H, 5.01; N, 20.91. Calcd. for $C_{12}H_{25}O_2N_7S_4Cr$: C, 28.44; H, 4.77; N, 21.10%.

***cis*-(4-Hydroxy-2-tetrahydrofurfuryl)methyldimethylamine (IXb).** — The cis-isomer IXb was prepared by exactly the same procedure as was the trans-isomer. The *cis*-dimethylamide VIIIb (0.7 g.) gave 0.42 g. of the *cis*-dimethylamine IXb, b. p. 75—80°C/4 mmHg, the infrared spectrum of which in high diluted conditions exhibited a broad band at 3194 $cm^{-1}$ ascribed to the intramolecularly-hydrogen-bonded hydroxyl group in carbon tetrachloride (0.0072 mol.). Infrared spectrum: $\nu_{max}^{CCl_4}$ 3220, 1110, 1086, 1062, 1037, 1027 $cm^{-1}$. Reineckate of IXb: m. p. 183—184°C (decomp.).

Found: C, 28.40; H, 5.05; N, 20.94. Calcd. for $C_{12}H_{25}O_2N_7S_4Cr$: C, 28.44; H, 4.77; N, 21.10%.

***trans*-Demethylmuscarine (Xa).** — To a solution of 0.2 g. of *trans*-amine IXa in ethanol an excess of methyl iodide was added, and the mixture was allowed to stand for 1 hr. at room temperature. The reaction mixture was then evaporated under reduced pressure to leave a solid which was recrystallized twice from ethanol-water to give 0.2 g. *trans*-demethylmuscarine (Xa), m. p. 119—120°C; infrared spectrum: $\nu_{max}^{Nujol}$ 3345, 1103, 1072, 992, 953, 918 $cm^{-1}$. (Ref. 7 reported an m. p. of 119.5—120°C.)

Found: C, 33.63; H, 6.24; N, 4.70. Calcd. for $C_8H_{18}O_2NI$: C, 33.47; H, 6.32; N, 4.88%,

The reineckate of *trans*-demethylmuscarine was recrystallized from water-enthanol; m. p. 175.5—177°C (decomp.).

Found: N, 20.32. Calcd. for $C_{12}H_{24}O_2N_7S_4Cr$: N, 20.49%.

***cis*-Demethylmuscarine (Xb).** — The same treatment of IXb as that of the trans-isomer Xa gave a crude product which was recrystallized from water-ethanol to yield *cis*-demethylmuscarine (Xb), m. p. 117—118°C; infrared spectrum: $\nu_{max}^{Nujol}$ 3395, 1103, 1067, 1015, 995, 968, 962, 940 $cm^{-1}$. (Ref. 7 reported an m. p. of 119.5—120.5°C)

Found: C, 33.33; H, 6.36; N, 4.71. Calcd. for $C_8H_{18}O_2NI$: C, 33.47; H, 6.32; N, 4.88%.

The reineckate of *cis*-demethylmuscarine showed an m. p. of 169—171°C (decomp.) after recrystallization from water-ethanol.

Found: N, 20.04. Calcd. for $C_{12}H_{24}O_2N_7S_4Cr$: N, 20.49%.

## Summary

Two stereoisomeric *dl*-demethylmuscarines have been prepared by the procedure described for the synthesis of *dl*-muscarine, starting from ethyl allylmalonate.

We are indebted to Professor Hiroshi Ooga, Veterinary Department, Hokkaido University, for performing pharmacological tests.

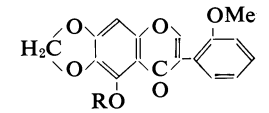
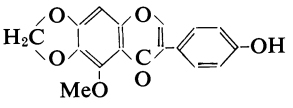
# The Synthesis of Tlatlancuayin and Some Related Compounds

By Kenji FUKUI, Takashi MATSUMOTO and Shigehiro NAKAMURA



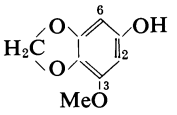
(Received November 19, 1964)

Tlatlancuayin was isolated from *Iresine celosioides L.* (*fam. Amarantaceae*) by Crabbé et al.[1] They established its structure as 2', 5-dimethoxy-6, 7-methylenedioxyisoflavone (I) from analytical, spectroscopic and degradative studies. As an isoflavone it is a unique compound which has a fully-alkylated system, with a lone 2'-methoxyl in the side phenyl and a methylenedioxy group in the chromone nucleus. Two methods for the synthesis of the compound have been reported by Arora et al.[2] In previous papers the present authors have reported the synthesis of irisolone (4'-hydroxy-5-methoxy-6, 7-methylenedioxyisoflavone) (II),[3] one of the few naturally-occurring isoflavones containing a methylenedioxy substituent, and some 6, 7-methylenedioxyisoflavones.[4,5]



The present paper will describe the synthesis of tlatlancuayin and some related compounds.

In previous papers,[3,6] the authors have shown that, in the Hoesch reaction, 3-methoxy-4, 5-methylenedioxyphenol (III)[7] was condensed with some acetonitriles at the 2-position (not at the 6-position). By a similar reaction with 2-methoxybenzyl cyanide, III yielded 2-hydroxy-4, 5-methylenedioxy-6-methoxyphenyl 2-methoxybenzyl ketone (IV) which had been obtained by the degradation[1] of natural tlatlancuayin with alkali. According to the method of Crabbé et al.,[1] IV was cyclized with ethyl formate to tlatlancuayin (I), whose identity with the natural substance was confirmed by mixed melting point determination and by ultraviolet and infrared spectral comparisons (Figs. 1 and 2). The synthetic substance, I, was converted into the known product, V, by demethylation.



By a similar reaction with benzyl cyanide, 3, 4-methylenedioxybenzyl cyanide and 3, 4-dimethoxybenzyl cyanide, III was derived to the

(II)

(III)

(IV)

respective ketones, VI, VII and VIII. These ketones were also cyclized with ethyl formate to the corresponding isoflavones (IX, X and XI). The treatment of IX and X with aluminum chloride in boiling ether gave the 5-demethyl derivatives (XII and XIII), which could also be methylated back into the parent isoflavones (IX and X), indicating that no

## Experimental*1

**2-Hydroxy-4, 5-methylenedioxy-6-methoxyphenyl 2-Methoxybenzyl Ketone (IV).** — 3-Methoxy-4, 5-methylenedioxyphenol (III)[7] (5.0 g.) and 2-methoxybenzyl cyanide[8] (5.0 g.) were dissolved in dry ether (120 ml.), and then fused zinc chloride (1.5 g.) was added. The mixture was saturated with dry hydrogen chloride in an ice-bath and allowed to stand overnight. The ether solution was decanted from the ketimine hydrochloride-zinc chloride complex which had separated. The residue was washed with dry ether and heated on a steam bath with water (100 ml.) for 75 min. The oil which had separated on cooling was extracted with ethyl acetate. The organic layer was washed with aqueous sodium bicarbonate and then with water. After the solvent had evaporated, the residue was distilled. The distillate (bath temperature 230—280°C/0.1 mmHg) was collected and crystallized from ether-petroleum ether to give IV as yellow needles; m. p. 115—116°C (reported m. p. 115—116°C[1]); yield, 0.6 g. This gave a green ferric chloride reaction in ethanol. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 243.5 (4.08), 284 (4.13), 351 (3.70). In all these properties it agreed with that substance obtained by Crabbé et al.[1]

Found: C, 64.26; H, 5.07. Calcd. for $C_{17}H_{16}O_6$; C, 64.55; H, 5.10%.

**Tlatlancuayin (2', 5-Dimethoxy-6, 7-methylenedioxyisoflavone) (I).**—According to the method of Crabbé et al.,[1] the ketone IV (1.44 g.) by cyclization with sodium (3.0 g.) in ethyl formate (200 ml.) gave I (480 mg.) as colorless prisms, m. p. 147—148°C (reported m. p. 145—147°C,[1] 147—148°C[2]). This gave no ferric chloride reaction. This substance was found to be identical with the natural substance by mixed melting point measurement and by infrared and ultraviolet spectral comparisons. IR; 1645, 1614, 1603, 1589, 1016, 938 $cm^{-1}$. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 246 (4.32), 281*2 (4.08), 321 (3.82).

Found: C, 66.28; H, 4.37. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

**The Partial Demethylation of Tlatlancuayin (I).**—According to the method of Crabbé et al.,[1] I was demethylated with aluminum chloride to give 5-hydroxy-2'-methoxy-6, 7-methylenedioxyisoflavone (V) as yellow needles, m. p. 191—192°C (reported m. p. 192—193°C[1]). This gave a green ferric chloride reaction in ethanol. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 243.5 (4.25), 271.5 (4.27), 332*2 (3.58).

Found: C, 65.21; H, 3.89. Calcd. for $C_{17}H_{12}O_6$; C, 65.38; H, 3.87%.

**2-Hydroxy-4, 5-methylenedioxy-6-methoxyphenyl Benzyl Ketone (VI).**—From the phenol III (5.0 g.), benzyl cyanide (4.0 g.), fused zinc chloride (1.5 g.) and dry ether (120 ml.), synthesis was carried out by a method similar to that used for IV. The product was recrystallized from methanol to give VI as yellow needles, m. p. 162—164°C, which gave a green ferric chloride reaction in ethanol; yield 2.0 g. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 245.5 (4.06), 289 (4.12), 357 (3.68).

Found: C, 67.21: H, 4.69. Calcd. for $C_{16}H_{14}O_5$: C, 67.12; H, 4.93%.

**2-Hydroxy-4, 5-methylenedioxy-6-methoxyphenyl 3, 4-Methylenedioxybenzyl Ketone (VII).** — From the phenol III (19.8 g.), 3, 4-methylenedioxybenzyl cyanide (21.0 g.), fused zinc chloride (6.0 g.) and dry ether (350 ml.), synthesis was carried out by a method similar to that used for IV. The product was recrystallized from chloroform-methanol to give VII as yellow needles, m. p. 153—154°C, which gave a green ferric chloride reaction in ethanol; yield 4.3 g. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 241.5 (4.12), 289 (4.21), 355 (3.70).

Found: C, 61.58; H, 4.17. Calcd. for $C_{17}H_{14}O_7$: C, 61.82; H, 4.27%.

**2-Hydroxy-4, 5-methylenedioxy-6-methoxyphenyl 3, 4-Dimethoxybenzyl Ketone (VIII).** — From the phenol III (15.0 g.), 3, 4-dimethoxybenzyl cyanide (17.5 g.), fused zinc chloride (4.5 g.) and dry ether (1000 ml.), synthesis was carried out by a method

*1 All melting points are uncorrected; the infrared spectra were measured in Nujol, while the ultraviolet spectra were measured in an ethanol solution.

*2 Inflection point.

similar to that used for IV. The product was distilled, and the distillate (bath temperature 300—330°C/0.05 mmHg) was collected and then crystallized from chloroform-methanol to give VIII as yellow needles, m. p. 121.5—122°C, which gave a green ferric chloride reaction in ethanol; yield 450 mg. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 287.5 (4.18), 355 (3.72).

Found: C, 62.23; H, 5.23. Calcd. for $C_{18}H_{18}O_7$: C, 62.42; H, 5.24%.

**5-Methoxy-6, 7-methylenedioxyisoflavone (IX).**—The ketone VI (1.0 g.) in freshly-distilled ethyl formate (60 ml.) was added slowly to sodium powder (2.0 g.) at −10°C. The reaction mixture was allowed to stand for 24 hr. at 0°C and then for 48 hr. at room temperature. Ice water containing hydrochloric acid was added, and the solution was extracted with ether. The ether solution was washed with aqueous sodium bicarbonate and then with water, and dried. The recrystallization of the residue from ethanol gave IX as colorless needles; m. p. 145—147°C; yield 330 mg. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 260 (4.41), 324 (3.82).

Found: C, 68.99; H, 3.95. Calcd. for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08%.

**5-Methoxy-6, 7; 3', 4'-bismethylenedioxyisoflavone (X).**—From the ketone VII (3.9 g.), freshly-distilled ethyl formate (320 ml.) and sodium powder (7.0 g), synthesis was carried out by a method similar to that used for IX. The product was recrystallized from chloroform-methanol to give X as yellow needles; m. p. 223—224°C; yield 1.5 g. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 267 (4.41), 290*[2] (4.18), 320*[2] (3.84).

Found: C, 63.36; H, 3.67. Calcd. for $C_{18}H_{12}O_7$: C, 63.53; H, 3.55%.

**3', 4', 5-Trimethoxy-6, 7-methylenedioxyisoflavone (XI).**—From the ketone VIII (450 mg.), freshly-distilled ethyl formate (60 ml.) and sodium powder (1.0 g.), synthesis was carried out by a method similar to that used for IX. The product was recrystallized from ethanol to give XI as colorless needles; m. p. 178—178.5°C; yield 110 mg. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 266.5 (4.45), 324 (3.82).

Found: C, 63.99; H, 4.61. Calcd. for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%.

**5-Hydroxy-6, 7-methylenedioxyisoflavone (XII).**—A mixture of IX (1.3 g.) and anhydrous aluminum chloride (13.0 g.) in dry ether (130 ml.) was refluxed for 10 hr. The reaction mixture was then poured into ice water and kept for 14 hr. at room temperature. The resulting yellow precipitate was collected and refluxed with a solution of acetic acid (45 ml.) and concentrated hydrochloric acid (45 ml.) for 30 min. The reaction mixture was then diluted with water. The precipitate was collected, washed with water, and recrystallized from acetone to give XII as yellow prisms, m. p. 198—199°C, which gave a green ferric chloride reaction in ethanol; yield 0.9 g. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 244 (4.32), 270.5 (4.38), 332*[2] (3.58).

Found: C, 68.03; H, 3.53. Calcd. for $C_{16}H_{10}O_5$: C, 68.08; H, 3.57%.

The acetate of XII: acetic anhydride-pyridine method; m. p. 178—179°C (colorless needles from ethanol). UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 251 (4.40), 321 (3.95).

Found: C, 66.42; H, 3.80. Calcd. for $C_{18}H_{12}O_6$: C, 66.67; H, 3.73%.

XII was methylated, by the usual dimethyl sulfate-potassium carbonate method, to IX, which was undepressed on admixture with the above sample.

**5-Hydroxy-6, 7; 3', 4'-bismethylenedioxyisoflavone (XIII).**—A mixture of X (1.47 g.), anhydrous aluminum chloride (12.0 g.) and dry ether (100 ml.) was treated by a method similar to that used for XII. The product was recrystallized from acetone to give XIII as yellow needles, m. p. 232.5—233.5°C, which gave a green ferric chloride reaction in ethanol; yield 780 mg. UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 274 (4.39), 294*[2] (4.29), 336*[2] (3.59).

Found: C, 62.87; H, 2.98. Calcd. for $C_{17}H_{10}O_7$: C, 62.58; H, 3.09%.

The acetate of XIII: acetic anhydride-pyridine method; m. p. 216—217°C (colorless needles from aqueous methanol). UV: $\lambda_{max}^{EtOH}$ mμ (log ε); 265 (4.29), 293.5 (4.11), 317*[2] (3.94).

Found: C, 61.71; H, 3.24. Calcd. for $C_{19}H_{12}O_8$: C, 61.96; H, 3.29%.

XIII was methylated, by the usual dimethyl sulfate-potassium carbonate method, to X, which was undepressed on admixture with the above sample.

The authors are grateful to Professor Carl Djerassi, Stanford University, for a gift of natural tlatlancuayin. Grateful acknowledgement is also made to the members of the Microanalytical Laboratory, Faculty of Pharmacy, Nagasaki University, for the microanalyses.

# Szilard-Chalmers Reaction of Trioxalatochromium Ion on Ion Exchange Resin—Static Irradiation and Its Kinetic Analysis

By Yoshihiro SENSUI and Tatsuo MATSUURA

(Received November 21, 1964)

The Szilard-Chalmers process can generally be divided into the following four consecutive processes.[1,2]

1) First process. This is purely a physical disruption of the bond due to the nuclear recoil. The yields in this process should be almost independent of the chemical constitution of the target material.

2) Second process. The hot atoms are thermalized in this epithermal process. In the case of a liquid phase, the hot atoms will be incorporated into some familiar stable chemical species at the end of this step.[3] Thus the yields may be more or less dependent on the chemical environment of the system.

3) Third process. During irradiation, the products of the second process undergo the radiation-induced thermal reactions. The yields are usually much influenced by various factors, such as irradiation time, chemical enviroment, and absorbed radiation dose of the system.[4]

4) Fourth process. This is the ordinary thermal annealing process. In addition, separation-induced processes may sometimes occur. The yields depend further on many factors, such as standing time and temperature[4].

It should be noted that the concomitant radiations other than the thermal neutrons in a reactor, i. e., the fast and the epithermal neutrons and the gamma rays, always produce the very same degraded species through processes similar to those mentioned above.[5] They usually decrease the separable yield through enhancement of the recombinations in the third process, and thus are the main factors complicating the true results of the recoil phenomena.

One of the authors has recently developed a flow method, using a complex-ion-loaded ion-exchanger in which an appropriate eluent continuously leaches out the recoil products from the target material immediately after their production.[6] Since this method can almost eliminate the third process, it may shed light on the immediate results at the end of the second process. Trioxalatochromium ion on an anion exchange resin is one of the most suitable samples for this purpose, considering its chemical constitution and the ionic stability in water. This paper deals with the results of the batch-wise experiments and their kinetic analysis, which have been done as an introductory approach to the flow method in this system.

## Experimental

**Material.**—Trioxalatochromium complex ion was adsorbed on the acetate form of the anion exchange resin,[7] Dowex 1X8 (100—200 mesh), from an aqueous solution of $K_3Cr(C_2O_4)_3 \cdot 3H_2O$ prepared by the usual method.[8] At about 15 hr. prior to irradiation, the resin was freed from aquated impurities with 0.01 N nitric acid and washed with water. As an irradiation sample, about 4 ml. of the resin was pipetted into a polyethylene vial with 3 ml. of the digesting solution, which was adjusted to pH 2.0 with nitric acid, pH 3.15 with acetic acid or pH 3.85 with acetic acid. The sample was stored in a frozen state until just before the irradiation.

**Pile Irradiation.**—Most of the samples were irradiated in a position of the reactor having minimum concomitant radiations, i. e., behind a leadblock (6.5 cm. thick) inserted in the thermal column of the TRIGA Mark II reactor, for 1.5—12 hr. at 100 kW. The thermal and the fast neutron fluxes here are about $3\times10^{10}$ and $1\times10^{8}$ n./cm$^2$/sec., respectively, and the external gamma exposure rate is about $7\times10^{3}$ r./hr. The internal radiation dose rate, i. e., the radiation energy absorbed by the sample per unit time due to the (n, $\gamma$) and the $N$(n, p) reactions and the collision of fast neutrons in the sample irradiated at this condition, was estimated to be about the same order of magnitude as the external exposure rate.

Some exploratory experiments were made using different positions, i. e., in the rotary specimen

8) H. S. Booth, "Inorganic Syntheses," Vol. I, 37 McGraw-Hill Book Co., Inc., New York (1939).

rack, in which the thermal and the fast neutron fluxes are about $6\times10^{11}$ and $5\times10^{10}$ n./sec./cm$^2$ respectively and the gamma exposure rate is about $1.4\times10^6$ r./hr., or in the thermal column without the lead shield, in which the gamma exposure rate is about $2\times10^4$ r./hr. However, with the samples which were irradiated in the rotary specimen rack, the yields of $^{51}$Cr in the cationic species were found to be negligibly small, and even with those which had received only threefold increased gamma ray exposures by omitting the lead shield in the thermal column, the yield decreased as much as 17% on the average compared with the samples with the lead shield. In view of these results, further experiments were always carried out with the lead shield in the thermal column of the reactor.

**Chemical Separation.**—Although it has been reported that some part of the chromium can change its initial oxidation state by recoil[9-13] most of the chromium in this liquid system seems to maintain its lower oxidation state,[14] because the oxalate ion and the strong basic type anion exchanger form a highly reductive environment. Thus the main products from the parent complex ion were assumed to be hexaquo-, monoxalatotetraquo- and dioxalatodiaquo-chromium ions. Within 5—30 min. after the irradiation, the resin was transferred into a column (1 cm. i. d.) containing about 0.5 ml. of the acetate form of Dowex 1X8; the cationic species [$Cr(H_2O)_6^{3+}$ and $Cr(OX)(H_2O)_4^+$] were firstly eluted from the resin with about 100 ml. of water, and the dioxalato species was separated from it with 300 ml. of 0.01 N nitric acid. The parent ion was finally eluted from the resin with 100 ml. of 1 N ammonium nitrate which had been adjusted to pH 1.0 with nitric acid. Though the dioxalato species was not so clearly separated from the parent one, they were distinguished by the steep change in the enrichment factors in the effluents. The cationic species were further separated by using 0.5 M perchloric acid and 6 N hydrochloric acid as eluents on a column of a cation exchange resin[15] in a few earlier runs, however this procedure was omitted in later runs and these portions were treated together as "cationic species," because the reported high rate of the equilibration reaction between them[16] was evidenced from about the same values of enrichment factors found in these fractions.

**Determination of $^{51}$Cr Activity and Total Chromium.**—The activities of aliquots of the effluents were measured by counting the 0.32 MeV. photon emission of the $^{51}$Cr with a well-type NaI(Tl) scintillation counter and a single channel analyzer. The amounts of total chromium (active and non-active chromium) were determined colorimetrically by the chromate method (using a filter of 372 m$\mu$).[17]

## Results

**The Percentage Yield of $^{51}$Cr.** — The $^{51}$Cr yields in the cationic, dioxalato and trioxalato chromium species are plotted against the irradiation time, for immersing solutions of varying pH values in Figs. 1, 2 and 3, respectively. They show that the yields of $^{51}$Cr in

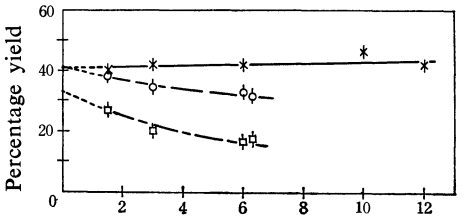

Fig. 1. Percentage yields of $^{51}$Cr in the cationic species (hexaquo and monoxalatotetraquo) species against irradiation time.

the cationic species decrease with the pH value of the digesting solution, whereas the yields of the parent species increase with it. It should be noted that while the yields of all species at pH 2.0 are almost unchanged with the irradiation time, the dependence of the yields on the irradiation time becomes noticeable as the pH value increases.

It follows from these figures, that the recombination rate is small at pH 2.0 but becomes noticeable with increasing pH value. The figures also show that the yields at zero irradiation time, i. e. the initial distribution of $^{51}Cr$ in each species in the epithermal process, is influenced by the pH value.

**The Percentage Yield of Total Chromium and Enrichment Factor.**—The yields of total chromium in the cationic, dioxalato and trioxalato species are plotted against irradiation time in Figs. 4, 5 and 6, respectively. Dividing the yields of $^{51}Cr$ in each species, by the yields of total chromium in the corresponding species, gives the enrichment factors shown in Fig. 7. The enrichment factors of the enriched species decrease with the irradiation time according

to the general law.[18] Figure 7 also shows that the enrichment factor increased with the pH value of the digesting solution.

## Discussion

The overall reaction including the epithermal process accompanied by both recoil and gross radiolysis, and the subsequent thermal process

18) G. E. Boyd, J. W. Cobble and S. Wexler, *J. Am. Chem. Soc.*, 74, 237 (1952).

of interconversion among the main products during irradiation, can be represented by the following scheme:

Here, it should be noted that although the first and the second processes can be distinguished in the case of the labeled species, this can not be so with the total chromium species, i. e., the rate constant of the actual degradation of $Cr(OX)_3^{3-}$ species is expressed as $\{G(\beta_2+\beta_{0,1})+k_{-3}\}$.

Then the labeled and the total chromium species can be followed simultaneously by the following rate equations, the radioactive decay terms for this nuclide being neglected:

$$\left.\begin{aligned}
\frac{d(X_{0,1}^*+X_{0,1})}{dt} &= \alpha_{0,1}FN_{cr} \\
&+k_{-2}(X_2^*+X_2)+\beta_{0,1}G(X_3^*+X_3) \\
&-k_2(X_{0,1}^*+X_{0,1}) \\
\frac{d(X_2^*+X_2)}{dt} &= \alpha_2FN_{cr}+k_2(X_{0,1}^*+X_{0,1}) \\
&+(\beta_{0,1}G+K_{-3})(X_3^*+X_3) \\
&-(k_{-2}+k_3)(X_2^*+X_2) \\
\frac{d(X_3^*+X_3)}{dt} &= \alpha_3FN_{cr}+k_3(X_2^*+X_2) \\
&-\{(\beta_{0,1}+\beta_2)G+k_{-3}\}(X_3^*+X_3)
\end{aligned}\right\} \quad (1)$$

where

$F$=rate constant of formation of $^{51}Cr$, $a\cdot\phi_{th}\cdot\sigma_{act}$,*

$G$=rate constant of initial decomposition of parent ion by radiolysis,**

$\alpha_i$=initial fraction of distribution of $^{51}Cr$ in each species by recoil,

$\beta_i$=initial fraction of distribution of total chromium in each species by radiolysis,

$k_{-i}$=apparent rate constants of the aquation under irradiation condition, with respect to the complex ion,

$k_i$=apparent rate constants for complex formation under irradiation condition, with respect to the complex ion,

$X_i^*$=number of $^{51}Cr$ in each species,

$X_i$=total number of chromium atoms in each species,

$N_{cr}$=total number of chromium atoms in the whole system.

We obtain the equations for the active chromium by eliminating the nonactive terms in Eq. 1, and those for the total chromium by neglecting the first and the labeled terms. We assume that not only the aquation rate but also the complexing rate are first order with respect to the complex ion for each pH value as is reported in the cold condition.[19,20]

Judging from the data for the yields of $^{51}Cr$ and the total chromium at pH 2.0, we can assume that the complexing rates are small compared with the respective aquation rates for both the labeled and total chromium at pH 2.0. Thus by disregarding the complexing terms in Eq. 1, the following solutions are obtained for active and total chromium at pH 2.0:

$$\left.\begin{aligned}
X_{0,1}^* &= \frac{x_{0,1}^*N_{cr}^*}{100} = (\alpha_{0,1}+\alpha_2)FN_{cr}t \\
&-\frac{\alpha_2FN_{cr}}{k_{-2}}\{1-\exp[-k_{-2}t]\} \\
X_2^* &= \frac{x_2^*N_{cr}^*}{100} \\
&= \frac{\alpha_2FN_{cr}}{k_{-2}}\{1-\exp[-k_{-2}t]\} \\
X_3^* &= \frac{x_3^*N_{cr}^*}{100} = \alpha_3FN_{cr}t
\end{aligned}\right\} \quad (2\text{-a})$$

$$\left.\begin{aligned}
X_{0,1} &= \frac{x_{0,1}N_{cr}}{100} = \frac{\beta_{0,1}GN_{cr}}{(\beta_{0,1}+\beta_2)G+k_{-3}} \\
&\times\{1-\exp[-\{(\beta_{0,1}+\beta_2)G \\
&+k_{-3}\}t]\} \\
X_2 &= \frac{x_2N_{cr}}{100} = \frac{(\beta_2G+k_{-3})N_{cr}}{k_{-2}-(\beta_{0,1}+\beta_2)G+k_{-3}} \\
&\times\{\exp[-\{(\beta_{0,1}+\beta_2)G \\
&+k_{-3}\}t]-\exp[-k_{-2}t]\} \\
X_3 &= \frac{x_3N_{cr}}{100} \\
&= N_{cr}\exp[-\{(\beta_{0,1}+\beta_2)G+k_{-3}\}t]
\end{aligned}\right\} \quad (2\text{-b})$$

where $x_i^*$ and $x_i$ are the percentage yields of $^{51}Cr$ and total chromium in the species $i$, respectively, and $N_{cr}^*$ is the number of $^{51}Cr$ atoms produced after $t$ hr. of irradiation.

* $a$=abundance of $^{50}Cr$,
$\phi_{th}$=thermal neutron flux,
$\sigma_{act}$=thermal neutron cross section for the reaction $^{50}Cr(n,\gamma)^{51}Cr$.

** This is not the rate constant of the apparent radiolytic decomposition but includes the immediate recombination into the parent form in the epithermal reaction, and thus is defined as pH-independent.

19) R. E. Hamm and R. E. Davis, ibid., 75, 3085 (1953).
20) R. E. Hamm and R. H. Perkins, ibid., 77, 2083 (1955).

At pH 3.15 and pH 3.85 it can safely be assumed that the complexing rate constants are much greater than the respective aquation ones, from the results in Figs. 1—7 and the data from the cold condition.[19-21] Thus by neglecting all the aquation terms for the $^{51}Cr$ and the total chromium in Eq. 1 except that for the aquation of the total parent ions, the following relationships are obtained for pH 3.15 and 3.85:

$$\left.\begin{aligned} X_{0,1}^* &= \frac{x_{0,1}^* N_{cr}^*}{100} \\ &= \frac{\alpha_{0,1} F N_{cr}}{k_2}\{1-\exp[-k_2 t]\} \\ X_2^* &= \frac{x_2^* N_{cr}^*}{100} = \frac{(\alpha_{0,1}+\alpha_2) F N_{cr}}{k_3} \\ &\times\{1-\exp[-k_3 t]\} - \frac{\alpha_{0,1} F N_{cr}}{k_3-k_2} \\ &\times\{\exp[-k_2 t]-\exp[-k_3 t]\} \\ X_3^* &= \frac{x_3^* N_{cr}^*}{100} = F N_{cr} t - (X_{0,1}^* + X_2^*) \end{aligned}\right\} \quad (3\text{-a})$$

$$\left.\begin{aligned} X_{0,1} &= \frac{x_{0,1} N_{cr}}{100} \\ &= \frac{\beta_{0,1} G N_{cr}}{k_2}\{1-\exp[-k_2 t]\} \\ X_2 &= \frac{x_2 N_{cr}}{100} = \frac{\{(\beta_{0,1}+\beta_2)G + k_{-3}\} N_{cr}}{k_3} \\ &\times\{1-\exp[-k_3 t]\} - \frac{\beta_{0,1} G N_{cr}}{k_3-k_2} \\ &\times\{\exp[-k_2 t]-\exp[-k_3 t]\} \\ X_3 &= \frac{x_3 N_{cr}}{100} = N_{cr} - (X_{0,1}+X_2) \end{aligned}\right\} \quad (3\text{-b})$$

From the experimental plots in Figs. 1—3, the initial fractions of distribution of $^{51}Cr$ at the end of the second process are read as $\alpha_{0,1}=0.41$, $\alpha_2=0.25$ and $\alpha_3=0.34$ for pH 2.0 and 3.15 and $\alpha_{0,1}=0.33$, $\alpha_2=0.32$ and $\alpha_3=0.35$ for pH 3.85, respectively. After these values were put into the Eqs. 2-a, 2-b, 3-a and 3-b, the other parameters $\beta_{0,1}G$, $\beta_2 G$, $k_{-i}$ and $k_i$ which may also be pH-dependent were estimated by trial and error method for each pH value, to give calculated yields of $^{51}Cr$ and total chromium which best fit the experimental ones, as is shown in Figs. 1—6. The agreement between the calculated curves and the observed plots implies that the assumptions made are reasonable. The rate constants thus determined are shown in Fig. 8.

As can be seen in Fig. 8 the gross decomposition rate constant of the parent ion under irradiation, $\{(\beta_{0,1}+\beta_2)G+k_{-3}\}$, and the rate constant of the initial direct formation of cationic species from the parent ion by radiolysis, $\beta_{0,1}G$, are only slightly dependent on the pH value, while the corresponding aquation rate constants under the cold condition have been reported to be much more dependent on the pH value.[21,22] However, the fact that the numerical values observed under irradiation condition were found to be much larger than those of the corresponding aquation rate constant of the parent ion under cold condition* may imply that the pH-independent radiation-induced term is predominant over the pH-dependent cold term even in low radiation fields as in this irradiation condition.

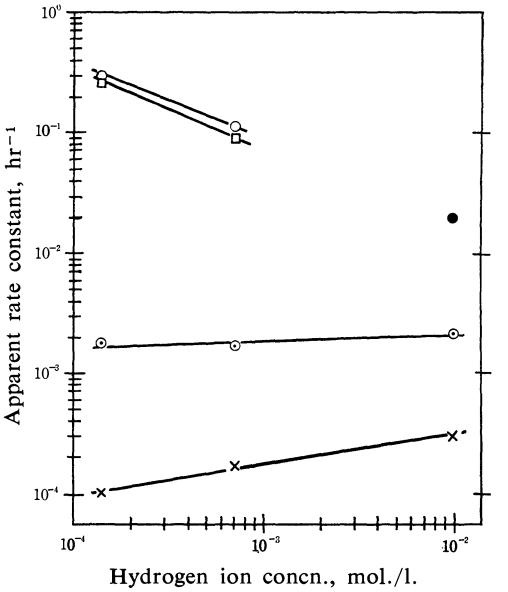

Fig. 8. The best-fit apparent rate constants against the hydrogen ion concentration.
○ $k_3$; □ $k_2$; ⊙ $(\beta_{0,1}+\beta_2)G+k_{-3}$; × $\beta_{0,1}G$; ● $k_{-2}$

On the other hand, Fig. 8 shows that the apparent rate constants of the complex-forming reaction, $k_i$'s, are nearly inversely proportional to the hydrogen ion concentration, in accord with the corresponding ones under the cold condition both in tendency and in magnitude.[19,20] This suggests that the radiation-induced term does not seriously contribute to the apparent complexing rate constant at least in the low radiation fields. However, as can be seen from the exploratory experiment, higher radiation fields may increase the recombination rate.

21) K. V. Krishnamurty and G. N. Harris, *J. Phys. Chem.*, **64**, 346 (1960).

22) N. K. Dutt and B. Sur, *Z. anorg. u. allgem. Chem.*, **293**, 195 (1957).

* These values are calculated to be $2.2\times10^{-4}$ and $5\times10^{-6}$ $hr^{-1}$ for pH 2.0 and 3.85 respectively according to Krishnamurty's data.[21]

We believe that the dependence on pH value, of the initial fraction of distribution of $^{51}Cr$ among each species, $\alpha_i$, is reasonable, because in the epithermal reaction, an immediate recombination of the degraded ion should have occured, and its extent will depend on the pH value. The lowest value of $\alpha_3$ obtained, 0.34 can be referred to as the "initial retention" in this system. However, as this is the value after the completion of the epithermal reaction in this chemical environment, it seems difficult to relate it with the nuclear inefficiency of the bond rupture due to the $^{51}Cr$ recoil in the first process. The authors believe this value for chromium should be almost zero, as was evidenced by the reported almost zero value of retention in the $Cr(SCN)_6^{3-}$ system.[23] The same author[23] reports that the most aquated species is the most enriched one, and this is just what we found in our system, as is shown in Fig. 7.

## Summary

Trioxalatochromium ion, on Dowex 1X18 immersed in a solution of pH 2.0—3.85, was irradiated batch-wise in the thermal column of a reactor for various irradiation times. With decreasing pH, the $^{51}Cr$ yield of the most enriched species (hexaquo- and monoxalatotetraquo-chromium ion) increased, but the enrichment factor decreased. With increasing irradiation time, while the changes in the $^{51}Cr$ yield of each chemical form are small at pH 2.0, the recombination reaction becomes noticeable at pH 3.15 and 3.85. These results were analyzed kinetically, and the rate constants of the aquation and the complex formation under irradiation condition as well as the initial fractions of distribution of $^{51}Cr$ and the total chromium among each chemical species were determined for the respective pH values.

The authors wish to express their hearty thanks to the IAEA, in whose research project (Contract No. 221/RB, "the use of an ion-exchanger to increase the specific activity of radioisotopes in Szilard-Chalmers reactions") this work is included. The authors' thanks are also to be extended to Professor Tetsuo Takaishi of our Institute for his helpful discussions on the kinetic analysis, and to the reactor operating staff of our Institute for their cooperation.

# The Determination of the Water Content in Acetaldehyde by Means of the Karl Fischer Reagent

By Kaname MUROI, Kunihiko OGAWA and Yaeko ISHII

(Received November 21, 1964)

Carbonyl compounds generally interfere with the Fischer titration. This is due to their tendency to form acetals or ketals by the reaction with methanol contained in Karl Fischer reagent, a process accompanied by the production of additional water:[1]

$$RCHO + 2CH_3OH \rightarrow RCH(OCH_3)_2 + H_2O \quad (1)$$

$$R_2CO + 2CH_3OH \rightarrow R_2C(OCH_3)_2 + H_2O \quad (2)$$

Mitchell et al.[2] have suggested, therefore, the use of Fischer reagent after converting carbonyl compounds to cyanohydrin with hydrogen cyanide. However, considerable difficulty is encountered in preparing a dried solution of toxic hydrogen cyanide and dioxane or pyridine; moreover, a complicated treatment is required prior to the titration.

Other methods have been proposed for the direct titration of water with modified Fischer reagents containing a great excess of pyridine[3] or containing methyl Cellosolve;[4] these methods are applicable to ketones, but not to aldehydes, in which the precise titration of water cannot be expected because reaction 1 accompanies the reaction 3 of absorbing water from the sample;[5]

$$RCHO + C_5H_5N \cdot SO_2 + H_2O \rightarrow C_5H_5N\langle_{H}^{SO_3CH(OH)R} \quad (3)$$

In previous papers, the present authors reported methods for the direct titration of water in low polymers[6,7] of formaldehyde and in ketones[8] by using the alcohol-free Karl Fischer reagent SS (Mitsubishi) and by keeping the interfering reactions under control. On the basis of these methods, the authors have now established the present method for the quantitative determination of water in acetaldehyde.

## Experimental

**Materials.**—Special-class reagents of acetaldehyde were used without further purification. Dried acetaldehyde was obtained by the distillation of para-aldehyde. Pyridine was obtained commercially. Propylene glycol was dried by boiling it. The Karl Fischer reagent SS (Mitsubishi), supplied by Mitsubishi Chemical Industries, was used (titer: 3.0 mg. $H_2O$/ml.)

8) K. Muroi, K. Ogawa and Y. Ishii, *Japan Analyst*, **12**, 963 (1963).

**Apparatus.**—The Karl Fischer electrometric titration apparatus, operating by the dead-stop method, was manufactured by the Tsutsui Chemical Instrument Co. The apparatus is illustrated in Fig. 1.

**Procedure.**—*Sampling Method.*—A carefully-dried injector (volume, 5 ml.; length of injection needle, about 10 cm.), with a small piece of silicone rubber stuck on the needle tip, was inserted in a polyethylene bag and then placed in an electric refrigerator. The injector thereby cooled and a vessel, which had been similarly stored and which contained the acetaldehyde sample and with a three-way cock for drawing the liquid, were taken out of the refrigerator. The injector was then inserted into the three-way cock in order to draw acetaldehyde from the vessel. The inside of the injector was rinsed twice with the sample, and then, the third time, 5 ml. of cold acetaldehyde was collected in the injector. (Each time after the drawing, the needle tip was wrapped with dry gauze so that the traces of moisture and of the sample which adhered to it were removed.)

*Titrating Method.*—Five milliliters of a solvent mixture of pyridine-propylene glycol (3 to 1, by volume) was added to a titration flask, which was then subjected to a water bath at 25 to 30°C. While passing dry nitrogen through the three-way cock, E, illustrated in Fig. 1, into this flask at the flow rate of 0.9 l./min., drops of the Karl Fischer reagent SS were added in order to bring it to the dead stop end point. The introduction of nitrogen was then stopped, and the injector was inserted through the three-way cock, E, into the titration flask until the needle tip was soaked in the liquid surface. Then the acetaldehyde was released into the pyridine - propylene glycol mixture as rapidly as possible. Now, while the solution was stirred, nitrogen was again introduced into the flask, and the titration was simultaneously carried out until the end point was obtained, where a drop of the SS (Mitsubishi) reagent kept the magic eye open as long as 50 to 60 sec.

## Results and Discussion

Acetaldehyde, among carbonyl compounds, showed the greatest velocity in the interfering reaction 1. Accordingly, an investigation with a view of avoiding this interference was carried out. Because of the difference in the boiling points of acetaldehyde and water, it was possible, after adding an exactly-weighed sample to a titration flask containing the pyridine - propylene glycol mixture solvent which was effective in controlling reaction 1, to evaporate almost all the interfering acetaldehyde with dry nitrogen directed toward the surface of the solution, and to titrate the remaining water in the solvent with the SS reagent. When acetaldehyde was evaporated with nitrogen, a small quantity of the liquid dissolved and remained in the solvent. In order to study any effect of the remaining acetaldehyde on the titration, 0.1, to 0.5 ml.

Table I. Effects of acetaldehyde in terms of its amounts employed

| Amount of sample ml. | Titration temp., °C | Titration value ml. | Interfering reaction | Nature of end point |

of purified acetaldehyde was added to 5 ml. of the 3 : 1 solvent mixture of pyridine - propylene glycol in a flask. The water content in the solution was then titrated with the reagent SS. Tables I, II and III show the results obtained in the investigation of how the interfering reactions were affected by the amounts of acetaldehyde employed, the titration temperatures and the mixing ratios of the solvent components. These tables confirmed that the interference from acetaldehyde was not observed at room temperatures when less than 0.2 ml. of acetaldehyde was contained in 5 ml. of the pyridine - propylene glycol. On the other hand, when a 5 : 1 mixture of pyridine-propylene glycol was employed as the titration solvent for the sample, the end point titration became indistinct because of the pyridine-inhibiting reaction between water and the reagent described. Therefore, the 3 : 1 mixture of pyridine-propylene glycol proved to be the most suitable solvent for the direct titration of water in acetaldehyde.

In determining the amount of the solvent to be employed, 0.1 to 0.5 ml. (both inclusive), of the sample (as in Table I) was added to 20 ml. of the mixture solvent, and then the water content in the solution was titrated. The results obtained show that the sample solvent had not much effect on the attempt to avoid interfering reactions, because acetaldehyde began to interfere when the amount of acetaldehyde present in the mixture exceeded 0.4 ml.

Next, 2 ml. of acetaldehyde was added to 5 ml. of the pyridine - propylene glycol solvent kept at 25°C in a titration flask. While dry nitrogen, adjusted to various velocities of 0.3 to 1.5 l./min., was passed into the flask, the water content in the solution was titrated with the reagent SS. Table IV shows the results obtained. Although acetaldehyde interfered with the titration because of its insufficient evaporation when nitrogen gas was added at a velocity of less than 0.6 l./min., it no longer interfered, because of its good evaporation when nitrogen was passed at a flow rate of

Table IV. Effects of the velocities of nitrogen gas

| Velocity of nitrogen l./min. | Titration values ml. | Interfering reaction | Nature of end point |
|---|---|---|---|
| 0.3 | — | Occurs | Indistinct |
| 0.6 | 4.68 | Occurs | Indistinct |
| 0.9 | 4.67 | Not occur | Distinct |
| 1.2 | 4.57 | Not occur | Distinct |
| 1.5 | 4.45 | Not occur | Distinct |

more than 0.6 l./min. However, a velocity of more than 1.2 l./min. was found to be undesirable because then the nitrogen tended to drive water from the solvent. Moreover, the amount of acetaldehyde remaining in 5 ml. of the solvent after nitrogen had been passed through at a velocity of more than 0.6 l./min. measured less than 0.1 ml. From this fact, as well as from the afore-mentioned results, it was concluded that a process which involved evaporating the sample by means of nitrogen could have a considerable effect on the elimination of interfering reactions in direct titration.

To 5 ml. of the pyridine-propylene glycol maintained at 25°C 0.2 to 5.0 ml. of acetaldehyde was added. The water content in the solution was then titrated, while nitrogen gas was passed through at a constant velocity of 0.9 l./min. The results, committed to a line graph in Fig. 2, show the rectilinearity and the stable nature of the end point in the titration when 0.2 to 2.50 ml. of acetaldehyde was present in the solvent. However, when more than 3 ml. of acetaldehyde was present, minus errors increased as the titration values increased. On a conjecture that these minus errors might be introduced by the interfering

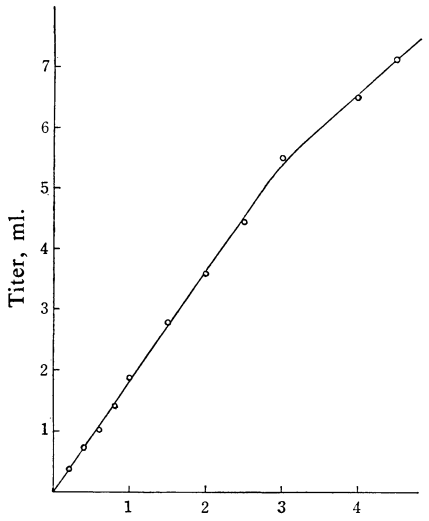

Fig. 2. Effects of amounts of acetaldehyde.

reaction 3, three kinds of reagents, in which molar ratios of $I_2$ to $SO_2$ to $C_5H_5N$ were maintained at 1 : 1.5 : 5, 1 : 3 : 10 and 1 : 6 : 20, were then prepared with the reagent SS. After 0.5 to 2.5 ml. of the sample had been added to 5 ml. of the solvent mixture, the water content in the solution was titrated with these modified reagents by directing nitrogen toward the surface of the solution. The results, shown in Fig. 3, indicate that minus errors tended to increase as the molar ratio between $SO_2$ and $C_5H_5N$ departed further from 1.5 : 5 ; these results confirmed the early conclusion that these minus errors might result from the interfering reaction 3.

Accordingly, it may be suggested that a restriction should be imposed upon titration values in order to eliminate the interference thoroughly. Moreover, a restriction on the titration value (i. e. $C_5H_5N \cdot SO_2$ concentration

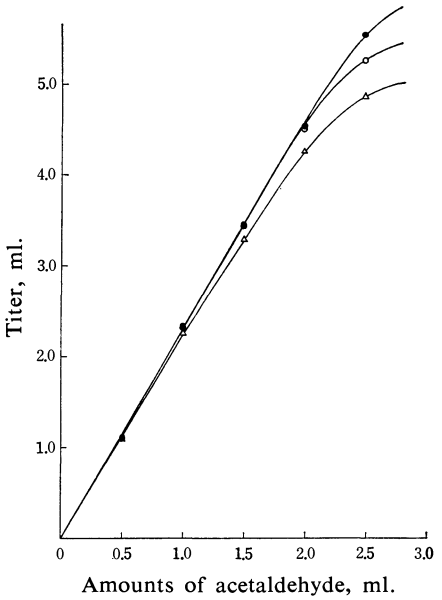

Fig. 3. Effects of molor ratios of $I_2$ to $SO_2$ to $C_5H_5N$ in the reagent.

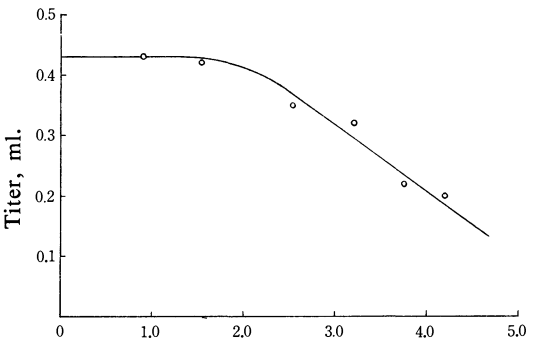

Fig. 4. Effects of water contents in the solvent.

in the reagent) involves a restriction of water content in the solvent employed. Therefore, for our present purposes, the effects of water content on the interfering reaction were studied. To 5 ml. of the 3 : 1 mixture of pyridine and propylene glycol containing various quantities of water, 0.2 ml. of the

| Commercial grade reagent | 88.7 | 10.1 | 1.0 | 99.8 |
| Acetaldehyde purified and distilled from the reagent | 99.5 | 0.67 | 0.08> | 100.2 |

sample was added. The results of the titrations, suggest that more than about 1.5 mg. (about 0.03%) of water in 5 ml. of the solvent caused minus errors (Fig. 4). Morever, the use of a large quantity of the solvent necessitated an increase in the amount of the reagent consumed for it, so it was found profitable to carry out the titration with the least possible amount of the solvent mixture.

In order to further develop the results shown in Table IV that water content, as well as acetaldehyde, tended to be evaporated when nitrogen was passed through at a velocity of more than 1.2 l./min., we attempted to determine the most suitable time for passing through nitrogen and for beginning the titration after acetaldehyde was added to the pyridine-propylene glycol. The results obtained show that the vaporizasion of water was not observed when nitrogen was introduced shortly after the beginning of titration, whereas it was obviously observed when nitrogen was passed through for more than about 30 sec. prior to the titration, and the resulting titration values were found to involve minus errors. When nitrogen was introduced almost at the end of the titration, interference from the acetaldehyde was observed because the acetaldehyde dissolved in about 4 ml. of the reagent was consumed, increasing the amount of it present in the solvent. Accordingly, in order to avoid evaporating the water, it was necessary to pass nitrogen through simultaneously with the titration, and to titrate the water content while the acetaldehyde was being evaporated.

The optimum conditions for the determination of the water content in acetaldehyde were established as follows:

*Solvent*: Five milliliters of 3:1 mixture (by volume) of pyridine-propylene glycol (water content, less than 0.03 per cent).

*Titration Temperature*: 25 to 30°C.

*Velocity of the Nitrogen Passed*: 0.8 to 1.0 l./min.

(Pass nitrogen into a titration flask simultaneously with the beginning of titration.).

*Sample*: Sample so that the titration value with the reagent (3 mg. $H_2O$/ml. titer) is approximately 4 ml. (equivalent to 12 mg. of water); for example, about 0.1 g. of the sample when it contains 10 per cent water; about 1 g. of the sample, when it contains 1 per cent water, and less than about 10 g. of the sample when it contains less than 0.1 per cent water.

In order to confirm the accuracy of the present method, quantitative determinations of acetaldehyde and the other impurities were made by means of the acid sodium sulfite method and by chromatography, and the values calculated were added to those of the water content. The results shown in Table V suggest the adequacy of the present method for the determination of the water content of acetaldehyde.

TABLE VI. RESULTS OF THE DETERMINATION OF A SMALL AMOUNT OF WATER IN REFINED ACETALDEHYDE

| Sample ml. | Titration value ml. | Water content mg. | Water content % |
|---|---|---|---|
| 1 | 0.14 | 0.42 | 0.053 |
| 3 | 0.41 | 1.23 | 0.052 |
| 5 | 0.65 | 1.95 | 0.050 |
| 7 | 1.06 | 3.17 | 0.057 |
| 10 | 1.32 | 3.95 | 0.050 |

TABLE VII. RESULTS OF THE DETERMINATION OF WATER IN REFINED ACETALDEHYDE CONTAINING A KNOWN AMOUNT OF WATER ADDED

| Sample ml. | Pyridine added ml. | Theoretical amount of water mg. | Water content value measured mg. | Difference from theoretical value mg. |
|---|---|---|---|---|
| 5 | — | — | 1.95 | — |
| 5 | 0.1 | 2.07 | 2.10 | +0.03 |
| 5 | 0.2 | 2.18 | 2.16 | −0.02 |
| 5 | 0.4 | 2.41 | 2.40 | −0.01 |
| 5 | 0.6 | 2.64 | 2.67 | +0.03 |
| 5 | 0.8 | 2.87 | 2.88 | +0.01 |
| 5 | 1.0 | 3.10 | 3.05 | −0.05 |

A small quantity of water in pure acetaldehyde prepared with para-aldehyde was determined by the present method. The water content values indicated in Table VI show a reproducibility. Moreover, from the water content values indicated in Table VII for 5 ml. of purified acetaldehyde determined in the presence of a fixed amount of pyridine containing a known quantity of water, it was reaffirmed that the determination of a minimal amount of water in acetaldehyde was carried out with accuracy by the present method.

## Summary

Approximately 5 ml. of the sample has been added to 5 ml. of a 3 : 1 solvent mixture of of pyridine - propylene glycol in a titration flask. The difference in boiling point between acetaldehyde and water made it possible to evaporate almost all the interfering acetaldehyde from the solution with nitrogen gas passed into the flask at a velocity of about 0.9 l./min. The water remaining in the solution was titrated with the Karl Fischer reagent SS (Mitsubishi).

Because this reagent is free from alcohol, which would show an interfering reaction in Eq. 1, and because it is somewhat lower than the general Karl Fischer reagent in its concentration of $C_5H_5N \cdot SO_2$, which is the main component responsible for the interfering reaction in Eq. 3, it proves to be the most satisfactory for the present titration method.

A small quantity of water in purified acetaldehyde was determined by the present method, and subsequent anlysis of water content values showed an excellent reproducibility.

# Studies of Antibiotics and Related Substances. XXI. The Synthesis of Deoxy and Chlorodeoxy Derivatives[1] of Kanamycin

By Tsutomu TSUCHIYA and Sumio UMEZAWA

(Received November 26, 1964)

In the course of our investigation into the effects of structural changes in kanamycin on its antibacterial activity, the syntheses of some aminosugar glucosides of deoxystreptamine and related compounds were previously reported.[2] The present report is concerned with the extension of this work.

Since kanamycin[3] contains two aminosugar moieties in the sequence 3-amino-3-deoxy-D-glucose—deoxystreptamine—6-amino-6-deoxy-D-glucose, an interesting type of structural variant would be the exchange of the aminosugars for another sugar by a partial synthesis from the antibiotic. Modifications of the primary alcoholic group in the 3-amino-3-deoxy-D-glucose moiety will be described in this paper.

As has previously been reported,[4] 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-deoxystreptamine and 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-deoxystreptamine were isolated from the acid-hydrolyzate of kanamycin by controlled hydrolysis; it was thus found that the former showed considerable antibacterial activity, whereas the latter did not show any activity against microorganisms tested. This suggested that (6-amino-6-deoxyglucosyl)-deoxystreptamine moiety may take the leading role in exhibiting the antibacterial activity of kanamycin. Accordingly, the synthetic variation of the 3-amino-3-deoxyglucose part of kanamycin was undertaken.

Kanamycin (I) contains seven alcoholic hydroxyl groups, one of which is primary; the others are all secondary. The difference[5]

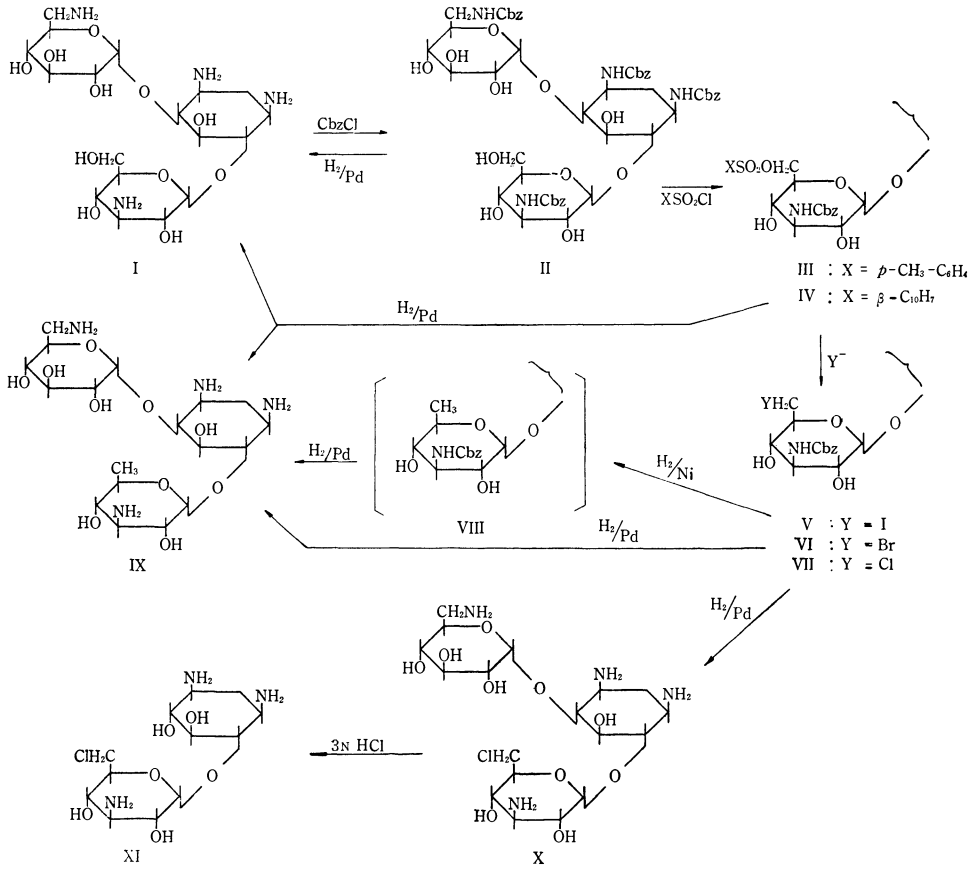

Chart 1

in the ease of the arylsulfonylation of primary and secondary alcoholic groups—the primary hydroxyl can be more easily esterified than the secondary ones—has been used for the present synthesis.

The treatment of an aqueous acetone suspension of kanamycin and sodium carbonate with carbobenzoxy chloride in toluene afforded tetra-*N*-carbobenzoxykanamycin (II). Since difficulty was experienced in avoiding contamination by the formation of an *O*-carbobenzoxylated product, the crude product was treated with dilute ethanolic hydrogen chloride at room temperature to afford an analytically pure sample of II (Chart 1).

The arylsulfonylation of the primary hydroxyl group of II was effected by *p*-toluenesulfonyl chloride, followed by fractional precipitation and silica gel column chromatography; by this method, a mono-*O*-tosylated product (III) was obtained in about a 20% yield. Alternatively, β-naphthalenesulfonyl chloride was used to convert II to a mono-*O*-nasylated product (IV). However, the yield of arylsulfonylation was only slightly improved.

The replacement of the tosyloxy group of III or the nasyloxy group of IV by an iodine atom was readily brought about by heating the ester (III or IV) with sodium iodide in an acetone-dioxane solution, thus affording the deoxyiodo derivative (V) of tetra-*N*-carbobenzoxykanamycin (II) in a 94% yield (from III). On the basis of the extensive studies by Oldham and Rutherford[6] and other workers[7], it can be said that the facility of the replacement reaction indicates that the tosyl group in III was joined to the primary hydroxyl group. The corresponding chlorodeoxy and bromodeoxy derivatives (VII and VI) were also obtained from IV by the use of lithium chloride and bromide in similar reactions. The well-known order of nucleophilic reactivity, $I^- > Br^- > Cl^-$, has been again observed in the fact that sodium iodide reacted faster than lithium bromide, which in turn reacted faster than lithium chloride, to precipitate the corresponding alkaline salt of β-naphthalenesulfonic acid. The

7) W. T. Haskins, R. M. Mann and C. S. Hudson, ibid., **64**, 132 (1942); G. R. Barker and R. W. Goodrich, *J. Chem. Soc.*, **1949**, *Supplm.*, 233; H. Schmid and P. Karrer, *Helv. Chim. Acta*, **32**, 1371 (1949).

crude product of VII, which could not be readily obtained in a pure form, was used for the next step without further purification.

The deoxyiodo derivative (V) was converted, by hydrogenolysis with a Raney nickel catalyst, to the corresponding deoxy derivative (VIII) of tetra-*N*-carbobenzoxykanamycin, and thence, by repeated hydrogenolysis with palladium black in a dioxane - water - acetic acid solution, to deoxykanamycin. Attempts to effect direct hydrogenolysis by the palladium catalyst to deoxykanamycin without the prior use of a Raney nickel catalyst were unsuccessful.

The hydrogenolysis of the bromodeoxy derivative (VI) with palladium black by a similar procedure also gave the deoxykanamycin.

A similar hydrogenolysis of the chlorodeoxy derivative (VII) with a palladium catalyst, followed by column chromatography on Dowex 1 X2 resin, led to chlorodeoxy-kanamycin (X).

The hydrogenolysis of the nasyl derivative (IV) by the palladium catalyst in aqueous dioxane containing a small amount of acetic acid proceeded smoothly, and the formation of the expected kanamycin, accompanied by deoxykanamycin, was confirmed by paper chromatography.

Paper chromatography of the deoxykanamycin (IX) and chlorodeoxy-kanamycin (X) by ninhydrin coloration, using a *t*-amylalcohol - pyridine - water - acetic acid (6 : 4 : 3 : 1) solvent system and Toyo filter paper No. 50, showed $R_f$ 1.3 and 2.2 respectively, the $R_f$-value of kanamycin being taken as 1.0.

Structural evidence for chlorodeoxy-kanamycin (X) and deoxykanamycin (IX) was further obtained from the results of the controlled hydrolysis of X. (3-Amino-6-chloro-3, 6-dideoxy-D-glucosyl)-deoxystreptamine (XI) has been isolated from the hydrolyzate of X by a paper chromatographic technique.

We[2c] have previously reported that the $R_{fD}$-value*1 of a di-glucoside of deoxystreptamine is approximately given by the product of the two $R_{fD}$-values of the constituent mono-glucosides. The application of the $R_{fD}$-values of XI ($R_{fD}$ 1.33) and 4-*O*-(6-amino-6-deoxyglucosyl)-deoxystreptamine ($R_{fD}$ 0.39) to the multiplication rule showed a good accordance with the experimental value of $R_{fD}$ (0.52) of X: $1.33 \times 0.39 = 0.52$.*2

Deoxykanamycin (IX) was hydrolyzed by refluxing it in 3 N hydrochloric acid, and the hydrolyzate was submitted to paper chromatography. Detection by ninhydrin-coloration showed a spot of $R_f$ (1.67) relative to the $R_f$-value of 3-amino-3-deoxy-D-glucose taken as 1.0, in addition to the spots corresponding to deoxystreptamine and 6-amino-6-deoxy-D-glucose. Evidently, the new spot indicated the presence of 3-amino-3, 6-dideoxy-D-glucose in the deoxykanamycin. The paper chromatography of the hydrolyzate obtained by mild hydrolysis of chlorodeoxy-kanamycin showed the spot of (3-amino-6-chloro-3, 6-dideoxy-D-glucosyl)-deoxystreptamine (XI), in addition to the spots of deoxystreptamine, 6-amino-6-deoxy-D-glucose, 4-*O*-(6-amino-6-deoxy-D-glucosyl)-deoxystreptamine[4] and unchanged chlorodeoxy-kanamycin.

Both deoxykanamycin and chlorodeoxy-kanamycin showed strongly antibacterial activity, and their antibiotic spectra*3 were essentially similar to that of kanamycin as shown in Table I. XI had no antibacterial activity against organisms tested.

## Experimental

**Paper Chromatography and Bioautography.**— Paper chromatography was performed by the descending technique, using Toyo filter paper No. 50. The solvent system used was *t*-amylalcohol - pyridine - water - acetic acid (6 : 4 : 3 : 1). Aminosugars and their glucosides were detected by ninhydrin-coloration, using a general procedure. Spots corresponding to the antibacterial components were also detected on the bioautograms by a general procedure[8] using *Bacillus subtilis* as the test organism.

**Tetra-*N*-carbobenzoxykanamycin (II).**— A mixture of a kanamycin base (1.5 g. 3.1 mmol.) and sodium carbonate decahydrate (4.1 g.) in 75% aqueous acetone (60 ml.) was cooled to about −5°C, and into the mixture was then vigorously stirred a solution of carbobenzoxy chloride (2.15 g. 12.6 mmol.) in toluene (7 ml.) in portions over a 5 min. period. After the addition was complete, stirring was continued at about 5°C for 3 hr. The reaction mixture became almost clear once, and then the resulting product began to separate. The reaction mixture was placed in a refrigerator overnight. The mixture was poured into a large volume of a mixture of water and ether, and then vigorously agitated. The flocculent product which had been precipitated between two layers was collected and pressed between filter papers to remove the solvents.

The product was added to a solution of ethanol and concentrated hydrochloric acid (10 : 1), and the mixture was stirred at room temperature for 1.5 hr.

*1 $R_{fD}$ is an $R_f$-value relative to the $R_f$-value of deoxystreptamine, taken as 1.0.

*2 In this experiment, by the general procedure described in the beginning of the "Experimental" section and analogous to that described in the report of Ref. 2c) The $R_{fD}$-values of (3-amino-3-deoxy-D-glucosyl)-deoxystreptamine and kanamycin were 0.60 and 0.23 respectively. The experimental value for kanamycin also showed a good accordance with the calculated value: $0.60 \times 0.39 = 0.23$.

*3 The antibiotic spectrum of deoxykanamycin was previously presented in a short communication by T. Tsuchiya, S. Iriyama and S. Umezawa; see Ref. 1.

8) The method first used for the analysis of penicillins: R. R. Goodall and A. A. Levi, *Nature*, **158**, 675 (1946); *Analyst*, **72**, 277 (1947).

The product was filtered and washed with water; yield 3.09 g. (96%), m. p. 259—261°C (decomp.). A sample (1.0 g.) was recrystallized from dioxane-water to give an analytically pure sample (0.76 g.) of the title compound (II); m. p. 259—261°C, $[\alpha]_D^{18}$ +68.2° (*c* 2.038, in dimethyl formamide).

Found: C, 58.89; H, 6.18; N, 5.41. Calcd. for $C_{50}H_{60}O_{19}N_4$: C, 58.81; H, 5.92; N, 5.49%.

It was confirmed by van Slyke determination that the pure sample did not contain the free $NH_2$ group.

**The Hydrogenolysis of II to Kanamycin.** — A sample (400 mg.) of II was dissolved in 15 ml. of aqueous dioxane (1 : 1) containing a drop of acetic acid and hydrogenated over palladium black (100 mg.) under atmospheric pressure at 45°C for 13 hr. The reaction mixture was filtered, and the filtrate was evaporated to dryness. An aqueous solution of the residue (270 mg.) was passed through a column of Amberlite IRA-400 resin (OH form) (4 ml.). Ninhydrin-positive, strongly-alkaline fractions were collected and concentrated to a small volume by evaporation. The addition of ethanol to the concentrate caused crystallization; yield 120 mg. The product was proved to be identical with intact kanamycin by elementary analysis and biological assay.

Found: C, 44.63; H, 7.26; N, 11.46; 11.2 (van Slyke). Calcd. for $C_{18}H_{36}O_{11}N_4$: C, 44.62; H, 7.49; N, 11.56%.

**Tetra-*N*-carbobenzoxy-mono-*O*-tosylkanamycin (III).**—A sample (10.2 g. 10 mmol.) of II was dissolved in dry pyridine (60 ml.) and cooled to −18°C, and then to it was added *p*-toluenesulfonyl chloride (2.10 g.) in one portion. The mixture was vigorously shaken and then allowed to stand at about the same temperature for 4 hr., at 0°C for 20 hr., and additionally at room temperature for 24 hr. After a small volume of water had been added and after it had stood for 1 hr., the reaction mixture was poured into a large volume of ice water. The precipitate was collected by centrifuge and washed with water; yield 10.5 g. The crude product was extracted with three 30-ml. portions of hot ethyl acetate in order to remove the higher tosylated product (1.05 g.; S, 5.28%). The insoluble residue was pressed between filter papers and dried in a desiccator; yield 7.8 g. The product was powdered and extracted with three 300-ml. portions of hot dry acetone to separate the unchanged II, which is almost insoluble in acetone. The resulting acetone extract was filtered and concentrated to a volume of about 65 ml. After the concentrate had been allowed to stand at room temperature for a while, the resulting solid was filtered; yield 1.9 g., S, 1.83%.

A sample (450 mg.) of the product was dissolved in a solvent of *n*-butanol - acetic acid - water (3 : 2 : 1) and was chromatographed through a silica gel column (17×310 mm.) using the same solvent system. After 30 ml. of the eluate had been collected, the desired product emerged in the next 13 ml. This fraction, after evaporation to dryness, weighed 370 mg. (13.3%). Additional material (770 mg.) was obtained by the concentration of the above acetone mother-liquor to 20 ml.; the total yield was 20%; m. p. 200—202°C (decomp.), $[\alpha]_D^{14}$ +67° (*c* 1.96, in dimethyl formamide).

Found: C, 58.29; H, 5.88; S, 2.41. Calcd. for $C_{57}H_{66}O_{21}N_4S$: C, 58.25; H, 5.66; S, 2.73%.

**Tetra-*N*-carbobenzoxy-mono-*O*-nasylkanamycin (IV).**—A sample (7.0 g.) of II was dissolved in dry pyridine (40 ml.) and cooled to about −18°C, and to it was added β-naphthalenesulfonyl chloride (1.95 g.). The reaction mixture was then submitted to a procedure similar to that described above for III, giving crude IV (8.4 g.). The crude product (720 mg.) was extracted with acetone (35 ml.) by refluxing it for a while, and, after it had cooled to room temperature, the acetone extract was filtered and evaporated to dryness (510 mg.). This was again extracted with ethyl methyl ketone (75 ml.) by refluxing it for a while; the extract was filtered and evaporated to dryness to give a residue (390 mg.) with a sulfur content of 3.03%. The product was further treated with hot ethyl acetate (20 ml.), and the insoluble residue was collected and dried in a desiccator; yield 230 mg. (32%); m. p. 186—187°C (decomp.).

Found: S, 2.69%. Calcd. for $C_{60}H_{66}O_{21}N_4S$: S, 2.53%.

**Tetra-*N*-carbobenzoxy-deoxyiodo-kanamycin (V).**—A solution of III (1.0 g.) and sodium iodide (0.38 g.) in anhydrous dioxane - acetone (1 : 1) was heated in a sealed tube in a boiling water bath for about 50 min. After the mixture had been heated for 5 min., sodium *p*-toluenesulfonate began to precipitate. After cooling, the reaction mixture was filtered and evaporated to dryness; the residue was washed with water and dried in a desiccator. A mixture of the product and anhydrous acetone was refluxed for a while and then allowed to stand overnight. The precipitate was collected by filtration to give the title compound; yield 900 mg. (94%); m. p. 220—223°C (decomp.).

Found: C, 53.32; H, 5.14; I, 11.30. Calcd. for $C_{50}H_{59}O_{18}N_4I$: C, 53.20; H, 5.26; I, 11.20%.

The infrared spectrum of the product showed the absence of the absorption at 1170 $cm^{-1}$ ($\nu_s$ $SO_2$) which was found in the spectrum of III.

This compound was also prepared from IV and sodium iodide by a procedure similar to that described above. In this reaction, the precipitation of sodium β-naphthalenesulfonate began after the reaction mixture had been heated for 10 min.

**Deoxykanamycin (IX).**—A sample of V (200 mg.) in 80% aqueous dioxane (6.0 ml.) was refluxed, hydrogen being passed through in the presence of Raney nickel (W-4) (0.2 ml.) for 10 min. After cooling, the mixture was filtered, and the filtrate was repeatedly treated with fresh Raney nickel and hydrogen. The concentration of the filtrate, followed by the addition of water, afforded a crude product of tetra-*N*-carbobenzoxy-deoxykanamycin (VIII); yield 150 mg.

The product was dissolved in a mixed solvent dioxane - water - acetic acid (4 : 1 : 0.04) (10 ml.) and hydrogenated with palladium black (40 mg.) under hydrogen-pressure of 3.0 atm. at 35°C for 1 hr. A small quantity of water was added to the mixture, and again the hydrogenation was continued for about 2 hr. The repetition of this procedure,

followed by filtration and evaporation, gave a crude product, which was washed with hot acetone. The resulting solid was dissolved in 95% ethanol, treated with a small quantity of active charcoal, and evaporated to give deoxykanamycin tetraacetate; yield 82 mg., $[\alpha]_D^{15}$ +99.6° (*c* 0.88, in water).

Found: C, 44.24; H, 7.13; N, 8.08. Calcd. for $C_{18}H_{36}O_{10}N_4 \cdot 4CH_3CO_2H$: C, 44.06; H, 7.39; N, 7.91%.

By the general procedure of paper chromatography, the product showed an $R_f$-value of 1.3 relative to an $R_f$-value of kanamycin of 1.0.

The acetate (70 mg.) was dissolved in a small quantity of water, placed on the top of a column of Amberlite IRA-400 resin (OH form) (1 ml.), and developed with water. Ninhydrin-positive fractions were collected, filtered, and evaporated to dryness. The residue was dissolved in a small quantity of hot 90% ethanol and filtered; concentration, followed by the addition of ethanol to turbidity, afforded the free base of deoxykanamycin; yield 25 mg.

Found: C, 46.36; H, 7.51; N, 11.81. Calcd. for $C_{18}H_{36}O_{10}N_4$: C, 46.15; H, 7.75; N, 11.96%.

A small quantity of IX was heated with 3 N hydrochloric acid for 2 hr. in a boiling water bath, and the hydrolyzate was submitted to paper chromatography by the general procedure. Detection by ninhydrin coloration showed the spot of 3-amino-3,6-dideoxy-D-glucose ($R_f$ 1.67, relative to an $R_f$-value of 3-amino-3-deoxy-D-glucose of 1.0), in addition to the spots corresponding to deoxystreptamine and 6-amino-6-deoxy-D-glucose.

**Chlorodeoxy-kanamycin (X).** — A mixture of a crude sample (400 mg.) of IV and dry lithium chloride in 14 ml. of anhydrous dioxane-acetone (1 : 1) was heated in a sealed tube for 5 hr. in a boiling water bath. No precipitation of lithium β-naphthalenesulfonate occurred until the heating of the mixture had been continued for 2 hr. After cooling, the resulting mixture was filtered and worked up by a procedure similar to that described above for V; the yield of the crude product of VII was 360 mg. (Cl, 2.83%).

A crude sample (1.74 g.) of VII was dissolved in a mixture of dioxane (40 ml.), water (25 ml.) and acetic acid (0.4 ml.) and hydrogenated with palladium black (250 mg.) under a hydrogen-pressure of 3.0 atm. at 35°C for 15 hr. When water (20 ml.) was added, the reaction mixture became turbid; this indicated that the hydrogenation was not completed. Hydrogenation was therefore continued for a further 3 hr. Water (15 ml.) was added to the reaction mixture, and the hydrogenation was again continued for about 10 hr., after which the reaction mixture was filtered and the filtrate was concentrated to about 50 ml. Since the paper chromatography of the concentrate still showed three, strongly ninhydrin-positive spots ($R_f$ 4.3, 8.7 and 14, relative to an $R_f$-value of X of 1.0) other than X, the concentrate was again treated with a fresh palladium catalyst (250 mg.) and hydrogen for 20 hr. and filtered. The filtrate was concentrated to about 10 ml., placed on a column (27×280 mm.) of Dowex 1 X2 (OH form), and developed with water at the rate of 0.5 ml./min.; the eluates were submitted to paper chromatography and bioautography. After 350 ml. of eluate had been collected, kanamycin emerged in the next 130 ml., and then chlorodeoxykanamycin emerged from 590 ml. to 710 ml. The former fractions (fraction A) were collected, neutralized with hydrochloric acid to pH 3.0, and concentrated, and acetone was added to give kanamycin tetrahydrochloride; yield 90 mg. By a similar procedure, the latter fractions (fraction B) gave a syrup, which was dissolved in a small quantity of methanol and treated with active charcoal, and acetone was added to afford chlorodeoxy-kanamycin tetrahydrochloride; yield 170 mg., $[\alpha]_D^{15}$ +95° (*c* 0.8, in water).

Found: C, 32.31; H, 6.19; N, 8.60; Cl, 26.20. Calcd. for $C_{18}H_{35}O_{10}N_4Cl \cdot 4HCl \cdot H_2O$: C, 32.42; H, 6.20; N, 8.40; Cl, 26.59%.

In another experiment, fraction B was neutralized

with acetic acid to pH 4 and worked up by a procedure similar to that used for the above hydrochloride to give chlorodeoxy-kanamycin tetraacetate; $[\alpha]_D^{15}$ +90° (*c* 0.9, in water).

Found: C, 39.42; H, 7.66; Cl, 4.54. Calcd. for $C_{18}H_{35}O_{10}N_4Cl \cdot 4CH_3CO_2H \cdot 2H_2O$: C, 40.08; H, 7.11; Cl, 4.55%.

A small quantity of X was heated with 3 N hydrochloric acid in a boiling water bath for 20 min., and the hydrolyzate was submitted to paper chromatography by the general procedure. Detection by ninhydrin coloration showed the spot ($R_{fD}$ 1.33) of XI, in addition to the spots of deoxystreptamine ($R_{fD}$ 1.00), 6-amino-6-deoxy-D-glucose ($R_{fD}$ 1.72), 4-*O*-(6-amino-6-deoxy-D-glucosyl)-deoxystreptamine ($R_{fD}$ 0.39) and unchanged chlorodeoxy-kanamycin ($R_{fD}$ 0.52).

**6-*O*-(3-Amino-6-chloro-3, 6-dideoxy-α-D-glucopyranosyl)-deoxystreptamine Hydrochloride (XI).*** — A sample (108 mg.) of chlorodeoxy-kanamycin tetrahydrochloride was dissolved in 3 N hydrochloric acid and heated for 20 min. in a boiling water bath. The reaction was quenched by cooling the mixture with tap water, and then the resulting solution was evaporated to dryness under reduced pressure and the residue dried in a desiccator to give a solid (109 mg.). This was dissolved in a small quantity of water, paper chromatographed on 3 sheets of Toyo filter paper No. 50 (40×40 cm.), and developed with the *t*-amylalcohol - pyridine - water - acetic acid (6 : 4 : 3 : 1) solvent system by the descending method for 40 hr. A zone corresponding to the compound of $R_{fD}$ 1.33 was clipped from each paper and extracted with water, and the aqueous extract was evaporated to dryness. The residue (28 mg.) dissolved in a small quantity of water was placed on a column (4×110 mm.) of Dowex 1 X2 resin (OH form) and developed with water. After a small amount of deoxystreptamine has been eluted, the desired compound emerged from 1.7 to 3.5 ml. of the eluate. The fraction, which was strongly alkaline and positive in the Beilstein test for halogen, was neutralized with hydrochloric acid to pH 3.0 and evaporated to dryness. The residue was dissolved in a small quantity of methanol, and acetone was added to precipitate the title compound; yield 11 mg.; $[\alpha]_D^{20}$ +73° (*c* 0.7, in water).

Found: C, 32.33; H, 6.25. Calcd. for $C_{12}H_{24}O_6N_3Cl \cdot 3HCl$: C, 31.94; H, 6.03%.

The product showed no reducing property.

**Tetra-*N*-carbobenzoxy-bromodeoxy-kanamycin (VI) and Hydrogenolysis.**—A mixture of a sample (30 mg.) of IV and dried lithium bromide (10 mg.) in 0.5 ml. of anhydrous dioxane - acetone (1 : 1) was heated in a sealed tube for 2 hr. in a boiling water bath. When the mixture was heated for 30 min., lithium β-naphthalenesulfonate was precipitated. The resulting mixture was worked up by a procedure similar to that described above for V to give 26 mg. of VI.

Found: Br, 7.7. Calcd. for $C_{50}H_{59}O_{18}N_4Br$: Br, 7.4%.

A small quantity of the above sample was hydrogenated with palladium black by a procedure similar to that used for the hydrogenolysis of VII to afford deoxykanamycin, which was detected by both paper chromatography and bioautography.

* According to Rinehart and Hichens, 3-amino-3-deoxy-D-glucose is linked to the C-6 of deoxystreptamine; see K. L. Rinehart and M. Hichens, *J. Am. Chem. Soc.*, **85**, 1547 (1963).

## Summary

1) Deoxykanamycin has been synthesized in a four-stage sequence beginning with kanamycin. Kanamycin has been converted to tetra-*N*-carbobenzoxykanamycin, and this transformed in turn to tetra-*N*-carbobenzoxy-mono-*O*-tosylkanamycin (or the corresponding nasyl derivative), to tetra-*N*-carbobenzoxy-deoxyiodokanamycin, and finally to deoxykanamycin.

2) The above nasyl derivative has been transformed via tetra-*N*-carbobenzoxy-chlorodeoxy-kanamycin to chlorodeoxy-kanamycin.

3) 6-*O*-(3-Amino-6-chloro-3, 6-dideoxy-α-D-glucosyl)-deoxystreptamine hydrochloride has been obtained by the controlled acid-hydrolysis of chlorodeoxy-kanamycin.

4) The hydrogenolysis of tetra-*N*-carbobenzoxy-bromodeoxy-kanamycin has given deoxykanamycin.

5) It has been found that deoxykanamycin and chlorodeoxy-kanamycin are strongly antibacterial and that their antibiotic spectra are essentially similar to that of kanamycin.

Part of the expenses for this work were defrayed by a grant-in-aid for Scientific Research from the Ministry of Education, a grant which is gratefully acknowledged. The authors are indebted to Mr. Saburo Nakada for his micro-analyses and to Mrs. Setsuko Iriyama of this Laboratory and to the Central Laboratories of the Meiji Seika Co. for their bioassays. The authors are also grateful to Mr. Kuniaki Tatsuta and Mr. Tadashi Takeshiro for their assistance in the experimental work.

# The Phosphorescence Spectra of 2, 2'- and 4, 4'-Bipyridyls

By Yasuhiko GONDO and Yoshiya KANDA

(Received December 11, 1964)

The blue-green phosphorescence spectra of 2, 2'-bipyridyl, and the blue phosphorescence spectra of 4, 4'-bipyridyl, in ethanol, carbon tetrachloride, and cyclohexane at 90°K, have been studied and the results are reported here. The phosphorescence spectra of 2, 2'- and 4, 4'-bipyridyls had not been observed previously. Kanda, Shimada, and Sakai[1] studied in detail the green-blue phosphorescence of biphenyl in EPA, petroleum ether, cyclohexane, and carbon tetrachloride at 90°K. Since the molecular structures of 2, 2'- and 4, 4'-bipyridyls are closely related to that of biphenyl, it was assumed that the phosphorescence spectra of the bipyridyls must be very similar to the spectrum of biphenyl. The vibrational analyses are discussed.

## Experimental

2, 2'-Bipyridyl, from Tokyo Kasei Co., was recrystallized twice from ethanol. The melting point was 69.5°C. 4, 4'-Bipyridyl-dihydrochloride was obtained from K & K Laboratories.[2] Three grams of 4, 4'-bipyridyl-dihydrochloride was treated with 1.2 g. of caustic soda in water, and the 4, 4'-bipyridyl which precipitated was recrystallized twice from hot water; the product was 4, 4'-bipyridyl-dihydrate which was dried in air for 2 days and then in a desiccator over sulfuric acid for 20 days until a theoretical loss in weight corresponding to two molecules of water resulted. The melting point was 110.2—110.5°C. Solvent used in this study were ethanol, cyclohexane, and carbon tetrachloride which were purified as described previously.[1,3] The optical setup was the same as described previously.[3]

## Results and Discussion

The triplet-singlet emission spectra of 2, 2'- and 4, 4'-bipyridyls in ethanol, carbon tetrachloride, and cyclohexane at 90°K have been observed, and the microphotometer tracing curves are shown in Figs. 1 and 2. Spectral data and the analyses are given in Tables I and III. The spectrum of 2, 2'-bipyridyl will be discussed first. This compound emitted blue-green phosphorescence with a lifetime of about 2 to 3 sec. by visual estimation. Exposure time ranged from 1 to 7 hr. with slit width of 100 $\mu$ and Kodak Tri-X film. The phosphorescence bands were broad in ethanol, somewhat resolved in carbon tetrachloride and very sharp and well resolved in cyclohexane. Therefore, the vibrational analyses ware made first with the spectrum in cyclohexane. The highest wave number band at 23545 $cm^{-1}$ was taken as the 0, 0-band of the system and vibrational frequencies of 235, 325, 460, 605, 755, 815, 895, 995, 1155, 1235, 1310, 1460, and 1570 $cm^{-1}$ were found; and the 1570 $cm^{-1}$ frequency was seen to form the main progression of the system. These frequencies seem to correspond to the Raman frequencies of 615, 995, 1150, 1239, 1302, 1475, and 1574 $cm^{-1}$. The Raman data were obtained by us but unfortunately the frequencies corresponding to the phosphorescence bands of 235, 325, 755, 815, and 895 $cm^{-1}$ have not yet been found. The phosphorescence band of 460 $cm^{-1}$ may be explained as $2\times235$ $cm^{-1}$. For comparison, the infrared spectrum was also studied. The vibrational frequencies are listed in Table II.

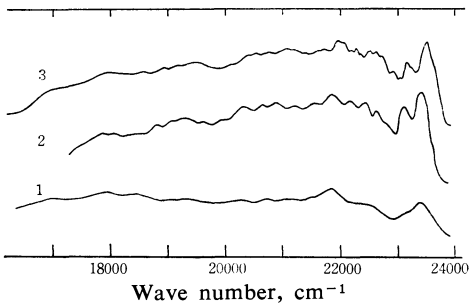

Fig. 1. Phosphorescence spectra of 2, 2'-bipyridyl at 90°K.
Concn.: $1\times10^{-2}$ M, in ethanol (1), carbon tetrachloride (2) and cyclohexane (3)

4, 4'-Bipyridyl emitted blue phosphorescence and the lifetime was about 2 sec. by visual estimation. Exposure time ranged from 5 to 10 hr. with slit width of 100 $\mu$ and Kodak Tri-X film. The phosphorescence bands were broad in ethanol, somewhat resolved in carbon tetrachloride and very sharp and well resolved in cyclohexane as shown in Fig. 2. This behavior is very similar to that of 2, 2'-bipyridyl.

The vibrational analysis was made with the spectrum in cyclohexane. Each strong band was accompanied by a weak satellite band with a separation of 145 $cm^{-1}$. The highest wave number band at 24530 $cm^{-1}$ was taken as the 0, 0-band of the system and the vibrational frequencies of 290, 475, 575, 755, 1005, 1270, and 1610 $cm^{-1}$ were found. The frequency of 1610 $cm^{-1}$ was seen to form the main progression of the system. These frequencies seem to correspond to the Raman frequencies of 575, 755, 1002, 1295, and 1595 $cm^{-1}$. The Raman data were obtained by us but unfortunately the frequencies corresponding to the phosphorescence bands of 145, 290, and 475 $cm^{-1}$ have not yet been found. For comparison, the infrared spectrum was also studied. The vibrational frequencies are listed in Table IV. Because of symmetry relations the infrared data may sometimes be useless. However, we can not neglect them, if the presence of any anomalous vibrational band structures in the spectrum is to be checked. Incidentally, anomalous band structures had been found in the phosphorescence spectra of aromatic compounds, such as benzoic acid and aniline.[4] It seems that both the spectra of 2, 2'- and 4, 4'-bipyridyls show no anomalous vibrational structure. The overall spectral features of the bipyridyls are very similar to those of biphenyl.[1]

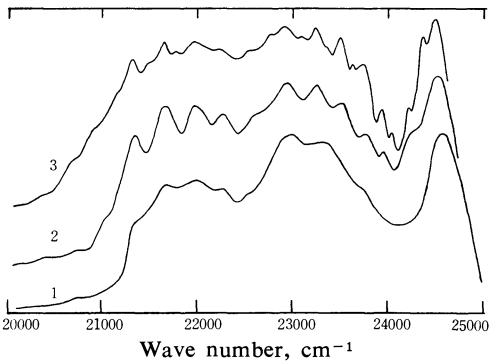

Fig. 2. Phosphorescence spectra of 4, 4'-bipyridyl at 90°K.

through addition of trichloroacetic acid. The spectrum showed a remarkable red shift as can be seen in Fig. 3. This shows that the broad band with maximum at 284 m$\mu$ belongs to a $\pi$-$\pi^*$ type transition.[5] The compound can be assumed to consist of two pyridine rings. The lowest excited level of pyridine is of an $n$-$\pi^*$ type and its second one is of a $\pi$-$\pi^*$ type. Now, because of the interaction of $\pi$-electron systems the lowest excited state of 2, 2'-bipyridyl is not of an $n$-$\pi^*$ type but a $\pi$-$\pi^*$ type. The spectral features of 2, 2'-bipyridyl do not resemble those of biphenyl. This has been clearly explained in a theoretical work by

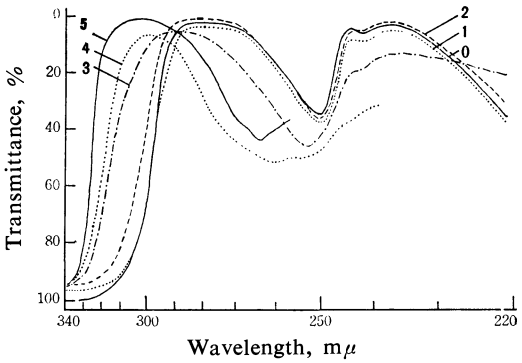

Fig. 3. Ultraviolet absorption spectra of 2, 2'-bipyridyl with trichloroacetic acid in cyclohexane.
2, 2'-Bipyridyl: $1\times10^{-4}$ M,
$CCl_3COOH$: 0; without acid, 1; $1\times10^{-5}$ M, 2; $1\times10^{-4}$ M, 3; $1\times10^{-3}$ M, 4; $1\times10^{-2}$ M, 5; $1\times10^{-1}$ M

Gondo.[6] If the 2, 2'-bipyridyl molecule is assumed to be trans-coplanar,[7,8] the lowest excited singlet state is a $^1B_u$, and the lowest triplet state is a $^3B_u$ state. Thus, a $\pi$-$\pi^*$ type excited triplet state is believed to be responsible for the phosphorescence of 2, 2'-bipyridyl, and may also be the case with 4, 4'-bipyridyl. The similarity found between the phosphorescence spectra of biphenyl,[1] 2, 2'- and 4, 4'-bipyridyl seems to support this interpretation. The rather long lifetimes of 2, 2'- and 4, 4'-bipyridyls are also compatible with the above interpretation.[5]

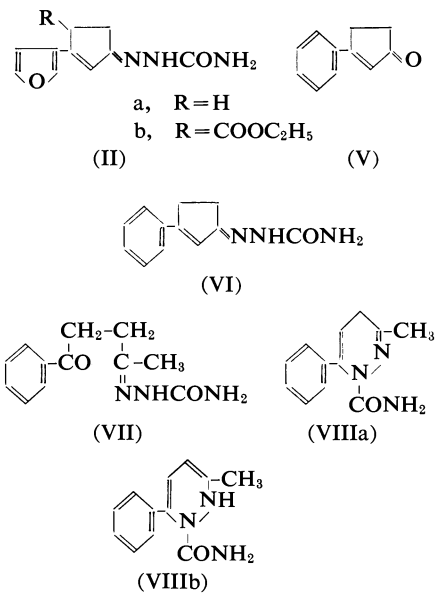
# Chemical Studies on the Black Rot Disease of Sweet Potatoes. XVII.*1,*2 Abnormal Semicarbazone of Ipomeanine and of Related Compounds

By Takashi KUBOTA, Teruo MATSUURA and Yasuzo KAKUNO



(Received December 11, 1965)

An abnormal semicarbazone, $C_{10}H_{11}O_2N_3$, was formed by the elimination of two molecules of water, when ipomeanine (I), one of the constituents of black-rotted sweet potatoes, was treated with semicarbazide by the usual procedure.[1] Kubota and Ichikawa[1] suggested, on the basis of an analogous finding by Borsche and his collaborators,[2] the formula IIa for the semicarbazone and the formula IIb for the abnormal semicarbazone of the ester III, an intermediate in the course of the synthesis of ipomeanine (I). The latter investigators gave the structure VI, the semicarbazone of 3-phenylcyclopentenone (V), for the abnormal semicarbazone of phenacylacetone (IV).

Recently, several questions have arisen about the structure II. First, the abnormal semicarbazone of ipomeanine is not regenerated to I by mild acid treatment but rather resinifies,[1] while the semicarbazone VI is easily regenerated to V under the same conditions. Secondly, the infrared spectrum of the abnormal semicarbazones is quite different from that of normal ones.[3] Thirdly, the ultraviolet maximum (265 m$\mu$) of the semicarbazone of ipomeanine is not consistent with the structure II, since the maximum of the structure II should be more bathochromically shifted than that (263—264 m$\mu$) of the semicarbazone of $\beta$-furylketone.[4] A reinvestigation of the structure of these semicarbazones has led us to the conclusion that the abnormal semicarbazones of ipomeanine and of the ester III possess the structures XIV and XV, respectively.

Finzi isolated a monosemicarbazone, m. p. 191°C, in the reaction of phenacylacetone (IV) and semicarbazide.[5],*3 The monosemicarbazone was easily obtained under mild conditions. It showed an infrared band of a benzoyl carbonyl at 1690 $cm^{-1}$ and a broad ultraviolet maximum at 231.5 m$\mu$, which is assigned as an overlapping absorption of a benzoyl group and of a semicarbazone of an aliphatic ketone.[6] The structure of the monosemicarbazone must be represented as VII.

When the semicarbazone VII was allowed to stand at pH 4.7 for ten days, two kinds of crystalline products were obtained, A, $C_{12}H_{13}ON_3$, m. p. 218—219°C as the main product and B,*4 m. p. 208—210°C, as the minor product. The product A was also obtained in a good yield by the treatment of an aqueous alcoholic solution of phenacylacetone (IV) with semicarbazide at room temperature for a long period of time, as has been described by Borsche et al.,[2] or at the refluxing temperature. They described the formation of the semicarbazone VI from phenacylacetone under

*4 The product B could not be isolated in several other runs.

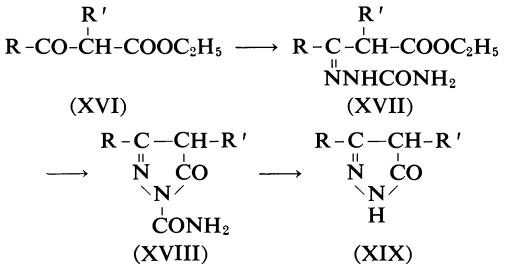
such conditions. However VI could not be detected in our experiments. The infrared spectrum of the compound A showed no bands assigned to normal semicarbazones,[3] and elemental analyses showed that the compound A is formed by the intramolecular dehydration of the monosemicarbazone (VII) of phenacylacetone. It follows that the dihydropyridazine structure, VIIIa or VIIIb, or the pyrrylurea structure, IX, should be suggested to the compound A.

Several examples of the formation of abnormal semicarbazones, such as XI,[7] XII,[8] and XIII,[9],*5 from 1, 4-dicarbonyl compounds have been reported, as is shown in Table I. However there is no clear evidence for the pyrrylurea structure of these substances, and it still remains questionable whether the pyrrylurea structure or an alternative dihydropyridazine structure is to be chosen. On the other hand, acetonylacetone gives a normal bis-semicarbazone.[10] The treatment of the bis-semicarbazone with formic acid yields *N*-(2, 5-dimethylpyrryl)-urea (X), whose structure was established by conversion to urea and 2, 5-dimethylpyrrolidine.[10] The infrared spectrum of *N*-(dimethylpyrryl)urea (X) showed characteristic bands, at 3480, 3320, 3200, 1675, 1585 and 1525 $cm^{-1}$, which differ from the bands[3] of the usual semicarbazones in shape and position. The infrared spectrum (Table I) of the abnormal semicarbazones XI, XII, XIII, XIV (from ipomeanine (I)), and XV (from the ester III) also showed bands at 3450±30, 3300±20, 3225 ±25 (νNH), 1670±10, 1595±10, and 1535±15 $cm^{-1}$ (νC=O and νC=C). These bands are characteristic of the pyrrylurea X. The pyrrylurea structures, XI, XII, XIII, XIV, and XV, may, therefore, be given to these abnormal semicarbazones.

TABLE I. STRUCTURES AND INFRARED BANDS OF ABNORMAL SEMICARBAZONES

| 1,4-Dicarbonyl compounds | Abnormal semicarbazone | Infrared bands: νNH | Amide I | νC=C or Amide II |
|---|---|---|---|---|
|  IV |  VIII | | | |
| IV |  IX | | | |
|  X |  | | | |
|  XXII |  XI | | | |
|  XXI |  XII[a] | | | |
|  |  XIII[b] | | | |
|  I |  XIV | | | |
|  III |  XV | | | |

a) Bands at 3300 $cm^{-1}$ and 3200 $cm^{-1}$ are overlapped.
b) Cf. Ref. 9.



Of the two abnormal semicarbazones, A and B, obtained from phenacylacetone (IV), the infrared spectrum (Table I) of the minor product (B) showed bands assigned to the pyrrylurea structure, as has been discussed above. Therefore, the product B can be formulated as IX. Since the infrared spectrum of the major product A differs considerably from the spectrum of the pyrrylurea type of compounds, it seems that the product A may possess a dihydropyridazine structure, VIIIa or VIIIb. In spite of the similarity in structure of 1, 4-dicarbonyl compounds, phenacylacetone (IV) cyclizes to give mainly the dihydropyridazine derivative under usual conditions, but ipomeanine (I) to the pyrrol derivative.

Furthermore, in the case of ethyl acetonylacetoacetate (XXI), the initial product is a normal bis-semicarbazone, which easily cyclizes to the pyrrol derivatives XII upon recrystallization from hot water. In conclusion, it is difficult to predict at present how the structural factor of the parent 1, 4-dicarbonyl compounds will be affected in the formation of a normal semicarbazone or an abnormal semicarbazone, such as VIII and IX.

It is known that, in the reaction of a β-ketoester (XVI) with semicarbazide, a normal semicarbazone (XVII) is initially formed and that it in turn is converted to a 3-pyrazolone, XVIII or XIX, depending on the conditions

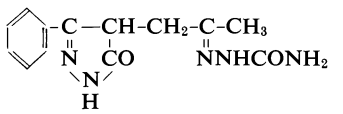
employed.[11-15] In previous reports[16,17] of this series, it was reported that the intermediate compounds XX of the syntheses of ipomeamarone and of its phenyl analog yielded abnormal semicarbazones whose structures were unknown. We can now formulate these compounds as XIX (R=β-furyl, R'=H and R=phenyl, R'=H) from the results of the elemental analyses and from the results of a comparison of the infrared spectrum with that of 5-phenyl-3-pyrazolone obtained from ethyl benzoylacetate.



(XVI) (XVII) (XVIII) (XIX)

Ethyl acetonylacetoacetate (XXI), ethyl acetonylbenzoylacetate (XXII), and the ester III, all of which have a β-ketoester group in addition to a 1,4-dicarbonyl function in the molecule, can form pyrazolone derivatives, such as XVIII and XIX, by the action of semicarbazide. In fact, ethyl acetonylbenzoylacetate (XXII) yields a pyrazolone derivative, XXIII, in addition to the abnormal semicarbazone, XI, at an elevated temperature.

## Experimental[*6]

**The Regeneration of the Semicarbazone (VI) of 3-Phenylcyclopent-2-en-1-one (V).** — The semicarbazone VI was prepared according to the procedure of Borsche et al.[2] m. p. 232°C. A mixture of 96 mg. of the semicarbazone and 30 ml. of 5% aqueous sulfuric acid was heated at 100°C for 1.5 hr. with occasional shaking until the mixture became clear. On cooling, 3-phenylcyclopent-2-en-1-one (V) was deposited as needles, m. p. 81—82°C,[*7] whose infrared spectrum was identical with that of an authentic sample. Yield, 74%. $\lambda_{max}^{EtOH}$ 284 mμ (ε 23300).

**The Monosemicarbazone (VII) of Phenacylacetone (IV).**—Into an ice-cooled solution of 1.0 g. of phenacylacetone[18] in 10 ml. of ethanol, a solution of 0.7 g. semicarbazide hydrochloride and 0.7 g. of anhydrous potassium acetate in 2 ml. of water was added with stirring. Precipitates were collected by filtration and recrystallized from ethanol to give 1.4 g. (48%) of the semicarbazone VII as needles, m. p. 191°C, lit. m. p. 191°C.[5] $\lambda_{max}^{EtOH}$ 231.5 mμ (ε 9400).

**The Formation of VIII and IX from the Monosemicarbazone (VII) of Phenacylacetone at pH 4.7** — A mixture of 72 mg. of the monosemicarbazone (VII), 72 mg. of anhydrous potassium acetate, 1.6 ml. of acetic acid. 1 m.l of water and 20 ml. of ethanol (PH 4.7) was allowed to stand at room temperature for 10 days. When the mixture was concentrated to about 10 ml. and cooled, 30 mg. (45%) of the crude VIII ("the product A" in the text) was obtained as crystals, m. p. 216—217°C. Recrystallization from ethanol yielded crystals, m. p. 218—219°C. $\lambda_{max}^{EtOH}$ 285 mμ (ε 16000) and $\lambda_{Infl.}$ 220 mμ (ε 9600).

Found: C, 67.26; H, 6.06; N, 19.14. Calcd. for $C_{12}H_{13}ON_3$: C, 66.95; H, 6.09; N, 19.52%.

The mother liquor from VIII deposited a few milligrams of IX ("the product B" in the text), m. p. 208—210°C, which could be sublimed. $\lambda_{max}^{EtOH}$ 205.5 mμ (ε 13800) and 285.5 mμ (ε 14000).

**The Formation of VIII from Phenacylacetone (IV).**—A mixture of 389 mg. of phenacylacetone, 390 mg. of semicarbazide hydrochloride, 390 mg. of potassium acetate, 2 ml. of water and 20 ml. of pyridine was allowed to stand at room temperature for 10 days. After concentrating, the mixture was diluted with 10 ml. of water and 285 mg. (57%) of the crude VIII, m. p. 218—219°C, which was identical with the VIII obtained above (as determined by mixed melting point and infrared spectrum determination).

When a solution of phenacylacetone, an excess of semicarbazide hydrochloride and potassium acetate in aqueous ethanol was refluxed for 5 hr., VIII was obtained in a 78% yield. In both cases, the semicarbazone (VI) of 3-phenylcyclopentenone could not be isolated.

*6 Melting points were uncorrected. The infrared spectra were measured in Nujol mull with a Nippon Bunko recording spectrophotometer, Model IR-S. The ultraviolet spectra were measured with a Hitachi recording spectrophotometer, Model EPS-2. The microanalyses were made by Mr. J. Goda and his associates of this Faculty.

*7 Lit. m. p. 83—84°C. Recrystallization from ethanol gave crystals, m. p. 63—64°C, whose infrared and ultraviolet spectra were identical with those of the sample, m. p. 83—84°C. Recrystallization from water or aqueous ethanol gave crystals, m. p. 83—84°C.

18) J. H. Helberger, *Ann.*, **522**, 269 (1963).

**The Bis-semicarbazone of Acetonylacetone.**—When a solution of 1.90 g. of acetonylacetone[19] in 10 ml. of ethanol was treated with a solution of 3.81 g. of semicarbazide hydrochloride and anhydrous potassium acetate in 3 ml. of water, white precipitates deposited immediately. After standing overnight, the precipitates (2.60 g., 71%) were collected and recrystallized from hot water to give the bis-semicarbazone as crystals, m. p. 225—226°C, lit. m. p. 223—224°C.[20] $\lambda_{max}^{EtOH}$ 224.5 mμ (ε 21800).

The mother liquor from the bis-semicarbazone deposited crystals (20 mg.) after standing several weeks. Recrystallization from aqueous ethanol yielded crystals, m. p. 215—217°C. $\lambda_{max}^{EtOH}$ 264 mμ (ε 21800). $\nu_{max}^{Nujol}$ 3460, 3200, 1680 and 1568 $cm^{-1}$.

Found: C, 54.83; H, 7.39. Calcd. for $C_7H_{11}ON_3$: C, 54.88; H, 7.24%.

This compound was considered to be a dimethyldihydropyridazine but it was not further investigated.

**1-(2, 5-Dimethylpyrryl) urea (X).**—According to the method of Blaise,[10] 100 mg. of the bis-semicarbazone of acetylacetone was mixed with 2 ml. of 50% aqueous formic acid, and then the mixture was heated at 70°C for 3 min. On cooling 27 mg. (40%) of crystals deposited; they were recrystallized from ethanol as crystals, m. p. 235—236°C, lit. m. p. 245°C.[10] $\lambda_{max}^{EtOH}$ 216 mμ (ε 6710).

Found: C, 55.13; H, 7.39; N, 27.76. Calcd. for $C_7H_{11}ON_3$: C, 54.88; H, 7.24; N, 27.43%.

**The Formation of XI and XXIII from Ethyl Acetonylbenzoylacetate (XXII).**—a) To a solution of 1.16 g. (4.5 mmol.) of ethyl acetonylbenzoylacetate (XXII)[7] in 10 ml. of ethanol, a solution of 0.56 g. (5 mmol.) of semicarbazide hydrochloride and 0.60 g. of anhydrous potassium acetate in 3 ml. of water was added. After standing for 1 hr., precipitates (0.51 g., 39%) deposited were collected and recrystallized from water to give XI as needles, m. p. 219—221.5°C, lit. m. p. 224—226°C.[7] $\lambda_{max}^{EtOH}$ 207 mμ (ε 13700) and 285 mμ (ε 4500).

Found: C, 62.78; H, 5.98; N, 14.64. Calcd. for $C_{15}H_{17}O_3N_3$: C, 62.70; H, 5.96; N, 14.63%.

b) A mixture of 1.54 g. of the ester XXII, 2.67 g. (a large excess) of semicarbazide hydrochloride, 2.7 g. of anhydrous potassium acetate, 5 ml. of water and 30 ml. of ethanol was heated under reflux for 5 hr. and then filtered while still hot in order to remove insoluble materials. After standing overnight, the filtrate deposited 0.22 g. (13%) of XI as needles, m. p. 218—220°C, which were identical with the compound obtained above (as ascertained by mixed melting point and infrared spectrum determination).

From the above mother liquor, crystals deposited after spontaneous evaporation. Recrystallization from aqueous ethanol yielded 40 mg. of XXIII as crystals, m. p. 230—231°C (decomp.). $\lambda_{max}^{EtOH}$ 230 mμ (ε 16400) and $\lambda_{infl.}$ 255 mμ (ε 12300). $\nu_{max}^{Nujol}$ 3520, 3380, 3280, 2800—2300, 1680, 1650, 1570 and 1520 $cm^{-1}$.

Found: C, 56.38; H, 5.73; N, 25.64. Calcd. for $C_{13}H_{15}O_2N_5$: C, 57.13; H, 5.53; N, 25.63%.

**The Reaction of Ethyl Acetonylacetoacetate (XXI) with Semicarbazide.**—To a solution of 500 mg. of ethyl acetonylacetoacetate[19] in 30 ml. of ethanol, a solution of 275 mg. (an equimolar amount) of semicarbazide hydrochloride and 360 mg. of anhydrous potassium acetate in 5 ml. of water was gradually added. The crystals deposited were collected by filtration, washed with water and dried. The yield of the bis-semicarbazone, m. p. 186—187°C, was 285 mg. (34%). The infrared spectrum and ultraviolet spectrum ($\lambda_{max}^{EtOH}$ 226 mμ (ε 17200)) showed bands characteristic of a normal semicarbazone.[3,6]

Found: C, 43.77; H, 6.90; N, 27.12. Calcd. for $C_{11}H_{20}O_4N_6$: C, 43.99; H, 6.71; N, 27.99%.

When the mother liquor from the bis-semicarbazone was allowed to stand for 1 week, 165 mg. (13%) of XII deposited as plates, m. p. 222—223°C, the melting point and infrared spectrum of which did not change after recrystallization from ethanol. $\lambda_{max}^{EtOH}$ 228.5 mμ (ε 6200) and 264 mμ (ε 6300). Lit. m. p. 230°C.[8]

Found: C, 53.60; H, 6.78; N, 18.56. Calcd. for $C_{10}H_{15}O_3N_3$: C, 53.32; H, 6.71; N, 18.66%.

**The Formation of XII from the Bis-semicarbazone of Ethyl Acetonylacetoacetate (XXI).**—The recrystallization of the bis-semicarbazone from water or ethanol gave needles, m. p. 233—234°C. The infrared and ultraviolet spectra were identical with those of XII, m. p. 222—223°C, obtained above. The mixed melting point was 233—234°C.

Found: N, 18.68. Calcd. for $C_{10}H_{15}O_3N_3$: N, 18.66%.

**5-Phenyl-3-pyrazolone (XIX; R=$C_6H_5$, R'=H).**—This compound was prepared according to the method of House et al.,[14] m. p. 239—240°C (decomp.), lit. m. p. 242—243°C (decomp.). $\lambda_{max}^{EtOH}$ 208 mμ (ε 16000), and 255 mμ (ε 16200), lit. $\lambda_{max}$ 274 mμ (ε 17000). $\nu_{max}^{Nujol}$ 2800—2300, 1630, 1600 and 1550 $cm^{-1}$.

**The Abnormal Semicarbazone (XIX; R=$C_6H_5$, R'=$-CH_2-C(CH_3)=CH-COOC_2H_5$)[16] of Diethyl 2-Methyl-4-benzoyl-1-butene-1, 4-dicarboxylate (XXa).**—$\lambda_{max}^{EtOH}$ 207 mμ (ε 19000) and 248 mμ (ε 10800). $\nu_{max}^{Nujol}$ 3400, 2800—2300, 1697, 1650, 1600 and 1550—1525 $cm^{-1}$.

**The Abnormal Semicarbazone (XIX; R=β-furyl, R'=$-CH_2-C(CH_3)=COOC_2H_5$)[17] of Diethyl 2-Methyl-4-(β-furyl)-1-butene-1, 4-dicarboxylate (XXb).**—$\nu_{max}^{Nujol}$ 3400, 2800—2300, 1695, 1645, 1590 and 1550 $cm^{-1}$. $\lambda_{max}^{EtOH}$ 207 mμ (ε 19000) and 248 mμ (ε 10800).

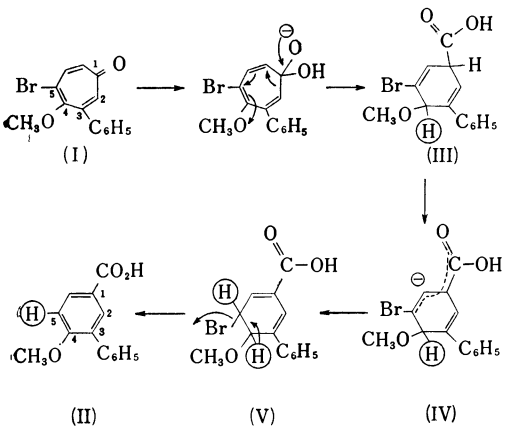
# The Mechanism of the Rearrangement Reaction of 3-Phenyl-4-methoxy-5-bromotropone to 3-Phenyl-4-methoxybenzoic Acid[1]

By Yoshio KITAHARA,*1 Ichiro MURATA*1 and Tadashi MUROI*2



(Received December 19, 1964)

An examination of the reaction mechanism of the rearrangement of 2-phenyl-4-bromotropone to 2-phenylbenzoic acid by using heavy water was described in a preceding paper.[2] A similar reaction has recently been found by one of the present authors (T. M.)[3] in the rearrangement of 3-phenyl-4-methoxy-5-bromotropone (I) to 3-phenyl-4-methoxybenzoic acid (II), a reaction which cannot be explained by the known mechanism of the rearrangement reaction of tropoids.

(I) (II)

The reaction mechanism depicted below has been assumed for the rearrangement of I to II; this hypothesis was examined, using deuterium as the tracer element.

As is shown in this chart, the reaction begins with the attack on the carbonyl carbon in I by a hydroxyl ion, which causes a ring contraction, and then the carbon atom carrying the methoxyl group undergoes protonization to form III. III forms the anion IV by the action of a base and, through the formation of V by protonization to the carbon atom in the 5-position or by an intramolecular proton 1, 3-transfer,[4] forms II by dehydrobromination.

If this rearrangement is carried out in a system containing deuterium, the position marked with Ⓗ in the above chart will be occupied by deuterium atoms. If, on the other hand, the formation of the intermediate V is due to protonization, the deuterium content at the 5-position in the rearrangement product should be close to the theoretical value (8.33 atom.%), while the value will be far smaller than the theoretical if the 1, 3-transfer of the proton has occurred. In any case, if the foregoing reaction mechanism is correct, the position of the deuterium ion in II should be 5 and not any other position.

A solution of I dissolved in a system of deuterium oxide,[5] sodium hydroxide-*d*, and methanol-O-*d*[6] was refluxed for 30 min.; the rearrangement product so obtained was converted to the methyl ester with diazomethane, and the ester was hydrolyzed with alkali,[2] thus affording deuterated 3-phenyl-4-methoxybonzoic acid (II) with a m. p. of 214—215°C.[7]

1) Paper read at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

2) Y. Kitahara, I. Murata and T. Muroi, This Bulletin, 34, 1359 (1961).

3) T. Muroi, This Bulletin, 34, 178 (1961).

4) The relative rates of the double-bond migration and of deuterium exchange of perdeuterio-1-pentene with unlabeled 2-methyl-1-pentene and solvent have been determined at 55°C in the system of potassium *t*-butoxide in dimethyl sulfoxide by S. Bank, C. A. Rowe, Jr., and A. Schriesheim, *J. Am. Chem. Soc.*, 85, 2115 (1963). They found that the isomerization is 16 times faster than the exchange. Thus they concluded that the isomerization reaction involves an intramolecular proton transfer. A reasonable mechanism can be developed on the basis of a tightly-bound ion pair.

5) Product of the Asahi Kasei Ind., Ltd. Purity, 99.80%, $d_4^{25}$ 1.1043.

6) D. H. Hill, B. Stewart, S. W. Kantor, W. A. Judge and C. R. Hauser, *J. Am. Chem. Soc.*, 76, 5129 (1954).

7) It was confirmed through infrared spectral identification that 3-phenyl-4-methoxybenzoic acid does not undergo secondary deuteration under these rearrangement reaction conditions.

The infrared absorption spectrum of II (cf. Table I) was somewhat different from that of the 3-phenyl-4-methoxybenzoic acid[8] (II') prepared from anisic acid from the out-of-plane to the finger-print region and indicated the presence of deuterium. The deuterium content was found to be 0.28 atom.% by mass analysis; this is far smaller than the theoretical value. This result shows that the base-catalysed protropic migration is intramolecular.

* IR spectra are measured using a Perkin-Elmer Model 21 double beam spectrophotometer in KBr pellet.

The position of the deuterium atom in II should be 5 (the position meta to the carboxyl carbon), according to the hypothetical mechanism, and this atom should be replaced by the bromine atom upon the bromination of II. The bromination of II with 1 mol. of bromine in glacial acetic acid afforded a monobrominated compound (VI) with a m. p. of 231—232°C, the infrared absorption spectrum of which was identical with that of the brominated product of II'.

It follows, therefore, that the deuterium atom in II is at the 5-position and that there are none in other positions. This fact supports the mechanism described above.

## Experimental[9]

**The Rearrangement Reaction of 3-Phenyl-4-methoxy-5-bromotropone (I) in a Heavy Water System.**—Sodium (0.11 g.) was dissolved in methanol-O-*d* (8 ml.); deuterium oxide (8 ml.) and I (0.4 g.) were added to it, and the mixture was refluxed on a water bath for 25 minutes, protected with a calcium chloride tube. Methanol was evaporated under reduced pressure, and the residue was diluted with 10 ml. of water and extracted with chloroform in order to remove a neutral portion. The aqueous layer was acidified to Congo red with hydrochloric acid; the crystals that separated out were collected, and the filtrate was extracted with chloroform. The crystals obtained were combined and suspended in ether, and an ether solution of diazomethane was added to it in order to effect esterification. The crystal obtained by the evaporation of ether were dissolved in a mixture of methanol (4 ml.) and 2 N sodium hydroxide (1.5 ml.), and the mixture was refluxed for 4 hr. Methanol was evaporated under reduced pressure, and the residue was diluted with water and acidified. The crystals that separated out were collected by filtration to crude crystals (0.25 g.) of II, m. p. 202—206°C. This was purified by sublimation under reduced pressure, and the sublimate was recrystallized from methanol to II as colorless prisms, m. p. 214—215°C.

Found: C, 73.48; H, 5.49; D, 8.33. Calcd. for $C_{14}H_{14}DO_3$: C, 73.67; H, 5.30%; D, 0.23 atom.%.

**3-Phenyl-4-methoxy-5-bromobenzoic Acid (VI).**—Bromine (70 mg.) was added to a solution of II (80 mg.) dissolved in glacial acetic acid (0.5 ml.) by heating, and then the mixture was heated on a water bath at 45—55°C for 4 more hours. The crystals that separated out were collected by filtration to 70 mg. of crude crystals with a m. p. of 217—222°C. Recrystallization from ethanol gave VI melting at 231—232°C.

VI was similarly obtained from II'.

Found: C, 54.55; H, 3.37. Calcd. for $C_{14}H_{11}O_3Br$: C, 54.74; H, 3.61%.

The determination of deuterium by mass analysis was carried out by Dr. Sumio Horibe, Faculty of Science, Tokyo Metropolitan University, while the infrared spectral measurement was made by Mr. Hideji Aono of this Institute, to both of whom the authors wish

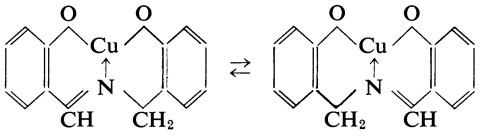
# Structure of Three-coordinated Copper(II) Complexes. Salicylalsalicylaminecopper(II) and Related Compounds



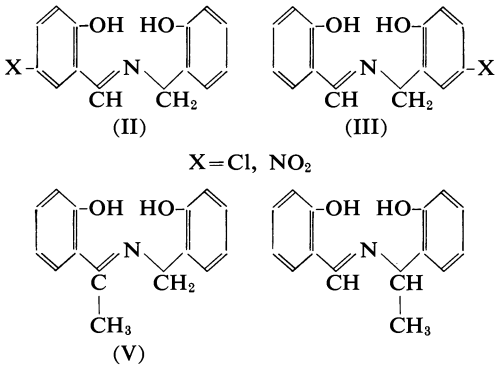
By Yoko INAGAKI, Osamu OHASHI, Michihiko KISHITA and Masaji KUBO

(Received December 21, 1964)

A majority of the so-called three-coordinated copper(II) complexes show magnetic moments per copper atom smaller than the theoretical spin moment, 1.73 Bohr magnetons, for one unpaired electron.[1] On the basis of this fact, the present writers predicted that the crystals of these compounds are made up of dimeric molecules having a pair of contiguous copper atoms close enough to permit spin interaction between them. The prediction was varified by an X-ray crystal analysis carried out by Barclay and collaborators[2] on a single crystal of acetylacetonemono(*o*-hydroxyanil)copper(II). It is noteworthy that the three-coordinated copper(II) complexes of this type were presumed to have monomeric units with a planar structure because they involve highly conjugated systems. In fact, the X-ray crystal analysis mentioned above confirmed this presumption. Therefore, one might suspect that the planar structure of ligands is an important factor leading to the subnormal magnetic moments of these copper(II) complexes. This generalization seems to be plausible because subnormal magnetic moments found for various copper-(II) complexes[2,3] are a result of close proximity of two copper atoms in a dimeric molecule and the geometric configuration of ligands is surely responsible for the approach of the two copper atoms.

There is another group of three-coordinated copper(II) complexes, which show normal magnetic moments of 1.8—1.9 B. M.[4] Complexes belonging to this group are characterized by the presence of a six-membered chelate ring having a nonplanar structure in a monomeric molecule. Arguments based on infrared spectroscopy have led to a conclusion that complexes of this type also form dimeric molecules in crystals, in which copper atoms are bridged in pairs by two Cu-O-C-O-Cu links rather than by two oxygen atoms as in the copper(II) complexes of the first group. Thus, one is led to an important conclusion that "three-coordinated copper(II) complexes" in the literal sense of the word do not exist.[5]

Salicylalsalicylaminecopper(II) or salicylal-*o*-hydroxybenzylaminecopper(II) presents a single exception to this rule. It shows a subnormal magnetic moment of 0.87 B. M. at room temperature notwithstanding that a copper atom of this complex takes part in the formation of a six-membered ring having only one aromatic bond. However, the chemical formula as given to this molecule is based on the synthesis of the corresponding Schiff base. When the copper(II) complex is formed, one half of the monomeric unit might become equivalent to the other half, leading to a symmetric planar structure. It is because prototropic rearrangement involving slight displacements of three hydrogen atoms might take place.



(I-Cu)

For this reason, the problem of possible prototropy in this compound is important in discussing the structure of three-coordinated

copper(II) complexes. The question can be answered by examining two derivatives of salicylalsalicylaminecopper(II), one having a substituent in the aldehyde portion of the Schiff base and the other having the same substituent at the corresponding position of the amine portion of the Schiff base. Yamaguchi[6] has already examined three isomeric pairs of Schiff bases which can form three-coordinated

copper(II) complexes on replacing two hydrogen atoms with a copper atom. It is reported that no appreciable difference was found between the isomers in their ability to form coordination compounds but that those Schiff bases having a substituent on the aldehyde side show slightly lower melting points than those of the corresponding isomers having the same substituent on the amine side. (The three-coordinated copper(II) complexes have no sharp melting points, because they readily decompose before they melt.) Since the measurement of melting points alone is not very conclusive in deciding whether or not prototropy takes place in the molecules of this type, the present writers have undertaken to determine the infrared absorption spectra, the X-ray powder patterns, and the nuclear magnetic resonance spectra of salicylalsalicylamine and related compounds as well as their copper(II) salts.

## Experimental

The following Schiff bases and the corresponding three-coordinated copper(II) complexes were prepared by essentially the same method as that employed by Yamaguchi.[6]

**Salicylalsalicylamine (I).**—This compound was prepared by the method described in a previous paper.[1] It forms yellow needle crystals, m.p. 182°C. This and the following Schiff bases were transformed into their copper(II) salts by means of copper(II) acetate dissolved in ethanol. Recrystallization from pyridine yielded monopyridine adducts, which lost pyridine completely on boiling in ethanol.

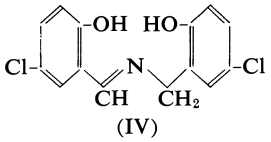
Found: N, 5.0; Cu, 22.0. Calcd. for $C_{14}H_{11}O_2NCu$: N, 4.9; Cu, 22.0%.

**5-Chlorosalicylalsalicylamine (II).**—Salicylaldehyde was chlorinated with sulfuryl chloride in the presence of aluminum trichloride. 5-Chlorosalicylaldehyde separated as white crystals and was recrystallized from ethanol, m. p. 100°C. It was subjected to condensation with salicylamine in an ethanol solution. Recrystallization from ethanol yielded yellow needle crystals, m. p. 200°C.

Found: C, 63.8; H, 4.6; N, 5.3. Calcd. for $C_{14}H_{12}O_2NCl$: C, 64.2; H, 4.6; N, 5.3%.

Found: C, 52.5; H, 3.3; N, 4.4. Calcd. for $C_{14}H_{10}O_2NClCu$: C, 52.0; H, 3.1; N, 4.3%.

**Salicylal-5-chlorosalicylamine (III).**—*N*-(Hydroxymethyl)phthalimide was prepared by the reaction of phthalimide and formalin, m. p. 142°C. It was allowed to react with hydrochloric acid to obtain *N*-(chloromethyl)phthalimide, which was recrystallized from benzene, m. p. 132°C. On heating a mixture of this compound, *p*-chlorophenol, and zinc chloride, the reaction product solidified. Extraction with hot ethanol yielded white needle crystals of 2-hydroxy-5-chlorobenzylphthalimide, m. p. 171°C.[7] This compound was heated with hydrochloric acid in a sealed tube. On cooling, phthalic acid separated. When the filtrate was concentrated, 5-chlorosalicylamine hydrochloride precipitated. The precipitates were dissolved in water and neutralized with ammonia. The crystals of 5-chlorosalicylamine separated and were crystallized from ethanol, m. p. 204°C. This compound was allowed to condense with salicylaldehyde in an ethanol solution to form a Schiff base. Recrystallization from ethanol yielded yellow hexagonal plate crystals, m. p. 214°C.



Found: C, 64.4; H, 4.5; N, 5.3. Calcd. for $C_{14}H_{12}O_2NCl$: C, 64.2; H, 4.6; N, 5.3%.

Found: C, 52.2; H, 3.2; N, 4.5. Calcd. for $C_{14}H_{10}O_2NClCu$: C, 52.0; H, 3.1; N, 4.3%.

**5-Chlorosalicylal-5-chlorosalicylamine (IV).**—This compound was obtained by the condensation of 5-chlorosalicylaldehyde and 5-chlorosalicylamine in an ethanol solution as yellow needle crystals, m. p. 203°C.

***o*-Hydroxyacetophenonesalicylamine (V).**—A solution of *o*-hydroxyacetophenone and salicylamine in ethanol was refluxed for 3 hr. The resulting condensation product was recrystallized from ethanol. Pale yellow crystals were obtained, m. p. 193°C (lit.[6] 188°C).

**Benzalbenzylamine (VI).**—Benzaldehyde and benzylamine were allowed to condense in an ether solution. After drying, ether was removed and the residue was fractionated under reduced pressure to obtain a colorless liquid, b. p. 140—145°C/5 mmHg (lit.[8] 200—202°C/10—20 mmHg).

Infrared absorpiton spectra were obtained of potassium bromide disks and Nujol mulls with a Model DS-402G grating spectrometer equipped with

7) M. Yamaguchi, ibid., 73, 393 (1952).
8) A. T. Mason and G. R. Winder, *J. Chem. Soc.*, 65, 191 (1894).

potassium bromide optics from Japan Spectroscopic Company, Ltd. The wave number range covered 400—4000 $cm^{-1}$.

The X-ray powder patterns were taken by use of a Norelco X-ray diffractometer at room temperature with the copper K$\alpha$ line filtered through nickel.

Nuclear magnetic resonance spectra were recorded at room temperature by means of a JNM-3 NMR spectrometer from the Japan Electron Optics Laboratory Company operating at 60 Mc. Materials were dissolved in dimethyl sulfoxide to 8—9% by weight unless otherwise specified. Cyclohexane was employed as an external standard.

## Results and Discussion

A crucial test in this study is to see whether or not 5-chlorosalicylalsalicylamine (II) and its copper(II) salt (II-Cu) are identical with salicylal-5-chlorosalicylamine (III) and its copper(II) salt (III-Cu), respectively. If the prototropic rearrangement of hydrogen atoms takes place in the molecules of compound I and its derivatives, tautomeric equilibrium would be established between compounds II and III as well as between the salts, II-Cu and III-Cu. As a result, one would obtain one and the same Schiff base and its copper(II) salt regardless of whether chlorine is introduced in the aldehyde portion or the amine portion of compound I. For this reason, experimental results on related compounds are consulted below only when they are pertinent to the solution of the problem.

The infrared spectrum of compound II bears fairly close resemblance to that of III. However, there are certain features indicative of the nonidentity of the two compounds as shown in Fig. 1. The same conclusion can be derived from the spectra of three-coordinated copper(II) complexes, II-Cu and III-Cu, shown in Fig. 2. The assignments of observed bands are feasible to some extent on the basis of analysis carried out by Ueno and Martell[9] on a variety of metal chelates and free ligand molecules. However, the results are trivial for the present purpose and need not be discussed here.

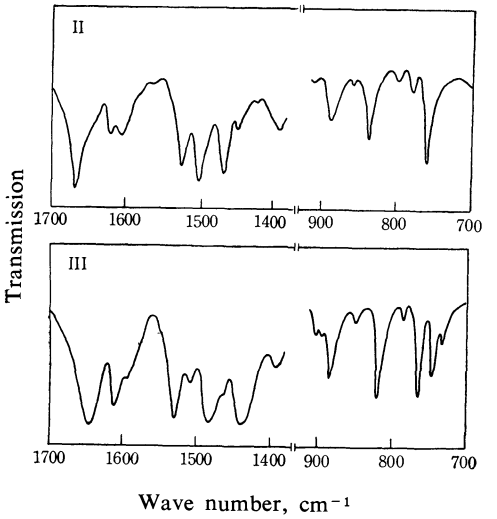


Fig. 1. Infrared spectra of 5-chlorosalicylalsalicylamine (II) and salicylal-5-chlorosalicylamine (III).

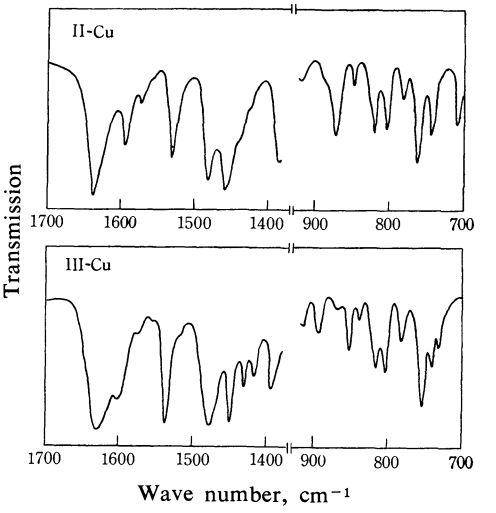

Fig. 2. Infrared spectra of 5-chlorosalicylalsalicylaminecopper(II) (II-Cu) and salicylal-5-chlorosalicylaminecopper(II) (III-Cu).

The X-ray powder patterns of free ligands, II and III, are quite different from each other (Fig. 3). The copper(II) salts of I, II, III, and IV also show powder patterns differing from one another as shown in Fig. 4.

It was not feasible to observe the nuclear magnetic reasonance spectra of the three-coordinated copper(II) complexes, because they are

9) K. Ueno and A. E. Martell, *J. Phys. Chem.*, **59**, 998 (1955); **60**, 1270 (1956).

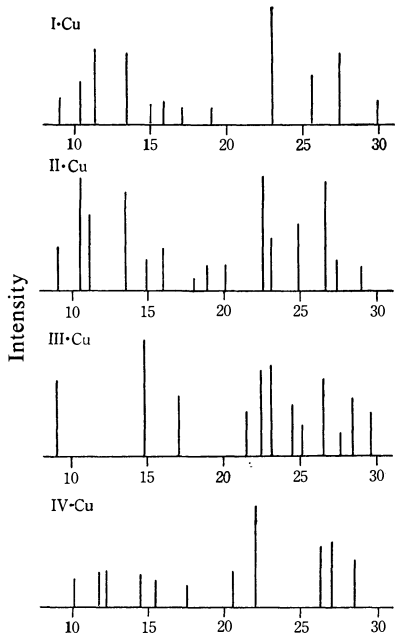

Fig. 4. Norelco X-ray powder patterns of the copper(II) complexes of salicylalsalicylamine (I-Cu), 5-chlorosalicylalsalicylamine (II-Cu), salicylal-5-chlorosalicylamine (III-Cu), and 5-chlorosalicylal-5-chlorosalicylamine (IV-Cu).

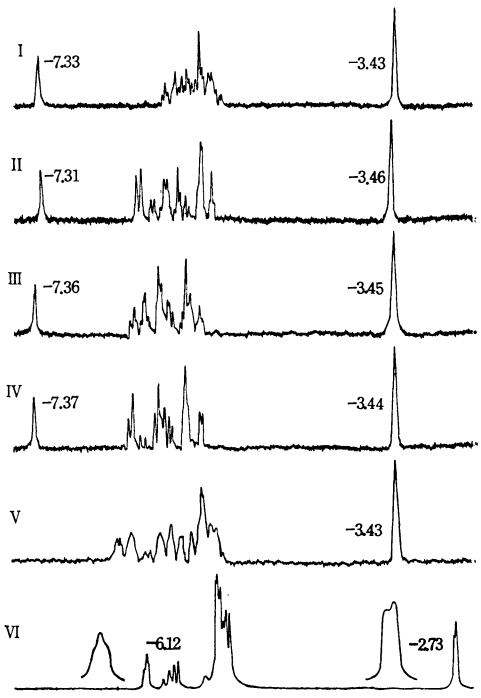

Fig. 5. Proton magnetic resonance spectra of salicylalsalicylamine (I) and related compounds (II—VI). The two peaks of compound VI as recorded in the pure liquid state show multiplet structure under a low sweep rate. They shift to low field when examined in solutions.

insoluble in almost all common solvents except pyridine, aniline, quinoline, etc. It is known that three-coordinated copper(II) complexes readily form monopyridine derivatives,[1,4] which show normal magnetic moments even when the corresponding pyridine-free complexes show subnormal magnetic moments. Accordingly, one is led to conclude that the dissolution of three-coordinated copper(II) complexes in pyridine involves the rearrangement of ligands and that the binuclear complex molecules dissociate into monomeric molecules each having a pyridine molecule as an additional ligand.[5] Undoubtedly, pyridine and other nitrogen-containing solvents are not suitable for the study of the structure of three-coordinated copper(II) complexes.

Therefore, proton magnetic resonance studies were made on free ligands, which also are sparingly soluble in a majority of common solvents. Internal standards were not employed, solely because it was desired to maintain the samples free from admixtures. No correction was made for the bulk magnetic susceptibility, because comparison between the NMR spectra of various compounds rather than the exact data of chemical shifts was the present writers' immediate concern.

The proton magnetic resonance spectra of compounds I—VI are shown in Fig. 5. The spectra of compounds I—IV look very much alike. Each consists of a sharp peak on the low-field side, a more intense sharp peak on the high-field side, and a group of closely spaced lines located between them. The intensity ratio of the two single lines is 1 : 2. Accordingly, the weak line is attributable to -CH= protons while the strong line is due to $-CH_2-$ protons. The group of lines can be assigned to protons attached to aromatic rings. The signal of -CH= protons is missing in the spectrum of compound V, which has $-C(CH_3)=$ in place of -CH=. The methyl signal of this compound was unobservable, because it overlaps the strong peak of dimethyl sulfoxide used as a solvent. The spectrum of compound VI also is comprised of a -CH= proton signal, a $-CH_2-$ signal, and a group of peaks due to protons in phenyl groups. Since this compound could be examined in the pure liquid state, it was feasible to detect the multiplet structure of the -CH= and $-CH_2-$ signals. The former signal has a line contour of a partly resolved 1 : 2 : 1 triplet while the latter shows a doublet structure. This indicates the existence of weak coupling between the -CH=

proton and $-CH_2-$ protons. The signals of OH protons could not be observed, except for compound V for which a barely detectable flat peak was observed at −15.16—15.36 p.p.m. Probably, they are broadened by the intermolecular exchange of protons involving solvent molecules to escape detection. The results of assignments are summarized in Table I.

Table I. Chemical shifts (in p.p.m.) of salicylalsalicylamine (I) and related compounds (II—VI) in dimethyl sulfoxide solutions with cyclohexane as a standard

| Compound | $-CH=$ | $C_6H_3$, $C_6H_4$, $C_6H_5$ | $-CH_2-$ |
|---|---|---|---|
| I | −7.33 | −5.34—6.25 | −3.43 |
| II | −7.31 | −5.39—6.30 | −3.46 |
| III | −7.36 | −5.47—6.28 | −3.45 |
| IV | −7.37 | −5.54—6.26 | −3.44 |
| V | | −5.33—6.45 | −3.43 |
| VI (pure liq.) | −6.12 | −5.23—5.96 | −2.73 |

The appearance of two separate peaks for $-CH=$ and $-CH_2-$ protons provides a conclusive evidence for discarding possible prototropy in these molecules. As pointed out by Katritzky and Waring,[10,11] fast exchange can render two or more protons equivalent in a tautomeric compound and therefore the molecules simulate a more symmetric structure. In other words, if prototropy takes place in the molecules of salicylalsalicylamine and related compounds, one would have a single line for the $-CH=$ and $-CH_2-$ protons in contradiction with the present observations.

## Conclusion

The experimental results described above indicate unequivocally that prototropy does not take place in the $-CH=N-CH_2-$ portion of molecules of salicylalsalicylamine (I) and its derivatives as well as of the copper(II) salts derived from them. This fact has an interesting bearing on the structure of three-coordinated copper(II) complexes.

The so-called three-coordinated copper(II) complexes can be classified into two main groups. Those belonging to group I show subnormal magnetic moments, whereas group II complexes show normal magnetic moments. The latter differ from the former in two respects. First, a six-membered chelate ring having only one aromatic bond is present in a molecule (condition 1). The resulting nonplanar structure of the chelate ring might hinder the approach of two copper atoms. Secondly, complexes belonging to group II have a carbonyl group separated from a copper atom by two chemical bonds (condition 2), whereas a carbonyl oxygen capable of being coordinated on a copper atom of another monomeric molecule is missing in complexes classified as group I.

If one could prepare complexes having a three-dimensional configuration without any carbonyl oxygen and also those of a planar structure involving a carbonyl group at an appropriate position, it would be possible to decide which of the aforementioned two conditions is the main factor leading to normal magnetic moments. Quite recently, the present writers have succeeded in preparing salicylaldehydeglycinecopper(II), which satisfies condition 2 but not condition 1 and found that it shows a subnormal magnetic moment.[12] Salicylalsalicylaminecopper(II) studied in the present investigation satisfies condition 1 but not condition 2, since the double bond in the $-CH=N-CH_2-$ portion of the molecule is localized. It shows a subnormal magnetic moment.[1] Thus, it is concluded that both of the aforementioned two conditions are necessary for three-coordinated copper(II) complexes to form a binuclear structure in which two copper atoms are bridged in a pair by two Cu-O-C-O-Cu links, whereas when either one or both of the two conditions are dissatisfied, dimeric complex molecules are formed, in which two copper atoms are bridged in a pair by two oxygen atoms.

## Summary

On the basis of infrared spectroscopy and X-ray powder patterns, it is shown that 5-chlorosalicylalsalicylamine and its copper(II) salt are different from salicylal-5-chlorosalicylamine and its copper(II) salt, respectively, in the crystalline state. The nuclear magnetic resonance studies on salicylalsalicylamine and related compounds in solutions show that the double bond in the $-CH=N-CH_2-$ portion of these molecules is localized, i. e., the prototropic rearrangement of hydrogen atoms does not take place. Therefore, salicylalsalicylaminecopper(II) presents an example of a new type of three-coordinated copper(II) complexes showing a subnormal magnetic moment in spite of having ligands of a three-dimensional structure. This provides an additional evidence in favor of a presumption made by the present writers on the structure of three-coordinated copper(II) complexes showing a normal magnetic moment.

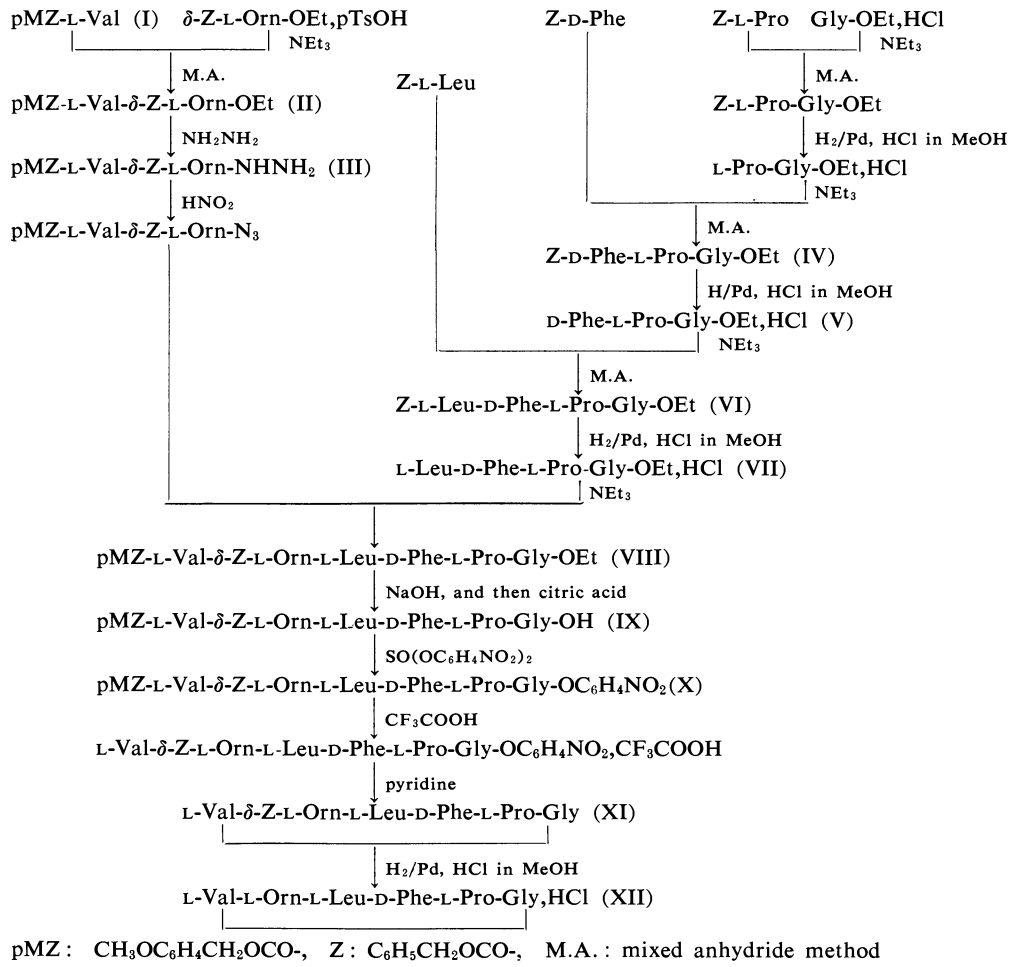
# Studies of Peptide Antibiotics. II. Cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolylglycyl

By Tetsuo KATO, Michio KONDO, Motonori OHNO and Nobuo IZUMIYA

(Received December 21, 1964; in revised form April 10, 1965)

A number of polypeptide antibiotics[1] such as gramicidin S, tyrocidine A and polymyxin B have several characteristic features in common. These features are, namely, the occurrence of D-amino acids, basic amino acids, and a cyclic structure in the molecule. For a study of the relationship between chemical structure and biological activities of antibacterial cyclic peptides, some dipeptide anhydrides, which are the simplest compounds possessing the characteristics mentioned above, were prepared and their biological activities were tested as described in a previous paper.[2] However, they were found to be devoid of antibacterial activity. Although the reason for the inactivity of the dipeptide anhydrides is not yet clear, it appears that in addition to the characteristics mentioned above, other structural features such as a certain minimum ring size and/or a specific amino acid sequence, are necessary in this type of molecule for the exhibition of antibacterial activity. Therefore, it became of interest to determine whether or not a larger cyclic peptide with an appropriate amino acid sequence would exhibit the antibacterial properties.

It appears that difficulties have been encountered in the synthesis of cyclic tripeptides. It has been found, for example, that a linear tripeptide active ester or azide yields a cyclic hexapeptide through cyclization by the dimerization reaction.[3,4] Furthermore, cyclization of a linear tetra or pentapeptide gave a cyclic tetrapeptide in very poor yield[3] or was accompanied with the dimerization reaction to yield a cyclic decapeptide.[5] On the other hand, it has been found that several cyclic hexapeptides can be synthesized without any difficulty.[3,6] Therefore, we have decided to attempt the synthesis of a cyclic hexapeptide with the appropriate amino acid sequence.



This paper is concerned with the synthesis and an antibacterial assay of the cyclic hexapeptide, cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolylglycyl, which contains the partial sequence -L-Val-L-Orn-L-Leu-D-Phe-L-Pro- found in gramicidin S and tyrocidines.[1]

The sequence of reactions employed in the synthesis of the cyclic hexapeptide (XII) is indicated in the following scheme (p. 1203). The final product XII was obtained as colorless crystals containing five moles of water of crystallization; its homogeneity was demonstrated by paper and thin layer chromatographies.

In order to ascertain whether or not the cyclic peptide XII described herein possesses antibacterial activity, the effect of various levels of XII on the growth of *Escherichia coli*, *Bacillus subtilis*, and several other microorganisms was examined. It was found that there was no retardation of growth of any of these microorganisms.

Hence, it appears that even the presence of six amino acid residues in a cyclic peptide does not satisfy the requirements for antibacterial activity. Experiments on the preparation and studies on the properties of several other cyclic hexapetides are in progress in this laboratory in order to extend this study further.

pMZ: $CH_3OC_6H_4CH_2OCO$-, Z: $C_6H_5CH_2OCO$-, M.A.: mixed anhydride method

In this connection, it should be noted that it was recently reported that gramicidin $J_2$, previously described as a cyclic hexapeptide, is identical with gramicidin S,[7] a cyclic decapeptide.

## Experimental

All melting points are uncorrected.

***p*-Methoxybenzyloxycarbonyl-L-valine (I).**—To a solution of L-valine (1.172 g., 10 mmol.) and sodium bicarbonate (1.64 g., 20 mmol.) in water (20 ml.) was added a solution of *p*-methoxybenzyloxycarbonyl azide[8] (2.486 g., 12 mmol.) in dioxane (20 ml.), and the reaction mixture stirred for 48 hr. at room temperature. After removal of dioxane in vacuo, water (20 ml.) was added to the residue. The aqueous solution was extracted with ethyl acetate (20 ml.). The combined aqueous layer was acidified with 0.5 M citric acid to pH 5 in an ice bath, and then thrice extracted with ethyl acetate (30 ml. each). The extract was dried over anhydrous sodium sulfate, and after removal of the salt by filtration, evaporated in vacuo. The residual oil weighed 2.036 g. (72%).

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithine Ethyl Ester (II).**—To a solution of I (2.036 g.) and triethylamine (1.0 ml.) in absolute tetrahydrofuran (20 ml.) at −5°C, was added isobutyl chloroformate (0.94 ml.). After 15 min., a cold mixture of δ-benzyloxycarbonyl-L ornithine ethyl ester *p*-toluenesulfonate (3.359 g.)[2] and triethylamine (1.0 ml.) in chloroform (20 ml.) was added, and the mixture was allowed to stand overnight at room temperature. After removal of the solvent by evaporation in vacuo, the resultant oily residue solidified. The solidified product was treated with water and the mixture was filtered; the residue was washed successively with 4% sodium bicarbonate, water, 10% citric acid, and water; yield, 3.379 g. This solid was recrystallized from methanol-ether-petroleum ether to give 3.126 g. (76%); m. p. 140—144°C; $[\alpha]_D^{23}$ −7.8° (*c* 1, acetic acid).

Found: C, 62.22; H, 6.96; N, 7.61. Calcd. for $C_{29}H_{39}O_8N_3$: C, 62.46; H, 7.05; N, 7.54%.

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithine Hydrazide (III).**—To a solution of II (1.115 g., 2 mmol.) in dimethylformamide (4 ml.) was added hydrazine hydrate (1 ml.)

7) K. Kurahashi, *J. Biochem.*, **56**, 101 (1964).
8) F. Weygand and K. Hunger, *Chem. Ber.*, **95**, 1 (1962).

and the solution was stored for 48 hr. at room temperature. The reaction mixture was evaporated in vacuo below 50°C. The hydrazide which precipitated upon the addition of water (20 ml.) was filtered off, washed with water and dried in a desiccator; 991 mg. (91%); m. p. 211—212°C (decomp.); $[\alpha]_D^{23}$ −4.2° (*c* 1, dimethylformamide).

Found: C, 59.53; H, 6.87; N, 12.77. Calcd. for $C_{27}H_{37}O_7N_5$: C, 59.65; H, 6.86; N, 12.88%.

**Benzyloxycarbonyl-D-phenylalanyl-L-prolylglycine Ethyl Ester (IV).**—To a chilled solution of benzyloxycarbonyl-D-phenylalanine (2.155 g., 7.2 mmol.) and triethylamine (1.01 ml.) in tetrahydrofuran (15 ml.) was added isobutyl chloroformate (0.94 ml.). After 15 min. a mixture of L-prolylglycine ethyl ester hydrochloride (1.805 g.),[9] triethylamine (1.01 ml.) and chloroform (20 ml.) was added. The mixture was left overnight at room temperature and then evaporated in vacuo. The residual oil was dissolved in ethyl acetate (50 ml.), and the solution was washed successively with 2% hydrochloric acid, 4% sodium bicarbonate and water, and then dried over anhydrous sodium sulfate. The filtered solution was evaporated in vacuo. The residual oil solidified after the addition of ether and petroleum ether. The product was filtered off, dried in air and weighed; 2.588 g. (75%); m. p. 105—106°C; $[\alpha]_D^{23}$ −52.6° (*c* 2, dimethylformamide).

Found: C, 63.85; H, 6.51; N, 8.25. Calcd. for $C_{26}H_{31}O_6N_3 \cdot 1/2H_2O$: C, 63.66; H, 6.57; N, 8.56%.

When dried at 100°C in vacuo, the crystals lost 1.5% of their weight. Calcd. for $1/2H_2O$: 1.8%.

**D-Phenylalanyl-L-prolylglycine Ethyl Ester Hydrochloride (V).**—To a solution of IV (2.407 g., 5 mmol.) in methanol (20 ml.) was added 0.494 N methanolic hydrogen chloride (10.7 ml.). The solution was then subjected to hydrogenolysis in the presence of palladium black. After being filtered from the catalyst, the solution was evaporated to dryness in vacuo; yield, 1.944 g. (100%).

**Benzyloxycarbonyl-L-leucyl-D-phenylalanyl-L-prolylglycine Ethyl Ester (VI).**—To a chilled solution of benzyloxycarbonyl-L-leucine (1.327 g., 5 mmol.) and triethylamine (0.70 ml.) in tetrahydrofuran (15 ml.) was added isobutyl chloroformate (0.66 ml.). After 15 min., a solution of V (1.944 g., 5 mmol.) and triethylamine (0.70 ml.) in chloroform (20 ml.) was added at −10°C. The mixture was left overnight at room temperature and evaporated in vacuo. The residual oil was treated in the manner described above. The oily residue weighed 2.910 g. (97%).

**L-Leucyl-D-phenylalanyl-L-prolylglycine Ethyl Ester Hydrochloride (VII).**—VI (1.189 g., 2 mmol.) was subjected to hydrogenolysis in the presence of palladium black and 0.48 N methanolic hydrogen chloride (4.5 ml.), and then treated as mentioned above. The resulting oil gradually solidified to form an amorphous powder; yield, 961 mg. (97%).

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolylglycine Ethyl Ester (VIII).**—The following operations were carried out in a cold room. To a chilled solution of III (544 mg., 1 mmol.) in glacial acetic acid (12 ml.) were added successively with stirring 1.09 N hydrochloric acid (1 ml.), 76 mg. of sodium nitrite in 1 ml. of water, and additional 1.09 N hydrochloric acid (1 ml.). After 6 min., cold water (50 ml.) was added. The azide which precipitated as a white mass was filtered off and washed successively with cold water, saturated sodium bicarbonate solution, and water, and then dried under vaccum in a desiccator. The azide was added to a solution of VII (497 mg., 1 mmol.) and triethylamine (0.14 ml.) in dimethylformamide (4 ml.), and the mixture was stirred for 3 days at 0°C. The insoluble substance was removed by filtration. The precipitate which formed upon addition of water (50 ml.) to the filtrate was collected, washed with 0.5 M citric acid, 4% sodium bicarbonate solution and water, and dried. Recrystallization from dioxane and ether gave 696 mg. (72%) of VIII; m. p. 125—129°C; $[\alpha]_D^{23}$ −33.5° (*c* 2, dimethylformamide).

Found: C, 62.15; H, 7.01; N, 9.93. Calcd. for $C_{51}H_{69}O_{12}N_7 \cdot 1/2H_2O$: C, 62.42; H, 7.19; N, 9.99%.

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolylglycine (IX).**—To a solution of VIII (990 mg., 1 mmol.) in methanol (15 ml.) was added 0.52 N sodium hydroxide (3 ml.), and the solution was allowed to stand for 4 hr. at 40°C. After the addition of water (15 ml.), the solution was concentrated in vacuo, extracted with ether and acidified with 0.5 M citric acid in an ice-cold bath. After storing in a refrigerator, the crystals were collected by filtration, washed with water and dried. Recrystallization from acetone and ether did not raise the melting point. The yield was 736 mg. (79%); m. p. 154—158°C; $[\alpha]_D^{23}$ −39.4° (*c* 2, dimethylformamide).

Found: C, 62.09; H, 6.83; N, 10.20. Calcd. for $C_{49}H_{65}O_{12}N_7$: C, 62.34, H, 6.94; N, 10.39%.

***p*-Methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolylglycine *p*-Nitrophenyl Ester (X).**—To a solution of IX (472 mg., 0.5 mmol.) in pyridine (4 ml.) was added di-*p*-nitrophenyl sulfite[10] (648 mg., 2 mmol.), and the reaction mixture was allowed to stand for 24 hr. at room temperature. After evaporation of the solvent, the oily product was triturated in petroleum ether and washed repeatedly with a mixture of ether and petroleum ether (1 : 1) by decantation. When the reaction mixture had been washed completely, the washings did not give the yellow color of *p*-nitrophenol on addition of sodium hydroxide solution. The residual solid was filtered off, washed with a mixture of ether and petroleum ether (1 : 1) and dried. It weighed 509 mg. (95%). A *p*-nitrophenyl group estimation was carried out spectrophotometrically by measuring the optical density of the compound at 412 mμ. The purity of the product was estimated to be 101%.

**Cyclo-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyglycyl (XI).**—To X (788 mg., 0.74 mmol.), were added successively

* In addition to *E. coli* and *B. subtilis*, microbiological assays were also performed against *Proteus vulgaris*, *Staphylococcus aureus*, *Bacillus cereus*, *Mycobacterium avium*, *Mycobacterium avium* (Streptomycin resistant St.), *Mycobacterium SP 607*, *Mycobacterium semegmatis*, *Candida albicans*, *Saccharomyces cerevisiae* and *Piricularia oryzae* in bouillon agar medium. Peptide XII was inactive at 50 μg./ml. against any of microorganisms tested here. Gramicidin S inhibits the growth of *Proteus vulgaris* in 10 μg./ml., *Staphylococcus aureus* in 5 μg./ml. and *Mycobacterium semegmatis* in 10 μg./ml. in bouillon agar medium.

anisole (0.4 ml.) and trifluoroacetic acid (3 ml.) at a temperature below 0°C. The solution was evaporated in vacuo at 0°C, and the residue was triturated with ether (10 ml.). The crude hexapeptide *p*-nitrophenyl ester trifluoroacetate was collected in the cold room, washed with ether - petroleum ether mixture and dried in vacuo over phosphorous pentoxide.

The dried trifluoroacetate was dissolved in dimethylformamide (5 ml.) containing 0.1 ml. of glacial acetic acid, and the solution was added dropwise to pyridine (200 ml.) at 62°C over a period of 3 hr. under continuous stirring; stirring was then continued for an additional 2 hr. at the same temperature. After removal of the solvent, the residual oil was dissolved in a mixture of methanol (40 ml.) and water (10 ml.), the insoluble substance was removed by filtration, and the filtrate was passed successively through columns of Dowex 1 ($OH^-$ form) and Dowex 50 ($H^+$ form). The columns were eluted with the same solvent (150 ml.), the collected effluent was evaporated to dryness in vacuo. The residual amorphous product (455 mg.) was dissolved in a mixture of ethyl acetate (20 ml.) and methanol (5 ml.). After removal of insoluble substances by filtration, the solution was evaporated, and the residue was triturated with ethyl acetate (4 ml.) and ether (1 ml.). The product which solidified as needles was filtered off, and recrystallized by the same procedure mentioned above. The yield was 139 mg. (32%); m. p. 224—226°C; $[\alpha]_D^{16}$ −22.9°(*c* 1.95, dimethylformamide); $R_f$=0.66 on thin layer chromatography.[11]

Found: C, 62.28; H, 7.18; N, 12.66. Calcd. for $C_{40}H_{55}O_8N_7 \cdot 1/3H_2O$: C, 62.56; H, 7.30; N, 12.77%. Mol. wt. Found: 652, 598.[12] Calcd. 762.

The air-dried compound lost 0.75% of its weight after drying over phosphorus pentoxide for 3 hr. at 120°C, 2 mmHg. Calcd. for $1/3H_2O$: 0.78%.

**Cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolylglycyl Hydrochloride (XII).**—XI (38 mg., 0.05 mmol.), dissolved in methanol (2 ml.) containing 0.0455 N methanolic hydrogen chloride (1.22 ml.), was subjected to hydrogenolysis in the presence of palladium black. The solution after being filtered from the catalyst was evaporated to dryness in vacuo. The residue was dissolved in ethanol (0.2 ml.), then acetone (4 ml.) and ether (1 ml.) were added dropwise to the solution which was then stored overnight at 0°C. The crystals of XII which formed were filtered off, washed with acetone-ether (1 : 1) and dried in air. The yield was 24 mg. (72%); m. p. 283°C (decomp.); $[\alpha]_D^{24}$ −125° (*c* 1.01, 50% methanol, v/v); $R_f$=0.88 on paper,[11] 0.61 on silica gel.[11]

Found: C, 50.77; H, 7.70; N, 12.83. Calcd. for $C_{32}H_{50}N_7O_6Cl \cdot 5H_2O$: C, 50.95; H, 8.02; N, 12.89%.

The compound lost 10.4% of its weight after drying over phosphorus pentoxide for 3 hr. at 120°C, 2 mmHg. Calcd. for $5H_2O$: 11.9%.

XII, after hydrolysis with 6 N hydrochloric acid at 110°C for 16 hr., gave six distinctly separated spots when chromatographed on paper. $R_f$ values were 0.69, 0.65, 0.53, 0.38, 0.23 and 0.17. The $R_f$ values of authentic L-Leu, D-Phe, L-Val, L-Pro, Gly and L-Orn are 0.68, 0.63, 0.51, 0.36, 0.22 and 0.16, respectively.[11]

**Microbiological Assays.***—The microorganisms employed are shown in Table I. The minimum amount of compound necessary for complete inhibition of growth was determined by a dilution

11) Toyo Roshi No. 52 paper was used for paper chromatography, and Merck silica gel G for thin layer chromatography. Solvent system used in both cases was a mixture of *n*-butanol: acetic acid: pyridine: water, 4:1:1:2 in v/v.

12) Micro Rast method. The solvent used was hexahydro-*p*-amino benzoic acid lactam (G. Wendt, *Chem. Ber.*, 75, 425 (1962)).

method with bouillon agar medium and with synthetic medium. As shown in Table I, cyclohexapeptide XII exhibited no antibacterial activity against any of the microorganisms tested, even at high concentration of the test compound, whereas gramicidin S, a cyclic decapeptide, exhibited considerable activity against some of the microorganisms at comparable concentration.

## Summary

A cyclic hexapeptide, cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolylglycyl, was synthesized for the purpose of comparing its antibacterial action, if any, with the cyclopeptide antibiotics, such as gramicidin S, with which it shares several common structural features.

Synthesis was achieved by condensation of *p*-methoxybenzyloxycarbonyl-L-valyl-*δ*-benzyloxycarbonyl-L-ornithine azide with L-leucyl-D-phenylalanyl-L-prolylglycine ethyl ester, followed by treatment of the resulting diacyl hexapeptide ester with alkali to remove the ethyl ester group. The diacyl hexapeptide so derived was converted to the *p*-nitrophenyl ester by the action of di-*p*-nitrophenyl sulfite, and after removal of the *p*-methoxybenzyloxycarbonyl group with trifluoroactetic acid, the hexapeptide *p*-nitrophenyl ester was transformed to the cyclic benzyloxycarbonyl-substituted hexapeptide by treatment with a large excess of pyridine. The cyclic benzyloxycarbonyl-substituted peptide was hydrogenated in the presence of palladium black to yield the desired cyclic hexapeptide hydrochloride.

The effects of the synthesized cyclic peptide on bacterial growth were examined. No antibacterial activities were observed against the microorganisms utilized here.

# Asymmetric Hydrogenation with Modified Raney Nickel. V. Studies on the Modified Hydrogenation Catalyst. VI

By Yoshiharu IZUMI, Susumu TATSUMI, Masami IMAIDA, Yoshio FUKUDA and Shiro AKABORI

(Received December 24, 1964)

In previous papers of this series, the asymmetric hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate using Raney nickel catalysts modified with various optically active compounds, such as amino acids and hydroxy acids, has been reported.[1-4]

In the present work, the asymmetric activity of Raney nickel catalysts modified with (+)-2-methylglutamic acid* or (+)-2-benzylglutamic acid* was tested to study the role of a substituent at the asymmetric $\alpha$-carbon atom in an $\alpha$-amino acid. The asymmetric activities of these catalysts were compared with that of the catalyst modified with L-glutamic acid.

2-Methyl- and 2-benzylglutamic acid are characterized by the lack of a hydrogen atom on the asymmetric $\alpha$-carbon atom, and thus have the structure, $HOOCCH_2CH_2(R)C(NH_2)$-COOH, where R is a methyl or a benzyl group. L-Glutamic acid however has an $\alpha$-hydrogen atom on the $\alpha$-carbon. It is interesting to find out whether a methyl or a benzyl group on the asymmetric $\alpha$-carbon in an amino acid takes part in the mechanism of the asymmetric hydrogenation.

## Results

**The Effect of the pH of the Modifying Solution.** — Measurements were made of the asymmetric activities of the catalysts modified at 0°C with solutions of (+)-2-methylglutamic acid, (+)-2-benzylglutamic acid or L-glutamic acid,[1)] the pH's of which had been adjusted to specified values. The results are shown in Fig. 1.

As shown in Fig. 1, the catalyst modified with (+)-2-methylglutamic acid produced

4) Presented at the 3rd International Congress on Catalysis, Amsterdam, July, 1964.
* The preparation of this amino acid was reported recently by the present authors, This Bulletin, in press.

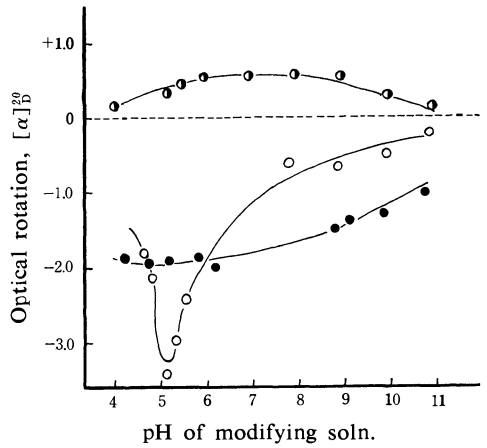

Fig. 1. Effect of modifying pH (modifying temp. at 0°C).
-○- L-Glutamic acid
-●- (+)-2-Methylglutamic acid
-◑- (+)-2-Benzylglutamic acid

levorotatory methyl 3-hydroxybutyrate and that modified with (+)-2-benzylglutamic acid produced the dextrorotatory form. With these amino acids, the asymmetric activities of both modifications of the catalyst were less influenced by the pH of the modifying solution than that of the catalyst modified with L-glutamic acid, and the optimum pH range for asymmetric activity was pH 5—8. This pH range approximately corresponds to the pH jumping region of the neutralization curves of these *α-C*-substituted glutamic acids. Thus, the two activity curves were alike in character except for the direction of their optical rotation. However, the asymmetric activity of the catalyst modified with L-glutamic acid was much influenced by the pH of the modifying solution. The greatest asymmetric activity was observed at pH 5.1 and there was considerable diminution in activity at both higher and lower pH values.

The effects of the pH values of modifying solutions at 100°C on the asymmetric activities of the modified catalysts are shown in Fig. 2.

Optimum asymmetric activities were observed when catalysts were modified with solutions of the three amino acids at pH 7—9.5. On modifications with (+)-2-methyl- and (+)-2-benzylglutamic acid, the asymmetric activity curves showed tendencies similar to those shown on modification at 0°C. In the case of modification with L-glutamic acid, however, the dextrorotatory product was obtained below pH 5.4 or above pH 11 and the levorotatory product in the intermediate range.

**The Effect of the Modifying Temperature.**— The effect of the temperature of the modifying solution was studied at pH 5.2; the results are shown in Fig. 3.

As shown in Fig. 3, the asymmetric activity of the catalyst modified with (+)-2-methylglutamic acid was greater than that of the catalyst modified with (+)-2-benzylglutamic acid and both activities increased with elevation of the modifying temperature. On modification with L-glutamic acid, however, the activity was characteristically different from those obtained on modification with the other two amino acids; the highest activity was obtained by modification at 0°C and the asymmetric

activity decreased at higher temperatures. If the catalyst was treated with the same modifying solution at temperatures higher than 80°C, the hydrogenation products showed reverse optical rotations.

## Discussion

Two kinds of asymmetric hydrogenation catalyst are obtained by modification with L-glutamic acid. One has the asymmetric capacity to hydrogenate methyl acetoacetate predominantly to levorotatory methyl 3-hydroxybutyrate and the other has the capacity to produce the dextrorotatory product. On the other hand, only one asymmetric catalyst is obtained by modification with (+)-2-methylglutamic acid or (+)-2-benzylglutamic acid under a variety of modifying conditions as shown in Figs. 1, 2 and 3.

These results show that on modification with L-glutamic acid, at least two types of asymmetric center are produced on the surface of the modified catalyst; but only one type is formed, or this type is in excess on modification with $\alpha$-*C*-substituted glutamic acid under all modifying conditions.

The difference between glutamic acid and $\alpha$-*C*-substituted glutamic acid is caused by the substituent on the asymmetric $\alpha$-carbon atom. The steric hindrance of the substituent on the $\alpha$-carbon atom regulates the adsorption of $\alpha$-*C*-substituted glutamic acid on Raney nickel catalyst and permits the formation of only one or mainly one type of asymmetric center. The relationship between the bulk of the substituent on the $\alpha$-carbon atom of the modifying reagent and the optical direction of the asymmetric activity of the modified catalyst will be discussed after the absolute configuration of (+)-2-methylglutamic acid and (+)-2-benzylglutamic acid have been confirmed.

## Experimental

The preparation and modification of the Raney nickel catalyst, the hydrogenation of methyl acetoacetate and the measurement of the asymmetric activity of the catalyst were performed as described in a previous paper.[1]

## Summary

1) The asymmetric activities of Raney nickel catalysts modified with (+)-2-methylglutamic acid or (+)-2-benzylglutamic acid have been formed to be quite different from that of the catalyst modified with L-glutamic acid.

2) Levorotatory methyl 3-hydroxybutyrate is obtained by the catalyst modified with (+)-2-methylglutamic acid, and the dextrorotatory product by the catalyst modified with (+)-2-benzylglutamic acid. With the catalyst modified with L-glutamic acid, however, the direction of optical rotation of the hydrogenation product is much influenced by the pH and by the temperature of the modifying solution.

# NOTES

## The Synthesis of New Silicon-functional Silanols*

By Shigemi KOHAMA

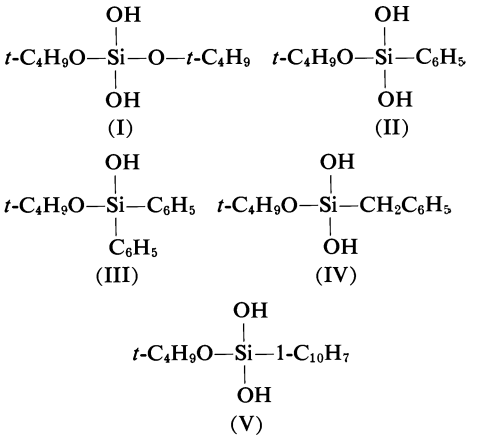
(Received March 4, 1964)

Some years ago a new method[1] for the preparation of diphenylsilanediol was applied to the synthesis of various organosilanols[2] and named as the "Silanolate method."[3] This procedure involves neutralization of sodium silanolate in an aqueous solution with hydrochloric acid to give silanol. Now it has been found that the above method can be extended to the preparation of silicon-functional silanols possessing both hydroxyl and alkoxyl groups on the silicon atom. The present paper describes the synthesis of such new silanols and their properties, reactions, and infrared absorptions. The synthetic route attempted to prepare various alkoxysilanols is indicated in the following scheme:

$$R_nSiCl_{4-n} + mR'OH + mC_5H_5N \rightarrow R_nSi(OR')_mCl_{4-n-m} + mC_5H_5N\cdot HCl$$

$$R_nSi(OR')_mCl_{4-n-m} + \text{excess } 5\%\ NaOH_{aq} \rightarrow R_nSi(OR')_m(ONa)_{4-n-m}$$

$$R_nSi(OR')_m(ONa)_{4-n-m} + (4-n-m)HCl_{aq} \rightarrow R_nSi(OR')_m(OH)_{4-n-m}$$



R: $CH_3$, $i$-$C_3H_7$, $C_6H_{11}$, $CH_2CH_2C_6H_5$, $CH_2C_6H_5$, $C_6H_5$, 1-$C_{10}H_7$

R': $CH_3$, $C_2H_5$, $n$-$C_3H_7$, $i$-$C_3H_7$, $n$-$C_4H_9$, $t$-$C_4H_9$, $C_6H_{11}$, $C_6H_5$, $CH_2CH_2NH_2$

$n$: 0—2, $m$: 1—2

Thus, five new silicon-functional silanols containing a $t$-butoxyl group were obtained, these being di-$t$-butoxysilanediol (I), phenyl-$t$-butoxysilanediol (II), diphenyl-$t$-butoxysilanol (III), benzyl-$t$-butoxysilanediol (IV) and 1-naphthyl-$t$-butoxysilanediol (V).

I, in particular, derived from tetrachlorosilane is a unique silanol containing no silicon-bond; other similar organoalkoxysilanols could not be so obtained. In these cases, the corresponding siloxanes and alcohols were afforded by further condensation and hydrolysis. Grubb[4] suggested that base-catalyzed silanol condensation-reactions are sensitive to steric factors. The fact that only alkoxysilanols surrounded with bulky groups were isolated might support this suggestion. In spite of the fact that di-$t$-butoxysilanediol (I) was isolated in a good yield, isolation of di-$t$-butoxyorganosilanols was not successful, because the reaction products were all liquids and decomposed during distillation even at low pressure. Details of the synthesis of $t$-butoxysilanols, and their analyses, melting points, and crystal forms are shown in Table I.

The infrared spectra for all of the silanols obtained show a band at 1385—1395 $cm^{-1}$ and a strong one at 1365 $cm^{-1}$; these are assigned to the $t$-butyl group.[5] Evidence for the presence of an OH group is provided by the existence of a band at 3350—3400 $cm^{-1}$, and for the Si-O grouping by a band at 1000—1100 $cm^{-1}$. In general, almost all organosilanols in the solid state have an OH absorption band

near 3250 $cm^{-1}$.[1,2,6-8] It is of interest that *t*-butoxysilanols show OH bands at frequences higher by about 100 $cm^{-1}$ than those for ordinary organosilanols. The OH stretching absorption bands of *t*-butoxysilanols are listed in Table II, together with those of various organosilanols for comparison. The butoxysilanols obtained were stable in a desiccator but, on standing in the air, turned greasy.

Treatment of these silanols with dilute sodium hydroxide solution gave a clear aqueous solution, from which the starting materials were recovered, together with a small quantity of oily matter, by neutralization. Diphenyl-*t*-butoxysilanol (III) in 90% aqueous acetone when hydrolyzed with a drop of aqueous hydrochloric acid at room temperature gave quantitatively diphenylsilanediol, in spite of the possibility of a silanol condensation taking place also.

$$(C_6H_5)_2Si(O\text{-}t\text{-}C_4H_9)OH \xrightarrow{H^+} (C_6H_5)_2Si(OH)_2 + t\text{-}C_4H_9OH$$

Under the same conditions, phenyl-*t*-butoxysilanediol (II) was converted into an oil which was soluble in almost all organic solvents but insoluble in dilute sodium hydroxide solution, and which exhibited a weak infrared band at 1365 $cm^{-1}$. Such a behavior of II towards acids is in accord with those of the previously reported silanols.[2,3]

## Experimental

**Materials.** — Methyltrichlorosilane, phenyltrichlorosilane, diphenyldichlorosilane and tetrachlorosilane were all commercial products and were purified by redistillation, b. p. 65—66°C, 200—202°C, 160°C/10 mmHg, 57—58°C, respectively. Isopropyltrichlorosilane, cyclohexyltrichlorosilane, benzyltrichlorosilane, 2-phenylethyltrichlorosilane and 1-naphthyltrichlorosilane were prepared by the usual methods ; b. p. 118—200°C, 195—199°C, 213—215°C 239—240°C and 181°C/30 mmHg, respectively. All alcohols used were purified by the ordinary way and redistilled before use.

**General Procedure for the Synthesis of *t*-Butoxysilanols.** — An organochlorosilane (about 10 g.) and 50 ml. of dry ether were placed in a 300 ml. three-necked flask. A solution of the appropriate amounts (equivalent in moles to chlorosilanes) of *t*-butanol and pyridine in 20 ml. of dry ether was added dropwise to the stirred contents

at room temperature over a period of 10 min. After the addition, the solution was warmed slightly to complete the reaction. Then the mixture was cooled in an ice bath and filtered from salts; the filter cake on a glass filter was washed with dry ether. The combined filtrate was poured cautiously with stirring into a mixture of excess 5% aqueous sodium hydroxide solution, ice and ether. The ether layer was separated and the aqueous layer was repeatedly extracted with small portions of ether totaling 50 ml. To the aqueous portion was added a small amount of ice so as to avoid further condensation of the silanol. Then the alkaline mixture was neutralized with aqueous hydrochloric acid (ca. 6%) using Brom-thymol Blue as an indicator. The solution was extracted with ether and the ethereal solution was dried over sodium sulfate. After the solvent had been removed in vacuo, the crude silanols obtained were recrystallized from hot benzene. Since diphenyl-*t*-butoxysilanol (III) is very soluble in petroleum ether, the extraction of III is conveniently carried out using this solvent. Analytical results and yields for the above *t*-butoxysilanols are given in Table I. All attempts to prepare other organoalkoxysilanols gave only tacky oils, which were insoluble in 5% aqueous sodium hydroxide solution and gradually changed into resins. These oils were assumed to be the corresponding siloxanes, from their silicon contents and infrared spectra.

**The Hydrolysis of III.**—Into a solution of III (5 g.) in 30 ml. of 90% aqueous acetone, a drop of concentrated hydrochloric acid (ca. 12 N) was added with stirring at room temperature; the mixture was further stirred for 10 min. and then allowed to stand for 1 hr. The precipitated crystals were filtered off. After the mother liquor had been repeatedly treated in the same manner as above, the aqueous acetone solution was evaporated to dryness. Recrystallization of the combined crystals from hot benzene afforded colorless needles (3.9 g.) melting at 165—167°C. This substance was identified as diphenylsilanediol by comparison of its infrared spectrum with that of an authentic sample[1] and by mixed melting point determination.

**The Condensation of II with Hydrochloric Acid.**—In the same treatment as described above, II (5 g.) gave only an oil. By removal of the solvent in vacuo, the oil was collected (3.9 g.). This was insoluble in 5% sodium hydroxide aqueous solution and, by heating in an electric heater at 150°C, 5 hr., gave a resin melting at 130°C.

**Absorption Spectra.** — Spectral measurements (Nujol mull) were performed with a Reiz infrared spectrophotometer at room temperature.

**Analysis.** — Silicon contents were determined gravimetrically by a simple digestion method,[9] and for active hydrogen the Zerewitinoff method[10] was used.

# Double Resonance Proton Spectra of Amides

By Hirotake KAMEI

(Received October 27, 1964)

Several groups of workers have used a double resonance technique in NMR spectroscopy to eliminate the effect of the $^{14}N$ nucleus, which causes quadrupole broadening of the resonance signals from amide protons.[1,2] The structure of the amine proton spectrum, however, has not been completely resolved and a full analysis of the spectrum could not be performed. This presumably can be attributed to incomplete decoupling of the $^{14}N$ nucleus from the protons. The completely decoupled spectra of formamide (pure, in water, and in acetone solution), acetamide (in water solution), and *N*-methyl acetamide, have now been observed and are analyzed in this work.

Proton resonance spectra were recorded at 40 Mc./s. using a JEOL JNM-3 spectrometer equipped with a double resonance system.[3] The groups in the various amides are labeled as follows:

The decoupled spectra of formamide in different conditions are shown in Fig. 1. The signal due to the formyl proton, $H_{(1)}$, appears as a quartet at low field. In the spectrum of the neat liquid, the signal due to the amine protons, $H_{(2)}$ and $H_{(3)}$, contains six lines, whereas with the same sample in aqueous solution, the $H_{(3)}$ signal shifts to lower field and appears as a triplet, as shown in Fig. 1(b). In the case of the pure liquid, therefore, the $H_{(2)}$ signal

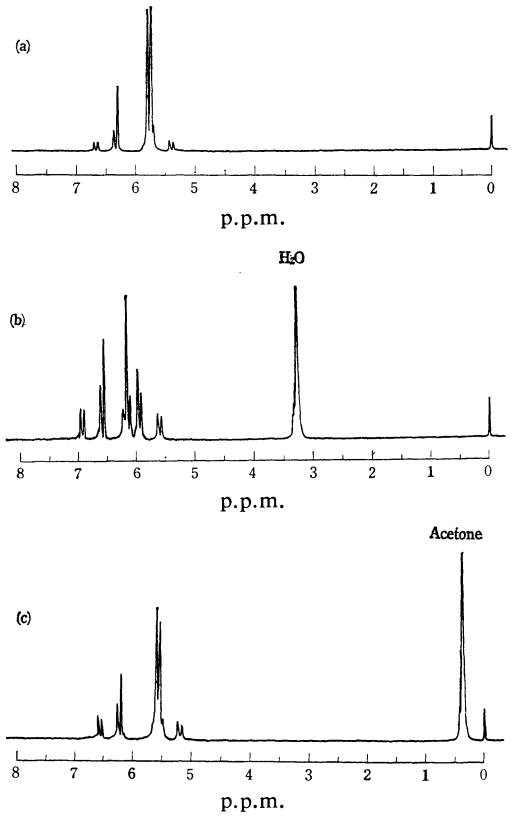

Fig. 1. Proton resonance spectra of $^{14}N$ decoupled formamide measured relative to cyclo hexane as external reference at 40 Mc./s. (a) pure liquid, (b) 18 mol.% in water, (c) 48 mol.% in acetone. The solvent resonances were recorded at lower amplifications.

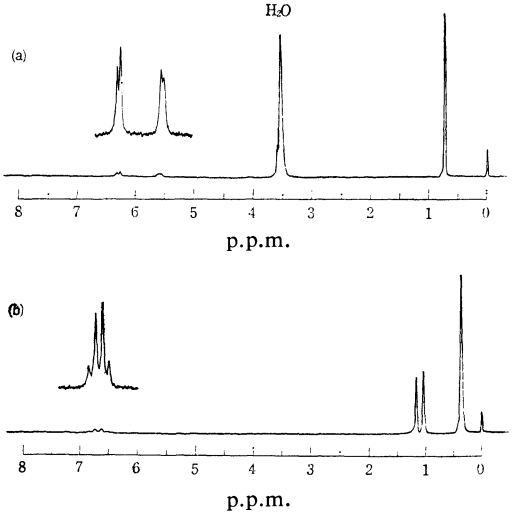

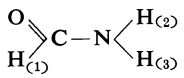

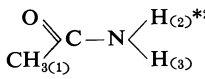

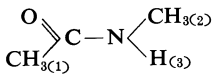

Fig. 2. Proton resonance spectra of $^{14}N$ decoupled (a) acetamide in 13 mol.% aqueous solution relative to external cyclohexane reference, and (b) *N*-methyl acetamide relative to internal cyclohexane reference at 40 Mc./s. The water resonance was recorded at a lower gain.

TABLE I. CHEMICAL SHIFTS (in p.p.m., relative to cyclohexane)*1 AND COUPLING CONSTANTS (in c./s.) OF SOME AMIDES

| |  | 18 mol.% $HCONH_2$ in water | 48 mol.% $HCONH_2$ in acetone |  |  |
|---|---|---|---|---|---|
| $\delta_1$ | −6.71 | −6.63 | −6.70 | −0.61 | −0.55*3 |
| $\delta_2$ | −5.78 | −5.70 | −5.67 | −5.36 | −1.29*3 |
| $\delta_3$ | −6.01 | −6.05 | −5.90 | −6.14 | −6.74*3 |
| $J_{12}$ | 13.4 | 13.4 | 13.8 | | |
| $J_{13}$ | 2.2 | 2.1 | 2.0 | | |
| $J_{23}$ | 2.4 | 2.2 | 2.5 | 2.4 | 4.7 |

*1 Corrected for bulk diamagnetic susceptibility, $\chi_v$. The values of $\chi_v(\times 10^6)$ for formamide, acetamide, water, acetone, and cyclohexane are taken to be −0.551, −0.618, −0.721, −0.460, and −0.631, respectively (Fujiwara et al., "Kōbunkainō Kakujikikyōmei, Kagaku eno Ōyō," Maruzen, Tokyo (1962); Hodgman et al., "Handbook of Chemistry and Physics," The Chemical Rubber Publishing, Cleveland (1963)).

*2 In 13 mol.% aqueous solution.

*3 Relative to cyclohexane as internal reference.

apparently consists of a quartet whose line at lowest field overlaps the highest field component of the $H_{(3)}$ triplet. The assignment of the lines is indicated in Fig. 1. Analysis of the spectra has been carried out on the basis of an ABX system and the estimated values of the chemical shifts and the coupling constants are shown in Table I. The values of these NMR parameters are in good agreement with those obtained for $^{15}N$-substituted formamide.[4] The variation in the chemical shifts and the coupling constants which occurs with change of solvent, may arise from the different natures of the hydrogen bonding interactions in the three systems.

Figure 2(a) shows the spectrum of acetamide in 13 mol.% aqueous solution, and Fig. 2(b) shows the spectrum of *N*-methyl acetamide at 30°C. The signal of the amine protons of acetamide appears as an AB type quartet which must be due to nonequivalence of the two protons, $H_{(2)}$ and $H_{(3)}$. By analogy with formamide the low-field doublet is assigned to the proton, $H_{(3)}$, which is in the cis position relative to the methyl group. Broadening of the line width may be caused by spin coupling with the protons of the methyl group. The amine proton of *N*-methyl acetamide appears as a quartet due to spin coupling with the *N*-methyl protons. The results of the analysis of the spectra are shown in Table I. The internal chemical shift between $R_{(1)}$ and $R_{(3)}$, $\delta_{13}$, in *N*-methyl acetamide is 0.66 p.p.m. greater than that observed in the case of acetamide. Substitution of an *N*-methyl group in formamide was observed to cause $\delta_{13}$ to decrease by 0.48 p.p.m.

The $^{14}N$ resonance frequency for the amides considered above has been found to be 2889500 ±25 c./s.

# Ultraviolet Spectrophotometric Determination of Lead using Thiomalic Acid*

By Yasuhisa HAYASHI, Shigeo HARA and Isao MURAKI

(Received November 9, 1964)

As has been reported,[1] thiomalic acid (henceforth abbreviated TMA) and lead form a stable, colorless complex in acidic and alkaline solutions. As can be seen from the absorption spectra of lead-TMA solutions at various pH values ranging from 5.8 to 10.5 (Fig. 1), the lead-TMA complex has a maximum absorption at 265 m$\mu$ in acidic, and at 305 m$\mu$ in alkaline solutions. As the absorption spectrum of a TMA solution is not affected by pH change,[1] the wavelength of 305 m$\mu$ is adopted for the spectrophotometric determination of small amounts of lead. Here are presented conditions for the ultraviolet spectrophotometric determination of lead; the composition of the complex is also discussed.

* Presented at the 13th Annual Meeting of the Japan Society for Analytical Chemistry, Sendai, Sept,, 1964.

1) I. Muraki, S. Hara and Y. Hayashi, *Japan Analyst*, in press.

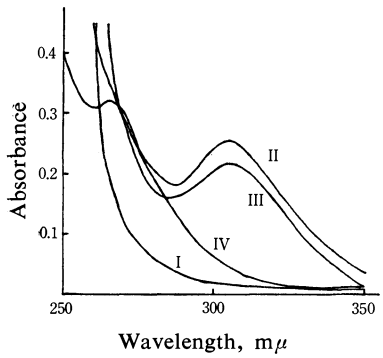

Fig. 1. Absorption spectra of lead-TMA solutions at various pH values.
Curve I 0.1% TMA soln. only, pH 10.5
Curve II Pb-TMA soln., 10 p.p.m. Pb, pH 10.5
Curve III Pb-TMA soln., 10 p.p.m. Pb, pH 9.2
Curve IV Pb-TMA soln., 10 p.p.m. Pb, pH 5.8
Buffer: 0.1 M $NaOH-Na_2B_4O_7$ system., 20 ml./100 ml.
Reference: Water Temp.: 18°C

Standard lead solution was prepared as follows: 1.0000 g. of 99.999% pure lead was dissolved in nitric acid, and the solution was evaporated to dryness; the residue was dissolved in water and diluted to 1000 ml. with water. An aliquot of this solution was then diluted with water to prepare a standard solution containing 100 p.p.m. of lead. Other materials and apparatus were the same as reported in the preceeding paper.[1] The procedure for making the calibration curve is as follows: Pipet an aliquot of the standard lead solution into a 100 ml. measuring flask, and add 20 ml. of 0.1% TMA solution and 20 ml. of buffer solution and dilute to the mark with water and then measure the absorbance of the solution at 305 mμ against water.

To obtain optimum conditions for the determination of lead, various factors were studied: In order to find an optimum pH range, the absorbances at 305 mμ were plotted against pH values. Maximum absorption was found in the pH range of 10.0—11.0. The absorbances of two series of solutions containing 5.0 and 10.0 p.p.m. of lead, respectively, and various amounts of the reagent were measured. It was found that the optimum amount of TMA was 15.0—25.0 ml. of a 0.1% solution in 100 ml.; a larger excess of TMA caused a slight increase in absorbance. The absorbance of the solutions of lead-TMA complex showed no appreciable change within about 20 hr. In order to confirm the mole ratio of the lead-TMA complex, the continuous variation method and the mole ratio method were used. In the first method,

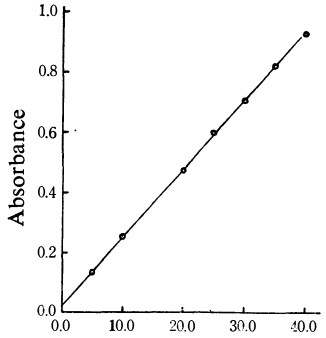

Fig. 2. Calibration curve.
TMA: 0.1% soln. 20 ml./100 ml.
Buffer: 0.1 M $NaOH-Na_2B_4O_7$ system, 20 ml./100 ml., pH 10.5
Wavelength: 305 mμ.
Reference: Water Temp.: 19°C

Table I. Effect of diverse ions added to the 10.0 p.p.m. solutions of lead

| Ion | Added p.p.m. | Added as | Absorbance at 305 mμ |
|---|---|---|---|
| — | — | — | 0.253 |
| Cd(II) | 50 | Sulfate | 0.247 |
| Cd(II) | 25 | Sulfate | 0.254 |
| Zn(II) | 30 | Sulfate | 0.245 |
| Zn(II) | 15 | Sulfate | 0.252 |
| Al(III) | 50 | Chloride | 0.252 |
| As(III) | 20 | Chloride | 0.245 |
| As(III) | 10 | Chloride | 0.252 |
| Sb(III) | 30 | Chloride | 0.485 |
| Sn(IV) | 20 | Chloride | Ppt. |
| Cu(II) | 20 | Sulfate | 1.08 |
| Cu(II) | 5 | Sulfate | 0.266 |
| Cu(II) | 2 | Sulfate | 0.254 |
| NaCl | 10 ml. | 1 M Soln. | 0.252 |
| $Na_2SO_4$ | 10 ml. | 1 M Soln. | 0.332 |
| $NH_4Cl$ | 10 ml. | 1 M Soln. | 0.250 |
| $NaNO_3$ | 10 ml. | 1 M Soln. | 0.252 |

absorbances of a series of solutions containing various amounts of $5\times10^{-3}$ M TMA were measured against the reagent blank. When the mole ratio of lead to TMA was 1 to 3, maximum absorbance resulted. The results of the second method also confirmed that the mole ratio corresponds to 1 to 3. The calibration curve (Fig. 2) shows that Beer's law is obeyed over the concentration range from 0.5 to 40.0 p.p.m. of lead. The molar absorptivity of the method is $5.2\times10^3$, and the sensitivity is 0.04 μg. Pb/cm$^2$ for $\log I_0/I=0.001$. As is shown in Table I, it is found that colored ions such as copper(II), cobalt(II), nickel(II), iron(II, III), etc., and metal ions forming precipitates in alkaline solutions such as tin interfere. The proposed method is much inferior to the

dithizone method[2] in sensitivity, but the procedure is simpler. As the procedure is operated in alkaline solution (pH 10.5), interferences from diverse ions must be considered.

# Concerning the Structure of Trimethyltin Fluoride

By Kiyoshi YASUDA, Yoshikane KAWASAKI, Nobutami KASAI and Toshio TANAKA

(Received November 12, 1964)

Recently there has been much interest in the structure of organotin compounds. Among the trimethyltin halides, trimethyltin fluoride is markedly different in physical and chemical properties from the remaining halides; the fluoride has a high melting point (>360°C) and does not sublime, while the other halides melt and sublime at lower temperatures. The former is soluble in hot alcohol, slightly soluble in water, and almost insoluble in non-polar organic solvents, while the latter are soluble in common organic solvents.

The structures of trimethyltin chloride, bromide, and iodide have been determined[1] by electron diffraction to be nearly tetrahedral in the vapor state, but no structural determination had been made on the fluoride until recently. In 1960, one of the present authors reported[2] on the basis of infrared spectral evidence that the fluoride contains a planar trimethyltin group. However, the X-ray analysis by Clark et al.[3] showed that the electron-density distribution could be equally well interpreted either in terms of a planar or pyramidal trimethyltin group. To clear up this ambiguity concerning the structure of the trimethyltin group and the nature of the bond represented by Clark et al.[3] as Sn–F···Sn (the bond distance; Sn–F 2.1 Å, Sn···F 2.2—2.6 Å) in this compound, it is necessary to consider the most probable structure of this compound with reference to some findings from the infrared and Raman spectra, as well as a few additional X-ray data obtained from this compound and from related trimethyltin compounds which have been studied in our laboratory.

In the infrared spectrum of this compound only one band* is observed at 556 $cm^{-1}$, which is assigned to the Sn–C stretching vibration, and we can assume the following two possible structures for the trimethyltin group. One is the planar equilateral triangular structure with the tin atom at the center and three carbon atoms at the corners, which gives infrared active degenerate and inactive symmetric stretching vibrations associated with the Sn–C bonds. Another possible structure is a pyramidal one. If we assume a point group of $C_{3v}$ for this molecule, this structure would give two Sn–C stretching vibrations of $A_1$ and E species in the infrared spectrum according to the selection rule. Our infrared studies seem to rule out this structure, but it is also possible** that the frequency associated with the Sn–F stretching vibration might be close enough to that of the Sn–C symmetric stretching vibration to cause coupling. We may then expect that one would be higher and the other lower than either of the original ones by this coupling; one of these two bands could fall near 550 $cm^{-1}$, overlapping with the Sn–C stretching vibration of E species. However, the Raman spectrum of solid trimethyltin fluoride showed that the assumed coupling does not take place, and hence the second structure is not probable, since two bands which are associated with the Sn–C stretching vibrations.

* Although it is reported in Ref. 3. that another band was observed at 515 $cm^{-1}$ in the infrared spectrum of very concentrated Nujol mulls of trimethyltin fluoride, no band was observed in this region in our repeated experiments.

** This was tentatively suggested by Dr. Ichiro Nakagawa of the The Universiuy of Tokyo.

at 517 $cm^{-1}$ (s) and 556 $cm^{-1}$ (w) were observed in the Raman spectrum.

Clark et al.[3] reported that the structure of this compound has trimethyltin groups and fluorine atoms arranged alternately in a chain-like manner along the a axis, and they offered two interpretations of the three dimensional electron-density distribution. One is that the non-planar trimethyltin group is ordered in any chain. The bond angles calculated by us from the electron-density distribution map given by them are about 111° and 117° for $C_2$-Sn-$C_3$ and $C_1$-Sn-$C_2$, respectively. This distortion of the trimethyltin group from the normally trigonal coplanar structure should give a fairly intense infrared absorption band due to the Sn-C symmetric stretching vibration. Their second structure, in which the planar trimethyltin groups are tilted alternately with respect to the a axis, should give a repeat distance of twice the cell length. Though we repeated their X-ray diffraction measurements with a larger crystal, we could not observe any reflection which corresponds to twice their reported cell length along the needle axis even with long exposures, and this suggests that their second structure also is not suitable.

If we assume that the space group given by Clark et al. is reasonable, the peculiarities in the electron-density distribution can be interpreted in terms of disorder in the crystal structure. Clark et al. proposed that the chains could be disordered with respect to each other. This kind of disorder was observed in trimethyltin hydroxide[4] and formate[5], which are now being studied in our laboratory. Besides, in the hydroxide, we found that the trimethyltin groups are disordered also in a chain, forming a helix-like structure. A structure having random chains has been found also in polyvinyl alcohol.[6] In the structure of trimethyltin fluoride, the disorder in one chain should also be taken into account.

Determination of the precise structure of any compound containing a heavy metal atom, such as tin, by X-ray diffraction is usually difficult, for there is often some ambiguity in the position of the light atoms. In the analysis of the fluoride, Clark et al. were not able to use the ($h$00) reflections, and the determination of the positions of carbon and fluorine atoms seems to be difficult, especially in the $x$-coordinates. We would like to propose a reasonable structure which is consistent with

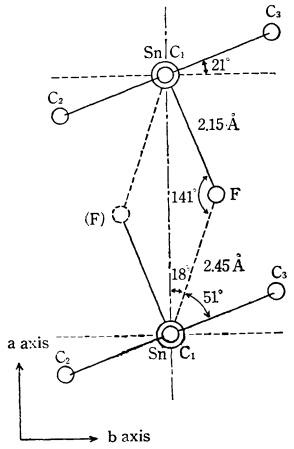

Fig. 1. A projection of the probable crystal structure of trimethyltin fluoride down to the (001) plane.
F and (F) indicates the two possible positions of fluorine atom of the same potential energy.

the results of the X-ray diffraction study by Clark et al., and takes into account the results from infrared and Raman spectra. We assume that the trimethyltin group forms a planar equilateral triangular structure and is inclined to the plane perpendicular to the a axis, and that one of the Sn-C bonds, Sn-$C_1$, lies along the c axis, and further that the trimethyltin groups and the fluorine atoms are arranged alternately along the a axis as shown in Fig. 1. Concerning the Sn-F bond, we observed a broad strong band at 350 $cm^{-1}$ in the infrared spectrum and assign this to the Sn-F stretching vibration. We could not observe any Raman line due to the Sn-F symmetric stretching in the region down to about 150 $cm^{-1}$, where the Raman lines due to the $SnC_3$ deformations are usually observed. It can be concluded, therefore, that one of the two Sn-F bonds is fairly strong and the other is weak, and this is consistent with the results of the X-ray study by Clark et al. The angle formed by the covalent Sn-F bond and the Sn-$C_1$ bond is shown to be almost 90° by the electron-density distribution map of Clark et al., but the angle between the covalent Sn-F bond and the plane of trimethyltin group can not be determined from their work. Taking for this angle a value of 90° and an Sn-F bond distance of 2.15 Å, the calculated distance between the fluorine atom and the carbon atoms in other chains is larger than the sum of the van der Waals radii of the atoms; this is consistent with the compound's crystal habit, i. e., bundles of very fine needles. As the repeat distance along the a axis has been determined[3] to be

5) N. Kasai, H. Matsumoto, N. Tanaka and R. Okawara, presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, 1964.
6) J. Kakinoki, *The Annual Reports of the Textile Research Institute of Osaka Univ.*, 5, 19 (1950) (in Japanese).

4.32 Å, the planes of the trimethyltin groups should be parallel to each other in the chain. The weak Sn···F bond is in the opposite direction to the strong Sn-F bond with respect to the plane, and the angle between the weak Sn···F bond and the plane of trimethyltin is calculated to be about 51°, so that the F-Sn···F bond is not linear and should have a bond angle of about 141°. This is consistent with the results of Clark et al. that the integrated electron-density of the Sn peak in the a axis projection was 50.08 electrons, indicating that the fluorine atom is not situated on the axis connecting the tin atoms, which is parallel to the a axis. This value for the Sn-F···Sn angle is reasonable if we take into account the fact that in solid hydrogen fluoride the angle H···F-H is about 134° [7] and that this bond angle is explained[8] in terms of participation of the lone pair orbital of the fluorine atom. This distorted bipyramidal configuration around the tin atom could be explained by assuming that the d-orbitals are involved in the hybridization of the orbitals in the tin atom; this is also expected to be the case in trimethyltin hydroxide. In the structure of trimethyltin fluoride proposed above, we can expect two positions of minimum potential energy for the fluorine atom, F and (F) given in Fig. 1. The potential barrier between them is considered to be small, and this can explain the anomaly in the electron-density distribution of the fluorine atom.

## Experimental

The infrared spectrum of trimethyltin fluoride as a Nujol mull was recorded in the 4000—270 $cm^{-1}$ region on a Perkin-Elmer double beam spectrometer model 221 equipped with NaCl or KBr optics, and on a Koken double beam spectrometer model DS-401 G equipped with a grating and CsBr optics. The Raman spectrum for the solid state was recorded on a Nippon Yuki-gosei Raman Spectrograph.

The needle crystal with average width 0.3 mm., used for the $CuK_\alpha$ oscillation photograph, was obtained by recrystallization of trimethyltin fluoride from ethyl alcohol.

## Summary

The structure and the nature of the bonds in trimethyltin fluoride are discussed on the basis of the infrared and the Raman spectra with reference to the results of the X-ray diffraction study by Clark et al. and a few additional X-ray data obtained on the fluoride and related trimethyltin compounds. The most reasonable structure is one in which the planar trimethyltin group is bridged by the fluorine atom forming a non-linear unsymmetrical Sn-F···Sn bond. The distorted bipyramidal configuration around the tin atom can be explained in terms of involvement of the d-orbitals of the tin atom in the bonding.

# Determination of the Purity of 2, 2-Diphenyl-1-picrylhydrazyl and 2, 2-Di-(*p*-tolyl)-1-picrylhydrazyl by Iodometry

By Shigeo TAZUKE, Koji UNO and Seizo OKAMURA

(Received November 16, 1964)

2, 2-Diphenyl-1-picrylhydrazyl (DPPH) has been often employed as a radical scavenger and as a standard substance for ESR measurements. In each case the purity of the hydrazyl free radicals was assumed to be 100% and a satisfactory method of determining the purity was not established.

Elemental analysis may be a measure of purity, but it is a rather insensitive way to determine the purity. It has been reported that DPPH reacts quantitatively with hydroquinone to yield 1, 1-diphenyl-2-picrylhydrazine and benzoquinone,[1] but no experimental results were presented. The extent of conversion of various hydrazines to the corresponding hydrazyl free radicals, has been estimated by the reaction of the hydrazyl free radicals with ascorbic acid.[2]

TABLE I. IODOMETRIC TITRATION OF DPPH AND DTPH

| Sample | Weight | 1/100 N $Na_2S_2O_3$ ($f$=0.9908) calcd. volume* ml. | Volume consumed ml. | $\frac{\text{Volume consumed}}{\text{Calcd. volume}} \times 100$ | |
|---|---|---|---|---|---|
| Crude DPPH before recrystallization | 37.7 | 10.02 | 8.67 | 86.3 | Average 87.1 |
| | 24.1 | 6.39 | 5.56 | 87.1 | |
| | 29.5 | 7.51 | 6.60 | 87.8 | |
| DPPH after once recrystallization | 28.7 | 7.35 | 7.11 | 96.8 | 97.0 |
| | 28.3 | 7.23 | 7.03 | 97.1 | |
| DTPH freshly prepared in benzene** | 60.36 | 14.42 | 14.17 | 98.3 | 98.6 |
| | 60.36 | 14.42 | 14.24 | 98.8 | |

* Based on one equivalent for reduction of the hydrazyl free radicals.
** The concentration of DTPH was calculated from the weight of the hydrazine used in its preparation.

The authors have found that DPPH and analogous hydrazyl free radicals can be satisfactorily determined by iodometry. The technique is almost the same as that used in the determination of organic peroxides.[3]

The iodometric determination of relatively stable phenoxy radicals has been reported by Müller and Ley.[4] They reduced the phenoxy radical to the corresponding phenol with sodium iodide using glacial acetic acid as a solvent and carrying out the determination under an atmosphere of carbon dioxide.

DPPH, prepared by the method of Goldschmidt and Renn,[1] was recrystallized from benzene-ligroin, then dried under reduced pressure at 77°C for 50 hr.

Found: C, 54.7; H, 3.08; N, 18.0. Calcd. for $C_{18}H_{12}O_6N_5$: C, 54.8, H, 3.07; N, 17.8%.

1, 1-Di-(*p*-tolyl)-2-picrylhydrazine was prepared by the method of Poirier and Benington.[5] M. p. 159.0°C (uncorrected), lit. 161°C.[5]

Found: C, 56.4; H, 4.16; N, 16.3. Calcd. for $C_{20}H_{17}O_6N_5$: C, 56.7; H, 4.05; N, 16.5%.

The hydrazine was oxidized to 2, 2-di-(*p*-tolyl)-1-picrylhydrazyl (DTPH) with a freshly prepared suspension of lead dioxide in benzene. DTPH is as stable as DPPH in solution. However, an attempt to separate pure DTPH in solid form failed. Gradual evaporation of a concentrated solution of DTPH in benzene under reduced pressure gave a dark violet solid which turned brown on standing. The solid DTPH reported in the literature[6] also seems to be contaminated since its analytical data do not agree with the calculated values, and N–H absorption occurs in its infrared spectra.

All other reagents were commercial materials.

Ten milliliters of redistilled acetic anhydride and an excess of sodium iodide (ca. 1 g. of sodium iodide for 0.1 g. of hydrazyl) were added to the hydrazyl in a glass stoppered flask. After being allowed to stand in the dark for 10 min., 50 ml. of water and 15 ml. of benzene were poured into the flask; the mixture was then saturated with sodium sulfate to clear the aqueous layer. The liberated iodine was titrated with 1/100 N sodium thiosulfate solution with vigorous shaking and using 0.5% starch solution as an indicator. Benzene was added to take up colored organic products so that the end point of titration was clearly detectable.

The results are shown in Table I.

The products from the titration were studied spectrophotometrically. The spectrum of DPPH after reduction with sodium iodide was exactly the same as that of 1, 1-diphenyl-2-picrylhydrazine, showing a maximum absorption at 320 mμ. The DPPH which had been formed in the reduction and extracted into benzene, was quantitatively reoxidized to DPPH on treatment with lead dioxide.

The origin of the hydrogen transferred to the hydrazyls is not clear. The violet color of the hydrazyl was observed to disappear after addition of sodium iodide to the acetic anhydride solution of the hydrazyl. This indicates that the reduction of the hydrazyl is completed in acetic anhydride before addition of water. Small amounts of acetic acid in the acetic anhydride may be the source of the proton transferred to the hydrazyl. Under the present experimental conditions, less than 0.1% of acetic acid in the acetic anhydride would be sufficient to complete the reaction. Reduction of the hydrazyl by sodium iodide also proceeds rapidly in acetic acid. However, the use of acetic acid as solvent brings about spontaneous oxidation of the sodium iodide unless the reaction is carried out under an

6) M. M. Chen, A. F. D'Adamo and R. I. Walter, ibid., **26**, 2721 (1961).

atmosphere of inert gas. The following reaction scheme may be proposed from these observations.

$$2\,\text{Hydrazyl} + 2\text{NaI} + 2\text{CH}_3\text{COOH} \rightarrow 2\,\text{Hydrazine} + 2\text{CH}_3\text{COONa} + \text{I}_2 \quad (1)$$

The ratio of the volume consumed to the calculated volume of 1/100 N sodium thiosulfate will then express the purity of the reducible nitrogen radicals in the sample. The purity of DPPH is quite high. Although DTPH is not a stable solid, conversion of the hydrazine to the hydrazyl is almost complete in solution.

# Neutron Activation Analysis for Traces of Sodium in Polycarbonate

By Hitoshi KAMADA, Yûsuke UJIHARA, Katsuaki FUKUDA, Shôtaro KEIMATSU and Yoshihiro TSURUMI

(Received November 19, 1964)

The determination of microgram quantities of sodium in polycarbonate has received particular attention, because of its importance in an investigation of the properties, as well as in the development of an improved process for the production of this polymer.

Although the p.p.m. level of sodium in the polymer may be detemined by a combination of preliminary chemical concentration and subsequent flame-photometry, acid-base titration or polarography, these analytical methods are either difficult or troublesome, time-consuming, and apt to be inaccurate, therefore reliable results are rarely expected.

The authors have applied neutron activation and $\gamma$-ray spectrometry to the determination of sodium in bisphenol A-Polycarbonate, following the successfull use of this method in the determination of traces of sodium in aluminum,[1,2] diamond,[3] polyethylene[4] and polypropylene[5].

## Experimental and Results

A half to two grams of the accurately weighed polycarbonate sample was sealed in a polyethylene pouch and, together with standard sample, irradiated for 2 hr. in the JRR-1 which produces neutron flux of about $10^{11}$ n./cm$^2$·sec. The irradiated sample was washed with nitric acid and water, and transferred to a test tube. No activity was found in the washings. The standard sample was prepared by impregnating a filter paper (Toyo Roshi, No. 5B, diam. 5.5 cm.) with 1 mg. of sodium (1 mg.-Na/ml. sodium oxalate solution), then drying the paper under an infrared lamp, and sealing it in a polyethylene pouch. After irradiation, the sodium was extracted with water, diluted to a suitable volume, and an aliquot of the resulting solution was transferred to a test tube.

2) R. Chauvin and P. Leveque, *Int. J. Appl. Rad. Isot.*, **1**, 115 (1956).
3) E. C. Lightowlers, *Anal. Chem.*, **34**, 1285 (1963).
4) Y. Suzuki, O. Saito, N. Sairenji and N. Saito, "Kiki Ni Yoru Kobunshi-Bunseki II," (Instrumental Methods in High Polymer Analysis, II) Hirokawa Publ. Co., Tokyo (1964), p. 172.
5) T. Takeuchi and D. Ishii, ibid., p. 180.

The $\gamma$-ray spectra of the polycarbonate and of the standard samples were obtained intermittently using a $3\times3$ inch$^2$ NaI(Tl) crystal attached to the TMC*1-256 channel pulse height analyzer, the spectral imformation being recorded on an electric paper printer.

A representative $\gamma$-ray spectrum of the irradiated polycarbonate is shown in Fig. 1. The activity of chlorine-38 (half-life 37 min.) was dominant shortly after the irradiation. This activity would have come from a $^{37}Cl$ (n, $\gamma$) $^{38}Cl$ reaction, since methylene chloride had been employed as solvent in the production of the polycarbonate. After the chlorine-38 activity had decayed away, only the activity of sodium-24 remained and this was counted at convenient intervals.

The sodium contents were calculated from the 1.37 MeV photopeak height (above broken line) of sodium-24, which decayed with a half-life of about 15 hr.

As spectrochemical studies had already established the absence of magnesium and aluminum,*2 interference by $^{24}Mg$ (n, p) $^{24}Na$ or $^{27}Al$ (n, $\alpha$) $^{24}Na$ reactions would be negligible.

No appreciable self-shielding effect was observed in this experiment. The purity of the 1.37 MeV. photopeaks was verified by measurements of the half-life.

Typical results of the analyses are shown in Table I, where the samples shown in column B were obtained by treating the samples indicated in column A in order to decrease sodium content.

The proposed analytical method was applied to an investigation of the efficiency with which sodium is extracted into water from a methylene chloride solution of the polycarbonate.

The extraction procedure was as follows: 100 g. of the polycarbonate sample was dissolved in 500 ml. of methylene chloride, and this solution was shaken for 1 min. with 500 ml. of water in a separating funnel.

A repetition of the above procedure with additional amounts of water gave the samples which had been repeatedly washed. After separation of the water layer, isopropyl alcohol was added to the organic layer with stirring until polycarbonate powder precipitated; the precipitate was then dried in vacuo.

The results are shown in Fig. 2 and indicate that the repeated washing of the polymer solution with water does not effectively remove the sodium.

SHORT COMMUNICATIONS

# The Polymerization of Tetrahydrofuran Catalyzed by Tungsten(VI) Chloride

By Yoshinobu TAKEGAMI, Toru UENO and Ryuichi HIRAI

(Received March 15, 1965)

Tetrahydrofuran (THF) has been known to be polymerized by such catalysts as Lewis acid - cocatalyst systems,[1,2] triethyl aluminum - cocatalyst systems,[3-5] the triethyl aluminum - water(1 : 1) -cocatalyst,[3] ferric chloride - triphenyl phosphite,[6] phosphorous(V) fluoride,[7] and antimony(V) chloride.[7] Of these catalysts, phosphorous(V) fluoride and antimony(V) chloride appear highly active. We will now report on the utility of tungsten(VI) chloride, whose activity nearly corresponds with those of the above two catalysts.

Tetrahydrofuran was dried over sodium and distilled immediately before use. Polymerization was carried out in a sealed tube which had been allowed to stand at a desired temperature while being occasionally shaken. The initiation of the polymerization was shown by a change in the color of the polymerization mixture from a black suspension to a reddish brown solution. The mixture was washed with acetone-water (20 : 1), and the crude polymer was isolated by cooling. The polymer was then purified by pouring a THF solution of the crude polymer into a large amount of water, followed by washing it with methanol and drying it in vacuo at room temperature.

In all the experiments presented, 0.5 g. of tungsten(VI) chloride was used for 20 ml. of THF. This catalyst level of 0.5 mol. % was found to be the optimum. A further increase in the amount of the catalyst resulted in a decrease in the yield of the polymer.

A summary of the results is presented in Table I. The first six runs indicate that the yield and the reduced viscosity maxima occur at 0°C. At 20—40°C, the color of the polymerization mixture turns blue after about 3 hr. It appears that in the blue-colored mixture no polymerization but, rather, a rather slow depolymerization occurs. At 0°C, the yield of the polymer is 80% at a reaction time of 8 hr. and is slightly affected by a further increase in the reaction time.

TABLE I. THE YIELD AND THE REDUCED VISCOSITY OF THE POLYMER

| Time hr. | Temp. °C | Yield % | $\eta_{sp}$* |
|---|---|---|---|
| 8 | −20 | 1.5 | — |
| 8 | −10 | 54.5 | 0.80 |
| 8 | 0 | 81.1 | 1.15 |
| 8 | 10 | 74.4 | 0.75 |
| 8 | 20 | 41.4 | 0.55 |
| 8 | 30 | 6.2 | 0.20 |

# Reactive Monomers Derived from *p*-Vinylbenzoic Acid

By Yoshio IWAKURA, Keikichi UNO, Nobuo NAKABAYASHI and Takakazu KOJIMA

(Received March 16, 1965)

The preparation and the application of reactive polymers have been studied in our laboratory.[1,2] Generally, reactive polymers can be obtained by the polymerization of so-called reactive monomers, which have a carbon-carbon double bond, and another functional group, such as epoxide, aziridine or isocyanate.

The present paper will describe the preparation of new reactive monomers derived from *p*-vinylbenzoic acid.[3,4] Jäger's method was adopted for preparing the acid in this report.

**Glycidyl *p*-Vinylbenzoate.**—*p*-$\beta$-Bromoethylbenzoic acid (I) was prepared by the procedure of Foreman.[5] I was treated with potassium hydroxide in ethanol in order to obtain potassium *p*-vinylbenzoate (II). The reaction of II and epichlorohydrin using triethylbenzylammonium chloride as a catalyst produced glycidyl *p*-vinylbenzoate (III), which was then distilled at 115.5—116.5°C/0.1 mmHg. The yield was 71%.

Found: C, 70.63; H, 6.01. Calcd. for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

The infrared absorption spectrum showed carbon-carbon double-bond bands at 1629, 987 and 918 $cm^{-1}$, epoxide at 907 and 839 $cm^{-1}$, carbonyl at 1720 $cm^{-1}$ and *p*-phenylene at 856 $cm^{-1}$. The epoxide content was 98.0%.

When the radical polymerization of III was carried out, linear poly-III was obtained; it had a $\eta_{sp}/c$ value of 0.20 (0.2 g./100 ml. dioxane at 30.0°C), and the epoxide content of the polymer was 96.0%. The copolymerization of III ($M_2$) with styrene ($M_1$) was also studied. The monomer reactivity ratios were as follows: $r_1=0.40\pm0.02$, and $r_2=0.95\pm0.10$ (at 70.0±0.1°C). Alfrey-Price's $Q$ and $e$ values were 1.18 and 0.18 respectively. Nucleophilic reagents such as hydrogenchloride and alkyl amine, could easily be added to epoxy groups in the poly-III and the copolymer.

***p*-Vinylphenylisocyanate.** — This compound[6] (b. p. 40.5—41.5°C/0.1 mmHg) was obtained through the acid chloride and the acid azide. The isocyanate gave a homopolymer with a vinyl group by means of the anionic polymerization of the isocyanate group at a low temperature. The radical polymerization, on the other hand, brought about one with a isocyanate group.

The details will be pulished in a short time.

# A Molecular Orbital Treatment of $^{13}C$–H Spin-Spin Coupling Constant

By Teijiro YONEZAWA, Isao MORISHIMA, Mutsuo FUJII and Kenichi FUKUI

(Received March 26, 1965)

The correlation between the $^{13}C$-H spin-spin coupling constant, $J_{C-H}$, and the degree of hybridization of the carbon atom has been investigated both experimentally and theoretically by several authors.[1-7]

Here we will present a semi-quantitative approach to an interpretation of the values of the coupling constant, $J_{C-H}$, for some saturated and unsaturated compounds; the approach uses an extended Hückel treatment which has recently been proposed by Hoffmann.[8] In this method, a molecular orbital is expressed by a linear combination of valency atomic orbitals, that is, the 1s orbitals of a hydrogen atom, the 2s, 2px, 2py and 2pz orbitals of a carbon atom, and so on. The orbital energy is then given by solving the secular equation:

$$det\,|H_{ij}-S_{ij}\varepsilon\,|=0 \qquad (1)$$

where $H_{ij}$ is a matrix element and $S_{ij}$ is the overlap integral between the $i$th and $j$th atomic orbitals. These are evaluated by a procedure similar to those previously reported.[8,9]

When we assume that $J_{C-H}$ is exclusively determined by the contact term, it is expressed by the equation:[10]

$$J_{C-H}=(1/h)(2\beta\hbar)^2\gamma_C\gamma_H(1/\Delta E)\times[(2\pi^2/3)P^2(2s_C\,|\,\delta\,|\,2s_C)(1s_H\,|\,\delta\,|\,1s_H)] \qquad (2)$$

where $P=2\sum_{i}^{occ} a^i_{1s_H}b^i_{2s_C}$, and where $a^i_{1s_H}$ and $b^i_{2s_C}$ are coefficients of the hydrogen 1s and carbon 2s orbitals in the $i$th molecular orbital respectively. $\Delta E$ is the mean excitation energy, which is assumed to be a constant throughout this treatment. Equation 2 is then simply written as:

$$J_{C-H}=AP^2 \qquad (3)$$

It may be seen that $J_{C-H}$ is proportional to the square of the bond order, $P^2$. The values of the calculated $P^2$ and the observed $J_{C-H}$ are cited in Table I. Since cyclobutane is nonplanar and has two groups of a nonequivalent C-H bond, their mean value is indicated in the table. For the sake of simplicity, the calculation of $J_{C-H}$ is carried out with respect to only one configuration, the chair form for cyclohexane, and the staggered form for ethane.

TABLE I. CALCULATED VALUES OF $P^2$ AND OBSERVED $J_{C-H}$

| Compound | $P^2$ | $J_{C-H}$, c. p. s. |
|---|---|---|
| Group a Cycloalkanes and epoxide | | |
| $C_2H_4O$ | 0.324 | 175 |
| $C_3H_6$ | 0.270 | 161 |
| $C_4H_8$ | 0.240 | 134 |
| $C_5H_{10}$ | 0.209 | 128 |
| $C_6H_{12}$ | 0.206 | 124 |
| Group b Halomethanes and ethane | | |
| $CHCl_3$ | 0.240 | 209 |
| $CH_2Cl_2$ | 0.206 | 178 |
| $CH_3Cl$ | 0.178 | 150 |
| $C_2H_6$ | 0.176 | 126 |
| $CH_4$ | 0.152 | 125 |
| Group c Unsaturated compounds | | |
| $HC\equiv CH$ | 0.377 | 248 |
| $C_6H_5{}^{13}CHO$ | 0.336 | 174 |
| Benzene | 0.268 | 159 |
| $CH_2=CH_2$ | 0.248 | 157 |

In each group, a, b and c, one can find a linear relationship between the values of $P^2$ and $J_{C-H}$, with a few discrepancies. These discrepacies may partly be attributed to the parametrization of the matrix element in an extended Hückel method, and partly also to the fact that only the contact term is taken into account as contributing to the coupling constant.

# The Photochemical Oxidation Reaction of Benzylic Alcohols in Dimethyl Sulfoxide

By Takeo SATO, Ei-ichi YAMADA, Takeo AKIYAMA, Hiroshi INOUE and Kazuo HATA

(Received March 27, 1965)

Of the numerous reactions using dimethyl sulfoxide (DMSO), the oxidation reaction of alcohols to aldehydes and ketones has been reported from several laboratories.[1-3] This paper will record a new approach, the use of DMSO as a solvent for the photochemical oxidation reaction of benzylic alcohols under neutral conditions at room temperature.

On irradiation,[4] a solution of 9-hydroxyfluorene in DMSO absorbed oxygen smoothly, and after 9 hr. 9-fluorenone was isolated in a 71% yield (conversion). 1-Phenylethanol was also converted to acetophenone in a 53% yield (as 2, 4-dinitrophenylhydrazone), whereas benzhydrol afforded 61.5% of benzophenone, together with 21% of bis(diphenylmethyl) ether.[5]

Since this oxidation reaction seemed to be rather general, several varieties of benzyl alcohols were also subjected to the reaction conditions in the hope of obtaining the corresponding aldehydes. A mixture of benzyl alcohol (0.5 mol.) and DMSO (2.5 mol.) absorbed 0.27 mol. of oxygen during 13.5 hr. to form 38% of benzaldehyde (as 2, 4-dinitrophenylhydrazone), the yield of benzoic acid being 13.6%. In one experiment, in which a 1 : 2 solution of benzyl alcohol and DMSO was used, the reaction mixture was analyzed by the vapor phase chromatography of the aliquots removed at one-hour intervals for over 20 hr. using 30% Carbowax-1500 on a celite column at 190°C.[6] It was found that the yield of benzaldehyde reached a maximum (48%) in 14 hr. It was well established that the otherwise very slow uptake of oxygen was much facilitated by the use of DMSO as a solvent. Although the formation of a small amount of dimethyl sulfone was shown to accompany this reaction, the rest of the DMSO could be recovered by distillation. Other solvents, including dimethylformamide, acetonitrile and ligroin, were shown to be not effective. The fact that the aldehyde group was protected in DMSO from further oxidation into the carboxyl group was confirmed by comparing the irradiation reaction of benzaldehyde in DMSO and in other solvents, for example ligroin, in which photo-oxygenation occurred quite rapidly. In the DMSO solution 83.7% of benzaldehyde could be recovered, even after irradiation for 9 hr. under vigorous shaking in oxygen.

*p*-Methyl- and *p*-methoxybenzyl alcohols gave the corresponding benzaldehydes in 46.5 and 37.5% yields respectively, the uptake of oxygen being much faster in these compounds than in benzyl alcohol. *m*-Methyl- and *p*-isopropylbenzaldehydes (35.1 and 37.7% yields respectively) were also prepared by this method. On the other hand, *p*-chloro-, *m*- and *p*-nitrobenzyl alcohols were recovered unchanged. *p*-Bromobenzyl alcohol, however, gave 15% of the aldehyde upon irradiation in a quartz vessel.

Finally, mention should be made of the photochemical stability of sulfoxides. DMSO itself resisted the photochemical oxygenation reacion, and only 1.4% of dimethyl sulfone was formed after 12.5 hr. In a quartz vessel it was irradiated for 20.5 hr. under nitrogen to give a small amount of dimethyl sulfide and dimethyl sulfone (both less than 1%), 92% of DMSO being recovered.[7] Likewise, diphenyl sulfoxide was found to be quite stable toward benzene light. In contrast, a benzene solution of dibenzyl sulfoxide, when irradiated under nitrogen in a quartz cell, was shown to be decomposed into benzyl mercaptan (isolated as dibenzyl disulfide) and benzaldehyde.

4) Unless otherwise stated, in all the photochemical reactions described here a solution of alcohol and DMSO (1 : 5) was placed in a Pyrex vessel connected with a buret for the measurement of the oxygen uptake; then, under vigorous shaking, it was irradiated with a 1000 W. mercury arc lamp (Wako Denki Co., HBC-1000) mounted in a water-cooled Pyrex jacket. The yield is based on the starting materials used, except for 9-fluorenone.

5) The irradiation of benzhydrol in a quartz cell led to the formation of benzopinacol.

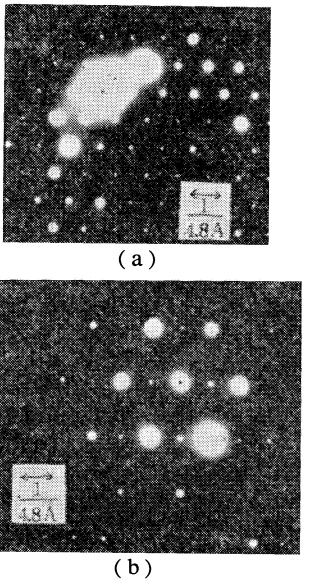
# Three New Synthetic Minerals with Tohdite-like Structures

By Goro YAMAGUCHI, Hiroaki YANAGIDA, Shuichiro ONO
Takehisa MIKI and Akira SETO



(Received March 31, 1965)

A new mineral, tohdite $5Al_2O_3 \cdot H_2O$, has been reported in previous papers.[1,2] The present authors have synthesized three more new minerals with tohdite-like structures, they have been named deuterium tohdite, rhombic tohdite and lithium tohdite.

**Deuterium Tohdite, $5Al_2O_3 \cdot D_2O$.**—Deuterium boehmite AlOOD was obtained from eta-alumina when it was treated with $D_2O$ in a Morey-type autoclave at 350°C under 150 atm. Then the deuterium boehmite was again treated hydrothermally with $D_2O$ and a small amount of $AlF_3$ as a mineralizer at 480°C under 1000 atm. for 20 hr. In this process deuterium boehmite was converted into deuterium tohdite.

Deuterium tohdite is distinguished from normal tohdite by its infrared absorption spectra. Absorption bands are found at 2440 $cm^{-1}$ for the OD-stretching mode and at 1080 $cm^{-1}$ for the OH-deformation mode (for normal tohdite, the locations are at 3260 $cm^{-1}$ and 1140 $cm^{-1}$ for the OH stretching and deformation modes respectively).

**Rhombic Tohdite, the Orthorhombic Form of $5Al_2O_3 \cdot H_2O$.**—Boehmite AlOOH was treated hydrothermally with a small amount of $AlF_3$ at 480°C under 300 atm. for 40 hr. In the product rhombic tohdite was found. Rhombic tohdite is characterized by an electron diffraction pattern which shows an orthorhombic symmetry (Fig. 1).

(a)

(b)

Fig. 1. *N*-Patterns of normal tohdite (a) and rhombic tohdite (b) (electron beam ∥ c-axis).

**Lithium Tohdite, $5Al_2O_3 \cdot LiHO$.** — Lithium aluminate gel was precipitated by ammonium hydroxide from an aqueous solution of lithium chloride and aluminum chloride (1 : 5). The precipitate was then washed, dried, and treated hydrothermally at 400°C under 200 atm. for 20 hr. Lithium tohdite was formed in this treatment.

Chemical analysis showed that the lithium tohdite was 1.69% water and 2.78% lithium oxide, and NMR measurement did not detect the existence of any fluorine. Therefore, the chemical formula was determined to be $5Al_2O_3 \cdot LiHO$.

The refractive index and the density were 1.726—1.730 and 3.73 respectively.

The infrared absorption bands are found at 3310 $cm^{-1}$ for the OH-stretching mode and at 1130 $cm^{-1}$ for the OH-deformation mode.

The X-ray powder diffraction pattern is similar to that of normal tohdite except for slight differences in the *d*-values. The electron diffraction pattern shows a pseudo-hexagonal orthorhombic symmetry, as is shown in Fig. 2. The pseudo-hexagonal lattice dimensions were determined to be $a=5.57$ Å and $c=8.87$ Å. (For normal tohdite, they are $a=5.576$ and $c=8.768$.)

# The Synthesis of Oxetanes by the Photochemical Reaction of Aliphatic Aldehydes and Styrene*

By Hiroshi SAKURAI, Kensuke SHIMA and Isao AONO

(Received April 9, 1965)

We wish to report on the synthesis of oxetanes by the photoaddition of acetaldehyde and propionaldehyde to styrene.

An equimolar mixture of acetaldehyde and styrene was irradiated under nitrogen at 10—15°C for 8 hr. using a 350 W. high-pressure mercury lamp.[1] After the irradiation, the unreacted materials were distilled off and a fraction with a b. p. of 69—70°C/2 mmHg ($n_D^{20}$ 1.5202) was obtained. Found: C, 80.80; H, 8.23; mol. wt., 150.[2] Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16%; mol. wt., 148. $\lambda_{max}^{EtOH}$, 249, 253.5, 259, 262, 265.3 and 269 mμ (log ε, 2.94, 3.04, 3.12, 3.08, 2.97 and 2.93). The infrared spectrum of this product showed the presence of an oxetane[3] (980 $cm^{-1}$), but the absorption bands characteristic of hydroxy and carbonyl groups were not observed. The orientation of the addition was established by means of a study of the NMR spectrum. The NMR spectrum[4] showed a sextet (1 H) at τ 6.38 (hydrogen β to oxygen on the ring) and a complex multiplet (3 H) centered at τ 5.4 (hydrogens α to oxygen). It was assigned the structure Ia on the basis of these data.

Ia R=$CH_3$

Ib R=$C_2H_5$

From propionaldehyde and styrene, a fraction with a b. p. of 70—71°C/2 mmHg ($n_D^{20}$ 1.5144) was obtained. Found: C, 81.40; H, 8.96; mol. wt., 162. Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.70%; mol. wt., 162. $\lambda_{max}^{EtOH}$, 249, 254, 259.5, 262.5, 265.5 and 269.3 mμ (log ε, 2.92, 3.02, 3.09, 3.05, 2.95 and 2.91). It was proposed that the product was Ib.

The reaction conditions and the yield of products are summarized in Table I.

Table I. The reaction conditions and the yields of products

| Aldehyde | Acetaldehyde | Propionaldehyde |
|---|---|---|
| Aldehyde used, g. | 42 | 58 |
| Styrene used, g. | 104 | 104 |
| Aldehyde consumed, g. | 6 | 4 |
| Styrene consumed, g. | 16.3 | 13.3 |
| Oxetane, g. | 8 | 4.3 |
| High boiling residue, g. | 13 | 10.5 |
| Wt.% of oxetane in the products | 38 | 29 |
| Ultimated yield of oxetane based on aldehyde consumed, mol. % | 49.4 | 38.5 |
| Ultimated yield of oxetane based on styrene consumed, mol.% | 31.5 | 20.7 |

It is of interest to note that the photoaddition of aliphatic aldehydes to styrene gives only oxetanes, while the addition of the aldehydes to 1-olefins generally gives ketones, which are formed by the addition of the acyl radical to olefins.[5]

These oxetanes will be stereochemically considered and the mechanistic implications will be discussed elsewhere.

# A Nuclear Gamma-ray Resonance Study of Several [$FeX_6$]-type Ferrous Complexes

By Hirotoshi SANO and Hiroko KONO

(Received April 12, 1965)

The study of the nuclear $\gamma$-ray resonance (the Mössbauer effect) has recently been extended to metal compounds, especially those of iron and tin.[1] A number of iron compounds have so far been investigated. However, there have been few studies of the effect of the nature of the ligand on the spectrum of various [$FeX_6$]-type ferrous complexes. The purpose of the present work is to clarify the features of the chemical bond between the central iron atom and the ligand in the complexes.

The potassium calcium hexanitroferrate(II)[2] and potassium hexathiocyanatoferrate(II)[3] used as absorbers were synthesized by conventional methods. Commercial analytical-grade potassium hexacyanoferrate(II) and hexaquoferrous ammonium sulfate (Mohr's salt) were also used as absorbers without further purification. The resonance absorption spectra of 14.4 keV. $\gamma$-rays in these compounds were measured at room temperature with a source of $^{57}Co$ diffused into copper foil. The sample was moved at a constant velocity by means of a mechanical drive.

Figures 1 and 2 illustrate the nuclear $\gamma$-ray resonance spectra of potassium hexacyanoferrate(II) and Mohr's salt, and of potassium calcium hexanitroferrate(II) and potassium hexathiocyanatoferrate(II), respectively. The latter two compounds show the same spectra as those reported by previous investigators.[4] The results suggest that the isomer shifts of the hexa-coordinated ferrous complexes increas in positive value when the $\pi$ bonding character between the ligands and the iron atoms decreases in the sequence of:

$$CNCH_3{}^* > CN^- > NO_2^- > SCN^- > OH_2$$

The little larger value of the isomer shift in hexanitroferrate(II) than that in hexacyanoferrate(II) suggests that the bond between the nitro ligands and the iron atoms still has a considerable $\pi$ bonding character, whereas the much larger isomer shift in hexathiocyanatoferrate(II) shows a poor $\pi$ bonding character, probably because of lesser availability of d orbitals in sulfur atoms.

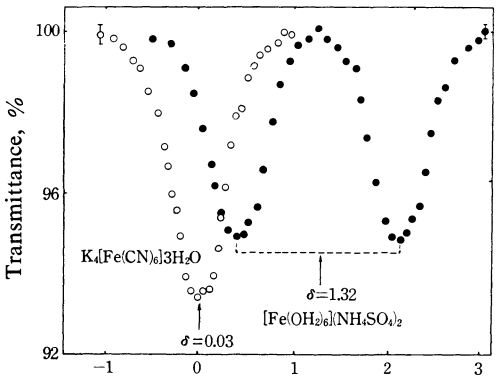

Fig. 1. Nuclear $\gamma$-ray resonance absorption spectra of $K_4[Fe(CN)_6]3H_2O$ and $[Fe(OH_2)_6](NH_4SO_4)_2$.

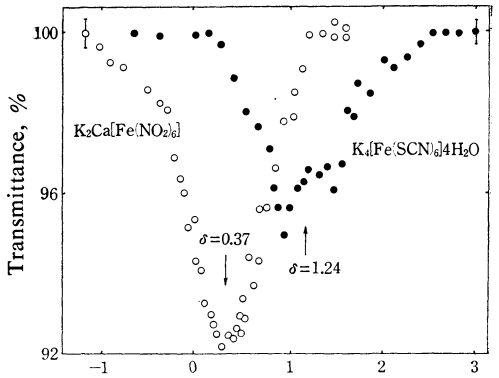

Fig. 2. Nuclear $\gamma$-ray resonance absorption spectra of $K_2Ca[Fe(NO_2)_6]$ and $K_4[Fe(SCN)_6]\cdot 4H_2O$.

# The Effect of Nitrous Oxide on the $\gamma$-Radiolysis of Liquid Methanol

By Hiroshi SEKI and Masashi IMAMURA

(Received May 7, 1965)

The formation of a solvated electron in irradiated liquid methanol has been generally assumed.[1,2] Evidence has also been given for methanol as well as for other alcohols.[3-5] Nitrous oxide has frequently been employed in determining the yield of the hydrated electron in aqueous solutions, for hydrated electrons react rapidly with nitrous oxide to produce nitrogen;

$$N_2O + e_{aq}^- \rightarrow N_2 + O^- \qquad (1)$$

while hydrogen atoms react relatively slowly. This communication will report our preliminary findings regarding the effect of nitrous oxide on the $\gamma$-radiolysis of liquid methanol.

Extra-pure methanol (Wako Pure Chemicals) was rectified after it had been refluxed with sodium borohydride. The middle third of the distillate was dried over magnesium turnings by refluxing. Pure nitrous oxide (Takachiho Chemicals, 99.9%) was further purified by distillation. The solutions were irradiated with $^{60}$Co-$\gamma$ rays at a dose rate of $(1.4—1.5)\times10^{17}$ eV./ml./min. for about 150 min. The determination of the products was carried out by methods similar to those described elsewhere.[6]

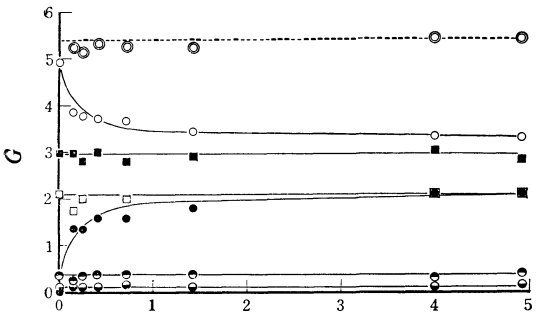

Fig. 1. Effect of $N_2O$ on the product yields of methanol.
○, $H_2$; ●, $N_2$; ■, $(CH_2OH)_2$; □, $CH_2O$; ◓, $CH_4$; ◒, CO; ◎, $H_2+N_2$

The results are shown in Fig. 1. The addition of nitrous oxide decreases the $G(H_2)$ and leads to the formation of nitrogen. It should be noted, however, that, in spite of the considerable effect of nitrous oxide on $G(H_2)$, the yields of all the other products remain unaffected, and that the limiting $G(H_2)+G(N_2)$ value is 5.4, which is the same as the $G(H_2)$ values for pure methanol ascertained by Meshitsuka and Burton,[7] and by Baxendale and Mellows.[2] It would appear, therefore, that no nitrogen-formation reactions other than reaction 1 take place. It is also reasonable to assume that the reaction of nitrous oxide with hydrogen atoms is negligible under the present experimental conditions.*

Thus, insofar as nitrous oxide is assumed to react solely with the solvated electrons in the irradiated methanol, the yield of the solvated electron should be equal to the limiting $G(N_2)=2.1$. This value is substantially higher than those obtained from kinetic study (1.2)[2] and from pulse radiolysis study (1.1).[5] The reason for this disagreement is not obvious at present. Further studies are therefore in progress into the effects of the pH value and of higher nitrous oxide concentrations; our results will be published in the future.

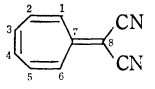
7) G. Meshitsuka and M. Burton, *Radiation Res.*, **8**, 285 (1958).



* The fact that the $G(N_2)$ value at a low pH value is negligibly small (unpublished results) would support this assumption.

# The Crystal Structure of 8, 8-Dicyanoheptafulvene

By Hirotaka SHIMANOUCHI,* Tamaichi ASHIDA, Yoshio SASADA, Masao KAKUDO, Ichiro MURATA and Yoshio KITAHARA

(Received May 15, 1965)

8, 8-Dicyanoheptafulvene (I) is a stable derivative of heptafulvene, which is a sort of the non-alternant hydrocarbon. This compound has been studied by several groups of workers in recent years.[1-5]

(I)

The present investigation was undertaken in order to reveal its molecular parameters by X-ray analysis.

This compound crystallizes in a monoclinic unit cell with dimensions: $a=7.84$ Å, $b=13.14$ Å, $c=3.99$ Å, and $\beta=97.9°$. The space group is $P2_1$ or $P2_1/m$. Since intensity statistics showed the existence of a center of symmetry, it was decided that the space group was the latter. There are two molecules in the unit cell, and the molecule should have a mirror plane in it.

Multiple-film equi-inclination Weissenberg photographs were taken for layers 0 to 3 about the c axis with Cu-$K\alpha$ radiation, and the integrated intensities were estimated visually against a standard scale.

The structure was solved by the interpretation of Patterson projections along the c and b axes and Harker section $P(u, 1/2, w)$. The positional and thermal parameters of each atom so obtained were refined by the least-squares method. The final electron density projection along the c axis is shown in Fig. 1. The molecule is planar and lies approximately parallel to the (101) plane; the interplanar spacing is 3.4 Å. A crystallographic mirror plane normal to the b axis passes through the atoms $C_7$ and $C_8$ and is perpendicular to the molecular plane.

A detailed account of this work will be presented in the near future.

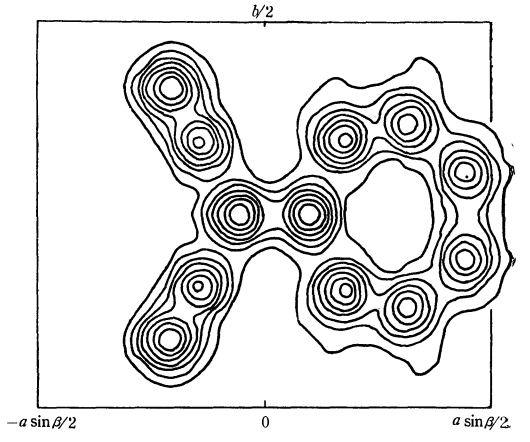


Fig. 1. The final electron density projection on the (001). Contours at intervals of 1.0 e. Å$^{-2}$, the lowest being at 1.0 e. Å$^{-2}$.

# The Thermal Condensation of Formaldehyde with Cycloolefins

By Shoji WATANABE

(Received April 14, 1964)

In a previous paper,[1] observations of the behavior of representative aliphatic olefins in their thermal condensation with formaldehyde were reported. It seemed desirable to extend this research by examining also the thermal condensation of some cycloolefins with formaldehyde. The present paper will describe the products obtained from β-pinene, camphene, thujopsene, dihydrothujopsene, 3-*p*-menthene, cyclohexene, 1-butyl-2, 6, 6-trimethyl-1-cyclohexene and 1-(2'-buten-1'-yl)-2, 6, 6-trimethyl-1-cyclohexene in their respective condensations with formaldehyde.

In this study all condensations with paraformaldehyde were carried out in acetic anhydride and at temperatures varying from 180 to 220°C, the products obtained being mainly acetates of olefinic, primary alcohols, in which the double bond, except those in the condensation products from camphene,[2] was located at a position adjacent to its original site in the starting olefins. The various condensation products are given in Table I.

β-Pinene (I) and camphene (III), which have an end methylene group, react readily with paraformaldehyde to give predominantly 2-acetoxyethyl-6, 6-dimethyl-bicyclo[3, 1, 1]-hept-2-ene (II) (nopyl acetate) and 8-acetoxymethylcamphene (V) respectively. From camphene, however, 8-hydroxymethylcamphene, isoborneol and isobornyl acetate were also obtained in fairly good yields under the experimental conditions shown in Table I.

The thermal condensations of thujopsene (V),[3] dihydrothujopsene (VIII) and 3-*p*-menthene (XI), which have a trisubstituted double bond, afforded rather complicated results. From the crude condensation product of thujopsene (V), an unsaturated acetate and an ether were separated successfully by means of column chromatography using a silica gel column. The acetate was saponified to give an alcohol, $C_{16}H_{27}OH$, which absorbed 95% of one equivalent amount of hydrogen over an Adams catalyst. The infrared spectrum showed primary hydroxyl absorption bands at 3300 and 1045 $cm^{-1}$, and a characteristic band of the trisubstituted double bond at 820 $cm^{-1}$. Therefore, this compound must be 1, 2, 3, 4, $4_a$, 5, 6, $8_a$-octahydro-6-(hydroxymethyl)-1, 1, $4_a$, 7, $8_a$-pentamethylnaphthalene (VI). The structural assignment was further supported by the nuclear magnetic resonance spectrum, as will be shown in the "Experimental" section (Fig. 1). On the other hand, the ether, $C_{17}H_{26}O$, $F_1$, was considered to be a cyclic ether, since the infrared spectrum showed a strong absorption band at 1100 $cm^{-1}$. The nuclear magnetic resonance spectrum indicated the signal of the allyl proton at 7.8 τ. The signal at 6.3 τ is presumably due to protons on the cyclic ether ($-CH_2-O-CH_2-$), while the signal at 9.3 τ was presumably due to the protons of the cyclopropane ring (Fig. 2). From this spectral evidence and from comparison with a similar case recently reported,[4] it was considered that this cyclic ether was 3, 4, 5, 6, 7, 8, $8_a$, 9, 10, $10_a$-decahydro-5, 5, $8_a$-trimethyl-10, $10_a$-methylene-1*H*-2-oxa-anthracene (VII).

Although dihydrothujopsene (VIII) scarcely reacted at all with paraformaldehyde in acetic

TABLE I. CONDENSATION OF OLEFIN WITH FORMALDEHYDE IN ACETIC ANHYDRIDE

| Olefin: Name | Olefin: Structure | Reaction temp. °C | Reaction time hr. | Recovered olefin % | Product (yield, %) |
|---|---|---|---|---|---|
| β-Pinene (I) |  | 200—205*1 | 5 | 31 |  (II) (60) |
| Camphene (III) |  | 180 | 5 | 53 |  (IV) (20) and  (4), Isobornyl acetate*3 (17) and Isoborneol*3 (10) |
| Thujopsene (V) |  | 185 | 3 | 38 |  (10) and  (10) Acetate of VI (VII) |
| Dihydrothujopsene (VIII) |  | 200—210*2 | 10 | 85 |  and  (5) Acetate of IX Acetate of X |
| 3-*p*-Menthene (XI) |  | 200 | 3 | 57 |  and  (22) Acetate of $XII_B$ Acetate of $XII_A$ |
| Cyclohexene (XV) |  | 220 | 9 | 50 |  (XVI) (12) |
| 2,6,6-Trimethyl-1-butyl-1-cyclohexene (XVII) |  | 200—210*2 | 10 | 75 | A primary alcohol, $C_{14}H_{26}O$ (XVIII) (6) |
| 2,6,6-Trimethyl-1-[2'-butyl-1'-yl]-1-cyclohexene (XIX) |  | 220 | 10 | 60 |  (10) Acetate of XX |

*1 Under 100 kg./cm² of hydrogen pressure.
*2 Acetic acid and a trace of $H_2SO_4$ added.
*3 Identified with authentic samples.

anhydride, it did react in a mixture of acetic anhydride, acetic acid and a trace of concentrated sulfuric acid to give an inhomogeneous acetate, which was then saponified to an inseparable mixture of unsaturated isomeric alcohols, $C_{16}H_{27}O$. The infrared bands at 810, 860 and 1040 $cm^{-1}$ indicated the presence of a trisubstituted double bond, a terminal methylene, and a primary hydroxyl group. Thus, the mixture presumably consisted of 1, 2, 3, 4, $4_a$, 5, 6, 7, 8, $8_a$-decahydro-7-methylene-8-(hydroxymethyl)-1, 1, $4_a$, $8_a$-tetramethylnaphthalene (IX) and 1, 2, 3, 4, $4_a$, 5, 8, $8_a$-octahydro-8-(hydroxymethyl)-1, 1, $4_a$, 7, $8_a$-pentamethylnaphthalene (X). The saponification of the condensation product from 3-*p*-menthene (XI) gave a mixture of unsaturated alcohols. The direct separation of the isomeric components by fractional distillation and gas chromatography was unsuccessful. The infrared absorption spectrum showed an absorption band at 810 $cm^{-1}$, indicating the presence of a trisubstituted ethylenic bond. Reduction gave 3-hydroxymethyl-*p*-menthane (XIV). Oxidation with potassium permanganate gave acetone, indicating the presence of an isopropylidene group, while oxidation with chromic anhydride gave an α, β-unsaturated aldehyde which was thought to be 3-formyl-3(4)-*p*-menthene (XIII). These results suggested that 3-hydroxymethyl-4(5)-*p*-menthene (XIIA) and 3-hydroxymethyl-4(8)-*p*-menthene (XIIB) were the main components of the mixture.

Cyclohexene (XV) reacted with paraformaldehyde to give (2-cyclohexenyl)methyl acetate (XVI) as the main product.

From the condensation product of 2, 6, 6-trimethyl-1-butyl-1-cyclohexene (XVII), which has a tetrasubstituted olefinic bond, an unsaturated alcohol, $C_{14}H_{26}O$, $F_1$ (XVIII) was obtained in a very poor yield. The infrared absorption spectrum indicated, however, that it was a primary alcohol, the structure of which has not yet been determined.

From the condensation of 2, 6, 6-trimethyl-1-[2′-buten-1′-yl]-1-cyclohexene (XIX) and paraformaldehyde, an unsaturated alcohol, $C_{14}H_{24}O$, $F_2$ (XX) was obtained in a poor yield. Its ultraviolet absorption spectrum ($\lambda_{max}$ 242 m$\mu$) indicated that it contained a dienic group. The infrared absorption spectrum showed the characteristic absorption bands of a trans-olefinic bond and a primary hydroxyl group. Therefore, 2-methyl-4-[2′, 6′, 6′-trimethyl-1′-cyclohexen-1′-yl]-3-buten-1-ol (XX) is a reasonable assignment for the alcohol.

The foregoing observations indicate that the thermal condensation of formaldehyde with cycloolefins in the presence of acetic anhydride occurs most readily with end methylene-type olefins, $CH_2=CR_1R_2$, and that trisubstituted olefins ($R_1CH=CR_2R_3$) and disubstituted olefins ($R_1CH=CHR_2$) are less reactive. Tetrasubstituted olefins of the $R_1R_2C=CR_3R_4$ type are least reactive.

## Experimental

**Materials.** — $\beta$-Pinene, camphene, thujopsene, 3-*p*-menthene and cyclohexene were obtained from the Takasago Perfumary Co., Ltd.

*Dihydrothujopsene (VIII)*[5] was prepared by the hydrogenation of thujopsene over palladised charcoal; b. p. 129—130°C/13 mmHg; $d_D^{20}$ 0.9252; $n_D^{20}$ 1.5039. The gas chromatogram showed one peak.

The preparation of *1-(2′-butenyl)-2, 2, 6-trimethyl-1-cyclohexene (XIX)*[6] was carried out as follows. A mixture of 450 g. of $\beta$-ionone, 280 cc. of absolute ethanol, and 250 g. of hydrazine hydrate was refluxed for 4 hr. To this mixture, 800 g. of diethylene glycol, 180 g. of potassium hydroxide and 70 cc. of benzene were added, and the new mixture was refluxed for 2 hr. Fractional distillation gave 200 g. of crude 1-(2′-butenyl)-2, 6, 6-trimethyl-1-cyclohexene (XIX) (b. p. 75—135°C/45—50 mmHg), which was then fractionally redistilled to give 100 g. of an oil, b. p. 81.5°C/5 mmHg; $d_D^{20}$ 0.8469; $n_D^{21}$ 1.4836 (reported[6] b. p. 91—93°C/11 mmg; $d_4^{18}$ 0.8580; $n_D^{18}$ 1.4795); molecular refraction: 60.18 (calcd. for $C_{13}H_{22}$, $F_2$, 59.10). IR (liq. film): $\nu_{max}$ 970 cm$^{-1}$ (trans-olefinic bond). The gas chromatogram showed one peak.

*1-Butyl-2, 6, 6-trimethyl-1-cyclohexene (XVII)* was obtained by the hydrogenation of 1-(2′-butenyl)-2, 6, 6-trimethyl-1-cyclohexene (XIX) at 20 kg./cm$^2$ hydrogen pressure and room temperature, using a Pd-C catalyst. Distillation gave an oil (b. p. 73—78°C/3 mmHg; $d_4^{20}$ 0.8460; $n_D^{20}$ 1.4700). Bromine value: 100 (calcd. for $C_{13}H_{24}$, $F_1$, 89). NMR: 8.4 $\tau$ ($=\overset{|}{C}-CH_3$), 9.05 $\tau$ (*gem*-dimethyl group), 9.1 $\tau$ ($-CH_3$).

**Condensation Procedure.** — A mixture of 1 mol. of an olefin, 1 mol. of paraformaldehyde, and 0.5 mol. of acetic anhydride was heated at 180—220°C in a stainless autoclave for several hours. After it had been cooled, the reaction mixture was extracted with ether. The ethereal solution was washed with water, dried over anhydrous sodium sulfate, and then treated in ordor to separate the components. For the respective condensations, the main conditions are given in Table I.

**The Condensation of $\beta$-Pinene (I) with Formaldehyde.** — From a mixture of 45 g. of I, 17 g. of acetic anhydride and 10 g. of paraformaldehyde, 14 g. of I and 41 g. of an oily product boiling at 98—168°C/10 mmHg were obtained. This product was proved by means of gas liquid chromatography to consist of 90% of 2-acetoxyethyl-6, 6-dimethyl-bicyclo[3, 1, 1]-hept-2-ene (II), and 8% of a high boiling fraction. Fractional distillation gave pure II (b. p. 98—100°C/10 mmHg). The saponification of II gave 6, 6-dimethyl-bicyclo[3, 1, 1]-hept-2-enyl ethanol (nopol), since the gas chromatogram and the infrared spectrum were identical with those of an authentic sample, b. p. 98—102°C/8 mmHg; $d_4^{11}$ 0.9716; $n_D^{13}$ 1.4945; bromine value, 99.51 (calcd. for $C_{11}H_{18}O$, $F_1$, 90.12); hydroxyl group, 8.62% (calcd. for monohydric alcohol, 10.2%).

**The Condensation of Camphene (III) with Formaldehyde.** — From a mixture of 340 g. (2.46 mol.) of III, 66.5 g. (2.2 mol.) of paraformaldehyde and 107 g. of acetic anhydride, 180 g. of III and 150 g. of a crude product (b. p. 100—130°C/7 mmHg) were obtained. This product consisted of 34% isobornyl acetate, 21% isoborneol, 40% 8-acetoxymethylcamphene (IV) and 5% 8-hydroxymethylcamphene, according to the gas liquid chromatographic analysis. The mixture (65 g.) was distilled to give the following fractions: (a) 20 g., b. p. 97—98°C/4 mmHg, (b) 25 g., b. p. 114—114.5°C/4 mmHg. The saponification of fraction b (24 g.) gave 18 g. of 8-hydroxymethylcamphene, b. p. 110—115°C/5 mmHg; $d_4^{25}$ 0.9810; $n_D^{25}$ 1.5016; molecular refraction, 50.20 (calcd. for $C_{11}H_{18}O$, $F_1$, 49.66); phthalic acid monoester, m. p. 127°C (reported[2] m. p. 127—127.5°C); 3, 5-dinitrobenzoate, m. p. 89°C. The saponification of the fraction a gave isoborneol (m. p. 130°C).

**The Condensation of Thujopsene (V) with Formaldehyde.** — From a mixture of 50 g. of thujopsene (V), 9 g. of paraformaldehyde and 13 g. of acetic anhydride, 19 g. of an unsaturated hydrocarbon and 12 g. of a crude product (b. p. 120—140°C/5 mmHg; $d_4^{18}$ 1.0196; $n_D^{22}$ 1.5193) were obtained. The saponification of the crude product (50 g.) gave an oil (37 g.), b. p. 135—140°C/5 mmHg; $d_4^{22}$ 1.0097; $n_D^{22}$ 1.5216; hydroxyl group, 4.45% (calcd. for monohydric alcohol, 7.23%). The liquid chromatography of 10 g. of the oil with silica gel (70 g.) gave 4 g. of a viscous oil (A) from the

6) R. Fischer, G. Lardelli and O. Jeger, *Helv. Chim. Acta*, **34**, 1577 (1951).

elute with benzene and 4 g. of a viscous oil (B) from the elute with methanol.

The redistillation of A gave 3,4,5,6,7,8,8a,9,10,-10a-decahydro-5,5,8a-trimethyl-10,10a-methylene-2*H*-2-oxa-anthracene (VII), b. p. 136°C/5 mmHg; bromine value, 139.2 (calcd. for $C_{17}H_{26}O$, $F_1$, 115.6). IR (liq. film): $\nu_{max}$ 1100 $cm^{-1}$ (a cyclic ether). NMR:[7] 7.8 $\tau$ (allyl proton), 8.85, 8.87, 9.37 $\tau$ (three methyl groups), 6.3 $\tau$ ($-CH_2-O-CH_2-$), 9.3 $\tau$ (cyclopropane ring).

Found: C, 81.37; H, 10.28. Calcd. for $C_{17}H_{26}O$ (VII): C, 82.34; H, 11.36%.

Similarly, 1,2,3,4,4a,5,6,8a-octahydro-6-(hydroxymethyl)-1,1,4a,7,8a-pentamethylnaphthalene (VI) was obtained from B, b. p. 139°C/5 mmHg; $d_4^{15}$ 0.9907; $n_D^{15}$ 1.5194; bromine value, 68.3 (calcd. for $C_{16}H_{26}O$, $F_1$, 74.6); hydroxyl group, 6.00% (calcd. for $C_{16}H_{25}(OH)$, 7.23%). IR: $\nu_{max}$ 3300, 1045 $cm^{-1}$ (primary alcohol), $\nu_{max}$ 820 $cm^{-1}$ (trisubstituted double bond). NMR: 4.93 $\tau$ (singlet, $-\overset{|}{C}-CH=\overset{|}{C}-$), 6.4 $\tau$ ($-\overset{|}{C}H-CH_2OH$).

Found: C, 81.18; H, 11.10. Calcd. for $C_{16}H_{28}O$ (VI): C, 81.29; H, 11.97%.

**The Condensation of Dihydrothujopsene (VIII) with Formaldehyde.** — From 124 g. of VIII, 21.6 g. of paraformaldehyde, 30.6 g. of acetic anhydride, 18 g. of acetic acid and one drop of concentrated sulfuric acid, 7 g. of a pale yellow oil (135—150°C/3 mmHg; $n_D^{20}$ 1.5040; $d_4^{20}$ 0.9920) was obtained. The saponification of this product gave an alcoholic compound. Liquid chromatography with silica gel gave a crude alcohol from the elute with methanol. The molecular distillation of this alcohol with a pot still gave 3 g. of 1,2,3,4,4a,5,6,7,8,8a-decahydro-7-methylene-8-(hydroxymethyl)-1,1,4a,8a-tetramethylnaphthalene (IX) and 1,2,3,4,4a,5,8,8a-octahydro-8-(hydroxymethyl)-1,1,4a,7,8a-pentamethylnaphthalene (X). Bath temperature, 70°C/$10^{-3}$ mmHg; $d_4^{20}$ 0.9918; $n_D^{20}$ 1.5193. IR: $\nu_{max}$ 810 $cm^{-1}$ (a trisubstituted olefinic bond), $\nu_{max}$ 860 $cm^{-1}$ (an end methylene group) and $\nu_{max}$ 1040 $cm^{-1}$ (a primary hydroxy group). NMR: 5.3 $\tau$ ($-\overset{|}{C}=CH_2$), 4.6 $\tau$ ($CH_2-CH=\overset{|}{C}-$), 6.4 $\tau$ ($-\overset{|}{C}H-CH_2OH$).

Found: C, 79.72; H, 11.39. Calcd. for $C_{16}H_{28}O$: C, 81.29; H, 11.97%.

**The Condensation of 3-*p*-Menthene (XI) with Formaldehyde.** — From a mixture of 180 g. of XI, 60 g. of paraformaldehyde and 75 g. of acetic anhydride, 102 g. of XI and 60 g. of a crude acetate (b. p. 90—110°C/5 mmHg) were obtained. The saponification of the product gave 25 g. of a mixture of 3-hydroxymethyl-*p*-menthene; b. p. 100—104°C/5 mmHg; $n_D^{30}$ 1.4815; $d_4^{30}$ 0.9160; molecular refraction, 52.21 (calcd. for $C_{11}H_{20}O$, $F_1$, 51.85); hydroxyl group, 10.81% (calcd. for monohydric alcohol, 10.11%); bromine value, 107 (calcd. for $C_{11}H_{20}O$, $F_1$, 95); IR (liquid film): $\nu_{max}$ 1050 $cm^{-1}$ (a primary alcohol), 810 $cm^{-1}$ (a trisubstituted double bond).

*3,5-Dinitrobenzoate* was recrystallized from methanol; m. p. 79—80°C.

Found: N, 7.88. Calcd. for $C_{18}H_{22}O_6N_2$: N, 7.73%.

**3-Hydroxymethyl-*p*-menthane (XIV).**—3-Hydroxymethyl-*p*-menthene (XII) was hydrogenated over a nickel catalyst in a methanol solution at 150°C under 50 kg./$cm^2$ of initial hydrogen pressure to give 3-hydroxymethyl-*p*-menthane (XIV); b. p. 91—94°C/5 mmHg; $n_D^{20}$ 1.4738. The gas chromatogram showed one peak.

**3-Formyl-3-*p*-menthene (XIII).**—To a mixture of 8 g. of XII and 50 cc. of glacial acetic acid, a mixture of 8 g. of chromic anhydride and 50 cc. of glacial acetic acid was added over an hour's period with vigorous agitation at 25°C; the mixture was then stirred for 2 hr., after which it was treated as usual. By fractional distillation, 3 g. of XIII (b. p. 70—80°C/5 mmHg) was obtained.

This gave a positive reaction with Schiff's reagent and reduced an ammoniacal silver nitrate solution.

*2,4-Dinitrophenylhydrazone* was recrystallized from a mixture of pyridine and methanol in the form of red needles; m. p. 141—142°C; UV: $\lambda_{max}$ 380 m$\mu$, $\varepsilon$ 24000.

Found: N, 16.14. Calcd. for $C_{17}H_{22}O_4N_4$: N, 16.18%.

**The Oxidation of XII with Potassium Permanganate.** — A mixture of 7 g. of potassium permanganate and 50 cc. of water was added to 4 g. of XII and 20 cc. of water with vigorous agitation over a 30 min. period, the mixture was then left at room temperature for two days. After the unreacted potassium permanganate had been decomposed with hydrogen peroxide, the solution was filtered and extracted with ether. The ethereal solution (A) was washed with water and dried over anhydrous sodium sulfate. The aqueous solution and the washings were then combined (B). The solution A was distilled to give a small amount of a carbonyl compound, the structure of which was not determined. From the solution B, a carbonyl compound was separated as crude 2,4-dinitrophenylhydrazone. Liquid chromatography with a silica gel column gave yellow needles (m. p. 121°C), which was identical with that of an authentic sample of acetone 2,4-dinitrophenylhydrazone.

**The Condensation of Cyclohexene (XV) with Formaldehyde.**—From a mixture of 82.1 g. (1 mol.) of cyclohexene (XV), 30 g. (1 mol.) of paraformaldehyde and 51 g. (0.5 mol.) of acetic anhydride, 40 g. of a crude product was obtained. Distillation gave 10 g. of 1-hydroxymethyl-2-cyclohexene and 5 g. of a high-boiling fraction. 1-Hydroxymethyl-2-cyclohexene has the following properties: b. p. 74°C/11 mmHg; $d_4^6$ 0.9816; $d_4^{25}$ 0.9697; $n_D^{15}$ 1.4914; $n_D^{25}$ 1.4825; molecular refraction, 33.2 (calcd. for $C_7H_{12}O$, $F_1$, 33.2); bromine value, 127.5 (calcd. for $C_7H_{12}O$, $F_1$, 142). $\alpha$-Naphthylurethan, m. p. 87°C (reported 87°C[8]).

Found: C, 76.66; H, 6.82. Calcd. for $C_{18}H_{19}O_2N$: C, 76.48; H, 6.81%.

1-Hydroxymethyl-2-cyclohexene (2 g.) was hydrogenated at 20 kg./$cm^2$ pressure in a stainless autoclave with Adam's catalyst. The usual workup

8) A. T. Blomquist, J. Verdol, C. L. Adami, J. Wolinsky and D. D. Phillips, *J. Am. Chem. Soc.*, 79, 4978 (1957).

gave 1.0 g. of cyclohexylmethanol; b. p. 176—177°C; $n_D^{25}$ 1.4617[6].

The high boiling fraction was found by gas liquid chromatography to be composed of various components, the structures of which were not determined.

**The Condensation of 1-Butyl-2, 6, 6-trimethyl-1-cyclohexene (XVII) with Formaldehyde.**—From a mixture of 25 g. of XVII, 7.2 g. of paraformaldehyde, 10.2 g. of acetic anhydride, 6 g. of glacial acetic acid and a trace of sulfuric acid, 3 g. of a crude product were obtained. The saponification of this product gave 1.5 g. of a crude alcohol (b. p. 100—115°C/3 mmHg). The chromatographic purification with activated silica gel gave 1 g. of an alcohol ($n_D^{20}$ 1.4898) from the elution of methanol. The gas chromatogram showed one peak. IR: $\nu_{max}$ 1050 $cm^{-1}$ (a primary alcohol).

Found: C, 78.91; H, 12.08. Calcd. for $C_{14}H_{26}O$: C, 79.52; H, 12.87%.

**The Condensation of 1-[2'-Butenyl]-2, 6, 6-trimethyl-1-cyclohexene (XIX) with Formaldehyde.**—From a mixture of 100 g. of XIX, 16.6 g. of paraformaldehyde and 24 g. of acetic anhydride, the following main fraction (10 g.) was obtained; b. p. 115—130°C/3 mmHg; UV: $\lambda_{max}^{C_2H_5OH}$ 240 m$\mu$, $\varepsilon$ 2162; IR: 1760 $cm^{-1}$ (acetate), 1240 $cm^{-1}$ (acetate), 970 $cm^{-1}$ (trans olefinic bond). The saponification of this product gave 5 g. of 2-methyl-4-[2', 6', 6'-trimethyl-1'-cyclohexene-1'-yl]-3-butene-1-ol (XX), b. p. 110—120°C/3 mmHg; $d_4^{15}$ 0.9164; $n_D^{15}$ 1.5012; molecular refraction, 66.89 (calcd. for $C_{14}H_{24}O$, 66.24); UV: $\lambda_{max}^{C_2H_5OH}$ 242 m$\mu$, $\varepsilon$ 3213; IR: 1045 $cm^{-1}$ (a primary alcohol), 970 $cm^{-1}$ (trans-olefinic bond). The gas chromatogram showed one peak.

Found: C, 81.43; H, 11.62. Calcd. for $C_{14}H_{24}O$: C, 80.69; H, 11.63%.

**Absorption Spectra.** — The infrared absorption spectra were measured by using a Koken IRS spectrophotometer, while the ultraviolet absorption spectra were measured with a "Shimadzu" photometric spectrophotometer type QB-50.

**Gas Liquid Chromatography.** — The gas liquid chromatography was measured under the following conditions:

I, III, XI and XV: Column, LAC-2R-446 (20%) on Celite 545, 2 m.; temperature, 120°C; carrier gas, He 45 ml./min.

V, VIII, XVII, XIX, II, IV, XII and XVI: Temperature, 180°C; other conditions, the same as above.

VI, VII, IX, X, XVIII and XX: Column; silicone DC 200 (20%) on Celite 545, 2 m.; temperature, 230°C; carrier gas, He 45 ml./min.

The author is indebted to the Takasago Perfumary Co., Ltd., for providing materials; to Professor Sho Ito of Tohoku University for the magnetic resonance spectroscopy, and to Professor Kyoichi Suga of Chiba University for his cordial guidance throughout this work.

# The Formation Constants of Chromium(III)-Glycinato and α-Alaninato Complexes*

By Hiroharu MATSUKAWA, Mitsuo OHTA, Shichiro TAKATA and Ryokichi TSUCHIYA

(Received June 20, 1964)

Few reports on the formation constants of chromium(III) complexes have been published. In their own preceding papers the present authors have discussed the formation constants of chromium(III) complexes with ethylenediamine, the simplest chelating agent coordinating by two nitrogen atoms,[1] and those with oxalate ion, the simplest chelating agent coordinating by two oxygen atoms.[2]

Glycine, the simplest α-amino acid, is the intermediate chelating agent between ethylenediamine and oxalate ions from the structural point of view. In the present study the formation constants of chromium(III) complexes with glycine and α-alanine will be determined.

## Experimental

**Hexaaquochromium(III) Perchlorate.**—The preparation of this salt and the method of the analyses of chromium and free perchloric acid were the same as those described in a preceding paper.[2] The compositions of the crystalline salts used for chromium(III) glycinato and α-alaninato complexes respectively were as follows:

* Read at the 13th Symposium on Coordination Compounds of the Chemical Society of Japan, Nagoya, October, 1963.

2) K. Nagata, A. Umayahara and R. Tsuchiya, ibid., 38, 1059 (1965).

$[Cr(H_2O)_6](ClO_4)_3$, 45.61 mol.%;
$HClO_4$, 54.39 mol.%
$[Cr(H_2O)_6](ClO_4)_3$, 55.37 mol.%;
$HClO_4$, 44.63 mol.%

**Glycine and α-Alanine.**—The glycine used was a guaranteed reagent, and α-alanine was a reagent of the highest commercial grade.

**Procedure.**—The formation constants were determined by a pH method similar to that used in a preceding paper.[2] A mixed solution of hexaaquochromium(III) perchlorate and glycine or α-alanine, the ionic strength of which was adjusted to 0.1 by adding sodium perchlorate, was kept in a thermostat at 25°C, and the pH of the solution was measured with a Toa Denpa pH meter, model HM-8, after the equilibrium had been established.

## Results

**The Determination of the Acid Dissociation Constants of Glycine and α-Alanine.**—It is reasonable to presume that α-amino acids are present in an aqueous solution in the three species as $H_3N^+$—CHR—COOH, $H_3N^+$—CHR—$COO^-$ and $H_2N$—CHR—$COO^-$, where R is H for glycine and R is $CH_3$ for α-alanine.

When these three species are expressed by $H_2A^+$, HA and $A^-$ respectively, the acid dissociation constants of the amino acid are defined as follows:

$$H_2A^+ \rightleftarrows H^+ + HA \quad K_1=[H^+][HA]/[H_2A^+] \quad (1)$$

$$HA \rightleftarrows H^+ + A^- \quad K_2=[H^+][A^-]/[HA] \quad (2)$$

where [ ] expresses the concentration of each species in mole per liter.

The acid dissociation constants of glycine at 0.1 of ionic strength and at 25°C were taken from a preceding work[3] to be $pK_1=2.43$ and $pK_2=9.62$, but those of α-alanine have never been known. They were determined by titrating the aqueous solution at an ionic strength of 0.1 and at 25°C with hydrochloric acid or sodium hydroxide and by applying the following equation[3]:

$$pK_1=pH-\log\left(\frac{C}{A-[H^+]}-1\right)$$

or

$$pK_2=pH-\log\left(\frac{C}{B-[OH^-]}-1\right)$$

where $C$ is the total concentration of amino acid, and $A$ and $B$ are the concentrations of hydrochloric acid and sodium hydroxide solution as calculated from their titres. The values of $[H^+]$ and $[OH^-]$ were calculated by applying the activity coefficient of hydrogen ion at an ionic strength of 0.1 to the activity of the hydrogen ion obtained by pH measurement. The results of titration with hydrochloric acid are listed in Table I, those with sodium hydroxide being, however, omitted. The acid dissociation constants of α-alanine have been found to be $pK_1=2.53$ and $pK_2=9.59$ respectively.

**The Determination of the Formation Constants of Glycinato and α-Alaninato Chromium(III) Complexes.**—When the total concentrations of chromium, of amino acid as a ligand and of the total ionizable hydrogen, including $HClO_4$, are expressed by $C_M$, $C_A$ and $C_H$ respectively, the following relationships exist:

$$C_A = [A^-] + [HA] + [H_2A^+] + \bar{n}C_M \quad (3)$$

$$C_H = [H^+] + [HA] + 2[H_2A^+] \quad (4)$$

where $\bar{n}$ is the average number of ligands attached to each chromium ion.

The value of $\bar{n}$ is calculated by the following equation, on the basis of Eqs. 3 and 4:

$$\bar{n}=\left\{C_A-\frac{C_H-[H^+]}{\bar{n}_H}\right\}/C_M \quad (5)$$

where $\bar{n}_H$ denotes the number of hydrogen atoms attached to amino acid against the number of the amino acid which does not coordinate to chromium. $\bar{n}_H$ is expressed by using the values of the acid dissociation constants, 1 and 2, such as:

$$\bar{n}_H=\{K_1+2[H^+]\}/\{K_1K_2/[H^+]+K_1+[H^+]\} \quad (6)$$

On the other hand, if the concentrations of

the free perchloric acid contained in the hexaaquochromium(III) perchlorate used as the starting material and of the sodium hydroxide added to the solution are expressed by $C_a$ and $C_{OH}$ respectively, the concentration of the total ionizable hydrogen is given as;

$$C_H = C_a - C_{OH} + C_A \quad (7)$$

By introducing the measured values of the acid dissociation constants and $[H^+]$ values into Eqs. 5, 6 and 7, the values of $\bar{n}$ and $p[A^-]$ were calculated; Table II lists them only for the glycinato chromium(III) complex, those for the α-alaninato complex being omitted. The plots of $\bar{n}$ vs. $p[A^-]$ with relation to glycinato and α-alaninato chromium(III) complexes are shown in Fig. 1. The approximate values of the formation constants of glycinato and α-alaninato chromium(III) complexes were found from the values of the abscissa at $\bar{n}=0.5$ and 1.5 in the formation curves in Fig. 1. The slope of the formation curves was not so steep that the correct values of the formation constants were obtained as $\log K_1 = 8.62$ and $\log K_2 = 7.65$ for the glycinato chromium(III) complexes and as $\log K_1 = 8.53$ and $\log K_2 = 7.44$ for the α-alaninato chromium(III) complexes by applying the method of successive approximation to the approximate values obtained above.

TABLE II. THE VALUES OF $\bar{n}$ AND $p[A^-]$ CALCULATED FOR GLYCINATO CHROMIUM(III) COMPLEX AT $\mu=0.1$ AND 25°C

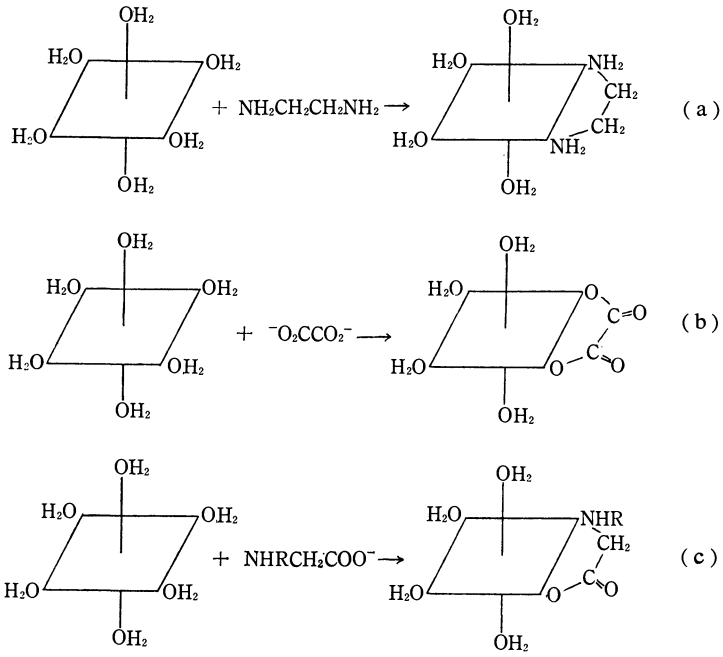
○ Chromium(III) glycinato complexes
◑ Chromium(III) α-alaninato complexes

## Discussion

The values of the formation constants of chromium(III) glycinato and α-alaninato complexes obtained in the present study are summarized in Table III, together with those of chromium(III) ethylenediamine and oxalato complexes reported by the present authors in preceding papers.[1,2]



This table indicates, first, that the formation constants of glycinato and α-alaninato complexs are nearly all the same. This may be due to the fact that these two amino acids form the same five-membered chelate ring with chromium ions except that α-alanine has a methyl group, whereas glycine has none. It may also be suggested that the presence of a methyl group in the side chain of α-amino acids has little influence upon the ability to form chromium(III) complexes.

Table III also shows that the values of the formation constants of glycinato and α-alaninato complexes are between those of ethylenediamine and oxalato complexes. This is to be expected from the fact that glycine and α-alanine are N, O-type ligands, whereas ethylenediamine is an N, N-type ligand and the oxalate ion is an O, O-type ligand.

TABLE III. THE FORMATION CONSTANTS OF ETHYLENEDIAMINE-, GLYCINATO-, α-ALANINATO-, AND OXALATO-CHROMIUM(III) COMPLEXES IN AQUEOUS SOLUTION OF IONIC STRENGTH 0.1 AT 25°C

| | $\log k_1$ | $\log k_2$ |
|---|---|---|
| Ethylenediamine complex | 16.5 | <14 |
| Glycinato complex | 8.62 | 7.65 |
| α-Alaninato complex | 8.53 | 7.44 |
| Oxalato complex | 5.34 | 5.17 |

When the values in Table III are compared with each other in more detail, it is found that the values of the formation constants of glycinato and α-alaninato complexes are closer to those of oxalato complexes rather than to those of ethylenediamine complexes. Although

it is impossible to account this fact completely satisfactorily, it may be roughly understood in terms of speculation concerning the entropy effect.

Let us take into account the processes by which mono-ethylenediamine, mono-oxalato and mono-$\alpha$-amino acid complexes are formed from the hexaaquo complex by the following processes, a, b and c:

The free energies of formation in the processes, a, b and c, are expressed by the enthalpy and entropy terms as follows:

$$\Delta G_{en} = \Delta H_{en} - T\Delta S_{en} \quad (8)$$

$$\Delta G_{ox} = \Delta H_{ox} - T\Delta S_{ox} \quad (9)$$

$$\Delta G_{a} = \Delta H_{a} - T\Delta S_{a} \quad (10)$$

where the suffixes en, ox and a designate the processes a, b and c. If it is crudely assumed that the bond energy of chromium with $\alpha$-amino acid as the N, O-type ligand is approximately equal to the mean value of the bond energy of chromium with ethylenediamine as an N, N-type ligand and that of the chromium with the oxalate ion as an O, O-type ligand, then the following equation may be roughly presented:

$$\Delta H_{a} \fallingdotseq 1/2\ (\Delta H_{en} + \Delta H_{ox}) \quad (11)$$

By substracting Eq. 10 from half of the sum of Eqs. 8 and 9 and by taking Eq. 11 into account, the following equation is obtained:

$$\Delta G_{a} - 1/2(G_{en} + \Delta G_{ox}) = T\left(\frac{\Delta S_{en} + \Delta S_{ox}}{2} - \Delta S_{a}\right) \quad (12)$$

As the rough values of the free energies of the formation of ethylenediamine, oxalato and glycinato complexes in the processes a, b and c, $\Delta G_{en} = -27$ kcal., $\Delta G_{ox} = -9$ kcal. and $\Delta G_{a} = -14$ kcal. are, respectively, obtained from the formation constants in Table III. When we insert those values into Eq. 12, we can obtain the difference between the mean values of the entropy changes of the formation of ethylenediamine in the process a and of oxalato complexes in b and the value of the entropy change of the formation of the glycinato complex in c. If the entropy changes of the formation of ethylenediamine and oxalato complexes are assumed to be approximately equal because of the resemblance between their changes in atomic configuration, the rough relation below is obtained:

$$(-\Delta S_{a}) - (-\Delta S_{en} \text{ or } -S_{ox}) = 14 \text{ e. u.}$$

This shows that the entropy decrease in the formation of the glycinato complex is larger by about 14 entropy units than the entropy decrease in the formation of the ethylenediamine or oxalato complex; this can be roughly understood by considering that mono-ethylenediamine and mono-oxalato complexes have roughly a symmetry such as $C_{2v}$, whereas the mono-$\alpha$-amino acid complexes have a lower symmetry such as $C_s$.

## Summary

The formation constants of chromium(III) glycinato and $\alpha$-alaninato complexes have been

determined by the pH method. The values connected with these two complexes are so close to each other that no effect of the presence of a methyl group could be found.

The values of the first formation constants of these complexes are smaller than the mean value of those of ethylenediamine and oxalato complexes. These facts have been explained in terms of the finding that the decrease in the entropies of the formation of $\alpha$-amino acid complexes is larger than that of ethylenediamine or oxalato complexes because the symmetry of the amino acid complexes is lower than that of the ethylenediamine or oxalato complexes.

# A Theoretical Treatment of the Kinetics of the Oxidation of Metals

By Hiroshi YOSHISAKI and Toyojiro ISANO

(Received July 14, 1964)

It is generally believed that the progression of the isothermal oxidation of metals is governed by the so-called parabolic law which can be represented by the following equation:

$$y^2 = Gt \qquad (1)$$

where $y$ represents the total quantity of oxide produced during the time lapse, $t$, both measured from the initiation of the progression, and where $G$ is a constant.[1,3]

Actually, the above law holds with moderate accuracy as long as the observations are restricted within sufficiently short periods and are made after sufficiently long lapses of time from the initiations. However, when the above conditions are not satisfied we can never use Eq. 1 with success, especially for early periods. According to the parabolic law, the initial rate of oxidation should be infinite, whereas no facts have ever been found to suggest the existence of an infinite rate; moreover, such a rate is, indeed, erroneous in principle also. In fact, we can see as much when we look at the example of our recent observations, still unpublished, shown in Fig. 1. It can clearly be seen from this figure that the process begins with a finite rate, not an infinite one.

Under these circumstances, we have undertaken this investigation with the purpose of looking into the discrepancies of the parabolic law and of deduction of a more reasonable law, one which can agree with the actual functions controlling the process of the oxidation of metals.

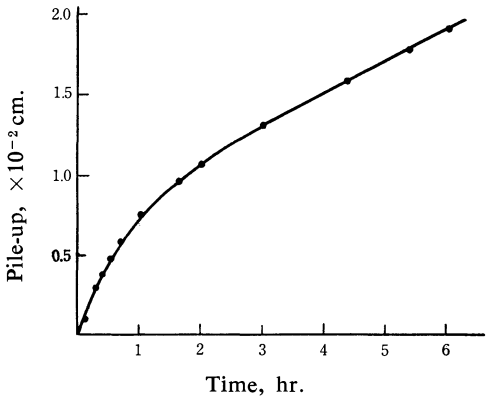

Fig. 1. Oxidation isotherm of copper in the air at 825°C.

## The Mechanism of the Progression

When a metal regulus is held at a high temperature under an oxidizing atmosphere, it becomes covered by an oxide film, which gradually grows thicker and thicker as time elapses. If the coverage is assumed to be perfect, then the oxidation must continue its progression by means of one of two processes; in one, oxygen molecules from the atmosphere pass by diffusion through the oxide layer towards the oxide-metal boundary surface, where they combine with the metal atoms upon arrival; in the other, metal atoms from the regulus diffuse through the layer towards the surface exposed to the atmosphere, where they combine with oxygen upon arrival. Several papers recently published suggest that in reality the latter is

1) P. V. Geld and A. K. Krasovskaya, *Zhur. Fiz. Khim.*, **34**, 1585 (1960).

the case, for in major cases the oxide scale produced shows evidence that the growth of the scale is due to the accumulation of oxide on the exposed surface.[2,3] This opinion, therefore, seems reasonable.

As to the time rate of the oxidation of metals, it is clear that it is determined by the slowest of the consecutive processes of which the whole change consists. According to our point of view, as the rate of the combination of metal with oxygen should greatly surpass that of its diffusion through the oxide layer, the rate of oxidation should be determined by the diffusion of metal.

However, there is a difficulty. If the oxidation progresses in the above-mentioned manner then the metal surface should of itself retire from the initial place into the interior of the regulus due to the surrendering of the metal material to the oxide layer, while, on the other hand, the inside surface of the oxide layer should stay unmoved, so that a vacant space or interstice grows up between them; nevertheless, in reality this is not the case. Probably this problem may be answered in terms of the heterogeneity in the structure of the scale, so as Mrowec states.[2,3]

## The Deduction of an Equation Isotherm

It is well known that the parabolic law comes from the assumption that the concentration of diffusing matter is distributed at a uniform gradient all through the medium, so that;

$$\nabla c = \text{constant}$$

where $c$ represents the concentration at any point. However, this condition can never be satisfied in reality since the medium can not be perfectly homogeneous nor can the surface of the regulus be ideally even, regardless of how it is made. Thus the diffusion must unavoidably be a turbulent one. For this reason we should refer to the general condition to begin with:

$$\nabla^2 c = k^2 c \qquad (2)$$

where $k$ represents a constant. If we now restrict ourselves to one dimention, the general solution of Eq. 2 is obtained as follows:

$$c = (K/k)\sinh(-kx+\kappa) \qquad (3)$$

where $x$ is the coordinate of the point at which the concentration, $c$, is measured, and $K$ and $\kappa$ are two constants. If we assume for the boundary condition that the concentration of the reactant metal on the surface of the scale in contact with the oxidizing atmosphere is zero, then Eq. 3 becoms:

$$c = (K/k)\sinh\{k(\xi-x)\} \qquad (4)$$

where $\xi$ represents the coordinate of a point on the exposed surface.

Now we will take up a small portion, $\sigma$, of the exposed surface, localized at will, so small that it can be taken as a part of a spherical surface with the center of curvature at O. Moreover, we will set up an x axis with O as the origin, and crossing $\sigma$ at a point, P, in its interior, as is shown in Fig. 2. The coordinate

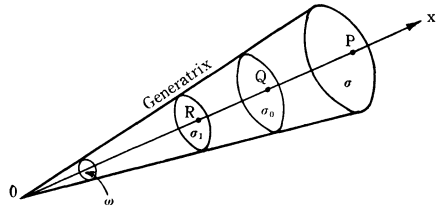

Fig. 2. Scheme of the space under consideration.

at P is $\xi$, of course. The solid segment based on $\sigma$ and with O as its vertex, cuts the surface elements, $\sigma_0$ and $\sigma_1$, from the initial metal surface and the oxide-metal boundary surface respectively, both of which can be taken as spherical and concentric with $\sigma$. The intersections of these surfaces with the x axis are Q and R, the coordinates at which being $x_0$ and $x_1$ respectively.

Now, if we assume, at time $t$, that the amount of metal which was initially contained in the disk-like space enclosed by $\sigma_0$, $\sigma_1$ and the generatrices has turned as a whole into the oxide scale contained in the disk-like space enclosed by $\sigma$, $\sigma_1$ and the generatrices, then the following equation should hold:

$$\frac{\omega}{4\pi}\cdot\frac{4}{3}\pi(x_0^3-x_1^3)c_r = \frac{\omega}{4\pi}\cdot\frac{4}{3}\pi(\xi^3-x_1^3)c_p \qquad (5)$$

where $c_r$ and $c_p$ represent the total concentrations of metal in the reactant regulus and in the resultant scale respectively, and $\omega$, the solid angle enclosed by the generatrices. Differentiating Eq. 5 with respect to $\xi$, we obtain:

$$\frac{dx_1}{d\xi} = -\frac{\xi^2}{x_1^2}\cdot\frac{c_p}{c_r-c_p} \qquad (6)$$

Assuming that the rate of the loss of metal in the regulus is equal to the rate of its transfer across any fixed surface section enclosed by the generatrices, we can write:

$$\omega x^2 cu = -c_0\omega x_1^2\frac{dx_1}{dt} \qquad (7)$$

2) S. Mrowec, *Zeit. f. pfys. Chem. Neue Folge*, **29**, 48 (1961).
3) L. Czerski, S. Mrowec and T. Werber, *J. Electrochem. Soc.*, **109**, 273 (1962).

where $u$ represents the average value of the $x$-components of the atomic velocities on the surface apart from O as far as x, and $c_0$ represents the concentration on the boundary surface, which can be taken as a constant. Combining this relation with the fundamental equation:

$$cu = -D\frac{dc}{dx}$$

we obtain the following equation:

$$Dx^2\frac{dc}{dx} = c_0 x_1^2\frac{dx_1}{dt} \tag{8}$$

where $D$ represents the diffusion constant of the metal in the scale. Substituting $dc/dx$ in the left hand side according to Eq. 4, we obtain:

$$\int_{x_0}^{\xi}\frac{\xi^2 d\xi}{\cosh\{k(\xi-x)\}} = \frac{KD}{c_0}\left(\frac{c_r}{c_p}-1\right)\int_0^t x^2 dt + L \tag{9}$$

where $L$ is the integration constant which must vanish for the initial condition, $\xi=x_0$, for $t=0$.

If we define $X$ as $X=\xi-x_0$, where the initial surface, $\sigma_0$, on which $x$ takes a value $x_0$, is prefered as a fixed reference surface, then $X$ represents in practice the pile-up of the exposed surface of the resultant oxide scale due to the progress, and is a measurable quantity. Then Eq. 9 becomes:

$$\int_0^X\frac{(X+x_0)^2}{\cosh(kX)}dX = Ax_0^2 t \tag{10}$$

where

$$A = \frac{KD}{c_0}\left(\frac{c_r}{c_p}-1\right)$$

As Eq. 10 has been derived for a convex portion of the metal surface, it can also be obtained for a concave portion with the identical terms. Thus this equation can be taken as a general equation isotherm at a point, either convex or concave, $x_o$ being the radius of the curvature. We can reasonably assume that, if the observation is done on a well-finished sound regulus, Eq. 10 may be satisfied in a macroscopic extent by substituting a function, $\bar{x}_0$, for $x_0$, $\bar{x}_0$ being characteristic of the evenness of the surface in a macroscopic scale. Moreover, if we define $\gamma$ as the reciprocal of $\bar{x}_0$, then Eq. 10 becomes:

$$\int_0^X\frac{\left(X+\frac{1}{\gamma}\right)^2}{\cosh(kX)}dX = \frac{1}{\gamma^2}At \tag{11}$$

where $\gamma$ represents a parameter indicating the coarseness of the surface. This is the general equation isotherm for the oxidation of metals holding in measurable scales.

For a small value of $X$, that is, unless too long a time has elapsed since the initiation, we can expand the integrand in Eq. 11 into a power series of $X$ and integrate it, writing it as follows:

$$X + \gamma X^2 + \frac{1}{3}\left(\gamma^2-\frac{k^2}{2}\right)X^3 - \frac{1}{4}\gamma k^2 X^4 - \frac{1}{2}k^2\left(\frac{1}{5}\gamma^2-\frac{1}{12}k^2\right)X^5 + \frac{5}{72}\gamma k^4 X^6 + \cdots = At \tag{12}$$

where $A$ represents a constant proportional to the diffusion constant of the metal in the oxide layer.

## Discussion

As has been established in the preceding section, the progression of isothermal oxidation is governed by a somewhat more complicated law than the parabolic law. That Eq. 12 begins with a linear term shows that, for a short initial period, the oxidation process begins with a finite velocity instead of an infinite one; a theory supported by the experimental facts.

Now, we find that the left hand side of Eq. 12 consists of three groups of terms: first, those independent of $\gamma$; second, those each containing a factor $\gamma$; and third, those each containing a factor $\gamma^2$. Thus we can rewrite Eq. 12 as follows:

$$\left[X - \frac{1}{6}k^2X^3 + \frac{1}{24}k^4X^5 - \cdots\right] + \gamma\left[X^2 - \frac{1}{4}k^2X^4 + \frac{5}{72}k^4X^6 - \cdots\right] + \gamma^2\left[\frac{1}{3}X^3 - \frac{1}{10}k^2X^5 + \cdots\right] = At \tag{13}$$

As $\gamma$ can vary from zero to infinity, it may be seen that the progression of oxidation may have considerably different aspects, even for the same reactant species, because of the fluctuation of the coarseness of the surface. If the surface is ideally flat, the progression of the oxidation will be governed by the following equation:

$$X - \frac{1}{6}k^2X^3 + \frac{1}{24}k^4X^5 - \cdots = At$$

since the second and third terms on the left hand side of Eq. 13 vanish for $\gamma\to 0$. On the other hand, for very coarse surfaces, for instance, with finely pulverized metals, it will be governed by:

$$\frac{1}{3}X^3 - \frac{1}{10}k^2X^5 + \cdots = \frac{1}{\gamma^2}At$$

the third term in Eq. 13 assuming prominent values because of the large value of factor $\gamma^2$, except in the early stages. In major cases, however, all terms in Eq. 13 will contribute equally. Thus we may suggest the following equation as a rough approximation for sufficiently small values of $X$:

$$X + \gamma X^2 + \frac{1}{3}\left(\gamma^2 - \frac{k^2}{2}\right)X^3 = At \qquad (14)$$

## Summary

We have attributed the deficiency of the parabolic law to its original assumption of a uniform gradient of the concentration of the reactant, and, beginning with a general assumption of a turbulent gradient, we have deduced an alternative equation, one somewhat more complicated than the parabolic one. In discussing the behavior of the new equation, it was found that the mode of progression largely changes its profile as a result of the fluctuation of the coarseness of the surface to be oxidized.

We are indebted to Messrs. Yutaka Sakuma and Tsutomu Itô for their honest assistance.

## Appendix

**Deduction of Equation 2.**—This equation was deduced as follows: Take arbitrarily, in the field of the turbulent stationary diffusion, a space element shaped like a rectangular cylinder; the axis thereof may be taken as a coordinate axis, $x$, as is shown in Fig. 3. We will designate the area of both base planes and the height of the cylinder as $\sigma$ and $\delta x$ respectively. When the coordinate of one base plane, $S_1$, on which the concentration of the diffusing substance may be designated as $c$, is taken as $x$, then the coordinate and the concentration at the other base plane, $S_2$, should be $x+\delta x$ and $c+(\partial c/\partial x)\delta x$ respectively. As is well known, the rate of the passage of a diffusing substance through a plane perpendicular to the x axis is proportional to

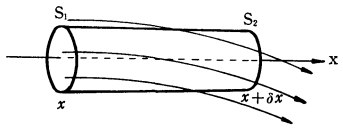

Fig. 3

$-\partial c/\partial x$. Thus, the rate of flow in the left-to-right direction through $S_1$ and $S_2$ in Fig. 3 should amount to $-D_1\sigma(\partial c/\partial x)$ and $-D_1\sigma[\partial c/\partial x+(\partial^2 c/\partial x^2)\delta x]$ respectively, where $D_1$ is a constant. On the other hand, the rate of the flow out through the generating surface of the cylinder can be taken as proportinal to the mean concentration in the cylinder, multiplied by a constant, $s$ for instance, chracteristic of the structure of the medium, which can be represented as $sl\delta x\cdot c$, where $l$ represents the length of the border-line of a rectangular cross-section of the cylinder. Consequently, the rate of the total flow out of the cylinder should be $D_1\sigma(\partial c/\partial x)-D_1\sigma[\partial c/\partial x+(\partial^2 c/\partial x^2)\delta x]+sl\delta x\cdot c$. For a stationary or quasi-stationary diffusion, the above quantity must vanish, so that

$$D_1\sigma\frac{\partial^2 c}{\partial x^2} = slc$$

namely:

$$\frac{\partial^2 c}{\partial x^2} = k^2{}_1 c$$

where

$$k^2{}_1 = \frac{sl}{\sigma D_1}$$

In three-dimentional treatments:

$$\nabla^2 c = k^2 c$$

where $k$ is a constant.

**Comparison with the Hatta Theory.**—The above equation takes the same form as that of the well-known Hatta theory, which treats diffusion phenomena accompanied with the consumption of diffusing substances due, for instance, to a chemical reaction of the first order, to absorption or to capillary phenomena. This coincidence seems to us very interesting, for these results, obtained by a different method of computation, may not yet be taken as utterly different in physical meaning. This theory is all the more convincing because we notice that the irregular turn-asides of stationary flow lines can reasonably be replaced with a definite distribution of wells and sinks in dynamical treatments of a turbulent flow of a fluid. For this reason, the present case can be taken as closely analogous to Hatta's case, and so it is not strange that the same hydrodynamic equation is applicable in both cases.

# The Oligomerization of Butadiene with an Iron Complex Catalyst

By Masanobu HIDAI, Yasuzo UCHIDA and Akira MISONO

(Received August 11, 1964)

Several complex catalyst systems for the selective dimerization and trimerization of butadiene have been reported,[1] most of them are composed of first-row transition metal complexes and organometallic compounds. Attempts have also been made to elucidate the relationship between the sorts of transition metals and electron-donating additives as catalyst components, on the one hand, and the structure of the oligomers formed therewith on the other.

In a previous paper[2] the authors reported that butadiene dimerizes selectively to 3-methylhepta-1, 4, 6-triene with the catalyst prepared by the reaction of cobalt(III) acetylacetonate and triethylaluminum in the presence of butadiene. It has now been found that *n*-dodeca-1, 3, 6, 10-tetraene is formed selectively with the catalyst prepared by the reaction of iron(III) acetylacetonate instead of the cobalt complex.

This paper will be concerned, in particular, with the structural determination of the trimers and of the factors affecting the reaction. Measurements of the visible light absorption spectra and of the magnetic susceptibility of the reaction solution for the elucidation of the transition complex of the oligomerization will also be described.

## Experimental

**Reagents.**—Benzene was purified by washing it with concentrated sulfuric acid and then distilling it over metallic sodium under nitrogen.

Triethylaluminum (Ethyl Corporation, U. S. A.) was used without further purification.

Butadiene (Nihon Petrochemical Company) was dried by passing it through columns of calcium chloride and silica gel.

Iron(III) acetylacetonate was prepared according to the method described by Steinbach et al.[3]

**Procedure.**—A 30 ml. Schlenk tube or a 200 ml. glass autoclave was used as a reactor. Calculated amounts of iron(III) acetylacetonate, benzene, butadiene and triethylaluminum were introduced in that order into the reactor, which had previously been swept with nitrogen. During the procedure, the reactor was cooled below −10°C to prevent the evaporation of butadiene. Then the reactor was sealed or stoppered and kept at 50°C during the reaction. Products were analyzed by gas chromatography immediately or after hydrogenation with palladium black.

**Analysis.**—*Gas Chromatography.*—For the analysis of the dimers, a copper tube (4 mm. in diameter and 2.5 m. long) packed with tricresylphosphate on Simalite (Shimadzu Seisakusho Ltd.) was used. The temperatures of the thermostat and the inlet were 90°C and 140°C respectively; the helium gas speed was 30 ml./min. For the trimers, a copper tube (4 mm. in diameter and 7 m. long) packed with polydiethylene glycol-succinate on Diasolid (Shimadzu Seisakusho Ltd.) was used. The temperatures of the thermostat and the inlet were 130°C and 220°C respectively, and the helium gas speed was 22 ml./min. For the determination of the molecular distribution of the products, hydrogenated products were used. Hydrogenation was carried out with 5% of palladium black under atmospheric pressure at room temperature. $C_{16}$- and $C_{20}$-products were determined by gas chromatography with a copper tube (4 mm. in diameter and 7 m. long) packed with polydiethylene glycol-succinate on Diasolid. The conditions were as follows; temperature of thermostat, 190°C: that of inlet, 270°C, and helium gas speed, 22 ml./min.

*Distillation.*—For the determination of the molecular weight distribution of the reaction products, hydrogenated products were fractionated by vacuum distillation and molecular distillation ($10^{-3}$ mmHg) into 7 parts. The average molecular weight of each fraction was determined by vapor pressure osmometry.

*Infrared Spectra.*—The spectra of the samples were taken with a Nihon-bunko double-beam spectrometer model 401 G.

*NMR Spectra.*—The spectra were recorded on a Nihon-Denshi model 3H-60.

*Ultraviolet and Visible Light Spectra.*—The spectra were recorded on a Hitachi model EPS spectrometer, using a 10 mm.-path-length quartz cell for the ultraviolet measurements and a 0.1 mm.-path-length quartz cell for the visible light spectra measurements. Magnetic susceptibilities were measured with a Gouy balance in the field of 10000 gauss at room temperature.

## Results and Discussion

**The Identification Oligomers.** — Liquid polymer, trimers and dimers were obtained by the reaction. The conversion of butadiene versus the reaction time is shown in Fig. 1, while the

- ▲ 4-Vinylcyclohexene

yields of each oligomer is given in Fig. 2. The yield of the dimers was only a small percentage of the products. The dimers were identified as 3-methylhepta-1,4,6-triene, *n*-octa-1,3,6-triene, 4-vinylcyclohexene and cycloocta-1,5-diene by gas chromatography. Trimers consisted of two kinds of isomers. One of the main products was separated and purified with preparative gas chromatography, and then the structure was determined. The results of elemental analysis (C, 87.5%; H, 11.2%) and molecular weight determination (M.W.=162) indicate that this compound is a trimer of butadiene. From the iodine value and the infrared spectra, it was confirmed that the trimer has two isolated double bonds and a pair of conjugated double bonds in its structure. In the infrared spectra (shown in Fig. 4) the absorption of the C=C conjugated stretching vibration (1650, 1600 $cm^{-1}$), the C-H out of plane deformation vibration of the conjugated vinyl group (895, 1000 $cm^{-1}$), that of the trans double bond (970 $cm^{-1}$), that of the conjugated trans double bond (955 $cm^{-1}$), and that of the cis double bond (700 $cm^{-1}$) were observed. In the ultraviolet spectra, the absorption of the conjugated double bond was observed at 228 m$\mu$, the molecular absorption coefficient being $3\times10^4$. In the NMR spectra (shown in Fig. 5) the absorption of the protons of the methylene group between two double bonds, those of the methylene group adjacent to a double bond and those of the methyl group adjacent to a double bond were found at 7.1, 7.8 and 8.3 $\tau$ respectively. The ratio of the peak areas was 2:4:3. Moreover, the hydrogenated product of this trimer was identified as *n*-dodecane by gas chromatography. Judging from these results the structure of the trimer is *n*-dodeca-1,3,6,10-tetraene.

$$CH_2=CH-CH=CH-CH_2-CH=$$
$$CH-CH_2-CH_2-CH=CH-CH_3$$

Another trimer, which was formed in an amount about one-fourth of *n*-dodecatetraene, was a branched-chain isomer, judging from infrared and NMR observations.

**Molecular Weight Distribution of the Product.** —To solve the question of whether these trimers are the lower parts of liquid polybutadiene or those formed by a process different from polymerization, the molecular weight distribution was determined with the hydrogenated products. The hydrogenated products were fractionated into 7 fractions by vacuum distillation (trimers) followed by molecular distillation (5 fractions and the residue). The amounts and the average molecular weight of the fractions are given in Table I. For the fraction with the average polymerization degree of 4.5, the $C_{12}$, $C_{16}$ and $C_{20}$ contents were measured by gas chromatography. From these results and from the amount and average polymerization degree of the fraction, the $C_{24}$ content was calculated. In the same way, for the fraction with the average polymerization degree of 5.5, the $C_{12}$ (which could not be found), $C_{16}$ and $C_{20}$ contents were determined by gas chromatography. Then the $C_{24}$ and $C_{28}$ contents were calculated on the assumption that the fraction with an average polymerization degree between $n$ and $n+1$, obtained by molecular distillation, consists of $C_{4(n-1)}$, $C_{4n}$, $C_{4(n+1)}$ and $C_{4(n+2)}$. From the results concerning both fractions, the mole ratio of components was

estimated to be nearly $C_{4(n-1)} : C_{4n} : C_{4(n+1)} : C_{4(n+2)} = 1 : 3 : 3 : 1$. On the assumption that the fractions with an average polymerization degree larger than 5.5 consisted of components in the same 1 : 3 : 3 : 1 ratio, the amounts of all the component in the fractions were estimated. By obtaining the sum of the components of each fraction, the molecular weight distribution of products was estimated (Fig. 3). The result shows that the products evidently consist of two parts, one of which is dimers and trimers and the other is liquid polybutadiene, with an average polymerization degree of seven. It was,

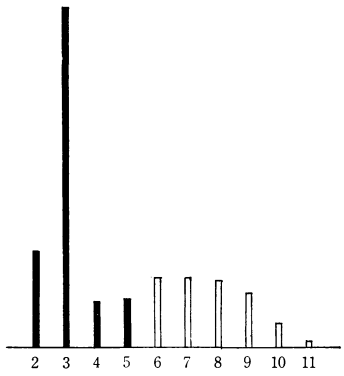

Fig. 3. Molecular weight distribution of products.

▬: The molecular weight distribution of these components was also determined by gas chromatography.

therefore, concluded that trimers were formed by a mechanism different from that of polymerization.

**The Effect of the Ratio of $AlEt_3$ to $Fe(acac)_3$.** —Figure 6 shows the relation between the selectivity of linear trimer formation and the mole ratio of catalyst components. When more than 3 times the amount of the iron(III) acetylacetonate of triethylaluminum was used, the selectivity of the formation of trimers was lowered and polymer formation became predominant. However, the *n*-dodecatetraene ratio in linear trimers was not affected. Figure 7 gives the effect of the ratio of catalyst components on the apparent reaction rates of the formation of the linear trimers and liquid polybutadiene. It indicates that the rate of the formation of liquid polybutadiene is nearly proportional to the ratio of triethylaluminum to the iron(III) acetylacetonate used. When

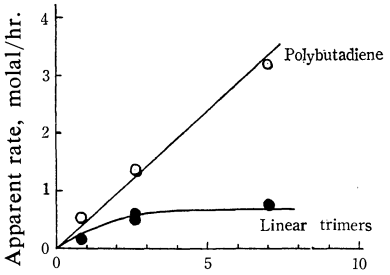

Fig. 7. Effect of $AlEt_3/Fe(acac)_3$ mol. ratio on apparent rate.

only triethylaluminum was applied as a catalyst, butadiene did not react. This phenomenon suggests that both iron and aluminum compounds take part in the formation of the active transition state of the catalyst for polymerization, while only the iron reduced, perhaps to the zero-valent state, by a definite amount of triethylaluminum is involved in the trimerization of butadiene.

**The Effect of Catalyst Concentration.**—The effect of the catalyst concentration on the apparent reaction rate is shown in Fig. 8. The apparent rates of the formation of both trimers and liquid polybutadiene were nearly proportional to the catalyst concentration.

**The Effect of the Mixing Order of the Catalyst Components.**—As has been mentioned in previous papers,[2,4] in the linear dimerization of butadiene with a catalyst composed of cobalt(III) acetylacetonate and triethylaluminum, the order of mixing the catalyst components and butadiene has a great effect on the rate of the formation of the dimer. The same phenomenon was expected in the present reaction. The effect of the order of mixing the catalyst components and butadiene is given in Table II. The apparent rate of the oligomerization of butadiene was greater when iron(III) acetylacetonate, butadiene and triethylaluminum were mixed in that order than when triethylaluminum was allowed to react with iron(III) acetylacetonate in the absence of butadiene. These results suggest that the coordination of butadiene to reduced iron prevents the coagulation of reduced iron and plays an important role in the formation of the oligomers.

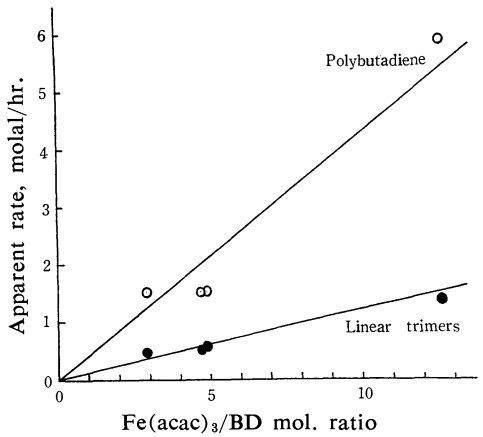

Fig. 8. Effect of concentration of catalyst.

Benzene: 7.3 g. Butadiene: 2.1 g.
$AlEt_3/Fe(acac)_3$: 2.5 Reaction temp.: 50°C

**The Observation of the Reaction Solution.**—When triethylaluminum was added to a benzene solution of iron(III) acetylacetonate ($Fe^{3+}$ was reduced to $Fe^{2+}$ and then to the zero-valent state.), the solution became unstable and immediately gave rise to a black precipitate. The system showed a ferromagnetism probably caused by the coagulated reduced iron. In the presence of butadiene, the solution became reddish brown and showed paramagnetism, while a shoulder absorption was found at about 400—420 m$\mu$ in the visible light absorption spectrum. This absorption has also been observed in $\pi$-[BD $Co(CO)_2]_2$ and $\pi$-BD $Fe(CO)_3$.[5] On the basis of these results and on the assumption that the active complex for polymerization is diamagnetic,[6] *n*-dodecatetraene is considered to be formed through a paramagnetic intermediate complex in which three molecules of butadiene coordinate to a zero-valent iron atom.

## Summary

The oligomerization of butadiene with the catalyst system of iron(III) acetylacetonate and triethylaluminum has been studied. The

4) T. Saito, Y. Uchida and A. Misono, This Bulletin, 37, 105 (1964).
5) S. Ohtsuka, *Kagaku-Zokan*, No. 13, 87, (1964).
6) K. Tamai, M. Hidai, Y. Uchida and A. Misono, This Bulletin, to be published.

products obtained by the use of this catalyst consist of two types, one of which is dimers and trimers, and the other is polybutadiene, with an average polymerization degree of seven. The dimers are 3-methylhepta-1, 4, 6-triene and cycloocta-1, 5-diene. The trimers have been confirmed to be *n*-dodeca-1, 3, 6, 10-tetraene and a branched isomer.

The effects of the ratio of the catalyst components to the concentration of the catalyst have been also studied.

From these results, it has been concluded that oligomerization proceeds by a mechanism different from that of polymerization.

To elucidate a transition state for oligomerization, the visible light spectra and the magnetic susceptibility of the reaction solution have been measured and a complex in which butadiene coordinates to reduced iron atom has been assumed as the transition state.

# A Study of the Acid Dissociation of Furan- and Thiophenedicarboxylic Acids and of the Alkaline Hydrolysis of Their Methyl Esters

By Shigeru OAE, Naomichi FURUKAWA, Takao WATANABE
Yoshio OTSUJI and Masayuki HAMADA

(Received August 15, 1964)

The physical and chemical behavior of furan- and thiophenemonocarboxylic acids and their derivatives has been investigated extensively and shown to be considerably different from that of benzoic acid.[1] Cocker et al. have suggested the formation of an intramolecular hydrogen bond in their study of the acid dissociations of four carboxylic groups and the infrared spectrum of furantetracarboxylic acid.[2] Meanwhile, a few dicarboxylic acids, such as succinic acid[3] and maleic acid,[4] have been known to form intra- or intermolecular hydrogen bondings that create substantial differences between their first and second dissociation constants.

Meanwhile, although there have been many reports on the alkaline hydrolysis of the monocarboxylic esters and the reaction mechanism of the saponification has been well elucidated,[5] only a few investigations of the hydrolyses of dicarboxylic esters have been carried out. This is perhaps due to the extreme difficulty of following the kinetics of the hydrolyses of these diesters, because they do not obey the simple second-order kinetic equation. However, a few noteworthy treatments have been made. Namely, one of the earliest treatments of the competitive consecutive second-order reaction for the alkaline saponification of diesters has been carried out by Ingold.[6] However, this graphic approximation gives by no means an accurate estimation. Meanwhile, other investigators have made many efforts to get accurate kinetic data for those dicarboxylic esters.[7] Frost and Schwemer have presented what appears to be the first legitimate method for the calculation of the consecutive competitive second-order kinetic equation of the alkaline hydrolysis of dicarboxylic esters.[8]

The present work was initiated in order to investigate the nature of the interaction between the two carboxyl groups attached to the furan and thiophene rings and the alkaline hydrolyses of the diesters of these carboxylic

acids in comparison with the dissociations of phthalic acids and maleic acid and the saponification of their esters.

## Experimental

**Materials.** — *2, 3-Furandicarboxylic Acid.*[9] — 4,4-Diethoxybutyronitrile, obtained from acrolein, was condensed with diethyl oxalate, giving 2-ethoxalyl-4,4-diethoxybutyronitrile. Ethyl 3-carbamyl-2-furancarboxylate, prepared by the cyclization of the above nitrile, was hydrolyzed to 2,3-furandicarboxylic acid. Colorless crystals of the acid melted at 221—222°C, and the yield was 20% on the basis of the 2-ethoxalyl-4,4-diethoxybutyronitrile used.

*The 2-Monomethyl Ester of 2,3-Furandicarboxylic Acid.*—The above acid was converted to its monosilver salt by adding 1.2 mol. of silver nitrate to one mole of the monosodium salt in water. To a solution of one mole of the dried monosilver salt obtained above in benzene, one mole of methyl iodide was added, and then the mixture was refluxed for two hours and filtered to remove the silver iodide. The benzene solution was evaporated to dryness, and recrystallization from water gave the monoester in a 70% yield. M. p. 118°C.

Found: C, 49.28; H, 3.97. Calcd. for $C_7H_6O_7$: C, 49.44; H, 3.56%.

Since in 2,3-furandicarboxylic acid the 2-carboxylic group is much more acidic than the 3-carboxylic group, it is reasonable to assume that 2,3-furandicarboxylic acid is esterified first at the 2-position by the method used in this investigation. Thus the monoester obtained would have to be 2-monomethylester of 2,3-furandicarboxylic acid.

*3, 4-Furandicarboxylic Acid.*[10]—Diethyl α-formylsuccinate was converted to its acetal, which was again formylated to diethyl 1-formyl-2-diethoxymethylsuccinate. 3, 4-Furandicarboxylic acid was prepared by the cyclization of the above compound. Recrystallization from water gave colorless crystals (m. p. 214°C), and the yield was 50% on the basis of the diethyl succinate used.

*The 3-Monomethyl Ester of 3, 4-Furandicarboxylic Acid.*—This ester was obtained in a 76% yield by the method used for the esterification of 2,3-furandicarboxylic acid (m. p. 135—137°C).

Found: C, 49.06; H, 3.76. Calcd. for $C_7H_6O_5$: C, 49.44; H, 3.56%.

*2, 5-Furandicarboxylic Acid.*[11] — This acid was obtained first by chloromethylating ethyl 2-furancarboxylate and then by oxidizing the resulting compound (m. p. 365°C) in a 70% yield.

*2,4-Furandicarboxylic Acid.*[12]—This acid was prepared by the rearrangement of the methyl 6-bromocoumalin 5-carboxylate obtained from coumalin 5-carboxylic acid (m. p. 268-269°C) in a 48% yield.

*3,4-Thiophenedicarboxylic Acid.*[10]—This acid was prepared from diethyl 1-formyl-2-diethoxymethylsuccinate, the method of synthesis which has been reported earlier. The cyclization of diethyl 1-formyl-2-diethoxymethylsuccinate was carried out using phosphorous pentasulfide. The diethyl 3,4-thiophenedicarboxylate thus obtained was hydrolyzed with aqueous sodium hydroxide to the acid (m. p. 225.5—226.5°C) in 20% yield.

*The 3-Monomethyl Ester of 3,4-Thiophenedicarboxylic Acid.*—The monoester of 3,4-thiophenedicarboxylic acid was prepared by the same method as was used for the synthesis of the 3-monomethyl ester of 3,4-furandicarboxylic acid (m. p. 115.5—116.5°C).

*2, 5-Thiophenedicarboxylic Acid.*[13]—Thiophene was chloromethylated with paraformaldehyde as usual to give 2,5-dichloromethylthiophene, which was further treated with sodium acetate and subsequent hydrolysis to yield 2,5-dihydroxymethylthiophene. This alcohol was oxidized with potassium permanganate to obtain the dicarboxylic acid (m. p. 358.5°C) in a 75% yield.

**p*K*-Measurements.**—p*K* measurements of the acids were made by potentiometric titrations using a Horiba model P pH meter (glass and calomel electrodes). The acids were dissolved in an aliquot amount of carbon dioxide-free distilled water, and then carbon dioxide-free nitrogen gas was added to the solution, while the temperature was maintained constant during the measurements. The titration was carried out using a 0.100 N standard potassium hydroxide solution, and the p*K*'s of the acids were calculated by the method described in the literature.[14] The graphical method using titration curves shown in Figs. 1 and 2 was also applied to the acids for which the $\Delta pK$ was small (the difference between $pK_1$ and $pK_2$).

**Infrared Spectrum.**—The infrared spectra of the acids were taken in their potassium bromide disks. In the case of 3,4-furandicarboxylic acid, carboxylic hydrogen was exchanged with deuterium by repeated recrystallization from $D_2O$, and this deuterated dicarboxylic acid was examined similarly.

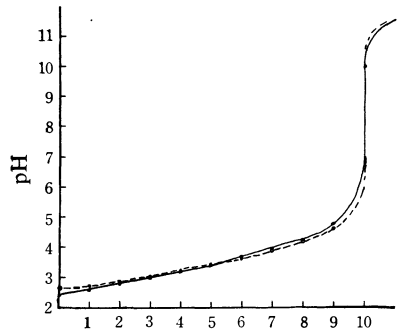

Fig. 2

—— 2,4-Furandicarboxylic acid
---- 2,5-Furandicarboxylic acid

**X-Ray Diffraction.** — The X-ray diffraction of 3,4-furandicarboxylic acid and its analysis[15] were carried out by Williams and Rundle at Iowa State University.

**Kinetics.**—*Dimethyl Esters.* — All the dimethyl esters except dimethyl terephthalate were synthesized in the following manner (dimethyl terephthalate was a commercially-available product which was purified just before use). Dicarboxylic acid (0.064 mol.) was refluxed with 10 ml. of anhydrous methanol in a benzene solution with one or two drops of concentrated sulfuric acid for several hours. After the removal of the excess methanol, the residual dimethyl ester was recrystallized from a suitable solvent several times to give the correct melting point.

By this method the following compounds were obtained:

| Ester | Solvent for recryst. | M. p. °C | Yield % |
|---|---|---|---|
| Dimethyl 2,5-furan-dicarboxylate | $H_2O$ - MeOH | 112 | 68.7 |
| Dimethyl 3,4-furan-dicarboxylate | Ether - *n*-Hexane | 47.5 | 77.2 |
| Dimethyl 2,5-thiophene-dicarboxylate | Benzene | 150—150.5 | 74.3 |
| Diemthyl 3,4-thiophene-dicarboxylate | Ether - *n*-Hexane | 60—61 | 81.5 |

*Monomethyl Terephthalate.*—Dimethyl terephthalate (20 g.) was dissolved in 50 ml. of an alcoholic aqueous solution containing 5.6 g. of potassium hydroxide and refluxed for several hours; then the unreacted dimethyl ester was filtered off. The aqueous alcoholic solution was acidified with concentrated hydrochloric acid. The precipitated monoester was recrystallized several times from water. The yield was 5.0 g. (25%), (m. p. 216.5—217°C).

*Kinetic Procedure.* — A detailed procedure for kinetic determination is described in the literature.[1a,b,8] The solvent used was 70% aqueous dioxane, which was made by diluting 30 ml. of carbon dioxide-free water with dioxane to 100 ml. of the solution. The rate measurements were carried out by mixing equal volumes of sodium hydroxide and ester solutions of the same concentration at the desired temperature, and then pippeting an aliquot into an excess of standard hydrochloric acid from time to time, it was then back titrated with a standard sodium hydroxide solution, using phenolphthalein as the indicator.

**The Calculation of Consecutive Competitive Rate Constants.**—The calculation of the consecutive competitive rate constants for the saponification of the diesters was carried out using the following Frost equation[8]:

$$A + B \xrightarrow{k_1} C + E, \qquad A + C \xrightarrow{k_2} D + E$$

$$dA/dt = -k_1AB - k_2AC, \qquad dB/dt = -k_1AB,$$

$$dC/dt = k_1AB - k_2AC$$

where A, B and C represent the molar concentrations of the corresponding chemical species. Then the above equations were expressed as follws, by

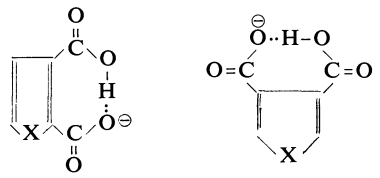
$A_0$, $B_0$; initial concentrations of $A$ and $B$.



A typical run is shown in Tables I and II.

The rate constants of the monomethyl esters were calculated as usual.

## Results and Discussion

The titration curves of the acids are shown in Figs. 1 and 2. The p$K$'s of the acids are summarized in Table III. The rate constants of the esters are also tabulated in Table IV.

The p$K$'s for the furan- and thiophene-dicarboxylic acids change considerably with the change in the location of two carboxyl groups in the furan or thiophene ring. The acids in which two carboxyl groups are at adjacent carbon atom, e.g., 2,3- and 3,4-furan- or thiophene-dicarboxylic acids, have large $\Delta$p$K$ values, while the other acids (2,4- and 2,5-acids) have relatively small $\Delta$p$K$ values. The relatively large $\Delta$p$K$ values found for the former acids are undoubtedly caused by the formation of strong intramolecular hydrogen bonds in the resulting acid ions, as is shown below:

X; O or S

Therefore, the acids which would from a strong intramolecular hydrogen bond increase the first dissociation of a dicarboxylic acid and decrease the second one, eventually giving rise to a large $\Delta$p$K$ value.

In contrast, those acids in which the two carboxyl groups are separated by extra CH groups in the furan or thiophene ring and cannot form intramolecular hydrogen bonding,

have small $\Delta pK$ values. Symmetrical dicarboxylic acids usually have a small statistical $\Delta pK$ value (ca. 0.1).

A substantially larger value of $\Delta pK$ than the statistical value must result from a specific interaction between the functional groups in a dicarboxylic acid. In the case of furan and thiophene dicarboxylic acids, small deviations from the statistical $\Delta$pK value are considered to be due to the polar interaction between the two carboxyl groups.

2, 3- and 3, 4-Furan- or thiophenedicarboxylic acids were found to give large $\Delta pK$ values. A similar large $\Delta pK$ value has also been observed for maleic acid (Table III), where the difference has been explained in terms of the formation of an intramolecular hydrogen bond of the resulted acid anion. Recently evidence for the existence of hydrogen bonding in maleic acid in the crystalline state has been given by Schahat and by others from their investigations of the acid by X-ray and infrarred analyses.[4a)] Phthalic acid is also considered to form a fairly strong intramolecular hydrogen bond, but the $\Delta pK$ value is found to be much smaller than those of 2, 3- and 3, 4-furan or thiophene-dicarboxylic acids. Hydrogen bonding is obviously involved as one of the important factors in determining these $\Delta pK$ values, and a heterocyclic aromatic ring such as furan or thiophene must also play a significant role in favoring the formation of a relatively stable acid ion from the furan- or thiophene-dicarboxylic acids than that from phthalic acid. One conceivable reason for this differences is the difference in geometry between the monohydrogen phthalate ion and the monohydrogen furan or thiophene dicarboxylate ion. The

—— 2,5-Furandicarboxylic acid
---- 2,5-Thiophenedicarboxylic acid

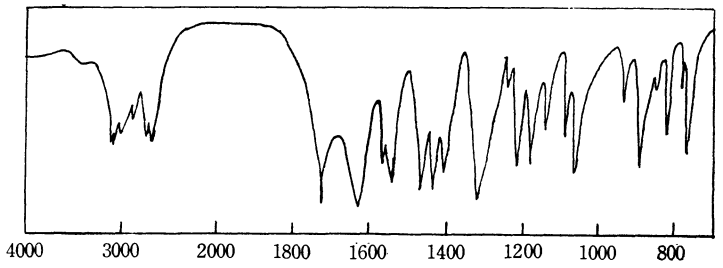

Fig. 5

Monomethyl ester of 3,4-furandicarboxylic acid

latter hydrogen-bonded ions are of 5- and 7-membered binuclear condensed rings, like an azulene ring, which are known to be quite stable. In the case of the monohydrogen phthalate ion, the structure is composed of 6- and 7-membered rings, which may not provide a very stable arrangement for an intramolecular hydrogen bond formation. It is also interesting to note that the $\Delta pK_a$ value for 3, 4-furandicarboxylic acid is larger than that for the corresponding thiophene counterpart. It may be that the furan ring is geometrically more favored for the hydrogen bond formation because of the smaller size of the oxygen atom than that of the sulfur atom of the thiophene ring.

A comparison of the strengths of the half esters of the dicarboxylic acids with these of the corresponding free acids, gives further support to the postulate that the internal hydrogen bonding in the carboxylate acid ions is an important factor. There is considerable evidence that the polar effect of carboalkoxyl group is similar to that of a carboxyl group. Consequently, in the absence of specific interactions, such as hydrogen bonding between the two functional groups, it may be expected that $\Delta pK_e$ (the difference between $pK_1$ and $pK_e$ for the monoester of the dicarboxylic acid) would have the value of 0.3, corresponding to the statistical value for the dicarboxylic acids. Phthalic acid has a value close to 0.3. Other acids for which a strong intramolecular hydrogen bonding is proposed exhibit considerably larger values: 2, 3-furandicarboxylic acid, 0.64; 3, 4-furandicarboxylic acid, 1.24; 3, 4-thiophenedicarboxylic acid, 0.76; maleic acid, 1.03. These values are consistent with the discussion above.

Other support for the existence of an intramolecular hydrogen bonding in 2, 3- and 3, 4-furan- or thiophene-dicarboxylic acids is given by the infrared data for the acids (Figs. 3, 4, and 5) and by the X-ray analysis for 3, 4-furandicarboxylic acid (Figs. 6 and 7).

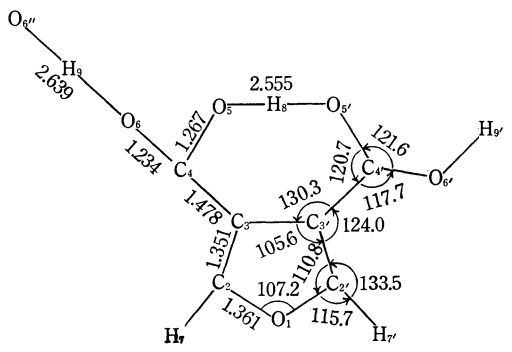

Fig. 6. Intramolecular distances and angles.

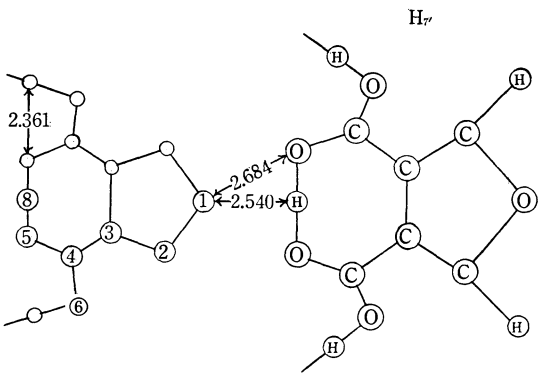

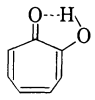

Fig. 7. The structure projected onto the ring square plane.

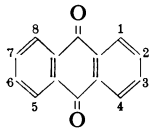
From the infrared spectra taken as KBr disks, the hydroxyl bands for all the acids investigated appear as broad absorption bands with many submaxima between 3000 $cm^{-1}$ and 2000 $cm^{-1}$ instead of the normal hydroxyl band near 3500 $cm^{-1}$. This fact is consistent with the existence of the intramolecular hydrogen bonding. Also, it has been proposed that the acids which are capable of forming an intramolecular hydrogen bonding give the carbonyl absorption between 1670 $cm^{-1}$ and 1650 $cm^{-1}$ [16] (the normal carboxylic acid C=O band appears near 1700 $cm^{-1}$) when examined in the solid or liquid state, while the normal aromatic acids absorb at 1700 $cm^{-1}$. Phthalic acid is normal in this regard, showing a simple C=O band at 1690 $cm^{-1}$, 2, 4- and 2, 5-furan- or thiophenedicarboxylic acids were also found to give a single intense carbonyl band between 1680 $cm^{-1}$ and 1700 $cm^{-1}$, indicating that these acids are normal. On the other hand, 2, 3- and 3, 4-furan- or thiophenedicarboxylic acids have double carbonyl bands (Fig. 3), one of which is near 1700 $cm^{-1}$ and the other between 1650 $cm^{-1}$ and 1620 $cm^{-1}$. The latter bands are fairly intense as compared to the normal carbonyl absorption band. All these observation are consistent with the assumption that these acids are intramolecularly hydrogen-bonded, even in undissociated forms. When hydroxyl hydrogen was replaced by deuterium, the absorption bands due to the -OH stretching shifted towards longer wavelengths. However, no remarkable effect appeared in the C=O stretching region. For example, acetic acid, which generally forms a dimer which absorbs at 3125 $cm^{-1}$ due to OH stretching, changes its band to 2299 $cm^{-1}$ upon deuterium substitution.[16] A better example would be tropolone, which forms a strong intramolecular

16) See, for example, L. J. Bellamy, "The Infra-red Spectra of Complex Molecules," John Wiley & Sons, New York (1958), pp. 161—176.



hydrogen bond[17] and the hydrogen-bonding structure of which is somewhat similar to that of 3, 4-furan- or thiophenedicarboxylic acid.

The -OH band is also shifted to a longer wavelength when -OH is changed to -OD, but no effect is observed in C=O stretching. Hadzi and Sheppard[18] have reported that the substituted anthraquinones show a remarkable shift of -OH upon deuterium substitution, as is shown in Table V.

Tropolone

TABLE V

| | | (OH) or (OD) $cm^{-1}$ | (C=O) $cm^{-1}$ |
|---|---|---|---|
|  Anthraquinone | 1,4-diOH | 2860 | 1626 |
| | 1,4-diOD | 2260 | 1626 |
| | 1,5-diOH | 2950 | 1637 |
| | 1,5-diOD | 2280 | 1637 |

In the case of 3, 4-furandicarboxylic acid, in which carboxyl -OH was exchanged with -OD, a similar effect was observed; the band due to the -O···H stretching at 2500—2800 $cm^{-1}$ disappeared and a new broad band was observed near 1980 $cm^{-1}$, a band which is assumed to be that of the intramolecular hydrogen-bonded -OD.

The X-ray analysis of 3, 4-furandicarboxylic acid in Figs. 6 and 7 gives fairly good proof for our suggestion of the existence of a strong intramolecular hydrogen bonding in 2, 3- and 3, 4-furan or thiophenedicarboxylic acids. The analysis of 3, 4-furandicarboxylic acid shows that because of the intramolecular hydrogen bonding hydrogen atom lies just in the middle of the two adjacent carboxyl oxygens. The distance of the O-H-O hydrogen bond reveals a marked shortening of O-H-O linkage as compared to the acetic acid dimer or other hydrogen-bonded acids.[19]

In Table II one can see substantial fluctuations in the rate constants obtained. The main reason for the deviations is that the determination of the end point with phenolphthalein is not sharp because of the facile hydrolysis of the second ester groups in the diesters during the hydrolysis. Therefore, each of the rates, actually observed and summarized in Table III, may contain a substantial margin of inherent error. However, even at its greatest the error is not so large as to lead to a wrong conclusion.

Despite the inherent errors, one can draw a few interesting conclusions from the data. First, the order of reactivity in the hydrolysis of the diesters is furan>thiophene>benzene. This is in accord with that of the alkaline hydrolysis of the ethyl esters of monocarboxylic acids in the same solvent[1] and also is to be expected from the magnitudes of the acidity constants of these mono or dicarboxylic acids. Here again, it was confirmed that the thiophene ring is more electron-attracting than the benzene ring, but less so than the furan ring. The fact that the first hydrolysis rate constant, $k_1$, for dimethyl 2, 5-furandicarboxylate is of an especially high value, is to be expected from the calculation by the Hammett equation using the data for the hydrolysis rate constants of furoic acid.[1]

Another interesting fact is that the rates of the hydrolyses of the diesters in which the two ester groups are attached to adjacent carbon atoms are substantially lower than those of the esters in which the carboxyl groups are separated by CH groups. One reason for this may be that the nucleophilic attack with the hydroxyl ion on the first carbonyl carbon is retarded by the charge repulsion with the adjacent carboxyl oxygen.

# A Study of Monolayer Penetration by the Radiotracer Method

By Akira MATSUBARA

(Received August 25, 1964)

The phenomenon of the penetration of insoluble monolayers of cholesterol, hexadecyl alcohol, etc., by long-chain water-soluble compounds such as sodium salts of long-chain alkyl sulfates was first discovered by Schulman and Hughes.[1] Since then, this phenomenon has been extensively investigated by Schulman and his co-workers, and it has been concluded that stoichiometric complexes between insoluble and soluble species are formed.[1]

Harkins, however, has questioned this idea of complex formation, because the surface tension data observed by Schulman et al. were not those of the true equilibrium.[2] Hutchinson has also shown that the surface tension of aqueous solutions containing octyl alcohol and sodium dodecyl sulfate in various mole ratios does not exhibit the obvious variation which would suggest the stoichiometric complex formation.[3]

Opposing these papers, Matalon[4] and Goddard and Schulman[5] have published experimental evidence for their own views as follows: "By injecting sodium hexadecyl sulfate (SHS) below cholesterol monolayer at constant surface pressure the occupied area of cholesterol molecule increases and its rapid initial increase is from 20 to 27 Å$^2$. Since this increase approximately corresponds to a cross-sectional area of SHS, a 1 : 1 complex is formed. For hexadecyl alcohol monolayer this rapid initial increase does not correspond to a 1 : 1 complex, but a considerable quantity of SHS is held and stabilized in the surface by hexadecyl alcohol. These complexes are stable up to the collapse points of the mixed monolayers." [5]

Dervichian has considered the monolayer penetration as a partition of soluble species between the surface phase containing the monolayer and the substrate phase. On the basis of this idea he has suggested that certain particular patterns in the mutual arrangement of the molecules appear and that, in the case of the penetration of the hexadecyl alcohol monolayer by SHS, 1 : 1, 1 : 2 and 1 : 3 associations exist.[6]

The thermodynamics of monolayer penetration has been studied by Pethica and Anderson[7] and by Fowkes.[8,9] Especially, Fowkes has asserted that the mixed film resulting from the penetration may be regarded as an ideal mixture rather than as a stoichiometric complex.

The above-mentioned arguments have been based on the data obtained by the measurement of the surface pressure, potential and viscosity. However, data decisive enough to persuade us have not been reported yet on either side of the question. If detergent molecules penetrate into monolayers to form 1 : 1 complexes, the penetrated amount should be of the order of $10^{-10}$ mol./cm$^2$, which is enough to be detectable by means of the radiotracer method. Hence, the direct measurements of the amount of some long-chain alkyl sulfates penetrating cholesterol and hexadecyl alcohol monolayers were carried out by the radiotracer method, using $^{35}$S-labeled detergents. In addition, octadecyl amine, which is known to form a 1 : 1 salt with these anionic detergents in a bulk solution, was used as a reference monolayer.

A short communication has already come from our laboratory on this subject.[10]

## Experimental

**Materials.**—The $^{35}$S-labeled sodium dodecyl sulfate (SDS), sodium tetradecyl sulfate (STS) and sodium hexadecyl sulfate (SHS) used were synthesized from the corresponding fatty alcohols and $^{35}$S-labeled sulfuric acid according to the published method.[11]

Pure fatty alcohols were obtained from commercial alcohols by fractional distillation through a

rectifying column of 65 plates at a reflux ratio of 15. Fractions which distilled at 130—131°C/8.0 mmHg, 168°C/13.8 mmHg and 181.5—181.7°C/10.0 mmHg for dodecyl, tetradecyl and hexadecyl alcohols respectively were collected. The melting points of these alcohols showed normal values.

The $^{35}S$-labeled sulfuric acid was obtained from the Radiochemical Center, England, in a carrier-free state and was isotopically diluted with a small amount of sulfuric acid before use. The specific radioactivity of the $^{35}S$-labeled sodium alkyl sulfates thus prepared were ca. 10 mc./mmol.

Octadecyl amine was distilled in the same way as were fatty alcohols, and a fraction which distilled at 198.5—198.8°C/9.2 mmHg was collected. Distilled hexadecyl alcohol and octadecyl amine and the cholesterol of Merck's reagent were all recrystallized from their ethanol solutions and dried in a vacuum. These monolayer substances were spread from benzene solutions.

The water used was redistilled from a quartz still.

**Method.**—The procedure of measuring the surface excess by the radiotracer method was the same as that in the preceding paper.[12] The surface excess of a detergent at the free surface of its solution, $\Gamma_d$ (in mol./cm$^2$), and that at the surface with a monolayer, $\Gamma_m$, were calculated according to the following equations:

$$\Gamma_d=\frac{I_d-I}{SA},\quad \Gamma_m=\frac{I_m-I}{SA} \qquad (1)$$

where $I_d$ and $I_m$ are the intensities, in count/min., of the radiation from the detergent solution in the absence and in the presence of a monolayer respectively, and where $I$ is the intensity of the radiation from a sulfuric acid solution, used as a reference, which has the same specific activity and concentration as the detergent solution. $S$, the specific activity of the detergent in count/min./mol., and $A$, the surface area of the solution in cm$^2$, were determined by using a point source, as has been reported previously.[12]

The measurement of the surface pressure was simultaneously carried out by a modified Wilhelmy-type balance.[13]

All experiments were carried out at 35°C.

## Results and Discussion

So far various insoluble and soluble substances have been used in the study of the monolayer penetration. The aim of this study was, however, to obtain more exact information on the phenomenon of the monolayer penetration itself. Hence, cholesterol and hexadecyl alcohol as insoluble species and sodium alkyl sulfates as soluble species were used as typical examples.

Three kinds of experimental procedures were applied in order to obtain exact information on the mechanism of the monolayer penetration. Namely, the surface pressure and the surface excess of the detergent as a function of the surface area or of time were measured with (1) the monolayer spread on the detergent solution; (2) the monolayer under which the detergent solution was injected, and (3) the monolayer formed by the spreading of a film substance-detergent mixture on water.

Since the results obtained for three sodium alkyl sulfates are qualitatively similar, the results for SHS only will be described in detail.

**The Monolayers Spread on the Surface of the Detergent Solution.**—In order to minimize the effect of adventitious ionic contamination, the experiments were carried out on the SHS solution with $10^{-3}$ mol./l. sodium chloride for cholesterol and hexadecyl alcohol monolayers, and on that with $10^{-3}$ mol./l. hydrochloric acid for the octadecyl amine monolayer, as was done by Goddard and Schulman.[5] On the other hand, the experiment with the octadecyl amine nonolayer was also carried out on the SHS solution without an added electrolyte.

Prior to the penetration experiment, the measurements were carried out on the free surface of the SHS solution. After sweeping the surface of the SHS solution, the surface excess of SHS at the free surface, $\Gamma_d$, and the surface pressure, $\Pi$, were measured simultaneously. It was found that both values increase with time and that the former reaches equilibrium within an hour, while the latter still increases very slowly. Two hours after the sweeping, the $\Gamma_d$ and the change in $\Pi$ with compression, $\Delta\Pi$, were measured by compressing the free surface of the SHS solution. The

compression was carried out at the rate of 1 cm. of the trough scale a minute (trough: $15\times30$ cm$^2$) and at three-minute intervals.

At the end of the measurements on the free surface of the SHS solution, the surface was again swept and the monolayer was spread as quickly as possible. Two hours after the spreading, the values of $\Gamma_m$ and the surface pressures referred to each substrate solution, $\Pi'$, were measured as a function of the occupied area of the insoluble molecule by compressing the monolayer at the same rate and interval as in the measurement with the free surface. The results are shown in Figs. 1—4 (for $\Delta\Pi$ and $\Pi'$) and in Figs. 5—8 (for $\Gamma_d$ and $\Gamma_m$).

It should be noticed in these figures that, with the compression of the free surface of the SHS solution, the surface pressure increased with a considerable stability, as is shown by the broken lines in Figs. 1—4, while there was little change in the surface excess, as Figs. 5—8 show. It may also be seen in these figures that cholesterol and hexadecyl alcohol monolayers spread on the SHS solutions expanded two or three times in comparison with those on water, while the surface excess of SHS did

not increase so much as to explain this large expansion and was insufficient to form the 1 : 1 complex, as is shown by solid lines in Figs. 1—8. Especially at higher concentrations of SHS, the $\Gamma_m$'s were almost the same as the corresponding $\Gamma_d$'s, indicating that no extra detergent ion was taken up by the insoluble monolayer.

Since in the surface the adsorbed detergent ions are present in addition to the cholesterol or hexadecyl alcohol molecules, it is quite natural that these monolayers expand remarkably. In addition, it should be noted that the abnormally large expansion of the $\Pi'$-$A$ curves, as seen in Figs. 1—4 and in previous papers,[1,5] involves the effect of the compression of the free surface. In fact, subtracting the area of the free surface from that of the penetrated film at the same surface pressure, we obtain the surface pressure - area curve ($\Pi'$-$A'$ curve), as is shown in Figs. 9(a) and (b). These curves indicate only small expansions of the limiting areas of monolayers. The presence of this free surface effect is characterized by the features of the $\Pi'$-$A$ curves,

indicating an increase in the surface pressure from just the area at which the spreading solution has been dropped, as Figs. 1—4 show. This feature is observed also in the $\Pi$-$A$ curves reported by Schulman et al.[1,5] It has been stated[5] that the complex produced by the penetration of the detergent is stable up to the collapse point. This statement is inconsistent with the present findings that the apparent increase in the surface area is mainly due to the compression of the free surface and that the $\Gamma_m$ is almost constant with the compression of the monolayer and never reaches the amount corresponding to the 1 : 1 complex. Further, the $\Pi'$-$A$ curves of the monolayers on the SHS solution are strongly time-dependent. From these reasons it should be concluded that the $\Pi'$-$A$ curves obtained by compressing the insoluble monolayer on the SHS solution can not be used for the thermodynamic consideration.

In the experiments with the octadecyl amine monolayer spread on the SHS solution without hydrochloric acid, the $\Pi'$-$A$ curves showed a much more remarkable expansion than those of cholesterol and hexadecyl alcohol monolayers, and the surface excess of SHS also increased pronouncedly in comparison with that in the case of the free surface. The differences between $\Gamma_m$ and $\Gamma_d$ nearly corresponded to the 1 : 1 salt formation at the $5\times10^{-6}$ and $10^{-5}$ mol./l. concentrations of SHS and over a larger area. However, these differences are almost constant, independent of the compression of the monolayer.

In the experiments with the octadecyl amine monolayer spread on the SHS solution containing $10^{-3}$ mol./l. hydrochloric acid, the $\Pi'$-$A$ curves are quite similar to those of cholesterol and hexadecyl alcohol monolayers in spite of the fact that the surface excess of SHS corresponds to the 1 : 1 salt formation at the SHS concentration of $10^{-5}$ mol./l. and over a larger area. In Fig. 10, $\Pi'$-$A'$ curves for the octadecyl amine monolayers on SHS solutions, in the absence of hydrochloric acid, are given. As may be seen in this figure, the curves still indicate a remarkable expansion as compared with the monolayer on water. This seems to be a characteristic feature, one which provides us with evidence for the complex formation. However, $\Pi'$-$A'$ curves obtained in the presence of $10^{-3}$ mol./l. hydrochloric acid show only a small expansion, as is shown in Fig. 9(c). These findings suggest that the expansion of the $\Pi'$-$A'$ or $\Pi'$-$A$ curve cannot be an indication of the complex formation.

**The Injection of Detergents below Monolayers.**—Insoluble monolayers were spread on the surface of water and compressed up to a surface pressure of 15 dyn./cm. Then the solution of detergents was injected below the monolayer by means of a wide-mouth pipette and the substrate solution was rendered uniform by gentle sucking and blowing for five minutes. The concentration of the injecting solution was twenty-five times as high as the equilibrium concentration of the substrate solution, and its volume was 10 cc. The $\Gamma_m$'s at a constant area were measured as a function of the time. The results are shown in Figs. 11—13 for combinations of three kinds of monolayers and three detergents. It may be seen from these figures that, after the injection of the detergents, the surface excesses of detergents increase with the time. In the case of cholesterol and hexadecyl alcohol monolayers, their equilibrium values are approximately the same as

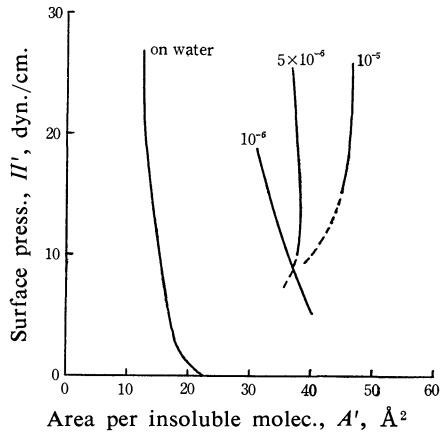

Fig. 10. $\Pi'$-$A'$ curve for octadecyl amine monolayer on SHS solutions without added electrolyte.

that at the surface without a monolayer. On the other hand, in the case of the octadecyl amine monolayer the surface excess increases remarkably beyond that of the free surface. This is incontrovertible evidence that cholesterol and hexadecyl alcohol monolayers do not interact with SHS in such a way as to form the 1 : 1 complex, as has been observed with the octadecyl amine monolayer. It has been suggested[4,5] that, in the experiment with the injection of SHS below the cholesterol monolayer at a constant surface pressure, the rapid initial change in the surface area is due to the 1 : 1 complex formation and that the subsequent slow increase is due to the "solution" of SHS in excess of a 1 : 1 ratio into the monolayer. This interpretation is clearly a misunderstanding. Our suggestion is that the rapid initial change is due to the formation of the adsorbed film of detergents at the surface in the presence of the monolayer, and that the subsequent slow change is to be attributed to the so-called surface ageing which is frequently observed in the surface tension measurement of detergent solutions. Incidentally, the surface potential vs. time curves obtained by Goddard and Schulman[5] are similar to our surface excess vs. time curves; i. e., both curves show a rapid initial change, followed by no slow change.

**The Mixed Monolayers of Insoluble and Soluble Species Spread on the Surface of Water.** —A mixture of insoluble substances and soluble detergents in the ratio of 1 : 1 was spread on the surface of water by using a mixed solvent composed of benzene, isopropanol and water (25 : 23 : 2 in volume). Thirty minutes after the spreading of the mixture, the surface film was compressed at the same rate and interval as those used previously and the surface concentration, $\Gamma$, of the detergent was measured as a function of the occupied area of the insoluble molecule. In these experiments, even if all the molecules of the detergents have dissolved into the substrate, the radiation from the bulk of the substrate is negligibly small, because only a minute amount of detergent has been spread.

The $\Pi$-$A$ and $\Gamma$-$A$ curves for the mixed monolayers of insoluble species and SHS molecules in the ratio of 1 : 1 are shown in Figs. 14—16. In the case of cholesterol- and hexadecyl alcohol - SHS mixed films, the surface concentrations of SHS are very low, approximately the same as that obtained by spreading SHS only; in addition, there is no appreciable increase in the surface count with the compression of the mixed films. On the contrary, the surface concentration of SHS in the octadecyl amine - SHS mixed film is much higher

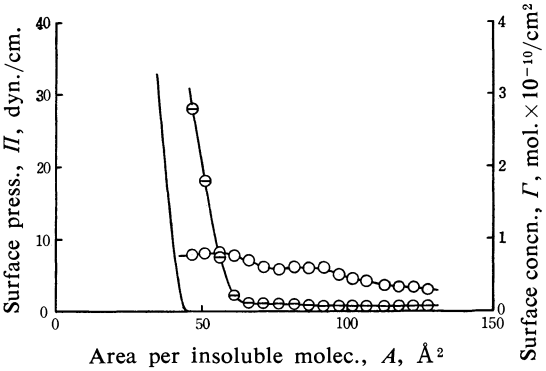

Fig. 14. $\Pi$-$A$, ⊖; and $\Gamma$-$A$, ○; curves for cholesterol-SHS (1 : 1) mixed film. Solid line represents $\Pi$-$A$ curve for cholesterol monolayer.

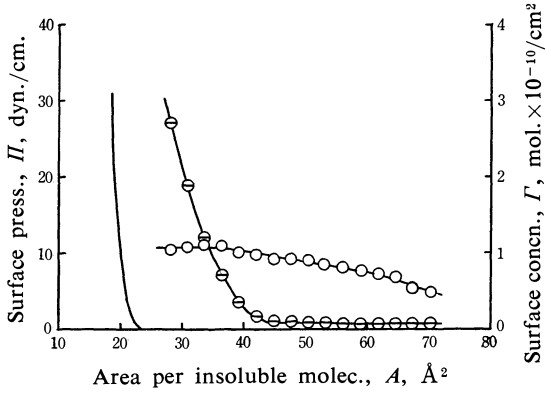

Fig. 15. $\Pi$-$A$, ⊖; and $\Gamma$-$A$, ○; curves for hexadecyl alcohol - SHS (1 : 1) mixed film. Solid line represents $\Pi$-$A$ curve for hexadecyl alcohol monolayer.

than those in the case of cholesterol and hexadecyl alcohol and increases in accordance with the increase in the surface concentrations with the compression of the mixed film at a low surface pressure. The mole ratio of SHS to octadecyl amine at the surface is ca. 0.8 at the limiting area. In conformity to this fact, the $\Pi$-$A$ curve for the octadecyl amine - SHS mixed film shows a remarkable expansion. It should, however, be pointed out that the increase in the limiting area in the cholesterol- and hexadecyl alcohol - SHS mixed films are ca. 20 Å² per insoluble molecule, although the surface concentrations of SHS in these films are much lower than that corresponding to the 1 : 1 complex. This situation is similar to that which holds for the monolayers spread on the SHS solution.

It has been reported by Goddard and Schulman[5] that the result obtained by injecting SHS below the spread cholesterol-SHS mixed film also shows a rapid initial change. This has been considered to be an unexpected result, one inconsistent with the concept they themselves had proposed, that the rapid initial change was due to the 1 : 1 complex formation. This, however, seems quite natural in terms of our interpretation that it is due to the formation of the adsorbed film of SHS. Namely, most of SHS molecules in the spread mixed film have dissolved into the substrate, and only a very low surface concentration of SHS molecules in equilibrium with the bulk concentration remains at the surface. Therefore, if SHS is again injected below such a film, the surface excess of SHS may increase as a result of the increase in the bulk concentration. Hence, a rapid initial change occurs again to form the adsorbed film of SHS.

It may be seen in Fig. 16 that the surface concentration of SHS in the spread octadecyl amine - SHS mixed film does not increase with the compression of the film over areas smaller than the limiting area of the mixed fiilm. As has been mentioned already, in the case of the octadecyl amine monolayer spread on the SHS solution, the surface excess of SHS also shows no increase with the compression of the monolayer. This seems to be due to the collapse of the octadecyl amine - SHS film at a relatively low surface pressure.

When cholesterol- and hexadecyl alcohol - STS mixed films are spread, molecules of STS dissolve almost completely into the substrate. On the other hand, for the octadecyl amine - STS mixed film, molecules of STS corresponding to the ratio of 1 : 1 remain at the surface, as Fig. 17 shows.

All the results obtained in the present experiments clearly indicate that the mode of interaction of sodium alkyl sulfates with the

monolayer of cholesterol or hexadecyl alcohol is quite different from that with the monolayer of octadecyl amine. In the latter case the evidence is ample for the formation of the 1 : 1 salt, but we can not obtain any direct evidence for the 1 : 1 complex formation in the former case. Although the true nature of the interaction between sodium alkyl sulfates and cholesterol or hexadecyl alcohol monolayer is as yet obscure, we may suppose that a very weak interaction, such as the van der Waals force, may play a role between two species. But in any way, we can completely deny the well-defined 1 : 1 complex formation.

As Figs. 1—8 show, the surface pressure of the SHS solution, both with and without an insoluble monolayer, increases with compression, while the surface excess does not change appreciably. This phenomenon has not yet been explained completely, but it may be supposed that such a mechanism as, for example, the rearrangement of the adsorbed detergent molecules may influence the kinetic surface pressure, while it has nothing to do with the surface excess. (The disagreement between the surface pressure and the surface potential as regards the time effect had already been noticed by Addison.[14])

On the basis of the experimental results obtained with a cholesterol or hexadecyl alcohol monolayer on detergent solutions in the present study, we may show the change occurring in the monolayer on compression schematically as in Fig. 18. In this figure the II-b state corresponds to the limiting area of the resulting mixed film. This limiting area is larger than that, the I-b state, for the monolayer on water. Therefore, even if the surface excess of SHS at the surface with a monolayer is the same as that at the free surface, the resulting mixed film must expand. This expansion of the monolayer by SHS molecules adsorbed at the surface will be discussed quantitatively.

The *Π-A* curves of the monolayers on the detergent solutions previously obtained by many workers involve the effect resulting from the compression of the free surface. The reason why the surface pressure increases, while the surface excess of detergent does not, with the compression of the free surface, has not yet been made clear. It is important here that the increase in the surface pressure is not due to the increase in the surface density of SHS. In order to avoid this effect, Harkins et al. have measured the surface pressure by injecting SHS below the hexadecyl alcohol monolayer at each area.[2] These *Π-A* curves are very different from those obtained by Schulman et al.[1] Therefore, by assuming that the expansions of *Π-A* curves are due to the presence of SHS molecules adsorbed at the surface, the surface excess of SHS can be estimated from the increase in the limiting area and can be compared with that obtained directly by the radiotracer method.

According to Harkins et al., the limiting areas obtained by extrapolating the linear portions of each curve to the surface pressure of each substrate solution are larger than that for the monolayer on water by ca. 13.5, 24.5 and 25 Å$^2$ per hexadecyl alcohol molecule for the SHS concentrations of $3\times10^{-6}$, $10^{-5}$ and $3\times10^{-5}$ mol./l. respectively. These values represent the difference in the area between the I-b and II-b states in Fig. 18 in Å$^2$ per hexadecyl alcohol molecule.

In the hexadecyl alcohol monolayer, which is in the closely packed state, there are $5\times10^{14}$ molecules per cm$^2$. Therefore, the increase in the total surface area of the mixed film per unit area of hexadecyl alcohol molecules is

14) C. C. Addison and D. Litherland, *Nature*, **171**, 393 (1953).

$24.5\times5\times10^{-2}$ cm$^2$ for the SHS concentration of $10^{-5}$ mol./l. This increase is regarded as being due to the SHS molecules adsorbed at the surface. If it is assumed that the molecular area of SHS is 40 Å$^2$,[8] this increase in the surface area corresponds to $(24.5\times5\times10^{14})/(40\times6\times10^{23})$ mol. of SHS. Since this quantity of SHS exists within the surface area of $(1+24.5\times5\times10^{-2})$ cm$^2$, $\Gamma_m$ is $2.3\times10^{-10}$ mol./cm$^2$. This value is in excellent agreement with that obtained by our direct measurements, as is shown in Table I. The estimated results for other concentrations of SHS are also shown in Table I.

TABLE I. THE SURFACE EXCESS OF SHS CALCULATED FROM THE DATA OF HARKINS ET AL.

| Concn. of SHS mol./l. | $\Delta A$ Å$^2$ | $\Gamma_m$ (Calcd.) mol. $\times10^{-10}$/cm$^2$ | $\Gamma_m$ (Obs.) mol. $\times10^{-10}$/cm$^2$ |
|---|---|---|---|
| $3\times10^{-6}$ | 12.5 | 1.6 | 1.0 |
| $10^{-5}$ | 24.5 | 2.3 | 2.0 |
| $3\times10^{-5}$ | 25 | 2.3 | 2.0 |

These results show that the expansion of the monolayer can be interpreted as being due to SHS molecules adsorbed at the surface, without assuming the 1 : 1 complex formation. Accordingly, it may be expected that the monolayer will expand as the surface concentration of detergent becomes higher because then the surface concentration of species, including both soluble and insoluble species, becomes higher.

By injecting the identical detergent below various monolayers, the increase in the surface pressure has been measured and has been considered as a measure of the interaction of insoluble with soluble species.[1] However, even if the same adsorption of SHS takes place at the surface with different monolayers, the increases in the surface pressure are not necessarily the same. For the monolayers in the closely-packed state especially, the stability of the monolayer and the change in the chemical potential of the monolayer substance due to the adsorption of SHS, etc., which are also responsible for the increase in the surface pressure, should be taken into consideration.

It can be concluded from the foregoing discussion that the so-called reactivity for penetration is nothing but the surface activity of the detergent. In other words, although Schulman et al. have considered the complex formation to be the principal factor in the phenomenon of the monolayer penetration, we consider it to be the surface activity of soluble species. This concept is consistent with these previous experimental data:

(1) The soluble species which are known to cause the monolayer penetration are all surface active substances.

(2) Therefore, the order of the penetration reactivity of detergents for the identical monolayer should be that of the surface activity of soluble species.

a) It has been shown that, for the detergents with a $C_{12}$-alkyl chain, the order of the penetration reactivity of polar heads is as follows;[15]

$$-SO_4^{2-} > -SO_3^{2-} > -NH_3^+ > -COO^- > -N(CH_3)_3^+$$

By regarding the CMC of detergents as a measure of the surface activity, the order of the penetration reactivity is the same as that for the surface activity of soluble species.

b) For long-chain alkyl sulfates, the longer the alkyl chain, the stronger the penetration reactivity of the detergents.[1] The surface activities of detergents are, of course, in the same order.

c) It has been shown that the penetration reactivity of detergents increases with the addition of salt.[7] This should be attributed to the well-known fact that the addition of salt increases the surface adsorption of detergents.[16]

In the present paper we have pointed out the misinterpretation of the monolayer penetration and have verified that the difference between the properties of the monolayers on the detergent solution and those on water is to be attributed merely to the presence of the detergent molecules adsorbed at the surface.

Finally, it is important to note here that the change in the surface pressure alone in the course of the penetration experiment provides no exact information as to whether the complex is formed or not.

## Summary

The surface pressure - area isotherms of monolayers of cholesterol, hexadecyl alcohol and octadecyl amine on sodium alkyl sulfate solutions and the surface excess of alkyl sulfate have been measured by the film balance and the radiotracer methods respectively. These measurements were carried out with (1) the monolayers spread on the alkyl sulfate solutions, (2) those below which the detergent solutions were injected, and (3) those formed by the spreading of the insoluble species - detergent mixtures on water.

All the surface pressure - area curves showed

15) B. A. Pethica and J. H. Schulman, *Biochem. J.*, **53**, 177 (1953).

16) R. Matuura, H. Kimizuka and A. Matsubara, This Bulletin, **34**, 1512 (1961).

remarkable expansions; the results were essentially the same as those observed by Schulman et al. and by others.

On the other hand, the surface excess of alkyl sulfates showed no appreciable increase in the case of cholesterol and hexadecyl alcohol, and it was too low to form a stoichiometric complex between the insoluble species and the alkyl sulfate; only in the presence of the octadecyl amine did it increase to an amount sufficient to form the 1 : 1 stoichiometric salt.

Thus it has been concluded that the expansion of the surface pressure - area curve can not be an indication of the stoichiometric complex formation. It has been pointed out that the surface pressure of the detergent solution increases with the compression, even in the absence of a monolayer; this is the main cause for the expansion of the surface pressure - area curve of the penetrated monolayer. The phenomenon of monolayer penetration has been explained in terms of the formation of the adsorbed layer of alkyl sulfate, and the reactivity for penetration has been related to the surface activity of detergents.

The author wishes to express his thanks to Professor Ryohei Matuura and Dr. Hideo Kimizuka of our laboratory for their valuable advice and constant encouragement.

# A Molecular Orbital Treatment of Hydrogen Bonds. I. Preliminary Results

By Keiji MOROKUMA, Hiroshi KATO, Teijiro YONEZAWA and Kenichi FUKUI

(Received September 2, 1964)

The hydrogen bond, a weak bonding between a hydrogen donor, such as hydroxyl and amino groups, and an acceptor, such as oxygen and nitrogen atoms, has long attracted the attention and interest of many researchers, in both the experimental and theoretical fields.[1,2]

As to the theoretical study, Coulson and Dannielsson[3] calculated semiempirically the delocalization energy of the hydrogen bond in a fictitious O—H···O fragment. Tsubomura's nonempirical study was carried out on water.[4] Arranging existing theoretical treatments, Coulson[5] tabulated the contribution of various kinds of energy to the hydrogen-bond stabilization of water, thus emphasizing that the delocalization energy plays an important role in the stabilization.

This series of papers will attempt to discuss the stabilization energy and other changes in electronic structures by the hydrogen-bond formation from the point of view not of the fictitious fragment but of the whole molecule.

In the present paper, as a preliminary discussion, we will calculate the changes in the electronic energy and the charge distribution upon the hydrogen-bond formation, by using the simple LCAO MO method extended by Hoffmann,[6] in which all valence atomic orbitals (AO) are taken into account. The Coulomb integral, $H_{rr}$, of an atomic orbital is the negative value of the ionization potential of the valence state of the neutral atom,[7] which is tabulated in Table I. The resonance integral,

Table I. Coulomb integral of various atomic orbitals (eV.)

| Atom | Orbital | | |
|---|---|---|---|
| | 1s | 2s | 2p |
| Hydrogen | −13.60 | — | — |
| Carbon | — | −21.43 | −11.42 |
| Oxygen | — | −35.30 | −17.76 |

$H_{rs}$, between the $r$th and the $s$th AO's is given by the following equation:

1) "Hydrogen Bonding," Ed. by D. Hadzi, Pergamon Press, London (1959).
2) G. Pimentel and A. L. McClellan, "The Hydrogen Bond," W. H. Freeman & Co., San Francisco (1960).
3) C. A. Coulson and V. Dannielsson, *Arkiv Fysik*, **8**, 239, 245 (1954).
4) H. Tsubomura, This Bulletin, **21**, 415 (1954).
5) C. A. Coulson, *Research*, **10**, 149 (1957).
6) R. Hoffmann, *J. Chem. Phys.*, **39**, 1397 (1963).
7) H. O. Pritchard and H. A. Skinner, *Chem. Revs.*, **55**, 745 (1955).

$$H_{rs}=\frac{1}{2}KS_{rs}(H_{rr}+H_{ss})$$

where $K=1.75$ and $S_{rs}$ is the overlap integral between the AO's. Calculation is carried out on formic acid and its dimer, acetylacetone and salicylaldehyde (with a hydroxyl group as a proton donor and with a carbonyl group as an acceptor), and also on benzyl alcohol and allyl alcohol (with a hydroxyl group as a proton donor and a $\pi$ electron system as an acceptor).

The program was coded so that, on giving tables of the Coulomb integrals of every kind of atom included, of the three-dimensional coordinates of atoms, and of the effective nuclear charges of atomic orbitals, the overlap integrals can be calculated with Slater AO's by means of the formulae of Mulliken et al.,[8] the resonance integrals can also be calculated, and the secular equation can be diagonalized to give the eigen-values and eigenvectors, the total energy, the atomic orbital populations, and the atomic populations. The effective nuclear charges employed were $Z_H=1.0$, $Z_C=3.25$ and $Z_O=4.55$.

In all compounds, except for those noted, the atomic distances were taken as follows:[9] C-H: 1.09Å, C-C: 1.54Å, C=C: 1.34Å, C-C (aromatic): 1.40Å, C-O: 1.23Å, C-O (alcohol): 1.43Å, C-O (carboxylic acid): 1.36Å, O-H: 0.96Å. The bond angles are assumed to be 120° for an unsaturated carbon atom, the tetrahedral angle for a saturated carbon atom.

## The Electronic Structure of Non-Hydrogen-Bonded Molecules

Prior to discussing the hydrogen bond, a brief review of the calculated electronic structures of some carboxylic acid, of ketone, of aldehyde and of alcohol will be given in this section, since the extended LCAO MO method has not previously been applied to such polar compounds.

Figure 1 shows the net charge on each atom of formic acid and salicylaldehyde. One can see in the figure that, though the general tendency of the polarization is well visualized, the net negative charge on each oxygen atom seems to be too large, whereas the population on the hydroxyl hydrogen atom is unexpectedly small. In this approximation the polarity of a polar bond seems to be overestimated. This is because the Coulomb integral of an atomic orbital was kept constant although it might really be more positive when the population on the atom increases. It is indispensable for this extended LCAO MO method to decide the Coulomb integral of an atomic orbital in a polar group not merely by the ionization potential of the neutral atom but also by the population on the atom. On this point we will give a detailed discussion is a following paper.

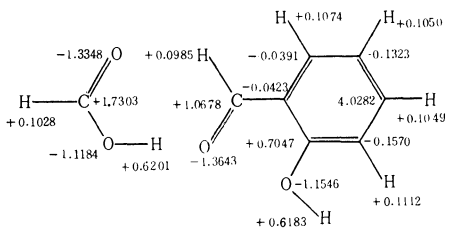

Fig. 1. Net charge of formic acid and salicylaldehyde.

The total energy of methyl alcohol is calculated for various configurations in Table II. As to the rotational isomers, the configuration I, in which the OH bond takes the trans conformation to the CH bond in the C-O-H plane*, is predicted to be a configuration of local minimum energy.

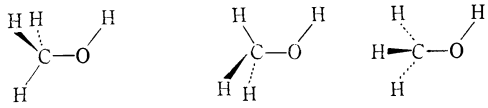

TABLE II. TOTAL ENERGY OF METHYL ALCOHOL AND ACETYLACETONE

A) Methyl alcohol

| Configuration | ∠COH | Total energy, eV. |
|---|---|---|
| III | 110° | −287.4014 |
| II | 110° | −287.3941 |
| I | 110° | −287.4087 |
| I | 105° | −287.3293 |
| I | 100° | −287.2362 |

B) Acetylacetone

| Configuration | Total energy, eV. |
|---|---|
| Keto | −789.4969 |
| Enol | −788.3440 |

(I) (II) (III)

Keto and enol forms of acetylacetone are also compared in Table II. The keto form is more stable than the enol form, contrary to experience. This is either due to the inappropriate parametrization in this method, mentioned in the previous section, or to a substantial defect involved in the present method,

where electronic and nuclear repulsion energies are not explicitly taken into account.

## Energy and Electron-distribution Changes Caused by Hydrogen-bond Formation

In this section will be calculated the energy and electron distribution changes caused by the hydrogen-bond formation. The configurations on which the calculations were carried out are shown in Fig. 2, as are the coordinates and the numbering of the atomic orbitals. They include some configurations in which the hydroxyl hydrogen is located near the carbonyl group (IV, V and VIII) or near the conjugated system (XI and XIII).

**Overlap Integral.**—Table III shows some values of the overlap integral between the hydroxyl hydrogen or the hydroxyl oxygen of a formic acid monomer and the carbonyl oxygen of the other monomer at various $O_3$-$O_7$ and $O_7$-$H_6$ distances. One can see from the table that a considerable amount of overlapping exists between the hydrogen, $H_6$ and the oxygen, $O_3$. (Compare the 1s—2s overlap integral in a normal O-H bond, 0.5076.) The overlap between $O_3$ and $O_7$ is very small.

**Delocalization Energy.**—Tables IV, V and VI give the total electronic energy of each configuration of the formic acid dimer, of salicylaldehyde and of acetylacetone respectively. In the tables "tetra" means the tetrahedral angle, 109°28′.

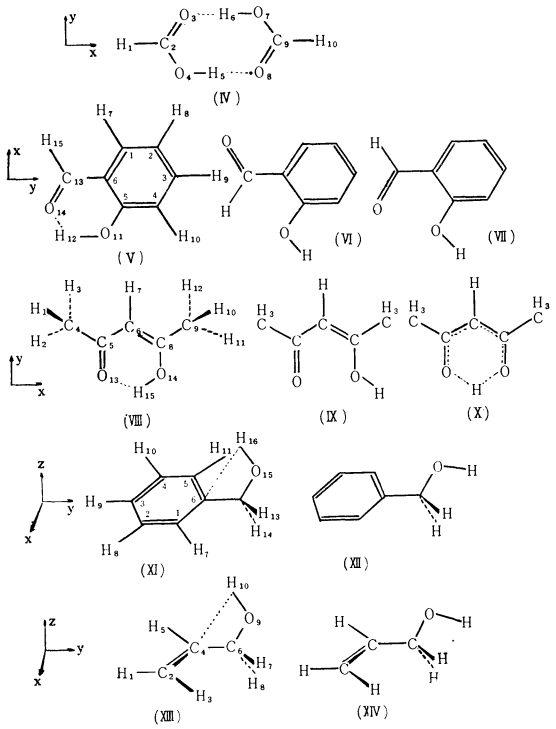

Fig. 2. Configurations compared.

In the present treatment, the delocalization energy due to hydrogen bonding, $E_d$, is given by the difference in the total electronic energies between a configuration with a hydrogen bond and a configuration without it.

For the formic acid dimer, the delocalization energy is calculated in Table IV as the difference between the total electronic energy of two monomers and that of a dimer. Model 2 (O···O distance 2.7Å and O-H distance 0.96Å) is the most stable from the viewpoint of the delocalization energy. It is interesting that the approach from 2.7Å to 2.6Å makes the dimer more unstable, though the O···H overlap gets larger. As was discussed in the preceding section, factors other than the delocalization will participate in deciding the most stable configuration of the hydrogen-bonded species. However, it is noteworthy that, in this example, the observed O···O distance in the gaseous dimer, 2.72—2.73Å,[10] corresponds well with the prediction. Model 3 shows that a also shortened O···O distance decreases the stabilization, though it also causes an increase of the oxygen-hydrogen overlap (Table III). The delocalization energy of model 2 is 0.164 eV., 3.77 kcal./mol., whereas the observed stabilization energy, $\Delta H$, of two hydrogen bonds in the gaseous dimer is ca. 7.1 kcal./mol.[11] Coulson estimated the contribution of the delocalization energy to the stabilization energy of the hydrogen bond of water to be 8 ± 4 kcal./mol.[4,5] The value obtained in this approximation might be somewhat too small. There may be two reasons for this in addition to the one stated in the preceding chapter: 1) As was stated in the previous section, since in this approximation the polarity of a bond is emphasized too much, the delocalization of electrons on the proton acceptor to the proton donor seems to be hindered. 2) In this approximation the delocalization energy is exclusively attributed to the $\sigma$ electrons (including so-called lone pairs), and not at all to the $\pi$ electrons. Since a hydrogen atom has no

$\pi$ orbital, the direct overlap between oxygen atoms is very small, as is shown in Table III. This small overlap contributes almost nothing to the stabilization energy.

The contribution of the vacant $2p\pi$ orbital on the intervening hydrogen atom, which might play the role of a stepping stone between two oxygen orbitals, will be discussed below.

There is another possibility of the $\pi$-electron stabilization. The transfer of the $\sigma$ electron on the carbonyl oxygen to the O-H bond (see the next section) will actually change the Coulomb integral of their $\pi$ orbitals. This effect may cause a variation in the total $\pi$ electron energy of the system. As was shown in the previous section, this effect was not taken into account in the approximation employed here.

For salicylaldehyde the energy of the hydrogen-bonded configuration (V) is lower than those of other configurations (VI and VII). The delocalization energy is of the order of 0.07 eV. When the COH angle, i.e., the distance between the hydroxyl hydrogen and the carbonyl oxygen, is decreased, the delocalization energy seems to increase with the formation of a stronger hydrogen bond, though the total energy decreases. For the enol form of acetylacetone, the delocalization energy of model 1 referred to that of model 2 is 0.081 eV. Model 3 is the configuration in which the hydrogen atom, $H_{15}$, is situated between two oxygen atoms, with the COH angle tetrahedral, and in which the molecule has a normal plane of symmetry, with the C-O bond length of 1.33Å and the C-C bond length of 1.44Å. The calculation shows this configuration to be very unstable.

**Orbital Energy.**—Table VII shows the energy levels and their atomic orbital coefficients of the formic acid monomer, with the corresponding energy levels of its dimer. In the extended LCAO approximation every atomic orbital can conjugate with other atomic orbitals; therefore, no completely localized molecular orbital (lone-pair orbital) remains. In the present calculation, the highest occupied orbital is a sigma-type bond, and the next highest orbital seems to correspond to the lone-pair orbital. This point seems to be a difficulty which might be overcome by an SCF technique.

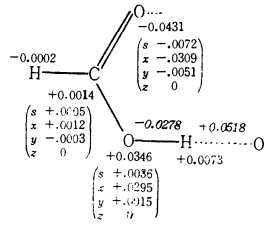
In the present calculation, each level of the monomer splits into two levels upon the dimer formation, one being higher and the other lower than the initial level, as may be seen in Table VII, which may cause a red shift for both $\pi$-$\pi^*$ and $n$-$\pi^*$ types of transitions in contradiction to the experimental finding by Barnes and Simpson (*J. Chem. Phys.*, **39**, 670 (1963)). They observed that the spectrum undergoes a blue shift upon dimerization. As to salicylaldehyde, the calculated sequence of the lone pair, the $\pi$ and the $\sigma$ orbitals does not agree with the order expected from the references.[12] Hence, the present result is unsuccessful in predicting the shift of their transition.

This discrepancy probably stems from an inappropriate parametrization of the lone-pair atomic orbitals. The Coulomb integral of the 2p lone pair atomic orbital of oxygen remains at −17.76 eV., too low to be compared with the experimental results.

**Population Analysis.**—The atomic orbital population, $N_r$; the atomic population, $M_x$; the atomic orbital bond population, $N_{rs}$, and the

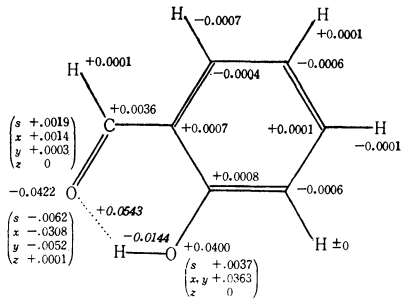
12) E. g., J. W. Sidman, *Chem. Revs.*, **58**, 689 (1958).

bond population $M_{xy}$, are defined as follows:[13]



$$N_r = 2 \sum_{l}^{occ} \sum_{s} C_r^l C_s^l S_{rs}$$

$$M_x = \sum_{r}^{onX} N_r$$



$$N_{rs} = 4 \sum_{l}^{occ} C_r^l C_s^l S_{rs}$$

$$M_{xy} = \sum_{r}^{onX} \sum_{s}^{onY} N_{rs}$$

where $C_r^i$ is the coefficient of the $r$th AO in the $i$th molecular orbital. Figure 3 shows the increase in the AO population and in the atomic population caused by the hydrogen bonding. The population on the carbonyl oxygen decreases, while, on the other hand, the population on the hydroxyl group increases. This is what one may expect. One can see in Fig. 3, in the case of formic acid, that the population on the 2px orbital, the orbital directing to the hydrogen atom of the partner molecule, plays a dominant role. An inspection of the orbital coefficients of the formic acid dimer makes it clear that the population transfers not within a monomer but from the carbonyl group of one monomer to the hydroxyl bond of the other. It is interesting that the increase in the population takes

a) Formic acid (difference between the model 2 and monomer)

b) Salicylaldehyde (difference between the models 1 and 3)

Fig. 3. Increase of population by hydrogen bond.

13) R. S. Mulliken, *J. Chem. Phys.*, **23**, 1833, 1841, 2338, 2343 (1955). The notation is a little different from that of Mulliken's paper.

place at the oxygen atom, not at the hydrogen atom. The population on the hydrogen atom increases in some cases (e. g., formic acid) and decreases in other cases (e. g., salicylaldehyde).

The bond populations of several interesting bonds are also given in Fig. 3 in italic letters. The bond population, $N_{O\cdots H}$, between the carbonyl oxygen and the hydroxyl hydrogen is positive, showing that there is a weak "bond" between them. The ratio of the AO population of the 2s atomic orbital of the oxygen to the sum of those of the 2px and 2py orbitals is approximately 1 to 2.2. On the other hand, the bond population, $N_{OH}$, of the hydroxyl group decreases. In the case of formic acid, for instance, the $N_{OH}$ of the monomer, 0.458, decreases by (0.028) about 5% of the initial value.

These results qualitatively correspond to the lowering of the O-H stretching frequency in the infrared spectrum.[1]

**The Contribution of the 2p$\pi$ Orbital on the Hydrogen Atom.**—As has been stated previously, the vacant 2p$\pi$ orbital on the hydroxyl hydrogen was taken into consideration in order to see the effect of the direct conjugation of $\pi$ electrons through the hydrogen atom.[14] The Coulomb integral of the orbital is taken to be −3.4 eV. on the basis of the spectroscopic date,[15] with the effective nuclear charge being $Z=1.0$. The energy levels thus calculated are shown in Table VIII. (The 2p$\pi$ orbital is considered only on the hydroxyl hydrogen.)

The $\pi$ delocalization energy, which was −0.0002 eV. without the orbital, rises to 0.002 eV. when the 2p$\pi$ orbital is included ; the amount is still negligible, however. Thus, we can hardly expect the delocalization energy due to the 2p$\pi$ conjugation through the hydrogen atom.

Paoloni[16] discussed the contribution of the 2p$\sigma$ orbital on the hydrogen atom to the delocalization energy. In this paper this effect is not considered.

**The $\pi$ Hydrogen Bond.**—It has been recognized that $\pi$ electron systems, such as the phenyl group or the olefinic group, can be proton acceptors when they interact with proton donors. Benzyl alcohol and allyl alcohol, for instance, are known to have a $\pi$ hydrogen bond. The stabilization energy, $\Delta H$, due to a $\pi$ hydrogen bond has been estimated to be 1 to 2 kcal./mol.,[2] smaller than that of usual hydrogen bonds.

With respect to benzyl alcohol and allyl alcohol, we made the same calculation as was

carried out in the previous sections. The geometrical data of the molecules calculated are collected in Table IX. The overlap integrals between the hydroxyl hydrogen, $H_{10}$, and the nearest $sp^2$ carbon, $C_4$, for instance, in model 3 (with the hydrogen bond) and model 4 (without the hydrogen bond) of allyl alcohol are as follows:

| | Model 3 | Model 4 |
|---|---|---|
| Hls-C2s | 0.1519 | 0.0321 |
| Hls-C2py | 0.0898 | 0.0350 |
| Hls-C2pz ($\pi$) | 0.1368 | 0.0138 |

The magnitude of these overlap integrals for model 3 is of the same order as for the dimer of formic acid (Table III).

In spite of this large overlap, the delocalization energy calculated is extremely small. For the most stable CCO and COH angles (models 1 and 2) of allyl alcohol, the hydrogen-bonded configurations, XIII, is a little more unstable than the nonbonded configuration, XIV. There are two factors affecting the delocalization energy. One is the energetic contribution of the methylol group to the total electronic energy. Referring to Table II, in which the total energy of methyl alcohol is given with respect to three configurations, it may be considered that the methylol group in the configuration XIII of Fig. 2 makes a smaller contribution to the total energy than that in the configuration XIV of the same figure. The other factor is the stabilization due to the formation of a $\pi$ hydrogen bond. On comparing models 1 and 2, since the $C_4\cdots H_{10}$ distance is rather large and since, therefore, the delocalization energy is small, and is, furthermore, in this approximation estimated

to be too small, the former factor overcomes the latter. If we shorten the $C_4 \cdots H_{10}$ distance by reducing the CCO or/and the COH angles, the energy of the configuration XIII referred to that of XIV becomes more stable, as is shown in Table IX.

Thus, the small stabilization energy of a $\pi$ hydrogen bond seems partly due to the compensation with the energy difference between the configurations, such as I and II.

The change in atomic and bond population upon the hydrogen bonding, that is, the population difference between models 3 and 4 of allyl alcohol, is shown in Fig. 4. One can notice that the population transfers from the allyl group to the hydroxyl group. However, the change amounts to only 10% of that in a usual hydrogen bond (Fig. 3).

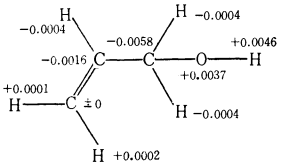

Fig. 4. Increase of population by $\pi$ hydrogen bond (difference between the models 3 and 4).

## Discussion

In discussing the changes in electronic structures by the hydrogen-bond formation, some defects of the extended LCAO MO method were revealed: 1) The absolute value of the Coulomb integral of the so-called lone-pair atomic orbital is too large. 2) A change in the population on a orbital does not affect the Coulomb integral of the orbital. Accordingly, the stabilization energy is very small.

These two defects may be overcome if the Coulomb integral is varied according to the AO population on the atomic orbital and according to those on the other atomic orbitals on the same atom. This correction may mean considering the electronic interaction implicitly.

Finally, a certain apparent parallelism between the delocalization energy and the experiments is observed; the electronic and nuclear repulsion energies are, however, not taken into account explicitly, as has been pointed out above, in the present treament. The agreement should be checked by further investigation. These improvements, together with the problems of the parametrization of the resonance integral, will be reported on in the near future.

## Summary

1) The changes caused by hydrogen bonds in the electronic structure of several molecules have been discussed by the use of the extended LCAO MO method.

2) The delocalization energy have been calculated to be 3.8 kcal./mol.

3) The frequency shifts in the ultraviolet spectrum cannot be explained.

4) In the formic acid dimer it has clearly been shown that the population transfers from the carbonyl group to the hydroxyl group and that a small bond population arises between them.

5) The $2p\pi$ orbital on the hydrogen atom contributes almost nothing to the $\pi$ delocalization energy.

6) The $\pi$ hydrogen bond has also been discussed.

7) The defects in the extended LCAO MO method in treating molecules with polar groups or lone pairs have been pointed out, a method for improvement suggested, and some critical discussion of the present treatment added.

The calculation was carried out on the IBM 7090 at the Japan IBM Co., with the permission of the UNICON Committee, whose kindnees we hereby acknowledge.

# The Nuclear Magnetic Resonance Spectra of Some 4, 6-Disubstituted *o*-Cresols*

By Michio KONDO

(Received September 12, 1964)

In the application of the NMR technique to the organic structure determination, it is a useful principle that chemical shifts of aromatic ring protons can be estimated by using several substituent parameters. Many studies have been carried out in order to obtain such substituent parameters. Spiesecke and Schneider[1] determined the shielding parameters of substituents from their study of a series of partially-deuterated monosubstituted benzenes. Diehl[2] also evaluated these parameters by an indirect method, in which he assumed that two equal or different substituents in the meta or the para position behave additively with respect to the chemical shift of a ring proton. The discrepancies between the two results, which probably reflect the approximate validity of the additivity rule, are less than 0.1 p. p. m. The utility of these substituent parameters has been demonstrated for several *m*- and *p*-disubstituted benzenes.[3] Martin and Dailey[4] showed that the ring-proton chemical shifts of a number of polysubstituted benzenes can be represented by simple sums of substituent-shielding constants with an accuracy of about 0.1 p. p. m., except for ring protons adjacent to substituents which are ortho to each other. In these positions, the large deviations observed presumably arise from strong interaction between the neighboring substituents separated approximately by the sum of van der Waals radii. They discussed the shielding mechanism and concluded that the proton chemical shifts in the disubstituted benzenes appear to arise primarily from changes in the $\pi$-electron density in the ring due to substituent perturbation. Other factors, for example, electric field and magnetic anisotropy of substituents, have minor effects upon ring proton chemical shifts.

Since it is not obvious whether or not the shielding parameters remain unchanged in the case of tetrasubstituted benzenes, it is of interest to test the additivity of shielding parameters in some 4, 6-disubstituted *o*-cresols. In addition, these compounds are suitable for studying the correlation between ring proton-coupling constants and the electronegativities of substituents, because there are only meta proton couplings.

On the other hand, the broadening of the NMR signals of methyl-substituted benzenes has been ascribed to the spin-spin coupling between methyl and ring protons (hereafter referred to as "benzylic coupling"). Quite recently, Nair and Gopakumar[5] studied the correlation between the variation in the benzylic coupling and changes in the $\pi$-electron distribution in some methyl-substituted aromatic compounds. They reported that the values of benzylic couplings in 2-methylnaphthalene and 2-methylanthracene are 0.7 and 0.8 c. p. s. respectively, and that the well-known difference in the bond order for the 1–2 bonds in naphthalene and anthracene is reflected in the observed splittings. The coupling to the 3-protons was reported to be weak. The following conclusion was drawn regarding the possibility of the splitting of the NMR signal of a methyl group attached to an aromatic ring with protons in both ortho positions. When the bond order values of the two bonds adjacent to a C–$CH_3$ bond are comparatively small and not very different from each other, no splitting can be expected for its resonance peak. On the other hand, when there is a considerable difference between the bond-order values or when the bond order values are both quite large, clear splittings should be observable. Shoolery[6] presented a good example, showing a close relation between the benzylic coupling and the bond-order values of the ring. Whereas a benzenoid thymol system shows no resolvable benzylic coupling, a thymoquinone system shows clear splittings in the signals. Regarding this point, it is suggestive that the coupling between methyl and ring protons is observed in heteroaromatic compounds, such

as 2-methylthiophenes[7], methylfurans,[8] and methyl-substituted *N*-heteroaromatic compounds.[9,10] These facts seem to indicate that the benzylic coupling might be observed when a ring system is less aromatic, i.e., when $\pi$-electrons are much localized in a C–C bond involving a carbon atom to which a methyl group is bonded.

## Experimental

**Materials.**—Commercial products were available for 4,6-dinitro-, 4,6-dichloro-, $\alpha$, 4,6-tribromo-, and 4,6-dimethyl-*o*-cresol. The bromination in acetic acid[11a] of 4-nitro-*o*-cresol, derived from 2-amino-5-nitrotoluene by boiling it in 30% aqueous sodium hydroxide for 20 hr.,[11b] yielded 4-nitro-6-bromo-*o*-cresol. Two halogenated compounds, 4,6-dibromo-*o*-cresol and 4,6-diiodo-*o*-cresol,* were prepared by the bromination and by the iodination of *o*-cresol respectively.[11c,11d] All the materials used were purified by recrystallization from appropriate solvents.

**Measurements of NMR Spectra.** — The NMR spectra were obtained with a Varian A-60 spectrometer in dilute deuterochloroform solutions (ca. 8 mol. %) containing a small amount of tetramethylsilane as an internal standard. Chemical shifts were read on standardized charts calibrated with the signal of chloroform. The resolution was checked with acetaldehyde. The accuracies of the chemical shifts and of the coupling constants are within about $\pm 0.02$ p. p. m. and $\pm 0.2$ c. p. s. respectively.

## Results and Discussion

All the spectra of the examined compounds show simple first-order patterns. As an example, the spectrum of 4,6-dichloro-*o*-cresol is illustrated in Fig. 1. Each of the ring proton signals A and B consists of a pair of quartets. The methyl signal is composed of three peaks with a relative intensity of about 1 : 2 : 1. The middle component is somewhat broader than the outer components, suggesting the superposition of two signals. These features of the spectrum reveal the spin-spin coupling between the two ring protons and the methyl protons. Of the two signals A and B, the signal B, indicating a stronger coupling with the methyl protons, was assigned to the proton 3, while the signal A was assigned to the proton 5.

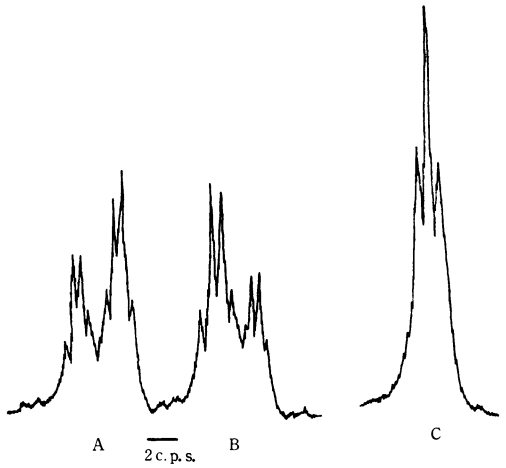

Fig. 1. The NMR spectrum of 4,6-dichloro-*o*-cresol.
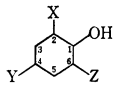
A: ring proton 5, B: ring proton 3, C: methyl protons

The positions of the signals of various kinds of protons are given in Table I in p. p. m. relative to the internal standard.

**Chemical Shifts.** — The signals of the ring protons 5 are always observed at lower fields than are those of the protons 3, except for 4,6-dimethyl-*o*-cresol (2,4,6-trimethyl phenol), in which the two ring protons are magnetically equivalent. It appears reasonable that the proton 5, which is ortho to both of the electronegative substituents, 4 and 6, is more deshielded than is the proton 3, which is ortho to 4 and para to 6, because the deshielding effects of the substituents in question are strongest on the ortho proton (see Table II).

If the effects of substituents on the chemical shift of a ring proton are simply additive, the shift should be equal to the algebraic sum of substituent constants. In the present case, the chemical shifts of protons 3 and 5 should be:



$$\delta(3) = d_o(CH_3) + d_m(OH) + d_o(Y) + d_p(Z) + \delta(\text{benzene})$$

$$\delta(5) = d_p(CH_3) + d_m(OH) + d_o(Y) + d_o(Z) + \delta(\text{benzene})$$

Therefore, the proportional relationship between these chemical shifts should be observed, provided that the proportional relationship is observed between substituent parameters, $d_o(R)$

○: Spiesecke and Schneider;[1] △: Martin and Dailey;[4] □: Diehl[2]

and $d_p$(R). This is the case, as Fig. 2 shows. Comparisons of the observed and calculated chemical shifts were made in order to ascertain the validity of the additivity rule. Table II gives the values relative to the chemical shift of benzene in deuterochloroform. The agreement among them is good in view of the rough approximation used. This fact indicates that

the additivity rule holds in the case of tetrasubstituted benzenes. A good agreement is again observed in the case of durene. The observed chemical shift of the ring protons in durene[13] (6.741 p. p. m.) agrees well with that estimated from the assumed additivity rule (6.716 p. p. m.).

The OH proton signal of 4, 6-dinitro-*o*-cresol was observed at an extraordinarily low field. This observation can be ascribed to the formation of an intramolecular hydrogen bond between OH and $NO_2$ groups. It has been pointed out that the OH proton signal of 2, 4-dinitrophenol appears at a field lower than that of 2, 4-dichlorophenol by about 5.6 p. p. m. because of the formation of strong intramolecular hydrogen bonds.[14] The OH proton signal of $\alpha$, 4, 6-tribromo-*o*-cresol was observed at a field lower than that of 4, 6-dibromo-*o*-cresol. This downfield shift results from the formation of intramolecular hydrogen bonds between $CH_2Br$ and OH groups, in addition to that between OH and Br groups.*

Methyl signals are shifted to lower fields with the increasing electronegativities of substituents. In the case of 4, 6-dinitro-*o*-cresol, it appears at a field lower than that of the parent compound by 0.21 p. p. m. Yamaguchi[15] studied the shielding effect of nitro groups and observed that a nitro group deshields methyl protons at the meta position of *m*-nitrotoluene by 0.12 p. p. m. The chemical shift of the methyl protons described above on 4, 6-dinitro-*o*-cresol is in good agreement with the calculated value, $2\times0.12=0.24$ p. p. m.

**Spin-Spin Coupling.**—The spin-spin coupling constants obtained are summarized in Table III.

TABLE III. SPIN-SPIN COUPLING CONSTANTS

| | $J$(3-5) c. p. s. | $J$(3-$CH_3$) c. p. s. | $J$(5-$CH_3$) c. p. s. |
|---|---|---|---|
| I | 2.9 | 0.9 | 0.6 |
| II | 2.7 | 0.8 | 0.5 |
| III | 2.5 | 0.7 | 0.5 |
| IV | 2.4 | 0.7 | 0.5 |
| V | 2.2 | 0.8 | 0.6 |
| VI | — | — | — |
| VII | 2.4 | — | — |

The coupling constants between two ring protons are in the 2.2—2.9 c. p. s. range. The coupling constant is larger when substituents at the positions 4 and 6 are more electronegative. Figure 3 shows the correlation between the meta coupling and the sum of the electronegativities of substituents 4 and 6. This proportional relationship indicates the additive effect of substituents on the ring proton coupling. A similar situation of meta coupling was reported for some *m*-[16] and

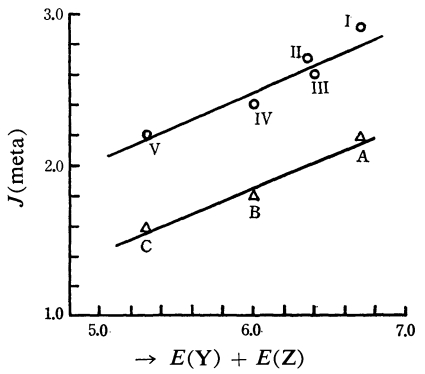

Fig. 3. Correlation between the meta coupling and the sum of electronegativities of the substituents 4 and 6.
-○-: $J$(3-5) for 4,6-disubstituted *o*-cresols
-△-: $J$(2-6) for *m*-disubstituted benzenes[16]

*p*-disubstituted benzenes.[17] It was reported[17] that proportionality exists between the proton-proton coupling and the electronegativity of substituents, although no detailed discussion of coupling mechanism has yet been undertaken.

Proton-proton coupling constants are, in general, affected by two contributing factors, $\sigma$- and $\pi$-electrons. The dependence of the vicinal coupling constant on the electronegativities of substituents has been studied in some ethane[18] and ethylene derivatives.[19] For ethane and ethylene derivatives, the vicinal coupling constants are expressed as:[20]

$$J(CH_3CH_2X)=7.9(1-0.09\Delta E)$$

$$J_{trans}=19(1-0.17\Delta E);$$

$$J_{cis}=11.7(1-0.34\Delta E)$$

where $\Delta E$ is the difference in electronegativity

between X and the hydrogen atom. In ethylene derivatives, the variation in coupling constants with the electronegativity is much greater than that in substituted ethanes. From this fact, it may be concluded that the contributions of both $\sigma$- and $\pi$-electrons are reduced by the introduction of an electronegative group. In other words, a decrease in the charge density in the double bond caused by the introduction of an electronegative groups is reflected in a decrease in the coupling constant of vicinal protons.

In the case of 4, 6-disubstituted *o*-cresols, however, the meta coupling intensifies the proportionality with an increase in the electronegativity of substituents. This discrepancy indicates the participation of another mechanism, which probably arises from the presence of a benzene ring contributing to the coupling. Since the angle between two C–H bonds can be assumed to be fixed, the change in the meta coupling is attributable to that in electron distribution, but it is not possible to give a clear interpretation immediately, because it is not clear whether the changes in the proton-coupling constants in these compounds are due to changes in the $\sigma$-electronic system or to changes in the $\pi$-orbitals.

**Long-range Coupling.** — The coupling constants, $J(3\text{–}CH_3)$ and $J(5\text{–}CH_3)$, are less than 1 c. p. s. It is reasonable that $J(3\text{–}CH_3)$ is slightly larger than $J(5\text{–}CH_3)$. However, it is noteworthy that an unexpectedly large value was observed for the spin-spin coupling constant between the methyl group and the ring proton at the para position across six bonds. Whereas the value of $J(5\text{–}CH_3)$ is quite similar within the range of the accuracy of this experiment, the value of $J(3\text{–}CH_3)$ seems proportional to the electronegativity of the substituents 4 and 6.

It is to be expected that a larger contribution from the methyl-hyperconjugation and the resulting shift of the NMR signal of methyl protons to a lower field will be observed for compounds with more powerful electron-withdrawing substituents. Therefore, there should be a proportional relationship between the chemical shift of the methyl protons and the benzylic coupling constant, $J(3\text{–}CH_3)$, provided that the hyperconjugation of the methyl group contributes considerably to the benzylic coupling. In Fig. 4, the plots for compounds I, II, III, and IV fall well on a straight line, but the plot for compound V deviates from the line, probably because of the effect of the large volume of iodine atoms at the ortho position.

It can also be expected that the replacement of a methyl group with a bromomethyl group

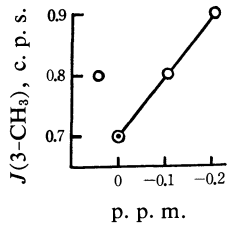

Fig. 4. Difference between methyl proton chemical shifts of 4, 6-disubstituted *o*-cresols and that of 4, 6-dichloro-*o*-cresol vs. $J(3\text{–}CH_3)$.

decreases the extent of hyperconjugation because of the fixation of the bromomethyl group in a conformation inadequate for hyperconjugation by an intramolecular hydrogen bond. As expected, no benzylic coupling was observed in the case of $\alpha$, 4, 6-tribromo-*o*-cresol. This fact indicates a significant contribution by the hyperconjugation to the benzylic coupling. In other words, the hyperconjugation of a methyl group with the benzene ring is due to the partial transfer of charges from the methyl group to the ring system. The introduction of bromine into the methyl group reduces the charge transfer from the substituent to the ring system and makes the benzylic coupling very weak. In short, a resolvable benzylic coupling indicates an appreciable migration of charges from the methyl group to the ring system. From this point of view, it seems possible to give an interpretation of the facts described in the introduction.

Although there are two kinds of methyl groups in 4, 6-dimethyl-*o*-cresol, only a single signal was observed for the methyl protons. It is not possible to estimate the benzylic coupling constants directly from the spectrum, but a considerable magnitude of benzylic coupling may be inferred from the appreciable broadening of the signals of both the methyl and ring protons.

Freeman et al.[21] have reported the presence of a weak long-range coupling between the OH proton and the ring proton 4 at the meta position in methyl salicylate. In the present case, however, it may be concluded that the OH proton couples with neither of the two ring protons at the meta positions since no changes in the fine structure of signals were observed in methanol, acetone, or NaOD-$D_2O$.

## Summary

The nuclear magnetic resonance spectra of seven 4, 6-disubstituted *o*-cresols (4, 6-dinitro-, 4-nitro-6-bromo-, 4, 6-dichloro-, 4, 6-dibromo-, 4, 6-diiodo-, 4, 6-dimethyl-, and $\alpha$, 4, 6-tribromo-*o*-cresol) have been examined in dilute

21) R. F. Freeman, N. S. Bhacca and C. A. Reilly, *J. Chem. Phys.*, 38, 293 (1963).

deuterochloroform solutions at 60 Mc./sec.

The observed chemical shifts of the ring protons 3 and 5 of 4, 6-disubstituted *o*-cresols are in good agreement with the values calculated from the shielding parameters of substituents by assuming the additivity rule.

The spin-spin coupling constant between two ring protons is proportional to the sum of the electronegativities of the substituents 4 and 6.

There are weak long-range couplings between the methyl and ring protons. It has been suggested that hyperconjugation contributes to these couplings.

The author wishes to thank Dr. Munetoshi Matsui and Dr. Akira Itō for their encouragement throughout this investigation.

# The Magnetic Susceptibilities of Mononuclear and Binuclear Chromium(III) Complexes*

By Toshiyuki MORISHITA, Kuniko HORI, Eishin Kyuno and Ryokichi TSUCHIYA

(Received September 19, 1964)

A chromium(III) ion under the ligand field in an octahedral environment has three unpaired electrons in the three-fold degenerated $t_{2g}$ orbitals, irrespective of whether the field is strong or weak. Since the degree of the covalency of the bonding in a chromium(III) complex cannot, in general, be estimated by measuring only the magnetic susceptibility, the measurement has so far been of little interest to investigators of chromium(III) complexes.

In spite of this, however, there have been found almost diamagnetic binuclear complexes, such as $[Cr_2(NH_3)_{10}O](ClO_4)_4$,[1] and nitrosyl complexes of abnormal valency, such as $K_4 \cdot [Cr(CN)_5NO] \cdot H_2O$,[2] whose magnetic moment, 0.7 B. M., is smaller than the spin-only value for three unpaired electrons.

In addition, there have been several reports[3-5] with respect to the magnetic susceptibility of mono- and bi-nuclear chromium(III) complexes, but most of them have not described the magnetic moment and have not even mentioned the relation between the presence of the exchange interaction between two chromium atoms and the color of the binuclear complexes. In order to establish the relation in detail, the magnetic susceptibility of several mono- and bi-nuclear chromium(III) complexes and of the salts consisting of complex cations and anions was measured.

## Experimental

The samples used for the measurement of the magnetic susceptibility are those listed in Table I. The methods of preparing several of them will be described below; otherwise they were prepared as in the foot notes in the table.

***cis*-Potassium Hydroxobis(oxalato)aquochromate(III) Hydrate, $K_2[Cr(OH)ox_2(H_2O)] \cdot H_2O$.**—This was prepared by adding pyridine to the *cis*-potassium bis(oxalato)diaquochromate(III) (6) in Table I.

Found: Cr, 14.78. Calcd.: 15.24%.

**Hydroxooxalatoaquoethylenediaminechromium(III), [Cr(OH)ox($H_2O$)en].**—This was prepared by adding pyridine to the oxalatodiaquoethylenediaminechromium(III) bromide (8) in Table I.

Found: Cr, 22.43; N, 11.95. Calcd.: Cr, 22.11; N, 11.91%.

**Di-$\mu$-hydroxobis(bisethylenediaminechromium(III)) Bromide Dihydrate, $[en_2Cr(OH)_2Cr\,en_2]Br_4 \cdot 2H_2O$.**—This was prepared by the reaction of ammonium bromide with the binuclear complex (9) in Table I.

Found: Cr, 13.95; N, 13.18. Calcd.: Cr, 13.99; N, 15.26%.

The molecular conductivity, $\Lambda_{10000}$, was 480.9 mho·cm²/mol. at the concentration of $10^{-4}$ mol./1. at 25°C.

**Sodium Di-$\mu$-hydroxobis(bisoxalatochromate(III)) Tetrahydrate, $Na_4[ox_2Cr(OH)_2Crox_2] \cdot 4H_2O$.**—This was prepared by the reaction of sodium

bromide with ammonium di-$\mu$-hydroxobis(bisoxalatochromate(III)).

Found: Cr, 14.94. Calcd.: Cr, 15.07%.

$\Lambda_{10000}=504.3$.

**Di-$\mu$-hydroxobis(bis-$\alpha$-alaninatochromium (III)), [$\alpha$-ala$_2$Cr(OH)$_2$Cr $\alpha$-ala$_2$]·H$_2$O.**—This was prepared from a mixed solution of chromic chloride hexahydrate and $\alpha$-alanine in a way similar to that used for the binuclear glycinato complex (16) in Table I.

Found: Cr, 20.72; N, 11.92. Calcd.: Cr, 21.65; N, 11.66%.

Samples 18, 19 and 20 in Table I were precipitated by mixing the saturated solutions of the two complex salts containing a corresponding cation or anion.

The magnetic susceptibility was measured by a Gouy balance at room temperature. The effective magnetic moment per chromium atom was evaluated from the value of the magnetic susceptibility on the assumption that the magnetic susceptibility is inversely proportionate to the absolute temperature, as $\chi=C/T$, where $\chi$, $C$ and $T$ are the magnetic susceptibility, a Curie constant, and the absolute temperature respectively.

## Results

The values of the magnetic susceptibility and of the calculated magnetic moment of mono- and bi-nuclear complexes and salts consisting of the complex cation and anion are listed in Table I. The table shows that the magnetic moment of the mononuclear complexes, except for sample 9, is close to the spin-only value for three unpaired electrons.

The values of the magnetic moment of binuclear complexes are remarkably lower than the value of the magnetic moment for the spin-only value except for sample 11. This fact makes us expect the exchange interaction between two chromium atoms in the binuclear complexes.

However, when we compare the values in detail, it is found that even if the binuclear complex ions contained are the same, the magnetic moment of sample 11 is larger than that of sample 12, and that that of 13 is larger than that of 14, where the former two samples have the same binuclear cation and the latter two have the same binuclear anion. Since the ionic radius of the anti-ion of the binuclear complex cation in 11, the dithionate ion, is larger than that of the bromide ion in 12, and since that of the potassium ion in 13 is larger than that of the sodium ion in 14, we may

suppose that, as the radius of the anti-ion becomes smaller, the exchange interaction between the chromium atoms through the hydroxy group becomes stronger.

The magnetic moments of samples, 15, 16 and 17 are especially small. This fact can be understood by considering that the exchange interaction between two chromium atoms in a binuclear complex is very large, though the reason for this can not be exactly determined. In addition, there may be some exchange interaction between chromium atoms in the neighboring complex molecules in these cases, since they do not contain the anti-ions.

The values of the magnetic moments of 18 and 19 are obviously lower than the spin-only value, which suggests the presence of an exchange interaction between chromium atoms in the neighboring complex cation and anion.

The magnetic moments of mono- and bi-nuclear complexes in relation to their color and the position in their synthetic course are summarized in Fig. 1. The qualitative information is deduced from Fig. 1 that the complexes which have a normal magnetic moment (close to 3.87 B. M.) exhibit a reddish color in general, except for a few fundamental complexes used as starting materials, whereas the complexes

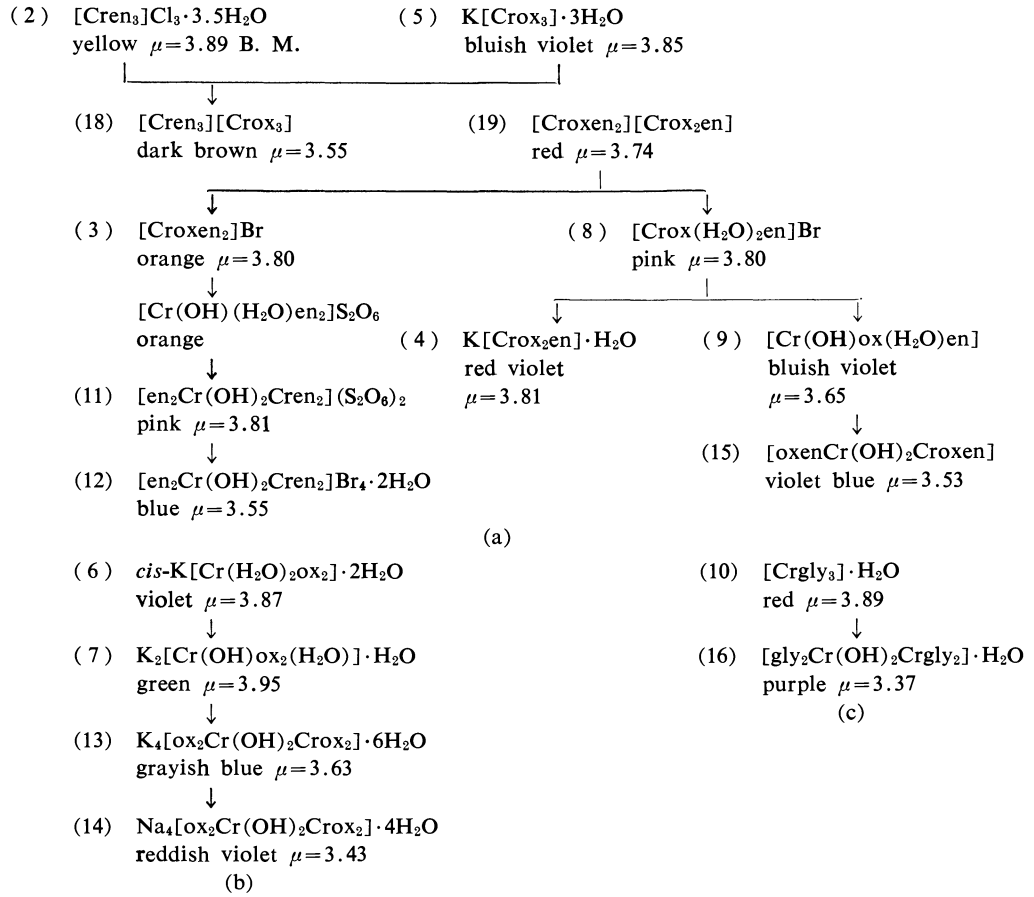

Fig. 1. The magnetic moment and the color of the complexes in the diagrams of the synthesis course of (a) ethylenediaminechromium(III) series, (b) oxalatochromium(III) series and (c) glycinatochromium(III) series.

TABLE II. THE WAVELENGTH AT A PEAK IN THE FIRST ABSORPTION BAND, $\lambda_{max}$, OF THE BINUCLEAR COMPLEXES AND THE MONONUCLEAR ONES WHICH ARE THE MOTHER MATERIALS FOR THE SYNTHESES OF THE FORMERS

| Mother material | $\lambda_{max}$, mμ | Binuclear complex | $\lambda_{max}$, mμ |
|---|---|---|---|
| $[Cr(H_2O)_2en_2]^{3+}$ | 515[6] | $[en_2Cr(OH)_2Cren_2]^{4+}$ | 530[10] |
| $[Crox_2(H_2O)_2]^-$ | 570[6] | $[ox_2Cr(OH)_2Crox_2]^{4-}$ | 580[10] |
| $[Crox(H_2O)_2en]^+$ | 524[6] | [oxenCr(OH)2Croxen] | 550[10] |

which have a subnormal magnetic moment (lower than the spin-only value) show a bluish color such as samples 9, 12, 13, 14 and 15 or, at least, show purple, as does 16.

The wavelengths at the maximum absorption peak in the first absorption band of the binuclear chromium(III) complexes, $\lambda_{max}$, are compared with those of the mononuclear complexes which are the mother materials for the syntheses of the former in Table II. It may be concluded from Fig. 1 and Table II that, as the exchange interaction between the chromium atoms appears, the first absorption band is shifted to red and that, as a result, the color of the compounds changes from reddish to bluish.

# The Preparation of Heavy Metal Hydride and Its Catalytic Activity. VII. The Hydrogenation of Various Olefins with a Ferric Chloride-Lithium Aluminum Hydride or a Cobaltous Chloride-Lithium Aluminum Hydride Catalyst*

By Yoshinobu TAKEGAMI, Toru UENO and Takao FUJII

(Received October 26, 1964)

In preceding publications[1,2] we reported our observation that certain heavy metal halides react readily with a solution of lithium aluminum hydride in tetrahydrofuran to give a new catalyst system for the hydrogenation of styrene and cyclohexene. A typical catalyst is composed of ferric chloride plus lithium aluminum hydride (the iron catalyst) in an $LiAlH_4/FeCl_3$ ratio of 1:1. In the course of investigating this catalyst system, we were led to the conclusion that iron hydride, present in appreciable concentrations in the catalyst system, might be responsible for the hydrogenation reaction.

We will now report on an extension of the scope of this iron catalyst. The hydrogenations of various compounds containing olefinic linkages have been studied. In addition, a cobaltous chloride plus lithium aluminum hydride (the cobalt catalyst) system has been included in this study in order to compare the two catalysts.

## Experimental

**Materials.**—Lithium aluminum hydride was obtained from Metal Hydride, Inc. A lithium aluminum hydride solution in tetrahydrofuran was prepared and used as a clear solution. The concentration of the stock solution (0.2–0.3 mol./l.) was determined by analysis using active hydrogen prior to use (by hydrolysis). The anhydrous heavy metal halides and olefins used were the purest among the available commercial materials. Tetrahydrofuran was dried over sodium and freshly distilled just before use.

**Procedure.**—Since in all cases the catalysts were sensitive to air and moisture, all operations were carried out in a nitrogen or a hydrogen atmosphere. The apparatus for the preparation of catalysts and the hydrogenation of olefins consisted of a four-necked flask equipped with a stirrer, a dropping funnel (60 ml.), and a thermometer, and was jointed to a gas burrete through a silica gel tube. Before the reaction, the apparatus was flushed with hydrogen. A solution of 70 ml. of tetrahydrofuran containing about 0.005 mol. of the heavy metal halide was stirred at 0°C for 40 min. To this solution a desired amount of a lithium aluminum hydride solution was then added through the dropping funnel. The time of addition varied from 2 to 10 min. The color of the solution immediately changed black or brown-black, and there was an accompanying hydrogen evolution. The mixture was stirred for an additional several hours until the hydrogen evolution ceased.

The hydrogenation of the olefin was carried out by introducing 5 ml. of the olefin into the catalyst solution described above. The speed of stirring was kept at 900 r.p.m. during the hydrogenation reaction. After the hydrogenation, the catalyst was destroyed

by the addition of 20 ml. of 15% aqueous hydrochloric acid; the amount of hydrogen thus evolved was measured. The hydrogenation product was extracted with diethyl ether, washed with water, concentrated by the evaporation of ether, and analyzed by gas chromatography.

The amounts of hydrogen evolved on the hydrolysis of the catalysts at several $LiAlH_4/FeCl_3$ ratios are given in Table I. For purposes of comparison, the amounts of hydrogen evolved during the preparation of the catalysts, reported in a preceding paper,[2] are also included in Table I.

## Results

**Hydrogenation with Iron Catalysts.** — The hydrogenation reaction was carried out under hydrogen at an atmospheric pressure and at 0°C. Among the solvents tested, diethyl ether, pyridine and tetrahydrofuran, the last was the best for this catalyst system. For most of the experiments, 5 ml. of olefin was used, the ratio of olefin to the iron catalyst being about 10 : 1. In order to establish a general relationship between the activity and the composition (the $LiAlH_4/FeCl_3$ ratio) of the iron catalyst, the amounts of absorbed hydrogen are plotted in Fig. 1 against the reaction times for the hydrogenation reaction of cyclohexene with the iron catalyst at various $LiAlH_4/FeCl_3$ ratios. No attempt has been made to estimate the rate constants of the hydrogenation reaction. The first reaction was carried out with the iron catalyst at an $LiAlH_4/FeCl_3$ ratio of 0.71 : 1. No hydrogen absorption was observed with this catalyst. Then several aliquots of a lithium aluminum hydride solution were added to the system at intervals. An appreciable activity appeared when the $LiAlH_4/FeCl_3$ ratio reached 0.89 : 1. Then the catalytic activity of the iron catalyst was found to rise steadily as the $LiAlH_4/FeCl_3$ ratio rose from 0.89 : 1 to 1.00 : 1, but thereafter to decrease as the ratio increased further. These successive procedures, in which the $LiAlH_4/FeCl_3$ ratio is raised step by step, will be described as "the step-by-step procedures" in a further discussion. In addition to the step-by-step procedures, the hydrogenation was also carried out with an iron catalyst freshly prepared in the $LiAlH_4/FeCl_3$ ratio of 1.00 : 1, the most active of the step-by-step procedures. The rate of this single hydrogenation, shown by a dotted line in Fig. 1, nearly corresponds to that observed in the hydrogenation at an $LiAlH_4/FeCl_3$ ratio of 1.00 : 1 in the step-by-step procedures.

*2 The amounts of hydrogen evolved are represented by the ratio $R/R_0$, where $R$ is the amount of hydrogen evolved during hydrolysis subsequent to the hydrogenation (mol./mol. $FeCl_3$) and $R_0$ is the amount of hydrogen evolved during the hydrolysis of the catalyst with same $LiAlH_4/FeCl_3$ ratio without hydrogenation.

*3 A mixture of cis- and trans-isomers.

In order to determine how the olefin structure influences the rate of hydrogenation, the iron catalyst was tested with various olefinic compounds. The bulk of the experiments were performed according to the step-by-step procedures, and the value of the $LiAlH_4/FeCl_3$ ratio of the most active catalyst was determined in each case. The hydrogen absorption curves obtained with the most active catalysts are shown in Fig. 2. The values of the $LiAlH_4/FeCl_3$ ratios of the catalysts employed and the amounts of hydrogen evolved on the hydrolysis subsequent to the hydrogenation are given in Table II.

On the basis of the information given in Fig. 2, the olefins and unsaturated compounds employed in this work can be divided into three groups according to the ease of hydrogenation : (I) styrene, α-methylstyrene, safrole, isosafrole, indene, anethole and isoprene ; (II) cyclohexene and *d*-limonene, and (III) α-pinene, squalene, furan, vinyl acetate, ethyl acrylate, allyl chloride and acrylonitrile.

*The Hydrogenation of the Olefins in the First Group.*—When compared at the most active composition of the catalysts, the rates of the hydrogenation of the olefins of this group were almost the same, as Fig. 2 shows. However, the ranges of the $LiAlH_4/FeCl_3$ ratios of the active catalysts and the values of the ratios of the most active catalysts varied to some extent ; the ranges of the $LiAlH_4/FeCl_3$ ratios of the active catalysts for the hydrogenation of styrene, isosafrole, anethole and isoprene, for instance, were 0.78—1.45 : 1, 0.99—1.43 : 1, 1.21—1.41 : 1 and 0.78—1.23 : 1 respectively.

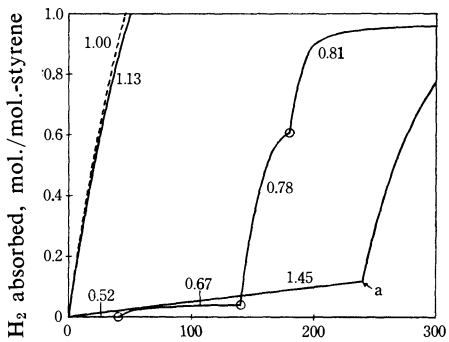

Fig. 3. Hydrogenation of styrene with the iron catalyst.

$FeCl_3$ : 4.94 mmol., THF : 100 ml., styrene : 5 ml. (43.5 mol.), reaction temp. : 0°C
5 mmol. of water was added at "a."
Others are same to in Fig. 1.

The results of a representative run for styrene are shown in Fig. 3. At low $LiAlH_4/FeCl_3$ ratios, the initial rates were high, but either instantaneously or gradually the rates decreased, as may be seen from the curves corresponding to the (0.67) and (0.78) ratios in Fig. 3. For the run carried out with the optimum ratio, the plots of the amounts of hydrogen absorbed vs. the reaction time were linear up to almost 100% conversion. The slope, however, became gentle with a further increase in the $LiAlH_4/FeCl_3$ ratio, as may be seen from the curve representing the (1.45) ratio in Fig. 3. Similar trends were observed in the runs carried out with the other olefins.

If a small amount (0.005 mol.) of water was added to the less active catalyst with a larger $LiAlH_4/FeCl_3$ ratio, the catalyst became highly active, as may be seen in Fig. 3. A similar phenomenon was observed for the hydrogenation of indene with the iron catalyst with the $LiAlH_4/FeCl_3$ ratio of 1.69 : 1. We previously reported[1] that the iron catalyst has catalytic activity when its hydrogen content is limited in a certain region and that the hydrogen content rises with an increase in the $LiAlH_4/FeCl_3$ ratio. From these facts, it is evident that the iron catalyst with a high $LiAlH_4/FeCl_3$ ratio

is less active because of its large hydrogen content. Therefore, the activation of the catalyst when a small amount of water is added is conceivably due to the diminution of the hydrogen content of the catalyst.

On the other hand, in the hydrogenation of anethole with the iron catalyst with the $LiAlH_4/FeCl_3$ ratio of 1.61 : 1, which had no activity at the initial stage of the hydrogenation, an appreciable activity gradually appeared after a long induction period (about 12 hr.) with no addition of water.

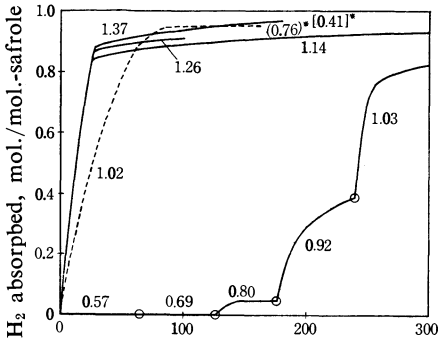

Fig. 4. Hydrogenation of safrole with the iron catalyst.

$FeCl_3$ : 4.60 mmol., THF : 100 ml., safrole : 5 ml. (33.9 mmol.), reaction temp. : 0°C

* Amount of hydrogen evolved during the hydrolysis subsequent to the hydrogenation (see footnote of Table II). The amount of hydrogen evolved during the hydrolysis subsequent to the single hydrogenation is given in parenthesis and that subsequent to the stepwise hydrogenation is given in brackets. Others are same to in Fig. 1.

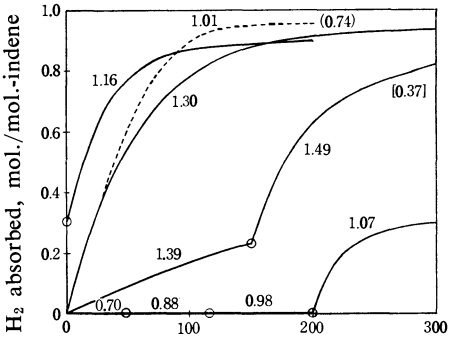

Fig. 5. Hydrogenation of indene with the iron catalyst.

$FeCl_3$ : 4.26 mmol., THF : 100 ml., indene : 5 ml. (42.7 mmol.), reaction temp. : 0°C
Others are same to in Figs. 1 and 4.

The ranges of the $LiAlH_4/FeCl_3$ ratios of the active catalysts for the hydrogenation of safrole, indene and ethyl vinyl ether were somewhat different from those of styrene. The results of the hydrogenation of safrole and indene are shown in Figs. 4 and 5 respectively. As may be seen in Fig. 4, the iron catalysts with the $LiAlH_4/FeCl_3$ ratios of 1.26 : 1, 1.37 : 1 and 1.41 : 1 had almost the same activities in the hydrogenation of safrole. If the catalyst was hydrolyzed after the step-by-step hydrogenation, the amount of hydrogen evolved* was relatively small (0.41), whereas it was relatively large (0.76) after the single hydrogenation. As may be seen in Fig. 5, the range of the $LiAlH_4/FeCl_3$ ratio of the active catalyst for the hydrogenation of indene was also different from that for styrene, and the amount of hydrogen evolved on hydrolysis subsequent to the step-by-step hydrogenation was again relatively small.

On the other hand, as may be seen in Fig. 5, the iron catalyst freshly prepared in the $LiAlH_4/FeCl_3$ ratio of 1.01 : 1 was more active than the catalyst with the $LiAlH_4/FeCl_3$ ratio of 1.07 : 1 in the step-by-step procedures. A similar phenomenon was observed in the hydrogenation of isoprene; the iron catalyst freshly prepared in the $LiAlH_4/FeCl_3$ ratio of 1.04 : 1 was more active than the catalyst with the ratio of 1.01 : 1 in the step-by-step procedures, as may be seen in Fig. 6. Thus, the catalytic activity of the catalyst with the same $LiAlH_4/FeCl_3$ ratio can be greatly altered by the method of preparation chosen (that is, it depends on whether the step-by-step or the single procedure is used).

The relationship between the $LiAlH_4/FeCl_3$

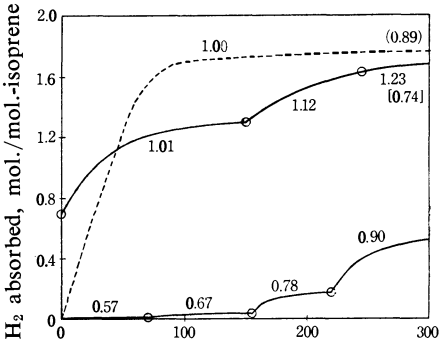

Fig. 6. Hydrogenation of isoprene with the iron catalyst.

$FeCl_3$ : 4.71 mmol., THF : 80 ml., isoprene : 5 ml. (50.0 mmol.), reaction temp. : 0°C
Others are same to in Figs. 1 and 4.

* See footnote of Table II.

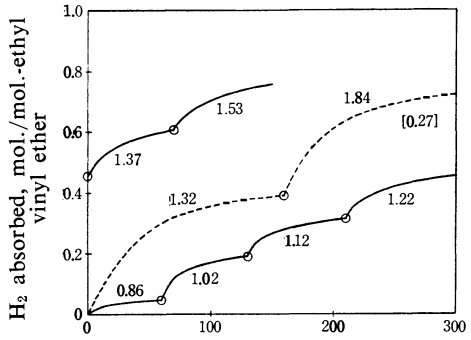

Fig. 7. Hydrogenation of ethyl vinyl ether with the iron catalyst.
$FeCl_3$: 4.68 mmol., THF: 110 ml., ether: 5 ml. (52.9 mmol.), reaction temp.: 0°C
Others are same to in Figs. 1 and 4.

ratio and the catalytic activity was much more complicated in the hydrogenation of ethyl vinyl ether; as may be seen in Fig. 7, when the $LiAlH_4/FeCl_3$ ratio was raised step-by-step, $0.86 \rightarrow 1.02 \rightarrow 1.12 \rightarrow \cdots$, the rate of hydrogen absorption decreased after about 0.15 (mol./mol.-ether) of hydrogen had been absorbed at each ratio. With the iron catalyst prepared in the $LiAlH_4/FeCl_3$ ratio of 1.32:1, the rate decreased after about 0.4 (mol./mol.-ether) of hydrogen had been absorbed, as the dotted line in Fig. 7 shows. A similar phenomenon was observed when the ratio was raised from 1.32:1 to 1.84:1. That is, the amount of hydrogen absorbed seems to correspond to the amount of lithium aluminum hydride added to raise the $LiAlH_4/FeCl_3$ ratio. The amount of hydrogen evolved on the hydrolysis subsequent to the hydrogenation was quite small.

*The Hydrogenation of d-Limonene (Olefins in the Second Group).*—The range of the $LiAlH_4/FeCl_3$ ratio for the active catalyst for the hydrogenation of *d*-limonene was almost the same as that for the hydrogenation of cyclohexene described above, whereas the value of the $LiAlH_4/FeCl_3$ ratio for the most active catalyst was somewhat different—1.00:1 and 1.08:1 for the hydrogenation of cyclohexene and *d*-limonene respectively. *d*-Limonene did not absorb more than 1.0 (mol./mol.-limonene) of hydrogen.

*The Hydrogenation of Unsaturated Compounds in the Third Group.*—Squalene, α-pinene, furan, vinyl acetate, ethyl acrylate, allyl chloride and acrylonitrile did not appreciably absorb hydrogen in the presence of the iron catalyst at any $LiAlH_4/FeCl_3$ ratio. The amounts of hydrogen evolved on the hydrolysis subsequent to the hydrogenation seem to indicate that these compounds can be divided into two groups. In the cases of squalene, α-pinene and furan, the amounts of hydrogen evolved were relatively large, whereas they were quite small or practically zero in the cases of vinyl acetate, ethyl acrylate, allyl chloride and acrylonitrile. For the latter compounds, the color of the reaction mixture changed during the course of the hydrogenation, from black to blackish brown for ethyl acrylate and acrylonitrile, and to ocher for allyl chloride.

**Hydrogenation with Cobalt Catalysts.**—Since the iron catalyst was less active in the hydrogenation of cyclohexene, *d*-limonene, squalene, α-pinene, ethyl vinyl ether, vinyl acetate, ethyl acrylate, allyl chloride and acrylonitrile, the hydrogenation of these compounds was performed with the cobalt catalyst with a view to exploring the more active catalyst. The results obtained with the cobalt catalyst are shown in Fig. 8 and Table III. As may be seen in Fig. 8, cyclohexene and *d*-limonene were rapidly hydrogenated with this catalyst. *d*-Limonene probably did not absorb more than 1.0 (mol./mol.-limonene) of hydrogen in spite of the very rapid hydrogenation because only the terminal bouble bond of *d*-limonene was hydrogenated. The hydrogenation of ethyl vinyl ether, which was achieved with only a limited success with the iron catalyst (Fig. 7),

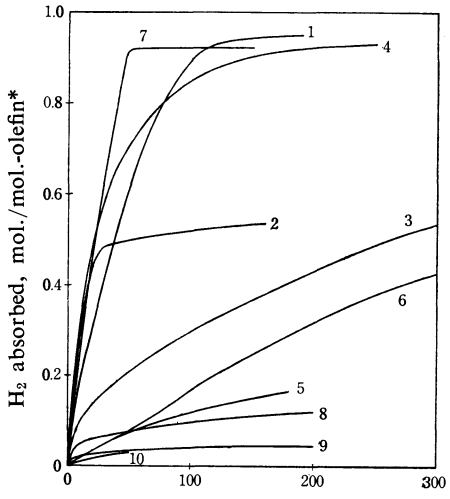

Fig. 8. Hydrogenation of various olefins with the cobalt catalyst.
Names of the compounds, the $LiAlH_4/CoCl_2$ ratio for the catalyst used and the amounts of hydrogen evolved during the hydrolysis subsequent to the hydrogenation are given in Table III.
* It changes to 1/2 (mol./mol.-olefin) in the cases of *d*-limonene(2) and furan(5), and to 1/6 (mol./mol.-olefin) in the case of squalene(6).

TABLE III. HYDROGENATION WITH THE COBALT CATALYST*1

| Curve No. in Fig. 8 | Olefin | $LiAlH_4/CoCl_2$ ratio | Ratio of hydrogen evolution*2 |
|---|---|---|---|
| 1 | Cyclohexene | 0.82 | — |
| 2 | *d*-Limonene*3 | 0.98*4 | 0.58 |
| 3 | $\alpha$-Pinene | 1.00*4 | 0.63 |
| 4 | Ethyl vinyl ether | 0.81 | 0.71 |
| 5 | Furan | 0.79 | 0.62 |
| 6 | Squalene | 0.98*4 | 0.60 |
| 7 | Ethyl acrylate | 0.80 | 0.66 |
| 8 | Vinyl acetate | 0.80 | 0.36 |
| 9 | Acrylonitrile | 0.82 | 0.00 |
| 10 | Allyl chloride | 0.81 | 0.06 |

*1 $CoCl_2$: ca. 0.005 mol., THF: ca. 100 ml., olefin: 5 ml., reaction temp.: 0°C. Hydrogen absorption curves are given in Fig. 8.

*3 A mixture of cis- and trans-isomers.
*4 When the $LiAlH_4/CoCl_2$ ratio was 0.78—0.80, no appreciable hydrogen absorption was observed.

was performed successfully with the cobalt catalyst. It is noteworthy that a very large variation in catalytic activity for the hydrogenation of ethyl acrylate exists among the iron and cobalt catalysts. Furthermore, squalene and $\alpha$-pinene were found to undergo a relatively fast hydrogenation, while furan was found to undergo a slow hydrogenation with the cobalt catalyst, although these compounds did not undergo any hydrogenation at all with the iron catalyst. Only a small amount of hydrogen was evolved on the hydrolysis subsequent to the hydrogenation of vinyl acetate, acrylonitrile and allyl chloride. However, a relatively large amount of hydrogen was evolved on the hydrolysis subsequent to the hydrogenation of ethyl acrylate. This hydrogen evolution seems to be related to the fast hydrogenation of ethyl acrylate with the cobalt catalyst.

## Discussion

The effect of the nature of the olefin on the hydrogenation rate with the iron catalyst is illustrated in Fig. 2. The relative order of the hydrogenation rate expressed by the half-periods is: styrene > $\alpha$-methylstyrene $\simeq$ safrole $\simeq$ isosafrole $\simeq$ anethole > isoprene $\simeq$ indene > cyclohexene $\simeq$ *d*-limonene $\gg$ squalene $\simeq$ $\alpha$-pinene. Evidently, terminal olefins are hydrogenated more rapidly than internal olefins.

*d*-Limonene absorbed only 1.0 (mol./mol.-limonene) of hydrogen, and $\alpha$-pinene did not absorb any appreciable amount of hydrogen at all. These facts suggest that only the terminal double bond of *d*-limonene was hydrogenated. Comparisons of the rate for $\alpha$-methylstyrene with that of *d*-limonene and of indene with cyclohexene show that the conjugated olefins were hydrogenated more rapidly than the nonconjugated ones.

The $LiAlH_4/FeCl_3$ ratios corresponding to the active catalysts vary with the nature of the olefins, such as styrene, safrole, indene and ethyl vinyl ether. We shall discuss this variation in the $LiAlH_4/FeCl_3$ ratios below.

We have previously studied[2,3] the amount of ethylbenzene produced during the reaction of the iron catalyst with styrene under a nitrogen atmosphere; the results may be summarized thus: (a) the hydrogen which migrates from the catalyst (iron hydride) to the styrene amounts to 1.0 g. atom/mol. $FeCl_3$ when the $LiAlH_4/FeCl_3$ ratio is 1:1; (b) after the hydrogen migration, a part of the iron hydride is regenerated rapidly when the reaction atmosphere is changed from nitrogen to hydrogen, but the remaining part is regenerated very slowly; (c) this rapidly-regenerated hydride is considered to be responsible for the catalytic activity, and (d) the rapidly-regenerated hydride amounts to 0.3—0.4 g. atom/mol. $FeCl_3$ when the $LiAlH_4/FeCl_3$ ratio is 1:1 and decreases with the increase in the ratio, although the total hydrogen content of the catalyst increases steadily with the increase in the ratio. The variation in the ranges of the $LiAlH_4/FeCl_3$ ratio for the active catalysts and the values of the ratios for the most active catalyst may be explained in terms of the diminution of the hydrogen content of the catalyst through the hydrogen migration from the catalyst to olefins, followed by a very slow hydrogen absorption. The fact that the iron catalysts with the relatively high $LiAlH_4/FeCl_3$ ratios of 1.3—1.4:1 were active in the hydrogenation of safrole and indene in the step-by-step procedures, whereas the iron catalyst with the $LiAlH_4/FeCl_3$ ratio of 1.41:1 was less active in the hydrogenation of styrene, is due to the diminution in the hydrogen content of the catalyst through the hydrogen migration from the catalyst to the safrole or indene. This hydrogen migration may occur more rapidly in the hydrogenation of ethyl vinyl ether, in which the successive addition of a lithium aluminum hydride solution is necessary to continue the hydrogen absorption (Fig. 7). The facts that the amounts of hydrogen evolved during the hydrolysis subsequent to the step-by-step procedure were smaller than those subsequent to the single hydrogenation, and that a long induction period appeared in the

3) Y. Takegami, T. Ueno and T. Fujii, *Catalyst (Shokubai)*, **6**, 339 (1964).

hydrogenation of anethole with the iron catalyst with the relatively high $LiAlH_4/FeCl_3$ ratio of 1.61 : 1, can be taken as further support of the diminution of hydrogen content through the hydrogen migration from the catalyst to the olefins.

In the hydrogenation of vinyl acetate, ethyl acrylate, acrylonitrile and allyl chloride, no hydrogen absorption was observed, and the amounts of hydrogen evolved during the hydrolysis subsequent to the hydrogenation were quite small. In these cases, not hydrogenation but, rather, the reaction of these compounds with the iron catalyst occurred.* When vinyl acetate was added to the active catalyst with the $LiAlH_4/FeCl_3$ ratio of 1 : 1, the catalyst was "killed" and became quite inactive in the hydrogenation of styrene.

* For example, 3-pentanol and ethyl acetate were obtained by the reaction of the iron catalyst with diethyl ketone and vinyl acetate respectively.

As has been mentioned above, the iron catalyst is selective in its hydrogenating ability. On the other hand, it can be seen from a comparison of Figs. 2 and 8 that the cobalt catalyst is highly active in its hydrogenating ability; internal olefins can be hydrogenated successfully with the cobalt catalyst.

For practical purposes, perhaps only the slow addition of a lithium aluminum hydride solution to a mixture of olefin and heavy metal salt, before the occurrence of hydrogen absorption, can provide a simple and convenient procedure for the hydrogenation of various olefins.

We are grateful to Dr. Kunio Okamoto for his helpful advice and discussions.

# Complex Compounds of Gallium with Mandelic Acid

By T. N. Srivastava and D. C. Rupainwar

(Received October 26, 1964)

In a previous communication from this laboratory[1] it has been reported that aluminium hydroxide and mandelic acid form two compounds, an insoluble basic salt and a water-soluble chelate, both possessing a metal-to-ligand ratio of 1 : 2. Gallium, indium and thallium, other metals of the same group, are known to show a close resemblance to aluminium in their tendency to form coordination complexes. A study of the gallium chloride - mandelic acid - water system has been undertaken with a view of establishing the nature of the complex species. The results are communicated in this paper.

## Experimental

**pH and Conductivity Studies.**—A stock solution of gallium chloride was prepared by dissolving freshly-precipitated gallium hydroxide in a minimum quantity of dilute hydrochloric acid. The metal content was determined gravimetrically by the use of 8-quinolinol. The gallium chloride solution was adjusted to an initial pH of 2.95 in each case by adding a requisite quantity of a standard sodium hydroxide solution prior to the preparation of a particular set of mixtures.

Mandelic acid (British Drug House, extra pure quality) was dissolved in conductivity water and used as such.

Using 0.004 M solutions of gallium chloride and mandelic acid, three sets of mixtures, with metal-to-ligand ratios of 1 : 1, 1 : 2 and 1 : 3, were prepared. To these solutions varying quantities of a standard alkali solution were added and the volumes made up to the same mark in each case. The mixtures were then shaken well and left overnight to attain equilibrium. The pH values and conductances of these solutions were measured at a constant temperature. For purposes of comparison, solutions of gallium chloride and mandelic acid of the same concentration were also separately titrated with the standard alkali under identical conditions.

The pH determinations were carried out with the help of a sensitive pH meter (made by Leeds and Northrup Co ; Philadelphia, U. S. A. Cat. No. 7667) equipped with a glass and a saturated calomal electrode. The pH values of all the sets are plotted against the amount of alkali added, and the curves obtained are shown in Fig. 1.

Conductivity experiments were performed with a dip-type conductivity cell (cell constant, 1.46 ml.)

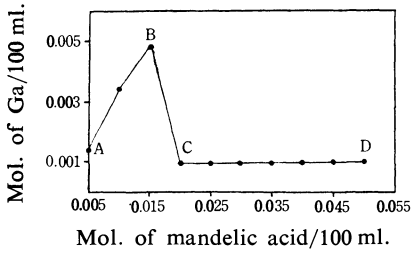
**Solubility Measurements.**—A set of ten samples containing almost the same weight of freshly-precipitated gallium hydroxide and a 100 ml. aqueous solution of mandelic acid of the different concentrations ranging from 0.005 M to 0.05 M, was prepared in 250 ml. Erlenmeyer flasks. The amount of the hydroxide was so chosen that in a few of the later samples the gallium-to-mandelic acid ratio exceeded 1 : 3, while in several sets in the beginning the amount of the hydroxide was always larger than that required for a 1 : 3 ratio. All the flasks were shaken in a mechanical shaker at room temperature for 24 hr. Known aliquots were taken out with cotton-plugged pipettes, and their metal and mandelic acid contents were analysed, the former gravimetrically by 8-quinolinol and the latter volumetrically with cerium(IV) sulphate.[2] The observations are represented graphically in Fig. 3.



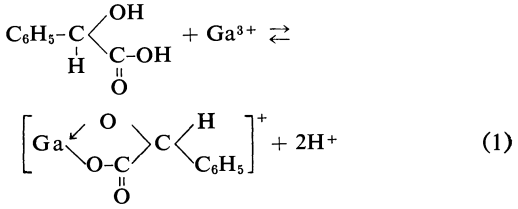


Fig. 3 Solubility of gallium hydroxide in aqueous mandelic acid solution (0.005—0.05 M) at 31±1°C.
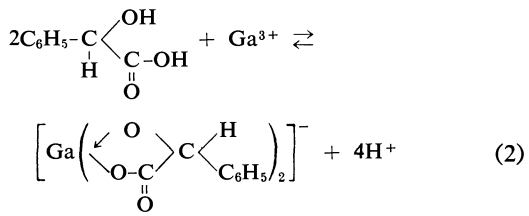
Portion AB=Excess of gallium hydroxide
Portion CD=Excess of mandelic acid

## Results and Discussion

**pH and Conductivity Measurements.**—Curve A (Fig. 1) represents the titration of mandelic acid alone; as is to be expected for a monobasic acid, it shows a sudden rise in pH when nearly one equivalent of alkali has been added. Curve B for a 1 : 1 mixture of gallium chloride and mandelic acid gives an inflection at 2 equivalents of alkali, indicating the formation of a 1 : 1 chelate. The chelation takes place by the donation of a lone pair of electrons from the hydroxyl oxygen atom, making the hydrogen atom attached to it more labile and causing a lowering of the pH value. Consequently, two equivalents of alkali are consumed in the titration. The overall equation may, then, be represented as follows:

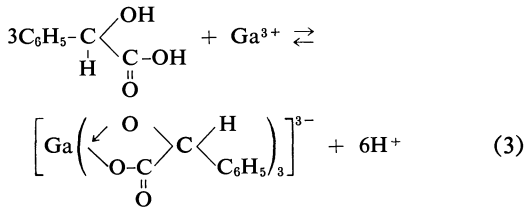
(1)



This is supported by the lower pH value of the mixture (2.40) as compared to that of individual gallium(III) chloride (2.95) and mandelic acid (3.60) solutions.

The further addition of alkali brings about a sudden increase in the hydroxide ion concentration, and the curve registers an abrupt rise in pH value.

Titrations of the 1 : 2 and 1 : 3 mixtures represented by curves C and D respectively



2) M. R. Varma and S. D. Paul, *J. Sci. Ind. Res.*, **13B**, 347 (1954).

(Fig. 1) show inflection points at four and six equivalents of alkali. This corresponds to the formation of complexes with 1 : 2 and 1 : 3 metal-to-ligand ratios respectively; the complexes may be represented by the following equations:

(2)

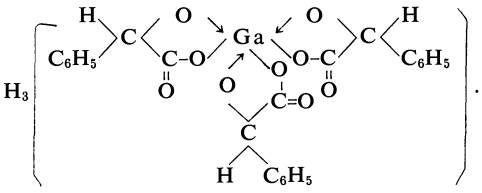
and

(3)

Curve A (Fig. 2), representing the conductometric titration of a 0.004 M gallium chloride solution with sodium hydroxide, shows a well-defined inflection at 3 equivalents of alkali corresponding to the precipitation of the hydroxide. Curves B, C and D, obtained for 1 : 1, 1 : 2 and 1 : 3 mixtures respectively, show minimum conductances at two, four and six equivalents of alkali. The decrease in conductivity with the addition of an alkali solution in the beginning may be due to the replacement of the fast-moving $H^+$ by the slow-moving $Na^+$. When all the $H^+$ is removed, the conductance rises abruptly on account of the excess $Na^+$ and $OH^-$ present in the solution, which cause a break in the curve. The formation of the three chelates may be explained by the same three equations given above for pH titrations.

**Solubility.**—The straight line marked AB in Fig. 3 represents a consistent ratio of 1 : 3 between the metal and the ligand, indicating the nature of the soluble species formed in this region. The curve registers an abrupt fall at point B, showing that almost all the gallium has gone out of the solution, forming an insoluble compound which separates as a white granular solid in the flasks. The CD portion of the curve may represent the solubility of this species in a solution with an excess of mandelic acid. The experiment thus shows the formation of two compounds, a soluble 1 : 3 chelate (compound I) when the hydroxide is present in excess and an almost insoluble white crystalline solid (compound II) when mandelic acid is present in excess.

**The Isolation and Characterisation of the Compounds.**—*Compound I.*—The combined filtrate obtained from the samples in the region AB of the solubility curve (Fig. 3) was concentrated by slow evaporation on a water bath, and then left for crystallisation when a white crystalline solid separated. This was washed with an ethanol-water mixture and with ether, and air-dried.

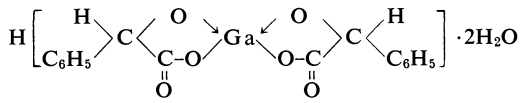


*Compounds II.*—Compound II obtained as a white insoluble granular solid from samples after the point B on the solubility curve was collected, washed with an ethanol-water mixture and with ether, and air-dried.

The gallium and mandelic acid contents of both the compounds were analysed. The water molecules were also examined by heating a known weight of the air-dried sample in an oven at 110°C and then ascertaining the loss in weight. The results of the analysis, along with the formulae tentatively assigned, are given below:

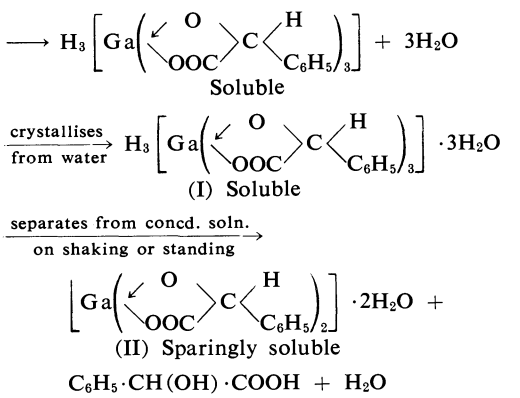
| Tentative formula for the compound | | % Gallium | % Mandelate | % Water |
|---|---|---|---|---|
| $C_{24}H_{27}O_{12}Ga$ (I) | Found | 12.10 | 79.3 | 9.15 |
| | Calcd. | 12.07 | 79.1 | 8.89 |
| $C_{16}H_{19}O_8Ga$ (II) | Found | 16.80 | 71.92 | 8.68 |
| | Calcd. | 17.12 | 73.96 | 8.87 |

The good agreement between the calculated and the experimental values observed above indicates that the molecular formulae tentatively assigned are correct.



Compound I, with a metal-to-ligand ratio of 1 : 3, is soluble in water and ethanol, but insoluble in other common organic solvents. It is acidic to litmus and needs 3 equivalents of alkali for complete neutralisation. Taking three molecules of water as the water of crystallisation, its structure, in analogy with several other such chelates of tervalent metals,[3-6] may be given as:

Compound II, possessing a metal-to-ligand ratio of 1 : 2, is sparingly soluble in water, the solubility being 0.025 g./100 cc. at room temperature (30.5°C). It is insoluble in ethanol, ether and other common organic solvents. It is acidic to litmus and requires for complete



3) T. Moellor, *J. Am. Chem. Soc.*, **62**, 2444 (1940).

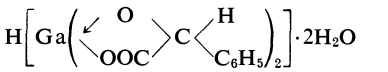
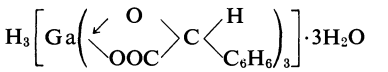
5) K. Peters, *Chem. Abstr.*, **53**, 13525 (1959).
6) E. N. Deichman and G. V. Rodicheva, *Zhur. Neorg. Khim.*, **9**(4), 807 (1964).

neutralisation three equivalents of alkali, two of which are consumed by the released mandelic acid formed by the ready hydrolysis of the compound, and the remaining one, by the cationic hydrogen. The complex thus behaves as a monobasic acid. On being heated at 110°C, it loses two molecules of water. The structure of compound II may be written as:

The structures assigned to the two complexes support Eqs. 2 and 3, which represent the physico-chemical investigations. Attempts to isolate the 1 : 1 complex shown by Eq. 1 were, however, unsuccessful.



The reaction between gallium hydroxide and mandelic acid solutions represented by the portion CD of the solubility curve (Fig. 3) may now be reconsidered. It appears that when the concentration of the 1 : 3 chelate is relatively large in the solution and when it is vigorously shaken to induce precipitation, the more stable and less soluble 1 : 2 complex separates out. This was supported by separately taking a concentrated solution of the 1 : 3 chelate and shaking it vigorously for a few hours, a compound thereupon separated which, on analysis, was found to be identical with compound II. The change was found to be irreversible; no former species could be identified in solution when the latter was shaken with an excess of mandelic acid. The changes taking place may be represented by the following equation:



The metal-to-ligand ratio obtained for compound II is similar to that of aluminomandelic acid reported previously.[1] The compound differs from the aluminium complex in being more insoluble and thus is not converted into the corresponding basic salt. Further, unlike the $Al^{3+}$ - mandelic acid - water system, the treatment of the mixture containing concentrated solutions of gallium chloride and mandelic acid with ammonia did not result in the precipitation of a basic salt. On the other hand, the above solution, when shaken and left overnight, gave a white crystalline compound, the analysis of which agreed with that of compound II.

## Summary

pH and conductometric studies of the gallium chloride - mandelic acid - water system show the existence of three chelates in solution with a metal-to-ligand ratio of 1 : 1, 1 : 2 and 1 : 3. The solubility of freshly-precipitated gallium hydroxide in aqueous solutions of mandelic acid of varying concentrations, however, indicates the presence of only, 1 : 2- and 1 : 3-type species. These two complexes have here been isolated in the crystalline state. Their structures may be represented by

and

respectively. The 1 : 1 complex indicated by electrometric titrations appears to be fairly unstable, as it could neither be inferred from solubility experiments nor isolated in the crystalline state.

The authors are thankful to Professor S. N. Shukla, Head of the Chemistry Department, for providing laboratory facilities, and to the Director, Indian Sugar Cane Research Institute, Lucknow, for permission to use their instruments for physico-chemical studies. One of us (D. C. R.) is also thankful to the C. S. I. R., New Delhi, for the award of a junior research fellowship.

# The Synthesis of 1-Phenylpropane Derivatives. IV*

By Takeshi MATSUMOTO and Haruhisa SHIRAHAMA

(Received November 2, 1964)

In previous papers[1,2] the syntheses of several *threo* and *erythro* 1-phenyl-2-amino-1, 3-propanediol derivatives, starting from benzoyl chloride and ethylene, have been described. The steric courses which led to these stereoisomeric products have also been discussed. In this paper, the preparation of *threo* and *erythro* 1-phenyl-2-acetamido-1, 3-propanediol and related compounds starting from benzoly chloride and vinyl chloride will be reported. The synthetic processes are outlined in Fig. 1.

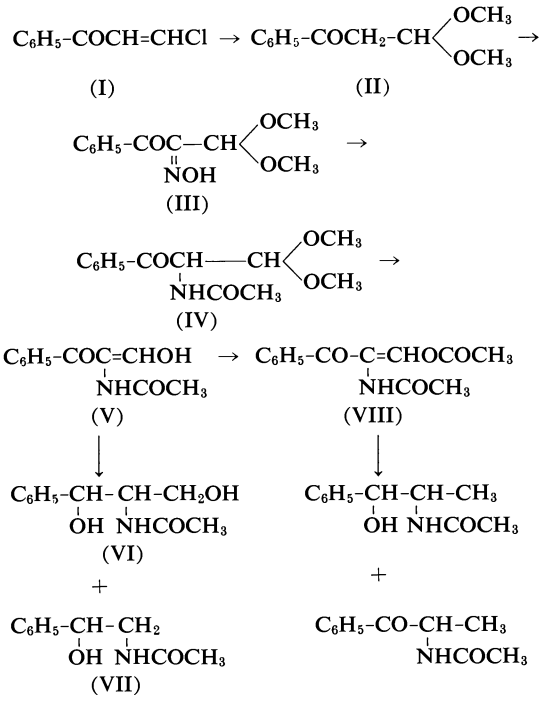

Fig. 1

The starting material, phenyl β-chlorovinyl ketone, was obtained in a 70—90% yield by a modification of Klinko's method.[3] After this compound had been converted to benzoylacetaldehyde dimethy acetal (II)[4] by methanolic sodium hydroxide, the product was treated with amyl nitrite in methanolic sodium methoxide.[5] The isolation of the desired oximinoketone (III), which is present in the reaction mixture as a sodium salt, offered considerable difficulty, however.[6] The compound III appears to be sensitive to acidic substances; neutralization with even such weak acids as acetic, phosphoric, and boric acids resulted in the formation of only an intractable mixture. After many unsuccessful attempts, the difficulty was overcome by the use of ammonium chloride as a neutralizing agent. By this procedure, the pure oximinoketone was obtained in a 76% yield. In the hope of preparing 1-phenyl-2-amino-1, 3-propanediol derivatives by the routes shown in Fig. 2, attempts were made to convert oximinoketone (III), acetoximinoketone (III′) and their reduction products IX and IX′ to the alcohols X, X′, XI, and XI′ respectively. However, the hydrolysis of the acetal group of III, III′, IX and IX′ with a variety of acids, including boric, phosphoric, and acetic acids, did not afford pure crystalline materials.

5) L. Claisen and O. Manasse, *Ber.*, **20**, 2194 (1887).

6) The reaction mixture in which oximinoketone (III) is present exhibits deep blue coloration upon the addition of an aqueous ferrous sulfate solution. On the contrary, the ferrous sulfate test for oximinoketones according to Feigl's procedure, which is performed in the presence of ammonia (F. Feigl, "Tüpfelreaktionen," Akademishe Verlagsgesellshaft, Leibzig (1938), p. 87) was negative for pure III. However, the addition of dilute ethanolic sodium ethoxide seems to provide a more sensitive method, at least for this case.

Syntheses along these lines were, therefore, abandoned.

The catalytic hydrogenation of oximinoketone (III) in 3 N methanolic hydrogen chloride in the presence of palladium was examined next. The stereospecific formation of norephedrine from α-oximinopropiophenone under similar conditions has been reported.[7] The removal of the solvent left, however, an intractable tarry material, probably formed by the hydrolysis of the acetal group by hydrogen chloride and by subsequent condensation between the aldehyde group and the newly-formed amino group. Therefore, the reaction mixture was, in the next attempt, at first neutralized by passing through ammonia. The removal of ammonium chloride by the addition of ether, the evaporation of the solvent, and the subsequent benzoylation of the residue afforded a small amount of crystals. Elemental analysis indicates that the product is dibenzoyl-1-phenyl-2-amino-3, 3-dimethoxy-1-propanol (the configuration was not examined). In a separate attempt, after the absorption of three moles of hydrogen, a small amount of water was added to effect the hydrolysis of the acetal group. The catalyst was then replaced by platinum oxide, and the hydrogenation was continued until one further mole of hydrogen had been absorbed. The benzoylation of the product afforded a compound with an elemental composition corresponding to that of a tribenzoyl derivative (m. p. 204—207°C) of 1-phenyl-2-amino-1, 3-propanediol, which is probably a mixture of threo and erythro diastereoisomers judging by a comparison of its melting point with those of pure isomers.[8] However, the yield of this route was, again, not satisfactory.

The hydrogenation of α-oximino-β-ethoxypropiophenone by palladium in a mixture of acetic anhydride and acetic acid has been shown to afford α-acetamido-β-ethoxypropiophenone in a good yield.[2] Under similar conditions, parallel to this result, the reduction of oximinoketon (III) give a 90% yield of α-acetamido-β, β-dimethoxypropiophenone (IV). The hydrolysis of the acetal group of the latter compound IV by hydrochloric acid, did not, however, produce V in a good yield, the starting material being recovered. On the other hand, the treatment of IV with an aqueous alkaline solution afforded the desired hydroxymethylene compound, V, in an excellent yield. It is well known that the acetal group resists base-catalyzed hydrolysis. In this particular case, however, the seemingly anomalous hydrolysis by the base probably proceeds through a vinyl ether, which is a vinylog of ester, as is shown below:

The attempted hydrogenation of the hydroxymethylene ketone thus obtained resulted in the recovery of the starting meterial. The inertness to hydrogenation of the carbonyl group in V is probably due to the carboxylic group-like character of the -COCH=CHOH system.

Several examples of the successful hydrogenation of hydroxymethylene ketone to the corresponding diol by means of a Raney nickel catalyst have been reported.[9]

The reduction of V by this method afforded an excellent yield (90%) of the desired 1-phenyl-2-acetamido-1, 3-propanediol (VI). That the product was a mixture of approximately equal amounts of threo and erythro compounds was inferred from a comparison of its infrared spectrum with those of pure stereoisomers. From the product, the threo isomer was isolated through recrystallization, while the erythro isomer was separated as a triacetyl compound (47% based on the hydroxymethylene compound) after the treatment of the reaction product with acetic anhydride and pyridine.

A minor product of catalytic hydrogenation with Raney nickel was isolated in the course of separation; it had an elemental composition of $C_{10}H_{13}NO_2$ and was identified as 1-phenyl-2-acetamido-1-ethanol (VII) by comparison with an authentic specimen prepared by treating acetamidoacetophenone with sodium borohydride. The course which led to this product is obscure; it might involve the deformylation of the hydroxymethylene ketone by alkaline substances on the surface of Raney nickel.

Lastly, the reduction of enolacetate (VIII) was attempted. The enolacetate (m. p. 117°C) was readily obtained by treating the sodium salt of the hydroxymethylene ketone (V) with acetic anhydride under cooling. The acetate is very susceptible to alkaline hydrolysis, regenerating V. Acetylation without cooling gave a product, $C_{13}H_{13}NO_4$ with a m. p. of 130°C, this also regenerates V on alkaline

9) H. Rupe and O. Klemm, *Helv. Chim. Acta*, 21, 1538 (1938); B. D. Astill and V. Boekelheide, *J. Am. Chem. Soc.*, 77, 4079 (1955).

hydrolysis and exhibits an infrared spectrum consistent with an enolacetate structure. The compounds with m. p. of 117 and 130°C may, therefore, be cis and trans isomers of the enolacetate. The catalytic hydrogenation of the enolacetate with Raney nickel gave a 50% yield of an erythro compound *N*-acethylnorephedrine and 14% of acetamidopropiophenone. *N*-acethylpseudonorephedrine was not present in an isolable amount.

## Experimental

**Phenyl β-Chlorovinyl Ketone (I).**—This compound was prepared by a modification of the method of Klinko et al. A mixture of 100 g. of benzoyl chloride and 100 g. of aluminum chloride was heated gently to give an adduct. The adduct was then dissolved in 200 ml. of tetrachloroethane. Dry vinyl chloride was introduced into the solution through an inlet tube reaching to the bottom of the vessel. A large test tube was employed as a reaction vessel in order to keep the gas in good contact with the solution. The vinyl chloride was then generated by the decomposition of 120 g. of dichloroethane with 150 g. of sodium hydroxide in 500 ml. of 60% ethanol. The temperature of the generating flask was adjusted so that the gas produced was effectively absorbed in the reaction mixture. It took 10 hr. for the reaction to be completed. After it had been set aside for several hours, the resultant solution was poured into a mixture of ice and dilute hydrochloric acid. The product was extracted with ether, and the extract was washed successively with dilute hydrochloric acid, twice with a 10% sodium hydroxide solution, and with water, then it was dried over sodium sulfate. After the removal of the solvent, the residue was distilled in vacuo. A pale-yellow viscous oil boiling at 124°C (12 mmHg) was collected; yield 93 g. (78.5%).

**Benzoylacetaldehyde Dimethyl Acetal (II).**—The general procedure described by Nelles[10] was used.

**α-Oximino-β, β-dimethoxypropiophenone (III).**—A solution of 5.8 g. sodium in 180 ml. of methanol was cooled in an ice-water bath and stirred. To this solution, 29.5 g. of isoamyl nitrite (or an equivalent amount of isopropyl nitrite) and 49 g. of acetal II was added successively. After it had stood for three days in a refrigerator, the light orange reaction mixture was poured onto ice water. The solution was then washed with ether three times. From this ethereal solution, 9 g. of unchanged acetal was recovered. The aqueous solution of the product was saturated with ammonium chloride and extracted with ether. The extract was dried over sodium sulfate, and the solvent was removed. The residual yellow paste was crystallized after being set aside for several hours. The crystalline cake was washed with a small amount of benzene and recrystallized from the same solvent; yield 20 g. From the benzene used for washing and recrystallization, a further 15 g. of the product was obtained by extraction with an adequate quantity of 5% aqueous sodium hydroxide, followed by saturation with ammonium chloride and subsequent extraction with ether (76%). The purified product melted at 86—87°C.

Found: C, 59.92; H, 5.37; N, 6.34. Calcd. for $C_{11}H_{13}NO_4$: C, 59.19; H, 5.87, N, 6.28%.

The acetoxyimino compound was obtained as follows. A yellow solution of 500 mg. of the isonitroso ketone III in 4 ml. of 5% aqueous sodium hydroxide was shaken with a solution of few drops of acetic anhydride in 4 ml. of ether. The mixture was decolorized immediately. From the ether extract the product was obtained in a crystalline condition, m. p. 90—92°C. Yield 600 mg. (quantitative).

Found: C, 59.22; H, 5.97; N, 5.68. Calcd. for $C_{13}H_{15}NO_5$: C, 58.86; H, 5.70; N, 5.28%.

The treatment of the oximino compound with benzoyl chloride gave the corresponding benzoyl oximino derivative; m. p. 63—65°C. Yield 95%.

Found: C, 66.15; H, 5.20. Calcd. for $C_{18}H_{17}NO_5$: C, 66.05; H, 5.24%.

Both acetoximino and benzoximino compounds were dissolved in 5% aqueous sodium hydroxide to give a yellow solution. The original oximino ketone III was regenerated by saturation with ammonium chloride and by extraction with ether.

**The Catalytic Hydrogenation of α-Oximino-β, β-dimethoxypropiophenone (III).**—a) Oximino ketone III (2 g.) was dissolved in a 3 N methanolic hydrogen chloride solution and hydrogenated in the presence of 400 mg. of palladium charcoal. After 3 mol. of hydrogen had been absorbed, an equal amount of water was added to the solution. The catalyst was then replaced by platinum oxide, and the hydrogenation was continued until 1 mol. of hydrogen had been further absorbed. The catalyst was then removed, the solution was washed with ether, and the aqueous solution was made alkaline with concentrated sodium hydroxide. The product was next taken up in ethyl acetate, and the extract was dried and evaporated to leave an yellow oil. The benzoylation of this oil by the Schotten-Baumann method gave a small amount of white crystals. The benzoate, recrystallized from ethyl acetate, melted at 204—207°C. The comparison of the melting point of this crystal with those described in the literature[8] indicates the product to be a mixture consisting of two diastereoisomers of 1-phenyl-2-amino-1, 3-propanediol tribenzoate.

Found: C, 75.09; H, 5.71; N, 3.33. Calcd. for $C_{30}H_{25}NO_5$: C, 75.14; H, 5.26; N, 2.92%.

b) Two grams of oximino ketone III in a 3 N methanolic hydrogen chloride solution were hydrogenated in the presence of 400 mg. of palladium-charcoal. After 3 mol. of hydrogen had been absorbed, the catalyst was removed and the solution was made alkaline by passing through gaseous ammonia. Ether was then added to the solution, and the precipitated ammonium chloride was removed by filtration. The evaporation of the solvent under reduced pressure at room temperature left a brown past which was treated with benzoyl

10) a) J. Nelles, Brit. Pat. 466890 (1937); *Chem. Abstr.*, 31, 7886 (1937); b) T. Matsumoto, R. Ishida and H. Shirahama, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 83, 147 (1962).

chloride under Schotten-Baumann conditions to give white crystals. The benzoate, recrystallized from methanol, melted at 155—157°C. The analysis indicated that the product was 1-phenyl-2-amido-3, 3-dimethoxy-1-propanol dibenzoate.

Found: C, 71.54; H, 6.20. Calcd. for $C_{25}H_{25}NO_5$: C, 71.58; H, 6.01%.

**α-Acetamidohydroxymethyleneacetophenone (V).**—a) A solution of 9 g. of the oximino ketone III in a mixture of 40 ml. of acetic acid and 40 ml. of acetic anhydride was shaken with hydrogen in the presence of 1.5 g. of 10% palladium on charcoal until 2 equivalents of hydrogen had been absorbed. After the catalyst had been removed by filtration and the solvent had been evaporated, the residue was vigorously shaken with 160 ml. of 0.5 N aqueous sodium hydroxide. The solution was washed with benzene, made acidic with 2 N hydrochloric acid, and extracted with benzene. The extract was dried and the solvent removed to leave the crystalline hydroxymethylene ketone V. The product, washed with ethanol and recrystallized from benzene, melted at 113—115°C. Yield 6.7 g. (81%).

Found: C, 64.58; H, 5.62; N, 6.88. Calcd. for $C_{11}H_{11}NO_3$: C, 64.38; H, 5.40; N, 6.83%.

b) The hydrogenation of 3 g. of oximino ketone was carried out in the manner described in a). The paste obtained after the removal of acetic acid - acetic anhydride, crude α-acetamido-β, β-dimethoxy propiophenone, was dissolved to a homogeneous solution by shaking it with 190 ml. of 2 N hydrochloric acid for 2 hr. The ultraviolet spectra of the resultant solution showed $\lambda_{max}$ 251 mμ (ε 1030), whereas a solution of pure V in 2 N hydrochloric acid showed $\lambda_{max}$ 251 mμ (ε 11400). Thus, in the reaction mixture only 10% of the original acetal was estimated to be converted to the hydroxymethylene compound. Since further treatment of the solution for 6 hr. did not produce any increment in the extinction coefficient, the solution was extracted with ethyl acetate. The extract afforded 0.3 g. of the desired V.

**α-Acetamidoacetoxymethyleneacetophenone (VIII).**—A solution of V in an equivalent amount of 0.5 N aqueous sodium hydroxide was overlayered by ether, and an equivalent amount of acetic anhydride was added portion by portion with continuous shaking and cooling. When the yellow color of the alkaline solution had disappeared, the ethereal layer was separated and dried. After the solvent had been removed, the crystalline acetate VIII was obtained in a good yield; m. p. 116—117°C.

Found: C, 63.47; H, 5.47; N, 5.60. Calcd. for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.30; N, 5.67.

An isomeric acetate was obtained as a colorless crystal which melted at 128—130°C when acetylation was carried out without cooling. Both acetates gaves red coloration with ferric chloride and were converted to the original aldehyde (m. p. 113—115°C) when treated with aqueous alkali.

Found: C, 63.35; H, 5.35; N, 5.52. Calcd. for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.30; N, 5.67%.

**The Hydrogenation of V with a Raney Nickel Catalyst.**—To a solution of 1 g. of the hydroxymethylene compound in 10 ml. of tetrahydrofuran, 1 ml. of Raney nickel was added. Hydrogenation at 100 atm. was carried out at room temperature. After the catalyst and solvent had been removed, the residue was dissolved in a small amount of ethyl acetate. Upon scratching the wall of vessel, a mixture of two diastereoisomers of 1-phenyl-2-acetamido-1,3-propanediol (m.p. 92—117°C, 310 mg.) was crystallized out. Recrystallization from ethyl acetate and then from ethanol gave the threo isomer (m. p. 134°C), whose melting point and infrared spectra were identical with those of the literature.

Found: C, 63.09; H, 7.53; N, 6.36. Calcd. for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.23; N, 6.69%.

The paste obtained from the mother liquor was chromatographed on a column of aluminum oxide by ethyl acetate. Fractions eluted at earlier stages contained 101 mg. (10%) of 1-phenyl-2-acetamido-1-ethanol, which was identified with a sample prepared by the sodium-borohydride reduction of acetamidoacetophenone.

Found: C, 67.98; H, 7.57; N, 7.78. Calcd. for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82%.

The fraction eluted later contained 595 mg. of a mixture of the isomeric propanediols VI, bringing the total yield to 88.5%. For the separation of each diastereoisomer, the mixture was converted to a triacetly compound by treating it with acetic anhydride and pyridine. The *erythro* triacethyl-1-phenyl-2-amino-1, 3-propanediol (595 mg.; 47% yield based on aldehyde) thus obtained melted at 115—118°C. Both the melting point and the infrared spectrum were consistent with those of the literature.

Found: C, 61.07; H, 6.61. Calcd. for $C_{15}H_{19}NO_5$: C, 61.42; H, 6.53%.

**The Hydrogenation of α-Acetamidoacetoxymethyleneacetophenone (VIII).**—One gram of α-acetamidoacetoxymethyleneacetophenone (VIII) in 5 ml. of ethanol was hydrogenated with 0.5 ml. of a Raney nikel catalyst at room temperature under a pressure of 50 atm. After 4 hr. shaking, the catalyst and solvent were removed to leave a pasty mass containing crystalline *N*-acetyl-norephedrine. The product (320 mg.), recrystallized from ethyl acetate, melted at 134—135°C. The mixed melting point determination with an authentic specimen prepared by a known process showed no depression. The noncrystalline portion of the product was dissolved in ether and chromatographed on aluminum oxide. A further quantity (75 mg.) of *N*-acetyl-norephedrine was obtained (total yield, 46.7%). Besides, 165 mg. (14%) of α-acetamidopropiophenone and 105 mg. of a paste, the infrared spectrum of which was consistent with 1-phenyl-2-acetamido-1, 3-propanediol monoacetate, were obtained. In the reaction mixture *N*-acetylnorpseudoephedrine could not be detected.

**1-Phyenyl-2-oximino-3, 3-dimethoxy-1-propanol (IX).**—To a solution of oximinoketone (III) in methanol an excess of sodium borohydride was added. The reaction mixture foamed vigorously and became yellow. After 24 hr., the foaming ceased and the solution became colorless. The methanolic solution was evaporated to dryness, and the residue was dissolved in dilute aqueous sodium hydroxide and the product taken up by extraction with ethyl acetate. The extract was then dried. The removal of the solvent left a crude product

which was recrystallized from ethyl acetate to give a pure sample (m. p. 83—85°C). The treatment of the product obtained above with acetic anhydride and pyridine gave an acetoxyimino alcohol (m. p. 83—85°C). A mixed melting point determination with the original isonitroso alcohol showed a distinct depression.

Found: C, 58.04; H, 6.14; N, 4.92. Calcd. for $C_{15}H_{19}NO_6$: C, 58.24; H, 6.19; N, 4.53%.

# Some Unexpected Reactions in the Synthesis of 1-Phenyl-2-aminopropane-1, 3-diol Starting from Phenyl β-Chlorovinyl Ketone*

By Haruhisa SHIRAHAMA and Takeshi MATSUMOTO

(Received November 24, 1964)

In a previous paper[1] the synthesis of 1-phenyl-2-aminopropane-1, 3-diol (VI) from phenyl β-chlorovinyl ketone (I) was described. The reactions to be recorded below were examined in an attempt to find other routes to prepare VI from I. However, in each process, unexpected results were obtained. These new findings obtained in the course of this work will be reported here.

**Route. 1.**—The synthetic process described in the preceding paper involved two hydrogenation steps starting from α-oximino-β, β-dimethoxypropiophenone (V), derived from I. It was felt that the replacement of V by α-oximino-β, β-dibenzyloxypropiophenone (IV) might directly give the diol VI by a single hydrogenation through the hydrogenolysis of the benzyl group. Although the synthesis along this line was not successful, as will be described below, some interesting information about the reactivity of β, β-dibenzyloxypropiophenone (II) was obtained. Some chemical properties of II will therefore be reported on here.

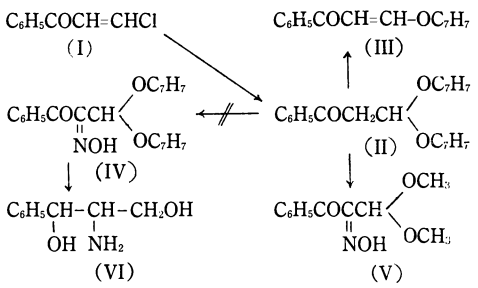

Fig. 1

The acetal (II) was prepared from I following the method for the preparation of VII.[1] A benzyl alcoholic solution of sodium benzyloxide was used as the alkaline reagent. Since the solution was very viscous and since a 5% solution gradually solidified at room temperature, a specially-designed separatory funnel was needed to add it portion by portion to the reaction vessel. The reaction proceeded as in the case of dimethyl acetal.[1] The product II looses benzyl alcohol upon prolonged heating and gives phenyl β-benzyloxyvinyl ketone (III). The elimination of alcohol from the β-keto acetal by heat was also observed in the case of the dimethyl acetal (VII). The oximation of II in methanol following Claisen's method[2] unexpectedly yielded V instead of IV. A possible explanation for the exchange of the alkoxy group of II may be that described in Fig. 2. In fact, V could be derived from II, III, VII and VII' by the same treatment.

In order to prepare IV, therefore, it was anticipated that the oximation of II in benzyl

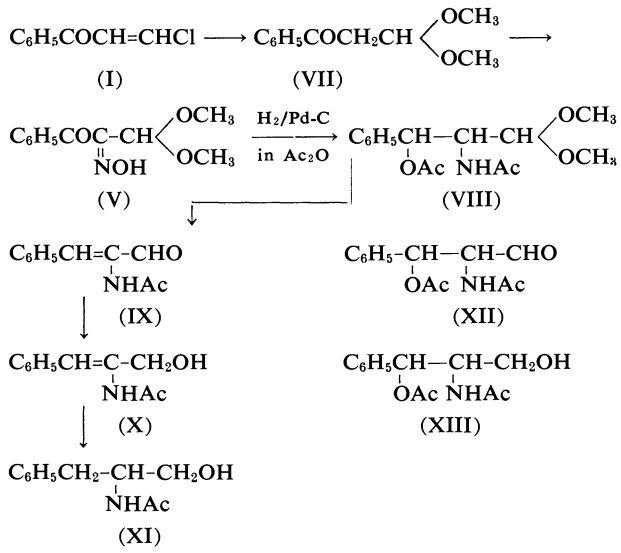

Fig. 3

alcohol would give favorable results. However, the reaction did not proceed in benzyl alcohol, and the original material was recovered after a few days treatment.[3] The inertness of II in a benzyl alcoholic solution may be due to the steric hindrance exerted by the benzyloxy group and/or to the polarity of the solvent.

**Route 2.**—The experiments outlined in Fig. 3 were originally attempted in order to convert VII to α-acetamido-β-acetoxyhydrocinnamaldehyed (XII), a possible intermediate for the synthesis of 1-phenyl-2-aminopropane-1, 3-diol. However, the hydrolysis of the α-acetamido-β-acetoxyhydrocinnamaldehyde dimethyl acetal under a variety of conditions was found to yield the α, β-unsaturated aldehyde (IX) invariably. Although the attempt along the original lines was thus unsuccessful, *N*-acetyl phenylalaninol was obtained for the first time in the crystalline state through the aldehyde (IX).

The hydrogenation of V with palladium charcoal in a mixture of acetic acid and acetic anhydride afforded a mixture of *threo* and *erythro* α-acetamido-β-acetoxyhydrocinnamaldehyde dimethyl acetals (VIII) in a ratio of 1 to 1. Although the separation of these isomers by recrystallization was difficult, it was achieved by forming large crystals and collecting the crystals of each component by hand. According to infrared studies of chloramphenicol and allied compounds by Suzuki and Shindo,[4] *threo O, N*-diacyl 1-phenyl-2-aminopropane-1-ol in its crystalline state invariably exhibits the amide I band at a higher wave number and the amide II band at a lower wave number than does the *erythro* isomer, and a strong absorption band always appears in the 950—1000 $cm^{-1}$ region in the *threo* series and in the 900—950 $cm^{-1}$ region in the *erythro* series. Of the two diacetyl compounds VIII, one absorbs at 1640, 1570 and 940 $cm^{-1}$ and the other, at 1650, 1555 and 995 $cm^{-1}$. These results indicate that the former, which is in the form of needles and which melts at 132—133°C, belongs to the *erythro* series and that the latter, which is cubic and which melts at 137—138°C, belongs to the *threo* series. A solution of either *threo* or *erythro* VIII in acetic acid diluted with a small amount of water was boiled for a short time in order to hydrolyze the acetal group. The products (m. p. 125—126°C) reduced Fehling's solution, and the analytical data as well as its infrared spectrum suggested that the product was α-acetamidocinnamaldehyde (IX). The reduction of IX with sodium borohydride afforded the known[5] α-acetamidocinnamyl alcohol (X). The hydrogenation of X yielded crystalline *N*-acetylphenylalaninol (XI) (m. p. 90—95°C), which was hitherto known[6] only in the form of an oil.

The action of aqueous calcium chloride upon the acetal (VIII) was next examined for the purpose of preparing α-acetamido-β-acetoxyhydrocinnamaldehyde (XII). This treatment,

3) During the oximation reaction, the presence of oximino ketone was determined by means of ferrous sulfate.[1]

however, also resulted in the formation of IX, with a loss of acetic acid. The treatment of finely-powdered VIII with dilute sulfuric acid at room temperature gave a small amount of IX, most of the starting material also being recovered.

**Route 3.**—The experiments were initially started in order to prepare 1-phenyl-2-phthalimidopropane-1, 3-diol from the same starting material (Fig. 4). However, the treatment of $\alpha$-bromo-$\beta$, $\beta$-dimethoxypropiophenone (XIV), derived from I, with potassium phthalimide unexpectedly yielded the phenyl $\alpha$-methoxy-$\beta$-phthalimidovinyl ketone (XVI) rather than the desired $\alpha$-phthalimido-$\beta$, $\beta$-dimethoxypropiophenone (XVII). Moreover, the methoxyl group of XVI located at the $\alpha$ position to the carbonyl group was readily hydrogenolysed to afford 1-phenyl-3-phthalimidopropane-1-ol (XXX).

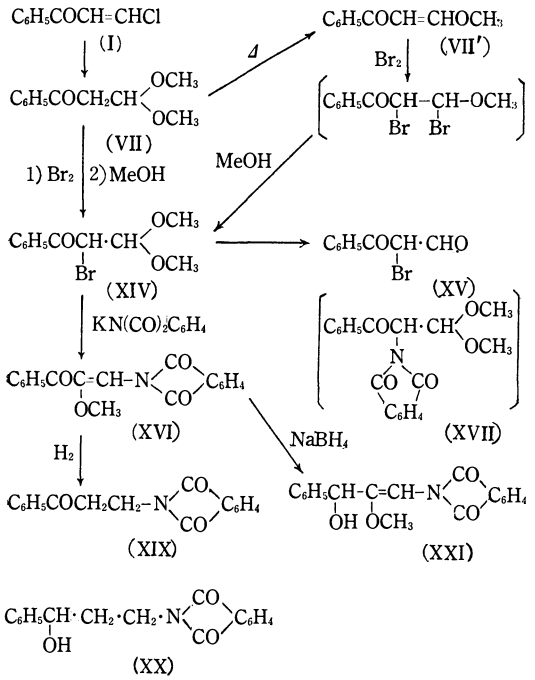

Fig. 4

The bromination of $\beta$, $\beta$-dimethoxypropiophenone[1] with bromine in carbon tetrachloride was attempted at first to prepare the bromo compound XIV. However, the reaction was accompanied by the hydrolysis of the acetal group by the hydrogen bromide generated during the reaction and yielded benzoyl-$\alpha$-bromoacetaldehyde (XV). The product was identified by comparing it with an authentic sample prepared by a known method.[7] The desired bromoacetal was obtained by first adding bromine to the phenyl $\beta$-methoxyvinyl ketone (VII) formed from VII upon distillation at 20 mmHg in a carbon tetrachloride solution and subsequently treating the product with methanol. The bromoacetal was also obtained by treating VII in the same manner.

The reaction of the bromoacetal XIV and potassium phthalimide was carried out first in dimethylformamide.[8] However, only an intractable tar was obtained even though the reaction conditions were carefully controlled. When methanol was employed as the solvent, a crystalline product (m. p. 81.5—82.5°C $\lambda_{max}$ 298 m$\mu$ ($\varepsilon$ 22600), $\nu_{max}$ 1730, 1645, 1600 and 1585 cm$^{-1}$) was produced. The analytical and spectral data of the product first suggested that it was phenyl $\alpha$-phthalimido-$\beta$-methoxyvinyl ketone (XVIII). The attempt to obtain the corresponding aldehyde by the hydrolysis of the vinyl ether group[9] was not successful, and the product (m. p. 82.5°C) was shown to be stable against cold aqueous sodium hydroxide and hydrochloric acid.

The hydrogenation of the product (m. p. 82.5°C) eventually revealed that the compound was not an $\alpha$-, but a $\beta$-phthalimide derivative. Namely, by hydrogenation over platinum oxide in acetic acid, the compound yielded $\beta$-phthalimido propiophenone (XIX) (m. p. 128—129°C) and 1-phenyl-3-phthalimidopropane-1-ol (XXV) (m. p. 76.5—78°C), both of which are known in the literature.[10,11] Therefore, the compound with a m. p. of 82.5°C must be either the

8) J. C. Sheehan and W. A. Bolhofer, *J. Am. Chem. Soc.*, 72, 2786 (1950).

9) It is known that, in alkaline conditions, $\beta$-methoxyvinyl ketone undergoes readily hydrolysis to give $\beta$-ketoaldehyde, which then further decomposes into methyl ketone.[1]

10) R. E. Davis and G. Powell, *J. Am. Chem. Soc.*, 67, 1466 (1945).

11) R. E. Lutz, J. W. Wilson, A. J. Deinet, G. H. Harnest, H. A. Martin and J. A. Freek, *J. Org. Chem.*, 12, 103 (1947).

phenyl α-methoxy-β-phthalimidovinyl ketone or the phenyl β-methoxy-β-phthalimidovinyl ketone. For the purpose of differentiating between these two alternatives, the compound was reduced by sodium borohydride to an unsaturated alcohol. The NMR spectrum of the product exhibited, in addition to aromatic proton signals, four singlets at τ 6.5 ($CH_3O$-), 5.7 (-CH-OH), 4.3 (OH) and 3.26 (-C=CH-). These results clearly indicate that the alcohol produced is phenyl α-methoxy-β-phthalimidovinyl carbinol (XXI) and that hence, the ketone is the α-methoxy-β-phthalimidovinyl ketone (XVI). The formation of XVI may be explained as follows (Fig. 5).

## Experimental

**β, β-Dibenzyloxypropiophenone (II).**—Into a mixture of 10 g. of the phenyl chlorovinyl ketone (I) and 10 g. of benzyl alcohol, a solution of 1.4 g. of sodium in 23 g. of benzyl alcohol was gradually added and stirred. During the reaction period, the vessel was kept in an ice-salt bath and the temperature was adjusted so as not to rise over −5°C. Since the solution of sodium benzylate solidified at lower temperatures, the addition was carried out by the use of a specially-designed separatory funnel. After being set aside overnight, the reaction mixture was poured into ice water and extracted with ether. The extract was then dried and distilled. β, β-Dibenzyloxypropiophenone (II) was distilled out at 186°C (1.5 mmHg) as a sticky yellow oil; yield 5 g. (24%).

Found: C, 79.89; H, 6.19. Calcd. for $C_{23}H_{22}O_3$: C, 79.74; H, 6.40%.

**Phenyl β-Benzyloxyvinyl Ketone (III).**—On the slow redistillation of the benzyl acetal (II), an appreciable amount of benzyl alcohol ran out first, and phenyl β-benzyloxyvinyl ketone distilled out as a deep yellow oil (b. p. 185°C (2 mmHg) $\nu_{max}$ 1655, 1600, 1585, 1570, 1491, 1185 and 1170 $cm^{-1}$). The vinyl ketone readily decolorized the permanganate solution, was unstable, and was used without purification for the oximation. The treatment of this ketone with alkyl nitrite and sodium methoxide in methanol, as described in the next section, yielded α-oximino-β, β-dimethoxypropiophenone.

**The Oximation of II.**—a) To a solution of 0.2 g. of sodium in 5 ml. of methanol, 1.2 ml. of isoamyl nitrite and 2 g. of β, β-dibenzyloxypropiophenone (II) were gradually added under cooling in an ice bath. After it had then been set aside for 2 or 3 days in a cool place, the reaction mixture was poured into ice water and washed three times with ether in order to remove the isoamyl alcohol and the unchanged ketone. The product was then taken up in ether after the addition of excessive ammonium chloride. The removal of the ether left white crystals (m. p. 83—85°C) which showed no depression on admixture with authentic α-oximino-β, β-dimethoxypropiophenone. The identity was confirmed by a comparison of the infrared spectra.

b) The same procedure was used as in a) except that 5 ml. of benzyl alcohol was used instead of 5 ml. of methanol. Even after 3 days the reaction mixture gave only a faint coloration in the ferrous complex test. After it had been set aside for 4 days, the reaction mixture was treated with ice water and ether. The working up of the ether extract afforded original β, β-dibenzyloxypropiophenone.

**α-Acetamido-β-acetoxyhydrocinnamaldehyde Dimethyl Acetal (VIII).**—A solution of 500 mg. of α-oximino-β, β-dimethoxypropiophenone (V) in a mixture of 10 ml. of acetic acid and 10 ml. of acetic anhydride was hydrogenated in the presence of 150 mg. of 10% palladium-on-charcoal[12] for 3 hr. The absorption ceased when 3.5 equivalents of hydrogen were taken up. The catalyst was then filtered off, and the solution was allowed to stand overnight with four drops of pyridine. After the removal of the solvent, the crystalline residue was recrystallized from ethyl acetate to afford colorless crystals of α-acetamido-β-acetoxyhydrocinnamaldehyde dimethyl acetal (m. p. 135—137°C).

Found: C, 60.77; H, 7.50; N, 4.75. Calcd. for $C_{15}H_{21}NO_5$: C, 61.00; H, 7.17; N, 4.74%.

A sample of the acetal was recrystallized slowly to afford a mixture of two kinds of large crystals. Both the crystals, which were obtained in almost the same amounts, were separated by a pincette and recrystallized respectively to yield white needles, VIIIa (m. p. 132—132.5°C) and cubic crystals, VIIIb.

VIIIa: $\nu_{max}^{Nujol}$ 3300 (-NH-); 1735 (OAc); 1640, 1570 (-NHAc); 1120, 1090, 1060 (acetal); 940 $cm^{-1}$.

Found: C, 61.05; H, 7.24. Calcd. for $C_{15}H_{21}NO_5$: C, 61.00; H, 7.17%.

VIIIb: $\nu_{max}^{Nujol}$ 3350 (-NH-); 1730 (-OAc); 1650, 1555 (-NHAc); 1180, 1100, 1065 (acetal); 995 $cm^{-1}$.

Found: C, 60.96; H, 7.16. Calcd. for $C_{15}H_{21}NO_5$ C, 61.00; H, 7.17%.

**The Hydrolysis of α-Acetamido-β-acetoxyhydrocinnamaldehyde Dimethyl Acetal (VIII).**—*a) The Production of α-Acetamidocinnamaldehyde.* 1) To a solution of 100 mg. of the acetal (VIIIa or VIIIb) in 1 ml. of acetic acid, a few drops of water were added, and then the solution was boiled for a short time, until a light brown coloration was obtained. The removal of the solvent and recrystallization of the residue from ethyl acetate or benzene yielded white needles (m. p. 125—126°C); it reduced the Fehling solution and the Nessler reagent.

Found: C, 69.25; H, 5.93; N, 7.03. Calcd. for $C_{11}H_{11}NO_2$: C, 69.82; H, 5.86; N, 7.40%.

2) To a 10% aqueous solution of calcium chloride the acetal (VIII) was added; the solution was then refluxed for 3 hr. and extracted with ethyl acetate. After drying, the removal of the solvent left crystalline aldehyde (IX).

*b) An Attempt to Obtain α-Acetamido-β-acetoxyhydrocinnamaldehyde (XII).*—A sample of 20 mg. of the crystalline acetal (VIII) was well ground into fine powder and dissolved in 4 ml. of 1 N sulfuric acid. After an hour, the solution was extracted with ethyl acetate. The working-up of a extract yielded the original acetate (VIII) and a small amount of the cinnamaldehyde (IX).

12) R. Mozingo, "Organic Syntheses," Vol. 26, 77 (1948).

**α-Acetamidocinnamyl Alcohol.** (X).—A solution of a sample (about 20 mg.) of α-acetamidocinnamaldehyde in ethanol was allowed to stand overnight with an excess of sodium borohydride. After the removal of the solvent, the residue was dissolved in dilute alkali and extracted with benzene. The evaporation of the benzene left a crystalline cake which was then recrystallized from benzene to yield the cinnamyl alcohol (X) quantitatively (m. p. 101—103°C). The melting point corresponded to that which appeared in the literature.[5]

***N*-Acetyl Phenylalaninol (XI).**—A solution of a sample (20 mg.) of cinnamyl alcohol (X) in ethanol was hydrogenated in the presence of 10% palladium charcoal. One mole of hydrogen was readily absorbed, and fine crystals (m. p. 90—95°C) were obtained. Though repeated recrystallizations from ethyl acetate - benzene had no effect in narrowing the melting point range, the analysis of the crystals gave good values for *N*-acetyl phenylalaninol.

Found: C, 68.39; H, 7.70. Calcd. for $C_{11}H_{15}NO_2$: C, 68.37; H, 7.82%.

**The Bromination of β, β-Dimethoxypropiophenone (VII).**—a) To a solution of the ketone VII in twice the volume of carbon tetrachloride, an equivalent amount of bromine was added slowly. The resulting mixture was distilled under reduced pressure to give a yellow oil (b. p. 110°C ($10^{-2}$ mmHg)), which soon crystallized. Recrystallization from benzene gave a pure sample (m. p. 110—111°C) which shows no depression on admixture with authentic benzoylbromoacetaldehyde.

b) To a solution of the ketone VII in twice the volume of carbon tetrachloride, an equivalent mole of bromine was added drop by drop. The resulting mixture was diluted with an equal volume of methanol and allowed to stand overnight. The solution was then concentrated to a quarter and extracted with petroleum benzine, and the extract was dried and distilled to remove the volatile solvent. The residue, crude α-bromo β, β-dimethoxypropiophenone (XIV), exhibited in the infrared spectrum bands at 2800 ($OCH_3$), 1690, 1600 (COPh); 1115, 1160 (acetal) $cm^{-1}$. Although the compound was unstable and was not purified, it afforded benzoylbromoacetaldehyde in a very good yield upon hydrolysis and was pure enough for use in the next reaction. Yield, 70%.

**Phenyl β-Methoxyvinyl Ketone (VII').**—A sample of VII was distilled at reduced pressure with a small amount of potassium bisulfate. The β-methoxyvinyl ketone (VII') distilled off with methanol at 140°C. The distillate was redistilled, and the fraction boiling at 135°C (5—6 mmHg) was collected; $\nu_{max}$ 1660, 1600, 1590, 1578, 1200 $cm^{-1}$; yield 20%. Although it was difficult to remove completely the unchanged acetal VII ($\nu_{max}$ 2800, 1675, 1590, 1580, 1115, 1075, 1050 $cm^{-1}$), the distillate was pure enough for the next reaction. Treatment with semicarbazide yielded benzoylacetaldehyde monosemicarbazone.

Found: C, 58.39; H, 5.17; N, 20.40. Calcd. for $C_{10}H_{11}N_3O_2$: C, 58.50; H, 5.37; N, 20.50%.

**The Bromination of the Phenyl β-Methoxyvinyl Ketone (VII').**—In the same way as has been described in the bromination of VII—b), this yielded α-bromo-β, β-dimethoxypropiophenone.

**Phenyl α-Methoxy-β-phthalimidovinyl Ketone (XVI).**—The bromoacetal XVI (35.5 g.) and potassium phthalimide (23.9 g.) were added to methanol (40 g.), and the whole was refluxed for 6 hr. After the solvent had been removed, the residue was extracted with benzene. The extract was washed with 1 N sodium hydroxide and then with water, and dried over sodium sulfate. The evaporation of the benzene left a crystalline cake which was recrystallized from ethanol. The purified product, which melted at 81.5—82.5°C, weighed 14.6 g. and exhibited an ultraviolet absorption maximum at 298 mμ (ε 22600) in an ethanol solution and infrared bands at 1730, 1645, 1600 and 1585 $cm^{-1}$.

Found: C, 70.16; H, 4.07; N, 4.58. Calcd. for $C_{18}H_{13}NO_4$: C, 70.35; H, 4.26; N, 4.56%.

**The Hydrogenation of the Phenyl α-Methoxy-β-phthalimidovinyl Ketone (XVI).**—A sample of XVI was dissolved in acetic acid and hydrogenated in the presence of platinum oxide. After the absorption of hydrogen had ceased, the catalyst and the solvent were removed. The residue, a colorless paste, was chromatographed to afford two kinds of crystals. They were recrystallized separately from a mixed solvent of benzene-petroleum. The one melting at 128—129°C was β-phthalimidopropiophenone.[11]

Found: C, 72.97; H, 4.71; N, 5.31. Calcd. for $C_{17}H_{13}NO_3$: C, 73.11: H, 4.69; N, 5.02.

The other product melted at 76.5—78°C and was phenyl β-phthalimidoethyl carbinol (XX').

Found: C, 72.59; H, 5.32; N, 4.77. Calcd. for $C_{17}H_{15}NO_3$: C, 72.58; H, 5.37; N, 4.98%.

**The Reduction of the Phenyl α-Methoxy-β-phthalimidovinyl Ketone (XVI) with Sodium Borohydride.**—A sample of XVI was treated with sodium borohydride in dioxane. After it had been set aside overnight, the reaction mixture was worked up in the usual way. The product was obtained as a colorless paste which was difficult to crystallize. The NMR spectrum of the product was measured at 56.4 Mc. in carbon tetrachloride. Four singlets at τ 6.5 ($CH_3O$-), 5.7 (C<u>H</u>-OH), 4.3 (OH), 3.26 (>C=C<u>H</u>), and an aromatic multiplet signal were observed. When the ethereal solution of the pasty alcohol was oxidized[13] with chromic acid and a few drops of sulfuric acid, the original ketone XVI was obtained.

# The Electronic Structures of the Benzenium Ion and Its Methyl Derivatives

By Ichiro HANAZAKI and Saburo NAGAKURA

(Received November 7, 1964)

It is well known that methylbenzenes are protonated in acidic media (HF, $HF+BF_3$, etc.) to give benzenium-type ions. They are considered to be a typical model of the intermediates of aromatic substitution reactions.[1]

Mackor et al.[2] studied the electronic absorption spectra of the methyl-substituted benzenium ions in $HF+BF_3$. According to them, the 2, 4, 6-trimethylbenzenium, 2, 3, 4, 6-tetramethylbenzenium and pentamethylbenzenium ions show two bands in the wavelength region longer than 200 m$\mu$. One of them appears at 350—400 m$\mu$, the other, at $\sim$250 m$\mu$.

Reid[3] also studied the ultraviolet absorption spectra of the benzenium ion and its methyl derivatives under low temperatures ($\sim$70°C); he found that the benzenium ion itself shows a band at 410 m$\mu$. Mackor et al.,[4] however, reported that, at least at room temperature, they could not detect the formation of the benzenium ion in the benzene-HF-$BF_3$ system.

Kilpatrick and Hyman[5] also observed the absorption spectra of benzene, mesitylene and hexamethylbenzene in various solvents. In the case of benzene, no new band appears in the visible and ultraviolet regions, even in strong acid (HF). On the other hand, in the case of mesitylene and hexamethylbenzene in strong acid, a new band appears in the 350—400 m$\mu$ region.

Recently Olah et al.[6] succeeded in isolating the salts of the methyl-substituted benzenium ions with $BF_4^-$ in the solid form. They were prepared at a low temperature and were gradually decomposed at room temperature even in a sealed capsule. They showed a rather high electric conductance in the solid state. This fact seems to support the existence of ionic species.

Mulliken et al.[7] calculated the $\pi$-electron structure of the benzenium ion, including the hyperconjugation effect of the methylene group, by the $\omega$-technique. They evaluated the stabilization energy (hyperconjugation energy) to be 14.5 kcal./mol. This work was restricted to the Hückel approximation, so it may not give reliable predictions to the excitation energies.

The SCFMO calculations were performed by Mackor et al.[2,8] Although their calculation considered no hyperconjugation effect, they succeeded in predicting the excitation energies qualitatively.

Recently Morita[9] studied the $\pi$-electronic structure of the benzenium ion by the SCFMO method including the hyperconjugation of the methylene group and obtained a reasonable agreement with the experimental results. There remain some ambiguities, however, in his determination of the parameters belonging to the methylene group.

In the present work, we have undertaken to improve the calculation of the $\pi$-electron structure of the benzenium ion by evaluating the molecular integrals belonging to the methylene group as rigorously as possible and by considering the effect of the electronic charge and of the configurational interaction with doubly excited electron configurations. Moreover, the effect of the substituted methyl groups has been studied in the following manner. The methyl-substituted ion is divided into its components, the benzenium ion and the methyl groups. Then the interaction among them is taken into account in terms of the configurational interaction among several electron configurations constructed by putting the electrons in the orbitals of the components.

## The Benzenium Ion

**The Simple SCFMO Calculation (Method I).**—The geometrical structure of the benzenium

ion was confirmed by the NMR measurements[4a,10,11] as follows: $H^+$ attacks an appropriate carbon atom of the benzene ring, and two hydrogen atoms are both bonded to the atom symmetrically with respect to the ring plane. The hybridization of the carbon atom changes from $sp^2$ of the benzene to $sp^3$ of the benzenium ion* (Fig. 1).

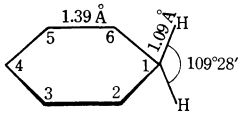

Fig. 1. The geometrical configuration of the benzenium ion.
(The conformation of the ring is assumed to be identical with benzene.)

First of all, let us consider the linear combination of the two hydrogen 1s orbitals, $\chi_1$ and $\chi_2$, of the methylene group:

$$\left.\begin{aligned}\chi_\sigma &= [2(1+S)]^{-1/2}(\chi_1+\chi_2)\\ \chi_\pi &= [2(1-S)]^{-1/2}(\chi_1-\chi_2)\end{aligned}\right\} \quad (1)$$

where $S$ denotes the overlap integral between the two hydrogen 1s AO's. Of these, $\chi_\sigma$ corresponds to the $\sigma$-type orbital and $\chi_\pi$ corresponds to the $\pi$-type orbital. The $sp^3$ hybridized orbitals of the carbon, to which the two hydrogen atoms are attached, can be reduced into three nonequivalent $sp^2$ hybrid orbitals and the one $2p\pi$ AO by taking linear combinations of them. One of the nonequivalent $sp^2$ hybrid orbitals can make a bond with the $\chi_\sigma$ orbital, and the $2p\pi$ one can interact with the $\chi_\pi$ orbital and the conjugated system of the cyclopentadienyl ring. (See Appendix for the justification of this procedure.)

We have performed the SCF calculation taking the six $2p\pi$ AO's of the ring and the $\chi_\pi$ orbital into account. The calculation has been made by the method combining Pariser-Parr's method[12] with Roothaan's SCF method[13,14]. The orbital energy of the AO is replaced by the minus of the valence state ionization potential of the atom, and the one-center repulsion integrals (pp|pp) are replaced by the ionization potentials minus electron affinities.

To perform the above-mentioned calculation procedure, we must evaluate the ionization potential and the electron affinity of the pseudo $\chi_\pi$ orbital. Using the Slater 1s AO, the valence state energy of the pseudo atom $H_2$ is found to be:

$$E = I_\sigma + I_\pi + J_{\sigma\pi} - 1/2\, K_{\sigma\pi} \quad (2)$$

where

$$\left.\begin{aligned} I_1 &= \int \chi_1(1)\mathbf{H}^{\mathrm{core}}(1)\chi_1(1)\,dv_1\\ J_{\sigma\pi} &= \int \chi_\sigma(1)\chi_\sigma(1)e^2/r_{12}\chi_\pi(2)\chi_\pi(2)\\ &\quad \times dv_1 dv_2\\ K_{\sigma\pi} &= \int \chi_\sigma(1)\chi_\pi(1)e^2/r_{12}\chi_\sigma(2)\chi_\pi(2)\\ &\quad \times dv_1 dv_2\end{aligned}\right\} \quad (3)$$

The valence state energy of the $H_2^+$ ion, in which an electron in $\chi_\pi$ is removed, is;

$$^+E = I_\sigma \quad (4)$$

Therefore, the valence state ionization potential is:

$$^+E - E = -I_\pi - J_{\sigma\pi} + \frac{1}{2}K_{\sigma\pi} \quad (5)$$

If we reduce these molecular integrals into integrals over the Slater-type 1s AO's with $Z=1$, we can evaluate them non-empirically.*

Similarly, the electron affinity can be evaluated from the relation:

$$E - E^- = -I_\pi - J_{\sigma\pi} - J_{\pi\pi} + \frac{1}{2}K_{\sigma\pi} \quad (6)$$

where $E^-$ is the valence state energy of $H_2^-$ in which two electrons occupy $\chi_\pi$:

$$E^- = I_\sigma + 2I_\pi + J_{\pi\pi} + 2J_{\sigma\pi} - K_{\sigma\pi} \quad (7)$$

Using the Slater AO's for hydrogen 1s:

$$\left.\begin{aligned} I_p(H_2) &= {}^+E - E = 9.4219\ \mathrm{eV.}\\ A_p(H_2) &= E - E^- = -0.7007\ \mathrm{eV.}\end{aligned}\right\} \quad (8)$$

10) C. MacLean and E. L. Mackor, *Mol. Phys.*, **4**, 241 (1961).
11) C. MacLean and E. L. Mackor, *J. Chem. Phys.*, **34**, 2208 (1961).
* If $sp^3$ hybrid orbitals are formed completely, the carbon skeleton of the benzene ring may be deformed to a considerable extent. In fact, the hybridization may be in some intermediate state between $sp^2$ and $sp^3$. In the present work, however, the two hydrogen atoms are assumed to take the same geometrical configuration as in the case of methane, and the deformation of the ring skeleton is not considered explicitly.
12) R. Pariser and R. G. Parr *J. Chem. Phys.*, ibid., **21**, 466, 767 (1953).
13) C. C. J. Roothaan, *Revs. Mod. Phys.*, **23**, 69 (1951).

* Strictly speaking, the values of the same type of molecular integrals are different when they appear in $E$ and in $E^+$:

$$E^+ - E = -I_\pi - J_{\sigma\pi} + \frac{1}{2}K_{\sigma\pi} + (I_\sigma^+ - I_\sigma)$$

the difference, $I_\sigma^+ - I_\sigma$, being attributed to the difference in the electron distribution. (if we consider the Slater AO's, it is reduced to the difference in the effective charge.) Fortunately, $I_\sigma^+ - I_\sigma$ may be canceled out with other types of errors (for example, the error coming from the atomic orbitals), so that we may still expect a good result when $I_\sigma^+ - I_\sigma$ are disregarded. This is the reason why Koopmans' theorem holds generally with considerable exactness. (Cf. W. Moffitt, *Proc. Roy. Soc.*, **A202**, 534 (1950); R. G. Parr and R. S. Mulliken, *J. Chem. Phys.*, **18**, 1338 (1950).).

* See Table I for the notation.

On the basis of these results and of the valence state ionization potential (11.24 eV.) and electron affinity (0.62 eV.) of the carbon 2p$\pi$ AO, which have been derived from spectroscopic data,[15] two center repulsion integrals (pp|qq) over $\pi$-type AO's have been evaluated by using the Pariser-Parr method.[12]

The resonance integral, $\beta_{CC}$, between the adjacent carbon 2p$\pi$ AO's of the ring is taken to be −2.39 eV. which is the value determined by Pariser and Parr for benzene.[12] The resonance integral, $\beta_{C-\chi_\pi}$, between $\chi_\pi$ and the adjacent carbon 2p$\pi$ AO is determined from the equation:

$$\beta_{C-\chi_\pi} = (S_{C-\chi_\pi}/S_{C-C})\beta_{C-C}$$

where $S_{C-\chi_\pi}$ is the overlap integral between $\chi_\pi$ and the adjacent carbon 2p$\pi$ AO and $S_{C-C}$ is the overlap integral between the adjacent carbon 2p$\pi$ AO's of benzene ($S_{C-C}=0.248$). Assuming the geometrical configuration shown in Fig. 1, $S_{C-\chi_\pi}$ has been evaluated as 0.613. Thus, $\beta_{C-\chi_\pi}$ is determined to be −5.90 eV.

The numerical calculation was performed using a FACOM 202 electronic computer at our Institute.* The result of the SCF calculation is shown in Table I. Of seven MO's, the lower three are occupied in the ground configuration.

**The Effect of Changing the Effective Charge (Method II).**—The above-mentioned calculation is based on the parameters which are determined from the ionization potentials and the electron affinities of neutral atoms.

In the present case, however, the molecule as a whole possesses a +1 charge in the conjugate system. For this reason, the appropriate $Z$ values may differ to some extent from those of neutral atoms. In this connection, we have performed the 'SCE' calculation[16] in which the effective nuclear charge, $Z$, of an atom is changed proportionally to the change in the charge density of the atom; that is, for the carbon atom,

$$Z_p = 3.25 + 0.35\, q_p \qquad (9)$$

where $q_p$ is the formal charge on atom p. For $H_2$ pseudo AO, $\chi_\pi$, the relation is;

$$Z_H = 1.00 + 0.39\, q_H \qquad (10)$$

according to the Slater rule.

* Oscillator strength

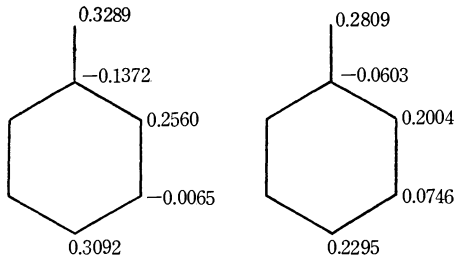
We then take the valence state ionization potential and the electron affinity[15] of the isoelectronic series of the carbon ($B^-$, C, $N^+$, $O^{2+}$) and hydrogen (H, $He^+$, $Li^{2+}$) atoms, and plot them against the $Z$ values obtained by means of the Slater rule. Thus approximate quadratic equations are obtained between $I_p$ or $A_p$ and $Z_p$:

$$\left.\begin{aligned}
&\left.\begin{aligned}
&I_p=3.69\,Z_p^2-10.04\,Z_p+4.89\\
&A_p=3.75\,Z_p^2-16.50\,Z_p+14.64
\end{aligned}\right\}\text{(carbon)}\\
&\left.\begin{aligned}
&I_p=13.6064\,Z_p^2-4.2579\,Z_p+0.0734\\
&A_p=13.6051\,Z_p^2-12.7417\,Z_p-1.5641
\end{aligned}\right\}\text{(hydrogen)}
\end{aligned}\right\}\quad(11)$$

These relations, together with Eqs. 9 and 10, allow us to determine the appropriate $I_p$'s and $A_p$'s as the functions of the charge densities. We calculate $I_p$ and $A_p$ by the use of the $q_p$, the formal charge of atom p, obtained by method I. The SCF procedure is then performed again by using the newly-evaluated $I_p$ and $A_p$ values. This procedure is repeated until the charge distribution becomes self-consistent.* The results are shown in Table II.

**Configuration Interaction.** — The above-mentioned two kinds of SCF calculations have

* In the present calculation, the one-center integrals,



$$W_p=-I_p$$

and

$$(pp\mid pp)=I_p-A_p$$

are adjusted by the SCE procedure. However, the two-center integrals ($\beta$ and $(pp\mid qq)$) are not adjusted because the change in these integrals caused by the change in the charge distribution is small.

been improved by considering the configuration interaction. Singly excited configurations, the excitation energies of which are below 10 eV., are taken into account. The selected configurations and matrix elements are shown in Table III. The resultant energies and wave functions for the ground and lower-excited states are shown in Table IV. The charge distributions of the ground state are shown in Fig. 2.

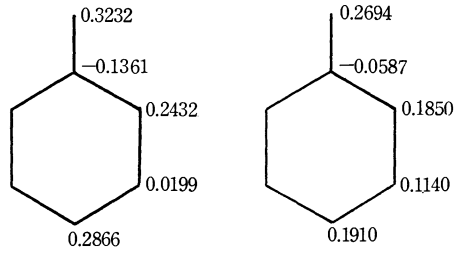


Fig. 2. The charge distribution in the ground state of the benzenium ion.
(The charge distributions calculated by SCF without CI and by SCF with CI among singly excited configurations are identical because the singly excited configurations do not mix with the ground configuration)

### The Methyl-Substituted Benzenium Ions

In order to evaluate the hyperconjugation effect of the methyl group, the charge-transfer configuration, $A \rightarrow \phi_4$, where A denotes the occupied pseudo $\pi$ MO of the methyl group A and $\phi_4$ denotes the lowest vacant MO of the benzenium ion, was taken into account, in addition to the singly excited configurations mentioned above.

The ionization potential for removing an electron from the pseudo $\pi$ MO of the methyl group had been evaluated in the case of the *t*-butyl cation: the pseudo $\pi$ AO which can be constructed from the three 1s AO's of the $H_3$ group can form a pseudo $\pi$ MO by means of interaction with the $2p\pi$ AO of the carbon atom of the methyl group. The calculations on this system were performed by the SCFMO method and gave the following results[17]:

$$\left.\begin{aligned} &\varepsilon_1 = -13.245 \text{ eV.} \\ &\phi_1 = 0.5505\chi_H + 0.8348\chi_C \\ &\varepsilon_2 = +0.708 \text{ eV.} \\ &\phi_2 = 0.8348\chi_H - 0.5505\chi_C \end{aligned}\right\} \quad (12)$$

where $\chi_C$ is the carbon $2p\pi$ AO and where the pseudo $\pi$ AO $\chi_H$ is defined as:

$$\chi_H = \frac{1}{\sqrt{6(1-S)}}(2\chi_1 - \chi_2 - \chi_3) \quad (13)$$

$\chi_1$, $\chi_2$ and $\chi_3$ being the 1s AO's of the three hydrogen atoms. The ionization potential for removing an electron from $\phi_1$ is a minus of the orbital energy of $\phi_1$:

$$I_p(\text{methyl}) = -\varepsilon_1 = 13.245 \text{ eV.} \quad (14)$$

The electron affinity of the benzenium ion has never been measured; therefore, the minus of the calculated orbital energy of the lowest vacant MO was adopted. In the present calculation, however, we make use of the zero-differential overlap approximation, so there is probably some error. Hush and Pople[18] calculated the ionization potentials of alternant hydrocarbons and of odd alternant radicals with the approximation of neglecting the overlap integrals. They found that it is necessary to take the orbital energy of the carbon $2p\pi$ AO to be about −9.50 eV. in order to obtain a good agreement with the experimental data. The valence state ionization potential of carbon $2p\pi$ AO is 11.24 eV., so a correction of about 1.7 eV. is necessary. Therefore, in the present case, the electron affinity of the benzenium ion is corrected by about 1.7 eV. The calculated electron affinity by method I (neutral parameters) is 8.957 eV.; after the correction of 1.7 eV., it is reduced to 7.257 eV.

The diagonal element for the charge-transfer (hereafter abbreviated as 'CT') configuration is

$$E_{CT} = I_p(\text{methyl}) - A_p(\text{benzenium}) \quad (15)$$

where the small correction resulting from the electrostatic interaction between the methyl and benzenium groups has been disregarded. Putting the above-mentioned values into Eq. 15, the diagonal element is

$$E_{CT} = 13.245 - 7.257 = 5.988 \text{ eV.} \quad (16)$$

(Taking the energy of the ground configuration as the standard)

The off-diagonal elements can also easily be obtained. When, for example, a methyl group

17) I. Hanazaki, H. Hosoya and S. Nagakura, This Bulletim, **36**, 1673 (1963).
18) N. S. Hush and J. A. Pople, *Trans. Faraday Soc.*, **51**, 600 (1955).

is substituted at the 2 position,* the CT configuration, $CT_{A\to4}$, must be considered in addition to the configurations included in the case of the configuration interaction of the benzenium ion:

$$(G|\mathbf{H}|CT_{A\to4}) = \int |1\bar{1}2\bar{2}3\bar{3}A\bar{A}| \times \mathbf{H}\frac{1}{\sqrt{2}}\{|1\bar{1}2\bar{2}3\bar{3}A\bar{4}| + |1\bar{1}2\bar{2}3\bar{3}4\bar{A}|\}\,d\tau = \sqrt{2}\,(A|\mathbf{H}^{core}|4)^{**} \quad (17)$$

where the zero-differential overlap approximation is invoked. If we neglect resonance integrals between the non-adjacent atoms,

$$(A|\mathbf{H}^{core}|4) = \int (c_1\chi_H + c_2\chi_C)\mathbf{H}^{core} \times (\sum_p c_{4p}\chi_p)\,d\tau = c_2c_{42}\beta \quad (18)$$

where $c_2$ denotes the coefficient of the carbon AO $\chi_C$ in the methyl group; $c_{42}$ denotes the coefficient of the AO $\chi_2$ in the MO $\phi_4$ of the benzenium ion, and $\beta$ is the resonance integral between ring carbon 2 and the carbon atom in the methyl group.

Next, the electronic structure of the 2,4,6-trimethylbenzenium ion was calculated. The wave functions of the CT configurations in this case are as follows:

$$\left.\begin{aligned} \Psi_{CT_1} &= \frac{1}{\sqrt{2}}[\Psi_{CT_A} + \Psi_{CT_E}]^{***} \\ \Psi_{CT_2} &= \Psi_{CT_C} \\ \Psi_{CT_3} &= \frac{1}{\sqrt{2}}[\Psi_{CT_A} - \Psi_{CT_E}] \end{aligned}\right\} \quad (19)$$

the first two wave functions being symmetric and the last antisymmetric. The matrix elements between the ground and locally excited configurations and those within the locally excited configurations are the same as in the case of the non-substituted benzenium ion. The matrix elements including the CT configurations are as follows:

$$\left.\begin{aligned} \langle G|\mathbf{H}|CT_1\rangle &= \frac{1}{\sqrt{2}}\{\langle G|\mathbf{H}|CT_A\rangle + \langle G|\mathbf{H}|CT_E\rangle\} = 2\langle\phi_4|\mathbf{H}|A\rangle \\ \langle G|\mathbf{H}|CT_2\rangle &= \langle G|\mathbf{H}|CT_C\rangle = \sqrt{2}\langle\phi_4|\mathbf{H}|C\rangle \end{aligned}\right.$$

* See the footnote of Table I for the numbering. Hereafter, the methyl groups substituted at the 2, 3, 4, 5 and 6 positions are denoted as A, B, C, D and E respectively.

** Here A denotes the $\pi$-type MO ($\phi_1$ of Eq. 12) of the methyl group A.

* $CT_A$ and $CT_E$ denote the CT configurations $CT_{A\to E}$ and $CT_{E\to4}$ respectively.

&\quad=-\sqrt{2}\langle\phi_3\,|\mathbf{H}|\,A\rangle
\end{aligned}
\qquad (20)
$$

All other elements including the CT configurations vanish.

The pentamethyl- and 2, 3, 4, 6-tetramethylbenzenium ions are treated in a similar manner. The results are shown in Table V, together with the experimental data. Some other methyl-substituted benzenium ions are also calculated in the same manner. The results are shown in Table VI.

### The Effect of Doubly Excited Configurations

In the last part of this work, we shall examine the effect of doubly excited configurations. Let us take the naphthalenium ion as an example.* There are two possibilities of protonation when naphthalene is dissolved in a $HF+BF_3$ solution; protonation at the $\alpha$- or at the $\beta$-position.[2] The SCF calculation was carried out for the two ions by method I to give $\pi$-electron energies of −427.2 eV. and −422.8 eV. for the $\alpha$- and $\beta$-ions respectively. Therefore, the $\alpha$-ion probably predominates in the $HF-BF_3$ solution.**

TABLE VIII. THE RESULTS OF CONFIGURATION INTERACTION FOR α-NAPHTHALENIUM ION

| Calcd. | | | | Obs. | |
|---|---|---|---|---|---|
| I[a] | | II[b] | | | |
| eV. | (f) | eV. | (f) | eV. | (ε) |
| 3.172 | (0.053) | 2.887 | (0.043) | 3.024 | (shoulder) |
| 3.459 | (0.211) | 3.277 | (0.323) | 3.179 | (10900) |
| 5.175 | (0.139) | 4.811 | (0.059) | 4.430 | (14800?) |
| 5.406 | (0.048) | 5.228 | (0.024) | 4.880 | (13000?) |

a) Singly excited configurations alone.
b) Singly and doubly excited configurations included.

The result of the SCF calculation (method I) for the $\alpha$-naphthalenium ion is given in Table VII. The results improved by considering the configuration interaction with and without doubly excited configurations are shown in Table VIII.

The 2, 4, 6-trimethyl-, 2, 3, 4, 6-tetramethyl- and pentamethylbenzenium ions are also calculated by means of the configuration interaction, including the doubly excited configurations (Table IX).

### Discussion

It can be seen from the results summarized in Tables V, VIII and IX that the calculated

* The methyl-substituted benzenium ions are not adequate for examining the effect of the doubly excited configurations because of some arbitrariness in the choice of parameters belonging to the CT configurations. The absorption spectrum of the benzenium ion itself has not been observed, so it is necessary to examine the effect in the case of the non-substituted naphthalenium ion.

** The energy of the σ-electron system is approximately the same for both ions, so it is reasonable to compare the total stabilities in terms of the π-electron energies.

b) Oscillator strength.

transition energies for the methyl-substituted benzenium ions and for the $\alpha$-naphthalenium ion are in good agreement with the experimental results. Although the calculated absorption intensities can not be expected to be satisfactorily coincident with the observed values in this type of calculation, the results obtained by considering the configuration interaction including the doubly excited configurations seem to be rather good (The $\varepsilon$ values for the 280 m$\mu$ and 254 m$\mu$ bands of the $\alpha$-naphthalenium ion do not represent true intensities, since these two bands are superposed with the very intense band with a peak probably below 200 m$\mu$; the true intensities are far less than that of the second transition).

The shift of the 350 m$\mu$ and 250 m$\mu$ bands upon the methyl substitution is well explained by the present calculation. It has been observed that the substitution of a methyl group for one of the ring hydrogen atoms of the 2, 4, 6-trimethylbenzenium ion causes these two bands to shift toward a longer wavelength by 0.1 eV. The corresponding calculated values are 0.13 (0.12) and 0.16 (0.09) eV. respectively (the results with doubly excited configurations are shown in parentheses). When a methyl group is substituted for the ring hydrogen atom of the 2, 3, 4, 6-tetramethylbenzenium ion, the first and second bands shift toward longer wavelengths by 0.1 and 0.2 eV. respectively. The corresponding calculated values are 0.11 (0.10) and 0.18 (0.11) eV. respectively.

As has been pointed out earlier, the SCE treatment does not have any significant effect on the excitation energy or on the transition intensity of the benzenium ion* (see Table IV).

The results of the NMR absorption measurement, however, show that the charge distribution (0.22, 0.16 and 0.25 for the ortho-, meta- and para-positions respectively[8)]) is more even than that calculated by the usual SCF procedure. In this connection, the charge distribution calculated by method II seems to be more adequate than that calculated by method I (see Fig. 2). However, too much importance should not be attached to this comparison, because there is some ambiguity in determining the charge distributions from the NMR data.

* The same is true for the methyl-substituted benzenium ions, although the calculated results are not shown in the present paper.

TABLE X. THE LOWER EXCITED STATES OF THE BENZENIUM ION BY SEVERAL METHODS*1,*2

| 6.45 (0.536) | 6.73 (1.079) | 6.34 (0.549) |

*1 Energies are shown in eV. (the ground state is taken to be zero.)
*2 Oscillator strengths are shown in parenthesis in each case.
*3 Configuration interaction with the singly excited configurations alone.
*4 Configuration interaction with the singly and doubly excited configurations.

The inclusion of the doubly excited configurations changes the energies and the wave functions to some extent. The effect is negligible on the first excitation energies and on the intensities of the benzenium, methyl-substituted benzenium and $\alpha$-naphthalenium ions. However, the effect seems to be significant on the second excited states of the benzenium and methyl-substituted benzenium ions (see Table X for a comparison in the case of the benzenium ion), while there is no significant effect on the four excited states of the $\alpha$-naphthalenium ion. When we compare the calculated intensity ratio of the methyl-substituted benzenium ions with the experimental results, the calculation with the doubly excited configurations seems to be better.

The results of the semi-empirical calculation of this type always depend on the choice of the parameter $\beta$ (the resonance integral). The value selected in the present work, $-2.39$ eV., was originally evaluated to fit to the lowest excitation energy of benzene in the configuration-interaction calculation with singly excited configurations alone.[12] Anno et al.[19] examined the effect of the doubly excited configurations in the case of benzene and found the $\beta$ value of $-2.72$ eV. to be adequate. If we also take $\beta=-2.72$ eV. in our calculation of the configuration interaction including the doubly excited configurations, the lower excitation energies may become closer to the values evaluated by the configuration-interaction calculation without the doubly excited configuration.

As is shown in Table VI, the methyl substitution at ortho- and para-positions stabilizes the ground state of the benzenium ion by $\delta_o=0.146$ eV. (3.45 kcal./mol.) and $\delta_p=0.165$ eV. (3.89 kcal./mol.) respectively, while the meta-substitution causes little stabilization. An approximate additivity is satisfied for the stabilization due to the methyl-substitution. Thus the following equation can be obtained assuming that the stabilization energy due to the methyl substitution at the meta-position is zero:

$$\Delta=n_o\delta_0+n_p\delta_p$$

where $\Delta$ is the total stabilization energy of the methyl-substituted ion, and where $n_o$ and $n_p$ are the numbers of the methyl groups substituted at the ortho- and para-positions respectively. For example, the stabilization in the 2, 4-dimethylbenzenium ion is evaluated at 0.302 eV., while the sum of the stabilization energies of the ortho- and para-methylbenzenium ions is $0.146+0.165=0.311$ eV.

## Appendix

**The Valence State Energy of the Carbon Atom.** —The carbon atom to which $H^+$ is attached may be considered to be nearly in the $sp^3$ hybrid valence state. In the present calculations, a pure $2p\pi$ AO was extracted by taking a linear combination of the $sp^3$ hybrid AO's, and the valence state ionization potential of the 2p AO of the non-hybridized carbon was used for the orbital energy of the extracted $2p\pi$ AO. In order to examine the validity of this choice, we shall consider here the valence state of the carbon atom in the methane molecule.

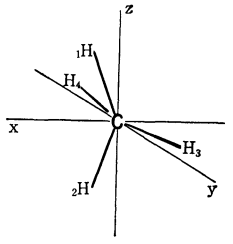

Fig. 3. Location and numbering of the four hydrogen atoms in the methane molecule.

If two hydrogen atoms, $H_1$ and $H_2$, are located in the xz plane and $H_3$ and $H_4$, in the xy plane (Fig. 3), the electronic states can generaly be represented by the following four bonding MO's:

$$\left.\begin{aligned}
\phi_1&=\frac{1}{\sqrt{1+\lambda_1^2}}\left[s+\frac{\lambda_1}{2}(h_1+h_2+h_3+h_4)\right]\\
\phi_2&=\frac{1}{\sqrt{1+\lambda_2^2}}\left[x+\frac{\lambda_2}{2}(h_1+h_2-h_3-h_4)\right]\\
\phi_3&=\frac{1}{\sqrt{1+\lambda_3^2}}\left[y+\frac{\lambda_3}{\sqrt{2}}(h_3-h_4)\right]\\
\phi_4&=\frac{1}{\sqrt{1+\lambda_4^2}}\left[z+\frac{\lambda_4}{\sqrt{2}}(h_1-h_2)\right]
\end{aligned}\right\}\quad(21)$$

19) T. Anno and A. Sado, *J. Chem. Phys.*, **39**, 2293 (1963).

and the corresponding antibonding MO's. (Here s, x, y and z denote the 2s, 2px, 2py and 2pz AO's of carbon respectively, and $h_1$ denotes the 1s AO of hydrogen $H_1$.) If the ideal $sp^3$ hybridization is achieved, the relation:

$$\lambda_1=\lambda_2=\lambda_3=\lambda_4=1$$

must hold. In this case the ground state energy is;

$$E=2\sum_{i=1}^{4}I_i+\sum_{i=1}^{4}J_{ii}+4\sum_{i<j}J_{ij}-2\sum_{i<j}K_{ij} \qquad (22)$$

The orbital energy of the MO $\phi_4$ is:

$$\begin{aligned}\varepsilon_4&=I_4+\sum_{j=1}^{4}(2J_{4j}-K_{4j})\\&=\frac{1}{2}\alpha_z+\frac{1}{4}J_{zz}+\frac{1}{2}(J_{yz}+J_{xz}+J_{sz})\\&\quad-\frac{1}{4}(K_{yz}+J_{xz}+J_{sz})\\&\quad+\{\text{Integrals belonging to the hydrogen 1s AO's}\}\\&\quad+\{\text{Integrals representing the interaction between the carbon and hydrogens}\}\end{aligned} \qquad (23)$$

If we define:

$$W_z=\alpha_z+(J_{yz}+J_{xz}+J_{sz})-\frac{1}{2}(K_{yz}+K_{xz}+K_{sz}) \qquad (24)$$

then

$$\varepsilon_4=\frac{1}{2}W_z+\frac{1}{4}J_{zz}+\cdots\cdots \qquad (25)$$

In the conventional $\pi$-electron treatment, $W_z$ is taken to be the minus of the valence state ionization potential of the carbon 2p AO.

The valence state ionization potential is determined from the atomic spectroscopy data as follows. For example, we consider first the ionization potential for removing an electron from the 2p AO in the non-hybridized carbon (in $(2s)(2p)^3$ configuration). The valence state energies of C and $C^+$ are;

$$E=\alpha_s+3\alpha_p+3(J_{sp}+J_{pp'})-\frac{3}{2}(K_{sp}+K_{pp'})$$

$$E^+=\alpha_s^+ +2\alpha_p^+ +2J_{sp}^+ +J_{pp'}^+ -K_{sp}^+ -\frac{1}{2}K_{pp'}^+,$$

and the ionization potential in question is:

$$-I_p(sxyz\rightarrow sxy)=\alpha_p+J_{sp}+2J_{pp'}-\frac{1}{2}K_{sp}-K_{pp'}+\Delta$$

where $\Delta$ is the sum of the differences in the corresponding integrals in C and $C^+$ caused by the change in the distribution of the electron cloud (the change in the effective charge, $Z$, if we consider the Slater atomic orbitals).

We will consider next the ionization of the electron in the $2p\pi$ AO in sp-hybridized carbon:

$$\begin{aligned}E&=\alpha_{d_1}+\alpha_{d_2}+\alpha_y+\alpha_z+J_{d_1y}+J_{d_1z}+J_{d_2y}+J_{d_2z}\\&\quad+J_{d_1d_2}+J_{yz}-\frac{1}{2}(K_{d_1y}+K_{d_1z}+K_{d_2y}+K_{d_2z}\\&\quad+K_{d_1d_2}+K_{yz})\\&=\alpha_s+3\alpha_p+\frac{1}{8}(J_{ss}+J_{pp})+\frac{11}{4}J_{sp}+3J_{pp'}\\&\quad-2K_{sp}-\frac{3}{2}K_{pp'},\end{aligned}$$

$$\begin{aligned}E^+&=\alpha_{d_1}^+ +\alpha_{d_2}^+ +\alpha_y^+ +J_{d_1y}^+ +J_{d_2y}^+ +J_{d_1d_2}^+\\&\quad-\frac{1}{2}(K_{d_1y}^+ +K_{d_2y}^+ +K_{d_1d_2}^+)\\&=\alpha_s^+ +2\alpha_p^+ +\frac{1}{8}(J_{ss}^+ +J_{pp}^+)+\frac{7}{4}J_{sp}^+ +J_{pp'}^+\\&\quad-\frac{3}{2}K_{sp}^+ -\frac{1}{2}K_{pp'}^+,\end{aligned}$$

$$\therefore\quad -I_p(d_1d_2yz\rightarrow d_1d_2y)=E-E^+=\alpha_p+J_{sp}+2J_{pp'}-\frac{1}{2}K_{sp}-K_{pp'}+\Delta$$

Here $d_1$ and $d_2$ are the digonal orbitals:

$$d_1=\frac{1}{\sqrt{2}}(s+x)$$

$$d_2=\frac{1}{\sqrt{2}}(s-x)$$

Therefore, if we neglect $\Delta$, $-I_p(d_1d_2yz\rightarrow d_1d_2y)$, $-I_p(sxyz\rightarrow sxy)$ and $W_z$ should be equal. The same equality can be proved for $-I_p(t_1t_2t_3z\rightarrow t_1t_2t_3)$.

There is a little difference between the ionization potentials of the various hybridization states tabulated in the references:[15]

| | $I_p$, eV. |
|---|---|
| $sxyz\rightarrow sxy$ | 11.31 |
| $d_1d_2yz\rightarrow d_1d_2y$ | 11.24 |
| $t_1t_2t_3z\rightarrow t_1t_2t_3$ | 11.22 |

It is possible to calculate the total $\pi$-electron state of the $CH_4$ molecule starting from several sets of orbitals; that is, non-hybridized (s, $p_x$, $p_y$ and $p_z$), digonally-hybridized ($d_1$, $d_2$, y and z), trigonally-hybridized ($t_1$, $t_2$, $t_3$ and z) or tetragonally-hybridized ($T_1$, $T_2$, $T_3$ and $T_4$) AO's. There are some differences in the orbital energies (the ionization potentials) of these orbitals depending on whether we choose one set of orbitals or another. For example, the ionization potential of the $2p_z$ orbital differs to some extent (see the data tabulated above) according to the choice of the set of $\sigma$-orbitals. This difference, however, may be canceled by the difference in $\sigma$-$\pi$ interaction caused by the difference in the type of $\sigma$-orbitals; if we adopt an approximation or a set of parameters in common, the calculations based on different hybridization states give the exactly same result.

In the present case, however, we adopt the $\pi$-electron approximation, so the above-mentioned cancellation does not appear exactly. Fortunately, the difference, caused by the choice of the $\sigma$-orbitals (caused by the difference in $\Delta$) is very small, and no significant effect may be expected even if we chose any value of the ionization potentials tabulated above.

# Electron Paramagnetic Resonance Study of $\gamma$-Ray Irradiated Phosphate Glasses*

By Yasuo NAKAI

(Received November 26, 1964)

In the last few years considerable progress has been made in acquiring knowledge about network defects in the glassy state by using paramagnetic resonance measurements.

Paramagnetism due both to defects produced in the lattice and to the presence of impurity atoms has been observed in irradiated quartz,[1] some silicate glasses[2] and alkali borate glasses.[3] Typical paramagnetic centers ascribed hitherto in silicate or borate glasses are an electron trapped at an oxygen vacancy, an electron trapped in the alkali ion, and a hole trapped at an oxygen ion. The paramagnetic centers described as impurity centers are a hole trapped on a bridging oxygen which is bonded to a substitutional $Al^-$ ion for silica in the silicon oxide, and an electron trapped in an interstitial hydrogen atom in a glass network.

The phosphate glasses become strongly colored under $\gamma$-ray irradiation. The most sensitive glass for irradiation is silver-activated phosphate glass. The phosphate glasses offer a simple and precise method of measuring gamma-ray doses with a commercial densitometer or a spectrophotometer.

The EPR study of the defect centers in irradiated glass containing phosphorus was first reported by Karapetyan and Yudin.[4] They observed an EPR spectra consisting of a two-line structure at $g=2.0038$. This two-line structure was attributed to hyperfine interaction with a $^{31}P$ nucleus.

In the present investigation, it has been found that there are three distinct types of defect centers in irradiated phosphate glasses. These paramagnetic centers seem to be connected with the peculiar structure of phosphate glass.

The basic structure of phosphate glass, which consists of $sp^3$ orbitals with an unsymmetric $PO_4$ tetrahedron, shows a considerable $\pi$-bond character.[5] The structure of such multiply-bonded glass is different from that of the silicate or borate glasses. Moreover, the compositions of the phosphate glasses have ratios of "modifier" oxide to phosphorus(V) oxide between one and three. In contrast, the silicate or borate glasses usually investigated have such compositions that this ratio is less than one.

In the present study, the relation between defect centers and the composition of phosphate glass will be discussed.

## Experimental

The EPR spectra were obtained by using a Varian Model 4501 EPR spectrometer at a microwave frequency of 9.4 kMc./sec. operating with a 100 kc./sec. field modulation. The EPR data presented in this study were obtained at room temperature.

The hyperfine structure of an alcoholic dilute solution of manganese(II) chloride was used as a standard for the magnetic field, and DPPH, for the $g$-value. Powder or glassy samples were enclosed in evacuated glass tubes during the $\gamma$-ray irradiation and the measurements.

The composition of alkaline phosphate glasses was $x\%M_2O(100-x)\%P_2O_5$ [M=Li, Na, K], where M/P=1.5 and 2.0, while that of alkaline earth phosphate glasses was $x\%RO(100-x)\%P_2O$ [R=Ca, Ba], where R/P=0.5 and 1.0 (in this paper weight percentages are used). These samples were melted in a platinum crucible at about 1100—1400°C. Metaalkaline phosphate glass was made from $(MPO_3)$, where M=Li, Na. The composition of the alumino alkaline phosphate glasses used in this investigation was $50\%LiPO_3 - 50\%AlPO_3$ and $80\%LiPO_3 - 20\%AlPO_3$.

Samples of condensed phosphate were prepared by the dehydration of $(RH_{1-2}PO_4)$ [R=Li, Na, K, Ca or Ba] at an elevated temperature, usually in the 500—800°C range.

The samples were irradiated at room temperature with $^{60}Co$ rays ($5—6\times10^6$ r.).

## Results

Before irradiation no paramagnetic resonance was found on any sample, but after irradiation all of them showed resonance and were purple or pink rose.

Figures 1 and 2 shows the EPR spectra of irradiated alkaline or alkaline-earth phosphate glasses. In the case of a sodium or potassium phosphate glass, the peaks of $P_a$ and $P_b$ disappear, leaving only two central peaks, $P_{c1}$ and $P_{c2}$. No spectra were observed from the sample of $(KPO)_3$-condensed phosphate irradiated with γ-rays ($5\times10^6$ r.).

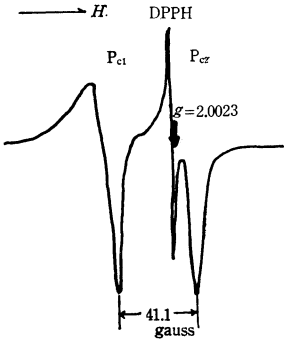

Fig. 1. The EPR spectrum obtained for γ-ray irradiated alkaline or alkaline earth phosphate glass.

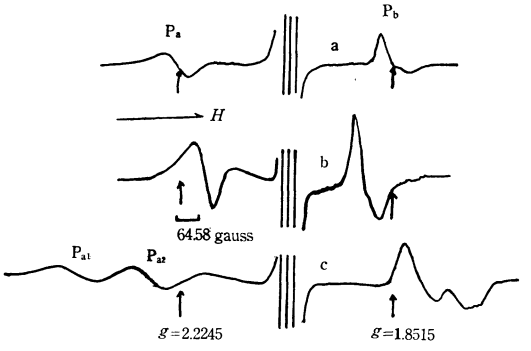

Fig. 2. The EPR spectra in low and high magnetic fields obtained for γ-ray irradiated phosphate glasses. The central lines are the spectra due to the phosphorus center shown in Fig. 1.
a) $LiPO_3$ glass
b) 10% $BaCO_3$ - 90% $LiPO_3$ glass
c) 41.3% $CaCO_3$ - 49.7% $P_2O_5$ glass

The $g$-values of the derivative peaks denoted $P_{c1}$ and $P_{c2}$ are independent of the kind of alkaline or alkaline earth modifier incorporated. These correspond to those reported by Karapetyan and Yudin.[4] The $g$-value at the center of these two peaks is measured as 2.0058. The distance between the derivative peaks, $P_{c1}$ and $P_{c2}$, is 41.1 gauss.

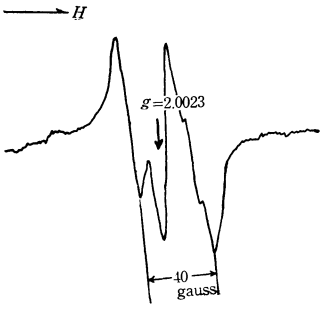

Fig. 3. The EPR spectrum obtained for γ-ray irradiated $(LiPO_3)_n$ condensed phosphate.

Figure 3 shows the EPR spectrum obtained from the irradiated condensed phosphate from which $LiPO_3$ glass was made. As a result, the difference between $LiPO_3$ glass and $LiPO_3$ condensed phosphate was found.

The intensity of the two-line structure, $P_{c1}$ and $P_{c2}$, can easily be reduced by heating it at 130—160°C. The fading speed by the thermal treatment is dependent on the kind of alkaline or alkalin-earth modifiers. The resistance to thermal bleaching increases in the order $Ca\approx Ba<Li<Na<K$. Moreover, the fading speed is dependent on the $R=M/P$ ratio. As the ratio ranges from three to one, the fading speed shows a tendency gradually to become slower. The two-line structure has the same response to both thermal annealing and optical annealing.

In addition to the two-line structure, the observed spectra appear to display other two weak absorption lines, $P_a$ and $P_b$, on the low and high magnetic field sides. Figure 2 shows that the position and the width of the anisotropic resonances, $P_a$ and $P_b$, depend greatly upon the type of alkaline or alkaline-earth ions.

The position and the width of two weak resonances in lithium phosphate glasses contaminated with calcium or barium are different from those exhibited in pure lithium phosphate glass, but the shape may be substantially the same, as Figs. 2a and 2b show.

It appears that the relative intensity of the two weak peaks increases in the order $Li<Ba\approx Ca$. Moreover, a relation exists between the radiation-induced paramagnetic intensity and the constitution of glass. As the proportion of the network-modifying atom increases in glasses, the relative intensity greatly increases. We have found that the two weak peaks are completely removed by annealing them at 380—450°C for 30 min.

It is remarkable that the derivative curve on the low magnetic field side obtained from alkaline-earth phosphate glasses consists of

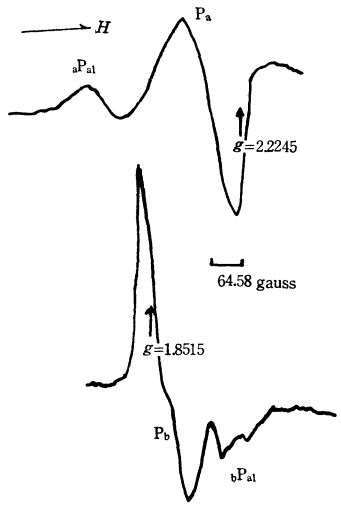

Fig. 4. The EPR spectrum obtained for $\gamma$-ray irradiated alumino phosphate glass of composition 50% $Al(PO_3)_3$ - 50% $LiPO_3$.

two peaks, as is shown in Fig. 2c. The fading speed of $P_{a1}$ to the thermal annealing may be a little more rapid than that of $P_{a2}$.

In phosphate glasses modified with such an ion as calcium, barium or lithium, the two weak resonances, $P_a$ and $P_b$, seem to appear easily.

Alumino alkaline phosphate glasses irradiated with $\gamma$-rays exhibit the same two-line structure, $P_{c1}$ and $P_{c2}$ as that displayed in $LiPO_3$ glass. The EPR intensity of the outer side peaks, ${}_aP_{a1}$ and ${}_bP_{a1}$, increases in proportion to the $Al_2O_3$ content of the $LiPO_3$ glass. However, as Fig. 4 shows, the shapes of the $P_a$ and $P_b$ centers are independent of the $Al_2O_3$ content.

## Discussion

**Alkali or Alkaline-earth Phosphate Glasses.**—The irradiated phosphate glasses exhibit the EPR spectra of two strong lines ($P_{c1}$ and $P_{c2}$) and of the other two weak absorption lines. One of the weak absorption lines appears to display a broad derivative peak on the low magnetic field side ($g=2.2245$), and the other, a broad asymmetric derivative peak on the high magnetic field side ($g=1.8575$). The former is denoted by $P_a$, and the latter, by $P_b$.

***$P_c$ Center.***—Two peaks ($P_{c1}$ and $P_{c2}$) in the derivative curve have the same response in the thermal annealing and optical bleaching, and this structure is independent of the kind of alkaline modifier and of the isotopic substitution of hydrogen. These facts suggest that the two lines arise from only one type of paramagnetic center, and so the magnetic hyperfine structure of two peaks may be ascribed to $^{31}P$ with $I=1/2$.

The observed $g$-value of the two-line structure shown in Fig. 1, which is larger than that of a free electron, suggests that the paramagnetic center is a trapped hole produced in the glass network by irradiation.

In order to analyze the observed two-line structure in terms of the hyperfine interaction of an unpaired spin, $S=1/2$, with a $^{31}P$ nucleus, it is assumed that the phosphorus center experiences a crystalline field whose symmetry is axial. If the crystalline electric field experienced by the phosphorus center were spherically symmetric or lower than axial, the shape of the derivative curve would be symmetrical or more complicated.

The spin resonance of the $(PO_4)$ defect can be described in terms of the following spin Hamiltonian:[6]

$$\mathscr{H}=\beta[g_{\parallel}S_zH_z+g_{\perp}(S_xH_x+S_yH_y)]+AS_zI_z+B(S_xI_x+S_yI_y) \quad (1)$$

where $g_{\parallel}$ and $g_{\perp}$ are the $g$ factors along and at right angles to the z direction, while A and B are the hyperfine interaction parameters of the $^{31}P$ nuclei. The $^{31}P$ nuclei ($I=1/2$) have no quadrupole moment, and the dipole-dipole interaction of neighboring centers is neglected in order to simplify the analysis of the observed hyperfine structure.

In the case of a glassy or powdered substance, $\theta$ takes random values, and the hyperfine structure is the envelope of the properly-weighted spectra obtained in simple crystals at all possible orientations.

According to the theoretical calculation,[7] the shape of the glassy spectrum, $g(H)$, is the sum of the line shape functions of $2I+1$ components as follows:

$$g(H)=\sum_{M=-I}^{I} g_M(H)$$

where $$g_M(H)=\frac{No}{2}\sin\theta\frac{d\theta}{dH}$$

The first-order hyperfine resonance condition given by the spin Hamiltonian is shown as follows:[6]

$$H=\frac{h\nu_0}{\beta}(g^2_{\parallel}\cos^2\theta+g^2_{\perp}\sin^2\theta)^{-1/2}-\frac{M}{\beta}(A^2g^2_{\parallel}\cos^2\theta+B^2g^2_{\perp}\sin^2\theta)^{1/2}\times(g^2_{\parallel}\cos^2\theta+g^2_{\perp}\sin^2\theta)^{-1} \quad (3)$$

6) B. Bleaney, *Phil. Mag.*, **42**, 441 (1951).
7) R. H. Sands, *Phys. Rev.*, **99**, 1222 (1955); S. M. Blinder, *J. Chem. Phys.*, **33**, 748 (1960); R. Neiman and D. Kivelson, ibid., **35**, 156 (1961).

Differentiating 3 with respect to $\theta$, and substituting $d\theta/dH$ in 3, we find the glassy spectrum, $g(H)$.

From the present measurements of the phosphorus center, $P_c$, which gives rise to the two-line hyperfine structure observed at the X-band frequency, we find

$$S=\frac{1}{2}, \qquad I=\frac{1}{2}$$

$$g_{\parallel}=2.0243, \quad g_{\perp}=2.0058$$

$$|A|=3.81\times10^{-3}\,\mathrm{cm}^{-1}, \quad |B|=3.75\times10^{-3}\,\mathrm{cm}^{-1}$$

This result is consistent with the two-line hyperfine structure observed in the irradiated phosphate glasses and shown in Fig. 5.

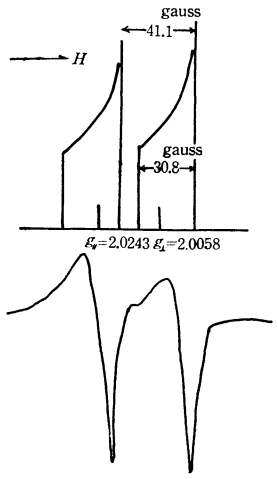

Fig. 5. Comparison between the hyperfine structure contructed from the spin Hamiltonian of Eq. 1 for the case of X-band frequency and the first derivative obtained for γ-ray irradiated phosphate glass.

As models for this resonance, two possibilities were considered: (1) a hole trapped on a singly-bonded oxygen, and (2) a hole trapped on the phosphorus atom in the $PO_4$ unit.

The wave function of the hole is assumed to occupy an orbital:

$$\Psi=\eta_P\phi_P+\eta_O\phi_O \qquad (4)$$

where $\phi_O$ and $\phi_P$ are hybrid orbitals on singly-bonded oxygen and phosphorus respectively. The coefficients are subjected to the normalizing requirements:

$$\eta^2_P+\eta^2_O+2\eta_O\eta_P S=1$$

where $S$ is the overlap, $\int\phi_P\phi_O d\tau$.

The hybrid orbital on phosphorus, $\phi_P$, is considered to consist mainly of a tetrahedral bonding orbital of the form $[(1/2)(|3s>+\sqrt{3}\,|3p>)]$, where $|3s>$ and $|3p>$ are the 3s and 3p orbitals of the phosphous that are used in the P—O covalent bonding. After γ-ray irradiation, the configuration of the $PO_4$ structure assumed to remain tetrahedral.

The hyperfine interaction parameters, $A$ and $B$, of the molecular orbital 4 with the phosphorus nucleus are related to the contact and the dipolar interaction by:[8]

$$A=\frac{1}{4}g\beta\left(\frac{\mu}{I}\right)\left[\frac{8\pi}{3}|\varphi_{3s}(0)|^2_P+\frac{12}{5}\langle r^{-3}\rangle_{3p,P}\right]\eta^2_P$$

$$B=\frac{1}{4}g\beta\left(\frac{\mu}{I}\right)\left[\frac{8\pi}{3}|\varphi_{3s}(0)|^2_P-\frac{6}{5}\langle r^{-3}\rangle_{3p,P}\right]\eta^2_P$$

where $\varphi_{3s}(0)$ denotes the wave function of the unpaired electron evaluated at the phosphorus, and $\langle r^{-3}\rangle$ is the average for the 3p orbital about the phosphorus atom.

Mayers[9] has performed a SCF treatment of the ground state phosphorus atom, and for his wave function the 3s orbital has $(8\pi/3)\times|\varphi_{3s}(0)|^2=46.93$ a. u. Similarly, Mayer's wave function gives, for the 3p orbital, $\langle r^{-3}\rangle=3.34$ a. u.

Therefore, it is possible to evaluate the hyperfine parameters of the ground-state phosphorus atom. We find that the isotropic part, $(8\pi/3)g\beta(\mu/I)|\varphi_{3s}(0)|^2$, is $0.33\,\mathrm{cm}^{-1}$; the anisotropic part, $(6/5)g\beta\times(\mu/I)\langle r^{-3}\rangle_{3p,P}$, is $2.86\times10^{-2}\,\mathrm{cm}^{-1}$, and the calculated values of the hyperfine interaction parameter, $A/\eta^2_P$ and $B/\eta^2_P$, are $96.8\times10^{-3}\,\mathrm{cm}^{-1}$ and $75.3\times10^{-3}\,\mathrm{cm}^{-1}$ respectively.

By comparing the experimental data and the calculated values of the hyperfine interaction parameters, we find $\eta_P=0.2$.

It can be seen, thus, that the experimental data obtained for the phosphorus center suggest that the hole interacting with a P nucleus is only weakly associated with the phosphorus atom. Perhaps the phosphorus center consists mainly of a hole trapped at a singly-bonded oxygen atom in the $PO_4$ unit, and the hole would spend 95—96% of its time on the oxygen and 4—5% of its time on the phosphorus atom.

The material from which $LiPO_3$ glass was made was subjected to γ-ray irradiation at room temperature. After irradiation, the spectrum shown in Fig. 3 was observed. In spite of its having the same composition, however, the position and also the shape of the EPR spectrum in the glassy state are different from those of the condensed phosphate. However, the EPR spectrum of the phosphorus center obtained at room temperature from the irradiated $(NaPO_3)_3$ of a ring structure was the same as those obtained from irradiated phosphate glasses. In the

8) See, for example, A. R. Reinberg, *J. Phys. Chem.*, **41**, 850 (1964).

9) See, J. R. Morton, *Mol. Phys.*, **6**, 193 (1963).

irradiated $(KPO_3)_n$ condensed phosphate, no paramagnetic resonance could be observed at room temperature. This point is difficults to explain.

*$P_a$ and $P_b$ Center.*—The compositions of the phosphate glasses lie between one and three in the M/P ratio. Therefore, the quantity of alkali or alkaline-earth modifier in the phosphate glasses is much larger than that in silicate or borate glasses. As the proportion of the network-modifying atom is increased, the breakdown of the phosphorus-oxygen network occurs, and the average molecular weight of the phosphate anions is found to decrease quite rapidly with time toward a moderately low limiting value. The alkaline-metal or alkaline-earth metal occasionally associates with the chain anions by attaching oxygen atoms of the "End" groups.[5]

The EPR intensity of $P_a$ and $P_b$ peaks increases in proportion to the alkaline or alkaline earth content under conditions of the same dosage. The line width, the position and the shape of resonance are dependent on the kind of alkaline or alkaline-earth incorporated. The formation of these centers becomes easier in the order $K<Na<Li<Ba\approx Ca$, and, according as the samples change from the vitreous state to the crystalline state, the formation of these centers seems to become more difficult. In the irradiated phosphate glasses of $Na/P=1$, these peaks disappear.

In the case of the alkaline-earth and alkaline-metal ions, it would be logical to expect that the tendency toward coordinate formation would increase with an increase in the charge/radius$^2$ ratio.[10] The charge/radius$^2$ ratios for $Ca^{2+}$, $Ba^{2+}$, $Li^{1+}$ and $Na^{1+}$ are 3.4, 2.6, 1.7 and 1.0 respectively. Therefore, the stability of the coordinate formation may increase in the order $Na<Li<Ba<Ca$. As has been shown by Takahashi[11] in studying the effect of network modifiers on the expansion coefficients of binary phosphate glasses, the expansion coefficient decreases in the order $K<Na<Li<Ba<Ca$, and decreases as the cation behaves as a network former rather than as a modifiers.

These facts suggest that, in phosphate glass modified with such ions as calcium, barium or lithium, which can coordinate with the tetrahedral oxygen atom in "End" groups, the weak resonance lines of two distinct types seem to appear easily; this is probably connected with the ability of coordinate formation.

In the region of the "End" group $(-PO_3)$, two, four or six nonbridging anions and some alkali cations as counter ions may be accidentally adjacent to each other, giving a localized region of excess negative charge. This configuration can trap holes.

The observed *g*-value of the $P_a$ center which is larger than that of a free electron, as is shown in Fig. 2, suggests that the paramagnetic center is a trapped hole produced in the glass network by irradiation, as in the above discussion.

In the case of irradiated alkaline-earth phosphate glass, it appears that the $P_a$ center consists of two different peaks which show a different fading speed to thermal annealing. However, the author believes that these two peaks may be the same type of center, while the electric coulombic field near these centers is different.

The *g*-value of the $P_b$ center which is smaller than that of a free electron, as is shown in Fig. 2, suggests that the paramagnetic center is the trapped electron in the vicinity of alkaline or alkaline-earth ions. The difference between the *g*-value of the $P_b$ center and the free electron value, $g=2.0023$, is contributed by the orbital magnetic moment. An electron in a paramagnetic ion is influenced not only by the applied magnetic field but also by the field due to its own orbital motion. It follows that the $P_b$ center has an appreciable amount of orbital angular momentum: a 1s hydrogen atom-like model would give a poor approximation for the wave function of the center.

The change of the line width in proportion to the measuring frequency has not been observed. However, the author believes that the *g*-value and the width depend upon the electric coulombic field near the center and on its orientation in the diamagnetic field. The shape of the resonance in lithium phosphate glass exhibited a very high symmetry. The coordination number of the $Li^+$ ion is high in the glass. Therefore, the electric field around the lithium atom in the glass network would be of a considerably high symmetry. In contrast, the coordination number of the alkaline-earth ion is low. The electric field would be of a low symmetry. The shape of barium or calcium phosphate glass was observed to be of low symmetry.

In lithium phosphate glass containing a small quantity of an alkaline-earth modifier as an impurity, the position and the width of the resonance are different from that displayed in pure lithium phosphate glass, but the shape is substantially the same, as Figs. 2a and 2b

show. If the resonances of the lithium center and the barium center are observed independently, these types of resonances would appear. Therefore, the electric field created by the oxygen atoms that are in the sphere around the lithium atom would be changed by the addition of an alkaline-earth impurity.

In short, the defect center in glass should be discussed from the viewpoint of the dynamic state of the glass structure and the stability of the glass structure.

**Alumino Phosphate Glasses.** — The network in aluminophosphate glasses is said to be formed by the interlinking of $(AlO_4)^{5-}$ and $(PO_4)^{3-}$ groups via bridging oxygens.[5]

A paramagnetic center due to hyperfine interaction with the nucleus of a four-co-ordinated aluminum ion has been observed in irradiated alumino silicate glasses and a single crystal of qurtz contaminated with aluminum ions, and the aluminum center has exhibited a spectrum consisting of a six-line structure in the vicinity of $g=2.010$.[1,2]

In the present investigation, thus, it was to be expected that a broad resonance caused by such a hyperfine interaction with a phosphorus and an aluminum nucleus would appear in the vicinity of $g=2.01$. However, samples of alumino alkaline phosphate glasses irradiated with γ-rays were not found to exhibit a six-line structure with a $g$-value of ca. 2.01. The formation of a paramagnetic center due to a four-co-ordinated aluminum atom in phosphate glasses would be protected against γ-ray irradiation.

In contrast, the EPR intensity of the outer side, ${}_aP_{a1}$ and ${}_bP_{a1}$, increases in proportion to the aluminum oxide content of the glass. The EPR spectra of these outer sides may arise from the defect centers due to the interstitial aluminum.

## Summary

The EPR spectrum, consisting of a two-line structure and two other distinct types of weak resonances, obtained from irradiated phosphate glasses suggests that these paramagnetic centers are connected with the peculiar structure of phosphate glasses.

The two-line structure arises from an axially-symmetric hyperfine interaction of a hole with a $^{31}P$ nucleus. Two distinct types have been demonstrated: one is a trapped hole produced in the glass network, and the other is the trapped electron in the alkaline or alkaline-earth ion. In phosphate glasses modified with such ions as calcium, barium or lithium that can coordinate with the tetrahedral oxygen atom in "End" groups ($-PO_3$), the weak resonances seem to appear easily.

The author wishes to express his thanks to Professor Kozo Hirota and Associate Professor Keiji Kuwata of Osaka University for their helpful advice and kind encouragement throughout this work. The author would also like to express his deep thanks to Dr. A. R. Weeks of the Oak Ridge National Laboratory and to Professor P. J. Bray of Brown University for reading the manuscript.

# Theory of Solvent Effects on Molecular Electronic Spectra. Frequency Shifts

By Takehiko ABE

(Received November 26, 1964)

Several quantitative theories[1-9] have been presented for solvent effects on electronic spectra. These theories give good theoretical interpretations for observed frequency shifts, but they can be used only with difficulty to calculate general frequency shifts, since their expressions are either very complicated or only applicable to non-polar solvents.

In the present work, by the application of the van der Waals interaction, an attempt has been made to derive a general theoretical expression for the frequency shifts, from which expression the frequency shifts can be calculated by the use of other observed values.

Among the solvent effects on the electronic spectra, there is the important effect of hydrogen bonding between a solute and solvent molecules found by Nagakura and Baba.[10] In the present theory, however, this effect has not been considered.

## Theoretical

The method of treatment consists of the application of the van der Waals interaction to the calculation of the electronic interactions among molecules of a solution containing N identical solvent molecules and one solute molecule. The spectra of solutions are usually measured at very low concentrations in the longer wavelength regions in which no solvents absorb. We will, therefore, consider the $i$th excited electronic state of the solution in which the solute molecule is in its $i$th excited electronic state and all the solvent molecules are in their ground states. We will suppose that all the spherical molecules have fixed positions. In view of the Franck-Condon principle, the same positions are appropriate to the ground and excited states of the solution.

In the zeroth order of approximation, we consider that all the spherical isotropic molecules do not interact. The zeroth-order electronic state energies are sums of the electronic state energies of the unperturbed component molecules; the energies corresponding to the ground and excited states of the solution are given, respectively, by:

$$E_0^0 = w_0^{\mathrm{u}} + Nw_0^{\mathrm{v}}$$
$$E_i^0 = w_i^{\mathrm{u}} + Nw_0^{\mathrm{v}}$$

where $w$ denotes the electronic state energy of an unperturbed molecule. Throughout this paper the notations u and v($p$) will refer to the solute and the $p$th solvent molecule, while the subscript zero will indicate the ground electronic state, and $i$, the $i$th excited electronic state. Thus, the energy difference in $cm^{-1}$ between the zeroth and $i$th states of the solute in gas will be expressed by:

$$\nu_{i0}^0 = (w_i^{\mathrm{u}} - w_0^{\mathrm{u}})/\boldsymbol{hc} \qquad (1)$$

where $\boldsymbol{h}$ is the Planck constant and $\boldsymbol{c}$, the velocity of light.

Assuming that there are no strong dipole orientations among the molecules, we represent the energy of the interaction of all the molecules in solution by the energy of the van der Waals interaction,[11] which is given by:

$$\begin{aligned} E_i' = &-\sum_{p=1}^{N} \frac{1}{R_{\mathrm{u}\mathrm{v}(p)}^6} \left\{ \frac{2}{3} \cdot \frac{(\mu_i^{\mathrm{u}})^2 (\mu_0^{\mathrm{v}(p)})^2}{\boldsymbol{kT}} \right. \\ &+ (\alpha_i^{\mathrm{u}})(\mu_0^{\mathrm{v}(p)})^2 + (\alpha_0^{\mathrm{v}(p)})(\mu_i^{\mathrm{u}})^2 \\ &\left. + \frac{3}{2} \cdot \frac{I_i^{\mathrm{u}} \cdot I_0^{\mathrm{v}(p)}}{I_i^{\mathrm{u}} + I_0^{\mathrm{v}(p)}} \cdot (\alpha_i^{\mathrm{u}})(\alpha_0^{\mathrm{v}(p)}) \right\} \\ &- \frac{1}{2} \sum_{p=1}^{N} \sum_{q=1}^{N} \frac{1}{R_{\mathrm{v}(p)\mathrm{v}(q)}^6} \left\{ \frac{2}{3} \cdot \frac{(\mu_0^{\mathrm{v}(p)})^2 (\mu_0^{\mathrm{v}(q)})^2}{\boldsymbol{kT}} \right. \\ &+ (\alpha_0^{\mathrm{v}(p)})(\mu_0^{\mathrm{v}(q)})^2 + (\alpha_0^{\mathrm{v}(q)})(\mu_0^{\mathrm{v}(p)})^2 \\ &\left. + \frac{3}{2} \cdot \frac{I_0^{\mathrm{v}(p)} \cdot I_0^{\mathrm{v}(q)}}{I_0^{\mathrm{v}(p)} + I_0^{\mathrm{v}(q)}} \cdot (\alpha_0^{\mathrm{v}(p)})(\alpha_0^{\mathrm{v}(q)}) \right\} \qquad (2) \end{aligned}$$

where $R$ denotes the distance between two molecules in solution, and $I$, the ionization potential of an unperturbed molecule in gas.

Here $k$ is the Boltzmann constant, and $T$ is the absolute temperature.

The energy of the perturbed $i$th excited state of the solution, corresponding in the zeroth order of approximation to the unperturbed $i$th excited state, is given by:

$$E_i = E_i^0 + E_i' \tag{3}$$

A similar expression for the ground state of the solution is obtained by replacing $i$ by 0. The frequency shift, $\Delta\nu_{i0}$, is given by:

$$hc\cdot\Delta\nu_{i0} = (E_i - E_0) - (E_i^0 - E_0^0) \tag{4}$$

With the aid of Eq. 3, Eq. 4 can be written:

$$hc\cdot\Delta\nu_{i0} = E_i' - E_0' \tag{5}$$

The ionization potential of the $i$th excited state of the solute molecule is approximated as smaller than that for the ground state by $hc\nu_{i0}^0$ erg. We then obtain for $I_i^u$ (in erg):

$$I_i^u = I_0^u - hc\nu_{i0}^0 \tag{6}$$

From the assumption that all the spherical solvent molecules are identical, it follows that they have identical dipole moments of $\mu_0^v$ (gas) and identical ionization potentials of $I_0^v$. From Eqs. 2, 5 and 6, we find:

$$hc\cdot\Delta\nu_{i0} = -\left(\sum_{p=1}^{N} 1/R_{uv(p)}^6\right)\left[\frac{2}{3}\cdot\frac{(\mu_0^v)^2}{kT}\{(\mu_i^u)^2 - (\mu_0^u)^2\} + (\mu_0^v)^2\{(\alpha_i^u) - (\alpha_0^u)\} + (\alpha_0^v)\{(\mu_i^u)^2 - (\mu_0^u)^2\} + \frac{3}{2}\cdot(\alpha_0^v)\cdot I_0^v\left\{\frac{I_0^u - hc\nu_{i0}^0}{I_0^v + I_0^u - hc\nu_{i0}^0}\cdot(\alpha_i^u) - \frac{I_0^u}{I_0^v + I_0^u}\cdot(\alpha_0^u)\right\}\right] \tag{7}$$

**The Reduction of** $\left(\sum_{p=1}^{N} 1/R_{uv(p)}^6\right)$. — If the solute and the solvent molecules are spherical, their radii can be written, respectively, as:

$$r^u = (3M^u/4\pi A_0 d^u)^{1/3} \tag{8}$$

$$r^v = (3M^v/4\pi A_0 d^v)^{1/3} \tag{9}$$

Here $A_0$ is the Avogadro number; $M$, a molecular weight, and $d$, a liquid density. We then have for the values of $R_{uv(p)}$:

$$(r^u + r^v),\ (r^u + 3r^v),\ (r^u + 5r^v), \cdots$$

The numbers of the solvent molecules at the distances corresponding to the above values of $R_{uv(p)}$ may be approximated as, respectively:

$$\frac{4\pi(r^u + r^v)^2}{(2r^v)^2},\ \frac{4\pi(r^u + 3r^v)^2}{(2r^v)^2},\ \frac{4\pi(r^u + 5r^v)^2}{(2r^v)^2}, \cdots$$

We then write:

$$\sum_{p=1}^{N}\frac{1}{R_{uv(p)}^6} = \frac{4\pi(r^u + r^v)^2/(2r^v)^2}{(r^u + r^v)^6} + \frac{4\pi(r^u + 3r^v)^2/(2r^v)^2}{(r^u + 3r^v)^6} + \frac{4\pi(r^u + 5r^v)^2/(2r^v)^2}{(r^u + 5r^v)^6} + \cdots \tag{10}$$

where we can neglect terms higher than the third, so that we derive, approximately:

$$\sum_{p=1}^{N} 1/R_{uv(p)}^6 = \frac{\pi}{(r^v)^2}\{(r^u + r^v)^{-4} + (r^u + 3r^v)^{-4} + (r^u + 5r^v)^{-4}\} \tag{11}$$

**General Formula.**—From Eqs. 7, 8, 9 and 11, we obtain, for the frequency shift in an absorption transition from the ground state to the $i$th excited state of an isotropic molecule:

$$\Delta\nu_{i0} = -\frac{16\pi^3 A_0^2}{9hc}\cdot\left(\frac{d^v}{M^v}\right)^{2/3}\times\left[\left\{\left(\frac{M^u}{d^u}\right)^{1/3} + \left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4} + \left\{\left(\frac{M^u}{d^u}\right)^{1/3} + 3\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4} + \left\{\left(\frac{M^u}{d^u}\right)^{1/3} + 5\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}\right]\times\left[\frac{2}{3}\cdot\frac{(\mu_0^v)^2}{kT}\{(\mu_i^u)^2 - (\mu_0^u)^2\} + (\mu_0^v)^2\{(\alpha_i^u) - (\alpha_0^u)\} + (\alpha_0^v)\{(\mu_i^u)^2 - (\mu_0^u)^2\} + \frac{3}{2}\cdot(\alpha_0^v)\cdot I_0^v\left\{\frac{I_0^u - hc\nu_{i0}^0}{I_0^v + I_0^u - hc\nu_{i0}^0}\cdot(\alpha_i^u) - \frac{I_0^u}{I_0^v + I_0^u}\cdot(\alpha_0^u)\right\}\right] \tag{12}$$

where $16\pi^3 A_0^2/9hc = 1.007\times10^{65}$ erg$^{-1}$ cm$^{-1}$ and $2/3kT = 1.647\times10^{13}$ erg$^{-1}$ at 20°C.

**Approximate Formula.** — It is well-known that a molecular deformation polarization is approximately equal to a molecular refraction. We, therefore, have:

$$\alpha_0^v = \frac{3}{4\pi A_0}\cdot[R]^v \tag{13}$$

where $[R]^v$ denotes the molecular refraction of the solvent, which can be calculated as a sum of the atomic refractions from a table.

The values of $\alpha_i^u$ and $\mu_i^u$ are for the solute molecule in gas. According to the Clausius-Debye equation, we have:

$$\alpha_0^u = \frac{3}{4\pi A_0}\cdot\frac{M^u}{d_0^{u(g)}}\cdot\frac{\varepsilon_0^u - 1}{\varepsilon_0^u + 2} - \frac{(\mu_0^u)^2}{3kT} \tag{14}$$

$$\alpha_i^u = \frac{3}{4\pi A_0}\cdot\frac{M^u}{d_i^{u(g)}}\cdot\frac{\varepsilon_i^u - 1}{\varepsilon_i^u + 2} - \frac{(\mu_i^u)^2}{3kT} \tag{15}$$

where $d^{u(g)}$ and $\varepsilon^u$ denote the density and the dielectric constant of the solute in gas respectively.

On the assumption that all the molecules have the same positions in the ground and excited states of the solution, we may write:

$$d_0^{u(g)} = d_i^{u(g)} \tag{16}$$

From $I_0^u - h c \nu_{i0}^0 < I_0^u$, we may suppose the following inequality, since $I_0^v + I_0^u - h c \nu_{i0}^0 > I_0^u - h c \nu_{i0}^0$, although $I_0^v + I_0^u - h c \nu_{i0}^0 < I_0^v + I_0^u$:

$$\frac{I_0^u - h c \nu_{i0}^0}{I_0^v + I_0^u - h c \nu_{i0}^0} < \frac{I_0^u}{I_0^v + I_0^u} \tag{17}$$

It may be assumed that the dielectric constant of the excited state of the solute is greater than that for the ground state; that is:

$$\varepsilon_i^u > \varepsilon_0^u$$

From Eqs. 17 and 18, we may assume the following approximation:

$$\frac{I_0^u - h c \nu_{i0}^0}{I_0^v + I_0^u - h c \nu_{i0}^0} \cdot \frac{\varepsilon_i^u - 1}{\varepsilon_i^u + 2} = \frac{I_0^u}{I_0^v + I_0^u} \cdot \frac{\varepsilon_0^u - 1}{\varepsilon_0^u + 2} \tag{19}$$

Using Eqs. 13, 14, 15, 16 and 19, we may reduce Eq. 12 approximately to:

$$\begin{aligned} \Delta\nu_{i0} = & -\frac{4\pi^2 A_0}{3hc} \cdot \left(\frac{d^v}{M^v}\right)^{2/3} \times \left[ \left\{ \left(\frac{M^u}{d^u}\right)^{1/3} + \left(\frac{M^v}{d^v}\right)^{1/3} \right\}^{-4} + \left\{ \left(\frac{M^u}{d^u}\right)^{1/3} + 3\left(\frac{M^v}{d^u}\right)^{1/3} \right\}^{-4} \right. \\ & \left. + \left\{ \left(\frac{M^u}{d^u}\right)^{1/3} + 5\left(\frac{M^v}{d^v}\right)^{1/3} \right\}^{-4} \right] \times \left[ \frac{4\pi A_0}{9kT} \cdot \right. \\ & (\mu_0^v)^2 \{(\mu_i^u)^2 - (\mu_0^u)^2\} + [R]^v \{(\mu_i^u)^2 - (\mu_0^u)^2\} \\ & - \frac{1}{2kT} \cdot I_0^v \cdot [R]^v \cdot \left\{ \frac{I_0^u - h c \nu_{i0}^0}{I_0^v + I_0^u - h c \nu_{i0}^0} \cdot (\mu_i^u)^2 \right. \\ & \left. \left. - \frac{I_0^u}{I_0^v + I_0^u} \cdot (\mu_0^u)^2 \right\} \right] \end{aligned} \tag{20}$$

where $4\pi^2 A_0/3hc = 3.992 \times 10^{40}\ \mathrm{erg^{-1}\,cm^{-1}}$, $4\pi A_0/9kT = 2.078 \times 10^{37}\ \mathrm{erg^{-1}}$, and $1/2kT = 1.236 \times 10^{13}\ \mathrm{erg^{-1}}$ at 20°C.

## Discussion

Assuming that all the molecules in the solution are spherical, we have derived Eqs. 12 and 20. Accordingly, these equations are not applicable to rod-like molecules. For the rod-like molecules, the values of $\sum_{p=1}^{N} 1/R_{uv(p)}^6$ must be otherwise estimated.

Equations 12 and 20 are limited for use to solutions in which no complete dipole orientations occur between solutes and solvent molecules, because Eq. 2 includes the isotropic polarizabilities. These equation, however, hold for the solutions in which there are strong dipole orientations among the solvent molecules, because Eq. 5 excludes this effect. When there is a complete dipole orientation between a solute and the solvent molecules, anisotropic polarizabilities must be used instead of the isotropic ones and Eq. 11 can not be applied.

When the frequency shifts are small, Eqs. 12 and 20 cannot be applied quantitatively, since the above assumptions do not hold.

When there is a small orientation effect between a solute and the solvent molecules, $\Delta\nu_{i0}^0$ is chiefly governed by the third term of the dispersion effect in the second bracket in Eq. 12. Accordingly, in order to calculate $\mu_i^u$, it is better to apply Eq. 12 to the polar solvents, since the first term of the orientation effect in the second bracket is included.

As has been mentioned above, Nagakura and Baba[10] have found that the hydrogen bonding causes the frequency shifts. Since Eqs. 12 and 20 do not include this effect, they will give the deviated $\Delta\nu_{i0}$ from the observed frequency shift for a polar solvent forming a hydrogen bond with a solute. This deviation may be due to the hydrogen bonding.

**The Relationship Between $\Delta\nu_{i0}$ and the Refractive Index and the Dielectric Constant of the Solvent.** — Considering that all the molecules do not interact in the zeroth order approximation, we have derived Eqs. 12 and 20. When we consider an unperturbed solute molecule and the solvent molecules already interacting with one another in the zeroth order approximation, we must write:

$$\begin{aligned} E_i' = -\sum_{p=1}^{N} \frac{1}{R_{uv(p)}^6} \left\{ \frac{2}{3} \cdot \frac{(\mu_i^u)^2 (\mu_0^{v(p)})^2}{kT} \right. \\ + (\alpha_i^u)(\mu_0^{v(p)})^2 + (\alpha_0^{v(p)})(\mu_i^u)^2 \\ \left. + \frac{3}{2} \cdot \frac{I_i^u \cdot I_0^{v(p)}}{I_i^u + I_0^{v(p)}} \cdot (\alpha_i^u)(\alpha_0^{u(p)}) \right\} \end{aligned} \tag{21}$$

where $\mu_0^{v(p)}$ is the dipole moment, $\mu_0^{v(l)}$, of the liquid solvent. By the same procedure we obtain the same final formulae as Eqs. 12 and 20. According to Onsager,[12] the dipole moment of the liquid solvent is given approximately by:

$$(\mu_0^{v(l)})^2 = \frac{9kT}{4\pi A_0} \cdot \frac{M_v}{d^v} \cdot \frac{\{\varepsilon^v - (n^v)^2\}\{2\varepsilon^v + (n^v)^2\}}{\varepsilon^v \{(n^v)^2 + 2\}^2} \tag{22}$$

Here $\varepsilon^v$ and $n^v$ denote the static dielectric constant of the solvent, and its refractive index extrapolated to zero frequency, respectively.

It is well-known that the molecular refraction can be expressed by:

$$[R]^v = \frac{(n^v)^2 - 1}{(n^v)^2 + 2} \cdot \frac{M^v}{d^v} \tag{23}$$

For example, by putting Eqs. 22 and 23 into the same form as Eq. 20, we obtain:

12) L. Onsager, *J. Am. Chem. Soc.*, **58**, 1486 (1936).

TABLE I. THE $\pi$-$\pi^*$ TRANSITION (240 m$\mu$) IN NITROBENZENE

| No. | Solvent | $\nu_{max}$(cm$^{-1}$) | $\mu_0$(D, gas)[15] | $\alpha_0\times10^{25}$(cm$^3$)[15] | $I_0$(eV.) |

| 4 | Dioxane | 38650[13] | 0 | 94.4 | 9.52[17] |
| 5 | Chloroform | 38150[14] | 1.05 | 82.3 | 11.5[15] |

$$\Delta\nu_{i0}=-\frac{4\pi^2A_0}{3hc}\cdot\left(\frac{M^v}{d^v}\right)^{1/3}\times\left[\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}+\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+3\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}+\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+5\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}\right]\times\left[\frac{\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}\cdot\{(\mu_i^u)^2-(\mu_0^u)^2\}+\frac{(n^v)^2-1}{(n^v)^2+2}\{(\mu_i^u)^2-(\mu_0^u)^2\}-\frac{1}{2kT}\cdot\frac{(n^v)^2-1}{(n^v)^2+2}\cdot I_0^v\left\{\frac{I_0^u+hc\nu_{i0}^0}{I_0^v+I_0^u-hc\nu_{i0}^0}\cdot(\mu_i^u)^2-\frac{I_0^u}{I_0^v+I_0^u}\cdot(\mu_0^u)^2\right\}\right] \quad (24)$$

where the refractive index may be replaced approximately by the value appropriate to the sodium-D line.

## Application

**The Application of Eq. 12 to Nitrobenzene.** —The frequency shifts of the 239.9 m$\mu$ band of nitrobenzene in solvents and the other observed values to be used are listed in Table I. The values of $d$ from Lange's table[18] and other sources were used for 20°C. Assuming that the temperature is 20°C, the author can apply Eq. 12 to nitrobenzene. By means of the least square method, $\alpha_i^u$ and $\mu_i^u$ are estimated as $580.7\times10^{-25}$ cm$^3$ and 8.18 D respectively. Putting the above values into Eq. 12, the author obtained a good agreement in the frequency shifts between the theoretical and the experimental results, as is indicated in Fig. 1. The finding that the dipole moment of the excited state caused by the 240 m$\mu$ transition in nitrobenzene is greater than that for the ground state is consistent with Nagakura and Tanaka's theory.[19] They have interpreted the band of nitrobenzene in terms of the intramolecular charge-transfer involving an excitation of a bonding electron of the highest-occupied orbital of benzene to the vacant orbital of the nitro group. Bayliss and McRae[15,20] have also mentioned that there is a greater dipole moment in the excited state of nitrobenzene.

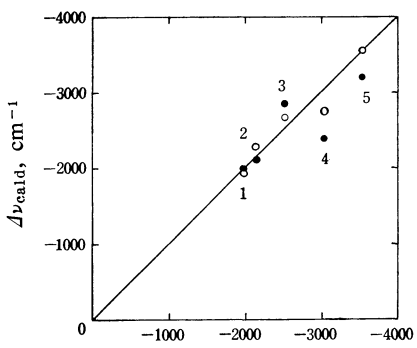

Fig. 1. Calculated vs. observed frequency shifts in the 240 m$\mu$ band of nitrobenzene.
○ calculated from Eq. 12
● calculated from Eq. 20

**The Application of Eq. 20 to Nitrobenzene.**— Equation 20 is applied to the frequency shift of the 240 m$\mu$ band of nitrobenzene at 20°C. The values of $[R]^v$ were calculated from a table. By putting the observed shift for *n*-heptane into Eq. 20, the author estimated $\mu_i^u$ to be 4.67 D, and then, using that value, he calculated the frequency shifts for other solvents, as Fig. 1 indicates. The $\mu_i^u$ value of 4.67 D is considerably smaller than that obtained from Eq. 12. The points calculated from Eq. 20 are also worse fitted to the full straight line than those calculated from Eq. 12, as is shown in Fig. 1.

**The Application of Eq. 20 to Acetophenone.** —The frequency shifts of the 231.3 m$\mu$ band of acetophenone in non-polar solvents are listed in Table II.

TABLE II. THE $\pi$-$\pi^*$ TRANSITIONE IN ACETOPHENONE

| Solvent | $\nu_{max}$ ($cm^{-1}$)[13] |
|---|---|
| Acetophenone (gas) | 43230 |
| *n*-Heptane | 41980 |
| Cyclohexane | 41940 |

The ionization potential of acetophenone is 9.77 eV.[15] Putting the observed shifts into Eq. 20 at 20°C, the author has estimated $\mu_0^u$ and $\mu_i^u$ to be 3.81 and 4.42 D respectively. The value of 3.81 D accords fairly with the experimental value of 3.00 D (gas).[15] The result of $\mu_i^u > \mu_0^u$ is consistent with the intramolecular charge-transfer band[19,21,22] and with Bayliss and McRae's interpretation.[20]

The author is particularly indebted to Professor Hiroshi Azumi and Professor Yoshito Amako for their discussions with him.

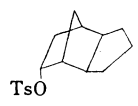
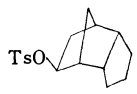
# The Solvolysis of 5, 6-Trimethylene-2-norbornyl *p*-Toluenesulfonates. Evidence for the Formation of Classical Carbonium Ion Intermediates in the Solvolysis

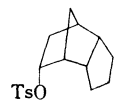


By Ken'ichi TAKEUCHI, Takao OSHIKA and Yuzo KOGA

(Received November 27, 1964)

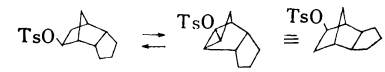


Kinetic studies of the solvolysis of four isomeric 5, 6-trimethylene-2-norbornyl *p*-toluenesulfonates (I, II, III and IV) were carried out by Bartlett and Barnes.[2] These authors observed that these isomers obeyed good first-order kinetics in glacial acetic acid, absolute ethanol, and 80% ethanol, and that the first-order rate constants were different with each isomer.



I

II



III

IV

These results have been interpreted as indicating that the isomers are not interchanged during solvolysis.[2b,3] However, Winstein and Trifan observed that the rate of the racemization of optically-active *exo*-2-norbornyl *p*-bromobenzenesulfonate exceeds the rate of the formation of *p*-bromobenzenesulfonic acid.[4] This was explained by the mechanism involving internal return. Accordingly, when we consider the solvolyses of I and III, it is conceivable that isomerization between I and III would occur.

(III) (I)

On the other hand, Cristol and his coworkers[3] reported that the addition of methanol to *endo*- and *exo*-5, 6-trimethylenenorbornene, in the presence of sulfuric acid, yielded products with different compositions. This seems to suggest that two different precursors exist in these systems.

The purposes of this study were to test the previous work[2] and to clarify the behavior of I and III during solvolysis. We also hoped to examine the propriety of explaining the solvolysis of these systems by the non-classical carbonium ion mechanism which has been proposed by Bartlett and Barnes.[2]

## Results and Discussion

**The Preparation and Characterization of *endo*-5, 6-Trimethylene-*exo*-2-norbornyl *p*-Toluenesulfonate (III).**—The *p*-toluenesulfonate III was prepared by the usual method of treating the corresponding alcohol with *p*-toluenesulfonyl chloride in pyridine at 0°C overnight.

Surprisingly enough, the III synthesized by us exhibited a melting point of 76.5—77.0°C instead of 48—49°C or 49—50.5°C, as Bartlett and Barnes[2] or Cristol et al.[3] respectively had reported. The analytical data agreed well with the calculated values, and NMR and infrared spectra also showed that our III should have the assigned structure.[5] A detailed investigation of the melting-points diagram of the mixtures of I and III, as shown in Fig. 1, indicated that an eutectic mixture has a melting point of ca. 50°C.

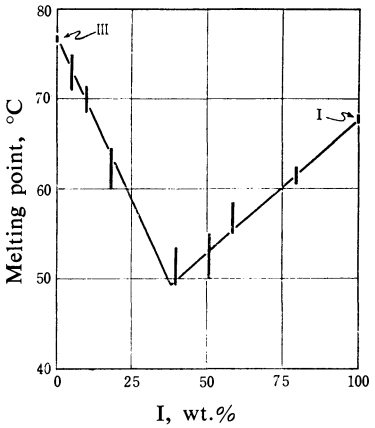

Fig. 1. Melting point diagram for mixtures of I and III.

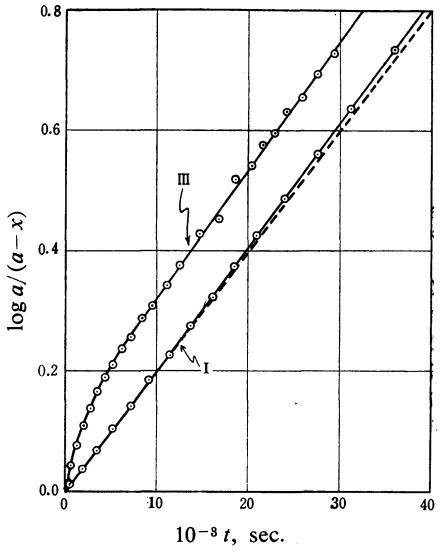
These results suggested that the III prepared by the authors was pure, while those described in previous articles[2,3] were mixtures of I and III.

**The Kinetics of the Solvolyses of I and III in Methanol.**—The solvolyses of I and III were followed titrimetrically to approximately 90% completion in methanol at 59.7°C. The plots of $\log a/(a-x)$ vs. the reaction time for the methanolyses of I and III are shown in Fig. 2.

In the case of I, the first-order plot was almost linear to about 53% reaction, but afterwards a slight upward drift was observed.[6] On the other hand, the first-order plot for III showed a considerable downward drift to 44% reaction,[7] and then it became linear, which was nearly parallel to what had been calculated



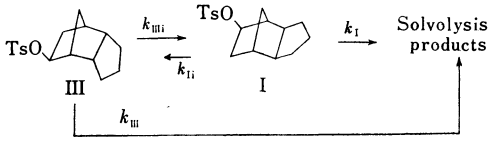


Fig. 2. Solvolysis rates of I and III in absolute methanol at 59.7°C.
[Tosylate]$_0$=0.1000 M

for I between 50 and 90% reaction. These observations suggested that III solvolyzed and isomerized simultaneously in methanol and that isomerization was essentially complete by approximately 44% reaction. This was verified by isolating unsolvolyzed *p*-toluenesulfonate and by observing its melting point and infrared spectrum

The solvolytic behavior of the isomeric *p*-toluenesulfonates I and III are summarized by the following scheme:

Scheme 1

That the first-order plot for the solvolysis of I showed a slight upward drift after 53% reaction indicates that a small portion of I also isomerized to III.

This behavior is very analogous to the solvolysis of $\alpha,\alpha$-dimethylallyl chloride, which proceeds with a concurrent intramolecular isomerization to primary chloride $\gamma,\gamma$-dimethylallyl chloride;[8] thus, the same kinetic procedure was used in this work to calculate the

5) See "Experimental" section.

6) Similar trends were observed for the solvolyses in acetic acid and ethanol.

7) In acetolysis, the first-order plot became linear after about 23% reaction, and in ethanolysis, after about 29% reaction.

8) W. G. Young, S. Winstein and H. L. Goering, *J. Am. Chem. Soc.*, **73**, 1958 (1951). Similar behavior was found in the solvolysis of bicyclo(2.2.2)octan-2-yl *p*-toluenesulfonate (H. L. Goering and M. F. Sloan, *J. Am. Chem. Soc.*, **83**, 1992 (1961)) and of *exo*-4-*syn*-8-dichlorodibenzobicyclo(3.2.1)octadiene (S. J. Cristol and D. D. Tanner, *J. Am. Chem. Soc.*, **86**, 3122 (1964)).

specific rate of the solvolysis of III and that of the isomerization of III to I. Table I gives the data for a representative kinetic run for III.

a) Instantaneous first-order rate constant.
b) Values obtained from integrated equation for a first-order reaction, using a starting point after equilibration is attained: $t=8400$ sec.; [Tosylate]$=0.0515$ M.
c) Extrapolated value.

By extrapolating the instantaneous rate constants to 0% reaction, the first-order rate constant for solvolysis ($k_{III}$) was estimated to be approximately $16.9\times10^{-5}$ $sec^{-1}$. The rate constant after equilibration was calculated from the integrated equation ($k_{IIIe}=(1/t)\ln a/(a-x)$), using a starting point after equilibration had been attained. The estimated value was $(4.92\pm0.08)\times10^{-5}$ $sec^{-1}$. On the other hand, the first-order rate constant for isomerization ($k_{IIIi}$) was found to be approximately $37\times10^{-5}$ $sec^{-1}$ by calculating ($k_{III}+k_{IIIi}$) (the procedure is shown in Fig. 3).

For the methanolysis of I, the rate constants before 50% ($k_I$) and after 55% reaction ($k_{Ie}$) were calculated to be $(4.59\pm0.03)\times10^{-5}$ and $(4.81\pm0.04)\times10^{-5}$ $sec^{-1}$ respectively. From these rate constants, the mole fraction of III, $F$, after equilibration was calculated from Eq. 1[8] to be 2—3%;

$$F=(k-k_I)/(k_{III}-k_I) \quad (1)$$

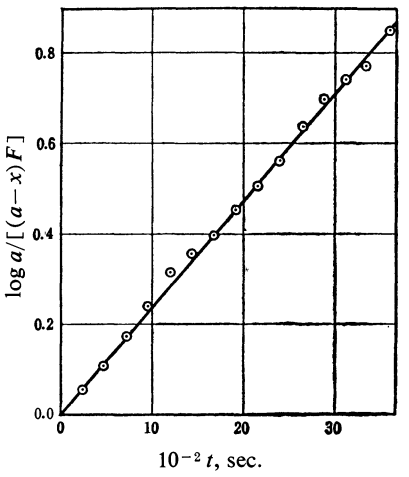

Fig. 3. Calculation of ($k_{III}+k_{IIIi}$) for the methanolysis of III at 59.7°C.
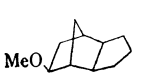
$F=(k-k_I)/(k_{III}-k_I)$ : cf. Ref. 8
$k_{III}+k_{IIIi}=54\times10^{-5}$ $sec^{-1}$

where $k$ is $k_{Ie}$ or $k_{IIIe}$.



The first-order rate constants of the solvolyses and isomerizations of I and III are summarized in Table II.

**The Distributions of Products from Methanolyses of *exo*- and *endo*-5, 6-Trimethylene-*exo*-2-norbornyl *p*-Toluenesulfonates (I and III).**— The distributions of products from methanolyses of I and III at an infinite reaction time have been investigated by Cristol et al.[3,9] by means of the v. p. c. technique; it has thus been revealed that the products are composed of a large portion of V and a small portion of VI, and that no other product is yielded. These authors reported that I and III yielded VI in essentially identical amounts.

V

VI

In the present study, the distributions of products from the methanolyses of I and III

⊙, from III; ⊡, from I;
Dotted line, calculated by Eq. 5

at various percentages of reaction were also determined by the v.p.c. technique. The products were composed of a large portion of V and a small portion of VI; no other product was detected. The results are shown in Table III and Fig. 4.

The distributions of products at an infinite reaction time differed between isomeric *p*-toluenesulfonates I and III; moreover, in the case of III, the percentage of VI in the solvolysis products decreased from 7.3% at 5% reaction to 4.4% at completion (100%). On the other hand, VI in the products from the methanolysis of I was approximately constant (ca. 3.2%) throughout the reaction.

These results show that the distribution of the direct products from III is different than in the case of I. The decrease in the percentage of VI obtained from the methanolysis of III may be attributed to the occurrence of the solvolysis of I which was formed from III through isomerization.

These results were further confirmed by being duplicated with those of isomerization as follows. The solvolytic behavior of III may be described by the following scheme:

Scheme 2

Since it is reasonable to assume $k_{I_i}$ to be negligibly small, the sum ($x$) of isomerized and solvolyzed III may be obtained by Eq. 2, where $a$ is the initial concentration of III:

$$x=a(1-e^{-(k_{III_i}+k_{III})t}) \quad (2)$$

Then the concentration of $P_n$ is defined by Eq. 3:

$$P_n=a(k_{III}/(k_{III_i}+k_{III}))(1-e^{-(k_{III_i}+k_{III})t}) \quad (3)$$

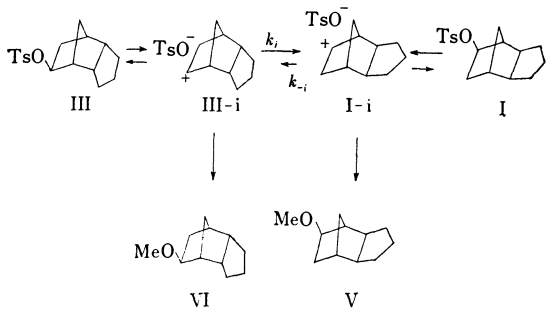
By dividing $P_n$ by the titrimetric conversion, it is possible to derive the fraction of product which is produced from III itself, which is given by Eq. 4:

$$P_n/(P_n+P_x)=\frac{(k_{III}/(k_{III_i}+k_{III}))(1-e^{-(k_{III_i}+k_{III})t})\times 10^2}{\text{Titrimetric conversion (\%) at time } t} \quad (4)$$

When we estimate that the VI values in $P_n$ and $P_x$ are 7.3 and 3.2% respectively, by means of extrapolation in Fig. 4, it is possible to estimate the percentage of VI in the products at any reaction time by Eq. 5:

$$\text{VI in the solvolysis products (\%)}=7.3(P_n/(P_n+P_x))+3.2(1-(P_n/(P_n+P_x))) \quad (5)$$

These values were calculated and are plotted with a dotted line in Fig. 4, a line which is in good agreement with the observed values.



**The Mechanism of the Solvolyses of *exo*- and *endo*-5, 6-Trimethylene-2-norbornyl *p*-Toluenesulfonates (I and III).**—The results of the distributions of products suggest that the intermediates are classical carbonium ions. A reasonable reaction mechanism would be as follows:

9) The melting point of III used by these authous was 49—50.5°C.

TABLE IV. FIRST-ORDER RATE CONSTANTS FOR SOLVOLYSES OF FOUR ISOMERIC *p*-TOLUENESULFONATES

| *p*-Toluene-sulfonate | Solvent | Temp. °C | $k$ $10^5$ sec$^{-1}$ | $\Delta H^{\neq}$ kcal./mol. | $\Delta S^{\neq}$ e. u. | Relative rates for methanolysis at 74.8°C | | |

| | | 99.5 | 2.19 | 27.5 | −6.7 | | | |

a) Initial rate. b) Extrapolated from the values at other temperatures.

Scheme 3

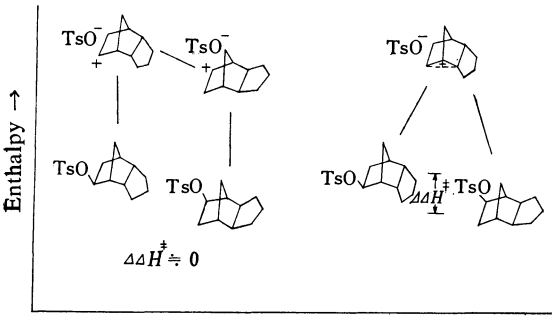
The fact that the isomerization of III to I is much faster than the reverse may be explained by assuming that III-i isomerizes to I-i faster than the reverse; i. e., $k_i \gg k_{-i}$. This is supported by the fact that *exo*-trimethylenenorbornanes are more stable than their *endo*-counterparts to the extent of 2—3 kcal./mol.[10] A common non-classical carbonium ion VII cannot account for the quite different distribution observed in the products from I and III. In addition, it appears difficult to account for the very large amount of V in the product (97% V, 3% VI) on the basis of a highly selective opening of the non-classical ion, VII. On the other hand, the marked difference in the stabilities of the two classical ions (or ion-pairs), III-i and I-i, provides a simple, plausible explanation for the observed

VII

distribution.

**The Solvolysis Rates of Four Isomeric 5, 6-Trimethylene-2-norbornyl *p*-Toluenesulfonates (I, II, III and IV).**—Although the kinetics of the solvolysis of these four isomers had been extensively studied by Bartlett and Barnes,[2] it seemed necessary to investigate them again, this time using the *p*-toluenesulfonates prepared by us. The results are summarized in Table IV. The solvolyses of II and IV obeyed good first-order kinetics, no trend of isomerization being observed.

In the last column of Table IV, the relative rates of the methanolysis of the four isomers at 74.8°C are given. A comparison of the rate ratio of 10.4 for I to II with that of 156 for III to IV suggests that the trimethylene group in III assists ionization, while that in IV retards it. This is also verified by the finding that $k_{III}/k_I$ is 3.84, while $k_{IV}/k_{II}$ is only 0.255. Apparently the retarding effect by the trimethylene group in IV should be attributed to a steric hindrance toward the leaving TsO-group.[11]



10) L. Kaplan, H. Kwart and P. von R. Schleyer, *J. Am. Chem. Soc.*, **82**, 2341 (1960), footnote 15.

11) A similar interpretation has been made for the solvolysis of the *endo*-2-norbornyl system, in which the steric hindrance by the hydrogen atoms at the 5- and 6-carbons toward the leaving group was considered. H. C. Brown, F. J. Chloupek and Min-Hon Rei, *J. Am. Chem. Soc.*, **86**, 1248 (1964).

With respect to the activation enthalpy $\Delta H^{\neq}$, I has about the same value as III. This fact supports the theory that the intermediate is different with each isomer; that is, if the intermediate is common to two isomers, some higher $\Delta H^{\neq}$ for I may be expected. As the schemes show, the approximately identical values of $\Delta H^{\neq}$ for I and III can be explained only by assuming two classical carbonium ions. It has also been reported that anchimeric assistance is but slight in the case of I.[12]

Scheme 4. Classical ions

Scheme 5. Non-classical ions

**The Distributions of Products from Methanolyses of *endo*- and *exo*-5,6-Trimethylene-*endo*-2-norbornyl *p*-Toluenesulfonates (II and IV).**— The finding that the solvolyses of II and IV obeyed good first-order kinetics shows that these *p*-toluenesulfonates do not isomerize to any other isomers, which is in accord with the solvolysis of *endo*-2-norbornyl *p*-bromobenzenesulfonate, in which no internal return was observed.[13] Accordingly, the products of the solvolysis of II and IV at completion (100%) give exactly the distribution of products from II and IV respectively.

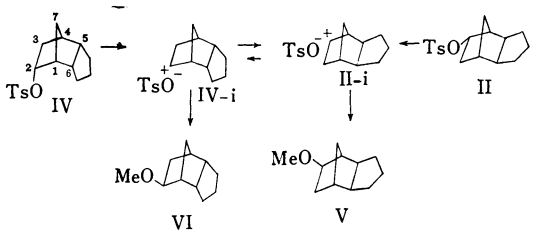


TABLE V. PERCENTAGES OF VI IN THE PRODUCTS FROM METHANOLYSES OF FOUR ISOMERIC *p*-TOLUENESULFONATES

$[\text{Tosylate}]_0 = 0.1000$ M

| | *p*-Toluenesulfonates | | | |
|---|---|---|---|---|
| | I | II | III | IV |
| Reaction temp., °C | 59.7 | 74.8 | 59.7 | 74.8 |
| % Reaction | 100 | 100 | 0[a] | 100 |
| VI in products, % | 3.2 | 1.6 | 7.3[a] | 23.4 |

a) Extrapolated to 0% reaction in Fig. 4.

The results are shown in Table V, where they are compared with those from I and III. In all cases, the products were composed of V and VI. The finding that IV yielded 23% of VI may be explained by the mechanism by which the reaction proceeds through ion pairs with classical structures. The finding that the percentage of VI from IV was greater than that from III may be explained by assuming that the $C_1-C_6$ bond migration is hindered by the departing $TsO^-$ and also that the attack by the solvent molecule from the *exo*-direction is more favored for IV-i than for III-i.

## Experimental[14]

**Materials.**—Four isomeric 5,6-trimethylene-2-norborneols (VIII, IX, X and XI) were prepared by the methods described in early articles. *exo*-5,6-Trimethylene-*exo*-2-norborneol (VIII) was prepared by adding water to *endo*-dicyclopentadiene in the presence of sulfuric acid,[15] followed by hydrogenation in the presence of platinum(IV) oxide in ethanol at room temperature; m. p. 51.5—53.5°C (reported,[3] 53—54°C).

*exo*-5,6-Trimethylene-*endo*-2-norborneol (IX) was prepared by the oxidation of VIII to ketone with Chromium(VI) oxide in acetic acid, b. p. 105—106°C/12 mmHg (reported,[2a] 113.5—116.5°C/19 mmHg), $n_D^{20}$ 1.5024[16] (reported,[2a] $n_D^{24}$ 1.5152), followed by reduction with lithium aluminum hydride, b. p. 113—114°C/11.5 mmHg (reported,[2a] 129°C/24 mmHg), $n_D^{20}$ 1.5136, *p*-nitrobenzoate, m. p. 107.5—108.5°C (reported,[2b] 108—109°C). *endo*-5,6-Trimethylene-*exo*-2-norborneol (X) was prepared by the method described by Cristol et al.,[17] via the reaction of NBS with *exo*-5,6-trimethylenenorbornene derived from VIII, m. p. 80.0—80.8°C (reported,[17] 80.5—81.5°C), *p*-nitrobenzoate, m. p. 128—128.5°C (reported, 123—124°C,[2b] 129.5°C[17]). *endo*-5,6-Trimethylene-*endo*-2-norborneol (XI) was prepared by the oxidation of X to ketone with chromium trioxide in acetic acid, followed by reduction with lithium aluminum hydride; m. p. 113.5—115.0°C (reported, 89—90°C,[2a] 120—121°C[18]). The alcohols VIII, IX and X were proved not to be contaminated with other isomeric alcohols on v. p. c. analyses. Analyses were carried out with a Perkin-Elmer vapor phase fractometer, model 154-D, on a 1/4″×2 m. (4 m. in the case of X)

18) Although Bruson and Riener did not confirm the structure, the compound they synthesized was probably XI. See Ref. 14.

stainless steel column packed with "R" Ucon oil LB-550-X. The alcohols showed the following retention times under the respective corresponding conditions; VIII, 81.2 min.; X, 92.0 min. at 150°C with a helium flow of 72 cc./min.; and IX, 79.9 min. at 190°C with a helium flow of 40 cc./min. The analysis of XI has not been carried out.

Four isomeric *p*-toluenesulfonates (I, II, III and IV) were prepared by treating the above alcohols with *p*-toluenesulfonyl chloride in pyridine at 0°C overnight. All the *p*-toluenesulfonates, with the exception of II, were recrystallized three times from *n*-hexane: m. p.: I, 67.5—67.8°C (reported, 60—61°C,[2] 65.3—67.5°C[3]); II, liq. (reported,[2] liq.); III, 76.5—77.0°C (reported, 48—49°C,[2] 49—50.5 °C[3]); IV, 54.0—55.0°C (reported,[2] 59.5—60°C). Anal. for III, calcd. for $C_{17}H_{22}O_3S$; C, 66.63; H, 7.24; S, 10.46; solvolysis equiv., 306.42; molecular weight, 306.42. Found; C, 67.11; H, 7.71; S, 10.29; solvolysis equiv., 301; molecular weight, 310 (determined by vapor pressure osmometer model 301 A, Mechrolab Inc.). II was used without any purification.

Methanol and ethanol were dried by refluxing them over the corresponding magnesium alkoxide for 10 hr. and then distilled carefully. Anhydrous acetic acid was prepated by refluxing reagent-grade acetic acid with the calculated amount of acetic anhydride for 10 hr. and by subsequent distillation. They were stored under an argon atmosphere.

**The Mixed Melting Points of I with III.**—About 50-mg. portions of mixtures of I and III were prepared. The melting points were observed in capillary tubes by heating these portions in a sulfuric acid bath.

**Infrared Spectra Measurements.**—The infrared spectra of the *p*-toluenesulfonates (I, II, III and IV), corresponding alcohols (VIII, IX, X and XI), corresponding methyl ethers and tetrahydro-*endo*-dicyclopentadiene were taken in 0.1 M carbon disulfide; it was thus revealed that the compounds posessing an *endo*-trimethylene group exhibited a characteristic peak at 1250 $cm^{-1}$.

**NMR Spectra Measurements.**[19]—Proton NMR spectra of I, III and tetrahydro-*endo*-dicyclopentadiene were run at 20±2°C on a Japan Electron Optics Lab., model JNM-C-60, high-resolution spectrometer at 60 Mc. in carbon tetrachloride solutions, using tetramethylsilane as an internal standard. The spectra of III and tetrahydro-*endo*-dicyclopentadiene exhibited characteristic peaks between $\tau$=8.7 and 8.3, whereas I exhibited a broad peak between $\tau$=9.5 and 8.8 which was not observed in either III or tetrahydro-*endo*-dicyclopentadiene. The complete analysis of the NMR spectra has not been carried out.

**Kinetic Measurements.** — The sealed ampoule technique was emloyed. Methanolysis and ethanolysis were followed by titrating produced *p*-toluenesulfonic acid with standard sodium ethylate in ethanol, using bromocresol purple as an indicator. Acetolysis was followed by titrating with standard sodium acetate in acetic acid, using crystal violet as an indicator. Several infinity titers showed the purities of the *p*-toluenesulfonates to be; I, 99.2%; II, 96.2%; III, 99.0%; IV, 99.2%.

**The Isolation of the Unsolvolyzed *p*-Toluenesulfonate in the Methanolysis of III.**—A solution of 733 mg. (2.5 mmol.) of III in 25 ml. of absolute methanol was heated in an ampoule at 59.7°C in a constant temperature bath. After 184 min. (55% reaction), the reaction mixture was cooled at 0°C and poured into 100 ml. of ice-water. Unsolvolyzed *p*-toluenesulfonate, separated as fine crystals, was isolated by filtration and washed with two 5-ml. portions of water and dried in a vacuum desiccator. The yield was 198 mg. (60% of theor.); m. p. 66—67°C. The infrared spectrum (0.1 M in carbon disulfide) agreed exactly with that of an authentic sample (I) in the 650—4000 $cm^{-1}$ range.

**The Analysis of the Products from the Methanolyses of Four Isomeric *p*-Toluenesulfonates (I, II, III and IV).**—A solution (50 ml.) of the *p*-toluenesulfonates in anhydrous methanol (0.1000 M) was divided into several portions (5—25 ml.), placed in ampoules, and heated in a constant temperature bath. The reaction was stopped by cooling at various percentages of reaction, and the reaction mixture was poured into ice-water and extracted with two 5-ml. portions of *n*-pentane. The pentane extracts were combined, washed with a 10% sodium carbonate solution and water, and dried over sodium sulfate. After concentration to about half volume, the pentane solution was cooled to −50°C in order to crystallize the unsolvolyzed *p*-toluenesulfonate. After the solution had stood overnight at that temperature, the pentane layer was decanted and concentrated to about 0.5 ml. The v. p. c. analyses of the products, methyl ethers, were carried out with a Perkin-Elmer vapor phase fractometer, model 154-D, on a 1/4"×4 m. stainless steel column packed with "R" Ucon oil LB-550-X at 190°C and with a helium flow of 40 cc./min. The ethers V and VI showed retention times of 37.2 and 40.1 min. respectively. The percentage compositions of a mixture were determined by measuring the peak areas of the chromatogram by the triangularization method. Analytical data were reproducible to about ±0.3%.

The authors wish to thank Professor Herbert C. Brown for his many helpful suggestions, Dr. Kunio Okamoto for his valuable discussions, and Mr. Hiroshi Wakida for his measurements of the solvolysis rates.

# Studies on Amino-hexoses. VIII. The Fischer Synthesis of Methyl D-Glucosaminides

By Yoshio MATSUSHIMA and Tsuyoshi MIYAZAKI

(Received December 4, 1964)

The Fischer synthesis of methyl glycosides using methanolic hydrogen chloride[1] seems to have failed in the case of glucosamine[2] because the positive charge on the amino-sugar repels the catalyst proton. Some of the known ways of glucosaminide synthesis detour to *N*-benzyloxycarbonyl- or *N*-acetylglucosamine, which do not have a cationic nature. The fission of the benzyloxycarbonyl group by catalytic hydrogenation[2] or by reduction with sodium in liquid ammonia[3] after the Fischer glycosidation regenerates the free amino group. *N*-Deacetylation by hydrazinolysis of methyl *N*-acethylglucosaminide also provides a way to methyl glucosaminide.[4]

As has been mentioned above, the glycosidation reaction of the amino-sugar may be slow under the usual conditions of the Fischer method, but the reaction will be appreciably accelerated when the reactants and the catalyst are brought to a satisfactorily high concentration. As one of way of realizing the idea, the authors treated glucosamine and excess methanol with an excess amount of a strong cation exchanger, which combines glucosamine through the salt linkage and limits the site of the reaction to the surface of the resin only, thus bringing the reactants and the catalyst close to one another. As will be shown in the Experimental section below, D-glucosamine hydrochloride was converted, in a considerably high yield, into a methyl glucosaminide mixture, of the components of which methyl 2-amino-2-deoxy-$\alpha$- and $\beta$-D-glucopyranoside were unambiguously identified after separation by the recently-developed column chromatography using Dowex-1 X 4 free base resin.[5] The probable formation of the two furanosides was inferred from paper chromatographic and other physical data.

## Experimental

**Glycosidation.**—A mixture of 15 g. D-glucosamine hydrochloride, 150 g. of dried Amberlite IR-120 ($H^+$-form, 200—400 mesh) and 1500 ml. of absolute methanol was refluxed while being mechanically stirred for 10 hr. The reaction mixture was then poured into a glass tube 5.5 cm. in diameter, and the methanol was sucked off. After the resin had been washed with absolute methanol, the glycoside mixture was eluted with methanolic ammonia. The evaporation in vacuo of the eluted solution (1600 ml.) gave 13.1 g. of a brown syrup. It was found by the Somogyi method[6] that the syrup contained reducing sugar, corresponding to 2.3 g. of glucosamine hydrochloride, which had escaped the glycosidation.

**The Separation of the Glycoside Mixture by Column Chromatography.**—Thirteen grams of the above-mentioned syrup in 30 ml. of water was placed in a Dowex-1 X 4 column ($OH^-$-form, 200—400 mesh) 55 cm. high by 3.7 cm. in diameter and was eluted with water. Each 10 ml. of the fraction was then collected, and the elution was traced by optical rotation measurements. After the elution pattern had been established, the appropriate fractions were combined and evaporated in vacuo, and the specific rotation of each combined fraction, A to I (as shown in Fig. 1), was measured. The recovery of the glycosides was 7.8 g. This corresponded to about 70% of the total non-reducing material obtained. The reducing sugar which escaped the

glycosidation was supposed to have changed to some acidic substance during contact with the strong base resin[7] and to have been retained in the column. Of fractions A to I, only fraction B was obtained as a crystalline material; the others were all a brown syrup.

**Methyl 2-Amino-2-deoxy-α-D-glucopyranoside.**—The raw crystalline material (2.1 g) obtained from fraction B was recrystallized using absolute ethanol. The colorless crystals obtained weighed 1.6 g. and melted at 155—159°C alone or at 154—159°C on admixture with an authentic specimen[4]. $[\alpha]_D^{30}$ +159.8 (*c* 1.01, water).

Found: C, 43.65; H, 7.92; N, 7.32. Calcd. for $C_7H_{15}O_5N$: C, 43.51; H, 7.82; N, 7.25%.

**Methyl 2-Benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside.**—A solution of 0.4 g. of methyl 2-amino-2-deoxy-α-D-glucopyranoside in 15 ml. of water was mixed with 0.4 g. of sodium bicarbonate and 0.4 g. of benzyloxycarbonyl chloride. The reaction was continued for 2.5 hr. at room temperature while the mixture was being mechanically stirred. The crystals thus obtained were washed with chloroform. The specimen melted at 158—160°C alone or at 153—158°C on admixture with a sample prepared by the literature method.[2,4] $[\alpha]_D^{30}$ +100.2[5] (*c* 1.04, pyridine)

Found: C, 54.72; H, 6.50; N, 4.25. Calcd. for $C_{16}H_{21}O_7N$: C, 55.04; H, 6.47; N, 4.28%.

Another crop, with essentially the same physical constants, was obtained from the mother solution. The total yield was 0.57 g.

**Methyl 2-Amino-2-deoxy-β-D-glucopyranoside.**—An absolute ethanol solution of 0.45 g. of a syrup from fraction E gave a crystalline material when left standing for a long time in a refrigerator. The specimen melted at 130—132°C. $[\alpha]_D^{18}$ −40.7 (*c* 1.57, water)

Found: C, 43.31; H, 7.87; N, 7.29. Calcd. for $C_7H_{15}O_5N$: C, 43.51; H, 7.82; N, 7.25%.

The compound, on paper chromatography using two solvent systems, behaved in the exactly same way as the standard specimen[9] which was prepared by the deacetylation of methyl 2-acetamido-2-deoxy-β-D-glucopyranoside.

**Methyl 2-Benzyloxycarbonylamino-β-D-glucopyranoside.**—The syrup from fraction D was *N*-benzyloxycarbonylated by a method similar to that used for the corresponding α-isomer, and 1.2 g. of the syrup gave 1.3 g. of a crystalline material which melted at 165—167°C after recrystallization from ethanol. $[\alpha]_D^{30}$ −34.6 (*c* 1.00, pyridine) The melting point and the optical activity data are in good agreement with those in the literature.[2,3]

Found: C, 54.32; H, 6.49; N, 4.24. Calcd. for $C_{16}H_{21}O_7N$: C, 55.04; H, 6.47; N, 4.28%.

**Methyl 2-(2′, 4′-Dinitrophenyl)amino-2-deoxy-α-D-glucofuranoside.**—Ten milliliters of an aqueous solution of 0.3 g. of the syrup from fraction I was mixed with 0.2 g. of sodium carbonate and 0.3 g. of 2, 4-dinitrofluorobenzene in 3 ml. of acetone, and then the mixture was shaken overnight at room temperature. The reaction mixture was dried in vacuo, and the crystalline residue was successively washed with water and petroleum ether. Recrystallization from ethanol gave 0.12 g. of yellow crystals melting at 113—167°C. $[\alpha]_D^{27}$ +36.5 (*c* 0.96, acetone)

Found: C, 42.96; H, 4.11; N, 12.44. Calcd. for $C_{13}H_{17}O_9N_3$: C, 43.46; H, 4.78; N, 11.69%.

As the broad range of the melting points shows, the purification of the compound was unsatisfactory. Paper chromatography with *n*-butanol: ethanol: water (4: 1: 5) gave two spots, with $R_f$ values of 0.89 and 0.92 respectively. The literature[10] gave the following physical constants: m. p. 166—167°C; $[\alpha]_D^{18}$ +30.6 (*c* 1.0, acetone); $R_f$ 0.88 in the same solvent system.

**Methyl 2-Acetamido-2-deoxy-β-D-glucofuranoside.**—The syrup (0.22 g.) from fraction F was mixed with 20 ml. of acetic anhydride, 50 ml. of water and Dowex-1 X 4 ($OH^-$-form), and then the mixture was stirred at room temperature overnight. The resin was removed by filtration and washed with water. The filtrate and washing were combined and evaporated in vacuo. The syrup thus obtained was decolorized with a small amount of active charcoal and dried over phosphorus pentoxide. The syrup (0.18 g.) obtained failed to crystallize. $[\alpha]_D^{30}$ −20.9 (*c* 1.24, water). This syrup showed the same $R_f$ value (0.45) in the ascending paper chromatographic system (*n*-butanol: ethanol: water =4: 1: 5) as did the specimen obtained by the literature method.[11]

## Summary

The direct synthesis of methyl D-glucosaminides by proton catalysis using a strong cation exchanger has been investigated. The formation of the two anomeric pyranosides has been proved unambiguously. Also, the two anomeric furanosides, which have been obtained in an unsatisfactory purity, have been inferred, according to their physical constants, to have formed in the glycosidation reaction.

This investigation was supported by U. S. Public Health Service Grant No. AI-04586-03.

# The Addition Reaction of Dinitrogen Trioxide with Cinnamyl Acetate

By Yoshie KURIHARA* and Kazuo YAMAGISHI**

(Received December 5, 1964)

A number of investigations[1-4] have been carried out into the reaction between dinitrogen trioxide and unsaturated compounds, and it is well known that the dimer of the nitro-nitroso compound is the main product in those reactions. In an earlier paper[5] from our laboratory, it was demonstrated, however, that not the nitro-nitroso compound but nitro-alcohol and nitro-olefin were formed in the reaction between methyl crotonate and dinitrogen trioxide. The present study was undertaken, firstly, to examine whether or not only the nitro-nitroso compound is obtained in the addition reaction of dinitrogen trioxide to cinnamyl acetate (I) and, secondly, to synthesize from the reaction products 2-amino-1-phenyl-1, 3-propanediol, which is an important intermediate for synthesizing chloramphenicol.

Fodor et al.[6] examined the reaction of dinitrogen trioxide with compound I according to the technique presented by Bruckner[3] and obtained the dimer of the nitro-nitroso compound, from which chloramphenicol could be derived. In the present study, however, through a close examination of this reaction under Bruckners condition, two reaction products were isolated; they are white and relatively stable crystals and unstable yellow oil. The crystalline substance was found, through its elemental analysis and through the fact that it becomes blue when dissolved in benzene, to be the dimer of the nitro-nitroso compound (IIa). Although the purification of the oily substance by vacuum distillation was unsuccessuful, it was purified chromatographically by the use of silica gel as the adsorbent. We assigned the structure IIb to the second oily product on the basis of the elemental analysis, its infrared spectrum and Liebermann's nitroso reaction, which indicated the presence of -NO and/or -ONO groups. The infrared spectrum of the oil indicated the presence of both -ONO (1659 $cm^{-1}$) and $-NO_2$ groups (1561 and 1367 $cm^{-1}$).[7] Compound IIb gradually lost nitrous acid at room temperature, forming $\beta$-nitro cinnamyl acetate (III). When the benzene solution of IIb was passed through a alumina column or warmed with sodium acetate for one or two hours, compound III, was quantitatively obtained. For the purpose of synthesizing 2-amino-1-phenyl-1, 3-propanediol, it is recommended that the crude product be directly transformed into compound III without isolation.

The ratio of IIa to IIb formed by the addition of nitrogen trioxide to cinnamyl acetate was greatly influenced by the solvent used and by the other experimental conditions. Toluene was the best among the solvents tried (i.e. toluene, ether and cyclohexane) for minimizing the product, IIb. The IIa/IIb ratio decreased progressively when the solvent was changed in the following order: toluene—cyclohexane—ether. With 20 mol. of toluene to cinnamyl acetate, the main product was IIa. The decrease in the amount of toluene greatly affected the relative amounts of IIa and IIb formed. For example, the use of less than 10 mol. of toluene yielded IIb in a greater quantity than IIa. When the reaction temperature was raised higher than 0°C, the formation of IIb also increased.

Compound IIa and compound III obtained from IIb underwent substitution or addition reaction to yield, finally, 2-amino-1-phenyl-1, 3-propanediol. Figure 1 illustrates the entire process adopted in this research. When IIa was treated with sodium methylate at 0°C, the nitroso group of IIa was converted into the methoxy group and compound IV was obtained in a 76% yield.

As an analogous reaction of this type, it was found in our laboratory that 1-methoxy-2-nitro-1-phenylethane (XI) was obtained directly

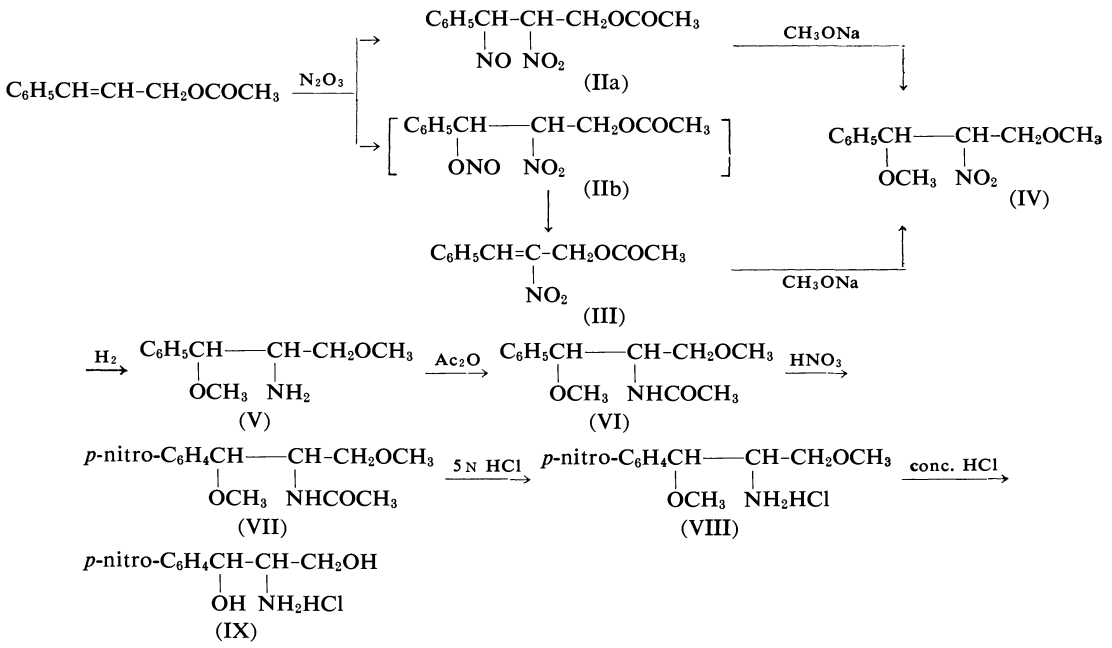

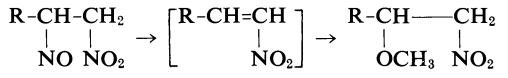

Fig. 1

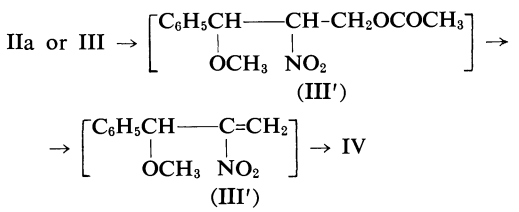
in a good yield by the reaction of 1-nitroso-2-nitro-1-phenylethane (X) with sodium methylate. Meisenheimer[8] and Rosenmund[9] reported that ω-nitrostyrene (X′) reacted with sodium alcoholate to afford 1-alkoxy-2-nitro-1-phenylethane. Moreover, Wieland[1] described how compound X was transformed into compound X′ through treatment with sodium methylate. Therefore, it may be supporsed that the reaction between X and sodium methylate would proceed via ω-nitrostyrene, as is described below (1) :



(X) (X′) (XI)

$R = C_6H_5$ (1)

When sodium methylate was added to compound III, the same reaction product IV was obtained. A new finding in this reaction was that the acetyl group of compound IIa or III was transformed into the methoxy group. Probably, with one mole of sodium methylate, IIa or III may be changed into compound III′ which then may be transformed into compound III″ by losing acetic acid,[10] and finally compound IV may be formed with the excess sodium methylate.

Compound IV was reduced to V in the presence of a Raney nickel catalyst in methyl

(III′)

alcohol at 40°C under the pressure of 110 atm. of hydrogen. Glittering white crystals (VI) were obtained by the acetylation of V. After the introduction of the nitro group at the para position of the benzene ring by the known method,[11] VII (m. p. 109—110°C) was obtained. Compound VII seems to be *dl-erythro*-2-acetoamido-1, 3-dimethoxy-1-(*p*-nitrophenyl)-propane, because Gabor et al.[11] reported that the melting point of the threo form of VII was 129—130°C. Compound VII was hydrolyzed into compound VIII with 5 N hydrochloric acid; then, after the hydrolysis of VIII with concentrated hydrochloric acid, white crystals were obtained. The melting point of this end product was 209°C, which agreed with the melting point of *dl-erythro*-2-amino-1-(*p*-nitrophenyl)-1, 3-propanediol hydrochloride.[12] As has been described above (reaction 1), the nitroso group was converted into the methoxy group, probably via nitro-olefin (trans form) through the action of sodium methylate. Therefore, it seems likely that compound IIa

reacts with sodium methylate to afford IV via an intermediate, III. This is the reason why the erythro form was obtained in the reaction of IIa with sodium methylate.

## Experimental[13]

**3-Acetoxy-1-nitroso-2-nitro-1-phenylpropane (IIa).**—To a mixture of 30 g. (0.17 mol.) of cinnamyl acetate (b. p. 102—103°C/0.2 mmHg, $n_D^{25}$ 1.5391) in 430 ml. of toluene and 94 g. (1.4 mol.) of sodium nitrite in 100 ml. of water, 370 ml. of 20% sulfuric acid (0.85 mol.) was stirred in drop by drop at 0°C for 6—7 hr. The stirring was then continued for thirty minutes after the addition had been completed. The precipitate in the toluene layer was filtered and washed with cold water, and then with ether. A white powder of IIa, 21 g. (49%), was obtained; m. p. 116—117°C (decomp.) (lit.[6] 124°C).

Found: N, 11.01. Calcd. for $C_{11}H_{12}O_5N_2$: N, 11.11%.

**3-Acetoxy-2-nitro-1-phenyl-1-propyl-nitrite (IIb).**—The filtrate of the toluene layer, which is free from IIa, contained unreacted cinnamyl acetate and compound IIb. It was neutralized with a 5% sodium dicarbonate solution and dried over magnesium sulfate. By removing toluene under reduced pressure, 9 g. of a crude red oil was obtained. The crude oil was dissolved in anhydrous benzene, passed through a silica gel column, and eluted with benzene. First, the unreacted cinnamyl acetate (2.5 g.) was eluted, and then the second fraction was collected. When the solvent was removed, 5.4 g. of IIb was obtained as a pale yellow oil. The infrared spectrum showed bands at 1561, 1367 $cm^{-1}$ ($NO_2$) and 1659 $cm^{-1}$ (ONO).

Found: C, 49.55; H, 4.71; N, 10.22. Cacld. for $C_{11}H_{12}O_6N_2$: C, 49.25; H, 4.51; N, 10.45%.

When the reaction was carried out at 7—10°C, no IIa was obtained; the only reaction product was IIb (22 g.). When the reaction was carried out at 0°C, however, using 200 ml. of toluene and the other experimental conditions were not varied, 4.5 g. of IIa and 23 g. of IIb were obtained. When 450 ml. of ether was employed instead of toluene and the other experimental conditions were not varied, a small amount of IIa (1.8 g.) was obtained, while most of the reaction product was IIb (20 g.). When 450 ml. of cyclohexane was used as the solvent, 8 g. of IIa and 18 g. of IIb were formed from 30 g. of cinnamyl acetate.

Compound IIb, if desired, could be isolated as has been mentioned above. However, IIb was highly unstable. It is, therefore, recommended that, after neutralizing it with a sodium bicarbonate solution and removing the solvent, the crude product be directly transformed into compound III without the isolation of IIb.

**β-Nitro Cinnamyl Acetate (III).**—A mixture of 3 g. of the crude product of IIb and 1.5 g. of sodium acetate in 100 ml. of benzene was warmed at 60—80°C for 5 hr. When the mixture was poured into cold water, yellow needle crystals were formed. 1.8 g. of III was obtained; m. p. 81.5—82°C (recrystallized from alcohol and water (15 : 5)). Compound III was also obtained by passing the benzene solution of the crude product of IIb through an alumina column.

Found: C, 59.76; H, 4.95; N, 6.57. Calcd. for $C_{11}H_{11}O_4N$: C, 59.72; H, 5.01; N, 6.33%.

**1-Nitroso-2-nitro-1-phenylethane (X).**—To a mixture of 160 g. (1.53 mol.) of styrene in 900 ml. of ether and 570 g. (8.3 mol.) of sodium nitrite in 570 ml. of water, 1500 g. of 20% sulfuric acid was added drop by drop in the course of four or five hours at about 0°C. When the addition of sulfuric acid was complete, the precipitate present in the ether layer was filtered off and washed thoroughly with cold water in order to remove the inorganic salt; then it was washed with ether. One hundred and sixty-eight grams (61%) of X was obtained; m. p. 130°C (lit.[3] m. p. 129°C).

Found: N, 15.63. Calcd. for $C_8H_8O_3N_2$: N, 15.56%.

**1-Methoxy-2-nitro-1-phenylethane (XI).**—To a suspension of 9 g. (0.025 mol.) of compound X in 50 ml. of anhydrous methyl alcohol, sodium methylate prepared from 2.3 g. of sodium and 50 ml. of methyl alcohol was added with a rapid agitation at −5°C. The temperature immediately rose from −5°C to 7°C, and the reaction was completed within one or two minutes. A clear red solution was obtained. After it had been neutralized with carbon dioxide, the mixture was poured into a large amount of water and extracted with three 30-ml. portions of ether. The ether solution was dried over anhydrous magnesium sulfate, and the ether was removed. The nitro ether was distilled at 0.3 mmHg; b. p. 90—91°C (lit.[9] 140—141°C at 15 mmHg), $n_D^{20}$ 1.5190. Yield: 4.9 g. (55%).

Found: C, 59.71; H, 6.11; N, 7.85. Calcd. for $C_9H_{11}O_3N$: C, 59.66; H, 6.08; N, 7.74%.

***dl-erythro*-1, 3-Dimethoxy-2-nitro-1-phenylpropane (IV).**—*Procedure from IIa.*—Sodium methylate which had been prepared from 4.6 g. (0.2 g.-atom) of sodium and 118 ml. of methyl alcohol was added quickly at −5°C to a suspension of 25.2 g. (0.1 mol.) of IIa in 100 ml. of anhydrous methyl alcohol. The reaction proceeded spontaneously, and the mixture became transparent. After it had been neutralized with carbon dioxide, the mixture was poured into a large amount of water and extracted three times with 50 ml. of ether. Anhydrous magnesium sulfate was then added to the ether extract. Compound IV was purified by distillation at 118°C/0.08 mmHg, m. p. 58—59°C (recrystallized from water and methyl alcohol (1 : 1)). Yield: 17 g. (76%).

Found: C, 58.48; H, 6.63; 6.18. Calcd. for $C_{11}H_{15}O_4N$: C, 58.65; H, 6.71; N, 6.22%.

*Procedure from III.*—The same procedure as above was employed in the preparation of IV from III. Thus, 16.5 g. (70%) of IV was obtained from 22.1 g. of III in 100 ml. of methyl alcohol.

***dl-erythro*-2-Acetoamido-1,3-dimethoxy-1-phenylpropane (VI).**—Compound IV (13.7 g.) in 30 ml. of methyl alcohol was hydrogenated in an autoclave with 4 g. of Raney nickel at 40°C under an initial

13) Boiling points and melting points are uncorrected. infrared spectra were measured with a Perkin-Elmer Model 321 double-beam spectrophotometer.

pressure of 110 atm. Three molecular equivalents of hydrogen were absorved over a five-hour period. The solvent, methyl alcohol was removed under reduced pressure. The residue (7.5 g.) was mixed with 22.5 g. of acetic anhydride and warmed at 50°C. After the mixture had cooled, 5.0 g. of white crystals were obtained; m. p. 106°C (recrystallized from *n*-hexane and ethyl acetate (4 : 14)).

Found: C, 66.05; H, 8.10; N, 6.00. Calcd. for $C_{13}H_{19}O_3N$: C, 65.80; H, 8.07; N, 5.90%.

***dl-erythro*-2-Acetoamido-1, 3-dimethoxy-1-(*p*-nitrophenyl)-propane (VII).**—According to the method of Gabor,[11] from 2 g. of VI, 3.4 ml. of acetic anhydride and 10 ml. of fuming nitric acid, 1.1 g. of VII was obtained as pale-yellow-needle crystals, m. p. 109—110°C (from benzene).

Found: C, 55.98; H, 6.77; N, 9.69. Calcd. for $C_{13}H_{18}O_5N_2$: C, 55.31; H, 6.43; N, 9.92%.

***dl-erythro*-2-Amino-1, 3-dimethoxy-1-(*p*-nitrophenyl)-propane Hydrochloride (VIII).**—A 1.5 g. of sample of VII was mixed with 5 ml. of 5 N hydrochloric acid, and then the mixture was heated at 100°C for 4 hr. After the mixture had cooled, white crystals of VII (0.9 g.) were obtained; m. p. 216°C (from ethyl alcohol).

Found: C, 47.23; H, 6.27; N, 10.24. Calcd. for $C_{11}H_{16}O_4N_2 \cdot HCl$: C, 47.70; H, 6.15; N, 10.11%.

***dl-erythro*-2-Amino-1-(*p*-nitrophenyl)-1, 3-propanediol Hydrochloride (IX).**—The mixture of 0.8 g. of VIII and 15 ml. of concentrated hydrochloric acid was heated at 120—125°C for 2 hr. in the sealed tube. Then the solution was concentrated in a vacuum, and the residue was recrystallized from methyl alcohol. White crystals were obtained; m. p. 209°C (lit.[12] 206—208°C).

Found: C, 43.60; H, 5.12; N, 11.66. Calcd. for $C_9H_{12}O_4N_2 \cdot HCl$: C, 43.42; H, 5.22; N, 11.26%.

## Summary

This study of the reaction between dinitrogen trioxide and cinnamyl acetate has indicated that the 3-acetoxy-2-nitro-1-phenyl-1-propyl-nitrite (IIb) is formed, in addition to 3-acetoxy-1-nitroso-2-nitro-1-phenylpropane (IIa), in yield depending on the experimental conditions. Those products have been transformed in good yields into 1, 3-dimethoxy-2-nitro-1-phenylpropane, from which *dl*-erythro-2-amino-1-(*p*-nitrophenyl)-1, 3-propanediol has been synthesized.

The authors wish to express their heartfelt gratitude to Professor Toshio Hoshino for his guidance and constant encouragement throughout this study. The authors also are grateful to Dr. Asaji Kondo for his help in the elemental analyses of the products and to Dr. Yoichiro Mashiko for his advice for interpreting the infrared spectra.

# The Electrolytic Formation and Dissolution of the Oxide Layer on Rhodium in an Acid Solution

By Shigeo SHIBATA

(Received December 8, 1964)

The surface oxidation of rhodium has been studied in parallel with that of platinum by means of chronopotentiometry,[1] the triangular voltage sweep[2,3] and rest-potential measurement[4]. However, there has as yet been very little study aimed at giving a coherent mechanism of the formation and dissolution of the surface oxide under the conditions of controlled current electrolysis.

The present paper will describe the results obtained with rhodium electrodes using techniques similar to those applied to the platinum electrode in this laboratory.[5]

## Experimental

The electrical circuit and the electrolytic cell used were fundamentally similar to those previously described.[4] The electrode was a smooth rhodium wire 0.5 mm. in diameter and 10.3 mm. long. The electrode was stored in 10 N nitric acid when not in use. The counter electrode was a platinum cylinder placed concentrically around the test electrode. The electrolytic solution was 2 N sulfuric

acid, which had been freed from dissolved oxygen by passing purified nitrogen gas through, unless otherwise stated.

The experiments were made in an all-glass, double-wall cell which allowed the electrolyte to be thermostated and also permitted the bubbling of nitrogen gas. All experiments were made at 25 ±0.1°C.

The reference electrode was a mercury-mercurous sulfate electrode in 2 N sulfuric acid. The values of the potential described in this paper are on the standard hydrogen scale.

## Results and Discussion

**Charging Curves.**—Typical charging curves for oxygen- and hydrogen-free solutions are shown in Figs. 1A and 2A.

A constant current is passed through, and the potential of the electrode is followed as a function of the time. The potential rises slowly (the $\alpha_a$ region) until all the hydrogen adsorbed on the electrode has been oxidized. The potential then rises rapidly through the region, $\beta_a$, where the only process is the charging of the electrical double layer. At 0.6 V. an anodic process begins, and the potential increases more gradually through the $\gamma_a$ region. Eventually the oxygen evolution potential is reached, causing a leveling off of the potential (the $\delta_a$ region). If the current is reversed and the electrode thus anodized is made the cathode, the cathodic charging curve

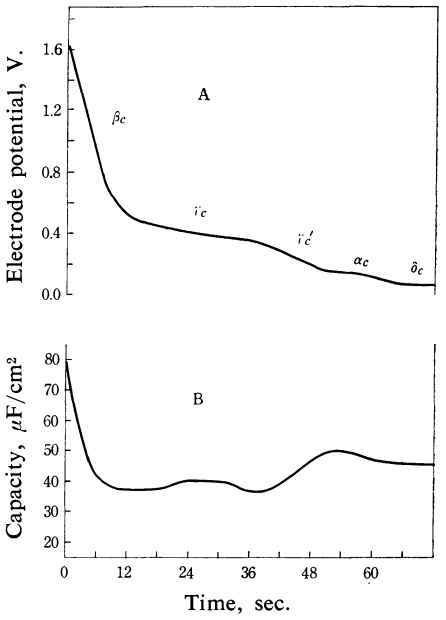

Fig. 2. Comparison of charging and capacity curves.
A Cathodic charging curve of the oxidized electrode. $i_c$=46 μamp/cm²
B Differential capacity curve recorded simultaneously with curve A.

of Fig. 2A is observed. The potential drops very rapidly to about 0.5 V., where there is a plateau (the $\gamma_c$ region) due to the reduction of the oxide layer formed in the $\gamma_a$ region of the anodization. The potential drop is slow in both the $\gamma_c$ and $\gamma_c'$ regions, and the difference in the slopes of these curves is so small that the starting potential of $\alpha_c$ is not satisfactory determined. The $\delta_c$ region is attributed to the evolution of hydrogen.

The anodic and cathodic charging curves do not have the same shape. If the difference in their shapes were due to the effect of the polarization as the result of a slow reaction, the curves would become more similar as the current density is decreased. However, a very low current density study showed that the hysteresis is not decreased significantly by a decrease in the current density. Such an intrinsic hysteresis suggests a reaction which is so irreversible that the oxidation and reduction occur by different mechanisms.

A comparison of the anodic and cathodic curves shows that the $\gamma_a$ region is always larger than the $\gamma_c+\gamma_c'$ region, indicating that more electricity is used to form the oxide than is required to remove it. (The $\gamma_c$ region is also the reduction stage of the oxide layer. Its experimental evidence will be given later.) This inequality in electricity can be explained without inconsistency if, in the course of

cathodization, the reduction of the oxide to hydrogen peroxide is assumed.[6] However, it was shown in a previous paper[5] that this hypothesis is not applicable to platinum. It is necessary to examine whether or not the hydrogen peroxide theory is true for rhodium.

**The Variation in Double Layer Capacity during the Anodic and Cathodic Polarizations.**— The differential double layer capacity of the rhodium electrode was measured by the galvanostatic pulse method previously described.[5] The pulse-rise time was 0.2 $\mu$sec., and the duration was 5 $\mu$sec. The ratio of the current to the slope of the potential-time curve, $\Delta E/\Delta t$, gives the double layer capacity. In practice, the pulse current was so adjusted that $\Delta E$ was 1—4 mV. at a $\Delta t$ of 5 $\mu$sec. To prevent the lowering of the double layer capacity by the traces of surface-active impurities adsorbed on the electrode, the electrode was first anodized in order to eject the impurity.[7] The clean electrode was then reduced before measurements made.

The value of the double layer capacity thus observed showed an interesting mode of time change during the constant current anodic and cathodic polarizations, as may be seen in Figs. 1B and 2B respectively. These results suggest that the $\gamma_a$ region of the anodic charging curve can be divided into three regions, $\gamma_a'$, $\gamma_a''$ and $\gamma_a'''$, in spite of its simple tone. Starting with the oxygen deposition potential of 0.6 V., the first stage, $\gamma_a'$, is characterized by a fall of the double layer capacity with an increase in the potential until 0.9 V. The second stage, $\gamma_a''$, is marked by a constant minimum value of 34 $\mu$F./cm$^2$ in the potential from 0.9 to 1.2 V., and the final stage, $\gamma_a'''$, by an increase in the value until the potential of 1.5 V., at which the evolution of oxygen begins.

It has been suggested by Llopis and Colum[8] that the cause of the increase in the electrode capacity at the anodization is the presence of such dipoles as M···O or M···OH at the electrode-solution interface. These dipoles would replace the water molecules and the ions which form the electrical double layer at the reduced electrode surface. The behavior of the electrode capacity due to the anodization seems to give us some information about the mechanism of the surface oxidation. In the first stage, $\gamma_a'$, with the high capacity value, highly polar groups may be expected to exist at the metal-solution interface of the electrode, which may be represented as Rh···OH. In the $\gamma_a''$ stage, these polar groups of the hydroxyl radical may be converted into non-polar groups or into the definite oxide, and in the final stage, $\gamma_a'''$, the polar groups may be adsorbed on this oxidized surface.

The capacity change during the cathodization of the oxidized electrode is monotonic compared with that during the anodization.

**The Electrode Reaction in the $\gamma_c'$ Region.**— For the platinum electrode, the oxide layer is reduced exhaustively at the one stage of 0.8 V. which corresponds to the plateau, $\gamma_c$, of 0.5 V. for the rhodium electrode. When all of the oxide on the platinum has been reduced, the potential drops rapidly to about 0.3 V., where the deposition of hydrogen begins. However, for the rhodium electrode, following the $\gamma_c$ plateau a slow linear fall of the

potential, $\gamma_c'$, is observed. In order to look into the reaction taking place in this region, the following measurements were carried out.

The electrodes oxidized by a constant current anodization up to the potential of 1.55 V., which is the end potential of the $\gamma_a$ region, were polarized cathodically with a constant current up to various potentials, and then the current was reversed immediately. The charging curves obtained by these procedures are shown in Fig. 3. In general, following the initial steep ascent of the potential ($\beta_a$), the potential curves turn to a slow linear rise, $\gamma_a$. However, when the cathodic current was reversed at the potential below 0.2 V., the $\alpha_a$ plateau, the ionization stage of the adsorbed hydrogen, appears on the anodic curves. As long as the quantity of electricity, which has been passed through the oxidized electrode at the cathodization, $q_c$, does not suffice to reduce the oxide layer exhaustively, the quantity of electricity, $q_a$, which is required to restore the thus-cathodized electrode to the oxidized state will increase as $q_c$ is increased. The number of coulombs required to oxidize a given electrode from the completely reduced state into the completely oxidized state would be constant. Consequently, it may be seen from the comparison of the potential curve in Fig. 3A with the coulombic curve I in Fig. 3B that the $\gamma_c'$ region, together with the $\gamma_c$ of the cathodic charging curve corresponding to the steeper branch of the curve I, can be attributed to the reduction of the oxide layer. The $\alpha_c$ region, corresponding to the less sloped branch of curve I and to curve II, can be ascribed to the adsorption of hydrogen on the electrode after the completion of the reduction of the surface oxide.

The fact that the oxide layer is reduced in two regions by the consecutive cathodization suggests that the oxide layer consists of two different species of oxide or that it is removed subsequently through two-stage reactions.

**The Anodic and Cathodic Coulombs.** — The applied anodic current is immediately reversed at various potentials, $E_\gamma$'s, in the $\gamma_a$ region. The charging curves thus obtained are shown in Fig. 4. The ratio of $q_a$, the quantity of electricity used in the region from the initial potential of $\gamma_a$ to the potential, $E_\gamma$, on the anodic curve, to $q_c$, that used from $E_\gamma$, to the end potential of $\gamma_c'$ on the cathodic curve, was traced against $E_\gamma$; the results are represented by curve A in Fig. 5. Furthermore, the anodic and cathodic charging curves were taken in the same manner as above except that the circuit was let stand open for one minute after the anodic polarization up to $E_\gamma$ till the outset of the cathodic one. The results thus obtained

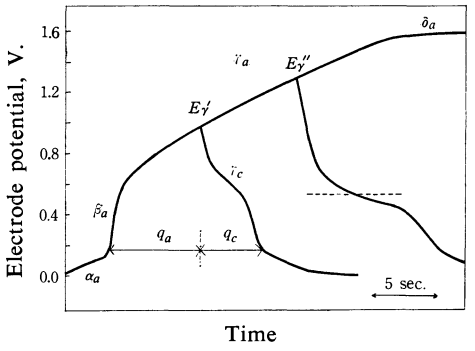

Fig. 4. Alternating anodic-cathodic charging curves when the current was reversed at potentials, $E_\gamma'$ and $E_\gamma''$. $i_a=i_c=94$ $\mu$amp./cm$^2$

are represented as curve B in Fig. 5. The spontaneous decrease in the $q_c/q_a$ ratio for the electrode anodized up to potentials in the $\gamma_a'$ region indicates that the oxygen deposited in this potential region is unstable and less tightly bound with the metal than the oxygen in higher potential regions, $\gamma_a''$ and $\gamma_a'''$.

**The Reduction Potential of the Oxide Layer, the Open Circuit Potential and the Quantity of Electricity Required for the $\gamma_c'$ Stage as a Function of the Pre-anodization Potential.** — The potential of the $\gamma_c$ plateau, i. e., the reduction potential of the oxide layer on the electrode, varies with the potential at which the electrode is pre-anodized, as is shown in Fig. 6. This curve can be divided into three linear sections corresponding to three potential regions, $\gamma_a'$, $\gamma_a''$ and $\gamma_a'''$, of the anodic charging curve.

When the pre-anodization potential was taken in the $\gamma_a'$ region, the slope of the

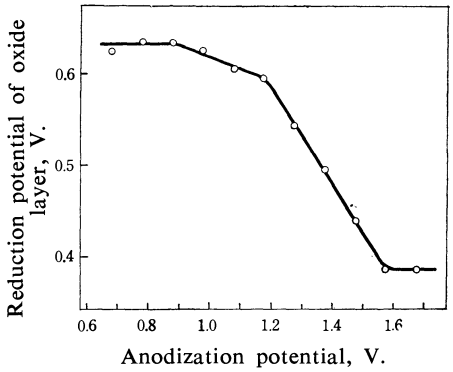

Fig. 6. Plot of the reduction potential of oxide layer at the stage $\gamma_c$ vs. the pre-anodization potential.

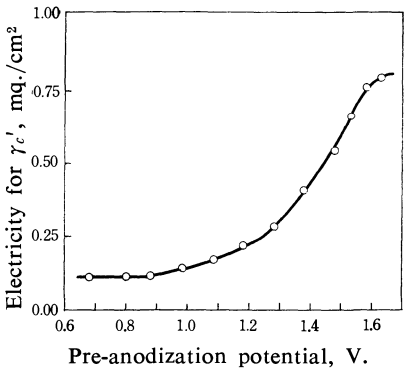

Fig. 7. Plot of the quantity of electricity required for the region $\gamma_c'$ vs. the pre-anodization potential.

curve $\gamma_c'$, for this electrode was almost equal to that of the curve, $\beta_a$, which is attributed only to the charging of the double layer. Consequently, under this pre-anodization the current passing through the electrode in the $\gamma_c'$ region should be nonfaradaic. However, the slope of $\gamma_c'$ decreases and the electricity required for this stage increases with an increase in the pre-anodization potential in the region of $\gamma_a'''$, as may be seen in Fig. 7. This plot indicates that only when the electrode is polarized at potential above 1.2 V. is the stable oxide which is reduced at a more negative potential formed.

When the current is turned off after the anodic polarization, the electrode potential drops rapidly at first, but more slowly as time elapses. The open circuit potential of the electrode was measured 1 and 5 min. after the circuit was broken. The open-circuit potential increases linearly with an increase in the pre-anodization potential up to about 1.2 V., and then it remains approximately constant in the region of the pre-anodization potential from

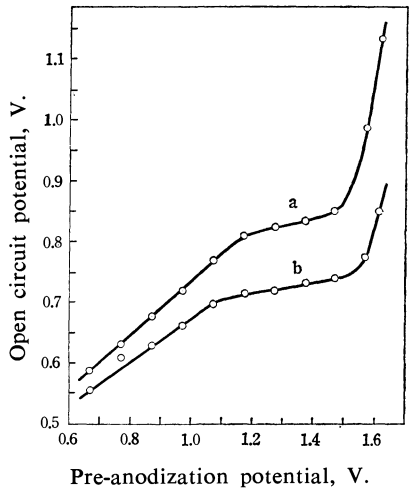

Fig. 8. Plots of the open circuit potential vs. the pre-anodization potential.
Curve a, 1 min. after the pre-anodization current was turned off.
Curve b, 5 min. after the pre-anodization current was turned off.

1.2 to 1.5 V. corresponding to the $\gamma_a'''$ (Fig. 8).

**The Cathodic Behavior of the Electrode in the Solution Containing Hydrogen Peroxide.**— If the hydrogen peroxide theory[6] is correct as to the cause of the inequality between the quantity of electricity required for the $\gamma_a$ stage and that for $\gamma_c+\gamma_c'$, the hydrogen peroxide formed during the cathodization of the oxidized electrode and also the oxygen which may be produced by the decomposition of hydrogen peroxide would diffuse away from the surface of the electrode into the solution, without being further reduced cathodically to water at the reduction potential of the oxide layer. In other words, the reduction potential of hydrogen peroxide or oxygen molecules on the electrode should be sufficiently less positive than that of the oxide layer.

To find the reduction potential of hydrogen peroxide and oxygen on the rhodium electrode, the cathodic charging curves were measured with a smooth rhodium wire in a 2 N sulfuric acid solution containing each of these substances. The mesurements were started one minute after the electrode had been introduced into the solution in order to keep the solution quiescent.

Curve a in Fig. 9 is the cathodic curve obtained with a reduced electrode in the solution containing hydrogen peroxide of $3.7\times10^{-4}$ mol./l. The potential was confined at a constant value of 0.65 V. during the electrolysis. Curve b is for the oxidized electrode. From a comparison of curve d, which is the reduction curve of the oxidized electrode in the

solution freed from both hydrogen peroxide and oxygen, with curves a and b, it is evident that the remaining of constant potentials on curves a and b can be attributed to the reduction of the hydrogen peroxide. The chronopotentiometric reduction potentials of hydrogen peroxide on the reduced and oxidized electrodes are 0.65 and 0.45 V., while those of oxygen on the reduced and oxidized electrodes are 0.62 and 0.41 V. respectively. All of these potentials are more positive than the reduction potential of the oxide layer. When electrodes are polarized with a larger current density, the potential falls after a definite time, $\tau$ (the transition time), as may be seen in curves c and c' of Fig. 9.

For chronopotentiograms with a wire electrode, Eq. 1 has been derived theoretically:[9]

$$\frac{i\tau^{1/2}}{C}=\frac{\pi^{1/2}nFAD^{1/2}/2}{1-\pi^{1/2}D^{1/2}\tau^{1/2}/4r+D\tau/4r^2-3\pi^{1/2}D^{3/2}\tau^{3/2}/32r^3} \quad (1)$$

where $i$ is the constant current; $C$, the concentration of the electroactive substance in the bulk solution; $D$, the diffusion coefficient; $n$, the number of electrons per molecular unit of reaction; $F$, the Faraday constant; $A$, the area of the electrode, and $r$, the radius of the electrode.

If a completely-reduced electrode is used, the oxide will be formed by the direct reaction between the metal and the hydrogen peroxide included in the solution while the electrode is let stand in the cell before the measurement starts. When the oxide thus formed is reduced at the same time as the hydrogen peroxide, it is necessary to make a correction for the value of the observed current, $i_{obs}$, in the chronopotentiometry. The value of the current, $i$, used to reduce the hydrogen peroxide during the transition time can be estimated by substracting the current for the reduction of the oxide from $i_{obs}$. The values of $i$ were calculated by assuming that the amount of the oxide formed during the standing time of the electrode is constant and that the current resulting from the reduction of the oxide remains constant during the entire time of transition.

$$i=i_{obs}-q/\tau \quad (2)$$

where $q$ is the quantity of electricity used to reduce the oxide. The value of $q$ was selected by trial and error.

The corrected values of $i\tau^{1/2}/C$ were plotted against $\tau$ and are represented as tiny circles in Fig. 10. The solid line in the same figure is the theoretical curve according to Eq. 1 using the

9) J. J. Lingane, *J. Electroanal. Chem.*, 1, 379 (1960); 2, 1, 46 (1961).

diffusion coefficient of hydrogen peroxide ($1.71 \times 10^{-5}$ cm./sec.) reported by Kern.[10] The agreement of the observed values with those predicted by the theoretical equation shows that, in chronopotentiometry, hydrogen peroxide on the electrode is quantitatively reduced to water at a potential which is not less positive than the reduction potential of the oxide layer. Consequently, even if the oxide might be reduced to hydrogen peroxide during the cathodization, or even if this peroxide might be decomposed on the surface, these products should be further immediately reduced to water. Thus the hydrogen peroxide theory described above is not applicable to the rhodium electrode.

The fact that more electricity is used for the $\gamma_a$ stage than is required to remove the oxide may be caused by a mixed anodic process where a reaction of oxygen evolution occurs simultaneously with the oxide formation reaction and so consumes some of the electricity.

**The Corrosion by Square-wave Alternating-current Electrolysis.**—The test electrodes for these experiments were rhodium wires 0.5 mm. in diameter and 4—6 mm. long; a new one was used for every run of measurement. The frequency of the square-wave alternating current was 78 c. p. s., the rise time was 1 $\mu$sec., and the output voltage of the generator was 100 V. The square-wave alternating current from the generator was passed through a current-limiting resistor in order to obtain the constant current.

The electrolysis was carried out in a hydrogen-saturated solution. The amplitude of the oscillating-electrode potential during the alternating-current electrolysis increased with the increase in the current density. The minimum value of the potential which appears during negative semicycle of alternating current electrolysis was slightly increased by the hydrogen overpotential when the current density was increased, whereas the maximum potential during a positive semicycle increased rapidly with the increase in the current. The current was so adjusted that this maximum potential was the desired value, $E_s$, during the electrolysis.

The degree of the corrosion of the surface by alternating current electrolysis may be estimated by measuring the increase in the true area per apparent unit area, i. e., the increase in the roughness factor, because the surface is coarsened by the electrolytic attack. Since the value of the electricity, $Q_a$ (coulombs/apparent unit area), required to form the oxide layer is proportionate to the true area of the electrode, the degree of the corrosion is estimated by the ratio of the $Q_a'$ for the electrode already electrolyzed for one hour to the $Q_a^0$ for that not yet electrolyzed. The values of the $Q_a'$ and $Q_a^0$ were obtained from anodic charging curves, which were measured by means of the cathode-ray oscilloscopic technique.

The dependence of the degree of the corrosion on the maximum potential, $E_s$, was traced; the results are shown in Fig. 11. It can be seen from this curve that the surface does not suffer from the corrosion until the $E_s$ potential reaches a critical value, $E_s^0 = 0.88$ V., but after the potential has exceeded this value, the $Q_a'/Q_a^0$ ratio rises very rapidly and the bright surface becomes cloudy.

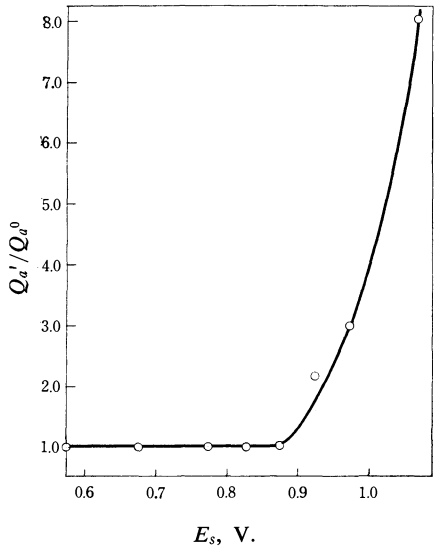

Fig. 11. Plot of the extent of corrosion vs. the maximum value, $E_s$, of oscillating potential in square wave alternating current electrolysis.
Frequency, 78 c.p.s. Etectrolyzing time, 1 hr.

The corrosion by the alternating-current electrolysis may be attributed to the repetition of the alternate formation and reduction of the "oxide" layer, as has been suggested previously for the platinum electrode.[5] The rearrangement of the rhodium atoms on the surface due to the repeated formation and dissolution of oxide lattices should cause a recrystallization on the surface. The fact that the surface did not suffer from any attack at all until the $E_s^0$ potential was reached indicates that the oxygen atoms deposited on the surface in the potential region, $\gamma_a'$, are only in a state of adsorption or are attached to the surface by relaxed bonds so that they

10) D. M. Kern, *J. Am. Chem. Soc.*, **78**, 4207 (1954).

are not able to effect a serious change in the Rh-Rh bonds.

On the basis of the observed data for the rhodium electrode, the mechanism of the surface oxidation can be considered. The oxidation is completed through three steps taking place at the different potential regions. The number of coulombs required for each of these regions, $\gamma_a'$, $\gamma_a''$ and $\gamma_a'''$, are equal to one other.

The first step of the $\gamma_a'$ region can be attributed to the formation of an intermediate which is adsorbed on the electrode surface. The intermediate may be hydroxyl redicals which come from water with one electron per molecular unit change:

$$Rh + H_2O \rightarrow Rh\cdots OH + H^+ + e^- \quad (3)$$

The highly polar group, Rh···OH, thus formed is unstable and may be converted to a less polar group which is close to the oxide, Rh-OH or $Rh_2O$, as the electrode potential increases.

The second stage, $\gamma_a''$, is the reaction in which the "oxide" is formed;

$$Rh\text{-}OH \rightarrow Rh\text{-}O + H^+ + e^- \quad (4)$$

Sidgwick[11] stated that the only stable oxide formed by rhodium is $Rh_2O_3$, while Hoare[4] found that the end product formed by the anodic polarization is $Rh_2O_3$. From the polarization data and the coulombic studies of Butler and Drever,[12] and Böld and Breiter,[3] it seems true that the oxide layers on the rhodium do not grow much beyond a monolayer. Therefore, in the third stage, $\gamma_a'''$, the following reaction may take place, with an intermediate of a polar group:

$$Rh\text{-}O + H_2O \rightarrow Rh\text{-}O\cdots OH + H^+ + e \quad (5)$$

where Rh-O···OH has the same empirical formula as hydrated $Rh_2O_3$.

At the cathodization, the oxide layer is reduced in two stages of different potentials. As the quantity of electricity required for the first reduction stage, $\gamma_c$, is almost twice as much as that required for the second stage, $\gamma_c'$, which is equal to that for the hydrogen deposition stage, $\alpha_c$, the first stage seems to be a reducing reaction using two electrons per molecular unit of reaction, and the second stage, one using one electron.

## Summary

Surface oxides on the smooth rhodium electrode have been characterized by anodic oxidation and by cathodic stripping with a constant current under various conditions.

The oxidation reaction of the surface should consist of three stages with a characteristic potential region; the adsorption of OH, the formation of an oxide, Rh-O, and, finally, the formation of a higher oxide, $Rh_2O_3$. The oxide thus formed is cathodically reduced step-by-step in two different potential regions. These mechanisms are supported by the experimental data of the charging curves taken under various conditions, the corrosion by the square-wave alternating-current electrolysis, and the variation in the electrode capacity during the electrolysis.

The author is indebted to N. Yamamoto and T. Sugimoto for their assistance in the experimental work.

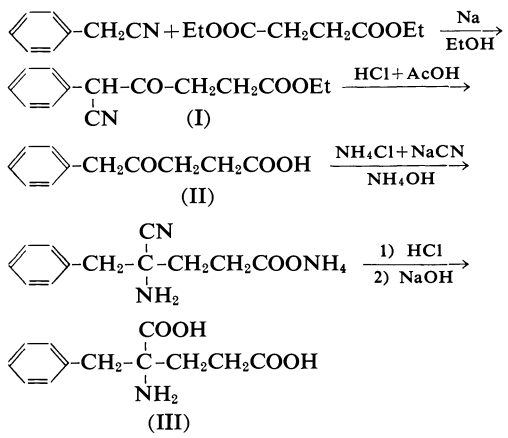
# The Preparation of Optically Active α-C-Substituted Glutamic Acid



By Yoshiharu IZUMI, Susumu TATSUMI, Masami IMAIDA, Yoshio FUKUDA and Shiro AKABORI

(Received December 10, 1964)

α-C-Dialkyl-substituted glycine is an interesting substance from the biochemical point of view, with regard to α-amino acid and also with ragard to the relation between its optical rotation and its absolute configuration. However, although several α-C-dialkyl-substituted glycines have been synthesized, only two have been resolved into the optically active isomers.[1,2]

In the present work, two optically active α-C-dialkyl-substituted glycines, 2-methyl and 2-benzylglutamic acid, were prepared. DL-2-Methylglutamic acid was synthesized from levulinic acid by Takenishi's procedure,[3] and then its optical resolution was performed. *N*-Benzoylated DL-2-methylglutamic acid was resolved with brucine by the method of the differential solubility of the isomers in water. The optical rotation values of the isomers were as follows; (+) isomer, $[\alpha]_D^{20}$ +12.1° (*c* 4, 6 N HCl); (−) isomer, $[\alpha]_D^{20}$ −12.1° (*c* 4, 6 N HCl).

DL-2-Benzylglutamic acid was prepared from benzyl cyanide and diethyl succinate by the following process:

The optical resolution of this amino acid was performed by means of a methanolic solution with strychinine. The optical rotation values of two optically active isomers of this amino acid were as follows:

(+) isomer, $[\alpha]_D^{20}$ +1.65° (*c* 10, 4 N HCl);
(−) isomer, $[\alpha]_D^{20}$ −1.60° (*c* 10, 4 N HCl).

## Experimental

**The Preparation of DL-2-Methylglutamic Acid.**—DL-2-Methylglutamic acid was prepared from levulinic acid by Takenishi's procedure.[3]

**The Preparation of *N*-Benzoyl-2-methylglutamic Acid.**—One hundred and fifty milliliters of 2 N sodium hydroxide and 42.5 g. of benzoyl chloride in 100 ml. of dioxane were simultaneously stirred, drop by drop, into a solution of 48.3 g. of DL-2-methylglutamic acid in 600 ml. of N sodium hydroxide at 5—10°C; the addition took about 2 hr. Stirring was then continued for one more hour at the same temperature. The reaction mixture was washed with two 100 ml. portions of ethyl ether and concentrated to about 500 ml. in vacuo. This solution was then acidified with 100 ml. of concentrated hydrochloric acid, and stored for two days in an ice box. The crude material obtained was washed several times with boiling ligroin. The resulting crystals were dissolved in 230 ml. of methyl alcohol and filtered. The filtrate was stirred into 500 ml. of water, and the mixture was allowed to stand overnight in an ice box. White crystalline *N*-benzoyl-2-methylglutamic acid was collected, washed with cold water, and dried in air. m. p. 198°C. Yield, 50 g.

Found: C, 58.48; H, 5.66; N, 5.15. Calcd. for $C_{13}H_{15}NO_5$: C, 58.86; H, 5.70; N, 5.28%.

**The Optical Resolution of *N*-Benzoyl-2-methylglutamic Acid.**—After 69 g. of *N*-benzoyl-2-methylglutamic acid and 255 g. of brucine had been dissolved in 3.4 l. of boiling water, the solution was left to stand overnight in a refrigerator. The crystals were then collected, washed with cold water, and dried in air at room temperature. Two recrystallizations of this crude product from 1.4 parts of water gave 125 g. of pure *N*-benzoyl-2-methylglutamic acid brucine salt. One hundred and ten grams of the brucine salt were decomposed with 150 ml. of 2 N sodium hydroxide solution, and the brucine was removed by filtration. The alkaline solution was neutralized with hydrochloric acid and then evaporated to about 100 ml. in vacuo. This solution was boiled with 100 ml. of concentrated hydrochloric acid for 4 hr. and then left to stand overnight in a refrigerator. Benzoic acid was removed by filtration and extraction with 100 ml. of

ethyl ether. The aqueous layer was evaporated to dryness in vacuo. To the residue a small amount of water was added, and the solution was evaporated to dryness in order to remove the free hydrochloric acid. Then the residue was taken up in 30 ml. of water, decolorized with charcoal, and adjusted to pH 3.2 with 20% sodium hydroxide. The mixture was stored overnight in a refrigerator, and the resulting crude crystals were collected, washed with 5 ml. of 50% methanol, and dried in air, yielding 7.1 g. of (+)-2-methylglutamic acid. On recrystallization from 10 ml. of boiling water, pure (+)-2-methylglutamic acid was obtained as fine needles. Yield, 6.3 g. $[\alpha]_D^{20}$ +12.1° (*c* 4, 6 N HCl).

Found: C, 44.99; H, 6.80; N, 8.60. Calcd. for $C_6H_{11}NO_4$: C, 44.71; H, 6.88; N, 8.69%.

The mother liquor of the *N*-benzoyl-(+)-2-methylglutamic acid brucine salt was concentrated to a paste. After it had stood for a week in a refrigerator, the brucine salt was collected. (−)-2-Methylglutamic acid was similarly obtained from the brucine salt by the procedure described above. Yield, 1.8 g. $[\alpha]_D^{20}$ −12.1° (*c* 4, 6 N HCl).

Found: C, 43.39; H, 6.77; N, 8.44%.

**The Preparation of DL-2-Benzylglutamic Acid (III).**—*Ethyl 5-Phenyl-5-cyanolevulinate (I).*—A mixture of 37.2 g. of freshly-distilled benzyl cyanide and 26.1 g. of diethyl succinate was added, with vigorous shaking, to 120 ml. of a sodium ethoxide solution containing 8.4 g. of sodium. The mixture was then refluxed for 2 hr., stored overnight at room temperature, poured into 350 ml. of cold water, and neutralized slowly with glacial acetic acid. An oily brown ester was separated, and the aqueous layer was extracted with ethyl ether. The ether layer was combined with the oily ester, washed twice with water, and dried over magnesium sulfate. Then the ether was evaporated off, and unreacted benzyl cyanide and diethyl succinate were removed by distillation in vacuo. The residual oily substance was allowed to stand for a few hours at −20°C. Brown crystals were thus obtained. Recrystallization from benzene - petroleum ether (1 : 1) gave white crystals. Yield, 54.8 g. M. p. 154°C. Betts and Davey[4] reported a m. p. of 152°C for this material.

Found: C, 68.05; H, 6.15; N, 5.69. Calcd. for $C_{14}H_{15}NO_3$: C, 68.55; H, 6.16; N, 5.71%.

*5-Phenyllevulinic Acid (II).*—Crude I (44 g.) was added to a mixture of glacial acetic acid (300 ml.), concentrated hydrochloric acid (100 ml.) and water (90 ml.), and the mixture was refluxed for 14.5 hr. Then it was evaporated to dryness in vacuo, and the residue was taken up in ether. The ether layer was washed twice with water and repeatedly extracted with a 5% potassium carbonate solution. The alkaline solution was then washed with ether and adjusted to pH 3—4 with 3 N hydrochloric acid. II was obtained as a brown oil. For the purification of crude II, this oil was dissolved in a small amount of water containing equimolar potassium hydroxide, and then a large quantity of acetone was added to the solution. After the mixture had stood in an ice box for 4 hr., the colorless crystalline potassium salt of II was collected. Recrystallization from water-acetone (1 : 4) gave 32 g. of the pure salt. This was dissolved in water, adjusted to pH 3—2 with concentrated hydrochloric acid, and extracted with ether. The ether layer was washed with water and dried over magnesium sulfate. When the ether was evaporated off, II was obtained as white crystals. Yield, 25 g. M. p. 57°C.

Found: C, 68.89; H, 6.29. Calcd. for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

**DL-2-Benzylglutamic Acid (III).**—After a solution containing 23 g. of II and 34 ml. of 12% aqueous ammonia had been cooled to 0—5°C in an ice water bath, 7.4 g. of sodium cyanide in 27 ml. of water and 8 g. of ammonium chloride in 27 ml. of water were added. The flask was tightly stoppered, and the mixture was shaken vigorously in a water bath at 50—70°C for 6 hr. Then the reaction mixture was cooled in an ice water bath and poured into 1.5 l. of concentrated hydrochloric acid; the mixture was allowed to stand overnight at room temperature before it was refluxed for 2 hr. The hydrolyzate was concentrated in vacuo, and during this procedure inorganic salts were removed by filtration. The residue was dissolved in a small amount of water and redried in vacuo in order to remove the free hydrochloric acid. It was taken up in a small amount of water, and the solution was decolorized, adjusted to pH 3.2 with dilute sodium hydroxide, and allowed to stand in a refrigerator. White crystals of III were collected, washed with cold water, and dried in air. Yield, 21 g. M. p. 214—215°C (decomp.).

Found: C, 60.71; H, 6.35; N, 5.88. Calcd. for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

**The Preparation of *N*-Benzoyl-DL-2-benzylglutamic Acid.**—*N*-Benzoyl-DL-2-benzylglutamic acid was prepared from 47.4 g. of III and 91 g. of benzoyl chloride using a procedure similar to that described for the preparation of *N*-benzoyl-DL-2-methylglutamic acid. Yield, 50 g. M. p. 193°C.

Found: C, 66.80; H, 5.61; N, 4.08. Calcd. for $C_{19}H_{19}NO_5$: C, 66.85; H, 5.61; N, 4.10%.

**The Optical Resolution of *N*-Benzoyl-DL-2-benzylglutamic Acid.**—Seventy-three grams of strychinine and 37 g. of *N*-benzoyl-DL-2-benzylglutamic acid were dissolved in 600 ml. of boiling methanol. The solution was then cooled to room temperature, 20 ml. of water was added with vigorous shaking, and the mixture was allowed to stand overnight in a refrigerator. The crystalline precipitate was collected and recrystallized twice from methanol. An optically pure *N*-benzoyl-2-benzylglutamic acid distrychinine salt was obtained. Yield, 44 g. M. p. 173—175°C, $[\alpha]_D^{20}$ +11.9° (*c* 1.2, methanol).

Forty-four grams of the distrychinine salt were decomposed with 270 ml. of 0.5 N sodium hydroxide at 5°C, and crystallized strychinine was removed. The alkaline solution was washed twice with 50 ml. of chloroform, and the aqueous layer was concentrated to half its volume and then acidified with 15 ml. of concentrated hydrochloric acid. The acidic solution was then left to stand overnight in an ice box, and 15 g. of *N*-benzoyl-(+)-2-benzylglutamic acid was obtained. $[\alpha]_D^{20}$ +52.6° (*c* 2.5, methanol). *N*-Benzoyl-(+)-2-benzylglutamic acid

4) B. E. Betts and W. Davey, *J. Chem. Soc.*, **1961**, 3336.

(14.7 g.) were hydrolyzed with 90 ml. of 20% hydrochloric acid for 4 hr. After standing overnight in a refrigerator, the crystallized benzoic acid was removed from the hydrolyzate and the filtrate was washed twice with ether. The solution was evaporated to drynesss in vacuo. The residue was dissolved in a small amount of water, and the solution was evaporated to dryness again in order to remove the free hydrochloric acid. To the residual syrup, 20 ml. of water was added. The resulting solution was decolorized with charcoal, neutralized with alkali, and allowed to stand in an ice box. The crude product was collected, and for purification it was converted to the hydrochloride and neutralized with sodium hydroxide. Crystals of optically pure (+)-2-benzylglutamic acid were collected, washed with methanol-water, and dried. Yield, 6.0 g. M. p. 209°C, $[\alpha]_D^{20}$ +1.65° (*c* 10, 4 N HCl).

Found: C, 60.67; H, 6.28; N, 5.86. Calcd. for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

When the mother liquor of the *N*-benzoyl-(+)-2-benzylglutamic acid distrychinine salt was treated in the manner described above, crystals of (−)-2-benzylglutamic acid were obtained. Yield, 3.2 g. M. p. 208°C, $[\alpha]_D^{20}$ +1.60° (*c* 10, 4 N HCl).

Found: C, 60.70; H, 6.33; N, 5.83. Calcd. for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

**Summary**

1) The optical resolution of DL-2-methylglutamic acid has been performed using brucine as a resolving reagent; the two optically active isomers have been obtained.

2) DL-2-Benzylglutamic acid has been synthesized using benzyl cyanide and diethyl succinate as the starting materials. Moreover, the optical resolution of this amino acid has been performed using strychinine as a resolving reagent. The two optically active isomers were obtained.

# Chemical Effects Associated with $\beta$-Decay Process. I. The Chemical Behavior of a Decayed Product, $^{144}Pr$, in the EDTA Complex System

By Takanobu SHIOKAWA, Hiroshi KUDO and Takashi OMORI

(Received December 11, 1964)

Many papers on the chemical effects of $\beta$-decay processes have appeared in current literature, with especial emphasis laid on the change in the oxidation state of radioactive daughter atoms. It has been widely accepted that the unusual behavior of radioactive daughter atoms is to be attributed, in the main, to an electronic excitation resulting from the abrupt change in the nuclear charge. On the other hand, the probability of a bond rupture resulting from the recoil only is fairly small, because in many cases the effective recoil energy and the chemical bond energy are of the same order of magnitude.

The lanthanides provide an opportunity to study the chemical behavior of the radioactive daughter atoms formed by the $\beta$-decay process, especially the effects of the electronic excitation; that is, their chemical properties are similar to each other, and the daughter atoms are in an excited state or are thermodynamically unstable, even in the simple $\beta$-decay.

Cerium-praseodymium-144 possesses several advantages in its nuclear and chemical properties for this purpose. The present investigation will study the chemical behavior of $^{144}Pr$ atoms formed by the $\beta^-$-decay of the $^{144}Ce$-labeled cerium(III) ethylenediaminetetraacetate (Ce(III)-EDTA) complex in aqueous and aqueous-alcohol solutions. Previously, the chemical behavior of $^{144}Pr$ in the $^{144}Ce$(III) acetylacetonate system was investigated by Edwards and Coryell[1] and was found to be considerably different from that of the parent $^{144}Ce$. In the lanthanide system it was also reported that 59 per cent of the $^{177}Lu$ atoms formed by the

1) R. R. Edwards and C. D. Coryell, TID-13363 (1961).

$\beta^-$-decay of the $^{177}Yb(III)$-EDTA complex escape from the complex, and appear in solution in the cationic form, $^{177}Lu^{3+}$.[2]

## Experimental

**Reagents.**—Carrier-free Ce-Pr-144 in a hydrochloric acid solution was imported from the Oak Ridge National Laboratory. The solution of disodium ethylenediaminetetraacetate (EDTA) was standardized against a standard zinc(II) solution by volumetric titration, using Eriochrome Black T as an indicator. A stock solution of cerium(III) was prepared by dissolving guaranteed-reagent-grade $Ce(NO_3)_3 \cdot 6H_2O$ in hydrochloric acid, and it was standardized volumetrically against the standard EDTA solution with Eriochrome Black T. All the other chemicals used were of guaranteed-reagent grade.

**Apparatus and Procedure.**—An aliquot of the cerium(III) chloride solution labeled with $^{144}Ce$ was evaporated to dryness in the presence of hydrogen peroxide. To the solid cerium(III) chloride, a known amount of a EDTA solution was added, less in amount than the equivalent ([EDTA]/[Ce(III)]=0.766), and then the Ce(III)-EDTA complex solution was prepared by passing it through a Dowex 50W-X8 column at pH 6.5 in order to remove the excess cerium. The separate experiments ensured that the separation was quantitative, indicating the presence of no excess EDTA. The final concentration of cerium(III) was $1.2 \times 10^{-3}$ M. The pH was adjusted by the addition of an ammonium acetate buffer. Aliquots of the solution were allowed to stand in a bath of the desired temperature for 4 hr. The samples were then withdrawn through a Dowex 50W-X8 column (8 mm.×20 mm.), and the free-ion fraction was separated from the complex fraction. The resin used had been treated previously with an appropriate buffer.

The yield of the free-ion fraction was obtained by counting the $\gamma$-activities of both the resin phase and the combined effluents. The cerium-144 was assayed by counting only the hard $\gamma$-activities of $^{144}Pr$ in secular equilibrium with $^{144}Ce$ 3 hr. later. The yield of $^{144}Pr$ ions was obtained by extrapolating the $^{144}Pr$ decay (or growth) curve to the time of chemical separation, using the half-life of 17.5 min.[3] The pH of the solution was measured with a glass-electrode pH meter, with an accuracy of 0.02 pH.

## Results

The experiments have shown that the apparent yield of the $^{144}Pr$ ion, which is defined as the extent of the free-ion fraction absorbed on the resin, depends on the pH, the concentration of ethyl alcohol, and the temperature.

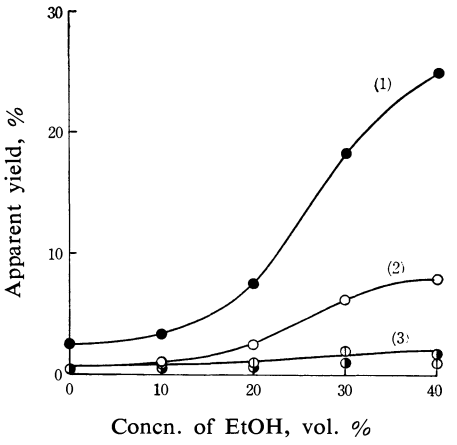

Fig. 1. Effect of concentration of ethyl alcohol on apparent yields of $^{144}Pr^{3+}$ and $^{144}Ce^{3+}$ at pH 6.7.
(1) and (2) : $^{144}Pr$ ; (3) : $^{144}Ce$
○ and ⓘ : 28°C ; ● and ◑ : 3°C

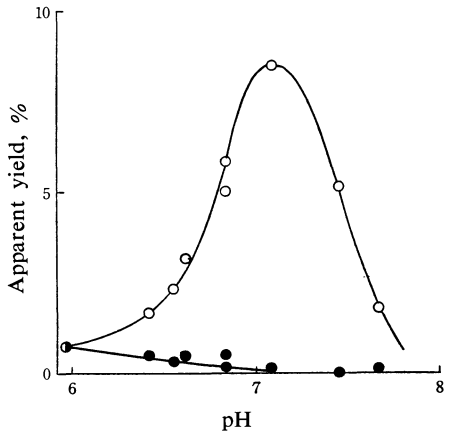

Fig. 2. Apparent yields of $^{144}Pr^{3+}$ and $^{144}Ce^{3+}$ in aqueous solution at 3°C.
○ : $^{144}Pr$ ; ● : $^{144}Ce$

As Fig. 1 shows, the apparent yield of $^{144}Pr$ ions increases slightly up to 20 per cent ethyl alcohol, while above this point the yield increases abruptly. The maximum concentration of ethyl alcohol used in the experiments was 40 per cent because of the small solubility of the Ce(III)-EDTA complex.

The distribution of the apparent yields of $^{144}Pr$ ion and $^{144}Ce$ ion as a function of the pH at a constant temperature is shown in Figs. 2 and 3. These figures show that there is a remarkable difference between the distribution curves of $^{144}Pr$ and $^{144}Ce$. For instance, the yield of free cerium ions decreases gradually as the pH increases, whereas the distribution curves of praseodymium have a maximum.

According to the formation constant of the

3) B. S. Dzhelepov and L. K. Peker, "Decay Schemes Radioactive Nuclei," Pergamon Press, New York (1961), p. 422.

Ce(III)-EDTA complex,[4] cerium(III) forms completely the complex with EDTA under these experimental conditions. Because of the absence of excess EDTA, however, it should be noted that the cerium absorbs to some extent on the resin as the apparent formation constant decreases. These facts are clearly shown by the distribution behavior of $^{144}Ce$ in Figs. 2 and 3.

The distribution curves of $^{144}Pr$ may be influenced by both the normal distribution and the so-called "hot-atom" effect. To obtain the net "hot-atom" effect of $^{144}Pr$, we subtracted the extent of normal distribution from the apparent distribution curve, on the assumptions that the normal distribution curve of praseodymium is similar to that of cerium, and that the distribution constants of cerium and praseodymium are equal. The results are shown in Fig. 4.

## Discussion

The maximum yield of the $^{144}Pr$ ion is 28 per cent in a 40 per cent alcohol solution at 3°C, suggesting that in at least 28 per cent of the events the cerium(III)-EDTA bonds were ruptured as a result of the $\beta^-$-decay of $^{144}Ce$. Since the nuclear event itself is insensitive to the surrounding conditions, the extent of the bond rupture should also be independent of the pH. The results shown in Fig. 4, therefore, suggest that, after nuclear events, the de-excited $^{144}Pr$ atom causes a chemical reaction with environmental substances during its lifetime.

It has been found that the rate of isotopic exchange reaction in the La(III)(Nd(III))-EDTA systems is fairly rapid.[5] In these systems, the rate of the exchange reaction, $R$, is expressed as:

$$R=k[\mathrm{LnY^-}]\ [\mathrm{H^+}] \qquad (1)$$

where $k$ is a rate constant of about $10^5$ l.·mol$^{-1}$min$^{-1}$ and where $\mathrm{LnY^-}$ designates the EDTA complex. Although the mechanism of the exchange reaction in the alkaline region has not been investigated, the mechanism seems to be similar to that in the In(III)-EDTA system:[6]

$$R=k[\mathrm{InY^-}]\ [\mathrm{OH^-}]^2 \qquad (2)$$

in which the rate of exchange is expressed as in Eq. 1 in the acid region. These values of the rate constants cannot be directly applied to the present system. On the basis of kinetics, however, the distribution curves of $^{144}Pr$ ion can be qualitatively explained. In the neutral region, the exchange rate has a minimum value, producing a maximum point in the distribution curve. The pH at which the yield of $^{144}Pr$ ions is at a maximum shifts to a lower value with an increase in the concentration of ethyl alcohol. These results suggest that the reaction expressed in Eq. 1 is depressed as compared with the reaction expressed in Eq. 2 in the alcoholic solution. As the temperature rises, the re-chelation of $^{144}Pr$ with EDTA

4) J. Bjerrum, G. Schwarzenbach and L. G. Sillén, "Stability Constants of Metal Ion Complexes, Part I. Organic Ligands," The Chemical Society, London (1958), p. 76.

5) R. H. Betts, O. F. Dahlinger and D. M. Munro, "Radioisotopes in Scientific Research. Proceedings of the First UNESCO International Conference, Paris, 1957," Vol. II, Pergamon Press, New York (1958), p. 326.

6) K. Saito and M. Tuchimoto, *J. Inorg. Nucl. Chem.*, **25**, 1245 (1963).

will be promoted; therefore, the yield of $^{144}Pr$ ion decreases with the temperature. These considerations lead to the conclusion that, in the $^{144}Ce(^{144}Pr)$-EDTA system, the very extensive disruption of the EDTA complex takes place as a result of the $\beta^-$-decay of $^{144}Ce$.

The cerium-144 is transformed to $^{144}Pr$ by $\beta^-$-decay with energies of 0.320 (60 per cent) and 0.184 (30 per cent) MeV.[3] The recoil energy is low, ranging from 0 to 1.6 eV. according to the partition of energy between the $\beta^-$-particle and neutrino. This means that the probability of bond rupture as a result of the recoil only is much less than 1. Consequently, the fairly complete disruption of the complex may arise from the abrupt change in the atomic number of the metal ion.

Positively-charged species result from the increase in the nuclear charge in the $\beta^-$-decay, even in the absence of orbital electron ionization. At the instant of the simple $\beta^-$-decay of the $^{144}Ce$(III)-EDTA complex, $^{144}Pr$ exists in the tetravalent state, and the instability of tetravalent praseodymium in solution is favorable for an instantaneous stabilization reaction. For this stabilization reaction, it was suggested that, in the $\beta^-$-decay of $^{144}Ce$(III) acetylacetonate, the electron transfer of tetravalent $^{144}Pr$ with parent cerium(III) acetylacetonate might reduce the excited complex to stable $^{144}Pr$(III) acetylacetonate.[1] In the present system, however, considering that the EDTA is a reducing agent,[7] it is most probable that the electron transfer between the tetravalent $^{144}Pr$ and EDTA is predominant and that it, via an intermediate complex, results in the extensive bond rupture needed to liberate the $^{144}Pr$ ion. Moreover, it has been confirmed that such an intramolecular electron-transfer is often followed by a bond-rupture process.[8] (In order to treat the results strictly, however, it should be borne in mind that the presence of higher-charged $^{144}Pr$ in consequence of internal conversion cannot be ignored.)

Although the explanation offered here is not rigorous, it will be recognized that the most important factor in determining the fate of $^{144}Pr$ atoms is an increase in the nuclear charge of $^{144}Pr$ as a result of the $\beta^-$-decay of $^{144}Ce$. Furthermore, it is evident that the exchange reaction plays an important part in determining the $^{144}Pr^{3+}$-yield, even if the question remains unresolved of whether the intermediate complex has a finite lifetime, or whether it decomposes instantaneously.

## Summary

The chemical behavior of $^{144}Pr$ formed by the $\beta^-$-decay of the $^{144}Ce$(III)-EDTA complex has been investigated. The chemical behavior of $^{144}Pr$ is remarkably different from that of $^{144}Ce$. The results suggest that an increase in the nuclear charge of $^{144}Pr$ plays the most important role in determining the yield of $^{144}Pr$ ions and leads to the extensive disruption of the complex molecule by intramolecular electron-transfer. The liberated $^{144}Pr$ ion reforms the complex according to its kinetic law. The recoil as a result of $\beta^-$-decay seems not to be the cause of the formation of the free $^{144}Pr$ ions.

# Sorboses. VI. 1, 2-Unsaturated-L-sorboses[1]

By Kanji TOKUYAMA, Etsuko TSUJINO (née HONDA) and Masumi KIYOKAWA

(Received December 14, 1964)

Although the 1, 2-unsaturated aldoses (glycals), which were first synthesized by Fischer,[2] have become important intermediates in the synthesis of a variety of carbohydrates,[3] no information about the synthesis of 2, 3-unsaturated ketoses, corresponding to glycals, has yet been reported. Our attempt to synthesize the 2, 3-unsaturated derivative of L-sorbose (I), a glycal homologue of ketohexose, was also unsuccessful. That is, by Fischer's method,[2] 1, 3, 4, 5-tetra-*O*-acetyl-α-L-sorbopyranosyl chloride (II),[4,5] which had been derived from 1, 2, 3, 4, 5-penta-*O*-acetyl-α-L-sorbopyranose (III),[4] was not converted into the compound with a double bond, but into 1, 3, 4, 5-tetra-*O*-acetyl-α-L-sorbopyranose (IV).[4] Under the reaction conditions employed, only solvolyses were always observed. These results prompted us to synthesize 1, 2-unsaturated L-sorbose.

Ts=*p*-Tolylsulfonyl Ac=Acetyl

Chart 1

The synthesis of 1, 2-dideoxy-1, 2-ene-L-sorbopyranose was achieved by the schemes outlined in Chart 1. For the introduction of a double bond into the C-1, 2 position, the synthesis of 1-*O*-tosyl-2-bromo derivatives of I was desired. At the outset, 1-*O*-tosyl-L-sorbose (VII),[6] which was obtainable from 2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (V)[7] via 1-*O*-tosyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (VI),[8] was prepared as the starting material.

The acetylation of VII with acetic anhydride in pyridine gave triacetate (VIII), whose infrared spectrum showed the characteristic bands due to a pyranose ring[9,10] and whose optical rotation suggested that it was an α-anomer. Therefore, the structure VIII was confirmed to be 1-*O*-tosyl-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranose. The further acetylation of VIII with acetic anhydride in the presence of sodium acetate at room temperature gave 1-*O*-tosyl-2, 3, 4, 5-tetra-*O*-acetyl-α-L-sorbopyranose (IX), whose configuration was supported by the optical rotation and the infrared spectrum.[9,10] This compound is not very stable, but it can be kept well under cold conditions. The treatment of IX with dry hydrogen bromide in acetic acid gave a crystalline bromo-derivative, 1-*O*-tosyl-2-deoxy-2-bromo-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranose (X), which was very sensitive to moisture. The configuration of this compound was confirmed as follows (see Chart 2). The methanolysis of X in the presence of silver

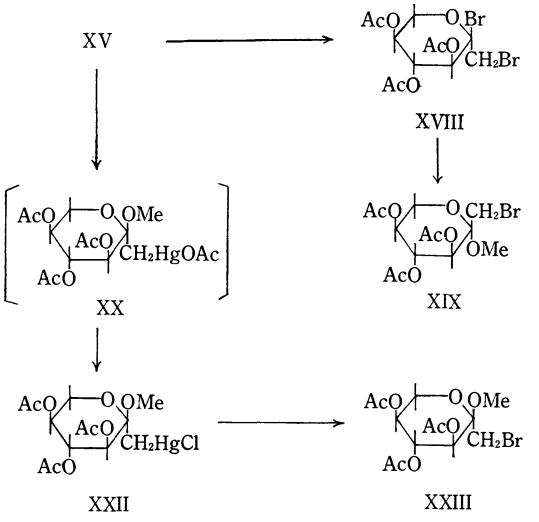
Me=Methyl

Chart 2

carbonate gave methyl 1-*O*-tosyl-3,4,5-tri-*O*-acetyl-β-L-sorbopyranoside (XI), whose optical rotation become much more positive than that of X. The deacetylation of XI with lithium aluminum hydride in tetrahydrofuran to form methyl 1-*O*-tosyl-β-L-sorbopyranoside (XII), followed by reduction with sodium in liquid ammonia, gave methyl β-L-sorbopyranoside (XIII). A comparison of the optical rotation of XIII obtained here with that of methyl α-L-sorbopyranoside (XIV)[11] indicated that the former was a β-anomer. Therefore, X was confirmed to be an α-anomer, and XI and XII to be β-anomers.

The treatment of X with sodium iodide in acetone under absolutely anhydrous conditions gave unstabl crystals (XV) with no bromine atom. Its infrared spectrum showed no band of a *p*-tolyl group, but that of a double bond at 1660 $cm^{-1}$. Some chemical investigations were carried out to decide whether or not the double bond is of an exo-methylene type because the out-of-plane deformation band at 1800—1750 $cm^{-1}$, which is characteristic of an exo-methylene type, was not observed because of overlapping with bands of the acetate groups around 1760 $cm^{-1}$. The deacetylation of XV with sodium methylate in methanol gave a deacetylated compound (XVI), which had no band of a double bond in the infrared spectrum, but two singlet peaks of a methyl ($\tau$ 8.66) and a methoxyl group ($\tau$ 6.81) in the NMR. Therefore, the structure of XVI was determined to be methyl 1-deoxy-L-sorbopyranoside formed by the addition of methanol to XV. When a benzene and ether solution of XV was passed through a silica gel column, another product, XVII, was obtained; it also had no double bond in the infrared spectrum and a methyl group in the NMR ($\tau$ 8.60). This compound reduced the Fehling solution. On the basis of these facts, the structure of XVII was determined to be 1-deoxy-3,4,5-tri-*O*-acetyl-L-sorbopyranose, which is an addition product of water to XV. The sugars obtained here seem to be α-anomers, judging from their optical rotations. The conversion of XV into XVI and XVII gave positive support to the assignment of the double bond, which should be an exo-methylene type. Thus, the structure of XV was established as 1,2-dideoxy-1,2-ene-3,4,5-tri-*O*-acetyl-L-sorbopyranose. A similar attempt to add ammonia or hydrogen sulfide to XV did not yield crystalline products.

Further studies of the addition reactions of XV were carried out (see Chart 3). The treatment of XV with bromine in a carbon tetrachloride solution at room temperature gave unstable 1,2-dideoxy-1,2-dibromo-3,4,5-tri-*O*-acetyl-α-L-sorbopyranose (XVIII). The methanolysis of XVIII in the presence of silver carbonate gave methyl 1-deoxy-1-bromo-3,4,5-tri-*O*-acetyl-β-L-sorbopyranoside (XIX). On the other hand, the reaction of XV with methanolic mercuric acetate yielded a sirup mixture containing mercury. The purification



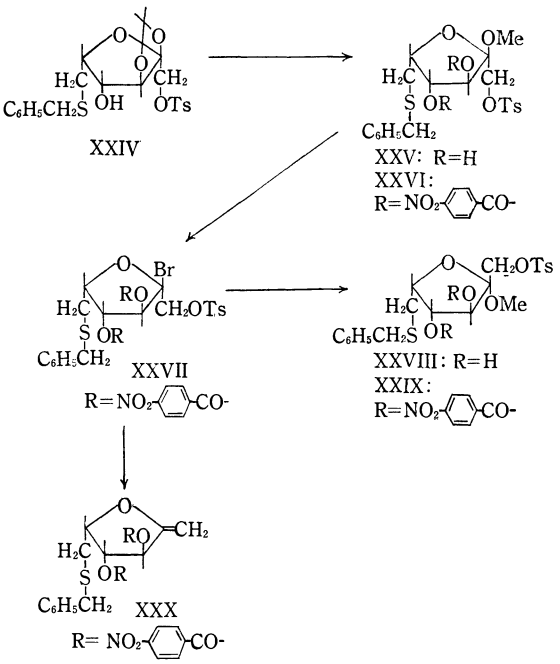


Chart 3

of the sirup was unsuccessful, but it was, on the basis of the evidence presented below, composed mainly of methyl 1-deoxy-1-acetoxymercuri-3,4,5-tri-*O*-acetyl-α-L-sorbopyranoside (XX), plus its β-anomer (XXI). When the sirup was shaken with a saturated solution of sodium chloride, a crystalline chloromercuric compound (XXII) was separated in a pure state. The optical rotation of the mother liquor shifted to a positive side than that of XXII. After the mother liquor had been evaporated, the residual solid gave satisfactory analytical data for the structure of XXII. Therefore, the structure of XXII was confirmed

11) E. Fischer, *Ber.*, **28**, 1145 (1895).

to be methyl 1-deoxy-1-chloromercuri-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranoside, while the mother liquor was composed of XXII and its β-anomer. These results suggest that the major component (XX) in the former sirup is probably methyl 1-deoxy-1-acetoxymercuri-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranoside, while the minor component (XXI) is a β-anomer of XX. The displacement reaction of mercury of XXII with bromine in a chloroform solution at room temperature gave methyl 1-deoxy-1-bromo-3,4,5-tri-*O*-acetyl-α-L-sorbopyranoside (XXIII). The conclusion that XXIII is an α-anomer and XIX, a β-anomer was obtained from the comparison of their optical rotations. Consequently, the configurations of XVIII, XX and XXII were confirmed as α-anomers.

The preparation of 1, 2-unsaturated sorbofuranose is also shown in Chart 4; it is almost identical with that used for 1, 2-unsaturated sorbopyranose (XV). In order to obtain an acylated sorbofuranose, we used 1-*O*-tosyl-2, 3-*O*-isopropylidene-6-*S*-benzyl-6-thio-α-L-sorbofuranose (XXIV)[12] as the starting material.

Chatr 4

The deacetonation of XXIV in a methanol solution with 1% of hydrogen chloride yielded methyl 1-*O*-tosyl-6-*S*-benzyl-6-thio-α-L-sorbofuranoside (XXV), which, under the standard conditions of *p*-nitrobenzoylation, formed a crystalline di-*p*-nitrobenzoate, methyl 1-*O*-tosyl-3, 4-di-*O*-*p*-nitrobenzoyl-6-*S*-benzyl-6-thio-α-L-sorbofuranoside (XXVI). The di-*p*-nitrobenzoate (XXVI) reacted with dry hydrogen bromide in acetic acid to yield 1-*O*-tosyl-2-deoxy-2-bromo-3, 4-di-*O*-*p*-nitrobenzoyl-6-*S*-benzyl-6-thio-α-L-sorbofuranose (XXVII), which was not obtainable in a pure state because of its instability. The glycosidation of XXVII with methanol in the presence of silver carbonate gave methyl 1-*O*-tosyl-6-*S*-benzyl-6-thio-β-L-sorbofuranoside (XXVIII), which was then converted into crystalline 1-*O*-tosyl-3, 4-di-*O*-*p*-nitrobenzoyl-6-*S*-benzyl-6-thio-β-L-sorbofuranoside (XXIX) A comparison of the optical rotations of two anomers, XXVI and XXIX, indicated that the former was an α-anomer and the latter, a β-anomer. Therefore, XXVII was determined to be an α-anomer. The treatment of XXVII with sodium iodide in acetone under absolutely anhydrous conditions gave 1, 2-dideoxy-1, 2-ene-3, 4-di-*O*-*p*-nitrobenzoyl-6-*S*-benzyl-6-thio-L-sorbofuranose (XXX), which has a band characteristic of a double bond at 1660 $cm^{-1}$ in the infrared spectrum. However, further studies of XXX failed because of its instability to moisture.

## Experimental[13]

**1-*O*-Tosyl-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranose (VIII).**—Into a cooled solution of 1-*O*-tosyl-L-sorbose (VII) (10 g.) in dry pyridine (100 ml.), acetic anhydride (100 ml.) was stirred in portions. After having been stirred at 0—5°C for 3 hr., the reaction mixture was poured onto ice, made alkaline with sodium carbonate, and extracted with benzene. The extract was washed with 5% sulfuric acid and then with water, and dried, after which the solvent was removed under reduced pressure. The recrystallization of the residue from ether and acetone or from alcohol gave colorless needles (10.7 g.); m. p. 141—144°C (decomp.), $[\alpha]_D^{24.5}$ +4.3 (*c* 0.997, chlororform).

Found: C, 49.79; H, 5.40; S, 6.94. Calcd. for $C_{19}H_{24}O_{11}S$ (460): C, 49.57; H, 5.22; S, 6.96%.

**1-*O*-Tosyl-2, 3, 4, 5-tetra-*O*-acetyl-α-L-sorbopyranose (IX).**—A solution of VIII (9 g.) and sodium acetate (9 g.) in acetic anhydride (90 ml.) was stirred at room temperature for 10 hr. The reaction mixture was then poured into chilled water. Neutralizing the solution with sodium carbonate separated a sirup which became crystalline on cooling. The solution was then filtered, and the residue washed with water. Recrystallization from ether gave colorles needles (9 g.); m. p. 118°C (decomp.), $[\alpha]_D^{26}$ −20.8 (*c* 1.097, chloroform).

Found: C, 50.28; H, 5.42; S, 6.38. Calcd. for $C_{21}H_{26}O_{12}S$ (502): C, 50.20; H, 5.18; S, 6.37%.

12) K. Tokuyama and M. Kiyokawa, *J. Org. Chem.*, **29**, 1475 (1964).

13) All melting points were measured by a Kofler block and are corrected. The NMR spectra were determined on a Varian A-60 spectrometer at 60 Mc. in deuteriochloroform at room temperature, using tetramethylsilane as an internal standard.

**1-*O*-Tosyl-2-deoxy-2-bromo-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranose (X).**—A solution of IX (5 g.) in acetic acid (20 ml.) was saturated with dry hydrogen bromide at 5—10°C. After it had stood at this temperature for 1 hr., the reaction mixture was extracted with chloroform, washed with a cooled sodium bicarbonate solution and then cold water, and dried, and the chloroform was removed. The recrystallization of the residue from ether and petroleum ether (b. p. 40—60°C) gave colorless needles (4 g.); m. p. 105—107°C (decomp.), $[\alpha]_D^{25.5}$ −69.7 (*c* 1.031, chloroform).

Found: C, 43.43; H, 4.42; S, 6.59; Br, 15.08. Calcd. for $C_{19}H_{23}O_{10}SBr$ (523): C, 43.59; H, 4.40; S, 6.12; Br, 15.11%.

**Methyl 1-*O*-Tosyl-3, 4, 5-tri-*O*-acetyl-β-L-sorbopyranoside (XI).**—A solution of X (0.8 g.) and silver carbonate (1.6 g.) in methanol (24 ml.) was stirred at room temperature for 1.5 hr. The solution was then filtered, the filtrate was evaporated to dryness under reduced pressure, and the residue was extracted with ether. After the removal of the ether, XI was obtained as a powder (0.6 g.); $[\alpha]_D^{23.5}$ +59.6 (*c* 1.094, chloroform).

Found; C, 50.40; H, 5.55; S, 6.67. Calcd. for $C_{20}H_{26}O_{11}S$ (504): C, 50.63; H, 5.48; S, 6.75%.

**Methyl 1-*O*-Tosyl-β-L-sorbopyranoside (XII).**—A solution of XI (0.95 g.) in tetrahydrofuran (10 ml.) was cooled at 0°C, and lithium aluminum hydride (0.126 g.) was added. After it had stood overnight at room temperature, the solution was refluxed for 8 hr. and then extracted with chloroform. The chloroform solution was washed with diluted hydrochloric acid and then water, and dried. The evaporation of the chloroform gave a sirup (0.2 g.), $[\alpha]_D^{23.5}$ +37.5 (*c* 0.62 methanol).

Found: C, 48.03; H, 5.96; S, 8.92. Calcd. for $C_{14}H_{20}O_8S$ (348): C, 48.26; H, 5.78; S, 9.20%.

**Methyl β-L-Sorbopyranoside (XIII).**—With constant stirring at −40°C, enough small pieces of sodium metal were added to a solution of XII (0.57 g.) in liquid ammonia (20 ml.) for the blue color to persist for 20 min. Then water was added to discharge the blue color. The ammonia was allowed to evaporate, and the residue was diluted with water. The aqueous solution was passed through an Amberlite XE 100 column, neutralized with silver carbonate, and evaporated to dryness under reduced pressure. The residue was extracted with methanol, and the solvent was removed. The residue was purified by silica gel thin-layer chromatography with chloroform and methanol (4:1, v/v). XIII was obtained as a colorless sirup (0.08 g.); $[\alpha]_D^{23.5}$ −13.3 (*c* 0.817, methanol).

Found: C, 42.70; H, 6.82. Calcd. for $C_7H_{14}O_6$ (194): C, 43.29; H, 7.27%.

**1, 2-Dideoxy-1, 2-ene-3, 4, 5-tri-*O*-acetyl-L-sorbopyranose (XV).**—Sodium iodide (12 g., freshly dried at 180°C and 3 mmHg pressure) was dissolved in acetone (60 ml.) which had been dried over potassium carbonate. The solution was then chilled to 5°C and stirred while X (3.9 g.) was added. The bromide was dissolved promptly, and the brown color of free iodine became apparent almost immediately. After the reaction mixture had stood overnight at room temperature, it was filtered and the residue was washed with acetone (15 ml.). The combined filtrate and washings were concentrated to dryness at room temperature under reduced pressure. Benzene was added, and the resulting solution was washed with cooled aqueous sodium bicarbonate containing a little sodium thiosulfate. After drying, the halogen-free solution was evaporated under reduced pressure. The recrystallization of the residue from ether and *n*-hexane gave colorless needles (1.35 g.); m. p. 80—82°C, $[\alpha]_D^{26.5}$ −9.3 (*c* 1.135, chloroform).

Found: C, 52.88; H, 6.09. Calcd. for $C_{12}H_{16}O_7$ (272): C, 53.06; H, 5.92%.

**Methyl 1-Deoxy-L-sorboside (XVI).**—XV (480 mg.) was dissolved in methanol (120 ml.) containing 2% of sodium. After standing overnight at room temperature, the reaction mixture was passed through the cation exchange resin column (Amberlite IR 120, 20 ml.) and then through the anion exchange column (Dowex 1, 20 ml.), and evaporated to dryness under reduced pressure. The recrystallization of the residue from acetone gave colorless needles (120 mg.); m. p. 149—150°C, $[\alpha]_D^{27.5}$ −103.4 (*c* 1.016, water).

Found: C, 46.94; H, 8.05. Calcd. for $C_7H_{14}O_5$ (178): C, 47.19; H, 7.87%.

**1-Deoxy-3, 4, 5-tri-*O*-acetyl-L-sorbopyranose (XVII).**—A solution of XV (100 mg.) in benzene and ether (1:1, v/v) was passed through the silica gel column (5 g.). After the solvent had been removed, colorless needles were obtained which were then recrystallized from acetone; m. p. 156—158°C, $[\alpha]_D^{27.6}$ −28.4 (*c* 1.055, chloroform).

Found: C, 49.56; H, 6.32. Calcd. for $C_{12}H_{18}O_8$ (290): C, 49.65; H, 6.25%.

**1, 2-Dideoxy-1, 2-dibromo-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranose (XVIII).**—To a solution of XV (0.4 g.) in carbon tetrachloride (2 ml.), bromine in carbon tetrachloride was added until the color persisted. After the mixture had been stirred at room temperature for 10 min., the solvent was removed and the residue was recrystallized from ether. Colorless needles were obtained (0.25 g.); m. p. 130°C (decomp.), $[\alpha]_D^{24}$ −3.5 (*c* 0.116, methanol).

Found: C, 33.54; H, 3.90; Br, 36.30. Calcd. for $C_{12}H_{16}O_7Br_2$ (432): C, 33.55; H, 3.73; Br, 36.99%.

**Methyl 1-Deoxy-1-bromo-3, 4, 5-tri-*O*-acetyl-β-L-sorbopyranoside (XIX).**—To a solution of XVIII (0.25 g.) in methanol (10 ml.), silver carbonate (0.5 g.) was added. After it had been stirred at room temperature for 2 hr., the solution was filtered and the residue was washed with methanol. The combined filtrate and washings were concentrated to dryness under reduced pressure. The residue was purified by thin layer chromatography (silica gel, chloroform-acetone, 9:1, v/v). XIX was obtained as a sirup (45 mg.); $[\alpha]_D^{24}$ +57.6 (*c* 0.184, methanol).

Found: C, 41.12; H, 5.14; Br, 20.33. Calcd. for $C_{13}H_{19}O_8Br$ (383): C, 40.74; H, 5.00; Br, 20.85%.

**Methyl 1-Deoxy-1-chloromercuri-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranoside (XXII).**—To a solution of mercuric acetate (1.54 g.) in absolute methanol

(25 ml.), XV (1.4 g.) was added. After the mixture had stood overnight at room temperature, the solvent was removed and extracted with ether, and then the ether was removed. The residue, which was a mixture of XX as the major component and XXI as the minor component, was dissolved in chloroform, shaken with a saturated aqueous sodium chloride solution for 20 min., washed with sodium bicarbonate and then with water, dried, and the solvent removed. The recrystallization of the residue from ethanol gave colorless crystals (0.48 g.); m. p. 150—152°C, $[\alpha]_D^{25}$ −8.9 (*c* 1.025, methanol).

Found: C, 29.42; H, 3.61; Hg, 37.86. Calcd. for $C_{13}H_{19}O_8HgCl$ (539): C, 29.09; H, 3.84; Hg, 37.14%.

**Methyl 1-Deoxy-1-bromo-3, 4, 5-tri-*O*-acetyl-α-L-sorbopyranoside (XXIII).**—Bromine in chloroform was stirred at room temperature into a solution of XXII (0.2 g.) in chloroform (4 ml.) until the color persisted. The solution was then filtered and evaporated to dryness under reduced pressure. The recrystallization of the residue from methanol gave needles (80 mg.); m. p. 106—107°C, $[\alpha]_D^{24}$ −28.6 (*c* 1.040, methanol).

Found: C, 40.62; H, 5.03; Br, 21.16. Calcd. for $C_{13}H_{19}O_8Br$ (383): C, 40.70; H, 5.00; Br, 20.85%.

**Methyl 1-*O*-Tosyl-3, 4-di-*O*-*p*-nitrobenzoyl-6-*S*-benzyl-6-thio-α-L-sorbofuranoside (XXVI).**—A solution of XXIV (1.1 g.) in methanol (120 ml.) containing 1% of hydrogen chloride was refluxed for 3 hr. After it had cooled, the solution was neutralized with silver carbonate and filtered, and then the solvent was removed under reduced pressure. A solution of the residue (crude XXV) and *p*-nitrobenzoyl chloride (1.4 g.) in dry pyridine (8 ml.) was stirred at room temperature for 3 hr. After standing overnight at room temperature, the reaction mixture was poured onto ice, neutralized with sodium carbonate, and extracted with chloroform. The chloroform was washed with diluted sulfuric acid and then water, and the chloroform was removed. The recrystallization of the residue from ethanol gave colorless crystals (0.8 g.); m. p. 55—57°C, $[\alpha]_D^{23}$ −50.8 (*c* 0.748, chloroform).

Found: C, 55.32; H, 4.37; N, 3.92; S, 8.33. Calcd. for $C_{35}H_{32}N_2O_{13}S_2$ (752): C, 55.85; H, 4.25; N, 3.72; S, 8.51%.

**1-*O*-Tosyl-2-deoxy-2-bromo-3, 4-di-*O*-*p*-nitrobenzoyl-6-*S*-benzyl-6-thio-α-L-sorbofuranose (XXVII).**—A solution of XXVI (1 g.) in acetic acid (5 ml.) was saturated with dry hydrogen bromide at 0—5°C. After standing at this temperature for 30 min., the reaction mixture was extracted with chloroform, washed with cooled aqueous sodium bicarbonate, dried, and evaporated under reduced pressure to give XXVII as an unstable sirup (1.17 g.); $[\alpha]_D^{24}$ −110.7 (*c* 1.073, chloroform).

Found: Br, 11.77. Calcd. for $C_{34}H_{29}N_2O_{12}S_2Br$ (801): Br, 9.99%. (The attempt to purify the sirup obtained here failed because of its instability.)

**Methyl 1-*O*-Tosyl-3, 4-di-*O*-*p*-nitrobenzoyl-6-*S*-benzyl-6-thio-β-L-sorbofuranoside (XXIX).**—To a solution of XXVII (500 mg.) in methanol (100 ml.), silver carbonate (7 g.) was added. After it had been stirred at room temperature for 9 hr., the reaction mixture was filtered and the residue washed with methanol. The filtrate and washings were concentrated under reduced pressure to give a colorless sirup (162 mg.). To a solution of the sirup in dry pyridine (5 ml.), *p*-nitrobenzoyl chloride (300 mg.) was added. After it had been stirred at room temperature for 11 hr. the reaction mixture was poured into ice water, neutralized with sodium carbonate, and extracted with chlorofrom. The chloroform solution was then washed with cooled dilute sulfuric acid and then water, and the solvent was removed. The recrystallization of the residue gave colorless needles (236 mg.); m. p. 46—50°C, $[\alpha]_D^{23.5}$ −8.3 (*c* 1.058, chloroform).

Found: C, 55.86; H, 4.36; N, 3.88; S, 8.15. Calcd. for $C_{35}H_{22}O_{13}N_2S_2$ (752): C, 55.85; H, 4.25; N, 3.72; S, 8.51%.

**1, 2-Dideoxy-1, 2-ene-3, 4-di-*O*-*p*-nitrobenzoyl-6-*S*-benzyl-6-thio-L-sorbofuranose (XXX).**—To a solution of XXVII (300 mg.) in dry acetone (8 ml.) freshly-dried sodium iodide (600 mg.) was added. After the reaction mixture had stood at room temperature for 68 hr., it was filtered and the residue was washed with acetone (15 ml.). The combined filtrate and washings were concentrated to dryness at room temperature under reduced pressure. Benzene was added to the residue, and the resulting solution was washed with cooled aqueous sodium bicarbonate containing a little sodium thiosulfate. After it had been dried, the halogen-free solution was evaporated under reduced pressure. The recrystallization of the residue from alcohol gave unstable crystals (240 mg.); m. p. 55—57°C, $[\alpha]_D^{23}$ −58.7 (*c* 0.732, chloroform).

Found: C, 58.64; H, 4.08; N, 4.86; S, 5.93. Calcd. for $C_{27}H_{22}O_9N_2S$ (550): C, 58.91; H, 4.00; N, 5.09; S, 5.82%.

The authors wish to express their deep gratitude to Dr. Ken'ichi Takeda, Director of this Laboratory, and to Dr. Kaname Hamamoto for their encouragement. They are also indebted to Dr. Kazuo Tori of this Laboratory for his valuable discussion of the NMR spectra.

# Reactive Fiber. IV. The Graft Copolymerization of Glycidyl Methacrylate onto Polypropylene and Polyvinyl Chloride Fibers

By Yoshio IWAKURA, Toshikazu KUROSAKI, Kuniharu NAGAKUBO
Kenji TAKEDA and Masatoshi MIURA

(Received December 14, 1964)

In a series of studies of reactive fibers, the epoxide group containing fibers[1] from acrylonitrile-glycidyl methacrylate (GMA), the acrylonitrile-glycidyl acrylate copolymer, the GMA-grafted cellulose fiber[2] and fibers[3] from *N-p-*(*N'-β*-chloroethylaminosulfamoyl)phenylacrylamide and *N-p-*(*N'-β*-chloroethylaminosulfamoyl)phenylmethacrylamide copolymers were synthesized and their chemical reactivities investigated.

In this paper, the graft copolymer of GMA onto polypropylene (PP) and polyvinyl chloride (PVC) fiber were prepared by the $\gamma$-ray pre-irradiation technique in vacuo. The present method avoided the homopolymerization of GMA and the oxidative degradation of PVC fiber, and introduced epoxide groups into the fibers under mild conditions.

The grafted fibers obtained had high chemical reactivities with amines and hydroxyamines.

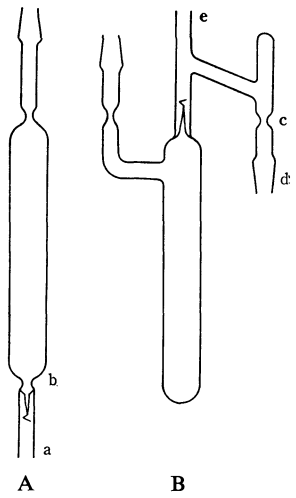

Fig. 1. Ampoules for grafting.

## Experimental

**Materials.** — Polypropylene fiber, the product of Avisun (3—4 deniers), extracted with acetone for six hours in a Soxhlet apparatus.

Polyvinyl chloride fiber, the product of the Teijin Co. (3—4 deniers), was wound on an aluminum plate and extracted with benzene for an hour, and then with acetonitrile for an additional hour in a Soxlet apparatus.

Glycidyl methacrylate (GMA) was purified by distillation under reduced pressure through a column with copper McMahon packing.

Tetrahydrofuran was washed with a mixture of ferrous sulfate and concentrated sulfuric acid in order to remove peroxides, and then distilled.

The other solvents were purified by the usual methods.

**Graft Copolymerization.**—Graft copolymerization was carried out in the sealed-glass apparatus[4] shown in Fig. 1. Tube A, which contained the fiber, was evacuated at $10^{-3}$ mmHg for eitht hours, sealed, and then irradiated by $\gamma$-ray from 4000 curie $^{60}$Co at room temperature. Tube B, which contained a monomer solution, was degassed and sealed. The irradiated tube A was connected to B through a and e, evacuated to $10^{-3}$ mmHg through d, and sealed at f. The monomer in B was transferred into A by breaking two breakable joints, and then the system was sealed at b and placed in a constant temperature bath for a definite time. The grafted fiber was separated from the system, washed with acetone (in the case of polypropylene) or with acetonitrile (polyvinyl chloride) by means of a Soxhlet apparatus, and dried in vacuo. The grafting ratio was expressed by the ratio of the weight gain to the initial weight.

**The Measurement of the Dye Exhaustion.**—The fiber was treated in a dyeing bath at 90°C for 60 min. (in the case of polypropylene) or at 60°C for 100 min. (polyvinyl chloride). The extent of dye exhaustion was measured by a spectrophotometer. The dyes used were Direct Sky Blue FF and Benzopurprine 4B (direct dyes), and Acid Orange II, and Acid Brilliant Scarlet 3R (acid dyes). The composition of the dyeing bath was as follows:

For direct dye: 0.02 parts of dye, 0.02 parts of sulfuric acid, 0.04 parts of anhydrous sodium sulfate and 50 parts of water.

For acid dye: 0.02 parts of acid dye, 0.02 parts of acetic acid and 50 parts of water.

One part of the grafted fiber was used for the dyeing bath prepared above.

3) Y. Iwakura and N. Nakabayashi, *Makromol. Chem.*, will be published.
4) M. Miura and S. Kawamatsu, *Kobunshi Kagaku*, **19**, 175 (1962).

**The Determination of the Epoxy Value.**—The epoxide value of the grafted fiber was determined by the HCl-Dioxane method.[5] A portion of approximately 100 mg. of grafted PVC fiber was immersed in a solution of 25 ml. of dioxane and 20 ml. of 0.1 N hydrochloric acid-dioxane. The mixture was then allowed to stand overnight, and the excess hydrochloric acid was treated with 0.1 N sodium hydroxide aqueous solution, using phenolphtalein as an indicator.

## Results and Discussion

**The Graft Copolymerization of Glycidyl Methacrylate to Polypropylene.** — When the polypropylene fiber irradiated at dose of 5 Mr. was immersed in undiluted GMA at 30°C, the monomer polymerized into a jelly state. The homopolymer producted was insoluble in acetone and dioxane, which are good solvents for polyglycidyl methacrylate. The cross linking of the homopolymer was prevented by adding a solvent, such as acetone, ethyl acetate, tetrahydrofuran or benzene, in the graft polymerization. The Influence of the solvent on the grafting ratio is given Fig. 2. A solvent such

as ethyl acetate or acetone gave a slow initial grafting rate, while benzene gave a higher one. The former two solvents cannot swell as polypropylene fiber, but the latter one can swell the fiber. Figures 3 and 4 show the relation between the grafting ratio and the monomer concentration in benzene or tetrahydrofuran. On all occasions, the addition of a small amount of solvent to GMA increased the

grafting ratio. The effect of the solvent can be explained by assuming that the monomer molecules could diffuse into the polymer swelled by the solvent.

**The Graft Copolymerization of Glycidyl Methacrylate to Polyvinyl Chloride.**—The graft copolymerization was carried out at 16°C in a 20 wt. % monomer solution, using benzene, acetone, *n*-hexane, carbon tetrachloride or ethanol as the solvent. It was found that no graft polymerization proceeded in a solvent, such as *n*-hexane, carbon tetrachloride or ethanol, which did not swell the polyvinyl chloride. On the other hand, the graft polymerization did proceed in benzene or acetonitrile. The influence of the temperature on the grafting in benzene is shown in Fig. 6.

○ 5°C ● 8.5°C ◑ 16°C ⊙ 26°C △ 35°C

The optimum temperature for grafting is in a range from 10 to 20°C. Figure 5 shows the influence of the grafting temperature on the grafting ratio when tetrahydrofuran was used as solvent. The preferred temperature range for grafting was 30—45°C. At a temperature lower than 30—45°C, the initial grafting rate decreased because of the slow diffusion of the monomer molecules into the polymer. At a temperature higher than 30—45°C, the termination and the recombination of the trapped free radicals predominated the propagation and the grafting ratio was saturated, as is shown in Fig. 5.

Comparing polypropylene with polyvinyl chloride, the difference in the optimum temperature range for grafting may be explained as follows. In the case of polypropylene, the intermolecular forces in the crystalline regions are strong enough to keep the crystalline state up to a comparatively high temperature, even in the presence of a solvent. In the case of polyvinyl chroride, however, the intermolecular forces at the crystallline region become weak when the monomers diffuse into the amorphous region and the trapped free radicals recombine easily.

The temperature dependency on the grafting rate in acetonitrile is shown in Fig. 7. The grafting rate decreased in a temperature range from 8.5 to 52°C. Figure 8 shows the influence of the monomer concentration on the

grafting in benzene. The addition of a small amount of solvent to the monomer increased the grafting ratio, as in the case of polypropylene.

**The Reaction of Grafted Polypropylene with Polyhydroxyamines and the Dyeability of the Resultant Polymer.** — The epoxide groups are reactive with various reagents, such as amines,[6] acids,[7] phenols,[8] etc. Here, the reaction was investigated with polyhydroxyamine. The polypropylene fibers with a grafting ratio of 40.1% or 76.1% were refluxed in an acetone solution containing a 20 wt. % of diethanolamine.

The extent of the reaction of amine with the epoxide group in the grafted polymer was calculated from the nitrogen values by the Kjeldahl method. As can be seen from Fig. 9, the reaction of the epoxide group with the amine proceeds quantitatively, regardless of the grafting ratio. It has been known that such bases as pyridine catalyze the reaction of epoxide and amine. In this paper, 2.5 mol. % of pyridine was added to the solution of diethanolamine. However, the effect of pyridine was not noticeable, as Fig. 9 shows. Figure 10 shows the infrared absorption spectra of the GMA grafted polypropylene film and of the grafted film treated with diethanolamine.

The grafted polypropylene showed the absorption characteristic of epoxide group at 910 $cm^{-1}$, but not the absorption around 3500 $cm^{-1}$ characteristic of the hydroxyl group. After it had been treated with diethanolamine, a hydroxyl absorption appeared at 3300 $cm^{-1}$ and the absorption at 910 $cm^{-1}$ disappeared. This indicates the ring opening of the epoxide group.

Grafting ratio 64.7%, methylglucamine concentration 4 wt. %

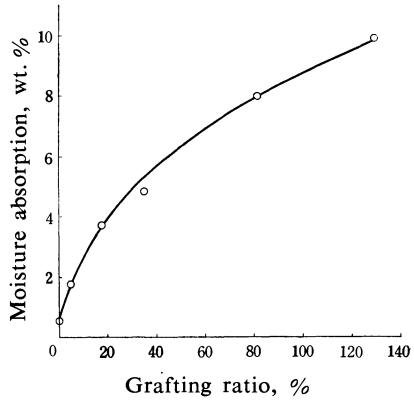

Fig. 12. Moisture absorption of GMA-grafted polypropylene treated with diethanolamine. Amine treatment was carried out for 5 hr. at the same condition as in Fig. 9, relative humidity 60%.

The reaction of methyl gulcamine with the grafted polypropylene fiber was also examined. The grafted polymer was treated with 4 wt. % of methyl glucamine in dioxane at 100°C. The conversion of epoxide groups was 70%, as is shown in Fig. 11.

The moisture absorption of the grafted fiber treated with diethanolamine is given in Fig. 12. The moisture absorption of the polypropylene fiber was increased by grafting. The dyeability of the polypropylene fiber was improved remarkably by treating the grafted fiber with polyhydroxyamine. The results are summarized in Table I.

Table I. Dyeability of GMA-grafted polypropylene fiber treated with polyoxyamines

| Grafting ratio, % | Amine | Dyeability: Direct dye | Dyeability: Acidic dye |
|---|---|---|---|
| 12 | Methyl glucamine | +++ | ++ |
| 12 | Diethanolamine | ++ | ++ |
| 23 | Diethanolamine | ++ | +++ |
| 100 | Diethanolamine | +++ | +++ |

+++ 100% of dye was absorbed in fiber.
++ More than 50% was absorbed.
+ Less than 50% was absorbed.
Conentration of dye 0.04%, weight ratio of dyestuff to fiber grafted.

The fiber of grafting ratio of 12% had a good dyeability by direct dyes after treatment with methyl glucamine. The diethanolamine-treated fiber of 23% grafted polypropylene showed encough dyeability to acid dyes.

**The Reaction of the Grafted Polyvinyl Chloride with Amines.** — The epoxide values of GMA-grafted polyvinyl chloride were determined by the HCl-dioxane method. The results are shown in Table II. The epoxide values obtained were more than 90% of the epoxide values calculated from the grafting ratio.

The amine treatment was carried out in a mixture of water and acetone (water 60, acetone 40). The results of the diethanolamine treatment are shown in Fig. 13. The extent of the reaction was 60% for epoxide groups. The addition of pyridine increased the initial grafting rate, but it had no influence on the ultimate conversion. Figure 14 shows the reaction of aniline with the grafted polymer.

Both the reaction rate and the ultimate conversion were lower in the case of aniline than in the case of diethanolamine.

The polyvinyl chloride fiber grafted with GMA were gradually discolored from yellow to brown during treatment with an aliphatic amine such as diethylamine or diethanolamine. Table III shows the nitrogen and chlorine values of the ungrafted PVC fiber treated with

Table II. Amount of epoxy group in GMA-grafted polyvinyl chloride

| Diethylamine | 53.09 | 0.31 |

diethylamine or diethanolamine at 50°C. The chlorine values decreased with the treatment, while the nitrogen values increased. Therefore, the substitution of chlorine in polyvinyl chloride with amines seems to occur.

The extent of dye exhaustion was measured using 10% grafted fiber which had been treated with diethanolamine for five hours. The dyes were almost 100% exhausted into the fiber.

## Summary

The graft polymerization of glycidyl methacrylate onto polypropylene or polyvinyl chloride fiber has been carried out by the technique of $\gamma$-ray pre-irradiation in vacuo, and the reactions of the grafted fiber with amines have been investigated. In the case of polypropylene, the addition of benzene or tetrahydrofuran to the monomer remarkably increases the grafting rate.

The initial grafting rate is slow in acetone or ethylacetate. The epoxide groups of the grafted polypropylene react with diethanolamine quantitatively, but with methyl glucamine partially, with a yield of 70%. In the case of polyvinyl chloride, benzene or acetonitrile is suitable as a grafting solvent. Graft polymerization proceeds in a narrow range of temperature from 10 to 20°C. Diethanolamine or aniline reacts with yields of 50—60% with the epoxide groups of the grafted polyvinyl chloride. Polyhydroxyamine-treated graft fibers have a good dyeability to both direct and acid dyes.

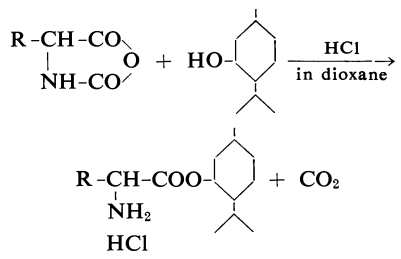
# The Synthesis of α-Amino Acid Menthyl Esters. II[1]

By Tadao HAYAKAWA* and Kaoru HARADA

(Received December 15, 1964)

In the previous study,[2] menthyl esters of α-amino acids have been synthesized from amino acids and menthol by the use of the azeotropic distillation method. However, the reaction conditions of this method were so strong as to decompose serine during the reaction. Some amino acids, such as optically active α-phenylglycine, one of the most racemizable amino acids, may also lose their optical activity during the reaction. In order to use these menthyl esters of α-amino acids as stereochemical standard compounds, it is necessary to compare them with α-amino acid menthyl esters which have been synthesized under milder reaction conditions.



1) Contribution No. 43 of the Institute of Molecular Evolution, University of Miami.

* Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa.

2) K. Harada and T. Hayakawa, This Bulletin, 37, 191 (1964).

α-Amino acid *N*-carboxy anhydride (α-amino acid NCA) has been used in the synthesis of amino acid benzyl esters by Bergmann et al.[3] and later by Erlanger and Brand[4].

In this report, the synthesis of α-amino acid *l*-menthyl esters, under mild conditions, by the use of α-amino acid NCA and *l*-menthol will be described. α-Amino acid NCA prepared by the phosgene method[5] was dissolved in dry dioxane or in a dioxane-ether mixture

containing *l*-menthol ($[\alpha]_D$ −50.0° (*c* 3.50, abs. EtOH), m. p. 42—44°C) and hydrogen chloride. The reaction mixtures were then allowed to stand for one to four days at room temperature. The α-amino acid menthyl esters were isolated as the hydrochlorides; their names will be abbreviated as amino acid M·HCl. The fact that the amino acid M·HCl synthesized under these milder reaction conditions exhibited physical properties almost identical to those observed in the earlier study[2] suggests that the racemization of the amino acid M·HCl prepared by the earlier azeotropic distillation method[2] is small. In this method and also in the earlier method,[2] higher yields of D-amino acid M·HCl than of L-amino acid M·HCl were observed. The fractionation of two diastereomers of the racemic amino acid M·HCl was also observed. The specific rotations of the isolated DL-phenylalanine M·HCl before and after recrystallization were −56.0° and −65.0° respectively, whereas the calculated value is −47.8.°

One advantage of this method is that it can be used for the synthesis of L- and DL-serine M·HCl from *O*-benzyl L- and DL-serine NCA and menthol. *O*-Benzyl-L-serine[6] and *O*-benzyl-DL-serine[7] were treated with phosgene to convert them to the corresponding *O*-benzyl L-serine NCA and *O*-benzyl DL-serine NCA. These NCAs were reacted with *l*-menthol in dry dioxane and ether in the presence of hydrogen chloride at room temperature for four days. *O*-Benzyl L-serine and DL-serine menthyl-esters were thus isolated as hydrochlorides. The attempted debenzylation of these *O*-benzyl L- and DL-serine menthyl-esters by acid hydrolysis (5 N hydrochloric acid, boiling for one hour) was not successful, whereas *O*-benzyl serine was easily debenzylated by acid hydrolysis.[6,7] The debenzylation of α-amino acid M·HCl was carried out under relatively strong hydrogenolysis conditions through the use of 5% palladium on charcoal.

The specific rotations of *O*-benzyl L-ser M·HCl and *O*-benzyl DL-ser M·HCl were found to be −47.5° and −46.5° respectively. However, after debenzylation, L-ser M·HCl and DL-ser M·HCl showed specific rotations of −69.8° and −56.6° respectively. The fractionation of *O*-benzyl DL-ser M·HCl by the recrystallization procedure (ethyl acetate - ether) was also observed. Three fractions of *O*-benzyl DL-ser M·HCl were isolated (see Experimental section): Fractions I (m. p. 179—180°C), II (m. p. 135—150°C) and III (m. p. 128—130°C). The melting point of fraction I (the least soluble fraction) rose to 181—182°C after recrystallization. Fraction III (the most soluble fraction) has the same melting point and optical rotation as *O*-benzyl-L-ser M·HCl. The mixed melting point test of fraction III with *O*-benzyl-L-ser M·HCl showed no depression of the melting point. The hydrogenolysis of fraction III gave serine M·HCl, which showed $[\alpha]_D^{17}$ −67.8° and a m. p. of 218—219°C. The mixed melting point test of serine M·HCl obtained from fraction III and L-serine M·HCl indicated that the two compounds were identical. These results show that *O*-benzyl DL-serine M·HCl is considerably fractionated by the recrystallization procedure to the least soluble fraction (*O*-benzyl-D-ser M·HCl rich) and the most soluble fraction (*O*-benzyl-L-ser M·HCl rich). DL-Serine M·HCl was also prepared from *O*-acetyl DL-ser NCA and *l*-menthol under similar reaction conditions. The *O*-acetyl group was removed during the reaction. The specific rotation of the isolated DL-serine M·HCl was −56.9° before recrystallization. After recrystallization, two fractions of DL-serine M·HCl, I and II, were isolated. Fraction I decomposed at 213—220°C and showed a specific rotation of $[\alpha]_D^{26}$ −61.6°. Fraction II, which was less alcohol-soluble, decomposed at 209—214°C and showed a specific rotation of $[\alpha]_D^{26}$ −68.7°. Elemental analyses of both I and II agreed with the theoretical value of serine M·HCl. Fractions I and II are both supposed to be L-rich fractions, while fraction II might be an almost pure L-ser M·HCl.

a) Recrystallization solvent: Et=ethyl acetate and ether; EP=ethyl acetate and petroleum ether; A=alcohol and ether.
b) All melting points are uncorrected.
c) Melting point and decomposition points are not sharp.
d) All samples were measured in abs. ethanol at 25—26°C.
All samples exhibited negative rotations except L-phenylgly M·HCl.
e) Prepared from *O*-acetyl DL-serine.
f) Prepared from *O*-benzyl L-serine.
g) Prepared from *O*-benzyl DL-serine.
h) Measured at 17°C.

## Experimental

**L-α-Phenylglycine *N*-Carboxy Anhydride.**—Phosgene was bubbled through a stirred suspension of finely pulverized L-α-phenylglycine[8] (1.51 g. (0.01 mol.) ($[\alpha]_D^{20}$ +156.4°, 1 N HCl)) in 50 ml. of dry dioxane in a water bath at 50°C until a clear solution was obtained. The reaction mixture was then treated with a stream of dry nitrogen for one hour at room temperature in order to expel the unreacted phosgene. The solvent was distilled off in vacuo at 40°C. The residual oily product was crystallized by treating it with petroleum ether. The crystals were filtered, washed with petroleum ether, and dried. The product was recrystallized from ethyl acetate and petroleum ether. A yield of 1.45 g. (82%) of L-phenylglycine NCA was obtained; m. p. 114°C. Titration: calcd. for $C_9H_7O_3N$, neut. equiv. 177.2. Found: neut. equiv. 177.5. The neutral equivalent values were determined by titration in methanol with N/50 sodium methoxide, using thymol blue as an indicator.

The NCAs of D-α-phenylglycine and DL-α-phenylglycine were prepared in the same way as has been described above. The specific rotation of the original D-α-phenylglycine[8] was $[\alpha]_D^{20}$ −155.4° (*c* 0.49, 1 N HCl). The yields, melting points, and neutral equivalents of D- and DL-α-phenylglycine NCA[9] are as follows:

| | D | DL |
|---|---|---|
| Yield, % | 84 | 85 |
| M. p., °C | 112 | 100 |
| Neut. equiv. | 175.8 | 176.5 |

**L-α-Phenylglycine Menthyl Ester Hydrochloride.**—To a solution of 1.42 g. (0.008 mol.) of L-α-phenylglycine NCA in 40 ml. of dry dioxane, 6.0 g. of *l*-menthol and 25 ml. of dioxane previously saturated with hydrogen chloride were added at 0°C. After the reaction mixture had been stirred magnetically for 24 hr. at room temperature, the solvent was distilled off in vacuo at 50°C. The residual crystals were treated with petroleum ether, filtered, and dried. The crystals thus obtained were mixed with an 8% sodium hydrogen carbonate solution, and the resulting oil was extracted with ether to obtain the free menthyl ester. The ethereal layer was washed once with water and dried with anhydrous sodium sulfate. To this dried solution, dry hydrogen chloride gas was introduced in order to precipitate the L-α-phenylglycine M·HCl, which was then kept in a refrigerator overnight. The ester hydrochloride crystals were filtered and washed with petroleum ether. L-α-Phenylglycine M·HCl (2.0 g., 77%) was obtained. This was recrystallized from abs. ethanol and ether; m. p. 253—254°C $[\alpha]_D^{25}$ +9.6° (*c* 0.98, ethanol). The analytical data are shown in Table I.

Menthyl ester hydrochlorides of D- and DL-α-phenylglycine were prepared in the way which has been described earlier. The physical and analytical data are shown in Table I.

***O*-Benzyl L-Serine *N*-Carboxy Anhydride.**[10]—*O*-Benzyl L-ser NCA was synthesized by the phosgene method in the same way as α-phenylglycine NCA. Yield 81%, m. p. 71—72°C.

Found: neut. equiv., 222.5; N, 6.43. Calcd. for $C_{11}H_{11}O_4N$: neut. equiv., 221.2; N, 6.33%.

***O*-Benzyl-L-serine Menthyl Ester Hydrochloride.**—A mixture of *O*-benzyl-L-ser NCA[10] (4.4 g. (0.02 mol.) in 10 ml. of dry dioxane) and *l*-menthol (10.0 g. in 15 ml. of dry dioxane) was mixed with 80 ml. of ether which had been saturated with hydrogen chloride at 0°C. This mixture was then stirred at room temperature for four days. After the evaporation of the solvent under reduced pressure, the residual syrup was dissolved in 200 ml. of petroleum ether, and the resulting *O*-benzyl-L-ser M·HCl was extracted with water three times. The aqueous layers were combined, and sodium hydrogen carbonate was added in order to precipitate the oily free ester. The free ester was extracted with ether twice, and the ether solution was dried with anhydrous sodium sulfate and filtered. To the filtrate, dry hydrogen chloride gas was introduced, and the ether was evaporated. After the crystallization of *O*-benzyl-L-ser M·HCl, petroleum ether was added. The crystals were filtered and dried. *O*-Benzyl L-ser M·HCl (5.0 g.) was obtained (68%); m. p. 125—130°C. This was recrystallized from ethyl acetate and petroleum ether; m. p. 132—133°C, $[\alpha]_D^{17}$ −47.5° (*c* 1.11, ethanol). The analytical data are shown in Table I.

***O*-Benzyl-DL-serine Menthyl Ester Hydrochloride.**—A mixture of *O*-benzyl-DL-ser NCA[7] (5.1 g. (0.023 mol.) in 10 ml. of dioxane) and menthol (12.0 g. in 15 ml. of dioxane) was mixed with 80 ml. of ether which had been saturated with hydrogen chloride at 0°C. The reaction mixture was treated in the same way as that of the L-serine derivative.

*O*-Benzyl-DL-ser M·HCl (5.8 g.) was obtained (68%); m. p. 135—151°C, $[\alpha]_D^{17}$ −46.5° (*c* 1.01, ethanol). This was recrystallized from ethylacetate and ether. Three fractions were isolated by the recrystallization procedure: fraction I, 2.0 g., m. p. 181—182°C, $[\alpha]_D^{17}$ −46.0° (*c* 1.13, ethanol), fraction II, 1.80 g., $[\alpha]_D^{17}$ −47.0° (*c* 0.962, ethanol) m. p. 135—150°C, and fraction III, 1.50 g., $[\alpha]_D^{17}$ −46.8° (*c* 0.960, ethanol), m. p. 128—130°C. No melting point depression was observed in the mixed melting point test of fraction III with *O*-benzyl L-ser M·HCl. Elemental analyses of carbon, hydrogen, and nitrogen of fractions II and III also agreed with the theoretical values.

**L-Serine Menthyl Ester Hydrochloride.**—The hydrogenolysis of *O*-benzyl-L-ser M·HCl (1.0 g. in 100 ml. of 80% ethanol) was carried out with 2.0 g. of 5% palladium on charcoal for 12 hr. After the reaction had been completed, the catalyst was removed by filtration. The filtrate was then evaporated in order to crystallize the ester hydrochloride. The crystals were dissolved in water containing excess sodium hydrogen carbonate. The liberated free ester was extracted with ether. The ether solution was washed once with water, dried with anhydrous sodium sulfate, and filtered. Dry hydrogen chloride gas was introduced into the ether

solution in order to crystallize L-serine M·HCl. The crystals were filtered, washed with ether, and dried. L-Serine M·HCl (0.50 g.) was obtained (66%); m. p. 216—219°C (decomp.), $[\alpha]_D^{17}$ −69.8° (*c* 0.702, ethanol). The analytical data are shown in Table I.

**DL-Serine Menthyl Ester Hydrochloride I.**—*O*-Benzyl-DL-serine M·HCl (fraction I; m. p. 181—182°C, 0.5 g.) was dissolved in 50 ml. of 80% ethanol. In order to remove the benzyl group, hydrogenolysis was carried out with 1.0 g. of 5% palladium on charcoal for 12 hr. The reaction product was treated in the same way as that of the L-serine derivative; 0.34 g. (90%) of DL-serine M·HCl was thus obtained, m. p. 164—166°C, $[\alpha]_D^{17}$ −56.6° (*c* 1.08, ethanol). The analytical data are shown in Table I.

**DL-Serine Menthyl Ester Hydrochloride II.**—*O*-Benzyl-DL-ser M·HCl (fraction III: m. p. 128—130°C, 0.50 g.) was treated in the manner which has been described above. When debenzylated serine M·HCl was recrystallized from ethanol and ether, 0.20 g. of the product was obtained; m. p. 217—219°C (decomp.), $[\alpha]_D^{17}$ −67.8° (*c* 0.640, ethanol). The mixed melting point test with L-ser M·HCl did not show any melting point depression. The analytical data are shown in Table I.

# Photo-induced Reaction. II.[1),*1] The Photo-sensitized Oxidation of Hindered Phenols

By Teruo MATSUURA, Kanji OMURA and Ruka NAKASHIMA

(Received December 25, 1964)

It is well known that a phenol produces a phenoxy radical by oxidation with so-called "one electron transfer oxidizing agents" and that the radical couples to form various types of products.[2)] Since the type of the product largely depends upon the oxidant and the starting phenol employed, it is rather difficult to predict the structures of such products. It has been suggested that a large number of natural products may be formed by the oxidative coupling of their phenol precursors in vivo.[2,3)] It may also be supposed that such phenol precursors can be oxidized photochemically in the presence of natural pigments serving as sensitizers, particularly in plants. We expected that the photo-sensitized oxidation of phenols might give some specific products, and so we investigated the photo-oxidation of several hindered phenols.

In general, phenols are destructively oxidized under the influence of ultrasonic radiation.[4)] Arnow has reported that when an aqueous solution of tyrosine is irradiated with an ultraviolet light 3,4-dihydroxyphenylalanine is formed.[5)] Several investigators have reported that the primary reaction in the irradiation of phenols with an ultraviolet light or a visible light in the presence of a photo-sensitizer is the formation of phenoxy radicals,[6-8)] but they did not describe the subsequent behavior of the radicals in detail. Very recently Johnson and Tam have reported that some simple phenols dimerize on ultraviolet irradiation under bubbling oxygen.[9)]

As a preliminary experiment, we examined the photochemical oxidation of 2,6-di-*t*-butylphenol (I) using various photo-sensitizers: eosin Y, erythrosin, methylene blue, chlorophyllin, methyl orange, riboflavin tetraacetate, and 2,5-di-*t*-butyl-*p*-benzoquinone. Eosin Y and

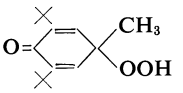
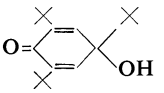
TABLE I. PHOTOSENSITIZED OXIDATION OF HINDERED PHENOLS[a]



| Phenol | Sensitizer | Tungsten lamp, W. | Irradiation period, hr. | Recovered phenol, % | Non-volatile products, g. | Peoduct isolated or identified (yield[b]) |
|---|---|---|---|---|---|---|
| 2, 6-Di-*t*-butylphenol | Eosin Y | 200 | 50 | 41 | 1.02 | IV (11%) V (18%) |
|  | Erythrosin | 500 | 30 | 23 | 1.01 | IV (12%) V (33%) |
| | Erythrosin[c] | 500 | 30 | 16 | 0.86 | IV (11%) V (42%) |
| (I) | Methylene blue | 500 | 32 | 64 | 0.32 | IV (12%) V (15%) |
| 2, 6-Di-*t*-butyl-*p*-cresol | | | | | | |
|  | Eosin Y | 200 | 20 | 16 | — | VI (4.2%) VII (2.8%) |
| (II) | | | | | | |
| 2, 4, 6-Tri-*t*-butylphenol | | | | | | |
|  | Eosin Y | 500 | 30 | 53 | — | IV (13%) VIII (1.1%) |
| (III) | | | | | | |



a) A solution of 3.00 g. of the starting phenol and 0.30 g. of the sensitizer in 100 ml. of methanol was irradiated under bubbling oxygen.
b) Yields were based on consumed starting phenol.
c) Crystals of 3, 5, 3′, 5′-tetra-*t*-butyl-4, 4′-diphenoquinone deposited in the course of the reaction were collected time to time.

(IV)

(V)

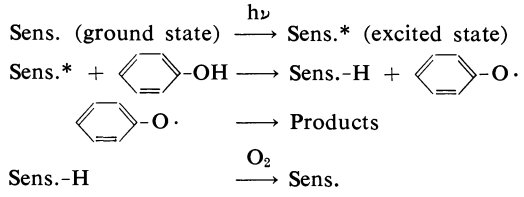
(VIII)

erythrosin were found to be most effective (see Experimental). A solution of a hindered phenol and a sensitizer in methanol was irradiated with a tungsten lamp under bubbling oxygen. The products were either isolated by column chromatography or analyzed by infrared and ultraviolet spectra and vapor phase chromatography. Three hindered phenols, 2, 6-di-*t*-butylphenol (I), 2, 6-di-*t*-butyl-*p*-cresol (II) and 2, 4, 6-tri-*t*-butylphenol (III), were oxidized under these conditions. The results are shown in Table I.

The photo-sensitized oxidation of 2, 6-di-*t*-butylphenol (I) with eosin Y yielded 2, 6-di-*t*-butyl-*p*-benzoquinone (IV) and 3, 5, 3′, 5′-tetra-*t*-butyl-4, 4′-diphenoquinone (V).[10] When erythrosin wasused as the sensitizer, the yield of the diphenoquinone V was considerably increased, but the yield of the benzoquinone IV was not altered. In both cases, some of the starting phenol I was recovered, and non-volatile products, probably several polymerized substances, were formed.

10) C. D. Cook, E. S. English and B. J. Wilson, *J. Org. Chem.*, **23**, 755 (1958).

The reaction with 2, 6-di-*t*-butyl-*p*-cresol (II) seems to be rather complicated, giving many products. Among them, two crystalline products, a phenol and a hydroperoxide, were isolated in low yields. The NMR spectrum*2 of the former phenol showed five singlets, at $\tau$ 8.57, 6.73, 5.75, 4.99, and 3.03, which were assigned to two *t*-butyl, a methoxyl, a hydroxyl, a benzyl, and two aromatic protons respectively. The structure VI was suggested for the compound; this was confirmed by comparing it with an authentic sample of VI.[11,12] The hydroperoxide was shown to have the structure VII by comparing it with an authentic sample.[13]



2, 4, 6-Tri-*t*-butylphenol was somewhat resistant to the photo-oxidation under these conditions. 2, 6-Di-*t*-butyl-*p*-benzoquinone (IV) was isolated as the main product, and 2, 4, 6-tri-*t*-butyl-4-hydroxy-2, 5-cyclohexadien-1-one (VIII),

*2 The NMR spectrum was kindly measured at the Faculty of Pharmaceutical Science of this University.

as the minor product. The formation of IV can be explained in terms of the thermal[14] or photochemical[1] conversion of the peroxide, XII, which is formed from the tri-*t*-butylphenoxy radical X (R=*t*-butyl) and oxygen.

When the photo-oxidation reaction was carried out without irradiation or in the absence of the sensitizer, all the startiug phenols, I, II and III, were recovered unchanged. It appears, therefore, that the formation of a phenoxy radical in the primary process of this reaction requires both the irradiation and the presence of the sensitizer. The radical may be formed by hydrogen abstraction from the phenolic hydroxyl group by the excited photosensitizer molecule (Scheme 1), as has been suggested by Grossweiner and Zwicker.[6] Another possible mechanism, that the excited sensitizer-oxygen complex, proprosed by Schenck[15] in connection with the photosensitized addition of oxygen to olefins, can remove a hydrogen atom from the phenolic hydroxyl group, may also be taken into consideration (Scheme 2). In any case, the phenoxy radical, IX, can give various products via either its mesomeric form X or its tautomeric form XI.

Scheme 1

Scheme 2

A large number of reports on the oxidation of these three phenols, I, II, and III, with one electron-transfer oxidizing agents have recently been published. The oxidation of 2,6-di-*t*-butylphenol gives mainly 2,6-di-*t*-butyl-*p*-benzoquinone (IV) and the diphenoquinone V,[10,13,16-18] in accordance with the results we obtained in the photo-sensitized oxidation. Because of the capability of the formation of the benzyl radical XI the oxidation of 2,6-di-*t*-butyl-*p*-cresol (II) with various oxidants is complicated and the products are obtained usually in low yields.[13,16,19-22] The oxidation of 2,4,6-tri-*t*-butylphenol (III) gives the stable free radical IX (R=*t*-butyl), under a nitrogen atmosphere, while it forms the peroxide XII and other products in the presence of oxygen.[16,20,23,24]

An unhindered phenol, *p*-cresol, was submitted to photosensitized oxidation using erythrosin under the same conditions. From the reaction mixture, some non-volatile products were also obtained besides volatile products, including the starting material. The analysis of the volatile products by vapor phase chromatography showed a pattern similar to that[25] of the products obtained from *p*-cresol by the oxidation with alkaline ferricyanide, except for the appearance of a new peak in the former case. Further studies of the photosensitized oxidation of *p*-cresol and of other unhindered phenols are in progress.

## Experimental

**The Photo-sensitized Oxidation of 2,6-Di-*t*-butylphenol (I).**—A typical procedure using eosin Y as the sensitizer will be described below. A solution of 3.00 g. (15 mmol.) of 2,6-di-*t*-butylphenol and 0.30 g. (0.43 mmol.) of eosin Y in 100 ml. of methanol was placed in a 300-ml. flask and irradiated with a 200 W. tungsten lamp under bubbling oxygen at the reflux temperature. After it had been irradiated for 50 hr., the mixture was concentrated

to a small volume. The crystals (0.29 g.) which formed were collected by filtration and recrystallized from methanol and ethanol to give reddish brown crystals, m. p. 235—237°C. The infrared spectrum was identical with that of an authentic sample (m. p. 238°C) of 3, 5, 3', 5'-tetra-*t*-butyl-4,4'-diphenoquinone (V),[10] lit. m. p. 240—241°C.

The filtrate was then evaporated to dryness, and the residue was treated with petroleum ether to remove the eosin Y. The insoluble eosin Y (quantitatively recovered) was filtered off. The evaporation of the filtrate left a reddish-orange liquid which, on distillation, yielded 1.43 g. of a yellow liquid, b. p. 100—140°C/1 mmHg. The residue weighed 1.04 g. The distillate consisted of 2, 6-di-*t*-butylphenol (I) and 2, 6-di-*t*-butyl-*p*-benzoquinone (IV). The two components in the distillate were measured i) by vapor phase chromatographic analysis (conditions: stationary phase, silicone D. C. 550 on celite; carrier gas, helium; gas pressure, 0.8 kg./cm$^2$; temperature, 178°C), ii) by analysis of the intensity of the infrared bands, 750 cm$^{-1}$ of I and 1660 cm$^{-1}$ of IV, and iii) by analysis of the ultraviolet maxima, 255.5 m$\mu$ (log $\varepsilon$ 4.25) of IV and 278.5 m$\mu$ (log $\varepsilon$ 3.29) of I in cyclohexane, as 85.3% of I and 14.7% of IV. The amount (0.07 g.) of the diphenoquinone V in the residue was estimated from the intensity of its ultraviolet maximum, 403 m$\mu$ (log $\varepsilon$ 4.74) in cyclohexane. Therefore, the amounts of IV, V, and I were found to be 0.21 g., 0.35 g., and 1.22 g. respectively.

Photo-sensitized oxidation reactions of I with erythrosin, and methylene blue were carried out in a similar manner; the results are summarized in Table I.

A solution of 3.00 g. of 2, 6-di-*t*-butylphenol (I) in 150 ml. of methanol was heated under reflux and bubbled with oxygen for 55 hr. The reaction mixture was evaporated to dryness and then treated with petroleum ether and filtered. The evaporation of the filtrate gave a residue whose infrared spectrum was identical with that of the starting phenol I, except for very small bands at 1600 and 1660 cm$^{-1}$.

**The Photo-sensitized Oxidation of 2, 6-Di-*t*-butyl-*p*-cresol (II).**—A solution of 3.00 g. (14 mmol.) of the phenol II and 0.30 g. of eosin Y in 100 ml. of methanol was irradiated for 20 hr., as has been described above. The residual liquid (2.46 g.), which was obtained by the removal of the sensitizer, was dissolved in petroleum ether and passed through a column containing 80 g. of silica gel. Elution with petroleum ether yielded 0.48 g. of the starting phenol II, which was identified by infrared spectrum and vapor phase chromatography. Elution with benzene yield 0.12 g. of crystals. Recrystallization from petroleum ether gave colorless crystals, m. p. 98—100°C, which were identical with 3, 5-di-*t*-butyl-4-hydroxybenzyl methyl ether (VI)[11,12] (infrared spectrum and mixed melting point).

Elution with benzene-ether (9 : 1) yielded 80 mg. of yellow crystals, m. p. 106—111°C. The infrared spectrum was identical with that of an authentic sample (m. p. 112—114°C) of 2, 6-di-*t*-butyl-4-methyl-4-hydroperoxy-2, 5-cyclohexadien-1-one (VII).[13]

Elution with methanol yielded 0.87 g. of a yellow liquid which showed several peaks in vapor phase chromatography but which was not further investigated.

A solution of the phenol II (3.00 g.) and eosin Y (0.30 g.) in methanol (100 ml.) was placed in a brown flask and heated under reflux with bubbling oxygen for 50 hr. The product 2.60 g. was obtained as colorless crystals, m. p. 64—65°C. The infrared spectrum was identical with that of the starting phenol II, m. p. 66—68°C.

**The Photosensitized Oxidation of 2, 4, 6-Tri-*t*-butylphenol (III).**—A solution of 3.00 g. (11 mmol.) of 2, 4, 6-tri-*t*-butylphenol*3 and 0.30 g. of eosin Y in 100 ml. of methanol was irradiated with a 500 W. tungsten lamp for 50 hr., as has been described above. The mixture was then treated in the same manner. The residual liquid (2.90 g.) was dissolved in petroleum ether and passed through a column containing 110 g. of neutralized alumina (grade I). Elution with petroleum ether yielded 1.76 g. of pale yellow crystals which were found, by vapor phase chromatographic analysis, to be a mixture of the starting phenol III, 2, 6-di-*t*-butyl-*p*-benzoquinone (IV) and a minor product (ratio, 91 : 7 : 2). The analysis was carried out under the following conditions: stationary phase, silicon D.C. 550 on celite; carrier gas, helium; gas pressure, 0.8 kg./cm$^2$; temperature, 240°C. Elution with petroleum ether-benzene (1 : 1) yielded 145 mg. of a semi-solid, from which 16 mg. of colorless crystals, m. p. 102—123°C, were obtained. The infrared spectrum was identical with that of 2, 4, 6-tri-*t*-butyl-4-hydroxy-2, 5-cyclohexadien-1-one (VIII),[26] m. p. 133—134°C.

A solution of the phenol III (3.00 g.) in methanol (1.00 ml.) was irradiated with a 500 W. tungsten lamp under bubbling oxygen for 31 hr. The evaporation of the mixture left colorless crystals, which were identified as pure 2, 4, 6-tri-*t*-butylphenol by infrared and vapor phase chromatographic analyses.

**The Photo-sensitized Oxidation of *p*-Cresol.**—A solution of 1.20 g. (11 mmol.) of *p*-cresol and 0.20 g. of erythrosine in 100 ml. of methanol was irradiated with a 500 W. tungsten lamp, as has been described above. The distillation of the products gave 0.40 g. of a distillate, b. p. 120—180°C/$10^{-1}$ mmHg, and 0.35 g. of a residue. The pattern of the vapor phase chromatographic analysis of the distillate was almost identical with that of the products obtained from *p*-cresol by oxidation with alkaline ferricyanide,[25] except for one unknown peak.

On irradiation without a sensitizer, *p*-cresol was recovered unchanged.

**A Comparison of the Effect of Sensitizers in the Oxidation of 2, 6-Di-*t*-butylphenol (I).**—Solutions of the phenol I and 0.05 mmol. of each of the following sensitizers in 10 ml. of methanol were irradiated with a 200 W. tungsten lamp under bubbling oxygen for 6.5 hr.: eosin Y (35 mg.) erythrosin (44 mg.), methylene blue (19 mg.), riboflavin tetraacetate (29 mg.), chlorophyllin (36 mg.), methyl orange (16 mg.), and 2, 5-di-*t*-butyl-*p*-benzoquinone (11 mg.). After the removal of the sensitizer, the intensities of the infrared bands, 1660 cm$^{-1}$ (characteristic of

# Studies of Halogenoacetato Cobalt(III) Complexes.* I. The Preparation and Some Properties of Bromoacetato Cobalt(III) Complexes

By Kashiro KURODA and Philip S. GENTILE

(Received December 28, 1964)

Although several species of fluoroacetato and chloroacetato ammine cobalt(III) complexes have been prepared and their chemical and physical properties studied,[1-6] bromoacetato and iodoacetato ammine cobalt(III) complexes have not yet been isolated. Riolo and Soldi[4] attempted to prepare $[Co(CH_2BrCO_2)(NH_3)_5]X_2$ and $[Co(CH_2ICO_2)(NH_3)_5]X_2$ by the reaction between $[CoCO_3(NH_3)_5]NO_3$ and $CH_2BrCO_2H$ or $CH_2ICO_2H$ in carbon tetrachloride, but they could not isolate the desired compounds. The difficulty in making such a preparation has been attributed to the instability of the bromoacetate and iodoacetate ions at high temperatures, which must be maintained during the reaction period since halogenoacetate ions do not coordinate rapidly enough with cobalt at room temperature. However, the higher the temperature, the larger the danger of the decomposition and/or the hydrolysis of the halogenoacetate ions. Despite the possibility of many side reactions occurring, bromoacetate ions are not so unstable[7,8] as to deter entirely the formation of their complexes. It was, therefore, considered that the desired compound must be present in the reaction products of a carbonato-complex with bromoacetic acids, and that by regulating the reaction temperature, time, and concentration of the reactants and by applying fractional extraction and precipitation, the complexes could be isolated with a high level of purity. Accordingly, after many attempts, several new species of monobromoacetato- and dibromoacetato-complexes were isolated.

The group of halogenoacetato complexes is of especial interest because, since the atomic and/or electronic configuration around the coordination bond is the same in all of the complexes, and since the basicity and the volume of the ligands change regularly with the increase in the number of halogen atoms in the halogenoacetato ligands, one is able to examine the influence of these factors on the physical and chemical properties of the complexes. This standpoint will be maintained throughout this series of studies.

## Experimental

**Materials.**—Monochloroacetic acid, dichloroacetic acid and trichloroacetic acid (Fisher Scientific Co.), monobromoacetic acid (Eastman Organic Chemicals), dibromoacetic acid, tribromoacetic acid (K & K Laboratories, Inc.), and all other reagent-grade chemicals were used without further purification.

**Analysis.**—Cobalt was analyzed by a direct EDTA titration, using murexide as an indicator,[9] after the decomposition of a complex with hot concentrated sulfuric and nitric acid. The other elements were analyzed microquantitatively by the Schwarzkopf Microanalytical Laboratory.** An indication of the degree of purity of the complexes was also

* The most part of this research was done in the laboratory of Department of Chemistry, Fordham University, New York 58, N. Y., U. S. A., during the period in which the former of the authors was a visiting chemist to the University.

obtained by converting the perchlorate to other salts, and by using equivalent weights, comparing the molar extinction coefficients at their maxima in the visible region.

**Apparatus and Spectral Measurements.**—The visible and ultraviolet absorption spectra of the complexes were measured with a Cary 15 spectrophotometer using a pair of 1 cm. quartz cells; in some cases the maxima in the absorption bands were confirmed using a Beckman DU spectrophotometer. The concentrations were 0.005 mol./l., except in the case of *cis*-$[Co(CHBr_2CO_2)_2(en)_2]ClO_4$, where a 0.0025 mol./l. solution was used because of the solubility limitation. The complexes were dissolved in 0.01 N and 0.04 N perchloric acid in order to avoid the possibility of a rapid base hydrolysis; it was confirmed that a difference in the acid concentration does not change the spectra in most cases. However, where the acidity accelerates the aquation of the complexes, i.e., in *cis*-$[Co(CH_3CO_2)_2(NH_3)_4]^+$ and *cis*-$[Co(CH_3CO_2)_2(en)_2]^+$, the spectra of aqueous solutions were measused. Infrared spectra were also taken with a Perkin-Elmer Infracord in order to verify the composition of the compounds. All of them showed absorptions characteristic of $NH_3$, CO, and $ClO_4$ groups. The results are shown in Table I and in Figs. 1 and 2.

**The Assignment of the Configuration.** — For complexes of the $Coa_4b_2$ type it has been established,

experimentally[1,10] and theoretically[11,12], that the first band of the trans-isomer splits significantly into two parts, whereas that of the cis-isomer does not. In addition, the third band (the charge-transfer band) of the trans-isomer appears at a low frequency than that of the cis-isomer.[13-15] In all the cases studied here, the corresponding isomers showed these spectral characteristics, as the figures show.

**Some Physical and Chemical Properties.**—Solubilities were measured semiquantitatively by the following method: A definite amount (0.1—1.0 g.) of a complex was placed in a 50 ml. flask; water was then added in 1 ml. increments until the solid was completely dissolved. The temperature was maintained at 20±1°C. The solubility data are, therefore, not equilibrium values; however, because all complexes were powdery or fine crystalline, the data are fairly accurate.

In the precipitation tests, 1 ml. of a reagent was added to 1 ml. of a saturated solution of the complex which had been obtained from the solubility test and cooled to 0°C. In several cases, where the complexes were very soluble, 0.05 molar solutions were tested. The results are summarized in Table II.

**Preparations.**—*1) Monobromoacetato-pentammine-cobalt(III) Perchlorate, $[Co(CH_2BrCO_2)(NH_3)_5](ClO_4)_2$.*—Ten grams of $[CoCO_3(NH_3)_5]NO_3$ was suspended in 20 ml. of water, and a solution was added which contained 30 g. of $CH_2BrCO_2H$ in 30 ml. of water. The solution was heated for one hour at 70°C, and then cooled to 0°C. After the violet residue which had formed had been removed, 10 ml. of a 25 per cent ammonium nitrate solution was added to the filtrate, and the resulting reddish-orange precipitate was also filtered off. Then 30 ml. of ethanol was added to the cold filtrate with continuous stirring. After the mixture had stood in an ice-water bath for an hour, a reddish-white precipitate formed; this was collected and washed with ethanol and ether. The nitrate, the bromine content of which was a little low, was purified by transformation to the perchlorate. To a saturated solution of the nitrate (one gram of it dissolves in 100 ml. of water at room temperature), concentrated perchloric acid was added. After the mixture had stood at 0°C, the pinkish-orange precipitate was collected, washed with ethanol and ether, and then dried in a desiccator. Yield, ca. 2 g.

Found: Co, 12.15; C, 5.13; H, 3.77; N, 14.67; Br, 16.91. Calcd. for $[Co(CH_2BrCO_2)(NH_3)_5](ClO_4)_2$: Co, 12.25; C, 4.99; H, 3.56; N, 14.56; Br, 16.62%.

*2) Dibromoacetato-pentammine-cobalt(III) Perchlorate, $[Co(CHBr_2CO_2)(NH_3)_5](ClO_4)_2$.*—Seven grams of $[CoCO_3(NH_3)_5]NO_3$ was suspended in 10 ml. of water, and then a solution of $CHBr_2CO_2H$ (20 g.) in 30 ml. of water was added. The solution was heated for one hour and then cooled in an ice bath. The residue which formed was collected on a glass-filter, and an extract was obtained by washing the residue with 100 ml. of a 50 per cent ethanol-water mixture, A 25 per cent ammonium nitrate solution was added to the extract until precipitation was almost complete. The reddish-white nitrate was isolated and washed with ethanol and ether. The nitrate, the bromine content of which was a little low, was transformed to the perchlorate. The nitrate (ca. 5 g.) was dissolved in 125 ml. of water, and 15 ml. of concentrated perchloric acid was added. The precipitate formed was washed with ethanol and ether. Yield, 5 g.

Found: Co, 10.38; C, 4.38; H, 2.77; N, 12.77; Br, 28.80. Calcd. for $[Co(CHBr_2CO_2)(NH_3)_5](ClO_4)_2$: Co, 10.53; C, 4.29; H, 2.88; N, 12.51; Br, 28.55%.

*3) cis-Bis(acetato)-tetrammine-cobalt(III) Perchlorate, $cis$-$[Co(CH_3CO_2)_2(NH_3)_4]ClO_4$.*—Although this compound was originally prepared by Linhard and Weigel,[1] the following procedure was found to be much simpler. To 3 g. of $[CoCO_3(NH_3)_4)ClO_4$, a 30 per cent perchloric acid at 50°C was added until the evolution of $CO_2$ ceased. Sodium acetate (1.7 g.) was added to the solution, which was then evaporated to almost complete dryness at ca. 60°C. Ten milliliters of absolute alcohol was stirred into the product, and the residue which had collected on a filter was washed with absolute alcohol and ether. This perchlorate (3 g.) was dissolved in 60 ml. of an 85 per cent alcohol-water mixture, and, after filtration, 90 ml. of ether was added. The

reddish-purple crystals formed were washed with a 50 per cent ethanol - ether mixture and ether. Yield, 2 g.

Found: Co, 17.08. Calcd. for *cis*-$[Co(CH_3CO_2)(NH_3)_4]ClO_4$: Co, 17.10%.

*4) cis - Bis(monobromoacetato) - tetrammine - cobalt(III) Perchlorate, cis-*$[Co(CH_2BrCO_2)_2(NH_3)_4]ClO_4$.—A mixture of $[CoCO_3(NH_3)_4]ClO_4$ (3 g.), $CH_2BrCO_2H$ (3.2 g.), and water (4 ml.) was evaporated to almost complete dryness at 50—55°C. The product was then dissolved in 20 ml. of a very dilute perchloric acid solution at 40°C and filtered. Five milliliters of concentrated perchloric acid was added to the filtrate, which was then cooled to 0°C. The resulting reddish-purple crystals were washed with ethanol and ether. The crude perchlorate, the yield of which was ca. 3 g., was recrystallized from 20 ml. of a slightly acidified water with perchloric acid at 40°C. Yield, 2.0 g.

Found: Co, 11.61; C, 9.79; H, 3.23; N, 11.46; Br, 32.02. Calcd. for *cis*-$[Co(CH_2BrCO_2)_2(NH_3)_4]ClO_4$: Co, 11.73; C, 9.56; H, 3.21; N, 11.15; Br, 31.81%.

*5) cis-Bis(dibromoacetato)-tetrammine - cobalt(III) Perchlorate, cis-*$[Co(CHBr_2CO_2)_2(NH_3)_4]ClO_4$. — A solution of $CHBr_2CO_2H$ (4.8 g.) and $[CoCO_3(NH_3)_4]ClO_4$ (3 g.) in 4 ml. of water was evaporated to dryness at 50—55°C. After the addition of a dilute perchloric acid and filtration, the residue on the filter was extracted with 50 ml. of warm water. The extract was cooled, and several drops of perchloric acid were added. The resulting reddish-purple crystals were recrystallized in the same way as 4). Yield, 3.5 g.

Found: Co, 8.95; C, 7.49; H, 2.22; N, 8.67; Br, 48.50. Calcd. for *cis*-$[Co(CHBr_2CO_2)_2(NH_3)_4]ClO_4$: Co, 8.93; C, 7.28; H, 2.14; N, 8.49; Br, 48.41%.

*6) cis - Bis(dibromoacetato) - bis(ethylenediamine) - cobalt(III) Perchlorate, cis-*$[Co(CHBr_2CO_2)_2(en)_2]ClO_4$.—A mixture of $[CoCO_3(en)_2]ClO_4$ (2 g.), $CHBr_2CO_2H$ (2.7 g.) and water (3 ml.) was evaporated at ca. 60°C until the mixture nearly solidified. The product was then mixed with 20 ml. of dilute perchloric acid; the reddish precipitate which formed was washed with alcohol and ether. The crude perchlorate, the yield of which was 1.5 g., was dissolved in 40 ml. of warm water and recrystallized in a way similar to that used in 4). Yield, 1.5 g.

Found: Co, 8.12; C, 13.58; H, 2.71; N, 8.05. Calcd. for *cis*-$[Co(CHBr_2CO_2)_2(en)_2]ClO_4$: Co, 8.27; C, 13.49; H, 2.55; N, 7.87%.

*7) cis-Bis(acetato)-bis(ethylenediamine)-cobalt(III) Perchlorate, cis-*$[Co(CH_3CO_2)_2(en)_2]ClO_4$.—This compound has already been prepared,[2] but it was found that the following procedure was simpler and gave a high yield. To 3 g. of $[CoCO_3(en)_2]ClO_4$, a 30 per cent solution of perchloric acid at 50°C was added until the evolution of carbon dioxide ceased. Sodium acetate (1.5 g.) was then added to the mixture, and it was evaporated to almost complete dryness at 60—65°C. The product was thoroughly mixed with 10 ml. of alcohol, and the resulting precicipitate was washed several times with alcohol and finally with ether. The bright red crystals thus obtained were the double salt, *cis*-$[Co(CH_3CO_2)_2(en)_2]ClO_4 \cdot NaClO_4$, judging from the analytical results and the spectra of its solution. Yield, 3.5 g. The neutral perchlorate is very soluble in water and unobtainable by usual methods. It was isolated as follows: To a mixture of 30 ml. of alcohol and the double salt, water was slowly added, drop by drop, by continuous stirring, until the color suddenly changed to violet. At this point a few extra drops of water were added, and the precipitate was collected and washed with alcohol several times and finally with ether. The filtrate also contained a large amount of the complex, and upon the addition of ether, additional perchlorate was obtained in a pure state. Yield, 3 g. Although the perchlorate and the double salt are different colors in the solid state, the absorption spectra of their solutions were exactly identical.

Found: Co, 14.73. Calcd. for *cis*-$[Co(CH_3CO_2)_2(en)_2]ClO_4$: Co, 14.86%.

*8) cis - Bis(chloroacetato) - tetrammine - cobalt(III) Perchlorate, cis-*$[Co(clac)_2(NH_3)_4]ClO_4$ *and cis-Bis(chloroacetato)-bis(ethylenediamine)-cobalt(III) Perchlorate, cis-*$[Co(clac)_2(en)_2]ClO_4$, where clac= $CH_2ClCO_2$, $CHCl_2CO_2$, $CCl_3CO_2$. These complexes were prepared by the method of Linhard and Weigel.[1]

## Results and Discussion

**Preparations.**—The usual procedure for the preparation of $[Co(X)(NH_3)_5]^{n+}$-type complexes[16] requires that the mixture of $[Co(H_2O)(NH_3)_5]^{3+}$ and X be kept at a temperature (usually higher than room temperature) for a suitable period in an acidic solution. This approach was used for the preparation of $[Co(CH_2BrCO_2)(NH_3)_5]^{2+}$ and $[Co(CHBr_2CO_2)(NH_3)_5]^{2+}$. However, unlike many other ligands, the bromoacetate ions are relatively unstable at high temperatures and yet do not rapidly coordinate at low temperatures. It was, therefore, observed, from the color and absorption spectra of the by-products, that at higher temperatures and for longer periods than those described in the Experimental section, the yield of the desired complexes became lower as a result of the decomposition and/or hydrolysis of the ligands, whereas at lower temperatures the main product was the unreacted aquo-complex.

The preparation of $[Co(CBr_3CO_2)(NH_3)_5]X$ was also attempted in a similar way. In this case, however, the tribromoacetate of the aquo-complex, $[Co(H_2O)(NH_3)_5](CBr_3CO_2)_3$, precipitates immediately after the starting materials are mixed. When the temperature is elevated, the tribromoacetate ion decomposes to an oily material, and the desired complex is not obtained.

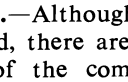
16) J. C. Bailar, Jr., "Inorganic Syntheses," Vol. IV, 171 (1953).

Linhard and his co-workers[1-3] studied the $[Co(clac)_2(NH_3)_4]X$ complexes and found that cis-isomers were obtained when $[CoCO_3(NH_3)_4]ClO_4$ and an equivalent amount of chloroacetic acid were evaporated at a relatively low temperature, whereas trans-isomers were obtained when a large excess of acids was used and the evaporation occurred at a higher temperature. This principle was used for the preparation of the cis-isomers of the bromoacetato complexes, and the desired complexes, except for *cis*-$[Co(CH_2BrCO_2)_2(en)_2]ClO_4$, were obtained with comparative ease. The preparation of *cis*-$[Co(CH_2BrCO_2)_2(en)_2]ClO_4$ was attempted, with varying temperatures, solvents and starting materials. However, the resulting reaction products were always extremely hygroscopic and no definite solid material was obtained, although the spectra of solutions of some products showed fairly satisfactory features.

**Solubilities.**—Although several reversed cases may be noted, there are definite trends in the solubilities of the complexes. That is, the larger the halogen content of the ligands, the less soluble they are in water and the more soluble they are in ethanol, especially when the compound is slightly moist.

**Precipitation Reactions.**—In addition to the anions shown in Table II, it was observed that a 1 N solution of sodium carbonate, sodium acetate, sodium nitrite and sodium sulfite, and a saturated solution of sodium hydrogen phosphate, 6 N sulfuric acid and 2 N ammonium sulfate did not precipitate any of the complexes. This table may prove useful for the transformation of the anion of the complexes, and it suggests the possibility of utilizing the complexes for the analysis of anions. For example, $[Co(CHBr_2CO_2)(NH_3)_5]^{2+}$ precipitates with iodide but not with bromide and chloride. Therefore, the complex presents the possibility of detecting the $I^-$ ion in the presence of $Br^-$ and $Cl^-$ ions.

**Visible and Ultraviolet Absorption Spectra.**—As may be seen in Table I, in the case of pentammine complexes the maxima of the first band appear at almost identical frequencies, and those of the second band are also very close to each other. However, in the tetrammine series, obvious differences in the maxima are observable; that is, the larger the halogen content in the halogenoacetato ligand, the larger the frequencies of both the first and the second bands. The same order exists in the bis-(ethylenediamine) series. It has been pointed out[17] that if the ligand "a" is replaced in a complex $Ma_6$ by a ligand "b", the shift of the maxima is approximately as represented by the following equation:



$$\nu(Ma_{6-n}b_n)=\frac{6-n}{6}\nu(Ma_6)+\frac{n}{6}\nu(Mb_6)$$

Therefore, the difference in $\nu$ between $Ma_4b_2$ and $Ma_4b'_2$ should be twice as large as that between $Ma_5b$ and $Ma_5b'$. This relation holds in the present complexes. Thus, the relative position of the ligands in the spectrochemical series is determined to be:

$$I<\cdots<CH_3CO_2<\left\{\begin{matrix}CH_2ClCO_2<CHCl_2CO_2<CCl_3CO_2\\ \wr\qquad\qquad\wr\\ CH_2BrCO_2<CHBr_2CO_2<(CBr_3CO_2)\end{matrix}\right\}<\cdots<CN$$

from the data of bis-(halogenoacetato) as well as mono-(halogenoacetato) series.

Now, since all the complexes have the

atomic arrangement, it may be said that the factors which may influence the spectra are: (1) the polarity of the cobalt-halogenoacetato bond, (2) the volume of the ligands, and (3) the chemical (especially the oxidation-reduction) property of halogens. We shall now consider these factors.

Previously, Linhard and his co-workers[1-3] measured the absorption spectra of $[Co(RCO_2)(NH_3)_5]^{2+}$ and *cis*-$[Co(RCO_2)_2(NH_3)_4]^+$ where R=alkyl, and found that in each case the absorption maxima of both the first and the second bands appear at almost identical frequencies, with a variety of R. This indicates that the volume of a ligand is a minor factor in the spectral characteristics of complexes. The same situation exists in the present case, since there is little shift in the absorption maxima with the variety of halogen species, and chlorine and bromine have fairly different atomic radii.

It is well-known that, when halogens coordinate to the central atom directly, the corresponding halogeno-complexes (e.g., $[CoCl(NH_3)_5]^{2+}$ and $[CoBr(NH_3)_5]^{2+}$) have greatly different spectral features. This phenomena have been attributed to the different oxidation-reduction properties of halogens. On the contrary, corresponding chloroacetato- and bromoacetato-complexes show identical features, as may be seen in Figs. 1 and 2. Furthermore, the halogen-carbon bondings have no absorption in the visible and near ultraviolet region. Thus, it is clear that the differences in the chemical property of halogens in the ligands are also a minor factor in affecting the positions of the first and the second absorptions.

17) Y. Shimura and R. Tsuchida, This Bulletin, **28**, 572 (1955).

(Since carbon-halogen bondings have a slight absorption in far ultraviolet region, the third band may be influenced by the variety of halogen.)

The first factor, the polarity of Co–O bonds, is not known exactly, but it may be assumed that it parallels the polarity of the H–O bonds of the halogenoacetic acids, which can be placed in a qualitative order by the dissociation constant of each acid, or by the basicity of each halogenoacetate ion. The experimental results show that the smaller the basicity of the halogenoacetato ligand, the larger the frequencies of the absorption maxima, as may be seen in Table I. That the polarity of central atom - ligand bonding is the predominant factor in the energy splitting of the d-electrons in a complex is a fundamental assumption of the recent ligand field theory of complex compounds; this assumption has been experimentally verified by the present results.

# Studies of Halogenoacetato Cobalt(III) Complexes. II.[1],* The Preparation and Some Properties of *trans*-Bis(halogenoacetato)-tetrammine-cobalt(III) and *trans*-Bis(halogenoacetato)-bis(ethylenediamine)-cobalt(III) Complexes

By Kashiro KURODA and Philip S. GENTILE

(Received December 28, 1964)

In the preceding communication,[1] the authors have reported on the *cis*-isomers of bis(halogenoacetato)-tetrammine and bis(halogenoacetate)-bis(ethylenediamine) cobalt(III) complexes, *cis*-$[Co(halac)_2(NH_3)_4]^+$ and *cis*-$[Co(halac)_2(en)_2]^+$, where halac=$CH_3CO_2$, $CH_2ClCO_2$, $CHCl_2CO_2$, $CCl_3CO_2$, $CH_2BrCO_2$ and $CHBr_2CO_2$. There should be a geometrical isomer (trans-isomer) for each of the cis-isomers. Previously, Linhard and his co-workers[2,3] studied the complexes, $[Co(clac)_2(NH_3)_4]X$ and $[Co(clac)_2(en)_2]X$ (clac=acetato and three chloroacetato ligands); although they isolated many of the cis-isomers, only a few trans-isomers were obtained. The difficulties in the preparation of trans-isomers are to be attributed to the fact that the fraction of trans-isomer is small in a reaction product of a carbonato complex ($[CoCO_3(NH_3)_4]X$ or $[CoCO_3(en)_2]X$) and a halogenoacetic acid, and that no suitable reagent is known for the separation of geometrical isomers. As will be described in the following sections, the authors have found that trichloroacetic acid is an excellent precipitant for trans-isomers; it can separate them from mixtures which contain a large fraction of cis-isomers. As a result, many new species of the trans-isomers of bromoacetato-complexes as well as of chloroacetato-complexes have been isolated as trichloroacetates, and they have been converted to the perchlorates. Some of their physical and chemical properties have been studied, and interesting phenomena have been observed, especially in their absorption spectra.

## Experimental

**Materials.**—Monochloroacetic, dichloroacetic and trichloroacetic acid (Fisher Scientific Co.), monobromoacetic acid (Eastman Organic Chemicals) and dibromoacetic acid (K & K Laboratories, Inc.), and all the other reagent-grade chemicals were used without further purification.

**Analysis.** — Cobalt was analyzed by a direct

* The most part of this research was done in the laboratory of Department of Chemistry, Fordham University, New York 58, N. Y., U. S. A., during the period in which the former of the authors was a visiting chemist to the University.

—: No precipitation
1: A small amount of deposit observable on the surface of the test tube
2: A small amount of precipitate
3: A large amount of precipitate (the liquid phase has still the color of the complex)
4: Almost complete precipitation (the liquid phase is almost colorless)
vs: Very soluble
* All cis-isomers of these complexes do not precipitate with trichloroacetic acid.

EDTA titration, using murexide as an indicator,[4] after the decomposition of a complex with hot concentrated sulfuric and nitric acid. The other elements were analyzed microquantitatively by the Schwarzkoph Microanalytical Laboratory (Woodside, New York, U. S. A.).

**Apparatus and Measurments.** — The absorption spectra of the complexes were measured with a Cary 15 spectrophotometer using a pair of 1 cm. quartz cells. The concentration of the complexes was 0.005 mol./l. (for *trans*-$[Co(CH_3CO_2)_2(en)_2]^+$, a 0.01 mol./l. solution was used) for the measurments in the visible and near ultraviolet region, whereas the original solutions were diluted to 0.0005 and 0.00005 mol./l. for the far ultraviolet region. In most cases, the complexes were dissolved in a 0.01 N and 0.04 N perchloric acid solution in order to avoid the possibility of a rapid base hydrolysis. It was found that a different concentration of the acid does not change the spectra. The spectra of the trichloroacetates of the complexes were also measured; it was found that the absorption curve was identical within the range of experimental error with that of the corresponding perchlorate in the visible and near ultraviolet region. The results are shown in Figs. 1 and 2 and Table I.

The solubility of the complexes was measured semiquantitatively in the same way as has been described in the previous report.[1] The precipitation reactions with various anions were also tested by a previously-reported[1] method. These experimental results are summarized in Table II.

**Preparations.** — *1) trans-Bis(acetato)-tetrammine-cobalt(III) Perchlorate, trans-*$[Co(CH_3CO_2)_2(NH_3)_4]ClO_4$*, and trans-Bis(monochloroacetato)-tetrammine-cobalt(III) Perchlorate, trans-*$[Co(CH_2ClCO_2)_2(NH_3)_4]ClO_4$. — These complexes were prepared by the method of Linhard and Weigel.[2]

*2) trans-Bis(dichloroacetato)-tetrammine-cobalt(III) Perchlorate, trans-*$[Co(CHCl_2CO_2)_2(NH_3)_4]ClO_4$. — A mixture of $[CoCO_3(NH_3)_4]ClO_4$ (5 g.), $CHCl_2CO_2H$ (10 g.) and water (10 ml.) was evaporated to almost complete dryness at 70—75°C. The cooled reaction product was mixed with 30 ml. of dilute perchloric acid and filtered with a glass-filter, then the residue on the filter was extracted with 10 ml. of alcohol. After the addition of 50 ml. of water to the extract, 3 g. of trichloroacetic acid was added and the solution was cooled to 0°C. The violet crystals formed were collected and washed with alcohol(10%)-ether mixture and ether. (If concentrated perchloric acid is added to the alcoholic extract, the perchlorate is obtained, but it is always contaminated with the cis-isomer, which is difficult to remove.) The yield of the trichloroacetate is ca. one gram. The trichloroacetate was dissolved in 60 ml. of a alcohol(90%)-water mixture and, after filtration, 20 ml. of concentrated perchloric acid was added. After the mixture had stood at 0°C, the resulting light violet crystals, the acidic salt, were collected on a filter and washed with ether in order to remove the aqueous phase mechanically as completely as possible, and then with absolute alcohol and ether. During the treatment with alcohol, the acidic salt changes to the neutral salt. Since the acidic salt is very soluble in alcohol when it is wet, it should be dry when it is treated with alcohol, as has been described above. Yield, 0.7 g.

Found: Co, 12.18; C, 10.06; H, 3.02; N, 11.80. Calcd. for *trans*-$[Co(CHCl_2CO_2)_2(NH_3)_4]ClO_4$: Co, 12.22; C, 9.96; H, 2.92; N, 11.62%.

*3) trans-Bis(trichloroacetato)-tetrammine-cobalt(III) Perchlorate, trans-*$[Co(CCl_3CO_2)_2(NH_3)_4]ClO_4$. —A solution of $[CoCO_3(NH_3)_4]ClO_4$ (3 g.) and $CCl_3CO_2H$ (15 g.) in 10 ml. of water was evaporated to dryness at 70—75°C. The product was washed four times with 25 ml. portions of very dilute perchloric acid to remove the cis-isomer, and then extracted with 50 ml. of warm (~40°C) water. After three grams of $CCl_3CO_2H$ had been added to the extract, the resulting light violet precipitate was collected and washed in the way described in 2). Yield of the trichloroacetate, 1.5 g. To convert it to the perchlorate, 1 g. of the trichloroacetate was dissolved in 30 ml. of water. and 15 ml. of a 50 per cent sodium perchlorate solution was added. The precipitate formed was washed as in 2). Yield, 0.6 g. Even if perchloric acid is used for the precipitation, the acidic perchlorate is obtained.

Found: Co, 10.43; C, 9.17; H, 2.46; N, 10.40. Calcd. for *trans*-$[Co(CCl_3CO_2)_2(NH_3)_4]ClO_4$: Co, 10.69; C, 8.71; H, 2.19; N, 10.16%.

*4) trans-Bis(monobromoacetato)-tetrammine-cobalt(III) Perchlorate, trans-*$[Co(CH_2BrCO_2)_2(NH_3)_4]ClO_4$. — A mixture of $[CoCO_3(NH_3)_4]ClO_4$ (5 g.), $CH_2BrCO_2H$ (12.5 g.) and water (10 ml.) was evaporated to a small, tarry, volume at 60—65°C. The product was mixed with 20 ml. of a very dilute perchloric acid and the precipitate formed, after having been washed with a small amount of cold water, was extracted with 40 ml. of warm water. Two milliliters of concentrated perchloric acid was added to the extract, which was then cooled, and the violet precipitate formed was washed with a small amount of cold water, alcohol and ether. For further purification, the complex was converted once to the trichloroacetate and then to the perchlorate, as in 2). Yield, 0.7 g.

Found: Co, 11.66; C, 9.86; H, 3.32; N, 11.60. Calcd. for *trans*-$[Co(CH_2BrCO_2)_2(NH_3)_4]ClO_4$: Co, 11.73; C, 9.56; H, 3.21; N, 11.15%.

*5) trans-Bis(dibromoacetato)-tetrammine-cobalt(III) Perchlorate, trans-*$[Co(CHBr_2CO_2)_2(NH_3)_4]ClO_4$. — A mixture of $[CoCO_3(NH_3)_4]ClO_4$ (2 g.), $CHBr_2CO_2H$ (7 g.) and water (7 ml.) was evaporated at 70—75°C until crystals appeared. The product was mixed with 20 ml. of dilute perchloric acid, and the resulting precipitate was washed with 60 ml. of warm water. This treatment washed out the cis-isomer almost completely. (From the extract, the cis-isomer can be obtained by cooling.) The violet residue was dissolved in 100 ml. of warm water, and the solution was cooled to 0°C after the addition of several drops of perchloric acid. The violet crystals formed were washed with a small amount of cold water, an ethanol(10%)-ether mixture and ether. Yield, 0.7 g. The complex in the final filtrate is recoverable as the

4) H. Flaschka, *Mikrochemie ver. Mikrochim. Acta*, **39**, 38 (1952).

trichloroacetate by the addition of trichloroacetic acid. Yield of the trichloroacetate, 0.5 g.

Found: Co, 8.98; C, 7.40; H, 2.37; N, 8.60. Calcd. for *trans*-$[Co(CHBr_2CO_2)_2(NH_3)_4]ClO_4$: Co, 8.93; C, 7.28; H, 2.14; N, 8.49%.

*6) trans-Bis(acetato)-bis(ethylenediamine)-cobalt(III) Perchlorate, trans-*$[Co(CH_3CO_2)_2(en)_2]ClO_4$.— Although this compound had already been prepared by Linhard and Stirn,[3] it was found that the following procedure was simpler and gave a high yield. A mixture of $[CoCO_3(en)_2]ClO_4$ (3 g.), $CH_3CO_2H$ (4.5 g.) and water (5 ml.) was evaporated, using a small free flame, until solidification occurred. The product was mixed with 30 ml. of water, and, after filtration, 3 ml. of concentrated perchloric acid was added. The reddish crystals which formed were the acidic perchlorate, *trans*-$[Co(CH_3CO_2)_2(en)_2]ClO_4 \cdot HClO_4$; they were washed with dilute perchloric acid, ethanol and ether. Yield, 4.0 g. In order to obtain the neutral complex, 3 g. of the acidic salt was covered with ether in a flask, and anhydrous gaseous ammonia was bubbled through the mixture for ten minutes. The complex should be slightly wet; otherwise neutralization does not occur. The crystalline salt gained in volume by this treatment. After filtration, the residue on a filter was extracted with a small amount (<5 ml.) of warm (~40°C) water, and the filtrate was cooled sufficiently at 0°C. The red precipitate formed was washed with ethanol and ether. Yield, 0.5 g. After the dilution of the final filtrate to 50 ml. and the addition of perchloric acid, the complex can be recovered as the acidic perchlorate almost quantitatively.

Found: Co, 14.81; C, 24.32; H, 5.62; N, 14.20. Calcd. for *trans*-$[Co(CH_3CO_2)_2(en)_2]ClO_4$: Co, 14.86; C, 24.22; H, 5.59; N, 14.12%.

*7) trans-Bis(monochloroacetato)-bis(ethylenediamine)-cobalt(III) Perchlorate, trans-*$[Co(CH_2ClCO_2)_2(en)_2]ClO_4$. — A reaction product was obtained by the evaporation of a mixture of $[CoCO_3(en)_2]ClO_4$ (3 g.), $CH_2ClCO_2H$ (7 g.) and water (10 ml.) at ~70°C. It was mixed with 20 ml. of dilute perchloric acid, and the resulting precipitate was washed with ethanol and ether. The perchlorate thus obtained was dissolved in 180 ml. of warm water containing several drops of perchloric acid, and recrystallized. The violet crystals formed were washed with ethanol and ether. Yield, 2.0 g.

Found: Co, 12.63; C, 21.03; H, 4.56; N, 11.70. Calcd. for *trans*-$[Co(CH_2ClCO_2)_2(en)_2]ClO_4$: Co, 12.66; C, 20.64; H, 4.33; N, 12.03%.

*8) trans-Bis(dichloroacetato)-bis(ethylenediamine)-cobalt(III) Perchlorate, trans-*$[Co(CHCl_2CO_2)_2(en)_2]ClO_4$.—A product was obtained by the evaporation of a mixture of $[CoCO_3(en)_2]ClO_4$ (3 g.), $CHCl_2CO_2H$ (10 g.) and water at ~70°C. The precipitate which was formed by the addition of dilute perchloric acid was extracted, with 100 ml. of warm water; then the extract was set aside. (This extract contains the cis-isomer.) A second separate extract was made with another 300 ml. of warm water; It was cooled after the addition of several drops of perchloric acid. The reddish purple crystals which formed were washed with cold dilute perchloric acid, ethanol and ether. Yield, 2.0 g.

Found: Co, 10.97; C, 18.14; H, 3.64; N, 10.40. Calcd. for *trans*-$[Co(CHCl_2CO_2)_2(en)_2]ClO_4$: Co, 11.03; C, 17.98; H, 3.40; N, 10.48%.

*9) trans-Bis(trichloroacetato)-bis(ethylenediamine)-cobalt(III) Perchlorate, trans-*$[Co(CCl_3CO_2)_2(en)_2]ClO_4$. — A mixture of $[CoCO_3(en)_2]ClO_4$ (2 g.), $CCl_3CO_2H$ (8.5 g.) and water (6 ml.) was evaporated at ~70°C to a small volume; then it was heated on a small flame until the color changed from dark red to deep violet. As soon as the color change was finished, the mixture was quickly cooled. The product was mixed with 20 ml. of dilute perchloric acid, and the resulting precipitate, after having been washed with a perchloric acid solution, was extracted with 100 ml. of an ethanol (50%)-water mixture. The last 80 ml. portion was separated from the first 20 ml., which was contaminated with the cis-isomer. After the addition of several drops of perchloric acid, the extract was cooled. The violet crystals which formed were washed in the way described in 2).

Found: Co, 9.54; C, 16.02; H, 2.86; N, 9.70. Calcd. for *trans*-$[Co(CCl_3CO_2)_2(en)_2]ClO_4$: Co, 9.77; C, 15.92; H, 2.67; N, 9.29%.

*10) trans-Bis(monobromoacetato)-bis(ethylenediamine)-cobalt(III) Perchlorate, trans-*$[Co(CH_2BrCO_2)_2(en)_2]ClO_4$.—This complex was not isolated in a highly pure state. Many procedures similar to those used for the others were tried, but the reaction products were always very hygroscopic, as in the case of *cis*-$[Co(CH_2BrCO_2)_2(en)_2]ClO_4$. Trichloroacetic acid could form a precipitate with some of the reaction products, and although the spectra showed a fairly satisfactory feature (a large splitting of the first band), it was also hygroscopic.

*11) trans-Bis(dibromoacetato)-bis(ethylenediamine)-cobalt(III) Perchlorate, trans-*$[Co(CHBr_2CO_2)_2(en)_2]ClO_4$. — A mixture of $[CoCO_3(en)_2]ClO_4$ (2 g.), $CHBr_2CO_2H$ (7 g.) and water (5 ml.) was evaporated at 65—70°C and then heated and boiled carefully on a small flame for a few minutes. When the color suddenly changed from dark red to reddish-violet, the mixture was quickly cooled. The precipitate, which was formed by the addition of dilute perchloric acid, was washed with a dilute perchloric acid and then extracted with 150 ml. of an ethanol(75%)-water mixture. The last 120 ml. protion, which was kept separate from the first 30 ml., was cooled after the addition of several drops of perchloric acid. The dark purple crystals which formed were washed with ethanol and ether. Yield, 1.5 g.

Found: Co, 8.22; C, 13.78; H, 2.77; N, 7.94. Calcd. for *trans*-$[Co(CHBr_2CO_2(en))_2]ClO_4$: Co, 8.27; C, 13.49; H, 2.55; N, 7.87%.

## Discussion

**Preparation.** — Linhard and his co-workers[2] studied the $[Co(clac)_2(NH_3)_4]X$ complexes and found that the cis-isomer was obtained when an aqueous solution of $[CoCO_3(NH_3)_4]ClO_4$ and an equivalent amount of a chloroacetic acid was evaporated at a relatively low temperature, whereas the *trans*-isomer was

obtained when a large excess of chloroacetic acid was used and the evaporation occurred at a higher temperature. With dichloroacetato- and trichloroacetato-complexes, however, they could not isolate the trans-isomers.

The same principle was applied in the preparation of all the complexes which were studied in this report, (the preparations of cis-isomers have been reported already);[1] it was observed again that it was easier to isolate cis-isomers than trans-isomers, except for acetato-complexes. It was also noted that the yield of trans-isomers was small, especially for ligands with a high halogen content. Therefore, along with the known procedures, two new techniques were applied whereby the trans-isomer can be separated from a large amount of cis-isomer and/or the yield of trans-isomer can be raised. First, as has been described in the Experimental section and as may be seen in Table II, it was found that trichloroacetic acid selectively precipitated trans-isomers and that, therefore, a small quantity of trans-isomer could be isolated from a mixture containing a large quantity of cis-isomer. This method was applied in the isolation of *trans*-$[Co(CHCl_2CO_2)_2(NH_3)_4]^+$ and *trans*-$[Co(CCl_3CO_2)_2(NH_3)_4]^+$, and in the purification of the others.

Second, after the evaporation of the solution of the starting materials had nearly been completed, the product was boiled for a short time. In the bis(ethylenediamine)- series, the coordination of ethylenediamine is still stable at a high temperature; therefore, boiling the reaction mixture causes a rapid rearrangement of the cis- to the trans-configuration, resulting in a higher yield of the trans-isomer. This technique was used for the preparation of *trans*-$[Co(CCl_3CO_2)_2(en)_2]ClO_4$ and *trans*-$[Co(CHBr_2CO_2)_2(en)_2]ClO_4$. In the tetrammine-series, however, there is a possibility of the decomposition of the complexes themselves.

**Solubilities and Precipitation Reactions.**—Similarly to the case of cis-isomers,[1] it was noted that complexes with a large halogen content are soluble in alcohol or even in an alcohol-ether mixture, especially when they are slightly moist. One should therefore be careful in the washing of the complexes in their preparations.

In addition to the anions listed in Table II, it was observed that 1 N solution of sodium carbonate, sodium nitrite, sodium acetate, potasium chromate, sodium sulfite or sodium oxalate, and a saturated solution of sodium hydrogen phosphate, 6 N sulfuric acid and 2 N ammonium sulfate did not precipitate with any of the complexes. As has been described in the Experimental section, most of the *trans*-isomers form acidic salts with perchloric acid. In the cases of two acetato-complexes, acidic salts are relatively insoluble compared with the neutral salts; therefore, precipitation occurs upon the addition of perchloric acid but not upon that of sodium perchlorate. Similar phenomena take place in *trans*-$[Co(CH_3CO_2)_2(NH_3)_4]^+$ with hydrogen chloride and ammonium chloride.

**Absorption Spectra.**—The visible and ultraviolet absorption spectra of the *trans*-$[Coa_4b_2]$ complexes are of especial interest because of a large splitting which occurs in the first band. All of the present complexes showed the splitting, as can be seen in Figs. 1 and 2, by which the assignment of the geometrical configuration has been made.

Shimura[5] proposed an empirical rule regarding the relative positions between the maxima of cis- and trans-isomers of $Coa_4b_2$:

$$\nu_{cis} - \nu_{trans} \gtrless 0$$

if "a" is to the $\left\{\begin{array}{l}\text{left (I side)}\\ \text{identical}\\ \text{right (CN side)}\end{array}\right\}$ of "b" in

the spectrochemical series; this rule has been supported theoretically.[6] Concerning the present complexes, $NH_3$ or en (a) is to the right of the halogenoacetato ligands (b), and the $\nu_{cis}$'s are larger than the corresponding $\nu_{trans}$'s thereby confirming Shimura's rule.

The order of the ligands in the spectrochemical series has already been determined to be:[1]

$$\mathrm{I} < \cdots < CH_3CO_2 < \left\{\begin{array}{l}CH_2ClCO_2 < CHCl_2CO_2 < CCl_3CO_2\\ CH_2BrCO_2 < CHBr_2CO_2 (< CBr_3CO_2)\end{array}\right\} < \cdots < NH_3 < en < \cdots < CN$$

(increasing ligand field)

and it has been verified that the basicity of the ligands is the main factor in determining the spectral characteristic of each series of halogenoacetato-complexes. Therefore, it may be said that the degree of splitting increases with an increase in the halogen content in the halogenoacetato-ligands, or with a decrease in the basicity of the ligands, as may be seen in Table I and the figures.

Since the spectrochemical series represents the order of the strengths of the ligand fields, the tetragonality (tetragonal deviation from a cubic symmetry) of a $Coa_4b_2$ complex increases with the increase in the distance between "a" and "b" in the series. According to the ligand field theory, the

magnitude of the band splitting depends on the degree of tetragonality.[7] Therefore, it may be predicted that the splitting in the acetato-complex will be the largest and that in the trichloroacetato-complex the smallest. However, this predicted order seems to be entirely the reverse of the observed order. This reversal is considered to be of interest; further examination of the spectral curves is needed for an interpretation. After an analysis of the curves separating into single bands, a quantitative consideration of the band splitting will be reported.

The authors are grateful for the support provided for this research by the Atomic Energy Commission of U. S. A. under Contract No. AT(30-1)-906.

# 11-Deoxojervine, A New Alkaloid from *Veratrum* Species[1]

By Tadashi MASAMUNE, Yoichi MORI, Mitsuo TAKASUGI, Akio MURAI
Shigehiro OHUCHI, Norio SATO and Nobukatsu KATSUI

(Received January 9, 1965)

*Veratrum* species have been extensively investigated, and a large number of alkaloids have been isolated.[2] In connection with a study aimed at the synthesis of C-nor-D-homosteroid hormones, we have searched for alkaloids from a kind of *Veratrum* species and have found a new alkaloid to be a principal component. In a preliminary communication,[3] we reported that this alkaloid was 11-deoxojervine; the present paper will describe the details.

Benzene extracts of the alkalized, ground roots of *V. album L. var. glandiflorum Maxima. (V. glandiflorum Loesen. fil.)* which had been collected in May in the Tokachi district, Hokkaido, were subjected to separation according to a modified Jacobs' procedure.[4] The new alkaloid was isolated in a 0.30% yield, along with veratramine, rubijervine and solanidine,[5] from the basic fraction, and β-sitosterol, from the neutral fraction. While Saito and Suginome had obtained jervine,[6] together with veratramine,[7] as a major alkaloid from the plant collected in October at Nopporo, Hokkaido, no jervine was isolated in the present investigation. On the other hand, Takaoka[8] has reported the isolation of a sterol from the same plant; judging from a comparison of their melting points, the sterol seems to be the same compound as that obtained in the present research.

The new alkaloid (I) (m. p. 237—238°C, $[\alpha]_D^{23}$ −44.2°) was analyzed for $C_{27}H_{41}O_2N$; both the infrared and ultraviolet spectra indicated the absence of a carbonyl group and a conjugated diene. The acetylation of I with acetic anhydride and pyridine on a steam bath afforded the *O,N*-diacetyl derivative (Ia), which melted at 163—165°C, resolidified, and again melted at 195—197°C. The infrared spectrum showed no absorption due to a hydroxyl group in the region of 3 μ; therefore, the remaining oxygen must be an ether function. An attempted reduction of I with lithium aluminum hydride or with lithium in liquid ammonia led to a quantitative recovery of the starting material and ruled out the possibility of an epoxide group. Absorptions near 1050 $cm^{-1}$ in the infrared spectra of I and Ia (1062 and 1037 $cm^{-1}$ respectively) suggested[9] the

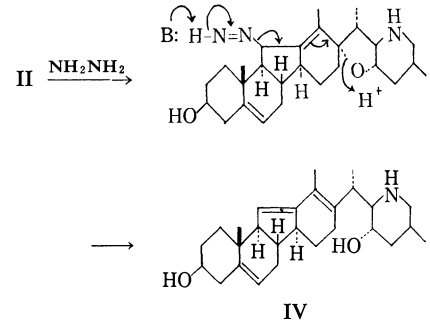
presence of a $\Delta^5$-3$\beta$-hydroxyl group, a probability of which was supported by the NMR spectrum. The NMR spectrum of Ia closely resembled that of diacetyljervine[10] (IIa), but two new sharp peaks appeared at $\tau$ 8.29 and 9.06; these were comparable to the signals due to C-18 methyl ($\tau$ 7.81) and C-19 methyl groups ($\tau$ 8.99) of IIa. Furthermore, the treatment of I with sulfuric acid in the presence of ferric sulfate yielded veratramine (III), although the yield was low. All these results strongly suggested that I was 11-deoxojervine.

The structure was confirmed by the removal of the oxygen on C-11 of jervine (II).



(I) R=H$_2$, R′=H
(Ia) R=H$_2$, R′=Ac
(II) R=O, R′=H
(IIa) R=O, R′=Ac

(III)

The carbonyl group of II is sterically hindered[11] and formed no oxime, even under severe conditions.[12] The Clemmensen reduction of 12, 13-dihydrojervine[13] gave rise to no crystalline substances beside the starting material. However, the Wolff-Kishner reduction of II according to the procedure by Barton[14] resulted in the formation of two crystalline compounds IV, m. p. 211—213°C, and V, m. p. 236—238°C. The former, IV, had a molecular formula of $C_{27}H_{41}O_2N$, and its infrared (1615 cm$^{-1}$) and ultraviolet spectra ($\lambda_{max}$ 245 m$\mu$, $\varepsilon$ 25500) showed that it was a conjugated diene. The diene was converted to the corresponding *O*, *O*, *N*-triacetyl derivative (IVa), m. p. 116—118°C. The NMR spectrum of IVa had a broad peak centered at $\tau$ 4.53 (2H), a broad multiplet which consisted of three peaks centered at $\tau$ 4.93, 5.25 and 5.36 (3H),[15] and a singlet at $\tau$ 8.29, indicating that two olefinic protons were present, that a methyl group was attached to olefinic carbon, and also that the cleavage of the ether linkage of II was taking place. On the basis of these facts, the formula IV seems to be the most favorable structure for the compound with a m. p. of 211°C, as the reaction has been considered to proceed through the following sequence:[16]

IV

This diene was also obtained by the treatment of jervine-11$\beta$-ol with sodium and butanol. On the other hand, the compound V has been shown to be identical with the compound I by a mixed melting point determination and by a comparison of the infrared spectra; thus, the new alkaloid is 11-deoxojervine. While the configuration of the B/C juncture has been established to be *trans* in the previous communication,[17] the direct transformation of the deoxojervine into veratramine also supports the $\alpha$-configuration of the hydrogen on C-9.

## Experimental

The melting points are uncorrected. The optical rotations and the ultraviolet spectra were measured in 95% ethanol and 99% ethanol, and the infrared spectra in Nujol unless otherwise stated. The NMR spectra were taken in deuterochloroform at 60 Mc., using tetramethylsilane as an internal standard.

**The Extraction and Fractionation of the Roots.**[4] —The ground, dried roots of *V. grandiflorum Loesen. fil.* (29 kg.), collected in May at Toyoni, Tokachi, Hokkaido, were moistened with about 1 N aqueous ammonia (16 l.) and extracted with benzene (116 l.) at room temperature for 5 days. During the extraction, the entire mixture was shaken several times a day. The extracts were drained through filter pads and found to amount to 60 l.

The extraction was repeated nine times; each time 40 l. of benzene was added anew, and 45 l. of the extracts were percolated every 4 days. The roots, after extraction with benzene, were finally treated with 95% ethanol (40 l.) for 1 week; the

alcoholic extracts were designated fraction A.

The benzene extracts were shaken seven times (15 min. each time) with 5% aqueous tartaric acid (500 ml. per 10 l. of the benzene extracts). The tartaric acid solutions were made alkaline to pH 9 with 20% aqueous sodium carbonate below 12°C, and an amorphous mixture of the bases thus separated was collected by filtration. The basic mixtures were then combined and dried, yielding 650 g. The aqueous filtrate was shaken with chloroform (3 l. per 10 l. of the aqueous filtrate), and the chloroform extracts were washed with water, dried, evaporated to dryness and combined (fraction B).

The entire alkaloidal mixture was divided, by treatment with seven portions of 9 l. of benzene, into benzene-soluble and benzene-insoluble fractions. These fractions were worked up as will be described in parts a and b below. During the fractionation of the mixture of alkaloids, the content and homogeneity of each fraction were always checked by paper chromatography.[18]

a) The benzene-soluble fraction (65 l.) was shaken twice with equal volumes of a 0.1 M aqueous citrate buffer solution (pH 6.0). The buffered solutions were extracted with chloroform after having been made alkaline to pH 9 with 20% aqueous sodium carbonate; the chloroform extracts left 155 g. of a tarry material (fraction C) when the solvent was removed.

The benzene solution which was separated from the buffered solutions was washed, dried, and evaporated to dryness. The residue was dissolved in 10% aqueous acetic acid (5 l.) and filtered to remove intractable tarry matters. To the acidic solution was added a saturated aqueous solution of ammonium sulfate (1.1 l.), yielding gelatinous precipitates which were collected by filtration. The aqueous filtrate was made alkaline with ammonia and extracted with chloroform. The chloroform extracts were washed with water, dried over sodium sulfate, and evaporated to dryness, leaving 50 g. of tarry substances (fraction D).

The precipitates of the sulfates were suspended in 10% aqueous sodium hydroxide and then shaken with chloroform (total 4.7 l.) vigorously and repeatedly, until the precipitates disappeared completely. The combined chloroform extracts were washed with water, dried, and evaporated to dryness, leaving 178 g. of an amorphous solid. The solid was dissolved in ethanol (1 l.) and concentrated hydrochloric acid (35 ml.) was added, yielding crystalline hydrochlorides, which were then collected by filtration. The filtrate was designated as fraction E. When the crystalline hydrochlorides were dissolved in boiling 65% aqueous ethanol (350 ml.), made alkaline with concentrated aqueous ammonia and then allowed to stand overnight, crude 11-deoxojervine (m. p. 224—227°C) was regenerated and collected by filtration (yield 15 g.).

b) The benzene-insoluble fraction left after the removal of the benzene-soluble part was fractionated in a way similar to that used for the benzene-soluble part; it was dissolved in 10% aqueous acetic acid (7.5 l.) and treated with a saturated solution of ammonium sulfate (800 ml.) to yield 225 g. of the precipitates of sulfates, which were then filtered. Regeneration from the filtrate with concentrated aqueous ammonia and extraction with chloroform gave 33 g. of a crystalline solid (fraction F).

The precipitates of sulfates suspended in 10% aqueous sodium hydroxide were repeatedly shaken with chloroform (total 6.9 l.); the chloroform extracts gave an amorphous solid after the solvent had been removed. The amorphous solid was dissolved in ethanol (700 ml.) and afforded, on the addition of cocentrated hydrochloric acid (40 ml.), crystalline hydrochlorides; these were then collected by filtration and found to amount to 103 g. The filtrate gave, when made alkaline with concentrated aqueous ammonia (200 ml.), 59 g. of an amorphous solid (fraction G). The regeneration of the free base from the crystalline hydrochlorides dissolved in boiling 65% aqueous ethanol (3.6 l.) with concentrated ammonia (190 ml.), cooling and filtration, afforded 80 g. of crude deoxojervine, m. p. 225—227°C.

**The Isolation of Veratramine from Fraction G.**—Fraction G consisted mainly of veratramine (III) and 11-deoxojervine (I); it was fractionated on the basis of the following facts; (1) the hydrochloride of I was less soluble in ethanol than that of III, and (2) I decomposed readily upon treatment with sulfuric acid in refluxing ethanol, whereas III was stable under those conditions. A part (50 g.) of fraction G was dissolved in boiling ethanol (130 ml.), cooled, and filtered. The crystalline precipitates (10.6 g.) were converted into the hydrochlorides and recrystallized three times. Each of the filtrates left after recrystallization was made alkaline to yield a mixture of bases; this mixture was collected by filtration and combined. The combined mixtures contained more III than I; they amounted to 5.8 g. after having been dried. On the other hand, water (100 ml.) was added to the filtrate after the removal of the first crystalline precipitates, separating 26.6 g. of an amorphous solid which contained more III than I. These veratramine-rich fractions (total 32.4 g.) were combined and worked up in a way similar to that mentioned above, yielding 20.2 g. of crude veratramine. To the crude veratramine dissolved in ethanol (500 ml.), concentrated sulfuric acid (20 ml.) was added under cooling; the mixture was then refluxed for 1 hr. The alkalification of the solution with ammonia (60 ml. of concentrated ammonia and 1 l. of water), followed by cooling and filtration, afforded veratramine, which was recrystallized from aqueous ethanol (200 ml. of ethanol and 140 ml. of water) and found to have a m. p. of 204—205°C. The yield was 14.3 g. Identification was made by a mixed melting point determination with an authentic sample and by a comparison of the infrared spectra and of the paper chromatograms.

**The Isolation of Rubijervine from Fraction F.**—Fraction F was dissolved in acetone; the concentration of the solution led to the separation of

18) The following three systems were used for paper chromatography; A) *n*-butyl acetate - *n*-butanol - formic acid - water (10 : 25 : 10 v. v.); B) ethylene chloride - Cellosolve acetate - pyridine (15 : 10 : 1), and c) *n*-butyl acetate - *n*-butanol - formic acid - water (100 : 1 : 1.5 : 0.5).

crude rubijervine (11.9 g.), m. p. 241—243°C. Recrystallization from acetone gave pure rubijervine, m. p. 246—246.5°C, which was identified by a mixed melting point determination with an authentic sample and by a comparison of the infrared spectra and of the paper chromatograms.

**The Isolation of Solanidine and Veratramine from Fraction E.**—One-third (350 ml.) of fraction E was evaporated in vacuo, and the residue was dissolved in water (240 ml.), made alkaline with 2 N aqueous ammonia, and extracted with chloroform (230 ml.). The chloroform solution was washed with water (300 ml.), dried over sodium sulfate, and then evaporated to dryness, leaving 45 g. of a tarry material. This was refluxed in 1 N methanolic sulfuric acid (300 ml.) for 2 hr. to remove 11-deoxojervine and cooled, and then water (400 ml.) was added. The whole mixture was made alkaline with 10% aqueous sodium carbonate and extracted with chlorom (200 ml.). The chloroform solution gave, on the removal of the solvent, 36.4 g. of a tarry material, which was then dissolved in benzene (200 ml.) and chromatographed on alumina (Merck neutral, 900 g.) in a column (diameter 50 mm.). All those fractions eluted with mixtures of benzene and ether, and all those eluted with mixtures of ether and chloroform (20 : 1 and 17 : 1) were crystallized, on the removal of the solvent and trituration with acetone, and were combined; they amounted to 350 mg. On recrystallization from acetone, pure solanidine (100 mg.), m. p. 217—219°C, was obtained.

Found: C, 81.70; H, 11.18; N, 3.70. Calcd. for $C_{27}H_{43}ON$: C, 81.55; H, 10.90; N, 3.52%.

On treatment with acetic anhydride and pyridine at room temperature overnight, this was converted to the acetate, m. p. 205—206°C.

Found: C, 79.00; H, 10.51; mol. wt. 439 by the mass spectrum. Calcd. for $C_{29}H_{45}O_2N$: C 79.22; H, 10.32%; mol. wt. 439.66.

Identification was made by means of a comparison of the infrared spectrum with that described in Ref. 19 and by an analysis of the NMR spectra.

Fractions eluted with mixtures of ether and chloroform (4 : 1 to 1 : 8) crystallized on the removal of the solvents, which contained veratramine as a major component. Recrystallizations from acetone afforded 4.0 g. of veratramine, m. p. 202—204°C.

**The Isolation of β-Sitosterol from Fraction A.**—Fraction A was concentrated to 2 l., and a part (500 ml.) of the concentrate thus obtained was shaken with three poritions of 500 ml. of petroleum ether (b. p. 30—60°C) to remove any resinous substances. The concentrate separated from the petroleum ether solution was shaken with 1 N aqueous acetic acid (1 l.), centrifuged, and divided into fractions soluble and insoluble in the acidic solution. The insoluble material (35 g.) was continuously treated with ether in a Soxhlet extractor for 6 hr. The resulting ether-insoluble solid (29 g.) was further refluxed with 2 N hydrochloric acid in 95% ethanol on a water bath for 2 hr., and then cooled. After the removal of the ethanol in vacuo, the residue was extracted with ether to yield a brown oil, which was then chromatographed on alumina (Merck neutral, 30 g.). Fractions eluted with mixtures of petroleum ether and benzene (5 : 5 to 3 : 8) and those eluted with benzene crystallized on the removal of the solvent and were combined; yield 200 mg. On recrystallization from ethanol, 60 mg. of β-sitosterol, m. p. 134—136°C and $[\alpha]_D^{23}$ −32°, was obtained. The alcohol gave, when treated with acetic anhydride and pyridine at room temperature overnight, the corresponding acetate, which had a m. p. of 118—119°C and $[\alpha]_D^{23}$ −33° on recrystallization from ethanol. Identification was made by a mixed melting determination with an authentic sample and by a comparison of the infrared spectra and the NMR spectra.[20] The sterol isolated by Takaoka[8] had a m. p. of 135—136°C.

**11-Deoxojervine and 3-*N*-Diacetyl-11-deoxojervine.**—The recrystallization of crude deoxojervine from methanol gave a pure sample, m. p. 236—238°C, which contained the solvent and which showed an infrared spectrum different from that of the sample after drying. For analysis, this was recrystallized from methanol and dried at the temperature of boiling xylene; it thus had a m. p. of 237—238°C and $[\alpha]_D^{23}$ −44.2°; UV only end absorption; IR $\nu_{max}$ 3270, 1067, 1060 and 809 $cm^{-1}$.

Found: C, 78.78, 78.87; H, 10.12, 9.91; N, 3.59, 3.53. Calcd. for $C_{27}H_{41}O_2N$: C, 78.78; H, 10.04; N, 3.40%.

11-Deoxojervine (101 mg.) was treated with acetic anhydride (1 ml.) and pyridine (1 ml.) on a water bath for 2 hr., and then worked up as usual to yield the crude diacetyl derivative. On recrystallization from aqueous ethanol, 84 mg. of diacetyl-11-deoxojervine was obtained; this contained the solvent and melted at 163—164°C, resolidified, and then melted again at 195—197°C; IR: $\nu_{max}$ 3550, (solvent), 3460 (solvent), 1722, 1655 (shoulder), 1640, 1254 and 817 $cm^{-1}$.

Found: C, 72.97; H, 8.93; N, 2.90. Calcd. for $C_{31}H_{45}O_4N \cdot H_2O$: C, 72.48; H, 9.22; N, 2.73%.

On being dried at the temperature of boiling xylene, this had a m. p. of 195—197°C and $[\alpha]_D^{23}$ +1.1°; IR: $\nu_{max}$ 1733, 1640, 1231 and 812 $cm^{-1}$; NMR: a broad peak centered at $\tau$ 4.56 (1H, olefinic proton on C-6), a broad multiplet centered at $\tau$ 5.40 (1H, proton on C-3), two singlets at $\tau$ 7.90 and 7.97 (each 3H, *N*- and *O*-acetyl groups), a singlet at $\tau$ 8.29 (3H, 18-methyl group), two doublets ($J$=7 and 6 c. p. s.) centered at $\tau$ 8.99 and 9.06 (each 3H, two secondary methyl groups), and a singlet at $\tau$ 9.06 (3H, 19-methyl group).

Found: C, 75.26; H, 8.93; N, 2.89. Calcd. for $C_{31}H_{45}O_4N$: C, 75.11; H, 9.15; N, 2.83%.

**The Treatment of 11-Deoxojervine with Sulfuric Acid.**—To a solution of 11-deoxojervine (220 mg.) in methanol (50 ml.) concentrated sulfuric acid (3.1 ml.) and ferric sulfate (55 mg.) were added under cooling. The solution was then stirred for 5 hr. at room temperature. After the addition of water (100 ml.), the solution was made alkaline with 2 N aqueous ammonia and extracted with three portions of 30 ml. of chloroform. The chloroform extracts were then washed with water, dried over sodium sulfate, and evaporated to dryness,

19) S. W. Pelletier and W. A. Jacobs, *J. Am. Chem. Soc.*, **75**, 4444 (1953).

20) G. Slomp and F. A. MacKellar, ibid., **84**, 204 (1962).

leaving 205 mg. of an amorphous solid which showed 5 spots on the paper chromatogram. The residue was dissolved in 5% aqueous acetic acid (10 ml.) and filtered. The addition of a saturated solution of ammonium sulfate yielded resinous precipitates, which were collected by decantation and then washed with water. A suspension of the precipitates in aqueous ammonia was shaken with three portions of 10 ml. of chloroform. The chloroform extract gave, after drying and the removal of the solvent, 53 mg. of an amorphous solid, which crystallized on trituration with acetone. Recrystallization from acetone afforded veratramine (10 mg.), m. p. 201—203°C.

**The Wolff-Kishner Reduction of Jervine.**[14]—To freshly-distilled diethylene glycol (325 ml.) sodium (7.5 g.) was added; the mixture was then heated to 180°C and cooled. To this solution anhydrous hydrazine (45 ml.)[21] was added, and the mixture was refluxed for a while and then cooled. After the addition of jervine (5.0 g.), the entire mixture was heated at 180±5°C for 60 hr., further heated to 210°C to remove the excess hydrazine, and again refluxed for another 24 hr. To the cooled solution water (250 ml.) was added, and the whole mixture was extracted with three 250 ml. portions of chloroform. The chloroform extracts were washed with water, dried over sodium sulfate, and evaporated to dryness, yielding 5.0 g. of an amorphous solid, which was then crystallized on trituration with acetone. Fractional recrystallizations from acetone, purity of each fraction being checked by paper chromatography, led to the successful separation of two crystalline compounds. One (1.1 g.) had a m. p. of 236—238°C on recrystallization from a mixture of methanol and acetone; it was identical with 11-deoxojervine in all respects.

Another compound, conjugated diene (IV), had a m. p. of 211—213°C and $[\alpha]_D^{23}$ +3.5° when recrystallaized from acetone or methanol, and it amounted to 0.45 g.; UV: $\lambda_{max}$ 245 mμ (ε 25500); IR: $\nu_{max}$ 3420, 1615, 1058, 878 and 815 $cm^{-1}$.

Found: C, 78.74; H, 10.24; N, 3.78. Calcd. for $C_{27}H_{41}O_2N$: C, 78.78; H, 10.04; N, 3.40%.

The acetylation of the conjugated diene (77 mg.) with acetic anhydride (1 ml.) and pyridine (1 ml.) on a water bath for 3 hr. afforded 48 mg. of the triacetyl derivative with a m. p. of 116—118°C and $[\alpha]_D^{23}$ +46° after recrystallization from a mixture of methanol and ethanol; UV: $\lambda_{max}$ 243 mμ (ε 23800); IR: $\nu_{max}$ 1733, 1637, 1615, 1242, 1022 and 811 $cm^{-1}$; NMR: a broad peak centered at τ 4.53 (2H, protons on C-6 and C-11), a broad multiplet which consisted of three peaks centered at τ 4.93, 5.25 and 5.36 (3H, protons on C-3, C-22 and C-23),[15] a singlet at τ 7.98 (9H, *N*- and two *O*-acetyl groups), a singlet at τ 8.29 (3H, 18-methyl group), a doublet ($J$=6 c. p. s.) centered at τ 8.86 (6H, two secondary methyl groups), and a singlet at τ 8.99 (3H, 19-methyl group).

Found: C, 71.27; H, 8.58; N, 2.59. Calcd. for $C_{33}H_{47}O_5N \cdot H_2O$: C, 71.32; H, 8.89; N, 2.52%.

**The Treatment of Jervine-11β-ol with Sodium and Butanol.** — To a solution of jervine-11β-ol (507 mg.)[22] in boiling *n*-butanol (500 ml.), 36 g. of sodium was added over a period of 5 hr.; the mixture was then refluxed for another 1.5 hr. while being stirred and cooled. After the removal of the butanol by steam distillation, the residue was extracted with three portions of 70 ml. of chloroform, and the chloroform extracts were dried over sodium sulfate and evaporated to dryness, leaving 501 mg. of an amorphous solid. The solid was dissolved in *n*-butanol (350 ml.) and treated with sodium (29 g.) for 6.5 hr. When the reaction mixture was worked up in a way similar to that mentioned above, it left 478 mg. of the residue. Crystallization and recrystallization from a mixture of acetone and ether afforded 83 mg. of the conjugated diene (IV), m. p. 213—214°C. The paper chromatogram of the filtrate showed that it consisted of IV and the starting material, which prevented IV from further isolation because of its lower solubility in the solvent.

Found: C, 78.36; H, 10.24; N, 3.78. Calcd. for $C_{27}H_{41}O_2N$: C, 78.78; H, 10.04; N, 3.40%.

The acetylation of the diene obtained above gave the corresponding triacetyl derivative, m. p. 120—121°C. For analysis it was dried at the temperature of boiling methanol for a long time.

Found: C, 73.86, 73.56; H, 9.02, 9.08; N, 2.88, 3.06. Calcd. for $C_{33}H_{47}O_5N$: C, 73.71; H, 8.81; N, 2.61%.

The conjugated diene and the acetyl derivative were identical with the corresponding compounds obtained by the Wolff-Kishner reduction of jervine.

The authors wish to express their thanks to Professor Toshi Irie for his encouragement and also to Mr. Shigezo Shimokawa and Mr. Seiichiro Ohnishi, the Toyo Rayon Company, Ltd., for their measurement of the NMR spectra. They are also indebted to Mr. Naoyuki Sakamoto and Mr. Shoji Ueno for collecting the plants.

# The Reaction of Dimethyltin Dichloride with Carboxylic Acids and Phenols in an Aqueous Solution

By Mitsuaki O'HARA, Rokuro OKAWARA and Yoshiaki NAKAMURA

(Received Junuary 12, 1965)

The reaction of dimethyltin dichloride in an aqueous solution with various inorganic and organic compounds has previously been reported by Rochow, Seyferth and Smith,[1] and the reaction with acetic acid anhydride or glacial acetic acid has also been studied by Okawara and Rochow.[1,2]

In this paper the reaction of dimethyltin dichloride with carboxylic acids and phenols in an aqueous solution will be described. In reactions with the acids and phenols shown in Table I, precipitation occurs only when deprotonating reagents such as concentrated aqueous ammonia are added. The precipitates are recrystallized from methanol containing a small amount of the corresponding acid or phenol in order to prevent decomposition, thus yielding tetramethyl-1, 3-di(substituted)-distannoxanes. These products all have a strong, and characteristic absorption near 600 $cm^{-1}$, as is shown in Table I, an absorption which has previously been assigned to the Sn-O-Sn stretching vibration in polymeric[4] or dimeric[3,5] compounds.

In the reaction with benzoic acid, the initial precipitate seems to be tetramethyl-1, 3-dibenzoyloxydistannoxane. However, recrystallization from methanol containing a small amount of benzoic acid gives large colorless crystals of $(CH_3)_2Sn(C_6H_5CO_2)_2$, which melts at 162—164°C. Reaction with catechol, mercaptoacetic acid or oxalic acid gives a precipitate without deprotonating reagents. The products are $(CH_3)_2Sn(C_6H_4O_2)$, $(CH_3)_2Sn(SCH_2CO_2)$ and $(CH_3)_2Sn(C_2O_4)\cdot H_2O$ respectively. Because of their poor solubility in non-polar solvents, the molecular weight of these three compounds, as well as those of the other distannoxanes shown in Table I, were not determined.

In the case of resorcinol, hydroquinone or malonic acid, precipitation does not occur by mixing in an aqueous solution of the reagents, but a precipitate can be obtained by adding concentrated aqueous ammonia. However, the products are not simple and, therefore, can not be characterized.

## Experimental

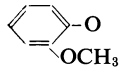
**Starting Materials.** — Crude dimethyltin dichloride was purified by recrystallization from benzene[1] or by sublimation.[2] Carboxylic acids and phenols commercially obtained were used without further treatment.

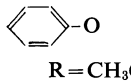
**Infrared Spectra*.**—The infrared spectra in the 5000—400 $cm^{-1}$ region were recorded in Nujol mull using a Hitachi-EPI-2G spectrophotometer with gratings. The positions of the bands associated with the Sn-O-Sn stretching vibration are listed in Table I.

**Tetramethyl-1, 3-diformoxy-distannoxane.**—To a solution of dimethyltin dichloride (5 g. 0.023 mol.) and formic acid (4 g. 0.087 mol.) in 100 ml. of water, concentrated aqueous ammonia was stirred in drop by drop until no additional precipitate was formed. The precipitate was then washed with dilute aqueous formic acid, and then by a small amount of methanol, and dried in vacuo. Recrystallization from methanol containing a small amount of formic acid gave large colorless crystals which melted at 185°C, as is shown in Table I. The analysis for tin content was carried out in a manner already described elsewhere.[2]

The other compounds shown in Table I were prepared by a similar procedure in a good yield (70—80%). However, the *o*-methoxyphenoxy compound could be recrystallized from methanol or benzene without adding guaiacol.

**Dimethyltin Dibenzoate.**—To a 500 ml. of a hot aqueous solution containing 4 g. (0.018 mol.) of dimethyltin dichloride and 6 g. (0.049 mol.) of benzoic acid, concentrated aqueous ammonia was added carefully until no additional precipitate formed. The white precipitate, which was washed with hot water and methanol and dried in vacuo, seemed to be a distannoxane derivative.[1]





Found: Sn, 42.25. Calcd. for $C_{18}H_{22}O_5Sn_2$: Sn, 42.71%.

Recrystallization from methanol containing a small amount of benzoic acid gave large colorless crystals of dimethyltin dibenzoate. M. p. 162—164°C. (Reported[7]: m. p. 160—162°C). Yield:

* Reported[6] m. p. 190—197°C with a crude product.

40—50%.

Found: C, 48.99; H, 3.90; Sn, 30.33. Calcd. $C_{16}H_{16}O_4Sn$: C, 49.15; H, 4.13; Sn, 30.36%.

**(*o*-Phenylenedioxy)dimethyltin.** — A white precipitate was obtained immediately by stirring in, drop by drop, 35 ml. of 10% aqueous catechol to a solution of 1.4 g. (0.0064 mol.) of dimethyltin dichloride in 50 ml. of water. After the reaction mixture had been digested on a water bath for several hours, the precipitate was filtered, repeatedly washed with hot water until the filtrate was free from chlorine, and dried at 120°C. Yield: 60%. It was purified by sublimation at 260—220°C in vacuo as has been reported.[8] The results of the analysis and of the infrared spectra in the 5000—400 $cm^{-1}$ region of the precipitate and the sublimate were quite identical. Neither compound showed any infrared absorption bands due to O-H stretching vibrations.

Found: C, 37.42; H, 3.92; Sn, 46.20. Calcd. for $C_8H_{10}O_2Sn$: C, 37.41; H, 3.92; Sn, 46.21%.

In the methanol solution, dimethyltin dichloride and catechol produced no precipitate in spite of the insolubility of $(C_6H_4O_2)Sn(CH_3)_2$ in methanol. On the other hand, dimethyltin dichlororide produced no precipitate with resorcinol or hydroquinone in an aqueous solution.

**The Reaction of Dimethyltin Dichloride with Marcaptoacetic Acid.**—To a solution of dimethyltin dichloride (5.5 g. 0.025 mol.) in 50 ml. of water, 50 ml. of 15% aqueous mercaptoacetic acid was added slowly. The filtrate was then washed thoroughly with water and then by a small amount of methanol, and dried in vacuo. Yield: 75—80%. This compound could be recrystallized from a large amount of boiling water without decomposition. The infrared spectra of the precipitate and the recrystallized product could be superimposed in the 5000—400 $cm^{-1}$ region and showed no absorption band due to the S-H or the O-H stretching vibration. The recrystalized product gradually became brown near 200°C and melted at 257—259°C.

Found: C, 20.03; H, 3.62; Sn, 49.80. Calcd. for $C_4H_8O_2SnS$: C, 20.11; H, 3.38; Sn, 49.69%.

**Dimethyltin Oxalate Monohydrate.**[1]—To 100 ml. of a 4% hot aqueous solution of dimethyltin dichloride, 100 ml. of 3% hot aqueous oxalic acid was added. The white precipitate thus obtained was digested on a steam bath for several hours, filtered, washed with hot water, and dried at 120°C. It could be recrystallized from a large amount of boiling water, but complete dehydration could not be accomplished without decomposition.

Found: C, 18.67; H, 3.12. Calcd. for $C_4H_8O_5Sn$: C, 18.85; H, 3.16%.

On the other hand, dimethyltin dichloride produced no precipitate with malonic acid in an aqueous solution.

## Summary

The reactions of dimethyltin dichloride with carboxylic acids and phenols in aqueous solution have been described, and ten new compounds reported. In many cases tetramethyl-1,3-di(substituted)distannoxanes are formed in good yields by adding such deprotonating reagents as concentrated aqueous ammonia. In other cases, simple dimethyltin derivatives can be obtained without deprotonating reagents.

# The Nucleophilic Replacement of the Phenolic Hydroxy Group by the Mercapto Group in Acidic Media*

By Shigeru OAE and Reiko KIRITANI

(Received January 18, 1965)

During our study of the acid-catalyzed hydrolysis of phenyl benzenesulfonate with concentrated hydrochloric acid in $^{18}O$-enriched water, we have found that the phenol recovered is always incorporated with an excess of $^{18}O$ when the hydrolysis is carried out at 180°C in a sealed tube, and also that the amount of $^{18}O$ incorporation increases as the heating prolonged.[1] Even in the case of *p*-nitrophenyl benzenesulfonate, it has been shown that the *p*-nitrophenol recovered is incorporated with an excess of $^{18}O$ only at the phenolic oxygen.[2]

We have suggested that, in a strong acidic medium, phenol readily accepts a proton at either the ortho- or para-position, thus forming a quasi-stable incipient carbonium ion intermediate in which the original hydroxyl function acquires more of a carbonyl character and, hence, facilitates the oxygen exchange with $^{18}O$-enriched water.[1,3]

Meanwhile, it has been known that carbonyl group of either ketone or aldehyde undergoes a very facile oxygen isotopic exchange in both acidic and alkaline aqueous media.[4] Therefore, it is not very surprising that a phenolic hydroxy group undergoes a nucleophilic replacement with $^{18}O$-enriched water, when the phenolic hydroxy group acquires a rather carbonyl character. In fact, β-naphthol, which is known to have some carbonyl character, has been known to react with nucleophilic reagents, such as sulfurous acid[5] and thioglycolic acid,[6] to replace the phenolic hydroxyl group and form β-naphthyl sulfonic acid and thioglycolic acid respectively.

If the oxygen isotopic exchange of the phenolic hydroxy group in acidic media takes place by means of the nucleophilic attack of the water molecule, phenols in general would react better with other nucleophiles, such as alcohols and mercaptans, under the same conditions as those in which the oxygen exchange takes place. Indeed, we have isolated the corresponding ethers or sulfides by adding alcohols or mercaptans to the reaction mixture of phenol with hydrochloric acid and heating the mixtures at 180°C for a few days in a sealed tube.

The present work was designed to investigate in detail the nature of the reaction by which sulfides are formed from mercaptans and phenols in the presence of a strong acid.

## Results and Discussion

We have proposed that the acid-catalyzed oxygen exchange reaction of phenol above 180°C in a sealed tube proceeds through the "quasi-stable quinoid intermediate"[1] with a proton attached to either the ortho- or para-position, and that the quinoid intermediate, which has a substantially long life, is attacked by water molecule on the quasi-carbonyl carbon in the succeeding step, thus causing the remarkable oxygen isotopic exchange. The essential feature of this mechanism is identical to that of any of the known nucleophilic replacements involving a carbonyl carbon. Therefore, one would expect that other nucleophiles would also undergo similar nucleophilic replacements.

Our first choice of nucleophilic reagents were mercaptans, since the thiol group has been known to be strong nucleophiles and quite stable in strong acidic media. Accordingly, under the conditions in which the oxygen isotopic exchange takes place, thiol may be expected to replace the phenolic hydroxy group. The results of rough kinetic experiments of the phenolic oxygen exchange carried out in strong acidic media enriched with $^{18}O$-water are shown in Table I.

Phenol was then heated in sealed tubes at 180°C and 110°C with various mercaptans for a long time in the presence of hydrochloric acid. Indeed, when heated at 180°C for some hours, at which the oxygen exchange occurs, and the mercaptans, i.e., *n*-butylmercaptan,

benzylmercaptan and thiophenol, were all found to react with phenol and to give the corresponding sulfides; on the other hand, no reaction took place under milder conditions, such as heating at 110°C, at which no oxygen exchange occurs. The phenyl sulfides obtained are shown in Table II, together with the yields.

When the three marcaptans were allowed to react with phenol at 180°C, the corresponding sulfides were obtained in considerable yields. The yields of sulfides increased with prolonged heating. It appears that the ease of sulfide formation is also related to the nucleophilicity of the mercaptan used. The *n*-butyl phenyl sulfide was identified by comparing it with an authentic sample, while the other sulfides were identified on the basis of their elemental analyses and their infrared spectra. The reaction appears to involve the attack of the thiol group on the 1-carbon of phenol, which is presumably protonated at either the ortho- or the para-position. This is analogous to the mechanism suggested for the acid-catalyzed phenolic oxygen exchange reaction involving nucleophilic substitution at the C-1 position, as is shown in Fig. 1.

Meanwhile, one may postulate another alternative pathway, i.e., one that involves the nucleophilic addition of the thiol group at one of the ortho-positions or at the para-position

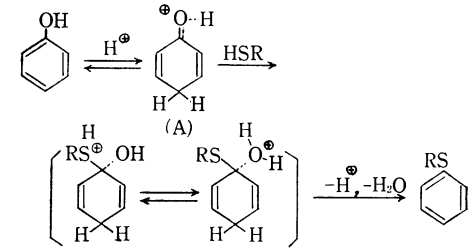

Fig. 1.

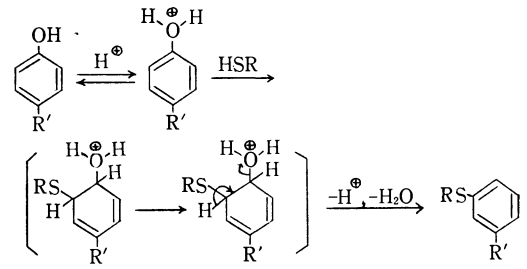

Fig. 2.

of phenol, followed by the elimination of water, as is shown below (in Fig. 2).

Recently Mc. Arnett and Wu,[7] in their study of the p$K_a$'s of the oxonium ions of phenol

Table III. Oxygen exchange reaction of cresols

| Compound | Reaction time hr. | $^{18}O$ Atom. % of aq. HCl soln. | $^{18}O$ Atom. % of Product | Exchange % |
|---|---|---|---|---|
| *o*-Cresol | 24 | 0.77 | 0.37 | 31.6 |
| *m*-Cresol | 24 | 0.77 | 0.45 | 43.9 |
| *p*-Cresol | 24 | 0.77 | 0.45 | 43.9 |

and various phenyl ethers under normal conditions, have suggested that the primary site of protonation in the phenolic compound is the oxygen. If this is the case, even at a higher temperature, the oxonium group would induce the nucleophilic attack at either the ortho- or para-position, as in the case of the Bamberger reaction.[8] In this case, one would expect to get a rearranged product. This mechanism was, however, contradicted by the reaction with *p*-substituted phenol. Namely, when *p*-cresol was allowed to react with *n*-butyl mercaptan in the presence of hydrochloric acid at 180°C for 48 hr. in a sealed tube, *p*-tolyl *n*-butyl sulfide was obtained in a 14% yield, while no *m*-tolyl *n*-butyl sulfide was obtained, as Table IV shows. The identification was made by comparing the infrared absorption spectrum with that of an authentic sample of *p*-tolyl *n*-butyl sulfide.

In separate experiments, *o*-, *m*- and *p*-cresols were subjected to the oxygen exchange reaction at 180°C in the same acidic medium, they were found to exchange their respective phenolic oxygen with $^{18}O$ of the medium, as is shown in Table III.

Here, one finds that the same amount of $^{18}O$ exchange occurred in both *m*- and *p*-cresols, whereas the amount of $^{18}O$ exchange of *o*-isomer was a little less, probably due to a small steric hindrance by the *o*-methyl group. These results, together with the formation of the sulfide, strongly suggest that the reaction involves the nucleophilic attack at the phenolic carbon rather than at the ortho-position of phenol.

Another possible path would be the aromatic $S_N2$-type reaction involving the nucleophilic replacement of the hydroxy group by thiol, as is shown in Fig. 3.

In this case, when the bond-forming is the controlling stage, electron-withdrawing substituents will enhance the reactivity, whereas if the reaction is controlled by the bond-fission stage, electron-releasing substituents will accelerate the reaction. However, in both oxygen exchange reaction and sulfide formation, the substitution of any group at the ring carbon usually retards the reactions. Furthermore, one would anticipate that the reaction would

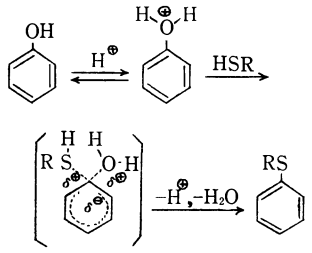

Fig. 3.

be more facile with a better leaving group, such as benzenesulfonate, instead of the hydroxy group. However, neither phenyl benzenesulfonate nor *p*-nitrophenyl benzenesulfonate undergoes any facile hydrolyses, nor do their hydrolyses proceed via Ar-oxygen cleavage, while there was no formation of the sulfides between these compounds and *n*-butyl mercaptan under similar reaction conditions. These results clearly disfavor the aromatic $S_N2$-type mechanism and favor the first one, since any substituent would destroy the symmetry of the protonated species and decrease the lifetime of the intermediate incipient carbonium ion (A),* thus effecting less change in the nucleophilic attack at the phenolic carbon, which will presumably assume a quasi-carbonyl character; moreover, the replacement of phenolic hydrogen by the benzenesulfonyl group will destroy the phenolic hydroxyl group, which is essential for the nucleophilic replacement via the incipient carbonium ion (A). As a corollary deduction from this mechanism, one may expect a more facile nucleophilic replacement with phenols with a more carbonyl character. In fact, naphthols were found to give naphthyl *n*-butyl sulfides in better yields in the acid-catalyzed reaction with *n*-butyl mercaptan, as Table IV shows.

The formation of β-naphthyl sulfide was noticed earlier by Furman et al.,[6] when β-naphthol was heated at 110—120°C with various mercaptans for 16 hr. in the presence of and also without any solvent. They have also proposed a similar reaction mechanism analogous to the Bucherer reaction involving the

attack of the mercaptan on the carbonium ion derived from *β*-naphthol by the protonation of the hydroxy group.

## Experimental

**Phenyl *n*-Butyl Sulfide.** — A mixture of phenol (0.94 g., 0.01 mol.), *n*-butyl mercaptan (4.5 g., 0.05 mol.) and 12 N hydrochloric acid (1 ml.) was sealed in a tube and then heated at 180°C for 48 hr. The sealed tube was then broken, the unreacted *n*-butyl mercaptan was distilled off under reduced pressure, and the residue was extracted with ether. The ether layer was treated with an aqueous sodium hydroxide solution to remove the unchanged phenol, and the two layers were separated. The ether layer was washed with dilute hydrochloric acid, and then with water, and dried. Distillation gave 0.52 g. of phenyl *n*-butyl sulfide in a 31% yield. The infrared spectra is completely in agreement with that of an authentic sample. Found: C, 72.35; H, 8.43%, $n_D^{20}$ 1.5426, b. p. 75°C/1 mmHg. Meanwhile, when the same reaction mixture was heated in a sealed tube at 110°C for 48 hr. and treated as above, no sulfide was obtained.

In a separated experiment, a mixture of phenol (0.94 g., 0.01 mol.), *n*-butyl mercaptan (0.9 g., 0.01 mol.) and 12 N hydrochloric acid (1 ml.) was heated at 180°C for 48 hr. in a sealed tube; 0.37 g. of phenyl *n*-butyl sulfide was thereby obtained (yield 22%). However, when the same mixture was heated at 180°C for 24 hr. in a sealed tube, only a trace amount of phenyl *n*-butyl sulfide was obtained. The sulfide was found to be identical with an authentic sample in infrared spectra. Meanwhile, an authenthic sample of phenyl *n*-butyl sulfide was prepared by reacting diazotized aniline with sodium *n*-butyl mercaptide in over a 90% yield; b. p. 83°C/2 mmHg.

**Phenyl Benzyl Sulfide.** — A mixture of phenol (0.94 g., 0.01 mol.), benzyl mercaptan (6.2 g., 0.05 mol.) and 12 N hydrochloric acid (1 ml.) was sealed in a tube and heated at 180°C for 48 hr. The sealed tube was then broken, and two layers were separated. The upper, yellow layer neutralized with an aqueous sodium hydroxide solution, dried, and then distilled under reduced pressure. Two and six-tenths grams of phenyl benzyl sulfide was obtained (yield 43.4%); b. p. 118°C/3.5 mmHg. Found: C, 77.92; H, 6.00%, $n_D^{20}$ 1.6083. From the lower layer 2 g. of dibenzyl disulfide was obtained; m. p. 71°C.

**Diphenyl Sulfide.**—A mixture of phenol (0.94 g., 0.01 mol.), thiophenol (5.5 g., 0.05 mol.) and 12 N hydrochloric acid (1 ml.) was sealed in a tube and heated at 180°C for 72 hr. The sealed tube was then treated as has been described in the case of phenyl *n*-butyl sulfide. Diphenyl sulfide (0.5 g., 26.7% yield) was obtained, together with 0.3 g. of diphenyl disulfide. Found: C, 77.18; H, 5.38%, $n_D^{20}$ 1.6298, b. p. 113°C/1 mmHg.

In a separate experiment, the same mixture was heated at 180°C for 119 hr., 0.6 g. of diphenyl sulfide was thereby obtained (yield 32.2%).

***p*-Tolyl *n*-Butyl Sulfide.**—A mixture of *p*-cresol (1.08 g., 0.01 mol.), *n*-butyl mercaptan (1 g., 0.011 mol.) and 12 N hydrochloric acid (2 ml.) was sealed in a tube and heated at 180°C for 48 hr. The sealed tube was then broken, and two layers were separated. The lower layer consisted of hydrochloric acid and was discarded. The upper layer was treated as has been described above, thereby removing the unreacted *p*-cresol and *n*-butyl mercaptan. Then the product was collected by distillation in vacuo. *p*-Tolyl *n*-butyl sulfide (0.7 g.) was obtained in a yield of 14%. The product was identified with that of the authentic sample by comparing their infrared spectra. Found: C, 73.19; H, 8.85%, $n_D^{20}$ 1.5397, b. p. 92—94°C/2 mmHg. An authentic sample of *p*-tolyl *n*-butyl sulfide was prepared by reacting diazotized *p*-toluidine with *n*-butyl mercaptan; 95% yield; b. p. 90°C/2 mmHg.

***β*-Naphthyl *n*-Butyl Sulfide.** — A mixture of *β*-naphthol (4.3 g., 0.03 mol.), *n*-butyl mercaptan (2.7 g., 0.03 mol.) and 12 N hydrochloric acid (2 ml.) was sealed in a tube and heated at 180°C for 48 hr. The sealed tube was then broken, and the entire contents were treated as has been described in the case of phenyl *n*-butyl sulfide. When the ether extract was distilled, 3.6 g. of *β*-naphthyl *n*-butyl sulfide was obtained (yield 55.4%). Found: C, 77.57; H, 7.40%, $n_D^{20}$ 1.6229, b. p. 130—135°C/2 mmHg.

***α*-Naphthyl *n*-Butyl Sulfide.** — A mixture of *α*-naphthol (1.44 g., 0.01 mol.), *n*-butyl mercaptan (4.5 g., 0.05 mol.) and 12 N hydrochloric acid (1

ml.) was sealed in a tube and heated at 180°C for 52 hr. The entire contents in the sealed tube were then treated as has been described above. When the ether extract was distilled, 1.9 g. of α-naphthyl *n*-butyl sulfide was obtained (yield 69.5%). Found: C, 77.77; H, 7.19%, $n_D^{20}$ 1.6190, b. p. 140—142°C/2.5 mmHg.

**Benzenesulfonate.**—Phenyl benzenesulfonate (2.34 g., 0.01 mol.) was sealed in a tube with *n*-butyl mercaptan (4.5 g., 0.05 mol.) and 12 N hydrochloric acid (1 ml.). The mixture was then kept at 180°C for 48 hr. The entire contents in the sealed tube were treated as has been described above. The reactants, phenyl benzenesulfonate and *n*-butyl mercaptan, were recovered quantitatively. Also when *p*-nitrophenyl benzenesulfonate (2.79 g., 0.01 mol.) was treated by a procedure similar to that used for phenyl benzenesulfonate, no reaction products were obtained.

# The Solvent Extraction and Spectrophotometric Determination of Vanadium(V) with Thenoyltrifluoroacetone[1]

By Akira IKEHATA and Tamako SHIMIZU

(Received January 27, 1965)

In 1963, De and Rahaman[2] reported a method for the rapid extraction of the vanadium(V)-thenoyltrifluoroacetone (TTA) complex using *n*-butyl alcohol. Except for this short communication, however, little work has been reported on this subject.[3-5] However, in the above method, the complex can not be extracted completely because *n*-butyl alcohol has a relatively large solubility in water. In this paper, a detailed study of the extraction of the vanadium(V)-TTA complex will be made, with special reference to the effect of solvents, the absorption spectra, and the composition of the extracted species.

## Experimental

**Reagents.**—All the reagents used were guaranteed reagents.

The standard vanadium(V) solution was prepared by the fusion of 0.9094 g. of vanadium pentoxide with five times as much sodium carbonate for about one hour at about 900°C. This was dissolved in diluted sulfuric acid and diluted to 1 l. The final sulfuric acid concentration was about 6 N. This solution contains $10^{-2}$ mol./l. of vanadium. A diluted vanadium(V) solution was prepared daily. The organic solvents used for extraction were isoamyl acetate, *n*-butyl acetate, methyl isobutyl ketone, chloroform, benzine, ethyl acetate, carbon tetrachloride, ethylbenzene, toluene, chlorobenzene, cyclohexane, kerosene, xylene, benzene and isopropyl ether.

TTA: Solutions in the above solvents (up to 0.3 M).

**Apparatus.**—A Hitachi model EPU-2A spectrophotometer, a Hitachi-Horiba model M-3 pH meter (accuracy ±0.05 pH unit), a Toadempa HM-8 pH meter (accuracy ±0.005 pH unit), and an Iwaki KM shaker were used.

Experiments were performed by extracting 50 ml. of an aqueous solution of vanadic acid with 10 ml. of organic solvents containing TTA at 25°C.

## Results and Discussion

**The Absorption Spectra of the Vanadium(V)-TTA Complex and of the Chelating Agent.**—As Fig. 1 shows, TTA is a typical diketone which is in keto-enol equilibrium in an aqueous solution.[6,7] It is the enol form that reacts with numerous metals.[8] Figures 2 and 3 show the various absorption spectra of the chelate extracted in various organic solvents.

In these experiments, vanadium(V) was extracted for about one hour at pH 3. It was apparent that this complex was extracted more easily in aliphatic solvents, especially isoamyl acetate and *n*-butyl acetate, than in aromatic solvents.

As is shown in Table I, the blue shifts of $\lambda_{max}$ and the increment of the absorbance of these chelates were observed in accordance with a decrease in the refractive indices and with an increase in the dielectric constants of organic solvents, with the exception of a few solvents. Within the range of experimental error, the shifts of these chelate bands in organic solvents seem to obey the equation set forth by McRae, which predicts a linear relationship between the frequency shifts in absorption spectra and the expression $(n^2-1)/(2n^2+1)$, and $(D-1)/(D-2)$, where $n$ is the refractive index and $D$ is the dielectric constant of the solvent.[9-12]

Table I. Shifts of the absorption maximum of the complex

| | Dielectric constant | Reflactive index | $\lambda_{max}$ mμ |
|---|---|---|---|
| *n*-Butyl alcohol | 17.1 | 1.39[a] | 410 |

| Carbon tetrachloride | 2.22[a] | 1.46[a] | 423 |
| Cyclohexane | 2.01 | 1.42[a] | 424 |

a) 20°C, b) 21°C, c) 23°C, d) 29°C, other datas are at 25°C.

**The Effect of the Concentration of the Chelating Agent.**—The effect of the concentration of the chelating agent on the extraction of the complex was determined by varying the concentration of the chelating agent at a constant vanadium(V) concentration. The changes in the absorbance of the organic phase were measured at 420 mμ since the absorption of the chelating agent was negligible at this point.

As Fig. 4 shows, the absorbance increased up to a maximum value of 0.1 M TTA, beyond which the increase in the chelating agent had no significant effect. Thus, in this experiment, the 0.2 M TTA concentration was used.

**The Effect of the Extracting Time.**—The effect of the extracting time was determined. About 30 min. were required for the attainment of the extraction equilibrium (Fig. 5).

**The Effect of pH.**—The effect of pH was determined by controlling the pH with sulfuric acid and sodium hydroxide. The results are as shown in Fig. 6. The chelate was completely extracted over the pH range from 2 to 3.

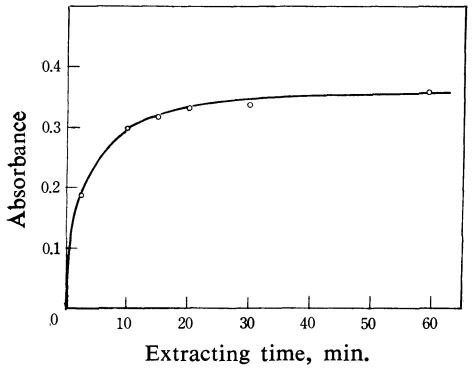

Fig. 5. Effect of the extracting time.

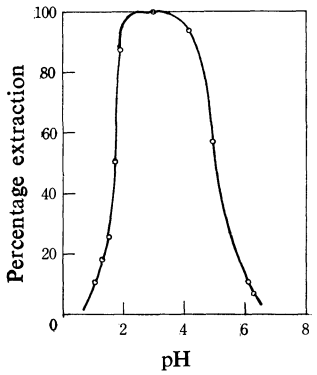

Fig. 6. Effect of pH.

**The Determination of the Mole Ratio of Vanadium(V)-TTA Complex.**—The determination of the mole ratio of vanadium(V) and TTA of this complex extracted in isoamyl acetate was made by the following two methods.

*The Continuous Variation Method.*[13]—The sum total of the concentrations of the metal ion and of the chelating agent was held at $10^{-2}$ mol./l., and the absorbance was plotted against the $[M^{n+}]/([M^{n+}]+[HR])$.

$[M^{n+}]$ and [HR] are the initial concentrations of the vanadium(V) and of the chelating agent respectively. In this method $n=2$ (Fig. 7).

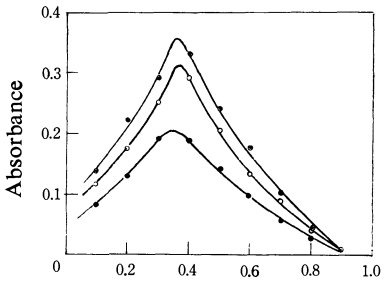

Fig. 7. Cotinueous variation method.
- ⊙ Determined at 410 mμ
- ○ Determined at 420 mμ
- ● Determined at 450 mμ

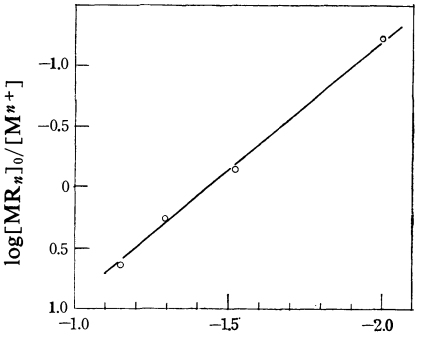

Fig. 8. Slope ratio method.

*The Slope Ratio Method.*[14]—Provided all intermediate complexes can be neglected,

$$M^{n+}+nR^- \rightleftharpoons MR_n$$

$$K_f=[MR_n]/[M^{n+}][R^-]^n$$

If the complexation of $M^{n+}$ with a ligand other than $R^-$ is not appreciable, we have:

$$K_f=K_{DR}^n[MR_n]_0[H^+]^n/K_{DX}K_A^n[M^{n+}][HR]_0^n$$

Then, at a constant pH:

$$n\log[HR]_0=C+\log D$$

where $C=-\log K_{DX}K_A^nK_f/K_{DR}^n[H^+]^n$ and $D$ refers to the distribution ratio of M between the aqueous and organic solvent.

From the plots of $\log[HR]_0$ vs. $\log[MR_n]_0/[M^{n+}]$, $n$ was obtained. As Fig. 8 shows, we obtain a slope of $n=2$.

**The Calibration Curve and the Effect of Foreign Ions.**—Under these conditions, the

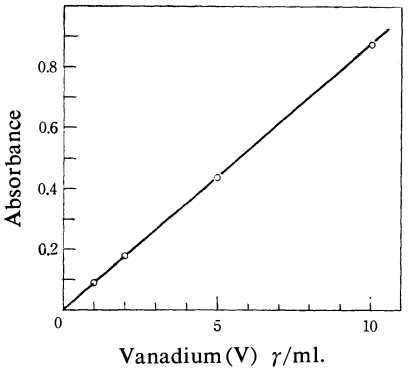

Fig. 9. Calibration curve.
TTA=0.2 mol./l., dissolved in isoamyl acetate, pH 2.5, at 420 mμ.

TABLE II. TOLERANCE LIMIT FOR DIVERSE IONS

| Foreign ion | Added as | Tolerance limit p. p. m. |
|---|---|---|
| $Ti^{4+}$ | Sulfate | 50 |
| $Fe^{3+}$ | $FeSO_4(NH_4)_2SO_46H_2O$ | 10 |
| $Al^{3+}$ | Sulfate | 500 |
| $Mn^{2+}$ | Sulfate | 500 |
| $Zn^{2+}$ | Sulfate | 500 |
| $Cu^{2+}$ | Sulfate | 50 |
| $Ca^{2+}$ | Chloride | 500 |
| $Mg^{2+}$ | Sulfate | 500 |
| $Mo^{6+}$ | $(NH_4)_2MoO_4$ | 500 |
| $Pb^{2+}$ | $Pb(NO_3)_2$ | 500 |

relation between the absorbance and the vanadium(V) concentration was linear up to 10γ/ml. of vanadium(V) in an aqueous solution (Fig. 9). The fading was almost negligible.

Table II shows the effect of several metal ions on this method. Experiments were made in the presence and in the absence of $2\times10^{-2}$ mol./l. of vanadium(V). The tolerance limit indicates the maximum concentration of diverse ions which affects the absorbance of the system by less than ±2%.

Because comparable amounts of $Ti^{4+}$, $Fe^{3+}$, $Cu^{2+}$ interfere with the method, these ions should be removed from the sample by the usual methods.

## Summary

The extraction of the vanadium(V)-TTA complex has been studied using various organic solvents. The complex has been extracted quantitatively in isoamyl acetate and *n*-butyl acetate. The quantitative extraction has been realized within a range from pH 2 to 3, with the absorption maximum at 410 mμ. The mole ratio of the complex is vanadium(V)-1 : 2-TTA, and Beer's law is applicable in the range from 0 to 10γ/ml. of vanadium(V) at 420 mμ. The solvent effects on the absorption spectra of this complex have also been studied.

# The Exchange Reaction of Oxygen Atoms between Inorganic Anions and Water

By Toshizo TITANI, Kaoru DATE and Mitsuko AMBE

(Received November 26, 1964)

About 25 years ago Titani and Goto[1] investigated the exchange reaction of O-atoms between some inorganic oxyanions and water, and found that the oxyanions of strong acids, such as $SO_4^{2-}$, $NO_3^-$, and $ClO_3^-$, exchanged their O-atoms with those of water in acid solutions, but not in neutral solutions. They found, further, that the same exchange reaction took place in the solutions of the neutral salts of such weak acids as potassium carbonate without any catalytic additives, although in this case the solutions turned alkaline as a result of the hydrolytic dissociation of the salts. The same result was obtained by Blumenthal and Herbert[2] with potassium phosphate. At almost the same time, it was reported by Ingold and his collaborators[3] that sodium sulfate rapidly exchanged its O-atoms with those of water in the presence of alkali. Since all these results suggested that

1) T. Titani and K. Goto, This Bulletin, **14**, 77 (1939).

2) E. Blumenthal and J. B. M. Herbert, *Trans. Faraday Soc.*, **33**, 849 (1937).

3) S. C. Datta, J. N. E. Day and C. K. Ingold, *J. Chem. Soc.*, **1937**. 1968,

the reaction was catalyzed by both acid and alkali, we assumed the conventional acid-base catalysis as a primary mechanism of the reaction. At the same time, however, we proposed as an alternative mechanism a reversible dissociation of the neutral acid molecules, such as:

$$H_2SO_4 \rightleftarrows H_2O + SO_3 \quad (1)$$

Neutral acid molecules can be formed either by the addition of hydrogen ions to the oxyanions:

$$2H^+ + SO_4^{2-} \leftrightarrows H_2SO_4 \quad (2)$$

as in the case of the acid solutions of strong acid salts, or by hydrolytic dissociation:

$$CO_3^{2-} + 2H_2O \rightleftarrows H_2CO_3 + 2OH^- \quad (3)$$

as in the case of weak acid salts. With this alternative mechanism, we can explain the results of Titani and Goto as well as those of Blumenthal and Herbert. The only exceptions were the results of the experiment of Ingold and his collaborators, who found the exchange of O-atoms between the oxyanions of such strong acids as $SO_4^{2-}$ and water in an alkaline solution, as has been described above. Therefore, we attempted first to repeat the experiment of Ingold and his collaborators. Unfortunately, however, it was very difficult to carry out such an experiment because the glass surface of the reaction vessel was seriously attacked by the aqueous alkaline solutions at elevated temperatures.

Since the publication of the papers mentioned above, several similar studies have appeared,[4-9] and the reversible anhydride formation has also been assumed by several workers[6,8,9] as the mechanism of the reaction. Furthermore, Winter, Carlton and Briscoe[4] could not observe the catalytic action of the hydroxyl ion on the exchange reaction of the sulfate ion and they suggested that, in view of the rapid exchange of sodium metasilicate, the reaction between the glass wall of the reaction vessel and the strongly alkaline solution might account for the observed exchange in such cases. The same finding and opinion were presented by Hall and Alexander.[7] Mill[6] observed, however, no exchange reaction between Pyrex glass and a strongly alkaline solution at a high temperature, even though the glass was markedly etched, and suggested that different kinds of glass react differently.

Such problems can now easily be solved by the use of a stainless steel vessel. In this way we have studied the reaction in a strongly alkaline solutions. As a result we have come to the conclusion that no exchange reactions take place betwen $SO_4^{2-}$ and water in an alkaline solution; the decrease in the heavy oxygen content of the water which is observed in the case of alkaline solutions in glass reaction vessels must be ascribed to the exchange of O-atoms between the water and the surface of the glass reaction vessel.

## Experimental and Results

The experiments were carried out using both ordinary glass ampoules and a stainless steel reaction vessel which will be described below. The stainless steel vessel consists of four parts, A, B, C and D, which are shown on the left hand side of Fig. 1. A is a stainless steel guard ring. B is a strainless steel plate, at the center of which a short Kovar tube K is welded. This Kovar tube is then welded to an ordinary glass tube, G, by means of Kovar glass, KG. C is a packing ring made of Teflon. D is a stainless steel cylinder which is 3 cm. in inner diameter and 20 cm. long. This lower end of the cylinder is sealed by welding, while the upper end of the cylinder is welded to a guard ring which has the same form and size as the guard ring A mentioned above. These four parts are tightly screwed together by six sets of bolts and nuts, as is shown on the

right hand side of Fig. 1. In this way this stainless steel vessel can be welded to a glass vacuum line just as an ordinary glass ampoule.

All the experiments were carried out in the same way, either with glass ampoules or with the stainless steel vessel. First, a weighed amount of purified anhydrous sodium sulfate and metallic sodium were placed in the reaction vessel. After this vessel had been welded to a vacuum line, a weighed amount of $^{18}O$-enriched water was distilled into the vessel. Then the vessel was evacuated, sealed off from the vacuum line, and heated at 100°C for more than 24 hr. in an air thermostat. After the heating, the vessel was again connected to the vacuum line and the water was distilled off into the other glass ampoule. The concentration of $^{18}O$ in the separated water was measured by the conventional method; the water was brought into equilibrium with the $CO_2$, and the $^{18}O$ content of the latter was measured by a mass spectrometer.

The experimental results are shown in Tables I and II, where $C_B$ and $C_A$ represent the atomic percentage of $^{18}O$ in the water before and after the experiment respectively.

Among the results of the experiments with glass ampoules which are shown in Table I, the results of Nos. 1 and 2 are in accord with the previous results of Titani and Goto; the exchange reaction of O-atoms does not take place between $SO_4^{2-}$ and water in neutral solutions, but it does in acid solution. On the contrary, the results of the experiments from Nos. 3 to 6, which were carried out with the addition of sodium, i. e., alkali, conflict somewhat with one other. Although a small decrease in the $^{18}O$-content of the water was observed in all experiments, as was expected from the experimental results of Ingold and his collaborators, the amount of the decrease is very irregular; it is not always proportional to the amount of sodium sulfate and sodium and to the time of the reaction, as may be seen, for example, by a comparison of the results of Nos. 4 and 5 and Nos. 5 and 6. These results suggest that the cause or the mechanism of the decrease in the $^{18}O$-content in water is too complicated to be explained solely by the exchange reaction between $SO_4^{2-}$ and water. From this point of view, we carried out experiments Nos. 7 and 8, where only sodium, but no sulfate, was added to the solutions. Here we have found also the same degree of decrease in the $^{18}O$-content of the water as in those experiments with the addition of sulfate, i. e., experiments from No. 3 to 6. We, therefore, assumed that the decrease in the $^{18}O$-content of the alkaline solution might be entirely due to the exchange reaction of O-atoms between the water and the surface of the glass reaction vessels.

This assumption was actually confirmed by the experiments with the stainless steel reaction vessel, the results of which are shown in Table II. From Table II, we can safely conclude that no exchange of O-atoms take place within the limits of experimental error when there is no glass surface in the reaction system; the decreases in the $^{18}O$-content of the water which is observed with alkaline solutions in glass reaction vessels are entirely due

to the exchange reaction of O-atoms between water and the glass surface of the reaction vessels.

## Discussion

From the present experiments it can be concluded that the exchange reaction of O-atoms between oxyanions of strong acids and water takes place only in acid solutions, but in neither neutral nor alkaline solutions. This result excludes the acid-base catalyzed mechanism, at least in its general form,[10] from the two alternative mechanisms which we have previously presented; the exchange reaction must be explained either by the reversible anhydride formation or by some other appropriate mechanism. The decreas in $^{18}O$-content in the alkaline solutions of oxyanions of strong acids is entirely due to the exchange of O-atoms between water and the glass surface of the reaction vessels. Recently it has been repoted by Maass[11] that the exchange of O-atoms between water vapor and the glass surface takes place above 100°C without the addition of alkali. If this result is taken into account, the exchange of the O-atoms observed in the present experiments at 100°C between alkaline solutions and the glass surface may be said to be due to the corrosion of the glass surface by alkali. At any rate, we must be very careful of the exchange reaction between water and the glass surface in the experiments with $^{18}O$-enriched water using glass reation vessels, as has already been pointed out by Maass.

# The Diamagnetic Study of the Nature of the Association of Acetic Acid. II. The Binary Systems of Acetic Acid with Triethylamine, Pyridine and Aniline

By S. Sriraman, V. Shanmugasundaram and R. Sabesan

(Received August 6, 1964)

The interpretation of the observed magnetic susceptibility of carboxylic acids in different solvents is complicated by the fact that they are mostly in polymeric forms in the pure state and tend to associate in some solvents but to ionize in others. In an earlier communication,[1] the authors investigated the nature of the association of acetic acid in solvents like benzene, carbon tetrachloride, toluene, and cyclohexane, all of the non-interacting type, and also with dioxan and ethyl acetate, which have powerful anionoid centres. The reaction of protonic acids with bases leads to the formation of ion-pair salts associated through a hydrogen bond, or if the solvent base is weak, the proton may remain covalently bonded to the acid itself and the base will be associated with the hydrogen through an electrostatic attraction. Various physico-chemical studies of liquid mixtures of acetic acid with bases like aniline, pyridine and triethylamine[2-6] have indicated many singularities in the property-concentration relationship. The intermolecular complex formation between the acetic acid and bases employed has been held responsible for such singularities by different workers.[7-10] However, Suriyanarayana and Venkatesan[11] have shown that the equivalent conductivity, viscosity, volume contraction and refractive index

of the acetic acid - pyridine system exhibit maxima at 83 mol.% of the acid and pointed out the possibility of the ionisation of the acetic acid molecule. A similar conclusion was obtained by Isobe et al.[12] on the basis of proton magnetic resonance studies of the acetic acid - aniline system. The present investigation was undertaken with a view of elucidating the nature of the association of acetic acid with sufficiently strong bases, such as triethylamine, pyridine and aniline.

## Experimental

All the solvents and the acid were of B.D.H.A.R. quality and were distilled in an all-glass apparatus before use. The acid and the solvents gave physical constants in good agreement with the previously-recorded values.

The magnetic susceptibilities of the pure liquids and the mixtures were determined by the Gouy method described in the earlier paper.[1] Benzene was used as the standard, its susceptibility being taken as 0.702.*

## Results

The specific susceptibility values of the pure liquids and mixtures studied at different concentrations are given in Table I with an experimental accuracy of ±0.5%. For mixtures, the $\chi$ values, calculated on the basis of the additive law, are also given in that table. If $W$ is the weight percentage of the acid and $\Delta\chi = \chi_{(observed)} - \chi_{(additive)}$, the values of $\Delta\chi/W$ are as given in the last column of Table I.

## Discussion

From Table I it can be seen that, for acetic acid - pyridine and acetic acid - triethylamine, the $\Delta\chi/W$ value is positive at all concentrations. In the case of acetic acid - pyrridine, Desphande and Pathki[13] have explained these positive exaltations as arising from the stabilization of monomers, neglecting the effect of hydrogen bonding on magnetic susceptibilty. Our results also confirm such positive deviation from additivity. However, the question arises of whether the effect of the hydrogen bond on magnetic susceptibility can be completely neglected. The recent precision magnetic measurements by Jatkar et al.[14] of several binary systems capable of forming intermolecular hydrogen bonding showed considerable deviations from linearity. Also, it has been shown by other physico-chemical studies that the species resulting from the reaction of acetic acid with pyridine and triethylamine is not completely an electrostatic complex but,

rather, is partially ionic, resulting in the formation of pyridinium and triethyl ammonium ions respectively. Barrow's infrared measurements[15] indicated the formation of such ions in at least the case of triethylamine. The maximum value of the equivalent conductivity observed by Suryanarayana and Venkatesan[11] at 83 mol.% of acid in the acetic acid - pyridine system has been explained as arising from the maximum ionisation at that concentration. According to them, the progressive fall of conductivity beyond 83% represents only the extent of ionisation. The degree of such deprotonation of acid will depend upon the energy required to break the bond, the stabilisation of the anion, and the strength of the base employed. The mixtures of acetic acid with triethylamine, pyridine and aniline are typical systems in which the bases are strong enough to produce ion-pair salts. The formation of such ion pairs results in an increased diamagnetism as a result of the release of constraints. Accordingly, it may be presumed that the positive exaltations of magnetic susceptibility observed in these cases only indicate the extent of ionisation, and that the maximum deviations observed at different concentrations in these three systems may be taken as indications of the maximum ionisation at these concentrations.

The behaviour of the acetic acid - aniline mixture is quite interesting. When acetic acid is diluted with aniline, there is a marked increase in $\Delta\chi/W$ at the initial dilutions, but the value decreases on further dilutions. In the free aniline molecule, the trivalent nitrogen can resonate with the phenyl group, and such resonance is held responsible for the negative exaltation of the magnetic susceptibility observed[16] in pure aniline. From the proton magnetic resonance study[12] of this system, it is found that such resonance is more pronounced in very dilute concentrations of the acid. This may be responsible for the negative exaltation at low acid concentrations. As more acid is added to the base, the aniline molecule is slowly converted into the anilinium ion, accompanied by a fast proton exchange reaction which gives rise to a positive exaltation.

## Summary

The diamagnetic susceptibilities of three binary systems have been studied using the Gouy method. Deviations of the observed diamagnetic susceptibility values from Wiedemann's additive law have been discussed in the light of the partial ionisation of acetic acid with the solvent bases.

two phase system, sodium formate - pyridine.[7] The present paper deals with the extraction of mercury by pyridine from sodium formate.

## Experimental

**Reagents.**—Reidel de Haen's recrystallized sodium formate, Baker's analytical grade pyridine and Merck's analytical grade mercuric nitrate were used.

**Extraction Procedure.**—To an aliquot of 5 ml. of 4 M sodium formate, mercuric nitrate is added, followed by 5 ml. of pyridine and the whole mixture is equilibrated for 2 min. After settling, both layers are separated. The mercury extracted into the pyridine layer is determined volumetrically using diphenyl carbazone as an internal indicator.[8]

**Effect of Formate Concentration.** — Mercuric nitrate solution is added to formate solutions of various molarities and in each case it is extracted with 5 ml. of pyridine and the amount extracted is determined. The results showed that the concentration of formate need not be kept rigorously constant but it should be in the range of 3—6 M.

**Effect of pH.**—Maximum extraction of mercury into the pyridine is obtained at a pH range of 7—7.5. Above pH 7.5, the whole of the mercury was precipitated and retained in the formate layer and therefore studies at higher pH's were not possible. (Table I)

**Effect of Volume of Pyridine.**—The effect of volume of pyridine on the extraction of mercury is studied by adding various volumes of pyridine to 5 ml. of 4 M sodium formate containing an aliquot of mercuric nitrate and the amount extracted in each case is determined. The % $E$ increased upto 5 ml. of pyridine and remained the same with further increase in volume of pyridine. (Table II)

Table I. Effect of pH on the extraction of mercury

| pH | %$E$ |
|---|---|
| 7.0 | 99 |
| 7.5 | 99 |
| 8.0 | 50 |
| 8.5 | 20 |
| 9.0 | 3 |

Table II. Effect of volume of pyridine

| Vol. of pyridine, ml. | %$E$ |
|---|---|
| 2 | 62 |
| 3 | 73 |
| 4 | 84 |
| 5 | 99 |
| 6 | 99 |

Table III. Extraction of mercury

Volume of pyridine, 5 ml.
Sodium formate, 5 ml. (4 M)
Temperature, 25°C

| Amount of mercury added, mg. | Amount of mercury extracted, mg. |
|---|---|
| 0.540 | 0.535 |
| 1.080 | 1.072 |
| 1.620 | 1.618 |
| 2.700 | 2.697 |
| 3.780 | 3.778 |

Almost complete extraction of mercury is obtained with 5 ml. of pyridine from 5 ml. of 4 M sodium formate at a pH range of 7—7.5. (Table III)

Elements like iron, aluminium, chromium, lead, and uranium do not interfere with this extraction procedure.

## Summary

The distribution of mercuric mercury in the two phase system sodium formate - pyridine is studied. Almost quantitative extraction of mercury into pyridine is obtained from sodium formate (4 M) at a pH range of 7—7.5 with 5 ml. of pyridine and the extracted mercury is determined volumetrically using diphenylcarbazone as an internal indicator.

# NOTES

## Measurements of the Self-diffusion Coefficients of Carbon Dioxide, Hydrogen Carbonate Ions and Carbonate Ions in an Aqueous Solution

By Takusei HASHITANI* and Kunihiko KIGOSHI

(Received June 13, 1964)

The diffusion coefficients of carbon dioxide in water have been reported by several workers,[1] but the observed values do not agree well with each other.[2] The present authors, therefore, desired to make a contribution to solving the problems of the measurement of the diffusion coefficients of carbon dioxide in water. This paper will report on the diaphragm cell technique as applied to an aqueous carbon dioxide solution and on the details of measurements of the self-diffusion coefficients of carbon dioxide, hydrogen carbonate ions and carbonate ions. The results obtained have been reported in a previous paper[3] except for the value obtained by one additional experiment.

### Apparatus and Procedures

The measurements of the self-diffusion coefficients were carried out by a diaphragm cell[4] of a modified Northrop-McBain type, as is shown in Fig. 1. The upper and lower compartments, each containing 20 ml., were filled with solutions of the same chemical composition, containing sodium ions, carbonate ions, hydrogen carbonate ions and carbon dioxide; these solutions were adjusted to pH 4.0, 8.0 and 12.5 at 25°C. These pH values were selected as best for solutions containing almost pure (at least 99%) carbon dioxide, hydrogen carbonate and carbonate ions respectively, as is shown by the calculations using $K_1=4.45\times 10^{-7}$ [5] and $K_2=4.69\times 10^{-11}$ [6] for the dissociation constants of carbonic acid. The concentration of the latter two ions in the solution was held at ca. 0.1 M, while that of carbon dioxide was ca. 0.06 M. The carbon tracer, C-14, of a $2.3\times 10^{-2}$ $\mu$c./ml. concentration was contained in the lower compartment.

might be attained. Then the cell was taken out of the bath and the upper compartment was refilled with a non-active solution. In the case of the solution with a pH of 4.0, no preliminary diffusion was allowed because it was difficult to prepare solutions with carbon dioxide of a constant concentration. In this case the results obtained were corrected on the basis of similar diffusion experiments on a potassium chloride solution, which showed that the diffusion coefficient measured without preliminary diffusion was 1.9% less than that measured with preliminary diffussion.

After the diffusion had been allowed to take place for one or two days, the solution in each compartment was taken out and barium carbonate was precipitated by adding barium hydroxide. In the case of pH 4, the escape of carbon dioxide after the diffusion process was prevented by the use of a sodium hydroxide solution. After the run with a solution of pH 4, the rubber tubes shown in Fig. 1(b) were filled with the sodium hydroxide solution and the screw clamps, E and E′, were loosened in order to mix the sodium hydroxide solution with the solution in the cell.

The barium carbonate samples for radioactivity measurements were mounted on dishes of stainless steel. The amounts of barium carbonate were adjusted in order to attain the condition of infinite thickness for $\beta$-rays of C-14. A proportional gas flow counter and a G-M counter were used for $\beta$ countings.

The self-diffusion coefficients were calculated by the formula originally developed by Northrop and Anson:

$$D = (1/Kt) \log (\Delta C_0/\Delta C)$$

where $K$ is a cell constant, and $\Delta C_0$ and $\Delta C$ are the differences between the concentration of C-14 in the two compartments of a cell at times zero and $t$ respectively. The cell constant was obtained by diffusion measurements for solutions of potassium chloride and hydrogen chloride of known diffusion coefficients. The diffusion coefficient of potassium chloride from a 0.1 M solution into water of $1.873\times10^{-5}$ $cm^2/sec$.[7] at 25°C and that of 0.43 M hydrogen chloride of $1.61\times10^{-5}$ $cm^2/sec$.[8] at 0°C were used. The measurements were conducted in a thermostat held at 0, 25, and 30±0.01°C.

## Results

Over-all self-diffusion coefficients of a given solution containing carbon dioxide, hydrogen carbonate ions, and carbonate ions can be estimated as a weighted mean of the self-diffusion coefficients of these species. For instance, in the solution of pH 10.0[9] at 30°C, the concentration ratio, $(HCO_3^-)$ : $(CO_3^{2-})$, is 66 : 34[10] and a calculated self-diffusion coefficient of carbon compounds becomes $(1.18\pm0.01)\times10^{-5}$, showing good agreement with the observed value in this measurement $(1.21\pm0.013)\times10^{-5}$.

# Transition Metal Complex Catalysts for the Oligomerization of Butadiene. III. The Behavior of Evolved Ethylene from Triethylaluminum in the Catalyst-forming Reaction

By Taro SAITO, Yasuzo UCHIDA and Akira MISONO

(Received August 11, 1964)

The reaction of the ethyl radical formed by the decomposition of such organoaluminum compounds as triethylaluminum and diethylaluminum chloride in the polymerization of butadiene with cobalt complex catalysts has aroused much interest and discussion in connection with the polymerization mechanism.[1-3]

In the course of our studies of the reaction of triethylaluminum and cobalt(III) acetylacetonate, which are used for the linear dimerization of butadiene,[4,5] we found that the gas evolution in the reaction was much less than the theoretical value (about 60% of the calculated volume) and that it was composed mostly of ethane.[6] However, when butadiene was present in the system, a product other than butadiene dimers was detected by gas chromatography. We supposed that this is a $C_6$ hydrocarbon formed by the reaction of butadiene and ethylene from triethylaluminum. In order to prove this hypothesis, we carried out the reaction of butadiene and ethylene with the same catalyst system, thus obtaining a product. On the basis of chemical analysis, infrared and NMR spectra, this product was determined to be *n*-hexa-1, 3-diene.

$$CH_3CH_2CH{=}CHCH{=}CH_2$$

The gas chromatographic retention time of the unknown product described above exactly coincided with that of *n*-hexa-1, 3-diene, and the amount of it nearly corresponded to the amount calculated for ethylene.

These findings can be explained by assuming that, in the reaction, the ethylation of the reduced cobalt takes place as the first step, followed by the rapid disproportionation of the ethyl radical to give equimolecular ethane and ethylene, while the ethylene remains complexed with the cobalt. The ethylene does not come out of the system because of the complexing, but it is active enough to react with butadiene to form *n*-hexa-1, 3-diene, which is also obtained in a large quantity by the reaction of ethylene and butadiene with the same catalyst as is used for methyl-heptatriene synthesis. At the present time, however, we do not know whether or not ethylene interacts with cobalt as a $\pi$-bonding ligand. If it did, it would prevent cobalt from coagulation even when butadiene is absent in the system. This is not the case, however, and so we tentatively propose that ethylene combines with cobalt as a ligand with a weak $\pi$-bonding nature.

## Experimental

1) $1\times10^{-3}$ mol. of cobalt(III) acetylacetonate, and $3.5\times10^{-3}$ mol. of butadiene were dissolved in

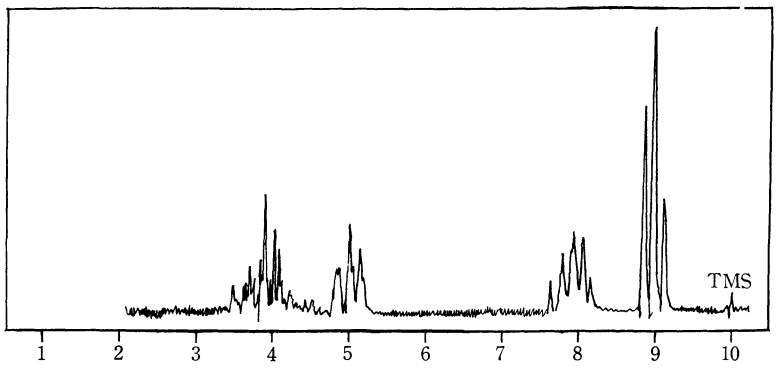

Fig. 2

10 g. of benzene, and then $1\times10^{-3}$ mol. of triethylaluminum was added to the solution under nitrogen. The reaction was carried out at 20°C, and the products were identified and quantitatively analyzed by a gas chromatograph. *n*-Hexa-1, 3-diene was formed in about 70% of the calculated value ($1.5\times10^{-3}$ mol., if the ethylene reacted completely with butadiene), in 100 hr.

2) 0.37 g. of cobalt(III) acetylacetonate and 10 g. of butadiene were dissolved in 50 ml. of toluene, and then 2 ml. of triethylaluminum in toluene (14.5 wt.% solution) was added to the solution at a low temperature under nitrogen. The whole solution was then transferred to a 300-ml. stainless autoclave and 6 g. of ethylene was pressured in. The reaction was carried out at 30°C overnight. (The initial pressure was ca. 8 atm.) The reaction mixture was washed with dilute hydrochloric acid and distilled. The yields of *n*-hexa-1, 3-diene and butadiene dimers were 10 mol.% and 25 mol.% respectively, based on the charged butadiene, and the rest were unreacted monomers and low molecular-weight polymers. The hexadiene part was further purified by a preparative gas chromatograph. The elemental analysis, the molecular weight measurement, and the infrared (Fig. 1) and NMR (Fig. 2) spectra indicated that it was *n*-hexa-1, 3-diene.

# The Formation of $Al^{3+}$–$SO_4^{2-}$ Ion-pair in an Aqueous Solution of Potassium Aluminum Alum*

By Takashi NISHIDE** and Ryokichi TSUCHIYA

(Received August 22, 1964)

In a previous paper[1] the formation constant of the $Cr^{3+}$–$SO_4^{2-}$ ion-pair in an aqueous solution of violet hexaaquochromium(III) sulfate or potassium chromium alum was reported by one of the present authors. Aluminum and iron have similar properties in an aqueous solution with chromium, as is shown by the fact that these three elements belong to the same group in qualitative analysis. In order to investigate the ionic state in an aqueous solution of potassium aluminum alum, the formation constant of the $Al^{3+}$–$SO_4^{2-}$ ion-pair was measured.

## Experimental

Potassium aluminum alum was purified by the recrystallization of the highest grade commercial reagent. The measurement of the electrical conductivity of the solution was carried out with a Yokokawa Universal Bridge BV-Z-13A; that of the pH, with a Toa Denpa pH meter HM-8, and that of the viscosity, with an Ostwald viscosimeter.

### Method of Calculation and Results

In an aqueous solution of potassium aluminum alum, the following equilibria are thought to be established:

$$[Al(H_2O)_6]^{3+} + SO_4^{2-} \overset{K}{\rightleftarrows} [Al(H_2O)_6]SO_4^{+} \quad (1)$$

$$[Al(H_2O)_6]^{3+} \overset{K_a}{\rightleftarrows} [Al(OH)(H_2O)_5]^{2+} + H^{+} \quad (2)$$

$$[Al(OH)(H_2O)_5]^{2+} + SO_4^{2-} \overset{K}{\rightleftarrows} [Al(OH)(H_2O)_5]SO_4 \quad (3)$$

$$K^{+} + SO_4^{2-} \overset{K'}{\rightleftarrows} K\text{-}SO_4^{-} \quad (4)$$

where the formation constants of reactions 1, 2 and 4 are expressed by $K$, $K_a$ and $K'$ respectively. It is reasonable to assume that the formation constant of reaction 3 is approximately equal to that of reaction 1. This assumption is justified by the two reasons described below.

By using the formation constant calculated below, we ascertained that the concentration of $[Al(OH)(H_2O)_5]SO_4$ is in the order of $10^{-6}$ if the initial concentration of $[Al(H_2O)_6]^{3+}$ is $10^{-4}$. Aluthogh the exact value of the formation constant of Eq. 3 is not known, it is thought to be at least not larger than that of Eq. 1. Therefore, the ratio of the variation of the concentration of $[Al(OH)(H_2O)_5]SO_4$ against the concentration of $[Al(H_2O)_6]^{3+}$ with the value used as the formation constant of Eq. 3, is in the range of a few per cent. The error of the formation constant of $K$ is very small, even where it is assumed to be equal to that of Eq. 3. The other reason, which will also be shown below, is based on the finding that the value of the acid dissociation constant, $pK_a = 4.9$, calculated by the assumption is in good agreement with the value, 5.036, in the literature.[2]

When the total concentration of aluminum contained in an aqueous solution of potassium aluminum alum is expressed by $a$; the concentration of sulfate ions spent for the formation of an $Al\text{-}SO_4^{+}$ ion-pair, by $x$, and that of sulfate ions spent for the formation of a $K\text{-}SO_4^{-}$ ion-pair, by $x'$, and when the molecular conductivities of $[Al(H_2O)_6]^{3+}$, $SO_4^{2-}$, $K^{+}$, and hydrogen ions are expressed by $\Lambda_1$, $\Lambda_2$, $\Lambda_5$, and $\Lambda_H$ respectively, we have, in a manner similar to that used in obtaining Eqs. 12 and 13 in the previous paper,[1] determined that:

$$K = x/(a-x)(2a-x-x') \quad (5)$$

$$(5a\Lambda_1 + C_H\Lambda_1 + 6a\Lambda_2)x + (6a\Lambda_5 + 4a\Lambda_2)x' = 6a^2(\Lambda_5 + \Lambda_1 + 2\Lambda_2) - 2aC_H\Lambda_1 + 6aC_H\Lambda_H - 3a^2\Lambda_0\eta \quad (6)$$

where $\Lambda_0$ is the observed conductivity of potassium aluminum alum in the aqueous solution and $\eta$ is the specific viscosity of the solution.

The plot of the molecular conductivity of a potassium aluminum alum solution, $\Lambda_0$, measured at 25°C against the square root of the concentration, $a$, is shown in Fig. 1.

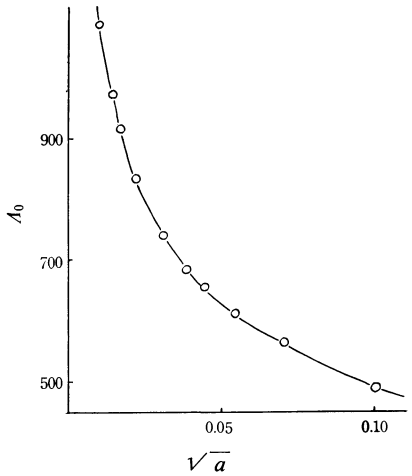

Fig. 1. The plottings of the molecular conductivities at 25°C vs. the square root of the concentrations of the potassium aluminum-(III) alum solution.

By using the value of the conductivity of the potassium sulfate solution and by applying an assumption similar to that used in obtaining Eqs. 9, 13 and 15 in the previous paper[1] to Eqs. 5 and 6, the formation constant of the ion-pair, $[Al(H_2O)_6]SO_4^{+}$, and the acid dissociation constant of $[Al(H_2O)_6]^{3+}$ were computed, were $\Lambda_1 = 189$[3] was employed as the molecular conductivity of $[Al(H_2O)_6]^{3+}$ instead of that of $[Cr(H_2O)_6]^{3+}$ as in the previous paper.[1]

The values of the formation constant of the ion-pair and the corresponding ionic strength are given in Table I, as are the values of the conductivity and the pH of the potassium aluminum alum solution. The logarithm of the formation constant is plotted against the square root of the corresponding ionic strength in Fig. 2. By extrapolation of the plottings up to $\mu \to 0$, the thermodynamic formation constant of the ion-pair at 25°C was obtained as $K = 5.4 \times 10^3$.

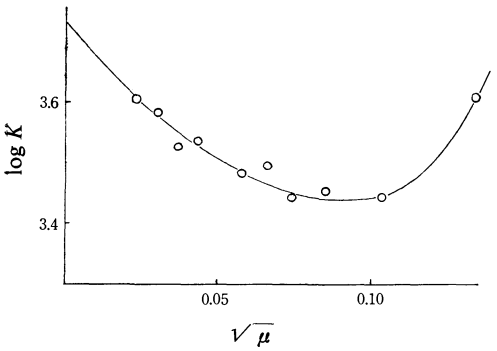

Fig. 2. The plottings of the formation constants of the ion-pair, $[Al(H_2O)_6]$-$SO_4^+$, in the potassium aluminum(III) alum solution vs. the square root of the ionic strength at 25°C.

In addition, the thermodynamic acid dissociation constant at 25°C was evaluated as $pK_a = 4.9$ in the same manner as in the previous paper.[1]

## Discussion

The values of the formation constant of the ion-pair, $[Al(H_2O)_6]SO_4^+$, and of the acid dissociation constant of $[Al(H_2O)_6]^{3+}$ obtained in the present study are summarized in Table II, together with the corresponding values concerning $[Cr(H_2O)_6]SO_4^+$ and $[Cr(H_2O)_6]^{3+}$ obtained in the preceding paper.[1]

Table II. The formation constants of the ion-pairs, $[Cr(H_2O)_6]SO_4^+$, and $[Al(H_2O)_6]SO_4^+$ and the acid dissociation constants of $[Cr(H_2O)_6]^{3+}$, and $[Al(H_2O)_6]^{3+}$ ions at $\mu=0$ and 25°C

| | $K$ | $pK_a$ |
|---|---|---|
| $[Cr(H_2O)_6]^{3+}$ | $6.3\times10^4$ | 3.95 |
| $[Al(H_2O)_6]^{3+}$ | $5.4\times10^3$ | 4.9 |

As Table II shows, both the formation constant of the ion-pair and the acid dissociation constant are a little larger in a chromium(III) aquo complex than in an aluminum(III) aquo complex. This can be explained as follows: in a chromium(III) aquo complex, the hydrogen atom in an aquo ligand is made more positive because the stronger inductive effect of chromium attracts the electron cloud from the ligand; consequently, the acid dissociation becomes easier, and the hydrogen bonding of an aquo ligand with a sulfate ion becomes a little stronger than in an aluminum(III) aquo complex.

# Studies in Rare Metal Tungstates—Amperometric Titrations of Lanthanum(III) with Alkali Tungstate

By C. M. Gupta

(Received September 8, 1964)

In view of the interesting results reported in the amperometric studies of certain isopoly acid salts,[1] it was considered of interest to study the similar rare isopoly tungstate. As no amperometric study on the composition of lanthanum tungstate, appears to have been carried out so far, the present investigation was initiated. Amperometric titrations have been performed between $La(NO_3)_3$ and $Na_2WO_4$ with a view of studying the possibility of developing the reaction as an analytical method for the determination of lanthanum at a definite pH value. Amperometric methods of analysis possess attributes which extend their value far beyond the direct determination of chemical elements.

AnalR (BDH) reagents sodium tungstate and lanthanum nitrate were used; their solutions were prepared in conductivity water. Lanthanum was estimated as an oxalate[2] by potentiometry, while the tungsten in $Na_2WO_4$ was determined as its oxinate.[3] A manual polarograph, with a scalamp galvanometer as a current recorder, was used for amperometric titrations. A capillary ($m=2.416$ mg./sec., $t=3.58$ sec. and $m^{2/3}t^{1/6}=2.226\ mg^{2/3}\ sec^{-1/2}$) was used in conjunction with a saturated calomel electrode connected to the cell by a low-resistance salt bridge. A series of polarograms of solutions containing lanthanum nitrate in the presence of 0.1 M potassium chloride and 0.01% gelatin were drawn, and the almost limiting current plateau potential was determined to be $-1.5$ V. (vs. SCE). This potential was applied to the electrodes of the cell throughout the investigations. All the amperometric titrations were carried out in the absence of a supporting electrolyte and in the presence of of 0.01% gelatin. Twenty millilitres of the titre solution was placed in the cell each time, and the cell solution was deaerated by bubbling in hydrogen. The observed current was corrected for the dilution effect, and the end-points were located graphically. The addition of alcohol has often been recommended in these titations, especially because of its favourable influence on the solubility of the precipitate. Therefore, investigations have also been undertaken in this direction. In 50% ethanol, the equivalence point was found to have been much improved.

The precipitation of $La_2O_3 \cdot 3WO_3$ is quantitative over the pH range from 5 to 6.5; the results are accurate within an error range of 1% at $10^{-3}$ M concentrations of the reactants studied. The only product formed at this pH is the normal tungstate of lanthanum, probably due to the fact that normal $WO_4^{2-}$ is predominant over the other species. The present method has limitations, although it is rapid, simple and accurate for the determination of small amounts of $La^{3+}$. Anions like molybdate, chromate, and vanadate, and such cations as cerium, thorium and silver interfere and hence must remain absent. The work at different pH values did not give satisfactory results.

The above results have been substantiated by pH titrations between alkali tungstate and lanthanum nitrate using glass electrode, both by direct and reverse methods. The electrometric curves reveal a sharp maxima in $dpH/dV$ at the stoichiometric end point corresponding to the formation of normal tungstate. The sharp inflexion in the curve when $Na_2WO_4$ is added to lanthanum nitrate in the presence of 40% ethanol suggests the possibility of using methyl red for the visual detection of the end point in the 5.0—6.8 pH range.

# The Polymerization and Polymers of Itaconic Acid Derivatives. VIII. A Cation Exchange Resin from Itaconic Anhydride[1,2]

By Susumu NAGAI and Keinosuke YOSHIDA

(Received September 25, 1964)

A cation exchange resin prepared from itaconic acid may be expected to have a large ion exchange capacity. The resins obtained by Akashi[3] and Sugihara[4], however, showed relatively low ion exchange capacities. The resins prepared by the solution copolymerization of itaconic acid and divinylbenzene in methyl alcohol, ethyl alcohol and acetone showed exchange capacities of 4.3—7.6, 7.86 and 9.57 meq./g. respectively. The resin obtained by the bulk copolymerization of the two materials at 160°C showed 7.35 meq./g. The pearl copolymerization in a sodium chloride solution resulted in a low-capacity resin, and an attempt to saponify the dimethyl itaconate-divinylbenzene copolymer did not succeed.

It might be due to the poor homopropagation reactivity of itaconic acid that a high-capacity resin was not obtained under these preparation conditions.

The authers have succeeded in the synthesis of a high-capacity ion exchange resin by using itaconic anhydride as the monomer and diallyl itaconate as the cross-linking agent.

## Results and Discussion

In order to prepare a copolymer rich in itaconic acid, the copolymerization system must be considered to be preferable to the homopropagation of itaconic acid. First, it is recognized that itaconic acid homopolymerizes only in an aqueous solution.[5] However, the application of the aqueous system seems unsuitable, for it requires a water-soluble cross-linking agent. Second, it is of interest to apply the finding reported by Higuchi that itaconic acid shows different copolymerization reactivities against styrene in such different solvents as methyl alcohol, pyridine and aniline.[6] Pyridine and aniline seem to promote the homopropagation of itaconic acid. However, these solvents are not only expensive, but they are also capable of some side reactions with itaconic acid. Third, it should be noticed that, when copolymerized with styrene, itaconic anhydride shows a larger reactivity ratio than that of styrene.[7] The author has also reported that itaconic anhydride readily homopolymerizes in bulk and that the polymer is rapidly hydrolyzed as soon as it is dissolved in water.[8] These facts suggest the probability of preparing the ion exchange resins with large capacity. The results obtained by means of the third method are described below.

The polymerization of itaconic anhydride was carried out in tetrahydrofuran, using divinylbenzene as the cross-linking agent. When the charged composition of divinylbenzene was 20 per cent, the polymerization product consisted exclusively of itaconic anhydride, showing much solubility to an alkaline solution as well as to acetone. Both runs, charged with 40 and 60 % divinylbenzene, on the contrary, yielded cross-linked polymers containing no carboxylic group.

These results suggest that cross-linking agents with an almost "ideal"[9] copolymerization reactivity against itaconic anhyride should be used instead of divinylbenzene. Therefore, we tried to use diallyl itaconate as the cross-linking agent.

The results of the copolymerization of itaconic anhydride and diallyl itaconate are shown in Table I.

The ion exchange resins thus obtained showed a satisfactorily large ion exchange capacity, though their swelling ratios (R-COONa/R-COOH) were relatively high.

There is a question of whether or not this type of resin, consisting of ester cross-linkage, is resistant to alkali and acid for a long time. The resin, afterward immersed both in alkali and acid (1 N) for one month, did not show as much decrease in weight as the commercial resin of the weak-acid type (Duolite CS 101).

* After they had been copolymerized for 1 hr. at 75°C, followed by an after cure for 3 hr. at 110°C, the copolymers were treated by the routine method of conditioning. The yield indicates the weight of the dry ion exchange resin obtained in this way, including no unreacted monomers or water-soluble polymers.

## Experimental

**Materials.** — Itaconic anhydride was synthesized by the reaction of itaconic acid and acetyl chloride. It was recrystallized twice from anhydrous ethyl ether. M. p. 67—68°C. Commercial divinylbenzene was used as supplied, composed of 50 per cent divinylbenzene and 50 per cent ethylstyrene. Diallyl itaconate was prepared by the esterification of itaconic acid with allyl alcohol in the presence of a catalytic amount of sulfuric acid. B. p. 130—132°C (~7 mmHg).

**The Copolymerization with Divinylbenzene.**— When the charged amount of divinylbenzene (net) was 20 mol. %, a mixture of 4.481 g. of itaconic anhydride, 2.853 g. of 50% divinylbenzene, 20 ml. of tetrahydrofuran, and 0.269 g. of benzoyl peroxide was copolymerized in a glass tube at 60°C. After 44 hr., the homogeneous solution was poured into water in order to precipitate the powdery polymer. The polymer precipitated in the water, however, expanded and dissolved when alkali was added to the system, though it reprecipitated when hydrochloric acid was added. The polymer was also soluble in acetone, though it was insoluble in ethyl ether. The yield was 2.9 g. The alkaline solution of the polymer sample indicated no sign of the existence of benzene derivatives in the ultraviolet spectrum. When charged with 40 and 60 mol. % of net divinylbenzene, the cross-linked, alkali-insoluble polymers were obtained. However, their ion exchange capacities were almost zero.

**The Copolymerization with Diallyl Itaconate.**— The four runs of the bulk copolymerization, in which the charged compositions of diallyl itaconate ranged from 3.65 to 15.0 mol. %, were carried out in glass tubes at 75°C. After 15—20 min., the reaction mixtures of all four runs solidified and then small cracks occurred in them. After one hour the solid products were discharged from the reaction tubes and were postcured for 3 hr. at 110°C. The products were crushed, poured into water, and then immersed in 1 N sodium hydroxide for about 24 hr. Then they were washed with water and immersed in 1 N hydrochloric acid. After the alternative immersions in alkali and acid had been repeated two more times, they were dried for 4 hr. at 105—110°C. The swelling ratio of the wet volume of the resin in the form of R-COONa against that of R-COOH was measured roughly by means of a graduated cylinder.

**The Determination of the Ion Exchange Capacity.**—About 0.5 g. of the resin was exactly weighed in a beaker. Then 30 ml. of 0.1 N sodium hydroxide and 40 ml. of 0.1 N sodium chloride were pipetted into the beaker. After about 20 hr., 10 ml. of the upper solution in the beaker was pipetted out and back-titrated with 0.1 N hydrochloric acid.

The authors wish to express their gratitude to Dr. Taizo Uno and Dr. Tadashi Kimura for their encouragement, and to Dr. Mizuho Sugihara, Dr. Toshio Yoshino and Mr. Masato Nishimura for their kind suggestions. They also wish to express their thanks to the Taito Pfizer Co. for supplying materials.

# Crystallographic Data on Ammonium Dioxovanadium(V) Bisoxalate Dihydrate by the X-Ray Powder Method

By D. N. SATHYANARAYANA and C. C. PATEL

(Received November 19, 1964)

Recently, we reported a new method for the preparation of ammonium dioxovanadium(V) bisoxalate dihydrate, $(NH_4)_3[VO_2(C_2O_4)_2]\cdot 2H_2O$, its physico-chemical properties and its structure.[1] X-Ray diffraction studies have now been carried out on the powdered crystals, and the crystal system and the unit cell parameters have been determined. The crystals of the complex were prepared in the manner reported earlier.[1] The crystals were then powdered to nearly a 300-mesh size and filled in a 0.5 mm. (inner diameter) Lindemann glass capillary. The X-ray diffraction pattern of the powdered substance was taken with a 114.6 mm. Philips Powder Camera using nickel-filtered Cu$K_\alpha$ radiation (1.5418 Å) at 34 kV. and 18 mamp. at 25°C. The exposure time was six hours.

The complex crystallized from aqueous solutions on a microscopic slide at the laboratory temperature, when viewed under a polarising microscope, gave straight extinctions, and the optic axis figure showed the biaxial nature of the crystals. The crystal growth also clearly demonstrated that the lengths of the edges were unequal. These observations point to the possibility of an orthorhombic system for the compound. Microscopic examination further showed a prismatic type of crystals with domed faces. Five faces, (100), (010), (001), (110), and (101), appeared to be present. The powder pattern was indexed for an orthorhombic system using Hesse-Lipson's procedure;[2] the observed and calculated $\sin^2\theta$ values, together with the visually-assigned relative intensities of the lines, are given in Table I. The results show that the observed and computed $\sin^2\theta$ values for the orthorhombic system compare well. The values for the unit cell parameters are: $a=15.75$ Å, $b=11.09$ Å, and $c=8.015$ Å, as calculated from the observed $\sin^2\theta$ values of the first three lines, the volume of the unit cell being 1400 Å$^3$. The density of the crystals was found to be 1.665 g. ml$^{-1}$ at 25°C, using carbon tetrachloride. Using this density, the

# The Thermal Decomposition of Zinc Oxide in an Oxygen and a Nitrogen Stream

By Tatsuya IMOTO, Yoshio HARANO and Yasuhide NISHI

(Received December 14, 1964)

In a previous paper[1] on the thermal decomposition of zinc oxide in vacuo, it was reported that oxygen and zinc are not evolved equally with stoichiometric composition, but that more oxygen is released than zinc. If zinc oxide decomposes by such a process, the rate of the decomposition of zinc oxide will be affected by the oxygen pressure. As far as we know, very few investigations of the rate of the decomposition of zinc oxide in an oxygen or a nitrogen stream have been made except for Moore and Williams's.[2] Their report, however, shows neither the initial amount of zinc oxide nor the pressures of the flowing gases, i.e., oxygen and nitrogen. Therefore, it is very difficult to gather enough quantitative information concerning the effect of oxygen on the rate of decomposition.

Meanwhile, we[3] have studied the kinetics of the reduction of zinc oxide by hydrogen over the range of temperature, 617—762°C, with a hydrogen pressure of 10—95 mmHg, and have deduced that the reduction proceeds via the following two processes: the decomposition of zinc oxide into oxygen and zinc vapor, and the reaction of the evolved oxygen with hydrogen. When the amount of zinc oxide is smaller than that of hydrogen, the decomposition process of zinc oxide controls the overall reaction.[4] In this case, the effect of nitrogen gas on the decomposition of zinc oxide is found to be represented by the following relation:

$$\frac{\text{Reduction rate by mixed gas}}{\text{Reduction rate by hydrogen}} = 1-\theta_{N_2}$$

where $\theta_{N_2}$ is expressed by a form similar to the Langmuir-type adsorption isotherm. Here, the rate of the decomposition of zinc oxide is expected to be affected by the nitrogen pressure. In this expectation the present work was carried out.

## Experimental

The apparatus is the same as that used in a previous work[6] on the reduction of zinc oxide by hydrogen by a flow method at low pressures. In this work, oxygen or nitrogen was used as the flowing gas instead of hydrogen. The samples used in this work are that used in our previous papers[1,3-6] and a sintered one. The former is a commercial product supplied by the Sakai Chemicals Co., Ltd., while the latter is prepared from the former by sintering it at 900°C for several hours and then sieving it (−40+60 mesh). The decomposition time was 200 min. In this period, the amount of decomposed zinc oxide was very small compared with its initial amount, and the change of its surface area by decomposition was negligibly small. Hence, the rate of decomposition can be expressed as $\Delta w/w_0 t$, where $\Delta w$ is the total weight loss for the decomposition time, $w_0$ is the initial amount, and $t$ is the decomposition time.

## Results and Discussion

Experimental results at 740°C are shown in Fig. 1. The ordinate is the rate of decomposition, and the abscissa is the pressures of oxygen or nitrogen.

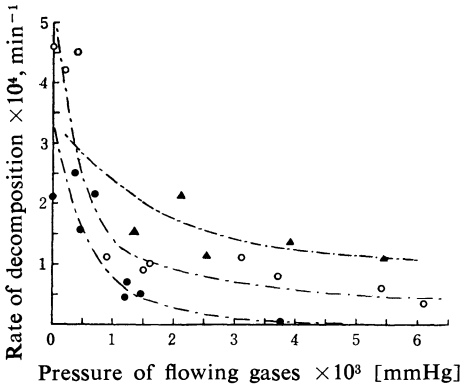

Fig. 1.
○·····unsintered ZnO
● ▲···sintered ZnO
$O_2$ $N_2$

**The Effect of Oxygen.**—Figure 1 shows that the rate of decomposition decreases with the increase in oxygen pressure, while the effect of oxygen is much greater than that of nitrogen. No sintered zinc oxide decomposed at about $10^{-2}$ mmHg of oxygen pressure, a level which is nearly equal to the decomposition equilibrium pressure at 740°C. These observations clealy reveal that oxygen in the gas phase retards the evolution of oxygen from the surface of zinc oxide. This is quite reasonable, since the higher oxygen pressure means a higher oxygen concentration in the vicinity of the zinc oxide surface.

**The Effect of Nitrogen.**—Figure 1 shows that the rate of decomposition also decreases with the increase in nitrogen pressure. The results obtained are applied to Eq. 1. From Eq. 1, one gets:

$$\theta_{N_2}=1-\frac{r_{N_2}}{r_{N_2=0}} \tag{2}$$

were $r_{N_2=0}$ is the rate of decomposition in vacuo, and $r_{N_2}$ is that in the nitrogen stream. Now, $\theta_{N_2}$ will be expressed by Eq. 3:[4]

$$\theta_{N_2}=\frac{K_{N_2}P_{N_2}}{1+K_{N_2}P_{N_2}}=1-\frac{1}{1+K_{N_2}P_{N_2}} \tag{3}$$

The combination of Eqs. 2 and 3 gives:

$$\frac{r_{N_2}}{r_{N_2=0}}=\frac{1}{1+K_{N2}P_{N_2}} \quad \text{or} \quad \frac{r_{N_2=0}}{r_{N_2}}=1+K_{N_2}P_{N_2} \tag{4}$$

When we substitute experimental values into Ep. 4, $K_{N_2}$ is calculated to be 533 $mmHg^{-1}$. This value is in fairly good areement with that of a previous paper[4] ($K_{N_2}=657$ $mmHg^{-1}$). In both cases the same sintered samples were used. The reactivity of zinc oxide depends very much on the nature of the surface state of the samples. It seems that the fluctuation in the experimental values and the difference between the two values for $K_{N_2}$ may originate in the variation in the surface state of zinc oxide. These results seem to verify our previous deduction that nitrogen interacts with the surface of zinc oxide to produce a retarding substance. At present, we have very little information about the nature of this retarding substance.

# Recoil Reactions in the Irradiated Tris-(ethylenediamine)-cobalt(III) Complexes

By Nobufusa SAITO, Takeshi TOMINAGA and Hirotoshi SANO*

(Received December 25, 1964)

It was previously reported[1] that the outer anions might play an important role in the radiocobalt recoil reactions in the neutron-irradiated hexammine- and aquopentammine cobalt(III) complexes. For the purpose of confirming such effects of outer anions, the present authors have investigated a similar system, a group of tris-(ethylenediamine)-cobalt(III) complexes containing various outer anions, of which only the nitrate and bromide have been studied before.[2-4]

The five kinds of complex compounds listed in Table I were irradiated with slow neutrons in JRR-1 reactor for 1 hr. at pile temperature in the presence of air. The neutron flux was estimated to be approximately $3\times10^{11}$ n/cm$^2$·sec. After it had been stored in dry ice for one to three days, the irradiated salt was dissolved in distilled water and the $^{60}$Co-labeled species present in the aqueous solutions were separated by means of paper electrophoresis, ion-exchange, precipitation, or recrystallization. The results are summarized in Table I. The dependence of the retention value and of the *S*-value** of the tris-(ethylenediamine)-cobalt complexes upon the stability as ligands of the outer anions are shown in Figs. 1 and 2 respectively. For convenience of discussion, the retention value and the *S*-value for hexammine- and aquopentammine-cobalt(III) complexes[1] are also shown together.

As may be seen in Fig. 1, the retention in the three systems generally tends to increase with a decrease in the stability of the outer anion as a ligand. Namely, the restoration of parent chemical forms may be more favored in the salt containing less stable outer anions. Figure 2 indicates that the *S*-value in the three systems increases in almost the same

manner with the increasing stability of the outer anion as ligand, and thus the incorporation of outer anions into ligands seems to be more favored in the salt containing more stable outer anions. This dependence of the retention value and the *S*-value on the stability of the outer anion may be generally explained by assuming that the outer anions and ligand groups ($NH_3$, ethylenediamine, or $H_2O$ molecules), more or less ruptured as a result of recoil, compete with each other in the subsequent reactions, during which various $^{60}Co$-labeled complexes are formed through the reactions of recoil cobalt atoms with neighboring entities according to their concentrations and stabilities as complexed with cobalt.

# The Oxidation of Red Phosphorus with Hydrogen Peroxide and the Isolation of Disodium Dihydrogen Hypophosphate

By Norimasa YOZA and Shigeru OHASHI

(Received January 16, 1965)

Hypophosphate has been prepared by the wet oxidation of elementary phosphorus with various oxidizing agents, i. e., hypochlorite,[1] chlorite,[2-5] bleaching powder,[6] copper nitrate,[7,8] permanganate,[9] iodine,[10] and hydrogen peroxide.[9,11]

Remy and Falius[4] pointed out that hypophosphate prepared by Vogel's method,[9] i. e., by oxidizing red phosphorus with hydrogen peroxide in a solution of sodium hydroxide, contained several oxo acids of phosphorus as impurities and that the further purification of it was very difficult. On the other hand, Dragulescu et al.[11] reported a method for the preparation of hypophosphate by the oxidation of red phosphorus with hydrogen peroxide in aqueous ammonia. In this case ammonium ions must be removed by passing the reaction products through ion exchange resin in order to isolate sodium hypophosphate.

The present work was undertaken in order to examine the oxidation products of red phosphorus with hydrogen peroxide in a solution of sodium carbonate or in a solution free from other electrolytes, and to isolate disodium dihydrogen hypophosphate by crystallization from a mixture of ethyl alcohol and water.

## Experimental

**The Preparation of Disodium Dihydrogen Hypophosphate.** — Ten grams of red phosphorus is suspended in 200 ml. of water (in a 1 l.-beaker), and then 30 ml. of a solution of hydrogen peroxide is added. After an hour 120 ml. more of the solution of hydrogen peroxide is added. (If 150 ml. of hydrogen peroxide is added at one time, a drastic reaction will occur.) The mixture is allowed to stand for 3 days at room temperature, after which

time the small, unreacted portion of red phosphorus is filtered off with Toyo No. 5B filter paper. After the pH of the filtrate is adjusted to 4.5 with a solution of sodium hydroxide, a half volume of ethyl alcohol is added. The precipitate, almost free from other oxo acids of phosphorus, is recrystallized by the same procedure and dissolved in 400 ml. of water. (It may be warmed to accelerate the dissolution of the precipitate.) The solution is adjusted to pH 5.2 and filtered off, if necessary, to remove such insoluble hypophosphates as alkaline earth hypophosphates. Finally, disodium dihydrogen hypophosphate hexahydrate, $Na_2H_2P_2O_6 \cdot 6H_2O$, is recrystallized from 1 : 2 ethyl alcohol. The crystals are filtered off, washed with 1 : 2 ethyl alcohol, and air dried. The yield is about 23% on the basis of the weight of the red phosphorus used.

Large crystals are obtained by dissolving the salt in hot water (60°C) with subsequent cooling in a refrigerator overnight.

The chemical composition of the final product was confirmed to be $Na_2H_2P_2O_6 \cdot 6H_2O$ by the following methods: I) the qualitative identification by paper chromatography[12] and spectrophotometry (hypophosphoric heteropoly blue[13]); II) the release of hydrated water at 110°C; III) the determination of the hydrogen ions released by precipitation reaction with silver nitrate ($Ag_4P_2O_6$) and IV) the determination of the total phosphorus by gravimetry as $Mg_2P_2O_7$.

## Discussion

The known method of preparing hypophosphate from red phosphorus and hydrogen peroxide in a solution of sodium hydroxide is complicated because of the necessity of suppressing the rise in temperature due to the heat of the reaction. The present work was undertaken to overcome this disadvantage. The new method for the preparation of hypophosphate described in the Experimental section does not need any special cooling apparatus. As will be mentioned below, the reaction of red phosphorus with hydrogen peroxide in a solution of sodium carbonate has some disadvantages, i. e., the violent evolution of heat and the difficulty of the complete removal of by-products.

**The Reaction in a Solution of Sodium Carbonate.**—Hydrogen peroxide reacts with red phosphorus in a solution of sodium carbonate with the evolution of the heat of the reaction. The products obtained by the oxidation of 10 g. of red phosphorus with 150 ml. of 30% hydrogen peroxide in a solution of sodium carbonate (10 g. of $Na_2CO_3$ in 200 ml. of water) include at least six oxo acids of phosphrus. The $R_f$ values of the species on paper chromatogram correspond to phosphite, phosphate, diphoshate, hypophosphate, $\overset{5}{P}\text{-O-}\overset{4}{P}\text{-}\overset{4}{P}\text{-}$, and $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-anions in the order of decreasing $R_f$. Some of them can be removed from hypophosphate by crystallization from 1 : 2 ethyl alcohol at pH 4.5. However, this procedure is not satisfactory in eliminating the phosphorus compounds with lower $R_f$ values than that of hypophosphate.

**The Reaction in a Neutral or Acid Solution.**—As has been described in the Experimental section, red phosporus is also oxidized with hydrogen peroxide in the absence of other electrolytes to form hypophosphate. The solution is neutral at the start of the reaction, while the acidity of the solution increases with the formation of oxo acids of phosphorus. The hypophosphate thus produced contains two components as impurities, i. e., phosphite and phosphate, which are easily removed from the hypophosphate by treatment with 1 : 2 ethyl alcohol at pH 4.5. The reaction under the conditions described in the Experimental section proceeds so slowly that it is not necessary to cool the reaction vessel.

# The Electrical Conduction of 10-Methylacridinium Polyiodides

By Shigekazu KUSABAYASHI and Hiroshi MIKAWA

(Received January 28, 1965)

In a previous paper,[1] it was indicated that the specific resistivities at 20°C and the band gap energies of organic polyiodides decrease with the number of iodine atoms in the polyiodide anion, not very much difference in these values being observed with different kinds of cations. It was also established that the iodine framework in the crystal structure is of primary importance in determining the electrical conductivity.

The present investigation has been made to find what influences, if any the size and shape of the cation has on the conduction.

**Preparation.**—*10-Methylacridinium Monoiodide.*—Monoiodide was prepared by the action of methyl iodide on acridine. The melting point agreed with the compound reported in the literature.[2]

*10-Methylacridinium Polyiodides.*—A hot solution of the required amount of iodine and 1.00 g. of monoiodide in 145 ml. of 99% alcohol was cooled to yield the product.

*10-Methylacridinium Triiodide.*—From 1.03 g. of iodine, 1.75 g. of triiodide was obtained. It was then recrystallized from the alcohol-tetrahydrofuran mixture. Dark brown crystals; m. p. 170°C.

Found: C, 28.35; H, 2.40; N, 3.07; I, 65.58. Calcd. for $C_{14}H_{12}NI_3$: C, 29.25; H, 2.10; N, 2.44; I, 66.21%.

*10-Methylacridinium Pentaiodide.*—The reaction of 2.85 g. of iodine gave 2.20 g. of pentaiodide. It was then recrystallized from the iodine-alcohol-tetrahydrofuran solution. Dark purple crystals, m. p. 94.5°C.

Found: C, 21.48; H, 1.92; N, 2.29; I, 74.40. Calcd. for $C_{14}H_{12}NI_5$. C, 20.29; H, 1.46; N, 1.69; I, 76.56%.

*10-Methylacridinium Heptaiodide.*—4.74 g. of iodine yielded 2.32 g. of heptaiodide. It was then recrystallized in the same way as pentaiodide. Dark green crystals; m. p. 86°C.

Found: C, 17.84; H, 1.51; N, 1.36; I, 79.51. Calcd. for $C_{14}H_{12}NI_7$: C, 15.53; H, 1.12; N, 1.29; I, 82.06%.

A drying of the crystal for analyses inevitably causes some loss of iodine, thus decreasing slightly the analytical iodine content.

**Absorption Spectra.**—The absorption spectra of 10-methylacridinium polyiodides are shown in Fig. 1. In a tetrahydrofuran solution all three spectra were nearly identical, except that

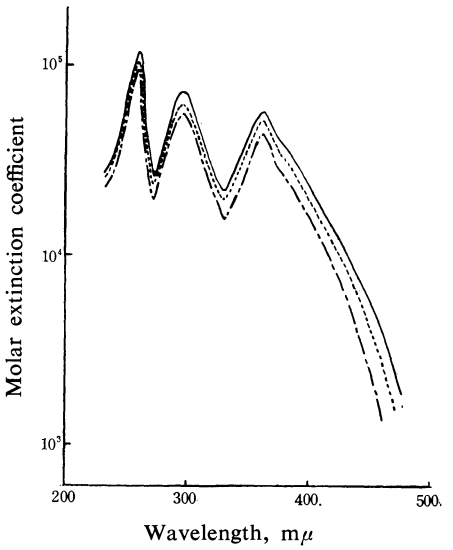

Fig. 1. Absorption spectra of 10-methylacridinium poyiodides in tetrahydrofuran.
— — — Triiodide ····· Pentaiodide
——— Heptaiodide

the molar extinction coefficicients were slighly different. The main peaks are at 259, 295 and 360 mμ. Subtracting from this absorption curve the absorption due to acridinium ion, which has main absorption peaks at 259 and 360 mμ, one obtains a curve with peaks at 295 and 360 mμ, peaks which conform fairly well with the absorption curves reported for the tetramethylammonium polyiodides in ethylene chloride[3] and several triiodides in various solvents.[4] Therefore, in the 10-methylacridinium polyiodides as well as in the tetramethylammonium polyiodides, these facts are consistent with the interpretation that the triiodide is the only polyiodide stable in a dilute solution.

The absorption spectra of the solid were also measured. However, the absorption band was very broad, extending over about a 500 mμ region from the ultraviolet region.

**Electrical Conduction.**—The electrical resistivity was measured on a compressed disk of crystalline powder by the DC method. The apparatus and method were the same as have been described previously.

The relation between the current and the applied voltage obeyed Ohm's law up to 2000 V./cm. at least.

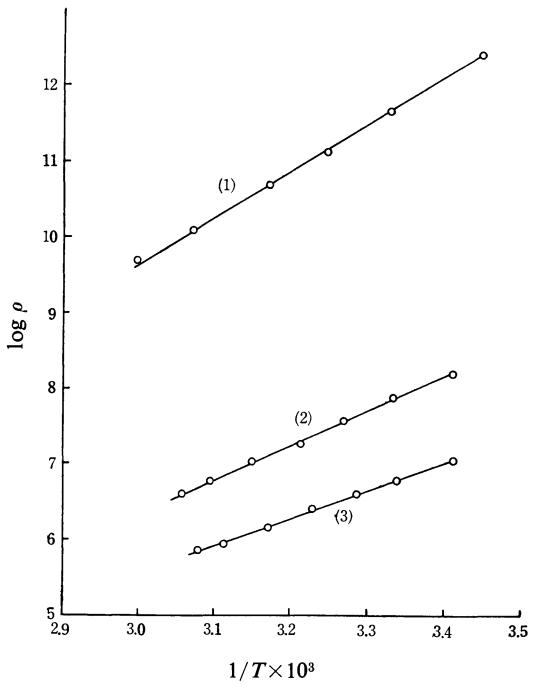

Fig. 2. Temperature dependence of the resistivity of 10-methylacridinium polyiodides.
(1) Triiodide (2) Pentaiodide
(3) Heptaiodide

The relationship between the logarithm of resistivity and the reciprocal of temperature is shown in Fig. 2. The specific resistivity at 20°C ($\rho_{20}$) and the band-gap energy ($\varepsilon$), as calculated from the temperature dependence of the resistivity by the equation $\rho = \rho_0 \exp(\varepsilon/2kT)$, are tabulated in Table I.

The values of $\rho_{20}$ and $\varepsilon$ decrease with an increase in the number of iodine atoms. This is similar to the previous finding. However, generally the present values of $\rho_{20}$ and $\varepsilon$ are larger than those reported for other polyiodides.

Table I. Electrical properties of 10-methylacridinium polyiodides

| Substance | $\rho_{20}$ Ω cm. | $\varepsilon$ eV. | Temp. range °C |
|---|---|---|---|
| Triiodide | $1.6\times10^{12}$ | 2.49 | 17—60 |
| Pentaiodide | $1.5\times10^{8}$ | 1.72 | 20—55 |
| Heptaiodide | $1.2\times10^{7}$ | 1.47 | 20—52 |

The size of the acridinium cation is the largest of all the polyiodides investigated. Therefore, it is possible that the iodine framework is deformed by the size and shape of the cation and that the shortest distance between anions is larger than those of other polyiodides. As has been shown in the previous paper, the shortest distances between neighboring polyiodide anions of the known crystal structures decrease with an increase in the number of the iodine atoms of polyiodide anions. In so far as the electrical conduction is effected through the overlap of the molecular orbitals of polyiodide anions, it is understandable that the values of $\rho_{20}$ and $\varepsilon$ are larger than those reported for other polyiodides.

On the basis of the present and previous papers, it is certain that the iodine framework in the crystal structure is of primary importance in determining the electrical conductivity; the theory has obtained an additional confirmation in the present paper's finding that the size of the cation increases the deformation of the iodine framework and, as expected, influences the electrical properties.

The authors wish to express their thanks to Professor Ryôiti Kiriyama and Dr. Shichio Kawai for their helpful advice, and to Mr. Takuzo Fujino and Mr. Tsuneyo Shishido for their elementary analyses.

SHORT COMMUNICATIONS

# A New Method for Releasing Oxytocin from Fully-protected Nona-peptides Using Anhydrous Hydrogen Fluoride

By Shumpei SAKAKIBARA and Yasutsugu SHIMONISHI

(Received April 23, 1965)

Methods of the synthesis of oxytocin[1] are generally based on the principle that the *S*-benzyl group is stable against hydrogen bromide or trifluoroacetic acid and can only be removed by treatment with sodium in liquid ammonia. This procedure, however, has several defects; for instance, the product is inevitably contaminated with sodium salts, and it may be partially decomposed by the strong alkali used during the procedure. The *S*-*p*-methoxybenzyl group is also stable against hydrogen bromide, but it can be removed by boiling trifluoroacetic acid in contrast with the *S*-benzyl group.[2] However, it has been shown[3] that it is more difficult to remove, with trifluoroacetic acid, the *S*-methoxybenzyl group in a large peptide such as oxytocin than that in a small peptide. Therefore, a more effective method for the removal of these protecting groups is required. Katz[4] first showed that anhydrous hydrogen fluoride (HF) is a good solvent for proteins, and that the biological activity of proteins is not irreversibly affected by this solvent. Moreover, anhydrous HF is known to be a very strong acid, although it becomes a weak acid in the presence of water.[5] These facts were effectively utilized by Hess et al.[6] in an *N*, *O*-acyl migration reaction with serine or threonine peptides. The above-mentioned facts also suggested that this solvent might be an effective reagent for the acidolysis of various protecting groups. The boiling point of the solvent (19.5°C) was also considered to give it an additional advantage. The basic idea of the present project arose from these considerations.

First, cysteine formation from *S*-benzylcysteine and from *S*-*p*-methoxybenzylcysteine in anhydrous HF was tested by iodometry, and the quantitative removal of the protecting groups was observed during one-hour reactions at room temperature in both cases. These experiments indicated clearly, as expected, that anhydrous HF is the first effective reagent for the acidolysis of *S*-benzyl groups. Then, the pre-oxytocin nona-peptides, *N*-carbobenzyloxy-*S*-benzyl-L-cysteinyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-*S*-benzyl-L-cysteinyl-L-prolyl-L-leucylglycine amide (I)[1] and the *N*-carbobenzyloxy-*S*-*p*-methoxybenzylpeptide of the same sequence (II),[3] were each subjected to the HF reaction under the same conditions. The addition of anisole to the reaction mixture effectively prevented the succeeding polymerization of the benzyl fluoride which may be formed in the solution; it also protected the tyrosyl residue from possible modification by benzyl fluoride. After the peptides had been oxidized by air to cystinyl peptides, the hormonal activities of the resulting products were determined by the rat-uterine contraction test; 133 units per mg. of I and 148 units per mg. of II were observed (about 370 units per mg. would correspond to quantitative recovery),[7] whereas the acidolysis of II with trifluoroacetic acid gave only 33 units per mg.[3]

Further possibilities for the use of HF in general peptide synthesis are being studied.

**Experimental.**—*Reaction in Anhydrous HF.*—The procedure was, in principle, the same as that for the *N*, *O*-acyl migration reaction in HF.[6] Compound I or II was dried over phosphorous pentoxide in vacuo at 80°C for 3 hr. before the reaction. The dried material (50

mg.) was placed in the reaction vessel, together with anisole (0.1 ml.); anhydrous HF (ca. 2 ml.) was then distilled into the mixture, which was then kept for one hr. at room temperature before the solvent was removed by distillation. The remaining HF was completely removed by letting the material stand over sodium hydroxide in vacuo, and the residue was dissolved in water (50 ml.). The solution was adjusted to pH 6.5 by adding dilute ammonia, and then carbon dioxide-free air was bubbled through the solution for about 2 hr. until the nitroprusside test became negative. Then the oxidized solution was brought to pH 4 with acetic acid, and the insoluble materials formed were removed by filtration. An aliquot of this filtrate was subjected to the biological test.

# Fluorescence Properties of Europium-trisbenzoylacetonate in a Chloroform Solution

By Takeshi MATSUO

(Received May 13, 1965)

There has been much interest in the fluorescence properties of europium chelates from the standpoint of the use of these compounds as laser devices.[1-3] However, it is very difficult to obtain a laser action by using these compounds in the form of a liquid or a fluid solution, because such organic laser materials as europium-trisbenzoylacetonate ($EuB_3$) have poor spectroscopic properties in organic solvents; in such cases the half-width of their fluorescence line becomes broader, the intensity of the fluorsesecence line becomes weaker, and the fluorescence decay time becomes shorter than the corresponding values of $EuB_3$ in the crystalline state.

Recently we found that the fluorescence decay time of $EuB_3$ in a chloroform solution was about twice as strong, and its fluorescence intensity stronger than those of $EuB_3$ in a methanol solution.

The chelate compound used here was prepared by adding an equivalent base and then an alcohol solution of $EuCl_3 \cdot 6H_2O$ to a solution of the benzoylacetone. The white-yellow precipitation was collected with suction, washed several times with alcohol, and then dried under 1 mmHg pressure for 20 hr. Found: C, 57.40; H, 4.16. Calcd. C, 56.60; H, 4.25%. The measurement of the fluorescence decay time constant was performed as follows. A xenon flash lamp with a 10 $\mu$ sec. pulse duration was used to excite the sample, and the decay curve was recorded with an oscilloscope. The spectral properties of the fluorescence of the $EuB_3$ solid and of the solutions were

TABLE I. OBSERVED FLUORESCENCE PROPERTIES OF $EuB_3$ IN VARIOUS STATES

measured with a Cary model 14 spectrophotometer.

The observed spectroscopic properties of $EuB_3$ in a chloroform solution are, in Table I and Fig. 1, compared with those of various other matrices.

It is highly probable, judging from the results of the investigation of these spectroscopic properties, that chloroform interacts with $EuB_3$, perhaps through something like hydrogen bonding, and that the co-ordinated $Eu^{3+}$ ion in the complex is protected from external perturbation.

The details of this study will be reported in a later paper.

# The Adsorbed State of Oxygen on Zinc Oxide as Revealed by the Electron Spin Resonance Method

By Morio SEDAKA and Takao KWAN

(Received May 18, 1965)

The asymmetrical doublet ESR signal around $g=2.0$ obtained when a small amount of oxygen is introduced on zinc oxide has been ascribed to the adsorbed peroxy radical or to the molecular oxygen ion by several workers.[1] None of them has, however, dealt with the dynamical characteristic of this signal. It is known from the simple temperature rising method that adsorbed oxygen on zinc oxide at room temperature is transformed into at least two types, near 200 and 370°C, when subjected to gradual heating up to 500°C.[2] Such changes in the adsorbed type has now been investigated by the ESR method. It has been found that the doublet signal is transformed into a singlet one above 170°C and that it decays at much higher temperatures.

The sample tube for the ESR measurement was connected, by means of several flexible joints, to a high vacuum apparatus. The Pirani gauge was affixed close to the tube so that the pressure of the oxygen inside could be measured during the ESR measurement. A sample of zinc oxide placed in the tube was outgassed at 500°C for one hour, and then oxygen ($10^{-1}$ mmHg) was introduced onto the adsorbent kept at room temperature. After having been shortly pumped off, the sample was heated at a rate of about 10°C per min.; changes in the doublet signal due to heating were followed in situ, while the pressure inside

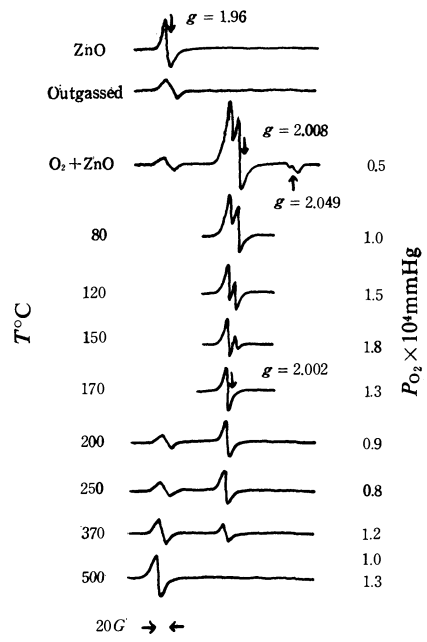

Fig. 1. ESR Spectra for $O_2$ on ZnO. The spectra were observed at the temperature shown by the respective figure on the left, except for those of the upper three and the last three, which were determined at room temperature. The pressure of oxygen inside the tube, as shown by the figure on the right, ranges from $0.5\times10^{-4}$ to $2\times10^{-4}$ mmHg.

2) M. Sedaka, N. Dokoshi, Y. Fujita and T. Kwan, presented at the 18th Annual Meeting of the Chemical Seciety of Japan, April, 1965. Cf. T. Kwan, "Hikari-kagaku to sono Oyo" Kagaku-Dojin, Kyoto (1965), p. 109.

the tube was being measured simultaneously. The ESR measuement was made with a JEOL-type P-10 spectrometer at the X band. The signals obtained, along with the heat treatment, are shown in Fig. 1.

Here we shall confine ourselves only to the change in the doublet signal at $g=2.008$, 2.002. The transition of the doublet to a singlet at $g=2.002$ is apparent. It took place near 170°C when the second type of adsorption* set in, as judged from the pressure change. This singlet was stable for a time beyond 250°C, but it appeared to decay near 370°C. The decay seemed to be associated with the appearance of the third type of adsorption.**

A singlet signal of the same $g$-value and of the same shape as that mentioned above was found to appear even when $N_2O$ was introduced onto the outgassed zinc oxide sample at room temperature. Thus, it seems very likely that the transition of the doublet to the singlet is due to the dissociation of the molecular oxygen ion into atomic species as $O^-$.

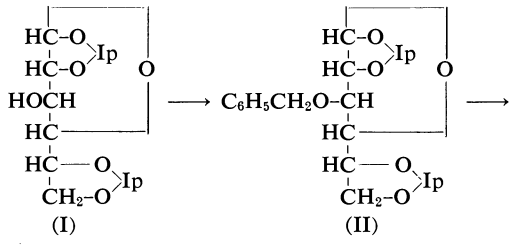
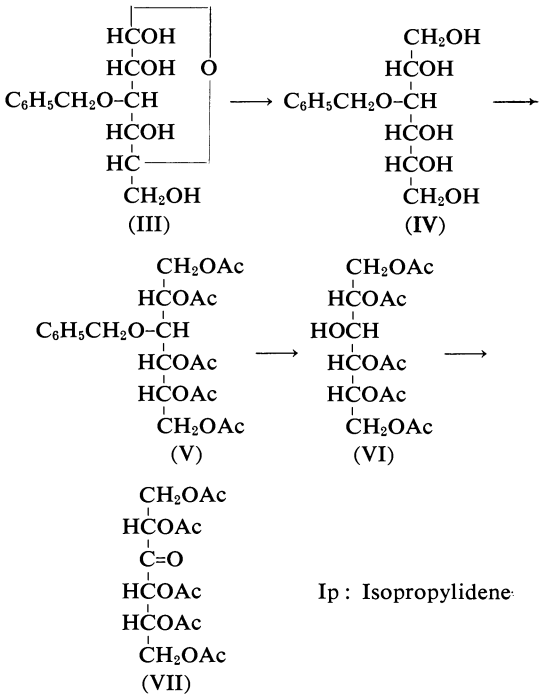
*Hongo, Tokyo*

* By the first type will be meant the oxygen adsorbed at room temperature.



** The third type is most probably $O^{2-}$, which is non-paramagnetic. Thus, the appearance of this type may mean the recovery of the original zinc oxide; this suggestion agrees with the resemblance of the ESR spectra between the initial and the final state.



# Studies on the Chemical Decomposition of Simple Sugars. XVIII. The Synthesis of D-*ribo*-3-Hexulose Pentaacetate*

By Akira SERA and Ryozo GOTO

(Received May 20, 1965)

Although some 3-hexuloses have been synthesized,[1-3] their chemical properties have been received only limited attention. In the mechanism posturated by Hayami[4] for the acetol formation from monosaccharides in a concentrated phosphate buffer solution, 3-hexulose might play an important role as an intermediate. However, there has been no unequivocal experimental evidence. In the present paper, a synthesis of D-*ribo*-3-hexulose pentaacetate, a new 3-hexulose derivative, and its rapid conversion to acetol in a phosphate buffer solution will be described.

The treatment of diacetone-D-glucose (I) with sodium hydride and benzyl bromide in

* Presented at the 18th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965.

2) J. M. Sugihara and G. U. Yuen, ibid., **79**, 5780 (1957).
3) G. U. Yuen and J. M. Sugihara, *J. Org. Chem.*, **26**, 1598 (1961).
4) J. Hayami, This Bulletin, **34**, 927 (1961).

ether gave 3-*O*-benzyl-1,2; 5,6-di-*O*-isopropylidene-D-glucofuranose (II).[5,6] The hydrolysis of II with sulfuric acid in aqueous methanol yielded 3-*O*-benzyl-D-glucopyranose (III),[6] 38%, m. p. 141.5—142.5°C. Compound III consumed 1.01 mol. of sodium metaperiodate per mole of substrate. The sodium borohydride reduction of III in water gave a thick syrup of 3-*O*-benzyl-D-sorbitol (IV) which, on acetylation with acetic anhydride and pyridine, gave a syrupy 3-*O*-benzyl-D-sorbitol pentaacetate (V) in a 83% yield. The removal of the benzyl group of V by catalytic hydrogenolysis with palladium black in acetic acid gave 1,2,4,5,6-penta-*O*-acetyl-D-sorbitol (VI) quantitatively as a slightly yellow syrup, b. p. 164—167°C/0.1 mmHg, $[\alpha]_D^{10}+8.2°$ (ethanol), $\nu_{OH}$ 3550 $cm^{-1}$. Found: C, 49.01; H, 6.10. Calcd. for $C_{16}H_{24}O_{11}$: C, 48.98, H, 6.17%. D-*ribo*-3-Hexulose 1,2,4,5,6-pentaacetate (VII) was obtained by the chromium trioxide oxidation of VI in acetic acid, 54%; pale yellow syrup, b. p. 138—139°C/0.05 mmHg, $[\alpha]_D^{10}-18.2°$ (ethanol), $\nu_{C=O}$ 1756 $cm^{-1}$, $\lambda_{max}$ 273 m$\mu$, $\varepsilon_{max}$ 109 (ethanol). Found: C, 49.11; H, 5.91. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.23; H, 5.68%.

The treatment of VII with a concentrated phosphate buffer solution (pH 9.0) gave an acetol more quickly than when D-glucose or $\beta$-D-glucose pentaacetate was used. This behavior of the 3-hexulose derivative might prove that 3-hexulose or its ene-diolate ion is an intermediate in an acetol formation from monosaccharides; it might also support the mechanism proposed by Hayami.[4] Further investigations are in progress, and additional details will be published later.

# A New Spectrophotometric Method for the Determination of Copper(II) with Calcichrome

By Hajime Ishii and Hisahiko Einaga

(Received June 8, 1965)

A new spectrophotometric method for the determination of trace of copper(II) has been developed. It is based upon the formation of a stable bluish-violet copper(II) complex of Calcichrome, which had been reported by some investigators[1-5] to be a reagent for the determination of calcium.

The absorption spectra of the complex are shown in Fig. 1. The complex spectrum has three absorption maxima with reference to the reagent blank in the visible ($\lambda_{max}$ 535 and 650 m$\mu$) and ultraviolet regions ($\lambda_{max}$ 310 m$\mu$), and also two isosbestic points, at 415 and 595 m$\mu$, in the pH range from 3 to 10. As may

Calcichrome: $4\times10^{-5}$ mol./1.
I; pH 5, II: pH 4

be seen in Fig. 2, the composition of the complex is 1 to 1. At 535 mμ, the concentration range in which copper(II) obeyed Beer's law is dependent upon the concentration of Calcichrome; for instance, up to 3.5 p. p. m. of copper(II), the law is obeyed when the concentration of Calcichrome is $6\times10^{-5}$ mol. The molar extinction coefficient is about $8\times10^{3}$, and the sensitivity is 0.008 μg. Cu/cm$^2$, which corresponds to $\log I_0/I=0.001$. At 310 mμ, similar results were obtained. The proposed procedure for the determination is as follows. To a sample solution containing copper(II) in a 50 ml. volumetric flask, 5.0 ml. of a Calcichrome solution ($6\times10^{-4}$ mol./1.) and 5 mol. of a sodium acetate - acetic acid buffer solution (pH 5) are added. After the solution has been diluted to the mark with distilled water, the absorbance of the solution is measured at 535 or 310 mμ with reference to a reagent blank solution. The full color develops instantaneously and is very stable. Copper(I) is also found to behave as copper-(II). Some metals, such as vanadium, nickel, and hydroxy group metals, interfere under the conditions proposed.

Further, detailed studies are now in progress.

# Faraday Rotation for the Hydrogen Molecule

By Yasumasa I'HAYA

(Received June 11, 1965; in revised form July 17, 1965)

Quantum mechanical theories of the magneto-optical rotation in polyatomic molecules have been developed by Kronig,[1] Serber,[2] Carroll,[3] and Groenewege.[4] Recently we included the contribution of the induced magnetic moment and of the perturbed Boltzmann factors and, using a time-dependent second-order perturbation theory, derived a general formula for the Faraday effect of diamagnetic molecules.[5] The Verdet constant, which is the rotation per gauss per cm., is shown to be temperature-dependent for polyatomic molecules of any symmetry, but temperature-independent for diamagnetic diatomic molecules (no paramagnetic rotation).

If we consider states of up to 3d, the molecular wave function in the hydrogen molecule is $(1s\sigma)^2$ for the ground state and $(1s\sigma)(2p\pi)$, $(1s\sigma)(3p\pi)$, $(1s\sigma)(4p\sigma)$ for the excited state. These are:

$$(1s\sigma)^2 : N=N_1[s_a(1)+s_b(1)]\ [s_a(2)+s_b(2)]$$

$$(1s\sigma)(2p\pi) : \Pi=N_2[s_a(1)+s_b(1)]\ [\pi_a(2)+\pi_b(2)]$$

$$(1s\sigma)(3p\pi) : \Pi'=N_3[s_a(1)+s_b(1)]\ [\pi'_a(2)+\pi'_b(2)]$$

$$(1s\sigma)(4p\sigma) : \Sigma=N_4[s_a(1)+s_b(1)]\ [\sigma_a(2)+\sigma_b(2)]$$

where $N_i$ is the normalization constant and where $s_i$, $\sigma_i$, $\pi_i$, and $\pi'_i$ are the complex normalized hydrogenic atomic orbitals of 1s, $2p_0$, $2p_+$, and $3p_+$ respectively. The other elements do not contribute to the theoretical expression for the Verdet constant because of their symmetry.

With these molecular orbitals, the Verdet constant may be expressed as:

1) R. de L. Kronig, *Z. Physik*, **45**, 458, 508 (1927).
2) R. Serber, *Phys. Rev.*, **41**, 489 (1932).
3) T. Carroll, ibid., **52**, 822 (1937).
4) M. P. Groenewege, *Mol. Phys.*, **5**, 541 (1962).
5) Y. I'Haya, to be published.

$$V=\frac{4\pi e^3 N\nu^2}{3hmc^2 i}\left[\frac{1}{\nu_4}\left(\frac{1}{\nu_1^2-\nu^2}-\frac{1}{\nu_3^2-\nu^2}\right)\times i\langle N|x|\Pi\rangle\langle\Pi\left|z\frac{\partial}{\partial x}-x\frac{\partial}{\partial z}\right|\Sigma\rangle\langle\Sigma|z|N\rangle+\frac{\nu_1^2}{(\nu_1^2-\nu^2)^2}\langle\Pi\left|x\frac{\partial}{\partial y}-y\frac{\partial}{\partial x}\right|\Pi\rangle\left|\langle N|x|\Pi\rangle\right|^2+\frac{2\nu_2^2}{(\nu_2^2-\nu^2)^2}\langle\Pi'\left|x\frac{\partial}{\partial y}-y\frac{\partial}{\partial x}\right|\Pi'\rangle\left|\langle N|x|\Pi'\rangle\right|^2\right] \quad (1)$$

$e$, $m$, $h$, and $c$ being the usual notations and $N$, the number of molecules per unit volume ($N=0.2686\times10^{20}\,\mathrm{cm}^{-3}$ at 0°C, 1 atm.). Here $\nu_i$ is the energy difference between the states measured in units of reciprocal seconds, as is shown in Fig. 1. Their observed values are[6]: $\nu_1=2.999249$, $\nu_2=3.414317$, $\nu_3=3.447654$ (estimated), and $\nu_4=0.448405$, all expressed in units of $10^{15}\,\mathrm{sec}^{-1}$. The matrix elements which appear in Eq. 1 are calculated using elliptical coordinates, the internuclear distance in $H_2$ being assumed to be 1.40 a.u. When the frequency of the incident light, $\nu$, is $0.519027\times10^{15}\,\mathrm{sec}^{-1}$ (5780A), the Verdet constant is calculated to be 3.140 $\mu$min. (microminutes) per oe.-cm.-atm.

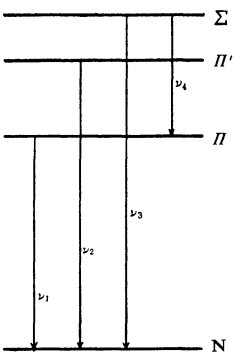

Fig. 1. Molecular electronic states in $H_2$, which contribute to the Faraday rotation.

The corresponding experimental value reported by Ingersoll and Liebenberg is 6.269 $\mu$min. per oe.-cm.-atm.[7] We cannot judge at this stage whether the many other excited states, $4p\pi$, $5p\pi$, and so on, contribute strongly. Further studies are, therefore, now in progress with more elaborate excited-state wave functions; the results will be published elsewhere.

# The Absorption Spectra of Naphthalene Sulfonic Acid Derivatives*

By Yoshié TANIZAKI, Hiroyasu INOUÉ and Noboru ANDO

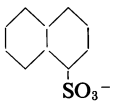
(Received July 27, 1964)

The purpose of the present investigation is to explain the electronic spectra of some naphthalene sulfonic acid derivatives which have the amino and/or the hydroxyl groups as the functional. The samples used here show a marked spectral change with the pH variation of the solution. In view of the fact that an intense effect as a proton acceptor or donor of the groups must be responsible for the spectral change, we attempted to explain this by considering the relative position between the functional and the sulfonic group, the intramolecular hydrogen bonding effect, and, moreover, the resonance effect of the functional groups. Further, the assignment of the electronic bands of the derivatives could be made experimentally from the band shift, taking into account the band assignment of naphthalene, which is already known.

## Experimental

The chemical structures of the samples used here are shown in Table I. Naphthionic acid (Sample No. 2), γ-acid (No. 5), J-acid (No. 6) and H-acid (No. 9) were purified by repeated precipitations by hydrochloric acid, and the rest, by repeated recrystallizations from water.

The concentrations of the sample solutions were about $10^{-5}$ mol./l. The pH value of the solution was adjusted by hydrochloric acid or sodium hydroxide. The absorption measurement was made immediately after the determination of pH. When the pH of a solution becomes higher than 10, the absorption of the solvent can not be neglected. In such cases, a sodium hydroxide solution with the same pH value is used as the reference.



The absorption measurement was carried out by a Shimadzu QR-50 spectrophotometer and also by a Hitachi EPSO22 spectrophotometer. The pH value was determined by a Tōa Denpa Kōgyo pH meter HM-5A.

## Results

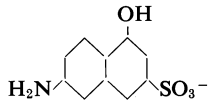


Figure 1 illustrates the absorption spectra of the naphthalene sulfonic acid ions (Nos. 1, 4 and 7 in Table I). None of them shows any appreciable spectral change within the limits of pH 2 to 11.

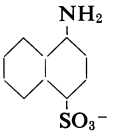
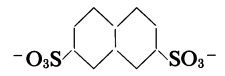
TABLE I. NAMES AND STRUCTURES OF SAMPLES



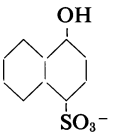
α-Naphthalene sulfonic acid

1 



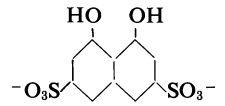
J-acid

6 



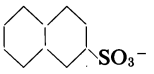
Naphthionic acid

2 



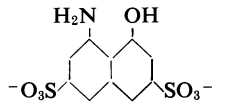
2, 7-Naphthalene disulfonic acid

7 



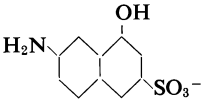
NW-acid

3 



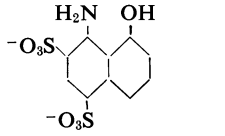
Chromotropic acid

8 



β-Naphthalene sulfonic acid

4 



H-acid

9 

γ-acid

5 

SS-acid
